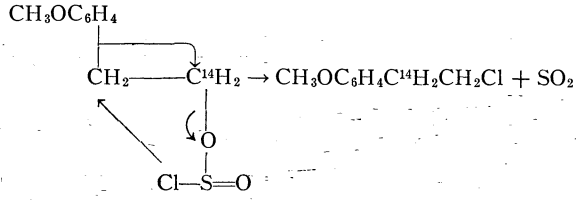
From the reactions of I with thionyl chloride in solvents other than pyridine (Table I), the extents of rearrangement appear to follow the capability of the medium in supporting ionization. The least ionizing solvent, *n*-hexane, gave the least rearrangement, while reaction in excess thionyl chloride, the most ionizing solvent employed, resulted in the largest observed rearrangement. These effects of changes in medium on the extent of rearrangement further support the suggestion that the observed results arise from intervention of ionic intermediates such as VII, and not from an S_Ni' mechanism (equation [1]) which maintains a large degree of covalent character (4–6).



[1]

It may be worth noting that of the two hydrocarbon solvents studied, reaction in toluene resulted in more rearrangement than reaction in *n*-hexane (Table I). In line with the idea that more rearrangement would result from reaction in a medium that can better support ion-pair formation, it may be pointed out that toluene has a higher dielectric constant than *n*-hexane (14) and that 2-butyl chlorosulphite has been found to decompose faster in toluene than in an aliphatic hydrocarbon such as isooctane (1).

Decomposition of chlorosulphites in dioxane is of special interest. Boozer and Lewis (1) have reported that this solvent is particularly effective in promoting retention of configuration in the decomposition of a number of optically active *s*-alkyl chlorosulphites. It was suggested that dioxane may solvate the carbonium ion as the chlorosulphite ion is displaced. A subsequent displacement of the dioxane by chloride ion would lead to overall retention (1). Relatively low degrees of rearrangement, attributable to the special solvent effect of dioxane, were reported for the decomposition in dioxane of allyl-1-C^{14} chlorosulphite (4) and of 2-butyl-1-C^{14} chlorosulphite (8). In the case of the 2-butyl-1-C^{14} system, the relative inability of neighboring hydrogen to participate and displace dioxane from the solvated cation was suggested as a possible explanation for the relatively small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rearrangement observed (8). In the 2-*p*-anisylethyl-1-C^{14} system, the rearrangement obtained for reaction in dioxane is almost as large as that found in the reaction in excess thionyl chloride (Table I). This finding is likely due to the fact that the bridged carbonium ion of ion pair VII is of considerable stability (9). One might visualize the neighboring *p*-anisyl group as much more effective than the neighboring hydrogen of the 2-butyl system in displacing dioxane from solvating a carbonium ion with classical structure. Participation of the *p*-anisyl group may be regarded as well developed before solvation and dioxane will solvate the cation with nonclassical structure as in VII, giving rise to a large degree of isotope position rearrangement in the final product. In line with these views are the results reported by Cram (3). For example, with optically active *threo*-isomer of 3-phenyl-2-butanol, reaction with thionyl chloride in dioxane and in excess thionyl chloride gave, respectively, 95% and 97% racemization, indicating a large degree of phenyl participation when the reaction was carried out with either dioxane or excess thionyl chloride as solvent.

EXPERIMENTAL

p-Anisylacetic Acid-1-C^{14} (II)

Amalgamated magnesium was prepared by stirring for a few minutes 10 g of magnesium turning in 100 ml of water containing about 200 mg of mercuric chloride. Upon this treatment, the metal lost its luster and assumed a dull grey appearance. It was rinsed with water until the washing was clear, and then rinsed with acetone and dried in a vacuum desiccator. The Grignard reagent was prepared, under nitrogen, by dropwise addition of a solution of 1.0 ml (7.4 mmoles) of *p*-methoxybenzyl chloride in 30 ml of anhydrous ether, over a period of 30 minutes, to a vigorously stirred mixture of 2.0 g of amalgamated magnesium in 20 ml of anhydrous ether. After refluxing for an additional 30 minutes, the Grignard solution was decanted, under nitrogen, from the excess magnesium and placed in a vacuum line for carbonation. Each run was carried out with carbon dioxide-C^{14} generated from roasting a mixture of barium carbonate-C^{14} (500–600 mg, 2.8–3.0 mmoles) and lead chloride (1.0–1.2 g). Overall yields of *p*-anisylacetic acid were of the order of 75–80% based on the barium carbonate.

Under conditions of higher reactant concentration and using magnesium powder, the chief product was *p,p'*-dimethoxydibenzyl. A sample trial is given below.

Under nitrogen, a solution of 5.0 ml (37 mmoles) of *p*-methoxybenzyl chloride in 100 ml of anhydrous ether was added dropwise, over a period of 45 minutes, to a stirred mixture of 2.7 g (111 mmoles) of magnesium powder in 40 ml of anhydrous ether. After refluxing for an additional 30 minutes, the mixture was treated with excess carbon dioxide, acidified, and extracted with ether. Only 0.5 g (8%) of acid II was obtained from the sodium hydroxide washing of the ether extract. Removal of most of the solvent from the sodium hydroxide washed ether solution resulted in the recovery of 3.1 g (69%) of crystalline product which recrystallized from ethanol as colorless needles, m.p. 127–128° C (lit. (15) m.p. of *p,p'*-dimethoxydibenzyl, 126–127° C).

2-p-Anisylethanol-1-C^{14} (I)

This labelled alcohol was prepared by the treatment of *p*-anisylacetic acid-1-C^{14} with lithium aluminum hydride in anhydrous ether according to the method of Jenny and Winstein (9).

Reaction of I with Thionyl Chloride

The reaction was carried out with pyridine, *n*-hexane, toluene, dioxane, or excess thionyl chloride as solvent. The general procedure adopted is described below, with minor modifications in certain cases as subsequently indicated.

2-*p*-Anisylethanol-1-C^{14} (I) (3.0 g, 19.7 mmoles) was added dropwise (10 minutes) at room temperature to a stirred solution of 3.0 ml (26 mmoles) of thionyl chloride in 50 ml of solvent (or to 25 ml of thionyl chloride only where this reagent also served as solvent). The mixture was allowed to stand at room temperature overnight, refluxed for 3 hours, poured onto ice, and then extracted with ether. The extract was washed with water, sodium bicarbonate solution, and again with water. After drying over anhydrous sodium sulphate, the ether was removed and the residue distilled under reduced pressure. The 2-*p*-anisylethyl-*x*-C^{14} chloride (III) was recovered at 86–90° at 1 mm (lit. (16) b.p. 129.5–131° C at 10 mm).

Anal. Calc. for $C_9H_{11}OCl$: C, 63.34; H, 6.50; Cl, 20.78. Found: C, 63.15; H, 6.68; Cl, 20.32 Identification of individual samples of III from the different runs was made by comparison of its infrared absorption spectrum with that of an analytically pure specimen as well as by its conversion to 3-*p*-anisylpropanoic acid.

The above procedure applies to reactions in *n*-hexane, toluene, and dioxane. For the reaction in pyridine, the mixture was worked up after standing at room temperature overnight without refluxing. The material was poured onto ice and hydrochloric acid instead of ice alone before extraction with ether. For the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in excess thionyl chloride, the reaction mixture was allowed to stand at room temperature for only 2 hours and then refluxed for 1 hour before the material was worked up the usual way. A typical set of yields of chloride III is 23, 32, 66, 67, and 34%, respectively, for reactions in pyridine, *n*-hexane, toluene, dioxane, and excess thionyl chloride.

Di-2-p-anisylethyl Sulphite (IV)

From the reaction of I with thionyl chloride in *n*-hexane, a solid product was recovered after the reaction mixture was poured onto ice. It crystallized as colorless needles from ether–pentane mixture, m.p. 45–47° C. Its analysis agrees with that expected for di-2-*p*-anisylethyl sulphite (IV).

Anal. Calc. for $C_{18}H_{22}O_5S$: C, 61.70; H, 6.28; S, 9.14. Found: C, 61.81; H, 6.44; S, 9.20. For the active runs in *n*-hexane, the yields of chloride III were 32 and 44%, and of sulphite IV were 12 and 9%, respectively, for runs 1 and 2. No sulphite IV was obtained from reactions in pyridine, toluene, dioxane, or excess thionyl chloride.

When I was treated with thionyl chloride in ether according to the general procedure described in the previous section, the only product, besides unreacted alcohol I, was a 4% yield of sulphite IV. The inclusion of 5 ml of pyridine in the reaction mixture of I and thionyl chloride in ether raised the yield of sulphite IV to 39%.

Degradation of p-Anisylethyl-x-C^{14} Chloride (III)

The conversion of chloride III to the corresponding Grignard reagent followed by reaction with carbon dioxide to give 3-*p*-anisylpropanoic acid-*x*-C^{14} (V), m.p. 104–105° C (lit. (17) m.p. 104–105° C), and the subsequent oxidation of V to *p*-anisic acid (VI) were carried out in a manner analogous to the conversion of 2-phenylethyl iodide to hydrocinnamic acid and the oxidation of the latter to benzoic acid previously reported from this laboratory (18). Samples of V and VI were repeatedly crystallized and sublimed before they were assayed for radioactivity.

THE STRUCTURE OF '3-HYDROXYPYRROLES'

R. S. Atkinson and E. Bullock
Department of Chemistry, University of Nottingham, Nottingham, England
Received October 24, 1962

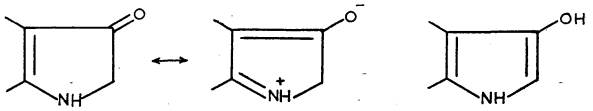
ABSTRACT

Spectroscopic studies by infrared, ultraviolet, and n.m.r. methods have shown that '3-hydroxypyrroles' exist in the 4-oxo-Δ^2-pyrroline form and are not tautomeric substances.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

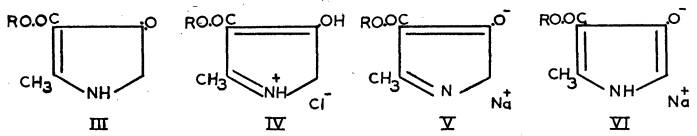
INTRODUCTION

Several authors have discussed the possibility of tautomerism in the '3-hydroxypyrrole' system (1–4). The earlier workers assigned a hydroxypyrrole (II) structure and the later ones (3, 4) an oxo-Δ^2-pyrroline (I) form for these compounds. Treibs (4) proposed that the oxo-Δ^2-pyrroline form was best represented by a dipolar structure (IA) (i.e. a resonance hybrid of I and IA but with very marked dipolar character). Examination of



I IA II

this problem by spectroscopic methods has so far been restricted to ultraviolet and solid phase infrared spectra, due to the insolubility of the compounds in organic solvents. (The results presented here establish III as the correct formula for one type of '3-hydroxypyrrole' and the compounds will subsequently be referred to as oxo-Δ^2-pyrrolines.) The synthesis of 3-carbethoxy-4-oxo-Δ^2-pyrrolines (III) is relatively easy and our study of is this type of compound. In an attempt to obtain spectra in organic solvents the *t*-butyl, benzyl (3), and *n*-octyl esters of III were prepared, and the last was sufficiently soluble in chloroform for our purpose.



III IV V VI

EXPERIMENTAL

The esters were prepared from the appropriate acetoacetate (1). *n*-Octyl acetoacetate was synthesized by ester exchange between *n*-octanol and ethyl acetoacetate in the presence of *p*-toluenesulphonic acid. *t*-Butyl 2-methyl-4-oxo-Δ^2-pyrroline-3-carboxylate (III; R = $C(CH_3)_3$) forms white needles, m.p. 197–200° (decomp.; m.p. very dependent on rate of heating, above value is from a preheated Kofler block). Calc. for $C_{10}H_{15}O_3N$: C, 60.89; H, 7.67; N, 7.1%. Found: C, 61.00; H, 7.66; N, 6.97%. *n*-Octyl 2-methyl-4-oxo-Δ^2-pyrroline (III; R = $(CH_2)_7CH_3$) crystallized as small buff needles from ethanol, m.p. 145–147°. Calc. for $C_{14}H_{23}O_3N$: C, 66.37; H, 9.15; N, 5.53%. Found: C, 66.2; H, 9.39; N, 5.91%. Molecular weight (Rast): 214 (requires 253).

The n.m.r. spectrometer is an A.E.I. RS2 60 Mc/sec instrument. Tetramethylsilane was used as internal reference where possible and results are given on the τ scale. Spectra were calibrated by generation of side bands from appropriate peaks. Ultraviolet spectra were recorded on a Perkin–Elmer model 137 ultraviolet spectrophotometer on ethanol solutions, unless otherwise stated. Infrared spectra were measured (generally on chloroform solutions) on Unicam SP100 and SP200 instruments.

RESULTS

(a) Nuclear Magnetic Resonance Spectroscopy

(i) n-Octyl Ester (III; R = $(CH_2)_7CH_3$)

The spectrum of a saturated solution in chloroform is shown in Fig. 1. The ratio of the

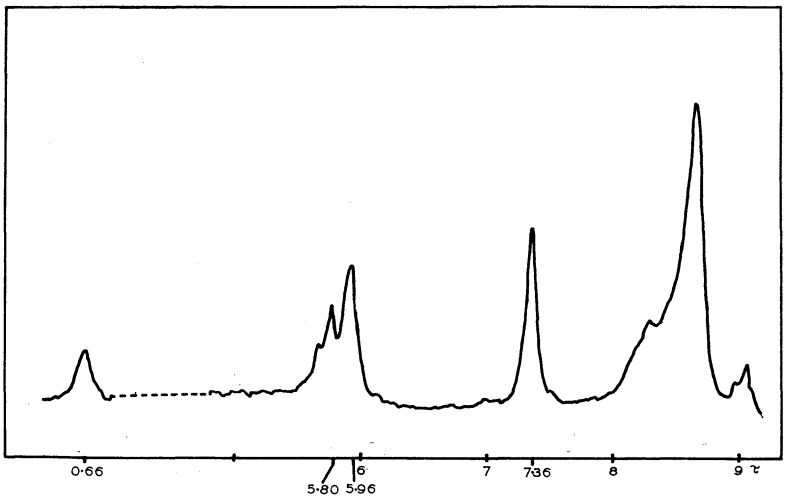


FIG. 1. Nuclear magnetic resonance spectrum of III; R = $(CH_2)_7CH_3$.

area under the combined peaks at 5.80 and 5.96 τ to that under the 7.36 τ absorption is 4:3. The NH (0.66 τ) signal is sensitive to concentration of solute and moves to high field with dilution. After shaking the solution with D_2O, the 0.66 and 5.96 τ peaks disappeared, showing the triplet nature of the 5.80 τ signal clearly.

Trifluoracetic acid was added to a chloroform solution (about 30% v/v) and caused several of the signals to shift to low field. The NH band became very broad (intensity $\equiv$ 1 proton) at -0.52 τ and the 5.96 τ signal was broadened and appeared at 5.12 τ. The ring-methyl group gave a slightly broadened signal at 7.22 τ.

(ii) Ethyl Ester (III; R = CH_2CH_3)

This ester was examined in trifluoracetic acid and the overall features were very similar to those of the acidified chloroform solution recorded above.

In alkaline solution (aqueous sodium hydroxide) the signals appeared sufficiently to high field of the solvent (solvent assumed at 5.31 τ) to facilitate a satisfactory interpretation. The absorption corresponding to the 5.96 τ signal in (i) now appears, as a poorly defined quartet, at 6.30 τ. The most striking change is in the ring-methyl signal, which is now a triplet (7.78 τ, J = 1.7 c.p.s.), clearly by long-range interaction with the pyrroline CH_2 group.

(b) Infrared Spectroscopy

Figure 2 shows the 3000 cm^{-1} region for four different samples of III, R = $(CH_2)_7CH_3$. The bands at 3162 and 3065 cm^{-1} in the solid phase spectrum (Fig. 2(*a*)) are presumably the 'immonium' bands of Treibs (4). It is clear from the subsequent solution spectra (Fig. 2(*b*, *c*, *d*)) that these are 'bonded' NH absorptions and that the free NH frequency is probably that at 3468 cm^{-1}. A second hydrogen-bonded band appears at 3252 cm^{-1} in strong solutions.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

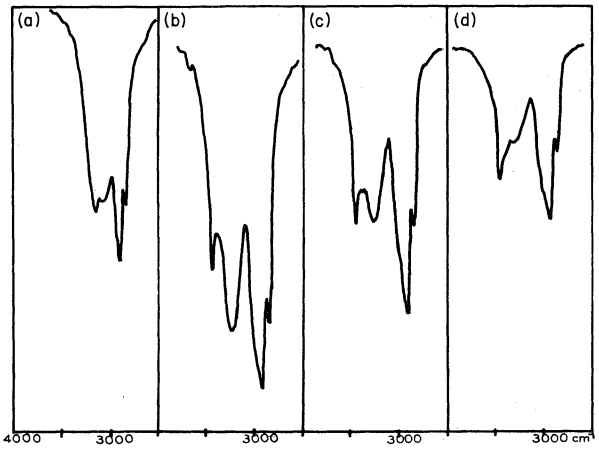

FIG. 2. Infrared spectrum of III; R = $(CH_2)_7CH_3$.

The carbonyl region is unresolved in KBr disk spectra though there appear to be two distinct absorptions at 1697 and 1722 cm^{-1} (shoulder). In chloroform solution these peaks are better resolved and appear at 1675 and 1710 cm^{-1}. The material was too insoluble in carbon tetrachloride to give satisfactory spectra.

(c) Ultraviolet Spectra

The absorption of III, R = $(CH_2)_7CH_3$, is sensitive to pH. The material is amphoteric, though both acidic and basic functions are relatively weak. In particular, addition of concentrated acid until the strength was about 3 *N* (in hydrogen chloride) was necessary to produce a marked change in spectrum. The positions and intensities of absorptions in various solutions are given in Table I.

TABLE I

Ultraviolet absorption of III, R = $(CH_2)_7CH_3$

Solution	λ_{max} (mμ)	Extinction coefficient
Neutral	241.3	14,500
	294.5	9,300
Approx. 2.2 *N* HCl	241.5	11,100
	291	8,430
Approx. 4.4 *N* HCl	223	9,950
	241 (infl.)	6,290
	282	7,680
Approx. 0.1 *N* NaOEt	254.3	17,530
	285	7,930

The absorptions in neutral and acidic solutions showed a marked isosbestic point, indicating that only protonation and not condensation (1) had occurred.

DISCUSSION

The n.m.r. spectra show that in neutral, acidic, and alkaline solutions the compounds exist as a single species and that one CH_2 group is present which can be satisfactorily ascribed only to the 5-position of a Δ^2-pyrroline.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Assessment of the contribution from a charged form (I ↔ IA) to the structure of the molecule in neutral solution is difficult. Treibs (4) quoted two main pieces of evidence: (*a*) the presence of bands in the infrared due to $\overset{+}{N}H$ and (*b*) a Rast molecular weight for III, R = CH_2CH_3, equivalent to a dimeric formula.

Point (*a*) is probably invalid. The 4-oxo-Δ^2-pyrroline formula is equivalent to the vinylogue of a γ-lactam. Certain simple γ-lactams, in the solid phase, show absorptions at 3175 and 3080 cm^{-1}, and an NH— stretching band near 3440 cm^{-1} is observed in dilute solution spectra of many secondary amides (5). These are very closely similar to the values for 4-oxo-Δ^2-pyrrolines and suggest that there are no grounds for proposing a more polar structure than is present in a simple amide, for these compounds. The anomalous molecular weight is probably due to the insolubility of the ethyl ester in camphor, since the octyl ester gave a value corresponding to a monomer.

The low-field NH band of intensity 1 and the low-field shift of the 5-proton signals in the n.m.r. spectra of acidified solutions of oxopyrrolines suggest that protonation occurs on the carbonyl oxygen atom (IV; cf. ref. 6). The protonated form is thus completely analogous to that of a simple pyrrole (7). It is surprising that the anions show no tendency to exist in the pyrrole (VI) form, but the evidence clearly supports V.

ABSTRACT

Tetrakis-(trimethylsilyloxy)-titanium $Ti(OSiMe_3)_4$ has been hydrolyzed under controlled conditions in dioxane. The initial products of hydrolysis undergo facile disproportionation, e.g. $3Ti_2O(OSiMe_3)_6 \rightarrow 4Ti(OSiMe_3)_4$ + polymeric $Ti_2O_3(OSiMe_3)_2$. Molecular weight determinations were made on the titanium oxide trimethylsilyloxide polymers (polytrimethylsiloxanotitanoxanes) obtained by thermal disproportionation. Structures have been suggested for the polymers on the basis of the variation of number-average degree of polymerization with the degree of hydrolysis.

INTRODUCTION

In a previous communication (1) we reported the preparation and properties of some trialkylsilyloxy derivatives of titanium, zirconium, niobium, and tantalum. It was observed that these compounds were less susceptible to hydrolysis than the metal alkoxides and it was suggested that this property was connected with the water-repellant nature of the trialkylsilyloxy group. A study of the controlled hydrolysis of tetrakis-trimethylsilyloxy-titanium was of interest because of the likely formation of titanium oxide trimethylsilyloxide polymers $[TiO_x(OSiMe_3)_{4-2x}]_n$ (also known as polytrimethylsiloxanotitanoxanes (9)). These polymers were of particular interest in connection with the structural work of Bradley and co-workers (2–8) on the metal oxide alkoxides and also because of their potentialities as thermally stable polymers and water-repellant agents.

Andrianov and co-workers (9) studied the hydrolysis of $Ti(OSiMe_3)_4$ in acetone at 50° C. They claimed that with the reactants in the molar proportions of 1 of water to 2 of $Ti(OSiMe_3)_4$ there was no reaction during 3 hours and that most of the $Ti(OSiMe_3)_4$ was recovered by distillation. However, with more than 1 g-mol of water to 1 of $Ti(OSiMe_3)_4$ in acid solution they found that polymers were formed which were soluble in organic solvents.

We now report some results on the hydrolysis of $Ti(OSiMe_3)_4$ in dioxane at room temperature. In the course of this work some interesting polymeric titanium oxide trimethylsilyloxides were isolated.

RESULTS AND DISCUSSION

In keeping with previous nomenclature (2–8) we call the molar ratio of water added to $Ti(OSiMe_3)_4$ h, but in contrast to the hydrolysis of the metal alkoxides the hydrolysis of $Ti(OSiMe_3)_4$ was incomplete and the degree of hydrolysis in the product was not h. The actual degree of hydrolysis x was determined by analysis of the polymer $[TiO_x(OSiMe_3)_{(4-2x)}]_n$, where n is the number-average degree of polymerization determined by cryoscopy in cyclohexane.

According to equation [1] hydrolysis with $h = 0.5$ should produce $Ti_2O(OSiMe_3)_6$.

$$2Ti(OSiMe_3)_4 + H_2O \rightarrow Ti_2O(OSiMe_3)_6 + 2Me_3SiOH \quad [1]$$

Aqueous dioxane (for $h = 0.5$) was added to $Ti(OSiMe_3)_6$ in dioxane (approx. 2 molal

solution) with vigorous stirring at room temperature (approx. 23° C) and after 1 hour the solvent and volatile products were evaporated off *in vacuo* at room temperature. Gas chromatographic analysis of the volatile products confirmed the presence of trimethylsilanol with some hexamethyldisiloxane and a trace of water. The non-volatile residue was a colorless liquid with the correct analysis for $Ti_2O(OSiMe_3)_6$ but it soon deposited some white precipitate. Vacuum distillation of the residue at 120° C gave a substantial recovery of $Ti(OSiMe_3)_4$ and after heating to 160° C left a non-volatile white residue corresponding in analysis to a highly hydrolyzed product (i.e. $x \sim 1.6$). This experiment demonstrated, contrary to the report of Andrianov *et al.* (9), that $Ti(OSiMe_3)_4$ is hydrolyzed at $h = 0.5$ in neutral solution and that the product of hydrolysis undergoes a ready disproportionation.

The experiment was repeated on a larger scale and again a liquid product corresponding to "$Ti_2O(OSiMe_3)_6$" was obtained and its infrared absorption spectrum suggested that no hydroxyl groups were present. The infrared spectrum also showed that the characteristic intense Ti—O—Si band at 918 cm^{-1} (10–12) of $Ti(OSiMe_3)_4$ was diminished in intensity and that a new strong band was present at 975 cm^{-1}.

A portion of the product was heated at 120° C for 1 hour and allowed to cool. Evaporation *in vacuo* at room temperature gave as condensate a small quantity of silanol, hexamethyldisiloxane, and water, and left a liquid containing a white precipitate (I). The formation of silanol, disiloxane, and water suggested that some hydroxy compounds, e.g. $Ti(OH)(OSiMe_3)_3$, $Ti(OH)_2(OSiMe_3)_2$, and (or) polymeric hydroxy compounds were present in "$Ti_2O(OSiMe_3)_6$", although no absorption due to hydroxyl was detected in the infrared. Compound I was separated by filtration and shown to be a titanium oxide trimethylsilyloxide ($x \sim 1.5$) whilst the filtrate was substantially $Ti(OSiMe_3)_4$. The remainder of the original "$Ti_2O(OSiMe_3)_6$" was kept at room temperature for 2 weeks, slowly depositing a white solid which was found to be similar in degree of hydrolysis to I, and the supernatant liquor was again substantially $Ti(OSiMe_3)_4$. Another interesting result of this experiment was the discovery from a material balance of reactants and products that the percentage hydrolysis based on equation [1] was only about 74%.

From these experiments it was concluded that at $h = 0.5$ hydrolysis is incomplete after 1 hour and that the titanium product of hydrolysis is unstable, undergoing disproportionation slowly at room temperature and rapidly at 120° C to give $Ti(OSiMe_3)_4$ and a solid approximating in composition to $Ti_2O_3(OSiMe_3)_2$ (see equation [2]). Molecular

$$3Ti_2O(OSiMe_3)_6 \rightarrow 4Ti(OSiMe_3)_4 + \frac{1}{n}[Ti_2O_3(OSiMe_3)_2]_n \qquad [2]$$

weight determinations (cryoscopic) in cyclohexane suggested that the solid I had a degree of polymerization of 12, which in comparison with titanium oxide alkoxides is very low for such a high degree of hydrolysis.

To explore the field more fully a number of hydrolyses were done over a range of h values (0.1 to 2.50) at room temperature under similar conditions. In each case the product remaining after evaporation of dioxane and volatile products was heated at 160° C *in vacuo* until no more $Ti(OSiMe_3)_4$ distilled out. The non-volatile residue was analyzed for % Ti and % Si, and its molecular weight (in cyclohexane) and infrared spectrum were determined. From the analytical data the degree of hydrolysis x was determined and from the molecular weights n was calculated. For $h > 1.5$ the non-volatile residues were sparingly soluble and molecular weights could not be obtained with sufficient accuracy. Values of h, x, and n are given in Table I together with some values for the percentage hydrolysis.

*With 1 mole Me_3SiOH/mole $Ti(OSiMe_3)_4$.
†With 1.5 moles Me_3SiOH/mole $Ti(OSiMe_3)_4$.
‡With 2 moles Me_3SiOH/mole $Ti(OSiMe_3)_4$.

It is extremely interesting to note that the lowest polymer obtained (from $h = 0.1$) corresponds to $Ti_8O_{12}(OSiMe_3)_8$ (found: Ti, 29.7; Si, 17.3; M.W., 1310; $Ti_8O_{12}(OSiMe_3)_8$ requires: Ti, 29.7; Si, 17.4; M.W., 1288). This could have a large ring structure but we are inclined to favor the compact cubical structure shown in the Fig. 1. This molecule

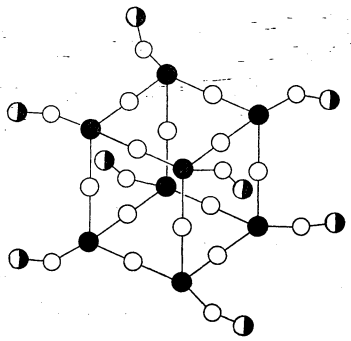

FIG. 1. $Ti_8O_{12}(OSiMe_3)_8$: ● = Ti; ○ = oxygen; ◑ = $SiMe_3$ group.

must possess considerable stability to be formed so readily at such a low value of h. The molecular weight determination showed no concentration dependence and we concluded that a single molecular species was present. A remarkable feature of the structure proposed for $Ti_8O_{12}(OSiMe_3)_8$ is the presence of 4-coordinated titanium in contrast to the titanium oxide alkoxides (2, 3), which are believed to involve 6-coordinated titanium.

Another interesting feature of the data in Table I is that as h is increased from 0.1 to 1.75 the value of x slowly increases from 1.5 to 1.7. It appears that x has a limiting value of 1.7 because increasing h to 2.5 appears not to increase x beyond ~1.7.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Also it is clear that as h is increased the percentage hydrolysis is steadily decreased. This suggested that the more highly hydrolyzed species are more resistant to hydrolysis or that the hydrolysis is reversible. To test the latter possibility more hydrolyses were made at $h = 0.6$ with the addition of trimethylsilanol in ratios Me_3SiOH:$Ti(OSiMe_3)_4$ of 1.0, 1.5, and 2.0. There are two possible consequences of the addition of trimethylsilanol: (i) to raise the value of h and hence x by addition of water caused by condensation of the unstable silanol, (ii) to lower h and x because of the reversal of the hydrolysis (e.g. in equation [1]). Attempts were made to preclude (i) by using freshly prepared silanol but the condensation of Me_3SiOH is notoriously sensitive to acid catalysis. The results in Table I show that the addition of Me_3SiOH caused a significant lowering in x although the suppression of hydrolysis did not increase in proportion to the ratio of Me_3SiOH:$Ti(OSiMe_3)_4$. This lack of quantitative correlation could be due to the condensation of silanol as already mentioned. Whilst not conclusive these experiments suggested that hydrolysis of $Ti(OSiMe_3)_4$ is reversible, thus explaining the decrease in percentage hydrolysis with increase in h.

Bradley and co-workers (1–8) have shown that metal oxide alkoxide polymers appear to conform to certain structural models determined by the stereochemistry of the metal and that each model gives a characteristic variation of the number-average degree of polymerization as a function of the degree of hydrolysis. Bradley and Holloway (8) have developed a mathematical approach to the analysis of the variation of n with x in terms of structural models for any system constituting a regular polymer series. Thus a regular polymer series built up by condensation of p-mer units ($n_0 = p$) with q linkages between adjacent units will have the following equation:

$$n^{-1} = p^{-1} - q^{-1}x. \qquad [3]$$

The data for n and x in Table I treated by the method of least squares gave the following equation: $n^{-1} = 1.028 - 0.604x$. The values of n_{calc} in Table I are those calculated from the least-squares equation assuming experimental values of x are correct. From the deviations $n_{calc} - n_{obs}$ the coefficient of variation for the 18 points was found to be $\pm 6\%$, corresponding to a most probable error of $\pm 4\%$ for any point. Bearing in mind that x calculated from the analytical data is very sensitive to analytical errors and the possibility of an error of 5% in n, the above agreement seems very satisfactory.

Putting $n^{-1} = 0$ in the least-squares equation gives a value $x_\infty = 1.70$ corresponding to an infinite polymer with $x = 1.70$. This agrees very well with our observation that the limiting value of $x = 1.7$ independent of $h > 1.75$ and that the products with $x \rightarrow 1.7$ were insoluble as would be expected for the higher polymers.

Putting $x = 0$ in the least-squares equation gives $n_0^{-1} = 1.028$, corresponding to $p = 0.97$ and suggesting that a monomer titanium unit is involved in the polymer series. However, we could not obtain polymers with $x < 1.5$ and hence the value of n_0 may have no real significance. On the other hand the least-squares equation gives $q = 1.65$ for the average number of linkages between each repeating unit in the polymer. In view of the facile formation of $Ti_8O_{12}(OSiMe_3)_8$ even at very low values of h we explored the possibility that the polymers with $x = 1.5$ to 1.7 were formed by condensation of the octamer $Ti_8O_{12}(OSiMe_3)_8$. In Fig. 2 is represented a polymer formed by condensing two $Ti_8O_{12}(OSiMe_3)_8$ units with one oxygen bridge. Continuation of such a mode of condensation leads to a regular polymer series of the general formula $Ti_{8(y+1)}O_{(13y+12)}(OSiMe_3)_{(6y+8)}$, where $y = 0$, 1, 2, etc., leading to the relationship $n^{-1} = 1.625 - x$. It was clear that such a series, which we will designate Series A, did not agree with the

FIG. 2. $Ti_{16}O_{25}(OSiMe_3)_{14}$: ● = Ti; ○ = oxygen ($Me_3SiO$ groups omitted).
FIG. 3. $Ti_{16}O_{26}(OSiMe_3)_{12}$: ● = Ti; ○ = oxygen ($Me_3SiO$ groups omitted).

results in Table I. In Fig. 3 is shown another polymer formed by condensation from two $Ti_8O_{12}(OSiMe_3)_8$ units but with two oxygen bridges. This process leads to Series B with the general formula $Ti_{8y}O_{2(7y-1)}(OSiMe_3)_{4(y+1)}$, where $y = 1, 2, 3$, etc., with $n^{-1} = 0.875-0.5x$. Clearly the least-squares equation is closer to the requirements of Series B than to Series A. Finally, in view of the value of $q = 1.65$, the possibility was considered that Series A and Series B were present simultaneously. Following the theory of Bradley and Holloway (8) it is readily shown that if the proportion of titanium atoms in Series B is α and in Series A is $1-\alpha$, then

$$n^{-1} = \alpha n_B^{-1} + (1-\alpha)n_A^{-1} = \alpha(0.875-0.5x) + (1-\alpha)(1.625-x). \quad [4]$$

Hence

$$n^{-1} = 1.625-0.75\alpha-(1.00-0.5\alpha)x. \quad [5]$$

If equation [5] is to be identical with the least-squares equation $n^{-1} = 1.028-0.604x$, it follows that $1.625-0.75\alpha = 1.028$. Hence $\alpha = 0.796$. A check on the theory is provided by the fact that the slope $d(n^{-1})/dx$ of equation [5] is given by $-(1.00-0.5\alpha)$. Substitution of the value for α gives a calculated slope of -0.602, which is remarkably close to the least-squares slope of -0.604. It thus appears that the variation of n with x for the polymeric titanium oxide trimethylsilyloxides is very well explained in terms of the two series (A and B) of regular polymers based on the octamer $Ti_8O_{12}(OSiMe_3)_8$. Other regular polymer series including one involving 6-coordinated titanium were considered either singly or as mixtures but the experimental variation of n with x could not be reproduced by any of them. A remarkable feature of the structure (Fig. 1) proposed for $Ti_8O_{12}(OSiMe_3)_8$ is the presence of 4-coordinated titanium in a near-tetrahedral configuration. Thus the polymeric titanium alkoxides and titanium oxide alkoxides appear to involve 6-coordinated octahedral titanium (2, 3) while titanium dioxide certainly contains octahedral titanium. It remains to be explained how the trimethylsilyloxy groups can promote the stabilization of 4-coordinated titanium in the new polymers. It is reasonable to assume that 4-coordinated titanium attached to electronegative ligands will achieve an increase in covalency by "intramolecular coordination" involving donation of p_π electrons of the ligand to vacant d_π orbitals of the titanium. Now in the Si—O—Ti groups there will be competition between silicon and titanium for a share in the p_π electrons of the oxygen whereas in the Ti—O—Ti groups the d_π–p_π bonding is presumably shared equally between the titaniums. It may be that the compact and symmetrical structure of $Ti_8O_{12}(OSiMe_3)_8$ (Fig. 1) with linear Ti—O—Ti bonds promotes the supplementary Ti—O π-bonding thereby providing additional stabilization for the structure. It is still not obvious how the trimethylsilyloxy groups

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

help to bring about this structure but it is possible that in the Si—O—Ti groups, the silicon by withdrawing the oxygen's π-electrons at the expense of the titanium causes the latter to draw upon the π-electrons of the oxygens in the Ti—O—Ti groups thus promoting the π-bonding within the Ti—O—Ti framework. It is hoped that infrared absorption spectra will throw further light on this problem. Preliminary results show that the polymers contain a strong characteristic band around 973 cm^{-1} in addition to the Si—O band at 918 cm^{-1}, which is also present in $Ti(OSiMe_3)_4$ (10–12). In addition, the intense band at 755 cm^{-1} due to the $SiMe_3$ group has in the polymers shoulders at around 775 and 735 cm^{-1} which may be due to the Ti—O—Ti system (11, 13).

EXPERIMENTAL

The preparation and analysis of $Ti(OSiMe_3)_4$ were carried out using essentially the procedures already reported (1). Dioxane was carefully purified by prolonged refluxing over sodium followed by fractional distillation. Molecular weights were determined cryoscopically in cyclohexane in a Beckman apparatus suitably modified to exclude atmospheric moisture. The infrared spectra were determined in approximately 2.5% solutions in carbon disulphide in a cell fitted with KBr windows. Measurements were made using the Beckman IR-7 and IR-5A instruments.

Preparation of Polymeric Titanium Oxide Trialkylsilyloxides

All experiments were carried out under essentially the same conditions. A measured quantity of water as aqueous dioxane was added with vigorous stirring to a solution of $Ti(OSiMe_3)_4$ in dioxane at approximately 23° C. The concentration of $Ti(OSiMe_3)_4$ was in each case approximately 2 molal. Stirring was continued for 1 hour after the addition of the water, and the clear solution was then evaporated to dryness at 0.1 mm pressure. The liquid residue thus obtained was heated at 120° C at 0.1 mm to distill out the $Ti(OSiMe_3)_4$ and finally heated at 160° C at 0.1 mm until $Ti(OSiMe_3)_4$ ceased to be evolved. In the experiments at $h = 0.5$, 1.0, 1.5, 2.0, and 2.5, the weights of reactants and products were carefully determined, thus allowing calculation of the percentage hydrolysis. Analysis (Ti and Si) of the polymers $[TiO_x(OSiMe_3)_{(4-2x)}]_n$ enabled the degree of hydrolysis x to be calculated and the determination of the molecular weight gave the value of n, the number-average degree of polymerization (i.e. the number of Ti atoms per average molecule). The data are presented in Table II, where the calculated values of % Ti and % Si provide a

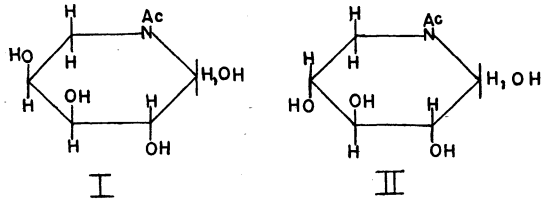
SYNTHESIS OF A SUGAR DERIVATIVE WITH NITROGEN IN THE RING

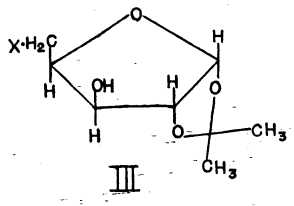
J. K. N. JONES AND W. A. SZAREK
Department of Chemistry, Queen's University, Kingston, Ontario
Received October 25, 1962

ABSTRACT

1-Acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine, a sugar derivative with nitrogen in the ring, has been synthesized from D-xylose. The synthetic route and proof of structure are described.

Very recently the first synthesis was achieved of a sugar derivative containing nitrogen as the hetero atom in the ring (1). The compound was obtained from L-arabinose and was shown to have the structure I. We now report the synthesis of the analogous compound from D-xylose. Structure II has been established for this new compound.





1,2-*O*-Isopropylidene-5-*O*-toluene-*p*-sulphonyl-D-xylose was prepared from D-xylose by the method of Levene and Raymond (2). Reaction with methanolic ammonia, followed by *N*-acetylation, gave 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose (III; X = NHAc). Hydrolysis of III with 20% aqueous acetic acid yielded a syrupy mixture of unchanged III and at least three other components. Cellulose column chromatography of this mixture gave in a pure state compound III and two new compounds. One of these was obtained as a brown syrup which could not be induced to crystallize; the other was obtained in crystalline form. The infrared spectrum of the syrupy compound was consistent with that of a xylofuranose. The results of periodate oxidation in unbuffered aqueous solution also indicated that the compound possessed the furanose ring form. The compound was therefore 5-acetamido-5-deoxy-D-xylofuranose. The crystalline compound, for which structure II is proposed, showed no *NH* band in its infrared spectrum. The results of periodate oxidation in unbuffered aqueous solution were consistent with the proposed structure. This compound has been named 1-acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Both 5-acetamido-5-deoxy-D-xylofuranose and 1-acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine gave the same crystalline phenylosazone. Analysis indicated it to be a phenylosazone of an acetamido-deoxy pentose and the compound gave absorptions in the infrared corresponding to *OH*, *NH*, the aromatic ring, and the amide linkage. Reduction with sodium borohydride of both reducing sugars also gave the same product, probably 5-acetamido-5-deoxy-D-xylitol. These results indicate that the two compounds differ only in the position of ring closure of the terminal aldehyde group.

5-Acetamido-5-deoxy-D-xylofuranose gave with methanolic hydrogen chloride a syrupy methyl glycoside which on periodate oxidation gave results in agreement with those expected for the oxidation of a furanoside.

1-Acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine with methanolic hydrogen chloride rapidly formed a methyl glycoside which was obtained crystalline. It was named 1-acetyl-D-*ido*(*gulo*?)-2-methoxy-3,4,5-trihydroxypiperidine. The results of periodate oxidation of this glycoside indicate the presence of a six-membered ring.

Both 5-acetamido-5-deoxy-D-xylofuranose and 1-acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine are stable in neutral aqueous solution at room temperature. A mixture of the two is formed, however, when an aqueous solution of either compound is heated.

Some light was shed on the nature of the product(s) not isolated from the syrupy hydrolyzate by the observation that the syrup gave on paper chromatograms a component which reacted with a ketose spray reagent as well as with the alkaline silver nitrate and *p*-anisidine hydrochloride spray reagents (*vide infra*). A ketose could conceivably be formed from compound II via an Amadori rearrangement of II in the acid hydrolysis medium. This sequence would give rise to a compound which could be named 1-acetyl-3-keto-4,5-D-*threo*-dihydroxypiperidine. An attempt is being made to isolate the unidentified substance(s).

EXPERIMENTAL

Solutions were concentrated under reduced pressure below 40° C with a rotating vacuum-type evaporator. Melting points were determined on a Fisher–Johns melting point apparatus. Optical rotations were measured at 23±3° C with a Hilger Standard Polarimeter. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrophotometer. Paper chromatography was carried out by the descending method at room temperature on Whatman No. 1 filter paper for qualitative purposes or on Whatman 3MM filter paper for preparative purposes in the following solvent systems (v/v): (A) butan-1-ol:ethanol:water, 3:1:1; (B) butan-1-ol:pyridine:water, 10:3:3. Sugars were detected on paper chromatograms by the following spray reagents: (i) alkaline silver nitrate (3); (ii) *p*-anisidine hydrochloride (4); (iii) modified ceric ammonium nitrate reagent (5); (iv) orcinol – trichloroacetic acid (ketose spray) (6). Rates of movement of the sugars on paper chromatograms are given relative to that of rhamnose (R_{rh}).

1,2-O-Isopropylidene-5-O-toluene-p-sulphonyl-D-xylose

This compound was prepared from D-xylose (33 g) by the method of Levene and Raymond (2). The crystalline product (44 g, 58%) was recrystallized from ethyl acetate and it then melted at 133–134° and had $[\alpha]_D = -12.4°$ (*c*, 2.9 in chloroform). Levene and Raymond report m.p. 133–134° and $[\alpha]_D^{20} = -13.0°$ (*c*, 2.0 in chloroform).

5-Acetamido-5-deoxy-1,2-O-isopropylidene-D-xylose

1,2-*O*-Isopropylidene-5-*O*-toluene-*p*-sulphonyl-D-xylose (26 g) was dissolved in anhydrous methanol (500 ml) and the solution was cooled to 0° and saturated with dry ammonia. The solution was then heated in an autoclave at 120° for 16 hours. After cooling, the dark reaction mixture was boiled with charcoal, filtered, and the filtrate was passed through Amberlite IRA 400 (OH form) anion exchange resin (300 ml). The eluate was evaporated to dryness under reduced pressure to yield a dark syrup (12.8 g). This material was dissolved in water (104 ml) and treated with acetic anhydride (14.5 ml). The solution was allowed to stand for 20 minutes with occasional shaking, then evaporated to dryness under reduced pressure to leave a syrup (14.9 g) which crystallized on standing. Two recrystallizations of this material from methanol–ether gave rectangular plates (7.2 g, 41%) which melted at 111–112° and had $[\alpha]_D = +31°$ (*c*, 2.29 in methanol) and R_{rh} 2.44 (solvent A, spray iii). The infrared spectrum in chloroform showed strong absorption at 3330

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

cm^{-1} and at 1527 cm^{-1} attributable to NH, strong absorption at 1657 cm^{-1} owing to N—Ac, and absorption at 1377 cm^{-1} attributable to CH of the isopropylidene group. Calc. for $C_{10}H_{17}NO_5$: C, 52.0; H, 7.4; N, 6.1%. Found: C, 52.3; H, 7.5; N, 6.0%.

*Hydrolysis of 5-Acetamido-5-deoxy-1,2-O-isopropylidene-*D*-xylose*

5-Acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose (6.4 g) was dissolved in 20% aqueous acetic acid (40 ml) and the solution was heated at 90° for 1.5 hours. The dark solution was then evaporated under reduced pressure to yield a brown syrup (5.9 g) which was examined on paper chromatograms. Sprays i and ii both showed the presence of components at R_{rh} 0.66 and 1.18 (solvent A) and 0.48 and 0.99 (solvent B). An elongated spot running slightly faster than that with R_{rh} 1.18 was also detected (solvents A and B, sprays i and ii). This spot was also detected with the orcinol – trichloroacetic acid ketose spray reagent (spray iv). Spray iii showed an additional component with R_{rh} 2.44 (solvent A) which was unchanged 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose. The syrup was placed on a cellulose column (54×4.5 cm) and irrigated with butan-1-ol half-saturated with water. Three components of the hydrolyzate were obtained in a pure state:

*(a) 5-Acetamido-5-deoxy-1,2-O-isopropylidene-*D*-xylose*

This component was obtained from the eluate as a brown syrup (2.9 g) which crystallized on standing. After recrystallization from methanol–ether the compound melted at 111–112°. There was no depression of the melting point on admixture with an authentic sample of 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose. The infrared spectrum in chloroform was also identical with that of 5-acetamido-5-deoxy-1,2-*O*-isopropylidene-D-xylose.

*(b) 5-Acetamido-5-deoxy-*D*-xylofuranose*

This component was obtained from the eluate as a brown syrup (0.43 g) which could not be induced to crystallize. The compound had $[\alpha]_D$ +13.2° (*c*, 1.36 in methanol) and R_{rh} 1.18 (solvent A), 0.99 (solvent B). The infrared spectrum (smear between "IR tran 2" plates) showed strong absorption at 3300 cm^{-1} attributable to OH and NH, weak absorption at 1730 cm^{-1} attributable to the C=O stretching vibration of a small amount of the acyclic aldehyde form of the compound, strong absorption at 1630 cm^{-1} owing to N—Ac, and strong absorption at 1557 cm^{-1} owing to NH.

*(c) 1-Acetyl-*D*-gulo(ido)-2,3,4,5-tetrahydroxypiperidine*

This component was obtained from the eluate as a white crystalline solid (1.80 g). After recrystallization from methanol–ether it melted at 153–154°, and had $[\alpha]_D = -11.3°$ (*c*, 0.95 in methanol) and R_{rh} 0.66 (solvent A), 0.48 (solvent B). The infrared spectrum of this material (0.8% in KBr) showed strong absorption at 3310 cm^{-1} attributable to OH, and strong absorption at 1598 cm^{-1} owing to N—Ac, but no absorption due to NH. Calc. for $C_7H_{13}NO_5$: C, 43.97; H, 6.85; N, 7.33%. Found: C, 43.93; H, 6.87; N, 7.54%.

Preparation of Phenylosazones

*(a) From 5-Acetamido-5-deoxy-*D*-xylofuranose*

5-Acetamido-5-deoxy-D-xylofuranose (0.036 g) in 20% aqueous acetic acid (2.5 ml) was heated at 70° C for 1 hour with sodium metabisulphite (0.030 g) and freshly distilled phenylhydrazine (0.5 ml). The solution was allowed to cool in a refrigerator and the osazone that crystallized (0.053 g) was removed by filtration. Recrystallization from ethanol–water gave yellow needles which melted at 162–164° (decomp.). The infrared spectrum of this compound (0.8% in KBr) showed absorption at 3260 cm^{-1} (OH and NH), 3080 cm^{-1} (aromatic CH), 1657 cm^{-1} (amide I), 1640 cm^{-1} (amide II), and 1605, 1500, 745, 686 cm^{-1} (aromatic ring).

*(b) From 1-Acetyl-*D*-gulo(ido)-2,3,4,5-tetrahydroxypiperidine*

The phenylosazone was prepared as above and was obtained as yellow needles, m.p. 162–164° (decomp.). There was no depression of the melting point on admixture with the phenylosazone from 5-acetamido-5-deoxy-D-xylofuranose. The two preparations of the phenylosazone gave indistinguishable infrared spectra over the range 4000–650 cm^{-1} and moved at identical rates on paper chromatograms. Calc. for $C_{19}H_{23}O_3N_5.H_2O$: C, 58.9; H, 6.5%. Found: C, 58.8; H, 7.0%.

Reductions with Sodium Borohydride

*(a) 5-Acetamido-5-deoxy-*D*-xylofuranose*

5-Acetamido-5-deoxy-D-xylofuranose (0.100 g) was dissolved in distilled water (50 ml) and an excess of sodium borohydride (0.100 g) was added. The solution was allowed to stand in a refrigerator and tested from time to time with Fehling's solution. When the solution became non-reducing (10 hours) acetone was added to destroy the excess sodium borohydride. The solution was passed through a column of Amberlite IR 120 (H form) resin (10 ml) and the resin was washed with an excess of water. The eluate and washings were evaporated to dryness under reduced pressure. Boric acid was removed by repeated distillation with methanol. The residual clear colorless syrup (0.090 g) could not be induced to crystallize from a variety of solvents. Paper chromatography in solvent A showed the presence of a major component at R_{rh} 0.74 and of a minor one at R_{rh} 1.18 (spray i); the latter was probably 5-acetamido-5-deoxy-D-xylofuranose. The component

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

having R_{rh} 0.74 was separated by chromatography on 3 MM paper in solvent A and obtained as a clear colorless syrup which could not be induced to crystallize. The syrup had $[\alpha]_D = +21.2°$ (*c*, 0.33 in methanol).

(b) 1-Acetyl-D-gulo(ido)-2,3,4,5-tetrahydroxypiperidine

This compound (0.100 g) was reduced with sodium borohydride as above. Reduction was considerably slower in this case and required 40 hours for completion. A clear colorless syrup (0.093 g) was obtained which had R_{rh} 0.74 (solvent A, spray i) and $[\alpha]_D = +20°$ (*c*, 0.60 in methanol). The reduced product and the one described above had identical infrared spectra over the range 4000–650 cm^{-1}.

Influence of Heat on 5-Acetamido-5-deoxy-D-xylofuranose and 1-Acetyl-D-gulo(ido)-2,3,4,5-tetrahydroxypiperidine

Aqueous solutions of each compound (2%) were heated in a water bath at 80° C for 1 hour and then examined on paper chromatograms run in solvent A. Two components with R_{rh} 0.66 and 1.18 were detected by sprays i and ii in each case. No interconversion was detectable by paper chromatography when aqueous solutions of either compound were kept at room temperature for 12 hours.

Reaction of 5-Acetamido-5-deoxy-D-xylofuranose with Methanolic Hydrogen Chloride

5-Acetamido-5-deoxy-D-xylofuranose (0.042 g) was dissolved in methanolic hydrogen chloride (1.2%, 4 ml) and allowed to stand at room temperature. The optical rotation was measured at intervals:

Time (hr)	0.23	0.58	1.10	3.50
$[\alpha]_D$	+27.4	+29.2	+23.6	+22.6

The solution became deep yellow and the optical rotation could not be measured after 3.5 hours. The solution was then neutralized with silver carbonate and filtered. The filtrate was treated with hydrogen sulphide and filtered again through Celite. The clear solution was evaporated under reduced pressure to yield a brown syrup (0.040 g) which was non-reducing towards Fehling's solution. Paper chromatography in solvent A gave only one spot, R_{rh} 1.04 (spray ii). The infrared spectrum (smear between "IR tran 2" plates) showed absorption at 3320 cm^{-1} (OH and NH), 1637 cm^{-1} (N—Ac), and 1565 cm^{-1} (NH).

Reaction of 1-Acetyl-D-gulo(ido)-2,3,4,5-tetrahydroxypiperidine with Methanolic Hydrogen Chloride

Qualitative Experiment

1-Acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine (0.045 g) was dissolved in methanolic hydrogen chloride (1.2%, 4 ml) and allowed to stand at room temperature. The optical rotation was measured at intervals:

Time (hr)	0.33	0.78	1.80	3.35	6.64
$[\alpha]_D$	+14.1	+15.0	+15.9	+15.9	+15.9

The solution remained clear and colorless.

Preparative Experiment

1-Acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine (0.126 g) was dissolved in methanolic hydrogen chloride (1.2%, 11.2 ml) and allowed to stand at room temperature for 2 hours. The solution was then worked up as described above to yield a yellow syrup (0.130 g) which crystallized on standing. Paper chromatography in solvent A showed the presence of traces of starting material at R_{rh} 0.65, a major component at R_{rh} 1.15, and a minor at R_{rh} 1.48 (spray ii). The crystalline material was recrystallized first from methanol – ethyl acetate and then from methanol–ether to yield colorless rectangular crystals which were non-reducing towards Fehling's solution. The melting point of this material was 153.5–154.5°; the mixed melting point on admixture with 1-acetyl-D-*gulo*(*ido*)-2,3,4,5-tetrahydroxypiperidine was 139–150°. Paper chromatography in solvent A showed only one major component, at R_{rh} 1.15. The infrared spectrum (0.8% in KBr) showed strong hydroxyl absorption at 3400 cm^{-1} and absorption owing to N—Ac at 1625 cm^{-1} but no absorption attributable to NH. Calc. for $C_8H_{15}O_5N$: C, 46.8; H, 7.37; N, 6.8; OCH_3, 15.1%. Found: C, 46.85; H, 7.24; N, 6.8; OCH_3, 13.2%.

Periodate Oxidation

The compound under examination (10–15 mg) was dissolved in water containing 0.3 *M* sodium metaperiodate solution (1 ml). The total volume was made up to 25 ml with additional water. A blank was prepared with 0.3 *M* sodium metaperiodate (1 ml), which was made up to 25 ml with water. The solutions were stored in the dark at room temperature and 2-ml aliquots were removed at intervals from each of the two solutions for the determination of periodate uptake (7). Formic acid production was determined by addition of ethylene glycol (1 ml) to an aliquot portion (2 ml), followed by titration after 10 minutes with 0.01 *N* sodium hydroxide using methyl red screened with methylene blue as the indicator. The results are summarized in Table I. (No formaldehyde was detected in either (*a*) or (*b*) by the chromotropic acid method (8).)

STUDIES ON THE PIGMENTS OF PENICILLIUM HERQUEI[1]

N. NARASIMHACHARI[2] AND L. C. VINING[3]

The National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received October 9, 1962

ABSTRACT

Several minor pigments from cultures of *Penicillium herquei* are described. One of these has been identified as the naphthalic anhydride which is formed when atrovenetin is oxidized with alkaline peroxide. Evidence is presented which suggests that the characteristic green pigment found in this fungus is formed by a reaction analogous to that between ninhydrin and amino derivatives. In *P. herquei* the 1,2,3-trione is probably generated by mild oxidation of perinaphthenone pigments known to be produced by this organism.

Two red pigments, norherqueinone and its monomethyl ether, herqueinone, have been shown (1, 2) to account in a large measure for the color of the mycelium of stationary cultures of *Penicillium herquei* Bainier and Sartory. These are known (3) to be related in structure to atrovenetin [I], the yellow perinaphthenone derivative produced by *P. atrovenetum* G. Smith, since the latter compound can be obtained from norherqueinone by mild reduction. It has been suggested (3) that in herqueinone and norherqueinone the aromaticity of the perinaphthenone system is blocked by a hydroxyl function but no detailed chemical structures for the two pigments have yet been published.

but, in media rich in peptone, a deep blue pigment was formed. The presence of dark green pigments in *P. herquei* and *P. atrovenetum* was noted by Raistrick and co-workers (2, 5). Unlike most other green pigments occurring in fungal mycelia these could be readily extracted into chloroform. They were not isolated in a pure condition but it was suggested that the formation of quinhydrones analogous to that prepared by Koelsch and Anthes (6) from a mixture of perinaphthenone and perinaphthanone might be responsible for the deep color. In this connection it is of interest that the perinaphthyl radical [II] is relatively stable (7, 8) and displays a blue-green color; the long wavelength absorption maximum for acetoxyperinaphthyl is reported (8) to be at 613 mμ. The presence of similar green pigments in *P. herquei* and *P. atrovenetum* was considered by Raistrick and his colleagues (5) to be further evidence of the close relationship between the two species of fungi.

A green chloroform-extractable pigment in the mycelium of *P. herquei* has also been observed by Riedhart and Porter (9). These authors showed that when a viable mycelium containing the green substance was incubated in the dark, a color change to yellow occurred. Reversion to the green product took place in the light in the presence of oxygen. They prepared both the green pigment and its reduced form in a crude state and described a number of their properties.

The presence of other pigments in extracts from the mycelium of *P. herquei* was recorded by Raistrick and co-workers (2). One of these was isolated in a pure state and identified as physcion. A yellow-brown crystalline substance with antibacterial activity was obtained by Burton (10) from culture filtrates of the fungus. A number of its properties were described but no structural studies appear to have been carried out. Gopalkrishnan and Narasimhachari (11) also isolated a brownish-yellow pigment from an Indian isolate of *P. herquei* which showed similar antibiotic activity to Burton's culture. The properties of this pigment differed markedly from those of herquein, as well as from other known pigments of *P. herquei*.

In the present study two strains of *P. herquei* were employed. The first was that used by Gopalkrishnan and Narasimhachari and is here designated the Ajmer strain. The second was strain I of the organism used by Riedhart and Porter (9). It is referred to here as the Purdue strain. Attention was directed initially towards identification of the pigment produced by the Ajmer strain. However, changes in the cultural characteristics of this organism resulted in loss of the desired properties after only a small quantity of the fermentation products had been accumulated. One of these appeared to be a new compound. Work was continued with the Purdue strain in the expectation that it would also produce the new substance and provide a quantity sufficient for chemical studies. This expectation was not realized and subsequent studies were devoted to the pigments isolated from the Purdue strain when the fungus was grown in surface or submerged culture.

Ajmer Strain

Chromatographic examination of material extracted from the mycelium of stationary cultures showed it to be a mixture of two pigments. One was identified as herqueinone. The other, which will be referred to as compound A, corresponded in most of its properties to the pigment isolated by Gopalkrishnan and Narasimhachari (11). Reliable elemental analyses could not be obtained because of the shortage of material, but the molecular weight estimation of 390 is of the same order as those of the hydroxyperinaphthenone pigments of *P. herquei*. The color reaction with ferric chloride and intense yellow fluores-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

cence obtained with concentrated sulphuric acid support such a structure. Reductive acetylation gave a product which, though not purified, showed some resemblance in its ultraviolet and visible absorption spectra to that of a 9-hydroxyperinaphthen-1-one (3). Compound A differed from known pigments of this type in possessing multiple carbonyl absorption peaks in the infrared spectrum. The positive reaction with 2,4-dinitrophenylhydrazine indicates that at least one of these is due to an aldehydic or ketonic function.

Purdue Strain, Surface Culture

A red pigment was obtained from the mycelium of stationary cultures grown and extracted in the manner used for the Ajmer strain. Chromatographic examination showed it to be mainly herqueinone, with smaller amounts of norherqueinone, and only traces of other pigmented and fluorescent products. One of the latter (compound B), which had an intense greenish yellow fluorescence, was obtained in a small amount as yellow crystals, m.p. 168° C. Analyses and molecular weight estimations agreed with the formula $C_{21}H_{22}O_9$. The substance showed only a single, broad absorption maximum in the carbonyl stretching region centered at 1612 cm^{-1} (cf. atrovenetin, 1620 cm^{-1}). It possessed neither ketonic nor quinonoid properties but gave, by acetylation under reducing conditions, an acetyl derivative different from that obtained by simple acetylation. Neither of these products possessed the typical ultraviolet absorption spectrum of perinaphthenone.

The ultraviolet absorption spectrum of ethanolic solutions of compound B underwent a slow change. The end product, which exhibited a blue fluorescence, had a spectrum similar in shape and the positions of the maxima to those of compound A, compound B leucoacetate, and atrovenetinone ethanolate (see later). It is suggested therefore that each of these substances contains perinaphthane-1,3-dione [III] as a common structural feature.

Purdue Strain, Submerged Culture

Prolonged Soxhlet extraction of the mycelium with ether gave atrovenetin as the major product. The isolation of this pigment, which had hitherto been found only in surface cultures of the related species *Penicillium atrovenetum* G. Smith, has already been commented upon (12). Mild oxidation of atrovenetin in ethanol with *p*-benzoquinone gave a pale yellow product, $C_{21}H_{22}O_7$. At approximately 130° C this is converted to an unstable, brownish-red compound which sublimes under high vacuum. The sublimate dissolves easily in ethanol to regenerate the initial oxidation product. Reduction of the latter with zinc in acetic acid gave a mixture of products, one of which was identified chromatographically as atrovenetin. Reductive acetylation gave atrovenetin triacetate. Methylation with diazomethane gave a derivative believed to be a dimethyl ether, but insufficient product was available for adequate characterization. Oxidation of atrovenetin yellow trimethyl ether or herqueinone with *p*-benzoquinone gave only unchanged starting material. The infrared spectrum of the oxidation product showed absorption maxima attributable to intramolecularly bonded and unbonded hydroxyl groups and at least one conjugated and hydrogen-bonded carbonyl function.

Mild oxidation of 2,3-dihydroxyperinaphthen-1-one with bromine water has been reported by Errera (13) to give perinaphthane-1,2,3-trione. This forms a stable hydrate or alcoholate, considered to have the structure [IV]. By analogy with this reaction and by considering the properties described above, the oxidation product from atrovenetin is formulated as [V]. The parent triketone has been named atrovenetinone.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

From the filtrates of submerged cultures of the Purdue strain of *P. herquei*, herqueinone, norherqueinone, and atrovenetin were isolated. Traces of other pigmented and fluorescent substances were also detected; chromatographic examination showed several of these as well as a small amount of herqueinone to be present also in the mycelial extracts. One of them, distinguished by its intense blue fluorescence, was isolated in sufficient quantity for chemical study and shown to be identical with the naphthalic anhydride obtained from atrovenetin by oxidation with alkaline peroxide and shown by Barton and colleagues (14) to have the structure [VI].

After solvent fractionation and repeated chromatography on silicic acid, a small amount of a green pigment was obtained in an apparently homogeneous condition. This was an amorphous solid of no distinct melting point with a molecular weight of 1090. Insufficient material was obtained for carbon and hydrogen analyses but the molecule contained 1 atom of nitrogen. Weakly basic properties were suggested by the color shift which occurred when an ethereal solution was shaken with dilute mineral acid. An unstable violet product was formed which, if neutralized within a short time, reverted to the original green pigment. On prolonged exposure to acid, irreversible decomposition occurred to a pale yellow product, the ultraviolet absorption spectrum of which was similar to that of atrovenetinone ethanolate. The green pigment was reversibly reduced with zinc in acetic acid to a yellow substance. Reoxidation took place slowly in air and appeared to be more rapid in the light than in the dark, though no definitive tests were made. Repeated reduction and reoxidation under these conditions caused a change in the color of the oxidized form to bluer shades, with a corresponding decrease in the visible absorption maximum from 612 mμ to 604 mμ.

These properties are consistent with those described by Riedhart and Porter (9) for the green pigment which they obtained from *P. herquei*, except that these authors apparently overlooked the transient reversible change in acid. The formation of colorless crystals by evaporation of a pyridine solution of the pigment and the sublimation from the crude solid of a yellow crystalline product could not be reproduced, but may well have been due to impurities. Samples of the green pigment prepared in the manner described by Riedhart and Porter were found to be chromatographically inhomogeneous. An indication that the green pigment is a perinaphthenone derivative is provided by the position of the carbonyl absorption maximum in the infrared spectrum. The similarity between the ultraviolet absorption spectra of its leucoacetate and substituted perinaphthenones, and of the acid degradation product and atrovenetinone ethanolate, affords further evidence.

Perinaphthane-1,2,3-trione (or its hydrate) has been shown by Moubasher and Awad (15) to react, as might be expected from its structural resemblance to ninhydrin, with amino acids, ammonia, or bases to give highly colored products. In view of the molecular weight of the green pigment from *P. herquei* and the presence of nitrogen in the molecule, we suggest that it is formed in the fungus by a similar reaction. In support of this argument, conditions have been discovered under which atrovenetinone will react with ammonia or amino acids to give a product with properties very similar to those of the pigment isolated from the natural source.

Such a structure for the blue-green pigments of *P. herquei* and *P. atrovenetum* offers a plausible explanation for Bainier and Sartory's observation that nutrient media with a high peptone content cause a change in pigmentation of *P. herquei* from orange-yellow to blue. We have also observed that lowering the redox potential of the culture medium,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

e.g., by the addition of sodium sulphite, prevents the appearance of blue-green pigmentation in the mycelium. That cultures of the fungus used in these studies are strongly oxidizing in character is attested to by the isolation of the anhydride [VI], which is almost certainly formed by oxidation of atrovenetin. Whether this and the postulated conversion of atrovenetin to atrovenetinone are brought about by chemical or enzymatic reactions is a matter requiring further study.

EXPERIMENTAL

Conditions of Culture

All cultures were grown in Erlenmeyer flasks (500 ml) containing a nutrient solution of the following composition: 5% sucrose, 0.3% $NaNO_3$, 0.2% corn steep liquor, 0.1% KH_2PO_4, 0.1% KCl, 0.05% $MgSO_4.7H_2O$, 0.001% $FeSO_4.7H_2O$, 0.005% $ZnSO_4.7H_2O$, and 0.3% $CaCO_3$.

For surface cultures, a young 3% vegetative inoculum and 350 ml of medium per flask were used. Cultures were left undisturbed at 25° C for 25 to 30 days, by which time a red-brown mycelial mat had developed.

Submerged cultures were prepared with a young 10% vegetative inoculum and 100 ml of nutrient per flask. They were agitated on a rotary shaker for 7 to 8 days. The mycelium became greenish yellow and finally dark green in color. The broth varied from yellow to reddish yellow but invariably had an intense greenish yellow fluorescence.

Isolation of Pigments

Ajmer Strain, Stationary Culture

The mycelial mat was separated, washed with water, pressed firmly on a Büchner funnel, and vacuum applied to remove excess moisture. It was then extracted in a Soxhlet apparatus for 24 hours with ether. Evaporation of the ethereal extract left an oily residue which could be converted to a red solid by trituration with petroleum ether. Circular paper chromatography on formamide-treated paper with benzene as mobile phase showed this to be a mixture of two pigments giving an orange zone with the same R_f value (0.82) as authentic herqueinone and a yellow zone, R_f 0.03.

A sample (49 mg), chromatographed on a column of silicic acid (10 g) developed with chloroform, separated into two fractions. A red zone was eluted first and gave, on evaporation, a partially crystalline substance (30 mg). This was recrystallized from methanol as red prisms, m.p. 224–226° C undepressed on admixture with authentic herqueinone. The ultraviolet, visible, and infrared spectra and R_f value (0.65), when examined by thin-layer chromatography on silica gel G using chloroform – acetic acid (7:3) as developing solvent, were also indistinguishable from those of herqueinone. The second zone, orange yellow in color, yielded a residue (compound A, 8 mg) which was crystallized from an acetone–petroleum ether (b.p. 60–80° C) mixture as orange-brown, boat-shaped prisms decomposing slowly above 190° C without exhibiting a distinct melting point; mol. wt. (Mechrolab Osmometer using acetone as solvent) 390; $\lambda\lambda_{max}$ (in ethanol) 257 mμ ($E^{1\%}_{1\,cm}$ = 353), 321 mμ ($E^{1\%}_{1\,cm}$ = 350), and 420 mμ (infl., $E^{1\%}_{1\,cm}$ = 26); ν_{max} (KBr disk) 3395, 1724, 1708, 1685, 1657, 1588, 840, and 802 cm^{-1}.

Compound A was insoluble in water or petroleum ether, sparingly soluble in benzene or carbon tetrachloride, but easily soluble in other common organic solvents. It dissolved slowly in 0.1 *N* $NaHCO_3$ and readily in dilute Na_2CO_3 or NaOH, giving an orange solution. In concentrated sulphuric acid it gave a yellow solution with bright yellow fluorescence but it was insoluble in dilute acids. With ferric chloride in ethanol it gave a brownish-green color and with 2,4-dinitrophenylhydrazine an orange-red precipitate. Treatment with zinc in acetic acid at room temperature rapidly reduced the orange solution to a pale greenish yellow. Prolonged shaking in air partially restored the original color. Reductive acetylation (30 minutes on a steam bath with acetic anhydride and anhydrous sodium acetate) gave a product with brilliant blue fluorescence and $\lambda\lambda_{max}$ at 230, 252 (infl.), 263, 333, 350, 367, 388 (infl.), and 435 mμ.

Purdue Strain, Stationary Culture

Mycelium.—The pigment was extracted as above with ether from the pressed mycelial mats of five flasks and gave, after trituration with petroleum ether, a red solid (500 mg). Extraction of this material with several portions of cold chloroform left a residue (64 mg) which, after two crystallizations from glacial acetic acid, gave fine red needles decomposing at 262° C on slow heating. The melting point behavior was unchanged on admixture with authentic norherqueinone. Found: C, 63.59%; H, 5.10%. Calc. for $C_{19}H_{18}O_7$: C, 63.58%; H, 5.06%. The ultraviolet, visible, and infrared spectra were also indistinguishable from those of authentic norherqueinone.

A sample (327 mg) of the chloroform-soluble fraction was chromatographed on a column (5×50 cm) of silicic acid developed initially with benzene. Three very minor zones were slowly eluted. The first contained an intensely blue fluorescent substance, $\lambda\lambda_{max}$ (in ether) 255, 355 (infl.), 360, and 378 mμ. The second and third contained yellow non-fluorescent products, $\lambda\lambda_{max}$ (in $CHCl_3$) 257, 280 (infl.), 344, 365 (infl.), 410 (infl.) mμ and $\lambda\lambda_{max}$ (in $CHCl_3$) 259.5, 344 mμ respectively. On changing the developing solvent to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

chloroform a major red zone was eluted. Evaporation of the solvent left deep red needles (280 mg) which after two recrystallizations from aqueous methanol gave clusters of small red prisms, m.p. 224° C, undepressed on admixture with authentic herqueinone. Found: C, 64.3%; H, 5.3%; OCH_3, 8.3%. Calc. for $C_{20}H_{20}O_7$: C, 64.5%; H, 5.4%; 1-OCH_3, 8.35%. The ultraviolet, visible, and infrared spectra were also indistinguishable from those of authentic herqueinone.

After herqueinone a minor zone showing intense yellow fluorescence was eluted. The ultraviolet absorption spectrum showed this fraction to be contaminated with herqueinone. It was therefore rechromatographed on a second column (2.5×30 cm) of silicic acid and the product from appropriate fractions of the chloroform eluate crystallized twice from a chloroform – carbon tetrachloride mixture to give lemon yellow needles (compound B, 18 mg), m.p. 168° C. Found: C, 60.51%; H, 5.24%; CCH_3, 16.5%; mol. wt. (Mechrolab Osmometer using acetone as solvent) 403. Calc. for $C_{21}H_{22}O_9$: C, 60.28%; H, 5.30%; 3CCH_3, 19.35%; mol. wt. 418; $\lambda\lambda_{max}$ (in ethanol) 244 mμ (ϵ = 24,000), 252 mμ (infl., ϵ = 21,500), 283 mμ (ϵ = 13,080), 340 mμ (infl., ϵ = 8500), 377 mμ (infl., ϵ = 14,950), 400 mμ (ϵ = 16,500), and 420 mμ (infl., ϵ = 15,150). In less polar solvents the shape of the spectrum changed appreciably so that the long wavelength maximum occurred at 378 mμ in ether and 377 mμ in $CHCl_3$ with inflections at 382 and 410 mμ in both solvents. The spectrum in ethanol underwent a slow change giving, after approximately 24 hours in redistilled 99% ethanol, a stable chromophore with a blue fluorescence and $\lambda\lambda_{max}$ 244 mμ (ϵ = 43,800), 265 mμ (infl., ϵ = 20,750), 343 mμ (ϵ = 13,400), and 372 mμ (infl., ϵ = 5750).

The infrared spectrum (KBr disk) of compound B had maxima at 3440, 1612 (broad), 1465, 1385, 910, and 854 cm^{-1}. The pigment was very soluble in ethanol, acetone, chloroform, or acetic acid; moderately soluble in ether or carbon tetrachloride; and insoluble in petroleum ether or water. It dissolved readily in 0.1 *N* $NaHCO_3$ or NaOH to a yellow solution which slowly decolorized. This was accompanied by a change in the fluorescence of the solution from yellow to blue. It was insoluble in dilute HCl but dissolved in concentrated H_2SO_4 to a greenish yellow solution with a bright yellow fluorescence. Ferric chloride in ethanol gave a green color. Tests for ketonic and aldehydic carbonyl functions were negative.

Acetylation (30 minutes at 100° C with acetic anhydride and anhydrous sodium acetate) gave a product with weak yellow fluorescence and $\lambda\lambda_{max}$ 243, 338 (infl.), 354, and 400 mμ. Reductive acetylation, as above but with the addition of zinc dust, gave a product with intense blue fluorescence and $\lambda\lambda_{max}$ 260, 341, and 412 mμ (infl.) in ether.

Culture filtrate.—A portion (1 liter) of the filtered broth from these stationary cultures was acidified to pH 2 and extracted twice with ethyl acetate. When the extracts were combined and evaporated, a red solid (100 mg) was obtained. Chromatography on a silicic acid column gave only a single, orange-red zone from which, by evaporation of the solvent and crystallization of the residue from methanol, herqueinone (75 mg), m.p. 224–226° C, separated.

Purdue Strain, Shaken Culture

Mycelium.—Removal of the pigment was found to be very difficult if the filtered mycelial solids were dried before extraction. When the pressed filter cake (wet weight 75 g) from 10 flasks was extracted with ether in a Soxhlet apparatus for 24 hours, then drained and re-extracted with methanol for a further 12 hours, most of the pigment was removed. The ether extract deposited on the walls of the receiver a yellow solid which, after several recrystallizations, yielded yellow needles, m.p. 290° C (decomp.) with prior darkening from 270° C. Found: C, 66.8%; H, 5.6%. Calc. for $C_{19}H_{18}O_6$: C, 66.7%; H, 5.3%. The melting point showed no depression on admixture with an authentic sample of atrovenetin, and the ultraviolet, visible, and infrared spectra of the two substances were indistinguishable.

The washings and mother liquors from the purification of atrovenetin were combined with the methanolic extract of the mycelium and the deep green solution evaporated to dryness *in vacuo*. The solid was taken up in chloroform, filtered, and the soluble portion chromatographed on a column of silicic acid. Development with chloroform eluted a dark zone, collected as a series of fractions ranging in color from blue to green. On keeping, they all changed to a stable, dark green color. Evaporation of the pooled solutions gave a green amorphous solid. By thin-layer chromatography on silica gel G using benzene as solvent and paper chromatography using benzene – petroleum ether (1:1) with formamide-treated paper, this was found to be heterogeneous.

The material (110 mg) was redissolved in benzene and applied to a column (30×2.5 cm) of silicic acid. On prolonged developing with benzene the deep green band resolved into a series of zones which were eluted in succession to give (*a*) orange yellow cubes (2 mg) by slow evaporation of an ethereal solution, $\lambda\lambda_{max}$ (in ether) 255, 382, and 404 mμ, (*b*) orange yellow rods (5 mg) by slow evaporation of an ethereal solution, $\lambda\lambda_{max}$ (in ether) 293 and 409 mμ, and (*c*) a blue fluorescent substance (compound C) which was crystallized from benzene, ethanol, or carbon tetrachloride as cream-colored needles (32 mg), m.p. 256° C. Found for a sample sublimed at 140° C in high vacuum: C, 65.97%; H, 4.97%; CCH_3, 12.52%; mol. wt. (Mechrolab Osmometer using acetone as solvent) 338. Calc. for $C_{18}H_{16}O_6$: C, 65.85%; H, 4.89%; 2CCH_3, 14.14%; mol. wt. 328.2. The ultraviolet and infrared spectra were indistinguishable from those of an authentic specimen of the anhydride [VI]. The authentic sample, m.p. 257–258° C, caused no depression of melting point on admixture with compound C and had similar properties. Compound C was very soluble in chloroform; moderately soluble in acetone, ethanol, ether, and carbon tetrachloride; poorly soluble in benzene and insoluble in petroleum ether, water, dilute HCl or Na_2CO_3. It dissolved only slowly in caustic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

alkali but easily in concentrated H_2SO_4 to an orange-brown solution with a weak yellow fluorescence. An intense reddish-violet color formed on addition of ferric chloride in ethanol. Acetylation (30 minutes at 100° C with acetic anhydride and anhydrous sodium acetate) afforded a product with an ultraviolet absorption spectrum similar to that given by an authentic specimen of the diacetate of [VI].

Further elution of the column gave (*d*) orange-yellow plates (15 mg) by slow evaporation from ether, $\lambda\lambda_{max}$ (in ether) 288 and 431 mμ; this fraction was contaminated with compound C; and (*e*) a deep green substance purified further by precipitating with ethanol from a solution in chloroform. It was an amorphous solid (7 mg) which decomposed slowly above 200° C. Found: N (Dumas), 1.44%; mol. wt. (Mechrolab Osmometer, using carbon tetrachloride as solvent), 1090; $\lambda\lambda_{max}$ (in ether) 260, 340 (infl.), 366, 400 (infl.), and 612 mμ; ν_{max} (KBr disk) 1610, 1458, 1385, 865, and 800 cm^{-1}.

The green pigment was very soluble in chloroform, carbon tetrachloride, and acetone; moderately soluble in ether; and poorly soluble in ethanol, methanol, acetic acid, water, dilute HCl, and NaOH. In concentrated H_2SO_4 it gave a greenish-brown solution with a bright yellow fluorescence. Ferric chloride in ethanol gave a weak orange-brown color. On treatment with zinc an acetic acid solution of the green pigment became yellow in color. The change was accompanied by loss of the peak at 612 mμ, a shift of the 366 mμ maximum to 384 mμ, and a reduction in intensity of the 260 mμ peak. When the excess zinc was removed and the solution shaken in air the green color returned and the spectrum reverted to that of the original green solution. Reductive acetylation (30 minutes at 100° C with acetic anhydride, zinc dust, and anhydrous sodium acetate) gave a yellow fluorescent product with $\lambda\lambda_{max}$ (in ether) at 370 and 402 mμ and an inflection at 425 mμ.

When a solution of the green pigment in chloroform or ether was shaken with dilute aqueous hydrochloric acid the color rapidly changed to violet and was accompanied by a shift in the visible absorption maximum at 612 mμ to 550 mμ. If the solution was neutralized at this stage the change was reversible. Prolonged contact with acid caused a slow disappearance of the 550 mμ maximum. By 3 hours the spectral changes were complete and no longer reversible. The product of the reaction showed $\lambda\lambda_{max}$ (in ether) at 250 (infl.), 259, 343, and 360 (infl.) mμ.

Culture filtrate.—From the filtered broth (800 ml) of submerged cultures, by acidification with hydrochloric acid to pH 2, and extraction with ethyl acetate, a red solid (150 mg) was obtained. This was dissolved in benzene and chromatographed on a column of silicic acid. Development with benzene eluted in succession: (*a*) a trace of blue fluorescent material identified spectrally and by thin-layer chromatography on silica gel G using chloroform – acetic acid (7:3) as the anhydride [VI] (R_f 0.89); (*b*) and (*c*) traces of non-fluorescent orange products (R_f 0.82) not further examined. Use of chloroform as developing agent eluted (*d*), a non-fluorescent orange zone from which herqueinone (50 mg) was obtained. Addition of 10% methyl ethyl ketone to the chloroform used as elutriant removed (*e*), a poorly defined, fluorescent, yellow zone from which atrovenetin (30 mg) was crystallized. Thin-layer chromatography of the mother liquor showed that, in addition to atrovenetin (R_f 0.05), compound B (R_f 0.25) was present. Finally, elution of the column with methanol removed an orange zone which, on evaporation, gave a red-brown amorphous substance (20 mg). Circular paper chromatography using formamide-treated paper and chloroform as mobile phase showed this to be mainly norherqueinone (R_f 0.64).

Oxidation of Atrovenetin with p-Benzoquinone

Atrovenetin (50 mg) suspended in ethanol (3 ml) was heated on a water bath for 15 minutes with *p*-benzoquinone (20 mg). From the resulting deep brown solution pale yellow needles of atrovenetinone ethanolate were deposited on cooling. These were separated and recrystallized from ethanol. The crystals begin to sinter and darken from 130° C, melting finally at 212–216° C. Found in a sample dried in high vacuum at room temperature: C, 65.35%; H, 5.74%; mol. wt. (Mechrolab Osmometer using acetone as solvent) 395. Calc. for $C_{21}H_{22}O_7$: C, 65.27%; H, 5.74%; mol. wt. 386; $\lambda\lambda_{max}$ (in ethanol) 251 mμ (infl., ϵ = 46,300), 259 mμ (ϵ = 70,300), 275 mμ (infl., ϵ = 8320), 339 mμ (ϵ = 23,300), and 366 mμ (infl., ϵ = 12,500); ν_{max} (KBr disk) 3440, 3000–2600, 1605–1660 (broad), 1458, 1380, 856, 815, 805, and 796 cm^{-1}; (in CCl_4) 3490, 3000–2600, 1640–1610, 1459, and 1380 cm^{-1}.

Atrovenetinone was readily soluble in acetone, ether, chloroform, carbon tetrachloride, and benzene; sparingly soluble in ethanol and methanol; and insoluble in water. Addition of zinc dust to a solution in acetic acid caused a marked increase in intensity of the yellow color. Thin-layer chromatography showed that the reaction gave a mixture of products; one of these possessed the same R_f value as atrovenetin. Reductive acetylation (30 minutes at 100° C in acetic anhydride with anhydrous sodium acetate) gave a product indistinguishable from atrovenetin triacetate.

Reaction of Atrovenetinone with Ammonia and Amino Acids

Atrovenetinone (1 mg) in acetone (1 ml) was added to 0.01 *M* solution of NH_4Cl, phenylalanine, or leucine in 1 *M* phosphate buffer of pH 7.0. On heating of the mixture for 10 minutes on a steam bath, a green precipitate formed. This, when separated and dissolved in ether, afforded a deep green solution with λ_{max} 612 mμ. The solubility, color reactions, and spectral changes of this pigment when treated with acid and alkali, or reduced with zinc and acetic acid and allowed to reoxidize in air, were identical with those of the green pigment isolated from *P. herquei*. Its infrared spectrum and content of nitrogen (0.9%)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were similar to, but not identical, with those of the natural product. Thorough purification of the product was not attempted.

No green color was obtained when ammonia or the amino acid was omitted. Pure atrovenetin, herqueinone, compounds A and B, and the anhydride [VI] did not give the reaction.

ACKNOWLEDGMENTS

The authors wish to thank Professor C. L. Porter, Purdue University, Lafayette, Indiana, for a transfer of *P. herquei*; Professor H. Raistrick, Belfairs, Sea Drive, Felpham, Bognor Regis, Sussex, Professor D. H. R. Barton, Imperial College, London, and Dr. G. A. Morrison, Department of Organic Chemistry, The University, Leeds, for providing authentic specimens of known pigments of *P. herquei* and derivatives; Dr. R. H. Haskins, Mr. L. R. Nesbitt, and Mr. E. G. Rogala of the Prairie Regional Laboratory, and Mr. K. S. Gopalkrishnan of Hindustan Antibiotics Limited, Pimpri, near Poona, India, for help with microbiological aspects of the problem. Microanalyses and infrared spectra were provided by Mr. M. Mazurek and Mr. W. C. Haid of the Prairie Regional Laboratory. Miss M. J. A. Gates gave valuable technical assistance.

LYCOPODIUM ALKALOIDS

V. THE BROMINATION OF LYCOPODINE AND THE STRUCTURE OF ALKALOID L.20[1]

W. A. Ayer, J. A. Berezowsky, and D. A. Law
Chemistry Department, University of Alberta, Edmonton, Alberta

Received November 13, 1962

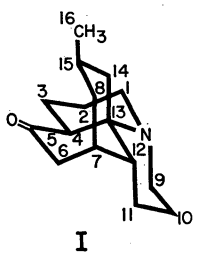
ABSTRACT

Monobromination of lycopodine hydrobromide in chloroform yields 6α-bromolycopodine hydrobromide, which can be epimerized to 6β-bromolycopodine hydrobromide. Hydrolysis of 6α-bromolycopodine proceeds with overall retention of configuration to give 6α-hydroxylycopodine, which is identical with the *Lycopodium lucidulum* alkaloid L.20. On the basis of some of the rotatory dispersion data presented it is suggested that positively charged nitrogen has a negative specific rotativity.

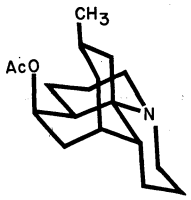
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In 1956 Barclay and MacLean reported (1) that the bromination of lycopodine, now known (2, 3) to have structure I, in carbon tetrachloride yielded a monobrominated product, isolated as its hydrobromide, of melting point 290–295° (decomp.). Attempts to isolate the corresponding free base were unsuccessful. In connection with structural studies on lycoclavine (4) we have had occasion to repeat and extend this work and wish at this time to report the results of this investigation.

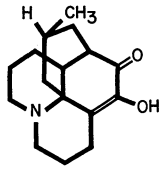
In our hands treatment of lycopodine with an equimolar amount of bromine in either carbon tetrachloride or chloroform without added hydrogen bromide led to the isolation of a crystalline product which proved to be a mixture of lycopodine hydrobromide and bromolycopodine hydrobromide. The melting point of this mixture (285–295°) corresponds to that reported by the earlier workers (1) and differs considerably from that of pure bromolycopodine hydrobromide (see below). The composition of the crystalline product was shown in the following manner. The analytical results obtained on an extensively recrystallized sample fitted best an approximately 1:1 mixture of bromolycopodine hydrobromide and lycopodine hydrobromide. Treatment of the mixture with aqueous sodium hydroxide followed by chromatography led to the isolation of lycopodine, in about 50% yield, as well as the enolic α-diketone III. Cocrystallization of equimolar quantities of lycopodine hydrobromide and bromolycopodine hydrobromide from a small volume of solvent yielded material the melting point and infrared spectrum



I



II



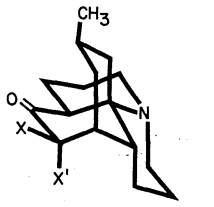
III

of which were similar to those of the recrystallized bromination product. The analytical results recorded by Barclay and MacLean suggest that their material contained approximately 80% of the bromo compound. Since bromolycopodine hydrobromide is some-

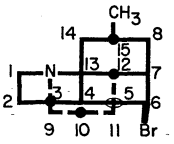
[1]*Part IV: W. A. Ayer and D. A. Law. Can. J. Chem.* **40**, *2088 (1962).*

what more soluble than lycopodine hydrobromide in the solvents used, the material obtained after several recrystallizations is actually richer in the non-brominated material. It was possible to obtain small quantities of pure bromolycopodine hydrobromide by fractional crystallization of the mother liquors. Since all of the bromine is consumed during the reaction, we attribute the incomplete bromination to competitive oxidative attack by bromine at the tertiary nitrogen. This view is supported by the observations that the preformed hydrobromide is cleanly monobrominated when treated with 1 mole of bromine (see below) and that acetyldihydrolycopodine (II) rapidly decolorizes 0.5 equivalent of bromine. In the latter reaction it was possible to recover 70% of the acetyldihydrolycopodine *as its hydrobromide*, indicating that reduction of the bromine had occurred.

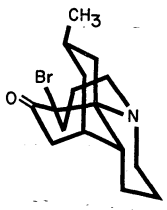
Bromination of lycopodine hydrobromide in chloroform containing a slight excess of hydrogen bromide gave, in better than 90% yield, 6α-bromolycopodine hydrobromide[2] (IV·HBr), m.p. 266–269°. The position and orientation of the bromine were shown in the following way. The nuclear magnetic resonance spectrum of IV showed a one-proton signal at 5.82 τ (broadened singlet), indicating that bromination had occurred at C-6 rather than C-4. The infrared spectrum of the hydrobromide in chloroform solution showed carbonyl absorption at 1711 cm^{-1}, little shifted from that of lycopodine hydrobromide (1707 cm^{-1}) and indicative of the axial nature of the C-6 bromine (6). The ultraviolet spectrum of the bromo compound (λ_{max} 306 mμ) showed the expected (7) bathochromic shift relative to lycopodine hydrobromide (λ_{max} 280 mμ).



IV X = H; X' = Br
VI X = Br; X' = H
X X = H; X' = OH



V



VII

With the structure of the bromo compound thus assigned, it was of interest to examine its optical rotatory dispersion curve in the light of the axial haloketone rule (8) and provide further evidence for the absolute configuration of lycopodine. The absolute configuration represented by structure I was first assigned by application of the octant rule to lycopodine itself (9). If structure IV represents the absolute configuration of 6α-bromolycopodine the axial haloketone rule predicts that it will show a positive Cotton effect whereas the enantiomer will show a negative Cotton effect. In fact, 6α-bromolycopodine hydrobromide does exhibit a *positive* Cotton effect with extrema at 332 and 280 mμ, amplitude[3] +10,650°. Lycopodine hydrobromide exhibits a negative Cotton effect with extrema at 305 and 268 mμ, amplitude −2770°. Since lycopodine itself shows a positive Cotton effect (9), amplitude +17,000°, it appears that positively charged nitrogen (which in the octant diagram (V)[4] for this system appears in the rear upper

[2]*The numbering system used is that suggested by Wiesner (5). Substituents in rings A, B, and C are referred to as α if trans to the C-7 to C-13 bridge and β if cis to the bridge.*

[3]*Amplitudes are given as the algebraic difference between molecular rotation for peak and trough.*

[4]*In the octant diagram V carbons 9, 10, and 11 lie directly behind carbons 3, 4, and 5, respectively, i.e., they they are in the horizontal plane.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

left octant) has, like fluorine, a negative specific rotativity (10). An alternate explanation, that the difference is due to a change in conformation on salt formation, seems, on the basis of the examination of molecular models (Dreiding), unlikely. Both lycopodine perchlorate and lycopodine methiodide show negative Cotton effects with amplitudes similar to that of the hydrobromide. A solution of lycopodine in acetic acid also exhibits a negative Cotton effect. In agreement with the octant rule (10) 6α-bromolycopodine shows a more strongly positive Cotton effect (amplitude +29,500°) than does lycopodine (see V).

When a solution of 6α-bromolycopodine hydrobromide (IV·HBr) in glacial acetic acid was heated for an hour on the steam bath the product, isolated in 75% yield after evaporation of the acetic acid and washing of the residue with acetone, showed carbonyl absorption (nujol) of approximately equal intensity at 1720 and 1703 cm^{-1}. By fractional crystallization from methanol it was possible to isolate the component responsible for the 1720 cm^{-1} band in about 10% overall yield. This has been assigned the structure 6β-bromolycopodine hydrobromide (VI·HBr) on the basis of its analysis and its infrared (ν_{max} 1728 cm^{-1} in $CHCl_3$) and ultraviolet (λ_{max} 276 mμ) spectra, both of which are indicative of an equatorial α-bromoketone (6, 7). The alternate formulation, 4β-bromolycopodine hydrobromide, although not excluded by this data, is considered highly unlikely, since it would force the molecule to adopt a conformation in which ring C is in a boat conformation involving a serious bowsprit–flagpole interaction (VII). The negative rotatory dispersion curve is almost plain, with a slight inflexion toward the negative side at 310 mμ. Attempts to effect the epimerization in higher yield by use of more strenuous reaction conditions resulted in extensive decomposition and much lower overall yields. When 6β-bromolycopodine hydrobromide (VI·HBr) was subjected to the epimerizing conditions noted above, the crude product did not show a detectable (by infrared) amount of the 6α-epimer, demonstrating that the product obtained from the 6α-compound is not an equilibrium mixture.

The free bromoketone IV was extremely sensitive to basic conditions. It was prepared by shaking a chloroform solution of the hydrobromide with cold dilute ammonium hydroxide or sodium bicarbonate. It decomposed on melting, with the elimination of hydrogen bromide and the formation of the unsaturated ketone VIII (see below), or on standing in methanol, as revealed by the decrease in amplitude of the optical rotatory dispersion curve with time and by the appearance of salt bands ($\overset{+}{N}H$) in the infrared spectrum of material recovered from the optical rotatory dispersion measurements. Treatment of 6α-bromolycopodine hydrobromide with aqueous sodium hydroxide at room temperature yielded a mixture of the enolic α-diketone III, previously prepared by selenium dioxide of lycopodine (4), and the unsaturated ketone VIII. The diketone III is presumably formed by aerial oxidation of the Δ^5-enolate form of the corresponding α-ketol (4), and the unsaturated ketone VIII by 1,4-elimination of HBr from the Δ^4-enol form of the bromoketone. The structure of the ketone VIII was shown in the following way. The ultraviolet spectrum showed a maximum at 244 mμ (log ε 3.9). The infrared spectrum showed peaks of almost equal intensity at 1680 and 1610 cm^{-1}, indicating (11) the cisoid nature of the α,β-unsaturated ketonic function. The n.m.r. spectrum revealed the presence of a single olefinic proton (poorly resolved triplet at 3.04 τ) located at the β-position of the unsaturated system (12). Reduction of the unsaturated ketone VIII with lithium and ammonia gave lycopodine (I), showing that no skeletal rearrangement had occurred during the dehydrobromination. The ketone VIII has recently been prepared by dehydration of flabelliformine (IX) (13).

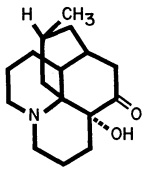
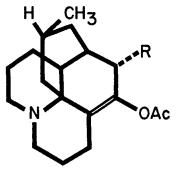
VIII



IX



XI R = OAc
XII R = H

When sodium bicarbonate was substituted for sodium hydroxide in the hydrolysis of 6α-bromolycopodine hydrobromide a crystalline compound, $C_{16}H_{25}O_2N$, m.p. 258–259°, was obtained in high yield. The high melting point and the infrared spectrum, which showed (in nujol) an unusually broad OH stretching vibration (2400–3200 cm^{-1}) were reminiscent of alkaloid L.20, first isolated by Manske and Marion from *Lycopodium lucidulum* Michx. (14) and later in these laboratories from the same plant.[5] Direct comparison (mixed melting point, infrared spectra, optical rotatory dispersion curves) confirmed the identity of the compounds from the two sources. This finding, coupled with the evidence presented below, necessitates a revision of the molecular formula of alkaloid L.20 from $C_{17}H_{27}O_2N$ (14) to $C_{16}H_{25}O_2N$.

The infrared spectrum of alkaloid L.20 in alcohol-free chloroform showed absorption at 3620 cm^{-1} (free OH) and 1710 cm^{-1} (ketone), thus defining the nature of the two oxygen atoms. Reduction of L.20 with calcium and ammonia (15) gave lycopodine, defining the carbon–nitrogen skeleton and the position of the carbonyl. The fact that the hydroxyl group was eliminated during the reduction shows that it is α to the carbonyl and suggests that it is axially orientated (15). This orientation is confirmed by the ultraviolet spectrum, which shows carbonyl absorption at 296 mμ (16), and the infrared spectrum, which reveals a non-hydrogen-bonded hydroxyl. The secondary nature of the hydroxyl group follows from the observation that L.20 is transformed to the diketone III in aqueous sodium hydroxide in the presence of air, and from the fact that the nuclear magnetic resonance spectrum of its acetyl derivative shows a one-proton signal at 5.11 τ (C*H*OAc). Thus alkaloid L.20 is 6α-hydroxylycopodine (X) and the hydrolysis of 6α-bromolycopodine proceeds with overall retention of configuration. When alkaloid L.20 (X) was treated with sodium propoxide in *n*-propanol in an atmosphere of nitrogen it was epimerized to the known (4) 6β-hydroxylycopodine. The epimerization also occurred when L.20 was passed through a column of basic alumina. The unsaturated ketone VIII was obtained when L.20 was subjected to the action of hot 10% hydrochloric acid.

Displacement reactions of α-haloketones normally proceed with inversion of configuration (17); however, in this case attack from the backside is extremely hindered by the C-7 to C-13 bridge and displacement is likely preceded by epimerization. In agreement with this view, the 6β-bromoketone (VI) also yields alkaloid L.20 (X) when treated with aqueous bicarbonate.

Acetylation of alkaloid L.20 with pyridine – acetic anhydride at −10° yielded the expected acetyl-L.20 (X, OAc in place of OH). However, when the acetylation was carried out at room temperature a high yield of the enol acetate XI was obtained. Compound XI absorbed in the infrared at 1760 and 1680 cm^{-1} (enol acetate carbonyl and double bond, respectively) and at 1735 cm^{-1} (acetoxyl). The nuclear magnetic resonance

[5]*We wish to thank Dr. L. Marion for an authentic sample of alkaloid L.20.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

spectrum showed two acetoxyl methyls (7.98 and 8.06 τ) as well as a one-proton signal at 5.02 τ (C*H*OAc). Hydrolysis of XI with dilute acid at room temperature afforded acetyl-L.20 and hydrolysis with aqueous bicarbonate gave back alkaloid L.20 (X). The same enol acetate XI was obtained, together with the unsaturated ketone VIII, when 6α-bromolycopodine hydrobromide was refluxed with sodium acetate in acetic acid – acetic anhydride.

It is interesting to note that the enol acetylation of lycopodine (I) with acetic anhydride – *p*-toluenesulphonic acid yields the Δ^4-enol acetate XII, as shown by the lack of olefinic absorption in the n.m.r. spectrum, whereas bromination occurs via the Δ^5-enol. Provided that the direction of acid-catalyzed enol acetylation is a measure of the preferred direction of acid-catalyzed enolization in this system, the position of bromination must be due to the greater degree of steric hindrance at C-4 than at C-6.

EXPERIMENTAL

Ultraviolet absorption spectra were determined in 95% ethanol. Optical rotatory dispersion spectra were measured on a Rudolph Automatic Recording Spectropolarimeter. Nuclear magnetic resonance spectra were measured on ca. 10% w/v solutions in deuteriochloroform using a Varian Associates Model A-60 spectrometer with tetramethylsilane as an internal standard. Melting points were determined on a hot stage and are uncorrected. Alumina, unless otherwise specified, means basic alumina of activity III–IV (Brockmann scale). Skellysolve B refers to Skelly Oil Company light petroleum, b.p. 62–70°.

Bromination of Lycopodine

A solution of lycopodine (0.45 g) in chloroform (20 ml) was treated with a solution of bromine (0.30 g) in chloroform (20 ml). After standing 2 hours at room temperature the faintly yellow solution was evaporated at the pump. The solid residue was washed with a small volume of cold acetone, leaving a colorless solid (0.57 g), m.p. 280–295° (decomp.). The analytical sample, prepared by recrystallizing three times from methanol, melted at 285–295° (decomp.). Calc. for $C_{16}H_{26}ONBr \cdot C_{16}H_{25}ONBr_2$: C, 52.26; H, 6.99; Br, 32.60%. Found: C, 51.95, 52.27; H, 6.93, 6.88; Br, 32.09%. Infrared spectrum: ν_{max}^{nujol} 2540 (+NH), 1700 cm^{-1} (C=O).

By fractional crystallization of the combined mother liquors of several such brominations from methanol–acetone it was possible to isolate small quantities of relatively pure 6α-bromolycopodine hydrobromide, m.p. 260–269° (decomp.).

The recrystallized bromination product (0.30 g) was stirred overnight with 3% aqueous sodium hydroxide, then the reaction mixture adjusted to pH 7.5 and extracted with ether to give a dark brown oil (0.21 g). Chromatography of the oil over alumina (5 g) gave lycopodine (91 mg), eluted with benzene, and the enolic α-diketone III (36 mg), eluted with chloroform–methanol (99:1).

Bromination of Lycopodine Hydrobromide

A solution of bromine (0.78 g) in chloroform (15 ml) was added dropwise with stirring to a solution of lycopodine hydrobromide (1.45 g) in chloroform (30 ml) to which had been added 0.1 ml of chloroform saturated with hydrogen bromide. The mixture (a small amount of precipitate formed shortly after bromine addition was completed) was kept at room temperature overnight, then evaporated at the pump, and cold acetone (20 ml) was added to the residual off-white solid. The solid was collected and crystallized once from methanol to give almost pure 6α-bromolycopodine hydrobromide (1.64 g, 91%), m.p. 261–265° (decomp.). Two further recrystallizations from methanol furnished the analytical sample, m.p. 266–269° (decomp.). Calc. for $C_{16}H_{25}ONBr_2$: C, 47.19; H, 6.19; N, 3.50; Br, 39.25%. Found: C, 47.25, 47.45; H, 6.32, 6.43; N, 3.44; Br, 39.27%. Infrared spectrum: $\nu_{max}^{CHCl_3}$ 2470 (+NH), 1711 cm^{-1} (C=O); ν_{max}^{nujol} 2550, 1703 cm^{-1}. Ultraviolet spectrum: λ_{max} 306 mμ (log ϵ 2.19). Rotatory dispersion in methanol (*c*, 0.10): $[\phi]_{589}$ +150°, $[\phi]_{400}$ +910°, $[\phi]_{332}$ +4550°, $[\phi]_{280}$ −6100°, $[\phi]_{250}$ −2300°.

Optical Rotatory Dispersion Spectra of Lycopodine Salts

The salts were prepared by the usual methods.

Lycopodine hydrobromide, in methanol (*c* 0.12): $[\phi]_{589}$ −330°, $[\phi]_{500}$ −430°, $[\phi]_{400}$ −600°, $[\phi]_{305}$ −2340°, $[\phi]_{268}$ +430°, $[\phi]_{253}$ ±0°.

Lycopodine, in acetic acid (*c* 0.10): $[\phi]_{589}$ −230°, $[\phi]_{500}$ −345°, $[\phi]_{400}$ −545°, $[\phi]_{300}$ −2270°, $[\phi]_{263}$ +540°, $[\phi]_{255}$ +400°.

Lycopodine methiodide, in methanol (*c* 0.12): $[\phi]_{589}$ −110°, $[\phi]_{500}$ −160°, $[\phi]_{400}$ −560°, $[\phi]_{304}$ −2450°, $[\phi]_{268}$ +260°, $[\phi]_{255}$ ±0°.

Lycopodine perchlorate, in methanol (*c* 0.096): $[\phi]_{589}$ +80°, $[\phi]_{500}$ ±0°, $[\phi]_{400}$ −360°, $[\phi]_{302}$ −1600°, $[\phi]_{260}$ +280°, $[\phi]_{250}$ ±0°.

Reaction of Acetyldihydrolycopodine with Bromine

A solution of bromine (14 mg, 0.09 mmole) in chloroform (10 ml) was added all at once to a solution of acetyldihydrolycopodine (II) (55 mg, 0.18 mmole). The solution decolorized immediately and after 15 minutes was evaporated to dryness to give a light brown foam.

Crystallization from acetone–ether yielded acetyldihydrolycopodine hydrobromide (49 mg, 71%), identical with an authentic sample. The mother liquors yielded a light brown oil which rapidly darkened on standing and failed to yield further crystalline material.

6α-Bromolycopodine (IV)

A solution of 6α-bromolycopodine hydrobromide (0.156 g) in chloroform (60 ml) was shaken with cold dil. ammonium hydroxide (aqueous sodium bicarbonate gave similar results). The chloroform layer was separated, washed with water, dried ($MgSO_4$), and evaporated to give a colorless solid (0.12 g). Crystallization from ether or acetone yielded colorless spars which melted at 163–165° with partial decomposition, then resolidified and melted with decomposition at 238–240°. Calc. for $C_{16}H_{24}ONBr$: C, 58.90; H, 7.41; N, 4.29; Br, 24.49%. Found: C, 59.63; H, 7.42; N, 4.46; Br, 24.80%. Infrared spectrum: ν_{max}^{nujol} 1702 cm^{-1}; $\nu_{max}^{CCl_4}$ 1711 cm^{-1}. Ultraviolet spectrum: λ_{max} 305 mμ (log ε 2.22). Nuclear magnetic resonance spectrum: 5.82 τ (C*H*Br, broadened singlet, half-height width 3.2 c.p.s.), 9.16 τ (CH—C*H*$_3$, doublet, splitting 3.8 c.p.s.). Rotatory dispersion in methanol (*c* 0.064, freshly prepared solution): $[\phi]_{400}$ +1,070°, $[\phi]_{335}$ +8,950°, $[\phi]_{294}$ −20,550°, $[\phi]_{250}$ −4,500°. After 2½ hours the amplitude had fallen to +27,250°, and after 24 hours, to +13,900°. The material recovered from the optical rotatory dispersion measurements (24 hours) showed distinct +NH bands in the infrared. When a sample of the 6α-bromoketone was heated to 170° for 1 minute the infrared spectrum of the dark solid remaining showed peaks (1690, 1620, 2520 cm^{-1}) characteristic of the unsaturated ketone VIII as well as typical +NH stretching vibrations.

6β-Bromolycopodine Hydrobromide (VI·HBr)

A solution of 6α-bromolycopodine hydrobromide (IV·HBr, 2.24 g) in glacial acetic acid (50 ml) was heated on the steam bath for 1 hour, then cooled to room temperature and evaporated to dryness under reduced pressure. The residue was washed with cold acetone (50 ml) and filtered to give a colorless solid (1.71 g). Infrared spectrum: ν_{max}^{nujol} 2450, 1720, 1703 cm^{-1}.

Seven recrystallizations from methanol yielded pure 6β-bromolycopodine hydrobromide (VI·HBr, 0.21 g), m.p. 257–262° (decomp.). Calc. for $C_{16}H_{25}ONBr_2$: C, 47.19; H, 6.19; N, 3.44; Br, 39.25%. Found: C, 47.21, 47.22; H, 6.28, 6.32; N, 3.71; Br, 39.62, 39.94%. Infrared spectrum: $\nu_{max}^{CHCl_3}$ 2440 (+NH), 1728 cm^{-1} (>C=O); ν_{max}^{nujol} 2590, 2550 (+NH), 1718 cm^{-1}. Ultraviolet spectrum: λ_{max} 276 mμ (log ε 2.07). Rotatory dispersion in methanol (*c* 0.10): $[\phi]_{589}$ −265°, $[\phi]_{500}$ −400°, $[\phi]_{400}$ −660°, $[\phi]_{350}$ −880°, $[\phi]_{310}$ −1000°, $[\phi]_{300}$ −1290°.

Because of the low yields obtained in the epimerization no attempt was made to prepare the free base. When a solution of 6β-bromolycopodine hydrobromide in glacial acetic acid was heated on the steam bath for an hour, the infrared spectrum of the solid recovered after evaporation of the acetic acid was almost identical with that of the starting material.

Reaction of 6α-Bromolycopodine Hydrobromide with Sodium Hydroxide

6β-Bromolycopodine (0.35 g) was suspended in 3% aq. sodium hydroxide (40 ml) and stirred at room temperature for 18 hours. The dark brown solution thus obtained was adjusted to pH 7.5 with acetic acid and extracted four times with chloroform to give a brown semisolid (0.15 g). The semisolid was chromatographed over alumina (5 g). Elution with ether yielded the unsaturated ketone VIII as a pale yellow oil (0.05 g). The unsaturated ketone did not crystallize readily and was characterized as the methiodide, which after recrystallization from acetone, melted at 271–273°. Calc. for $C_{16}H_{23}ON\cdot CH_3I$: C, 52.72; H, 6.77%. Found: C, 52.71, 52.47; H, 6.74; 6,82%. Infrared spectra: methiodide: ν_{max}^{nujol} 1698, 1629 cm^{-1}; free base: $\nu_{max}^{CCl_4}$ 1686, 1614 cm^{-1}. Ultraviolet spectrum: λ_{max} 244 mμ (log ε 3.90). Nuclear magnetic resonance spectrum: 3.04 τ (olefinic H), 9.18 τ (CHC*H*$_3$, doublet, splitting 3.5 c.p.s.).

Elution of the chromatogram with chloroform–methanol (49:1) yielded a light brown solid (0.057 g) which on sublimation afforded the pure diosphenol III (41 mg), m.p. 185–186°, identical with that prepared previously (4) from lycopodine.

Lithium–Ammonia Reduction of the Unsaturated Ketone VIII

3,4-Dehydrolycopodine (VIII, 0.103 g) in ether (25 ml) was added to a stirred solution of lithium (0.2 g) in ammonia (150 ml). After 30 minutes solid ammonium chloride was added until the blue color disappeared, and the ammonia was allowed to evaporate. The residue was distributed between chloroform and water and the layers separated. The aqueous layer was washed with chloroform and the combined organic extracts washed with water. Evaporation of the chloroform left a colorless oil (0.105 g) which solidified on scratching. The solid material was dissolved in acetone and neutralized with 70% perchloric acid. The perchlorate which separated (0.115 g) was identical with authentic lycopodine perchlorate.

Alkaloid L.20

(a) From 6α-Bromolycopodine Hydrobromide

6α-Bromolycopodine hydrobromide (IV·HBr, 1.32 g) was added to a stirred solution of 5% aq. sodium bicarbonate (80 ml) at room temperature. The bromo compound slowly dissolved but a second crystalline phase began to separate before solution was complete. After 24 hours the reaction mixture was transferred to a liquid–liquid extractor and continuously extracted with ether. The ethereal extract was dried ($MgSO_4$) and evaporated to yield an off-white solid (0.78 g, 92%) whose infrared spectrum was identical with that of an authentic sample of alkaloid L.20 (see Section (*b*)). Crystallization from methanol yielded colorless needles, m.p. 258–259°, both pure and mixed with an authentic sample of alkaloid L.20. Both samples had identical rotatory dispersion curves.

(b) From L. lucidulum Michx.

Dried, finely ground *L. lucidulum* Michx. (11 kg) was Soxhlet-extracted with methanol and the extract concentrated to a thick, dark residue. The residue was digested for 24 hours with cold, dilute hydrochloric acid, filtered, and the filtrate washed with ether. The acid solution was adjusted to ca. pH 8 with ammonium hydroxide and extracted with chloroform (extract A), then the aqueous layer was made strongly basic with ammonium hydroxide and again extracted with chloroform (extract B). Extract B was concentrated at the pump and the residue (19.1 g) dissolved in methanol. After standing several days in the refrigerator the solution deposited crystals (0.31 g) which, after recrystallization from methanol or acetone, melted at 258–259°. This substance was shown to be alkaloid L.20 by comparison (infrared spectrum, mixed melting point, rotatory dispersion curve) with an authentic sample kindly furnished by Dr. L. Marion. Calc. for $C_{16}H_{25}O_2N$: C, 72.96; H, 9.57; N, 5.32%. Found: C, 72.43, 72.57; H, 9.76, 9.81; N, 5.24%. Infrared spectrum: $\nu_{max}^{CHCl_3}$ 3620 (OH), 1710 cm^{-1} (>C=O). Ultraviolet spectrum: λ_{max} 296 mμ (log ε 1.85). Rotatory dispersion in methanol (*c* 0.137): $[\phi]_{500}$ +105°, $[\phi]_{400}$ +400°, $[\phi]_{330}$ +4,300°, $[\phi]_{285}$ −10,500°, $[\phi]_{270}$ −3,000°.

Chromatography of the mother liquors obtained from extract B yielded lycopodine and lycodoline (alkaloid L.8) as the only crystalline material. Extract A was reserved for future examination.

(c) From 6β-Bromolycopodine Hydrobromide

6β-Bromolycopodine hydrobromide (VI·HBr, 84 mg) was stirred for 24 hours with 5% aq. sodium bicarbonate (20 ml). The resulting brown solution was extracted six times with chloroform. The product obtained was crystallized from acetone to give alkaloid L.20 (19 mg, 35%). Although the yield is lower than that quoted in section (*a*) we believe that this is largely due to the change in reaction conditions (w/v ratio), since the 6α-bromo compound, when treated under conditions identical with those described here, gave only a 30% yield of alkaloid L.20.

Calcium–Ammonia Reduction of Alkaloid L.20

A solution of alkaloid L.20 (X, 97 mg) in tetrahydrofuran (7 ml) was added to a blue solution of calcium (0.10 g) in liquid ammonia (150 ml). The reaction mixture was stirred for 15 minutes, then the excess calcium destroyed by addition of bromobenzene followed by water (5 ml). After most of the ammonia had evaporated more water was added and the aqueous layer was extracted several times with chloroform. Evaporation of the chloroform left a light brown oil (0.07 g) which was dissolved in dichloromethane and chromatographed over alumina (3 g). Dichloromethane eluted lycopodine (43 mg), chloroform eluted epidihydrolycopodine (20 mg) (4), and chloroform–methanol (24:1) eluted the diosphenol III (3 mg). All three products were identified by comparison with authentic samples.

When lithium–ammonia–methanol was used for the reduction only epidihydrolycopodine was obtained.

6β-Hydroxylycopodine from Alkaloid L.20

(*a*) A solution of alkaloid L.20 (X, 45 mg) in *n*-propanol (10 ml) containing sodium propoxide (80 mg) was shaken in an atmosphere of nitrogen for 40 hours, then chloroform (50 ml) and water (50 ml) were added. The chloroform layer was separated, washed with water, and evaporated. The residue was crystallized from acetone, yielding 6β-hydroxylycopodine (30 mg), m.p. 121–122°, both pure and mixed with an authentic sample (4). Both samples had identical infrared spectra ($CHCl_3$).

(*b*) A solution of alkaloid L.20 (0.13 g) was absorbed on a column of basic alumina (10 g) in ether–benzene (1:1). After 12 hours the column was eluted with ether–methanol, affording a colorless semisolid (0.12 g) which on sublimation furnished 6β-hydroxylycopodine (0.10 g), identical with an authentic sample.

Dehydration of Alkaloid L.20

A solution of alkaloid L.20 (X, 0.19 g), in 10% aq. hydrochloric acid (30 ml) was heated under reflux for 3 hours. After being cooled, the solution was neutralized with sodium bicarbonate and continuously extracted with ether. The residue (0.18 g) was triturated with Skellysolve B (in which the starting material is insoluble). The Skellysolve solution was concentrated, the residual oil dissolved in cold acetone (5 ml), and methyl iodide (1 ml) added. On standing the solution overnight in the refrigerator crystals (0.23 g) of 3,4-dehydrolycopodine methiodide (VIII·CH_3I), m.p. 270–273°, separated.

Acetylation of Alkaloid L.20

(a) At Room Temperature, Formation of Enol Acetate XI

A solution of alkaloid L.20 (X, 0.31 g) in acetic anhydride – pyridine (9 ml of 1:1) was kept at room temperature for 12 hours, then diluted with chloroform and ice-cold dil. ammonium hydroxide. The chloroform layer was separated and the aqueous layer extracted twice more with chloroform. The combined chloroform extracts were washed with water, dried ($MgSO_4$), and evaporated to give a colorless oil (0.39 g). The oil could not be induced to crystallize and was purified and characterized as the perchlorate, formed in acetone and recrystallized from acetone–ether, which melted at 258–259° (decomp.). Calc. for $C_{20}H_{29}O_4N \cdot HClO_4$: C, 53.63; H, 6.75; N, 3.11%. Found: C, 53.78; H, 6.82; N, 3.03%. Infrared spectra: perchlorate: ν_{max}^{nujol} 3060 (+NH), 1740 (2 OAc), 1690 cm^{-1} (C=C); free base: $\nu_{max}^{CCl_4}$ 1760, 1735 (2 OAc), 1680 cm^{-1} (C=C). The nuclear magnetic resonance spectrum of the free base showed signals at 5.02 τ (1H, broadened singlet, half-height width 4 c.p.s.), 7.98 and 8.06 τ (total of 6H), and 9.17 τ (3H, doublet, splitting 5.5 c.p.s.).

Hydrolysis of the enol acetate XI (0.39 g) with 8% aq. hydrochloric acid (20 ml) at room temperature for 3 hours, followed by working up in the usual manner, afforded a yellowish oil which after filtration through alumina and crystallization from Skellysolve B gave acetyl-L.20 (0.12 g), m.p. 143–144° (see below). The mother liquors (0.15 g) contained mainly starting enol acetate as judged by the infrared spectrum.

Hydrolysis of the enol acetate XI with aqueous methanolic sodium bicarbonate at room temperature afforded alkaloid L.20 in about 50% yield.

(b) At −10°, Formation of Acetyl-L.20

A solution of alkaloid L.20 (0.12 g) in acetic anhydride (5 ml) – pyridine (2 ml) was kept at −10° for 4 hours, then poured into chloroform and dil. ammonium hydroxide. The aqueous layer was separated and washed twice more with chloroform. The combined chloroform extracts, after washing with water and drying, were evaporated to give a colorless solid (0.11 g), m.p. 126–134°. Three recrystallizations from Skellysolve B gave analytically pure needles of acetyl-L.20 (58 mg), m.p. 143–144°. Calc. for $C_{18}H_{27}O_3N$: C, 70.79; H, 8.92; N, 4.59%. Found: C, 70.97, 70.66; H, 8.92, 8.82; N, 4.72. Infrared spectrum: $\nu_{max}^{CCl_4}$ 1755 (OAc), 1723 (ketone), 1230 cm^{-1} (OAc). Ultraviolet spectrum: λ_{max} 300 mμ (log ϵ 1.95). The rotatory dispersion spectrum showed a positive Cotton effect with peak at 327 mμ (+1,800°) and trough at 282 mμ (−10,900°). Details of the nuclear magnetic resonance spectrum have been published (4).

Lycopodine Enol Acetate (XII)

The method used was that of Barton *et al.* (18). A solution of lycopodine (0.5 g) and *p*-toluenesulphonic acid (0.45 g) in acetic anhydride (25 ml) was heated until the acetic anhydride slowly distilled. After 4 hours most of the acetic anhydride had been removed. The residue was diluted with ether and dil. aq. sodium hydroxide and shaken. The aqueous layer was separated and washed twice more with ether. The combined ethereal extracts were washed with water, dried ($MgSO_4$), and evaporated, leaving an off-white solid which was crystallized from acetone to give lycopodine enol acetate (0.4 g), m.p. 98–100°. The analytical sample was prepared by recrystallization from acetone, then from Skellysolve B, and melted at 100–101°. Calc. for $C_{18}H_{27}O_2N$: C, 74.70; H, 9.41; O, 11.06. Found: C, 74.30, 74.49; H, 9.24, 9.40; O, 11.49%. Infrared spectrum: $\nu_{max}^{CCl_4}$ 1755 (OAc), 1696 cm^{-1} (C=C). Nuclear magnetic resonance spectrum: 7.86 τ (3H, $OCOCH_3$), 9.12 τ (3H, $CHCH_3$, doublet, splitting 6 c.p.s.).

ACKNOWLEDGMENTS

We wish to thank Drs. K. Wiesner and Z. Valenta for valuable correspondence in connection with the rotatory dispersion data, Mr. M. A. Stillwell for the collection and identification of the plant material, Mr. R. N. Swindlehurst and Mrs. G. B. Conway for most of the infrared, nuclear magnetic resonance, and optical rotatory dispersion measurements, and the National Research Council of Canada for financial support.

STERIC EFFECTS IN THE SYNERGIC EXTRACTION OF THE LANTHANIDES, YTTRIUM, AND SCANDIUM[1]

P. G. MANNING[2]

Mineral Sciences Division, Department of Mines and Technical Surveys, Ottawa, Canada

Received August 27, 1962

ABSTRACT

From a study of the partitioning of the carrier-free radioisotopes Tm^{170}, Ce^{144}, $Eu^{152/154}$, Tb^{160}, Lu^{177}, and Y^{91} between nitric acid and organic solutions containing various proportions of thenoyltrifluoroacetone (HTTA) and dialkyl alkyl phosphonates (S) in odorless kerosene, concentration equilibrium constants (k_2) have been computed for the reaction

$$M^{3+}_w + 3HTTA_o + 2S_o = M(TTA)_3S_{2o} + 3H^+_w,$$

where M represents a metal ion, and "w" and "o" are aqueous and organic species respectively.

When used in conjunction with the data of Bronaugh and Suttle, the equilibrium constants determined in this study yielded comparative equilibrium constants (k_3) for the solvation process

$$M(TTA)_{3o} + 2S_o = M(TTA)_3S_{2o}$$

for the rare-earth metals listed.

In the extraction of Sc^{46}, however, the species extracted is dependent on the alkyl groups of the phosphonates, the butyl and 2-ethylhexyl derivatives giving mono- and di-solvates respectively.

It is concluded that steric effects are dominant in these synergic systems.

INTRODUCTION

That steric effects can influence the formation and the stabilities of higher complexes of the lanthanide, Y, and Sc metals has been demonstrated by a number of workers, and much of this work has been summarized in a recent publication by Warren (2). The synergic extraction of Pm, Eu, and Tm by mixtures of thenoyltrifluoroacetone (HTTA) and tributyl phosphate (TBP) has been shown to proceed via the formation of the complex $M(TTA)_3(TBP)_2$ (3, 4), where M is the metal ion, and it is conceivable that steric hindrance could operate in such systems. Since the lanthanides, yttrium, and scandium possess almost identical chemical properties, variations in the ionic radii would then be expected to induce similar trends in the magnitude of the synergic enhancement.

Two systems have been chosen for study, namely (*a*) the metal – nitric acid – HTTA – dibutyl butyl phosphonate (DBBP) – kerosene and (*b*) the metal – nitric acid – HTTA – bis-2-ethylhexyl 2-ethylhexyl phosphonate (DEEP) – kerosene systems. Any steric effects may, therefore, be studied from two angles, that of varying cation radius and that of varying bulkiness of the alkyl group of the phosphonate.

Experiments were conducted at trace metal concentration ($<10^{-5}$ *M*) using radioisotopes; this ensured that there was no change in the effective concentrations of the extractants.

EXPERIMENTAL

DEEP, of approximately 0.3% acidic content, was purchased from the Virginia-Carolina Chemical Corporation and was used without further purification, previous experiments having shown that the acidic impurity had a negligible effect on the metal distribution coefficients. HTTA, obtained from the Fisher

[1]*Presented before the 45th Annual Conference of the Chemical Institute of Canada, Edmonton, Alberta, May 1962.*

For personal use only.

Scientific Company, was purified either by recrystallization from hexane or by a 3-hour stay in a vacuum desiccator at a pressure of 3 mm. Both methods gave identical metal distribution coefficients. All other reagents were as described in a previous publication (5).

The radioisotopes Ce^{144}, $Eu^{152/154}$, Tb^{160}, Tm^{170}, Lu^{177}, and Y^{91} were obtained from the Radiochemical Centre, Amersham, England, and Sc^{46} from Atomic Energy of Canada Ltd., Chalk River, Ontario. The radioactive content of the equilibrated aqueous and organic phases was determined using a NaI(Tl) scintillation counter in the $Eu^{152/154}$, Tb^{160}, and Sc^{46} measurements, and a Geiger–Müller counter for the other β-emitting isotopes.

Equal volumes (10.00 ml) of both aqueous and organic phases were shaken for 3 hours in ground-glass stoppered Erlenmeyer flasks fitted with polytetrafluoroethylene (PTFE) sleeves. All organic phases were pre-equilibrated. The temperature was 28±3° C.

The distribution coefficient of a given nuclide is defined as

$$K = \frac{\text{concentration of nuclide in organic phase}}{\text{concentration of nuclide in aqueous phase}}.$$

RESULTS

Metal – Nitric Acid – HTTA – DBBP – Kerosene System

For a general reaction

$$M^{n+} + x\text{Cl}^- + (n-x)\text{HX} + m\text{S} = \text{MCl}_x\text{X}_{n-x}\text{S}_m + (n-x)\text{H}^+,$$

where HX and S represent acidic and neutral extractants, the equilibrium constant is

[1] $$k_2 = \frac{[\text{MCl}_x\text{X}_{n-x}\text{S}_m][\text{H}^+]^{n-x}}{[\text{M}^{n+}][\text{Cl}]^x[\text{HX}]^{n-x}[\text{S}]^m} = \frac{K[\text{H}^+]^{n-x}}{[\text{Cl}]^x[\text{HX}]^{n-x}[\text{S}]^m},$$

whence

$$K = \frac{k_2[\text{Cl}]^x[\text{HX}]^{n-x}[\text{S}]^m}{[\text{H}^+]^{n-x}}.$$

A log–log plot of K against [S], with [H^+] and [HX] kept constant, has a slope of m. Similarly, log–log plots of K against [H^+] and K against [HX], with the other parameters constant, possess slopes of $-(n-x)$ and $+(n-x)$ respectively. These latter plots should, therefore, complement one another, provided that HTTA functions only as a bidentate chelating agent, i.e., the ability of undissociated HTTA to function as coordinated S molecules is negligible.

The metal extraction dependencies upon aqueous acidity, organic phosphonate concentration, and organic HTTA concentration are presented in Figs. 1, 2, and 3. Ignoring Sc for the time being, the plots possess slopes of −3.0, 2.0, and 3.0. This means that $n-x = n = 3$, $x = 0$, and $m = 2$, and the extraction mechanism is

$$M^{3+}_w + 3\text{HTTA}_o + 2\text{DBBP}_o = \text{M(TTA)}_3(\text{DBBP})_{2o} + 3\text{H}^+_w,$$

where "w" and "o" designate aqueous and organic species respectively.

The slopes of all plots have been calculated to within 0.05, and the estimated error in k_2 is ±3%.

The possibility exists that the mechanism of extraction at the higher phosphonate concentrations employed in the evaluation of $n-x$ (Figs. 1 and 4) differs from that at the lower phosphonate concentrations employed in the remainder of this work. Since the formation of the extractable species MX_3 and $M(NO_3)_3S_3$ may be ignored (1, 5), and since MX_3S_2 is the extractable complex at the lower phosphonate concentrations, then the formation of such molecules as $MX_3S_2.HX$ or MX_3S_3 would have to be considered were the mechanism concentration dependent. Both $MX_3S_2.HX$ and MX_3S_3 require a central metal ion coordination number of 9, which renders their formation unlikely.

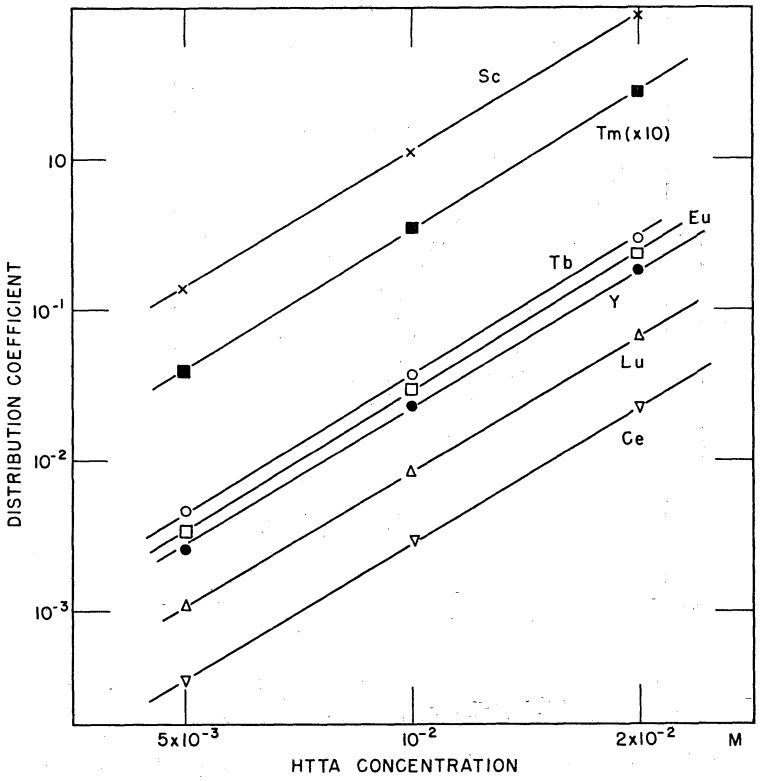

FIG. 3. Variation in K with HTTA concentration. 0.010 *M* DBBP, 0.0316 *M* HNO_3.

Moreover, Healy (6) has investigated similar synergic systems at extractant concentrations as high as those employed in the present work, and his results show that MX_3S_2 is the sole extractable complex.

The results of Peppard *et al.* (7) for the partitioning of Sc between nitric acid and TBP phases would suggest that the non-linearity of the Sc plot in Fig. 1 is due to extraction of the metal according to the reaction

$$Sc^{3+}_w + 3NO^-_{3w} + x\text{DBBP}_o = Sc(NO_3)_3(\text{DBBP})_{x_o}.$$

The limiting slope at lower acidities is, however, −3, and, since Sc obeys a first-power dependency upon DBBP concentration (Fig. 2) and a third-power dependency upon HTTA concentration (Fig. 3), the extraction process is

$$Sc^{3+}_w + 3\text{HTTA}_o + \text{DBBP}_o = Sc(\text{TTA})_3(\text{DBBP})_{1_o} + 3H^+_w.$$

The corresponding equilibrium constants have been calculated by substituting the following data in equation [1]:

[HTTA] = 0.0200 *M*	$n-x$ = 3.0
[DBBP] = 0.0100 *M*	m = 2.0 (metals other than Sc)
$[H^+]$ = 0.0316 *M*	m = 1.0 (Sc only)

These constants are tabulated in Table I.

DISCUSSION

That all the metals studied exhibit synergism is apparent from a comparison of the values of k_2, measured in both the DBBP and DEEP systems (Tables I and II), with those of k_1 (Table III) determined by Bronaugh and Suttle (1) for the extraction process

$$M_w^{3+} + 3HTTA_o = M(TTA)_{3o} + 3H_w^+,$$

whence

$$[2] \qquad k_1 = \frac{[M(TTA)_3]_o[H^+]_w^3}{[M^{3+}]_w[HTTA]_o^3}.$$

TABLE III

k_3 values for metal–HTTA–DBBP/DEEP systems

Metal	k_1	k_3(DBBP)	k_3(DEEP)	Ionic radius (9) (Å)
Ce	1.53×10^{-9}	5.6×10^{11}	1.0×10^{11}	1.03
Eu	9.2×10^{-8}	9.9×10^{10}	1.8×10^{10}	0.95
Tb	1.29×10^{-7}	8.5×10^{10}	1.6×10^{10}	0.92
Y	1.68×10^{-7}	3.6×10^{10}		0.90
Tm	4.6×10^{-7}	2.4×10^{10}		0.87
Lu	6.8×10^{-7}	4.0×10^{9}	1.6×10^{9}	0.85
Sc	0.69	5.1×10^{3} *	5.9×10^{6}	0.78

*For the reaction $Sc(TTA)_3 + DBBP = Sc(TTA)_3(DBBP)_1$.

These workers employed a 0.2 *M* solution of HTTA in benzene in extracting the lanthanides from chloride media.

Although the experimental conditions used by Bronaugh and Suttle (1) differ in some respects from those employed in the present investigation, e.g., different diluent, supporting anion, and HTTA concentration, we feel that k_1 and k_2 may still be compared for the following reasons:

(*a*) Cl^- and NO_3^-, anions of strong acids, take no part in the extraction reaction;

(*b*) at [HTTA] = 0.200 *M* (conditions employed by Bronaugh and Suttle) the organic phase may not be ideal, but Figs. 2 and 4 indicate that deviations from ideality are similar for all metals;

(*c*) from the data of Healy (6) for the extraction of Am, Cm, Pm, and Tm by 0.18 *M* HTTA and 0.1 *M* TBP, changes in diluent produce proportional changes in metal distribution coefficients, and, provided that the extracted species are of the same molecular composition, the ratios $K_{Am}:K_{Cm}:K_{Pm}:K_{Tm}$ remain constant for both benzene and cyclohexane.

The magnitude of the synergic enhancement, which we may define as $k_3 = k_2/k_1$, and values of which are tabulated in Table III, varies from metal to metal and is seen to be largest for Ce. The magnitude of k_3 decreases with decreasing ionic radius, and for Lu, whose ionic radius of 0.85 Å compares with that of 1.03 Å for Ce, the synergic enhancement has decreased by factors of 140 and 170, using DBBP and DEEP respectively. For Sc, using the latter reagent, the corresponding figure is 1.7×10^4. This correlation of k_3 with ionic radius holds for all the metals studied, including Y, and may be attributed to steric crowding, the geometrical obstruction to the addition of phosphonate molecules to the metal chelate increasing with decreasing central ion radius.

The fact that the Sc chelate forms a monosolvate with DBBP is also indicative of steric hindrance, but the species extracted, $Sc(TTA)_3(DBBP)_1$, presupposes a coordination number of seven. Similarly, the disolvates formed by the other trivalent metals

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

indicate coordination numbers of eight. It is possible, therefore, that the Sc species is a monohydrate, and that the actual solvation process is one involving replacement of water molecules by phosphonates (S), i.e.

$$M(TTA)_3.2H_2O + xS = M(TTA)_3.S_x.H_2O_{(2-x)} + xH_2O.$$

For all the metals studied, k_2 and k_3 values measured in the DBBP investigations exceeded those of the DEEP system by factors of 3–6. These figures indicate that the alkyl groups of the phosphonate also offer steric obstruction.

The value of k_3 for Y, when compared with those of the lanthanides (Table III), is in keeping with its ionic radius, and Y behaves as a lanthanide of atomic number 65–69.

In Fig. 7 are plotted metal distribution coefficients against atomic number. For the

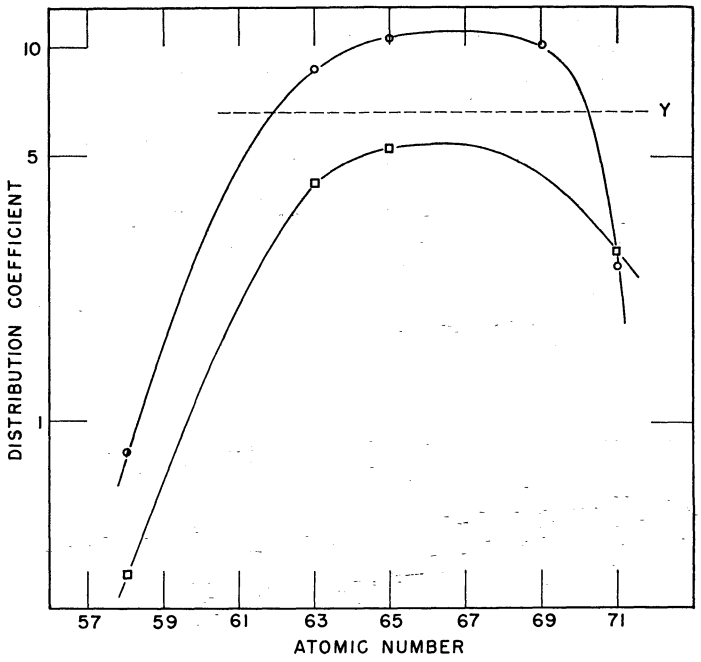

FIG. 7. Lanthanide and Y distribution coefficients against atomic number: ○ 0.020 *M* HNO_3, 0.020 *M* HTTA, 0.379 *M* DBBP; □ 0.024 *M* HNO_3, 0.020 *M* HTTA, 0.217 *M* DEEP.

middle members of the rare-earth series, increased Coulomb interaction (and therefore increased extractability) due to decreasing ionic radius is almost exactly counterbalanced by increased steric hindrance, and from $Z = 63$ to $Z = 69$ overall distribution coefficients are spread over a range of just 15%. In the overall synergic reaction, Y behaves as a rare earth of $Z = 62$ or $Z = 70$.

As a consequence of steric hindrance, separation factors between successive lanthanides (defined as K_{z+1}/K_z) are poor, and are inferior to those obtained by Cunninghame *et al.* (8) for the system Pr/Nd–HTTA–TBP–kerosene.

CONCLUSION

Both steric and synergic effects operate in the extraction of the lanthanides, yttrium, and scandium by mixtures of HTTA and coordinating organophosphorus reagents. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

former effects lead to poor separation factors, and synergic systems generally would seem to possess little practical application to the improved separation of the metals. An exception might be in cases where the lower lanthanide chelates form disolvates and the higher, monosolvates.

Further studies are being pursued in other potentially synergic systems.

THE COLORIMETRIC DETERMINATION OF PLATINUM WITH 5-(*p*-DIMETHYLAMINOBENZYLIDENE)-RHODANINE[1]

FRANCES E. PIERCY AND D. E. RYAN
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia
Received October 17, 1962

ABSTRACT

5-(*p*-Dimethylaminobenzylidene)-rhodanine is used to determine 0.5 to 6 p.p.m. of platinum colorimetrically, after reduction of platinum IV with ascorbic acid. Platinum can be determined in the presence of a 10-fold excess of palladium; low concentrations of the other platinum metals, except rhodium, do not seriously interfere.

INTRODUCTION

The colorimetric methods that have proved successful for the determination of platinum involve the use of valences lower than the usual quadrivalent state. The widely used stannous chloride method (1) contains tin, platinum, and chloride in a complex in which the platinum has a valence of zero (2). Both the *p*-nitrosodimethylaniline (3), and the N,N′-bis(3-dimethylaminopropyl)-dithiooxamide (4) procedures make use of the bivalent state, reduction of quadrivalent platinum occurring either through the action of excess reagent or by deliberate addition of a reducing agent. The colorimetric method described herein constitutes part of the results of an investigation into the use of the bivalent state in the determination of platinum.

EXPERIMENTAL

Preliminary

In preliminary studies, a large number of compounds were investigated as possible reagents for reducing platinum, at room temperature and in dilute acid solution, from the quadrivalent to the bivalent state. Since *p*-nitrosodimethylaniline gave immediate color development with bivalent platinum at room temperature, but not with quadrivalent platinum, the compound being investigated was added to platinum IV solutions containing *p*-nitrosodimethylaniline and the development of color taken as evidence of reduction. Only sodium sulphite, chromous chloride, and ascorbic acid, of the following compounds investigated, were effective for this purpose: resorcinol, hydrazine, hydroxylamine, ascorbic acid, *d*-glucose, hydrogen peroxide, chromous chloride, formic acid, methyl alcohol, sodium sulphite. Ascorbic acid, which is itself colorless and gives a colorless oxidation product, has been used by Maksimyuk (5) to reduce platinum IV to platinum II quantitatively, and was therefore used throughout the remainder of the experimental work.

5-(*p*-Dimethylaminobenzylidene)-rhodanine, of a number of reagents investigated for the determination of platinum in the bivalent state, appeared most promising. This reagent, which has been used for the colorimetric determination of palladium (6), reacted immediately with platinum II to give a dark red precipitate in aqueous solution but very slowly with platinum IV. The problem in using this reaction for the colorimetric determination of platinum was to find a suitable solvent or a suitable extractant for the precipitate. Difficulties in obtaining complete extraction with chloroform, petroleum ether, benzene, and carbon tetrachloride discouraged further investigation into extraction possibilities. Although water-miscible solvents, such as alcohols, acetone, and dioxane, dissolved the precipitate, the resulting solutions were unstable, with solid separating from solution or the color fading on standing. Propionic acid, however, used by Ayres and Narang in the determination of palladium, dissolved the platinum complex to give stable, red-colored solutions and proved a satisfactory solvent in the colorimetric determination.

Reagents

Standard platinum solutions.—These solutions were prepared by dissolving a known weight of Johnson Matthey, "Specpure" ammonium chloroplatinate in water containing a few drops of dilute hydrochloric acid, and diluting to volume.

[1]*This work received financial assistance from the National Research Council, and is abstracted from the M.Sc. Thesis of Frances E. Piercy.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

5-(p-Dimethylaminobenzylidene)-rhodanine.—The reagent was obtained from Eastman Kodak, and reagent solutions contained 0.04% reagent in 98% formic acid. Ninety percent formic acid was also satisfactory.

L-*Ascorbic acid.*—These solutions were prepared fresh daily to avoid possible deterioration. The solutions were 0.1 *M* ascorbic acid in water, adjusted to pH 2 with dilute hydrochloric acid.

Propionic acid.—Reagent grade was used.

Spectral Curves

The absorption curves for reagent and for a solution containing 2 p.p.m. of platinum are shown in Fig. 1. These curves were obtained using a Bausch and Lomb spectronic recording Spectrophotometer. Maximum absorption occurs at 545 mμ but, since the reagent absorbs strongly at that wavelength, all colorimetric results recorded were carried out at 590 mμ, where the reagent shows 100% transmittance.

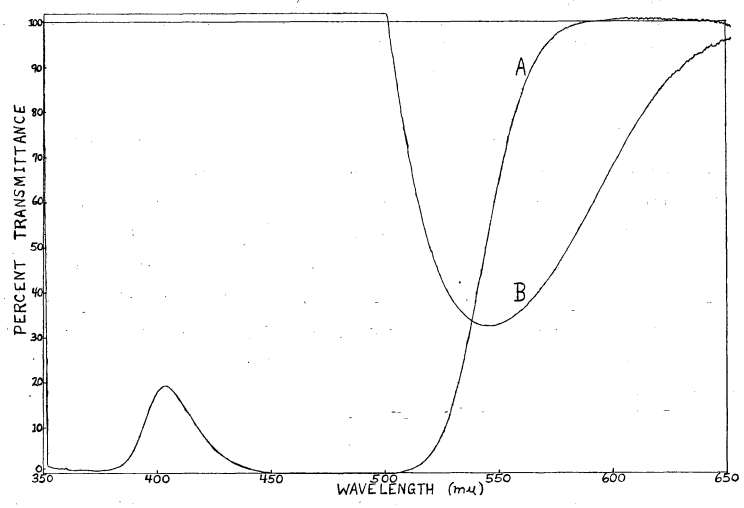

FIG. 1. Absorption spectra: A, 1 ml reagent solution (1.51×10^{-6} mole reagent) + 2 ml water + 3 drops ascorbic acid diluted to 10 ml with propionic acid; B, as A plus 2 p.p.m. of platinum.

Effect of Heating

Although immediate color development is obtained on adding reagent to platinum solutions reduced with ascorbic acid, maximum color is not attained for several hours. However, by heating the sample solutions at 65–75° C for 5 minutes, stable maximum color is obtained. For example, the optical density of a solution containing 2 p.p.m. of platinum changed from 0.158, without heating, to 0.233, after heating for 5 minutes at 70° C. In a number of experiments in which the heating was carried out by immersing the 10-ml volumetric flasks in a water bath at the desired temperature, consistent results were obtained in solutions heated for 5 to 10 minutes at temperatures between 65 and 75° C. There was some decrease in optical density if solutions were heated for a longer period; thus a reading of 0.219 was obtained after heating for 15 minutes at 70° C.

Effect of pH

For the reagent blank alone, the pH of the water solution may be varied between 2 and 6 without significant changes in the resulting spectra, and with 100% transmittance at 590 mμ; at pH 1, the reagent color is considerably faded. In samples containing 1.6 p.p.m. platinum, the optical density at 590 mμ was found to be 0.185, between pH 2 and 4. At pH 1, this falls off to 0.156; at pH 5, the reading is 0.174. From these experiments it was obvious that between pH 2 and 4, consistent results may be obtained.

Effect of Water, Ascorbic Acid, and Reagent

When optical density measurements are made at 590 mμ, the sample solution may contain from 5% to 25% water solution; if more than 2.5 ml of water per 10 ml final solution is present, the precipitate may be difficultly soluble in the propionic acid. Since the reagent does not absorb at 590 mμ, the concentration of reagent has no effect on the optical density; however, a large excess must be avoided due to the limit of its solubility in propionic acid. The volume of 0.1 *M* ascorbic acid solution added can be varied from 2 drops to 1 ml, with no effect on the resulting optical density.

Procedure

The platinum solution was adjusted to pH 2 to 4 with dilute hydrochloric acid, and a 0.5- to 2.5-ml aliquot (containing 5 to 60 μg platinum) was taken for analysis. To this aliquot, in a 10-ml volumetric

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

flask, was added three drops of 0.1 *M* ascorbic acid and the solution mixed. One milliliter of reagent was added and the flask placed in a water bath at 65–75° C for 5 minutes. The solution was then cooled to room temperature under cold water. Propionic acid was added, almost to volume, and the solution allowed to come to room temperature (about 15 minutes). The volume was then adjusted to 10 ml with propionic acid and the optical density read at 590 mμ against a reagent blank.

Optical densities obtained on a series of platinum samples are given in Table I. These results show that Beer's law is obeyed between 0.5 and 6 p.p.m. The color was stable for 1 hour, after which time it faded very slowly; a sample containing 2.0 p.p.m. platinum gave a constant optical density of 0.236 for 1 hour, falling to 0.233 after 90 minutes and to 0.226 after 2 hours.

TABLE I

Optical densities for varying platinum concentrations

Pt (p.p.m.)	Optical density	Pt (p.p.m.)	Optical density
0.5	0.058	4.0	0.454
1.0	0.112	5.0	0.577
2.0	0.232	6.0	0.688
3.0	0.335	7.6	0.796

Effect of Various Ions

No interference was noted when 2000 p.p.m. of the sodium, potassium, or ammonium salts of the following ions was added to 2 p.p.m. of platinum, as the chloride, and the usual colorimetric procedure carried out: Cl^-, SO_4^{-2}, NO_3^-, BO_2^-, PO_4^{-3}, CO_3^{-2}. Acetate ion, in excess of 500 p.p.m., and fluoride or bromide, beyond 100 p.p.m., interfere. Thiosulphate, sulphite, sulphide, oxalate, and iodide ions interfere by producing turbid solutions. Although sulphate in large amounts does not interfere in the determinations, the colored complex does not form in solutions that have been fumed with sulphuric acid.

Studies of the reactions of various ions, when 200 p.p.m. of the metal ions as chlorides or nitrates was added to 2 p.p.m. of platinum, showed no interference from the following ions: K^+, Na^+, NH_4^+, Ni^{+2}, Co^{+2}, Cd^{+2}, Mg^{+2}, Ca^{+2}, Sr^{+2}, Ba^{+2}, Al^{+3}, As^{+3}. Zinc and manganese interfered beyond 50 p.p.m. Antimony, tin, iron, and chromium ions interfere through precipitate formation or by giving low optical density readings.

Silver, mercury, copper, gold, palladium, and rhodium react with the reagent to give precipitates similar to that obtained with platinum. Of these, only interferences from palladium can be eliminated in the determination of platinum; 25 p.p.m. of palladium in the presence of 2 p.p.m. of platinum does not interfere if a small amount of dimethylgloxime is added. Some results obtained in the presence of other platinum group metals are given in Table II.

TABLE II

Platinum determinations in the presence of other platinum group metals

Pt taken (μg)	Pt found (μg)	Pt metal present (μg)	Remarks
20.0	20.0	21.5 Ir	Added as ammonium chloroiridate
19.0	19.2	43.0 Ir	
19.0	20.5	86.0 Ir	
57.0	57.0	107 Ir	
19.0	19.0	35.0 Pd	Two drops 0.1 *M* dimethylglyoxime
19.0	19.2	150 Pd	added
20.0	19.9	250 Pd	
19.0	18.5	300 Pd	0.5 ml dimethylgloxime added in excess
19.0	18.8	23.0 Ru	Added as ammonium chlororuthenate;
20.0	22.3	40.0 Ru	ruthenium absorbs itself at 590 mμ
19.0	18.8	108 Os	Added as ammonium chloroosmate
20.0	22.8	200 Os	
20.0	21.8	4.0 Rh	A color is developed with Rh alone
20.0	20.1	21.5 Ir, 20 Ru, 20 Os, 25 Pd	Two drops 0.1 *M* dimethylglyoxime added
30.0	30.0	21.5 Ir, 20 Ru, 20 Os, 25 Pd

Rhodium interferes seriously and gives a color nearly as intense as that of platinum. The results show that iridium, ruthenium, and osmium, in low concentration, do not interfere and that platinum can be determined (provided dimethylglyoxime is added) in the presence of a 10-fold excess of palladium.

Stoichiometry of the Reaction

The stoichiometry of the reaction was investigated spectrophotometrically by both the mole ratio method (7) and the method of continuous variations (8); both studies showed that three molecules of reagent reacted with one atom of platinum. Attempts to support this somewhat surprising result by analysis of the precipitated product were unsuccessful because of the inability to obtain a pure product.

AN INVESTIGATION OF THE ALUMINUM–OXYGEN–CARBON SYSTEM

J. H. Cox and L. M. Pidgeon

Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario

Received November 13, 1962

ABSTRACT

A differential thermal analysis technique was used to study the carbothermic reduction of aluminum oxide at reduced pressures in the temperature range 1700–2200° K. The reduction was found to proceed through the intermediate oxycarbide Al_4O_4C, identified by previous workers, to the aluminum carbide. The Al_4O_4C and another oxycarbide, Al_2OC, were formed by a direct solid–solid reaction, rather than by formation of a gaseous aluminum suboxide and subsequent reaction with carbon as has been postulated.

The carbon monoxide pressures over the following reactions were measured:

$$Al_2O_3 + 3C = Al_2OC + 2CO$$

$$2Al_2O_3 + 3C = Al_4O_4C + 2CO$$

$$Al_4O_4C + 6C = Al_4C_3 + 4CO.$$

Heats and free energies of reaction were found and standard heats and free energies of formation were calculated for Al_2OC, Al_4O_4C, and Al_4C_3. The values for Al_4C_3 agreed with previously published results.

The direct reaction

$$Al_2O_3 + 3C = 2Al + 3CO$$

did not occur. To account for the aluminum produced at high temperatures, the reaction below was postulated:

$$Al_4O_4C + Al_4C_3 = 8Al + 4CO.$$

The calculated equilibrium pressure above this reaction agreed with experimental observations.

INTRODUCTION

In the past few years, there has been a revival of interest in the production of aluminum by direct reduction (1, 2). Since a carbothermic reduction of aluminum oxide is involved in these processes, the present work was carried out to investigate the details of this reaction.

Despite the industrial supremacy of the Hall–Heroult electrolytic process, there has been a sustained experimental interest in the aluminum–oxygen–carbon* system. Previous experiments on the system may be divided into two main groups. The first of these involved studies of the gas pressures existing above the system and paralleled the present investigation. The second, and more recent group, was a study of the compounds and phase relations occurring in the system, as determined by analyses of solidified melts of varying composition. In the latter group, a large number of compounds have been postulated by various workers (3, 4), but the existence of many of these has been disproved at a later date. Foster, Long, and Hunter (5) have subjected the system to an extensive analysis in which two oxycarbides, Al_2OC and Al_4O_4C, were found, as well as the known carbide, Al_4C_3. The existence of the two oxycarbides has been confirmed by Filonenko *et al.* (6, 7).

**In the text, the words graphite and carbon are used interchangeably.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From the earlier work on reaction pressures, various reactions have been postulated as follows:

$$2Al_2O_3 + 9C = Al_4C_3 + 6CO \quad [1]$$

$$Al_2O_3 + 3C = 2Al + 3CO \quad [2]$$

$$Al_2O_3 + Al_4C_3 = 6Al + 3CO \quad [3]$$

$$Al_4C_3 = 4Al + 3C. \quad [4]$$

Since the gas pressures for reactions [1]–[3], as determined by previous workers (8, 9, 10), were of the same order of magnitude, it was thought that a pressure attributed to one reaction by one experimenter could easily have been linked with another reaction by a later worker. The major source of error in this case would be improper or inadequate analysis of the reaction products, and Foster *et al.* (5) have shown that this has occurred repeatedly in the phase diagram studies. Another source of error could be the methods of pressure measurement used. In the pseudostatic (8), static (9), and modified transportation (10) techniques, an "integrated" pressure measurement can be obtained at a specific temperature if two or more simultaneous reactions occur with nearly the same equilibrium pressure. A pressure-measuring method was required which could differentiate between the various reactions.

EXPERIMENTAL

(1) Pressure Measurement

The experimental methods (11, pp. 140–171; 12) which measure the gas pressure exerted at various temperatures will require excessive resolving power to separate the initial pressure contribution of a second reaction. It would be preferable to measure some other effect of the new reaction. One method involves measurement of the weight change produced by reactions which form volatile components. At the onset of a new reaction, the rate of change of weight will alter, and the corresponding pressure and temperature may be obtained by extrapolation. Such a method was used by Ruff (13). In this technique, a crucible containing the reactants was suspended from a spring balance inside a furnace. An inert gas at a predetermined pressure was added to the system and the temperature was increased at a constant rate while the change of weight was recorded. The position at which there was a change in the rate of weight loss was taken as the equilibrium point. The method is a dynamic or "boiling point" measuring technique. In a variation of this method, Fischer and Rahlfs (14) maintained a constant temperature and decreased the pressure. The change in rate was found to be more pronounced, and consequently the boiling point determination was more precise. Ruff's original procedure has recently been used by Chapman, Foster, and Shevlin (15) in a study of the silicon–oxygen–carbon system.

Theoretically, either of the procedures above would be suitable for the Al–O–C system, since the rate of weight loss would change with each successive reaction. In practice, however, the major disadvantage is the gradual change in weight loss which sometimes occurs near the reaction point. This causes uncertainties in the extrapolation to determine the equilibrium point. Other disadvantages are the relatively small size of the sample and container, and the possibility that the crucible might move in the furnace, thus causing a variation in heating conditions or a change in temperature of the sample.

The method adopted in this work measures the heat change which results from the onset of a new reaction, and is an adaptation of differential thermal analysis (D.T.A.). The measurement of the heat effect of a reaction is more sensitive than the change of weight, and the uncertainties of extrapolation were avoided. The method has been used in mineralogy to study a wide range of decomposition reactions at low temperatures. For example, Stone (16) studied the decomposition characteristics of various kaolin group minerals under an atmosphere of water vapor, and Haul and Heystek (17) investigated the decomposition of dolomite under varying carbon dioxide pressures.

In the experiments, the reactants and an inert reference sample were placed in the separate compartments of a divided reaction crucible, each compartment having a tight-fitting cap pierced by an aperture small enough to restrict diffusion, but large enough to permit flow when a small pressure differential was established. The crucible, with its differential thermocouple assembly, was placed in a furnace, and after preliminary outgassing and heating of the apparatus an atmosphere was added at a predetermined pressure. The reference and experimental sample were then heated at a constant rate, while readings of absolute and differential temperature against time were recorded. At the equilibrium point, the vapor pressure over the sample was just equal to the external pressure. At a slightly higher temperature, the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

proceeded and there was a quantity of heat evolved or absorbed. This produced a discontinuity in the differential trace, generally in the form of a reaction peak.

The method retains all the good points of the weight loss techniques and possesses some additional features. Unlike the thermobalance procedures, the reaction crucible is always stationary in the furnace and, therefore, it is easier to achieve uniform temperatures. The sample size may be increased considerably, the limit being governed by the need for temperature uniformity. The difficulty inherent in maintaining constant temperatures at high temperatures for long periods of time is bypassed. The D.T.A. is sensitive to all reactions which involve heat effects in the system.

Theoretically, the method can approach equilibrium from both sides. If the reaction is progressing at some temperature higher than the equilibrium, there will be a temperature effect on the differential trace. If the temperature is decreased linearly, a point will be reached where the reaction and the heat effect on the differential trace both cease. If the pressures are equal during the measurements from above and below, the equilibrium temperatures found should be the same. Since there is a ΔT effect for both determinations, they would differ by $2\Delta T$. This difference is an indication of the accuracy of the results. If small, the reaction point determinations can be treated as the correct equilibrium points, excluding errors in temperature and pressure measurement.

The method is similar to other high-temperature techniques in that the design of the apparatus and the establishment of suitable experimental conditions vary from reaction system to reaction system, and must be found empirically.

(2) Apparatus

The furnace used in the experiment is shown in Fig. 1. It consisted of a vacuum-tight water-cooled shell (volume 150±10 liters) which could be isolated from the pumps by either a baffle or a sliding valve (not shown). The pumping system consisted of a 4-in., three-stage, oil diffusion pump and a two-stage, air-ballasted, rotary mechanical pump. Points A, B, and C were Pirani-type thermocouple gauges and point D was a cold cathode gauge. For measurement of inert gas pressures, a mercury manometer was located at a point just ahead of the baffle valve. The mercury levels were determined with a cathetometer.

The furnace element shown in Fig. 1 was a tubular split graphite resistor. The power source was a 15.6 K.V.A. variable transformer connected in a series with 20:1 step-down transformer giving maximum power across the resistor at 12.5 v and 1300 amp, offering the furnace a maximum temperature of 2000° C. The furnace temperature was increased linearly by means of a motor-driven winch which drove the variable transformer. The rate of temperature increase could be varied by changing the motor reduction ratio. After experimenting with various rates of temperature increase, a rate of rise of 3.5° C per minute was selected.

Figure 2 is a diagram of one of the graphite reaction systems used for runs in which temperatures were measured optically. The disappearing filament-type pyrometer was sighted into the sight hole in the two-compartment reaction crucible by means of a quartz prism. Since temperature measurement at high temperatures was a possible major point of error, temperatures were also measured by a W-W 26% Re thermocouple. Both optical pyrometer and thermocouple were calibrated *in situ* against the melting points of analytical grade copper and nickel and nuclear grade zirconium. The accuracy of the temperature-measuring devices was ±10° C at 1850° C and ±3° C at 1083° C. When the thermocouple was used as a means of measuring absolute temperature, the graphite reaction assembly was modified slightly from that shown in Fig. 2 in that a thermocouple well extended up through the bottom of the reaction assembly to within $\frac{1}{8}$ in. of the bottom of the crucible compartments.

Because graphite was one of the reaction components, an all-alumina system was also used to ensure that the graphite assemblies did not interfere with the equilibrium point determinations. The alumina assembly consisted of a recrystallized alumina tube which extended through the top plate of the furnace of Fig. 1 and was connected to the inert gas pressure-controlling systems by a separate line so that the carbonaceous atmosphere surrounding the graphite resistor would not affect the reaction point determinations. Molybdenum baffles and spacers were used in this assembly.

The differential thermocouple was separated from the absolute temperature measuring devices and consisted of a tungsten–graphite–tungsten couple. This thermoelement was similar to that originally developed by Watson and Abrams (18), but was much smaller in size. In the graphite crucibles, the crucible bottom served as the common joining the two 0.010-in. tungsten wires. In an alumina crucible, a $\frac{1}{4}$-in. graphite rod was used as a common. The tungsten wires were forced into holes bored in the ends of 0.057-in. graphite rods, of $\frac{3}{4}$-in. length, and the free ends of the rods were inserted into holes bored in the graphite common. Figure 2 shows the graphite thermocouple pegs in position in the crucible. The tungsten wires, protected by alumina "spaghetti" tubing, were led out through the top plate of the furnace and connected to a precision potentiometer.

(3) Sample Preparation

In the examination of the alumina–carbon system, mixtures of alumina and graphite were prepared in the stoichiometric ratios $2Al_2O_3$:3C, $2Al_2O_3$:6C, and $2Al_2O_3$:9C. The aluminum oxide was analytical grade reagent and the graphite was National Carbon A.G.S.R. grade* (−100 mesh).

**Reaction assemblies and crucibles were also made from this graphite.*

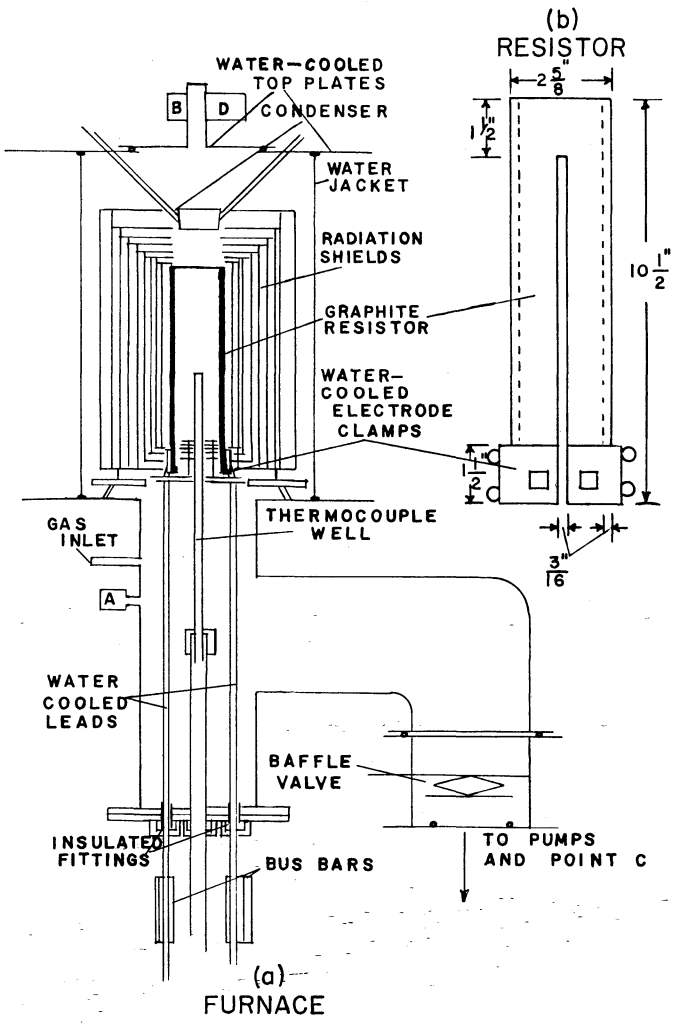

FIG. 1. Furnace (*a*) and resistor (*b*).

The mixtures were briquetted in a 1-in. steel die under 40,000 p.s.i. supplied by using a 3-in. hydraulic press. The pellets were then broken up and screened. Particles in the range −6, +20 mesh were retained. Blanks consisting only of alumina* were made in the same manner.

(4) Experimental Run

The differential thermocouple was assembled in the reaction crucible and the reference and sample were added to their respective compartments. The caps were placed on the crucible, followed by the alumina insulators. The assembly was lowered into the furnace by rods screwed into the tapped holes of the crucibles. The rods were removed, the various baffles and the condenser sleeve were added, and the tungsten wires were led out through the insulator in the top plate. The thermocouple outlet was sealed, and the leads connected to a potentiometer.

The system was evacuated at room temperature for 6 hours, after which a timing switch started the winch, and over a period of 4½ hours the temperature was increased from ambient to 1150° C. The furnace was degassed at this temperature for a further 3 hours prior to starting the differential thermal analysis. At the end of this degassing sequence, the baffle valve was closed and the pumps were isolated from the furnace. Purified argon was passed through the "cartesian diver" type controller and into the furnace.

**Reference samples of alumina were suitable only in the lower and intermediate temperature ranges. At higher temperatures, the carbon monoxide produced in the reactions reacted to some extent with the alumina in the reference compartment. The alumina was subsequently replaced with −6, +20 mesh graphite particles.*

For personal use only.

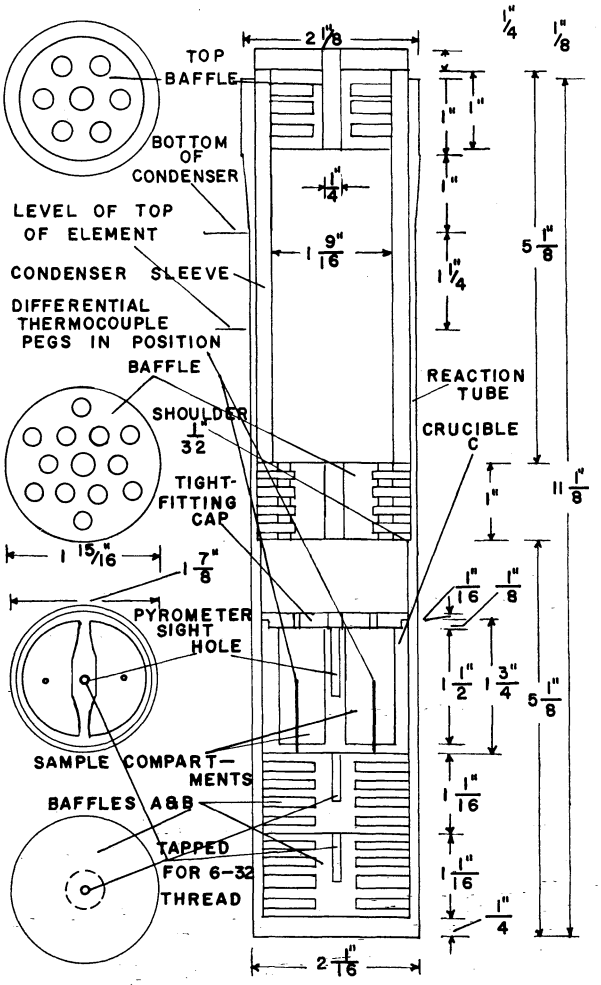

FIG. 2. Graphite reaction tube.

As the temperature of the furnace was increased linearly, readings of differential and absolute temperature were taken every 100 seconds, and the pressure, as indicated by the mercury manometer, was read every 10 minutes using the cathetometer.

After the completion of the run, the furnace was cooled and the crucible contents examined. Owing to the extreme fragility of tungsten after heating, excessive care was required to remove the differential thermocouple without damage. Therefore, the thermocouple was broken on removal from the furnace and a fresh couple was inserted for each run. This did not interfere with the results, as the readings of the differential thermocouple were only relative with respect to the reference compartment.

RESULTS

(1) Differential Traces

The differential traces obtained using the W-C-W thermocouple did not resemble the standard type of trace in which a discrete peak is formed for several reasons. In most of the standard forms (17) of D.T.A., extremely small samples are used and the reaction proceeds to completion in a short time, after which the differential trace returns to some value near its original. During the present work, the experimental samples were much

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

larger and the trace did not return to a near "normal" value and form a peak. The abnormal behavior was also due to the rate of reaction and will be discussed with reference to Figs. 3*a* and 3*b*. The figures are plots of the differential e.m.f. versus absolute tem-

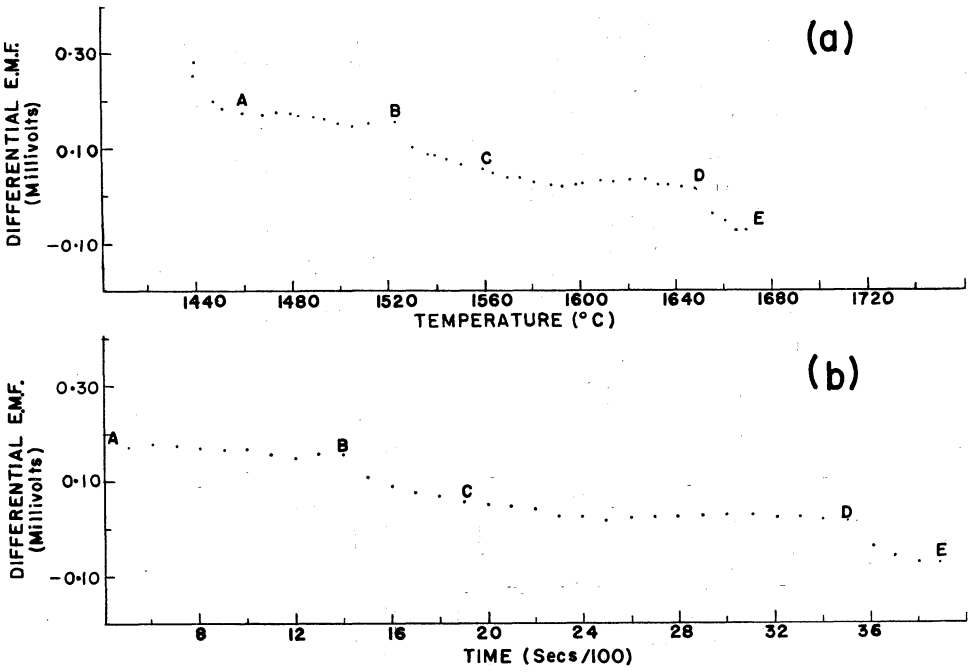

FIG. 3. (*a*) Differential e.m.f. vs. temperature (run 62). (*b*) Differential e.m.f. vs. time (run 62).

perature and time. Equivalent points on the curves are indicated by letter. Along AB, the rate of heating and the differential e.m.f. were constant. At B, the pressure of vapor product in the reaction crucible was equal to that of the argon in the system. As the temperature increased, the reaction proceeded to the right and there was a considerable change in the slope of the curve. After the initial rapid change (BC) the slope of the curve approached a steady-state condition once more. At D, a second reaction occurred and a curve similar to BCD was obtained (DE).

There was no "normal" differential peak after BC because the reaction was still proceeding up to D, where the second reaction started. Therefore, a distinct peak did not appear in the trace because, in the alumina–carbon system, the rate of reaction was a controlling factor and the mixture continued to react as the temperature was increased over the interval CD.

At D, because of the construction of the reaction tube, the original atmosphere of argon had been displaced in the space above the reaction crucible by the carbon monoxide generated by the reaction at B, over the time interval BD. Since the total pressure above the crucible was unchanged, this did not affect the reaction point determinations. The equilibrium points were taken as B and D for the two reactions.

The form of the D.T.A. curves made the task of obtaining equilibrium points for the back reactions somewhat easier. The curves were similar to those already described; the sole difference in method was that the equilibrium position was taken as the point at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which the differential trace returned to a constant or near-constant value after the change in slope caused by the reaction. Since the argon had been displaced from the reaction tube, the back reaction was measured under a carbon monoxide atmosphere.

(2) Reactions Present in the System

All the stoichiometric ratios showed the same reactions occurring. The pressure–temperature relationship for three of these reactions could be measured and a fourth was observed. Figure 4 shows these relationships. The first three reactions occurred at

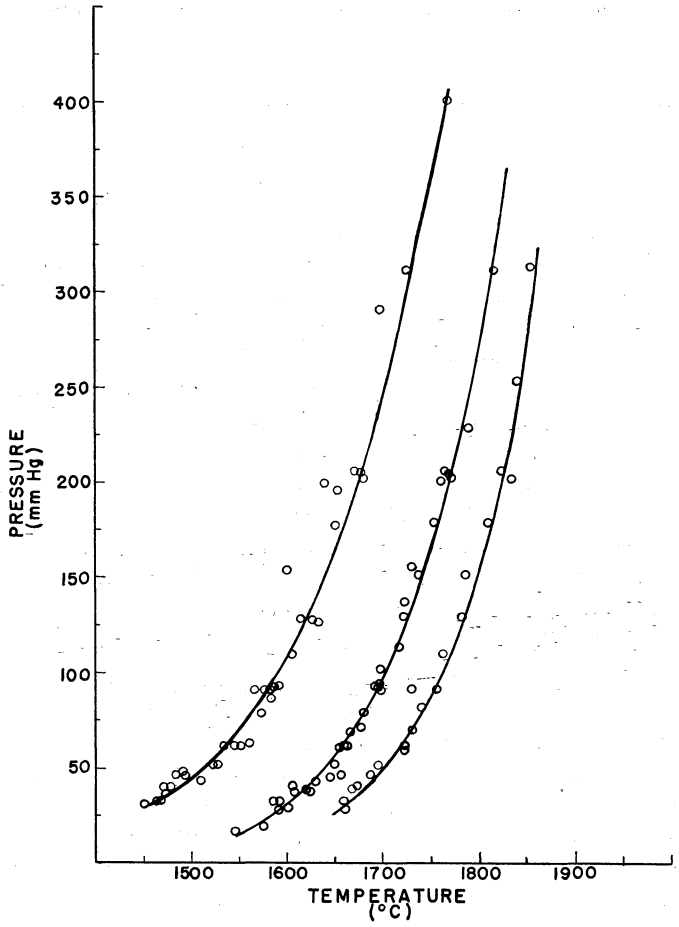

FIG. 4. Pressure vs. temperature for the reactions measured.

greatly different temperatures (at constant pressure), and gave a curve of the general form of Fig. 3. However, the fourth reaction occurred at almost the same temperature as reaction [3], and since the differential e.m.f. was still changing rapidly, the point for reaction [4] was obscured. For the first three reactions, the gaseous product was carbon monoxide. The product from the fourth reaction was a condensable vapor, and this condensed product was found to be a mixture of Al_4C_3, Al, C, and Al_2O_3, with some minor constituents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A high-angle X-ray diffractometer using a copper target and nickel filter was employed to identify the respective reactions. A sample mixture was placed in the furnace heated to the reaction point, as determined from the differential traces, and held there for varying lengths of time. The furnace was then cooled, a portion of the sample was removed for X-ray analysis, and the remainder was returned to the furnace. The process was repeated at 10° C intervals over the range of interest of the system. The patterns were compared with those in the ASTM files (19). The first reaction was found to be:

$$Al_2O_3 + 3C = Al_2OC + 2CO. \quad [5]$$

The second was the analogous reaction to form the second oxycarbide:

$$2Al_2O_3 + 3C = Al_4O_4C + 2CO. \quad [6]$$

The third was the reaction of the oxycarbide of reaction [6] with graphite to form the carbide Al_4C_3:

$$Al_4O_4C + 6C = Al_4C_3 + 4CO. \quad [7]$$

Reaction [5] had a relatively slow rate of reaction and produced only small amounts of the oxycarbide Al_2OC. However, reaction [6] proceeded rapidly and after a short period of time all the free alumina in the system was converted to Al_4O_4C.

Since Al_2OC was present in only minor amounts, and since there was no Al_2O_3 present, the reaction to produce the carbide must be reaction [7].

The fourth reaction could not be determined directly because of the condensable vapor product which appeared in the colder sections of the apparatus. It is likely that this fourth reaction yielded aluminum vapor as one of the gaseous products. This metal vapor then back-reacted in the cooler portions of the apparatus with either graphite or carbon monoxide to form the Al_4C_3, C, Al, Al_2O_3 mixture which was found. Since there was no alumina present in the system at this temperature, neither reactions [2] nor [3] could take place. The amount of Al vapor produced was too great for [4] to be the reaction occurring. However, aluminum may be produced by a reaction with the oxycarbide analogous to [3]:

$$Al_4O_4C + Al_4C_3 = 8Al + 4CO. \quad [8]$$

The reason why reactions [1], [2], and [3] were postulated by early workers would probably be in their methods of analysis. In the early work, the substances analyzed were the back-reaction products and the previous reactions were deduced from these products. Since these products were generally formed under non-equilibrium conditions, the wrong reactions were postulated. Reaction [1], measured by Prescott (8), is simply the sum of the reactions [6] and [7] measured in this work. Reaction [2], measured by Brunner (9) and Treadwell and Gyger (10), did not occur directly. Reaction [3], postulated by Brunner (9), would not take place because of the absence of alumina at this stage of the carbothermic reduction.

In the present work, the order of appearance of the oxycarbides was also unexpected. With respect to increasing percentages of carbon, the series is: $2Al_2O_3$–Al_4O_4C–$2Al_2OC$–Al_4C_3.

The appearance of Al_2OC at lower temperatures than the Al_4O_4C was probably due to the similarity in size between the Al_2OC and Al_2O_3 molecules. In this case, more energy would be required to form the larger Al_4O_4C molecule than the smaller and less complex molecule of Al_2OC.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It has been suggested (20) that the distillation of material was caused by the reduction of alumina to a suboxide, either AlO or Al_2O, and then a subsequent reaction with carbon occurred to form the oxycarbides. Possible reactions for this process would be:

$$Al_2O_3 + C = 2AlO + CO \quad [9]$$

$$Al_2O_3 + 2C = Al_2O + 2CO \quad [10]$$

followed by:

$$Al_2O + C = Al_2OC \quad [11]$$

or

$$4AlO + C = Al_4O_4C. \quad [12]$$

Using the data from Lewis and Randall (21), the free energies of reaction for [9] and [10] were calculated. The equilibrium pressure above the system was found by using the relation

$$\Delta F^0_T = -RT \ln K_p.$$

For [9]:

$$\Delta F^0_{2000} = 125{,}000 \text{ cal} = -2000R \ln P^3_{AlO/2}$$
$$(P_{AlO} = 4.3 \times 10^{-2} \text{ mm Hg})$$

For [10]:

$$\Delta F^0_{2000} = 47{,}700 \text{ cal} = -2000R \ln 4P^3_{Al_2O}$$
$$(P_{Al_2O} = 3.5 \text{ mm Hg}).$$

As seen in Fig. 4, the measured pressures at 2000° K were greater than the calculated pressures by one to two orders of magnitude. Therefore, neither [9] nor [10] were the reactions measured during the experiment.

(3) Validity of the Measurements

Two series of tests were carried out with the D.T.A. apparatus, to establish whether the true equilibrium points were being measured. In one case, the equilibrium was approached from both sides. The second method was an attempt to check the apparatus by examining an established, simpler system. (The alumina–carbon system is one of the most complex of the oxide–carbide systems, and aluminum oxide is second only to thoria in its high-temperature stability with respect to carbon.) The zirconium doixide – carbon binary is such a system.

It has been examined by both Prescott (22) and Kutsev *et al.* (23). They measured the carbon monoxide pressures above this system using a pseudostatic method in which equilibrium could be approached from both above and below. In the present method, the values obtained on runs approaching equilibrium from below fell between those of the two earlier workers in the temperature range covered (1790–1900° K).

When points were measured from above using the alumina–carbon system, the values obtained were equal to those obtained from below at the same pressure within the limits of experimental error (±10° C). Values could only be obtained for reactions [5] and [6] in the lower-temperature ranges because of the rapid distillation of materials out of the crucible by means of reaction [8] at higher temperature. This was not a drawback because Kutsev (23) has found that in the case of refractory oxide–carbon systems, errors that might occur in determinations from both sides were much greater at lower temperatures and were negligible at higher temperatures. Therefore, both checks indicated that equilibrium had been measured in the present work.

(4) Reproducibility of Results

Figure 5 shows the van't Hoff relation obtained for reaction [6]. The outer limits are the two-sigma limits and correspond to an uncertainty of ±1.2 mm Hg in the results.

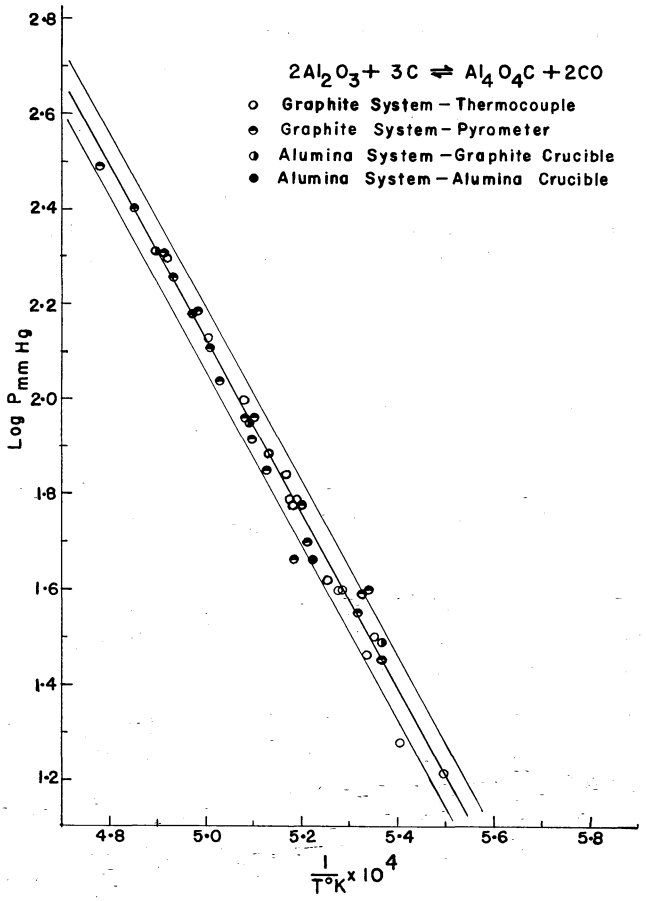

FIG. 5. Log $P_{mm\ Hg}$ vs. $(1/T)\times 10^4$.

The values for reactions [5] and [7] were ±1.3 and ±1.2 mm Hg respectively. These values were within the sensitivity limits of the instruments used for controlling the pressure of argon in the system.

It is apparent from Fig. 5 that there was no statistical difference between the results obtained using either the optical pyrometer or thermocouple, or the results obtained using either an alumina or a graphite system. (In these runs, the holes in the caps of the reaction crucible were also varied from 0.080 in. to 0.120 in. with no significant difference in the results obtained.)

(5) Thermodynamic Calculations

Because of the lack of heat capacity data for the aluminum oxycarbides, it was necessary to estimate values for these compounds. This, in turn, made it advisable to use "a third law" method of calculating the heats of reaction for reactions [5], [6], and [7]. For each equilibrium measurement, a value of $\Delta F^0_T/T$ was found, and by using the relation

$$\Delta H^0_{298} = T(\Delta F^0_T/T - \Delta(F^0_T - H^0_{298})/T)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a standard heat of reaction was obtained. Ideally, if there is no temperature-dependent error, and if the $(F_T^0-H_{298}^0)/T$ values are correct, the ΔH_{298}^0 values obtained are constant. In the case of a temperature-dependent error, or erroneous free energy functions, there is a drift in the ΔH_{298}^0 values obtained, but a fairly accurate (24) value of the standard heat may be obtained by taking an average value.

Kelley (25) has given a relation for the heat capacity of alumina in the range 298–1800° K. This relation was used over the temperature range 298–2200° K, with some unavoidable loss in accuracy.

Kubaschewski's (26) listed value of the heat capacity of the carbide was used. This molal heat capacity was recalculated to give the more usual three-term relation.

$$\text{For } Al_2O_3\text{: } C_p = 27.49+2.82\times10^{-3}T-8.38\times10^{5}T^{-2}$$

$$\text{For } Al_4C_3\text{: } C_p = 44.30+3.19\times10^{-3}T-12.39\times10^{5}T^{-2}.$$

Heat capacities for Al_4O_4C and Al_2OC were estimated using Kopp's rule and treating the oxycarbides as mixtures of Al_2O_3 and Al_4C_3.

$$\text{For } Al_2OC\text{: } C_p = \frac{C_p(Al_2O_3)+C_p(Al_4C_3)}{3}$$

$$C_p = 23.93+2.00\times10^{-3}T-6.92\times10^{5}T^{-2}$$

$$\text{For } Al_4O_4C\text{: } C_p = \frac{4C_p(Al_2O_3)+C_p(Al_4C_3)}{3}$$

$$C_p = 51.42+4.82\times10^{-3}T-15.30\times10^{5}T^{-2}$$

The absolute entropy of alumina at 298° K, S_{298}^0, was obtained from Kelley (27), that of the carbide from Circular 500 (28), and from these values, S_{298}^0 for Al_4O_4C was calculated according to the recommendation of Kubaschewski (11, p. 194). The value used for Al_2OC was estimated in a different manner and will be explained below:

For Al_2O_3, $S_{298}^0 = 12.5$ e.u. For Al_4C_3, $S_{298}^0 = 25$ e.u.

For Al_4O_4C, $S_{298}^0 = 25$ e.u. For Al_2OC, $S_{298}^0 = 6.5$ e.u.

From these values, the free energy functions were calculated and from these the heats and free energies of reaction were found. Using the values for alumina and carbon monoxide from Elliott and Gleiser (29), the standard heats and free energies of formation for the compounds were found and are given in Table I below.

TABLE I

Thermodynamic functions

Compound	ΔH_{298}^0 (kcal)	ΔF_{298}^0 (kcal)	Limits (kcal)
Al_2OC	−171.4	−158.9	±10
Al_4O_4C	−543.1	−511.7	± 8
Al_4C_3	− 35.9	− 28.4	± 8

The experimental heats and free energies of formation for the carbide could be compared with the values obtained by other workers using calorimetric and equilibrium pressure measurements. The standard heat of formation agreed favorably with the 40±3 kcal obtained by Roth (30). Meschi and Searcy (31) found 50±10 kcal and Elliott and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Gleiser (29) list -35.9 ± 3 kcal from the work of C. S. Campbell. The free energy of formation was reported as -38.1 kcal by Roth (30), -35.9 kcal by Elliott and Gleiser, and -28.4 kcal in the present work.

The estimated and experimental values for the oxycarbide Al_4O_4C could be treated with confidence since these values were used to calculate the thermodynamic functions for Al_4C_3, and the carbide values were similar to those obtained in calorimetric measurements.

The situation was somewhat less satisfactory for the other oxycarbide Al_2OC. Initially an estimated value of $S^0_{298} = 12.5$ e.u. was used to calculate the free energy functions. From the experimental values for the heats and free energies of formation, a value of $S^0_{298} = 1.0$ e.u. was obtained. The magnitude of $\Delta H^0_{298}-\Delta F^0_{298}$ was great enough so that the results were not affected unduly. Since the difference between the estimated and calculated values was so large, and since ΔS^0_{298} did not change very rapidly with the absolute values of ΔH^0_{298} and ΔF^0_{298}, a corrected value of S^0_{298} was obtained by averaging the calculated and estimated values in the first approximation. A value of $S^0_{298} = 6.5$ e.u. was therefore used. A second low treatment of the data also yielded a value approximately equal to this.

It was possible to calculate the total equilibrium pressure above reaction [8] using the experimentally derived free energies for the oxycarbide Al_4O_4C and the carbide Al_4C_3.

Volume 41, 1963

Page 682. The author has submitted the following regarding an error in lines 18–33:

"This has been pointed out to me by K. Motzfeldt, of the Norwegian Technical University, Trondheim, Norway, and involves the calculated pressure above the reaction

$$Al_4O_4C + Al_4C_3 \rightleftharpoons 8Al + 4CO. \qquad [8]$$

The correct total pressure above the reaction is 38.4 mm Hg and therefore [8] alone would not be the reaction observed in which volatile products were evolved. These products would occur by a combination of [8], and, possibly, the reactions given below,

$$Al_4O_4C + C \rightleftharpoons 2Al_2O + 2CO,$$

$$Al_4O_4C \rightleftharpoons 4AlO + C.$$

Because of this, the conclusion given in paragraph 3, page 683, is wrong."

) mm
'co is
) mm
ction
and
lated
The

calculated pressure of reaction [8] theoretically should be less than that of [7] but the difference noted was due to the errors in the experimentally determined thermodynamic functions (±8 kcal).

CONCLUSIONS

The method of determining vapor pressures produced results which were reproducible when equilibrium was approached from temperatures above and below the equilibrium value. The reproducibility was within $\pm1.5\%$, which was considerably better than that of static methods of measurement on similar systems.

The oxycarbides, Al_4O_4C and Al_2OC, were formed by a solid–solid reaction; the formation of aluminum suboxides as an intermediate step in the oxycarbide formation is unlikely. The carbothermic reduction to the carbide, Al_4C_3, proceeded through Al_4O_4C. There was no Al_2OC step in this reduction; it was formed only in small quantities and its formation was considered to be a side reaction in the process.

The equilibrium pressures above three reactions were measured in the system. These were:

$$Al_2O_3 + 3C = Al_2OC + 2CO$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$2Al_2O_3 + 3C = Al_4O_4C + 2CO$$
$$Al_4O_4C + 6C = Al_4C_3 + 4CO.$$

The reactions occurred at progressively higher temperatures in the order listed. From the experimental results, the heats and free energies of formation for Al_2OC, Al_4O_4C, and Al_4C_3 were calculated.

In the experiment, alumina was completely converted to the oxycarbide before the carbide was formed. Therefore, the direct reaction

$$Al_2O_3 + 3C = 2Al + 3CO$$

did not occur. To account for the large amounts of back-reaction products produced, the reaction below was postulated:

$$Al_4O_4C + Al_4C_3 = 8Al + 4CO.$$

The calculated equilibrium pressure above this reaction agreed with experimental observations.

PROTON COUPLING CONSTANTS IN SUBSTITUTED CYCLOPROPANES

H. M. HUTTON AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received September 5, 1962

ABSTRACT

Coupling constants between geminal protons are reported for a number of cyclopropane derivatives. They are compared with results from previous work and other values in the literature. It is suggested that the geminal couplings are of opposite sign to the vicinal couplings and therefore negative. Comparison of the H—C—H angles with the former are therefore no longer valid. It is also suggested that the geminal couplings are zero in ethylene sulphides and positive in epoxides and that there is a change in sign in going from carbon through sulphur to oxygen as the third atom in the ring. The vicinal coupling constants depend on the dihedral angle as predicted by theory but the substituent effects do not appear to follow a simple dependence on the electronegativity as they do in substituted ethanes.

INTRODUCTION

We recently determined fairly certainly that the cis proton coupling constant in the cyclopropane ring is larger than the trans coupling constant (1). The magnitudes are in reasonable agreement with the $\cos^2 \phi$ relationship between the coupling constant and the dihedral angle ϕ as predicted by Karplus (2). There had been some disagreement in the literature about the relative magnitudes of these constants (1, 3). We have now measured the geminal coupling constant between protons for a number of cyclopropane derivatives. In the meantime coupling constants for the cyclopropane ring have been measured by others, and these are compared with our results (4–7). As in our previous work we have again measured relative amounts of cis and trans isomers for one derivative. Some relative chemical shifts are also discussed.

EXPERIMENTAL

The proton resonance spectra were obtained on a Varian V4302 DP 60 Mc/s spectrometer at room temperature. Peak separations were measured by the side-band technique, using a frequency counter. The analyses were the averages of a minimum of 10 spectra and were repeated on a separate occasion to verify the findings.

The compounds were a gift from Dr. Layton L. McCoy. Their physical constants are given in his paper (26*b*) and were certainly of sufficient purity for our purposes since a weak impurity peak was found in only one case. Solvents were used which preferentially shifted the ring proton peaks so that they were not obscured by other peaks. For reasons of solubility a mixed solvent of acetone and benzene was used for the dicarboxylic acids. For these reasons chemical shift comparisons are of doubtful value. Tetramethylsilane was the internal reference.

RESULTS

Coupling between ring protons and substituents like methyl groups was not observable and must thus be less than 0.4 c.p.s. Therefore the ring proton spectra were of the four-peak AB type and were analyzed as such. Table I gives the chemical shifts relative to internal tetramethylsilane as well as the coupling constants. The assignment for the ring protons could conceivably be interchanged. It has been made on the basis of the assignment for cyclopropane-1,1,2-tricarboxylic acid given by Graham and Rogers (4). The carboxyl protons are not included in Table I. They occurred at approximately 600 c.p.s. from the reference and will be omitted from the discussion.

Figure 1 shows the proton resonance spectrum of a mixture of *cis*- and *trans*-1-chloro-2-methyl-2-cyanocylopropane carboxylates and is discussed below.

†Standard deviations.

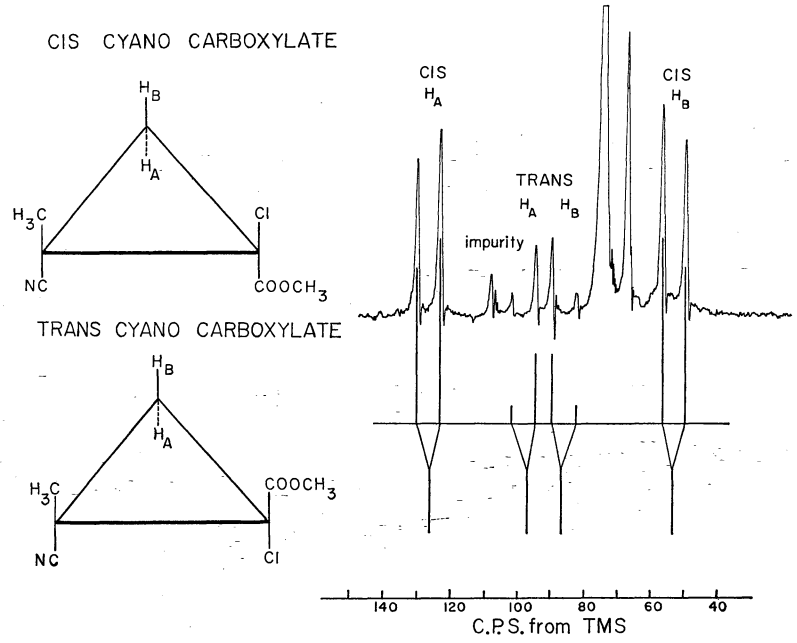

FIG. 1. The proton magnetic resonance spectrum of a mixture of *cis*- and *trans*-1-chloro-2-methyl-2-cyanocyclopropane carboxylates in benzene solution at 60 Mc/s. The internal reference is tetramethylsilane and occurs at high field.

DISCUSSION

Coupling Constants

The values of the three types of coupling constants for cyclopropane derivatives which are known fairly accurately are given in Table II. We examine them as to magnitude and sign.

(a) Vicinal Couplings

The average values of J_{cis} and J_{trans} in Table II are 8.67 and 5.71 c.p.s., respectively. The most recent determination of the cyclopropane geometry gives 113.8±2° for the H—C—H angle (8), compared to a previous value of 118° (9). The smaller angle improves the agreement between J_{trans} and the predicted value. For an H—C—H angle of 118°

*See text for discussion of the sign of the geminal coupling.

the dihedral angle is very nearly 147°, giving a predicted value of 6.4 c.p.s., while for 114° the dihedral angle is about 144°, giving a predicted value of 5.9 c.p.s.

However, apart from the fact that the theory assumes sp^3 hybridization and is, furthermore, one which is to be used as a rough guide only, substituent effects may be of some importance. Glick and Bothner-By (10) some time ago suggested that in ethyl compounds the average vicinal coupling constant was a linear function of the electronegativity: J (c.p.s.) $= 8.4-0.4E$, where E is the Huggins electronegativity of the substituent. A slightly different relation, based on more extensive data, has been recently given by Banwell and Sheppard (11). They have found it to be valid for more heavily substituted ethanes. In both relations the dependence on electronegativity is about 10 times smaller than that in vinyl compounds (12, 13).

Although there is a variation of vicinal coupling constants with the substituent for the cyclopropanes, it does not clearly depend on the electronegativity of the substituent. Thus, for compounds 9 and 14 the substituent is the carboxyl group and $J_{cis}+J_{trans} =$ 15.88 and 13.55 c.p.s., respectively. The neighbor groups are carboxyl groups in one case and phenyl groups in the other. In compound 15 we have $J_{cis}+J_{trans} = 15.0$ c.p.s. and the trend is in the opposite direction to that expected from the behavior of ethanes. In the latter compound there may be a certain amount of distortion of the molecule. One suspects that for all these compounds the high degree of substitution involves enough distortion of the molecule to obscure any small linear dependence of the couplings on the electronegativity of the substituent. This point can only be settled by a systematic study of a series of cyclopropanes. Compound 1, the only monosubstituted molecule in Table II, does show a substituent effect on vicinal couplings which appears to be appreciable and in the right direction.*

It has been suggested that the cyclopropane ring has some π-electron character (15(*b*)), but it appears that, if present, it does not contribute noticeably to the coupling. Otherwise, we should see a large substituent electronegativity effect as in ethylenic compounds (12, 13). Also, one might expect appreciable coupling to the methyl substituents through four bonds as is usually observed when the C—C bond has appreciably π character (15(*a*)).

(b) Geminal Couplings

In the two cases in Table II where it has been determined J_{gem} is of opposite sign to the vicinal couplings.† In almost all cases, with the exception of certain ethylenes and epoxide groupings, this is true also in other systems (16–20). The agreement between theory and experiment for vicinal couplings through three bonds leads to the conclusion that these are positive as required by theory. Then geminal couplings through two bonds are negative, at least in sp^3 systems. We suggest that all geminal coupling constants in Table II are negative, as predicted by the Dirac vector model (21).

The magnitudes are smaller than those found in tetrahedral systems but similar to the one found in propylene oxide, although it is zero in propylene sulphide (22). J_{gem} appears to be of the same sign as the vicinal coupling constants in a series of epoxides, with an average value of 5.7 c.p.s. (23). We suggest that J_{gem} therefore goes through about zero for the heterocyclic sulphides and becomes negative for the cyclopropanes. The

**In benzene solution the proton spectrum is nicely separated into three groups of lines (ignoring the carboyxl group) and we are analyzing the spectrum at both 60 Mc/s and 100 Mc/s as a check.*

There appears to be a definite solvent effect on the geminal coupling constant of compound 3 in Table II (see Table I). A similar situation exists for compound 12 where two different values for J_{trans} have been reported in different solvents (3, 4). This needs investigation.

†Preliminary spin decoupling experiments on a cyclopropane derivative in this laboratory indicate a third case of opposite signs for J_{gem} and J_{vic}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

H—C—H angles in both ethylene oxide and ethylene sulphide are almost equal (24) and the relation between J_{gem} and this angle is no longer justified (25), especially since J_{gem} is almost certainly negative in sp^3 systems. The reason for the change in sign of J_{gem} on going from the oxide to cyclopropane remains to be explained.

For compounds 7, 8, 9, and 15 the sum of the three coupling constants is fairly constant, as noted by Graham and Rogers (4). But if J_{gem} is negative for these compounds, as we suggest, then the sum varies between 4.8 and 11.1 c.p.s. and this regularity no longer holds.

Chemical Shifts

These were determined either for pure compounds or in solvents which would have large solvent effects. Detailed discussion is therefore not in order. Some instructive points may, however, be made about the mixture of *cis*- and *trans*-1-chloro-2-methyl-2-cyanocyclopropane carboxylates. An analysis by gas chromatography of this mixture gave approximately 20% trans ester (26(*a*)). From peak heights we find 20.5±0.8% for the less abundant component, which we therefore assume to be the trans isomer.

We can then argue as follows. Graham and Rogers find the proton trans to the two carboxyl groups in cyclopropane-1,1,2-tricarboxylic acid to be more shielded than the cis proton. On that basis we can assign the proton trans to the two carboxymethyl groups (proton B) in our cis ester to the peaks centered at 53.5 c.p.s. in Fig. 1. The shielding difference is presumably due to magnetic anisotropy effects since electronegativity effects should be the same for both protons. On interchanging the chlorine and carboxymethyl group proton A is shifted to high field by 27.2 c.p.s. and proton B to low field by 33.5 c.p.s. The difference between these values could then be attributed to the anisotropy of the chlorine.

Two weaknesses in this argument are clear. First, although the dielectric constant of benzene is low, field effects arising from the difference in dipole moment of the two isomers could be appreciable (27). Second, the solvent effect due to the magnetic anisotropy of the benzene molecules may be large (28). If the benzene molecules pack around the solute molecules in such a way as to avoid electron-rich centers (29) and if one considers that volume effects are also important, then proton B in the cis isomer should experience the highest solvent shift to high field. The size of this shift is possibly as large as 0.5 p.p.m. or even more (28).

The conclusion is, of course, that before any definite statements about substituent effects can be made systematic studies must be carried out in a number of well-chosen solvents. Dipole moments of the solutes are also needed. Due to the limited solubility of carboxyl-substituted cyclopropanes in electrically and magnetically inert solvents, the synthesis of a series of cyclopropane derivatives with other groups is indicated. That appreciable substituent effects are present is seen from the 13.2 c.p.s. shift of cyclopropane itself from tetramethylsilane (30).

ACKNOWLEDGMENTS

We are indebted to Dr. Layton L. McCoy for his generous gift of compounds. We are also in debt to Dr. N. Sheppard, who let us see some of his results prior to publication. One of us (H. M. H.) would like to thank Canadian Industries Limited for fellowship support. This work was aided by the National Research Council and the Research Corporation.

KINETICS OF THE REACTION $H + C_3H_8 = H_2 + C_3H_7$

H. A. KAZMI,[1] R. J. DIEFENDORF,[2] AND D. J. LE ROY
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 30, 1962

ABSTRACT

The kinetics of the reaction $H + C_3H_8 = H_2 + C_3H_7$ have been studied in the range 95 to 170° C by a method permitting the evaluation of the absolute value of the rate constant. This was found to be $2.2\times10^{-10} \exp(-8.2\times10^3/RT)$ cm^3 molecule^{-1}sec^{-1}.

For personal use only.

Some years ago we reported (1, 2, 3) the results of experiments designed to determine the rate constants and other kinetic parameters for elementary reactions of the type

$$H + RH = H_2 + R. \qquad [1]$$

The method involved the production of atomic hydrogen at a concentration of the order of 1% by the dissociation of hydrogen on a tungsten filament and the use of a detector to measure H atom consumption as a function of distance along a cylindrical reactor. The detector (3) consisted of a flat spiral of tungsten or platinum on which H atoms combined; operated as an isothermal calorimeter, it measured the number of H atoms combining on it in unit time in terms of W_H, the rate of liberation of the heat of combination in watts. Schulz and Le Roy (4) have recently modified the theory of the method to take into account diffusion effects. In the present paper the new theory is applied to the results of experiments on the reaction between atomic hydrogen and propane.

We have shown (4) that under suitable conditions the slope of a plot of $-\ln W_H$ vs. x_0, the distance between the detector and the point of admission of the RH, is equal to β_1, where β_1 is related to the first-order rate constant for H atom consumption, k, the flow rate, f, and the diffusion coefficient of atomic hydrogen, D, by the expression

$$\beta_1 = \frac{f}{2D}\left\{\left(1 + \frac{4kD}{f^2}\right)^{1/2} - 1\right\}. \qquad [i]$$

The values of D were taken from Amdur (5). In the absence of RH the rate constant k will be equal to k_b, the first-order rate constant for the consumption of H atoms on the walls of the reactor; in the presence of RH it will be equal to $k_b+\alpha k_1(RH)$, where k_1 is the rate constant for reaction [1] and α is equal to the number of H atoms consumed (other than by combination on the walls) for every RH molecule consumed in reaction [1].

If all R radicals are eventually converted to methane, and if this is formed by CH_3+H (+ M), rather than by CH_3+H_2 (3), then the theoretical value of α follows from stoichiometry. Thus, α would be equal to 4 if RH = C_2H_6, equal to 6 if RH = C_3H_8. If there should be any radical–radical combination or any combination of radicals (other than methyl) with atomic hydrogen α would have less than the theoretical value. The concentration of RH used in the expression $k = k_b+\alpha k_1(RH)$ should be that obtaining at the particular value of x_0 at which the slope of the plot of $-\ln W_H$ vs. x_0 is taken. In the first of two series of experiments the conditions were such that the change in RH concentration was small, and we used, as a first approximation, the initial value, $(RH)_0$. The

[1]*Present address: Department of Chemistry, University of Peshawar, Peshawar, Pakistan.*
[2]*Present address: General Electric Company, Schenectady, New York.*

second approximation was to use the average concentration, $(\overline{RH})$, estimated as described below. The condition required to ensure a small fractional change in (RH) is to start with a relatively high ratio of (RH) to (H). This also ensures a large fractional change in (H), a practically constant slope for the $-\ln W_H$ vs. x_0 plot, and greater accuracy in the evaluation of αk_1 from measurements of β_1 made in the presence and in the absence of RH.

In order to evaluate α and to calculate k_1 from the actual change in (RH) the RH concentrations used in the second series of experiments were, in all but one instance, made relatively small compared to the H atom concentrations. If RH is consumed only by reaction [1] and is not re-formed then

$$\ln \frac{(RH)_0}{(RH)_{x_0}} = \frac{k_1}{f} \int_0^{x_0} (H)dx. \qquad [ii]$$

As shown previously (4),

$$(H) = (H)_0 \frac{e^{\beta_1(x_0-x)} - e^{-\beta_2(x_0-x)}}{e^{\beta_1 x_0} - e^{-\beta_2 x_0}} \qquad [iii]$$

and

$$(H)_0 = \frac{W_H N}{4.184 \Delta H D A} \cdot \frac{1-e^{-(\beta_1+\beta_2)x_0}}{(\beta_1+\beta_2)e^{-\beta_1 x_0}}, \qquad [iv]$$

where $\beta_2 = \beta_1 + f/D$, ΔH is the standard enthalpy of formation of atomic hydrogen, A is the cross-sectional area of the reaction vessel (3.93 cm^2), and N is Avogadro's number. It follows that

$$\ln \frac{(RH)_0}{(RH)_{x_0}} = \frac{k_1 W_H N}{4.184 \Delta H D A f(\beta_1+\beta_2)} \left\{ \frac{e^{\beta_1 x_0}-1}{\beta_1} - \frac{1-e^{-\beta_2 x_0}}{\beta_2} \right\}. \qquad [v]$$

In order to obtain adequate accuracy in the determination of $(RH)_0/(RH)_{x_0}$ carbon dioxide was used as an inert reference substance. The condensable gases were trapped out downstream from the detector (beyond which there was presumed to be no further reaction) and analyzed by gas chromatography, using helium as the carrier gas and silica gel as the column material. Since the sensitivity factors for propane and carbon dioxide cancel, $(RH)_0/(RH)_{x_0}$ was obtained by substituting peak areas for concentrations in the expression

$$\frac{(RH)_0}{(RH)_{x_0}} = \frac{[(RH)/(CO_2)]_0}{[(RH)/(CO_2)]_{x_0}}. \qquad [vi]$$

In Table I the upper and lower values of β_1 for any particular experiment are the slopes of $-\ln W_H$ vs. x_0 plots corresponding to the absence and to the presence of RH, respectively. The corresponding values of k were derived from equation [i] expressed in the form

$$k = \beta_1 f(1+\beta_1 D/f). \qquad [vii]$$

(In our previous work we equated the slope of the $-\ln W_H$ vs. x_0/f plot to k; the present theory (4) introduces the factor $(1+\beta_1 D/f)$.) The quantity $\alpha k_1(\overline{RH})$ is simply the difference between the two values of k. The values of $(\overline{RH})$ were obtained by applying equation (v) and assuming that α was equal to 6 (see below). The decrease in RH concentration

in this series is seen to be small and the error that would have been introduced if $(RH)_0$ rather than $(\overline{RH})$ had been used would have been almost negligible.

The lower curve of Fig. 1 shows an Arrhenius plot for the values of αk_1. The least-

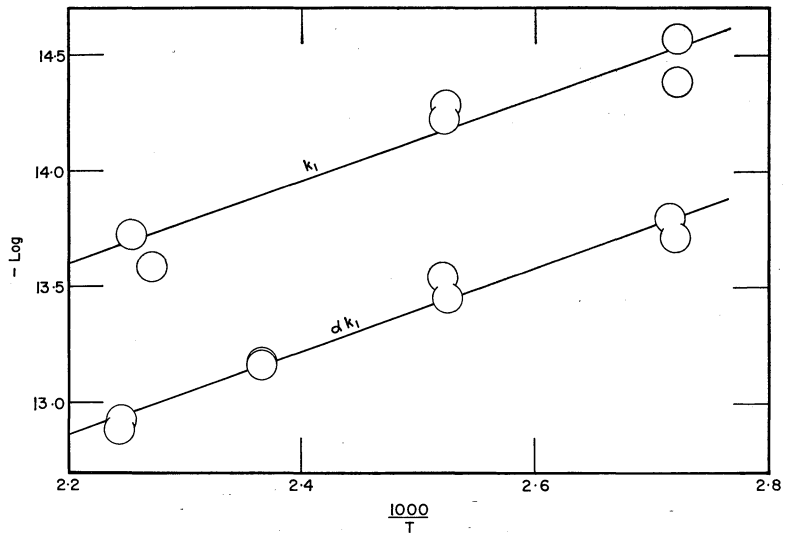

FIG. 1. Arrhenius plots for αk_1 and k_1.

squares line corresponds to $\alpha k_1 = 1.3_0 \times 10^{-9} \exp(-8.2_6 \times 10^3/RT)$. The values of k_1 given in Table II were obtained through the application of equation [v]. From the corresponding least-squares plot shown in Fig. 1 $k_1 = 2.2 \times 10^{-10} \exp(-8.2 \times 10^3/RT)$. The ratio of the pre-exponential factors for αk_1 and k_1 (13.0/2.2 = 5.8) affords some justification for the assumption that α is equal to 6. In the ordinary experiments, such as those referred to in Tables I and II, we could obtain no evidence for any products other than methane. However, by using much higher ratios of (RH) to (H) and placing the detector fairly close to the inlet we were able to detect a small amount of 2,3-dimethylbutane.

DISCUSSION

The determination of absolute, as opposed to relative, values of the rate constants of elementary reactions of atoms or free radicals is fraught with many difficulties, and the present work was not exceptional in this regard. Assuming that the combination of H atoms in the absence of RH is indeed first order, the accuracy of the values of αk_1 should be independent of the efficiency of the detector provided the slope of $-\ln W_H$ vs. x_0 is constant (4, 6). However, the constancy of the slope and its most accurate determination can only be achieved for relatively high values of (RH)/(H), a condition which decreases the accuracy with which RH consumption can be measured. On the other hand, the accurate determination of k_1 from RH consumption demands relatively small (RH)/(H) ratios, and one must be prepared to put up with some curvature in the $-\ln W_H$ vs. x_0 plots and hence some degree of uncertainty in β_1. This curvature arises, not because of failure of the theory (4), but because of the decrease in k $(=k_b+\alpha k_1(RH))$ as RH is used up in the reaction. The determination of k_1 from RH consumption also involves the assumption that the efficiency of the detector in removing H atoms is 100%. The experimental conditions used in the present work were chosen in the hope of minimizing the errors.

The most recent measurements on the kinetics of the reaction $H+C_3H_8 = H_2+C_3H_7$ with which the present results can be compared are those of Gorban and Nalbandyan (7), which have been discussed at some length by Voevodsky and Kondratiev (8). Their method was based on the effect of propane on the first explosion limit of stoichiometric mixtures of hydrogen and oxygen, and involved the use of kinetic data for the reaction of atomic hydrogen with O_2. Their values of A and E (8) were 7.8×10^{-10} liters mole^{-1}sec^{-1} (1.3×10^{-10} cm^3 molecule^{-1}sec^{-1}) and 9.6 kcal, compared to our present values of 2.2×10^{-10} cm^3 molecule^{-1}sec^{-1} and 8.2 kcal. It is interesting to note that at 480° C, in the range of their experimental conditions, their values of A and E correspond to $k_1 = 2.2\times10^{-13}$, while ours predict a value of 9.2×10^{-13}.

SYNTHESIS IN THE PYRIDINE SERIES

III. THE SYNTHESIS OF NEW 3,5-DIMETHYL-4-SUBSTITUTED PYRIDINES. STERIC EFFECTS AS AN AID TO SYNTHESIS

JAMES P. KUTNEY AND T. TABATA

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received July 23, 1962

ABSTRACT

A synthetic sequence leading to 3,5-dimethyl-4-substituted pyridines is described. The sequence takes advantage of the steric influence exerted by substituents attached to the pyridine nucleus at the 3- and 5-positions on functional groups at the 4-position. In this manner a number of new trialkylated pyridines become available.

Some time ago we became involved in the synthesis of 3,4,5-trialkylated pyridines since these substances were necessary for other studies in our laboratory. In two previous papers in this series (1, 2) we described a general synthetic approach to virtually any type of trialkylated pyridine of this type and indicated that these previously inaccessible substances can now be made readily available by rather simple modifications in our sequence. In related studies we had occasion to consider the preparation of 3,5-dimethyl-4-ethylpyridine and it appeared that an extension of the method of Wibaut and Arens seemed attractive. This method has been used rather effectively for the introduction of alkyl substitutents into the γ position of the pyridine ring (3–6). However, when we reacted 3,5-lutidine with acetic anhydride and zinc under the specified reaction conditions we did not isolate the expected 3,5-dimethyl-4-ethylpyridine but a compound which exhibited a strong carbonyl absorption in its infrared spectrum (5.83 μ). The ultraviolet spectrum indicated that the normal pyridine absorption was still present and it became obvious that we had most probably obtained the intermediate ketone, 3,5-dimethyl-4-acetylpyridine (I). Our suspicions were confirmed when we obtained a nuclear magnetic resonance (n.m.r.) spectrum of this substance. The n.m.r. spectrum indicated a sharp signal at 7.62 τ which served to establish the presence of the acetyl group. In addition, a very intense signal at 7.83 τ, characteristic of methyl groups attached at the β positions of the pyridine nucleus, and a signal at 1.82 τ attributable to α protons (1, 2), served to establish the assigned structure. It was thus clear that the steric influence of the two neighboring methyl groups had been sufficient to allow us to isolate the intermediate in this reaction.

The reduction of 3,5-dimethyl-4-acetylpyridine to the known 3,5-dimethyl-4-ethylpyridine could be accomplished by the use of zinc and acetic acid but only under much more drastic conditions. This conversion served to confirm further the structure of the acetylpyridine.

It became apparent to us that the steric effect of the methyl groups at the β positions could be used to advantage in synthesizing new 3,4,5-trialkylated pyridines since the 4-acetylpyridine derivative is a versatile synthetic intermediate. Consequently we have performed numerous experiments to obtain optimum reaction conditions for the preparation of 3,5-dimethyl-4-acetylpyridine and have been able to obtain this substance in high yield (70%).

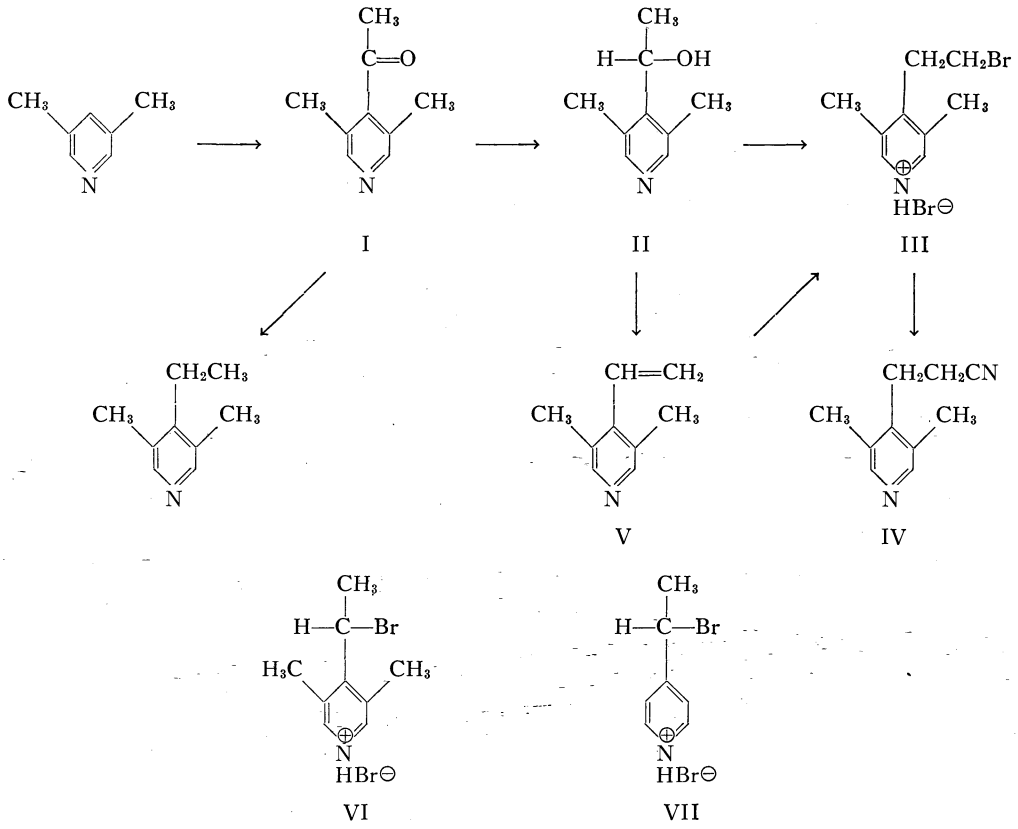
In order to provide entry into pyridine derivatives possessing branched alkyl chains at the γ position, we first considered the possibility of reacting I with organometallic

reagents although it could be anticipated that the steric factor may prevent a successful reaction. Reaction of the acetylpyridine with methylmagnesium iodide or bromide under various reaction conditions met with failure, a large proportion of the starting ketone was recovered in each case. It should be pointed out that we have used very drastic conditions in an attempt to obtain reaction and such high boiling solvents as diglyme or dibutyl carbitol were used on various occasions. In the latter instance a trace of an alcoholic component was obtained but the extremely low yield discouraged any further characterization. Similar unsuccessful attempts were made with methyllithium. It thus became apparent that the steric hindrance of the carbonyl group was so effective as to make this function completely unreactive to the action of organometallic reagents.

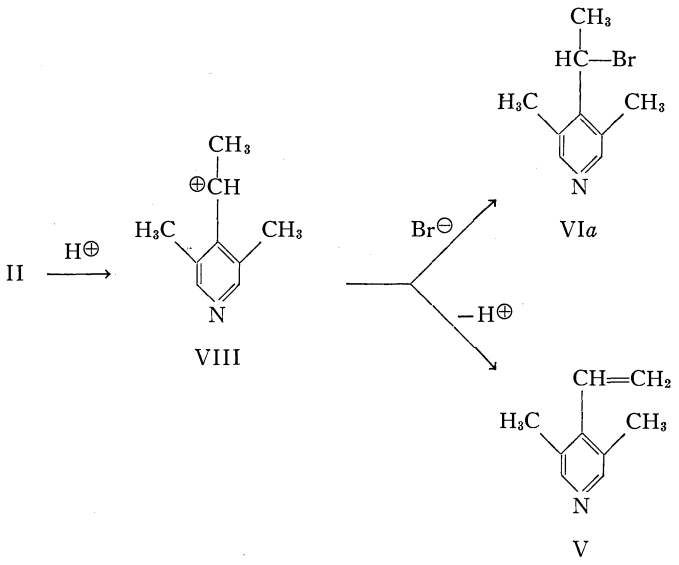
Our next consideration was to attempt reduction of the carbonyl function to an alcohol group since this substance could lend itself to a variety of interesting reactions. When 3,5-dimethyl-4-acetylpyridine was treated with lithium aluminum hydride the expected alcohol (II) was obtained as a crystalline material. The spectral properties of this product were in complete accord with the assigned structure. The presence of the hydroxyethyl group was clearly shown by the n.m.r. spectrum—a doublet centered at 8.62 τ as would be expected for the methyl group and a quartet centered at 4.88 τ for the tertiary proton on the oxygen-bearing carbon. Having obtained the desired alcohol, we considered its conversion to other analogues in this series. In our previous work in this series (1, 2) we had studied in some detail the reductive removal of a hydroxyl function by the use of hydriodic acid in the presence of red phosphorus. In these studies we obtained the intermediate olefinic substances which undoubtedly arise from an acid-catalyzed elimination reaction. It therefore appeared of some interest to see whether the steric environment of our alcohol, II, would lend itself to a reaction of this type. We chose to utilize hydrobromic acid for this purpose since under these conditions, the olefinic intermediate would readily enter into an addition reaction and thus it may be possible to obtain some relevant information about elimination and (or) substitution and addition in this series. When the alcohol, II, was treated with concentrated hydrobromic acid, under drastic conditions, we obtained a crystalline hydrobromide. The analytical data indicated that the hydroxyl function had been lost and that a bromine atom had entered into the molecule. At the outset, it could be argued that a simple displacement of the hydroxyl function had occurred and that the structure of the reaction product was VI. This argument was quickly dismissed when we considered the n.m.r. spectrum of this material. An obvious feature which was absent in the spectrum was a signal for the methyl group attached to the carbon atom bearing the bromine as would be expected if the structure VI was the correct one. Furthermore this signal would be expected to be split into a doublet by the tertiary hydrogen on the adjacent carbon atom. The highest signal which was observed in the spectrum was at 7.32 τ and its position as well as the high intensity indicated beyond any doubt that it was due to the two methyl groups at the β positions of the ring. The remaining signals were at lower fields and it was therefore clear that the structure of the hydrobromide was not VI. On the other hand, consideration of the nature of the entire spectrum and the integrated areas revealed that the alternative structure, III, was the correct one. A more detailed description of the n.m.r. results is given in the experimental portion.

In order to eliminate any doubt about the actual chemical shift that a methyl group of the type depicted in VI should exhibit, we decided to synthesize, unambiguously, an analogous structure and then consider its n.m.r. spectrum. The most direct approach to this problem involved the reaction of 4-ethylpyridine with N-bromosuccinimide, a

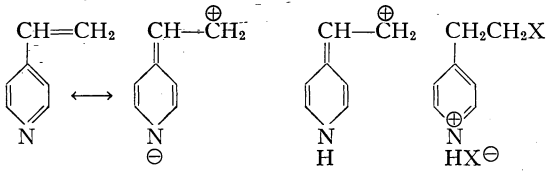
reagent which might be expected to introduce a bromine atom at the methylenic carbon (7). Indeed when this reaction was carried out and the reaction product treated with hydrogen bromide, a crystalline hydrobromide was obtained. The analytical data and the spectral properties were in complete accord with the expected structure VII. The n.m.r. spectrum was of particular significance and served to confirm our assignments in the n.m.r. spectrum of III. The presence of the 1-bromoethyl group in VII was established by a doublet at 7.89 τ, as would be expected for the methyl group attached to the halogen bearing carbon, and a quartet at 4.66 τ for the tertiary hydrogen atom.



The isolation of III is of some theoretical interest since it is apparent that a simple substitution of the hydroxyl group by the halogen atom has not taken place. Since the reaction conditions utilized in the preparation of III are similar to the conditions normally employed in the synthesis of the side chain halopyridines from hydroxyalkylpyridines (8, p. 360), and since this type of reaction normally proceeds through a S_N1 mechanistic pathway, it is necessary to comment on our present results. It is reasonable to postulate that the initial step leads to the carbonium ion, VIII, which can either react with bromide ion to provide VI*a* or eliminate a proton to yield V. In the instances where the carbonium ion is sterically unhindered, it reacts according to the S_N1 pathway to provide halopyridines. However, it is clear that in VIII, the steric shielding by the neighboring methyl groups will tend to make the S_N1 reaction less favorable and therefore proton elimination occurs to yield 3,5-dimethyl-4-vinylpyridine (V). The subsequent addition of hydrobromic acid to the olefinic bond provides the actual isolated product.



The mode of electrophilic addition to the double bond of alkenylpyridines has not been studied in great detail and, in particular, little is known about the addition of hydrogen halide to these types of compounds (8, p. 364). Although products resulting from the addition of hydrogen halide to vinylpyridines have been reported (9, 10), there is no conclusive evidence regarding the correct structures of these substances. It has been suggested (8, p. 364) that the halogen would enter at the carbon atom adjacent to the pyridine nucleus. Our present studies do not bear out this statement and, indeed, this statement does not agree with the expected addition based on theoretical arguments. Theoretical consideration of the electronic interaction of the pyridine nucleus with a conjugated double bond leads to the conclusion that 4-vinylpyridine should react according to the resonance structure IX. It would, therefore, be expected that, under acidic



conditions, the important species in the reaction would be IX*a* and that, in fact, the product resulting from the addition of such reagents as hydrogen halide would be X. An extension of this argument to 3,5-dimethyl-4-vinylpyridine (V) leads to the prediction that III would be the actual product formed in the reaction with hydrobromic acid. It is also pertinent to note that the addition of hydrazoic acid to 2-vinylpyridine has been shown to provide 2-(β-azideoethyl)-pyridine (11, 12). This work provides considerable strength to our argument.

Our rationalization for the formation of the bromide, III, from the alcohol, II, involves the possible formation of the intermediate olefinic substance, 3,5-dimethyl-4-vinylpyridine. In order to provide some support for this proposal we felt that we should investigate the reaction of the vinylpyridine with hydrobromic acid. For this reason, we reacted

the alcohol, II, with phosphorus pentoxide and obtained the expected 3,5-dimethyl-4-vinylpyridine (V). The spectral data was in complete agreement with this assignment. In particular, the n.m.r. spectrum exhibited multiplets at 4.27 τ and 3.62 τ to provide strong evidence for the presence of a vinyl group. When the vinylpyridine was subjected to the action of concentrated hydrobromic acid under conditions identical with those used for the alcohol, we obtained an excellent yield of a crystalline hydrobromide. This salt proved to be identical in every respect with the hydrobromide, III. This sequence of reactions therefore showed that the vinylpyridine could be an intermediate in the conversion II $\rightarrow$ III.

Finally we considered the possibility of converting the bromide, III, into a pyridine derivative which was somewhat more stable and where one could actually consider the n.m.r. spectrum of the parent base. It should be noted that the halopyridines of the type described above can only be isolated as salt derivatives since the parent bases decompose rapidly.

An attractive analogue appeared to be the corresponding nitrile since in addition to being somewhat more stable, it would provide a versatile synthetic intermediate for a variety of 4-substituted pyridines. Upon reaction of the bromide, III, with an aqueous alcoholic solution of potassium cyanide, an excellent yield of 3,5-dimethyl-4-(2-cyanoethyl)-pyridine (IV) was obtained. The substance which could be conveniently isolated as the parent base had an n.m.r. spectrum which was quite instructive and in accord with the structural assignment. The spectrum indicated an intense signal at 7.61 τ due to the methyl groups attached to the pyridine nucleus. The four protons of the cyanoethyl group were evident from two sets of multiplets centered at 6.94 τ and 7.34 τ and finally a signal at low field (1.67 τ) accounted for the α protons on the pyridine ring. The relative areas under the signals served to finally establish the structure, IV, for the nitrile. Since numerous modifications of the cyano group are possible, this material may be utilized to prepare new types of 4-substituted pyridine analogues.

It is therefore apparent that the steric hindrance created by substituents attached to the β positions of the pyridine nucleus can be used to considerable advantage in the synthesis of new and otherwise inaccessible 3,4,5-trisubstituted pyridines.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethyl alcohol on a Cary 14 recording spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer model 21 spectrophotometer. The n.m.r. spectra were done at 60 Mc on a Varian A60 instrument. The values are given in the Tiers τ scale, with the signal of tetramethylsilane, which was used as the internal standard, set at 10.0 τ units. Integration of areas under the signals was carried out in all cases and the number of protons is indicated in parentheses. The solvents used were carbon tetrachloride or deuteriochloroform. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr), Germany, and by Mrs. A. Aldridge, University of British Columbia.

3,5-Dimethyl-4-acetylpyridine (I)

The zinc which was used in this experiment was activated as follows. Zinc dust (208 g) was stirred in 10% aqueous hydrochloric acid (75 ml) for 2–3 minutes. It was then filtered, washed with distilled water (150 ml), acetone (100 ml), anhydrous ether (50 ml), and dried *in vacuo*. It was then ready for use.

A 1-liter three-necked flask was fitted with a mechanical stirrer and acetic anhydride (250 ml) and 3,5-lutidine (136 g, dried over calcium oxide and freshly distilled *in vacuo*) were then added to the flask. This stirred mixture was then treated with small portions of zinc until a total of 100 g had been added. The addition required about $\frac{1}{2}$ hour during which time the temperature of the reaction rose to 70° and the mixture developed a light green color. Glacial acetic acid (100 ml) and activated zinc (40 g) were added and the reaction mixture was refluxed for 15 minutes. After allowing to stand overnight at room temperature the mixture was cooled in ice and treated cautiously with 40% aqueous sodium hydroxide (700 ml). The resulting brown oil which formed as a layer at the top was extracted with ether. The ethereal extract was

dried over anhydrous magnesium sulphate, and the solvent evaporated to leave a brown viscous liquid (172 g). This liquid was fractionally distilled to yield an initial fraction (57.2 g, distilling up to 189°) of unreacted 3,5-lutidine. The second fraction (24.9 g) distilling in the range of 190–220° contained some 3,5-lutidine and some of the desired acetylpyridine whereas the last fraction (61.6 g), collected at 220–295°, was the desired 3,5-dimethyl-4-acetylpyridine. A second distillation of the last fraction at 167–169° at 100 mm provided the pure product (55.8 g). An analytical sample could also be conveniently obtained on purification by vapor phase chromatography on the Megachrome, operating at 240° with a column of Apiezon J and using helium as the carrier gas. The retention time was 10.2 minutes.

The product after this purification still distilled at 167–169° at 100 mm or 252–254°; n_D^{25} 1.5152; infrared: 5.90 μ; ultraviolet: λ_{max} 270 mμ (log ϵ 3.42), λ_{min} 234 mμ (log ϵ 2.54); n.m.r. signals (CCl_4): intense signal at 7.83 τ (methyls attached to ring, area = 6 H), signal at 7.62 τ (CH_3—$\overset{O}{\overset{\|}{C}}$—, area = 3 H), 1.82 τ (α H, area = 2 H). Found: C, 72.10; H, 7.48; O, 10.71; N, 9.32. Calc. for $C_9H_{11}NO$: C, 72.45; H, 7.43; O, 10.72; N, 9.37.

A picrate was prepared and after several recrystallizations from alcohol melted at 181–183°. Found: C, 47.81; H, 3.76; O, 33.37; N, 14.71. Calc. for $C_{15}H_{14}O_8N_4$: C, 47.62; H, 3.73; O, 33.84; N, 14.81.

It is pertinent to note that it was found imperative to carry out the initial fractional distillation of the crude reaction product at atmospheric pressure. In this way, the high temperature ensures that the intermediates are decomposed to the desired product. If the distillation is carried out at lower temperatures under reduced pressure, the intermediates are actually distilled over and it becomes necessary to heat these to a higher temperature to convert them to I.

3,5-Dimethyl-4-(1-hydroxyethyl)-pyridine (II)

A 50-ml three-necked flask was fitted with a dropping funnel, a reflux condenser, and a magnetic stirrer, and charged with a solution of lithium aluminum hydride (0.819 g) in anhydrous ethyl ether (12 ml). To this was added cautiously, from the dropping funnel, a solution of 3,5-dimethyl-4-acetylpyridine (3.22 g) in anhydrous ether (11 ml), over a period of 20 minutes. After the addition was complete, the reaction mixture was stirred at room temperature for ½ hour and then water (20 ml) was added slowly to destroy the excess hydride. The reaction mixture was filtered, the solid which remained on the filter paper was washed thoroughly with methanol, and the methanol washings were combined with the ethereal filtrate. The filtrate was then concentrated and the soluble organic materials were extracted with chloroform. After drying the chloroform extract over anhydrous magnesium sulphate and removing the solvent, the residual product was distilled. The initial fraction (220 mg) distilling up to a temperature of 130° (bath temperature) at 0.5 mm proved to be unreacted acetylpyridine. The second fraction (2.3 g) which came over at 145–210° (bath temp.) at 0.1 mm was the desired alcohol, II. An analytical sample was prepared by several recrystallizations from a chloroform – petroleum ether mixture, and melted at 85–86°; infrared: 3.09 μ; ultraviolet: λ_{max} 2.67 mμ (log ϵ 3.40), shoulder at 274 mμ (log ϵ 3.35), λ_{min} 231 mμ (log ϵ 2.69); n.m.r. signals (CCl_4): doublet centered at 8.62 τ (CH_3—$\overset{H}{\overset{|}{C}}$—OH, area = 3 H), intense signal at 7.75 τ (methyls attached to ring, area = 6 H), quartet centered at 4.88 τ (tertiary proton of CH_3—$\overset{H}{\overset{|}{C}}$—OH, area = 1 H), signal at 2.28 τ (α H, area = 2 H). Found: C, 71.57; H, 8.70; O, 10.76; N, 9.07. Calc. for $C_9H_{13}ON$: C, 71.49; H, 8.67; O, 10.58; N, 9.26.

A picrate, m.p. 148–148.5°, was prepared in ethanol and recrystallized from the same solvent. Found: C, 47.88; H, 4.29; N, 14.48. Calc. for $C_{15}H_{16}O_8N_4$: C, 47.37; H, 4.24; N, 14.73.

3,5-Dimethyl-4-(2-bromoethyl)-pyridine Hydrobromide (III)

A mixture of 3,5-dimethyl-4-(1-hydroxyethyl)-pyridine (196 mg) and concentrated hydrobromic acid (171 ml, 48%) was heated at 160° in a sealed tube for 24 hours. After cooling, the contents of the tube were evaporated to dryness *in vacuo*. The residual material was taken up in ethyl alcohol and recrystallized from a mixture of alcohol–chloroform to yield a first crop of crystals (235 mg). An additional 66 mg (total 301 mg) was obtained when the mother liquor was diluted with petroleum. Several recrystallizations of this product from ethanol – petroleum ether provided an analytical sample, m.p. 208–209°; infrared: absence of hydroxyl absorption; ultraviolet: λ_{max} 266 mμ (log ϵ 3.76), λ_{min} 245 mμ (log ϵ 3.62); n.m.r. signals ($CDCl_3$): intense signal at 7.32 τ (methyls attached to ring, area = 6 H), multiplet centered at 6.40 τ (CH_2CH_2Br, area = 4 H), 1.32 τ (α H, area = 2 H). Found: C, 36.43; H, 4.31; N, 4.62; Br, 54.22. Calc. for $C_9H_{13}NBr_2$: C, 36.64; H, 4.41; N, 4.74; Br, 54.44.

3,5-Dimethyl-4-(2-cyanoethyl)-pyridine (IV)

The pyridine hydrobromide, III (206 mg), was added to a solution of potassium cyanide (610 mg) in water (4.6 ml) and methanol (11 ml) and the mixture was refluxed for 2 hours. After the mixture had cooled, water (10 ml) was added and the reaction mixture was then made alkaline by the addition of sodium bicar-

bonate. This reaction mixture was extracted exhaustively with ethyl acetate. The ethyl acetate extract was dried over anhydrous magnesium sulphate and the solvent was removed to yield a viscous liquid. This liquid was distilled at 100–150° (bath temperature) at 0.1 mm to yield 106 mg of a viscous liquid which solidified partially on short standing. Crystallization from a mixture of benzene – petroleum ether – acetone provided a crystalline material, m.p. 74–75°. Infrared: 4.46 μ; ultraviolet: λ_{max} 266 mμ (log ϵ 3.31), λ_{min} 230 mμ (log ϵ 2.78); n.m.r. signals ($CDCl_3$): intense signal at 7.61 τ (methyls attached to ring, area = 6 H) two sets of multiplets centered at 7.34 τ and 6.94 τ (—CH_2CH_2—CN, area = 4 H), 1.67 τ (α H, area = 2 H).

A picrate of this material was readily prepared and upon several recrystallizations from alcohol an analytical sample was obtained, m.p. 177–178.5°. Found: C, 49.01; H, 4.08; N, 17.78. Calc. for $C_{16}H_{15}N_5O_7$: C, 49.36; H, 3.88; N, 17.99.

3,5-Dimethyl-4-vinylpyridine (V)

A solution of 3,5-dimethyl-4-(1-hydroxyethyl)-pyridine (991 mg) in anhydrous xylene (30 ml) was treated with phosphorus pentoxide (7.73 g) and the mixture was refluxed for 3 hours. After it had been cooled, the reaction mixture was treated cautiously with water (20 ml) to destroy the excess phosphorus pentoxide and the resulting solution was separated into the respective organic and aqueous portions. The acidic aqueous layer was neutralized, then made alkaline by the addition of potassium hydroxide pellets, and this mixture was extracted with ether. The ethereal extract was dried over anhydrous magnesium sulphate and the solvent evaporated to yield a mobile liquid. Distillation of this liquid provided the desired vinylpyridine (475 mg, b.p. 146–147° at 90 mm); n_D^{27} 1.5333; infrared: 6.11 μ; ultraviolet: λ_{max} 273 mμ (log ϵ 3.39), λ_{min} 261 mμ (log ϵ 3.32), λ_{max} 234 mμ (log ϵ 3.77), λ_{min} 223 mμ (log ϵ 3.71); n.m.r. signals (CCl_4): intense signal at 8.02 τ (methyls attached to ring, area = 6 H), multiplet centered at 4.72 τ (—C=CH_2, area = 2 H), quartet

centered at 3.62 τ (—C=C, area = 1 H), 2.10 τ (α H, area = 2 H). Found: C, 80.86; H, 8.34; N, 10.31. Calc. for $C_9H_{11}N$: C, 81.16; H, 8.33; N, 10.52.

A picrate, m.p. 155–156°, was prepared in ethanol and recrystallized from the same solvent. Found: C, 49.75; H, 3.90; O, 30.45; N, 15.41. Calc. for $C_{15}H_{14}N_4O_7$: C, 49.73; H, 3.84; O, 30.52; N, 15.20.

3,5-Dimethyl-4-(2-bromoethyl)-pyridine Hydrobromide (III) from 3,4-Dimethyl-4-vinylpyridine

A mixture of 3,5-dimethyl-4-vinylpyridine (188 mg) and concentrated hydrobromic acid (16 ml, 48%) was heated for 24 hours in a sealed tube at 160°. When the reaction mixture was worked up in exactly the same manner as given above for the alcohol, a crystalline hydrobromide (348 mg) was obtained. This was shown to be III by mixed melting point, infrared, ultraviolet, and n.m.r. comparison.

3,5-Dimethyl-4-ethylpyridine

A stirred solution of 3,5-dimethyl-4-acetylpyridine (19 g) in glacial acid (200 ml) was cautiously treated with activated zinc (10 g) and the whole mixture was then refluxed for 1 hour. An additional 18 g of activated zinc was added and refluxing was continued for a further 15 hours, by which time the reaction mixture had become intensely yellow in color. After it had been cooled, the mixture was made alkaline by the addition of 40% aqueous sodium hydroxide (400 ml) and the resulting mixture was steam-distilled until the distillate was clear. The distillate was then extracted exhaustively with ether and the ethereal extract dried over anhydrous magnesium sulphate. Evaporation of the solvent left a brown residual liquid (17.7 g) which, upon distillation (b.p. 218–219°), yielded 12.7 g of 3,5-dimethyl-4-ethylpyridine. Infrared: complete disappearance of carbonyl band; ultraviolet: λ_{max} 263 mμ (log ϵ 3.45), λ_{min} 231 mμ (log ϵ 2.87); n.m.r. signals (CCl_4): triplet centered at 8.94 τ (methyl of ethyl group, area = 3 H), intense signal 7.80 τ (methyls attached to ring, area = 6 H), quartet centered at 7.42 τ (methylene of ethyl group, area = 2 H), 1.96 τ (α H, area = 2 H). A picrate of this compound was readily prepared and the analytical sample melted at 156.5–157°. Found: C, 49.49; H, 4.17; N, 15.36. Calc. for $C_{15}H_{16}N_{14}O_7$: C, 49.45; H, 4.43; N, 15.38.

The literature values (13, 14) are b.p. 216–217°, 219–220° for the base, and m.p. 155–156° for the picrate.

4-(1-Bromoethyl)-pyridine Hydrobromide (VII)

A solution of 4-ethylpyridine (6.41 g) in anhydrous carbon tetrachloride (200 ml) was treated with N-bromosuccinimide (10.7 g) and benzoyl peroxide (0.91 g) and the whole mixture was refluxed for 3 hours. The slightly brown reaction mixture was filtered to remove the solid suspension and the filtrate was washed successively with 4% aqueous sodium hydroxide (100 ml), water (100 ml), 2% aqueous hydrobromic acid (100 ml), and finally dried over anhydrous magnesium sulphate. This dried carbon tetrachloride extract was then saturated with hydrogen bromide and finally the solvent was removed to furnish a residual gum (7.4 g). The latter was taken up in ethanol and then crystallized from a solvent mixture of ethanol – ethyl ether to afford 3.25 g of a crystalline hydrobromide, m.p. 151–151.5°; ultraviolet: λ_{max} 260 mμ (log ϵ 3.50),

λ_{min} 325 mμ (log ϵ 3.30); n.m.r. signals ($CDCl_3$): doublet centered at 7.89 τ (CH_3—C—Br, area = 3 H),

quartet centered at 4.66 τ (tertiary hydrogen of $CH_3—\underset{\displaystyle Br}{\overset{\displaystyle |}{\underset{|}{C}}}—H$, area = 1 H), doublet centered at 1.85 τ (β H, area = 2 H), doublet centered at 0.83 τ (α H, area = 2 H). Found: C, 31.56; H, 3.39; N, 5.40; Br, 59.87. Calc. for $C_7H_9NBr_2$: C, 31.47; H, 3.40; N, 5.25; Br, 59.88.

STEROIDS AND RELATED PRODUCTS

XXI. THE SYNTHESIS OF 17α-BROMO-6α-METHYLPROGESTERONE[1, 2]

S. RAKHIT, R. DEGHENGHI, AND CH. R. ENGEL[3]
Department of Chemistry, Laval University, Quebec, Que.
Received October 17, 1962

ABSTRACT

The synthesis fo 17α-bromo-6α-methylprogesterone, from pregnenolone acetate, is reported. The product is a potent luteoid with marked oral activity. In the course of this investigation, a useful variation of the synthesis of 6α-methylprogesterone, from pregnenolone, was devised. The rearrangement of a 5β,6β-epoxide to a 6-ketone, upon chromatography on aluminum oxide "Woelm", was observed.

A few years ago, this group reported the synthesis and marked progestational activity of 17α-bromoprogesterone (2). As we exposed recently (3), we considered that it would be useful to establish whether or not the enhancing effect on progestational activity of the 17α-bromine substituent is an isolated phenomenon in the case of 17α-bromoprogesterone, particularly in view of our thesis that bulky 17α-substituents increase, in general, the luteoid activity of 20-keto steroids of the progesterone type (cf. ref. 4). The investigation of 6α-substituted 17α-bromoprogesterones seemed attractive since it was known that the introduction of various 6α-substituents might lead to potentiation of the progestational activity, in particular of the oral progestational activity (cf. refs. 4–10 and 13, 14 of the article quoted as ref. 3). In a first paper (3), we reported the synthesis and considerable luteoid activity of 6α-fluoro-17α-bromoprogesterone (cf. also refs. 4 and 5[4]); in the present paper, we record the synthesis and high progestational activity of 17α-bromo-6α-methylprogesterone (XII). The introduction of a methyl substituent in position 6α appeared of particular interest in view of the observation that this group exerted, in a number of instances, a drastic potentiating effect on the *oral* progestational activity (cf. refs. 7–11).[5]

Pregnenolone acetate (I) served as starting material. It was transformed, in high yield, to the 20-ethylene ketal (II) (14) by slow evaporation of its solution in ethylene glycol in the presence of *p*-toluenesulphonic acid, according to the procedure of Allen *et al.* (15). The use of the classical method which was employed by Gut (14) and which consists in refluxing the benzene solution of the ketone with ethylene glycol in the presence of *p*-toluenesulphonic acid, with periodic removal of water, gives less satisfactory yields of the desired ketal.[6] Epoxidation of the unsaturated acetoxy ketal II*a* with monoperphtalic acid in chloroform afforded predominantly the α-epoxide III, as expected. The product gave no tetranitromethane reaction and the analytical data and spectral characteristics were in accord with structure III. The α-configuration was not only assigned in analogy with data from the literature (cf., e.g., refs. 16–19; also refs. 20 and 21) but was also

[1]*The main results of this paper were the subject of a communication presented before the 43rd Annual Conference of the Chemical Institute of Canada, June 1960.*
[2]*For the previous paper in this series, see ref. 1.*
[3]*Correspondence should be addressed to this author.*
[4]*Subsequent to our publication, Mills, Candiani, and Djerassi (6) also published a synthesis of 6α-fluoro-17α-bromoprogesterone, without indicating the progestational activity of the product.*
[5]*In this respect it may be mentioned that after completion of this work one of us (R. D.) established, in collaboration with R. Gaudry, that the addition of a 6α-methyl substituent transformed the parenterally potent but orally almost inactive 17α-methylprogesterone (12) to an orally active progestin (13).*

proved by the conversion of the epoxide III, with lithium aluminum hydride, to the 3β,5α-dihydroxy ketal VII, and hence, by an exchange reaction with acetone in the presence of *p*-toluenesulphonic acid (22), to the known (23) 3β,5α-dihydroxypregnan-20-one (VI).

In an attempt to isolate, out of the crude epoxidation product, the isomeric 5β,6β-epoxide IV—the formation of which was to be expected (cf. refs. 17, 18, and 20)—we subjected the mother liquors which remained after the separation of the α-epoxide III and of intermediate fractions to chromatography on non-alkaline aluminum oxide "Woelm". Apart from small quantities of the α-epoxide III, the only product which could be isolated in the pure state (by recrystallization of the less-polar chromatogram fractions) was an isomer of the oxide III, to which we assign the structure of 3β-acetoxy-20-ethylenedioxy-5α-pregnan-6-one (VIII*a*) since its infrared spectrum shows the band of a 6-membered-ring ketone. (The retention of the ketal function in position 20 was evident from the infrared spectrum and the analytical data.) Also, upon saponification with methanolic sodium hydroxide, there remains only a single ketonic carbonyl band, attributable to the 6-keto function (ν_{max}^{KBr} 1715 cm^{-1}) (cf. VIII), and reacetylation of the saponified product leads back to the acetoxy ketone VIII*a*, which has two distinct carbonyl-absorption bands (ν_{max}^{KBr} 1741 and 1713 cm^{-1}). Since the crude epoxidation product shows practically no carbonyl absorption in the infrared, we assume that the 5β,6β-epoxide, originally formed as the minor epoxidation product, was isomerized in the course of chromatography on the particular brand of aluminum oxide used (Woelm) to the 6-ketone. Such rearrangements are known to occur under the influence of Lewis acids (24, 25) and can be rationalized readily by assuming that, initially, the C—O bond is ionized at the most substituted carbon atom and that, subsequently, a cis hydrogen shift occurs. We thus suggest the 5α-configuration for the ketones VIII and VIII*a*. The assumption that the ketone arises from the 5β,6β-epoxide and not from the α-epoxide was substantiated by the fact that chromatography (on the same brand of aluminum oxide) of the α-epoxide III resulted in the quantitative recovery of unchanged α-epoxide. Henbest and Wrigley have already shown (24) that 5β,6β-epoxides are more prone to rearrangement to 6-ketones than the corresponding 5α,6α-epoxides.

Treatment of the acetoxy ethylenedioxy α-epoxide III with an excess of methyl magnesium bromide gave the 3β,5α-dihydroxy 6β-methyl ketal V in 50% yield. Deketalization with acetone and *p*-toluenesulphonic acid (22) afforded 3β,5α-dihydroxy-6β-methylpregnan-20-one (IX), which was converted directly to the acetate IX*a*. The structure of the intermediates V, IX, and IX*a* was confirmed by oxidation, with chromic acid and sulphuric acid in acetone (26, 27), of the dihydroxy ketone IX to the known (28, 29) 5α-hydroxy-6β-methylpregnane-3,20-dione (XIII). Since this diketone XIII is readily converted to 6α-methylprogesterone (XIV) (and also to its 6β-epimer) (28, 29, cf. also Experimental), the sequence of reactions described above represents a new and useful variation of the synthesis of 6-methylated progesterones from pregnenolone or pregnenolone acetate. In our syntheis, we protect the 20-keto function against the action of the Grignard reagent by the formation of a 20-ketal, while the British authors (29) reduce the 20-ketone to a mixture of epimeric 20-alcohols, which they acetylate prior to the Grignard reaction; the authors from Mexico (28) use a homogeneous, but less readily available, 3β,20β-diacetoxy derivative as starting material.

In pursuance of our main objective, we brominated 3β-acetoxy-5α-hydroxy-6β-methylpregnan-20-one (IX*a*) with N-bromosuccinimide under illumination (cf. refs. 30 and 3) and thus obtained the 17α-bromo adduct X*a*. Particularly rewarding results were achieved when a small amount of a tertiary base, such as pyridine, was added to the reaction mixture (cf. ref. 5). Since the acetoxy bromide X*a* is not readily purified, it was hydrolyzed directly to 17α-bromo-3β,5α-dihydroxy-6β-methylpregnan-20-one (X) with perchloric acid in methanol (2, 31). The resulting hydroxy bromide X was purified by chromatography

and recrystallization; the yield of pure bromide X from the acetoxy hydroxy ketone IX*a* amounted to 57%. Upon bromination in position 17α, the typical levorotatory shift (2, 3, 12, 32) was observed. The location of the bromine substituent could be anticipated from analogous reactions (cf. refs. 2, 3, and 30) and was proved by the conversion of the final product, 17α-bromo-6α-methylprogesterone (XII), to 16-dehydro-6α-methylprogesterone (XV), as described below. The α-configuration of the 17-halogen substituent follows from the fact that a free-radical bromination of a 20-ketone affords the same stereoisomer as an acid-catalyzed bromination (cf., e.g., refs. 32 and 33), which leads exclusively to the 17α-bromo derivative (34).

The hydroxy keto bromide X was oxidized, in high yield, with chromic acid and sulphuric acid in acetone (26, 27) to 17α-bromo-5α-hydroxy-6β-methylpregnane-3,20-dione (XI). Dehydration with concomitant epimerization in position 6, leading to the desired 17α-bromo-6α-methylprogesterone (XII), was achieved in good yield by treatment with hydrogen chloride in acetic acid (cf. refs. 3 and 19). The structure and the stereochemistry of the skeleton were proved by reduction of the progesterone derivative XII, with zinc and acetic acid, to 6α-methylprogesterone (XIV) (28, 29)[7] and was further confirmed by dehydrobromination with dimethylformamide and lithium chloride (cf. ref. 35) to the known (29) 16-dehydro-6α-methylprogesterone (XV). This last reaction also constitutes a proof of the location of the bromine substituent.

According to preliminary biological tests—for which we are indebted to Dr. E. G. Shipley of the Endocrine Laboratories of Madison, Inc., Madison, Wisc., and to Drs. J. Tripod and P. Desaulles of Ciba Ltd., Basle, Switzerland—17α-bromo-6α-methylprogesterone is a potent progestin which considerably exceeds in activity not only the natural hormone of the *corpus luteum* but also 17α-bromoprogesterone, both upon parenteral and oral administration.[8] The enhancing effect of the bulky 17α-bromine substituent on progestational activity (cf. refs. 2–4) is thus further substantiated. The implications of the establishment of high progestational activity of 17α-brominated progestins on activity–structure relationships will be discussed elsewhere on a broader basis.

EXPERIMENTAL[9, 10, 11]

Δ^5-3β-Acetoxy-20-ethylenedioxypregnene (IIa) (14)

Following the procedure of Allen *et al.* (15), 20 g of Δ^5-3β-acetoxypregnen-20-one (I) was ketalized with ethylene glycol in the presence of *p*-toluenesulphonic acid, by slow distillation of ethylene glycol, at 72–75° and 2 mm Hg pressure. The infrared spectrum of the reaction product revealed that hydrolysis in position 3 had occurred. The usual acetylation with acetic anhydride in pyridine at room temperature afforded 20.6 g of semicrystalline acetoxy ketal II*a*, which gave, upon crystallization from ether–methanol, 18.01 g of pure ketal II*a*, m.p. 156–158°, and a second batch of 600 mg, melting between 152 and 154° (yield of pure product 83%). A sample was recrystallized once from methanol for analysis; colorless scales; m.p. 159–161°; $[\alpha]_D^{24}$ −41.5° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 1740 and 1250 cm^{-1} (acetate), 1042 cm^{-1} (20-ketal). Anal. Calc. for $C_{25}H_{38}O_4$: C, 74.59; H, 9.52. Found: C, 74.30; H, 9.35.

5α,6α-Epoxy-3β-acetoxy-20-ethylenedioxypregnane (III) and 3β-Acetoxy-20-ethylenedioxy-5α-pregnan-6-one (VIIIa)

To a solution of 38.5 g of Δ^5-3β-acetoxy-20-ethylenedioxypregnene (II*a*), m.p. 156–158°, in 1.9 liters of chloroform, there was added, at −80°, over a period of 20 minutes, 520 cc of a 0.4 *N* ethereal monoperphtalic

[7]*We sincerely thank Dr. V. Petrow for an authentic sample of 6α-methylprogesterone.*
[8]*A detailed report on the biological effects of 17α-bromo-6α-methylprogesterone will appear elsewhere.*
[9]*The melting points were taken in evacuated capillaries and the temperatures were corrected.*
[10]*If not otherwise stated, Woelm's non-alkaline aluminum oxide and Davison's silica gel No. 923 were used for chromatography.*
[11]*The microanalyses were performed by Dr. O. Schwarzkopf, New York, N.Y.; Dr. C. Daesslé, Montreal, Quebec; Mr. J. F. Alicino, Metuchen, N.J.; and Mr. A. Bernhardt, Mülheim (Ruhr), Germany, and their associates, to whom we express our sincere appreciation.*

For personal use only.

acid solution. The mixture was kept at −80° for 2 hours, and between 0 and 5° for another 16 hours. Subsequently, the solution was washed with a cold 5% sodium carbonate solution and with water and was dried over sodium sulphate. Removal of the solvent gave 41.2 g of crude crystalline material which yielded, upon recrystallization from ether–methanol containing a few drops of pyridine, 27.06 g (67.6%) of pure *5α,6α-epoxy-3β-acetoxy-20-ethylenedioxypregnane (III)*, m.p. 183–185°. The infrared spectrum revealed no significant carbonyl absorption. A portion of this product was recrystallized once from ether–methanol for analysis; colorless needles; m.p. 184–186°; $[\alpha]_D^{25}$ −50° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 1740 and 1250 cm^{-1} (acetate), 1042 cm^{-1} (ketal). Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 71.54; H, 9.02.

From the mother liquors of the first crystallization two further batches of crystals were isolated: a first crop of 1.457 g, m.p. 154–161°, $[\alpha]_D^{24}$ −33.3° (*c*, 1.000 in $CHCl_3$), and a second crop of 1.04 g, m.p. 104–108°, $[\alpha]_D^{24}$ −5.9° (*c*, 1.000 in $CHCl_3$). The remaining mother liquors (10.1 g) were absorbed on 300 g of aluminum oxide Woelm, activity III, pH 7.5–8. Elutions with petroleum ether – benzene (4:1) afforded 5.199 g of crystals, m.p. 109–112°, $[\alpha]_D^{23}$ −5°; petroleum ether – benzene (1:1) eluted at first 2.316 g of crystals melting between 104 and 115°, $[\alpha]_D^{23}$ −6°, and subsequently 2.285 g of a crystalline product, representing a crude mixture and melting between 130 and 173°, with specific rotations ranging from −20.5 to −35°. The last petroleum ether – benzene (1:1) eluates represented 265 mg (0.66%) of pure α-epoxide III, m.p. 181–184°, $[\alpha]_D^{24}$ −46°, identified by mixed melting point and infrared analysis. The fractions with a specific rotation of −5 to −6° (7.5 g) showed in the infrared a ketonic carbonyl absorption and represented crude *3β-acetoxy-20-ethylenedioxy-5α-pregnan-6-one (VIIIa)*. They were recrystallized four times from ether for analysis; colorless plates; m.p. 141–143°; $[\alpha]_D^{24}$ −12.5° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 1741 cm^{-1} (acetate), 1713 cm^{-1} (6-ketone), 1250 cm^{-1} (acetate), 1040 cm^{-1} (ketal). Anal. Calc. for $C_{25}H_{38}O_5$: C, 71.74; H, 9.15. Found: C, 72.00; H, 9.07.

Saponification and Reacetylation

To a solution of 110 mg of the above-described 6-ketone VIII*a*, m.p. 140–142°, in 50 cc of methanol was added 2 cc of a 2 *N* sodium hydroxide solution. The mixture was refluxed for 7.5 hours and subsequently the volume of the solution was reduced, *in vacuo*, to 10 cc. The product was poured into cold water and the precipitate was extracted with ether. The ethereal solution was washed with water and was dried over sodium sulphate. Removal of the solvent afforded 100 mg of an amorphous product representing crude *hydroxy keto ketal VIII*, ν_{max}^{KBr} 1715 cm^{-1} (6-ketone), 1050 cm^{-1} (ketal). Upon reacetylation with 0.5 cc of acetic anhydride in 1 cc of pyridine, at room temperature, over a period of 16 hours, there was obtained 108 mg of crystalline ketone VIII*a*, which melted after one recrystallization from ether at 140–142°. The identity with the product isolated from the epoxidation mixture was established by a mixed melting point determination and infrared analysis.

Chromatography of Epoxide III

A quantity of 1 g of 5α,6α-epoxide III, m.p. 181–183°, was chromatographed on 40 g of non-alkaline aluminum oxide Woelm, activity III. Petroleum ether – benzene mixtures (4:1, 1:1, and 1:4) eluted 1 g of the 5α,6α-epoxide III; the melting points of the various fractions ranged from 180 to 184°. The product was in every respect identical with the starting material.

In other runs, there were obtained 10 g of α-epoxide III, m.p. 183–184°, from 14.05 g of ketal II*a* (68.4% yield) and 7.945 g of epoxide III, m.p. 178–184°, from 10 g of ketal II*a* (76.4% yield).

3β,5α-Dihydroxypregnan-20-one (VI)

A solution of 200 mg of 5α,6α-epoxy-3β-acetoxy-20-ethylenedioxypregnane (III), m.p. 181–183°, in 20 cc of absolute tetrahydrofuran was added, with stirring, to a slurry of 200 mg of lithium aluminum hydride in 100 cc of tetrahydrofuran. The mixture was refluxed for 1 hour with exclusion of moisture and was left for another 16 hours at room remperature. The excess reagent was decomposed by careful addition of moist ethyl acetate. Ice water was added and the mixture was extracted with ether. The organic layer was washed with iced dilute sulphuric acid, cold sodium bicarbonate solution, and with water and was dried over sodium sulphate. Removal of the solvent afforded 175 mg of a product representing crude *3β,5α-dihydroxy-20-ethylenedioxypregnane (VII)*; m.p. 217–222°; ν_{max}^{KBr} 3400 cm^{-1} (3β-hydroxyl), 3280 cm^{-1} (5α-hydroxyl), 1046 cm^{-1} (ketal). The product was dissolved without further purification in 10 cc of methanol and was treated for 1 hour, at reflux temperature, with 2 cc of an 8% sulphuric acid solution. The mixture was cooled and poured into a sodium bicarbonate solution. The precipitate was extracted with ether, the ethereal solution was washed with water and was dried over sodium sulphate. Removal of the solvent afforded 130 mg of 3β,5α-dihydroxypregnan-20-one (VI), m.p. 222–226°. A sample was recrystallized once from ethyl acetate – methanol and once from methanol, and was finally sublimed at 175° for analysis; prisms; m.p. 232–234°; $[\alpha]_D^{24}$ +105° (*c*, 1.000 in $CHCl_3$); ν_{max}^{KBr} 3480 cm^{-1} (3β-hydroxyl), 3450 cm^{-1} (partly associated 5α-hydroxyl), 1690 cm^{-1} (20-ketone). Anal. Calc. for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25. Found: C, 75.14; H, 10.00.

3β,5α-Dihydroxy-20-ethylenedioxy-6β-methylpregnane (V)

To an ethereal Grignard solution prepared from 1.5 g of magnesium and a slight excess of methyl bromide there was added a solution of 3 g of 5α,6α-epoxy-3β-acetoxy-20-ethylenedioxypregnane (III), m.p. 183–185°, in 450 cc of absolute benzene. The reaction mixture was refluxed for 4 hours, and, after cooling, the excess

For personal use only.

reagent was decomposed with an aqueous solution of ammonium chloride. The organic layer was washed with an aqueous ammonium chloride solution and with water and was dried over sodium sulphate. Removal of the solvent afforded 2.9 g of a solid which was chromatographed on 80 g of aluminum oxide, activity III, pH 7.5. Elutions with benzene–ether mixtures (4:1 and 1:1) and with pure ether afforded 1.4 g (50%) of 3β,5α-dihydroxy-20-ethylenedioxy-6β-methylpregnane (V), m.p. 162–164°. A sample was recrystallized twice, from ether, for analysis; fine needles; m.p. 168.5–169.5°; $[\alpha]_D^{25}$ −32° (*c*, 0.900 in $CHCl_3$); ν_{max}^{KBr} 3450 cm^{-1} (3β-hydroxyl), 3380 cm^{-1} (5α-hydroxyl), 1045 cm^{-1} (20-ketal). Anal. Calc. for $C_{24}H_{40}O_4$: C, 73.42; H, 10.27. Found: C, 73.63; H, 9.91.

3β-Acetoxy-5α-hydroxy-6β-methylpregnan-20-one (IXa)

A solution of 1.3 g of 3β,5α-dihydroxy-20-ethylenedioxy-6β-methylpregnane (V), m.p. 162–164°, and of 175 mg of *p*-toluenesulphonic acid in 100 cc of absolute acetone was refluxed for 1 hour. The volume of the solution was reduced *in vacuo* to approximately 25 cc and the product was poured into an iced sodium bicarbonate solution. The precipitate was extracted with dichloromethane, the organic solution was washed with water and was dried over sodium sulphate. Removal of the solvent afforded 1.2 g of crude *3β,5α-dihydroxy-6β-methylpregnan-20-one (IX)*, which was acetylated in the usual fashion with 1 cc of acetic anhydride in 4 cc of pyridine at room temperature, for a period of 16 hours. The usual working up afforded 1.15 g of a solid which, upon recrystallization from acetone–ether, gave 800 mg of pure *3β-acetoxy-5α-hydroxy-6β-methylpregnan-20-one (IXa)*, m.p. 195–197°. Chromatography of the mother liquors on aluminum oxide gave another 240 mg of the same product (total yield 80%). A sample was recrystallized once from acetone–ether for analysis; prisms; m.p. 198–200°; $[\alpha]_D^{24}$ +29.6° (*c*, 0.950 in $CHCl_3$); ν_{max}^{KBr} 3500 cm^{-1} (5α-hydroxyl), 1745 cm^{-1} (acetate), 1705 cm^{-1} (20-ketone), 1250 cm^{-1} (acetate). Anal. Calc. for $C_{24}H_{38}O_4$: C, 73.81; H, 9.81. Found: C, 73.69, 73.83; H, 9.60, 9.77.

In another run, 14.91 g of ketal V was transformed in a similar manner to 12.2 g of acetoxy ketone IX*a*, m.p. 192–193° (82% yield).

3β,5α-Dihydroxy-6β-methylpregnan-20-one (IX)

A solution of 100 mg of 3β-acetoxy-5α-hydroxy-6β-methylpregnan-20-one (IX*a*) in 15 cc of methanol and 0.75 cc of 70% perchloric acid was kept at room temperature for 20 hours. The product was poured into an iced sodium bicarbonate solution and the precipitate was extracted with dichloromethane. The organic solution was washed until neutral, dried over sodium sulphate, and taken to dryness. The resulting product (90 mg), representing *3β,5α-dihydroxy-6β-methylpregnan-20-one (IX)*, crystallized from ether; m.p. 186–187°; ν_{max}^{KBr} 3450 cm^{-1} (broad 3β,5α-dihydroxy band), 1707 cm^{-1} (20-ketone).

In another run, 4 g of acetate IX*a* was hydrolyzed in a similar manner to yield 3.2 g of purified dihydroxy ketone IX, m.p. 186–187°. The material was not further purified and was used directly in the following reaction.

5α-Hydroxy-6β-methylpregnane-3,20-dione (XIII) (cf. refs. 28 and 29)

To a solution of 160 mg of the dihydroxy ketone IX in 10 cc of absolute acetone there was added, dropwise and with stirring, at 0–5°, an oxidizing solution prepared by dissolving 267 mg of chromic acid in 230 cc of concentrated sulphuric acid and 770 cc of water. The addition was continued until the solution remained light brown. The mixture was stirred for another 3 minutes and was poured subsequently into ice water. The precipitate was collected, washed, and dried. The resulting 150 mg of crude material was absorbed on 5 g of aluminum oxide, Merck, activity II–III, pH 7.0, prepared as described under footnote 31 of reference 36. Methylene chloride and methylene chloride – acetone (4:1) eluted 55 mg of crystalline hydroxy diketone XIII. The product was recrystallized once from acetone–ether for analysis; needles; m.p. 250–252°; ν_{max}^{KBr} 3400 cm^{-1} (5α-hydroxyl), 1710 cm^{-1} (broad 3,20-diketo band). Anal. Calc. for $C_{22}H_{34}O_3$: C, 76.25; H, 9.85. Found: C, 76.20; H, 9.70.

In another run, 3.2 g of the dihydroxy ketone IX was oxidized in a similar fashion and gave 2.811 g of crude crystalline hydroxy diketone XIII, m.p. 230–235°, contaminated with some dehydrated product. This material was transformed directly to 6α-methylprogesterone (XIV) (cf. below).

17α-Bromo-3β,5α-dihydroxy-6β-methylpregnan-20-one (X)

A solution of 1.0 g of 3β-acetoxy-5α-hydroxy-6β-methylpregnan-20-one (IX*a*) in 80 cc of absolute carbon tetrachloride was refluxed for 10 minutes with 456 mg of N-bromosuccinimide and 0.2 cc of pyridine, over a photoflood lamp. The mixture was cooled and filtered through sodium sulphate, the sodium sulphate was washed with carbon tetrachloride, and the original solution and the washings were combined. The resulting solution was washed with iced 10% sodium bisulphite solution, iced bicarbonate solution, and with water and was dried over sodium sulphate. Removal of the solvent *in vacuo* afforded 1.21 g of a yellow foam which did not crystallize readily and which represented crude *17α-bromo-3β-acetoxy-5α-hydroxy-6β-methylpregnan-20-one (Xa)*. The product was not further purified and was hydrolyzed as follows.

A quantity of 1.2 g of the above-described crude acetoxy bromide X*a* was subjected, for 22 hours, to the action of 7.5 cc of 70% perchloric acid in 180 cc of methanol. Subsequently, the solution was poured into an iced sodium bicarbonate solution and the precipitate was extracted with methylene chloride. The organic layer was washed with water and was dried over sodium sulphate. Removal of the solvent *in vacuo* afforded

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1.05 g of an amorphous product. The material was dissolved in a small quantity of benzene and absorbed on 100 g of silica gel. Elutions with benzene – ethyl acetate (4:1) afforded 620 mg (56.6% yield from ketone IX*a*) of crystalline *17α-bromo-3β,5α-dihydroxy-6β-methylpregnan-20-one (X)*, m.p. 151–153° decomp. A sample was recrystallized three times from ether–hexane for analysis; small needles; m.p. 155–156° decomp.; $[\alpha]_D^{26}$ −68.0° (*c*, 0.750 in $CHCl_3$); ν_{max}^{KBr} 3450 cm^{-1} (3β-hydroxyl), 3350 cm^{-1} (5α-hydroxyl), 1709 cm^{-1} (20-ketone). Anal. Calc. for $C_{22}H_{35}O_3Br$: C, 61.82; H, 8.25; Br, 18.70. Found: C, 61.70, 61.66; H, 8.00, 8.56; Br, 18.48, 18.99.

17α-Bromo-5α-hydroxy-6β-methylpregnane-3,20-dione (XI)

To a solution of 600 mg of 17α-bromo-3β,5α-dihydroxy-6β-methylpregnan-20-one (X), m.p. 151–153° decomp., in 40 cc of absolute acetone there was added, at 0–5°, 0.9 cc of the previously described chromic acid solution in dilute sulphuric acid. The mixture was stirred for 3 minutes and was poured into an iced sodium bicarbonate solution. The precipitate was extracted with dichloromethane and the organic layer was washed with water and was dried over sodium sulphate. Removal of the solvent *in vacuo* afforded 580 mg of a semicrystalline solid which, upon crystallization from acetone–ether, gave 400 mg of 17α-bromo-5α-hydroxy-6β-methylpregnane-3,20-dione (XI), m.p. 168–170° decomp. The mother liquors were chromatographed on 18 g of silica gel. Elutions with benzene – ethyl acetate (96:4) gave another 150 mg of the bromo diketone XI, m.p. 168–170° decomp. (total yield 92%). A sample was recrystallized once from ether–acetone for analysis; fine needles; m.p. 170–171° decomp.; $[\alpha]_D^{26}$ −49.9° (*c*, 0.850 in $CHCl_3$); ν_{max}^{KBr} 3450 cm^{-1} (5α-hydroxyl), 1707 cm^{-1} (broad 3,20-diketo band). Anal. Calc. for $C_{22}H_{33}O_3Br$: C, 62.11; H, 7.82; Br, 18.78. Found: C, 62.36, 61.95; H, 8.01, 7.84; Br, 19.00, 19.08.

Δ^4-17α-Bromo-6α-methylpregnene-3,20-dione (17α-Bromo-6α-methylprogesterone) (XII)

Through a solution of 500 mg of 17α-bromo-5α-hydroxy-6β-methylpregnane-3,20-dione (XI), m.p. 168–170° decomp., in 100 cc of acetic acid, there was passed, at 10° and for 2 hours, a stream of dry hydrogen chloride. Subsequently, the solution was kept for 16 hours at 0–5° and was then poured into an iced sodium chloride solution. The precipitate was extracted with ether, the ethereal solution was washed with ice water, with iced sodium bicarbonate solution, and with water and was dried over sodium sulphate. Upon removal of the solvent *in vacuo* 450 mg of a semicrystalline material was obtained. The product was absorbed on 45 g of silica gel. Elutions with benzene – ethyl acetate (97:3) gave 280 mg (58.5% yield) of 17α-bromo-6α-methylprogesterone (XII), m.p. 149–151° decomp. A sample was recrystallized four times from ether–hexane for analysis; colorless prisms; m.p. 153–154° decomp.; $[\alpha]_D^{24}$ +10.2° (*c*, 1.580 in $CHCl_3$); λ_{max}^{EtOH} 237 mμ (log ε 4.19); ν_{max}^{KBr} 1703 cm^{-1} (20-ketone), 1672 and 1610 cm^{-1} (Δ^4-3-keto doublet). Anal. Calc. for $C_{22}H_{31}O_2Br$: C, 64.86; H, 7.67; Br, 19.62. Found: C, 64.97, 64.62; H, 7.80, 7.72; Br, 19.89, 19.77.

Δ^4-6α-Methylpregnene-3,20-dione (6α-Methylprogesterone) (XIV) (cf. refs. 28 and 29)

(a) From 5α-Hydroxy-6β-methylpregnane-3,20-dione (XIII)

Through a solution of 2.5 g of crude, partly dehydrated 5α-hydroxy-6β-methylpregnane-3,20-dione (XIII), obtained by oxidation of the dihydroxy ketone IX (see above), in 100 cc of acetic acid, there was passed, at 10–15°, for 2 hours, a stream of dry hydrogen chloride. The product was further treated and worked up as described for the preparation of 17α-bromo-6α-methylprogesterone (XII) (see above). Thus, 2 g of crude 6α-methylprogesterone (XIV), λ_{max}^{EtOH} 241 mμ (log ε 4.08), was obtained. Chromatography on 60 g of aluminum oxide, activity III, afforded 1.6 g (67.5% yield) of 6α-methylprogesterone (XIV), m.p. 119–122°, $[\alpha]_D^{23}$ +172° (*c*, 0.850 in $CHCl_3$). The infrared spectrum of the product was identical with that of an authentic sample of 6α-methylprogesterone, kindly supplied by Dr. V. Petrow,[7] and no depression of melting point was observed upon mixture of the two samples.

(b) From 17α-Bromo-6α-methylprogesterone (XII)

To a solution of 30 mg of 17α-bromo-6α-methylprogesterone (XII) in 10 cc of acetic acid there was added, at 80°, portionwise and with shaking, 500 mg of zinc dust. The mixture was heated with intermittent shaking for another 2 hours on a boiling water bath. The reaction mixture was cooled, diluted with ether, and filtered. The filtrate was further diluted with ether and the ethereal solution was washed with dilute hydrochloric acid, water, sodium bicarbonate solution, and with water and was dried over sodium sulphate. Evaporation of the solvent afforded 20 mg of an amorphous product which crystallized from acetone–hexane. Thus, 14 mg of 6α-methylprogesterone (XIV), m.p. 121–123°, $[\alpha]_D^{25}$ +176° (*c*, 0.600 in $CHCl_3$), λ_{max}^{EtOH} 241 mμ (log ε 4.19), was obtained. The identity of this product with authentic 6α-methylprogesterone[7] was established by a mixed melting point and by the comparison of the infrared spectra.

$\Delta^{4,16}$-6α-Methylpregnadiene-3,20-dione (6α-Methyl-16-dehydroprogesterone) (XV) (29)

A solution of 60 mg of 17α-bromo-6α-methylprogesterone (XII), m.p. 150–152° decomp., in 15 cc of dimethylformamide was refluxed, in a nitrogen atmosphere, with 12 mg of lithium chloride, for 1 hour. Subsequently, the mixture was cooled and extracted with ether. The ethereal solution was washed with dilute hydrochloric acid, water, sodium bicarbonate solution, and again with water and was dried over sodium sulphate. Removal of the solvent afforded 45 mg (93.6% yield) of crude, crystalline 6α-methyl-16-dehydroprogesterone (XV), m.p. 172–175°. The product was absorbed on a column of 2 g of silica gel and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

eluted with benzene – ethyl acetate (97:3). Thus, 30 mg (62.4%) of colorless crystals, m.p. 174–176°, were obtained. The product was recrystallized twice from ether for analysis; prisms; m.p. 180–182°; $[\alpha]_D^{24}$ +153° (*c*, 0.650 in $CHCl_3$); λ_{max}^{EtOH} 240 mμ (log ε 4.46); ν_{max}^{KBr} 1670 and 1610 cm^{-1} (Δ^4-3-keto doublet), 1661 cm^{-1} (shoulder), 1590 cm^{-1} (Δ^{16}-20-keto doublet). Anal. Calc. for $C_{22}H_{30}O_2$: C, 80.93; H, 9.26. Found: C, 80.54; H, 9.22.

ACKNOWLEDGMENTS

We sincerely thank Mrs. J. Capitaine and Mr. D. Capitaine for their most competent assistance in our experiments. We are greatly indebted to Dr. E. Shipley, Endocrine Laboratories of Madison Inc., Madison, Wisc., and to Dr. J. Tripod and Dr. P. Desaulles, Ciba Ltd., Basle, Switzerland, for the biological tests briefly mentioned in this paper. Sincere thanks are also due to Dr. M. Eisler and Dr. P. Perlman, Schering Corporation, Bloomfield, N.J., and to Dr. H. A. Salhanick, University of Nebraska, Omaha, Nebraska, for preliminary biological investigations. Generous financial support from the National Research Council of Canada, the Schering Corporation, Bloomfield, N.J., and the Schering Corporation Ltd., Montreal, Quebec, is gratefully acknowledged.

NUCLEAR MAGNETIC RESONANCE SPECTRA OF DURENE AND MESITYLENE DERIVATIVES

E. BULLOCK
Department of Chemistry, The University, Nottingham, England
Received October 24, 1962

ABSTRACT

The nuclear methyl groups and ring protons in nitro- and dimethylamino-durenes and -mesitylenes show considerable chemical shifts relative to the parent hydrocarbons. The shifts are generally in the direction expected from a mesomeric effect, despite the lack of coplanarity between the aromatic ring and the substituent.

INTRODUCTION

The n.m.r. spectra of a considerable number of 1-substituted 2,6-dimethylbenzene derivatives have been studied and an attempt made to relate the observed chemical shifts of the ring protons to steric effects of the substituents and Hammett sigma values (1). Since the degree of interaction of various substituents with adjacent methyl substituents is not generally known with any accuracy it seemed worthwhile to make a further study of very large substituents in which deviations from coplanarity are well known to be great and hence mesomeric effects will be very markedly reduced. Nitro and dimethylamino groups are particularly valuable in this respect since a recent study has given accurate chemical shift data for the benzene derivatives (2) and, also, they provide examples of the two opposite types of mesomeric effect. Nitromesitylene and nitrodurene have been studied extensively by X-ray and spectroscopic methods (3, 4) which provide ample evidence of the lack of coplanarity between the substituent and the aromatic ring. Ortho-substituted dimethylanilines are even more sterically hindered, one substituent being sufficient to inhibit mesomeric interaction (5).

Materials

Mesitylene was distilled commercial (B.D.H.) material. The three nitromesitylenes were prepared by standard methods (6) by Mr. C. E. Loader of this university. The dimethylamino derivatives were prepared from these by catalytic (PtO) reduction at room temperature and atmospheric pressure and methylation with dimethyl sulphate (7). Durene was also commercial material (B.D.H.) and the nitro compounds were prepared by literature methods (8). The dimethylamino compounds were prepared as above.

EXPERIMENTAL

The n.m.r. spectrometer is an A.E.I. RS2 instrument operating at 60 Mc/sec. A standard sweep rate of about 90 c.p.s./min was used. The samples were examined as very dilute solutions in carbon tetrachloride containing 2% tetramethylsilane, the concentration in all cases being just sufficient to permit reasonable recording of the spectra. The spectra were calibrated by generation of side bands from the tetramethylsilane absorption.

RESULTS

The results are expressed on the τ scale in Table I. The values were reproducible to about ± 0.01 p.p.m. over at least five runs. The table also includes the chemical shifts of methyl groups in the three N,N-dimethyltoluidines. The figures in the last two columns show the shift of signals, other than those which are affected by an ortho substituent,

TABLE I

Chemical shifts of nitro and dimethylamino derivatives

Compound	Methyl	Ring proton	NMe_2	ΔH	ΔCH_3
Mesitylene	7.73	3.29	—	—	—
Nitro-	7.71 (2), 7.65 (1)*	3.09	—	*m*, −0.20	*p*, −0.08
Dinitro-	7.74 (1), 7.64 (2)*	2.88	—	*m*, −0.41	—
Trinitro-	7.66	—	—	—	—
Dimethylamino-	7.77	3.31	7.20	*m*, +0.02	*p*, +0.04
Di(dimethylamino)-	7.82	3.34	7.19	*m*, +0.05	—
Durene	7.83	3.19	—	—	—
Nitro-	7.84 (1), 7.69 (1)*	3.00	—	*p*, −0.19	*m*, −0.14
Dinitro-	7.73	—	—	—	—
Dimethylamino-	7.81 (1), 7.83 (1)*	3.35	7.13	*p*, +0.16	*m*, +0.02
Toluene (9)	7.66	2.83	—	—	—
o-Dimethylamino-	7.69	—	7.30	—	+0.03
m-Dimethylamino-	7.69	—	7.07	—	+0.03
p-Dimethylamino-	7.74	—	7.11	—	+0.08

*Figures in parenthesis show relative intensities of the peaks.

relative to the corresponding parent hydrocarbon. It is clear that a methyl group with an ortho non-coplanar nitro group appears to *high* field of one with the corresponding meta or para relationship (cf. *o*-nitrotoluene and its isomers (9)).

DISCUSSION

In any attempt to relate the observed effects to simpler substituted benzenes, several factors must be considered. Diehl (10) has shown that substituent effects on aromatic systems are often additive, but the additivity rules may break down with polysubstituted (especially vicinal halogeno) compounds. Apart from inductive and resonance effects, field (11), anisotropy, and solvent effects and perhaps deviations of the aromatic ring from the regular hexagon form on substitution (2) may be important. The last effect can probably be neglected since meta-disubstituted benzenes show additive chemical shift relationships, even for the proton between the substituents (10) and yet there are often very large distortions of the ring (12) in such cases. Furthermore, the present study indicates that substituent effects on mesitylenes are additive for both nitro and dimethylamino substitution. The "substituent-shifts" are calculated using the parent hydrocarbon as a standard, rather than by reference to benzene (cf. ref. 1), and the values of Fraser (1) can be recalculated on the same basis (using chemical shift values for 1-*d*-2,6-dimethylbenzene) to give comparable results. Whilst many of the shifts are very small and cannot therefore be used for quantitative comparison, there is an unmistakable trend which suggests that despite lack of coplanarity the chemical shifts produced by substituents are in the same direction as would be expected from mesomeric effects. This is particularly interesting in the dimethylamino compounds since the inductive effect of this group is presumed to be in the opposite sense to the mesomeric effect and might be expected to be the main electronic effect in the hindered systems.

Nitro Compounds

The chemical shifts of ring protons of nitrobenzene (relative to benzene) are *o*, −0.95; *m*, −0.21; and *p*, −0.33 p.p.m. (2). The shifts of methyl groups in nitrotoluenes (relative to toluene) are *o*, −0.19; *m*, −0.08; and *p*, −0.09 p.p.m. (9). Comparison with Table I suggests that an "out-of-plane" nitro group produces shifts of (*a*) a meta proton and (*b*) a para-methyl group as large as does a coplanar nitro substituent. The values for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

nitrodurene are less clear-cut but still show marked low-field shifts for meta methyl and para proton.

Fraser's values (1) when calculated on the same basis give a meta-proton shift of −0.21 p.p.m. and a para-proton shift of −0.16 p.p.m., in good agreement with the present values.

Dimethylamino Compounds

The ring-proton shifts in dimethylaniline are +0.60, +0.10, and +0.62 for ortho, meta, and para positions respectively (2). The methyl shifts for dimethylaminotoluenes are included in Table I. The values are comparable in magnitude with those of the nitro compounds but all in the high-field direction. The ring-methyl resonances are not resolved in the dimethylaminomesitylenes.

The results of this and the earlier studies suggest that for the meta proton in nitrobenzene and the hindered ortho-substituted compounds there is no mesomeric contribution at all, although there is clearly some considerable para effect (cf. ref. 2). An analogous effect has been postulated to account for fluorine chemical shifts of meta-fluoro-substituted benzene derivatives (13).

Ortho-methyl Groups

The relative intensities of the resonances of the nuclear methyl substituents in the nitromesitylenes show that the ortho-methyl peaks are scarcely shifted from the value for the parent hydrocarbon. This can be understood if there is a magnetically induced circulation of the π electrons in the nitro group which produces a region of positive shielding above and below the plane containing the atoms of the group, thus neutralizing any electronic effects of the substituent (cf. ref. 14).

EXCHANGE BROADENING OF SPIN–SPIN TRIPLETS IN NUCLEAR MAGNETIC RESONANCE SPECTRA. APPLICATION TO THE SYSTEM ETHANOL–WATER

W. G. PATERSON

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 13, 1962

ABSTRACT

Using an extension of the method of McConnell (1), an expression is derived for the nuclear magnetic resonance spectrum of a hydroxyl proton in a —CH_2OH group which is undergoing intermolecular exchange. A graphical method is presented which enables a rapid evaluation of τ, the average lifetime of a hydroxyl proton between exchange events. Measurements of line widths and multiplet spacings in the n.m.r. spectra of ethanol–water solutions are interpreted in terms of the proton exchange reaction

$$C_2H_5OH + HOH^* \rightleftarrows C_2H_5OH^* + HOH,$$

for which a value of 2.7 l. mole^{-1} sec^{-1} at 42±1° C is suggested as an upper limit to the rate constant.

THEORETICAL

The quantitative description of exchange processes which modify the nuclear magnetic resonance spectrum of a system follows most easily from an appropriate modification of the Bloch phenomenological equations (1–26). This approach, first used by Gutowsky, McCall, and Slichter (5), has been presented in a simplified form by McConnell (1). The modification (2) of McConnell's (1) original treatment for nuclear exchange between two sites to include the movement of individual nuclei among n sites in a random statistical manner gives

$$\frac{dG_j}{dt} + \alpha_j G_j = -i\gamma H_1 M_0 p_j + \sum_k \left(\frac{G_k}{\tau_{kj}} - \frac{G_j}{\tau_{jk}}\right), \qquad [1]$$

where G is the complex moment $u+iv$ in the xy plane; u and v are the transverse components of the macroscopic nuclear magnetic moment M along and perpendicular to the rotating magnetic field H_1; γ is the nuclear magnetogyric ratio; M_0 is the equilibrium value of M; p_j is the fractional population of the j sites ($j = 1, 2, \ldots, n$); τ_{kj}^{-1} is the probability per unit time of a nucleus on a k site making a jump to a j site, and analogously for τ_{jk}^{-1}; and α_j is given by

$$\alpha_j = \frac{1}{T_{2j}} - i(\omega_j - \omega),$$

where T_{2j} and ω_j are the transverse relaxation time T_2 and the Larmor frequency, respectively, of a nucleus on a j site, and ω is the angular rotation frequency of H_1. Thus $\sum_k \tau_{kj}^{-1} G_k$ in equation [1] represents the rate of increase of G_j due to transfer of magnetization from k to j sites and $\sum_k \tau_{jk}^{-1} G_j$ represents the corresponding rate of loss. Since jumps between two sites of the same types have no effect on the spectrum (1, 2), τ_{jk}^{-1} and τ_{kj}^{-1} are zero if $j = k$.

Equation [1] may be applied to the n.m.r. spectra of alcohols containing the —CH_2OH group. The hydroxyl protons of such compounds show a triplet spectrum (due to coupling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with the methylene protons) in the absence of hydroxyl proton exchange, but the triplet structure collapses if the exchange rate is increased (10). The methylene group can have any one of four equally probable spin states, and in an exchange event, a hydroxyl proton is equally likely to become attached to a molecule with any of the four configurations. For the hydroxyl proton of a —CH_2OH group, all τ_{kj}^{-1} and τ_{jk}^{-1} are equal, all p_j are 1/4, and equation [1] becomes

$$\frac{dG_j}{dt} + \alpha_j G_j = -\frac{1}{4} i\gamma H_1 M_0 - \frac{3G_j}{\tau_{jk}} + \frac{1}{\tau_{kj}} \sum_{k \neq j} G_k. \qquad [2]$$

To a good approximation, the two inner frequencies of the triplet are coincident if the chemical shift between the methylene and hydroxyl protons is much larger than the spin coupling constant between them (2). Since in a symmetrical triplet a hydroxyl proton on a j site has a choice of only two other different sites in an exchange event, and since two protons are involved in each exchange event, the average lifetime τ of a hydroxyl proton before exchange is given by $\tau = \tau_{jk}/4$, and equation [2] becomes

$$\frac{dG_j}{dt} + \alpha_j G_j = -\frac{1}{4}\gamma H_1 M_0 - \frac{3}{4\tau} G_j + \frac{1}{4\tau} \sum_{k \neq j} G_k. \qquad [3]$$

In the case of a symmetric —OH triplet, there are only three different values of α_j, namely,

$$\alpha_j = \frac{1}{T_{2j}} - i(\Delta\omega + m\delta\omega), \qquad [4]$$

where $\Delta\omega$ is the angular frequency of the applied field, the center of the multiplet being taken as zero; $\delta\omega$ is half the multiplet spacing between adjacent lines; and $m = 2$, 0, or -2 depending on which triplet component is under consideration. The steady-state solution of equation [3] follows (1, 2) by setting dG_j/dt equal to zero, and solving the resulting set of linear equations for $G = \sum_j G_j$, which yields

$$G = \frac{\dfrac{-i\gamma H_1 M_0}{\delta\omega}\left\{t\left[\left(\dfrac{1}{t} + \dfrac{1}{Q} - iZ\right)^2 + 2\right]\right\}}{t\left(\dfrac{1}{t} + \dfrac{1}{Q} - iZ\right)\left[\left(\dfrac{1}{t} + \dfrac{1}{Q} - iZ\right)^2 + 4\right] - \left(\dfrac{1}{t} + \dfrac{1}{Q} - iZ\right)^2 - 2}, \qquad [5]$$

where, for convenience (22), $Q = T_2\delta\omega$, $t = \tau\delta\omega$, and $Z = \Delta\omega/\delta\omega$. Equation [5] has been derived by Meiboom *et al.* (17) using the more elegant and complicated argument of Gutowsky, McCall, and Slichter (5). A comparison of equation [5] and the equation $G = u + iv$ shows that the intensity of the absorption mode v is proportional to the imaginary part of equation [5]. Rationalization of the latter yields

$$v = \frac{-\dfrac{\gamma H_1 M_0}{\delta\omega}\{Z^4 + 2Z^2(x^2 + Qx - 2) + (x^2+2)(x^2+2Qx+2)\}}{\left\{QZ^6 + Z^4\left(2Qx^2 + \dfrac{1}{Q} - 8Q\right) + Z^2\left(Qx^4 + \dfrac{2}{Q}x^2 + \dfrac{4}{t} + 16Q\right) + \dfrac{1}{Q}(x^2+2Qx+2)^2\right\}}, \qquad [6]$$

where $x = (1/t) + (1/Q)$. When both τ and T_2 are large, this expression predicts three lines of intensity distribution 1:2:1, separated by a frequency interval $2\delta\omega$. For much smaller values of τ and T_2, the behavior of equation [6] is such that for some values three peaks are produced, and for others only a single peak is to be expected. Values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of τ may be obtained from experimental data by computing line shapes for all probable values of Q, Z, and t and comparing with the observed line shape (17). This method is convenient only for triplets with symmetric intensity distribution. In an alternative method described below, which is applicable under conditions of slow hydroxyl proton exchange, the derivative of v with respect to applied frequency $\Delta\omega$ is set equal to zero, and the resulting equation in Z is solved for the location of the maxima. This procedure has been used previously (22, 27) for spin–spin doublets. In cases where the triplet has a slightly asymmetric intensity distribution, the average observed line separation may be used. The result obtained is

$$\frac{dv}{dZ} = 0 = Z^9+4Z^7\{x^2+Qx-2\} +2Z^5\left\{3(x^2-1)^2+5Qx^3-\left(2Q+\frac{1}{Q}\right)x+11\right\} +4Z^3\left\{(x^2+2Qx+2)\left(x^4-2x^2-\frac{x}{Q}-8\right)\right\} +2Z\left\{(x^2+2Qx+2)\left(\frac{x^6}{2}+x^4-\frac{x^3}{Q}+6x^2+\frac{6x}{Q}+16\right)\right\}. \quad [7]$$

The roots of this equation must correspond to the maxima and minima of the triplet signal. One solution is obviously $Z = 0$; evaluation of $(d^2v/dZ^2)_{Z=0}$ shows that this is always a maximum. The roots of equation [7] which correspond to the outer maxima $Z_{max} = \Delta\omega_{max}/\delta\omega$ were obtained from a program written for the IBM 1620 computer. Some values of Z_{max}, calculated for a range of values of Q and t, are summarized in Table I and plotted in Fig. 1.[1] With the aid of such a graph, a measurement of T_2, $\delta\omega$,

and the maxima separation in the n.m.r. spectrum permits a rapid evaluation of τ, the average lifetime of the hydroxyl proton before exchange.

APPLICATION TO THE SYSTEM ETHANOL–WATER

Proton exchange in ethanol and in ethanol–water solutions has been investigated several times (10, 21, 28–32), with widely varying results being reported, but only once

has the work been on a quantitative kinetic basis. In the latter (21), rates of acid- and base-catalyzed protolysis of ethanol in aqueous solution were found, and the rate constant of reaction [8] was obtained by inference as $k = 0.8$ l. mole^{-1} sec^{-1} at 22±2° C. In the

$$C_2H_5OH + HOH^* \rightleftarrows C_2H_5OH^* + HOH \qquad [8]$$

present paper, a direct measurement of the rate of reaction [8] is reported, utilizing the method described in the preceding section.

EXPERIMENTAL

The n.m.r. spectra were measured on a Varian A-60 Analytical n.m.r. spectrometer operating at 60 Mc/s. Using a copper–constantan thermocouple, the temperature of the solutions when in the spectrometer probe was measured as 42±1° C. Calibration of the instrument was achieved by the customary side-band technique (33), using a Hewlett–Packard Model 200 AB audio-oscillator and a Hewlett–Packard Model 521C frequency counter. The precision in measurement was generally better than 0.1 c.p.s. All measurements were an average of at least five determinations. Transverse relaxation times (T_2) were considered to be governed chiefly by magnetic field inhomogeneities (34), and were estimated from the line width of a degassed spectrograde cyclohexane or purified water sample, by means of the relation $T_2 = 1/\pi\Delta\nu_{1/2}$, where $\Delta\nu_{1/2}$ is the full width of the signal at half-maximum amplitude. These two substances gave identical T_2 values within experimental error. The degree of resolution of the n.m.r. spectrometer was deliberately set at a lower value than would be generally used in order that the assumption made above concerning field inhomogeneities would be valid.

All glassware which was used either in the purification of materials or in the rate measurements was cleaned with the following substances in the order written, and then heated for several hours at 120°: Fisher "Sparkleen" detergent, distilled water, ~3 N HCl, distilled water, ~3 N NH_4OH, distilled water. The rinsings with distilled water were done 10–20 times. In the early experiments, no significant differences were observed in exchange rates when measurements were made using pyrex or quartz[2] sample tubes. All the results quoted in this paper are from measurements made with standard Varian pyrex sample tubes.

Anhydrous ethanol was prepared by Fieser's method (35). A 30-in. Vigreux fractionating column and a Kjeldahl spray trap were used in the distillation, and air was excluded from the apparatus by passing a slow stream of dried, carbon-dioxide-free nitrogen through it. A middle fraction was collected ($n_D^{26} = 1.358_5$; this slightly high value is possibly due to small amounts of benzene). The triplet spacing of the —OH signal in "pure" ethanol varied from 5.05±0.06 to 4.97±0.04 c.p.s. depending on the degree of purification and the resolution of the n.m.r. spectrometer. These variations should have a small effect on the results quoted

[2]*Baumbach Bros., Thundersley, Essex, England.*

since any set of measurements on ethanol–water solutions was compared to the "pure" ethanol prepared for that set. Pure water ($n_D^{28} = 1.332_3$) was prepared in two different ways: (1) by refluxing distilled water from the tap over alkaline $KMnO_4$ and distilling in the apparatus described above, and (2) by passing distilled water from the tap through a Barnstead "Bantam Demineralizer" ion-exchange column followed by a bubbling treatment with carbon-dioxide-free nitrogen. The pH of water thus prepared was usually 6.7, corresponding to $[H^+] = 2\times10^{-7}$ mole/l. or less. A 40% v/v ethanol–water solution gave a similar pH reading. pH measurements were made with a Radiometer pH meter calibrated with a standard phthalate buffer.

All flasks and n.m.r. tubes which were used in sample preparation were flushed with dried, carbon-dioxide-free nitrogen before use. Since the solutions slowly leach impurities from glass, it was found necessary to do a given set of n.m.r. measurements on the same day that the materials were distilled.

RESULTS AND DISCUSSION

In the kinetic analysis, it is assumed that the only exchange reaction of significance is reaction [8]. Since ionic concentrations in neutral alcohol–water solutions are extremely small (21, 36), proton transfer reactions other than [8] should be relatively unimportant. The pH measurements quoted in the experimental section suggest that the solutions used were approximately neutral. Separate experiments proved the absence of significant proton exchange in pure ethanol.

It follows that

$$\pm\frac{d[C_2H_5OH]}{dt} = k[C_2H_5OH][HOH].$$

The average lifetime $\tau_{C_2H_5OH}$ of a hydroxyl proton on a molecule of C_2H_5OH before exchange with a proton on a different site will be

$$\tau_{C_2H_5OH} = \frac{[C_2H_5OH]}{d[C_2H_5OH]/dt} = \frac{1}{k[HOH]}$$

or

$$\frac{1}{\tau_{C_2H_5OH}} = k[HOH].$$

Thus a plot of $1/\tau_{C_2H_5OH}$ vs. [HOH] should be a straight line with slope k passing through the origin. Figure 2 indicates that this is approximately true. The wide scatter of points

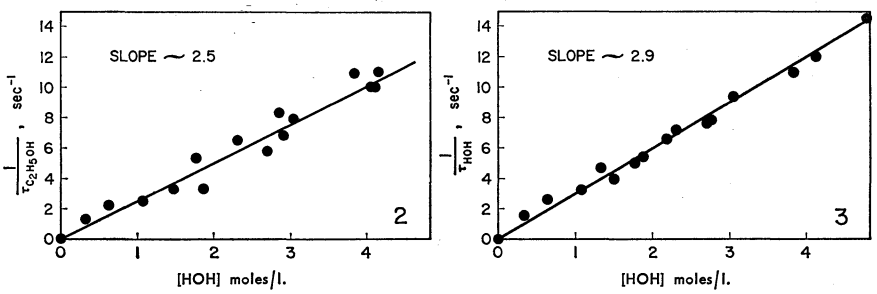

FIG. 2. Variation of $1/\tau_{C_2H_5OH}$ with [HOH].
FIG. 3. Variation of $1/\tau_{HOH}$ with [HOH].

is due to a number of factors. The rate of proton exchange is very susceptible to catalysis (21) and trace impurities (10, 27). Further errors are due to inaccurate T_2 values, but fortunately τ is relatively insensitive to the value of T_2. The identification of k as the rate constant for reaction [8] is valid only if it is the sole exchange reaction.

Since $\tau_{C_2H_5OH} = \tau_{HOH}$ for reaction [8], where τ_{HOH} is the average lifetime of a proton on a water molecule before exchange with a proton on ethanol, a plot of $1/\tau_{HOH}$ vs. [HOH]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

should also be a straight line with slope k passing through the origin. Figure 3 suggests that this is approximately the case.

The values of $1/\tau_{C_2H_5OH}$ were obtained from the transverse relaxation time, T_2, the triplet spacing in pure ethanol, and the maxima separations in the partially collapsed —OH triplet, using the method outlined in the theoretical section. The values of $1/\tau_{HOH}$ were obtained from the relation (1, 5, 21)

$$\frac{1}{\tau_{HOH}} = \pi\Delta\nu_{\frac{1}{2}} - \frac{1}{T_2},$$

where $\Delta\nu_{\frac{1}{2}}$ is the full width of the water signal of half-maximum amplitude. Typical —OH and HOH signals are shown in Fig. 4.

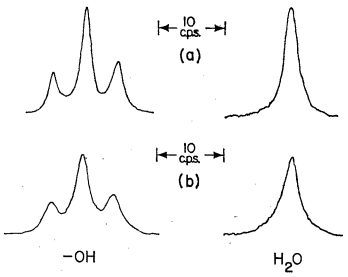

FIG. 4. Typical —OH and HOH signals. (*a*) [HOH] = 2.18 moles/l.; (*b*) [HOH] = 2.76 moles/l. The —OH and HOH signals were recorded at different gain settings.

The average of the slopes of Figs. 2 and 3, obtained by a least-squares treatment (37), yields a rate constant k for reaction [8] approximately equal to 2.7 l. mole^{-1}sec^{-1} at 42±1° C. This compares with the value 0.8 l. mole^{-1}sec^{-1} at 22±2° C reported by Meiboom and coauthors (21). These two rate constants yield a crude estimate of 10 kcal/mole for the activation energy for proton transfer between ethanol and water. An approximate value of 7.6 kcal/mole has been suggested by Schneider and Reeves (31).

It is quite possible that the rate constant quoted in the present work is too high due to the presence of trace acidic impurities. Inclusion even to a limited extent of reactions such as

$$C_2H_5OH + H_3O^+ \rightleftharpoons C_2H_5OH_2^+ + H_2O$$
$$C_2H_5OH + C_2H_5OH_2^+ \rightleftharpoons C_2H_5OH_2^+ + C_2H_5OH$$
$$C_2H_5OH + H_2O + C_2H_5OH_2^+ \rightleftharpoons C_2H_5OH_2^+ + H_2O + C_2H_5OH,$$

the first two of which have rate constants of 2.8×10^6 and 1.1×10^8 l. mole^{-1}sec^{-1} at 22±2° C, respectively, could result in a high value for the rate constant quoted here.

A possible formulation of the mechanism of reaction [8] is

IONIZATION OF ORGANIC COMPOUNDS

V. THIOLACTAMS IN SULPHURIC ACID

J. T. EDWARD AND H. STOLLAR
Department of Chemistry, McGill University, Montreal, Que.

Received November 19, 1962

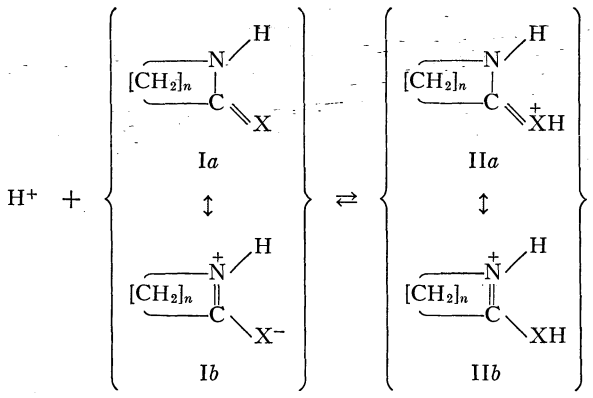
ABSTRACT

The ionization in aqueous sulphuric acid of thiolactams consisting of five-, six-, and seven-membered rings has been studied. With increasing concentration of acid the ionization ratio increases more rapidly than h_0. A possible explanation involving the hydration of the thiolactam is given. Changes in the basicity of thiolactams with ring size parallel changes previously found for lactams.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

By analogy with the resonance structures of simple amides (1), the structure of lactams (I; X = O) would be expected to be made up by a 60% contribution from structure I*a* (X = O) and 40% contribution from structure I*b* (X = O), although the relative weights of the contributions could be altered somewhat by ring strain (2). Thiolactams (I; X = S) have higher dipole moments (3), and so should be represented to a preponderant extent by the dipolar form I*b* (X = S). The high polarity of the thiolactams (I; X = S, n = 3, 4, and 5) may in part account for the fact that they are solids at room temperature while the corresponding lactams (I; X = O, n = 3, 4, and 5) are liquid, and that (as postulated later in this paper) they appear to be more extensively hydrated in aqueous solution than are the lactams.

It is probable that lactams and thiolactams in strong acid are protonated on the oxygen or sulphur atom to give the conjugate acids (II; X = O or S) (4). Consequently it became of interest to compare the basicities of the two classes of compounds. It seemed



possible that in spite of the greater intrinsic basicity of oxygen as compared with sulphur (cf. OH^- and SH^-), the greater negative charge on the sulphur of thiolactams would cause them to be more basic than lactams. We have accordingly determined the protonation constants of the thiolactams (I; X = S, n = 3, 4, and 5) for comparison with the protonation constants reported for the lactams (I; X = O, n = 3, 4, and 5) (2).

EXPERIMENTAL

Materials

Piperidone (I; X = O, $n = 4$) and caprolactam (I; X = O, $n = 5$) were prepared in 38% and 67% yields, respectively, by Cornforth, Hunter, and Popjak's modification (5) of the Schmidt reaction. Pyrrolidone (I; X = O, $n = 3$) was a commercial product. Thiolactams were prepared from these lactams by treatment with phosphorus pentasulphide following the procedure of Tafel and Lawaczeck (6), and recrystallized to constant (though not necessarily sharp) melting point: thiopyrrolidone from water, m.p. 110–114° (lit. m.p. 116° (6)); thiopiperidone from aqueous ethanol, m.p. 94–95° (lit. m.p. 93–94° (7)); and thiocaprolactam from aqueous ethanol, m.p. 105–107° (lit. m.p. 105–105.5° (7)).

Sulphuric acid solutions were prepared and standardized as described previously (8).

Procedure

Apparatus and procedure were essentially as described before (9), except that thiocaprolactam, because of its insolubility in water, was dissolved in ethanol to make up a stock solution. Aliquots (1.00 ml) of this stock solution were diluted with aqueous sulphuric acid to 50.0 ml, so that the thiocaprolactam solutions contained about 2% (v/v) ethanol. No account was taken of this content of the ethanol in calculations of the H_0 values of the solutions; this seems reasonable from data in the literature (10).

RESULTS AND DISCUSSION

The absorption spectra of thiolactams in aqueous solution (Table I) show a strong peak at about 260 mμ due to a $n \rightarrow \sigma^*$ transition (11), and a second peak at about

TABLE I

Absorption peaks of thiolactams

	In water		In sulphuric acid		
Compound	λ_{max} (mμ)	ϵ_{max}	Concn. (%)	λ_{max} (mμ)	ϵ_{max}
Thiopyrrolidone	211	5,860	78.8	234	10,200
	260	14,400			
Thiopiperidone	212	5,620	69.4	239.5	9,400
	269	13,000			
Thiocaprolactam*	210	5,410	87.0	243	10,500
	271	15,100			

*Solutions contained about 2% (v/v) ethanol.

210 mμ which may be due to a $\pi \rightarrow \pi^*$ transition, although the assignment is uncertain (11). In strong sulphuric acid these are replaced by a single peak at about 240 mμ (Table I) which may be the $\pi \rightarrow \pi^*$ peak shifted to longer wavelengths by protonation (12), the blue shift of the $n \rightarrow \sigma^*$ peak (11) caused by protonation having taken it out of the observable region of the spectrum. These spectral changes are very similar to those already observed for thioacetamide (11, 13).

In keeping with the conception that the spectra of the thiolactams in strong acid are due to the monoprotonated species (II), the curves obtained in intermediate concentrations of acid are intermediate in character, and pass through an isobestic point at about 250 mμ and almost through a second isobestic point at about 220 mμ. This is shown for thiopiperidone in Fig. 1. The failure of the curves to pass through the second isobestic point indicates that the peak at lower wavelengths is being shifted by changing acid concentration through a "medium effect" (14).

Plots of the molar extinction coefficients of the thiolactams at a given wavelength against the H_0 values of the acid solutions give sigmoid waves whose inflection points indicate protonation constants (pK_{BH^+}) of −2.0 for thiopyrrolidone, −1.4 for thiopiperidone, and −1.6 for thiocaprolactam. However, as shown in Fig. 2, the curves drawn

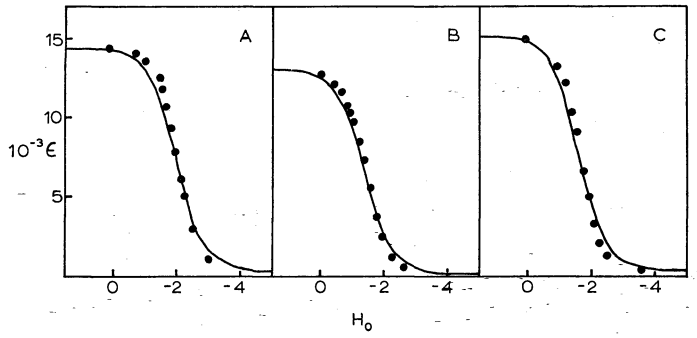

FIG. 2. Ionization of thiolactams in sulphuric acid. Points: experimental values of ε for wavelengths (λ) indicated below; curves: calculated from equation [1] using parameters indicated below. (A) Thiopyrrolidone: λ 260 mμ; pK_{BH^+} −2.0; ϵ_B 14,400; ϵ_{BH^+} 360. (B) Thiopiperidone: λ 269 mμ; pK_{BH^+} −1.4; ϵ_B 13,050; ϵ_{BH^+} 150. (C) Thiocaprolactam: λ 271 mμ; pK_{BH^+} −1.6; ϵ_B 15,100; ϵ_{BH^+} 400.

through the experimental points are all slightly steeper in the region of half-ionization than the curves theoretically required by the equation

$$pK_{BH^+} = H_0 - \log\{(\epsilon_{BH^+} - \epsilon)/(\epsilon - \epsilon_B)\}, \qquad [1]$$

ϵ_B, ϵ_{BH^+}, and ϵ being the molar extinction coefficients of the unprotonated base, the protonated base, and the mixture of protonated and unprotonated molecules in a solution of acidity function H_0, respectively.

Systematic deviation of experimental points from such a theoretical curve has often been attributed to the medium effect (14). However, in the present instance medium effects seem to be absent in the spectral region 240–270 mμ as shown by the behavior of the curves in passing through an isobestic point. It seems more probable that we are encountering another class of compounds whose protonation in acid solution does

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

not follow exactly the Hammett H_0 function. It has been shown already that the protonation of amides does not follow this function (9). However, the behavior of amides contrasts with that of thiolactams, in that plots of ϵ against H_0 for the former compounds are *less* steep in the region of half-ionization than required by equation [1].

The contrasting behavior of amides (A) and thiolactams (T) may be explained by postulating that their protonation equilibria (equations [2] and [3]) involve numbers of water molecules (m and p) differing from each other and from the number (n) involved in the protonation of the indicator (In) (equation [4]) used by Hammett (15) for establishing this range of the H_0 scale:

$$AH^+ + mH_2O \rightleftarrows A + H^+ \quad [2]$$

$$TH^+ + pH_2O \rightleftarrows T + H^+ \quad [3]$$

$$InH^+ + nH_2O \rightleftarrows In + H^+. \quad [4]$$

(The formulae in these equations represent hydrated ions or molecules.) If $p > n$, it can be shown (9) that this requires that the ionization ratio ($[TH^+]/[T]$) increase with acid concentration more rapidly than h_0, and hence that the curve of ϵ against H_0 should be steeper than required by equation [1] at half-neutralization, as was found for thiolactams. On the other hand, if $n > m$, the ionization ratio ($[AH^+]/[A]$) must increase less rapidly than h_0, and hence the curve of ϵ against H_0 must be less steep than required by equation [1], as was found for amides.

While at the moment it would be difficult to predict that $p > n > m$, it seems reasonable to expect $p > m$, because the very polar T should be expected to be more heavily hydrated than the less polar A (1). (AH^+ and TH^+, having very similar structures, are expected to be hydrated to approximately the same extent.) Similar considerations probably apply to the hydration of some thioureas, whose ultraviolet absorption changes with acidity in a fashion similar to that shown in Fig. 2 (16).

Thiolactams thus prove to be considerably weaker bases than the corresponding lactams (2), the greater intrinsic basicity of the oxygen atom evidently being more important than the greater negative charge on the sulphur atom. The change in basicity of thiolactams with ring size parallels the charge in basicity of lactams with ring size, as shown in Fig. 3. (In this figure pK_{BH^+} values of lactams (2) obtained by the indicator

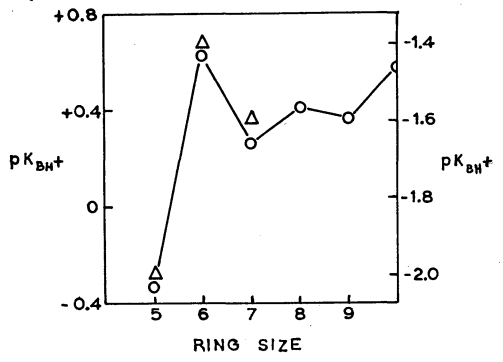

FIG. 3. Relation of protonation constants of lactams (○, left-hand scale) and of thiolactams (△, right-hand scale) to ring size.

method of Lemaire and Lucas (17) are used.) It is accordingly possible that the reasons given by Huisgen and his co-workers (2) for the variation in basicity of lactams with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ring size apply also to thiolactams. For the very limited data available the basicities of thiolactams are given with fair precision by the equation

$$pK_{BH^+}\text{ (thiolactam)} = 0.62pK_{BH^+}\text{ (lactam)} - 1.8. \quad [5]$$

No simple relationship is discernible between the dipole moments of lactams (18) or thiolactams (3) and their basicities.

PYRAZOLINES

PART III. THE PREPARATION AND PYROLYSIS OF 4,5-DIMETHYL-3-CARBOMETHOXY-Δ^2-PYRAZOLINE AND 3,5-DIMETHYL-3-CARBOMETHOXY-Δ^1-PYRAZOLINE

DONALD E. MCGREER, PETER MORRIS, AND GEORGE CARMICHAEL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received November 1, 1962

ABSTRACT

4,5-Dimethyl-3-carbomethoxy-Δ^2-pyrazoline and 3,5-dimethyl-3-carbomethoxy-Δ^1-pyrazoline have been synthesized and pyrolized neat and in the vapor phase. The product analysis from these and a related dimethyl-3-carbomethoxypyrazoline indicate that substituent effects of methyls in the ring are cumulative.

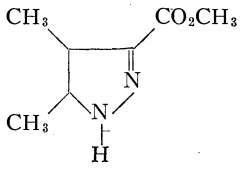
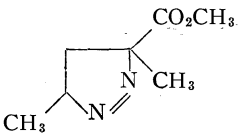
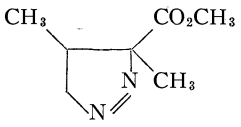
In an earlier study (1) it has been shown that of the methyl 3-carbomethoxypyrazolines studied the compound with methyl substitution at 3 gives a higher proportion of cyclopropane derivative in the product than was obtained from 3-carbomethoxy-Δ^2-pyrazoline. However, substitution by methyl at position 5 has little effect on the proportion of cyclopropane derivative and substitution at position 4 gives a reduced proportion of cyclopropane product. It is of interest to see if these effects are cumulative and for this reason we have investigated the pyrolysis of the dimethyl-substituted 3-carbomethoxypyrazolines I and II.



I



II



III

4,5-Dimethyl-3-carbomethoxy-Δ^2-pyrazoline (I) was prepared by the addition of diazoethane to methyl *trans*-crotonate. The stereochemistry in the pyrazoline was not determined but would be expected to be mainly with the methyls trans since these groups would be in close proximity in the transition state leading to the pyrazoline.

Pyrolysis of I (the pyrolysis of I has been reported (2) to give methyl 3-methyl-3-pentenoate as the sole product) gave the products indicated in Chart I in the proportions listed in Table I. These products were isolated by vapor chromatography and identified on the basis of their physical and chemical properties. The cyclopropane derivatives having methyls cis and trans (IX and VIII) were characterized through a comparison with the physical properties and infrared spectra reported for these compounds by Doering (3). The unsaturated esters were readily identified from their n.m.r. and infrared spectra.

The α,β-unsaturated esters (IV and V) showed carbonyl absorption at 1702 cm^{-1} and carbon–carbon double-bond absorption near 1645 cm^{-1}, and the n.m.r. spectra were in agreement with the structural assignments given by Wagner and Moore (4).

The β,γ-unsaturated esters (VI and VII) showed carbonyl absorption at 1725 cm^{-1} and weak carbon–carbon double-bond absorption at 1665 cm^{-1}. The n.m.r. spectra were

as expected for the isomeric methyl 3-methyl-3-pentenoates and excluded the possibility that one of these isomers was methyl 3-ethyl-3-butenoate. The stereochemistry of the β,γ-isomers was determined by the following sequence of steps.

Bromination of tiglic acid (methyl groups cis) under conditions to give trans bromination gave 2-methyl-2,3-dibromobutanoic acid. This acid was converted with thionyl chloride to the acid chloride and then by treatment with diazomethane to the diazoketone. Treatment of the dibromodiazoketone with silver oxide in methanol gave a mixture of brominated products. Reaction of this mixture with zinc gave a debrominated product from which was isolated methyl tiglate and the isomeric methyl 3-methyl-3-pentenoates in the ratio of 1:10. The major isomer was assigned the trans structure on the basis of earlier demonstrations of trans stereochemistry in the zinc debromination of 2,3-dibromobutane (5).

All of the unsaturated esters found in the product from the pyrazoline pyrolysis were also formed in the dehydration of methyl 3-methyl-3-hydroxypentanoate with phosphorus pentoxide by the procedure of Kon and Nargund (6). Under these conditions the β,γ-unsaturated esters formed 72% of the product (ref. 4 reports 61%). From the dehydration product there was isolated, in addition to the four unsaturated esters described above, a compound with infrared bands at 1725 and 1650 cm^{-1} believed to be methyl 3-ethyl-3-butenoate.

3,5-Dimethyl-3-carbomethoxy-Δ^1-pyrazoline (II) was prepared by the addition of diazoethane to methyl methacrylate. The n.m.r. of this pyrazoline showed it to be a 60:40 mixture of the two possible isomers; however, it was not possible to determine which was present to the greater extent.

Pyrolysis of II gave the products indicated in Chart I in the proportions listed in Table I. These products were isolated and identified on the basis of their physical constants. The low yield of the unsaturated esters prevented complete identification of these esters and thus the structural assignments are tentative. The cyclopropane derivatives having the methyls cis and trans (XIV and XIII) were characterized by comparison of their physical properties with those obtained by van Auken and Rinehart (7, 8).

The major unsaturated ester product showed infrared bands at 1700 and 1645 cm^{-1} indicative of an α,β-unsaturated ester. The n.m.r. was consistent with the structure methyl 2-methyl-*trans*-2-pentenoate (X) since the methyl hydrogens at C_4 gave a value of 7.94 τ (compare 7.73 τ for methylene hydrogens trans to the carbomethoxy group in methyl *trans*-3-methyl-2-pentenoate and 7.45 τ for methylene hydrogens cis to the carbomethoxy group in methyl *cis*-3-methyl-2-pentenoate).

A second unsaturated ester which was isolated (infrared bands at 1705 and 1641 cm^{-1}) was tentatively assigned the structure methyl 2-methyl-*cis*-2-pentenoate (XI). Insufficient sample was obtained for an n.m.r. spectrum.

A final sample (infrared bands at 1725 and 967 cm^{-1}) was isolated but could not be completely characterized. However, the infrared spectrum suggests that it is methyl *trans*-2-methyl-3-pentenoate (XII).

The product analyses reported in Table I when compared to the analyses of the products from the monomethyl pyrazolines (1) suggests that indeed the effects of methyl substitution are cumulative, although I yielded a higher proportion of cyclopropanes than might have been predicted. The product composition from a pyrolysis is somewhat influenced by the stereochemistry of the pyrazoline (see the results of van Auken and Rinehart given in Table I); however, in general it should now be possible to predict the usefulness of the pyrazoline method for synthesizing cyclopropane derivatives with a

For personal use only.

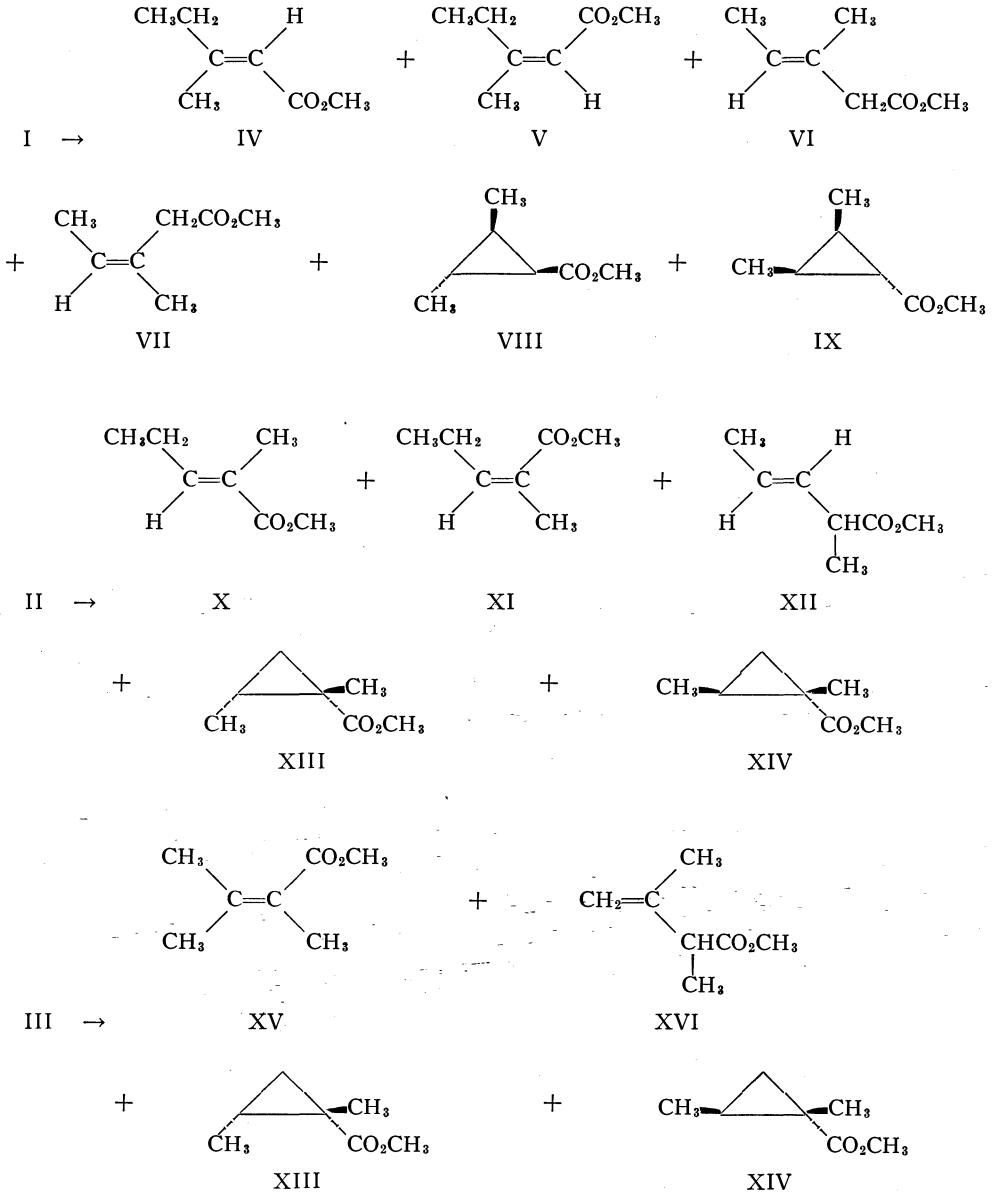

CHART I

variety of alkyl substituents. A number of examples in the literature (9–14) fit in well with the general trends found in this work.

Vapor phase pyrolysis of I and II yielded a higher proportion of cyclopropane derivative than was obtained in the liquid phase, proving again that this is a useful modification of the pyrolysis procedure. It has been found that 20-mesh firebrick makes an excellent column packing for the pyrolysis of Δ^2-pyrazolines in the vapor phase. Presumably there are sufficient acid sites on the firebrick to catalyze the tautomerism of the Δ^2-pyrazoline into the pyrolizable Δ^1-form.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Most boiling points were determined by the micro inverted capillary method. Infrared spectra were measured with a Perkin–Elmer Model 21 spectrometer using sodium chloride optics. The n.m.r. spectra were recorded on a 40 Mc/s Varian spectrophotometer with field stabilizer VK 3506, and the methylene chloride used as an external standard was observed to have a value of 4.60 τ. The vapor chromatography unit was an Aerograph A-100-C.

4,5-Dimethyl-3-carbomethoxy-Δ^2-pyrazoline

Methyl crotonate was reacted with diazoethane in ether prepared from ethyl nitrosourea. After distillation of the ether the product was distilled to give a yellow solid, m.p. 46–47° and b.p. 101–102° at 1.8 mm (lit. (15) b.p. 139–140 at 14 mm). The infrared spectrum showed bands at 3400, 1710, and 1557 cm^{-1} characteristic of a 3-carbomethoxy-Δ^2-pyrazoline (1, 16).

Pyrolysis of 4,5-Dimethyl-3-carbomethoxy-Δ^2-pyrazoline

Pyrolyses in the liquid and vapor phase were carried out as reported earlier except that 20-mesh firebrick was used as the packing material in the vapor phase pyrolysis apparatus. The product compositions are reported in Table I. The product from the liquid phase pyrolysis (12 g, b.p. 140–165°, from 17 g of pyrazoline) was separated into five components using a dinonyl phthalate column, and one of these fractions was further separated into two components with a Ucon Polar column. The components were identified as indicated below, where boiling point, refractive index, retention time in the vapor chromatogram using a 10-ft dinonyl phthalate column of 0.25-in. diameter at 116° with a helium flow rate of 67 cc/min, and infrared bands for 5% solutions in chloroform are given.

Methyl *trans*-3-methyl-2-pentenoate: b.p. 160°, n_D^{25} 1.4424 (lit. (4) b.p. 79° at 50 mm, n_D^{20} 1.4446), 44.8 minutes, 1702 and 1647 cm^{-1}. The n.m.r. spectrum (0.5 ml per ml of carbon tetrachloride) showed vinyl hydrogen signals at 4.55 τ (singlet), ester methyl hydrogens at 6.36 τ (singlet), methylene hydrogens at 7.73 τ (quartet with $J \simeq 7$ c.p.s.), and alkyl methyl hydrogens at 7.70 τ (singlet) and 8.66 τ (triplet with $J \simeq 7$ c.p.s.).

Methyl *cis*-3-methyl-2-pentenoate: b.p. 151°, n_D^{23} 1.4409 (lit. (4) b.p. 74° at 50 mm, n_D^{20} 1.4420), 36.8 minutes (67.2 minutes on a 10-ft Ucon Polar column at 112° and a flow rate of 45 cc/min), 1702 and 1645 cm^{-1}. The n.m.r. spectrum (0.30 ml per ml of carbon tetrachloride) showed a vinyl hydrogen signal at 4.51 τ (singlet) and peaks for the ester methyl hydrogens at 6.46 τ (singlet), methylene hydrogens at 7.45 τ (quartet with $J \simeq 6.9$ c,p.s.), and alkyl methyl hydrogens at 8.22 τ (singlet) and 8.19 τ (triplet with $J \simeq 7$ c.p.s.).

Methyl *cis*-3-methyl-3-pentenoate: b.p. 148°, n_D^{20} 1.4321, 29.6 minutes, 1725 and 1665 (weak) cm^{-1}. Calc. for $C_7H_{12}O_2$: C, 65.49; H, 9.45. Found: C, 65.65; H, 9.41. The n.m.r. spectrum (0.33 ml per ml of carbon tetrachloride) showed vinyl hydrogen signals at 4.70 τ (multiplet), ester methyl hydrogens at 6.40 τ (singlet), methylene hydrogens at 7.07 τ (singlet), and methyl hydrogens at 8.29 τ (singlet) and 8.43 τ (doublet with $J \simeq 6.8$ c.p.s.). This ester was assigned the cis structure on the basis of the synthesis of the trans ester described below.

Methyl *trans*-3-methyl-3-pentenoate: b.p. 150°, n_D^{21} 1.4323, (lit. (17) b.p. 74° at 50 mm, n_D^{20} 1.4306), 33.6 minutes, 1725 and 1665 (weak) cm^{-1}. Calc. for $C_7H_{12}O_2$: C, 65.49; H, 9.45. Found: C, 65.43; H, 9.51. The n.m.r. spectrum (0.50 ml per ml of carbon tetrachloride) showed vinyl hydrogen signals at 4.67 τ (multiplet), ester methyl hydrogens at 6.41 τ (singlet), methylene hydrogens at 7.14 τ (singlet), and methyl hydrogens at 8.33 τ (singlet) and 8.42 τ (doublet with $J \simeq 7$ c.p.s.). The trans geometry of this ester was assigned on the basis of its synthesis from tiglic acid (see below).

Methyl *trans*-1,2-cyclopropane-3-carboxylate: b.p. 143°, n_D^{25} 1.4241 (lit. (3) b.p. 40–50 at 20 mm, n_D^{20}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1.4252), 26.0 minutes; infrared bands found at 1365, 1302, 1165, 1095, and 1055 cm^{-1} are not found in the spectra of the other cyclopropane isomer (lit. (18) reports bands at 1363, 1302, 1164, 1093, and 1055 cm^{-1} for this isomer). The n.m.r. spectrum (0.50 ml per ml of carbon tetrachloride) showed signals assigned to the ester methyl hydrogens at 6.49 τ (singlet) and the remaining hydrogens in a group at 9.05 τ.

Methyl *cis*-1,2-dimethyl-3-*trans*-carboxylate: b.p. 150° at 759 mm, n_D^{18} 1.4330 (lit. (3) n_D^{20} 1.4306), 36.8 minutes (70.8 minutes on a 10-ft Ucon Polar column at 112° and a flow rate of 45 cc/min); infrared bands found at 1325, 1125, 1085, and 1040 cm^{-1} are not found in the spectra of the other cyclopropane isomer (lit. (18) reports bands at 1322, 1128, 1089, and 1040 cm^{-1} for this isomer and 1378, 1158, 1115, 1093, and 1026 cm^{-1} for methyl *cis*-1,2-dimethyl-3-*cis*-carboxylate). The n.m.r. spectrum (0.20 ml per ml of carbon tetrachloride) showed signals assigned to the ester methyl hydrogens at 6.42 τ (singlet) and the remaining hydrogens in a group at 8.9 τ.

Methyl trans-3-Methyl-3-pentenoate

Tiglic acid (30 g, 0.3 mole) in carbon tetrachloride was brominated with 48 g of bromine (0.3 mole) by the procedure of Buckles and Mock (19) to give 63 g (83%) of 2,3-dibromo-2-methylbutanoic acid, m.p. 85–88° (lit. (19) m.p. 82–88°).

2,3-Dibromo-2-methylbutanoyl chloride (62 g, 86%), b.p. 73–74° at 14 mm, was prepared by refluxing 39 g of thionyl chloride with 63 g of the acid. Calc. for $C_5H_7OBr_2Cl$: C, 21.54; H, 2.51. Found: C, 21.69; H, 2.38.

Methyl 2,3-dibromo-3-methylpentanoate.—2,3-Dibromo-2-methylbutanoyl chloride (36 g, 0.12 mole) was reacted with an ether solution containing 13 g of diazomethane at 0–5°. The solution was let stand for 12 hours and the ether distilled. Anhydrous methanol (200 ml) was added to the oily diazoketone and the solution stirred and warmed on a water bath. Silver oxide (50 g as a slurry in anhydrous methanol) was added in portions to the hot methanolic solution. After it was cooled the methanol solution was decanted from the silver residues, filtered through alumina to remove colloidal silver and silver salts, and distilled to give 13.6 g of a product, b.p. 62–64° at 2 mm. The n.m.r. spectra, the analysis, and the debromination results showed this to be a mixture of brominated esters. Calc. for $C_7H_{12}O_2Br_2$: C, 29.18; H, 4.20. Found: C, 36.39; H, 5.10. Further purification by V.P.C. was found not practical.

Methyl trans-3-methyl-3-pentenoate.—A mixture of 7 g of the brominated esters, 10 g of 20-mesh zinc, and 30 ml of water was stirred in the dark according to the procedure of Schubert *et al.* (5) for 20 hours. The product was extracted with ether and filtered. The ether solution was washed with water, dried over sodium sulphate, filtered, and distilled to give 2 g of product, b.p. 38–49° at 40 mm. Vapor chromatography of the product showed the presence of three components in the ratio of 11:1:10. The first component was identified as methyl tiglate, n_D^{28} 1.4346, b.p. 141° (lit. (20) b.p. 139.4–139.6°, n_D^{20} 1.4370). The infrared spectrum was identical with that of an authentic sample. The second component was shown by its V.P.C. retention time and infrared spectrum to be identical with the lower-boiling methyl 3-methyl-3-pentenoate. The third component, n_D^{25} 1.4308, b.p. 152°, had a V.P.C. retention time and infrared spectrum identical with those of the higher-boiling methyl 3-methyl-3-pentenoate. Because of the absence of methyl angelate in the debromination and the known stereochemical requirements of the debromination reaction (5), the higher-boiling isomer of methyl 3-methyl-3-pentenoate was assigned the trans structure. The cis and trans esters show some differences in the fingerprint region of their infrared spectra. Particularly, there is a band at 1380 cm^{-1} for the trans ester which is much stronger than any band near this region for the cis ester. For the trans ester below 1500 cm^{-1} bands are found at 1433 (s), 1510 (w), 1380 (m), 1330 (m), 1296 (m), 1255 (s), 1220 (m), 1188 (m), 1150 (s), 1112 (vw), 1090 (w), 1035 (m), 1002 (m), and 957 (w) cm^{-1} and for the cis ester at 1432 (s), 1420 (sh), 1372 (w), 1350 (vw), 1315 (m), 1285 (m), 1245 (s), 1192 (m), 1150 (s), 1175 (m), 1035 (w), and 1005 (m).

Methyl 3-Methyl-2- and -3-pentenoates from Methyl 3-Methyl-3-hydroxypentanoate

Methyl 3-methyl-3-hydroxypentanoate (28 g, 0.19 mole) prepared by the procedure of Kuhn *et al.* (21) was refluxed in 125 ml of benzene with 3 g of phosphorus pentoxide for 5 hours (6). Distillation gave 17 g (70%) of a methyl 3-methylpentenoate mixture, b.p. 145–160°.

Separation of the mixture by vapor chromatography on a dinonyl phthalate column gave:

Methyl *trans*-3-methyl-2-pentenoate: b.p. 160°, n_D^{25} 1.4425, 19%
Methyl *cis*-3-methyl-2-pentenoate: b.p. 150°, n_D^{17} 1.4431, 9%
Methyl *cis*-3-methyl-3-pentenoate: b.p. 148°, n_D^{25} 1.4307, 26%
Methyl *trans*-3-methyl-3-pentenoate: b.p. 150°, n_D^{25} 1.4302, 38%

Methyl 3-ethyl-3-butenoate (?): b.p. 146°, n_D^{23} 1.4261. Infrared bands at 1725, 1650, 1420, and 897 cm^{-1} indicate this to be a β,γ-unsaturated ester with a terminal double bond; however, insufficient sample was obtained for analysis.

3,5-Dimethyl-3-carbomethoxy-Δ^1-pyrazoline

Methyl methacrylate was reacted with diazoethane in ether and the product distilled to give a colorless liquid, b.p. 54° at 0.5 mm. Calc. for $C_7H_{12}N_2O_2$: C, 53.83; H, 7.74; N, 17.94. Found: C, 53.75; H, 7.91;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

N, 18.11. The n.m.r. spectrum showed this to be a mixture of the two possible isomers (C_5-methyl cis or trans to the carbomethoxy group) with peaks at 4.28, 4.34 τ (ester methyl), 8.53, 8.51 τ (doublet for C_5-methyl), 8.64, 8.39 τ (C_3-methyl), and 5.45 τ (multiplet), 7.69 τ (multiplet), and 9.26 τ (multiplet) for the various ring protons. The proportion of these isomers was 3:2 as determined by integration of the peaks. Where two signals are reported the larger signal is given first. It is felt that this data is not sufficient to permit designation of the isomer present in the larger amount as cis or trans.

Pyrolysis of 3,5-Dimethyl-3-carbomethoxy Δ^1-pyrazoline

Pyrolysis in the liquid phase was vigorous at 120°. In the gas phase the pyrolysis was carried out using a packing of glass beads and a pressure of 5 mm (1). The product compositions are reported in Table I. The product from the liquid phase pyrolysis (8 g from 11 g of pyrazoline) was separated into five components using a dinonyl phthalate column. The components were identified or partially identified as indicated below, where boiling point, refractive index, retention time in the vapor chromatogram using a 10-ft dinonyl phthalate column of 0.25-in. diameter at 98° with a helium flow rate of 55 cc/min, and infrared bands for 5% solutions in chloroform are given.

Methyl *trans*(?)-2-methyl-2-pentenoate: b.p. 156°, n_D^{24} 1.4394, 58 minutes, 1700 and 1645 cm^{-1}. Calc. for $C_7H_{12}O_2$: C, 65.49; H, 9.45. Found: C, 65.27; H, 9.45. The n.m.r. spectrum (0.05 ml per ml of carbon tetrachloride) had a triplet signal in the olefin region at 3.48 τ with $J \simeq 7.5$ c.p.s. Other peaks were due to ester methyl hydrogens at 6.41 τ (singlet), methylene hydrogens at 7.94 τ (multiplet), and alkyl methyl hydrogens at 8.26 τ (singlet) and 9.04 τ (triplet with $J \simeq 7.2$ c.p.s.).

Methyl *cis*(?)-2-methyl-2-pentenoate: b.p. 143°, n_D^{24} 1.4351, 36 minutes, 1705 and 1641 cm^{-1}. Calc. for $C_7H_{12}O_2$: C, 65.49; H, 9.45. Found: C, 65.23; H, 9.46.

In addition there was a minor component at 31.6 minutes with b.p. 139°, n_D^{23} 1.4229, and infrared bands at 1725 and 967 cm^{-1}. The position of the carbonyl band and the absence of carbon–carbon double-bond stretch indicate that this is a symmetric non-conjugated unsaturated ester. The presence of the characteristic band at 967 cm^{-1} for trans olefins suggests that this is methyl *trans*-2-methyl-3-pentenoate.

Methyl *cis*-1,2-dimethyl cyclopropane-1-carboxylate: b.p. 145°, n_D^{20} 1.4314 (lit. (7) n_D^{25} 1.4289), 39.6 minutes, 1720 cm^{-1}. The infrared and n.m.r. spectra were identical with those obtained by Rinehart and van Auken (8).

Methyl *trans*-1,2-dimethylcyclopropane-1-carboxylate: b.p. 136°, n_D^{27} 1.4220 (lit. (7) n_D^{25} 1.4218), 26.4 minutes, 1720 cm^{-1}. The infrared and n.m.r. spectra were identical with those obtained by Rinehart and van Auken (8).

ACKNOWLEDGMENTS

The authors gratefully appreciate the support received for this work from the National Research Council of Canada and from the President's Committee on Research of the University of British Columbia.

Thanks are also extended to Mrs. M. Zell for determining the infrared spectra and to Mrs. A. Aldridge for carrying out some of the microanalyses.

THE CHEMILUMINESCENT REACTION OF ACTIVE NITROGEN WITH THALLOUS HALIDES[1]

L. F. PHILLIPS
Chemistry Department, University of Canterbury, Christchurch, New Zealand
Received October 22, 1962

ABSTRACT

Energy transfer from active nitrogen to gaseous thallous halides leads to dissociation of the halide molecules with simultaneous production of excited thallium atoms. Thallium emission lines have been observed to correspond to the transfer of up to 221 kcal/mole to the TlX molecule. The process is kinetically third order but the high overall efficiency of light emission and thallous halide destruction requires a mechanism which involves a bimolecular reaction of TlX with an excited N_2 formed during N-atom recombination.

INTRODUCTION

Photodissociation of gaseous metallic iodides by ultraviolet radiation has been used as a means of producing excited metal atoms for quenching measurements (1, 2). The present work is concerned with the analogous process in which energy from the recombination of atomic nitrogen takes the place of the ultraviolet radiation. Such a process may be visualized as occurring either through a single termolecular step,

$$TlX + N + N \rightarrow Tl^* + N_2 + X, \qquad [1]$$

or by a bimolecular reaction of TlX with an excited nitrogen molecule formed during N-atom recombination,

$$N + N + M \rightarrow N_2^* + M \qquad [2]$$

$$N_2^* + TlX \rightarrow N_2 + Tl^* + X. \qquad [3]$$

Here M signifies a third body, which will usually be N_2 or the wall of the reaction vessel.

Both of these mechanisms lead to overall third-order kinetics, provided the N_2^* molecule is not too long lived, but at low concentrations of TlX the second mechanism can lead to a faster rate than the first because of the high concentration of M relative to that of TlX. Reaction [1] cannot have a rate constant greater than about 10^{-31} cm^6 molecule^{-2}sec^{-1} (3), and, because the present observations will be shown to require a much higher value than this for the third-order rate constant, the first mechanism may be excluded. An alternative scheme, involving the formation of an intermediate NTlX complex, is regarded as equivalent to equation [1] in the present discussion.

In the case of the second mechanism the excited states of N_2 are sufficiently well known for it to be possible, in principle, to decide which excited state is taking part in the reaction by observing which energy levels of thallium are able to be produced from halides of various dissociation energies. The relevant dissociation energies of thallous halides (4), thallium energy levels (5), and excited states of N_2 (6, 7, 8) are summarized in Table I.

EXPERIMENTAL

A diagram of the reaction vessel used for these experiments is given in Fig. 1. It consists of a 25-cm length of 34 mm o.d. quartz tubing with three quartz windows at one end. One window looks along the length of

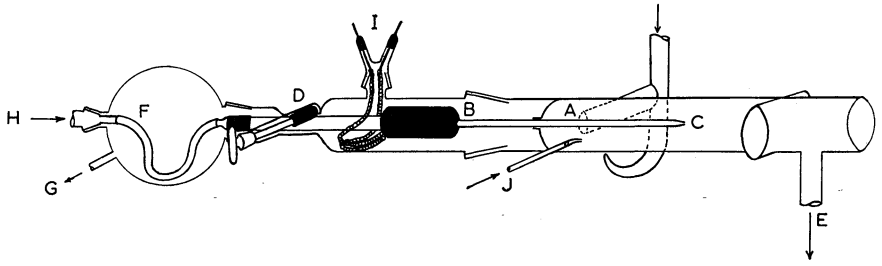

FIG. 1. Reaction vessel, heating jacket not shown. A, active nitrogen inlet; B, thallous halide oven; C, moveable inlet jet; D, rubber-covered rod, the rotation of which causes the thallous halide oven and inlet jet to move along the axis of the reaction tube; E, main pumping lead; F, flexible plastic tubing; G, subsidiary pumping lead; H, argon inlet; I, electrical leads for oven; J, fixed reactant inlet. Not drawn exactly to scale.

the tube and has been used for photographing spectra. Two parallel windows enable observations to be made at right angles to the gas stream. The tube is heated electrically to 400° C. Partially dissociated nitrogen from a microwave discharge passes a light trap and enters the reaction vessel at A. Thallous halide is carried by a slow stream of argon from the independently heated oven B through a 3-mm quartz tube to the inlet jet C, which can be moved along the axis of the reaction tube by rotating the rubber-covered rod D. A fixed jet J is provided for the addition of a third reactant such as nitric oxide. Reaction products are pumped away at E. Temperatures are measured by means of thermocouples in the heating jacket, gas stream, and thallous halide oven. Gas flows are controlled by needle valves and measured with capillary flowmeters.

Nitrogen-atom concentrations, as determined by visual titration with nitric oxide (9), vary from 0.02 to 0.05 mm for N_2 pressures of 1.5 to 6 mm Hg. The thallous halide concentration is calculated from the vapor pressure (10) at the known oven temperature, the argon flow, and the pressure drop across the inlet jet, and is generally about 10^{-4} mm Hg.

Emission spectra are photographed using a Hilger medium quartz spectrograph with Ilford Astra III plates. Exposures usually last 8 hours. The intensity of the thallium green line is measured using a 5350 Å interference filter and a 1P28 photomultiplier connected through a cathode follower to a 0–250 μamp meter.

Nitrogen is purified by being passed over hot, activated copper wool and through a liquid nitrogen trap. Nitric oxide is purified by distillation from KOH pellets at −80° C. Commercial 99.9% argon is used. Thallous chloride, bromide, and iodide are precipitated from hot solutions of recrystallized thallous sulphate by addition of the "Analar" brand potassium halides. Thallous fluoride is prepared by reacting excess thallium with "Analar" hydrofluoric acid in a platinum vessel, solid TlF being precipitated from the filtered solution by addition of ethanol.

Solid deposits are removed from the walls of the reaction vessel periodically by rinsing with 10% hydrofluoric acid.

RESULTS

With the discharge activated at low thallous halide flows the tip of the mobile jet was followed by an approximately spherical, bright green reaction flame. The yellow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

nitrogen afterglow persisted in the region which followed the flame, so it is apparent that under these conditions thallium itself is not readily excited by active nitrogen. This is in contrast to previous experiments in which the metal was present in the discharge (11). At high thallous halide flows the green flame filled the reaction vessel.

In the cool part of the apparatus immediately beyond the reaction vessel a dark, lustrous solid was deposited. Microanalysis (carried out by Dr. A. D. Campbell of Otago University) of the solid formed during the thallous iodide reaction showed that 30.64% of iodine and 2.00% of nitrogen were present, corresponding to the formula $Tl_{3.0}I_{2.2}N_{1.3}$. A similar product from the reaction of active nitrogen with germane (12) consisted of amorphous Ge_2N_3. However, no nitride of thallium is known, and in the present case an X-ray powder photograph[2] indicated that the solid contained crystalline thallous halide and thallium metal. It seems likely, therefore, that the nitrogen in the material may be held physically rather than chemically.

In Fig. 2 is shown the dependence of the intensity of the 5350 Å line on the concentrations of thallous halide and atomic nitrogen. The results for thallous iodide (in Fig.

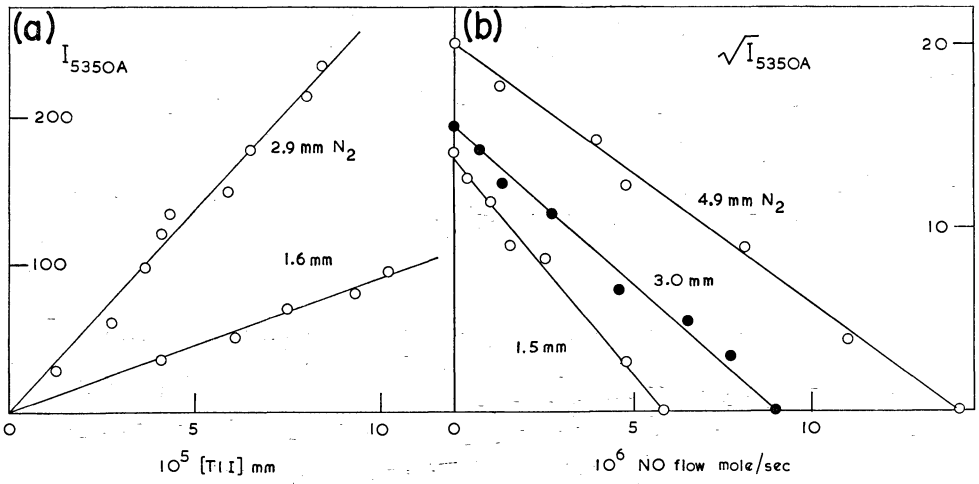

FIG. 2. Dependence of intensity of emission at 5350 Å on (*a*) thallous iodide concentration, and (*b*) N-atom concentration.

2*a*) show that the intensity is proportional to the first power of the halide concentration. Figure 2*b* shows the effect of reducing the N-atom concentration by adding various amounts of nitric oxide before the TlI inlet. Nitric oxide removes atomic nitrogen quantitatively (13) by reaction [4]. Graphs of the square root of intensity versus NO flow rate

$$N + NO \rightarrow N_2 + O \qquad [4]$$

are linear, showing that the intensity is proportional to the square of the N-atom concentration. Points for zero intensity are the NO flows which were found, in absence of TlI, to correspond exactly to removal of all N-atoms by reaction [4]. Preliminary experiments showed that no luminescent reaction occurred with thallous iodide and atomic oxygen (or hydrogen). During the addition of nitric oxide the photomultiplier was arranged to observe the reaction flame at a point sufficiently close to the TlI inlet for the results to be unaffected by variation in the amount of TlI consumed before the point of observation.

In order to determine the efficiency of the light-emitting process, the intensity at 400° C of the 5350 Å line at known TlI and N-atom concentrations was compared with the intensity at room temperature of the NO–O continuum (14) obtained by the addition of a known excess of nitric oxide to a stream of discharged nitrogen. The same filter was used for both intensity measurements. The fraction of the continuum passed by the filter was calculated from the wavelength variation of intensity in the continuum (15) and the transmission curve of the filter. The rate constant for emission of the continuum is 3×10^{-17} quanta $cm^3 molecule^{-1} sec^{-1}$ (16). The result obtained, expressed as

$$d[Tl(7.^2S_{\frac{1}{2}})]/dt = k_1[TlI][N]^2 - 7.2\times10^7[Tl(7.^2S_{\frac{1}{2}})], \quad [5]$$

was $k_1 = 1\times10^{-29}\ cm^6 molecule^{-2} sec^{-1}$. This is probably correct to within a factor of two. Allowance has been made for radiation emitted at 3776 Å (17). Quenching of $Tl(7.^2S_{\frac{1}{2}})$ is negligible at the pressures used in this work (1). At the steady state the left-hand side of equation [5] is zero. The total rate of production of excited thallium atoms will be several times greater than that given by the above value of k_1 because emission from $6.^2D_{1\frac{1}{2}}$, $6.^2D_{2\frac{1}{2}}$, and $8.^2S_{\frac{1}{2}}$ levels also occurs. Radiative transitions among these levels are forbidden.

A second estimate of k_1 is based on a measurement of the rate of consumption of TlI in the reaction, as indicated by the decrease of intensity of the reaction flame with distance from the TlI inlet. Since the N-atom concentration is invariably much greater than that of TlI it should be a good approximation to treat the intensity decay as first order, with a rate constant equal to $k_1[N]^2$. Logarithmic plots of intensity versus time from the TlI inlet are in fact linear, as is shown in Fig. 3. This linearity indicates that the species which reacts with TlI is either present in excess or is being produced continuously during the reaction. There is no obvious dependence of the slopes in Fig. 3 on N-atom or N_2 concentration. This is attributed to differences in the nature of the wall surface of the reaction vessel during the different sets of measurements. From a typical result of Fig. 3, namely that the slope of the log plot equals -28 for an N-atom concentration of 0.036 mm, the value of k_1 is $4\times10^{-29}\ cm^6 molecule^{-2} sec^{-1}$, in good agreement with the result of the intensity measurement. These values are too high for a termolecular reaction, and further discussion must be in terms of a bimolecular reaction of TlX with excited N_2.

Emission spectra of nitrogen afterglows and of the flames with thallium halides were photographed in order to determine how much energy was available to the excited species which reacted with the halide. If a number of different excited states are able to take part in the reaction then this approach will yield information only about the most energetic of them. Previous work in this field has shown that reactions with excited molecules in active nitrogen are likely to be quite specific with regard to the nature of the excited species involved (18). It will be assumed for the present that only one state of N_2 is important in the reaction with thallous halide.

The ordinary nitrogen afterglow consists largely of N_2 first positive system bands, arising from the $B(^3\Pi_g)$ level, with weak second positive system bands arising from the $C(^3\Pi_u)$ level (7). It was observed that the $(0,v'')$ progression of the latter system appeared strongly when the nitrogen was moist. In addition it was possible, with dry nitrogen, to produce the very energetic "pink afterglow" inside the reaction vessel, with enhanced first positive system emission and intense bands of N_2^+ (19).

All of the reaction flames showed the same features, namely the quenching of nitrogen afterglow emission and the appearance of strong lines of thallium at 5350, 3776, 3530,

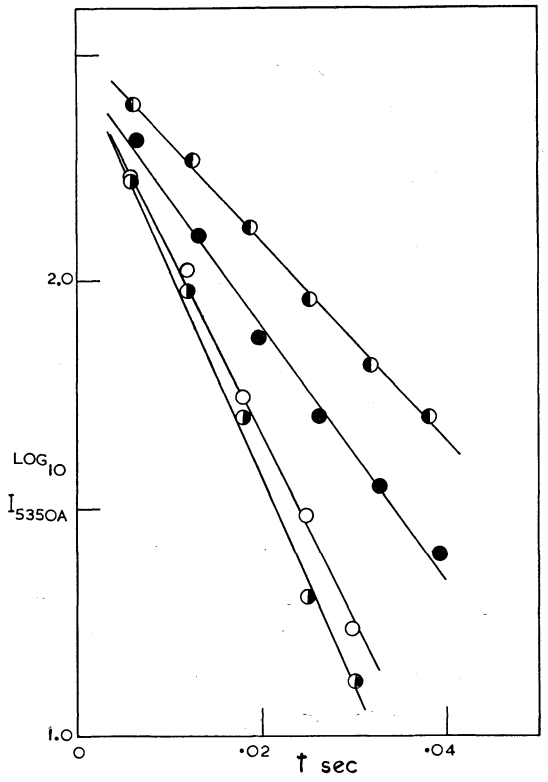

FIG. 3. Exponential decay of intensity of the 5350 Å line with time from the thallous iodide inlet. Points: ◑, 4.8 mm N_2, 0.045 mm N; ○, 2.0 mm N_2, 0.30 mm N; ●, 2.8 mm N_2, 0.036 mm N; ◐, 4.3 mm N_2, 0.052 mm N.

and 3519 Å, with a weaker line at 3230 Å. The resonance lines at 2765 and 2580 Å were too faint to be detected. With the "pink afterglow" the thallium emission was much more intense than usual, but no new lines appeared. Precise intensity comparisons among the various lines await the arrival of a photomultiplier carriage for the spectrograph.

Winkler and co-workers (18) have found that ammonia appears to react selectively with the $A(^3\Sigma_u^+)$ state of nitrogen, so that if the A state were taking part in the present reaction the addition of ammonia should bring about a reduction in the intensity of the thallium emission. In fact the addition of ammonia has been found to produce an increase in intensity for all of the emission lines, an effect which probably results from its action as a wall poison (18).

DISCUSSION

Inspection of Table I reveals that in order to produce thallium in the $8.^2S_{\frac{1}{2}}$ level from thallous fluoride the excited N_2^* molecule has to be able to provide at least 221 kcal/mole of energy. This eliminates the $A(^3\Sigma_u^+)$ state from consideration. Kenty (8) has presented evidence for the presence in discharged nitrogen of a metastable $^3\Delta_u$ state of N_2 having an energy of between 180 and 200 kcal/mole. This amount of energy would place it above the $B^3\Pi_g$ state and it would not be metastable, so in Table I the energy of the zeroth vibrational level of this state has been listed as less than 171 kcal. Only

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the lowest vibrational levels would be sufficiently long lived to react with TlX, and these levels would not possess the 221 kcal/mole that is necessary to explain the observed reaction. Both the $B(^3\Pi_g)$ and the $^5\Sigma_g^+$ states are capable of providing this energy, the former because many molecules are produced in this state with 10, 11, or 12 vibrational quanta as a result of collision-induced radiationless transitions from the $^5\Sigma_g^+$ state (20, 7). Reaction of TlX with either of these states would explain the observed quenching of the afterglow in the region of the reaction flame. However, in the case of the B state the transfer of energy to the thallium halide would have to compete with an allowed radiative transition to the A state, whereas with the $^5\Sigma_g^+$ state the competition would be between reaction with TlX and two other collision-induced processes, namely dissociation to ground-state N-atoms and non-radiative transition to the B or lower state. The best value for the radiative lifetime of the B state (in the zeroth vibrational level) is 1.2×10^{-6} sec (21), so that at the halide concentrations used here the emission of radiation from the B state should have been at least two orders of magnitude more probable than collision with TlX. Wright and Winkler (22) have recently obtained evidence that the radiative lifetime of the $^5\Sigma_g^+$ state is about 0.02 sec. These considerations favor the choice of the $^5\Sigma_g^+$ state, and on this basis the mechanism of the reaction is:

$$N + N + M \xrightarrow{k_6} N_2(^5\Sigma_g^+) + M \quad [6]$$

$$N_2(^5\Sigma_g^+) + M' \xrightarrow{k_7} N + N + M' \quad [7]$$

$$N_2(^5\Sigma_g^+) + M'' \xrightarrow{k_8} N_2 + M'' \quad [8]$$

$$N_2(^5\Sigma_g^+) + TlX \xrightarrow{k_9} N_2 + Tl^* + X; \quad [9]$$

whence

$$-d[TlX]/dt = k_6.k_9.[M][N]^2[TlX]/(k_7[M']+k_8[M'']) \quad [10]$$

at low TlX concentrations. When quenching of excited thallium is ignored this is equal to

$$d[Tl^*]/dt + \sum_\lambda A_\lambda[Tl^*], \quad [11]$$

where A_λ is the Einstein transition probability for emission of radiation at wavelength λ, and $d(Tl^*)/dt$ is zero in the steady state. From equations [10] and [11] and the value found for k_1, it follows that if the above mechanism is correct,

$$k_9[M] > 10^2(k_7[M']+k_8[M'']), \quad [12]$$

since k^9 is a normal termolecular rate constant. This implies that the kinetic lifetime of a $^5\Sigma_g^+$ molecule in nitrogen at 2 mm pressure is greater than 10^{-5} sec.

In these expressions the effects of processes occurring on the walls are included in the various M terms. It is to be expected that variation in the nature of the wall surface, as a result of a deposition of solid material consisting largely of metallic thallium, will not affect each term to the same extent, and this expectation is borne out by the unsystematic variation of the slopes of the lines in Fig. 3.

THE ALUMINUM REDUCTION OF MAGNESIUM COMPOUNDS

III. THE VAPOR PRESSURE OF MAGNESIUM OVER THE SYSTEM Al–Mg_2SiO_4 (OLIVINE)

K. GRJOTHEIM, O. HERSTAD, R. SKARBÖ, AND J. M. TOGURI[1]

Institute of Inorganic Chemistry, The Technical University of Norway, Trondheim, Norway

Received July 26, 1962

ABSTRACT

The equilibrium vapor pressure of magnesium over the reaction between olivine (Mg_2SiO_4) and aluminum was measured by means of the transportation method in the temperature range 943–1150° C.

It was concluded that olivine and aluminum form an unstable system which reacts completely according to the equation

$$3Mg_2SiO_{4(s)} + 4Al_{(l)} \rightarrow 2MgAl_2O_{4(s)} + 4MgO_{(s)} + 3Si_{(s)}.$$

However, in the presence of excess aluminum, an Al–Si alloy results. This alloy in turn reacts with magnesium oxide according to the equilibrium

$$4MgO_{(s)} + 2AlSi_{(l)} = MgAl_2O_{4(s)} + 3Mg_{(g)} + 2Si_{(s)}.$$

The vapor pressure of magnesium over this equilibrium system was found to obey the equation

$$\log P_{\text{mm of Hg}} = -\frac{7643}{T} + 7.06.$$

The aluminum activity of the Al–Si alloy along the liquidus line of the silicon side of the phase diagram has been calculated. Within the temperature range 943–1150° C this activity can be represented by the equation

$$\log a_{Al} = \frac{2455}{T} - 2.40.$$

INTRODUCTION

In the present investigation, the reduction of olivine with aluminum was examined. The reactions involved in this system are between condensed states, with the formation of a gaseous phase. The equilibrium vapor pressure of magnesium was therefore determined and the end products of the reaction were identified to establish the reaction scheme.

EXPERIMENTAL

Preliminary experiments indicated that the vapor pressure of magnesium over olivine and aluminum was about 11 mm of Hg at 1000° C. The well-established transportation method was therefore employed. The apparatus and procedures adopted have been fully described previously (1).

Argon (99.94%) was used as a carrier gas. The impurities CO_2 and H_2O were removed by passing the gas through ascarite and dehydrite towers respectively.

The aluminum powder (99.4%) was obtained from Merck, Germany. The olivine was obtained from A/S Olivin (Norway), with the following analysis, in weight percent: 48.0% MgO, 40.0% SiO_2, 7–8% FeO, 0.2–0.3% Cr_2O_3, 0.2% NiO, 0.1% Al_2O_3, 0.1% MnO, and 1.0% H_2O.

Since the reaction between iron oxide and aluminum is exothermic, it is reasonable that the iron oxide is readily reduced to form an aluminum–iron alloy. However, when a few experiments were performed with synthetic forsterite instead of olivine, the equilibrium vapor pressure of magnesium was identical with that over olivine and aluminum. The content of iron in the olivine therefore appears to have negligible influence on the equilibrium.

The olivine powder (−100 mesh) was dried at 1000° C for 1 hour, then mixed with aluminum in the required mole ratio, and ground in a ball mill for 12 hours. Finally, the mixture was pressed into briquettes, 2.0 cm in diameter by 1.0 cm in height, at a pressure of 500 kg/cm², then broken into pieces of approximately 5-mm size. Each charge contained about 150 g of such broken briquettes.

RESULTS

(a) Vapor Pressure Measurements

The vapor pressure of magnesium was found to vary with the ratio of aluminum to olivine in the reaction mixture. Below a mole ratio of 4:3 (aluminum:olivine), no magnesium was obtained even at 1000° C. However, at a ratio of 2:1 and higher, the vapor pressure of magnesium was constant and a function of temperature only. Consequently, a ratio of 2:1 (aluminum:olivine) has been selected for the present investigation.

Below a temperature of 943° C consistent results could not be obtained, while above 1150° C the iron reaction tube was seriously attacked by the aluminum. The measurements were therefore confined within this temperature range.

The results of the vapor pressure measurements over olivine and aluminum are summarized in Table I. In Fig. 1 log P is plotted against the reciprocal of the absolute

TABLE I

Experimental vapor pressure of magnesium

T (°C)	P (mm of Hg)	T (°C)	P (mm of Hg)
943	6.01	1046	18.46
949	6.38	1100	30.95
953	6.67	1150	48.86
999	10.94		

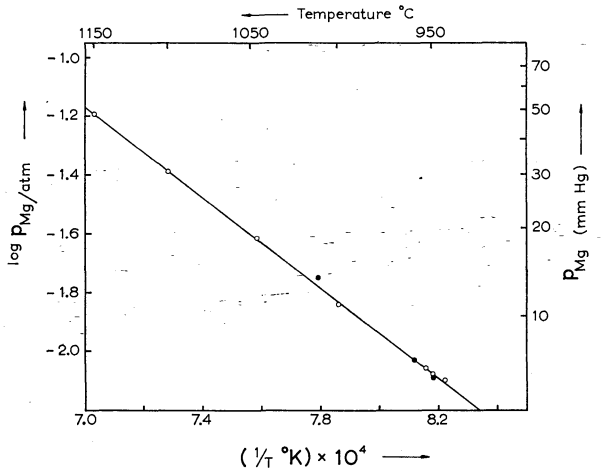

FIG. 1. Log(P_{atm}) of Mg versus $1/T$ (° K)×10^4: ○ Mg_2SiO_4 + Al; ● MgO + AlSiFe (Al: 0.38, Si: 0.54, Fe: 0.08 mole fraction).

temperature. The value of the equilibrium vapor pressure at each temperature is the result of a number of experiments at different flow rates. A least-square analysis of the results leads to a linear equation

$$\log P_{\text{mm of Hg}} = -\frac{7643}{T} + 7.06,$$

where P is pressure in mm of Hg and T is the absolute temperature.

(b) Analysis of the Reaction Products

X-Ray diffraction analysis was carried out on the solid residue. When the mole

ratio of aluminum to olivine was 4:3, large amounts of $MgAl_2O_4$, MgO, and Si and traces of metallic aluminum and olivine were present. As the aluminum was increased to the ratio 2:1, $MgAl_2O_4$, MgO, and Al–Si alloy were the only phases present.

DISCUSSION

To account for the present observations, a number of reactions can be formulated. One possible reaction to consider is reaction [I].

$$Mg_2SiO_{4(s)} + 2Al_{(l)} = MgAl_2O_{4(s)} + Si_{(s)} + Mg_{(g)} \quad [I]$$

From the available thermodynamic data (2), the ΔG^0 value at 1000° C is calculated to be −5 kcal. However, this would lead to an extremely large magnesium pressure and, further, would not explain the presence of magnesium oxide.

Reaction [II], on the other hand, will account for the observed magnesium oxide as well as the spinel and silicon.

$$Mg_2SiO_{4(s)} + 4/3\ Al_{(l)} = 2/3\ MgAl_2O_{4(s)} + 4/3\ MgO_{(s)} + Si_{(s)} \quad [II]$$

The value of the standard free energy change calculated for reaction [II] at 1000° C is −28 kcal. The reaction will therefore proceed completely to the right in agreement with the observed rapid reaction between olivine and aluminum. Reaction [II] also accounts for the absence of magnesium when the mole ratio Al:Mg_2SiO_4 is less than 4:3.

When larger amounts of aluminum than that required by reaction [II] are used, it appears reasonable that the excess aluminum forms an alloy with silicon. This alloy then reacts with magnesium oxide according to equation [III].

$$4MgO_{(s)} + 2AlSi_{(l)} = MgAl_2O_{4(s)} + 3Mg_{(g)} + 2Si_{(s)} \quad [III]$$

The measured vapor pressure of magnesium is therefore over the above equilibrium (equation [III]).

This was confirmed by determining the equilibrium between magnesium oxide and an aluminum–silicon alloy (Al: 0.38, Si: 0.54, Fe: 0.08). The measured vapor pressure of magnesium over this system, within the temperature range of the investigation, is identical with that over the present olivine and aluminum system. These results are shown in Fig. 1.

Using a mole ratio of Al:Mg_2SiO_4 of 2:1 should lead to an alloy containing Al:Si in a mole ratio 2:3. In the case of olivine the formed alloy also contains about 8 mole% iron, which together with silicon acts as a solute in aluminum. The phase diagram of the Al:Si:Fe system (3) shows that a liquid alloy of this composition is saturated with silicon at temperatures below 1200° C. On the basis that the measured pressure was found to be only a function of the temperature, the corresponding composition of the liquid alloy at each temperature is simply given by the liquidus line of the phase diagram.

At a constant temperature the phase diagram indicates that as the aluminum is consumed in reaction [III] silicon will also precipitate out from the liquid alloy in a manner such that the composition of the liquid alloy remains constant. It is therefore possible to use the Gibbs–Duhem relationship to calculate an approximate value for the activity of aluminum in the liquid alloy from the phase diagram combined with the knowledge of the heat of fusion of silicon.

However, a direct value of the activity of aluminum along the liquidus line on the silicon side of the phase diagram is obtainable, if the present vapor pressure measurements are combined with the previously reported magnesium pressure determinations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

over the equilibrium system MgO–Al (1). The activity of aluminum along the liquidus is given by the expression

$$a_{Al} = \left(\frac{P_1}{P_0}\right)^{3/2},$$

where P_1 is the equilibrium magnesium pressure over reaction [III], and P_0 the equilibrium magnesium pressure over the system MgO–Al.

Substituting for the values of P, the activity of aluminum along the liquidus in the temperature range 943–1150° C is given by

$$\log a_{Al} = \frac{2455}{T} - 2.40.$$

Thus, at 950° C, $N_{Al} = 0.55$ and $a_{Al} = 0.41$ and similarly at 1150° C, $N_{Al} = 0.36$ and $a_{Al} = 0.21$.

CONCLUSION

Olivine and aluminum form an unstable system which in the presence of excess aluminum reacts completely according to the equation

$$3Mg_2SiO_{4(s)} + 6Al_{(l)} \rightarrow 2MgAl_2O_{4(s)} + 4MgO_{(s)} + 2AlSi_{(l)} + Si_{(s)}.$$

The products of this reaction form the equilibrium system

$$4MgO_{(s)} + 2AlSi_{(l)} = MgAl_2O_{4(s)} + 3Mg_{(g)} + 2Si_{(s)}.$$

In the temperature range 943–1150° C the equilibrium vapor pressure of magnesium is given by the equation

$$\log P_{\text{mm of Hg}} = -\frac{7643}{T} + 7.06.$$

The present results also permit an evaluation of the aluminum activities in the liquid Al–Si alloy at compositions along the liquidus line on the silicon side of the phase diagram. Within the temperature range 943–1150° C the activity is given by

$$\log a_{Al} = \frac{2455}{T} - 2.40.$$

THE SYSTEM ALUMINUM–ANTIMONY–BISMUTH

A. N. CAMPBELL AND J. WINKLER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received September 12, 1962

ABSTRACT

A complete study, by the methods of thermal and isothermal analysis and of X-ray powder photography, has been made of the equilibrium diagram of the system aluminum–antimony–bismuth. The critical solution temperature and composition of the congruent liquids in the system aluminum–bismuth have been determined as have also the compositions of congruent liquids in the ternary system. The only compound occurring in this system is AlSb and the solid model is largely occupied by the equilibrium surface of this compound.

An explanation of the anomalous form of the solidus in the antimony–bismuth system is given.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The ternary alloy described by the title is based on the three binary systems aluminum–antimony, aluminum–bismuth, and antimony–bismuth. These systems are described briefly in what follows: complete bibliographies are given under References.

In the system aluminum–antimony, the compound AlSb, melting congruently at 1060° C, is formed. This compound decomposes rapidly in moist air, forming $Al(OH)_3$ and hydrogen. The two eutectics lie very close to pure aluminum and pure antimony respectively, and the solid solubilities of aluminum in antimony and of antimony in aluminum are exceedingly small. The crystal structure of AlSb is face-centered cubic. The literature on the system is extensive (1).

The system aluminum–bismuth forms two liquid layers at all temperatures hitherto investigated (2). Kempf and van Horn give the monotectic temperature (equilibrium of liquid 1, liquid 2, and solid aluminum) as 657.1°. The solubility of bismuth in solid aluminum does not exceed 0.2%. In view of the close chemical similarity of bismuth and antimony it is perhaps surprising that aluminum and bismuth do not form a compound analogous to AlSb, but there is no evidence for the existence of such a compound.

The equilibrium diagram of the system antimony–bismuth has presented difficulties (3). Alternative diagrams are shown in Fig. 1. There is no doubt that the liquidus is continuous

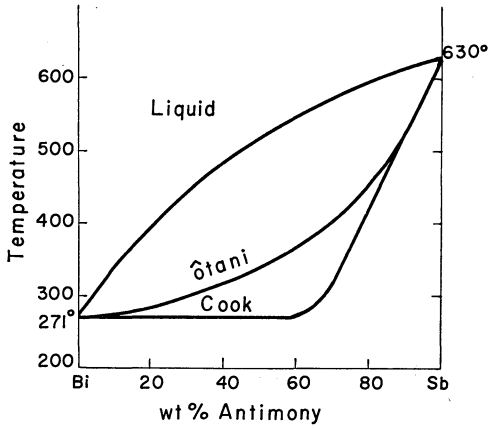

FIG. 1.

and therefore one would expect that the solidus would also be so. Thermal analysis, however, as applied for instance by Cook, results in a solidus as shown in Fig. 1, that is, unbroken but horizontal up to 60% antimony. Otani, however, using the method of electrical resistance, obtains a solidus which may be described as normal, i.e. temperature rises continuously with increasing antimony content. X-Ray analysis shows that the (solid) system antimony–bismuth consists of one phase only, corresponding to a complete series of solid solutions. An explanation is offered in the present work of the apparently abnormal form of the solidus, which results from thermal analysis on cooling.

The ternary system aluminum–antimony–bismuth has received little attention (4). Some preliminary work by Wright yielded nothing of importance. Some experiments were done by Kasten and these were offered, in an idealized form, as a practical illustration in a paper by Ritzau on the representation of quaternary systems.

EXPERIMENTAL

Aluminum was obtained from the Department of Mines and Technical Surveys, Mines Branch, Ottawa, and was stated to have the following composition: Al, 99.9945; Fe, 0.0019; Si, 0.0018; Cu, 0.0018%. The antimony used was Fisher Certified Reagent, the analysis being: Sb, 99.8; As, 0.0004; Cu, 0.001; Pb, 0.04; Fe, 0.0025%. The bismuth was also Fisher Certified Reagent with impurities given as: As, 0.0001; Cu, 0.002; Fe, 0.002; Pb, 0.005; Sb, 0.005%.

For the lower-temperature work, iron–constantan thermocouples were used, standardized by the freezing points of pure tin and pure cadmium. For the high-temperature work, thermocouples of platinum – platinum rhodium (10% Rh) were used. They were standardized from the freezing points of tin, cadmium, zinc, antimony, and silver, the last metal being allowed to freeze under a stream of hydrogen.

For thermal analysis, a Honeywell Brown single-pen recorder was used. The thermocouple was connected in parallel with the recorder and a vernier precision potentiometer, by means of a six-point switch, so that the temperatures corresponding to points of interest on the recorder diagram could be determined. The potentiometer had a sensitivity of ± 0.001 mv, corresponding to a temperature uncertainty of $\pm 0.05°$ C with the iron–constantan thermocouple and of $\pm 0.1°$ with the less sensitive platinum – platinum rhodium thermocouple. The accuracy of reading does not, of course, represent the accuracy of measurement, since all thermal analysis measurements suffer from supercooling effects, the amount of which it is difficult to estimate. Our results were, at least, all reproducible and we feel that they are accurate to within $\pm 1°$. A Hoskins combustion furnace (resistance type) was used for thermal and isothermal analysis but the alloys for investigation were prepared by melting appropriate weights of the pure metals, either under vacuum or in a current of argon, in an Ajax–Northrup high-frequency induction furnace.

For isothermal work, the resistance furnace was kept at constant temperature by means of a photocell, as described by Campbell and Kartzmark (5).

Thermal analysis was used only for the determination of the surface of primary crystallization of the compound AlSb. The alundum crucibles, in which the melts were contained, invariably ruptured on solidification of the alloy, because of the well-known expansion on solidification of bismuth and antimony. It was, therefore, not possible to repeat determinations with the identical alloy. As the compound AlSb forms from its components only very slowly at temperatures below the melting point of the compound, the procedure adopted was to add the compound itself to a mixture of aluminum and bismuth or of bismuth and antimony. For example, the composition of alloy No. 3, on the AlSb surface, was 20.0% Al, 50.0% Sb, and 30.0% Bi: the 80-g specimen therefore contained 16.0 g Al, 40.0 g Sb, and 24.0 g Bi. This composition was attained by using 48.9 g AlSb, 7.1 g Al, and 24.0 g Bi. The compound itself was readily prepared by melting stoichiometric quantities of aluminum and antimony in the induction furnace under argon atmosphere, at a temperature of 1200° C. It was necessary to keep the preparation in a vacuum desiccator, out of contact with moist air.

The determination of the eutectic temperatures, namely those of the eutectic Al–Bi, of the pseudobinary system AlSb–Bi, and of the ternary eutectic, was carried out by means of a differential thermocouple, similar to that described by Desch (6, p. 95). The reference body was pure bismuth, of the same weight as the alloy.

Because of the existence of (liquid) miscibility gaps in both ternary and in one of the binary systems, most of the work was isothermal. The alloys were kept at constant temperatures until equilibrium was attained, when both liquid layers were sampled for analysis. For work on the binary miscibility gap, equal volumes (78.4 g Bi, 21.6 g Al) were melted in the induction furnace: the stirring action of the eddy currents in this type of furnace is advantageous in attaining equilibrium. The melt was then transferred to the Hoskins furnace, already under control at the desired equilibrium temperature, and, after 1 hour, both layers were sampled by withdrawing through narrow (1.7-mm i.d.) alundum tubing. The variation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

temperature in the furnace was about ±1°. The method was used successfully up to 1180° but above this temperature the alundum tubing always broke. This temperature then, 1180°, represents the upper limit of our work, so that direct determinations of critical solution temperature and composition were not possible. The samples withdrawn as described above were weighed, dissolved in concentrated nitric acid, diluted to volume, and analyzed.

Essentially the same method was used for the investigation of congruent solutions in the ternary system, except that here more than one alloy had to be prepared, at each temperature, to obtain suitable variation in the tie lines.

Standard methods were used for the analysis of the alloys. In the bismuth-rich layer of the system aluminum–bismuth, the bismuth was determined by direct titration with EDTA (ethylenediaminetetracetic acid) using xylenol orange indicator (7). The aluminum was determined with 8-hydroxyquinoline. In the aluminum-rich layer only, bismuth was determined as BiOCl (8). Alloys containing all three metals were analyzed as follows: The antimony and bismuth were precipitated with H_2S and the antimony separated with ammonium sulphide. The bismuth was then titrated with EDTA and the antimony determined by titration with potassium bromate. Small quantities of aluminum were determined directly with 8-hydroxyquinoline but large amounts of aluminum were obtained by difference.

X-Ray powder photography was carried out in the usual way, using collodion rollings.

EXPERIMENTAL RESULTS

TABLE I

Equilibrium composition of the two congruent liquids in the system aluminum–bismuth

Temperature (° C)	Wt% Bi			Temperature (° C)	Wt% Bi		
	Liquid 1	Liquid 2	Mean		Liquid 1	Liquid 2	Mean
678	4.1	98.3	51.25	1018	25.1	96.1	60.6
720	5.8	97.9	51.85	1098	32.0	94.6	63.3
796	10.2	97.8	54.0	1183	41.2	89.7	65.45
903	16.8	97.2	57.0				

When the data of Table I are plotted, it appears that the miscibility gap will close at about 1300° C. The critical composition is then obtained by application of the law of the rectilinear diameter, as about 68% bismuth.

Eutectic Points

(a) Binary Eutectic in System Aluminum–Bismuth

The maximum decrease in the freezing temperature of bismuth was found to be 1.8°, produced by the addition of 0.30% Al. The effects of progressive additions of aluminum are shown in Table II, sample Nos. B1–B7.

(b) The Eutectic in the Pseudobinary System Bi–AlSb

The maximum decrease in the freezing temperature of bismuth was found to be 2.30° C, caused by the addition of 0.50% AlSb. The experimental results are given in Table II, Nos. C1–C4.

(c) The Ternary Eutectic

The addition of 0.20% Al to an alloy of the composition of the pseudobinary eutectic alloy caused a further decrease of 0.20° C. Hence we conclude that the eutectic temperature in the ternary system Al–Sb–Bi is 268.8° C, at a composition of 99.3% Bi, 0.40% Sb, and 0.30% Al. The experimental data are given in Table II, Nos. T1–T4. The solid phases are Al, AlSb, and solid solution of antimony in bismuth. Since antimony and bismuth form a continuous series of solid solutions, there is only one ternary eutectic in this system.

Thermal Analysis on Cooling

Since the equilibrium solid model is largely occupied by the AlSb surface, it was

4	35.0	60.0	768				

Thermal Analysis on Heating

Because of the uncertainty as to the true form of the solidus in the antimony–bismuth system two alloys were prepared, annealed for 120 hours at 280° C, and then heated uniformly. Hysteresis effects are usually less marked on heating than on cooling. The results are given in Table IV.

TABLE IV

Thermal analysis on heating

Composition of alloy	Temperature of inflection on heating curve (° C)
63 wt% Bi (50 atomic%)	350

From the totality of the preceding data, the solid model, of which Fig. 2 is a projection, can be constructed. This figure gives a complete picture of all equilibria.

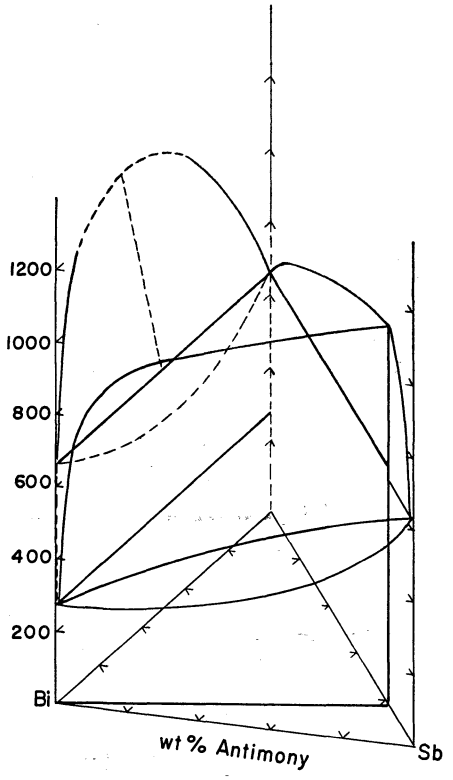

FIG. 2.

DISCUSSION OF RESULTS

The system as a whole is simple: it presents no features of unusual interest. The alloys of the system, however, have recently become of considerable commercial interest. The point of chief importance lies in the binary system antimony–bismuth, and is concerned with the true form of the solidus curve.

Our X-ray work, details of which we do not give, since it was merely a repetition of previous work, was directed to an examination of the question of the existence, or otherwise, of an unbroken series of mix-crystals between antimony and bismuth. We confirmed the results of previous workers: no lines indicative of the presence of a second solid phase ever occur on the X-ray powder photographs. Using annealed specimens, we found also that the lattice dimensions vary linearly with composition, especially if composition be expressed in atomic percent.

On the other hand, the X-ray photographs of the unannealed specimens showed a characteristic structure. The appearance was not that of a mechanical mixture, in which the lines both of bismuth and of antimony would have appeared sharply defined, but rather an indefinite spread of the blackening between the lines. The back-reflection of the unannealed specimens was almost completely extinguished. With increasing annealing time (24 → 280 hours) the sharpness of the diffraction lines improved greatly and the lines of the back-reflection reappeared. It is evident that an irregular lattice distortion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

takes place, when bismuth is added to antimony and that this is arrested by too rapid cooling. On annealing, a superstructure is formed, corresponding to the composition of the solid solution.

The conclusion seems inescapable that bismuth and antimony form a continuous series of solid solutions and that therefore the solidus should be continuous. The problem remains of why the solidus determined by the ordinary method of thermal analysis on cooling should exhibit an apparently horizontal portion, while the solidus determined by the method of electrical resistance, on annealed specimens, should be normal in form. For the sake of convenience, we describe the abnormal form of the solidus as "Cook's solidus" and the other one as "Otani's solidus". We think we have an explanation for the discrepancy as follows:

It was observed throughout the present investigation that all alloys containing an appreciable amount of bismuth release or press out drops or globules of alloy on solidification, an evident consequence of the well-known expansion of bismuth on solidification. Alloys containing less than 30 atomic% of bismuth showed no tendency to squeeze out alloy. Beginning with 30 atomic% increasing quantities of metal appear on the surface of the ingot as the concentration of bismuth is increased (Fig. 3). The crystallization of alloys (of isomorphous metals) whose freezing points all lie between those of the pure metals is discussed by Desch (6, p. 26), who shows how the solidus may undergo an apparent lowering owing to slow diffusion within the solid solution but the existence of a horizontal solidus cannot be explained by slow diffusion only. We think, however, that the existence of extruded globules from the solidified alloy offers an explanation.

Consider an alloy of composition X in Fig. 4. On cooling, the first crystals will appear at a temperature T_1, with composition x'. If the behavior is ideal, on further lowering of temperature the composition of the liquid will change along the liquidus and that of the equilibrium solid along the solidus. At temperature T_2, the last infinitesimal amount of melt has the composition x''. In the system containing antimony and bismuth, however, this last portion of the melt is squeezed out of the solidified ingot and, since it is no longer in equilibrium with the rest of the alloy, constitutes a new system. The final solidification temperature will be some such temperature as T_3. Following this reasoning, the curve Bi–T_3–Sb has been constructed for concentrations varying from 20 to 60% antimony, as shown in Fig. 4. The curve so obtained has a surprising similarity to Cook's solidus. Moreover, bearing in mind that solid diffusion in antimony–bismuth alloys is slow, it can be seen that the experimentally determined solidus will be still lower.

The conditions for the expulsion of the last melt are twofold. First, cooling must progress at a rate too great for the establishment of equilibrium, and this is nearly always true in thermal analysis, where the rate of cooling has to be great enough for inflections to show up. Secondly, the specimens must have a compact form, as with the ingots shown in Fig. 3. The specimens used by Otani were round bars of dimensions 5×90 mm. Here the expansion takes place mainly in one dimension without expulsion of liquid. This is why Otani finds higher temperatures for his solidus, even without annealing.

The last melt is squeezed out at the mechanically weakest point of the ingot and any temperature-measuring device introduced into the melt constitutes such a weak point, so that the last melt is squeezed out around the thermometer and the (erroneous) temperature T_3 recorded.

As mentioned under Experimental Results, two experiments were conducted in an endeavor to obtain the true solidus temperature by thermal analysis, using rising temperature. Two ingots of different composition were annealed for 120 hours at 280° C,

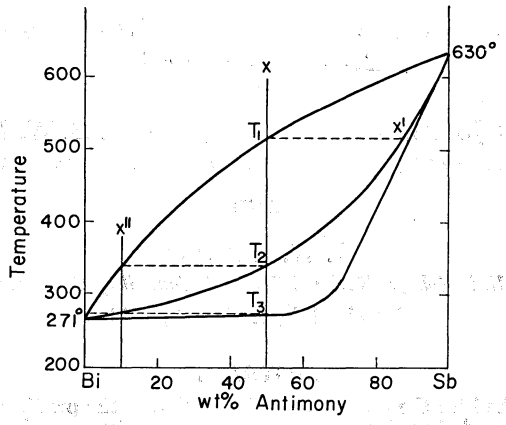

FIG. 4.

when it was observed that the (solidified) globules were incorporated again in the ingots. A 30-gauge iron–constantan thermocouple in a thin alundum tube was introduced into the center of the ingot and the heating curve recorded. The beginning of melting was found to lie at temperatures which, while they do not lie exactly on Otani's curve, are evidently higher than the temperatures of Cook's solidus.

ABSTRACT

A method is described for the quantitative description of the profile and asymmetry of an infrared absorption band, based on the computation of the second and third incomplete moments of the absorbance curve. Provision is included for differentiation between the intrinsic band asymmetry and that induced by instrumental factors dependent on the direction of scan. A program has been prepared for an I.B.M. 1620 computer to facilitate the calculation of the moments. This program also yields the incomplete fourth moments, the statistical kurtosis parameter ($\sqrt{\beta_2}$), and the Gauss–Cauchy index, though these quantities are not employed in the present investigation. Examples are given of the application of these computations to the analysis of the effect of the spectral slit width on the profiles of bands at 812.7 and 726.6 cm^{-1} respectively in the spectra of carbon disulphide solutions of perylene and anthracene, and of the effect of the amplifier time constant on the asymmetry of the band at 2234.4 cm^{-1} in the spectrum of *p*-chlorobenzonitrile in tetrachloroethylene solution.

INTRODUCTION

The current availability of commercially manufactured grating infrared spectrophotometers adds interest to the quantitative description of the profiles of infrared absorption bands, particularly for bands measured on liquids and solutions. With increasing resolution, the shape of the band provides progressively more information about the physical state of the absorbing system. A quantitative treatment of the band profile, and particularly of its asymmetry, would be valuable, the more so if the treatment could be made precise enough to quantify the small changes in band contour that result from changes in temperature, solvent, and other experimental variables. A quantitative description of the band shape is also desirable to facilitate the transfer of data between different spectrophotometers, and to place the analysis of instrumental distortion on a quantitative basis.

It is customary to describe infrared absorption bands of materials in the liquid phase in terms of the wavenumber at the band maximum (ν_0), the band width in cm^{-1} at half the maximal molecular extinction coefficient or absorbance ($\Delta\nu_{1/2}$), and the area beneath the absorption curve. For solutions, the extinction coefficient is expressed as

$$[1] \qquad \epsilon_\nu = \frac{1}{bc}\log_{10}\left(\frac{I_0}{I}\right)_\nu,$$

where b is the path length in cm and c the concentration in moles per liter of solution. In

[1]*Issued as N.R.C. No. 7170.*
Presented, in part, at the Symposium on Molecular Structure and Spectroscopy, The Ohio State University, Columbus, Ohio, U.S.A., June 14th, 1962.
[2]*National Research Council Postdoctoral Fellow.*

purely experimental work, the band area can be conveniently described by the I.U.P.A.C. "practical unit" (1),

$$[2] \qquad E_{\nu_1}^{\nu_2} = \int_{\nu_1}^{\nu_2} \epsilon_\nu d\nu,$$

with ν measured in cm^{-1}, though alternative expressions, differing dimensionally, or in the magnitude of the concentration units are also employed, particularly where it is desired to relate the measured band area to polar properties of the associated normal vibration. The relationships among these units have been summarized (2).

When dealing solely with the characteristics of the measured band profile, it is preferable to use either the absorbance ($\log_{10} (I_0/I)_\nu$), or the equivalent expression in terms of natural logarithms, for the ordinate scale. In the conversion to molecular extinction coefficients it is necessary to assume that the system obeys the Beer–Lambert law, and this involves physical considerations that are external to the analysis of the observed band profile. For analyses of instrumental distortion per se an ordinate scale of fractional absorption ($1-(I/I_0)_\nu$) should preferably be employed, but this considerably complicates the mathematical treatment. The statistical analysis of the band profiles developed in this article is based on the absorbance ordinate scale, though attempts are now in progress to extend this type of profile analysis to the fractional absorption curves.

If the band contour can be specified by a Lorentz or Gauss function, the three constants ν_0, $\log_{10} (I_0/I)_{\nu_0}$, and $\Delta\nu_{1/2}$ serve to define the location of the band and its profile at all points. These functions can be expressed

$$[3] \qquad \log_{10}\left(\frac{I_0}{I}\right)_\nu = \frac{a}{(\nu-\nu_0)^2+b^2}$$

for the Lorentz curve,* and

$$[4] \qquad \log_{10}\left(\frac{I_0}{I}\right)_\nu = \frac{a}{b^2}\cdot e^{-[(\nu-\nu_0)^2(\ln 2)]/b^2}$$

for the Gauss curve, where $a/b^2 = \log_{10} (I_0/I)_{\nu_0}$ and $2b = \Delta\nu_{1/2}$.

Unfortunately, band profiles conforming to equations [3] or [4] will rarely be encountered in practice. The observed profile will be perturbed by various physical factors affecting the true band shape, and also by instrumental distortion associated principally with the use of finite spectral slit widths and finite time constants in the electronic system of the recorder. As these perturbing factors have been recently reviewed (2) we need not discuss them further here.

If instrumental distortion is present, or if the true band profile departs significantly from the idealized forms discussed above, mathematical analysis in terms of the peak height and half-width parameters will not suffice. The curve form may become very complex, and at best, be resolvable into a convolution of several contributing functions which may contain asymmetric elements (2). It is therefore desirable to develop a calculus that will permit a quantitative description of the shape of an infrared absorption band based on purely empirical considerations. Such a technique should take account of the

**The expression "Lorentz curve" will subsequently be retained for the description of band contours that result from the Lorentz broadening effect. Equation [3] is, mathematically, a particular example of the more general Cauchy function. It is preferable to use this expression in dealing with the mathematical analysis of this type of curve profile, since the analysis is also applicable to the description of Cauchy type distribution functions arising from other causes, as for example, the natural width of a spectroscopic line, determined by the Heisenberg uncertainty principle, and other statistical applications outside the field of spectroscopy.*

fact that it is not usually practical to measure the band out into the wings to a point where the absorbance becomes negligible. Overlap with neighboring bands is almost invariably present, and it is therefore desirable to deal quantitatively with sections of the band envelope truncated at predetermined distances from the center.

These requirements can be met by statistical methods of analysis that involve no assumptions about the nature of the physical processes involved in the absorption. The technique of moment analysis, developed by Pearson (4, 5), has been applied extensively in the fields of biometrics and actuarial statistics. In these instances the applications have been concerned predominantly with Gaussian and near-Gaussian distribution curves. With the modifications described below, however, related procedures can be applied to truncated band profiles of Cauchy or Gauss form.

DEFINITION OF THE BAND MOMENTS

The general moments of the function $\log_{10}(I_0/I)_\nu = f(\nu)$ about the point $\nu = k$ are defined by the equation

$$[5] \qquad \mu_r' = \frac{\int_{-\infty}^{+\infty} (\nu-k)^r f(\nu)d\nu}{\int_{-\infty}^{+\infty} f(\nu)d\nu},$$

where r is a positive integer or zero.

It is necessary to specify the point about which the moments are taken. In principle, moments may be taken about any abscissal value, but in this article we shall be concerned only with absorption profiles having a single maximum, and with moments taken about this maximal ordinate at abscissa ν_0. Under these conditions equation [5] becomes

$$[6] \qquad \mu_r = \frac{\int_{-\infty}^{+\infty} (\nu-\nu_0)^r f(\nu)d\nu}{\int_{-\infty}^{+\infty} f(\nu)d\nu}.$$

It is important to note that ν_0 is not to be confused with the mean abscissal value of the curve, and will not coincide with this unless the function is symmetric. Likewise the μ_r should not be confused with the *central moments* which are those taken about the mean, i.e. centroid of the ν_0.

The Incomplete (Truncated) Moments of the Cauchy Curve ($\mu_r^C(j)$)

As the band profiles with which we shall be dealing can in many cases be approximated by Cauchy functions, it will be convenient to deal first with the analytic expressions for the moments of the Cauchy curve. These can be obtained by substituting equation [3] into equation [6] and integrating where it is feasible to do so.

Since the Cauchy function is symmetric about ν_0, all its odd central moments are zero, and except for μ_0 its even moments are all infinite.* Therefore the moments as defined by equation [6] do not give any useful information about this distribution.

In this instance, however, the numerators of equation [6] can be conveniently integrated within definite limits, and the resulting definite integrals evaluated numerically. These may then be used to compute incomplete moments of degree r for progressively increasing

*This follows from the fact that the even moments are functions of $\tan^{-1}((\nu-\nu_0)/b)$ (cf. equations [9], [10]) which become meaningless when $(\nu-\nu_0) \rightarrow \pm\infty$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$(\nu-\nu_0)$, and such incomplete moments will be quantitative characteristics of the curve profile.

When scaled in units of j, the semi-half-band width (Fig. 1), so that

$$[7] \qquad j = \frac{(\nu-\nu_0)}{b},$$

the incomplete moments

$$[8] \qquad \mu_r(j) = \frac{1}{b^r} \frac{\int_{-j}^{+j} (\nu-\nu_0)^r f(\nu)d\nu}{\int_{-j}^{+j} f(\nu)d\nu}$$

become dimensionless numbers, and may be regarded as pure shape parameters appropriate to comparisons of band profiles differing in band width. For quantification of instrumental distortion of a single profile, on the other hand, moments $\mu_r(\nu-\nu_0)$ in the scale of ν, in which instrumental factors actually interact, may be more appropriate. For comparisons the latter can readily be scaled to the dimensionless ratio $\mu_r(\nu-\nu_0)/\mu_2(\nu-\nu_0)^{r/2}$.*

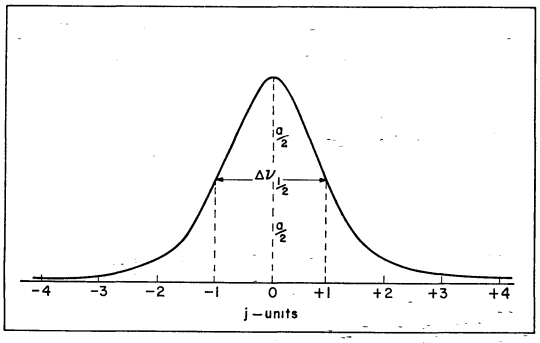

FIG. 1. Diagram illustrating the truncation of an infrared absorption band in units of j.

Making the appropriate substitutions, the expressions given in equations [9] and [10] are obtained for the second and fourth incomplete moments of the Cauchy curve in units of the semi-half-band width,

$$[9] \qquad \mu_2{}^C(j) = \left[\frac{j}{\tan^{-1} j} - 1\right]$$

$$[10] \qquad \mu_4{}^C(j) = \left[\frac{j(j^2-3)}{3\tan^{-1} j} + 1\right].$$

These are listed in Table I for the range $j = 0.2$ to $j = 4$ at intervals of 0.2.

The Incomplete Moments of the Gauss Curve ($\mu_r{}^G(j)$)

Comparable analytic expressions are not easily derived for the second and fourth incomplete moments of the Gauss curve, but by appropriate scaling the numerical values can be approximated from tables published by Pearson (6).†

*Specifically $\beta_1(\nu-\nu_0) = \mu_3(\nu-\nu_0)/\mu_2(\nu-\nu_0)^{3/2}$ is directly analogous to the statistically familiar $\beta_1 = \mu_3/\mu_2{}^{3/2}$ computed from complete moments.

†Pearson's tables are normalized with respect to the complete and not the incomplete zeroth moment, and his integration ranges are in units of the standard deviation ($\sigma = b\ (2\ \ln\ 2)^{-1/2}$) not of the semi-half-band width b.

Pearson's data have been transposed into the semi-half-band width used above for the Cauchy moments and are also listed in Table I for specified values of j. The second and fourth incomplete moments of the Cauchy and Gauss curves are compared in Figs. 2 and 3. It will be seen that the incomplete second moment of the Gauss curve rapidly

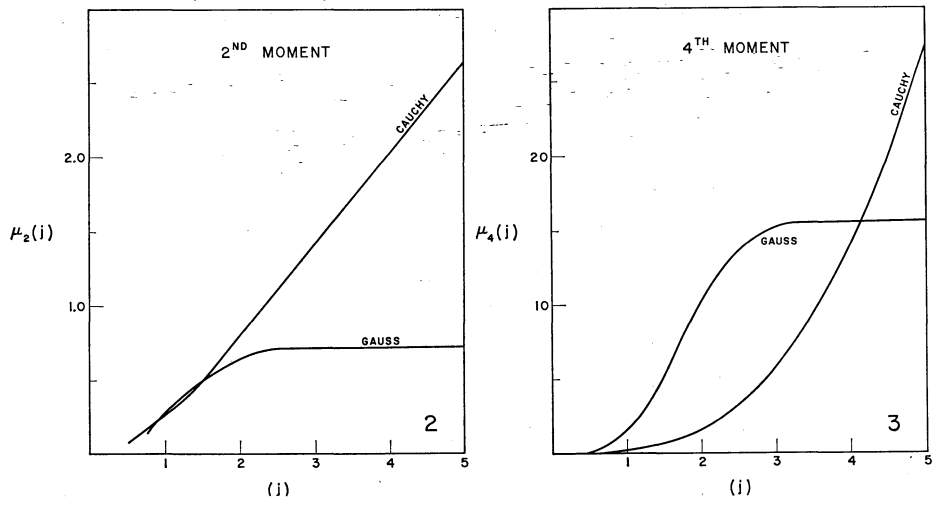

FIG. 2. Comparison of the incomplete second moments of Gauss and Cauchy curves.
FIG. 3. Comparison of the incomplete fourth moments of Gauss and Cauchy curves.

converges to a limiting value of 0.721 with increasing j, whereas the incomplete second moment of the Cauchy curve increases continuously with j in an approximately linear fashion. The incomplete fourth moments behave qualitatively in a similar fashion to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

second moments, though the fourth moments versus j plots for both functions are significantly non-linear over the calculated range.

Incomplete Moments of the Triangular Function ($\mu_r^{\triangle}(j)$)

Since triangular functions are encountered in the analysis of spectral slit widths, it is convenient to record here that the second and fourth truncated moments of the triangular function with apex at ν_0 and half width $2b$ are given by the expressions

$$\mu_2^{\triangle}(j) = \frac{j^2\left[\frac{1}{3} - \frac{j}{8}\right]}{\left[1 - \frac{j}{4}\right]} \qquad [11]$$

$$\mu_4^{\triangle}(j) = \frac{j^4\left[\frac{1}{5} - \frac{j}{12}\right]}{\left[1 - \frac{j}{4}\right]} \qquad [12]$$

The values are listed in Table I. They have no physical significance beyond $j = 2$.

Moments About Ordinates Displaced Slightly From the Band Maximum

There will inevitably be some error in evaluating the abscissal location of the maximum ordinate of an absorbance curve, and it is therefore important to assess the sensitivity of the incomplete moments to small displacements of the maximum. If the abscissal displacement is $\Delta\nu$, it can be shown that for the Cauchy distribution

$$\mu_2^{\leftrightarrow}(j) = \left[\frac{j'^{\,1/2}}{\tan^{-1} j'^{1/2}}\right] + \alpha^2 - 1 \qquad [13]$$

$$\mu_3^{\leftrightarrow}(j) = 3\alpha\left[\frac{j'^{\,1/2}}{\tan^{-1} j'^{\,1/2}} - 1\right] + \alpha^3 \qquad [14]$$

$$\mu_4^{\leftrightarrow}(j) = \left[\frac{j'^{\,1/2}(n-4+n\alpha^2)}{3\tan^{-1} j'^{\,1/2}} + 1\right] + 6\alpha^2\left[\frac{j'^{\,1/2}}{\tan^{-1} j'^{\,1/2}}\right] + \alpha^4, \qquad [15]$$

where $\alpha = 2\Delta\nu/\Delta\nu_{1/2}$, $n = j^2+1$, and $j' = n(\alpha^2+1)-1$.

When $\alpha = 0$, $\mu_3^{\leftrightarrow}(j) = 0$ and the equations [13] and [15] reduce to [9] and [10] respectively. Taking $\alpha = 0.1$, the values obtained for Cauchy $\mu_2^{\leftrightarrow}(j)$ are compared in Table II

TABLE II

Effect of abscissal displacement on the incomplete second moment of the Cauchy function ($\alpha = 0.10$)

j	$\mu_2(j)$	$\mu_2^{\leftrightarrow}(j)$
1.0	0.2732	0.2879
2.0	0.8064	0.8236

4.0	2.0170	2.0501

with those for the Cauchy distribution about ν_0. The differences are seen to be small: $\mu_2(1)$ is overestimated by about $1\frac{1}{4}\%$ and μ_2 (4.0) by about 5%. Measurements on a variety of absorption band profiles (7) indicate that the average uncertainty in the measurement of ν_0 is ± 0.3 cm^{-1}. Under these conditions a value of $\alpha \gtrsim 0.1$ would be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

obtained for bands having $\Delta\nu_{1/2} \lesssim 6$ cm^{-1}. It does not necessarily follow that α will increase at narrower half-band width since the precision in the measurement of ν_0 improves. Thus for the very narrow perylene band for which $\Delta\nu_{1/2} = 2.16$ the estimated uncertainty in ν_0 is ± 0.1 cm^{-1} corresponding to $\alpha = 0.09$.

The Effect on the Moments of a Uniform Displacement of the Base Line

The effect of a small ordinate displacement of the base of the curve on the incomplete moments of the Cauchy function has been examined to determine the sensitivity to errors resulting from drift of the 100%-transmission line. For a displacement α times the maximum ordinate height, the following expressions are obtained for the second and fourth incomplete moments:

[16] $$\mu_2^{\updownarrow}(j) = \frac{\left[j - d^{1/2}\tan^{-1}\left(\frac{j}{d^{1/2}}\right) - \frac{\alpha j^3}{3d}\right]}{\left[\frac{1}{d^{1/2}}\tan^{-1}\left(\frac{j}{d^{1/2}}\right) - \frac{\alpha j}{d}\right]}$$

[17] $$\mu_4^{\updownarrow}(j) = \frac{\left[d^{3/2}\left\{\frac{j^3}{3d^{3/2}} - \frac{j}{d^{1/2}} + \tan^{-1}\left(\frac{j}{d^{1/2}}\right)\right\} - \frac{\alpha j^5}{5d}\right]}{\left[\frac{1}{d^{1/2}}\tan^{-1}\left(\frac{j}{d^{1/2}}\right) - \frac{\alpha j}{d}\right]},$$

where $d = (1+\alpha)/(1-\alpha)$.

When $\alpha = 0$, giving $d = 1$, expressions [16] and [17] reduce to [9] and [10] respectively. Taking $\alpha = 0.01$, the second moments of the new distribution are compared with the true Cauchy moments in Table III, from which it will be evident that an error of 1% in

TABLE III

Effect of ordinate displacement of the base line on the incomplete second moment of the Cauchy function ($\alpha = 0.01$)

j	$\mu_2(j)$	$\mu_2^{\updownarrow}(j)$
1.0	0.2732	0.2782
2.0	0.8064	0.8112

4.0	2.0170	1.9521

the location of the base line would not greatly affect computation of the second moments of a Cauchy distribution, or, by inference, the second moments of an experimentally observed absorbance curve of near-Lorentzian contour.

EXPERIMENTAL

The experimental work described in this section was undertaken as a preliminary exploration of the use of the moment method for characterizing band shapes. These experiments are intended to be illustrative only, and a considerably more extended series of measurements, performed under more carefully controlled conditions, preferably on a double-beam spectrophotometer, will be necessary before significant conclusions can be drawn concerning the physical implications of the results.

Well-isolated bands in the spectra of solutions of perylene at 812.7 cm^{-1} and of anthracene at 726.6 cm^{-1} in carbon disulphide solution and of *p*-chlorobenzonitrile at 2234.4 cm^{-1} in tetrachloroethylene have been used in this investigation. The perylene was crystallized from toluene and further purified by vacuum distillation; the anthracene was zone refined and the *p*-chlorobenzonitrile was repeatedly recrystallized from *n*-pentane.*

**In a new series of experiments now in progress, perylene, anthracene, and p-chlorobenzonitrile have all been purified by repeated zone refining, and this method is preferable to those described above.*

The spectra were measured on a Perkin–Elmer Model 112G single-beam double-passed grating spectrometer. The main features of the bands and the experimental conditions of measurement are listed in Table IV; a typical instrumental chart record is reproduced in Fig. 4. The solvent base line and the experi-

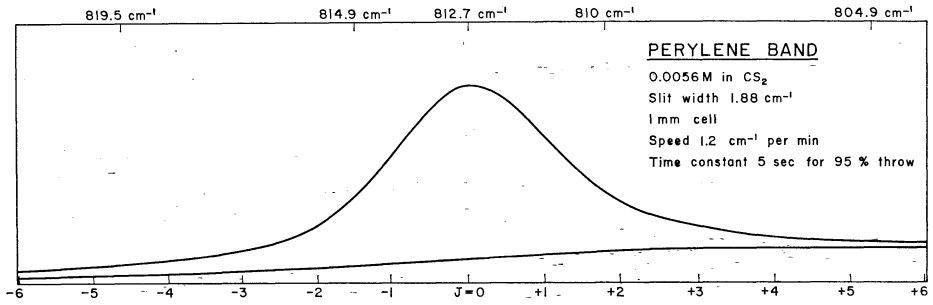

FIG. 4. A representative instrumental chart record from the 112G grating spectrometer under the scanning conditions used in these measurements.

mental curve were run consecutively using the same cell. The 100%-absorption line was recorded before and after the completion of the solvent and solute measurements. The instrumental stray light was less than 1% as measured by the method described in reference 2. The gain was adjusted so that the pen throw for 100%-transmission remained approximately the same through each series of measurements. In one set of experiments the effect of change of spectral slit width at a fixed amplifier time constant was investigated, while in a second series the time constant was varied while maintaining a fixed slit width. The spectral slit width was computed from the mechanical slit width as described in reference 2, and did not vary significantly over the scanning range of a band.

For each experimental curve, I and I_0 were read at intervals across the curve. Between 15 and 20 absorbance ordinates were determined; the readings were taken at close abscissal intervals in the neighborhood of the maximum and at increasing intervals out into the wings. The position of the maximum was estimated visually (ν_0'), and the half-band width with respect to this estimated maximum ordinate was determined ($\Delta\nu_{1/2}'$). Four points on the curve were next selected on either side of ν_0', within an abscissal range not exceeding $\frac{1}{2}\Delta\nu_{1/2}'$. The Part I program for the I.B.M. 1620 computer (8) was then used to pass second, third, and fourth degree polynomial curves through the selected points by a least squares approximation and the displacement ($\nu_0'-\nu_0$) was evaluated to give the corrected band maximum ν_0 (7).

Next the measured absorbance values were plotted against ($\nu-\nu_0$) for the complete band on a large sheet of graph paper, and a smooth curve passed through the points. The peak height was read from this curve, and the abscissal distances in cm^{-1} corresponding to half the peak height were obtained for both the negative and positive halves of the curve. For the perylene and anthracene bands, which are nearly symmetric, these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

values are almost identical, but for the more pronouncedly asymmetric *p*-chlorobenzonitrile band they differ appreciably. By convention, the averaged value of the two measurements was accepted as the semi-half-band width b.*

The abscissal scale unit j was next obtained, and the abscissal values (in cm^{-1}) tabulated with their corresponding absorbance ordinates at intervals of $0.1j$ for the complete curve, in a sequence of diminishing wavenumber. An equal number of measurements were taken on either side of the maximum which was included in the series. These data were then transferred to I.B.M. cards and processed through the Part II program of the I.B.M. 1620 computer, which is designed to evaluate the incomplete moments (8). The computer prints out the values of $\mu_2(j)$, $\mu_3(j)\cdot b^3 = \mu_3(\nu-\nu_0)$, $\mu_4(j)$, $\sqrt{[\beta_2(j)]}$, and the Gauss–Cauchy index at intervals of $0.4j$.

In the following discussion we shall consider only $\mu_2(j)$ and $\mu_3(\nu-\nu_0)$. The Gauss–Cauchy index is defined as

$$\frac{\mu_2(j)-\mu_2{}^{G}(j)}{\mu_2{}^{C}(j)-\mu_2{}^{G}(j)} \qquad [18]$$

and $\beta_2(j) = \mu_4(j)/\mu_2(j)^2$. The evaluation of these quantities, as well as of $\mu_4(j)$, has been incorporated into the Part II program in anticipation that they will provide additional information about the band profile that may be useful at a later date.

RESULTS

Effect of the Spectral Slit Width on the Perylene and Anthracene Band Profiles

The perylene and anthracene spectra were measured under instrumental conditions where the effect of the amplifier time constant on the asymmetry of the band profile should be negligible. The spectra were obtained over a range of spectral slit widths, and the values of the second moments are listed in Table V and illustrated graphically in Fig. 5. The corresponding values for the Cauchy and Gauss distributions are also included

difference increases progressively into the wings. As the slit becomes wider, the departure from Cauchy towards Gauss values becomes more pronounced. These results are consistent with the hypothesis that the observed band profiles are intermediate between Cauchy and Gauss distributions, and might be represented in good approximation by convolutions of Gauss and Cauchy functions, viz. by Voigt functions (2). This aspect of the curve analysis will be considered in more detail in a later publication; it is in accord with recent work of Abramowitz and Bauman (9) on other absorption bands. It is not, however, legitimate to conclude that the slit function itself is necessarily Gaussian. It must be remembered that, physically, it is the fractional absorption curve and not the absorbance curve that is convoluted with the slit function. This point is currently being studied in greater detail, and preliminary computations, based on an approximate deconvolution of the fractional absorbance curves of the perylene band with Gaussian and triangular slit functions, suggest that the best approximation may perhaps be a function intermediate between these two; if it be assumed that the absorbance band is truly Lorentzian, deconvolution with a triangular slit function appears to overcorrect, and to displace the $\mu_2(j)$ versus j plot above the Cauchy line, whereas a Gaussian slit function does not raise it sufficiently. A more complete analysis may modify these provisional conclusions.

The $\mu_2(j)$ versus j plots for the anthracene bands are qualitatively similar to the perylene band plots, but the band is intrinsically wider, having $\Delta\nu_{1/2}{}^t = 2.5$ cm^{-1} compared with 2.16 cm^{-1} for the perylene band ($\Delta\nu_{1/2}{}^t$ is the extrapolated value of $\Delta\nu_{1/2}$ at zero spectral slit width). This could explain why measurements at the narrowest slit width suggest more nearly Lorentzian $\mu_2(j)$ characteristics for the anthracene than for the perylene band. The anthracene plot for the narrowest slit width is included in Fig. 5.

Measurement of the Band Asymmetry—The Effect of the Amplifier Time Constant on the Profile of the p-Chlorobenzonitrile Band

In the initial study of the second moments described above, it was considered desirable to work with bands of high symmetry, and the perylene and anthracene bands were chosen for this reason. A preliminary study of the third moment, as a means to quantify instrumental effects on band asymmetry, is more conveniently carried out with a band that has appreciable intrinsic skewness, and the —C≡N stretching band of *p*-chlorobenzonitrile was selected for this purpose.* The spectra were measured in tetrachloroethylene solution, and the data were processed exactly as described for the perylene and anthracene bands.

In these measurements the slit width was maintained unaltered, but the amplifier time constant was varied. Whereas the instrumental distortion introduced by the finite slit width is approximately symmetrical, that introduced by the finite amplifier time constant contains a strongly asymmetric second order component (10), so that the asymmetry of the experimentally observed band will change as the time constant is altered, and this should be reflected in the third moment measurements.

In fact, the lag in the amplifier response caused by the finite time constant extends the band in the direction of scan, and this effect on the band shape will invert in sign when the direction of scanning is reversed. It is therefore possible to separate the intrinsic band asymmetry from that associated with the scanning process by scanning the band in both the forward and reverse directions, and observing the differences in the resulting third moments. Reversal of the scanning direction will also displace the location of the maximum, but this will not affect the third moment computations if ν_0 is obtained separately for the forward and reverse runs as described above.†

It is convenient to define the two distinct third moment parameters

$$\mu_3^{F}(\nu-\nu_0) = \mu_3^{F}(j)\cdot b_F^3 \quad [19]$$

and

$$\mu_3^{R}(\nu-\nu_0) = \mu_3^{R}(j)\cdot b_R^3 \quad [20]$$

for the dimensional moments measured in the forward (F) and reverse (R) directions (by convention the forward direction is that associated with increasing wavenumber).

We also define $\mu_3^{a}(\nu-\nu_0)$ and $\mu_3^{i}(\nu-\nu_0)$ as parameters associated respectively with the directional insensitive (largely intrinsic) band asymmetry and with the directionally sensitive, instrumentally induced asymmetry, such that

$$\mu_3^{a}(\nu-\nu_0) = \tfrac{1}{2}[\mu_3^{F}(\nu-\nu_0)+\mu_3^{R}(\nu-\nu_0)] \quad [21]$$

and

$$\mu_3^{i}(\nu-\nu_0) = \tfrac{1}{2}[\mu_3^{F}(\nu-\nu_0)-\mu_3^{R}(\nu-\nu_0)]. \quad [22]$$

The values obtained for $\mu_3^{a}(\nu-\nu_0)$ and $\mu_3^{i}(\nu-\nu_0)$ for the *p*-chlorobenzonitrile band measured at three different amplifier response settings are shown in Figs. 6 and 7 in relation to $j = (\nu-\nu_0)/b$. These effectively illustrate the separation of the intrinsic from

*The corresponding —C≡N stretching bands of several other substituted benzonitriles were also surveyed, but most of these are unsuitable because the wing contours are distorted by overlap with other weak bands. The p-chloro derivative is singularly favorable in this respect.

†There will be a real displacement of the maximum due to the first order effect of the electronic filter system, and also an apparent displacement due to scale shift associated with the backlash in the gears of the wavenumber drive.

FIG. 7. The 2234.4 cm^{-1} band of *p*-chlorobenzonitrile. The effect of the amplifier response setting on $\mu_3{}^i(\nu-\nu_0)$.

the instrumentally induced, directionally sensitive asymmetry. By repeating the measurements at different scanning rates it is possible to select, and to objectively describe, the optimum scanning conditions for a given instrument. More detailed analysis of these $\mu_3{}^a(\nu-\nu_0)$ versus j and $\mu_3{}^i(\nu-\nu_0)$ versus j plots should help in the quantitative treatment of electronic filter distortion. Brodersen (10) has emphasized the difficulties of dealing with this problem, even for simple RC-networks, and it will become increasingly more so as the electronic systems of infrared spectrophotometers become more complex with the increasing sophistication of the servo-operated response control circuits.

CONCLUDING REMARKS

The experimental work described in this paper is purely of an illustrative character, and the extent to which this treatment of band profiles can contribute to a better understanding of the spectra remains to be established. In making available a computer program to obtain the incomplete moments without undue tedium, we hope that we can encourage other investigators to apply these techniques to a variety of spectroscopic problems involving band shape and band intensity analysis. The necessity of separating the computation into Parts I and II, with the intermediary graphing of the absorbance curve, can probably be avoided if the number of data points is sufficiently large. This would probably necessitate the use of a spectrophotometer equipped with direct digital read-out, and would limit the application to the comparatively few laboratories that are so equipped. The method as described here can be applied to any laboratory possessing a good infrared spectrophotometer and access to comparatively modest computer facilities.

THE REACTION OF ISOPROPANOL VAPOR WITH Hg 6($^3P_1$) ATOMS

PART II. REACTION IN THE PRESENCE OF NITRIC OXIDE

ARTHUR R. KNIGHT AND HARRY E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

ABSTRACT

The reaction of isopropanol vapor with Hg 6($^3P_1$) atoms in the presence of nitric oxide has been investigated in a static system at room temperature as a function of exposure time. In addition to the major products hydrogen, pinacol, and acetone found in the pure substrate reaction, the new products isopropyl nitrite, nitrous oxide, and nitrogen were observed. The effect on the reaction of the inert gas carbon tetrafluoride was also studied.

Evidence is adduced for the production of excited isopropoxy radicals in the primary process, and the rise in the nitrite and acetone yields, observed upon increasing the added inert gas pressure, is ascribed to quenching of these excited species.

The nitrite produced in the decomposition of Me_2CDOH was found to be ca. 98% Me_2CDONO, dictating its formation from the isopropoxy radical and not from Me_2COH.

A nitrite-producing dark reaction was observed when high pressures of CF_4 were added and the reaction could be prevented only by measures designed to exclude trace quantities of NO_2 from the reaction vessel.

INTRODUCTION

In Part I (1) of this series the reaction of pure isopropanol vapor with Hg 6($^3P_1$) atoms was shown to produce H_2, pinacol, and acetone as major products of the reaction, in addition to smaller quantities of CH_3CHO, CO, C_2H_6, and CH_4. Under conditions of continuous illumination quantum yield values for hydrogen and acetone were 0.72 and 0.25 respectively. For intermittent illumination, where the light period, t_L, was less than 0.45 millisecond, $\Phi(H_2)$ was unity within experimental error.

Nitric oxide has been used previously in this laboratory, in studies (2–4) of the reactions of alcohol vapors with Hg 6($^3P_1$) atoms, to detect alkoxy radicals through the formation of the corresponding nitrite. Thus, on continuous illumination of 50 mm MeOH + 5.5 mm NO and 40 mm EtOH + 10 mm NO, initial quantum yields of 0.15 and 0.25 were found for methyl and ethyl nitrite respectively. These yields are lower than expected in view of the higher initial hydrogen quantum yields observed and the fact that the general features of the reactions indicate a primary scission into alkoxy radicals and H atoms. Now the energy of the Hg 6($^3P_1$) atom, 112 kcal/mole, is ca. 10 kcal/mole higher than D(RO—H) for the alcohols (5). Hence the alkoxy radicals initially formed may possess excess energy up to ca. 10 kcal/mole, thereby leading to a strong third-body restriction on the nitrite-forming step in these systems. Pertinently McMillan (6–8) has recently reported the formation of excited alkoxy radicals in the photolysis of dialkyl peroxides, attributable to the energy difference between D(RO—OR) and that of the exciting quanta. To investigate the importance of excited isopropoxy radicals in the present system, the effect of increasing pressure of inert gas on the nitrite yield has been examined.

Bäckstrom *et al.* (9) have investigated the reactions of liquid isopropanol in the presence of nitric oxide, using benzophenone as sensitizer. One mole each of N_2, N_2O, and Me_2CO and two moles of isopropyl nitrite were found for each six moles of NO taken up by the system. Since these authors assumed the production of $Me_2\dot{C}OH$ radicals in the initial interaction between sensitizer and substrate, the nitrite must then arise by combination

of $(Me)_2\dot{C}OH$ and NO, followed by isomerization. In view of these conclusions the deuterium content of the nitrite produced in the decomposition of Me_2CDOH in the presence of NO was investigated.

The present investigation extends the work on the pure substrate, as described previously (1), to include the Hg $6(^3P_1)$-sensitized decomposition of Me_2CHOH and Me_2CDOH in the presence of small amounts of nitric oxide, and in addition includes a study of the effect of added inert gas on the reaction.

EXPERIMENTAL

The apparatus and procedures have been partially described in Part I (1) of this series.

Matheson nitric oxide was purified by successive passes through a small Hg-diffusion pump, distillation from liquid oxygen temperature, and a final degassing at liquid nitrogen temperature. Matheson carbon tetrafluoride was purified by a preliminary distillation from −130° C (*n*-pentane slush), followed by three trap-to-trap distillations at −160° C isopentane slush), and finally a thorough degassing from liquid nitrogen.

Isopropanol (Nicholls, Reagent grade) was twice fractionally distilled, a small constant-boiling fraction being retained, which was admitted to the vacuum system, degassed, and trap-to-trap distilled, with rejection of large head and tail fractions. Me_2CDOH (Merck, Montreal) was chemically purified by preparative-scale gas chromatography, followed by thorough degassing on the line. Mass spectrometric analysis showed the presence of 1.3% Me_2CDOD, while an infrared spectrum of the sample revealed that the material contained a maximum of ca. 1% ROD alcohol. The isotopic purity of the refined material was therefore 98.7%.

Analytical procedures, as well as the determination of and values for the light intensity, have been given previously (1).

Preliminary experiments showed that while no nitrite formation could be detected when a mixture of 40 mm isopropanol and 10 mm nitric oxide was carried through all stages of the procedure except irradiation, a nitrite-producing dark reaction did occur when high pressures of CF_4 were added to the reaction cell. The possibility that trace quantities of oxygen, not removable from CF_4 by degassing, were responsible for the dark reaction was investigated. Levy (10), in the analysis of the products from the pyrolysis of ethyl nitrate, found that the alcohol present was converted quantitatively to ethyl nitrite when air was admitted to the analysis cell containing the alcohol and nitric oxide. The reaction was ascribed to the formation of NO_2 by air oxidation of NO, followed by reaction of NO_2 with ethanol. Since, in the present system, CF_4 appeared to be necessary for the occurrence of the dark reaction and since mass spectrometric analysis showed the material to be free from detectable impurities, it appeared likely that an analogous mechanism was operative here. To prevent the interaction of any NO_2 with the alcohol, the following procedure was adopted. NO and CF_4 were measured in the reaction cell and stored overnight in a side trap at room temperature. The mixture was then distilled into a cell containing the alcohol with the side trap cooled to −160° C. In this way any NO_2 formed during the storage period was excluded from the reaction vessel. Blank runs performed over the entire range of CF_4 pressures used in the reported runs showed that this method of reagent introduction resulted in the complete elimination of the dark reaction.

RESULTS

The reaction in the presence of nitric oxide resulted in the formation of the same products as in the case of pure substrate, although several were markedly reduced in yield, and in addition the products isopropyl nitrite, nitrous oxide, and nitrogen were observed. A careful search of the reaction products was made for any compound which might have arisen from the reaction of NO with hydroxy isopropyl radicals. Mixtures of 35 mm isopropanol and 3 mm nitric oxide were exposed for 60 minutes and the reaction products frozen in isopentane slush (−160° C), and non-condensable gases pumped off. Fractions were then removed at −130, −98, and −45° C, and infrared spectra taken of these fractions and the residue in the reaction cell. These analyses showed that a large yield of pinacol was formed even though NO was present and that no products were present other than those found previously by mass spectrometric examination of the various compounds eluted on the G.L.C. columns.

The results of a series of experiments designed to study the effect of exposure duration on the quantum yields (Φ) for a mixture of 40 mm isopropanol and 10 mm nitric oxide are displayed as follows: Fig. 1, $\Phi(Me_2CHONO)$, and Fig. 2, $\Phi(Me_2CO)$, $\Phi(H_2)$, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

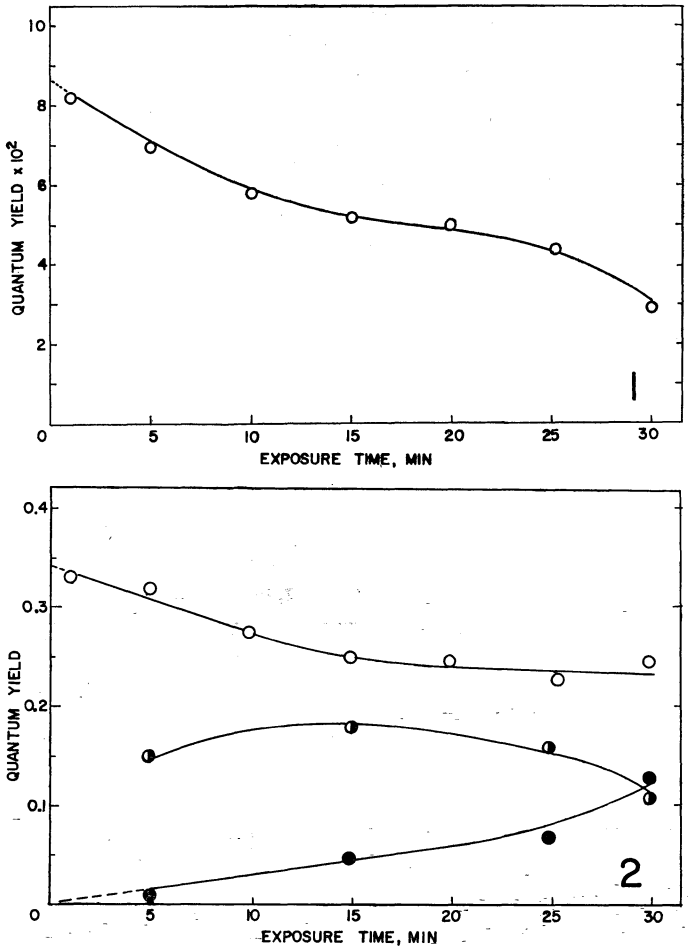

FIG. 1. Quantum yield of isopropyl nitrite as a function of exposure time for a mixture of 10 mm nitric oxide and 40 mm isopropanol.

FIG. 2. Quantum yield of acetone, ○; hydrogen, ◑; and carbon monoxide, ●, as a function of exposure time for a mixture of 10 mm nitric oxide and 40 mm isopropanol.

Φ(CO). In all figures the yields of products have been corrected for competitive quenching by nitric oxide assuming a quenching cross section (σ^2) of 12 Å^2 for isopropanol. The resulting correction factor was 1.7. Nitrous oxide and nitrogen were not determined as a function of exposure time (t), except at t = 30 minutes, where the values were $\Phi(N_2O)$ = 0.361 and $\Phi(N_2)$ = 0.071. The yields of MeCHO and CH_4 are not shown in the figures. Both these products appeared to remain constant within experimental error in the investigated range. The observed values were $\Phi(MeCHO) = 1.1\times10^{-2}$ (t = 10 to 30 minutes) and $\Phi(CH_4) = 5\times10^{-2}$ (t = 15 to 25 minutes).

Two experiments were performed with Me_2CDOH, at a pressure of 40 mm, and nitric oxide pressure of 10 mm. The condensable products of the reaction were analyzed in the usual manner and the nitrite trapped from the G.L.C. effluent and analyzed on the mass spectrometer. For 20 minutes of reaction, the nitrite was found to be 97.6% Me_2CDONO, with 2.4% Me_2CHONO present, while after 10 minutes of exposure, the heavy nitrite amounted to 97.4% of the total.

The data in Figs. 3 and 4 give respectively the yields of isopropyl nitrite and acetone as a function of pressure of added carbon tetrafluoride. This series of runs was performed with 40 mm isopropanol and 10 mm nitric oxide for an exposure time of 3.00 minutes.

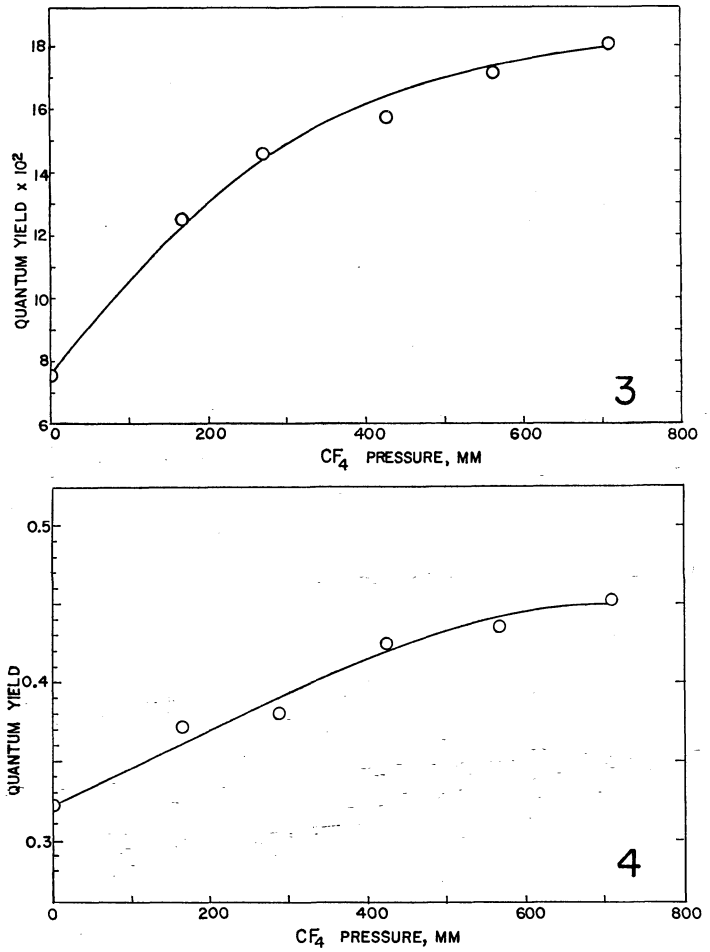

FIG. 3. Quantum yield of isopropyl nitrite as a function of pressure of carbon tetrafluoride for a mixture of 40 mm isopropanol and 10 mm nitric oxide at an exposure time of 3.00 minutes.

FIG. 4. Quantum yield of acetone as a function of pressure of carbon tetrafluoride for a mixture of 40 mm isopropanol and 10 mm nitric oxide.

DISCUSSION

The appearance of isopropyl nitrite as a reaction product suggests the presence of isopropoxy radicals in the system. The possibility that the nitrite arises by some mechanism other than the combination of $Me_2CH\dot{O}$ and NO must not be excluded immediately, however, particularly in view of the results of Bäckstrom *et al.* (9). If the $Me_2\dot{C}OH$ radical, produced in either a second primary process or by the abstractive attack of the primary fragments on the substrate, were the source of isopropyl nitrite through the sequence

$$Me_2\dot{C}OH + NO \rightarrow Me_2C(NO)OH \rightarrow Me_2CHONO, \qquad [1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

then the nitrite obtained from the decomposition of Me_2CDOH would contain no deuterium. The observed result that Me_2CDONO accounts for ca. 98% of the nitrite formed shows that reaction [1] does not occur to a significant extent in the present system. The observed nitrite formation in the liquid phase (9), rather than arising from photochemically produced $Me_2\dot{C}OH$ radicals, may in fact be linked with the occurrence of a dark reaction in that system between the alcohol and NO_2. (Bäckstrom *et al.* (9) reported a yellow discoloration of the solutions possibly due to NO_2 formation.) The formation of NO_2 by air contamination is rendered the more probable by the fact that the solutions were allowed to stand for 2 to 6 months before analysis for the nitrite was performed (9).

In the present system, the observation that no detectable products arise from the reaction of NO and hydroxy isopropyl radicals suggests either that this reaction is very inefficient or that the addition product is unstable or both. A possible route for the interaction would be

$$Me_2\dot{C}OH + NO \rightarrow Me_2C(NO)OH \rightarrow Me_2CO + HNO. \qquad [1']$$

The assumption made in Part I (1) that H-atoms are produced in the primary step is supported by the observed yields of N_2, N_2O, and water, which arise from the HNO formed by the scavenging of H-atoms by nitric oxide (*vide infra*).

The following mechanism is proposed to account for the observed results of the decomposition in the presence of nitric oxide:

$$Me_2CHOH + Hg\ 6(^3P_1) \rightarrow Me_2CH\dot{O} + H + Hg\ 6(^1S_0) \qquad [2]$$

$$H + Me_2CHOH \rightarrow H_2 + Me_2\dot{C}OH \qquad [3]$$

$$Me_2CH\dot{O} + Me_2CHOH \rightarrow Me_2CHOH + Me_2\dot{C}OH \qquad [4]$$

$$Me_2CH\dot{O} + NO \rightarrow Me_2CHONO \qquad [5]$$

$$H + NO + M \rightarrow HNO + M \qquad [6]$$

$$2HNO \rightarrow N_2O + H_2O \qquad [7]$$

$$HNO + 2NO \rightarrow N_2 + HNO_3 \qquad [8]$$

$$H + HNO \rightarrow H_2 + NO \qquad [9]$$

$$H + \dot{A} \rightarrow Me_2CHOH \qquad [10]$$

$$\dot{A} + Me_2CHONO \rightarrow Me_2CHOH + Me_2CO + NO \qquad [11]$$

$$2\dot{A} \rightarrow Me_2CO + Me_2CHOH \qquad [12]$$

$$2Me_2\dot{C}OH \rightarrow \text{pinacol}, \qquad [13]$$

where $\dot{A}$ represents either the $Me_2CH\dot{O}$ or the $Me_2\dot{C}OH$ radical.

Our findings can be explained through a single primary process, [2], involving O—H scission, as in the studies on methanol and ethanol (2–4). However, since the $\Phi(Me_2CHONO)$ values are considerably lower than $\Phi(H_2)$ in the uninhibited reaction (1), primary C—H cleavage cannot be excluded.

In the presence of NO, $\Phi(H_2)$ is reduced (Fig. 2). Thus at $t = 15$ minutes we find $\Phi(H_2) = 0.18$; whereas for the uninhibited reaction under the same conditions the value is 0.56 (1). Owing to the third-body restriction on [6], the primary H-atoms are probably not efficiently scavenged by NO, and abstraction from the substrate through [3] would still be operative.

The formation of the nitrite by step [5] has been observed in several systems containing isopropoxy radicals and NO (5, 6). Our finding that Me_2CDONO forms in the MeCDOH + NO system confirms this reaction. Extensive evidence is available for the occurrence of [6] and [7] to explain N_2O and H_2O formation from H atoms and NO (10–18). In

addition, in the H+NO system, it has been recently demonstrated that N_2 is a significant product (19). Reaction [8] has been postulated (19) to explain the formation of N_2, found also in this study. The formation of hydrogen through [9] has been shown by Clyne and Thrush (20), and this reaction could account for part of the hydrogen formed in the present inhibited system.

Since [6] is inefficient, there will be a finite concentration of H atoms in the system, and therefore back reaction through [10] can occur. In this step, Ȧ will likely be $Me_2\dot{C}OH$, since isopropoxy radicals can react with the substrate via [3], and be fixed as the nitrite in [5]. Furthermore, our observation that pinacol, which clearly forms via [13], is an important product even at the high NO concentrations used in this study indicates that the $Me_2\dot{C}OH$ radicals show low reactivity to NO, thereby suggesting high steady-state levels for these species.

The decrease in $\Phi(Me_2CHONO)$ with t (Fig. 1) can be explained by [11], first proposed by Steacie and Shaw (21), for Ȧ as $Me_2CH\dot{O}$. Alternately, or in addition, the nitrite can suffer photolysis and mercury photosensitization with increasing duration of exposure. This secondary photodecomposition readily accounts for the decay of $\Phi(Me_2CO)$ with exposure time (Fig. 2), with the concomitant rise in $\Phi(CO)$ (Fig. 2). As in the study of the uninhibited reaction (1), primary acetone formation is attributed to [12].

The low yield of isopropyl nitrite (Fig. 1) in the absence of inert gas requires that [2] account for only a small fraction of the primary reaction, or that [4] is very fast. A rough estimate of the activation energy of [4] can be made from the facts that abstraction by CH_3 from isopropanol has an activation energy of 7.3 kcal/mole (22), and that the value for $Et\dot{O}$ radicals abstracting from ethyl propionate (23) is 5.5 kcal/mole. Since [4] involves abstractive attack on a secondary hydrogen, E[4] would probably not exceed 5 kcal/mole. Now if we assume [2] to describe at least the predominant primary process, the resulting isopropoxy radicals would be expected to be scavenged by NO in [5], since E[5] should be near zero and the NO concentration is 20 mole% in the present system. Reaction [4] could only be significant if the primary radicals possess excess energy.

Compelling evidence for energy-rich species in the present system is seen in the effect of the inert gas, CF_4, on $\Phi(Me_2CHONO)$ in Fig. 3, and on $\Phi(Me_2CO)$ in Fig. 4. Thus with increasing CF_4 pressure, $\Phi(Me_2CHONO)$ rises steadily so that at $P(CF_4) = 710$ mm, the highest inert gas pressure used, the value is 2.4 times higher than that without added inert gas (Fig. 3). Similarly, $\Phi(Me_2CO)$ increases from 0.32 at $P(CF_4) = 0$ to 0.45 at $P(CF_4) = 710$ mm (Fig. 4). Now it has been pointed out that the initially formed $Me_2CH\dot{O}$ radicals could acquire up to 10 kcal/mole of excess energy in their formation in [2]. In short the isopropoxy radicals may possess more than the approximately 5 kcal/mole of energy required for reaction via [4]. And it should be noted that the substrate molecules will have the highest probability of first encountering these energized isopropoxy radicals. Now here CF_4 should function to deactivate the excited $Me_2CH\dot{O}$ radicals, and thereby the rate of [4] would be markedly reduced, with a concomitant rise in the concentration of thermalized $Me_2CH\dot{O}$ species. Since both the nitrite yield via [5] and the acetone yield via [12] will be directly dependent on $(Me_2CH\dot{O})$, the increase in these yields with increasing $P(CF_4)$ is readily explicable. It should further be noted that the almost first-order dependence of $\Phi(Me_2CO)$ on $P(CF_4)$ suggests that [12] involves $Me_2CH\dot{O}$ radicals interacting with excess $Me_2\dot{C}OH$ radicals:

$$Me_2CH\dot{O} + Me_2\dot{C}OH \rightarrow Me_2CO + Me_2CHOH. \qquad [14]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Further evidence for the presence of excited isopropoxy radicals in the system is provided by the fact that acetaldehyde is formed in the reaction, and that its yield is only slightly decreased by the presence of NO. This product evidently arises from the unimolecular decomposition of excited isopropoxy radicals, since in both the inhibited and NO-free systems its yield is almost invariant in exposure duration, with values of 1.1×10^{-2} and 1.5×10^{-2} respectively. The activation energy for the unimolecular reaction

$$Me_2CH\dot{O} \rightarrow MeCHO + CH_3 \qquad [15]$$

would be expected to be slightly higher than that for *t*-butoxy, for which a value of 13 kcal/mole has been found (5).

CONCLUSIONS

The present study has provided evidence that the reaction of isopropanol vapor with Hg $6(^3P_1)$ atoms proceeds through the formation of energy-rich isopropoxy radicals and H-atoms. Primary C—H scission may also occur, although no direct evidence for this mode of decomposition has been found. From the present study, and earlier work on the simple alcohols (1–4), primary alkoxy radical formation appears to be a general characteristic of the reactions of these molecules with Hg $6(^2P_1)$ atoms.

PENTAERYTHRITOL DERIVATIVES

I. MECHANISM OF FORMATION OF DIPENTAERYTHRITOL[1]

L. W. TREVOY AND M. E. MYERS
Research Department, Canadian Chemical Company, Limited, Edmonton, Alberta

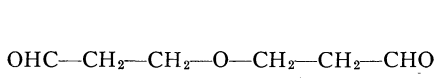
Received October 30, 1962

ABSTRACT

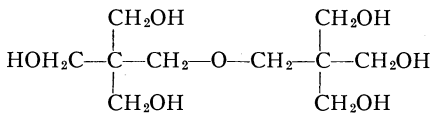
Dipentaerythritol, $(CH_2OH)_3CCH_2OCH_2C(CH_2OH)_3$, is a product of the base-catalyzed Tollens condensation of acetaldehyde with formaldehyde. The mechanism for formation of dipentaerythritol has not been hitherto established.

Three types of experimental evidence support the conclusion that monopentaerythritol, $C(CH_2OH)_4$, is an intermediate in the sequence of reactions leading to dipentaerythritol: (1) the isolation of radioactive dipentaerythritol from a Tollens condensation in which monopentaerythritol-C^{14} was present, (2) comparison of the radioactivity levels of mono- and di-pentaerythritol prepared by reaction of formaldehyde-C^{14} with inactive monopentaerythritol and inactive acetaldehyde, and (3) the observed dependence of the yield of dipentaerythritol on the concentration of monopentaerythritol present in the condensation reaction mixture.

Dipentaerythritol is a by-product (1) of the base-catalyzed condensation of acetaldehyde with formaldehyde. A number of different reaction mechanisms have been postulated to explain the formation of dipentaerythritol (II) from smaller building blocks in the Tollens hydroxymethylation reaction. Wawzonek and Rees (2) suggested a mechanism in which β-hydroxypropionaldehyde, from the condensation of formaldehyde with acetaldehyde, was considered to react with acrolein to form a dialdehyde (I). Further reaction of I with formaldehyde by consecutive condensation and Cannizzaro reactions



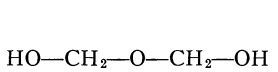
I



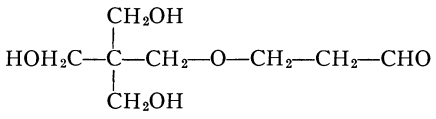
II

was considered to lead to dipentaerythritol (II). Wawzonek and Rees reached the conclusion that monopentaerythritol was not necessary for the formation of II.

A rather different reaction sequence was favored by Barth *et al.* (3). The hydrated dimer of formaldehyde (III) was thought to be capable of condensing with 2 moles of acetaldehyde, thus resulting in the generation of I, the precursor of the dimeric ether of monopentaerythritol (II).



III



IV

An alternate mechanism not heretofore considered seriously is the one in which monopentaerythritol is postulated as an intermediate which is converted by reaction with acetaldehyde and formaldehyde into the pentaerythrityl ether of β-hydroxypropionaldehyde (IV), which could readily be transformed into dipentaerythritol by further reaction with formaldehyde.

[1]*Presented at the Annual Meeting of the Chemical Institute of Canada in Montreal, August, 1961.*

Formation of ethers in the pentaerythritol reaction has also been observed when the reaction was conducted with alcohols as solvents (2, 4). Thus Wawzonek and Rees isolated both the monomethyl and dimethyl pentaerythrityl ethers as products of reaction in methanolic solution. They explained this ether formation by the addition of the alcohol to the olefinic linkage of acrolein; the base-catalyzed addition of alcohols to α,β-unsaturated aldehydes is a well-established reaction. Wawzonek and Rees considered that acrolein may be an intermediate in both the formation of methyl pentaerythrityl ethers and in the formation of dipentaerythritol.

By using a tracer technique it should be possible to distinguish between the mechanisms of Wawzonek and Barth on the one hand, in which dipentaerythritol is built up directly from acetaldehyde and formaldehyde, and the distinctly different mechanism in which a 5-carbon unit such as monopentaerythritol or pentaerythrose is first synthesized and reacts in further steps with acetaldehyde and formaldehyde to form dipentaerythritol. Thus, by introducing monopentaerythritol-C^{14} in the reaction medium and by examination of the dipentaerythritol produced for radioactivity, it should be possible to determine whether or not monopentaerythritol is a precursor of dipentaerythritol.

EXPERIMENTAL

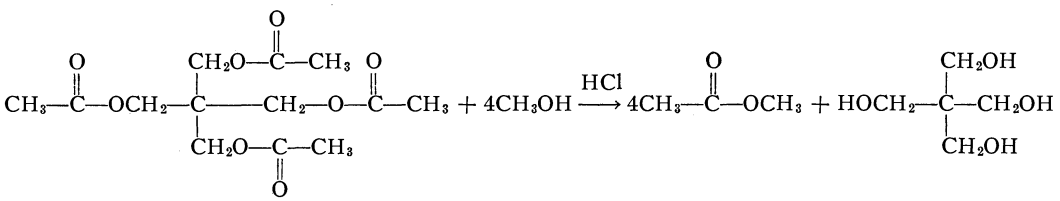
Radioactivity Measurements

Relative activities of mono- and di-pentaerythritol preparations were determined by counting solid samples under standard conditions. "Infinitely thick" samples were prepared by pelletizing 0.5 g of material into disks approximately 1.2 cm in diameter. The counting chamber was a CFlS-2 gas-flow counter purchased from Atomic Energy of Canada, Chalk River, Ontario, and Tracerlab G-1 Geiger Gas was used. Samples were counted for 10,000 counts in order to reduce the counting error to the 1% level. Correction was made for background count and the stability of the counter was checked periodically using a standard sample.

(1) Synthesis of Monopentaerythritol-C^{14}

Monopentaerythritol-C^{14} was synthesized by the sodium hydroxide catalyzed reaction of formaldehyde-C^{14} with inactive acetaldehyde. The preparation was conducted on a 0.4-mole scale, using formaldehyde (20% aqueous solution, sodium hydroxide (20% aqueous solution), and acetaldehyde in the mole ratio of 4.6:1.1:1.0. The initial reaction temperature was 25° C and the Cannizzaro reaction was completed at 50° C. Total radioactivity used was 0.1 mc and the monopentaerythritol which was isolated possessed an activity of approximately 0.12 μc/mmole. After neutralizing the reaction mixture with acetic acid, excess formaldehyde was removed by distillation and the crude pentaerythritol crystallized upon cooling the residual solution.

The monopentaerythritol-C^{14} was purified by conversion to the tetraacetate ester with acetic anhydride followed by fractional distillation to remove the dipentaerythritol hexaacetate. Methanolysis of the monopentaerythritol tetraacetate, b.p. 145–165° C at 0.4 mm, with methanolic hydrogen chloride regenerated the monopentaerythritol-C^{14}, which was further purified by recrystallization from water.



(2) Synthesis of Pentaerythritol in the Presence of Monopentaerythritol-C^{14}

A pentaerythritol synthesis was conducted in aqueous medium, in which, in addition to the acetaldehyde, formaldehyde, and sodium hydroxide which are required for the condensation reaction, monopentaerythritol-C^{14} was also present.

The monopentaerythritol-C^{14} (0.5 mole, radioactivity 817 c.p.m.) was dissolved in water and placed in a stirred reactor. After cooling the mixture to 16° C, a formaldehyde solution (75 g of 20% aqueous solution) and a sodium hydroxide solution (2 g in 8 g water) were added. Acetaldehyde (0.5 mole) was then added to the reactor and the temperature was held at 16° C for an additional 20 minutes. More formaldehyde (262 g of 20% aqueous solution) and sodium hydroxide (100 g of 20% aqueous solution) were added in succession. The reactor temperature was subsequently raised to 50° C for 90 minutes in order to complete the Cannizzaro

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reaction. After concentration of the solution and removal of the excess formaldehyde by distillation, the crude product crystallized upon cooling the solution and was collected by filtration.

The monopentaerythritol and dipentaerythritol were separated by conversion to the acetate esters, fractional distillation at reduced pressure (1 mm), and alcoholysis of the individual ester fractions. The recovered monopentaerythritol (68 g) and dipentaerythritol (7.7 g) were purified by recrystallization from water; purity was established by hydroxyl value determination (5), and the radioactivity levels of both monopentaerythritol and dipentaerythritol were determined. The final purified monopentaerythritol possessed an activity of 392 c.p.m. and hydroxyl value of 49.4 (calcd. for monopentaerythritol, 50.0); the purified dipentaerythritol had an activity of 316 c.p.m. and hydroxyl value of 39.0 (calcd. for dipentaerythritol, 40.0).

(3) Synthesis of Pentaerythritol in the Presence of Formaldehyde-C^{14}

Formaldehyde-C^{14} (0.1 mc) was diluted with inactive formaldehyde and was used with inactive monopentaerythritol (0.25 mole) and inactive acetaldehyde (0.5 mole) in the synthesis of pentaerythritol. The procedure was similar to that used in Section (2). Based on pentaerythritol recovered and the pentaerythritol present in the mother liquor, the conversion of acetaldehyde to pentaerythritols was calculated to be 70%.

An efficient separation of the acetates was achieved by distillation at 10^{-4} to 10^{-5} mm Hg pressure, and monopentaerythritol tetraacetate, dipentaerythritol hexaacetate, and tripentaerythritol octaacetate were recovered. Methanolysis of the esters yielded monopentaerythritol (31 g), dipentaerythritol (9.5 g), and tripentaerythritol (1 g). Radioactivities of the purified monopentaerythritol and dipentaerythritol, respectively, were found to be 1070 c.p.m. and 1255 c.p.m.

(4) Effect of Mole Ratio of Monopentaerythritol to Acetaldehyde on Product Composition

Using constant mole ratios of formaldehyde, acetaldehyde, and sodium hydroxide (4.5:1.0:1.1) the quantity of monopentaerythritol added prior to the condensation reaction was varied from 0 to 2.5 moles per mole of acetaldehyde. The product from each reaction was isolated, was recrystallized from aqueous solution after boiling the solution with dilute sulphuric acid in order to hydrolyze formals, and the hydroxyl value of the product was determined. The experimental data are presented in Table I and in Fig. 3A.

TABLE I

The effect of monopentaerythritol concentration on formation of dipentaerythritol

Experiment No.	Mole ratio of initial monopentaerythritol to acetaldehyde	Pentaerythritol recovered* (g)	Hydroxyl value (%)	Dipentaerythritol (mole)
1	0	86.6	47.8	0.087
2	0.25	98.4	46.8	0.124
3	0.5	137.5	46.7	0.163

9	2.4	335.0	47.1	0.382

*Based on the reaction of 1 mole of acetaldehyde.

DISCUSSION OF RESULTS

In the initial experiment in which monopentaerythritol-C^{14} was used, the recovered monopentaerythritol had approximately one-half the original activity because of dilution with a similar quantity of inactive monopentaerythritol which had been synthesized in the reaction from acetaldehyde and formaldehyde. The dipentaerythritol was found to be radioactive, which was a definite indication that monopentaerythritol had been a building block in the formation of dipentaerythritol.

By analysis of the data obtained from this tracer experiment it is possible to conclude that all of the dipentaerythritol formed was built up from monopentaerythritol as starting material. The reactions by which mono- and di-pentaerythritol are formed are competing reactions and occur simultaneously. For the reaction

$$\text{mono-PE-C}^{14} + CH_3CHO + 4CH_2O + OH^- \rightarrow \text{di-PE-C}^{14} + HCOO^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

with an initial monopentaerythritol activity of 817 c.p.m. the initial dipentaerythritol activity would be $817\times(136/254) = 437$ c.p.m. Similarly for a final measured monopentaerythritol activity of 392 c.p.m. the final dipentaerythritol formed would have an activity of $392\times(136/254) = 210$ c.p.m. Since dipentaerythritol is formed in parallel with monopentaerythritol via a competing reaction then the average monopentaerythritol activity of 604 c.p.m. should lead to an average dipentaerythritol activity of 323 c.p.m. Figure 1 presents the data for the reaction in which monopentaerythritol and

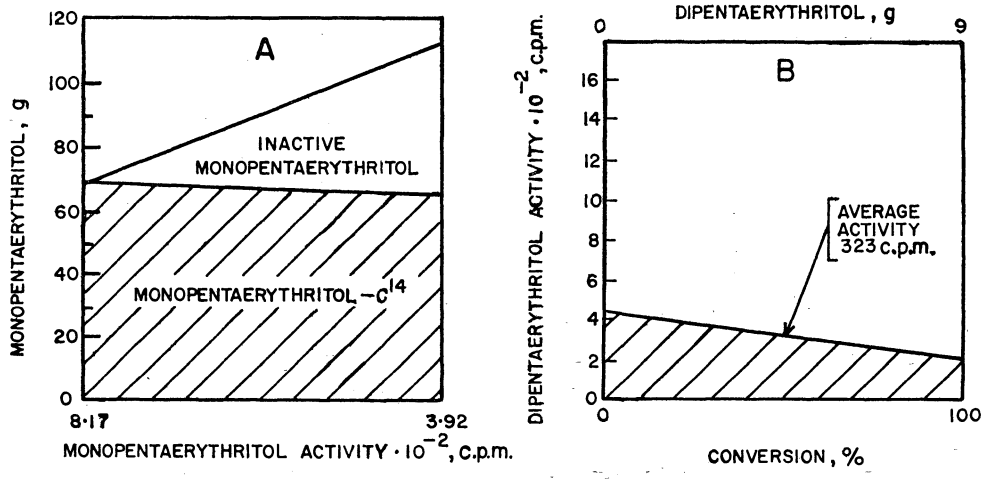

FIG. 1. Synthesis of pentaerythritol using monopentaerythritol-C^{14}. A. Dilution of monopentaerythritol during the condensation reaction. B. Dependence of dipentaerythritol activity on monopentaerythritol activity.

dipentaerythritol were formed in the presence of pentaerythritol-C^{14}. The experimentally determined activity of 316 c.p.m. for dipentaerythritol is the same as that calculated within experimental error and indicates that all of the dipentaerythritol synthesized was formed via the monopentaerythritol route.

In the tracer experiment in which C^{14}-formaldehyde was used in the synthesis of mono- and di-pentaerythritol, the data obtained are also in accord with a mechanism involving monopentaerythritol as an intermediate in dipentaerythritol formation. From the final observed activity of monopentaerythritol, and taking into account the 0.25 mole of inactive monopentaerythritol initially present, the activity of monopentaerythritol synthesized in the reaction may be calculated to be $1070\times[0.60/(0.60-0.25)] = 1835$ c.p.m. If all of the dipentaerythritol were formed directly from acetaldehyde and formaldehyde-C^{14} then the dipentaerythritol activity would be $1835\times(272/254) = 1964$ c.p.m. But since the dipentaerythritol activity was found to be 1255 c.p.m. then this is evidence against direct formation of dipentaerythritol from acetaldehyde and formaldehyde, and it is apparent that inactive monopentaerythritol initially present must also have been incorporated into the dipentaerythritol during synthesis. By comparing the calculated activity of 1964 c.p.m. with the observed activity of 1255 c.p.m. we may conclude that 64% of the monopentaerythritol units incorporated in the final dipentaerythritol were active and 36% were inactive. It follows that 72% of the dipentaerythritol was of the mixed variety, synthesized by reaction of inactive monopentaerythritol with inactive acetaldehyde and radioactive formaldehyde, while 28% was fully labelled dipentaerythritol, synthesized from radioactive monopentaerythritol or pentaerythrose formed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

during the reaction which had entered into further reaction with radioactive formaldehyde. Assuming that the dipentaerythritol is formed in parallel with the monopentaerythritol, we may again calculate the dipentaerythritol activity based on an average monopentaerythritol activity during the reaction. By reacting monopentaerythritol, average activity 535 c.p.m., with inactive acetaldehyde and labelled formaldehyde-C^{14}, the calculated activity of dipentaerythritol formed = $[(535+1835)/2]\times[272/254] = 1268$ c.p.m., which is in good agreement with the observed activity of 1255 c.p.m. (see Fig. 2).

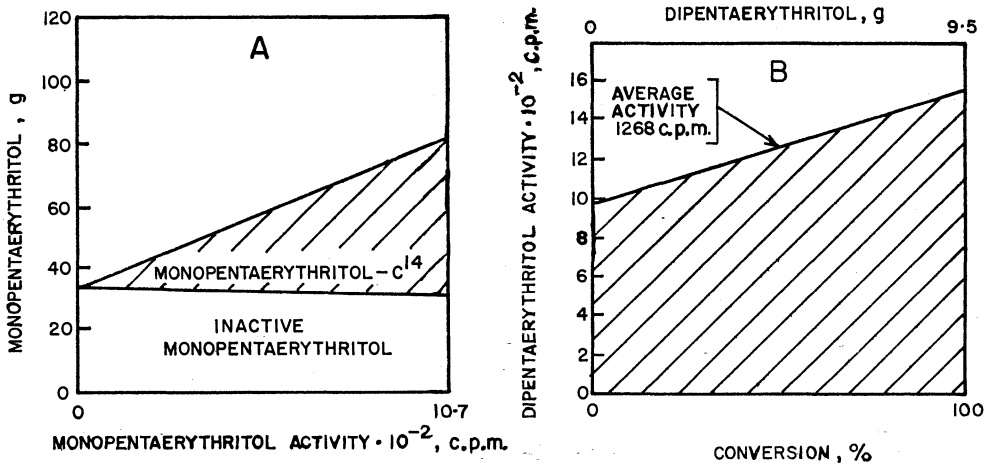

FIG. 2. Synthesis of pentaerythritol using formaldehyde-C^{14}. A. Change in monopentaerythritol activity during the synthesis. B. Dependence of dipentaerythritol activity on monopentaerythritol activity.

It may be concluded that some inactive monopentaerythritol which was originally present in the reaction mixture was used for synthesis of dipentaerythritol.

The experimental data presented in Fig. 3A show the effect of increasing monopentaerythritol concentration in the reaction mixture on the quantity of dipentaerythritol formed. The mass action effect of the increasing monopentaerythritol concentration is responsible for the substantial reduction of the hydroxyl value of the isolated reaction product, indicating an increase in the quantity of dipentaerythritol formed. With monopentaerythritol to acetaldehyde ratios greater than 1 the effect in Fig. 3A is obscured by the large quantities of monopentaerythritol present. From the experimentally determined hydroxyl values the quantity of dipentaerythritol produced in each experiment may be calculated and in Fig. 3B the dipentaerythritol formed is observed to increase as the concentration of monopentaerythritol in the original reaction was increased from 0 to 2.4 moles per mole of acetaldehyde. It may be noted that when the ratio of monopentaerythritol to acetaldehyde was increased to 2.4 then approximately 40% of the acetaldehyde was converted to dipentaerythritol in the course of the condensation reaction. The fact that the addition of monopentaerythritol to the pentaerythritol reaction mixture resulted in the formation of increased amounts of dipentaerythritol provides additional evidence in support of the conclusion that monopentaerythritol is an intermediate in the reaction sequence leading to dipentaerythritol.

The evidence presented here supports a reaction mechanism for dipentaerythritol formation in which a 5-carbon unit, monopentaerythritol, reacts with a 3-carbon unit (formed from acetaldehyde and formaldehyde) to generate an 8-carbon unit which in

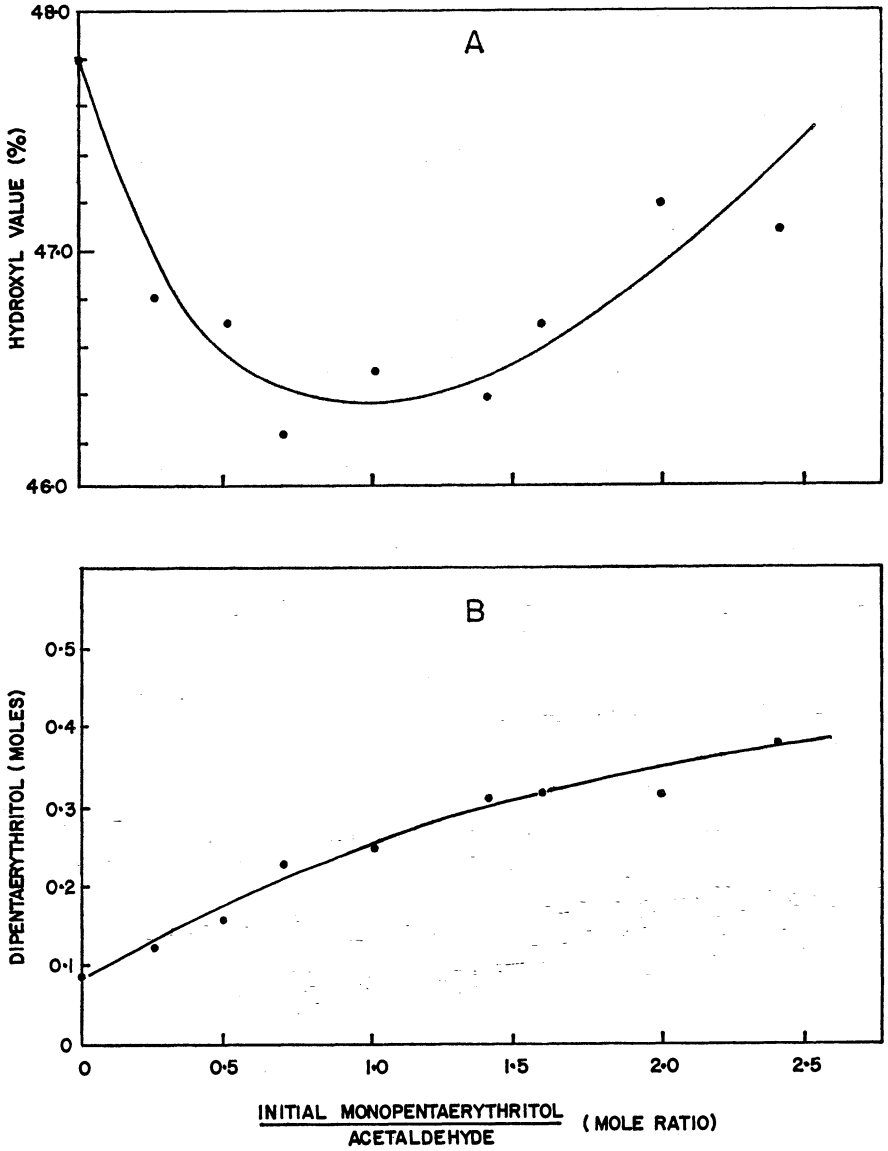

FIG. 3. The effect of monopentaerythritol concentration on the formation of dipentaerythritol in the condensation reaction. A. The effect of mole ratio of monopentaerythritol to acetaldehyde on the hydroxyl value of the isolated product. B. The relationship between dipentaerythritol formed and monopentaerythritol present in the condensation reaction.

turn reacts in the final stage with two single-carbon formaldehyde units. The results obtained in this investigation are contrary to the previously suggested mechanisms in which either a dimeric formaldehyde unit or 4-oxa-1,7-heptanedial was assumed to provide the ether linkage which was eventually converted to dipentaerythritol.

The present work has established that monopentaerythritol is an intermediate in the formation of dipentaerythritol and this conclusion is based on three different types of experimental evidence: (1) the isolation of labelled dipentaerythritol from a pentaerythritol reaction in which monopentaerythritol-C^{14} was used, (2) a comparison of the

radioactivity levels of monopentaerythritol and dipentaerythritol produced from formaldehyde-C^{14} and inactive monopentaerythritol and acetaldehyde, and (3) the dependence of the yield of dipentaerythritol upon the concentration of monopentaerythritol in the reaction mixture.

PROTON MAGNETIC RESONANCE SPECTROSCOPY AND THE SULPHATION OF LINEAR AND BRANCHED DEXTRAN[1]

W. M. Pasika and L. H. Cragg
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received November 22, 1962

ABSTRACT

The introduction of sulphate groups into dextran produces characteristic changes in its proton magnetic resonance spectrum. With linear dextran a new signal appears which can be attributed solely to an effect of sulphate groups; with branched dextran this signal coincides with that due to the branching. From a comparison of peak areas in these spectra with peak areas in the spectra of the unsulphated linear and branched dextrans it is concluded that during sulphation no appreciable degradation occurred, whether by chain scission or branch hydrolysis.

The proton magnetic resonance spectra also provide evidence for preferential substitution of sulphate at carbon 2 in the anhydroglucose unit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Recently we have been comparing (1) the viscosity behavior of branched and linear dextran sulphates prepared from samples of branched dextran and linear dextran of known structure. Although the sulphations were performed under mild conditions—with chlorosulphonic acid in formamide at 0° C—in order to minimize degradation (chain scission and branch hydrolysis) of the dextrans, it was clearly desirable to determine to what extent, if any, such degradation had occurred during sulphation.

Proton magnetic resonance spectroscopy, which we have already shown to be useful in detecting and estimating branching in dextran (2), proved to be a valuable means of obtaining this information about degradation. In addition, it yielded evidence for preferential sulphation at the C_2 position.

RESULTS AND DISCUSSION

Proton magnetic resonance spectra were obtained (see Experimental) for the linear dextran and the branched dextran and for the sulphated dextrans prepared from them. These spectra are reproduced in Fig. 1: (*a*) linear dextran, (*b*) branched dextran, (*c*) linear dextran sulphate, and (*d*) branched dextran sulphate. The peaks are numbered as in the earlier paper (2) (with one exception, peak 8, which will be discussed later). Peak 4 at −4.7 p.p.m. is due to the proton of deuterium hydroxide. Peaks 1 and 2 in the dextran sulphate spectra occur at the same positions as the corresponding peaks in the dextran spectra (see Table I); they may therefore be attributed to the C_5 and C_6 protons and the C_2, C_3, and C_4 protons respectively (2) (see Fig. 2). Similarly peak 5 occurs at the same position in the dextran sulphate spectra as in the dextran spectra (Table I); in all spectra it is due to anomeric (C_1) protons involved in 1,6-linkages.

Comparison of spectrum 1(*c*) with 1(*a*) and 1(*b*) reveals that there is a new peak, 8, in the linear dextran sulphate spectrum that is not present in the spectrum of the unsulphated linear dextran, and that this peak occurs, unfortunately, at just the same position as does the branching peak (peak 7) in the spectrum of branched dextran, namely at −5.4 p.p.m. In the spectrum of linear dextran sulphate this peak cannot be due to branching. Rather, it must be due in some way to the sulphate groups, the feature that distinguishes the dextran sulphate from the parent dextran.

TABLE I

Peak positions and assignments for dextrans and dextran sulphates

Spectrum	Peak	Protons responsible	Chemical shift (p.p.m.)*
B-512 dextran	1	C_5, C_6	−3.70
B-512 dextran sulphate	1		−3.70
B-742 dextran	1		−3.70
B-742 dextran sulphate	1		−3.72
B-512 dextran	2	C_2, C_3, C_4	−3.90
B-512 dextran sulphate	2		−3.95
B-742 dextran	2		−3.90
B-742 dextran sulphate	2		−3.91
B-512 dextran	5	C_1 (1,6-linkage)	−5.05
B-512 dextran sulphate	5		−5.06
B-742 dextran	5		−5.05
B-742 dextran sulphate	5		−5.06
B-512 dextran sulphate	8	C_1 (1,6-linkage)†	−5.35
B-742 dextran	7	C_1 (non-1,6-linkage)	−5.40
B-742 dextran sulphate	8	C_1 (1,6-linkage)† C_1 (non-1,6-linkage)	−5.38

*External standard was tetramethylsilane.
†C_1 carbon bonded to sulphate-bearing C_2 carbon.

The corresponding peak occurs in 1(*d*), the spectrum of branched dextran sulphate, and again it occurs at −5.4 p.p.m. where peak 7 occurs in the spectrum of branched dextran, 1(*b*). In this spectrum, then, peak 8 must be due to both sulphate and to branching (non-1,6-linkages).

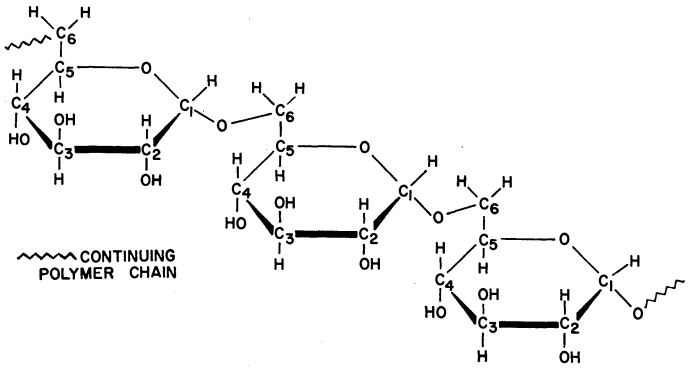

FIG. 2. Structural diagram of linear dextran.

Careful comparison also reveals the existence of a new feature in both the dextran sulphate spectra, a broad shoulder or "tail" between −4.0 and −4.5 p.p.m. For this, too, the sulphate groups must in some way be responsible. (In the branched dextran sulphate spectrum there is, moreover, a semblance of a peak, designated 2′ in Fig. 1(*d*), on this tail.) The presence of this "tail" in the sulphate spectra made impractical any attempt to measure the area of the combined peaks 1 and 2 or the area of peak 2′. Area measurements were therefore made only on peaks 5 and 8.

Peak Assignments

In the linear dextran sulphate, the sulphate groups will be attached to carbons 2, 3, and 4 of the anhydroglucose units (Fig. 2). The presence of these electronegative groups should reduce the electron density around the protons attached to these carbons and hence produce a shift downfield from −3.95 p.p.m. Since our samples are only partially sulphated, peak 2 would not disappear but would be diminished in area, with a new signal appearing at its expense.

The sulphate groups might also affect the C_1 protons (those associated with the 1,6-linkages), but if so only the sulphate groups on the adjacent carbon, C_2, would be expected to cause a shift large enough to produce a separate peak (3). Again, the effect would be an increased chemical shift from −5.05 p.p.m.; peak 5 would be diminished in favor of a new peak somewhere to its left on the spectrum as drawn.

On this basis, it is reasonable to assign peak 8 to anomeric protons attached to C_1 carbons that are bonded to sulphate-bearing C_2 carbons, and to assign the shoulder between −4 and −4.5 p.p.m. to protons on sulphate-bearing C_2, C_3, and C_4 carbons. Peak 8, then, would be formed at the expense of peak 5. The alternative would *not* be reasonable, for assignment of peak 8 to protons on the sulphate-bearing C_2, C_3, and C_4 carbons would imply a very large negative shift from −3.9 to −5.4 p.p.m., and the consequent assignment of the "shoulder" to the anomeric protons would imply a most unlikely *positive* shift from −5.05 to −4.5 p.p.m. Furthermore, the effect of sulphate groups on anomeric protons should be manifested as a sharp peak rather than as a broad shoulder, for only the groups on the C_2 carbons should contribute to the effect; the effects of sulphate groups attached to the C_2, C_3, and C_4 carbons on the protons on these carbons would be of various strengths and therefore might be expected to result in a number of closely spaced peaks merging into a shoulder. (The peak at 2′, found only in the branched dextran sulphate spectrum, may be attributed to C_6 protons affected by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

sulphate groups on the same C_6 carbons; the branched dextran contains many primary alcohol groups at the branch ends and these would be preferentially substituted.)

Evidence for or against degradation was obtained from comparison of peak areas in different spectra. In order to do this, we obtained proton magnetic resonance spectra at several different concentrations, under otherwise identical conditions, for the dextrans and dextran sulphates, and measured the areas of peaks 5, 7, and 8 in the same area units.

In Fig. 3 are plotted, against concentration: A, the area of peak 5 for the linear dextran; B, the area of peak 5 for the branched dextran; and C, the area of peak 7 for the

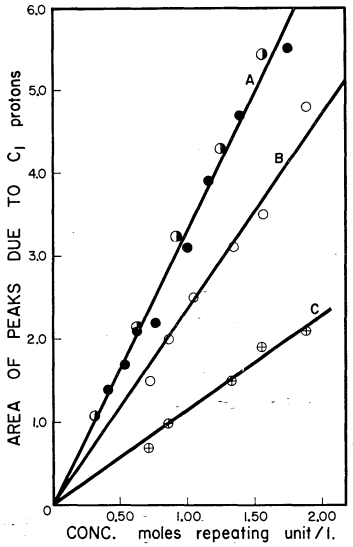

FIG. 3. Peak areas as a function of grundmolar concentration—linear and branched dextrans: ○, B, area peak 5 (branched dextran); ⊕, C, area peak 7 (branched dextran); ◑, A, sum of areas of peaks 5 and 7 (branched dextran); ●, A, area of peak 5 (linear dextran).

branched dextran. Points representing the sum of the areas of peaks 5 and 7 for branched dextran fall, as expected, on line A; for the same number (or number of moles) of anhydroglucose units, the number of 1,6-linkages and non-1,6-linkages, taken together, in branched dextran should equal the number of 1,6-linkages in linear dextran.

In Fig. 4 are plotted against concentration for linear dextran sulphate: B, the area of peak 5; C, the area of peak 8; and Σ, the sum of these areas (as taken from the lines B and C). If there is no degradation (scission of 1,6-linkages) the number of 1,6-linkages per given number of moles of the repeating unit will be the same in linear dextran sulphate as in the parent linear dextran, and hence the combined intensity of the two signals (5 and 8) due to anomeric (1,6-linkage) protons in the sulphated dextran should equal the intensity of the one signal, 5, due to anomeric (1,6-linkage) protons in the parent dextran. On the other hand, if degradation had occurred during sulphation, 1,6-linkages would have been broken and the combined areas of peaks 5 and 8 for sulphated dextran would be less than the area of peak 5 for the parent dextran (the percentage decrease being equal to the percentage of linkages broken). In Fig. 4, line Σ should coincide with line A (which is the same as line A of Fig. 3) if there is no degradation, or lie *below* it if there *is* degradation. Actually, it lies somewhat above it. We may conclude, then, that there has been no appreciable degradation of the dextran during the sulphation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This conclusion is strengthened by a similar consideration of peak areas of the spectra of branched dextran and branched dextran sulphate. In Fig. 5, line A is the same as

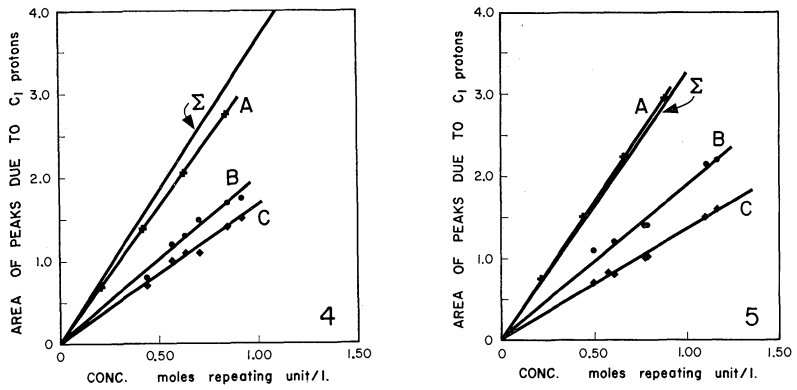

FIG. 4. Peak areas as a function of grundmolar concentration—linear sodium dextran sulphate and linear dextran (for comparison): B, peak 5 area; C, peak 8 area; Σ, sum of areas of peaks 5 and 8; A, peak 5 area (linear dextran).

FIG. 5. Peak areas as a function of grundmolar concentration—branched sodium dextran sulphate and branched dextran (for comparison): B, peak 5 area; C, peak 8 area; Σ, sum of areas of peaks 5 and 8; A, sum of peaks 5 and 7 (branched dextran).

line A of Fig. 3. Here it may be taken as a plot against concentration (in moles of repeating units—grundmoles—per liter) of the combined areas of peaks 5 and 7 of the branched dextran, i.e. of the total intensity of signals due to anomeric protons (1,6-linkages *and* non-1,6-linkages). Since line Σ is, for the branched dextran sulphate, a plot of the comparable measure of the total intensity of signals due to anomeric protons (1,6- and non-1,6-linkages), and since the abscissa for both plots is concentration in moles of repeating units per liter, line Σ should coincide with line A if there has been no chain scission (breaking of 1,6-linkages) and no branch hydrolysis (breaking of non-1,6-linkages) and it should lie *below* line A if there has been an appreciable amount of either branch hydrolysis or chain scission. Considering the imprecision of peak-area measurements, the two lines may be said to coincide within experimental error. (The experimental error should not be more than 10% and with cancellation of errors considerably less.)

We conclude, therefore, that during sulphation there has been no appreciable degradation of the dextran, and that the extent of branching in the branched dextran sulphate remains essentially the same as it was in the parent branched dextran.

Preferential Sulphation

Analysis of the spectrum of linear dextran sulphate also yields information regarding the carbon of the anhydroglucose unit on which sulphation preferentially occurs.

Our sample of linear dextran sulphate contained 9.96% sulphur* or 0.74 sulphate group per anhydroglucose unit (repeating unit). The signal at −5.35 p.p.m., peak 8, is due to anomeric (1,6-linkage) protons attached to C_1 carbons bonded to sulphate-bearing C_2 carbons, and the signal at −5.06 p.p.m., peak 5, is due to protons on 1,6-linked C_1 carbons linked to C_2 carbons which are not sulphated.

If the sulphate groups were equally distributed among the C_2, C_3, and C_4 carbons, only one-third of them would be effective in causing the shift from −5.06 to −5.35 p.p.m.,

**Commercial analysis.*

i.e. in producing peak 8 and reducing peak 5. The ratio of the area of peak 5 to the area of peak 8 then would be equal to the ratio

$$\frac{(\text{number of moles sulphate})\times 1/3}{(\text{number of moles of repeating unit}-\text{number of moles sulphate})\times 1/3} = \frac{0.74/3}{(1-0.74)/3} = 0.33.$$

The measured value of the peak ratio is 0.84. This means that sulphate groups have concentrated on C_2 carbons; in fact back calculation indicates that approximately 62% of the sulphate groups are in this position.

This evidence for preferential sulphation at the C_2 position is in qualitative agreement with earlier chemical evidence that, of the three secondary hydroxyls in polysaccharides, the one on carbon 2 is the most reactive. (See, for example, Mahoney and Purves (4) or, for a review, Sugihara (5).)

EXPERIMENTAL

Materials and Methods

The samples of linear dextran and branched dextran were those used earlier (2). They were sulphated by a procedure previously described (1) to produce the sulphated dextrans used in this investigation: linear dextran sulphate: 9.96% sulphur, 0.74 sulphate groups per anhydroglucose unit; branched dextran sulphate: 9.26% sulphur, 0.54 sulphate groups per anhydroglucose unit.

The sodium salts of these sulphated dextrans were used because of their greater solubility. They were prepared by passing the dextran sulphate solutions through columns of sodium-charged Dowex 50 cation exchange resin, and freeze-drying.

Prior to the determination of spectra, the dextran and dextran sulphate samples were treated, to exchange labile protons of the hydroxyl groups with deuterons, by thrice repeated dissolution in deuterium oxide and freeze-drying. (The deuterium oxide was the same as that used earlier (2).)

Spectra were obtained on a Varian A-60 analytical proton magnetic resonance spectrophotometer which operated at 60 Mc/s. The solvent in all instances was deuterium oxide, and all spectra were obtained at identical machine settings. The external standard was tetramethylsilane.

Peak areas were measured, as before, with a planimeter.

THE BIOSYNTHESIS OF HYDRASTINE AND BERBERINE[1]

J. R. GEAR AND IAN D. SPENSER
Department of Chemistry, McMaster University, Hamilton, Ontario
Received September 17, 1962

ABSTRACT

The biosynthesis of hydrastine and of berberine was investigated by administering radioactive glucose, phenylalanine, tyrosine, and dopamine to *Hydrastis canadensis* L. Both hydrastine and berberine were found to be specifically derived from two molecules of tyrosine. The ratio of incorporation of the two molecules of radiotyrosine into hydrastine was not unity, and varied with time. Dopamine was also incorporated into hydrastine without randomization, but only one molecule was utilized. These results, which are consistent with the classical hypothesis and disprove the prephenic acid hypothesis of biogenesis, provide direct evidence for some of the steps in the biosynthetic pathway by which hydrastine and berberine are formed in the plant.

INTRODUCTION

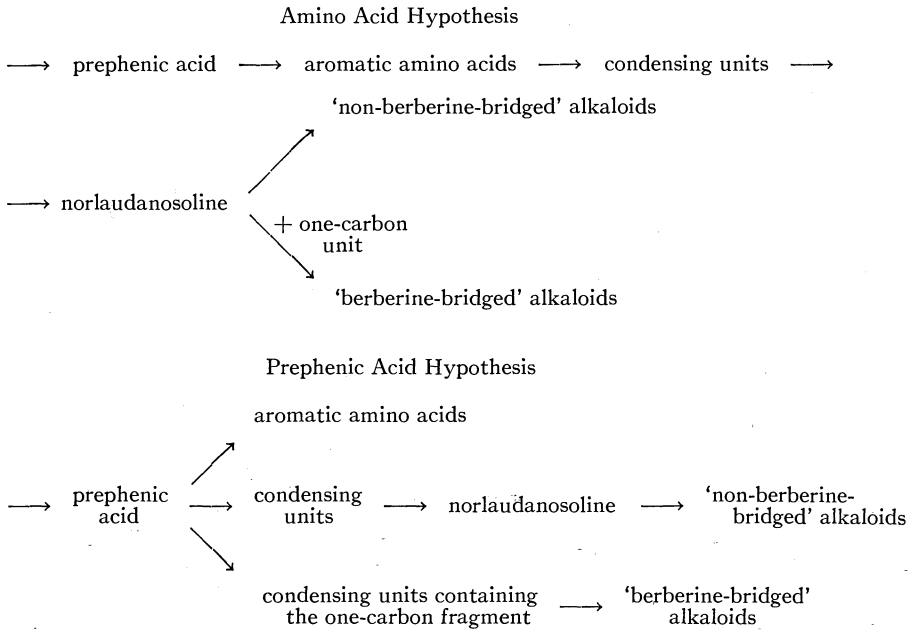
Two major hypotheses have been advanced concerning the biogenesis of alkaloids containing the isoquinoline ring system.

The classical hypothesis, put forward in 1910 by Winterstein and Trier (4), elaborated by Robinson (5), and refined and extended by Robinson (6) and others (e.g. ref. 7), looked upon the aromatic amino acids tyrosine (I) and, more particularly, dihydroxyphenylalanine (dopa) (II) as the progenitors of this group of alkaloids. By decarboxylation dopa was thought to give rise to the corresponding arylethylamine, dopamine (III), which may undergo condensation, in a Mannich reaction, with carbonyl compounds, derivable from amino acids by oxidative deamination. Such a condensation of dopamine with the arylpyruvate (IV) or arylacetaldehyde derived from dopa would yield norlaudanosoline (V). This compound contains a ring skeleton from which a large number of the structural variants of the isoquinoline alkaloids may be formally derived by such comparatively simple processes as methylation, aromatization, and intra- and intermolecular oxidative coupling. It was believed that a second Mannich reaction of norlaudanosoline with formaldehyde could lead, by introduction of the so-called 'berberine bridge', to a tetracyclic system (VI) from which, by various oxidative modifications, the skeletons of further alkaloids could be obtained. This well-known hypothesis, different aspects of which have been repeatedly discussed (8–14), encompasses the biogenesis of the great majority of known naturally occurring isoquinolines, and has received circumstantial support from model syntheses under chemical (e.g. 15, 16) and "pseudophysiological" (8, 17–21) conditions.

Recently an alternative hypothesis, based on current knowledge of the role of prephenic acid in the biosynthesis of the aromatic amino acids (22, 23), has been put forward by Wenkert (24). He advanced the view that it was not tyrosine but its biochemical precursor, prephenic acid, which served directly as the progenitor of the arylethylamine (III) and the arylpyruvate (IV) whose condensation would yield norlaudanosoline (V). 'Berberine-bridged' structures were thought to arise not by introduction of a one-carbon unit into norlaudanosoline but by interaction of two prephenate-derived precursors, one of which contained the one-carbon unit prior to condensation.

[1]*Parts of this work have been reported in preliminary communications (1, 2, 3).*

The differences between the amino acid and the prephenic acid hypotheses of biogenesis may be summarized as follows:



No experiments have yet been carried out which can differentiate between these two rival hypotheses. The general validity of the biogenetic approach has been established however. Two alkaloids which may be biogenetically derived from norlaudanosoline, papaverine (25) and morphine (26), have been the objects of unequivocal biosynthetic investigation. In both cases it was shown by unambiguous degradation of the labelled alkaloids, obtained from DL-[2-^{14}C]-tyrosine in *Papaver somniferum* L., that two units of precursor were incorporated without scrambling of radioactivity, in the manner predicted by the classical hypothesis. It was shown further that norlaudanosoline itself was also incorporated into both alkaloids without randomization (27).

Since these findings can also be reconciled with the prephenic acid hypothesis, however, the results of these investigations cannot serve to differentiate between the two biogenetic proposals. Both hypotheses predict that the two alkaloids are derived from norlaudanosoline, which arises by condensation of an hydroxylated phenylethylamine with an hydroxylated phenylpyruvic acid unit. The question at issue is therefore whether these two intermediates are *normally* derived from tyrosine or whether they are *normally* derived directly from prephenic acid.

It is difficult to design a critical experiment capable of giving an unequivocal answer to this question. In most cases the 'Wenkert precursor' would be predicted to yield the 'classical precursor' by known metabolic steps. Biosynthetic incorporation into an alkaloid of the labelled 'Wenkert precursor' would thus not invalidate the classical hypothesis. Also, the biogenetic condensing units (e.g., III and IV) could arise in most cases either from tyrosine or directly from prephenic acid, by unexceptional metabolic steps. It is conceivable that both of these pathways may be available simultaneously, one as the major route, the other as an alternative route of minor quantitative importance. Incorporation into an alkaloid of a labelled 'classical precursor' may thus represent the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

minor pathway and does not therefore disprove the prephenic acid hypothesis. It is for this reason that the investigations on papaverine (25) and morphine (26) do not distinguish between the two hypotheses.

The work to be described deals with one of the few instances where different pairs of biogenetic condensing units are postulated by the classical and by Wenkert's hypothesis so that clear-cut differentiation of the two hypotheses is possible. The results unequivocally disprove the prephenic acid hypothesis.

RESULTS

The plant chosen for experiment was the Canadian Goldenseal, *Hydrastis canadensis* L., which elaborates three alkaloids, berberine (VIII), hydrastine (IX), and canadine (VII). In a series of feeding experiments D-[U-^{14}C]-glucose, DL-[2-^{14}C]-phenylalanine, DL-[2-^{14}C]-tyrosine, DL-[3-^{14}C]-tyrosine, and [1-^{14}C]-dopamine were administered, either by way of the root or by infusion into the stem (expts. 1–10, Table I). In each experiment

*The wicks used in this experiment contained negligible residual activity at the end of the feeding period.
†The solution initially fed in this experiment had a total activity of 3.40×10^7 counts/min. Extraction of the wicks at the time of harvesting yielded a total activity of 1.24×10^7 counts/min, which was shown to be due to unchanged dopamine by chromatography in *n*-propanol – water (7:3) and by radioassay of the chromatogram. The total activity of dopamine taken up by the plant was thus 2.16×10^7 counts/min.

berberine and hydrastine were extracted from the roots and rhizomes of the plants, and in one case (expt. 4L) also from stems and leaves.

The alkaloids were assayed for radioactivity (Table II) and those derived from selected experiments were systematically degraded to ascertain the precise location of radiocarbon.

Of the compounds tested, tyrosine was found to be the most efficient precursor of the alkaloids (Table III). In experiments of the same duration, administration by infusion resulted in higher incorporation of radioactivity than administration by way of the root (expts. 7 and 9, Table IV). Stems and leaves contained only small amounts of alkaloids, and the specific activity of the alkaloids isolated from the aerial parts of the plant was much lower than that of the alkaloids isolated from roots and rhizomes of the same plant (expts. 4 and 4L). Dopamine was almost as good a precursor of berberine as was tyrosine, but appeared to be less efficient as a precursor of hydrastine. Glucose was a much less efficient precursor of the alkaloids, and phenylalanine incorporation was almost

negligible. Without exception berberine isolated from a particular experiment had a higher specific activity than hydrastine obtained from the same experiment, even though the quantity of berberine isolated always exceeded that of hydrastine. The specific radiochemical yields obtained in each of the experiments are shown in Table III.

Degradation of hydrastine (IX) derived from DL-[2-^{14}C]-tyrosine (expt. 4) showed that activity was located exclusively at carbon atoms 1 and 3 of the hydrastine skeleton. This establishes tyrosine as a specific precursor of hydrastine, and demonstrates that two molecules of tyrosine are utilized in the biosynthesis of each molecule of hydrastine. However,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the ratio (radioactivity in C_1/radioactivity in C_3) was not 1:1 but 2:3. To investigate whether this ratio was affected by the period of growth of the plants in contact with tracer, hydrastine obtained from experiments 5–8, in which plants had been exposed to DL-[3-^{14}C]-tyrosine for varying periods of time, was partially degraded.[2] The results are shown in Table V but no simple trend is apparent.

TABLE V

	Hydrastine		Hydrastinine		Opianic acid	
Expt.	Specific activity (counts/min mmole) $\times 10^{-4}$	Relative specific activity	Specific activity (counts/min mmole) $\times 10^{-4}$	Relative specific activity	Specific activity (counts/min mmole) $\times 10^{-4}$	Relative specific activity
5	1.19	100	0.50	42.0	0.65	54.5

Degradation of the hydrastine isolated from plants to which [1-^{14}C]-dihydroxyphenylethylamine had been administered (expt. 10) showed that activity was located exclusively at carbon atom 3. Thus dopamine was a specific precursor of hydrastine but only one molecule of dopamine was used in the biosynthesis of the alkaloid.

Degradation of the berberine obtained in experiment 4 showed that activity was confined to carbon atoms 1 and 3 of berberine (VIII). Tyrosine was therefore a specific precursor of berberine and two tyrosine units had been incorporated into the alkaloid. The ratio (radioactivity in C_1/radioactivity in C_3) in this case was found to be unity.

DISCUSSION

According to classical hypothesis the major steps in the biogenesis of hydrastine (IX) are (i) the condensation of dopamine (III) and dihydroxyphenylpyruvic acid (IV), both derived from tyrosine (I), to yield norlaudanosoline (V), (ii) the introduction of a one-carbon unit into norlaudanosoline, giving a tetrahydroberberine ring system (VI), and (iii) oxidative modification of the latter to yield the alkaloid.

The hypothesis demands that, in a biosynthetic experiment, radioactivity from [2-^{14}C]-tyrosine should enter hydrastine at two sites and should be confined to carbon atoms 1 and 3 (Fig. 1).

Wenkert's prephenic acid hypothesis, on the other hand, postulates that the skeleton of hydrastine is derived without the intervention of norlaudanosoline, by combination of two fragments thought to arise directly from prephenic acid (X), an arylethylamine (III) and an *o*-carboxyarylpyruvic acid (XII) (Fig. 2). The latter precursor retains carbon atom 7 of prephenic acid as an aromatic carboxyl group, from which the 'one-carbon bridge' of hydrastine is formed. Whereas the amine (III), derived according to Wenkert from prephenate, could also be derived from tyrosine by a sequence of enzymic reactions for which there is ample precedent (28), *there is no known metabolic process whereby the second fragment* (XII), also derivable from prephenate, *can originate directly from tyrosine*, since the enzymic conversion of prephenate to tyrosine has been shown to be irreversible (29).

[2]*Since incorporation of two molecules of tyrosine into hydrastine had already been proved, it was sufficient in these experiments to separate the two labelled carbon atoms (4 and 7') from one another, and unnecessary to isolate them completely.*

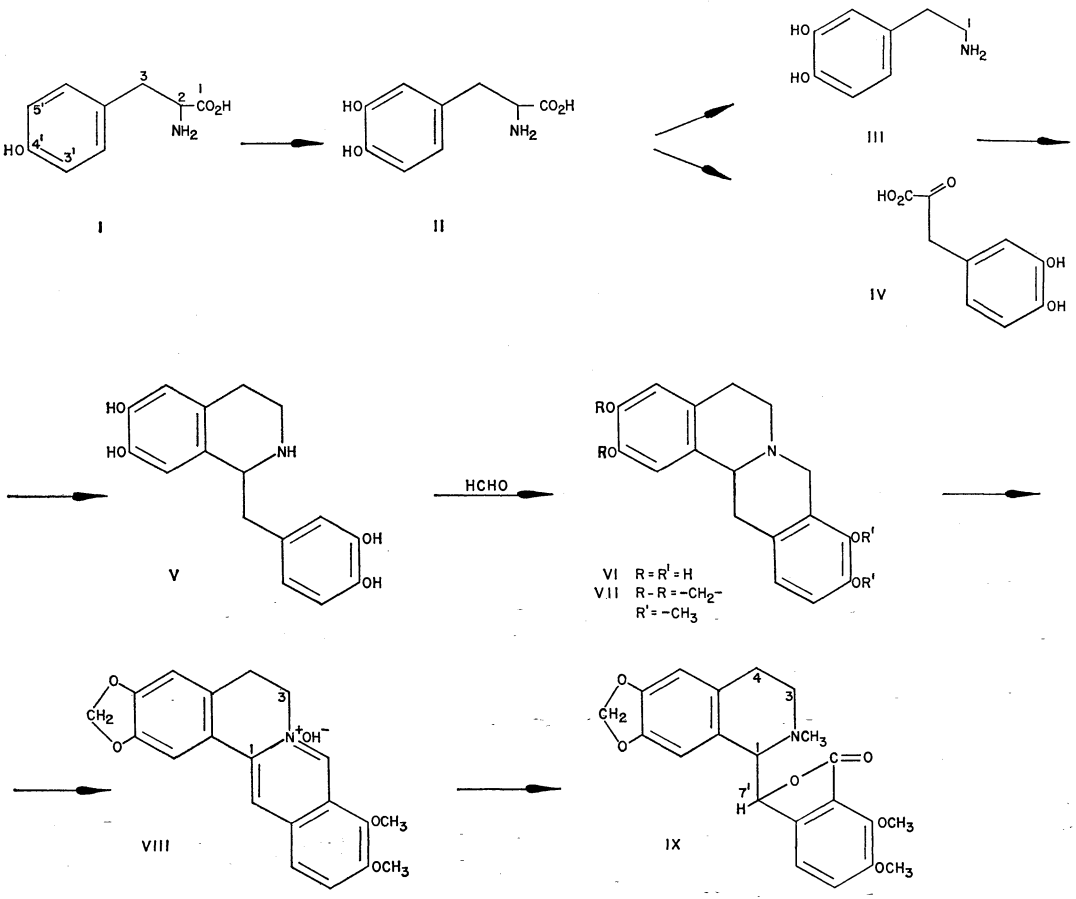

FIG. 1. Classical hypothesis of biogenesis of hydrastine and berberine.
Hydrastine (IX) could also be derived directly from V or VI and not by further oxidation of berberine (VIII). Experiments to establish the metabolic interrelationships of the two alkaloids are in progress.

Wenkert's hypothesis thus requires that if radioactivity from [2-^{14}C]-tyrosine were incorporated into hydrastine without randomization, it should be confined to carbon atom 3 of the molecule.[3]

[3]*Conversion of [2-^{14}C]-tyrosine to glucose (30) and of [U-^{14}C]-tyrosine to carbohydrates (31) has been reported to take place in plants. The steps of this pathway have not been investigated. If the metabolic breakdown of tyrosine in plants is analogous to that in microorganisms and in rats, as seems likely (31), then activity from [2-^{14}C]-tyrosine should appear at carbon atoms 3 and 4 of glucose, by way of [1-^{14}C]-acetoacetate, [1-^{14}C]-acetyl-CoA, [1-^{14}C]-citrate, [1,4-^{14}C]-oxalacetate, [1-^{14}C]-pyruvate, followed by reversal of glycolysis. If, furthermore, shikimic and prephenic acid biosynthesis in plants parallels that in microorganisms, and evidence for this view is accumulating (32), then activity from [3,4-^{14}C]-glucose or any of the intermediates between [2-^{14}C]-tyrosine and [3,4-^{14}C]-glucose would appear in carbon atoms 7, 3, and 4 of shikimic acid (23) and, after assimilation of a [1-^{14}C]-pyruvate moiety, in carbon atoms 3 and/or 5, 4, 7, and 10 of prephenic acid. If this prephenic acid then served as a precursor of hydrastine, according to Wenkert's scheme, activity in the alkaloid would be randomized over carbon atoms 6 and/or 8, 7, 2' and/or 4', 3' and 10'. If the above assumptions are valid, demonstration of such randomization of activity in hydrastine derived from [2-^{14}C]-tyrosine would favor Wenkert's hypothesis, but would not prove its validity conclusively, for if the process leading from [2-^{14}C]-tyrosine to [3,(5),4,7,10-^{14}C]-prephenic acid were rapid, the latter would yield [1,3',4',5'-^{14}C]-tyrosine, incorporation of which into hydrastine, as predicted by the classical hypothesis, would also yield multiply labelled alkaloid, which in addition to ^{14}C at carbon atoms 6, 7, 8, 3', 4', and 5' would also show activity at carbon atoms 1 and 3, from the original [2-^{14}C]-tyrosine. In either case carbon atoms 11, 12, 8', and 9' and in the latter case carbon atom 10' of hydrastine may also show radioactivity derived from the one-carbon fragment split off as carbon dioxide from carbon atom 7 of prephenic acid.*

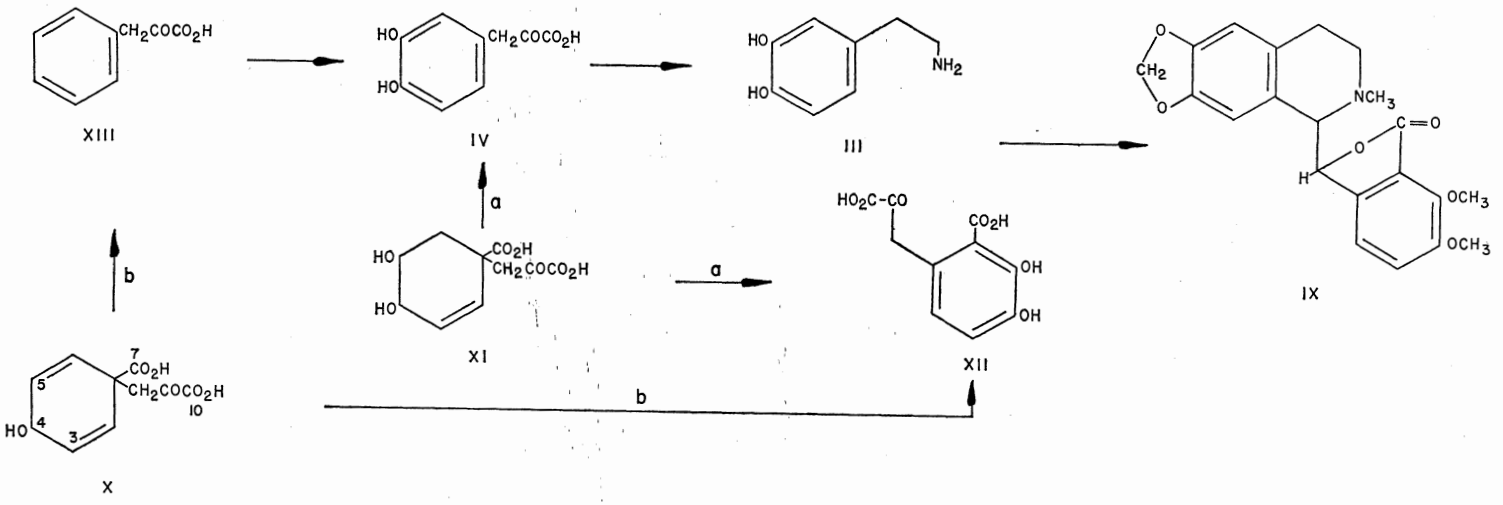

FIG. 2. Prephenic acid hypothesis of biogenesis of hydrastine. Original scheme (*a*) based on hydrated prephenic acid (XI) and revised scheme (*b*) based on prephenic acid (X).

Demonstration of specific incorporation of one tyrosine unit into the isoquinoline segment of hydrastine would clearly confirm Wenkert's hypothesis and invalidate the classical hypothesis. Demonstration of specific incorporation of two tyrosine units into hydrastine, on the other hand, would establish the validity of the classical hypothesis and unequivocally disprove Wenkert's scheme for the biogenesis of hydrastine.

The results of the present feeding and degradation experiments show that tyrosine is a direct precursor of hydrastine and that two molecules of tyrosine are used in the biosynthesis of hydrastine. It follows that Wenkert's scheme for the biogenesis of the phthalideisoquinoline alkaloids (Fig. 2) is not valid for hydrastine, a member of this group. The results are in agreement with the classical hypothesis (Fig. 1).

The significance of the unequal incorporation of radioactivity from DL-[2-^{14}C]-tyrosine into carbon 1 and carbon 3 of hydrastine, which was regarded as evidence for a split biosynthetic pathway, has been discussed elsewhere (1).

A study of the variation with time of the ratio (radioactivity in C_1/radioactivity in C_3) (Table VI) did not indicate a simple trend. Further experiments are required before a

TABLE VI

Variation of ratio C_1/C_3 or C_7'/C_4 of hydrastine with time

Expt.	Precursors fed to plants	Mode of administration	Duration of feeding (days)	Ratio of C_1 to C_3 or C_7' to C_4
5	3-^{14}C-Tyrosine	Root	3	1.30
6	"	"	6	1.00
7	"	"	9	1.01
9	"	Wick*	(9)	(0.75)
4	2-^{14}C-Tyrosine	Root	17	0.61
8	3-^{14}C-Tyrosine	"	24	1.23

*Since experiment 9 was a wick-feeding experiment whereas all others were root-feeding experiments, the ratio of 0.75 obtained from it is not directly comparable with the other ratios. At the same time it is interesting to see that the value of 0.75 lies between the values of 1.01 for experiment 7 and 0.61 for experiment 4. This would appear to indicate that wick-feeding causes faster uptake of precursor, and that a 9-day wick-feeding experiment is equivalent to a root-feeding experiment of greater than 9 but less than 17 days' duration.

meaningful interpretation of this variation can be attempted.

Dopamine was found to be a specific precursor of hydrastine. Since radioactivity from [1-^{14}C]-dopamine was confined to carbon 3 of hydrastine, only one dopamine unit was incorporated into the alkaloid molecule. This finding, which provides confirmation of the 'split biosynthetic pathway' and establishes the association of dopamine with one of the branches of the biosynthetic route to hydrastine, has already been reported (2). Present knowledge of the biosynthesis of hydrastine may be summarized as shown in Fig. 3.

The test which was applied to establish the validity of one or the other of the classical or the prephenate hypotheses in the case of hydrastine is not applicable in the case of berberine, another alkaloid of *H. canadensis* L. It was found that two tyrosine units were specifically incorporated into berberine, radioactivity from DL-[2-^{14}C]-tyrosine being located exclusively at carbon atoms 1 and 3 of the alkaloid. In this instance, however, specific incorporation of radiotyrosine is not of diagnostic value in differentiating between the two hypotheses, since *both* of the prephenate-derived 'Wenkert precursors' (IV and III*a*) (Fig. 4) *could* also arise by feasible metabolic routes from tyrosine.

A second line of evidence is available, however, which not only substantiates the conclusions reached with respect to Wenkert's scheme for hydrastine biogenesis, but also serves to invalidate his prephenic acid hypothesis in the case of berberine. In its original form (24) the prephenic acid hypothesis postulated that each of the two fragments, whose

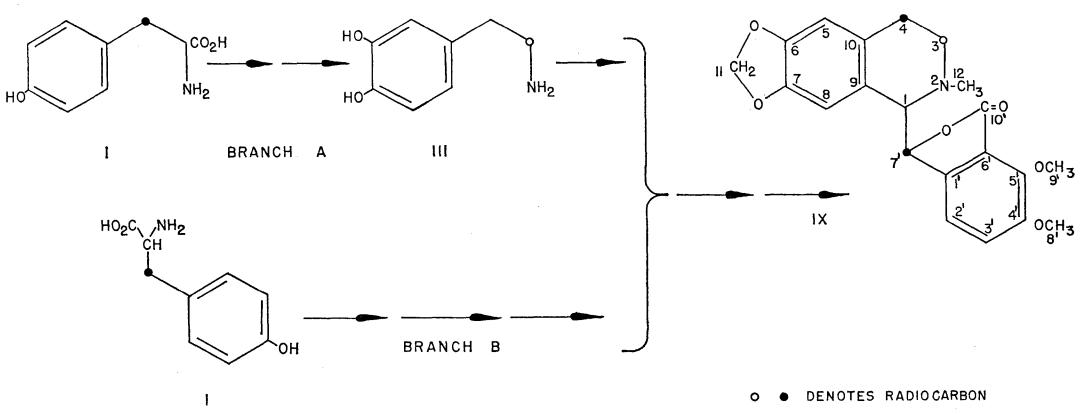

FIG. 3. Biosynthesis of hydrastine.

union yields the skeleton of the isoquinoline alkaloids, was derived from a hydrated prephenic acid moiety (XI). When it was demonstrated that the enzymic conversion of shikimate to prephenate proceeds without the intervention of such a hydrated form (33, 23), the hypothesis was modified (34) to accommodate this fact. According to the modified hypothesis the hydroxylated arylethylamine and arylpyruvate units required in the biogenesis of the isoquinoline alkaloids are derived from prephenate by way of phenylpyruvic acid (XIII). Phenylpyruvic acid is thus regarded as an intermediate in the hypothetical pathway. Since phenylpyruvate would be expected to arise from phenylalanine by transamination, and since transamination of phenylalanine is known to occur in plants (35), it can be predicted that, if this hypothesis were valid, phenylalanine would serve as an efficient precursor of the isoquinoline alkaloids. Incorporation of radiophenylalanine into hydrastine and berberine has now been shown to be almost negligible however, at a time of development of the plants when tyrosine was actively incorporated into the alkaloids. That this low level of incorporation of phenylalanine was not due to endogenous dilution is shown by the finding that the incorporation of radioglucose into hydrastine and berberine, at the same stage of development of the plants, was far more efficient than incorporation of phenylalanine. Nor is it likely that the low level of phenylalanine incorporation was due to lack of absorption of the precursor by the plant. Phenylalanine was found to disappear from the nutrient solution as rapidly as tyrosine and glucose. Assuming the biochemical equivalence of phenylalanine and phenylpyruvic acid in *H. canadensis*, the prephenate hypothesis is thus shown to be invalid in the case of berberine as well as in the case of hydrastine.

The present results provide strong evidence against the prephenic acid hypothesis only in the instances of hydrastine and berberine. A review of recent work on the biosynthesis of alkaloids (36) however shows that alkaloids of the same group, differing only in oxidation state and extra-skeletal substituents, are often derived from the same precursors. Since both hydrastine and berberine are representative of a much larger class of naturally occurring compounds of common and related skeletal structure, the present findings cast doubt on the validity of the prephenic acid hypothesis of biogenesis of the isoquinoline alkaloids in general.

The classical hypothesis of biogenesis, however, is supported by all available biosynthetic data (36). At the time this hypothesis was conceived half a century ago, experimental methods capable of eliciting supporting evidence were lacking. Despite this lack

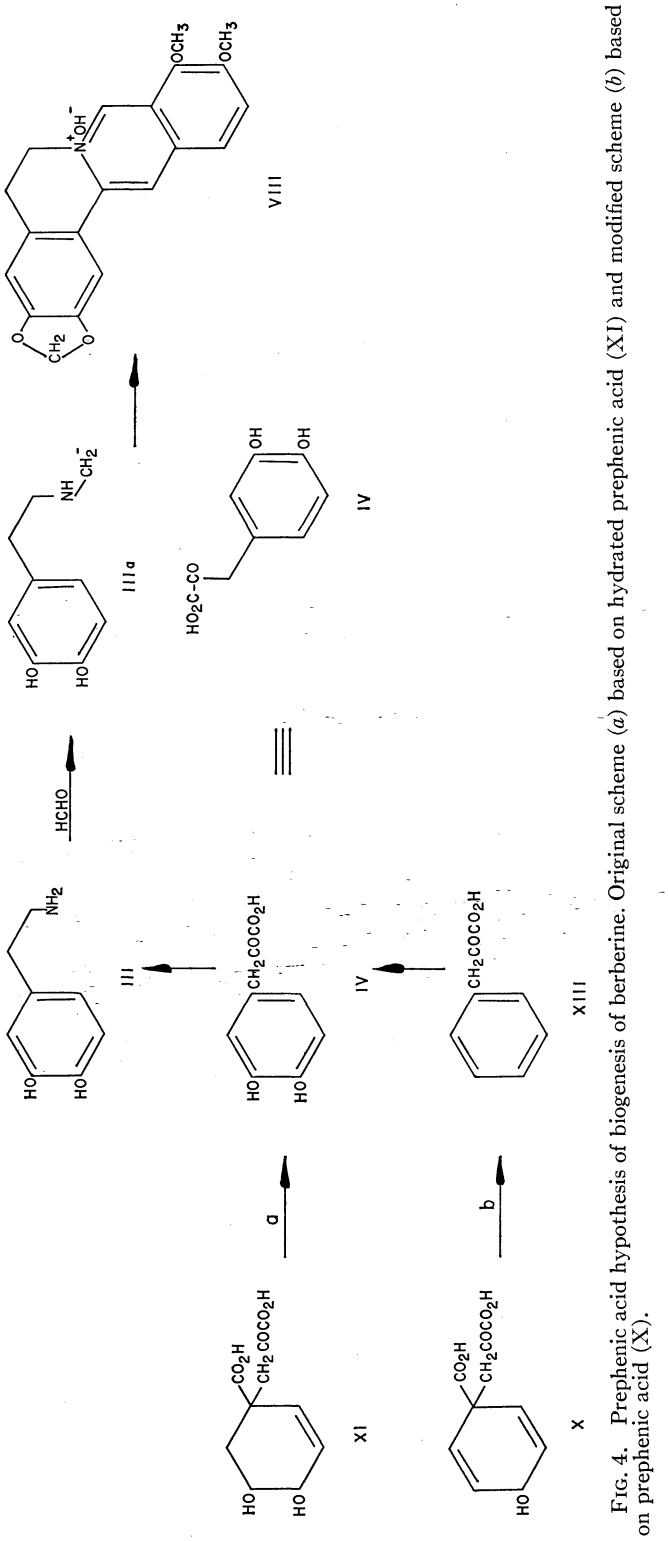

FIG. 4. Prephenic acid hypothesis of biogenesis of berberine. Original scheme (*a*) based on hydrated prephenic acid (XI) and modified scheme (*b*) based on prephenic acid (X).

of experimental proof, the importance of the hypothesis in giving direction to the use of the experimental tools, when these became available, is self-evident. Now that these tools are commonly used, there seems little to justify the publication of biogenetic speculations unsupported by direct experiment.

DEGRADATION SEQUENCES

Hydrastine

Specific incorporation of [2-^{14}C]-tyrosine was expected to yield hydrastine labelled at C_1 and/or C_3. A degradation, permitting the isolation of these two atoms, was therefore devised (Fig. 5).

Oxidation of hydrastine (IX) gave opianic acid (XIV) and hydrastinine (XV), the latter containing both C_1 and C_3 of hydrastine.

To remove the nitrogen atom and *N*-methyl group, hydrastinine was subjected to exhaustive methylation. Attempts to effect this reaction in two stages by way of the quaternary methiodide (37) gave low yields. Hofmann degradation in one step in a heterogeneous system (benzene–water), however, gave hydrastal (XVI) in high yield. Hydrastal was oxidized by silver oxide to 6-vinylpiperonylic acid (XVII), which still contained C_1 and C_3. C_1 of hydrastine was isolated by bromo-decarboxylation of the acid XVII. Jones and Robinson (38) had used this reaction for the removal of the carboxyl group from piperonylic acid, using bromine–water in dilute sodium carbonate. Since, in the degradation of radioactive material, the carbon dioxide from C_1 was to be collected and assayed for activity, these conditions were not applicable to the present problem. Attempts to carry out the reaction with bromine–water in acetone or carbon disulphide did not lead to decarboxylation. Bromination of XVII in carbon disulphide gave the dibromo derivative XVIII, which on recrystallization from acetone–water underwent spontaneous hydrolysis (cf. ref. 46) and lactonization to yield the lactone XIX. The same lactone was isolated directly when XVII was brominated in acetone solution.

Bromo-decarboxylation of the acid XVII by bromine–water in a solution of disodium hydrogen phosphate, however, gave the bromohydrin XX in good yield. The carbon dioxide (C_1 of hydrastine) was collected as barium carbonate, which, for radioassay,[4] was converted to benzoic acid XXI.

It remained to separate C_3 of hydrastine from the rest of the molecule. The bromohydrin XX did not undergo the haloform reaction, but oxidation with potassium permanganate in pyridine–water gave 6-bromopiperonal XXII. The other fragment was not isolated, but since only C_3 of hydrastine was lost its activity could be found by difference. 6-Bromopiperonal (XXII) was difficult to purify and was therefore converted into a derivative. Oxidation with silver oxide gave 6-bromopiperonylic acid (XXIII) in good yield, while condensation with acetone gave 6-bromopiperonylidene acetone (XXIV).

Berberine

In the degradation of berberine a series of reactions was used which had been originated by Freund and Fleischer (39) (Fig. 6). Berberine hydrochloride (VIII) was reacted with benzylmagnesium bromide to give benzyldihydroberberine (XXV) in good yield.

Reduction of this compound with tin and hydrochloric acid (39) could not be repeated. Sodium borohydride, however, converted XXV rapidly to benzyltetrahydroberberine (XXVI) in almost quantitative yield. The latter was converted into the methiodide

[4]*The carbon dioxide was converted into an organic compound in order that its radioactivity could be assayed under the conditions which were used for all other compounds of the degradation sequence, thus making direct comparison of count rates possible.*

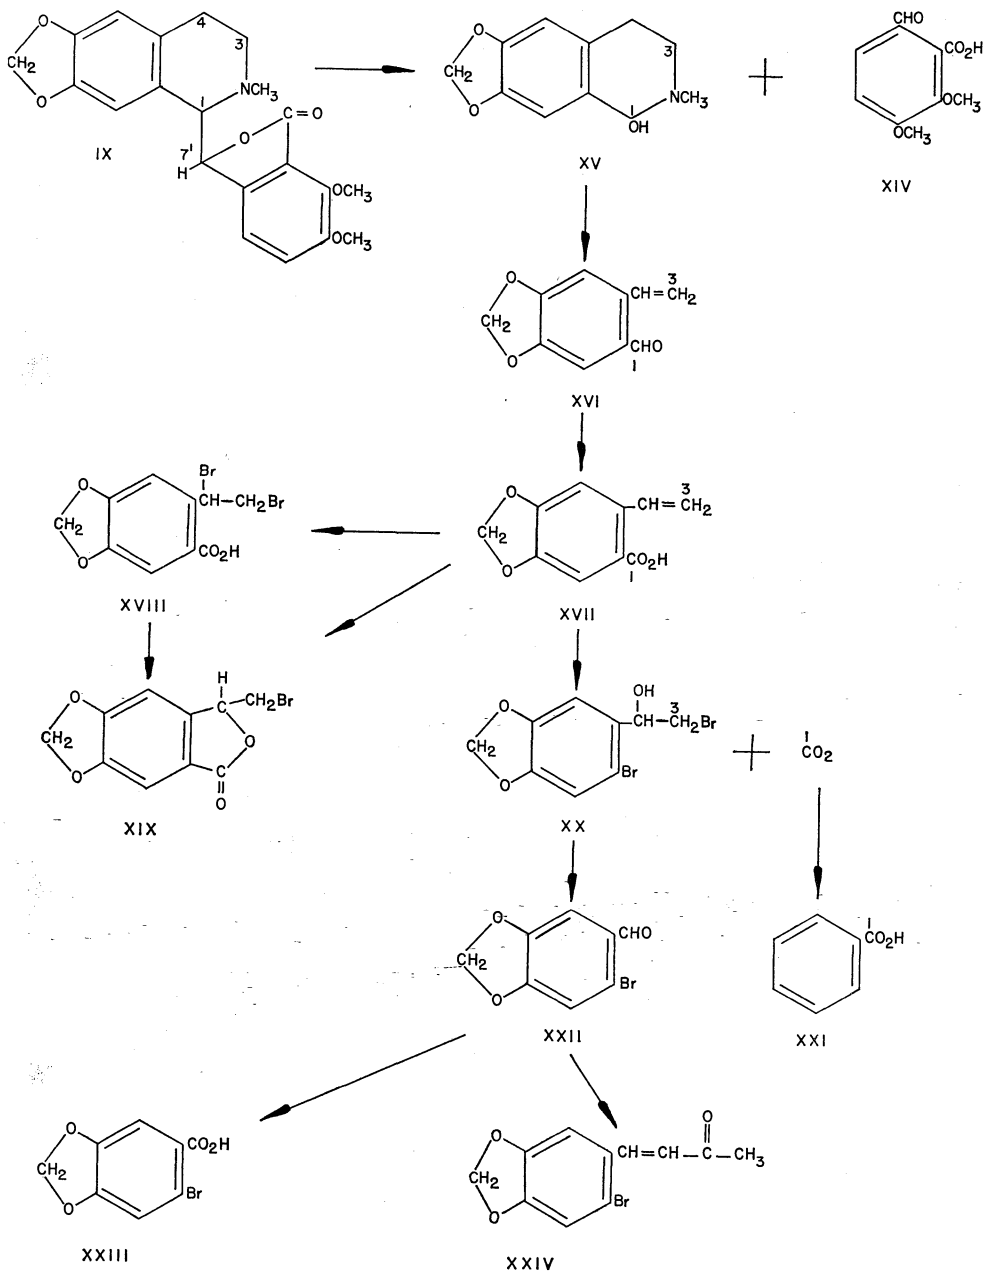

FIG. 5. Degradation of hydrastine.

(XXVII), which was then allowed to undergo Hofmann degradation. Silver oxide and solid sodium hydroxide (39) gave poor yields of product. Good yields of des-*N*-methyl-styryltetrahydroberberine (XXVIII) were obtained using methanolic potassium hydroxide.

Oxidation of XXVIII with sodium dichromate in acetic acid gave hydrastinine (XV) and 3,4-dimethoxy-2-styrylbenzaldehyde (XXIX). The hydrastinine, containing both

predicted sites of radioactive carbon (C_1 and C_3 of berberine), was degraded in the manner already described.

EXPERIMENTAL

Administration of ^{14}C-Labelled Compounds to Hydrastis canadensis L. Plants

For root-feeding experiments small 2- and 3-year-old plants were used, which had wintered in the open and had grown in soil during spring and early summer. For each experiment a number of plants were placed under hydroponic culture. Soil was removed from the roots by soaking in distilled water. The plants were inserted through holes in a wooden box, their stems supported by glass wool plugs, and their roots dipping into nutrient solution (40) in a glass dish which was left in the dark. Filtered air was bubbled through the solution continuously. The plants were kept in 75% shade. Each group of plants was allowed to grow under these conditions for 1 week, by which time they had recovered from transplanting, and fresh root growth was apparent. The nutrient solution was replaced by fresh nutrient solution (1500 ml), containing the labelled compound, and the plants were allowed to grow in this system for the required time. During this period the radioactivity of the nutrient solution and of specimens of leaf was assayed daily. In all cases 95% of the activity had disappeared from the nutrient solution within 40 hours.

The roots and rhizomes were separated from the leaves and stems, dried to constant weight in a vacuum desiccator over NaOH, and stored.

Wick-feeding experiments were carried out with large 3- and 4-year-old plants which were allowed to grow in soil under 75% shade. Wicks of unmercerized cotton were passed through the stem of each plant. The ends were allowed to dip into an aqueous solution[5] of the ^{14}C-labelled compound in a small container (capacity 1 ml) which was repeatedly refilled with distilled water after the original solution had been absorbed. After the required time in contact with tracer, the plants were harvested and stored in the same manner as the root-fed plants. The cotton wicks were extracted with methanol and with water, and the extracts were assayed for residual activity.

Eight root-feeding experiments (expts. 1–8) and two wick-feeding experiments (expts. 9, 10) were carried out. The details of these are summarized in Table I.

Extraction of Alkaloids from the Plants

Hydrastine and berberine were extracted by standard methods (41). A typical experiment (expt. 3) is described.

The roots and rhizomes of well-dried *H. canadensis* L. plants (9.3 g) were ground to a fine powder in a mortar. To extract hydrastine the powder was thoroughly moistened with 3 *M* ammonium hydroxide (10 ml), allowed to stand for 30 minutes, transferred to a Soxhlet thimble (Whatman, 35×80 mm), and extracted continuously with ether (125 ml) for 26 hours. The ether extract was transferred to a separatory funnel and washed, first with 3 *M* ammonium hydroxide (30 ml), and then with water (30 ml). The washings were rejected. The washed ether solution was extracted with 10% hydrochloric acid (4×25 ml), and the combined acid portions were made strongly basic with 15 *M* ammonium hydroxide. This ammoniacal solution was extracted with ether (4×50 ml), the combined ether extracts were evaporated to dryness, and the residue was dissolved in a very small amount of hot ethanol. Hydrastine (173 mg, 1.9%) crystallized on cooling.

To obtain berberine the material remaining in the thimble was extracted continuously with 95% ethanol (125 ml) for 24 hours. The ethanolic extract was evaporated to dryness, water (30 ml) was added to the residue, and the mixture was heated on the steam bath and filtered. The filtrate was made strongly acidic with concentrated hydrochloric acid and allowed to stand overnight, when berberine hydrochloride (205 mg, 2.2%) crystallized.

In this way hydrastine and berberine were isolated from roots and rhizomes of the plants from each of the 10 experiments. In one case the alkaloids were also isolated from the leaves and stems by the same procedure (expt. 4L). Chemical and radioactive yields from all experiments are shown in Table II.

Degradation of Hydrastine

Conversion of Hydrastine to Hydrastinine and Opianic Acid (Cf. Ref. 42)

Nitric acid (2.5 ml, 20%) was added to hydrastine (136 mg) and the mixture was kept at 41° for 8.5 hours. The solution was cooled in an ice bath, and concentrated aqueous sodium hydroxide was added at a rate such that room temperature was not exceeded. A gummy mass separated, which on vigorous stirring first solidified and then broke up into finer particles which were filtered off to give hydrastinine (65 mg, 88%) melting at 110–113°. One crystallization from ethyl acetate raised the melting point to 116–117°; reported melting point 116–117° (43). The filtrate remaining after hydrastinine had been removed was made strongly acidic with concentrated hydrochloric acid and stored in the freezer overnight. The solid which separated when the frozen mixture was restored to room temperature was filtered off to give opianic acid (38 mg, 51%) melting at 141–144°. One crystallization from water raised the melting point to 144–145°; reported melting point 146° (42).

Conversion of Hydrastinine to Hydrastal (Cf. Ref. 44)

Benzene (10 ml), 20% aqueous sodium hydroxide (10 ml), and methyl iodide (5 ml) were added to hydrastinine (101 mg). The mixture was shaken for 24 hours. Water (10 ml) was added, a downward condenser

[5]*A drop of hydrochloric acid was added to the aqueous solution in order to dissolve tyrosine.*

was fitted, and the flask was heated on a steam bath for 30 minutes. Benzene and excess methyl iodide distilled off, leaving an aqueous basic solution, from which hydrastal separated as an oil which solidified on cooling. After standing for 3 hours this solid was filtered off to give hydrastal (75 mg, 87%) melting at 75–78°. One crystallization from ethyl acetate raised the melting point to 78–79°; reported melting point 78–79° (45).

Conversion of Hydrastal to 6-Vinylpiperonylic Acid (Cf. Ref. 44)

Hydrastal (106 mg) was suspended in a solution of potassium hydroxide (425 mg) in water (4.25 ml), and a solution of silver nitrate (650 mg) in 50% ethanol (8 ml) was added. After 5 minutes the mixture was heated at 80° on a water bath for 15 minutes, was allowed to cool for 2.5 hours with occasional swirling, and was filtered. The pH of the filtrate was adjusted to pH 1 by means of 50% nitric acid, and the mixture was then heated on a steam bath (with the addition of a little ethanol if necessary) until a clear solution was obtained. The solution was allowed to cool, and the solid was filtered off to give *6-vinylpiperonylic acid* (95 mg, 82%) melting at 166–168°. One crystallization from aqueous ethanol raised the melting point to 168°. (Found: C, 62.4; H, 4.5. $C_{10}H_8O_4$ requires: C, 62.5; H, 4.2%.)

Conversion of 6-Vinylpiperonylic Acid to 6-Bromo-α-hydroxyhomopiperonyl Bromide

6-Vinylpiperonylic acid (59 mg) was dissolved in 3% disodium hydrogen phosphate (15 ml) by swirling for 1 minute, and the solution was cooled in an ice bath for 10 minutes. Saturated bromine–water (10 ml) was added dropwise over a period of 2 minutes, and the mixture was allowed to stand for 3 minutes. It was then filtered quickly under moderately reduced pressure, and the wet precipitate (A) was set aside. The filtrate was immediately transferred to a 50-ml round-bottomed flask which was attached to a gas line. Nitrogen, which had been purified by passage through saturated barium hydroxide solution and through concentrated sulphuric acid, was bubbled through the solution. The exit gases were passed through 1 *M* aqueous sodium hydroxide (15 ml), which was protected from the atmosphere by a trap containing saturated barium hydroxide solution. Through a small dropping funnel in a side arm concentrated hydrochloric acid (3 ml) was added to the flask containing the reaction filtrate. The liberated carbon dioxide was swept into the sodium hydroxide trap by a stream of nitrogen. After 1 hour 17% barium chloride solution (3 ml) was added to the solution in the trap. The precipitate of barium carbonate (44 mg, 61%) was filtered off.[6] Meanwhile the wet precipitate (A) was dissolved in warm methanol, the mixture was filtered, and the filtrate was evaporated to dryness at the water pump. The residue was 6-bromo-α-hydroxyhomopiperonyl bromide (79 mg, 79%) melting at 148–153°. Two crystallizations from aqueous methanol raised the melting point to 157–158°; reported melting point 158° (46), 157–158° (47).

Conversion of 6-Bromo-α-hydroxyhomopiperonyl Bromide to 6-Bromopiperonal

6-Bromo-α-hydroxyhomopiperonyl bromide (65 mg) was dissolved in pyridine (6 ml) in a 2-necked flask. A small reflux condenser and a small dropping funnel were fitted. Powdered potassium permanganate (65 mg) was dissolved in water (4 ml) by warming on a steam bath, and a pellet of potassium hydroxide was added. The solution was poured into the dropping funnel and the last drops washed in with water (2 ml). The flask was warmed on a heating mantle until the contents boiled gently. The permanganate solution was then added dropwise, and washed in with water (2 ml). After boiling for a further 10 minutes the mixture was allowed to cool, and a few drops of ethanol were added to destroy any unreacted potassium permanganate. When quite cold the mixture was filtered. The filtrate was made strongly acidic with concentrated hydrochloric acid and then extracted with ether (4×25 ml). The combined ether extracts were evaporated to dryness, leaving a residue of 6-bromopiperonal (28 mg, 61%) melting at 105–110°. Recrystallization from aqueous ethanol gave a purer sample of 6-bromopiperonal (*vide infra*), but it was found that the best way to purify this compound for the purposes of this experiment was to convert it either to 6-bromopiperonylic acid or to 6-bromopiperonylidene acetone.

Conversion of 6-Bromopiperonal to 6-Bromopiperonylic Acid (Cf. Refs. 48, 49)

A solution of potassium hydroxide (500 mg) in water (5 ml) was added to 6-bromopiperonal (28 mg). A solution of silver nitrate (750 mg) in 50% ethanol (10 ml) was added to this mixture, which, after standing for 5 minutes, was heated on a water bath at 85° for 30 minutes. The mixture was then allowed to stand for 2.5 hours and filtered. The filtrate was acidified with concentrated hydrochloric acid and then extracted with ether (3×30 ml). The combined ether extracts were evaporated to dryness and the residue dissolved in hot water (30 ml). The solution was filtered and allowed to cool. The solid was filtered off to give 6-bromopiperonylic acid (25 mg, 83%) melting at 200–202°. One crystallization from water raised the melting point to 204–205°; reported melting point 200–204° (48), 201–202° (47).

Conversion of 6-Bromopiperonal to 6-Bromopiperonylidene Acetone (50)

6-Bromopiperonal (28 mg) was dissolved in acetone (3 ml). Aqueous sodium hydroxide (2 ml, 3%) was added, and the solution was heated on a steam bath until a precipitate had formed and the excess acetone had evaporated. The solid was filtered off to give 6-bromopiperonylidene acetone (25 mg, 81%) melting at

[6]*It was found by several control experiments that if this procedure were followed exactly, 3 mg of the barium carbonate so obtained came from extraneous sources, and would thus act as an inactive impurity if the barium carbonate derived from the reaction contained* ^{14}C. *A correction factor to account for this must be incorporated into any calculations which derive results from the count rate of this barium carbonate or of its derivatives.*

For personal use only.

148–151°. One crystallization from methanol raised the melting point to 152–154°; reported melting point 152–154° (50).

Conversion of Piperonal to 6-Bromopiperonylidene Acetone (50, Cf. Ref. 49)

Piperonal (1.38 g) was dissolved in 95% ethanol (20 ml), and bromine–water was added until a brown oil and some crystals separated. The crystals were filtered off, washed well with water, and recrystallized from aqueous ethanol to give 6-bromopiperonal (390 mg, 19%) melting at 126–127°; reported melting point 129–130° (50). A portion of this 6-bromopiperonal was converted, in the manner just described, to 6-bromopiperonylidene acetone melting at 152–154°, identical in melting point, mixed melting point, and infrared absorption with 6-bromopiperonylidene acetone derived from the degradation of hydrastine.

Conversion of Barium Carbonate to Benzoic Acid

The apparatus used (cf. ref. 51), is illustrated in Fig. 7. All ground-glass joints were greased with Apiezon

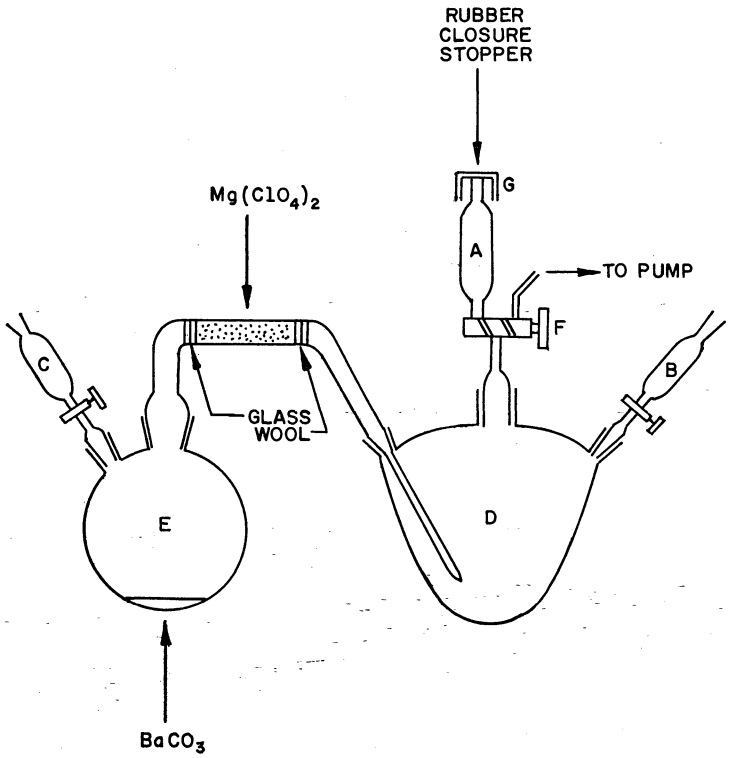

FIG. 7. Apparatus.

except F, which was greased with Dow-Corning high-vacuum grease. Barium carbonate (64 mg) was placed in flask E. The apparatus was assembled and evacuated (including funnel A) by a water pump to as low a pressure as possible. Hydrochloric acid (20%) was placed in funnels B and C. Using an all-glass hypodermic syringe with a 3-inch needle, phenylmagnesium bromide solution (8 ml, approximately 0.25 *M* (in dry ether), which had been stored at 10° in a flask with a rubber closure stopper) was withdrawn from the stock flask and inserted through the rubber closure stopper G into funnel A. The bottom of flask D was immersed in liquid air and a little hydrochloric acid was run into flask E from funnel C. The carbon dioxide which was liberated solidified at the bottom of flask D. A little of the phenylmagnesium bromide solution was then run into flask D. This at first vaporized the carbon dioxide, and then both froze as an intimate mixture. This procedure was repeated until all carbon dioxide and all of the phenylmagnesium bromide were frozen together in D. The liquid air was then replaced by an ice-water bath until the contents of D had melted. After 5 minutes the mixture was refrozen, and was then allowed to melt again. The ice bath was removed and hydrochloric acid was added from B until the vigorous reaction ceased, showing that excess phenylmagnesium bromide had been destroyed. The system was evacuated again to remove any unreacted carbon dioxide, and then allowed to reach atmospheric pressure. The contents of D were rinsed out with ether into a separatory funnel and the water layer was extracted with ether (3×20 ml). The combined ether

For personal use only.

extracts were evaporated to dryness and the residue was dissolved in hot water, filtered, and cooled. The solid was filtered off to give benzoic acid (17 mg, 43%) melting at 119–121°. One crystallization from water raised the melting point to 122°.

Conversion of 6-Vinylpiperonylic Acid to 6-(β-Bromo-α-hydroxyethyl)-piperonylic Acid Lactone

6-Vinylpiperonylic acid (150 mg) was dissolved in acetone (10 ml). Saturated bromine–water (15 ml) was added dropwise to the solution over a period of 30 minutes, followed by water (10 ml) over a period of 5 minutes. The solid was filtered off to give *6-(β-bromo-α-hydroxyethyl)-piperonylic acid lactone* (190 mg, 90%) melting at 134–134.5°. Recrystallization did not raise the melting point. (Found: C, 44.5; H, 2.7; Br, 29.5. $C_{10}H_7BrO_4$ requires: C, 44.6; H, 2.6; Br, 29.5%.)

The lactone was also obtained in the following manner. 6-Vinylpiperonylic acid (54 mg) was dissolved in carbon disulphide (5 ml), excess bromine in carbon disulphide was added, and the mixture was allowed to stand overnight. Excess petroleum ether was added and the product, presumably 6-(α,β-dibromoethyl)-piperonylic acid (87 mg, 88%), melting at 158°, was filtered off. When this compound (70 mg) was recrystallized from aqueous acetone, 6-(β-bromo-α-hydroxyethyl)-piperonylic acid lactone (40 mg, 74%) was obtained which melted at 134–134.5°. A mixed melting point of samples of the lactone prepared by the two different procedures showed no depression.

Degradation of Berberine (39)

Conversion of Berberine Hydrochloride to Benzyldihydroberberine (52)

Magnesium turnings (720 mg), which had been ground in a mortar, and a crystal of iodine were introduced into a flask. A solution of freshly distilled benzyl chloride (3.25 g) in sodium-dried ether (36 ml) was added, a condenser was fitted to the flask, and after the vigorous reaction had ceased the mixture was heated under reflux for 2 hours. The solution was then slowly added to berberine hydrochloride (800 mg) in sodium-dried ether (10 ml) in a 100-ml round-bottomed flask. When the initial reaction had subsided the mixture was heated under reflux for 2.75 hours. The contents of the flask were then extracted with 6 *M* hydrochloric acid (50 ml) in a separatory funnel and the aqueous layer was transferred to a 400-ml beaker. This solution was cooled in an ice bath, and 15 *M* ammonium hydroxide was added at a rate such that the temperature did not rise above room temperature. A gummy mass separated, which, when the cold solution was stirred vigorously, first solidified and then broke up into finer particles, which were filtered off to give benzyldihydroberberine (770 mg, 92%) melting at 131–134°. One crystallization from methanol–acetone raised the melting point to 135–137°. Further recrystallization did not raise the melting point again, and at no time was benzyldihydroberberine obtained which had the reported melting point of 161–162° (52).

Conversion of Benzyldihydroberberine to Benzyltetrahydroberberine (Cf. Ref. 39)

Benzyldihydroberberine (768 mg) was suspended in methanol (100 ml) and sodium borohydride (2.0 g) was added carefully in small portions. A reflux condenser was fitted to the flask, and when the vigorous reaction had ceased the solution was heated under reflux for 15 minutes. The solution was allowed to cool, and was acidified with 6 *M* hydrochloric acid while being stirred with a magnetic stirrer. The contents of the flask were then made basic with 15 *M* ammonium hydroxide and allowed to cool. The solid was filtered off to give benzyltetrahydroberberine (716 mg, 93%) melting at 162–165°. One crystallization from methanol–acetone raised the melting point to 165°; reported melting point 163–165° (39).

Conversion of Benzyltetrahydroberberine to Benzyltetrahydroberberine Methiodide (39)

Benzyltetrahydroberberine (715 mg) was introduced into a heavy-walled hard-glass tube (7 mm×600 mm which had been sealed at one end), and washed in with methyl iodide (8 ml). The tube was cooled in ice and the open end was sealed. It was then kept at 100–105° for 5 hours. After cooling in ice the tube was opened, and the solid in it was filtered off to give benzyltetrahydroberberine methiodide (798 mg, 84%) melting at 203–208°. One crystallization from methanol which contained a little sodium hydroxide raised the melting point to 220° (decomp.); reported melting point 224° (decomp.) (39).

Conversion of Benzyltetrahydroberberine Methiodide to Des-N-methylstyryltetrahydroberberine (Cf. Ref. 39)

Benzyltetrahydroberberine methiodide (795 mg) was suspended in methanol (2 ml). A solution of potassium hydroxide (2.0 g) in methanol (11 ml) was added, a condenser was fitted, and the mixture was heated under reflux for 1 hour. It was stored at 10° for 2 hours and the liquid layer was removed by decantation. The residue was dissolved in a minimum of hot methanol and stored in the freezer for several hours. The solid was filtered off to give des-*N*-methylstyryltetrahydroberberine (392 mg, 64%) melting at 121–123°. One crystallization from methanol raised the melting point to 123–124°; reported melting point 121–122.5° (39).

Conversion of Des-N-methylstyryltetrahydroberberine to Hydrastinine and 2-Styryl-3,4-dimethoxybenzaldehyde (39)

Des-*N*-methylstyryltetrahydroberberine (350 mg) was dissolved in glacial acetic acid (1 ml). A solution of sodium dichromate (271 mg) in 50% acetic acid (3 ml) was added, a condenser was fitted, and the solution was heated on a steam bath for 3.25 hours. The solution was cooled in an ice bath and water (4 ml) was added. After being stored at 10° for 3 hours the solution was decanted into a beaker, leaving an oily solid (A), which was set aside. The solution in the beaker was saturated with sodium carbonate, decanted from an oily residue into a separatory funnel, made strongly basic with concentrated sodium hydroxide, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extracted with ether (2×20 ml). The combined ether extracts were evaporated to dryness and the residue was suspended in water, and filtered off to give hydrastinine (105 mg, 64%) melting at 100–105°. One crystallization from ethyl acetate raised the melting point to 116–117°. Meanwhile, the oily solid (A) was dissolved in a minimum of hot methanol, filtered, and stored in the freezer overnight. The solid was filtered off to give 2-styryl-3,4-dimethoxybenzaldehyde (66 mg, 31%) melting at 64–67°. One crystallization from methanol raised the melting point to 68–70°; reported melting point 71–74° (39).

Degradation of Radioactive Alkaloids

Hydrastine from Experiment 3

Hydrastine (115 mg; specific activity 4.48×10^4 counts/min mmole) from this experiment was oxidized with nitric acid to give hydrastinine (50 mg, 81%; specific activity 4.10×10^4 counts/min mmole) and opianic acid (15 mg, 22%; specific activity 0.06×10^4 counts/min mmole). In order to have sufficient hydrastinine for further degradation, the active hydrastinine (44.85 mg; specific activity 4.10×10^4 counts/min mmole) was mixed with an equal weight of inactive hydrastinine.[7]

Hydrastinine (89.7 mg; specific activity 4.10×10^4 counts/min mmole*) underwent a Hofmann reaction to give hydrastal (62 mg, 82%; specific activity 4.51×10^4 counts/min mmole).

Hydrastal (55 mg; specific activity 4.51×10^4 counts/min mmole) was oxidized with silver oxide to give 6-vinylpiperonylic acid. However, when the reaction mixture was acidified, excess nitric acid was inadvertently added. This caused oxidation and subsequent loss of product when the solution was heated.

Hydrastine from Experiment 4

Hydrastine (144 mg; specific activity 5.17×10^4 counts/min mmole) from this experiment was oxidized with nitric acid to give hydrastinine (63 mg, 81%; specific activity 5.10×10^4 counts/min mmole) and opianic acid (40 mg, 51%; specific activity 0.04×10^4 counts/min mmole). In order to have sufficient hydrastinine to continue the degradation sequence the active hydrastinine (57.5 mg; specific activity 5.10×10^4 counts/min mmole) was mixed with an equal weight of inactive hydrastinine.

Hydrastinine (115 mg; specific activity 5.10×10^4 counts/min mmole*) underwent a Hofmann reaction to give hydrastal (79 mg, 81%; specific activity 5.16×10^4 counts/min mmole).

Hydrastal (72 mg; specific activity 5.16×10^4 counts/min mmole) was oxidized by silver oxide to give 6-vinylpiperonylic acid (67 mg, 86%; specific activity 5.02×10^4 counts/min mmole).

6-Vinylpiperonylic acid (59 mg; specific activity 5.02×10^4 counts/min mmole) was bromodecarboxylated to give barium carbonate (43 mg, 61%) and 6-bromo-α-hydroxyhomopiperonyl bromide (76 mg, 76%; specific activity 3.20×10^4 counts/min mmole). Active barium carbonate (22 mg) was diluted to 64 mg with inactive barium carbonate, and the mixture was converted to benzoic acid (17 mg, 43%; specific activity 2.00×10^4 counts/min mmole*).

6-Bromo-α-hydroxyhomopiperonyl bromide (65 mg; specific activity 3.20×10^4 counts/min mmole) was oxidized by potassium permanganate to 6-bromopiperonal, which was further oxidized by silver oxide to give 6-bromopiperonylic acid (23 mg, 47%; specific activity 0.14×10^4 counts/min mmole).

The results of the degradation of hydrastine samples from experiments 3 and 4 are summarized in Table VII.

Hydrastine from Experiment 5

Hydrastine (180 mg; specific activity 1.19×10^4 counts/min mmole) from this experiment was oxidized by nitric acid to give hydrastinine (84 mg, 86%; specific activity 0.50×10^4 counts/min mmole) and opianic acid (45 mg, 46%; specific activity 0.65×10^4 counts/min mmole).

Hydrastine from Experiment 6

Hydrastine (181 mg; specific activity 1.42×10^4 counts/min mmole) from this experiment was oxidized by nitric acid to give hydrastinine (87 mg, 89%; specific activity 0.70×10^4 counts/min mmole) and opianic acid (47 mg, 48%; specific activity 0.69×10^4 counts/min mmole).

Hydrastine from Experiment 7

Hydrastine (178 mg; specific activity 4.96×10^4 counts/min mmole) from this experiment was oxidized by nitric acid to give hydrastinine (83 mg, 86%; specific activity 2.44×10^4 counts/min mmole) and opianic acid (44 mg, 45%; specific activity 2.46×10^4 counts/min mmole).

Hydrastine from Experiment 8

Hydrastine (150 mg; specific activity 1.36×10^4 counts/min mmole) from this experiment was oxidized by nitric acid to give hydrastinine (73 mg, 90%; specific activity 0.60×10^4 counts/min mmole) and opianic acid (39 mg, 48%; specific activity 0.74×10^4 counts/min mmole).

Hydrastine from Experiment 9

Hydrastine (350 mg; specific activity 5.76×10^4 counts/min mmole) from this experiment was oxidized by nitric acid to give hydrastinine (166 mg, 88%; specific activity 3.28×10^4 counts/min mmole) and opianic acid (95 mg, 50%; specific activity 2.46×10^4 counts/min mmole).

[7]*This gave a total of 89.7 mg, with a specific activity half that of the original hydrastinine. The specific activity of all further degradation products was decreased correspondingly. In order to avoid confusion, however, the reported specific activities of further degradation products take into account this dilution factor, so that the figures quoted are directly comparable to the specific activity of the initial alkaloid. Wherever such a dilution was carried out, the specific activities are marked by an asterisk.*

TABLE VII

Degradation of hydrastine derived from DL-[2-^{14}C]-tyrosine

Compound	Specific activity (counts/min mmole) $\times 10^{-4}$	Relative specific activity (hydrastine = 100)
	Experiment 3	
Hydrastine	4.48	100
Hydrastinine	4.10	92
Opianic acid	0.06	1
Hydrastal	4.51	100
	Experiment 4	
Hydrastine	5.17	100
Hydrastinine	5.10	99
Opianic acid	0.04	1
Hydrastal	5.16	100
6-Vinylpiperonylic acid	5.02	97
6-Bromo-α-hydroxy-homopiperonyl bromide	3.20	62
Benzoic acid	2.00	39
6-Bromopiperonylic acid	0.14	3

The results of the degradation of hydrastine samples from Experiments 5–9 are summarized in Table V.

Hydrastine from Experiment 10

Hydrastine (450 mg; specific activity 0.87×10^4 counts/min mmole) from this experiment was oxidized by nitric acid to give hydrastinine (215 mg, 89%; specific activity 0.87×10^4 counts/min mmole) and opianic acid (96 mg, 35%; specific activity 0.0084×10^4 counts/min mmole).

Hydrastinine (197 mg; specific activity 0.87×10^4 counts/min mmole) underwent a Hofmann reaction to give hydrastal (148 mg, 89%; specific activity 0.83×10^4 counts/min mmole).

Hydrastal (126 mg; specific activity 0.83×10^4 counts/min mmole) was oxidized by silver oxide to give 6-vinylpiperonylic acid (112 mg, 82%; specific activity 0.87×10^4 counts/min mmole).

6-Vinylpiperonylic acid (97 mg; specific activity 0.87×10^4 counts/min mmole) was bromodecarboxylated to give barium carbonate (83 mg, 83%) and 6-bromo-α-hydroxyhomopiperonyl bromide (125 mg, 76%; specific activity 0.89×10^4 counts/min mmole). Barium carbonate (82 mg) was converted to inactive benzoic acid (20 mg, 40%; specific activity nil).

6-Bromo-α-hydroxyhomopiperonyl bromide (51 mg; specific activity 0.89×10^4 counts/min mmole) was oxidized by potassium permanganate to 6-bromopiperonal. This was reacted with acetone to give 6-bromopiperonylidene acetone (30 mg, 71%; specific activity 0.015×10^4 counts/min mmole).

The results of the degradation of hydrastine from Experiment 10 are summarized in Table VIII.

TABLE VIII

Degradation of hydrastine derived from [1-^{14}C]-dopamine (expt. 10)

Compound	Specific activity (counts/min mmole) $\times 10^{-4}$	Relative specific activity (hydrastine = 100)
Hydrastine	0.87	100
Hydrastinine	0.87	100
Opianic acid	0.0084	1
Hydrastal	0.83	96
6-Vinylpiperonylic acid	0.87	100
6-Bromo-α-hydroxyhomo-piperonyl bromide	0.89	102
Benzoic acid	0	0
6-Bromopiperonylidene acetone	0.015	2

Berberine from Experiment 4

In order to have sufficient alkaloid to complete the degradation sequence active berberine hydrochloride (319.6 mg; specific activity 10.50×10^4 counts/min mmole) was mixed with inactive berberine hydrochloride (639.2 mg) and recrystallized to give berberine hydrochloride (935 mg; specific activity 3.50×10^4 counts/min

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mmole). Berberine hydrochloride (894 mg; specific activity 3.50×10^4 counts/min mmole) then underwent a Grignard reaction with benzyl chloride and magnesium to give benzyldihydroberberine (876 mg, 94%).

This benzyldihydroberberine (876 mg) was reduced by sodium borohydride in methanol to give benzyltetrahydroberberine (637 mg, 72%; specific activity 3.60×10^4 counts/min mmole).

Benzyltetrahydroberberine (632 mg; specific activity 3.60×10^4 counts/min mmole) was converted by methyl iodide to benzyltetrahydroberberine methiodide (677 mg, 81%).

This benzyltetrahydroberberine methiodide (677 mg) underwent a Hofmann reaction to give des-*N*-methylstyryltetrahydroberberine (320 mg; specific activity 3.65×10^4 counts/min mmole), which was oxidized by sodium dichromate in acetic acid to give hydrastinine (114 mg, 76%; specific activity 3.40×10^4 counts/min mmole), and 2-styryl-3,4-dimethoxybenzaldehyde (69 mg, 36%; specific activity 0.03×10^4 counts/min mmole).

Hydrastinine (110 mg; specific activity 3.40×10^4 counts/min mmole) underwent a Hofmann reaction to give hydrastal (79 mg, 85%).

This hydrastal (79 mg) was oxidized by silver oxide to give 6-vinylpiperonylic acid (44 mg, 51%). In order to have sufficient 6-vinylpiperonylic acid to continue the degradation sequence, the active 6-vinylpiperonylic acid (32.3 mg) was mixed with an equal weight of inactive 6-vinylpiperonylic acid.

6-Vinylpiperonylic acid (64.6 mg) was bromodecarboxylated to give barium carbonate (59 mg, 89%) and 6-bromo-α-hydroxyhomopiperonyl bromide (91 mg, 83%; specific activity 1.72×10^4 counts/min mmole*).

Active barium carbonate (59 mg) was converted into benzoic acid (12 mg, 33%; specific activity 1.75×10^4 counts/min mmole*).

6-Bromo-α-hydroxyhomopiperonyl bromide (72 mg; specific activity 1.72×10^4 counts/min mmole) was oxidized by potassium permanganate to 6-bromopiperonal. This was reacted with acetone to give 6-bromopiperonylidene acetone (31 mg, 52%; specific activity 0.07×10^4 counts/min mmole).

The results of the degradation of berberine from experiment 4 are summarized in Table IX.

TABLE IX

Degradation of berberine derived from DL-[2-^{14}C]-tyrosine (expt. 4)

Compound	Specific activity (counts/min mmole) $\times10^{-4}$	Relative specific activity (berberine = 100)
Berberine hydrochloride	3.50	100
Benzyltetrahydroberberine	3.60	103
Des-*N*-methylstyryltetrahydroberberine	3.65	104
Hydrastinine	3.40	97
2-Styryl-3,4-dimethoxybenzaldehyde	0.03	1
6-Bromo-α-hydroxyhomopiperonyl bromide	1.72	49
Benzoic acid	1.75	50
6-Bromopiperonylidene acetone	0.07	2

Assay of Activity

Radioactivity was assayed on samples of finite thickness on aluminum planchettes, using a Model D47 gas flow counter with "micromil" window (Nuclear Chicago Co.) in a low-background automatic sample changer (Nuclear Chicago Co., Model C 115). Counts were recorded either on a scaler (Nuclear Chicago Co., Model 161A), or on an electronic counter (Beckman-Berkeley, Model 7060).

ACKNOWLEDGMENTS

We are greatly indebted to Mr. L. Laking, Director, and Mr. R. E. Halward, Propagator, of the Royal Botanical Gardens, Hamilton, without whose generous advice and help in the cultivation of *Hydrastis canadensis* L. this investigation could not have been undertaken.

Financial assistance by the National Research Council of Canada and by the Ontario Research Foundation is gratefully acknowledged. This work was carried out during the tenure (by J. R. G.) of a National Research Council of Canada Studentship.

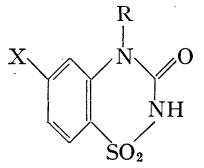
NOTES

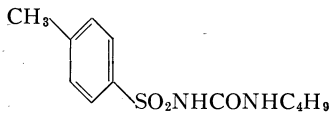
THE SYNTHESIS OF CYCLIC ANALOGUES OF TOLBUTAMIDE

D. L. Simmons, J. M. Dodsworth, and Francis L. Chubb

Since the original synthesis of 3-oxo-3,4-dihydro-1,2,4-benzothiadiazine (1) relatively few derivatives of this compound have been reported (2, 3). More recently sulphamyl substituted 3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxides have been synthesized as potential diuretics (4, 5) and as intermediates in the synthesis of diuretics (6, 7). These compounds are cyclic sulphonylureas, since they contain the —$SO_2NHCONH$— group in the heterocyclic ring. In this communication we wish to report the synthesis of a series of substituted 3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxides (I) which may be considered as cyclic analogues of the hypoglycemic sulphonylureas such as tolbutamide (II).



I



II

a: X = CH_3, R = H
b: X = Cl, R = H
c: X = CF_3, R = H

d: X = CH_3, R = *n*-C_4H_9
e: X = Cl, R = *n*-C_4H_9
f: X = CF_3, R = *n*-C_4H_9

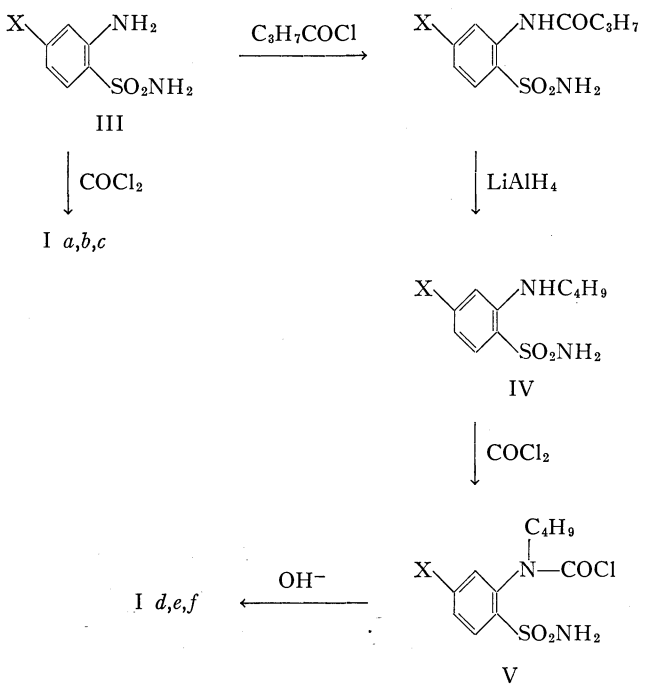
These compounds were obtained from the corresponding 2-sulphamylanilines by treatment with phosgene (7). In the case of the 2-sulphamylanilines (III) with no substituent on the aniline nitrogen, treatment with phosgene yielded the final products directly. However, when the N-butyl-2-sulphamylanilines (IV) were treated with phosgene, the intermediate N-carbonyl chlorides (V) were isolated. Treatment with base effected ring closure to yield I. The N-butyl-2-sulphamylanilines were obtained by acylation of the corresponding anilines (4) with *n*-butyryl chloride followed by reduction with lithium aluminum hydride. The anilines were obtained from the appropriate 2-chloronitrobenzene according to the procedure of Topliss, Sperber, and Rubin (8). The pharmacology of these compounds will be reported elsewhere.

EXPERIMENTAL

Melting points are uncorrected. Microanalyses were carried out at the microanalytical laboratory of C. Daesslé, 5757 Decelles Avenue, Montreal, Quebec. Infrared spectra were obtained on a Perkin–Elmer spectrophotometer Model 237. Ultraviolet spectra were obtained on a Beckman DK2 spectrophotometer.

5-Methyl-2-sulphamylaniline

5-Methyl-2-sulphamylaniline was prepared in 15% overall yield from 2-chloro-5-methylnitrobenzene according to the procedure of Topliss, Sperber, and Rubin (8). It crystallized from benzene and melted at 125–126°. λ_{max}^{MeOH} 246 mμ (7800), 304 mμ (3630). Anal. Calculated for $C_7H_{10}N_2O_2S$: C, 45.14; H, 5.41; N, 15.04; S, 17.21. Found: C, 45.14; H, 5.38; N, 15.58; S, 17.60.



5-Chloro-2-sulphamylaniline

5-Chloro-2-sulphamylaniline was obtained from 2,5-dichloronitrobenzene by the above procedure in 22% yield, and melted at 143–145° (reported 144–146°) (9).

3-Oxo-6-trifluoromethyl-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide

3-Oxo-6-trifluoromethyl-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide was prepared by the action of phosgene on 5-trifluoro-2-sulphamylaniline (4) according to the procedure of Close, Swett, and Nordeen (7) and was isolated in 89% yield. It crystallized from ether – petroleum ether and melted at 227°. λ_{max}^{MeOH} 244 mμ (10,800), 295 mμ (2,320); ν_{max}^{Nujol} 3550 cm^{-1}, 3510 cm^{-1}, 1748 cm^{-1} (strong), 1648 cm^{-1} (weak). Anal. Calculated for $C_8H_5N_2SO_3F_3$: C, 36.09; H, 1.89; N, 10.53; S, 12.04. Found: C, 36.02; H, 1.98; N, 10.40; S, 12.60.

6-Methyl-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide

6-Methyl-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide was obtained in 89% yield by the action of phosgene on 5-methyl-2-sulphamylaniline. It crystallized from alcohol–water and melted at 298–300°. λ_{max}^{MeOH} 243 mμ (11,600), 287 mμ (1,740); ν_{max}^{Nujol} 3208 cm^{-1}, 1716 cm^{-1}. Anal. Calculated for $C_8H_8N_2SO_3$: C, 45.27; H, 3.80; N, 13.20; S, 15.11. Found: C, 45.39; H, 3.83; N, 13.45; S, 15.03.

6-Chloro-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide

6-Chloro-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide was prepared by the action of phosgene on 5-chloro-2-sulphamylaniline in 88% yield. It crystallized from alcohol and melted at 300° decomp. λ_{max}^{MeOH} 245 mμ (10,000), 292.5 mμ (2,000); ν_{max}^{Nujol} 3290 cm^{-1}, 1685 cm^{-1}. Anal. Calculated for $C_7H_5N_2ClSO_3$: C, 36.14; H, 2.17; N, 12.04; S, 13.78. Found: C, 35.87; H, 2.26; N, 12.47; S, 13.95.

N-Butyryl-2-sulphamyl-5-trifluoromethylaniline

N-Butyryl-2-sulphamyl-5-trifluoromethylaniline was prepared from 2-sulphamyl-5-trifluoromethylaniline (4) by treatment with *n*-butyryl chloride in dioxane according to the procedure of Novello *et al.* (4). It separated from benzene as needles and melted at 135–136°. λ_{max}^{MeOH} 247 mμ (13,500), 292 mμ (3,800). Anal. Calculated for $C_{11}H_{13}N_2O_3SF_3$: C, 42.59; H, 4.19; N, 9.03. Found: C, 42.79; H, 3.98; N, 9.33.

N-Butyryl-5-methyl-2-sulphamylaniline

N-Butyryl-5-methyl-2-sulphamylaniline was prepared in 90% yield by the action of *n*-butyryl chloride on 5-methyl-2-sulphamylaniline as described above. It crystallized from alcohol as prisms and melted at 135–137°. λ_{max}^{MeOH} 247.5 mμ (12,900), shoulder 283 mμ (2,560), shoulder 288 mμ (2,480). Anal. Calculated for $C_{11}H_{16}N_2O_3S$: C, 51.54; H, 6.29; N, 10.93; S, 12.51. Found: C, 51.65; H, 6.67; N, 11.08; S, 12.24.

N-Butyryl-5-chloro-2-sulphamylaniline

N-Butyryl-5-chloro-2-sulphamylaniline was prepared in 87% yield by the action of *n*-butyryl chloride on 5-chloro-2-sulphamylaniline as described above. It crystallized from benzene as prisms and melted at 141–142°. λ_{max}^{MeOH} 248.5 mμ (15,200), shoulder 286.5 mμ (2,500), shoulder 292 mμ (2,450). Anal. Calculated for $C_{10}H_{13}N_2O_3SCl$: C, 43.40; H, 4.73; N, 10.13; Cl, 12.81. Found: C, 43.63; H, 4.79; N, 10.27; Cl, 12.84.

N-Butyl-2-sulphamyl-5-trifluoromethylaniline

N-Butyryl-2-sulphamyl-5-trifluoromethylaniline (2.23 g) was added portionwise and with stirring to a suspension of lithium aluminum hydride (0.7 g) in hydride-stable tetrahydrofuran (50 cc). After the addition was complete, the contents were gently refluxed for 3 hours. The excess hydride was destroyed by careful addition of ethyl acetate and water, and the contents then concentrated *in vacuo*. Water (100 ml) was added and the solution made acidic with concentrated phosphoric acid and extracted with ether. Evaporation of the dried ethereal extracts *in vacuo* provided a white solid (2.0 g) which crystallized from ether – petroleum ether as fine needles, m.p. 140–141°. λ_{max}^{MeOH} 254 mμ (20,000), 330 mμ (10,000). Anal. Calculated for $C_{11}H_{15}N_2O_2SF_3$: C, 44.59; H, 5.07; N, 9.46. Found: C, 44.80; H, 5.51; N, 9.69.

N-Butyl-5-methyl-2-sulphamylaniline

N-Butyl-5-methyl-2-sulphamylaniline was prepared in 75% yield from the N-butyryl derivative according to the procedure described above. It crystallized from ether – petroleum ether as needles and melted at 112°. λ_{max}^{MeOH} 253 mμ (18,000), 315 mμ (9,700). Anal. Calculated for $C_{11}H_{18}N_2O_2S$: C, 54.52; H, 7.49; N, 11.56; S, 13.23. Found: C, 54.66; H, 7.51; N, 11.75; S, 13.29.

N-Butyl-5-chloro-2-sulphamylaniline

N-Butyl-5-chloro-2-sulphamylaniline was obtained in 79% yield from the N-butyryl derivative by the above procedure. It crystallized from ether – petroleum ether as needles and melted at 119°. λ_{max}^{MeOH} 255.5 mμ (19,460), 320 mμ (10,000). Anal. Calculated for $C_{10}H_{15}N_2SO_2Cl$: C, 45.71; H, 5.75; N, 10.66; S, 12.20. Found: C, 45.98; H, 5.94; N, 10.77; S, 12.22.

N-Butyl-N-chlorocarbonyl-5-methyl-2-sulphamylaniline

N-Butyl-N-chlorocarbonyl-5-methyl-2-sulphamylaniline was prepared by the same procedure used in the preparation of the 3-oxo-benzothiadiazines (7) and was isolated in 92% yield. It crystallized from ether – petroleum ether and melted at 98°. $\nu_{max}^{CHCl_3}$ 3500 cm^{-1}, 3450 cm^{-1}, 3275 cm^{-1}, 1745 cm^{-1}, 1718 cm^{-1}. Anal. Calculated for $C_{12}H_{17}N_2SO_3Cl$: C, 47.28; H, 5.62; N, 9.19; S, 10.52; Cl, 11.63. Found: C, 47.05; H, 5.48; N, 9.36; S, 10.68; Cl, 11.58.

The corresponding 5-chloro- and 5-trifluoro-methyl analogues failed to crystallize and were employed in the following reactions without further purification. Infrared spectroscopy of these products revealed the characteristic doublet of carbonyl chlorides in the 1715–1750 cm^{-1} region.

4-Butyl-6-methyl-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide

The N-carbonyl chloride derivative (0.69 g) was gently refluxed with 5% methanolic potassium hydroxide (20 ml) for 1 hour. The reaction mixture was then cooled, diluted with water, and extracted with ether. The aqueous extract was acidified with concentrated hydrochloric acid and extracted with ether. Evaporation of the dried ethereal extracts (acidic) provided a white solid (0.65 g) which crystallized from methylene chloride – petroleum ether and melted at 173–174°. λ_{max}^{MeOH} 250 mμ (11,100), 290 mμ (1,960); $\nu_{max}^{CHCl_3}$ 3350 cm^{-1}, 1700 cm^{-1}. Anal. Calculated for $C_{12}H_{16}N_2O_3S$: C, 53.71; H, 6.01; N, 10.44; S, 11.95. Found: C, 53.96; H, 5.78; N, 10.75; S, 11.99.

4-Butyl-3-oxo-6-trifluoromethyl-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide

N-Butyl-3-oxo-6-trifluoromethyl-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide was prepared in 90% yield from the oily N-carbonyl chloride derivative by the above procedure. It crystallized from ether – petroleum ether and melted at 144°. λ_{max}^{MeOH} 250.5 mμ (12,690), 298 mμ (2,660); $\nu_{max}^{CHCl_3}$ 3350 cm^{-1}, 1708 cm^{-1}. Anal. Calculated for $C_{12}H_{13}N_2SO_3F_3$: C, 44.72; H, 4.06; N, 8.69; S, 9.95. Found: C, 44.47; H, 3.81; N, 8.95; S, 10.32.

4-Butyl-6-chloro-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide

4-Butyl-6-chloro-3-oxo-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide was obtained in 88% yield from the oily N-carbonyl chloride derivative by the above procedure. It crystallized from ether – petroleum ether and melted at 152°. λ_{max}^{MeOH} 252.5 mμ (11,310), 295 mμ (2,170); $\nu_{max}^{CHCl_3}$ 3350 cm^{-1}, 1705 cm^{-1}. Anal. Calculated for $C_{11}H_{13}N_2SO_3Cl$: C, 45.75; H, 4.54; N, 9.70; S, 11.10. Found: C, 45.78; H, 4.59; N, 9.51; S, 11.12.

THE VINYLTRIFLUOROBORATE ANION[1,2]

S. L. STAFFORD

Recent interest in vinyl-metallic compounds in general (1), and in particular in the extent of carbon–boron π-bonding in vinyl-boron derivatives (2), prompted the preparation of the new vinylfluoroborate anion $CH_2{=}CHBF_3^-$. The anion was desired in order to study the effect on carbon–boron π-bonding, and also as a member of a class of potentially useful compounds of which little is known, the mixed organohaloborates. Only two such anions—$(C_6H_5)_3BF^-$ (3) and $CF_3BF_3^-$ (4)—have been characterized previously.[3]

A solution of 2.59 g (27.5 mmoles) of $KF.2H_2O$ dissolved in 3 ml of water was introduced into a reaction tube and 560 cc (STP) (25 mmoles) of $CH_2{:}CHBF_2$ (prepared from $(CH_2{:}CH)_4Sn$ and BF_3 (6)) containing a small amount of BF_3 was condensed onto it. The tube was sealed and placed in an ice bath for 4 hours. Volatile products were then removed under high vacuum through traps held at −78° and −196°. The only volatile material removed other than water was 56 cc (STP) of ethylene, collected at −196°. The solid residue was extracted with boiling acetonitrile. Removal of the solvent gave 1.84 g (55% yield, based on $CH_2{:}CHBF_2$) of $K^+CH_2{:}CHBF_3^-$. Anal.: Required for $C_2H_3F_3BK$: C, 17.9; H, 2.24; F, 42.5; B, 8.2%. Found: C, 17.6; H, 2.46; F, 44.6; B, 7.7%.

The infrared spectrum (KBr disk) of the compound shows absorptions at 3067, 2967 (C—H stretch); 1623 (C=C stretch); 1422, 1294 (CH_2 and CH in-plane deformations); 1132, 1107 (B—C stretch); 1035 (B—F asymmetric stretch); 950–920; and 694 cm^{-1}.

The F-19 nuclear magnetic resonance spectrum, in aqueous solution, consists of a quartet centered at $\delta_{CCl_3F} = 138$ p.p.m., with $J_{B^{11}-F} = 51.8$ c.p.s. After standing in the tube for several days at room temperature, the solution was re-examined. In addition to the original quartet, a peak was observed at $\delta_{CCl_3F} = 150$ p.p.m. (assignable to BF_4^-) and there appeared to be a weak, very broad quartet centered near $\delta_{CCl_3F} = 143$ p.p.m. (perhaps due to $(CH_2{:}CH)_2BF_2^-$). This apparent disproportionation has not been studied further.

As would be expected, the $CH_2{:}CHBF_3^-$ anion shows greater hydrolytic stability than does $CH_2{:}CHBF_2$. Thus, $CH_2{:}CHBF_2$ in contact with water at room temperature gives appreciable amounts of ethylene in a few hours. Solutions containing $CH_2{:}CHBF_3^-$, on the other hand, are stable to hydrolysis for at least several days.

Solutions containing $CH_2{:}CHBF_3^-$, on the other hand, are stable to hydrolysis for at least several days.

[1]*This work was supported by the Advanced Research Projects Agency (ARPA) under Contract No. DA-30-069-ORD-2638.*

[2]*Presented in part at the Symposium on Organometallic Chemistry at the University of British Columbia, September, 1962.*

[3]*The formation of organohaloborate anions by addition of hydrogen halides to amine adducts of organoboron halides has been postulated (5).*

A sample of dry $K^+CH_2{:}CHBF_3^-$ was heated on the vacuum line. The solid did not melt below 225°, at which temperature decomposition of the salt began. Decomposition was rapid above 250°. The gas evolved was shown by its infrared spectrum to be $CH_2{:}CHBF_2$ of high purity. By way of comparison, $K^+BF_4^-$ does not dissociate appreciably below 500° (7, and references cited therein). Thus salts of organohaloborates may be an excellent means of storing and handling organohaloboranes, and of regenerating these compounds in a highly pure form.

Solutions of $K^+CH_2{=}CHBF_3^-$ were found to generate $(CH_2{=}CH)_2Hg$ rapidly when in contact with mercury, as in a sink trap. It should be stressed, therefore, that such solutions should be treated with nitric acid before attempting disposal, in order to prevent the formation of the highly toxic organomercury compounds.

The synthesis of $K^+CH_3BF_3^-$ in a similar manner is indicative of the general applicability of the reaction. Anal.: Required for CH_3BF_3K: C, 9.84; H, 2.46; F, 46.7%. Found: C, 9.43; H, 2.63; F, 46.8%. The F-19 n.m.r. spectrum in aqueous solution revealed a quartet centered at $\delta_{CCl_3F} = 132$ p.p.m., $J_{B^{11}-F} = 64$ c.p.s.

Further details of these and related studies will be reported more fully at a future date.

The author wishes to thank Mrs. N. Bolan and Dr. B. B. Stewart for their assistance in obtaining the infrared and n.m.r. spectra.

THE PHOTOLYSIS OF LIQUID O_2–N_2 SOLUTIONS[1]

W. B. DeMore and Odell Raper

INTRODUCTION

Recently McNesby has found that the irradiation of liquid O_2–N_2 solutions with a low-pressure mercury arc yields O_3 and N_2O as products (1). One question which has arisen from this work concerns the origin of the N_2O. The radiation emitted by the low-pressure arc which is photochemically active in this system is at 1849 Å and 2537 Å, and the formation of O_3 must be initiated by the interaction of 1849 Å radiation with O_2. The N_2O may be formed in a process involving photolysis of O_2 at 1849 Å or may result from photolysis of the product O_3, which absorbs strongly in the ultraviolet, particularly

A sample of dry $K^+CH_2{:}CHBF_3^-$ was heated on the vacuum line. The solid did not melt below 225°, at which temperature decomposition of the salt began. Decomposition was rapid above 250°. The gas evolved was shown by its infrared spectrum to be $CH_2{:}CHBF_2$ of high purity. By way of comparison, $K^+BF_4^-$ does not dissociate appreciably below 500° (7, and references cited therein). Thus salts of organohaloborates may be an excellent means of storing and handling organohaloboranes, and of regenerating these compounds in a highly pure form.

Solutions of $K^+CH_2{=}CHBF_3^-$ were found to generate $(CH_2{=}CH)_2Hg$ rapidly when in contact with mercury, as in a sink trap. It should be stressed, therefore, that such solutions should be treated with nitric acid before attempting disposal, in order to prevent the formation of the highly toxic organomercury compounds.

The synthesis of $K^+CH_3BF_3^-$ in a similar manner is indicative of the general applicability of the reaction. Anal.: Required for CH_3BF_3K: C, 9.84; H, 2.46; F, 46.7%. Found: C, 9.43; H, 2.63; F, 46.8%. The F-19 n.m.r. spectrum in aqueous solution revealed a quartet centered at $\delta_{CCl_3F} = 132$ p.p.m., $J_{B^{11}-F} = 64$ c.p.s.

Further details of these and related studies will be reported more fully at a future date.

The author wishes to thank Mrs. N. Bolan and Dr. B. B. Stewart for their assistance in obtaining the infrared and n.m.r. spectra.

THE PHOTOLYSIS OF LIQUID O_2–N_2 SOLUTIONS[1]

W. B. DeMore and Odell Raper

INTRODUCTION

Recently McNesby has found that the irradiation of liquid O_2–N_2 solutions with a low-pressure mercury arc yields O_3 and N_2O as products (1). One question which has arisen from this work concerns the origin of the N_2O. The radiation emitted by the low-pressure arc which is photochemically active in this system is at 1849 Å and 2537 Å, and the formation of O_3 must be initiated by the interaction of 1849 Å radiation with O_2. The N_2O may be formed in a process involving photolysis of O_2 at 1849 Å or may result from photolysis of the product O_3, which absorbs strongly in the ultraviolet, particularly

[1]*This paper represents the results of one phase of research carried out at the Jet Propulsion Laboratory, California Institute of Technology, under Contract No. NAS 7-100, sponsored by the National Aeronautics and Space Administration.*

at 2537 Å (2). This report describes studies of the mechanism of N_2O formation in the O_2–N_2 system by examination of the ratio of N_2O to O_3 as a function of the quantum dosage.

EXPERIMENTAL

In order to study the N_2O/O_3 ratio at the smallest possible quantum dosages and still obtain sufficient products for accurate analysis, an apparatus was designed which rapidly removed the products while recirculating the original O_2–N_2 solution. This apparatus is shown in Fig. 1. For a run, measured amounts

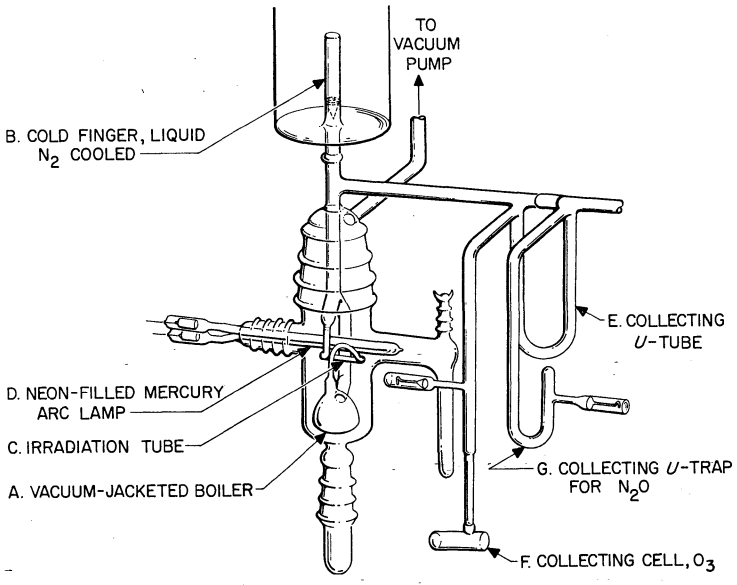

FIG. 1. Experimental apparatus.

of N_2 and O_2, purified by passage through a Drierite–Ascarite train and one distillation from the liquid, were condensed in the vacuum-jacketed boiler A, and the resultant solution boiled at a rate determined by its composition and the absorption of heat from the surroundings. The vapor was condensed in the inverted cold finger B, dripped into the quartz irradiation tube C, and was irradiated by the mercury arc D as it passed through the tube. Only the tube C was of quartz, and only that portion which was continuously filled with liquid was irradiated, all other areas being masked off. These precautions were taken to assure that no photolysis occurred in the gas phase or in the boiler. Due to fractionation the composition of the solution in the tube C was not the same as that in the boiler, so before any runs were made the true composition of the irradiated solution was determined by direct liquid sampling of the condensate in the irradiation tube over a range of liquid compositions in the boiler.

The O_3 and N_2O formed during irradiation were washed into the boiler, where they remained, while the volatile O_2 and N_2 were continuously recirculated. After a photolysis period of 4 hours, the lamp was turned off, the vacuum jacket removed from the cell, and a liquid nitrogen bath placed over the boiler. The excess O_2 and N_2 were then carefully pumped off by evacuation to a good vacuum. O_3 was separated from N_2O by placing a liquid oxygen bath over the boiler and collecting the O_3 in the U-tube E at liquid nitrogen temperature. The O_3 was then transferred to cell F and sealed off. A dry ice trap was then placed around the boiler and the N_2O was collected in the U-trap G at liquid nitrogen temperature and sealed off. The O_3 was converted to O_2 by flaming, and the O_2 and N_2O concentrations were determined by mass spectrometry. The mass 30 peak was used for N_2O analysis to avoid any possible confusion with CO_2 impurity, although blank runs showed such impurities to be small.

RESULTS AND DISCUSSION

The results of two experiments at different O_2/N_2 ratios are shown in Fig. 2. The lamp power, which was found to be linear with the 2537 Å intensity I, was varied for each run and plotted against R, the ratio of N_2O to O_3 produced. Most of the radiation absorbed

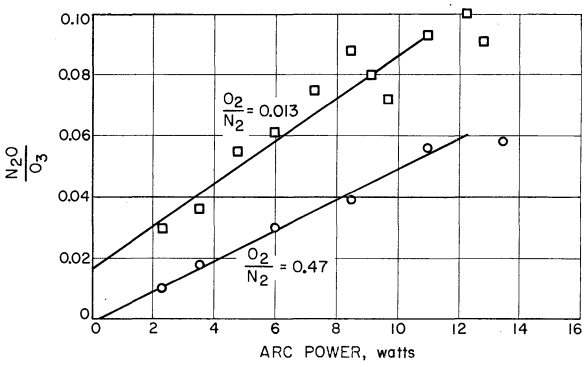

FIG. 2. N_2O/O_3 ratio as a function of arc power.

by O_3 was at 2537 Å, absorption of 1849 Å radiation by either product being negligible due to their low extinction coefficients in this region (3) and the small amount of 1849 Å light available. For a given O_2/N_2 ratio the photolysis time Δt remained constant, so the variation in lamp power represents a linear variation in the intensity of the light absorbed by O_3. If both N_2O and O_3 are formed in amounts proportional to the absorption of 1849 Å light by O_2, the ratio N_2O/O_3 should extrapolate to a non-zero intercept with decreasing quantum dosage. The results of Fig. 2 clearly indicate that N_2O is not being formed efficiently as a result of primary photolysis of O_2. In the upper curve, where N_2 is present in large excess over O_2, the intercept is small, indicating that N_2 is competing very weakly with O_2 for the primary reactive species present. At sufficiently high O_2 to N_2 ratios, as in the lower curve, initial N_2O formation can no longer be observed. A difficulty arises in attempting to place numerical values on the relative efficiencies for initial O_3 and N_2O formation in this system. Absorption of 1849 Å radiation by the O_2 molecule does not lead directly to its dissociation, producing instead O_2 in the excited $^3\Sigma_u^-$ state. In the gas phase these excited molecules may undergo predissociation to ground-state atoms (4–6), but in the liquid they may also react directly with the N_2 and O_2 present. Several mechanisms for initial product formation in this system are therefore possible and the data in the present work is insufficient to allow a choice to be made between them. By any reasonable mechanism compatible with the possible reactions in the system, however, the ratio of the efficiency of primary N_2O formation relative to that of O_3 is of the order of 10^{-4}.

The linear dependence of the N_2O/O_3 ratio on quantum dosage shown in Fig. 2 may be explained by formation of N_2O as a result of O_3 photolysis. Recent work by the authors in the ultraviolet photolysis of O_3 in liquid N_2 and N_2–O_2 solutions indicates that $O(^1D)$ is produced, which reacts with N_2 to form N_2O in a yield proportional to the light quanta absorbed by O_3, the actual quantum yield depending on the O_2/N_2 ratio (7). The average O_3 concentration in the irradiation tube was about 10^{-5} mole/liter, and therefore the amount of light absorbed by O_3 was proportional to the average O_3 concentration, since the optical density of the O_3 in the 2-mm tube was not greater than about 0.006 at 2537 Å. It then follows that the amount of N_2O produced was proportional to the product $I\Delta t[O_3]_{av}$. If the total amount of O_3 destroyed by photolysis was small, the ratio N_2O/O_3 would then be proportional to $I\Delta t$, the quantum dosage. The results of reference 7 show that at O_3 concentrations less than about 10^{-2} mole/liter the reaction $O + O_3 \rightarrow 2O_2$ can be neglected, since at such low concentrations it is not fast enough to compete with

the reaction of ^1D atomic oxygen with the N_2 and O_2. Therefore, the O_3 destroyed was equal to the N_2O produced, which, from Fig. 2, was not greater than 10% of the O_3. The conclusion is therefore drawn that the linearly increasing N_2O/O_3 ratio results from the photolysis of the product O_3 during the residence time in the irradiation tube.

Further support for the suggestion that N_2O is formed by O_3 photolysis may be obtained from the observed effect of the O_2/N_2 solution ratio on the N_2O/O_3 product ratio. If formation of N_2O by O_2 photolysis at 1849 Å is neglected, the ratio R is given by the following expression:

$$R = \frac{CI\Delta t}{1 + \dfrac{(k_{rO_2}+k_{dO_2})\,[O_2]}{(k_{rN_2}+k_{dN_2})\,[N_2]}}. \tag{A}$$

In this expression C is a constant proportional to the O_3 cross section for 2537 Å radiation, $I\Delta t$ the quantum dosage at this wavelength, and the k's are the appropriate rate constants for reaction and deactivation of $O(^1D)$ with O_2 and N_2. A value of the ratio of these rate constants was obtained from the experiment shown in Fig. 3. In this experiment, $I\Delta t$ was

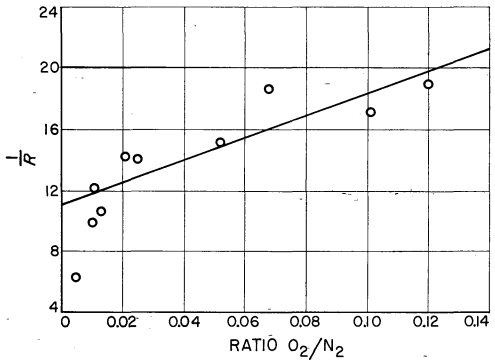

FIG. 3. O_3/N_2O ratio as a function of the ratio of O_2 to N_2.

held constant and $1/R$, or O_3/N_2O, determined as a function of the O_2/N_2 ratio. Dividing the slope by the intercept in Fig. 3 gives a value for $(k_{rO_2}+k_{dO_2})/(k_{rN_2}+k_{dN_2})$ equal to 6.5. This can be taken only as an order of magnitude value since primary N_2O formation has been neglected and also since Δt does not remain precisely constant as the O_2/N_2 ratio is varied. The value is in good agreement, however, with the value 4.5 obtained recently by the authors using a different method (7). The deviation at low O_2/N_2 ratios in Fig. 3 may be due to experimental error in preparing the dilute solutions, but is also compatible with the small contribution to R due to primary N_2O formation as determined in Fig. 2. This term becomes more significant as O_2/N_2 becomes smaller, and should cause a deviation towards zero in Fig. 3.

We conclude, therefore, that little or no N_2O formation occurs in this system as a direct result of the primary photolysis of O_2 by 1849 Å radiation, and that the N_2O yield can be attributed to the reaction between N_2 and the ^1D atomic oxygen produced in the secondary photolysis of O_3.

TEMPERATURE CONTROL ATTACHMENTS FOR VARIABLE AND FIXED PATH LENGTH INFRARED CELLS

M. S. SMITH AND P. A. D. DE MAINE

Quantitative studies of the temperature dependence of infrared spectra for liquids have been frustrated by the difficulties in designing adequate devices for controlling the liquid temperature in the cells. Lord *et al.* (1) have given full bibliography for cells designed before 1951.

The heating-block cells sold by the instrument manufacturers provide uncertain temperature regulation and are useful only above room temperature. The high and low temperature gas convection cells used by Bernstein and Powling (2, 3) are elaborate and lack precision because of the low thermal conductivity of dry air and nitrogen.

Maguire and West (4) used a hollow brass block to control the temperature between −17.5° C and 45° C in their study of hydrogen bonds. They reported a temperature sensitivity of 0.05° C above 0° C and 0.5° C below 0° C. We have found that the sample temperatures can be quite different from the cell casing or reservoir temperatures. Also, the measured temperature sensitivity of the sample liquid is determined by the potentiometer–thermocouple combination used. With this system the recorded "temperature of the solution" may be incorrect.

Becker (5) used a water-jacketed cell to measure spectra at temperatures between −15° C and 60° C. Vinogradov and Crawford (6) have described a demountable temperature-regulated fixed path length liquid cell sensitive to 0.1° C between 0° C and 80° C. This cell is designed specifically for the Perkin–Elmer 112G Spectrophotometer and requires modifications to the sample housing. Both the Becker and the Vinogradov–Crawford cells are primarily designed for single-beam instruments.

Here we describe an inexpensive attachment for controlling the sample temperature in ordinary infrared cells.

DESCRIPTION OF ATTACHMENTS

(a) Cooling Blocks

Two cooling blocks were machined from 1/2-inch DURAL plate and 1/4-inch brass rod, and each was attached to the front or back plate of an infrared cell. Details of construction and assembly are shown in Fig. 1. Either Dupont Duco or Dekaphane cements were used for the pressure sealant between the open face of the cooling blocks and the cell plates. A 1/16-inch flange is sufficient for a water-tight seal.

Polyethylene tubing and tubing connectors were used to couple the cells to each other and to the reservoir.

This cell is designed specifically for the Perkin–Elmer 112G Spectrophotometer and requires modifications to the sample housing. Both the Becker and the Vinogradov–Crawford cells are primarily designed for single-beam instruments.

Here we describe an inexpensive attachment for controlling the sample temperature in ordinary infrared cells.

DESCRIPTION OF ATTACHMENTS

(a) Cooling Blocks

Two cooling blocks were machined from 1/2-inch DURAL plate and 1/4-inch brass rod, and each was attached to the front or back plate of an infrared cell. Details of construction and assembly are shown in Fig. 1. Either Dupont Duco or Dekaphane cements were used for the pressure sealant between the open face of the cooling blocks and the cell plates. A 1/16-inch flange is sufficient for a water-tight seal.

Polyethylene tubing and tubing connectors were used to couple the cells to each other and to the reservoir.

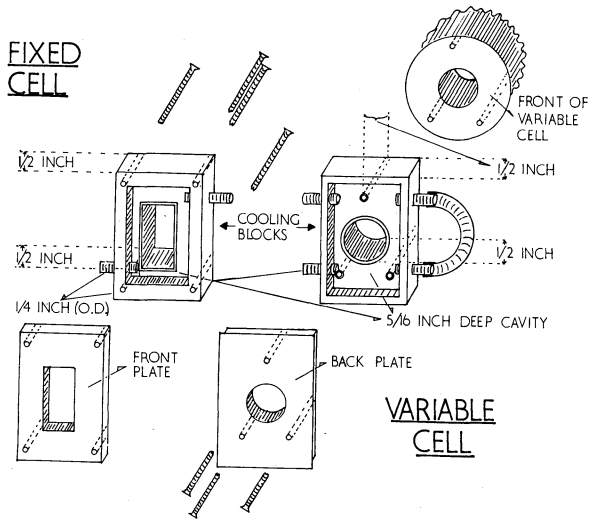

FIG. 1. Construction details and assembly of the variable and fixed path length cells.

(b) Constant-Temperature Bath

A constant-temperature bath was constructed from a 5-gal IGLOO insulated drinking water can, a 1/4- or 1/8-hp refrigerator compressor unit, a 500-watt immersion heater, and a heavy-duty double-pole relay switch (Potter and Brumfield type PRLLAY) with a Philadelphia microstat. A high-speed 1/20-hp air-cooled motor operated the stirrer for the reservoir liquid. A variable-speed pump (Fisher Scientific Company, Model B1) circulated the liquid through the cooling blocks. With the 1/4-hp compressor unit the reservoir could be varied between −30° C and 100° C.

At most temperatures the sensitivity of the reservoir controls was 0.05° C. However, below 10° C the sensitivity increased to 0.20° C. The sensitivity at all temperatures can be improved considerably with two independent mercury plunger relay switches to control the compressor and heater circuits. The uncertainty in measuring the temperatures in the cells does not justify the use of a high-precision temperature-controlled bath

CALIBRATION AND USE OF ATTACHMENTS

(a) Calibration

The equilibrium temperatures of the variable and fixed path length cells for different reservoir temperatures were measured with a Minneapolis-Honeywell Model No. 2745 potentiometer and an iron–constantan thermocouple in contact with the sample liquid. The reference thermocouple was in ice water. It was found that the equilibrium temperature in each cell does not vary with different sample liquids. The reproducibility of successive temperature measurements with either cell was within 0.15° C.

Because of the slight temperature difference between the two cells at equilibrium, calibration base lines were recorded at 5, 20, and 45° C with CCl_4 in both cells. When both cell path lengths were identical, no deviation was observed in the base line even in regions of high absorption (near 1200 cm^{-1}). Cell path lengths do not change measurably between 0° C and 50° C.

(b) Use of Attachments

At temperatures below 10° C appreciable fogging of the NaCl or KBr cell windows

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

occurs, even in the dry air purged cell compartment of the Beckman IR-7 spectrophotometer. To eliminate fogging at these lower temperatures two thermostated variable path length cells with IRTRAN-2 windows were used.

Once temperature equilibrium was established, both cells were flushed and filled with fresh solutions *in situ* in the cell compartment with the aid of hypodermic syringes and a glass trough. Temperature equilibrium was re-established in 2 to 3 minutes. With this technique a complete set of samples can be measured without the cells being removed from the cell compartment or uncoupled from the reservoir.

3-TRIFLUOROMETHYL AND 4-*t*-BUTYL DERIVATIVES OF TETRAPHENYLTIN

Roy G. Neville

Although in recent years many alkyl- and aryl-substituted derivatives of tetraphenyltin have been reported (1) only one trifluoromethyl derivative has been described, namely tetrakis(3-trifluoromethylphenyl)tin (2). Tetraphenyltin derivatives bearing a *t*-butyl substituent have not been reported.

In connection with other work in this laboratory certain derivatives of tetraphenyltin have been studied in which the substituents are either strongly electropositive or electronegative with respect to the phenyl–tin bond. This report describes seven derivatives of tetraphenyltin bearing 3-trifluoromethyl or 4-*t*-butyl substituents.

Four derivatives of the general formula $[(CH_3)_3C.C_6H_4]_nSn(C_6H_5)_{4-n}$, where $n = 1$–4, have been prepared. In the case of the 3-trifluoromethyl compounds, of general formula $(CF_3C_6H_4)_nSn(C_6H_5)_{4-n}$, only the derivatives for which n is 1, 3, or 4 are reported. Repeated attempts to prepare the derivative for which n is 2 were unsuccessful, the only product being an intractable oil which could not be induced to crystallize even on standing for several months. The reason for this lack of success has not been ascertained as no difficulty was encountered in obtaining the corresponding 4-*t*-butyl compound.

Both the 4-*t*-butyl and 3-trifluoromethyl derivatives were prepared using standard Grignard procedures. The products were colorless crystalline solids. As was anticipated, in the 4-*t*-butyl series melting points increased as the number of butyl substituents increased. Although tetraphenyltin melts at 225° (3), the "unsymmetrical" members

occurs, even in the dry air purged cell compartment of the Beckman IR-7 spectrophotometer. To eliminate fogging at these lower temperatures two thermostated variable path length cells with IRTRAN-2 windows were used.

Once temperature equilibrium was established, both cells were flushed and filled with fresh solutions *in situ* in the cell compartment with the aid of hypodermic syringes and a glass trough. Both the 4-*t*-butyl and 3-trifluoromethyl derivatives were prepared using standard Grignard procedures. The products were colorless crystalline solids. As was anticipated, in the 4-*t*-butyl series melting points increased as the number of butyl substituents increased. Although tetraphenyltin melts at 225° (3), the "unsymmetrical" members

(n = 1–3) of each series melted below this temperature despite their greater molecular weight. Tetrakis(4-*t*-butylphenyl)tin, I, on the other hand, could be heated almost to 300° before melting. The high melting point of this compound may not only be attributed to its large molecular weight but also to its overall molecular symmetry resulting from para substitution by the symmetrical *t*-butyl groups. In the case of tetrakis(3-trifluoromethylphenyl)tin, II, although the trifluoromethyl group is symmetrical (with regard to the carbon–phenyl bond), the molecule itself possesses less overall symmetry than compound I. Consequently, even though the molecular weights of I and II are comparable (651 and 699, respectively), II melts at a significantly lower temperature than I. Other factors also influence the temperature of fusion. The difference in the crystal lattice energy between a *t*-butyl- and a 3-trifluoromethyl-substituted derivative undoubtedly plays an important role in determining the melting point. However, within a given series, it was found that compounds possessing the highest degree of molecular symmetry melt at the highest temperature.

EXPERIMENTAL

Tris(4-t-butylphenyl)phenyltin

The procedure employed for the preparation of this compound is typical of that used for the other *t*-butyl derivatives.

The following reactants were placed in a 500-ml three-necked flask, fitted with reflux condenser, motor-driven stirrer, thermometer, and dropping funnel: magnesium turnings (2.7 g, 0.11 g-atom), sodium-dried diethyl ether (50 ml), and methyl iodide (0.5 ml). The flask was flushed with dry nitrogen and gently warmed on the water bath until the methylmagnesium iodide had formed. A solution of 4-bromo-*t*-butylbenzene (21.3 g, 0.1 mole) in ether (50 ml) was then added, dropwise with stirring, over a 20-minute period. The mixture was then refluxed for 1 hour. Trichlorophenyltin (10.08 g, 0.033 mole) dissolved in anhydrous (sodium dried) benzene (100 ml) was slowly added to the boiling solution and refluxing was continued for 5 hours. The flask was then cooled in an ice bath, and ice-cold water (300 ml) was run in at such a rate that the temperature of the well-stirred mixture did not exceed 20°. After filtering the mixture, the organic layer was washed three times with water (100 ml-aliquots), dried over anhydrous sodium sulphate, and the solvent removed by using a rotary evaporator. The resulting solid was recrystallized three times from a mixture of ethyl alcohol and benzene. The yield of white crystals was 25.0 g (42%), m.p. 190° (uncorr.). Analytical data are given in Table I.

Tetrakis(3-trifluoromethylphenyl)tin

The synthesis of this compound in 12% yield, by the reaction of stannic chloride with 3-lithio-α,α,α-trifluorotoluene, has been reported previously (2). In the present work all trifluoromethyl compounds were prepared by the Grignard reaction.

The procedure employed for the preparation of the 3-trifluoromethylphenyltin compounds was identical with that used for the *t*-butyl derivatives. The tetrakis compound was prepared using the following reactants: magnesium turnings (2.7 g, 0.11 g-atom), 3-bromo-α,α,α-trifluorotoluene (22.5 g, 0.1 mole), and stannic chloride (6.67 g, 0.025 mole). After refluxing for 5 hours, and working up as in the previous preparation, 11.0 g (15.8%) of white crystals was obtained which melted at 143°, in excellent agreement with the literature value (2). Analytical data are given in Table I.

Infrared Spectra

Each compound reported in Table I was characterized by its infrared spectrum (4), using a Nujol mull.

In the *t*-butyl series the following bands were identified: *p*-substitution at 825 cm^{-1}, aromatic C:C at 1600 cm^{-1}, Sn—C_6H_5 at 1065 cm^{-1}, and *t*-butyl at 1365 cm^{-1}.

The following bands were observed in the trifluoromethyl series: *m*-substitution at 805 and 690 cm^{-1}, C:C at 1600 cm^{-1}, Sn—C_6H_5 at 1065 cm^{-1}, and a very strong absorption for C—F stretching at 1325, 1175, 1120, and 1105 cm^{-1}.

THE ALDOL CONDENSATION WITH 2,3-DIPHENYL-4-THIAZOLIDINONE

FRANCES C. BROWN, R. SIDNEY JONES, AND MILDRED KENT

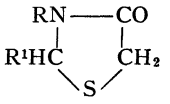
Department of Chemistry, Duke University, Durham, North Carolina, U.S.A.

Received November 13, 1962

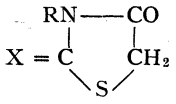
ABSTRACT

The aldol condensation between 2,3-diphenyl-4-thiazolidinone and aromatic aldehydes, which cannot be effected by the usual catalysts used in the analogous reactions of 2-thiono-, 2-oxo-, and 2-imino-4-thiazolidinones, was achieved by the use of ethoxide ion. The structure of the 2,3-diphenyl-5-arylidene-4-thiazolidinone was confirmed by ultraviolet spectral data.

Less information is available about the 4-thiazolidinones with hydrogen or hydrocarbon substituents in the 2-position (I) than about those 4-thiazolidinones with sulphur, oxygen, or an imino group in the same position (II) (1). For example, no aldol condensation



I



II (X = S, O, or NH)

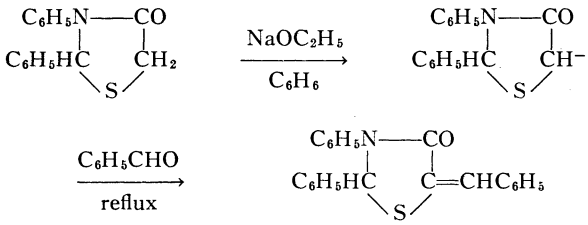
between the methylene group of I and an aromatic aldehyde has been reported, although this reaction occurs readily with all three types of compound II. From the information available in the literature, it was uncertain whether the aldol condensation between 4-thiazolidinones (I) and aromatic aldehydes could not be effected or whether it had never been tried. Therefore, efforts were made to prepare the 5-benzylidene derivative of I.

The compound chosen for study was 2,3-diphenyl-4-thiazolidinone, which is available by the reaction of mercaptoacetic acid and the Schiff base from benzaldehyde and aniline (2). When the aldol condensation of this compound with benzaldehyde was attempted using sodium acetate and acetic acid (3), or ammonia and ammonium chloride in an aqueous ethanolic solution (4), no condensation product was obtained and in each case the starting material was recovered in 88–94% yield. With anhydrous benzene as the solvent, piperidinium acetate as the catalyst, and a water separator attached to the reaction flask to displace the equilibrium (5), the starting material was likewise recovered. After this work was completed, it was found that Baranov (6) had been unable to condense I (R = H; $R^1 = C_6H_5$) with carbonyl compounds such as *p*-dimethylaminobenzaldehyde. Presumably, he used sodium acetate in acetic acid solution to effect the condensation since these are the conditions which he had used in similar condensations.

It seemed probable that the failure of the reaction was caused by the decreased reactivity of the methylene group and that a stronger base, such as ethoxide ion, would be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

able to form the anion of 2,3-diphenyl-4-thiazolidinone. The reaction was run in anhydrous benzene, and 2,3-diphenyl-4-thiazolidinone was added to sodium ethoxide, which had been prepared from sodium sand and anhydrous ethanol. The color of the solution became yellow and a small sample, withdrawn and neutralized, gave, on evaporation of the solvent, 2,3-diphenyl-4-thiazolidinone. Recovery of the starting material at this point indicated that the thiazolidinone nucleus had not been ruptured by contact with ethoxide ion. Addition of benzaldehyde, followed by refluxing for 30 minutes, yielded a pale yellow product which, after recrystallization from benzene, melted at 193–194° and which, from its analysis and spectra, is 2,3-diphenyl-5-benzylidene-4-thiazolidinone.



The 2,3-diphenyl-5-benzylidene-4-thiazolidinone is stable in the presence of several fairly drastic reagents and under fairly rigorous conditions. It was recovered unchanged after 1½ hours of heating with $KHSO_4$ in refluxing xylene, after 3 hours of heating with acetic anhydride, after 3 hours of heating with phosphorus oxychloride in benzene, after 4½ hours of heating at 100° in polyphosphoric acid (raising the temperature of the polyphosphoric acid solution to 200° decomposed the compound), and after 1½ hours of heating with acetyl chloride in benzene solution.

Similar condensations took place when the anion of 2,3-diphenyl-4-thiazolidinone was treated with other aromatic aldehydes. Anisaldehyde, *p*-chlorobenzaldehyde, and *p*-bromobenzaldehyde gave the corresponding 5-arylidene derivatives. The infrared spectra of these compounds are consistent with the structures assigned.

Table I gives the ultraviolet spectral data for the four compounds. 2,3-Diphenyl-4-thiazolidinone has no band present in the region 300–400 mμ. The introduction of a high-intensity band in this region into the spectra of the 5-arylidene derivatives must be attributed to conjugation of the phenyl group with the 4-thiazolidinone nucleus. includes the ultraviolet spectral data for 5-benzylidenerhodanine. The greater electron-attracting capacity of the thione group in the 2-position (II) over that of a phenyl and a hydrogen (I) causes a bathochromic shift of the *K* band from 323 to 376 mμ. The shift agrees qualitatively with that reported for compounds of the structure $[(CH_3)_2NC_6H_4]_2$-C=X (7) where X represents the groups attached to position 2 of formulas I (R^1 = H) and II.

Baranov (8) has measured the ultraviolet spectra of the 5-benzylidene derivatives of II (R = H). The location of the *K* band varies with the nature of X (X = S, 370 mμ; X = NH, 333 mμ; X = O, 329 mμ). The mobility of the hydrogen atoms of II varies in the same order, with X = S > X = NH > X = O. Since the ultraviolet spectra of 5-*p*-acetaminobenzylidenerhodanine is very similar to that of its 3-phenyl derivative (9), the spectra of our 3-phenyl derivative of 2-phenyl-5-benzylidene-4-thiazolidinone should be comparable with the series he has reported. The position of the *K* band of 2,3-diphenyl-5-benzylidene-4-thiazolidinone is in the same region as that of the 5-benzylidene derivatives of pseudothiohydantoin and 2,4-thiazolidinedione, but the intensity is greater with the former. From the ultraviolet spectra of its 5-benzylidene derivative the decreased reactivity of the hydrogens of the methylene group of 2,3-diphenyl-4-thiazolidinone would not be evident.

EXPERIMENTAL

All melting points were taken on a Fischer-Johns melting point apparatus and are uncorrected. Infrared spectra were determined with a Perkin–Elmer spectrophotometer No. 237 and ultraviolet spectra with a Cary 14 spectrophotometer.

2,3-Diphenyl-5-arylidene-4-thiazolidinones

Sodium sand (10), prepared from 1.5 g (0.065 g-atom) of sodium, was covered with 120 ml of anhydrous benzene. The flask was cooled with an ice bath and 3–4 ml of absolute ethanol (dried over magnesium methoxide) was added with stirring. After the vigorous reaction was over, 16.0 g (0.063 mole) of 2,3-diphenyl-4-thiazolidinone was added. When the thiazolidinone had dissolved, the yellow solution was allowed to warm up to room temperature, and the color deepened. The aldehyde (0.063 mole) was added slowly at room temperature, after which the solution was refluxed for 30 minutes. The solution was cooled to room temperature and any unreacted sodium destroyed by the careful addition of 50 ml of glacial acetic acid. After the addition of 50–75 ml of water, the aqueous layer was discarded. The benzene layer was concentrated by distillation at atmospheric pressure and cooled in an ice bath. The crystals were collected and purified by recrystallization from benzene. The melting points, yields, and analytical data are assembled in Table II. Strong bands in the infrared spectra are present at 1680–1690 cm^{-1} (carbonyl group), at 1610 cm^{-1} and at 1495–1510 cm^{-1} (phenyl group), and at 700–800 cm^{-1} (phenyl with one substituent), and, where *p*-substituted aldehydes were used, additional bands are present in the 800–850 cm^{-1} region.

ACKNOWLEDGMENTS

This research was supported by a grant from the Duke University Research Council. The authors are indebted to Roland Brierre, who measured the ultraviolet spectra.

HYDROXYMETHYL PHOSPHORUS DERIVATIVES FROM TETRAKIS(HYDROXYMETHYL) PHOSPHONIUM CHLORIDE. REACTION WITH LEAD CARBONATE AND OXIDE

N. FILIPESCU, L. M. KINDLEY, H. E. PODALL, AND F. A. SERAFIN
Melpar, Incorporated, Research Division, Falls Church, Virginia, U.S.A.
Received November 13, 1962

ABSTRACT

A novel and convenient method has been developed for the preparation of tris(hydroxymethyl) phosphine oxide (THPO) from tetrakis(hydroxymethyl) phosphonium chloride (THPC). The method consists essentially of oxidative deformylation of THPC with lead carbonate in *n*-propyl alcohol. The reaction is facilitated by azeotropic distillation of di-*n*-propylformal and *n*-propyl alcohol.

The reaction of THPC with lead carbonate as well as with lead oxide has been studied in detail in aqueous solution and in *n*-propyl alcohol. The reaction proceeds via the initial formation of tetrakis(hydroxymethyl) phosphonium hydroxide (THPOH) followed by deformylation to tris(hydroxymethyl) phosphine (THP). THP then undergoes oxidation by air as well as by lead carbonate or oxide to THPO. If air is bubbled through the mixture at elevated temperatures, atmospheric oxidation predominates with little or no oxidation by the lead compound.

Depending upon the reaction conditions, a phosphonium hydroxide, a phosphine, or a phosphine oxide are products of the reaction of tetrakis(hydoxymethyl) phosphonium chloride with lead carbonate or oxide.

For several years this laboratory has been engaged in the synthesis of phosphorus-containing polymers in order to provide flame resistant and thermally stable end products. One of the starting materials for the introduction of phosphorus into the polymeric molecules was tetrakis(hydroxymethyl) phosphonium chloride, referred to as THPC.

Although several polymers derived from THPC have been reported (5, 6), we have found that in many instances phosphorus was not incorporated into the polymeric chains which are primarily formed by polycondensation reactions of formaldehyde resulting from the degradation of THPC. These polymers, insufficiently characterized, possessed poor hydrolytic stability and fracture strength. By use of tris(hydroxymethyl) phosphine oxide (THPO) and its monobenzoylated derivative we were able to obtain polymers containing phosphorus in the polymeric chain which possessed markedly improved hydrolytic stability, fracture strength, flame resistance, etc. (3).

A key problem which arose in the initial stages of work with THPO-derived polymers was the conversion of commercially available THPC to THPO. Methods previously described for this conversion required a number of tedious operations to isolate the product. In attempting to devise a better method for the synthesis of THPO from THPC some interesting chemistry was uncovered involving not only the preparation of THPO but also the formation of tetrakis(hydroxymethyl) phosphonium hydroxide (THPOH) and tris(hydroxymethyl) phosphine (THP). This paper is concerned with a new synthesis of THPO from THPC and with the properties and reactions of some of the intermediates.

THPC was reported (1, 2) to react with aqueous sodium hydroxide at room temperature or upon gentle heating *below* 80° C to yield THPO with the evolution of one molecule of hydrogen. On boiling, a second molecule of hydrogen is given off with the formation of the sodium salt of bis(hydroxymethyl) phosphinic acid. The same results are obtained if one uses an alkali metal carbonate instead of the hydroxide, but the reaction rate is

slower. An insoluble carbonate, such as calcium or barium carbonate, produces only THPO and one molecule of hydrogen even after prolonged boiling.

Each of these procedures yields THPO in an aqueous solution mixed with soluble inorganic chloride (sodium, barium, or calcium). Separation of THPO from the inorganic chloride is difficult because of the former's extreme solubility in water and low solubility in organic solvents. Isolation by distillation is not possible because THPO decomposes at temperatures far below its boiling point. The most successful isolation of THPO to date involves long, tedious extractions of the dry mixture of THPO and inorganic salts with relatively low molecular weight alcohols, such as isopropyl alcohol.

In our laboratory, attention was directed toward an approach which had appeal as a simple, economical reaction for converting THPC to THPO and at the same time avoiding the isolation problems encountered heretofore. The proposed method was:

$$2[(HOCH_2)_4P]^+Cl^- + PbCO_3 \xrightarrow{\text{air}} 2(HOCH_2)_3PO + PbCl_2 + 2CH_2O + H_2O + CO_2. \quad [1]$$

Experimental investigation, however, proved that the reaction of THPC with lead carbonate was considerably more complex than originally believed, and that several different organophosphorus compounds can be formed depending on the reaction conditions.

The conditions under which the reaction of THPC with lead carbonate was investigated may be summarized as follows:

(1) in water at 55–65° C,
(2) in water at temperatures from 65 to 90° C,
(3) in *n*-propyl alcohol at 60–65° C,
(4) in *n*-propyl alcohol at approximately 96° C.

Under each of these conditions the reaction time was varied over wide ranges (1 hour to several days). In the reactions conducted in water, it was observed that metallic lead precipitated if the reaction temperature exceeded about 65° C. For this reason, a series of experiments was carried out below 65° C and another series above this temperature.

In the "low" temperature experiments THPC and lead carbonate were heated in water at 55–65° C, and the solids were removed by filtration. After removal of water from the filtrate there remained a syrupy, liquid product. Removal of final traces of volatile materials, particularly water, was attempted by long periods of stirring under vacuum, azeotropic distillation with benzene, and repeated extractions with acetone. Infrared spectra of this product (still a syrupy liquid) indicated very little P → O absorption and thus very little formation of THPO. Furthermore, several qualitative reactions of the product were quite different from those of THPO. For example, the product reacted violently with oxidizing agents such as H_2O_2 and HNO_3 (indicating the presence of a strong reducing compound), it exhibited a highly exothermic reaction with α,β-unsaturated carbonyl compounds, and cured unsaturated polyester resins to elastomeric materials. Furthermore it possessed a strong odor suggestive of a phosphine.

Based on the above results and evidence obtained in later experiments it appears that the main reaction occurring between THPC and lead carbonate in water at 55–65° is:

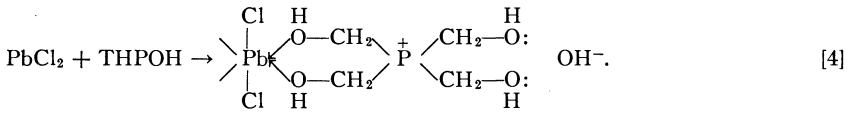
$$2[(HOCH_2)_4P]^+Cl^- + PbCO_3 \xrightarrow{H_2O} \underset{\text{(THPOH)}}{2[(HOCH_2)_4P]^+OH^-} + PbCl_2 + 2CH_2O + CO_2. \quad [2]$$

The THPOH (tetrakis(hydroxymethyl) phosphonium hydroxide) is believed to exist in equilibrium with tris(hydroxymethyl) phosphine (THP), i.e.,

$$[(HOCH_2)_4P]^+OH^- \rightleftharpoons \underset{\text{(THP)}}{(HOCH_2)_3P} + CH_2O + H_2O. \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

It was found that not all of the ionic chloride was completely removed as $PbCl_2$. The main reason for this appears to be due to the fact that hydroxymethyl-phosphorus compounds, such as THPC, THPOH, etc., were found to form *soluble* complexes with $PbCl_2$ as well as with AgCl. We believe that these complexes are formed by coordination of the metal ion with the hydroxyl functions of the phosphorus compound, e.g.



[4]

Not all of the complexes were water or alcohol soluble. The solids removed from the reaction by filtration even after repeated washing with hot water contained significant amounts of phosphorus compounds strongly adsorbed or complexed with the lead carbonate or lead chloride. These solids were similar in appearance to litharge–glycerine cements, suggestive of some polymerization.

In the second series of experiments, THPC and lead carbonate were heated in water at 65–90° C for various lengths of time. In addition to the reactions which occur at lower temperature, a redox reaction was found to occur with the formation of metallic lead. The reaction appears to be as follows:

$$(HOCH_2)_3P + PbCO_3 \rightarrow (HOCH_2)_3PO + Pb + CO_2. \qquad [5]$$

The evidence for this reaction is based upon the following facts:

(1) isolation and identification of THPO,
(2) no evidence of hydrogen formation,
(3) PbO gave similar results, and
(4) similar results were obtained in *n*-PrOH instead of water at elevated temperatures.

It was also found that when air was passed through the mixture while it was being heated, less metallic lead was produced, and the conversion of THP to THPO appeared to occur more rapidly. The predominant reaction under these conditions appears therefore to be simply the direct atmospheric oxidation of THP to THPO. The product recovered after filtration of the solids from the reaction mixture and exhaustive removal of water and other volatile materials was a partially crystallized syrupy mixture. Attempts to separate this mixture into pure individual compounds by a variety of techniques were not successful. It was, however, possible to separate two major fractions—one containing a large percentage of THPO and another consisting mostly of THP plus some THPOH.

By thoroughly drying the reaction mixture and cooling it for a long period of time, it was possible to obtain a distinct crystalline solid which could be separated from the syrupy liquid. This solid reacted with benzoyl chloride in a Schotten–Bauman reaction to give the known pure tribenzoate (5) of THPO in good yield. The presence of THP in the syrupy liquid phase was indicated by formation of the known yellow benzoquinone–THP complex (4), its "characteristic" exothermic reactions with oxidants such as H_2O_2 and HNO_3, and finally its reactions with unsaturated carbonyl compounds such as diethyl maleate, acrolein, acrylamide, etc. (The latter reactions will be the subject of another communication.)

Vacuum distillation (5 mm) of the product resulting from the reaction of THPC and lead carbonate at 65–90° C yielded a viscous colorless liquid distilling at 130–140° C. The pH of this distillate was 4 and elementary analysis indicated its composition to be as follows: THP, 51.8; CH_2O, 31.5; water, 9.4; HCl, 7.6%. The distillate gave reactions with H_2O_2, HNO_3, and unsaturated carbonyl compounds previously described as those of THP.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The residue from the distillation failed to react with any of the above-mentioned reagents. It had a pH of 6 and elementary analysis which corresponded to the following composition: THPO, 53.0; THPC, 18.0; CH_2O, 25.6; water, 3.4%.

Further verification of the composition of the distilled and residue fractions was obtained by measuring the amount of hydrogen evolved upon boiling a sample of each fraction with an excess of aqueous sodium hydroxide. The reactions of sodium hydroxide with the compounds of interest are as follows:

$$(HOCH_2)_3PO + NaOH \rightarrow (HOCH_2)_2PO(ONa) + CH_2O + H_2 \quad [6]$$

$$(HOCH_2)_3P + NaOH + H_2O \rightarrow (HOCH_2)_2PO(ONa) + CH_2O + 2H_2 \quad [7]$$

$$[(HOCH_2)_4P]^+Cl^- + 2NaOH \rightarrow (HOCH_2)_2PO(ONa) + 2CH_2O + NaCl + 2H_2. \quad [8]$$

The experimental results were as follows (based on 100 g of sample). Distillate: 20.6 l. of H_2; calc. for indicated composition (51.8% THP), 20.2 l. Residue: 12.9 l. of H_2; calc. for 53.0% THPO and 18.0% THPC, 12.7 l.

In the third series of experiments, water was present only in traces in the reaction of THPC with lead carbonate. The THPC and lead carbonate was *suspended* in *n*-propyl alcohol and the mixture was heated at 60–65° C for 6 to 8 hours. After filtration and removal of alcohol, a syrupy liquid was obtained. This product contained practically no ionic chloride and reacted exothermally with oxidizing agents and with α,β-unsaturated carbonyl compounds. Comparison of this product with samples prepared by an alternate route* strongly indicated that it was essentially THPOH containing some THP. The reaction scheme may be described as follows:

$$2[(HOCH_2)_4P]^+Cl^- + PbCO_3 + H_2O \xrightarrow{n\text{-PrOH}} 2[(HOCH_2)_4P]^+OH^- + PbCl_2 + CO_2 \quad [9]$$

$$THPOH \rightleftharpoons THP + CH_2O + H_2O. \quad [10]$$

If an excess of lead carbonate is used in the above reaction and the intermediate product is not isolated, further reaction occurs when the reaction temperature is raised to 96° C. The reactions in this step appear to be as follows:

$$[(HOCH_2)_4P]^+OH^- \rightleftharpoons (HOCH_2)_3P + CH_2O + H_2O \quad [11]$$

$$CH_2O + n\text{-PrOH} \rightarrow (n\text{-PrO})_2CH_2 + H_2O \quad [12]$$

$$THP + PbCO_3 \rightarrow THPO + Pb + CO_2. \quad [13]$$

During reaction, metallic lead precipitated and the dipropyl formal – propyl alcohol azeotrope was removed at 96° C. Removal of formaldehyde as an azeotrope evidently facilitates the formation of THP, which is immediately oxidized to THPO. The final product (THPO) was recovered as a white solid after filtration of metallic lead and removal of volatile components by vacuum distillation at about 50° C. Its identity was confirmed by formation of the tribenzoate derivative and by comparison of its infrared spectrum with an authentic sample of THPO. In a typical reaction 1 mole of THPC and 1.8 mole of $PbCO_3$ in 1500 ml *n*-propyl alcohol were stirred with heating. During the reaction (8–10 hours) the distillate was continuously removed and fresh *n*-propyl alcohol added from time to time. The reaction mixture was cooled in an ice bath and filtered. The filtrate was dried *in vacuo* to obtain crystalline THPO. The yields were in excess of 90%.

*THPOH *was prepared by reaction of* THPC *with methanolic sodium hydroxide at room temperature, filtration of* NaCl, *and vacuum removal of solvent.* THP *was prepared by passing phosphine through an alcoholic solution of* THPOH *in the presence of a platinum oxide catalyst. The* THP *was recovered as a white waxy solid after solvent removal in vacuo and identified via its benzoquinone and mercuric chloride complexes.*

For personal use only.

A possible explanation for the difficulties encountered in separating THPO from THP and/or THPOH may be due to the high association and possible complex formation between these compounds, e.g.,

$$\mathrm{THP} + \mathrm{THPO} \rightarrow [\mathrm{THPH}]^{+}(\mathrm{HOCH_2})_2\overset{\uparrow}{\underset{\mathrm{O}}{\mathrm{P}}}\mathrm{—CH_2O^-} \qquad [14]$$

$$\mathrm{THPOH} + \mathrm{THPO} \rightarrow [(\mathrm{HOCH_2})_3\overset{+}{\mathrm{P}}\mathrm{CH_2OH} \ldots \mathrm{O—P(CH_2OH)_3}]\mathrm{OH^-}. \qquad [15]$$

In summary it has been found that:

(1) THPO can be conveniently prepared by reaction of THPC with $PbCO_3$ in *n*-PrOH at 96° while azeotropically distilling di-*n*-propyl formal and *n*-propyl alcohol;

(2) the conversion of THPC to THPO in the presence of $PbCO_3$ proceeds via THPOH and THP, respectively;

(3) $PbCO_3$ and PbO each oxidize THP to THPO;

(4) $PbCl_2$ and AgCl form two types of complexes with THPO and related compounds, viz. soluble and insoluble products.

THE PHOTOLYSIS OF ISOCYANIC ACID VAPOR[1]

J. Y. P. MUI[2] AND R. A. BACK
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received December 6, 1962

ABSTRACT

The photolysis of isocyanic acid vapor has been studied at temperatures ranging from −31 to 200° C, and pressures from about 2 to 200 mm. Products identified were CO and N_2 in a ratio which varied from 2.5 to 5, together with much smaller amounts of hydrogen. The mechanism

$$HNCO + h\nu \rightarrow NH + CO$$
$$NH + HNCO \rightarrow NH_2 + NCO$$
$$NH_2 + HNCO \rightarrow NH_3 + NCO$$
$$2NCO \rightarrow N_2 + 2CO$$
$$2NH \rightarrow N_2 + H_2$$

accounts approximately for the products of the photolysis at low HNCO pressures and low temperatures. Additional reactions of NCO radicals with HNCO are postulated to account for increased production of CO and N_2 as the temperature and HNCO pressures were increased.

The effects of adding ethylene and hydrogen to the system were briefly investigated. The results are explained in terms of reactions of NH and NCO radicals with hydrogen and ethylene.

INTRODUCTION

After some earlier controversy, it was shown conclusively in 1950 that cyanic acid in the vapor phase had the structure H—N=C=O, and should thus properly be called isocyanic acid (1). This structure is analogous to that of ketene, and similar photolytic behavior might be anticipated. Flash photolysis of isocyanic acid vapor (2, 3) has yielded strong absorption spectra of NH radicals, together with NCO and NH_2, but apart from these spectroscopic experiments, the photolysis of the vapor has apparently not been studied. It would appear to be a promising source of NH radicals, suitable for kinetic studies of their reactions.

EXPERIMENTAL

Isocyanic acid was prepared by the pyrolysis of cyanuric acid vapor in a stream of dry nitrogen at 750° C (1, 4). Repeated bulb-to-bulb distillation *in vacuo*, a large middle fraction being kept, reduced the impurities, CO_2, HCN, and C_2N_2, to less than 1%. This was estimated by gas chromatography on a 1-m column of dinonyl phthalate on firebrick at 50° C, which gave appearance times of 0.5, 2.5, 3.8, and 8.5 minutes for CO_2, HCN, C_2N_2, and HNCO, respectively, with a flow rate of 100 cc/min of helium. Treatment of the acid with silver oxide powder (4) reduced the content of HCN and C_2N_2 to about 0.2 and 0.3% respectively, and the only other impurities detectable by mass spectrometry or gas chromatography were small amounts of CO_2 and NH_3. It proved almost impossible to remove these latter compounds completely, probably because they are formed readily by hydrolysis of the isocyanic acid by traces of water. The mass spectrum of the purified HNCO vapor, which has not been previously reported, is shown in Table I.*

Isocyanic acid is a gas at room temperature (b.p. ~ 24° C), and behaves, in a vacuum system, much like ketene. It tends to trimerize slowly on standing as a vapor, forming a mixture of the two trimers, cyanuric acid and cyammelide (5, 6). This is apparently a surface recation, very slow in a clean vessel, but catalyzed by the trimers which are deposited on the surface. The trimerization was slow enough that the acid vapor could be stored in a darkened vessel at pressures below 10 cm without serious loss.

The acid vapor was photolyzed in a conventional cylindrical quartz vessel, 10 cm long and 5 cm in diameter, with plane windows at each end, which was mounted in an air thermostat. The rate of trimerization

TABLE I
Mass spectrum of HNCO vapor

Mass	Relative intensity	Ion	Mass	Relative intensity	Ion
12	0.6	C^+	28	22.6	CO^+
14	1.1	N^+	29	10.1	HCO^+
15	6.6	NH^+	30	1.5	NO^+
16	0.4	O^+	42	19.0	NCO^+
26	2.0	CN^+	43	100.0	$HNCO^+$
27	4.2	CNH^+			

of the acid was considerably enhanced during the photolysis, and in a typical 30-minute experiment from 1 to 2% of the HCNO would be converted to trimer. The deposition of these compounds on the windows caused a progressive reduction in the light intensity during a series of experiments. This difficulty was circumvented by baking the reaction vessel for several hours (usually overnight) at 200° C, so that the slightly volatile trimers were sublimed out of the vessel. This technique gave an approximately constant light intensity and reproducible rates of photolysis. The trimerization was also favored by high pressures of acid, and in practice pressures greater than 200 mm were avoided.

Careful blank experiments were done at all temperatures, both with the light off, to look for possible thermal reactions of HNCO, and with the light on, but no HNCO vapor, to look for possible products of the photolysis of the trimers. No non-condensable products were found in any of these experiments; a small trace of CO_2 was the only detectable product from the photolysis of the trimers.

The light source was an unfiltered Hanovia S-500 medium-pressure mercury arc, partially collimated to fill the reaction vessel uniformly. Isocyanic acid vapor absorbs continuously at wavelengths below 2240 Å, with diffuse bands from 2570 to 2250 Å (7), so that the effective light was mostly between 2240 and 2000 Å.

Non-condensable products, CO, N_2, and H_2, were removed at −196° C, measured in a gas burette, and analyzed by combustion on copper oxide. Hydrogen was measured by difference in this technique, and to confirm that the very small yields observed in some experiments were real, samples were analyzed by mass spectrometry. The results agreed very closely with the combustion analysis, and also showed that CO, N_2, and H_2 were the only non-condensable products.

Careful analysis by low-temperature distillation and gas chromatography showed that CO_2 was not a product of the photolysis, although traces of it, probably formed by hydrolysis of HNCO, were always present. Small amounts of NH_3 and N_2H_4 have been detected in the reaction products by gas chromatography (8), but quantitative analysis of these basic compounds in the presence of a large excess of HNCO is very difficult. No other reaction products have been detected by gas chromatography on a variety of columns, or by mass spectrometry.

Ethylene (Phillips research grade) was added in some experiments, and a solid-nitrogen trap at −210° C was used to separate the non-condensable gases. Hydrogen was added in a few experiments, and was introduced into the vacuum line from a cylinder, through a hot palladium thimble.

RESULTS

The non-condensable products of the photolysis were CO and N_2 in a ratio which varied from about 2.5:1 to 5:1, together with much smaller amounts of H_2. In Fig. 1 is shown the rate of production of CO as a function of HNCO concentration, at several temperatures, with constant light intensity. In Fig. 2 are shown values of the N_2:CO ratio found in the same experiments, and in Fig. 3 are similar plots of the ratio H_2:CO multiplied by 100.

The effect of added ethylene on the products of the photolysis at 37° C and constant pressure of acid (~22 mm) is shown in Fig. 4. The hydrogen yield in the same experiments was negligibly small, even at the lowest concentration of ethylene. In Fig. 5 is shown the yield of CO from the photolysis of HNCO at several pressures and temperatures, in the presence of a high pressure (~600 mm) of ethylene. These data are directly comparable with those for the photolysis of the pure acid plotted in Fig. 1. The yields of both N_2 and H_2 in the experiments with high pressures of ethylene were close to zero.

In a few experiments, hydrogen was added to the system, and in Table II are shown

the results. Rates of production of CO and N_2 are expressed as yields relative to the normal yields in the pure acid. Hydrogen, of course, could not be measured in these experiments.

TABLE II

Effect of hydrogen on the photolysis of HNCO
(HNCO = 21 mm, H_2 = 52 mm)

Temperature (°C):	37	100	200
$CO/(CO)_0$	1.06	1.52	5.09
$N_2/(N_2)_0$	0.85	0.75	0.68

NOTE: $(CO)_0$ and $(N_2)_0$ are yields of CO and N_2 in the absence of hydrogen.

In all the experiments, rates of production of products were independent of irradiation time up to about 1 hour, and if care was taken to avoid the accumulation of solid materials on the windows, for much longer times. Thus a sample of HNCO could be photolyzed, removed from the vessel, and the non-condensable products taken away; if the sample of acid were then returned to the reaction vessel (thoroughly baked out in the interim) and photolyzed again, the product yields were unchanged. In fact, a single sample of acid could be reused many times, and gave results indistinguishable from those obtained with a freshly prepared sample.

As mentioned earlier, no other products, condensable or non-condensable, could be detected by low-temperature distillation, mass spectrometry, or gas chromatography. In particular, CO_2, HCN, C_2N_2, NO, N_2O, or NO_2 could have been easily detected but were unobserved. Small amounts of NH_3 and N_2H_4 have been found as products, but their quantitative estimation is difficult. Traces of CO_2 were always found, but a careful series of experiments showed that this was not produced in the photolysis.

DISCUSSION

The following simple mechanism roughly accounts for the main features of the photolysis, and while its inadequacies will become evident, it is a useful point of departure.

$$h\nu + HNCO \rightarrow NH + CO \quad [1]$$

$$NH + HNCO \rightarrow NH_2 + NCO \quad [2]$$

$$NH_2 + HNCO \rightarrow NH_3 + NCO \quad [3]$$

$$NCO + NCO \rightarrow N_2 + 2CO \quad [4]$$

The persistent production of CO, and the complete suppression of N_2 and H_2, in the presence of ethylene, strongly supports reaction [1] as the primary step, rather than the possible alternative

$$h\nu + HNCO \rightarrow H + NCO. \quad [1A]$$

The pressure dependence of the photolysis products, and the approximately constant CO production, independent of ethylene pressure above about 3×10^{-3} mole/liter (Fig. 4), indicate that any intermediate excited HNCO molecule in reaction [1] was too short lived to suffer collisional deactivation, which is not surprising in view of the high energy of the light quanta absorbed.

The observed values of N_2:CO, and the very low yields of H_2, would appear to favor reaction [2] over the alternative

$$NH + HNCO \rightarrow CO + N_2H_2 \rightarrow CO + N_2 + H_2, \quad [2A]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

which would have led to a product ratio $CO:N_2:H_2$ of 2:1:1. It will be seen later that the persistent low yield of hydrogen at high pressures of HNCO (Fig. 3) may have arisen from reaction [2A] occurring to a very slight extent. The predominance of reaction [2] over [2A] is just the reverse of the behavior found in the photolysis of ketene, where the reaction of CH_2 with ketene to form ethylene and CO (analogous to [2A]) is much faster than the abstraction of hydrogen (9–12).

The detection of NH, NH_2, and NCO radicals by their absorption spectra in the flash photolysis of HNCO vapor (2, 3) lends some support to the occurrence of reactions [1], [2], and [3].

Reaction [4] was suggested previously to be the fate of NCO radicals in the photolysis of methyl isocyanate (13). In the absence of reaction products other than N_2 and CO, reaction [4] again seems the most reasonable possibility in the present system.

The simple mechanism comprising reactions [1], [2], [3], and [4] predicts a ratio of N_2:CO of 0.33, corresponding to the upper horizontal line in Fig. 2. At low temperatures and pressures of HNCO, N_2:CO rose somewhat above this level. With increasing temperature and HNCO pressure, N_2:CO decreased systematically to much lower values. The simple mechanism also takes no account of the production of hydrogen in the photolysis. The pressure and temperature dependence of the H_2:CO ratio (Fig. 3) strongly suggest that H_2 arose from the radical combination reaction

$$NH + NH \rightarrow N_2 + H_2. \qquad [5]$$

A simple kinetic treatment of a competition between reactions [5] and [2] yielded reasonably linear plots of $R_2/R_5^{1/2}$ against HNCO concentration for the data at 0 and 37° C and low pressures of HNCO. Values of $k_2/k_5^{1/2}$ were obtained from the slopes of these plots, and if $E_5 = 0$, a very rough estimate of $E_2 = 3.6$ kcal/mole may be made. In a simple competition between reactions [5] and [2], the H_2:CO ratio should have fallen to zero at high pressures of HNCO, but it is seen instead that the ratio reached a constant value, small but measurable, at 37 and 100° C (Fig. 3). Reaction [2A] is the most probable source of this hydrogen, which corresponded to about 6, 2, and 1% of the estimated rate of reaction [2] at 37, 100, and 200° C respectively, with the dependence on temperature presumably reflecting a slightly higher activation energy for reaction [2].

If reaction [5] is taken into account, the mechanism then predicts that the ratio $(N_2–H_2):(CO–2H_2)$ should equal 0.33, and in Fig. 6 it is seen that this modification has eliminated the high values observed at low HNCO pressure in the similar plot of N_2:CO (Fig. 2). However, the downward trend with increasing pressure of HNCO and temperature persists in Fig. 6, and only as the HNCO pressure approaches zero does the ratio

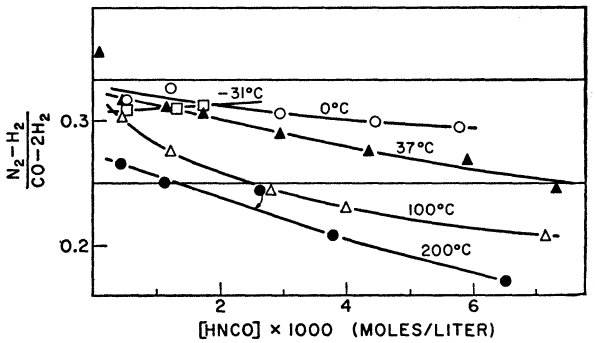

FIG. 6. Values of the ratio $(N_2–H_2):(CO–2H_2)$ in the photolysis of HNCO.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$(N_2–H_2)$:$(CO–2H_2)$ approach the predicted value of 0.33. Values as low as 0.25, the lower horizontal line in Figs. 2 and 6, could be explained if hydrazine, rather than ammonia, were a reaction product. The radical combination reactions

$$NH_2 + NH_2 \rightarrow N_2H_4 \quad [6]$$

$$NH_2 + NH \rightarrow N_2H_3, \quad [7]$$

followed by

$$N_2H_3 + HNCO \rightarrow N_2H_4 + NCO \quad [8]$$

are possible sources of hydrazine, but could not explain the decrease in N_2:CO with increasing HNCO pressure, and in fact should lead to just the reverse. The production of hydrazine would also require a reduction in the yield of CO from three to two molecules for each HNCO photolyzed by reaction [1], whereas it will be seen that the yield of CO rose much above this value. Reactions [6], [7], and [8] must thus be considered unlikely, and the variation of N_2:CO with HNCO pressure remains unexplained.

The temperature dependence of the yields of CO and N_2 is also not explained by the simple mechanism. An examination of Figs. 1 and 2 shows that there was a marked increase in the rates of production of both CO and N_2 with increasing temperature, as well as an increase in CO relative to N_2. It is seen from Fig. 5 that up to 100° C, the yield of CO in the presence of a high pressure of ethylene was independent of temperature. The most probable interpretation of these experiments is that reaction with ethylene removed NH, NH_2, and NCO radicals, thus suppressing formation of N_2 and CO by reaction [4], so that the residual CO production was a measure of reaction [1], the primary photolytic process. Thus the primary quantum yield was apparently independent of temperature between 37 and 100° C; on raising the temperature to 200° C, however, it appears to have increased sharply. This seems unlikely, on several counts, although it cannot be entirely ruled out, and it seems more probable that at the higher temperature ethylene failed to completely supress the formation of CO by secondary reactions. The nitrogen yield was close to zero in these experiments, so that a simple failure to scavenge NH or NCO completely would not suffice. The reaction

$$NCO + C_2H_4 \rightarrow CO + [NC_2H_4] \rightarrow \text{higher products}, \quad [9]$$

which would supress N_2 formation, but not CO, is one possibility, but a more thorough study of the system at 200° C is obviously needed.

If it is accepted tentatively that the extent of reaction [1] was constant at all temperatures, and is given by the yield of CO measured at 37 and 100° C in the presence of excess ethylene (Fig. 5), some values of quantum yield (yield per primary photolytic act) may be calculated, and are shown in Table III. The simple mechanism (reactions [1] to [4]) predicts quantum yields of 3 and 1 for CO and N_2 respectively; the measured yields were lower than this at low temperature, but rapidly rose to much larger values with increasing temperature and HNCO pressure. If allowance is made for the formation of H_2 and N_2 by reaction [5], then $(CO + 4H_2)$ and $(N_2 + H_2)$ should have had quantum yields of 3 and 1 respectively, and it is seen in Table III that this modification raises the yields at low temperature close to the predicted values.

The quantum yield data show a behavior very similar to that of the N_2:CO ratios. Both tend towards agreement with the simple mechanism at low temperatures and HNCO pressures, but indicate sharply increasing production of "extra" CO and N_2 as temperature and HNCO pressure were raised, and it is evident that additional reactions must be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

TABLE III
Calculated quantum yields in the photolysis of HNCO

Temperature (°C)	HNCO×1000 (mole/l.)	Yield per primary photolytic act			
		CO	N_2	$CO + 4H_2$	$N_2 + H_2$
−31	1.2	1 92	0.69	2.94	0.94
0	1.2	2.62	0.94	3.67	1.21
0	2.9	2.96	0.99	3.85	1.22
37	1.2	4.05	1.32	4.74	1.49
37	2.9	5.15	1.55	5.69	1.68
100	1.2	5.11	1.42	5.27	1.46
100	2.9	6.89	1.67	7.08	1.72
200	1.2	7.26	1.81	7.32	1.82
200	2.9	10.0	2.23	10.0	2.25

occurring. Reactions of NCO radicals with HNCO would seem the most promising source of extra products. The sequence

$$NCO + HNCO \rightarrow HN_2CO + CO \quad [10]$$

$$HN_2CO \rightarrow H + N_2 + CO \quad [11]$$

$$H + HNCO \rightarrow NH_2 + CO \quad [12]$$

$$NH_2 + HNCO \rightarrow NH_3 + NCO \quad [3]$$

constitutes a chain carried by NCO radicals which yields CO, N_2, and NH_3 in the same porportion as the simple mechanism, and would be favored by increasing HNCO pressure and temperature. This could account for extra CO and N_2 in a 3:1 ratio, but the marked increase in CO:N_2 requires another reaction producing CO without N_2. This is a stoichiometric problem as well as a mechanistic one, for as long as CO and N_2 are accompanied only by NH_3, they must be formed in a 3:1 ratio. Hydrazine formation could lead to a 4:1 ratio, but also decreased quantum yields, and, as discussed earlier, seems improbable. A product deficient in CO and stable and slightly volatile at 200° C (since no involatile compounds or polymers accumulated on the vessel windows) is required. One such possible product is urazine, NH·CO·NH·NH·CO·NH, which might be formed by reaction [10] followed by stepwise reaction of HN_2CO with three more molecules of HNCO, according to the overall equation

$$4HNCO \rightarrow \text{urazine} + 2CO. \quad [13]$$

The reactions [10] to [13] suggested here to account for the deviation from the simple mechanism are obviously tentative. Analysis for NH_3, N_2H_4, urazine, and other nitrogenous products will be needed to resolve the details of the reaction mechanism, but the separation of these basic compounds from the excess of HNCO presents some difficulties.

The effect of hydrogen on the photolysis of HNCO, shown in Table II, was rather unexpected. If the reaction

$$NH + H_2 \rightarrow NH_3 \quad [14]$$

had occurred, then the yields of N_2 and CO should have been reduced in much the same way as with ethylene. On the other hand the reaction

$$NH + H_2 \rightarrow NH_2 + H \quad [15]$$

(which is about 10 kcal endothermic), followed by reactions of NH_2 and H with HNCO, would have caused no reduction in the yields of CO and N_2. From Table II, N_2 is seen to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

have decreased steadily with increasing temperature, suggesting that reaction [14] did occur with rates approximately 14, 7, and 5 times slower than reaction [2] at 37, 100, and 200° C respectively. The CO yield, however, increased, slightly at 37° and much more at the higher temperatures. Again, a reaction sequence involving NCO radicals,

$$NCO + H_2 \rightarrow NH_2 + CO \quad [16]$$

$$NH_2 + HNCO \rightarrow NH_3 + NCO, \quad [3]$$

which generates CO and NH_3 without otherwise affecting the system may be tentatively suggested as the source of the extra CO.

It is interesting to compare the photolysis of HNCO with that of its analogue, ketene. The chief similarities are in the primary process, and in the formation of excess CO accompanied by reactions leading to higher products. The chief differences between the two photolyses arise from the apparent tendency of NH radicals to abstract hydrogen from HNCO (reaction [2]) in preference to reaction [2A]. In the ketene photolysis, the reaction of CH_2 radicals with ketene analogous to [2A] is very fast and predominates over the abstraction reaction (9–12). This contrasting behavior probably depends on the weaker bonding of the hydrogen atom in HNCO, and perhaps on the lower stability of N_2H_2 compared to C_2H_4, which might require the formation of N_2 and H_2 in the reaction complex, and a consequent low frequency factor. The reaction of NH with HNCO, whether by [2] or [2A], must be considerably slower than the reaction of CH_2 with ketene, since the combination reaction, [5], competed appreciably with reaction [2], while in the ketene photolysis the combination of CH_2 radicals appears to have been suppressed almost completely by their removal by reaction with ketene, even at low temperatures and high light intensity (11, 12).

The photolysis of HNCO appears to be a useful source of NH radicals for kinetic studies of their reactions. Its chief disadvantage would seem to be the complications arising from the simultaneous presence of the three radicals NH, NH_2, and NCO.

THE PREPARATION OF DEHYDROABIETANE-1-AMINE

RICHARD F. STOCKEL[1]
Department of Chemistry and Geology, Clemson College, Clemson, South Carolina, U.S.A.
Received September 18, 1962

ABSTRACT

The preparation of dehydroabietane-1-amine (II) has been achieved and characterized by base hydrolysis of the methyl carbamate (VII) via the following path: acid (I) → acid chloride (IV) → amide (V) → methyl carbamate (VII) → primary amine (II). The overall yield from acid (I) to amine (II) was approximately 50%. Other reactions leading to poor yields of the primary amine are discussed.

INTRODUCTION

The investigation of resin acids has been an active field of endeavour for a number of workers (1–8), the purpose of which was to synthesize 1-ketonordehydroabietane (X) either from dehydroabietic acid (I) or by total synthesis.

It seems remarkable that dehydroabietane-1-amine (II), the subject of this report, had not previously been characterized nor prepared in good yields, since it would be a natural precursor to the tricyclic ketone 1-ketonordehydroabietane (X).

It was reported (1) that dehydroabietane-1-isocyanate (III) upon acid hydrolysis gave a negligible amount of the primary amine (II), but no data were given. The only other report of this amine (7) gave indirect evidence of its existence via infrared analysis and by conversion to the known tertiary amine (1), N,N-dimethyldehydroabietane-1-amine (IX).

Since the Curtius reaction led to the isocyanate (1), it was decided to study the Schmidt and Hofmann reactions and some of their many modifications.

DISCUSSION

It has been found that the Schmidt reaction, on dehydroabietic acid (I), run in the conventional way, led to considerable sulphonation of the C ring (8). No doubt the sulphonation occurred in the 6- or 8-positions or both (9). This was not unusual since the C ring is formally a 1,2,4-trisubstituted aromatic ring, thus being very reactive towards electrophilic substitution. Although the carboxyl group was converted to the amine, the sulphonic acid group was resistant to hydrolysis; therefore, the desired product could not be obtained.

A modification of the Schmidt reaction on the acid (I), employing polyphosphoric acid (10, 11), gave 18.8% yield of the amine (II) along with 80.6% of unchanged acid (I). Replacement of the polyphosphoric acid by a mixture of trifluoroacetic acid and trifluoroacetic anhydride (12) gave the isocyanate (III) and unchanged acid (I), in yields of 27.3% and 63.6%, respectively. Longer reaction time resulted in little change in the ratio of these two products.

The results of these two modifications of the Schmidt reaction seem incongruous since the intermediate in this reaction is the isocyanate. Why the isocyanate is completely hydrolyzed in one method while not in the other is not at all obvious. It may be a temperature-dependent factor or it may be due to the fact that in the first case a basification is performed. This situation is not found in the second method. The formation of

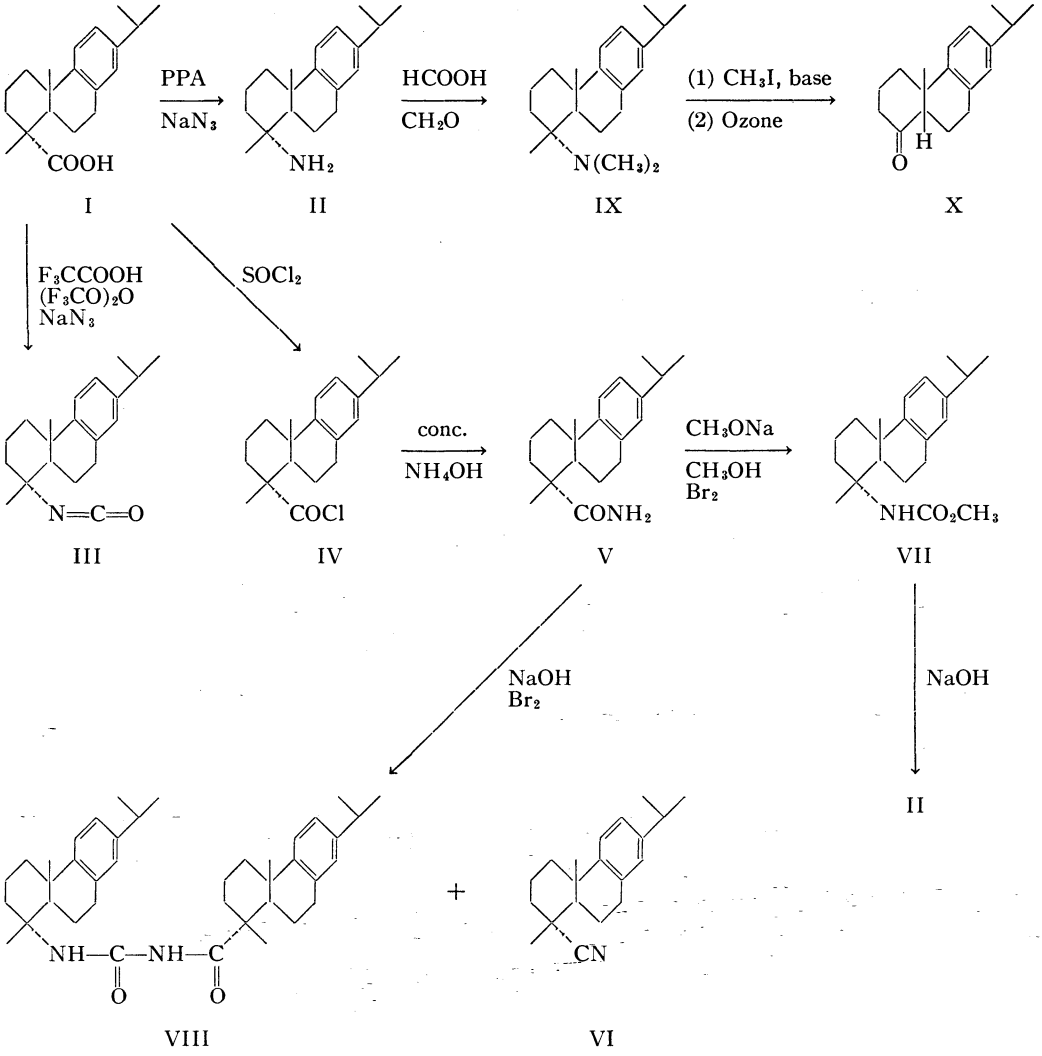
For personal use only.



the isocyanate with trifluoroacetic acid and trifluoroacetic anhydride was compatible with the observation that 4-phenanthrenecarboxylic acid gave 4-phenanthreneisocyanate (12). Also the fact that the isocyanate (III) was not hydrolyzed by aqueous hydrochloric acid (1) may be due to the heterogeneous system.

The Hofmann reaction performed on the amide (V), made in excellent yield by treating the acid halide (IV) with concentrated ammonium hydroxide (14), gave a complex mixture. Infrared analysis revealed the presence of the nitrile (VI), the alkyl acyl urea (VIII), plus unchanged amide (V). The formation of the nitrile and urea is not unusual, since for aliphatic monoamides having more than eight carbons and also for many alicyclic monoamides these are the only products obtained (13). In view of the complex nature of the mixture and the fact that no primary amine (II) was obtained, it was decided not to pursue this procedure and attempt to characterize the products. The innovation of the Hofmann reaction using methanol and bromine (13) gave a good yield of the methylcarbamate (VII), which could then be hydrolyzed under basic conditions to the amine (II).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The greatest overall yield of amine was obtained by the sequence (I) → (IV) → (V) → (VII) → (II), as shown in the accompanying chart.

EXPERIMENTAL

Melting points were determined on a Hershberg melting point apparatus and are uncorrected. Infrared spectra were carried out as liquid films, or Nujol mulls on a Perkin–Elmer Model 317 spectrophotometer.

Preparation of Dehydroabietane-1-amine

A. Schmidt Reaction Using Polyphosphoric Acid

To 30 g of polyphosphoric acid was added 3 g (0.01 mole) of dehydroabietic acid at room temperature and the mixture stirred vigorously. Then 0.8 g of sodium azide (0.012 mole) was added over a period of 1 hour so that no temperature rise was noticed. After the reaction mixture had been stirred for 3 hours, an ice-cold aqueous solution of KOH (50%) was added until the mixture was slightly basic. The solution was extracted with ether and the ether dried over anhyrous magnesium sulphate. After removal of the solvent, 0.51 g (18.8%) of the primary amine was left. Upon acidification of the aqueous layer 2.29 g (76.3%) of unreacted acid was obtained.

In every case where the primary amine was obtained, the following characterizations were performed.

The primary amine was a white glassy substance which resisted molecular distillation at temperatures up to 200° at pressures of 0.02–0.04 mm. Purification was effected by extraction of the glassy substance with 10% aqueous hydrochloric acid. An ether extract of the neutralized aqueous solution afforded the purified amine. Its infrared spectrum (neat) gave the following peaks: 2.90 μ (N—H asymmetric stretch), 2.99 μ (N—H symmetric stretch), and 6.20 μ (N—H deformation).

The amine gave a yellow picrate from a saturated ethanolic solution of picric acid. The melting point was 222–223°. Anal. Calc. for $C_{25}H_{32}N_4O_7$: C, 59.98; H, 6.44; N, 11.19. Found: C, 59.86; H, 6.30; N, 11.20.

The primary amine was converted to the tertiary amine by the usual reductive methylation technique (8). The melting point and infrared spectrum of this tertiary amine and its picrate agreed with those for the known authentic compounds (1, 8).

B. Schmidt Reaction Using Trifluoroacetic Acid and Trifluoroacetic Anhydride

To 30 ml of trifluoroacetic acid and 30 ml of trifluoroacetic anhydride at 0° was added 2 g of dehydroabietic acid (0.0066 mole). Then 0.65 g of sodium azide (0.01 mole) was added while the solution was vigorously stirred. After the solution had been stirred for 10 minutes, it was poured into water and the resulting mixture extracted with ether. Unreacted dehydroabietic acid was extracted from the ether with 5% sodium bicarbonate to give 1.2 g (63.6%). The neutral material, a viscous yellow oil (0.6 g or 27.3%), gave an infrared spectrum (neat) with a strong peak at 4.45 μ (N=C=O stretch). The isocyanate was then treated with absolute methanol to form the methyl carbamate. This latter compound is described under Section D below.

C. Hofmann Reaction Using Sodium Hydroxide and Bromine

The dehydroabietamide (2 g, 0.0066 mole) was dissolved in 25 ml of sodium hypochlorite prepared by mixing 7 g of sodium hydroxide, 50 ml of water, and 1 ml of bromine. This was warmed on a steam bath and after 25 minutes the solution was clear. The solution was heated on a steam bath for an additional 1½ hours, then poured into water, the water extracted with ether, and the ether extract dried. When the ether was evaporated, a viscous oil (1.85 g) was obtained. The infrared spectrum (neat) gave the following peaks: 2.86, 2.95, and 6.18 μ (unreacted amide), 4.42 μ (probably the nitrile), and a series of carbonyl vibrations at 5.80, 5.85, 5.98, and 6.04 μ (probably the alkyl acyl urea). No basic material could be obtained from this reaction.

D. Hofmann Reaction Using Sodium Methoxide and Bromine

To 20 ml of absolute methanol was added 0.5 g of amide (0.00167 mole), 0.18 g of sodium methoxide (0.0034 mole), and 0.27 g of bromine (0.00167 mole). The solution was refluxed for 2 hours. Then it was taken up in ether and washed thoroughly with water. The crude yield was 0.32 g (59.2%); however, if the refluxing was continued for a period of 10 hours or longer, a crude yield of 0.39 g (70.9%) was obtained. The methyl carbamate was recrystallized from either 95% ethanol or petroleum ether – absolute ether mixture. The infrared spectrum (Nujol mull) showed the following characteristic peaks: 2.94 μ (N—H stretch) and 5.82 μ ($\diagdown$C=O vibration). The methyl carbamate was obtained as a white crystalline solid which melted at 68–69°. Anal. Calc. for $C_{21}H_{31}NO_2$: N, 4.25. Found: N, 4.01.

The ethyl carbamate was prepared by refluxing with absolute ethanol. Its infrared spectrum was similar to that of the methyl carbamate. However, it melted considerably higher, at 216–217°. Anal. Calc. for $C_{22}H_{33}NO_2$: C, 76.92; H, 9.68. Found: C, 76.96; H, 9.48.

Hydrolysis of the Methyl Carbamate

To 2 ml of water, 6 ml of 95% ethanol, and 0.5 g of sodium hydroxide was added 0.5 g of the methyl carbamate (0.0015 mole). The solution was refluxed on a steam bath for 3–5 hours. A yield of 0.36 g (88.0%) of amine was found. This compound has been described in Section A of Experimental.

Preparation of Dehydroabietamide

To 3.18 g (0.01 mole) of the acid chloride (1) in 100 ml of absolute ether was added concentrated ammonium hydroxide in excess with vigorous stirring. The stirring was continued for 10–20 minutes, then the contents were poured into ice water and the amide filtered off. The yield was 2.8 g (96.2%). The amide was recrystallized from 95% ethanol to give a white crystalline solid which melted at 165–166°. The infrared spectrum (Nujol mull) gave peaks at 2.86 μ (asymmetric N—H stretch), 2.95 μ (symmetric N—H stretch), and 6.18 μ ($\diagdown$C=O vibration). Anal. Calc. for $C_{20}H_{29}NO$: C, 80.21; H, 9.76; N, 4.67. Found: C, 80.21; H, 9.82; N, 4.60.

KINETICS AND MECHANISMS OF THE PYROLYSIS OF *n*-BUTANE

PART I. THE UNINHIBITED DECOMPOSITION

N. H. SAGERT AND K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received October 31, 1962

ABSTRACT

The kinetics of the pyrolysis of *n*-butane have been studied at temperatures from 520° to 590° C, and at pressures from 30 to 600 mm Hg; the rate was followed from pressure changes and by gas chromatography. The reaction was accurately of the three-halves order; the activation energy was found to be 59.9 kcal mole^{-1}, and the frequency factor 3.24×10^{15} cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}. The reaction is sensitive to surface; packing the vessel and 'conditioning' it usually led to a decrease in rate and an increase in activation energy. The reaction is concluded to be largely homogeneous, and to occur almost entirely by a free-radical mechanism; the initiation reaction is considered to be the dissociation of a butane molecule into two ethyl radicals, in its first-order region, and termination is believed to be the second-order combination of ethyl radicals. The mechanism proposed is shown to account satisfactorily for the observed behavior. The surface effect is attributed to a certain amount of initiation by abstraction, by a surface atom, of a hydrogen atom from butane, and to surface catalysis of the recombination of ethyl radicals.

INTRODUCTION

Recent papers from this laboratory have dealt with the kinetics and mechanisms of the thermal decomposition of ethane (1) and propane (2). The *n*-butane decomposition presents an interesting contrast in that hydrogen atoms are no longer predominant as chain carriers; the free-radical mechanisms are therefore of a different character. A considerable amount of recent work has been done on the pyrolysis of *n*-butane, but certain features of the mechanism have still remained obscure; in particular may be mentioned the order of the initiating reaction, the nature of the main chain-ending step, and the role of the surface. A reinvestigation of the reaction was therefore considered to be worthwhile, and was carried out in conjunction with the study of the inhibited reaction described in the following paper (Part II).

The main features of the previous work on this reaction may be summarized as follows. Pease (3) and Pease and Durgan (4) established that the reaction is largely homogeneous and approximately of the first order; the overall reaction could be represented mainly by the equations

$$C_4H_{10} \rightarrow C_3H_6 + CH_4$$

$$C_4H_{10} \rightarrow C_2H_4 + C_2H_6.$$

Steacie and Puddington (5) found that the reaction products could initially be represented by the equation

$$C_4H_{10} = \tfrac{2}{3}CH_4 + \tfrac{2}{3}C_3H_6 + \tfrac{1}{3}C_2H_4 + \tfrac{1}{3}C_2H_6.$$

They reported the first-order rate constant as

$$k = 5.1\times10^{12}e^{-58{,}700/RT}\ \text{sec}^{-1}.$$

Echols and Pease (6) found that the order was closer to 3/2 than to unity.

The presence of free radicals in the reaction system was demonstrated by Rice, Johnston, and Evering (7), and Rice and Rice (8) proposed a free-radical mechanism which has been modified by Steacie (9), Semenov (10), and Benson (11). The latter proposed termination steps of the $\beta\beta$ type, leading to 3/2-order kinetics.

Purnell and Quinn have made a detailed investigation of the effect of surface on the pyrolysis of *n*-butane (12(*a*)), and in a recent paper* (12(*b*)) have described a study of the overall kinetics, in which they pay particular attention to the rate of production of the chief products. They concluded (12(*a*)) that 'conditioning' the surface, by carbon deposition, increases the rate of the heterogeneous removal of the radicals. Much of the work in their second paper (12(*b*)) was concerned with the breakdown of the ethyl radical, which they conclude to be in its pressure-dependent region. Kuppermann and Larson (13) have recently reported a first-order rate constant given by

$$k = 1.7\times10^{10}e^{-52,500/RT}\ \text{sec}^{-1}.$$

Their frequency factor and activation energy are significantly smaller than those of other investigations, including the present one. They found that packing the vessel and adding carbon dioxide had very little effect on the rate.

EXPERIMENTAL

The apparatus was essentially as described in previous papers (14, 1, 2). The reaction was carried out in vessels of approximately 200-ml capacity supported inside a large metal block the temperature of which was electrically controlled to within 0.2° C. Two quartz reaction vessels were used; one was unpacked and the other packed with quartz tubing to give a 11.6-fold increase in the surface:volume ratio. Except for runs carried out to investigate special surface effects, the results were obtained in vessels cleaned by three washings at 60° C with concentrated nitric acid, followed by rinsing with distilled water. A quartz spiral pressure gauge was used to follow pressure changes, the pressures being recorded on a Beckman photo-pen recorder; rates were determined by measuring the slopes of these records.

The *n*-butane used was research grade (99.9% pure), obtained from the Phillips Petroleum Company; it was further purified by one bulb-to-bulb distillation and was rigorously degassed.

Analyses were carried out on a Perkin–Elmer Vapor Fractometer. The C_1 to C_3 hydrocarbons and *n*-butane were analyzed using a 2-m silica gel column at 60° C; butenes were analyzed using a 3-m column containing 30% (w/w) 2,5-hexanedione on 30- to 60-mesh firebrick.

RESULTS

The pyrolysis of *n*-butane was studied in the temperature range from 520 to 590° C, and at pressures from 30 to 600 mm Hg. Figure 1 shows a typical pressure–time record.

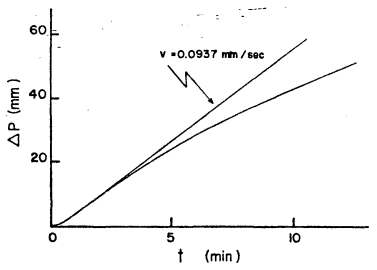

FIG. 1. A typical pressure–time curve. Temperature = 530° C, initial butane pressure = 386 mm, unpacked vessel.

There is seen to be a short induction period, and slopes were measured at the inflection point. Figure 2 shows double logarithmic plots of initial rate against pressure at various temperatures, in both packed and unpacked vessels. The order in the unpacked vessel is close to 3/2, while that in the packed vessel is slightly lower. Table I lists the 3/2-order rate constants obtained in the unpacked vessel, and Table II gives the rates at 200 mm

**This paper appeared while our paper was in course of publication.*

For personal use only.

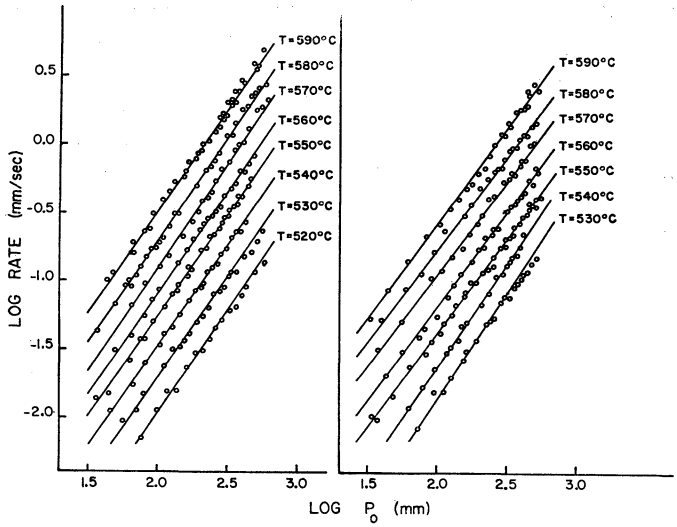

FIG. 2. Logarithmic plots of rate against pressure. The left-hand plots are for the unpacked vessel, the right-hand ones for the packed vessel.

TABLE I

Three-halves-order rate constants in the unpacked unconditioned vessel

Temperature (°C)	10^5k ($mm^{-1/2}$ sec^{-1})	Temperature (°C)	10^5k ($mm^{-1/2}$ sec^{-1})
520	1.09	560	7.92
530	1.94	570	13.0
540	3.29	580	20.4
550	5.50	590	32.5

TABLE II

Rates at 200 mm initial pressure in the packed vessel

Temperature (°C)	Rate$\times 10^2$ (mm sec^{-1})	Temperature (°C)	Rate$\times 10^2$ (mm sec^{-1})
530	4.34	570	28.1
540	7.24	580	43.7
550	11.0	590	70.5
560	16.8		

Hg in the packed vessel. Figure 3 shows a comparison of the rates in the packed and unpacked vessels at 550° C; there is seen to be a small but significant inhibition by surface, accompanied by a slight decrease in order of reaction.

Figure 4 shows an Arrhenius plot, on which the results of other workers (5, 6, 15) are included for comparison; where necessary the results were converted from first-order constants to 3/2-order ones. The activation energy is calculated to be 59.9 kcal $mole^{-1}$. Figure 5 shows that the addition of a $2\frac{1}{2}$-fold excess of carbon dioxide leads to no significant increase in the rate.

Figure 6 shows the effect of packing the reaction vessel and of conditioning it by pyrolyzing butane in it at 300 mm Hg for 48 hours. The reaction is quite sensitive to the state of the surface, and almost any change from a clean unpacked vessel tends to raise the activation energy; that in the packed vessel is 62.3 kcal $mole^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

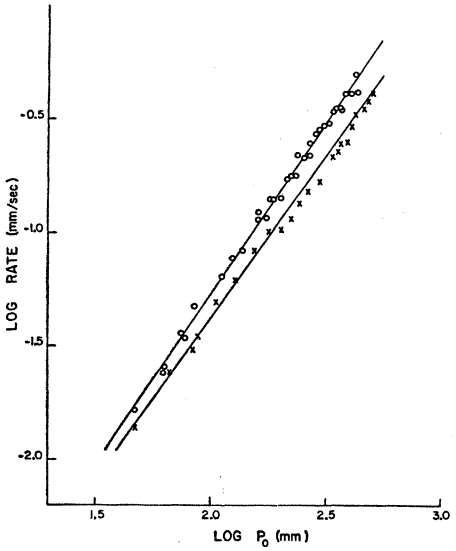

FIG. 3. Rates in the packed (×) and unpacked (○) vessel at 550° C, plotted logarithmically against the initial pressure of butane.

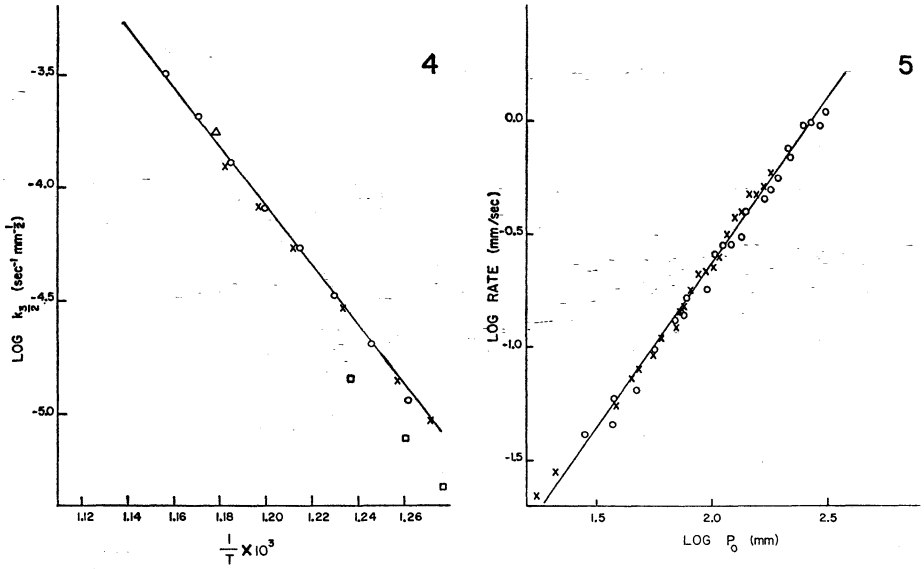

FIG. 4. Arrhenius plot for the unpacked vessel. The results of this investigation are shown as ○, those of Steacie and Puddington (5) as ×, those of Frey and Hepp (15) as △, and those of Echols and Pease (6) as □.

FIG. 5. Plot of the logarithm of the rate against the logarithm of the pressure at 580° C, showing the effect of added CO_2. ○ denotes no added CO_2, × denotes rate measured with $CO_2/C_4H_{10} \approx 2.5$.

Some of the analytical results are presented in Fig. 7. Figure 7(*a*) shows that unit decrease in butane pressure corresponds roughly to unit increase of the total pressure, while Fig. 7(*b*) represents the production of methane and ethane. Additional analytical data are shown in Table III; it gives some product ratios at three temperatures, all at 15% conversion and 200 mm Hg initial pressure.

On the basis of the present work the 3/2-order rate constant for the reaction is concluded to be

$$k_{3/2} = 3.24\times10^{15}e^{-59,900/RT}\ \text{cc}^{1/2}\ \text{mole}^{-1/2}\ \text{sec}^{-1}.$$

DISCUSSION

Overall Reaction Mechanism

The work of Purnell and Quinn (12(*a*)), and the results described in Part II, indicate that the molecular component of the reaction is of minor importance; this conclusion is supported by the fact that the order in a clean unpacked vessel is accurately three-halves. The following free-radical mechanism, which is very similar to that of Echols and Pease (6), is proposed to explain the facts:

$$C_4H_{10} \rightarrow 2C_2H_5 \quad [1]$$

$$C_2H_5 + C_4H_{10} \rightarrow C_2H_6 + C_4H_9 \quad [2]$$

$$C_4H_9 \rightarrow CH_3 + C_3H_6 \quad [3]$$

$$C_4H_9 \rightarrow C_2H_5 + C_2H_4 \quad [4]$$

$$CH_3 + C_4H_{10} \rightarrow CH_4 + C_4H_9 \quad [5]$$

$$C_2H_5 \rightarrow C_2H_4 + H \quad [6]$$

$$H + C_4H_{10} \rightarrow H_2 + C_4H_9 \quad [7]$$

$$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \text{ or } C_2H_6 + C_2H_4. \quad [8]$$

Table IV lists the known and estimated rate constants, activation energies, and frequency factors.

TABLE IV

Kinetic parameters for elementary reactions

Reaction	Frequency factor*	Activation energy (kcal mole^{-1})	Rate constant* at 570° C	Reference

The proposed mechanism gives rise to the following expressions for the steady-state radical concentrations:

$$[H] = \frac{k_6}{k_7}\left(\frac{2k_1}{k_8}\right)^{1/2}[C_4H_{10}]^{-1/2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$[C_2H_5] = \left(\frac{2k_1}{k_8}\right)^{1/2}[C_4H_{10}]^{1/2}$$

$$[C_4H_9] = \frac{k_2}{k_4}\left(\frac{2k_1}{k_8}\right)^{1/2}[C_4H_{10}]^{3/2} + \frac{k_6}{k_4}\left(\frac{2k_1}{k_8}\right)^{1/2}[C_4H_{10}]^{1/2}.$$

With the assumption of long chains, so that the removal of butane by reaction [1] is negligible, the overall rate is found to be

$$v = \left(\frac{k_3}{k_4} + 1\right)\left\{k_2\left(\frac{2k_1}{k_8}\right)^{1/2}[C_4H_{10}]^{3/2} + k_6\left(\frac{2k_1}{k_8}\right)^{1/2}[C_4H_{10}]^{1/2}\right\}.$$

The data from Table IV indicate that k_3 and k_4 are very close to each other, although k_3 is usually slightly higher.

Experimentally it is found that the reaction is strictly of the 3/2 order over the range of conditions employed, and this requires that the second term in the rate equation be negligible compared with the first. At first sight the mechanism proposed would not seem to lead to this conclusion; thus, insertion of the values of the rate constants from Table IV leads to the result that, at 570° C and 500 mm Hg,

$$\frac{\text{term 1}}{\text{term 2}} = \frac{k_2}{k_6}[C_4H_{10}] = 0.85,$$

so that the two terms appear to be comparable in magnitude. The reason for this apparent discrepancy is presumably that, as found by Purnell and Quinn (12(*b*)), the decomposition of the ethyl radical is not in its first-order region, but in the pressure-dependent region, the apparent order of the reaction being slightly greater than unity. In view of this the rate of decomposition of the ethyl radical is less than it would be if the reaction were of the first order. The predominance of the first term in the rate equation is therefore explained.

In the scheme as written above all butyl radicals are treated as the same. In fact *s*-butyl radicals are formed slightly more easily, as shown by Kuppermann and Larson (13) and by McNesby and Gordon (25). Kuppermann and Larson (13) estimate that for abstraction reactions such as [2] and [5] the ratio of secondary to primary hydrogen atom abstraction is

$$\frac{k_p}{k_s} = 2.43e^{-2640/RT}.$$

This ratio is about 0.5 at 570° C. About one-third of the C_4H_9 produced is thus *n*-C_4H_9, and two thirds is *s*-C_4H_9. The ratio (propylene+methane)/(ethylene+ethane) should therefore be about 2, in reasonable agreement with the experimental ratios of 1.8–1.9 (Table III). According to McNesby and Gordon (25) the ratio k_p/k_s is $1.50e^{-2100/RT}$, and this leads to a $(CH_4+C_3H_6)/(C_2H_4+C_2H_6)$ ratio of 2.4. The fact that our ratios are significantly less than this may be due to the fact that there is hydrogen-atom abstraction from propylene; the resulting radical may combine with a methyl or ethyl radical, giving butene-1 in the former case. This suggestion is related to the conclusion by Dintses and co-workers (27) that the butane decomposition is inhibited by products. Some isomerization of butyl radicals is possible, but Gordon and McNesby (26) detected none at somewhat lower temperatures (up to 450° C).

The mechanism proposed does not explain the small amounts of butenes formed in the reaction. The kinetic parameters for the decomposition of either *n*-butyl or *s*-butyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

radicals into butenes and hydrogen atoms have not been determined, but the activation energy is probably (21) well above 40 kcal mole^{-1}. On this basis, assuming normal frequency factors, the amounts of butenes should be less than 0.1% of the total products; actually they are 10 to 20 times this (Table III). Possibly the butenes arise from surface dehydrogenation or from a small molecular component of the reaction. It is to be noted that the butenes are about one-quarter butadiene, the formation of which is difficult to explain by any chain mechanism.

According to the rules of Goldfinger, Letort, and Niclause (28) (cf. Table 2 of ref. 2), in order to have 3/2-order overall kinetics one must postulate one of the following possibilities:*

(1) first-order initiation, $\beta\beta$ recombination;

(2) second-order initiation, $\beta\mu$ recombination;

(3) second-order initiation, $\beta\beta$M recombination.

The first is the one that is believed to apply. The second can be eliminated since it predicts a positive inert gas effect, which was not found, and also the $\beta\mu$ termination can be shown, by the insertion of kinetic parameters, to be considerably slower than the $\beta\beta$ recombination (by ~50 times at 500 mm Hg). This termination might become important at very low pressures, when the order should change to unity (assuming initiation to remain first order). The third possibility cannot be positively eliminated on the basis of the present work, since it predicts the same kind of behavior as the first; our reasons for preferring the first possibility are considered in the next section.

In connection with the lack of inert gas effect found for this system it is to be noted that a small inert gas effect was reported by Jach and Hinshelwood (29, 30), who used mainly sulphur hexafluoride. This substance was shown in an investigation of the propane decomposition (2) to be not inert, and results with it are therefore suspect.

The Initiation and Termination Reactions

The initiating reaction has been postulated to be the breakdown of *n*-butane into two ethyl radicals, in its high-pressure first-order region. Brinton and Steacie (31) have shown that at 250° C the recombination of ethyl radicals is certainly first-order at pressures of 0.5 mm and higher, and is probably first-order at pressures as low as 0.02 mm Hg. The Kassel–Rice–Ramsperger theories predict that the transition pressure should vary with the $(s - 1/2)$th power of the temperature, where s is the number of effective degrees of vibrational freedom. If s is taken as 12 in this case the initiating reaction should be first-order down to very low pressures; even if s were as large as 19 the reaction is probably still first-order at 100 mm Hg. It therefore seems most reasonable to consider that the initiation is in its first-order region under all of the experimental conditions employed in this work, and that the termination step [8] is in the second-order region. Support for this view is provided by the fact that for the ethane decomposition the evidence strongly supports the conclusion that the ethyl radical recombination is in its second-order region (1).

Another possible initiation reaction is the split into a methyl and a propyl radical. However, Trotman-Dickenson (16) has estimated that the dissociation energy for this process is some 4 kcal mole^{-1} higher than for the split into two ethyl radicals. The frequency factor may be slightly higher and may partly compensate for this; on the whole, however, it seems likely that the split into two ethyl radicals will predominate.

**A β radical is one which undergoes second-order propagation reactions, a μ radical one that undergoes first-order reactions. In the present scheme the ethyl radical is both a β and a μ radical (reactions [2] and [6]), but is predominantly a β radical since reaction [2] is more rapid than reaction [6].*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

If initiation is first order the termination step must be $\beta\beta$. The reactions

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [9]$$

and

$$CH_3 + C_2H_5 \rightarrow C_3H_8 \quad [10]$$

occur in their third-order regions (1, 2) under the conditions of these experiments; the termination must therefore be by reaction [8]. By inserting numerical values it can in fact be shown that this reaction should be the predominant one.

Surface Effects

The rates in the packed clean vessel are seen from Fig. 6 to be lower at all temperatures than those in the unpacked clean vessel. They are most depressed at lower temperatures, so that the activation energy is slightly higher in the packed vessel. It is suggested that free surface sites (S) on the quartz can abstract hydrogen atoms from the butane molecule, in a manner similar to nitric oxide. According to this view the reaction occurs in part as

$$C_4H_{10} + S \rightarrow SH + C_4H_9 \quad [1s]$$

$$C_4H_9 \rightarrow C_3H_6 + CH_3 \quad [3]$$

$$C_4H_9 \rightarrow C_2H_4 + C_2H_5 \quad [4]$$

$$C_2H_5 + C_4H_{10} \rightarrow C_2H_6 + C_4H_9 \quad [2]$$

$$CH_3 + C_4H_{10} \rightarrow CH_4 + C_4H_9 \quad [5]$$

$$SH \rightarrow S + H \quad [14s]$$

$$S + C_2H_5 \rightarrow S{-}C_2H_5 \quad [11s]$$

$$S{-}C_2H_5 \rightarrow S + C_2H_5 \quad [12s]$$

$$S{-}C_2H_5 + C_2H_5 \rightarrow C_4H_{10} + S. \quad [13s]$$

Application of the steady-state treatment leads to the following expression for the overall rate:

$$v \approx k_2 \left(\frac{k_3}{k_4}\right) \left(\frac{k_{1s}k_{12s}}{k_{11s}k_{13s}}\right)^{1/2} [C_4H_{10}]^{3/2}.$$

No reliable estimates of the individual rate constants can be made. The surface-controlled reaction should become more important as the temperature is lowered, and an increase in activation energy is to be expected.

The results in the 'conditioned' vessel are of some interest. The reaction in the conditioned unpacked vessel has a very high activation energy, and its rate at high temperatures is greater than that in the clean vessel. The effect of packing in the conditioned vessel is much more pronounced than in the clean vessel. These results confirm the conclusion that some of the initiation and termination is taking place at the vessel walls. The larger effect of packing indicates that the conditioned surface is a better inhibitor than initiator, compared with the clean surface. As graphite consists of a two-dimensional fused ring it is not surprising that atoms and small free radicals are able to recombine readily on the surface. The slight increase in rate over that in the clean vessel at the highest temperatures suggests that a small, purely heterogeneous decomposition may be taking place in addition.

Kinetic Parameters

If the reaction is assumed to be completely homogeneous the predicted activation energy is

$$E = E_3 - E_4 + E_2 + \tfrac{1}{2}(E_1 - E_8).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Insertion of the values in Table IV leads to 52.4 kcal mole^{-1}, to be compared with the experimental value of 59.9 kcal mole^{-1}. The calculated frequency factor is 2.5×10^{14} cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}, to be compared with the experimental value of 3.2×10^{15}. The calculated absolute rate is 6.5 cc$^{1/2}$ mole$^{-1/2}$ sec^{-1} at 570° C, to be compared with the experimental value of 0.97.

The agreement is not as good as with ethane (1) and propane (2); this is probably to be attributed to the greater importance of the heterogeneous reaction. This, as seen in the previous section, tends to raise the experimental activation energy.

KINETICS AND MECHANISMS OF THE PYROLYSIS OF *n*-BUTANE

PART II. THE REACTION INHIBITED BY NITRIC OXIDE

N. H. SAGERT AND K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received October 31, 1962

ABSTRACT

The kinetics of the pyrolysis of *n*-butane, when maximally inhibited by nitric oxide, were studied at temperatures from 540° to 610° C, and at pressures from 30 to 550 mm Hg. The reaction has a short induction period and is accurately of the three-halves order; the activation energy was 65.9 kcal mole^{-1} and the frequency factor 5.3×10^{16} cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}. The reaction was somewhat less inhibited by surface than was the uninhibited reaction. Excess of carbon dioxide had no effect on the rate. The results are explained in terms of a free-radical mechanism for the maximally inhibited decomposition. It is proposed that the initiation step in the inhibited decomposition is mainly $C_4H_{10} + NO \rightarrow C_4H_9 + HNO$. This is followed by the ordinary chain-propagating reactions, and by processes such as $C_2H_5 + NO \rightarrow C_2H_5NO$. The main chain-terminating step, of the type $\beta + \beta NO$, is concluded to be $C_2H_5 + C_2H_5NO \rightarrow C_4H_{10} + NO$ or $C_2H_6 + C_2H_4 + NO$. This scheme leads to three-halves-order kinetics, and provides a satisfactory quantitative interpretation of the experimental behavior.

INTRODUCTION

Previous work from this laboratory (1–4) has led to the conclusion that reactions that are maximally inhibited by nitric oxide are not occurring by molecular mechanisms, but take place by free-radical mechanisms. General schemes for maximal inhibition have been worked out (1, 4) and have been applied in detail to the experimental results for ethane (2), propane (3), and dimethyl ether (4). In the cases of ethane and propane hydrogen atoms are chain carriers, and it is found that the species HNO plays an important role in the inhibited decompositions. Butane presents an interesting contrast in that hydrogen atoms are not important chain carriers (cf. Part I). The present paper is concerned with the detailed eludication of the free-radical mechanism for the decomposition of *n*-butane in the presence of nitric oxide.

A good deal of previous work has been done on this problem, and the main features are as follows. Following Staveley's (5) discovery that organic decompositions can be inhibited by nitric oxide Echols and Pease (6) found this effect with *n*-butane. Rice and Polly (7) studied the inhibition by propylene and proposed a free-radical mechanism that was later modified by Goldanskii (8). These mechanisms were not, however, completely satisfactory in that they could not account for the limiting inhibition.

Evidence against the hypothesis that the maximally inhibited reaction is a molecular process was obtained by Steacie and Folkins (9), who found that small amounts of ethylene oxide could sensitize the maximally inhibited reaction; at 450° C they obtained a chain length of four in the presence of nitric oxide. They also found (10) that the products of the inhibited reaction were identical with those of the uninhibited reaction; they concluded from this, in agreement with the present point of view, that the inhibited and uninhibited reactions occurred by similar mechanisms.

The maximally inhibited decomposition of *n*-butane was studied by Stubbs, Ingold, and Hinshelwood (11–14), who concluded that the reaction was of the first order; this result is in disagreement with the present work, which indicates the order to be three-halves. They found that the activation energy varied with pressure. Jach and Hinshelwood (15, 16) reported that added inert gas caused some increase in the rate, and reported that

the absolute increase was the same for the maximally inhibited reaction as for the uninhibited reaction; this fact was taken to be evidence for the molecular nature of the inhibited reaction. These results are, however, suspect, since the chief inert gas used was sulphur hexafluoride: this gas has been shown (3) to be not truly inert. It was seen in Part I that carbon dioxide has no effect on the rate of the uninhibited decomposition of butane.

Purnell and Quinn (17) have recently studied the kinetics of the propylene-inhibited decomposition of *n*-butane. They found that as the pressure was lowered there was an increase in the production of ethylene relative to ethane, and attributed this to competition between decomposition of and abstraction by the ethyl radical:

$$C_2H_5 \rightarrow C_2H_4 + H$$
$$C_2H_5 + C_4H_{10} \rightarrow C_2H_6 + C_4H_9.$$

The decomposition is favored by lower pressures and higher temperatures. Their work clearly provides some evidence that the fully inhibited reaction proceeds by a free-radical mechanism.

The fact that the maximally inhibited decomposition is not a molecular process was established by Kuppermann and Larson (18, 19) using deuterium-mixing techniques. They pyrolyzed a mixture of C_4H_{10} and C_4D_{10} and found that the ratio of CD_3H to CD_4 in the products was independent of the amount of nitric oxide. They found that whereas the ethanes and methanes are mixed, ethylenes and propylenes are essentially unmixed. This result is consistent with the view that ethylene and propylene are formed by the unimolecular decomposition of larger radicals.

EXPERIMENTAL

The work was carried out in the same apparatus, and in the same way, as that described in Part I. The *n*-butane was prepared and purified as in Part I. The nitric oxide was Matheson C.P. grade purified by passing the vapor over silica gel (to remove higher oxides) and pumping to remove nitrogen; this procedure was followed by two distillations.

RESULTS

The work was carried out in the temperature range from 540 to 610° C and at butane pressures from 30 to 550 mm Hg. A typical pressure–time record for an inhibited reaction is shown in Fig. 1. The induction period is slightly more pronounced than in the uninhibited reaction; it was lengthened by lowering the butane pressure but was not much affected by changes in the partial pressure of nitric oxide.

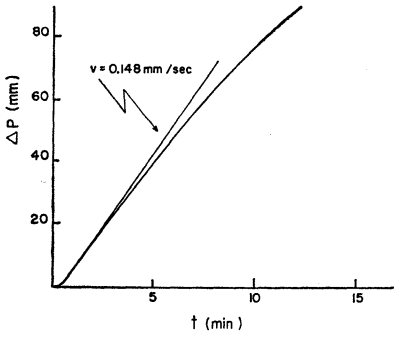

FIG. 1. A typical pressure–time curve, obtained at 570° C, with an initial butane pressure of 225 mm Hg and a nitric oxide pressure of 32 mm Hg, in an unpacked vessel.

About 12% nitric oxide gave maximal inhibition, and large amounts (over 40%) produced a slight increase in rate compared with the maximally inhibited rate. Most of the experiments were carried out with about 15% nitric oxide.

Double logarithmic plots of rate against pressure of *n*-butane are shown for the maximally inhibited reaction in Fig. 2. The reaction is seen to be accurately of the three-halves

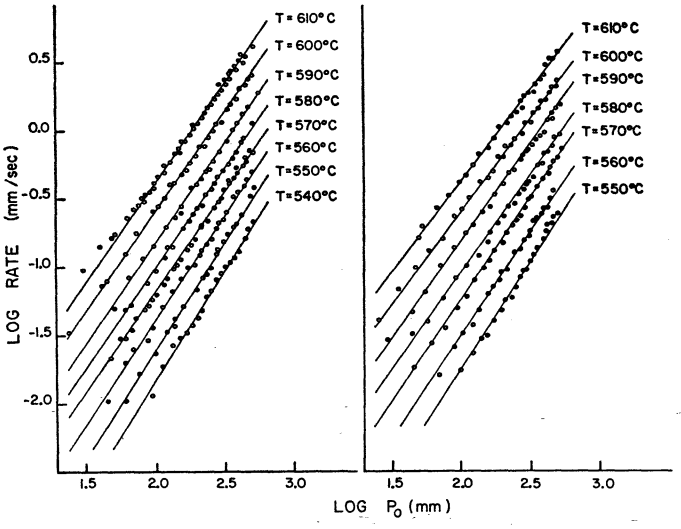

FIG. 2. Logarithmic plots of rate against pressure. The plot on the left-hand side is for the unpacked vessel, that on the right-hand side for the packed vessel.

order. Table I lists the three-halves-order rate constants obtained in the unpacked and packed vessels.

TABLE I

Three-halves-order rate constants for the inhibited decomposition of *n*-butane

Temperature (°C)	Rate constant $\times 10^5$ ($mm^{-1/2}$ sec^{-1}) Unpacked vessel	Packed vessel	Temperature (°C)	Rate constant $\times 10^5$ ($mm^{-1/2}$ sec^{-1}) Unpacked vessel	Packed vessel
540	1.46	—	580	9.55	8.32
550	2.24	1.79	590	14.38	13.17
560	3.68	3.08	600	24.45	22.4
570	6.32	5.48	610	37.6	35.6

Figure 3 shows a typical comparison of the maximally inhibited and uninhibited rates at 570° C. The orders are seen to be the same (3/2); the ratio of rates is therefore independent of pressure, in contrast to the conclusion of Stubbs and Hinshelwood (12). An Arrhenius plot is shown in Fig. 4, which includes rates obtained by other workers (10, 13). The three-halves-order rate constant for the maximally inhibited reaction may be written as

$$k_{3/2} = 4.6 \times 10^{12} e^{-65{,}100/RT} \text{ mm}^{-1/2} \text{ sec}^{-1}.$$

Figure 5 shows that there is no significant effect of adding an excess of carbon dioxide.

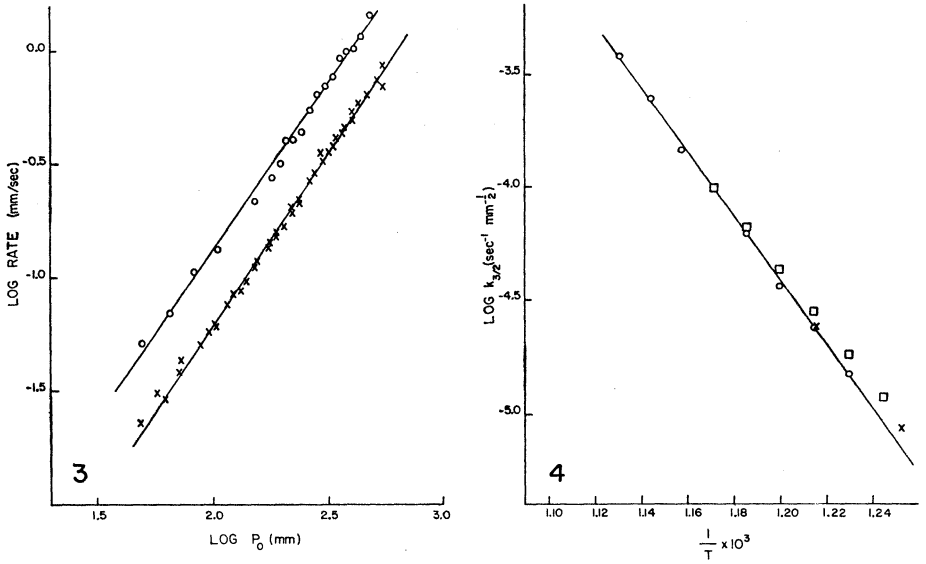

FIG. 3. Plots of the logarithm of the rate against the logarithm of the pressure for the uninhibited (×) and inhibited (○) reaction at 570° C.

FIG. 4. Arrhenius plot for the clean, unpacked vessel. The results of this investigation are shown as ○, those of Steacie and Folkins (10) as ×, and those in Ingold, Stubbs, and Hinshelwood (13) as □.

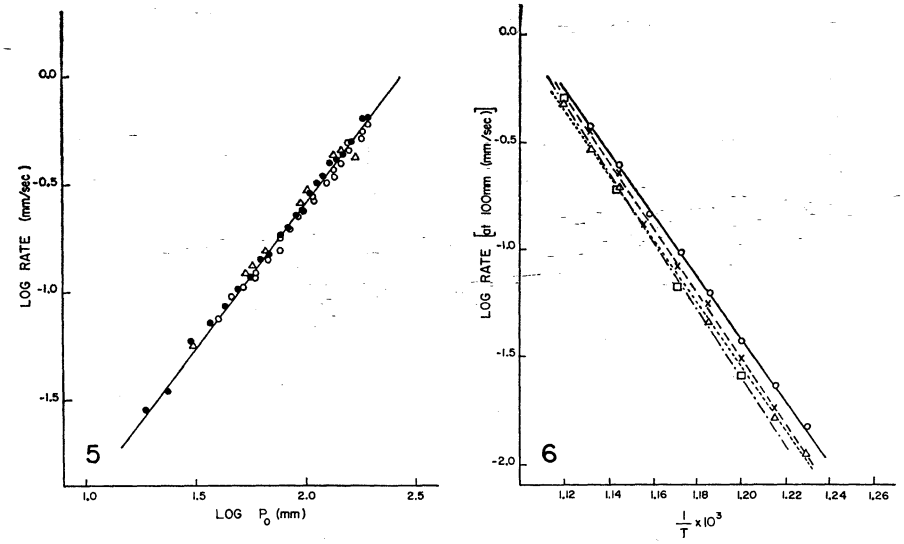

FIG. 5. Plots of the logarithm of the rate against the logarithm of the pressure, showing the effect of added carbon dioxide. ○ denotes results with no added CO_2, △ denotes rates with $CO_2/C_4H_{10} \approx 3$, and ● denotes rates with $CO_2/C_4H_{10} \approx 2.1$.

FIG. 6. Arrhenius plots showing the effect of surface. Rates measured in a clean unpacked vessel are given as ○, those in the clean packed vessel as ×, those in the conditioned unpacked vessel as △, and those in the conditioned packed vessel as □.

Figure 6 shows the effects of various surface conditions. Some of the reactions were done in a 'clean' vessel; this was washed three times with concentrated nitric acid, and then with water, before each run (a similar procedure was employed in Part I and by Purnell and Quinn (20)). The 'conditioned' vessel was prepared by pyrolyzing 300 mm Hg

of *n*-butane for 48 hours before carrying out a series of reactions. The packed vessel had a surface:volume ratio 11.6 times that of the unpacked vessel. The rates in the conditioned vessel and in the packed vessel are close to those in the unpacked vessel; they are somewhat lower at the lower temperatures, so that the activation energy is higher. The effect of surface is much smaller for the inhibited reaction than for the uninhibited.

Figure 7 summarizes the analytical results. Figure 7(*a*) relates the pressure increase

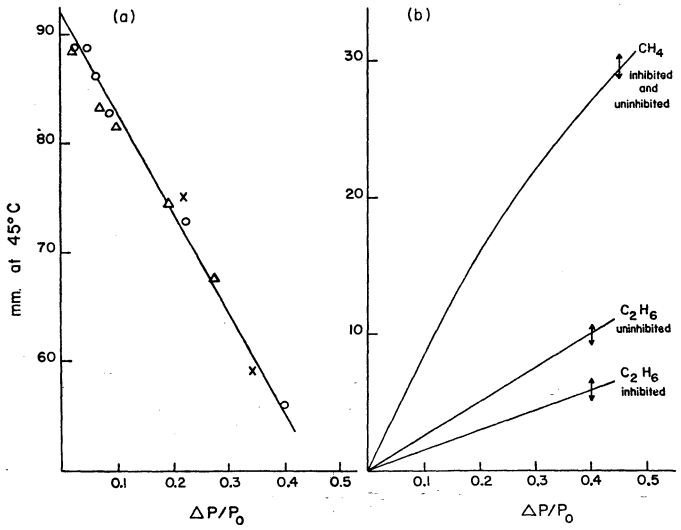

FIG. 7. Analytical results showing the partial pressure of butane (left-hand side) and of methane and ethane (right-hand side) plotted against the extent of reaction for 570° C (○), 590° C (×), and 610° C (△).

to the amount of *n*-butane used up; there is seen to be a close correspondence. Figure 7(*b*) shows the production of methane and ethane, and compares the behavior in the inhibited and uninhibited reactions. The relative rate of production of methane is seen to be unaffected by the presence of nitric oxide, whereas with nitric oxide present relatively smaller amounts of ethane are formed. Table II lists the C_2H_6/C_2H_4 ratios, as well as other

TABLE II

Ratios of reaction products

610	0.366	0.905	0.014	1.66

product ratios, at three temperatures. It is to be noted that, comparing the C_2H_6/C_2H_4 ratio at 570° C with that obtained in Part I for the uninhibited reaction, about 25% extra ethylene is produced.

On the basis of the kinetic and analytical results it is concluded that the 3/2-order rate constant for the disappearance of *n*-butane is given by

$$k_{3/2} = 5.3\times10^{16}e^{-65,900/RT} \text{ cc}^{1/2} \text{ mole}^{-1/2} \text{ sec}^{-1}.$$

DISCUSSION

The Overall Reaction Mechanism

In line with previous suggestions (1–4) it is proposed that in the maximally inhibited reaction the main initiating step is

$$C_4H_{10} + NO \rightarrow C_4H_9 + HNO. \qquad [1i]$$

The usual chain-propagating steps then occur. The species HNO will dissociate into H+NO, and other equilibria involving NO will be set up, in particular

$$C_2H_5 + NO \rightleftarrows C_2H_5NO.$$

In order for the overall kinetics to be three-halves order termination must be by steps such as

$$C_2H_5 + HNO \rightarrow C_2H_6 + NO$$
$$C_2H_5 + CH_3NO \rightarrow C_3H_8 + NO,$$

that is by processes of the type $\beta + \beta NO$. (It should be noted that, as discussed in Part I, C_2H_5 is a β radical under the conditions of these experiments.) The mechanism to which these considerations lead is

$$C_4H_{10} + NO \rightarrow C_4H_9 + HNO \qquad [1i]$$
$$C_4H_9 \rightarrow C_3H_6 + CH_3 \qquad [3]$$
$$C_4H_9 \rightarrow C_2H_4 + C_2H_5 \qquad [4]$$
$$C_2H_5 + C_4H_{10} \rightarrow C_2H_6 + C_4H_9 \qquad [2]$$
$$CH_3 + C_4H_{10} \rightarrow CH_4 + C_4H_9 \qquad [5]$$
$$C_2H_5 \rightarrow C_2H_4 + H \qquad [6]$$
$$C_2H_5 + NO \rightarrow C_2H_5NO \qquad [11]$$
$$C_2H_5NO \rightarrow C_2H_5 + NO \qquad [12]$$
$$C_2H_5NO + C_2H_5 \rightarrow C_4H_{10} + NO \text{ or } C_2H_6 + C_2H_4 + NO \qquad [13]$$
$$H + C_4H_{10} \rightarrow C_4H_9 + H_2 \qquad [7]$$
$$X + HNO \rightarrow H + NO + X \qquad [14]$$
$$C_2H_5NO \rightarrow CH_3CH_2NOH \rightarrow \text{products.} \qquad [15]$$

Values for the rate constants, activation energies, and frequency factors for these reactions are listed in Table III.

The above scheme leads to the following expressions for the radical concentrations, some small terms having been dropped:

$$[C_2H_5] = \left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{1/2}$$

$$[H] = \frac{k_{11}}{k_7}[NO] + \frac{k_6}{k_7}\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{-1/2}$$

$$[CH_3] = \frac{2k_{11}k_3}{k_4k_5}[NO] + \frac{k_3k_6}{k_4k_5}\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{-1/2} + \frac{k_2k_3}{k_4k_5}\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{1/2}$$

$$[C_4H_9] = \frac{2k_{11}}{k_4}[C_4H_{10}][NO] + \frac{k_2}{k_4}\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{3/2} + \frac{k_6}{k_4}\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{1/2}$$

$$[HNO] = \frac{k_{11}}{k_{14}}[NO]$$

$$[C_2H_5NO] = \left(\frac{k_{11}k_{11}}{k_{12}k_{13}}\right)^{1/2}[C_4H_{10}]^{1/2}[NO].$$

TABLE III

Kinetic parameters for elementary reactions

*In the units sec^{-1} or cc mole^{-1} sec^{-1}.

The overall rate of disappearance of butane is then found to be, with small terms being neglected as in Part I,

$$v = \frac{k_2k_3}{k_4}\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{3/2}.$$

The mechanism thus predicts three-halves order, in agreement with experiment.

Rates of Production of Methane, Ethane, and Ethylene

The above expression is for the rate of disappearance of butane. The rate of appearance of ethylene is

$$\begin{aligned} v_{C_2H_4} &= k_4[C_4H_9] + k_6[C_2H_5] \\ &= 2k_{11}[C_4H_{10}][NO] + k_2\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{3/2} \\ &\quad + 2k_6\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{1/2}. \end{aligned}$$

The rate of production of ethane is

$$v_{C_2H_6} = k_2\left(\frac{k_{11}k_{12}}{k_{11}k_{13}}\right)^{1/2}[C_4H_{10}]^{3/2}.$$

More ethylene than ethane is produced, largely because of reaction [6]. In addition, when enough nitric oxide is added to make reaction [1i] important a small amount of additional ethylene will be produced. The mechanism thus predicts that as nitric oxide is added the rate of production of ethylene should increase relative to that of ethane, and this is found experimentally. The mechanism also gives a quantitative interpretation of this effect; at 570° C, 500 mm Hg of butane, and 75 mm Hg of nitric oxide, introduction of the rate constants leads to the result that 18% additional ethylene should be produced; this compares satisfactorily with the experimental result that 20–25% extra ethylene is formed under these conditions.

In a similar way it can be shown that the mechanism predicts that the rates of formation of methane and of propylene should be equally increased by large amounts of nitric oxide, in agreement with experiment.

The Initiation and Termination Steps

An estimated activation energy and frequency factor for the initiation reaction [1i] are given in Table III. The activation energy is based on a value of 48.0 kcal for the HNO dissociation energy (1, 2, 3, 28), and on 96.0 for the C—H dissociation energy. Using the parameters for reactions [1] (for the uninhibited reaction) and [1i] the latter reaction is found to be significant at maximal inhibition.

In order to obtain 3/2-order kinetics the termination reaction must be of the type $\beta + \beta\text{NO}$; the β radical in this case may be H, CH_3, or C_2H_5. By using the kinetic parameters in Table III it is readily shown that reaction [13] and the analogous reaction

$$CH_3 + CH_3NO \rightarrow C_2H_6 + NO \qquad [16]$$

are much more important than any other terminating reaction. The situation is to be contrasted with that with propane (3); there hydrogen atoms are chain carriers and therefore are present in much larger amounts; HNO thus plays a role in termination in the propane decomposition, but not in the butane decomposition. Termination by reaction [16] would mean that more propylene should be produced relative to methane when nitric oxide is added, while the ratio C_2H_6/C_2H_4 should remain constant. Since in fact the amount of C_2H_4 increases relative to C_2H_6, while the CH_4/C_3H_6 ratio remains constant on adding nitric oxide, termination by reaction [13] would seem to be more important.

The rate of reaction [13] can be shown to be much more important than that of the termination step $C_2H_5+C_2H_5$ in the uninhibited reaction. Thus

$$\frac{v_{13}}{v_8} = \frac{k_{13}[C_2H_5][C_2H_5NO]}{k_8[C_2H_5][C_2H_5]}$$

$$= \frac{k_{13}k_{11}}{k_8k_{12}}[NO].$$

At 570° C and 75 mm pressure of nitric oxide this ratio $\approx$ 50. The termination by reaction [13] is therefore dominant at all pressures used.

Effect of Inert Gas

Reactions [3], [4], [6], [11], [12], and [14] are influenced by the presence of an inert gas. Reactions [11] and [12], however, form a reversible equilibrium, and all of the expressions for free-radical concentrations and for rates involve the ratio k_{11}/k_{12}, which is not affected by inert gas. The rate constant for reaction [14] does not appear in the important terms in the rate expressions, and in any case this reaction probably remains in its second-

order region under all of the experimental conditions employed. Reactions [3], [4], and [6] are probably first-order under all ordinary conditions.

Kinetic Parameters

The activation energy predicted on the basis of the proposed mechanism is

$$E = E_2+E_3-E_4+\tfrac{1}{2}(E_{11}+E_{12}-E_{11}-E_{13}).$$

Introduction of the values in Table III gives 66.9 kcal mole^{-1}, in good agreement with the experimental value of 65.9 kcal mole^{-1}. The activation energy calculated from inflection point rates extrapolated to initial conditions is 66.9 kcal mole^{-1}.

The predicted frequency factor is

$$A = \frac{A_2A_3}{A_4}\left(\frac{A_{11}A_{12}}{A_{11}A_{13}}\right)^{1/2} = 1.53\times10^{16}\ \text{cc}^{1/2}\,\text{mole}^{-1/2}\,\text{sec}^{-1},$$

in good agreement with the experimental value of 5.30×10^{16} cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}. The calculated overall rate constant at 570° C is 7.02×10^{-2} cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}, as compared with the experimental value of 0.44 cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}.

Surface Effects

The fact that there is some inhibition by surface, and that the effect is less in the reaction maximally inhibited by nitric oxide than in the uninhibited reaction, is consistent with the mechanism proposed. The surface sites permit a new type of initiation, and of termination, to occur, as discussed in Part I.

THE CONFIGURATION OF DEOXYSTREPTAMINE[1]

R. U. LEMIEUX AND R. J. CUSHLEY
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received October 29, 1962

ABSTRACT

The nuclear magnetic resonance (n.m.r.) spectrum of 5-*O*-methyl-1,3-di-*N*-methyl-4,6-di-*O*-acetyldeoxystreptamine dihydrogenperchlorate requires the all-trans configuration since the signal for the equivalent ring hydrogens at the 4- and 6-positions is in the form of a triplet with a spacing of 10 c.p.s. This spacing requires these hydrogens to be axial and coupled with axial hydrogens at the neighboring 1-, 3-, and 5-positions.

For personal use only.

Streptamine is obtained by hydrolysis of the antibiotic streptomycin (1) and evidence has been obtained (2, 3) that the compound is 1,3-dideoxy-1,3-diaminoscylloinositol. The substance known as deoxystreptamine, first isolated from the antibiotics neomycin A (neamine), B, and C (4), was found to be a meso form of 1,3-diamino-4,5,6-trihydroxycyclohexane (4) and its name was assigned on the basis of the assumption that it was configurationally related to streptamine. Although circumstantial evidence has accumulated (5) which rendered the correctness of this assumption highly probable, the evidence cannot be considered definitive. Deoxystreptamine is also a building unit of the kanamycins A (6) and B (7) and paromomycin (8). This widespread occurrence renders a knowledge of its configuration of particular interest and especially since Hoeksema, Argoudelis, and Wiley (9) have recently isolated the 1,3-di-*N*-methyl derivative of the 2-epimer (10) of streptamine from the antibiotic actinospectacin. The compound was termed "actinamine." It could be anticipated that a direct proof of the configuration of deoxystreptamine may be available by application of n.m.r. spectroscopy along the lines described by Lemieux, Moir, and Kullnig (11). Advantage is taken of the fact that neighboring hydrogens in axial orientation are coupled to the extent of 8 or more c.p.s. and this coupling is three to four times stronger than when the hydrogens are in gauche relationship (12).

The n.m.r. spectrum of deoxystreptamine in deuterium oxide is shown in Fig. 1. The structures of the signals for the hydrogens of the methylene group require the two amino groups to be equatorially oriented. This is evident from the 12- and 13-c.p.s. spacings found in the signal for the axial hydrogen at 1.28 p.p.m. and demonstrated through the first-order analysis shown in Fig. 1. However, the spectrum provides no simply derivable information about the configurations at the other centers because of the small chemical shift between the signals for the 4-, 5-, and 6-hydrogens in the region 3.0 p.p.m. Slomp and MacKellar (10) found the equivalent axial 4- and 6-hydrogens of actinamine to produce their signal about 0.7 p.p.m. to lower field than that for the axial 5-hydrogen at 3.46. This situation is mainly due to the deshielding effect on the 4- and 6-hydrogens by the axial and opposing hydroxyl group at the 2-position (13).

The signals for the 4-, 5-, and 6-hydrogens were also bunched together in the n.m.r. spectrum for the diperchlorate salt of tri-*O*-acetyldeoxystreptamine. However, the signals for the 1- and 3-hydrogens were well separated from those at the 4-, 5-, and 6-positions. Consequently, it was evident that a solution of the configuration of deoxystreptamine through first-order analysis of the spectrum could be obtained (14) if the acetyl group

[1]*Presented at the 45th National Conference of the Chemical Institute of Canada, Edmonton, Alberta, May 28–30, 1962.*

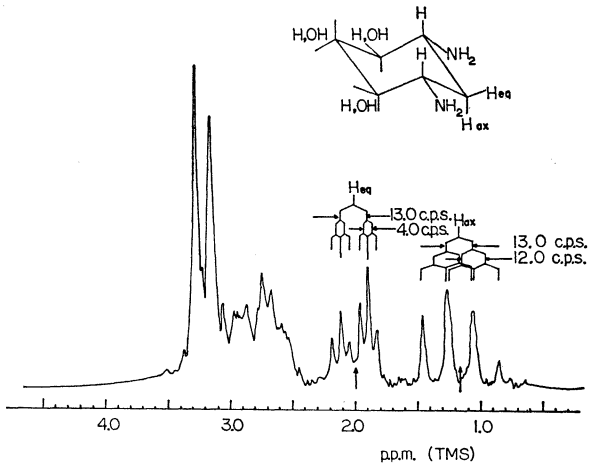

FIG. 1. The proton magnetic resonance spectrum of deoxystreptamine in deuterium oxide.

at the 5-position could be substituted in such a way as to achieve a substantial chemical shift between the signal for the 5-hydrogen and that for the neighboring 4- and 6-hydrogens. The antibiotic kanamycin A provided a convenient starting point for the preparation of such a derivative of deoxystreptamine.

Umezawa and co-workers (15) have reported the methylation of the tetra-*N*-acetyl derivative of kanamycin. Acid hydrolysis of the permethylated compound provided a substance, m.p. 207–209°, reported to be 5-*O*-methyldeoxystreptamine dihydrochloride. It has now been observed that methylation with methyl iodide and silver oxide in dimethylformamide (16) (instead of dimethyl sulphate in aqueous sodium hydroxide (15)) and acid hydrolysis produced a mono-*O*-methyl-di-*N*,*N*′-methyl derivative of deoxystreptamine dihydrochloride with a melting point, 207–210.5°, very close to that reported by Umezawa and his co-workers (15). It seems possible that the two compounds are identical.

The derivative of deoxystreptamine was converted to the dihydrogenperchlorate salt for *O*-acetylation (17). Although the product failed to crystallize, the n.m.r. spectrum (Fig. 2) and microanalyses require the substance to be virtually pure 5-*O*-methyl-1,3-di-*N*-methyl-4,6-di-*O*-acetyldeoxystreptamine dihydrogenperchlorate. It is seen that, as expected for this structure, sharp signals are present with the chemical shifts and intensities for two *O*-acetyl groups, two *N*-methyl groups, and one *O*-methyl group. The triplet of intensity two at 5.30 p.p.m. is in the region expected for the signal from hydrogens bonded to secondary carbons attached to acetoxy groups and must arise from the 4- and 6-hydrogens. The spacing of 10 c.p.s. requires these hydrogens to be axial and coupled with two neighboring axial hydrogens. Therefore, the spectrum comprises direct evidence for the all-trans configuration for deoxystreptamine and confirms the previous evidence for the points of attachment of the aminosugars to deoxystreptamine in kanamycin A (15, 18).

EXPERIMENTAL

Tetra-N-acetyl Kanamycin A

A solution of 100 g of kanamycin A* in 150 ml of water and 450 ml of methanol was cooled to 0–5°, and 100 ml of acetic anhydride was added dropwise. The temperature rose to 50°. After standing at room temperature for 1 hour, acetone (4 liters) was added with stirring. After 1 hour, the precipitate was collected by filtration and washed with acetone. The solid was dried *in vacuo* for 2 days. The crude material was

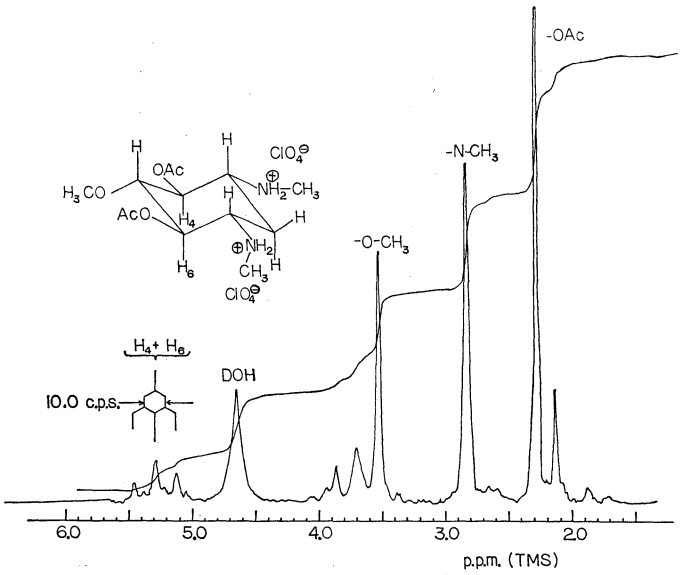

FIG. 2. The proton magnetic resonance spectrum of 4,6-di-*O*-acetyl-5-*O*-methyl-1,3-di-*N*-methyldeoxystreptamine dihydrogenperchlorate in deuterium oxide.

recrystallized from a minimum amount of water to which equal volumes of methanol and ethanol were added until crystals began to appear. The product was powdered and dried for 6 hours in a vacuum oven at 80°. The yield was 112.5 g of a product which melted at 265–266° (literature (6) m.p. 250–255° (with decomposition)), gave a negative test with ninhydrin, showed absorption at 1640 cm^{-1} characteristic of the *N*-acetyl group, and had $[\alpha]_D$ +88.3° (*c*, 5 in water). Calculated for $C_{26}H_{44}N_4O_{15}$: CH_3CO, 26.35%. Found: CH_3CO, 24.15%.

Methylation of Tetra-N-acetyl Kanamycin A

A suspension of 25.8 g of tetra-*N*-acetyl kanamycin A (39.5 mmoles) in dimethylformamide (800 ml) and methyl iodide (142 ml) was reacted with 280 g of freshly prepared silver oxide. The silver oxide was added to the rapidly stirred mixture in four 70-g portions at intervals of 20 minutes. After stirring at room temperature for 12 hours, a further 70 g of silver oxide and 50 ml of methyl iodide were added. Stirring was continued for a total of 48 hours. The silver salts were collected by filtration and washed with dimethylformamide (2×100 ml). The combined filtrate and washings were evaporated. The salts were extracted with several portions of methanol and evaporated to dryness. The amber oil was dissolved in chloroform and the solution was washed once with water. The chloroform was removed and several small portions of benzene were distilled from the residue to leave an orange amorphous solid (13.0 g, 41%); m.p. 123–125°; $[\alpha]_D$ +94.5 (*c*, 4 in chloroform). The infrared absorption indicated that the substance was free of hydroxyl groups. The product, formed on hydrolysis in refluxing 4 *N* hydrochloric acid for 20 minutes, when chromatographed on paper using 1-butanol – pyridine – acetic acid – water (6:4:3:1) showed three ninhydrin-positive (19) spots, R_f = 0.16 (brown), 0.34 (orange), 0.55 (violet), and no trace of deoxystreptamine, R_f = 0.05.

5-O-Methyl-1,3-di-N-methyldeoxystreptamine Dihydrochloride

Fully methylated kanamycin A tetra-*N*-acetate (4.80 g) was dissolved in 4 *N* hydrochloric acid (150 ml) and the solution refluxed for 1.5 hours. The solution was evaporated *in vacuo* at 50°. The solid residue was dissolved in water (20 ml) and decolorized with charcoal (0.6 g). Evaporation left 4.02 g of a solid which was dissolved in methanol (6 ml), and ether (29 ml) was then added to precipitate the 5-*O*-methyl-1,3-di-*N*-methyldeoxystreptamine dihydrochloride (2.26 g). A further similar treatment yielded 1.0 g of material which was dissolved in the developing phase (8 ml) for chromatograghy on a column of cellulose (18 cm×1.5 cm) using 1-butanol – ethanol – water (4:1:5). Three-milliliter fractions were collected and fractions 11 to 13 contained 560 mg of 5-*O*-methyl-1,3-di-*N*-methyldeoxystreptamine dihydrochloride, which was recrystallized by solution in a minimum amount of methanol and the addition of ethanol to turbidity. The yield was 510 mg of a crystalline substance; m.p. 207–210.5°. Chromatography on paper using the above solvent system showed only one spot (R_f = 0.16) using either ninhydrin (19) or periodate–permanganate (20) spray reagents. Calculated for $C_9H_{22}Cl_2N_2O_3 \cdot H_2O$: C, 36.95; H, 8.19; N, 9.49; *O*-CH_3, 10.51%. Found: C, 36.71, 37.01; H, 7.80, 8.03; N, 9.80; *O*-CH_3, 13.16%.

4,6-Di-O-acetyl-5-O-methyl-1,3-di-N-methyldeoxystreptamine Dihydrogenperchlorate

5-*O*-Methyl-1,3-di-*N*-methyldeoxystreptamine dihydrochloride (104.0 mg, 0.375 mmole) was added to 0.194 ml of 3.87 *M* perchloric acid (0.75 mmole) in acetic acid. The mixture was cooled to 0–5° and acetic anhydride (0.4 ml) was added dropwise. Solution was completed after 1 hour. After 4 hours, the reaction was complete, as indicated by a constant n.m.r. spectrum. The solution was freeze-dried to remove excess acetic anhydride and acetic acid. The residue was dissolved in water and the solution freeze-dried to leave a white amorphous solid. The substance was triturated with boiling chloroform and, after drying, dissolved in water and freeze-dried. Calculated for $C_{13}H_{26}Cl_2N_2O_{13}\cdot 2H_2O$: C, 29.74; H, 5.75; N, 5.33; *O*-CH_3, 5.90; *N*-CH_3, 5.72; CH_3CO, 16.36%. Found: C, 29.14, 29.36; H, 5.27, 5.33; N, 5.51; *O*-CH_3, 6.25; *N*-CH_3, 4.65; CH_3CO, 14.00, 15.76%.

After freeze-drying twice from deuterium oxide (2×1 ml), the material (145 mg, 88%) gave the n.m.r. spectrum shown in Fig. 2. The ratio of the intensity of the signal of the *N*-methyl groups to that of the *O*-acetyl groups was only 0.9 to 1. A further indication that the compound was not pure was the presence of the low-intensity triplet to slightly higher field in the region 5.30 p.p.m. for the 4- and 6-hydrogens.

When a paper chromatogram, using the above-mentioned conditions, was run for 60 hours, two components were separated. It seems most probable that the substance was about a 9:1 mixture of the di-*N,N'*-methyl and mono-*N*-methyl derivatives of 4,6-di-*O*-acetyl-5-*O*-methyldeoxystreptamine dihydrogenperchlorate.

Deoxystreptamine

Kanamycin A (25 g) in 4 *N* hydrochloric acid (250 ml) was refluxed for 20 minutes. The cooled solution was diluted with water (200 ml) and treated with decolorizing charcoal (40 g). The filtered solution was concentrated *in vacuo* to 50 ml and methanol (50 ml) was added. When crystals began to appear, 400 ml of ethanol was added with stirring. After 24 hours at room temperature, the crude deoxystreptamine dihydrochloride (14.4 g) was collected and dissolved in a minimum amount of boiling methanol. Ethanol was added to turbidity. The precipitate was examined by paper chromatography and found to contain traces of 6-deoxy-6-amino-D-glucose hydrochloride. The precipitate was therefore added to a Dowex 50 (H^+) ion exchange resin contained in a column (32 cm×2.5 cm) which had been washed with 4 liters of 0.7 *N* hydrochloric acid. The column was washed free of the aminosugar with 0.7 *N* hydrochloric acid. Stronger hydrochloric acid (2.5 *N*) was required to elute the deoxystreptamine dihydrochloride (21). The free base was prepared by passing the hydrochloride through an Amberlite IR-120 (OH^-) column and eluting with water.

4,5,6-Tri-O-acetyldeoxystreptamine Dihydrogenperchlorate

A solution of 25 ml of acetic acid, 2 ml of 70% perchloric acid, and 15 ml of acetic anhydride was added to 500 mg of deoxystreptamine dihydrochloride. The mixture was shaken overnight, and the hydrochloride slowly dissolved. The white gelatinous product was collected by filtration, washed with acetic acid, and dried *in vacuo*. The yield was 500 mg (67%). After two recrystallizations from water, the nicely crystalline compound possessed the following physical properties: the infrared spectrum showed a strong band at 1726 cm^{-1} characteristic of the carbonyl group of *O*-acetates but no signal in the region (about 1640 cm^{-1}) characteristic of *N*-acetates, the n.m.r. spectrum showed two bands for the *O*-acetyl groups, one at 2.22 p.p.m. which was half the intensity of that at 2.28 p.p.m. Calculated for $C_{12}H_{22}Cl_2N_2O_{14}$: C, 29.47; H, 4.53; N, 5.73; CH_3CO, 26.32%. Found: C, 29.51; H, 4.33; N, 5.79; CH_3CO, 24.80, 25.70%.

ELECTRICAL POLARIZATION OF TETRAMETHYLCYCLOBUTANES

F. LAUTENSCHLAEGER AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received October 31, 1962

ABSTRACT

Because the postulated non-planarity of *sym*-tetramethylcyclobutanedione is based on a small value of electrical polarization, the *cis*- and *trans*-2,2,4,4-tetramethylcyclobutane-1,3-diisocyanides have been prepared and stereospecifically rearranged to the analogous dicyanides. These substances show sufficiently large polarizations that the explanation of ring non-planarity is substantiated. Calculations in terms of the expected and observed dipole moments show that the ring deviates 20–30° from planarity. Although this non-planarity is not static, according to consideration of the cis geoisomers it would appear that one conformation is more prevalent than any others.

For personal use only.

Although many investigators have concluded that their cyclobutanes existed in planar ring conformation (1–7) there have been others who found evidence for non-planarity on the basis of infrared and Raman absorption (8) (perfluorocyclobutane) and of electron diffraction with perfluorocyclobutane and methylcyclobutane (9) as well as with unsubstituted cyclobutane (10) and 1,3-dimethylenecyclobutane (11).

Electrical polarization studies also have indicated non-planarity. An apparent moment which was increased by higher temperature was found for 1-↑-2-↑-3-↓-4-↓-tetraphenylcyclobutane. Also the difference between the total polarization of 2,2,4,4-tetramethylcyclobutane-1,3-dione and its electronic polarization could no longer be attributed to abnormally high atom polarization, as Coop and Sutton had done (3), after the distortion polarization (P_{E+A}) of the substance was measured (12) and was found to be only 0.6 cc higher than the calculated electronic polarization. An apparent moment of 0.8 D had then to be assigned to tetramethylcyclobutanedione. Assuming the group moment of the carbonyl group to be 2.8 D the apparent deviation from ring planarity thus is calculated to be 20°, a value conforming roughly with earlier postulations (7, 9).

We have confirmed this evidence for non-planarity by preparation of the 1,3-diisocyanides and the 1,3-dicyanides of 2,2,4,4-tetramethylcyclobutane. These compounds were prepared from the geoisomeric diamines, I, which recently have been made available (13), but the reaction of Hofmann was not satisfactory for conversion of the amines to the isocyanides. However, Ugi's method (16) involving formamides with phosphorus oxychloride and pyridine gives good conversions of the *cis*- and *trans*-tetramethycyclobutane-1,3-diformamides, II, to the diisocyanides, III. Although an efficient method for separation of the geoisomeric amines has not yet been evolved the mixture obtained by formylation may easily be separated into *cis*- and *trans*-II by crystallization.

The diisocyanides III (cis and trans) are reconvertible to the corresponding formamides II by treatment with acetic acid. Also, they form cis and trans dibromides, VI. Of greater interest is the ease with which they are rearranged stereospecifically in good yield to the cis and trans cyanides, IV, by rapid heating at temperatures of about 310°. This reaction is most welcome, because any doubt about the linearity of the isocyanide group (and linearity is a necessary condition for unequivocal interpretation of the observed electrical polarization) is allayed by the well-known linearity of the cyanide group. The results of electrical polarization measurements (Table I) confirm that the isocyanide group is

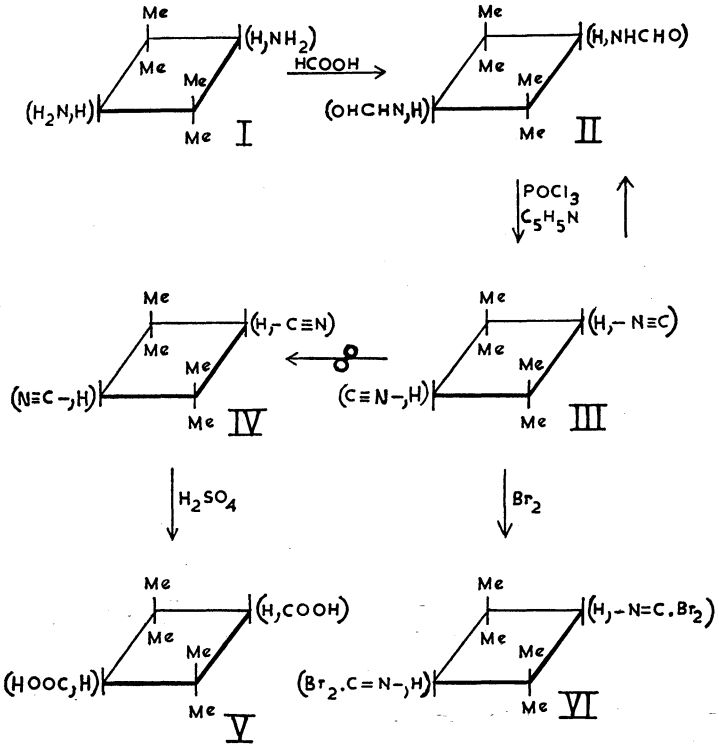
†See Table II.
‡Evaluated from $d_4^{20} = 1.428$ and $n_D^{20} = 0.821$.
§Evaluated from $d_4^{20} = 1.4143$ and $n_D^{20} = 0.824$.



linear, at least in cyclobutanes, since the observed moments of *trans*-III and *trans*-IV are almost identical.

The rearrangement of isocyanides to cyanides at elevated temperatures has long been known (17–19). Our reactions are noteworthy only because the behavior is not in accord with that observed by Wade (20). This worker found that thoroughly dried methyl and ethyl isocyanide did not rearrange during 2 hours at 250° although the moist substances reacted rapidly below 184°. Likewise impure phenylisocyanide in his hands rearranged rapidly whereas the pure compound resinified without a trace of rearrangement.

Our reaction conditions differ from Wade's in respect of our higher temperature (310° because we found that temperatures of 220–240° for 8–10 hours led to extensive side reaction) but our rearrangements were complete within 3 minutes despite the fact that our isocyanides were dried and freed from amine at least as rigorously as were Wade's. Consequently we cannot for our reaction accept Wade's postulation that the contaminating parent amine acts as catalyst even though his suggestion would be compatible with our observation of stereospecificity:

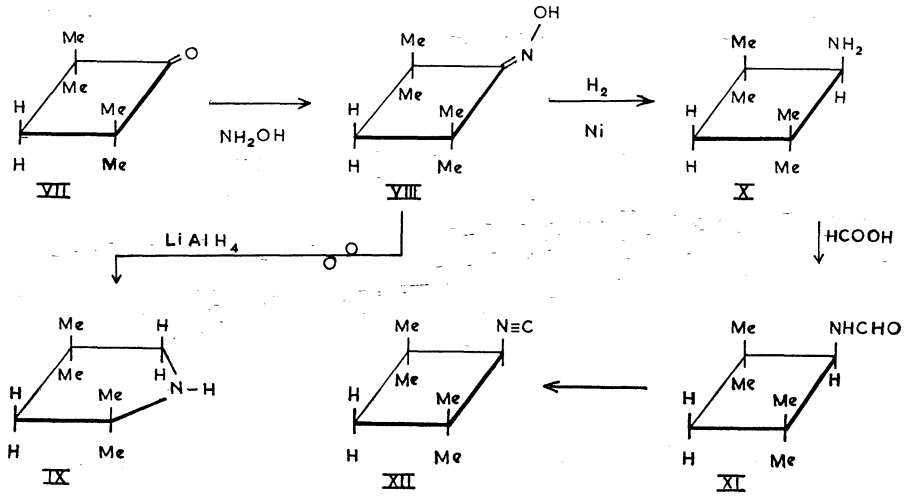
$$\phi\text{—N}\equiv\text{C} + \text{H}_2\text{N—}\phi \rightarrow \text{H—C(=N—}\phi\text{)—NH—}\phi$$

$$\phi\text{—C}\equiv\text{N} + \text{H}_2\text{N—}\phi \leftarrow \phi\text{—C(=N—H)—NH—}\phi$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Certainly our stereospecificity precludes the possibility that the isocyanide–cyanide rearrangement is acid catalyzed because the cyclobutane ring system is amenable to protonic isomerization. This catalyzed interconversion of stereoisomers was demonstrated for norpinic acid (21) and has also been observed during our acid hydrolysis of tetramethylcyclobutanedicyanide, IV, cis or trans, to the same equilibrium mixture of dicarboxylic acids, V.

The dipole moments of many aliphatic nitriles have been determined (22). On the other hand moment data for aliphatic isocyanides are sparse and none includes the cyclobutane ring. For this reason it seemed advisable to prepare 2,2,4,4-tetramethylcyclobutylisocyanide, XII. To this end 2,2,4,4-tetramethylcyclobutanone VII was prepared in low yield (together with 1,1,3,3-tetramethylcyclobutane) by the method of Herzog (23) and then was converted to the oxime VIII. Reduction with hydrogen and nickel gave the amine, X, but lithium aluminum hydride produced a secondary amine. This product of reductive rearrangement must evidently be 2,2,4,4-tetramethylpyrrolidine, IX. The formamide XI, which was prepared with ease from the amine X, was converted in good yield to the isocyanide, XII, by the method of Ugi and Meyr. The moment of XII, 3.5 D, is in reasonable agreement with values found for other aliphatic isocyanides (except methyl isocyanide) (22). Assuming that the C—H moment, which must be added algebraically, is directionally negative toward hydrogen (22), the group moment (in benzene) for the isocyano group is 3.8 D. Upon the same assumption (C → H), the cyano group has essentially the same moment (3.8 D).



One might expect from similarity in group moment that the moments of the tetramethylcyclobutane-dicyanides and -diisocyanides would be nearly identical. As may be seen in Table I the moments of the trans isomers are the same (1.23 and 1.24 D) within experimental error. Of interest is the fact that the values are not zero; i.e., the groups do not mutually cancel one another. It is evident that the *trans*-tetramethylcyclobutanedicyanide and -diisocyanide present some asymmetry to the external electric field; they are dipolar.

The alternative interpretation (in which the excess of total polarization over that which may be assigned as electronic polarization is due to atom polarization, P_A) is unrealistic. This is apparent in view of our measurements from which the distortion polarization can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be calculated according to the method reported previously (12). These values are shown in Table II. Although a correlation between molecular geometry and atom polarization

*Since refraction values for —N≡C are unknown a group refraction (Eisenlohr atom, 6.10 cc or Vogel bond, 5.34 cc) has been calculated from n_D^{20} and d_4^{20} of cyclohexane and tetramethylcyclobutane versus their analogous isocyanides. Similarly for —C≡N the Eisenlohr value is 5.46 cc and the Vogel value is 4.82 cc.

†TMCB refers to "2,2,4,4-tetramethylcyclobutane".

is not at present discernible it is at least apparent that P_A is not large (0–2 cc per nitrile or isonitrile group). In view of a general tendency to disregard our earlier determinations of distortion polarization which lead to assignment of orientation polarizations to benzoquinone (24), diphenylmercury (25), and tetramethylcyclobutanedione (12) it is satisfying that the high moment values for the dicyanides IV and the diisocyanides III do not depend very much on the spread of P_{E+A} values shown in Table II.

Since the measured dipole moments of the tetramethylcyclobutane-dinitrile and -diisonitrile are not zero the cyclobutane ring cannot be rigidly planar. It remains to ascertain the mode and the magnitude of this non-planarity. Evaluation of this magnitude does in general require a vectorial analysis which depends upon the angular distribution of hydrogen and cyano (or isocyano) substituents about the atom to which they are bound, but there is no fixed value for their angular distribution. Referring to Fig. 1 Friedlander

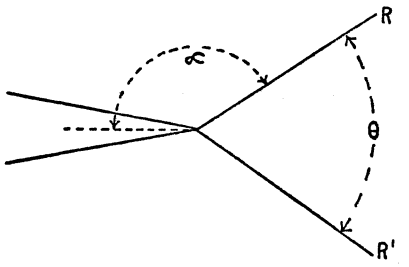

FIG. 1.

and Robertson (26) found in 2,2,4,4-tetramethylcyclobutanedione that θ was 111° while Lemaire and Livingston (7) called θ 107–112° in octofluorocyclobutane. The same authors (9) assigned to θ in methylcyclobutane a value of 100°. There is then a choice for α of 125° or 130°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

However, the vectorial analyses for the trans isomers do not involve the angle α if (as seems reasonable) the deformation from planarity is symmetrical. Reference to Fig. 2

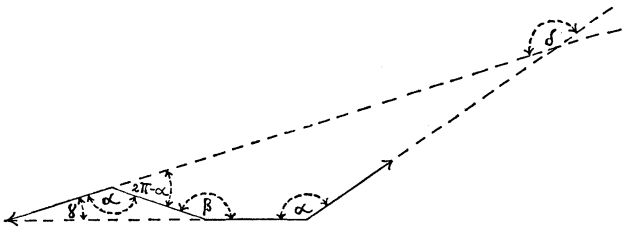

FIG. 2.

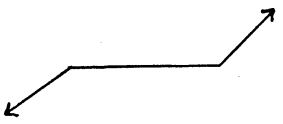
shows by consideration of the congruent triangles which include the angles $2\pi-\beta$, γ, α and the angles $2\pi-\delta$, γ, α respectively that $\delta = \beta$. Therefore, the resultant moment depends only on the group moments and the dihedral angle β, that is,

$$\mu_{res}^2 = (1.24)^2 = 2m^2+2m^2 \cos \beta,$$

where m = 3.8 Debye = group moment of cyanide or isocyanide, the moment contribution of the hydrogens being neglected.

The existence of a moment for the trans isomers of III and IV precludes the fixed planar structure XII in favor of the non-planar XIII. If XIII were fixed then β is 162°



XII

XIII

for both the cyanide and the isocyanide. Alternatively one may consider an oscillating "structure" in which XII and XIII partake equally. Then the resultant (observed) moment, μ_{res}, may be used to ascertain the moment of conformer XIII:

$$\mu_{res}^2 = n_{XII}\mu_{XII}^2+n_{XIII}\mu_{XIII}^2,$$

where $n_{XII} = n_{XIII} = 1/2$;

then $2\mu_{res}^2 = \mu_{XII}^2+\mu_{XIII}^2$;

but since $\mu_{XII}^2 = 0$,

$\mu_{XIII} = \sqrt{(2\mu_{res}^2)}$.

So if μ_{res} for *trans*-III or -IV = 1.24 D then μ_{XIII} = 1.76 D. Similarly if μ_{res} for tetramethylcyclobutanedione = 0.8 D then μ for the non-planar conformer = 1.26 D.

A graph may be constructed from calculations of expected moment at various β angles for 1,3-disubstituted tetramethylcyclobutane using a group moment of 3.8 D for cyano and for isocyano in benzene. A similar graph has been constructed for cyclobutanedione using a group moment (benzene solution) of 3.1 D (2.8+0.3) for keto. For an oscillating "structure" where μ_{XIII} = 1.76 D the angle β may be interpolated, 152° for the diisocyanide III and 152° for the dicyanide IV. An oscillating "structure" for 2,2,4,4-tetramethylcyclobutanedione (μ_{obs}, 0.8 D) would have β = 156° in contrast to a β angle of 165° for a rigid non-planar structure.

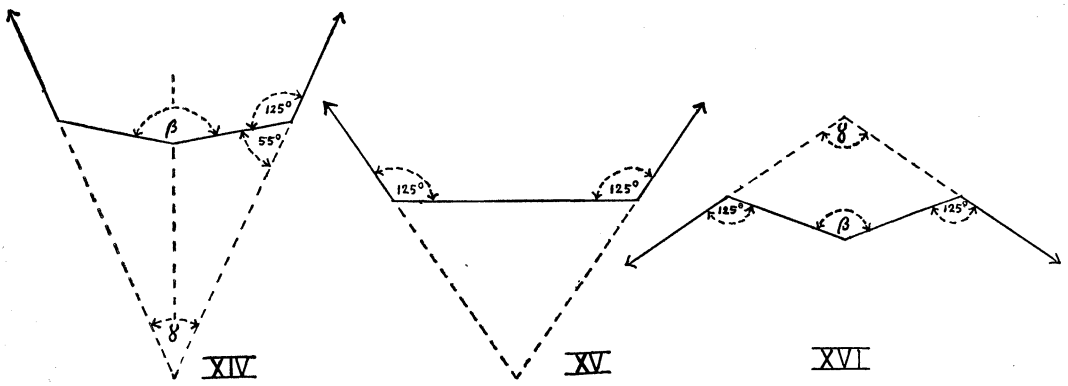
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

We do not attach any significance to the relatively narrow range (4°) between the values derived from the β vs. moment graphs for the trans dicyanide and diisocyanide on the one hand and the diketone on the other. These values depend on the choice of group moment that is chosen for a substituent. Although the choice of 3.1 D for carbonyl in the dione is not completely arbitrary, being derived from the observed moment of 2,2,4,4-tetramethylcyclobutanone, there is no certainty that this moment is applicable. The carbonyl absorption of the monoketone in potassium bromide occurs strongly at 1770 cm^{-1}, in the same range and extent that does 3-hydroxy-2,2,4,4-tetramethylcyclobutanone (1780 cm^{-1} in chloroform) (27). These high frequencies are comparable with that found (28) for cyclobutanone. On the other hand the absorption of the dione carbonyls (potassium bromide) is split into two strong bands at 1725 and 1750 cm^{-1}, which indicates a marked difference from carbonyl in the monoketone.

It should be emphasized that the deviations from ring planarity as exemplified by angle β are not to be construed as absolute values because solvent effects will contribute to the apparent moment. A real moment may be estimated only after apparent moments have been found in a number of solvents (24). The contrast in the present study (μ = 1.24 D in benzene versus 1.38 D in dioxane for trans diisonitrile III) is not sufficiently diverse for choice of a real dipole moment.

The electrical polarization data for the trans dicyanide IV and diisocyanide III do not permit a choice of rigid versus oscillating "structure" but additional information about 2,2,4,4-tetramethylcyclobutanedione favors the oscillating "structure". The nuclear magnetic resonance spectrum of this dione ought to show a difference in methyl–hydrogen environments if the substance were rigidly non-planar. On the other hand, it would display a single hydrogen-atom absorption either if the substance were rigidly planar or alternatively if it were oscillating at a rate greater than the several hundred cycles per second which is involved in the measurement of n.m.r. Since the rigidly planar structure is excluded by the existence of a dipole moment for *trans*-III and -IV it would appear that these molecules are oscillating at a rate between 200 and 10^6 cycles/sec in view of the single peak which we have observed as the n.m.r. spectrum. The more rapid of these rate limits is favored by the low-temperature coefficient of moment (Table I) found for the diisonitriles and the dione.

Whereas the angle (α) which the cyano or isocyano group forms with the tetramethylcyclobutane ring is inconsequential in respect of trans geoisomeric configurations, it becomes crucial in consideration of cis isomers. The choice of α = 125° will be used in the following calculations.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The three conformers to be considered for the cis isomers are shown as XIV, XV, and XVI. The angle of vector interaction in XV is obvious (70°) while that in XIV is

$$\gamma/2 + 55 + (180-\beta/2) = 180$$
$$\beta = \gamma+110$$

and that in XVI is

$$\gamma/2 + \beta/2 + 55 = 180$$
$$\beta = 250-\gamma.$$

A set of resultant moments using μ_{-CN} and μ_{-NC} of 3.8 D for different β values has been calculated for XIV and XVI and is shown in Fig. 3. The intersection of these two at 180° marks the calculated moment of the planar conformer XV.

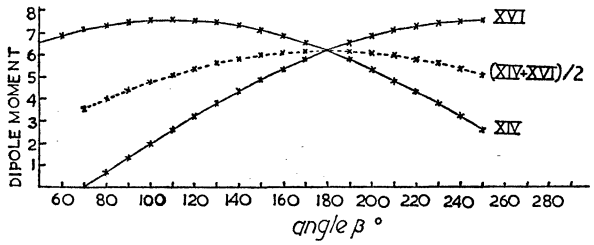


FIG. 3.

From Fig. 3 it may be concluded that conformation XV with calculated resultant moment of 6.2 D cannot alone represent the *cis*-2,2,4,4-tetramethylcyclobutane-1,3-dicyanide of observed moment 4.26 D in benzene at 20°. It may be seen that if XVI were the sole conformer then β would be 138° but that XIV would have μ = 4.26 D only if β were 222°, i.e., if it were XVI. Finally, an oscillating species comprised of XVI, XIV, and XV in proportion 1:1:2 could according to the dotted line of Fig. 3 have a resultant moment of 4.26 D only if β were 87°, which is absurd. It is evident then that XVI must be grossly preponderant in order to account for the observed moment. It may be noted that XVI is the equatorial conformer.

Exactly the same analysis for the cis diisocyanide shows that conformer XV (dotted line at 180°) would have a moment (6.2 D) much larger than that observed (3.68 D) for *cis*-III in benzene at 20°. This observed moment would be explained by conformer XVI alone if β were 129° but not by XIV alone unless β were 231°, i.e., identical with XVI. As before, a 1:1:2 oscillating mixture of XIV, XVI, and XV would lead to an absurdly small β angle. It would seem that *cis*-tetramethylcyclobutane-1,3-diisocyanide (III) also exists preponderantly as the equatorial conformer XVI.

Of course any contribution from conformer XIV would require that β were smaller than the 141° and 145° attributed to the geometry of the diisocyanide and the dicyanide of conformation XVI (Fig. 3), but this further deviation from 180° (planarity) required by a dynamic molecule should not be taken too seriously. If in the calculations outlined above for the cis isomers the angle θ (between C≡N and H at carbons 1 and 3) had been chosen as 105° rather than 110° then all of the β angles would be about 10° higher than those specified here.

EXPERIMENTAL

Melting points have been corrected against known standards.

trans-2,2,4,4-Tetramethylcyclobutane-1,3-diformamide

To an ice-cooled mixture of *cis-* and *trans*-2,2,4,4-tetramethylcyclobutane-1,3-diamine (13) (44 g, 0.33 mole) was added 60 g (1.3 mole) of 98+ % formic acid. The solid was heated until, after bubbling ceased when the pot temperature reached 260°, all water and formic acid had distilled off. The residue, m.p. 175–222°, weighed 60 g (90%) and was finely ground before it was eluted with 400 ml of boiling 95% ethanol to leave 26 g, m.p. 240–244°. Three crystallizations from dioxane raised the melting point to 257–258°, 22 g. By repetition of this procedure with the evaporated mother liquor from the initial isolation of both geoisomers an additional 6 g, m.p. 257–258°, was isolated. This total yield of the trans isomer was 47% of the 91% yield of both isomers. Calc. for $C_{10}H_{18}N_2O_2$: C, 60.5; H, 9.16; N, 14.1. Found: C, 60.3; H, 9.14; N, 14.2.

cis-2,2,4,4-Tetramethylcyclobutane-1,3-diformamide

The 400 ml of ethanolic extract mentioned above was concentrated to a volume of 100 ml and 24 g, m.p. 160–185°, crystallized out. These crystals were dissolved in 100 ml of boiling 95% ethanol, and 500 ml of ethyl acetate was added. Upon chilling, 20.5 g crystallized, m.p. 205–212°. This portion was recrystallized four times from ethanol – ethyl acetate (1:3), 15 g, m.p. 216–217°. An additional 12 g of this pure cis isomer was obtained via the repetition step used in the isolation of the additional trans isomer. The total amount of cis isomer (27 g, m.p. 216–217°) amounted to 45% of the combined yield (91%) of formamides. Calc. for $C_{10}H_{18}N_2O_2$: C, 60.6; H, 9.16; N, 14.1. Found: C, 60.5; H, 9.17; N, 14.0.

cis-2,2,4,4-Tetramethylcyclobutane-1,3-diisocyanide

A suspension of 19.8 g (0.1 mole) of *cis*-tetramethylcyclobutane-1,3-diformamide (m.p. 216–217°) in 100 ml of barium-oxide-dried pyridine and 65 ml of petroleum ether (b.p. 40–60°) was ice-cooled and stirred while 24 g (0.156 mole) of freshly distilled phosphorus oxychloride was added dropwise during 10 minutes. The suspension became cheesy and blue-green. Subsequent reflux for 30 minutes at 55° was followed by the addition of 200 ml of ice water with cooling of the system, which was then thrice extracted with a total of 200 ml of petroleum ether (b.p. 40–60°). The extract was washed with 2% hydrochloric acid, then water, and finally was dried by use of anhydrous magnesium sulphate. Vacuum evaporation left 11 g (67%) of a brown solid, m.p. 46–54°. This was sublimed at 40° (10 mm) to give 9.7 g, m.p. 57.5–58°, colorless. The substance was decomposed (5 days to an oil) by ultraviolet radiation, maximum at 360 mμ. In a potassium bromide pellet (1/400 by weight) it absorbed at the following cm^{-1}: 2970 (s); 2950 (s, shoulder); 286 (w); 2135 (s); 2040 (vw), 1465 (s), 1455 (m); 1400, 1388, 1375 (m); 1362, 1325, 1280 (m), 1215 (w), 1185 (m); 1077, 1065, 1032 (m); 975 (s); 797, 771 (m). Calc. for $C_{10}H_{14}N_2$: C, 74.0; H, 8.69; N, 17.3. Found: C, 73.9; H, 8.65; N, 16.9.

When 0.01 mole of this diisonitrile in 3 ml of acetic acid was heated to 100° for 5 minutes the vacuum-evaporated system left 98% of crude cis diformamide, m.p. 195–205°. Crystallization from dioxane yielded 80% of the crude product, m.p. 216–217°, m.m.p. not depressed.

Bromine was added to a solution of 0.162 g (0.001 mole) of the diisonitrile in 25 ml of hexane until a faint yellow color persisted. Although crystals separated, the system was concentrated under vacuum to a volume of 5 ml before 0.29 g (68% as the tetrabromide) was filtered, m.p. 128–129°. A second crop (0.21 g, 44%) was obtained by complete evaporation of solvent, m.p. 110–129°. This tetrabromide was too unstable for routine analysis. It was soluble in water but insoluble in diethyl ether.

cis-2,2,4,4-Tetramethylcyclobutane-1,3-dicyanide

When 3.42 g (0.02 mole) of the cis diisocyanide was heated in a sealed tube at 320° (electric oven) for 3 minutes and cooled the resulting crystals melted at 89–97°. Crystallization from carbon tetrachloride and from 4:6 aqueous ethanol gave 2.91 g (85%) of rearranged product, m.p. 99.5–100.5°, unreactive toward bromine. In potassium bromide pellets (1/400) it absorbed at cm^{-1} as follows: 2970 (s), 2950 (s), 2880 (w), 2240 (s); 1465 (s), 1455 (m, shoulder), 1403 (w), 1395 (w), 1385 (m); 1282 (m), 1200 (m), 1180 (s). Calc. for $C_{10}H_{14}N_2$: C, 74.0; H, 8.69; N, 17.3. Found: C, 74.2; H, 8.79; N, 17.4.

trans-2,2,4,4-Tetramethylcyclobutane-1,3-diisocyanide

A. From Trans Diformamide

A finely ground suspension of 19.8 g (0.1 mole) of *trans*-2,2,4,4-tetramethylcyclobutane-1,3-diformamide (m.p. 256–257°) in 100 ml of barium-oxide-dried pyridine and 65 ml of petroleum ether (b.p. 40–60°) was ice-cooled and strongly stirred while 24 g (0.156 mole) of freshly distilled phosphorus oxychloride was added dropwise during 10 minutes. The cheese-like green suspension was heated subsequently for 1 hour at 55° and then was chilled while 200 ml of ice water was added. The solid and the non-aqueous phases were separated. The aqueous phase was repeatedly extracted with a total of 150 ml of petroleum ether (b.p. 40–60°). This extract was combined with the solid phase and the non-aqueous phase, and the whole was evaporated. The residue was digested with 1% hydrochloric acid, then with aqueous sodium bicarbonate, and finally with water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

When this crude product was dried it weighed 13 g (80%, m.p. 136–138°) and was almost soluble in 250 ml of hot commercial hexane. This solution yielded 11.2 g (69%) of colorless trans diisocyanide, m.p. 138–139°, in several crops when it was cooled and concentrated. Calc. for $C_{10}H_{14}N_2$: C, 74.0; H, 8.69; N, 17.3. Found: C, 74.0; H, 8.92; N, 17.3. The trans diisocyanide absorbed in 2% carbon tetrachloride solution as follows: 2960 (s), 2940 (m), 2880 (w), 2140 (s), 2065 (w), 1470 (s), 1460 (m), 1455 (m), 1329 (m), 1383 (m), 1352 (m), 1240 (w), 1190 (w), 998 (m), 977 (w), 954 (w).

B. By Chromatography of a Cis–Trans Mixture

A mixture of 50 mg each of the cis and trans diisocyanides was dissolved in 5 ml of benzene plus 5 ml of commercial hexane and was washed by the same solution onto 22 cm of alumina on a column 1 cm in diameter and 20 cm long (150–170 mesh activated 10 hours at 200° C). The column was washed with 150 ml of the same solution and then was developed with a solution of commercial hexane – ethyl acetate (50:1), which gave a first fraction, m.p. 57.5–58.5° C. A second fraction, m.p. 138–139°, was developed with pure ethyl acetate.

The trans diisocyanide, m.p. 138–139°, could be reconverted to the trans diformamide if it were heated (0.005 mole) in 8 ml of acetic acid for 5 minutes at 100°. A quantitive yield was obtained by vacuum evaporation of the solvent and crystallization of the residue from boiling water. A mixture melting point with original trans diformamide was not depressed.

Like the corresponding derivative of the cis diisocyanide, the tetrabromide of the trans diisocyanide was unstable, although the two were not identical (m.m.p. depressed). An 88% yield was obtained, m.p. 129–130°, when all but 5 ml of solvent was evaporated from the system comprised of 0.198 g diisocyanide, 40 ml of petroleum ether (b.p. 40–60°), and bromine in slight excess.

By contrast to the cis diisocyanide, exposure to ultraviolet light (max. 360 mμ) during a month did not depress the melting point of the trans diisocyanide.

trans-2,2,4,4-Tetramethylcyclobutane-1,3-dicyanide

When 1.62 g (0.01 mole) of trans diisocyanide (m.p. 138–139°) was heated in a sealed tube for 4 minutes at 310° (electric oven) it was converted to the dinitrile, m.p. 153–154° after crystallization from carbon tetrachloride and 4:6 water–ethanol. The product (yield 1.34 g, 83%) did not react with bromine in carbon tetrachloride. In potassium bromide pellets (1/400) it absorbed at the following cm^{-1}: 2970 (s), 2950 (m), 2880 (w), 2250 (m), 1470 (s), 1460 (m), 1395 (s), 1385 (s); 1205, 1188, 1177 (m) with no further absorption down to 650 cm^{-1}. Calc. for $C_{10}H_{14}N_2$: C, 74.0; H, 8.69; N, 17.3. Found: C, 73.8; H, 8.62; N, 17.2.

trans-2,2,4,4-Tetramethylcyclobutane-1,3-dicarboxylic Acid

A solution either of 3 g of *cis-* or *trans*-tetramethylcyclobutanedicyanide (0.018 mole) in 15 ml of 70% (w/w) sulphuric acid was boiled for 7 minutes. The cooled system was diluted with 20 ml of water, then was continuously extracted with diethyl ether. The ether solution, water washed to remove sulphuric acid and dried by use of magnesium sulphate, was evaporated to a volume of 25 ml, whereupon 2.2 g (59%) of crude trans acid, m.p. 264–266°, separated and was filtered off. Crystallization from water raised this melting point to 270–271.5° (sample introduced at 268°). Calc. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.06. Found: C, 60.0; H, 8.19. The dimethyl ester, prepared by use of diazomethane, melts at 8–10° after crystallization from petroleum ether (b.p. 40–60°). Titration of an aqueous acetone solution gave a pK_A^1 of 6.60; the pK_A^2 value could not be observed.

cis-2,2,4,4-Tetramethylcyclobutane-1,3-dicarboxylic Acid

The ether filtrate from which the trans acid was isolated according to the procedure described above was evaporated to leave 1.2 g, m.p. 233–236°. Crystallization from water raised this m.p. to 235–236°. Calc. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.06. Found: C, 59.8; H, 8.12. The dimethyl ester (from diazomethane) melted at 3–6° after crystallization from petroleum ether (b.p. 40–60°). The pK_A^1 found for an aqueous acetone solution was 6.78.

2,2,4,4-Tetramethylcyclobutane

The disemicarbazone of 2,2,4,4-tetramethylcyclobutanedione was prepared in 98% yield, m.p. 213 (decomp.) (23).

Into a solution prepared from 229 g (10 atom weight) of sodium and 2800 ml of diethylene glycol at 110° was added (at 130°) 305 g (1.2 mole) of the disemicarbazone, and the temperature was raised. At 155° nitrogen evolution commenced and continued during 45 minutes after the temperature had been raised to 210° during 30 minutes. The vapors were caught in a dry ice trap. Then 2 liters of water were added to the residue and it was steam-distilled.

The non-aqueous phase of steam distillations, the ether extract of the aqueous phases, and the trap condensates from five such experiments were combined, washed with 1% hydrochloric acid, dried by use of magnesium sulphate, and distilled (760 mm) to give 8 g b.p. 75–84°, 20 g b.p. 84–85°, and 50 g b.p. 85°. After this tetramethylcyclobutane had been separated (b.p. according to Herzog 86–87° at 745 mm) subsequent fractions were distilled off: 52 g b.p. 62–87° (42–38 mm), 176 g b.p. 96° (52 mm), 40 g b.p. 96–124° (52 mm), leaving a pot residue which crystallized but was discarded.

For personal use only.

2,2,4,4-Tetramethylcyclobutanone

The 176 portion (conforming approximately with the b.p. 90–93° at 45 mm reported by Herzog from tetramethylcyclobutane hydrazone) represents a 23% yield of this substance. A solution of 155 g (1.1 mole) in 350 ml of conc. hydrochloric acid was shaken until a sample of the non-aqueous top phase did not diminish in volume when treated with fresh conc. hydrochloric acid nor did it produce cloudiness in the test-acid phase during 5 minutes. The top layer was then separated and was augmented by ether extractions of the aqueous phase. The combination (ether solution of the non-aqueous phase) was washed acid free by means of water, then dried by use of magnesium sulphate, and was distilled at 760 mm to yield 13 g b.p. 124–130.5° and 108 g b.p. 130.5–131°. This latter fraction (77% on the basis of hydrazone used) was redistilled and the distillate was allowed to crystallize (slowly) at about 19° C. The crystalline portion (100 g) with camphor-like odor melted at 19–21°, n_D^{20} 1.41425. This ketone, which boiled like that of Herzog (128.5–129° at 745 mm), absorbed in 1.4% carbon tetrachloride at cm^{-1} as follows: 2970 (s), 2900 (m), 1770 (s), 1470 (m), 1460 (m), 1390 (m), 1370 (m), 1290 (w), 1240 (w), 1200 (w), 1160 (w), 1028 (s), 910 (m). The 2,4-dinitrophenylhydrazone of this ketone melted at 114–115°. The ketone was recovered (80%) unchanged upon attempted conversion to the amine by means of the Leuckart reaction using a nickel catalyst (29).

2,2,4,4-Tetramethylcyclobutanone Oxime

A solution of 6.3 g (0.05 mole) of ketone in 50 ml of ethanol was treated with 3.8 g (0.055 mole) of hydroxylamine hydrochloride in 4.5 ml of water and 5 ml of pyridine. After 2 hours at 60° dilution with 200 ml of water gave 6.9 g (98%) of oxime, m.p. 88.5–89.7°. Crystallization by solution of 1 g in 10 ml of water plus 8.5 ml of methanol at 70° raised the melting point to 89–90°. The oxime was quite soluble in petroleum ether (b.p. 40–60°) and in diethyl ether. Calc. for $C_8H_{15}NO$: C, 68.0; H, 10.8; N, 9.92. Found: C, 68.2; H, 10.4; N, 9.65. A 2% solution in carbon tetrachloride showed the following absorption at cm^{-1}: 3620 (m); 3240, 3140 (s); 2980, 2950, 2860 (s); 1705 (m); 1465, 1455, 1440 (s); 1380, 1370, 1345 (m); 1230, 1197, 1162 (w); 1070 (m); 980 (w); 950, 930, 920, 893 (s).

2,2,4,4-Tetramethylpyrrolidine

A solution in 800 ml of absolute diethyl ether of 63.5 g (0.45 mole) of the oxime described above was added during 30 minutes to a stirred suspension of 29.2 g (0.77 mole) of lithium aluminum hydride. The suspension was refluxed for 8 hours. The now-light-grey and thickened suspension was stirred with 12 g (0.2 mole) of acetone and, after 1 hour, with 100 ml of water. The non-aqueous layer was separated and the aqueous layer was extracted by use of 50 ml of diethyl ether. The combination of non-aqueous phases was washed with a little water, and then with 5% hydrochloric acid. The aqueous acid layer was washed with a little ether, then was basified, and continuously extracted during 1 day by use of diethyl ether. The extract, dried by use of potassium carbonate, was fractionally distilled. The main fraction, b.p. 128–132°, weighed 30 g (53%). Calc. for $C_8H_{17}N$: C, 75.6; H, 13.47; N, 11.0. Found: C, 75.3; H, 13.5; N, 11.2.

This 2,2,4,4-tetramethylpyrrolidine is strongly basic and slightly soluble in water. Reactions with nitrous acid and with benzene sulphonyl chloride show that it is a secondary amine. In carbon tetrachloride solution it shows medium absorption at 3250, 3150, and 2680 cm^{-1}. It reacts with phenylisocyanate to give N-phenylcarbamyl-2,2,4,4-tetramethylpyrrolidine, m.p. 157–157.5°, after crystallization from petroleum ether (b.p. 90–100°, 0.45 g from 10 ml); from petroleum ether (b.p. 60–70) – chloroform, 1:1; from carbon tetrachloride; and from chloroform – petroleum ether (b.p. 90–100), 1:1. Calc. for $C_{15}H_{22}N_2O$: C, 73.1; H, 9.00; N, 11.4. Found: C, 73.0; H, 8.93; N, 12.0. The amine forms a picrate, m.p. 132–133.5°, and a *p*-nitrobenzoyl derivative, m.p. 184.5–186.5°.

2,2,4,4-Tetramethylcyclobutylamine

A solution of 11.3 g of the oxime (m.p. 88–89°) in 120 ml of absolute ethanol was saturated with ammonia at +5° and reduced by hydrogen using pelleted Raney nickel (British Drug House) from which the paraffin was removed by use of petroleum ether. The reduction was first carried out at 500 p.s.i. (90°) for 45 minutes and then at 14,000 p.s.i. (90°) for 3 hours. Stirring in the stainless steel container was effected magnetically with a bar constructed by vacuum shrinkage of Corning 7052 glass onto Kovar alloy which had previously been treated with hydrogen at 1100° C. The filtered system was then distilled through a 10-in. Vigreux column at atmospheric pressure, to obtain finally 1.2 g b.p. 80–134°, 0.4 g b.p. 134–136°, and 4 g b.p. 136°. The 0.2-g and 0.4-g portions were combined with the distilled ethanol from the original hydrogenation product, acidified with formic acid, and distilled, to give finally 2.8 g of the formamide described below, b.p. 246°. The total yield may thus be calculated as 63%, of which 4 g is free amine. The absorption spectrum of the amine in 7% solution in carbon tetrachloride was found in cm^{-1} to be: 3480 (w); 3200 (w); 2970, 2870 (s); 2750 (w); 1620 (m); 1470, 1455 (m), 1450 (m, shoulder); 1390 (w, shoulder); 1380 (w, shoulder); 1360 (m); 1290 (w), 1140 (m); 1110 (m); 1010 (w); 980 (w); 965 (m); 880 (m, broad). The amine evolved nitrogen on treatment with nitrous acid, formed the carbonate salt readily in air, and was insoluble in water or 5% aqueous sodium hydroxide but was readily soluble in 5% hydrochloric acid. Calc. for $C_8H_{17}N$: C, 75.3; H, 13.6; N, 11.0. Found: C, 74.9; H, 13.1; N, 10.4. The amine formed a picrate, m.p. 207°. It was converted into the phenylthiourea derivative in 97% yield, m.p. 151–154°. After two crystallizations from petroleum ether (b.p. 90–100°) and 1:1 ethanol–water this derivative melted at 153–154°. Calc. for $C_{15}H_{22}N_2S$: C, 68.6; H, 8.45; N, 10.7. Found: C, 68.5; H, 8.33; N, 10.8.

2,2,4,4-Tetramethylcyclobutylformamide

A solution of 3.8 g (0.03 mole) of tetramethylcyclobutylamine in 1.8 g (0.04 mole) was prepared with cooling and then was heated gradually to 205° to distill off formic acid and water. The residue was distilled at 242–245°. This distillate (4.1 g, 87%), m.p. 65–67°, was crystallized from petroleum ether, first of b.p. 40–60° and then of b.p. 90–100°, by chilling to −50°. Finally the formamide was sublimed, m.p. 68–68.8°. Calc. for $C_9H_{17}NO$: C, 69.6; H, 11.0; N, 9.02. Found: C, 69.4; H, 11.2; N, 8.77. The formamide, soluble in organic solvents but insoluble in water, showed the following absorptions in 1.5% carbon tetrachloride in cm^{-1}: 3460 (m), 3920 (m), 3210 (m), 3100 (m), 2960 (s), 2870 (s), 1690 (s), 1480 (s), 1460 (s), 1380 (s), 1370 (s), 1325 (m), 1300 (m), 1250 (m), 1235 (m), 1220 (m), 1190 (m), 1135 (m), 1070, 1028, 1015, 965, 878, 555 (w).

2,2,4,4-Tetramethylcyclobutylisocyanide

A procedure identical with those described above was effected using 6 g (0.04 mole) of the formamide, from which 2.9 g (60%) of isocyanide, b.p. 160° (m.p. −25.5 to −24.5°), was obtained, n_D^{20} 1.4506. It reacted with bromine in carbon tetrachloride. In 2% solution in carbon tetrachloride it showed the following absorptions at cm^{-1}: 2960, 2860 (s, with shoulder at 2850); 2140 (s); 1460, 1450, 1445 (m); 1380, 1370 (m); 1330, 1280, 1250, 1230, 1190, 1130, 1100, 1035, 1005, 970 (w). Calc. for $C_9H_{15}N$: C, 78.8; H, 11.0; N, 10.2. Found: C, 78.9; H, 10.9; N, 10.0. When 0.2 g of the isocyanide was boiled for 10 minutes in 2 ml of acetic acid it was recovered in 91% yield as the formamide, m.p. 65–67°, m.m.p. not depressed.

Electrical Measurements

The dielectric constants of solutions were determined in the customary manner (30). The apparatus described recently (31) was used for measurement of the dielectric constants of the nitriles and isonitriles in the solid state. Because of the unexpected lack of correlation among the measured distortion polarizations of the geoisomeric nitriles and isonitriles a large number of experiments were made. These data made it possible to examine the unexplained phenomenon that the slope of the linear plot of apparent dielectric constant with respect to pellet thickness for any substance is variable from run to run. When the extrapolated dielectric constants of a series of six separate determinations of terephthalonitrile were plotted against the slopes, ϵ/thickness, a reasonably linear relationship was found which showed that change in slope from 0.5 to 2.0 would cause a change in dielectric constant from 2.945 to 2.940. Therefore it appears that an uncontrolled error is present in the determination. However, the variation in dielectric constant shows that this error is less than that inherent in the overall determination of solid dielectric constant.

COORDINATION COMPOUNDS OF HYDRAZINE

PART III. THE INTERACTION OF SILICON TETRAFLUORIDE WITH HYDRAZINE[1, 2]

R. C. AGGARWAL[3] AND M. ONYSZCHUK
Department of Chemistry, McGill University, Montreal, Que.

Received November 28, 1962

ABSTRACT

Silicon tetrafluoride and hydrazine react in a vacuum to produce a white, non-volatile, solid, 1:2 complex, $SiF_4.2N_2H_4$. This compound sublimes with decomposition above 200° and is insoluble in common organic solvents. It reacts with (*a*) 55% hydrofluoric acid, (*b*) anhydrous hydrogen chloride, (*c*) ethylenediamine, (*d*) ammonia, and (*e*) boron trifluoride, producing: (*a*) $(N_2H_5^+)_2SiF_6^{2-}$, (*b*) $N_2H_5^+Cl^-$, (*c*) $SiF_4.NH_2(CH_2)_2NH_2$, (*d*) $SiF_4.2NH_3$, and (*e*) $BF_3.N_2H_4$. A comparison of the infrared spectra of $SiF_4.2NH_3$, $SiF_4.2N_2H_4$, and $SiF_4.NH_2(CH_2)_2NH_2$ suggests that all three complexes have cis octahedral structure.

INTRODUCTION

Both nitrogen atoms in hydrazine are electron-pair donors since each is capable of coordinating with borane (BH_3) (1, 2), boron trifluoride (3), or trimethylborane (4). With the object of obtaining further information about the donor activity of hydrazine, we have examined its interaction with silicon tetrafluoride, a powerful acceptor molecule.

The behavior of silicon tetrafluoride as a strong electron-pair acceptor arises from the tendency of silicon to increase its covalency from four to six by using two of its five vacant 4*d*-orbitals in octahedral bonding through sp^3d^2 hydridization. Monofunctional nitrogen donors such as ammonia (5), trimethylamine (6), pyridine (7), dimethylanaline (8), and cyclic amines (9) form complexes of the type $SiF_4.2$ donor; trimethylamine (6) and pyridine (10, 8) also produce 1:1 complexes. Ethylenediamine functions as a bidentate ligand in forming a 1:1 complex (11). The results reported in this paper reveal that hydrazine, conceivably a bidentate ligand, behaves only as a monodentate ligand towards silicon tetrafluoride, forming $SiF_4.2N_2H_4$, some properties of which are also reported.

RESULTS AND DISCUSSION

Preparation of $SiF_4.2N_2H_4$

An exothermic reaction occurred between SiF_4 and N_2H_4 in a vacuum at 60–70°, and a finely divided white powder with composition $SiF_4.2N_2H_4$ was the only product. This product resulted no matter which reactant was taken in excess initially. Tensimetric titration of N_2H_4 by addition of successive small amounts of SiF_4 to N_2H_4 (Fig. 1A), and the reverse titration (Fig. 1B) confirmed the 1:2 composition of the compound and showed conclusively the absence of a 1:1 complex.

Properties of $SiF_4.2N_2H_4$

The new compound $SiF_4.2N_2H_4$ is a white, non-hygroscopic solid which is insoluble in common organic solvents, such as ethanol, acetone, dimethylsulphoxide, acetonitrile, benzene, chloroform, carbon tetrachloride, and ethyl acetate. Its hydrolysis yielded a turbid solution due to precipitation of colloidal hydrated silica:

$$2(SiF_4.2N_2H_4) + (2+x)H_2O \rightarrow 4N_2H_5^+ + SiF_6^{2-} + 2F^- + SiO_2.xH_2O.$$

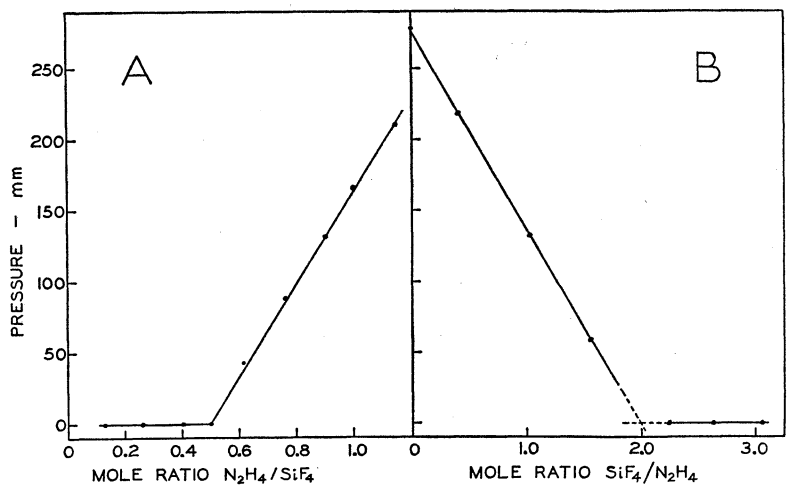

FIG. 1. Tensimetric titrations. A: SiF_4 added to N_2H_4; B: N_2H_4 added to SiF_4.

The compound $SiF_4.2N_2H_4$ sublimed slowly at 100° without measureable decomposition, and above 200° it decomposed (without melting) into nitrogen, ammonia, and an unidentified heterogeneous, non-volatile, white solid.

Hydrofluoric acid (55%) reacted almost quantitatively with $SiF_4.2N_2H_4$ according to the following stoichiometry:

$$SiF_4.2N_2H_4 + 2HF \rightarrow 2N_2H_5^+ + SiF_6^{2-}.$$

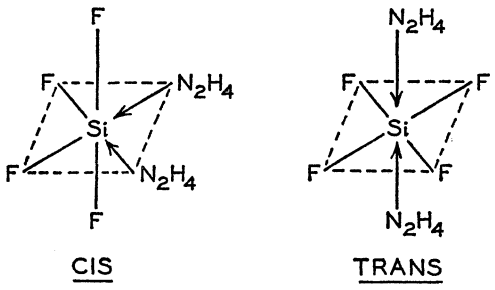
Anhydrous hydrogen chloride liberated SiF_4 almost completely from $SiF_4.2N_2H_4$, as expected in the reaction

$$SiF_4.2N_2H_4 + 2HCl \rightarrow 2N_2H_5^+ + 2Cl^- + SiF_4.$$

Ethylenediamine displaced hydrazine quantitatively from $SiF_4.2N_2H_4$:

$$SiF_4.2N_2H_4 + NH_2(CH_2)_2NH_2 \rightarrow SiF_4.NH_2(CH_2)_2NH_2 + 2N_2H_4.$$

This displacement is favored by an entropy increase due to a net increase in number of particles in going from reactants to products. Both complexes are octahedral as evident from their infrared spectra, which are discussed later. In the octahedral structure the following cis and trans arrangements of ligands are possible:



Silicon tetrafluoride – ethylenediamine must exist in the cis form because the distance between trans sites is greater than that which can be spanned by ethylenediamine. If

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

displacement of two hydrazines with one ethylenediamine does not occur with change of configuration, $SiF_4.2N_2H_4$ must also exist in the cis configuration.

Ammonia displaced hydrazine from $SiF_4.2N_2H_4$ to an extent of only 31%, whereas the reverse displacement, i.e. of NH_3 from $SiF_4.2NH_3$ by N_2H_4, was about 75% complete. These crude results show that the equilibrium constant at 150° in the following reaction,

$$SiF_4.2N_2H_4 + 2NH_3 \leftrightarrows SiF_4.2NH_3 + 2N_2H_4,$$

is less than unity. Silicon tetrafluoride – 2-hydrazine appears to be more stable than $SiF_4.2NH_3$. This is also indicated by the observation that $SiF_4.2NH_3$ dissociates rapidly above 80° (5), while $SiF_4.2N_2H_4$ does not dissociate or decompose appreciably below 200°.

Boron trifluoride displaced SiF_4 quantitatively from $SiF_4.2N_2H_4$ at 170°, and $BF_3.N_2H_4$ rather than $2BF_3.N_2H_4$ was formed:

$$SiF_4.2N_2H_4 + 2BF_3 \rightarrow 2(BF_3.N_2H_4) + SiF_4.$$

This suggests that BF_3 is a stronger electron-pair acceptor than SiF_4, but this will have to be verified by determination of the heats of formation of their hydrazine adducts. These measurements are now in progress.

Infrared Spectra

The infrared spectra of $SiF_4.2NH_3$, $SiF_4.2N_2H_4$, and $SiF_4.NH_2(CH_2)_2NH_2$ are shown in Fig. 2 and frequency assignments for the main bands are given in Table I together

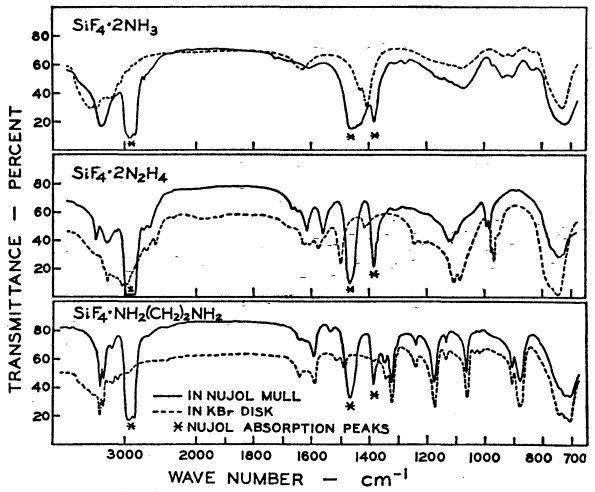


FIG. 2. Comparison of infrared spectra of $SiF_4.2NH_3$, $SiF_4.2N_2H_4$, and $SiF_4.NH_2(CH_2)_2NH_2$.

with those for gaseous ammonia (12), liquid hydrazine (13), and liquid ethylenediamine (14). There is surprisingly little difference between spectra taken in Nujol mulls and in KBr disks.

Transition metal amines show four principal absorption bands in the 4000–650 cm^{-1} range; these have been assigned to N—H stretching (3300–3200 cm^{-1}), degenerate NH_3 deformation (~1600 cm^{-1}), symmetric NH_3 deformation (~1300 cm^{-1}), and NH_3 rocking (~850 cm^{-1}) vibrations (15). In addition to a similar set of four bands, $SiF_4.2NH_3$ exhibits a strong, broad band at 725 cm^{-1}, which has been identified with stretching vibrations of Si—F bonds in octahedral positions (16). These vibrations occur 305 cm^{-1}

lower than the tetrahedral Si—F bond stretching mode in SiF_4 (17). The doublet at 935 and 905 cm^{-1} in the spectrum of $SiF_4.2NH_3$ might be due to asymmetric and symmetric Si—N stretching vibrations, respectively. A variety of compounds having Si—N bonds show bands in the 900–1000 cm^{-1} region which have been assigned to Si—N stretching vibrations (18–21). The 935 and 905 cm^{-1} doublet in $SiF_4.2NH_3$ strongly suggests that the complex has cis structure. If it were trans, only the asymmetric Si—N stretching mode would be infrared active and only one absorption band would appear. Alternatively, the observed splitting might be due to crystal lattice effects of the type described by Cotton (15, p. 372).

Except for some minor changes in position and intensity, absorption bands of hydrazine and ethylenediamine are easily recognized in their SiF_4 complexes. Like $SiF_4.2NH_3$, $SiF_4.2N_2H_4$ shows a doublet at 988 and 978 cm^{-1}, which probably results from stretching of Si—N bonds in cis positions, although this splitting might be due to crystal lattice

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

effects. Surprisingly, $SiF_4.NH_2(CH_2)_2NH_2$ does not show a similar doublet, unless it is masked by the bands at 903 and 877 cm^{-1} which are characteristic of ethylenediamine. Both $SiF_4.2NH_3$ and $SiF_4.2N_2H_4$ show the strong band near 740 cm^{-1} which is characteristic of Si—F octahedral bond stretching vibrations. If these complexes were trans octahedral, only one Si—F stretching mode would be infrared active and this would produce a single, presumably sharp absorption band near 725 cm^{-1}. By contrast, four Si—F stretching modes would be infrared allowed if the complexes had cis octahedral structure, and four bands would be expected in the 725 cm^{-1} region unless coupling of these vibrations occurred, in which case a broad, unresolved band would probably result. In each of the complexes in Fig. 2 the band near 725 cm^{-1} is broad and poorly resolved. A similar band appears at above 740 cm^{-1} in the spectra of SiF_4 – cyclic amine complexes reported recently by Gutmann *et al.* (9). Although the broadness and lack of detail in these bands might result from solid-state effects, at least in the case of $SiF_4.NH_2(CH)_2NH_2$, undoubtedly cis octahedral, the well-defined maxima in its broad 740 cm^{-1} band are probably associated with its cis structure. In the absence of any convincing evidence to the contrary, we believe that $SiF_4.2N_2H_4$, whose 740 cm^{-1} band shows some detail, also exists in the cis octahedral form. Additional evidence in support of the cis structure is provided by the replacement of two hydrazines by one ethylenediamine, as mentioned earlier. Unfortunately our complexes are insoluble and therefore other measurements such as dipole moment and F^{19} magnetic resonance cannot be made to test the validity of the cis structure for $SiF_4.2NH_3$ and $SiF_4.2N_2H_4$ that was suggested by our infrared data, which are not conclusive.

Muetterties (8) measured the F^{19} magnetic resonance spectra of some soluble octahedral SiF_4 complexes and found only a single resonance line in each case. This suggests trans octahedral structure because a cis configuration would give two triplets of equal intensity. This evidence is not conclusive, however, because fast ligand exchange might prevent detection of the cis form if it existed. Muetterties (22) concluded that the dimethylsulphoxide complexes $SiF_4.2(CH_3)_2SO$ and $GeF_4.2(CH_3)_2SO$ have trans octahedral structure because their infrared spectra show that the S—O stretching bands are not split into two, as they would be if the complexes were cis octahedral. He proposes that in octahedral Group IV tetrafluoride complexes the cis structure is stabilized by secondary π-bonding between acceptor and donor atoms, an effect which appears to be greater in the cis than in the trans form. Such bonding, he suggests, is not significant in SiF_4 complexes so that they are trans. This cannot be true in SiF_4 complexes with NH_3 and N_2H_4 which appear to be cis. Either hyperconjugative π-bonding is strong enough in these complexes to favor the cis form, or other factors are significant. One possibility is dipole–dipole interactions in the solid phase;* these would favor the cis form because its dipole moment is undoubtedly finite while that of the trans form is probably zero. If this effect is predominant, the preferred structure of SiF_4 complexes in the solid should be cis, but in solution they may be either cis or trans. The fact that Muetterties found some SiF_4 complexes to be trans in solution does not preclude the possibility that they might well be cis in the solid state.

Several Group IV tetrahalide complexes appear to exist in the trans form in the solid state. Titanium tetrahalide – nitrile complexes are thought by Rao (23) to be trans because their infrared spectra (as solids in Nujol mulls) do not show splitting of nitrile absorption bands. Brown and Kubota (24) have reported low-frequency infrared data which support a trans structure for solid $SnCl_4.2p\text{-}CH_3OC_6H_4CN$. X-Ray measurements

We are grateful to Dr. A. D. Westland of the University of Ottawa for this suggestion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by Hulme *et al.* (25) reveal that the pyridine complex $GeCl_4.2NC_5H_5$ is trans octahedral, and infrared measurements (as solid deposits on NaCl plates) suggest that $SiCl_4.2NC_5H_5$ and $TiCl_4.2NC_5H_5$ are structurally similar. The reason for the preferred trans structure of these complexes in the solid phase is not obvious.

EXPERIMENTAL

The apparatus and techniques have been described in Part I of this series (3).

Anhydrous hydrazine was obtained by refluxing the 95+% material (Eastman Kodak) for several hours over sodium hydroxide pellets in an atmosphere of dry nitrogen. This was repeated three times with fresh sodium hydroxide pellets before the material was fractionally distilled. The fraction boiling in the range 111–113° was found to be 100% pure by the iodate method (26). Ethylenediamine (Eastman Kodak) was also purified by refluxing with sodium hydroxide pellets followed by fractional distillation in a vacuum; the pure fraction boiled at 117.0° (lit. (27) value 116.1°). Samples (Matheson) of SiF_4, BF_3, HCl, and NH_3 were purified by several low-temperature fractionations immediately before they were used. The purities of all volatile reagents were checked by vapor pressure (v.p.) and molecular weight (M) measurements.

Hydrazine was determined by the iodate method (26) and fluoride as lead chlorofluoride (28). Infrared spectral measurements were made in the range 4000–650 cm^{-1} using a Perkin–Elmer Model 21 spectrophotometer equipped with sodium chloride optics. Samples were examined in KBr disks or in Nujol mulls.

Preparation of $SiF_4.2N_2H_4$

(a) Using Excess SiF_4

When N_2H_4 (12.16 mmole) and SiF_4 (27.57 mmole) were condensed together in a vacuum and warmed to 70°, a vigorous exothermic reaction occurred, producing a finely divided white powder. The amount of SiF_4 (21.32 mmole), recovered by distillation of the product mixture at −130°, showed that SiF_4 (6.25 mmole) and N_2H_4 (12.16 mmole) had combined in a mole ratio of 1:1.95, corresponding to the complex $SiF_4.2N_2H_4$. (Found: N_2H_4, 37.8%; F, 45.4%. Calc. for $SiF_4.2N_2H_4$: N_2H_4, 38.11%; F, 45.18%.)

(b) Using Excess N_2H_4

Silicon tetrafluoride (26.85 mmole) and N_2H_4 (70.50 mmole) gave, on interaction in a vacuum at 70°, a white powder and unreacted hydrazine (16.70 mmole). The mole ratio of SiF_4 to N_2H_4 was 1:2.04, indicating the formation of $SiF_4.2N_2H_4$. (Found: N_2H_4, 38.3%; F, 45.0%. Calc. for $SiF_4.2N_2H_4$: N_2H_4, 38.11%; F, 45.18%.)

(c) Tensimetric Titrations

In the first series of measurements SiF_4 (25.57 mmole) was added in successive small portions to N_2H_4 (22.48 mmole); after each addition the reaction vessel was heated to 70° for 10–15 minutes before it was cooled to −78°, at which temperature pressure measurements were made. The results (Fig. 1A) show that the pressure remained zero until the mole ratio SiF_4/N_2H_4 was 0.5, corresponding to $SiF_4.2N_2H_4$; thereafter the pressure increased due to the excess SiF_4. In a second series of measurements, N_2H_4 (57.47 mmole) was added in successive small portions to SiF_4 (18.76 mmole) and pressure measurements were made as before. As shown in Fig. 1B, the pressure decreased linearly until the mole ratio SiF_4/N_2H_4 was exactly 2.0, when the pressure became zero. The pressure remained zero at higher ratios of N_2H_4/SiF_4 because the product, $SiF_4.2N_2H_4$, and excess N_2H_4 are involatile at −78°. The two titrations prove that the 1:2 complex is the only one formed by SiF_4 and N_2H_4.

Properties of $SiF_4.2N_2H_4$

(a) Thermal Decomposition

When $SiF_4.2N_2H_4$ (2.26 mmole) was heated for 20 hours at 230°, nitrogen (1.05 mmole; found: M, 27.2, calc. for N_2: M, 28.02) and ammonia (1.85 mmole; found: M, 17.2, calc. for NH_3: M, 17.05) were the only volatile products. The non-volatile residue was not homogeneous and no attempt was made to analyze it.

(b) Reaction with HF (55%)

Silicon tetrafluoride – 2-hydrazine (0.2744 g) was treated with 55% HF (3 ml) in a platinum crucible and the mixture heated to 100–110°. The residue was $(N_2H_5)_2SiF_6$ (found: N_2H_4, 30.3%; calc. for $(N_2H_5)_2SiF_6$: N_2H_4, 30.08%) in an amount (0.3405 g) which is slightly greater than expected (0.3397 g) for quantitative conversion of $SiF_4.2N_2H_4$ into $(N_2H_5)_2SiF_6$.

(c) Reaction with Anhydrous HCl

Anhydrous HCl (5.85 mmole) and $SiF_4.2N_2H_4$ (2.93 mmole) were heated together for 12 hours at 150°. The non-volatile product was N_2H_5Cl (found: N_2H_4, 46.6%, m.p. 90°, lit. m.p. (27) 89°; calc. for N_2H_5Cl: N_2H_4, 46.75%), and the volatile product (3.15 mmole; found: M, 94.3) was a mixture of SiF_4 (2.87 mmole) and HCl (0.46 mmole). These results indicate that there was a 91.8% conversion of $SiF_4.2N_2H_4$ into N_2H_5Cl.

(d) Reaction with Ethylenediamine

Anhydrous ethylenediamine (2.8636 g) and $SiF_4.2N_2H_4$ (0.4220 g) were refluxed for 24 hours, and then distilled. The amount of hydrazine (0.1603 g) in the distillate was almost exactly that expected (0.1608 g)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for quantitative displacement of N_2H_4 from $SiF_4.2N_2H_4$ by $NH_2(CH_2)_2NH_2$. The residue was $SiF_4.NH_2(CH_2)_2NH_2$. (Found: F, 46.5%. Calc. for $SiF_4.NH_2(CH_2)_2NH_2$: F, 46.35%.)

(e) Reaction with BF_3

A vigorous reaction occurred when $SiF_4.2N_2H_4$ (2.17 mmole) and BF_3 (11.28 mmole) were heated at 180° for 30 minutes. The volatile product (8.91 mmole; M, 75.7) was a mixture of SiF_4 (2.18 mmole) and BF_3 (6.73 mmole), and the residue was $BF_3.N_2H_4$ (found: N_2H_4, 31.9%, m.p. 86°, lit. m.p. (3) 87°; calc. for $BF_3.N_2H_4$: N_2H_4, 32.09%). Thus, SiF_4 was quantitatively displaced from $SiF_4.2N_2H_4$ by BF_3.

(f) Reaction with NH_3

The reaction of $SiF_4.2N_2H_4$ (2.73 mmole) with NH_3 (6.05 mmole) at 150° for 20 hours produced N_2H_4 (1.67 mmole), unreacted NH_3 (4.36 mmole), and a non-volatile, heterogeneous, white solid. Thus, 1.67 mmole of N_2H_4 was liberated by an equimolar amount (1.69 mmole) of NH_3, indicating that the displacement reaction $SiF_4.2N_2H_4 + 2NH_3 \rightarrow SiF_4.2NH_3 + 2N_2H_4$ had occurred to an extent of only 30.5%. In another experiment $SiF_4.2NH_3$ (1.85 mmole) and N_2H_4 (10.53 mmole) were heated for 20 hours at 150°, and NH_3 (2.78 mmole) was recovered from the product mixture. This indicated that the reverse displacement, i.e. of NH_3 from $SiF_4.2NH_3$ by N_2H_4, was 75.3% complete.

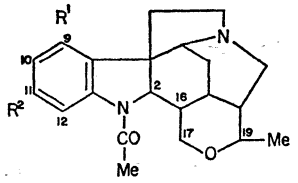
THE STRUCTURE OF STRYCHNOSPERMINE EVIDENCE FROM DOUBLE IRRADIATION AND VARIABLE TEMPERATURE N.M.R.

F. A. L. ANET
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received October 26, 1962

ABSTRACT

The nuclear magnetic resonance spectrum of strychnospermine has been measured at −20°, room temperature, and at +80°. The changes observed are attributed to restricted rotation in the *N*-acetyl group. At room temperature the rate of rotation is such that the band of one aromatic proton is extremely broad and therefore almost invisible. Double irradiation has been used to determine the environment of the *C*-methyl group of the alkaloid. The n.m.r. results confirm the structure previously postulated.

In a previous paper (1) structures I and II respectively were proposed for spermostrychnine and strychnospermine, two alkaloids isolated (2) from *Strychnos psilosperma.* Although the two alkaloids were chemically related to each other and to strychnine, two features, apart from the stereochemistry, remained uncertain, namely the exact position of the cyclic ether ring, and, for strychnospermine, that of the methoxyl group. The



I, $R^1 = R^2 = H$
II, $R^1 = H$, $R^2 = OMe$
III, $R^1 = OMe$ $R^2 = H$

cyclic ether was placed largely on biosynthetic arguments which were not above objections. The methoxyl group of strychnospermine was found to be definitely meta to the nitrogen atom, but the choice between the two alternatives (II and III) was made solely on the basis of minor differences in the ultraviolet spectra and color reactions of the alkaloids and of model compounds of known structures.

In order to try to settle these uncertainties, the high-resolution proton magnetic resonance spectra of the alkaloids were studied. Since the coupling constants in benzenoid compounds vary (3) as follows: $J_{ortho} \sim 8$ c.p.s., $J_{meta} \sim 2$ c.p.s., $J_{para} \sim 0$ c.p.s., the determination of the substitution pattern (II or III) in strychnospermine should be straightforward, provided there is sufficient chemical shift between the aromatic protons that the coupling constants can be measured.

The n.m.r. spectrum of strychnospermine in deuterated chloroform at room temperature is shown in Fig. 1. The doublet at 8.83 τ confirms the presence of a single methyl group, and shows that the adjacent carbon atom bears a single hydrogen atom. Certain features of this band will be discussed later in this paper. The acetyl methyl and the *O*-methyl groups appear as sharp bands at 7.63 τ and 6.23 τ respectively, as expected (4).

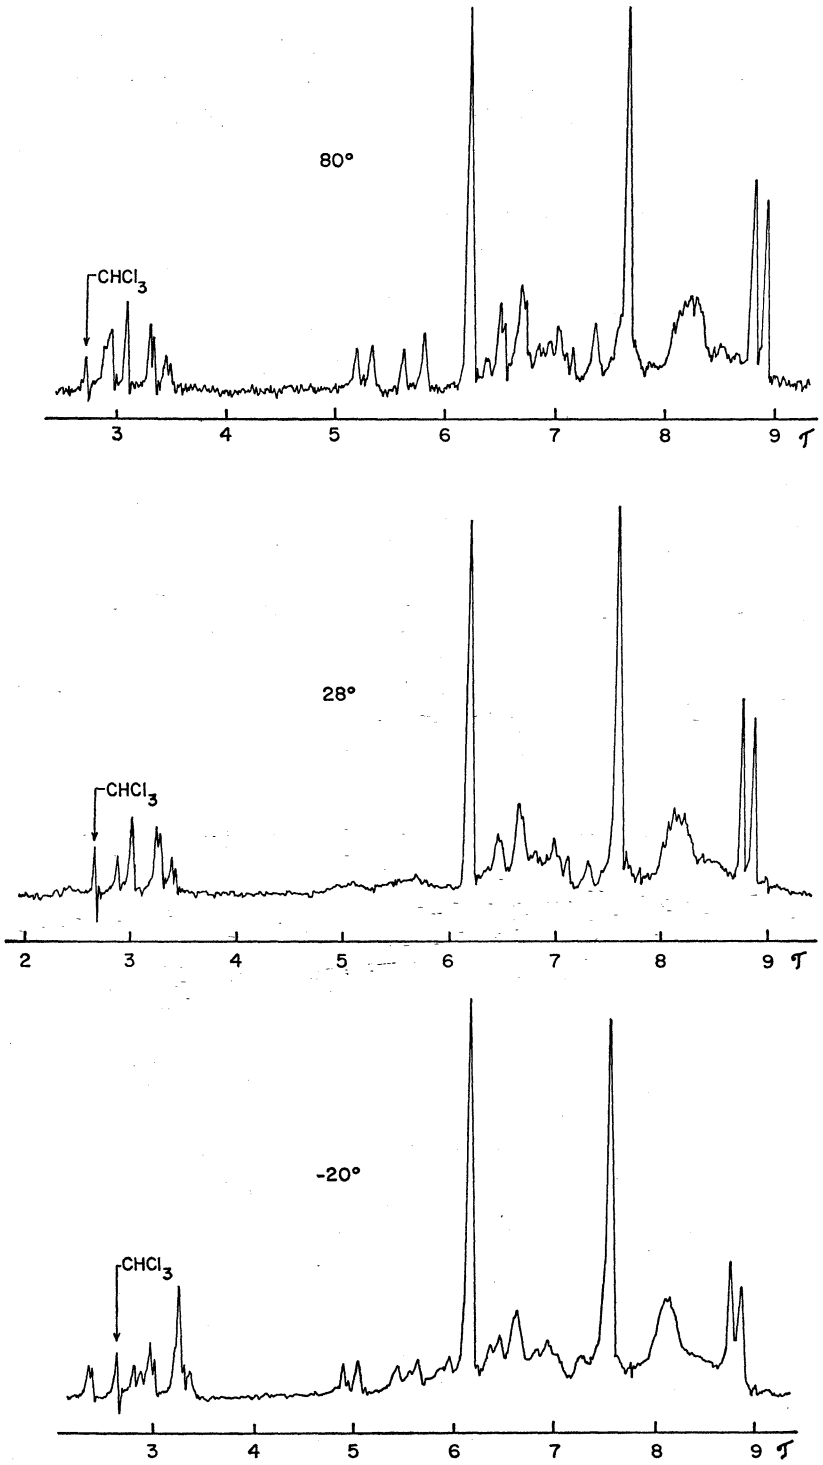

FIG. 1. Nuclear magnetic resonance spectra (60 Mc/sec) of strychnospermine in deuterated chloroform at various temperatures. The scale (3) is in tau units (p.p.m.). Tetramethylsilane was used as an internal standard. Spectra were measured on a high-resolution Varian spectrometer.

The aromatic region of the spectrum is, on the other hand, quite puzzling. Superficially, the bands around 3 τ have the appearance of two protons coupled together by about 8 c.p.s. with the upfield proton further coupled to a third proton by about 2 c.p.s. Unfortunately, there is no sign of bands for this third aromatic proton. To the extent that the spectrum can be interpreted, structure II is supported over structure III, but calculations of ABC spectra show that no theoretical spectra can be matched to the observed bands in the aromatic region.

One possibility is that the band of the third proton is so broad as not to be visible. This can be the case, for example, if the proton is coupled to the nitrogen atom of the dihydroindole ring. The broadening can then be due to quadrupole relaxation, provided this is of the correct magnitude, and that the coupling constant is sufficiently large. Although the α protons of pyridine have been found (5) to be very slightly broadened by such a mechanism, the coupling required in the present case seems to be unreasonably great. This possibility can in fact be eliminated since it is found that the spectrum is unchanged by double irradiation at the nitrogen resonance frequency.

Another reason for broadening can be the presence of the *N*-acetyl group. For example, in *N*,*N*-dimethylacetamide at room temperature, two different methyl signals are observed (6, 7) because of restricted, and hence slow, rotation about the N—CO bond. As the temperature is raised, the two bands become broad and finally coalesce. At still higher temperature, when the rate of rotation about the nitrogen–carbonyl bond has become sufficiently high, only a single, sharp band is observed. Such effects have not been observed in *N*-methylacetanilide (6), but it is not known whether the reason is that the barrier to rotation is too low or whether one conformation is so much more stable that practically none of the compound exists in the alternative conformation. A lower barrier than that in the aliphatic amides would be expected because the resonance interaction of the nitrogen lone pair of electrons with the benzene ring would decrease the amount of double-bond character in the N—CO bond.

Since the bands of the three methyl groups and two aromatic protons of strychnospermine were normal in appearance, it was at first considered that restricted rotation was unlikely as an explanation for the missing third aromatic proton. Nevertheless, measurements of the spectrum at various temperatures clearly reveal that restricted rotation is responsible for the anomalies previously mentioned in the room-temperature spectrum and confirm structure II for strychnospermine. Owing to a remarkable coincidence, the chemical shifts of the three methyl groups and of two aromatic protons change very little on going from one conformation of the *N*-acetyl group to the other. Thus (7) these bands are sharp at room temperature.

As the temperature is lowered, the n.m.r. spectrum of strychnospermine changes greatly. At about $-20°$, the spectrum (Figs. 1 and 2) is no longer changing, and at this temperature, therefore, the two conformations are 'frozen'. What is observed is now the superposition of two spectra, which can be interpreted, in part at least, when taken in conjunction with the high-temperature spectrum described below.

The doublet at 2.35 τ can be assigned to H-12 of conformation A; the low-field position is consistent with the strong magnetic anisotropy of the carbonyl group (3, 8). The band is a doublet ($J \sim 2.3$ c.p.s.) because of coupling with H-10. The band of the same proton in conformation B lies at about 3.25 τ but cannot be seen clearly because of overlap with H-10. H-9 has only slightly different chemical shifts in the two conformations and gives rise to the two overlapping, widely spaced doublets near 2.9 τ as a result of a coupling of ca. 8 c.p.s. to H-10 and practically zero coupling to H-12. The bands (Fig. 2) of H-10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

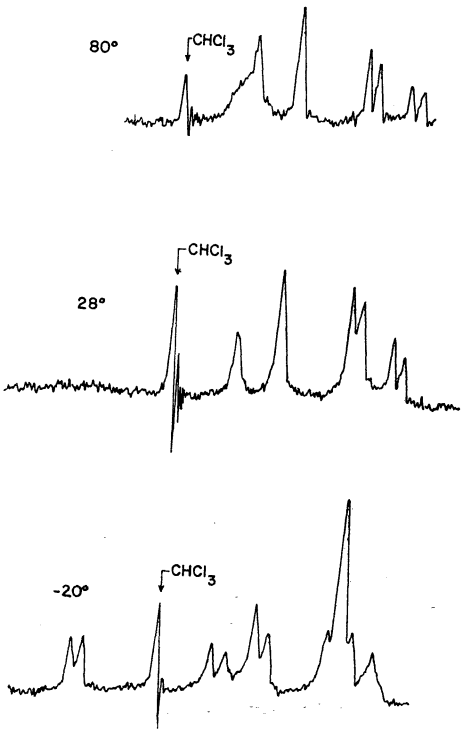

FIG. 2. Nuclear magnetic resonance spectra of the aromatic protons of strychnospermine in deuterated chloroform at various temperatures. The sweep rate is about the same for the three tracings.

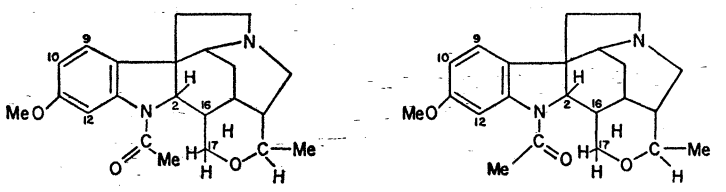


cannot be clearly analyzed because of overlap with part of H-12 and because the splitting pattern would in any case be expected to be complicated. In both conformations the chemical shift of H-10 is about 3.25 τ.

The bands of the methyl groups show practically no change with temperature. This is especially unexpected for the band of the acetyl group, in view of the large magnetic anisotropy of the benzene ring, which should cause a low-field shift of the methyl group in conformation B. The other *C*-methyl group does show slight broadening compared to the room-temperature band and this may be due to a small unresolved chemical shift in the two conformations.

As the temperature is raised from −20°, gradual changes take place, the first being a loss in the doublet character associated with the H-12 of conformation A and the chemical shift difference between H-9 in the two conformations. These changes take place at low temperatures because they involve averaging over only a few c.p.s. At room temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

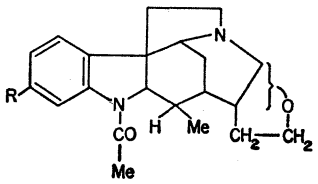
the band of H-12 is almost uniformly spread out over about 55 c.p.s., so that it is not surprising that it is almost completely obscured.

At 80°, the spectrum (Figs. 1 and 2) has become simpler, since rotation around the N—CO bond is now fast enough to cause almost complete averaging of all the protons of the two conformations. H-12 is now a single, rather broad band and at still higher temperatures it should become a sharp doublet (separation, ca. 2 c.p.s.), but measurements were not made above 80°. H-10 and H-11 give the expected bands, reminescent of those found at room temperature, but now of the correct intensities. These results are clearly consistent with structure II but not with III.

The bands at 4.8 to 6.0 τ also show interesting changes with temperature. The low-temperature spectrum is rather difficult to interpret because of superposition of bands. At room temperature all the bands in this region are extremely broad, but at 80° just two doublets of one proton each are left. The lower-field doublet (5.2 τ) (separation 8.7 c.p.s.) can be assigned to H-2, as this should be at quite low field. In *Aspidosperma* alkaloids (9), where H-2 is in a similar environment to the above, the chemical shift is about 5.5 τ. If the stereochemistry is similar to that of strychnine (10), this proton is axial and vicinal to another axial proton (H-16), in keeping with the large coupling constant found.

The other doublet at 5.71 τ (separation 11.3 c.p.s.) is assigned to one of the protons on C-17. Such a proton should show a large (geminal) coupling to the other proton on C-17 and might well show (3) a negligible coupling to H-16 provided that the dihedral angle between the CH bonds lies in the range 70–100°. Its rather low-field position is consistent with the attachment of an oxygen atom to C-17 and to the nearness in space of H-17 to the *N*-acetyl group. The skewness of the intensity of the band is also consistent with coupling to a proton on the same carbon atom and therefore not greatly chemically shifted.

A further confirmation of the position of the cyclic ether ring can be obtained from the *C*-methyl band. The two components of the doublet at 8.83 τ are nearly equal in intensity, suggesting that the proton to which the methyl group is coupled is well downfield, and thus that the methyl group is attached to a carbon atom bearing an electronegative substituent as well as a proton. Although the proton in question cannot be seen, its chemical shift can be determined precisely by double irradiation ("spin decoupling") (11). Thus the proton is found to be at 6.41 τ (145 c.p.s. from the methyl band) in agreement with II but not with a *C*-methyl group in the environment of partial structure IV.



IV

The spectrum of spermostrychnine was studied only at room temperature. Apart from the aromatic region and the lack of a methoxyl band, it is identical with the spectrum of strychnospermine. The aromatic region consists of a single, not very sharp band, as expected.

For personal use only.

The present results show that the n.m.r. spectra of natural products can yield valuable information if taken at different temperatures, and that techniques such as "spin decoupling" are useful.

THE β-D-CONFIGURATION OF THE RIBOSYL NICOTINAMIDE PORTION OF DIPHOSPHOPYRIDINE NUCLEOTIDE

R. U. LEMIEUX AND J. W. LOWN[1]
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received October 9, 1962

ABSTRACT

The configurations of the anomeric *N*-(tetra-*O*-acetyl-D-glucopyranosyl)-3-carboxamidopyridium bromides were established by nuclear magnetic resonance (n.m.r.) spectroscopy. The β-D-anomer was found to undergo deacetylation without anomerization. This compound on oxidation with periodate has been shown (M. Viscontini and E. Hürzeler-Jucker. Helv. Chim. Acta, **39**, 1620 (1956)) to yield a different product than did a synthetic *N*-(D-ribofuranosyl)-3-carboxamidopyridinium chloride. Therefore, the anomeric configuration of the latter compound must be α-D. Since its anomer was used (N. A. Hughes, G. W. Kenner, and A. Todd. J. Chem. Soc. 3733 (1957)) to synthesize diphosphopyridine nucleotide (DPN), the configuration of the anomeric center in this portion of the coenzyme must be β-D. Optical rotatory dispersion curves are reported for DPN, its component nucleotides, and the above-mentioned D-glucosides.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Because of its great biological importance, considerable interest attaches to the structure and configuration of diphosphopyridine nucleotide. The gross structure is well known and has been confirmed by synthesis (1, 2). However, the anomeric configuration of the ribosyl nicotinamide portion has remained an open question. The currently held view that the configuration is β-D rests on the following work by Todd and his co-workers (2). The anomeric *N*-(D-ribofuranosyl)-3-carboxamidopyridinium salts were known, the α-anomer having a specific rotation (D-line of sodium) of +49° (3) and the β-form −28° (1). DPN was synthesized (2) from a mixture of the α- and β-anomers of *N*-(D-ribofuranosyl)-3-carboxamidopyridinium chloride assumed to be present in a 1:4 ratio from arguments based on optical rotation. Since purified synthetic DPN was obtained in about 20% yield and had an active coenzyme content of 90%, it could be concluded that it had formed from the levorotatory D-ribofuranoside which was assigned to the β-series of anomers on the basis of Hudson's rules of isorotation (4). It was tentatively assumed to possess the 1,2-*trans*-configuration by analogy to the structure – optical activity correlations now well established for *O*-glycofuranosides (5). However, it has been recently shown (6) that pyrimidine deoxyribofuranosides may have rotations opposite to those expected on the basis of these rules. It has also been observed[2] that the tri-*O*-acetyl-2-deoxy-2-iodo derivatives of the β-D-glucopyranosyl and α-D-mannopyranosyl pyridinium perchlorates have specific rotations of +157°, +298°, +604°, +1270°, and +1740° for the β-D-isomer and of −4°, −4°, −92°, −380°, and −650° for the α-D-compound at wavelengths of 590, 450, 350, 300, and 280 mμ, respectively. Although these compounds are not anomers, as was found for thymidine and its α-anomer (6), the optical rotatory dispersion trends are definitely opposite to those which would be expected on the basis of Hudson's rules of isorotation. Thus, it can be anticipated that the anomers for these pyranosides, which have an absorbing group attached directly to the anomeric center, may well provide further exceptions to Hudson's rules of isorotation. Clearly, therefore, care must be exercised in the application of these empirical rules for structure – optical activity correlations. As it was pointed out by Todd *et al.* (2), the conclusion,

[1]*University of Alberta Postdoctoral Fellow, 1961–1962.*
[2]*Unpublished results by R. U. Lemieux and A. R. Morgan.*

reached by Viscontini and Hürzeler-Jucker (3) to the effect that the D-ribofuranosyl nicotinamide with rotation +49° possesses the β-configuration, is defective in several respects and can be neglected. As will be seen below, the assignment of the α-configuration to a synthetic D-glucopyranosyl nicotinamide was erroneous and the convention proposed for the assignment of the α- and β-designations to *N*-glycosides which is based on the sign of rotation of the product of oxidation by periodate should be abandoned.

There exists no direct evidence for the assignment of configuration on the basis of optical rotation for *N*-glycosides wherein the nitrogen is quaternized. It is now well established (7, 8) that the n.m.r. signal for the anomeric hydrogen often can be used to unequivocally establish anomeric configurations, since the anomeric hydrogen is generally considerably shifted from the envelope of other C—H resonances and the spin–spin splitting can be related to dihedral bond angle by employing the Karplus relation (9). The purpose of this communication is to demonstrate such an application in the determination of the configurations of the anomeric D-glucopyranosyl derivatives of nicotinamide. Published information (2, 3) could then be used to correlate the configurations of these compounds to the natural D-ribofuranosyl nicotinamide.

The *N*-(tetra-*O*-acetyl-D-glucopyranosyl)-3-carboxamidopyridinium bromides were prepared as described by Haynes and Todd (10). The product (I) which formed in preponderance could be purified simply by recrystallization. The mother liquors provided a residue the n.m.r. spectrum of which required the material to be a roughly equimolar mixture of I and its anomeric form. Repeated partition chomatography and fractional crystallization provided a pure compound (II) with the n.m.r. spectrum expected for the anomer of I.

Compound I, $[\alpha]_D$ −20.5°, provided the n.m.r. spectrum in Fig. 1A. The doublet of intensity one at 6.46 p.p.m. has a spacing of 9 c.p.s. Since the anomeric proton forms part of a strongly coupled system of protons extending around the pyranose ring, one may legitimately question whether the observed spacing reflects the true coupling constant between the protons at the 1- and 2-positions. In fact, such a spacing is influenced by "second order" effects (11, 12) so that, for example, if the protons at the 1,2- and 3-positions form a strongly coupled set, the spacing of the proton is dependent upon the ratio of the chemical shift between the 2- and 3-protons and their coupling constant. The spacing will approximate the true coupling constant more closely the larger the ratio becomes. If this system is regarded as an AMX then the theory of the system (13) states that the separation of the centers of gravity of the two main groups of lines comprising the X branch corresponds to J_{AX}. Therefore, an estimate of the centers of gravity of the two branches of the doublet for the anomeric center may be safely regarded as a *minimum* value of $J_{1,2}$. This is an important consideration when doublet spacings are used to decide anomeric configuration.

In the case of compound I, it is clear that $J_{1,2}$ is approximately 9 c.p.s. Since the compound has a six-membered ring, this value requires the 1- and 2-hydrogens to define a dihedral angle of about 180° (9). Therefore, the compound possesses the β-D-configuration as shown in Fig. 1A. Compound II, $[\alpha]_D$ +22.1°, provided the n.m.r. spectrum shown in Fig. 1B. The doublet of intensity one at 7.06 p.p.m. can be assigned to the anomeric hydrogen. The spacing of 3 c.p.s. requires a dihedral angle of about 60° and the substance therefore possesses the α-D-*gluco*-configuration.

Compounds I and II were deacetylated to afford the β- and α-anomers (III and IV, respectively) for *N*-(D-glucopyranosyl)-3-carboxamidopyridinium bromide. The n.m.r. spectra for these compounds are in obvious agreement with the structures shown in Fig. 2.

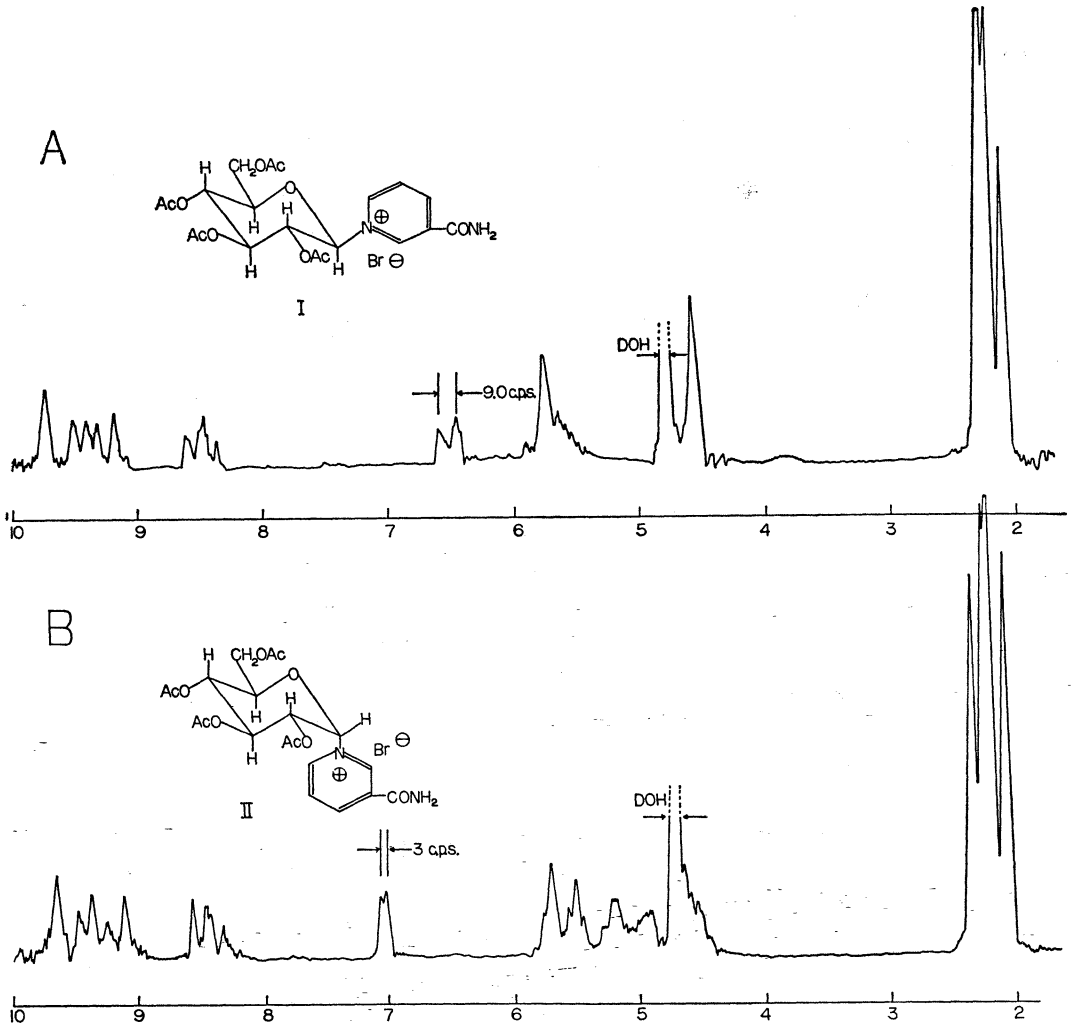

FIG. 1. Nuclear magnetic resonance spectra measured in deuterium oxide and the chemical shifts expressed in p.p.m. from the signal for tetramethylsilane as external reference. A. *N*-(Tetra-*O*-acetyl-β-D-glucopyranosyl)-3-carboxamidopyridinium bromide (I). B. *N*-(Tetra-*O*-acetyl-α-D-glucopyranosyl)-3-carboxamidopyridinium bromide (II).

Thus, the deacetylations proceeded without complication and the configuration of the products are those shown in Fig. 2. It is well established (7) that, for anomeric structures, barring the presence of unusually large screening effects, the axial anomeric proton resonates at higher field than does the equatorial proton. The greater shielding of the axial proton most likely arises from the diamagnetic anisotropy of C—C and C—O bonds in gauche relationship (7, 14). The above configurational assignments are consistent with this finding.

The n.m.r. spectra of DPN and DPNH are shown in Fig. 3. One of the doublets of intensity one at about 6 p.p.m. in the spectrum for DPN can be assigned to the anomeric proton of the ribose residue which is bonded to the pyridine base since one of these signals disappeared on reduction to DPNH. The anomeric configuration cannot be assigned directly from the observed spacing (4 or 5 c.p.s.) since coupling constants of this

magnitude can arise from structures wherein the 1- and 2-hydrogens define dihedral angles of either about 40° or 140°. The 40° angle is readily possible for the hydrogens in either cis or trans relationships on a flexible five-membered ring (15). In fact, for cis-neighboring hydrogens, coupling constants in the range $J_{0°} \cong 8$ to $J_{46°} \cong 3$ c.p.s. can be reasonably expected. When the configurational relationship is trans, the coupling constants can fall in the range $J_{166°} \cong 9$ to $J_{74°} \cong 0.2$ c.p.s. Thus, a direct assignment of configuration can only be made when the coupling constant is very small (in view of the evidence (16) that the Karplus curve is subject to vertical displacements of at least 2 c.p.s., only values less than 1 c.p.s. should be taken as indicative of the trans configuration (17)). These considerations would of course not apply should it be possible to predict with reasonable certainty the conformations of anomeric furanosides.

Viscontini and Hürzeler-Jucker (3) oxidized the compound now known to be III with periodic acid to form a dialdehyde product with a specific rotation of +67°. We have confirmed this result. The periodic acid oxidation of a *N*-(D-ribofuranosyl)-3-carboxamidopyridinium chloride preparation with rotation of +49° provided (3) a dialdehyde with a specific rotation of −70°. Since both dialdehydes were derived from D-sugars, the diastereoisomeric compounds differ only in the configuration of the anomeric center. Since

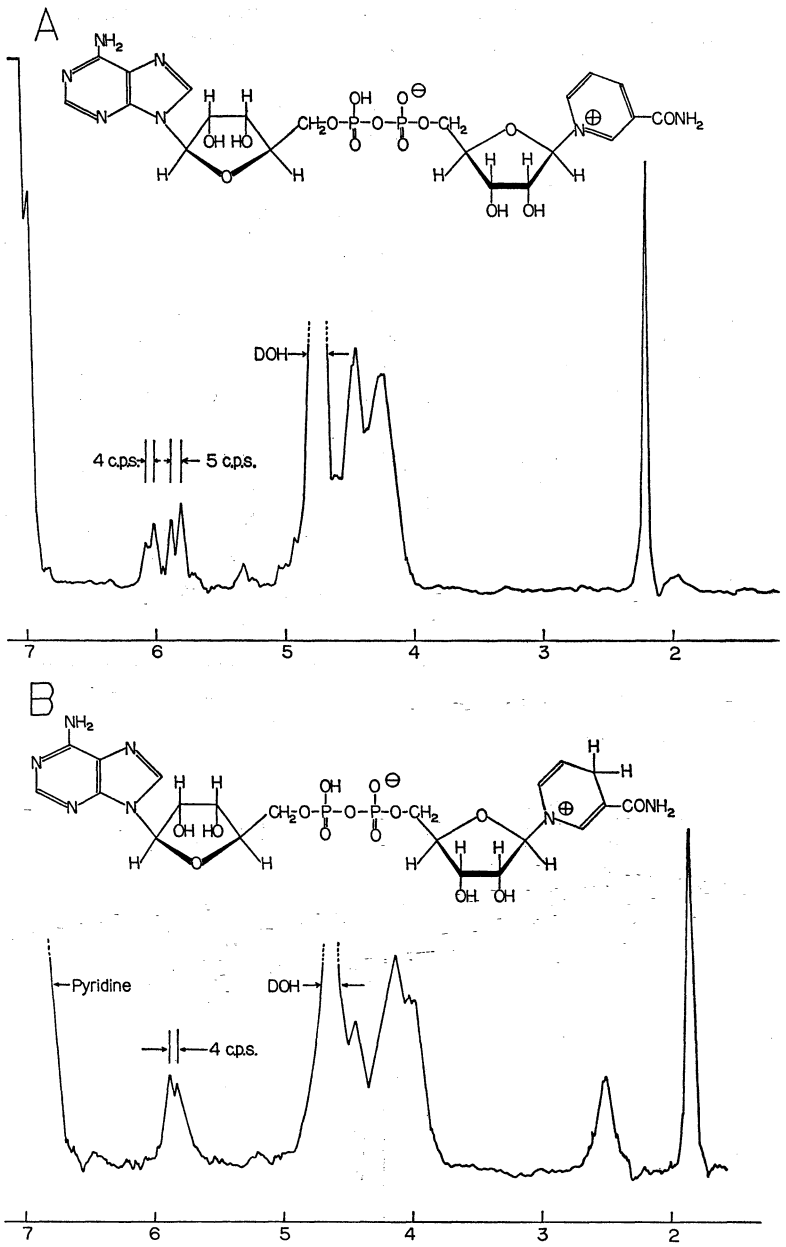

FIG. 3. Nuclear magnetic resonance spectra measured in 1:1 deuterium oxide – pyridine mixture and the chemical shifts expressed in p.p.m. from the signal for tetramethylsilane as external reference. A. Diphosphopyridine nucleotide (DPN). B. Reduced diphosphopyridine nucleotide (DPNH).

compound III is now known definitely to have the β-D-configuration, the dextrorotatory ribonucleoside which was oxidized must have had the α-D-configuration. Therefore, the levorotatory anomer used by Hughes, Kenner, and Todd (1) to synthesize DPN must have had the β-D-configuration and this must be the configuration of the anomeric center of the ribosyl nicotinamide portion of DPN.

EXPERIMENTAL

All n.m.r. spectra were recorded on a Varian A-60 analytical spectrometer operating at a fixed radio frequency of 60 Mc/sec. The spectra were measured on approximately 20% (w/v) solutions in an appropriate solvent using tetramethylsilane as a standard.

The optical rotatory dispersion curves were measured on a Rudolph automatic recording spectropolarimeter, Model 260/655/850–614, using about 10^{-3} *M* aqueous solutions at room temperature. The nucleotides reported in Figs. 3 and 5 were purchased from Pabst Laboratories, Milwaukee, Wisconsin.

Tetra-O-acetyl-β-D-glucopyranosyl-3-carboxamidopyridinium Bromide (I) and its α-Anomer (II)

A solution of 15 g of freshly recrystallized tetra-*O*-acetyl-α-D-glucopyranosyl bromide and 5 g of nicotinamide in 70 ml of dry acetonitrile was heated on the steam bath for 4 hours under conditions similar to those employed by Haynes and Todd (10). The crystalline precipitate, 12 g (60% yield), was purified by recrystallization from methanol. The pure substance (I) melted with decomposition at 193–195° and possessed a $[\alpha]_D^{24} = -20.5°$ (*c*, 2.09 in water). The values reported (10) for these physical constants are m.p. 195–200° (decomp.) and $[\alpha]_D^{19} = -18.3°$. The n.m.r. spectrum is reported in Fig. 1A and the optical rotatory dispersion in Fig. 4.

The filtrate was evaporated to dryness under reduced pressure and the residual dark oil taken up in 30 ml of chloroform. After filtration, 150 ml of anhydrous ether was added. The resulting white precipitate was washed with ether and dried *in vacuo*. The n.m.r. spectrum showed two doublets, of approximately equal intensity, at 2.94 and 3.54 τ assignable to anomeric protons. The material was therefore subjected to partition chromatography (18) on Celite with *n*-butanol – diethyl ether (3:2) saturated with water as eluant. The fraction of the eluant which contained the α-nucleoside was identified by n.m.r. and was purified by several recrystallizations from a mixture of isopropanol and acetonitrile. The white crystalline powder (II), m.p. 185–190° and $[\alpha]_D^{24} = +22.1$ (*c*, 7 in water), possessed the n.m.r. spectrum reported in Fig. 1B, which showed it to be free of the β-anomer. The optical rotatory dispersion is shown in Fig. 4. Haynes and Todd (10) have reported an amorphous preparation of II with a specific rotation of +20.9° in water.

N-(β-D-Glucopyranosyl)-3-carboxamidopyridinium Bromide (III)

The acetylated glucoside (I), 2.03 g, was dissolved in 200 ml of a 3% solution of hydrobromic acid and the solution was kept at 45° for 20 hours. The solution was evaporated to dryness and the residual oil was treated with 1 ml each of isopropanol and acetonitrile and set aside at 0°. After 3 weeks, crystallization occurred and the solid was purified by recrystallization from a 1:1 mixture of isopropanol and ethanol. The yield was 0.624 g (39%) of material (III) with the physical constants, m.p. 151–152°, $[\alpha]_D^{27}$ +29.4 (*c*, 3.1 in water), in good agreement with the literature values (19). The n.m.r. spectrum is reported in Fig. 2A and the optical rotatory dispersion in Fig. 4.

A solution of 98.2 mg of the glucoside (III) in 5 ml of water was kept at 0° with 192 mg of sodium metaperiodate. After 4 hours, the rotation of the solution reached a steady value, $[\alpha]_D^{25} = +63.8°$ (*c*, 2.5 in water).

N-(α-D-Glucopyranosyl)-3-carboxamidopyridinium Bromide (IV)

The pure crystalline acetylated α-D-glucoside (II), 164 mg, was dissolved in 10 ml of a 3% solution of hydrobromic acid and kept at 45° for 24 hours. The solution was lyophilized to leave 100 mg of a dark gum which could not be induced to crystallize. The substance was dissolved in chloroform and reprecipitated as a yellow gum by the addition of anhydrous ether. The n.m.r. spectrum reproduced in Fig. 2B establishes beyond doubt the identity of the substance (IV) which gave the optical rotatory dispersion shown in Fig. 4.

ACKNOWLEDGMENTS

This research was supported in part by a National Research Council of Canada grant (T172) to R. U. L. The n.m.r. spectra and the optical rotatory dispersions were measured by R. N. Swindlehurst of this laboratory.

HYDROLYTIC REACTIONS OF DISULPHUR MONOXIDE IN A HOMOGENEOUS MEDIUM

C. G. RAMACHANDRAN NAIR AND A. R. VASUDEVA MURTHY
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, India
Received September 27, 1962

ABSTRACT

The hydrolytic reactions of disulphur monoxide are studied in a homogeneous medium. Alkaline hydrolysis gives a mixture of sulphide, sulphite, and thiosulphate. Hydrolysis in the presence of sulphite in neutral medium gives equimolar amounts of trithionate and thiosulphate. These reactions are closely similar to the reactions of derivatives of thiosulphurous acid. The production of trithionate is explained on the basis of the formation of thiosulphurous acid as the primary product during hydrolysis and therefore it is suggested that disulphur monoxide is the true anhydride of this acid.

INTRODUCTION

It has recently been shown (1) that pure solutions of disulphur monoxide, S_2O, in carbon tetrachloride can be prepared by absorbing the products of combustion of sulphur in oxygen at 5 to 7 mm pressure, in the dry solvent kept cooled at $-16°$. Since the solubility of sulphur dioxide in carbon tetrachloride at this temperature is small, any dissolved sulphur dioxide could be conveniently pumped off. Somewhat more concentrated solutions could be prepared (2, 3) in toluene (at $-75°$) and anisole (at $-16°$), but these solutions were largely contaminated with sulphur dioxide, which could not be completely removed.

In view of the probable status of disulphur monoxide as the anhydride of the hypothetical thiosulphurous acid, $H_2S_2O_2$, an investigation of its hydrolytic reactions was undertaken in a homogeneous medium. It has been found advantageous to study the hydrolytic reactions in homogeneous media, since elemental sulphur and its compounds are more amenable to such studies (4, 5). Highly reactive species of sulphur compounds have been postulated as intermediate species during these reactions.

The hydrolytic reactions of disulphur monoxide in alkaline and sulphite solutions have been carried out. The products of reaction are sulphide, sulphite, and thiosulphate in alkaline hydrolysis and equimolar amounts of trithionate and thiosulphate in the reaction with sulphite.

EXPERIMENTAL

(a) Preparation of Disulphur Monoxide Solutions

The apparatus employed was essentially similar to that of Schenk (6) except that a quartz tube was used to burn sulphur (1). Sulphur was burnt in a stream of pure dry oxygen at a pressure of 5 to 7 mm and the products of combustion were absorbed in cooled organic solvents in suitable traps. The following organic solvents, kept cooled at the temperature noted against each, were used: toluene ($-75°$), anisole ($-25°$), carbon tetrachloride ($-16°$), and dioxane ($+20°$). All the solutions were clear yellow to orange-yellow in color.

(b) Analysis of the Disulphur Monoxide Solutions (1)

Aliquots of the disulphur monoxide solutions were shaken up with mercury in an all-glass assembly, when the disulphur monoxide decomposed, forming mercuric sulphide and sulphur dioxide in terms of the equation

$$2S_2O + 3Hg \rightarrow 3HgS + SO_2. \qquad [1]$$

The sulphur dioxide was swept off by a stream of pure dry nitrogen, absorbed in dilute alkali, and estimated iodometrically. The mercuric sulphide was estimated by the hydriodic acid method (7). It may be seen

from equation [1] that for a pure solution of disulphur monoxide, the ratio HgS/SO_2 should be 3. The results of the "mercury decomposition reaction" are presented in Table I.

TABLE I

6	Dioxane	57.95	125.10	183.05	77.27

*Quantities of sulphur and sulphur compounds are all expressed in terms of g-atoms of $S \times 10^5$.

(c) Procedure for Hydrolytic Reactions

The hydrolytic reactions were carried out in a homogeneous medium as follows: Forty-five milliliters of an aqueous solution of carbonate-free sodium hydroxide (or sodium sulphite—for the sulphite reaction) was taken in a 500-ml stoppered conical flask, and 100 ml of aldehyde-free ethyl alcohol was added to it. To this solution was added 5 ml of the disulphur monoxide solution, and the mixture was shaken well, when a homogeneous solution was obtained. In the case of the dioxane solutions, addition of alcohol was not necessary for homogenization since dioxane is completely miscible with water. The yellow color of the disulphur monoxide solution disappeared quickly with the progress of the reaction.

The products of reaction were analyzed by the analytical procedures of Kurtenacker and co-workers (8) for a mixture of sulphide, sulphite, thiosulphate, and polythionates. Typical results of the alkaline hydrolysis and of the sulphite reaction are given in Tables II and III respectively.

TABLE II

Alkaline hydrolysis of disulphur monoxide solutions*

(Overall alkali strength 1.0 *N*; 5-ml aliquots of S_2O solutions taken)

Expt. No.	Solvent	S_2O content	Free SO_2 content	$S^=$ formed	$SO_3^=$ formed	$S_2O_3^=$ formed	Elemental S	Total S
1	Carbon tetrachloride	26.00	0.30	8.70	7.10	10.60	Nil	26.40
2	Toluene	41.87	318.60	6.30	307.60	52.10	"	366.00

6†	Nil	—	—	37.4	1301.3	145.00	11.6	1495.3
7†	Nil	—	—	65.2	1150.0	151.8	22.0	1389.0

*Quantities of sulphur and sulphur compounds are all expressed in terms of g-atoms of sulphur $\times 10^5$.
†In these experiments the products of combustion were directly absorbed in 1 *N* NaOH (50% alcoholic solution). In expt. 7, a suspension of cadmium hydroxide was taken along with the sodium hydroxide solution.

It was of interest to study the reactions of disulphur monoxide with aqueous solutions of alkali and sulphite, without prior dissolution in organic solvents. The products of combustion were accordingly passed through aqueous alkali or sulphite solutions (containing alcohol to inhibit the oxidation of sulphite) at −5°. The results of these experiments are also included in Tables II and III.

All the hydrolytic reactions in homogeneous medium were carried out at the laboratory temperature (25±2°).

RESULTS

It may be seen from Table I that the HgS/SO_2 ratio is nearly 3 for solutions in carbon tetrachloride, indicating that these were fairly pure solutions of disulphur monoxide. The solutions in other solvents were largely contaminated with sulphur dioxide. The disulphur monoxide content of all the solutions could be computed in all cases from the mercury

decomposition reaction. It may be seen from equation [1] that, expressing quantities of sulphur compounds in terms of g-atoms of sulphur, $S_2O = 4/3\ HgS$.

Alkaline Hydrolysis

The products of alkaline hydrolysis of disulphur monoxide solutions in homogeneous medium were found to be sulphide, sulphite, and thiosulphate (Table II). For the carbon tetrachloride solutions, the percentage yields of sulphide, sulphite, and thiosulphate were about 32%, 28%, and 40% respectively. In the case of the other solutions, the sulphite yields were considerably higher, this being due to the free sulphur dioxide retained by these solvents.

Alkaline hydrolysis of disulphur monoxide solutions has been studied earlier employing a two-phase-reaction technique (1, 9). Solutions of disulphur monoxide in carbon tetrachloride were shaken with aqueous alkali containing some cadmium hydroxide suspension. The products obtained were sulphide (16%), sulphite (18%), thiosulphate (29%), and elemental sulphur (37%). No elemental sulphur is formed in the present homogeneous hydrolysis, because elemental sulphur is quantitatively hydrolyzed by alkali in homogeneous medium to a mixture of sulphide, thiosulphate, and a small quantity of sulphite (4).

When the products of combustion were directly absorbed in 1 N alkali containing 50% alcohol, colloidal white sulphur was rapidly formed. The other products were sulphide, thiosulphate, and sulphite (experiments 6 and 7 in Table II). The ratio of sulphide to thiosulphate was increased when a suspension of cadmium hydroxide was taken along with the sodium hydroxide solution, since the sulphide was now fixed as soon as it was formed (4).

Reaction with Sulphite

It may be seen from Table III that the products of reaction of disulphur monoxide with sulphite are trithionate and thiosulphate. Approximately equimolar amounts of trithionate and thiosulphate were obtained in the case of carbon tetrachloride solutions,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

whereas considerably greater thiosulphate yields were obtained for the other solutions. It was interesting to find that the thiosulphate yield was only slightly higher than the trithionate yield when the products of combustion were directly absorbed in aqueous sulphite solution (experiments 14 and 15 in Table III). The solutions in this case were clear and colorless.

DISCUSSION

The results of the present investigation show that the hydrolytic reactions of disulphur monoxide are similar to those of disulphur dichloride (5), and of dialkyl thiosulphites and tetraalkyl dithiodiamines (10). All these compounds have been looked upon as derivatives of the hypothetical thiosulphurous acid, $H_2S_2O_2$; the common hydrolytic reactions may be considered as reactions of this acid, which is formed as primary product during the hydrolysis of these compounds:

$$S_2X_2 + 2H_2O \rightarrow H_2S_2O_2 + 2HX \qquad [2]$$

(where X = Cl, OR, or NR_2)

$$S_2O + H_2O \rightarrow H_2S_2O_2. \qquad [3]$$

Thiosulphurous acid has been known to give rise to sulphide, sulphite, and thiosulphate during the alkaline hydrolysis of its derivatives in a homogeneous medium (5, 10).

On the basis of the quantities of sulphide, sulphite, and thiosulphate produced during the hydrolytic reaction, it is possible to calculate the oxidation state of sulphur in disulphur monoxide and it is found to be +1.28. From the consideration of the structure of S_2O and also from the results of the oxidation studies of derivatives of S_2O such as the esters and amides of thiosulphurous acid, $S_2(OR)_2$, $S_2(NR_2)_2$, it has been shown that the average oxidation state of sulphur in S_2O is +1 (11). This average oxidation state of sulphur in S_2O also follows from the equation for complete oxidation:

$$S_2O + 5(O) \rightarrow 2SO_3,$$

where 10 equivalents of oxidant are required to bring both the sulphur atoms in S_2O to the sulphur trioxide stage. From this theoretical consideration also the oxidation state of sulphur in S_2O should be +1. However, the average oxidation state of sulphur obtained by hydrolytic reactions is slightly higher than the expected one. This discrepancy may perhaps be attributed to the complicated nature of the reaction involving hydrolysis, decomposition, and thionization of S_2O as well as the hydrolysis of elemental sulphur in homogeneous medium.

In addition to the above reactions, there is the possibility of polysulphide formation during the hydrolytic process. This has been observed in the hydrolytic reactions of the derivatives of thiosulphurous acid, of which disulphur monoxide is the anhydride. The formation of the polysulphide was indicated by a yellow color found at the initial stages which fades off gradually as thiosulphate forms. This particular step increases the positive oxidation state of the sulphur. However, it is difficult to evaluate this quantitatively.

The formation of equimolar amounts of trithionate and thiosulphate during the reaction with sulphite in a neutral medium is a characteristic reaction of thiosulphurous acid (12). The primary product would be tetrathionate, formed according to the equation

$$OH—S—S—OH + 2HSO_3^- \rightarrow {}^-O_3S—S—S—SO_3^- + 2H_2O. \qquad [4]$$

But tetrathionate is known to undergo quantitative degradation in a neutral or faintly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

alkaline medium to give trithionate and thiosulphate, by the action of excess of sulphite:

$$S_4O_6^{=} + SO_3^{=} \rightarrow S_3O_6^{=} + S_2O_3^{=}. \quad [5]$$

It may be seen that disulphur monoxide answers this reaction almost quantitatively, as may be seen from the nearly equimolar amounts of trithionate and thiosulphate formed in the case of the carbon tetrachloride solutions as well as in the direct reaction of the gaseous product with sulphite solutions.

The considerably greater yields of thiosulphate and lower yields of trithionate in the experiments using solutions in toluene, anisole, and dioxane must be attributed to the complications arising from the large contamination of these solutions with sulphur dioxide. A direct thionization reaction,

$$2S_2O + 2SO_2 + 3H_2O \rightarrow 3H_2S_2O_3, \quad [6]$$

involving part of the disulphur monoxide, would perhaps explain this greater thiosulphate yield. It may be noted that significant amounts of trithionate are formed even in the case of these solutions.

The technique of homogeneous hydrolysis adopted in the present investigation enabled the reactions to be carried out fast, minimizing the chance for the decomposition of disulphur monoxide. The present studies seem to indicate that disulphur monoxide is the anhydride of the hypothetical thiosulphurous acid.

ACKNOWLEDGMENT

The authors wish to express their grateful thanks to Professor M. R. A. Rao for his kind interest in the work.

THE STUDY OF VIBRATIONALLY EXCITED N_2 MOLECULES WITH THE AID OF AN ISOTHERMAL CALORIMETER[1]

J. E. MORGAN AND H. I. SCHIFF
Upper Atmosphere Chemistry Group, McGill University, Montreal, Que.

Received November 26, 1962

ABSTRACT

Vibrationally excited nitrogen molecules produced both by a microwave discharge in nitrogen and also by the reaction

$$N + NO \rightarrow N_2 + O + 75 \text{ kcal}$$

have been examined using an isothermal calorimetric probe.

In the first case the energy associated with an 'active' nitrogen stream, due to vibrationally excited N_2, was found to be 6.03 kcal mole^{-1} of total nitrogen. The subsequent relaxation of this species was found to occur almost entirely on the walls of the reaction vessel, with a collision efficiency of 4.5×10^{-4}. The addition of other gases greatly accelerated the homogeneous relaxation rate. Collisional efficiencies of N_2O, CO_2, and Ar were found to be 0.8×10^{-4}, 2.3×10^{-5}, and 1.0×10^{-6} respectively.

The vibrationally excited nitrogen produced by the N/NO reaction was found to possess 20 ± 4 kcal mole^{-1} of energy compared with the maximum of 75 kcal mole^{-1} allowed by the exothermicity of the reaction.

Calorimetric probes have been used extensively to measure atom concentrations. Such probes measure either the temperature rise (1) or the energy release (2, 3) resulting from atom recombination on a catalytic surface. They are, however, non-selective, and other energetic species, such as vibrationally and electronically excited molecules, can also be deactivated on these surfaces. While this places a serious restriction on the use of such probes for atom measurement, it affords a way of studying other excited species if the energy release due to atom recombination can be estimated independently.

The energy content of 'active' nitrogen, due to ground state (^4S) nitrogen atoms, can be calculated from their concentration determined by NO titration. This calculated energy content was compared in the present work with the energy content measured with an isothermal calorimetric probe. The discrepancy between these values clearly demonstrates the presence of energetic species other than ground state atoms in 'active' nitrogen. The presence of substantial quantities of vibrationally excited molecules in 'active' nitrogen has been inferred by Kaufman and Kelso (4) and observed spectroscopically by Dressler (5).

The nitrogen formed in the reaction

$$N + NO \rightarrow N_2 + O + 75 \text{ kcal} \qquad [1]$$

can also be expected to be vibrationally excited (6). Phillips and Schiff (7) have shown that the nitrogen produced in this reaction is capable of dissociating ozone, and must therefore be excited to at least the fourth vibrational level. This species was also investigated in the present study.

EXPERIMENTAL

Apparatus

The probe used in this study was of the 'isothermal' type described by Elias *et al.*(3). It consisted essentially of a filament through which an accurately measured electric current could be passed. In the absence of an

[1]*This work was supported in part by the U.S. Air Force Cambridge Research Laboratories and in part by the Defence Research Board of Canada.*

activated gas the power input to the probe has some arbitrary value P_0. When the gas is activated, the electrical power input is reduced to a value P_f sufficient to restore the resistance (and consequently the temperature) of the filament to its original value. The difference $P_0 - P_f$ can then be equated to the rate of energy release to the probe from the gas.

The essential features of the apparatus are shown in Fig. 1. The reaction vessel consisted of a 26 mm I.D.

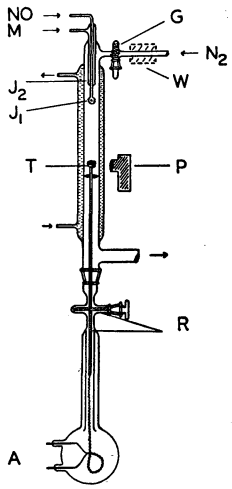

FIG. 1. Reaction vessel. W = microwave cavity; G = glass-wool plug; J_2 = inlet for M; J_1 = inlet for NO; P = photomultiplier; T = calorimetric probe; R = rack and pinion; A = leads from probe to resistance bridge.

pyrex tube surrounded by a water jacket. Nitrogen (Dinsmore Premium grade) was subjected to a 2450 Mc/s microwave discharge and was passed through the reaction tube at linear flow rates of 100–300 cm sec^{-1}. The relative N-atom concentration was determined as a function of the distance, d, along the reaction tube by measuring the afterglow intensity with a 1P21 photomultiplier. This detector was equipped with collimating slits and could be moved on rails parallel to the reaction tube. The absolute N-atom flow rate at J_1 ($t = 0$) was determined by NO titration.

The NO inlet jet, J_1, consisted of a spherical bulb containing 6 peripheral holes of 0.20 ± 0.01 mm diameter. The inlet J_2, concentric with J_1, was of similar construction. Close tolerances of the hole diameters were found to be essential for good mixing. The filament of the catalytic probe was made of approximately 100 cm of 28 B and S gauge platinum wire. Several catalytic surfaces were examined for use in the 'active' nitrogen system. Although freshly electroplated copper appeared to be very efficient in terminating the afterglow, volatile materials were found to be liberated during use, which contaminated the walls of the reaction tube. A cobalt surface electroplated from a dilute solution of ammoniacal cobalt sulphate was found to be equally efficient and free from this defect. It was therefore used throughout the work on the 'active' nitrogen system.

To examine the vibrationally excited nitrogen from the NO reaction (1), it was necessary to use a surface capable of recombining atomic oxygen. A silver peroxide coating formed by electroplating silver from a dilute solution of carefully purified $KAg(CN)_2$ followed by exposure to atomic oxygen was found to be very effective in this system.

'Active' Nitrogen System

A stream of partially dissociated nitrogen was first titrated with NO, which was added through inlet J_1. The end point of the titration is defined by the absence of either the blue NO emission obtained when N atoms are in excess, or the greenish NO_2 emission obtained when NO is in excess. After recording its value at the end point, the NO flow was discontinued. The relative nitrogen atom concentration along the reaction tube was then determined with the movable photomultiplier tube.

From these measurements the rate of energy release to the probe, arising from atom recombination, H_A, can be calculated from the relation

$$H_A = f_N(D/2) \text{ mcal sec}^{-1},$$

where f_N is the flow rate of atomic nitrogen in μmole sec^{-1} and D is the dissociation energy of N_2 in kcal $mole^{-1}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A typical plot of H_A against t is shown as curve A in Fig. 2. The rate of energy release actually measured by the probe, H_E, is shown as curve B. Curve C is a plot of ln ΔH, where $\Delta H = H_E - H_A$.

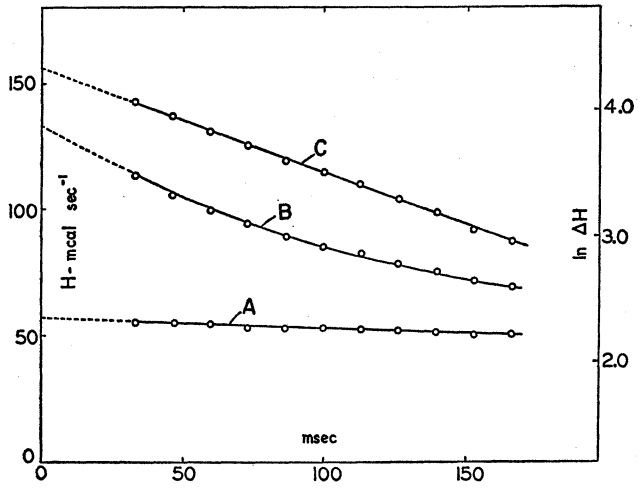

FIG. 2. Probe measurements on discharged nitrogen at $P_{N_2} = 1.65$ torr and $(P_N)_0 = 0.014$ torr. (A) H_A calculated from atom concentration at $t = 0$ and afterglow intensity; (B) H_E measured by cobalt-plated probe; (C) ln $(H_E - H_A)$.

The discrepancy between H_E and H_A indicates that some excited species, N_2^*, is being deactivated on the probe in addition to the recombination of atoms. The observed exponential decay of ΔH is consistent with a collisional deactivation mechanism such as

$$N_2^* + N_2 \rightarrow N_2 + N_2 \qquad [2]$$

$$N_2^* + \text{wall} \rightarrow N_2 + \text{wall} \qquad [3]$$

Such a mechanism would yield a pressure-dependent first-order rate constant given by

$$k_{obs} = k_2[N_2] + k_3$$

and a plot of k_{obs} against $[N_2]$ should permit evaluation of k_2 and k_3. Table I gives the results of four determinations of k_{obs} at different pressures. The independence of k_{obs} on $[N_2]$ suggests that $k_2 = 0$. The

homogeneous deactivation of N_2^* therefore appears to be extremely slow and virtually all the deactivation occurs on the walls. The average value of k_3 found in this way is 8.8±0.3 sec^{-1}. This can be expressed as a heterogeneous collisional deactivation coefficient, γ, by use of the familiar relation

$$\gamma = \frac{2k_3 r}{\bar{c}} = (4.5\pm0.2)\times10^{-4},$$

where r is the radius of the tube and $\bar{c}$ the average molecular velocity.

The magnitude of the energy $E_{N_2}^*$ associated with the excited molecules in the gas equals $\Delta H/f_{N_2}$, where f_{N_2} is the total molar flow rate of N_2. The value of $E_{N_2}^*$ just below the discharge should indicate the energy content of the excited molecules formed by the discharge. The varying geometry of the apparatus between the discharge and the reaction tube, as well as the ill-defined position of the discharge, make a direct extrapolation difficult. However, if the energy content of the gas stream leaving the discharge is independent of pressure, the value of $E_{N_2}^*$ at the *effective* discharge position can be obtained from the intersection of two or more plots of ln ΔH against d at different pressures. These plots will have different slopes due to the differences in time scales.

Figure 3 shows the data of four such experiments plotted in this way. The point of intersection corresponds to a value of $E_{N_2}^* = 6.03$ kcal mole^{-1}.

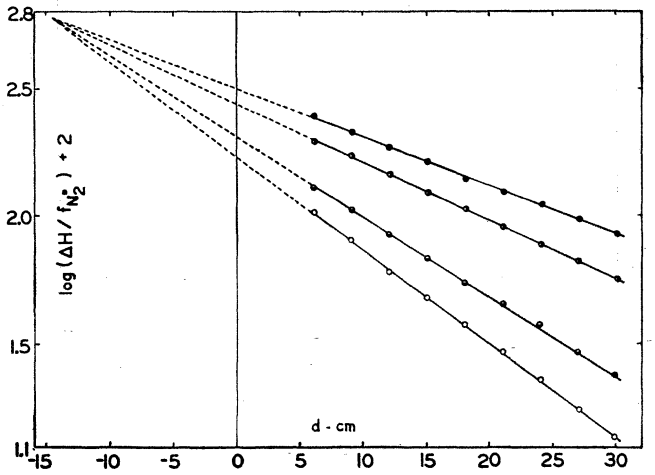

FIG. 3. Probe measurements of discharged nitrogen at four different linear flow rates f_{N_2}. ● $f_{N_2} = 200$ cm sec^{-1}, $P_{N_2} = 2.3$ torr, $(P_N)_0 = 0.0188$ torr; ◑ $f_{N_2} = 165$ cm sec^{-1}, $P_{N_2} = 2.95$ torr, $(P_N)_0 = 0.0229$ torr; ◒ $f_{N_2} = 126$ cm sec^{-1}, $P_{N_2} = 4.10$ torr, $(P_N)_0 = 0.0313$ torr; ○ $f_{N_2} = 110$ cm sec^{-1}, $P_{N_2} = 5.84$ torr, $(P_N)_0 = 0.0415$ torr.

Addition of N_2O through inlet J_2 was found to be an effective means of deactivating N_2^*, in agreement with the findings of Kaufman and Kelso (4). Figure 4 shows that the addition of N_2O at a rate approximately

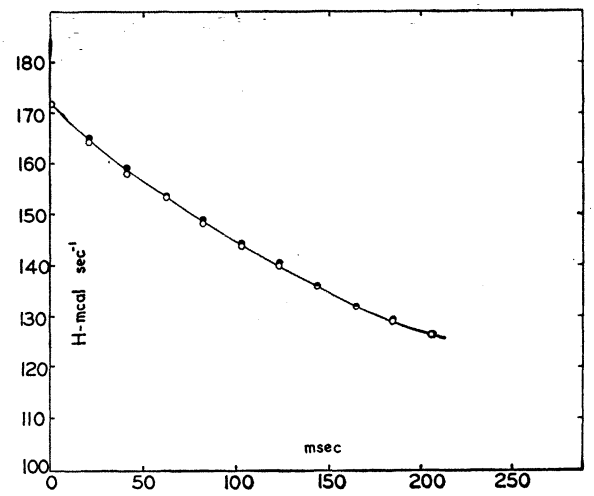

FIG. 4. Probe measurements of discharged nitrogen to which N_2O had been added. $P_{N_2} = 3.80$ torr; $P_{N_2O} = 0.37$ torr. ○ heat calculated from atom concentration at $t = 0$ and afterglow intensity; ● heat measured by probe.

0.1 that of the nitrogen flow rate resulted in the measured energy release to the probe being identical with that calculated for N atoms alone. These results also confirm the validity of the NO titration as a quantitative method for determining N-atom flow rates. In addition, it may be inferred that most of the N atoms are present in their ground state since the calculated energy release, H_A, was obtained using $D_{N_2} = 225$ kcal mole^{-1}.

To obtain a measure of the efficiency of N_2O, CO_2, and Ar in deactivating N_2* much lower flow rates of these gases were used. The observed relaxation rate constants were measured as a function of the concentration of added gas. The results, plotted in Fig. 5, suggest that deactivation occurs by reaction [3] and by

$$N_2^* + M \rightarrow N_2 + M. \qquad [4]$$

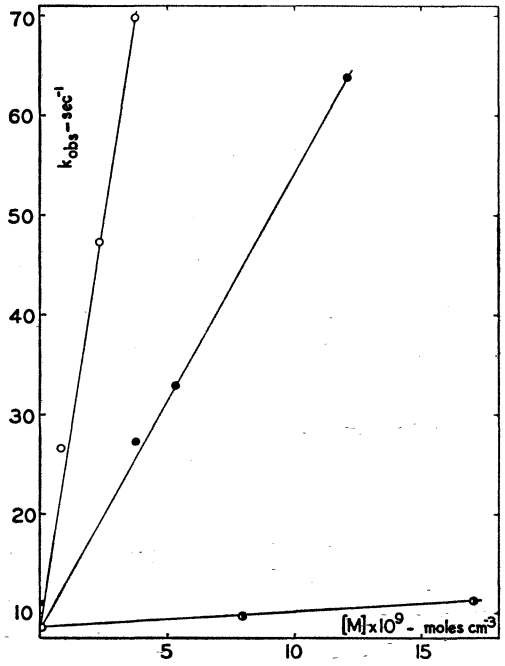

FIG. 5. Variation of deactivation rate of N_2* as a function of the concentration of added gas M. ○ N_2O; ● CO_2; ◑ Ar.

The overall rate constant will be given by

$$k_{obs} = k_4[M] + k_3.$$

Values of k_4 obtained from the slopes of these plots are given in Table II. The values of the homogeneous

collisional efficiencies, α_M, were calculated from the relation

$$\alpha_M = k_4/[1.142\times10^4(\sigma_{N_2}{}^*+\sigma_M)^2\left(\frac{M_{N_2}+M_M}{M_{N_2}\cdot M_M}\right)^{\frac{1}{2}}\cdot T^{\frac{1}{2}}],$$

where σ and M represent collision diameters and molecular weights respectively.[2] Although α_{N_2} was found to be zero in these experiments, an upper limit of 2×10^{-8} can be set from the magnitude of the experimental errors.

Vibrationally Excited $N_2{}^+$ Produced in the NO-titration Reaction

The titration of 'active' nitrogen with NO produces atomic oxygen and molecular nitrogen which may possess all or part of the exothermicity of the reaction. Such a system will, however, contain excited $N_2{}^*$ produced in the discharge as well as the excited $N_2{}^+$ produced by the reaction. The concentration of $N_2{}^+$ cannot be higher than that of atomic oxygen, i.e. about 1% of the total gas stream. Its contribution to the total energy content of the gas will therefore be smaller than that due to the $N_2{}^*$ from the discharge. It was, however, possible to remove the $N_2{}^*$ molecules from the gas stream before the titration.

In the previous section, it was shown that $N_2{}^*$ is deactivated by pyrex with an effective collision efficiency of 4.5×10^{-4}. Since the corresponding value for recombination of atomic nitrogen on pyrex is about 2×10^{-5} (8–10), it was possible to remove $N_2{}^*$ preferentially by insertion of a glass-wool plug between the discharge and the NO-inlet position. The effect of this plug is illustrated in Fig. 6, which shows that, according to

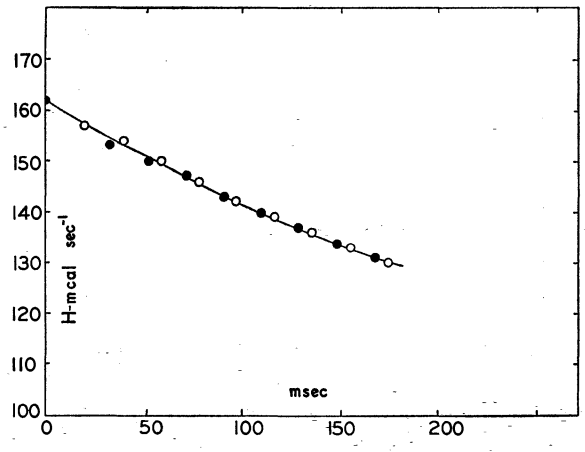

FIG. 6. Probe measurements of discharged nitrogen with pyrex-wool plug, located between discharge and reaction vessel. ○ heat measured by probe; ● heat calculated from atom concentration at $t = 0$ and afterglow intensity.

the calorimetric probe, all the $N_2{}^*$ has been removed without a drastic reduction of nitrogen atoms.

Titration of such a 'filtered' nitrogen atom stream should therefore produce oxygen atoms and excited nitrogen molecules in equimolar amounts. This system was examined with a silver-peroxide-coated probe. The results of a typical experiment are shown in Fig. 7. Curve A is a plot of H_A' calculated from the reaction

$$H_A' = f_O(D'/2),$$

where f_O is the flow rate of O atoms and D' is the dissociation energy of O_2. The value of f_O at $t = 0$ was obtained from the titration, and the variation of f_O with t was calculated from the O-atom recombination rate obtained previously for a similar system (11). The rate of O-atom recombination in this experiment is so small that no appreciable error will be introduced by neglecting the effect of any $O_2{}^*$ which might possibly be formed by the recombination.

The differences between the experimental points H_E', shown in curve B, and H_A' are small but significant. Curve C is a plot of ln $\Delta H'$ against t. Since $\Delta H'$ represents a small difference between relatively large quantities, the precision is not high. However, the slopes of a number of such plots gave a relaxation rate constant of 8.5 ± 0.3 sec^{-1}, which agrees quite well with the value found for the relaxation of $N_2{}^*$ produced in the discharge. This suggests that $N_2{}^*$ and $N_2{}^+$ are similar species.

The energy $E_{N_2}{}^+$ associated with $N_2{}^+$ equals $\Delta H'/f_O$ at $t = 0$. The results of a number of experiments are shown in Table III and yield an average value for $E_{N_2}{}^+$ of 20 ± 4 kcal mole^{-1}.

[2] $\sigma_{N_2}{}^*$ was assumed to be the same as σ_{N_2}.

DISCUSSION

The results can most readily be interpreted on the assumption that the N_2^* molecules formed by the discharge are vibrationally excited. The results of previous studies (12–16) on vibrational deactivation, summarized in Fig. 8, indicate that about 10^{10} collisions are necessary to effect homogeneous collisional deactivation of vibrationally excited N_2 at 300° K. This is consistent with the failure to observe any significant homogeneous deactivation of N_2^* in the present work.

The marked increase in relaxation rate upon addition of other gases also agrees with the vibrational relaxation measurements of Huber and Kantrowitz (14) and with the theoretical considerations of Schwartz *et al.* (15). The high deactivation efficiency of N_2O has been discussed recently by Callear (17). He considers the deactivation to be due to the energy exchange process

$$N_2^*(v = 1) + N_2O(v = 0) \rightarrow N_2(v = 0) + N_2O^*(v = 1).$$

Since N_2O has a fundamental vibrational frequency at 2223 cm^{-1}, which is only 129 cm^{-1} below that of N_2, he calculates that such an exchange should occur at every 10^3 collisions. The subsequent deactivation of N_2O is probably governed by its lowest vibrational frequency at 588 cm^{-1}, which Callear calculates should have a deactivation probability of about 10^{-4}. This probability should correspond to the rate of energy loss in the present study and is, in fact, in fair agreement with our observed efficiency of N_2O of 0.8×10^{-4}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

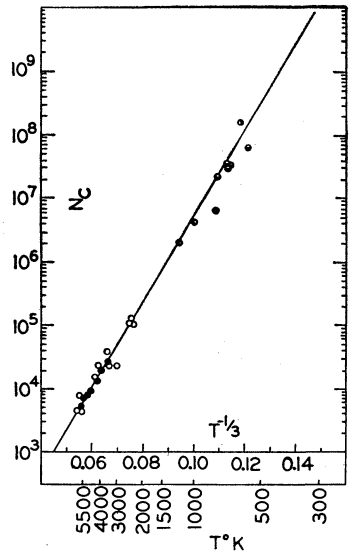

FIG. 8. Plot of number of collisions, N_c, required to deactivate vibrationally excited nitrogen as a function of temperature. ○ Strenlow and Cohen, ref. 16 (shock tube); ● Blackman, ref. 12 (shock tube); ◐ Lukasik and Young, ref. 13 (acoustical); ◒ Huber and Kantrowicz, ref. 14 as corrected in ref. 13 (impact tube); ◑ Schwartz, Slawsky, and Herzfeld, ref. 15 (calc.).

The same reasoning could probably also be applied to deactivation by CO_2. In this case the matching is almost perfect since CO_2 has a fundamental frequency of 2349 cm^{-1} compared with 2352 cm^{-1} for N_2. The subsequent energy loss from the CO_2* is probably also governed by its lowest vibrational frequency at 667 cm^{-1}, which might explain the lower deactivation efficiency of CO_2 relative to N_2O.

The collisional deactivation coefficient, γ, used above to characterize the heterogeneous deactivation of N_2*, does not necessarily represent the probability of complete deactivation of a molecule upon collision with the wall. This macroscopic collision efficiency will probably depend upon the energy distribution and cannot be directly related to the detailed, microscopic deactivation mechanism.

The experimental results simply show that the rate of loss of total energy can be represented as

$$-\frac{dE}{dt} = kE.$$

Now $E = \sum_i n_i\epsilon_i$, where ϵ_i is the energy and n_i is the concentration of molecules in the ith vibrational level. Thus

$$-\frac{d\sum_i n_i\epsilon_i}{dt} = k\sum_i n_i\epsilon_i.$$

There are two different ways in which a molecule can lose its energy:

(1) It may lose all its energy in one deactivating collision. This implies that the energy ϵ_i associated with each excited molecule remains constant so that the total energy loss is governed by the decrease in the number of excited molecules and its rate of decrease will be

$$-V\epsilon_i\frac{dn_i}{dt} = \frac{\gamma_i A n_i \epsilon_i \bar{c}}{4},$$

where V is the volume, A the surface area, and γ_i the efficiency for this process.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(2) It may lose only a fraction of its energy on each deactivating collision. In this case n_i will remain constant and the rate of energy loss will be equal to the rate of decrease of ϵ_i.

$$-Vn_i\frac{d\epsilon_i}{dt}=\frac{\gamma_i'An_i\epsilon_i\bar{c}}{4},$$

where γ_i' defines the efficiency for this kind of collision. If both processes occur simultaneously, the total rate of energy loss will be given by the sum over all i's:

$$-V\left(\sum_i \epsilon_i\frac{dn_i}{dt}+\sum_i n_i\frac{d\epsilon_i}{dt}\right)=\frac{A\bar{c}}{4}\sum_i(\gamma_i+\gamma_i')n_i\epsilon_i.$$

The bracketed term on the left-hand side is simply

$$\frac{d\sum_i n_i\epsilon_i}{dt}=k\sum_i n_i\epsilon_i.$$

The experimental results show, however, that k is a constant as $\sum_i n_i\epsilon_i$ changes. This implies that $(\gamma_i'+\gamma_i)$ must also be constant and the expression reduces to

$$k=\frac{A\bar{c}}{4V}(\gamma_i+\gamma_i').$$

For a cylindrical tube, therefore,

$$(\gamma_i+\gamma_i')\equiv\gamma=\frac{2kr}{\bar{c}}.$$

For a system in which there is simultaneous relaxation from different vibrational levels, γ_i and γ_i' would not be expected to be individually constant. The value of γ_i, the probability of complete deactivation on a single collision, should decrease with increasing vibrational quantum number, i. On the other hand the value of γ_i', the probability of the loss of a single vibrational quantum, should increase with increasing values of i because the vibrational levels get closer together. However, it is improbable that γ_i and γ_i' should vary in such a way as to retain $(\gamma_i+\gamma_i')$ constant for all values of i.

The constancy of γ observed in the present study is perhaps more readily understandable if the N_2* molecules were mainly in the first vibrational level. It is conceivable that the 'active' nitrogen may have been formed initially with considerable excitation of a relatively small fraction of the molecules. There might then be a rapid redistribution to a condition in which a large fraction of the molecules is present in the first vibrational level. The final relaxation of vibrational to kinetic energy ($v = 1$ to $v = 0$) would be relatively slow and be the one measured here. There may therefore be some significance to the observation that the measured energy content of N_2* corresponds to 6.03 kcal mole^{-1} of the total gas present, which is quite close to the first vibrational level of nitrogen (6.7 kcal mole^{-1}).

The extrapolation method used to determine the energy content of the N_2* does not preclude the presence of short-lived species which are deactivated before reaching the reaction vessel. In fact, Beale and Broida (18) have recently presented convincing evidence for the production of very energetic short-lived species by microwave discharge of nitrogen.

It is apparent that experiments of this type are incapable of providing detailed relaxation mechanisms unless independent information is available concerning the variation of the energy distribution with time.

The vibrationally excited N_2^+ formed in the titration reaction was found to possess an average energy of excitation of 20 ± 4 kcal mole^{-1}. The maximum energy available for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

excitation is 75 kcal mole^{-1}. Again, the measurements made here cannot give detailed information regarding the distribution of energy.

Basco and Norrish (6) favor the hypothesis that molecules formed by reactions of this type possess, initially, all the exothermicity of the reaction, but their initial relaxation is so rapid that it is only possible to observe a distribution among lower levels. The present method measures the *total* energy of the $N_2^{\ddagger}$, which should not be altered by relaxation to different vibrational levels. This total energy will only be altered by vibrational–translational energy exchange, which was found to be relatively slow in this system. The value of 20 ± 4 kcal mole^{-1}, measured at the beginning of the reaction zone, can then be taken as evidence against an initial distribution in which all the molecules are formed with energy close to the exothermicity of the reaction.

A STUDY OF THE VAPOR PHASE REACTION OF OZONE WITH OLEFINS IN THE PRESENCE AND ABSENCE OF MOLECULAR OXYGEN[1]

Y. K. WEI[2] AND R. J. CVETANOVIĆ
Division of Applied Chemistry, National Research Council of Canada, Ottawa, Canada
Received December 12, 1962

ABSTRACT

Relative rates of reaction of ozone with a number of olefins in the vapor phase have been determined at room temperature in the presence and absence of molecular oxygen. In the absence of oxygen the rates appear to follow more closely an electrophilic trend, although some of the deviations observed previously in the presence of oxygen still persist to some extent. The ratio of olefin to ozone consumed is unity in the absence of oxygen and varies from about 1.4 to 2 in its presence. In the presence of molecular oxygen, therefore, a secondary attack on the olefins takes place as well. The yields of products are similarly affected.

INTRODUCTION

Reactions of ozone with olefins in the vapor phase are of importance from the point of view of chemistry of air pollution and have been recently reviewed (1) in that connection. The reactions are complex and are not fully understood. Their study is subject to considerable experimental and analytical difficulties. As a result there are uncertainties in the literature regarding the reaction order, the ratio of olefin to ozone consumed, and the rate constants.

In a previous study carried out in this laboratory (2, 3) a certain amount of information was obtained on the type of products formed in the vapor phase reactions of ozonized oxygen with a number of olefins (2). At the same time a competitive technique was used to determine the relative rate constants (3). As anticipated, these showed a general electrophilic trend, but there were also strong deviations from it in the case of some olefins. Although feasible explanations for these deviations could be suggested, there were also large differences between some of the observed rates and the corresponding values in the literature, obtained by different techniques. The present work was undertaken primarily with the object of checking the rate constants determined previously and obtaining some information on the role of the presence of excess molecular oxygen. Reactions have been carried out in the presence and absence of molecular oxygen under conditions where no appreciable temperature increase in the reaction mixture was detectable in the course of the reaction. Relative rate constants, ratios of olefin to ozone consumption, and the yields of some of the reaction products have been determined and compared. Qualitative observations of the aerosol formation have also been made.

EXPERIMENTAL

The reaction apparatus was constructed of pyrex glass and was incorporated into a conventional high-vacuum line. It contained an ozone-generating and -purifying section with a storage bulb, a calibrated volume with a sulphuric acid manometer, a 500-ml ozone–nitrogen mixer, and two matched 100-ml spherical reaction vessels. The arrangement is shown schematically in Fig. 1.

The ozonized oxygen was produced in a standard Tower ozone apparatus. It was purified by passing the mixture through a liquid nitrogen trap and slowly pumping out the oxygen and subjecting the condensed ozone to repeated bulb-to-bulb distillation *in vacuo*. Precautions were taken to guard against possible explosions. The freezing trap was surrounded by a steel cylinder and use was made also of a heavy protective

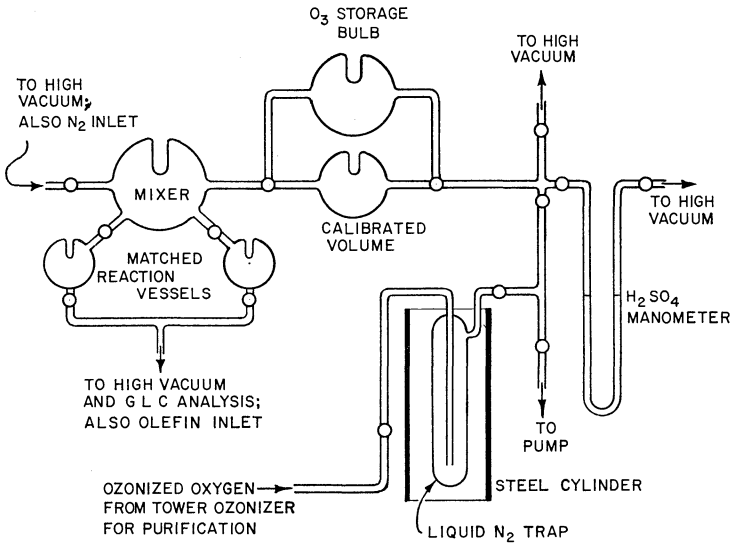

FIG. 1. Schematic diagram of a part of the reaction system.

safety glass shield. Only relatively quite small amounts of ozone (not greater than about 2 mmole) were handled at a time. Several small explosions occurred but the damage was slight and was limited mainly to the freezing trap.

The purity of the ozone was determined iodometrically and found to be 97±2 mole%. The calibrated volume provided with the sulphuric acid manometer was used to measure the required amount of ozone. This was then frozen into the mixer, where a known amount of nitrogen was admitted and allowed to mix with the ozone. The necessary amounts of the olefins were measured and transferred into the two reaction vessels. A known pressure of the diluent gas, nitrogen or oxygen, was then also introduced into the reaction vessels. After bringing up the mixtures of the gases to room temperature (25±2° C), the ozone–nitrogen mixture was expanded in turn into the two reaction vessels through the connecting capillaries. The amounts of ozone admitted into each of the two reaction vessels could be readily calculated and controlled by adjusting the pressures of the gases in the mixer and in the reaction vessels.

Batch procedure was employed. In most cases the same olefin, or mixture of a pair of olefins, was in both reaction vessels and different diluent gases (oxygen and nitrogen) were used so that the products and the relative rates could be compared. In some cases both vessels contained the same diluent gas but one contained a single olefin to monitor its products while the other contained the same olefin mixed with another olefin in order to determine their relative rate. In all cases the reactions in the two vessels were carried out under as similar conditions as possible.

The amounts of olefin and ozone used in the studies of the reaction products were 120±20 and 20±5 μmoles, respectively. Their initial concentrations in the diluent gases, before mixing for the reaction, were 2.0±0.2 mole% in the case of ozone, and 20±2 mole% in the case of the olefins. In the determinations of the relative rates, the total concentration of the two olefins was 30±5 mole% while the concentration of ozone remained unchanged. The total pressures of the gases in the mixer and in the reaction vessels were, respectively, 360±35 mm and 100±20 mm.

Care was taken to prevent the ozone from coming in contact with mercury or its vapors. Halofluorocarbon grease* was used for stopcocks exposed to gas mixtures containing ozone. With freshly greased stopcocks the ozone concentration calculated from the amounts of products formed was lower than the value calculated from the sharing ratios and the partial pressure of ozone in the mixer. However, the difference was not large and a good agreement was restored after two or three runs. The experimental arrangement used, with two matched reaction vessels operated under closely similar conditions, would compensate for any small consumption of ozone by the grease. Low ozone values were also observed when the sulphuric acid manometer was in use for a longer period of time, and it was then necessary to replace the acid.

The condensable reaction products were retained by pumping off the non-condensable gases slowly through a regulating stopcock, a capillary constriction, and three liquid nitrogen traps in series. The condensables were analyzed by gas–liquid chromatography (GLC) using a 12-ft, 1/4 in. I.D. copper column

packed with β,β'-thiodipropionitrile on firebrick and operated at 50±1° C. The reactant olefins were analyzed on the same column, although in a few cases their purity was checked on a 18-ft, 1/4 in. I.D. pyrex glass column packed with propylene carbonate on firebrick and operated at room temperature. Quantitative calibrations were made with standard samples. No attempt was made to analyze the non-condensable gases and only the main (non-hydrocarbon) products observed by GLC were followed quantitatively.

The olefins used were either Phillips research grade or American Petroleum Institute standard samples, with the exception of 4-methyl-2-pentene and 2-hexene, which were Phillips pure grade. The 2-hexene was a mixture of the cis and trans isomers with apparently less than about 10% of trans (as estimated roughly from the gas–liquid chromatogram).

The diluent gases used, oxygen and nitrogen, were passed through concentrated sulphuric acid, followed by a tube packed with potassium hydroxide and a tube packed with glass wool.

Thermocouples placed in wells in each of the two reaction vessels at a distance of about 2 cm from the orifice of the ozone inlet tube were used to determine any temperature change in the reacting gases taking place in the course of the reaction. No noticeable temperature increase was observed.

RESULTS

The major products of the vapor phase reaction of ozone with a number of olefins in the presence and absence of oxygen, as analyzed by GLC, are listed in Table I. The quantities are expressed as moles of products formed per mole of ozone originally employed. It should be pointed out that, as in the previous (2) work, the quantities reported are those observed *after* the passage of the condensables through the GLC column and may include any products of decomposition of the original compounds in the course of the analysis. In several experiments, in particular with 2,3-dimethyl-2-butene, the reaction mixture was left overnight in the reaction vessel (in the presence of oxygen) before removing the non-condensable gases and analyzing the condensables. In such cases there was a substantial increase in the yields of the main carbonyl products and a smaller increase in carbon dioxide.

For the olefins investigated the olefin consumption per mole of ozone was always close to unity when only nitrogen was used as the diluent. In the presence of oxygen, on the other hand, the ratios of olefin to ozone consumed were greater than unity and varied from 1.4 to 2.0 for different olefins. These values and the ratios of the main reaction products observed in the presence of oxygen (O_2) and its absence (N_2) are listed in Table II.

Formation of an aerosol in the course of the reaction was observed in many cases. It formed within a very short time after mixing the reactants, along the path of the inlet stream of ozone–nitrogen mixture, and diffused quickly throughout the reaction vessel. Only visual observations were made and crude estimates of its relative abundance for various olefins are given in the last column of Table II.

In some cases, mostly with olefins of more than four carbons, a non-volatile semi-transparent liquid deposited on the reaction vessel wall. It was of low volatility and could be pumped out only on heating (for example around 120° C). Inasmuch as this liquid was left in the reaction vessel, it appeared to affect the results of the subsequent run. In most cases a white film remained on the wall of the liquid nitrogen trap in which the products were condensed on pumping off the non-condensable gases. This deposit also was volatile when heated.

The competitive method described previously (3) was used to determine the relative rate constants. Two olefins (A_1, A_2) are made to compete for ozone in the reactions

$$A_1 + O_3 \rightarrow \alpha_1 P_1 + \text{other products} \quad [1]$$

$$A_2 + O_3 \rightarrow \alpha_2 P_2 + \text{other products.} \quad [2]$$

P_1 and P_2 are the main carbonyl products observed in the two reactions. The relative rate constants (k_1/k_2) were calculated by comparing the GLC peak heights (ΔP) of these

products at different ratios of the concentrations of the two olefins (A_1/A_2):

$$\frac{\Delta P_1}{\Delta P_2} = \frac{k_1}{k_2}\frac{\alpha_1}{\alpha_2}\frac{(A_1)}{(A_2)}. \qquad [a]$$

For the competitive reaction of isobutene and ethylene the following expression was used instead (P_1 = acetone):

$$\frac{\Delta P_1}{\Delta P_1{}^* - \Delta P_1} = \frac{k_1}{k_2}\frac{(A_1)}{(A_2)}. \qquad [b]$$

ΔP^* is the amount of product formed when one of the competing olefins is taken singly, and $\alpha = \Delta P^*/\Delta O_3$.

Experimental data gave in most cases fairly good linear plots, in agreement with these expressions, and from their slopes the mean values of the relative rate constants given in Table III were obtained. The major products used in these determinations are indicated in the table. For some internal olefins both major carbonyl compounds produced in the reaction could be conveniently measured. In such cases the relative rates of these olefins could be checked for consistency from two or more linear plots using different combinations of the major carbonyl compounds from the same set of experimental data. An example of such plots is given in Fig. 2.

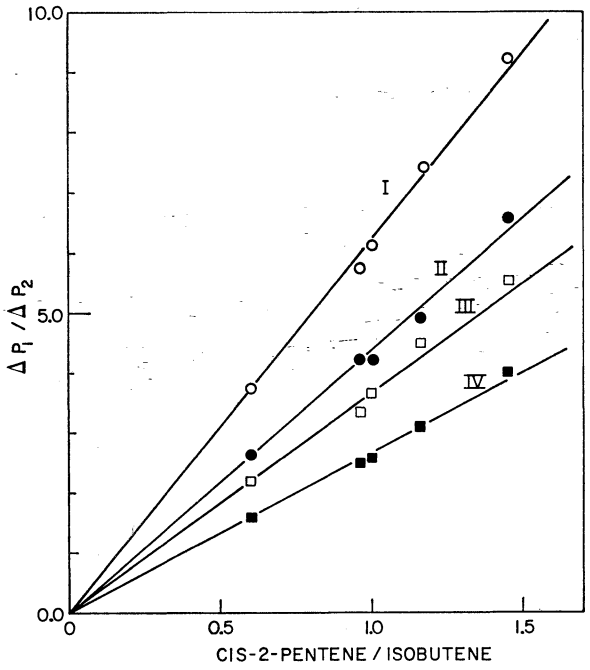

FIG. 2. Plots of equation [a] for *cis*-2-pentene and isobutene. The curves are: I and II for P_1 = acetaldehyde, P_2 = acetone, in the presence (I) and absence (II) of oxygen; III and IV for P_1 = propionaldehyde, P_2 = acetone, in the presence (III) and absence (IV) of oxygen.

A greater number of values of relative rate constants was obtained for 2,3-dimethyl-2-butene competing for ozone with a number of different olefins. The values obtained, expressed relative to isobutene as unity, are shown in Table IV and are discussed in the following section.

DISCUSSION

Of primary interest for the present work have been the determinations of the relative rate constants and these will be discussed first.

Equations [*a*] and [*b*], used in the evaluation of the rate constants, are valid provided the ratios of the monitored products (P_1, P_2) formed per mole of ozone consumed are always proportional to the rates of the respective primary reactions [1] and [2] of ozone with the olefins, both when the olefins react singly and in pairs. This presupposes that no cross interaction of any kind occurs which would tend either to decrease or increase the yields of these products relative to each other when two olefins compete for ozone. Absence of such interactions has to be verified by cross checking the relative rate constants obtained with a number of different overlapping pairs of competing olefins. The results of a number of experiments of this kind are given in Table III and in particular in Table IV. If the attention is focussed for the moment on the relative values of rate constants obtained in the absence of molecular oxygen (k_{N_2}), there seems to be a fairly good overall consistency. Some scatter of the k_{N_2} values in Table IV is probably explainable by the cumulative experimental errors. At the same time some cross interaction cannot be ruled out, although it seems justifiable to assume that this cannot be large. In view of this the k_{N_2} values in Table III are believed to represent to a good approximation the relative second-order rate constants of the primary reactions of ozone with the olefins. A support for this view comes also from the simple stoichiometry observed in the absence of molecular oxygen.

The relative rate constants in the absence of molecular oxygen (k_{N_2}) are seen in Table III to be distinctly dependent on the number of alkyl groups attached to the two doubly bonded carbon atoms. They increase continuously with the number of substituents and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

evidently follow an electrophilic trend, as anticipated. At the same time one anomaly is immediately evident: the rates of 1,1-dialkyl ethylenes are appreciably smaller than those of the 1,2-dialkyl derivatives, although they would be expected to be comparable in magnitude. This is perhaps brought out more clearly in the "free energy" plot against the corresponding rates of the oxygen atom reactions (k_O) in Fig. 3. The latter exhibit an

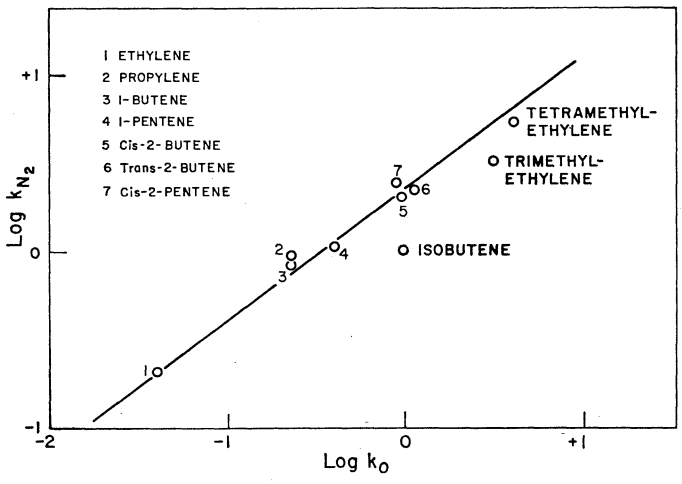

FIG. 3. Free energy plot for the reactions of olefins with ozone in the absence of molecular oxygen (k_{N_2}) and with the ground-state oxygen atoms (k_O).

electrophilic trend (4) and the plot shows therefore that there is also a general electrophilic trend in the k_{N_2} values. This trend is considerably better than that shown by k_{O_2} values obtained previously (3) or in the present work. At the same time, as observed earlier with the k_{O_2} values, the 1,1-dialkyl, trialkyl, and tetraalkyl ethylenes still show smaller rates than would be expected although the deviations are now smaller. As suggested previously, these deviations can be explained either by a large steric hindrance of two alkyl groups on the same carbon atom of the double bond or by their adverse inductive effect which slows down the nucleophilic ring closure in the formation of the "initial ozonides". This is discussed in greater detail in the earlier communication (3) and the same views appear to be still pertinent.

In the presence of molecular oxygen there is a departure from the simple stoichiometry and the ratios of olefin to ozone consumed are greater than unity. Evidently a secondary attack of some kind on the olefins takes place. If this secondary attack on the olefins were only due to a regeneration of ozone in some manner, i.e. involving chain reactions of very short chain length, the k_{O_2} and k_{N_2} values could be expected to be the same. Although the two are seen in Tables III and IV to be roughly similar, they are not the same and it appears therefore likely that in the presence of molecular oxygen active species other than ozone may be involved in the process as well. This in itself could be responsible for an effect on the relative rates determined by the present technique similar in its consequences to the cross interaction discussed above. The k_{O_2} values in Table IV are indeed appreciably less mutually consistent than the k_{N_2} values.

In the case of the 1,2-dialkyl ethylenes the k_{O_2} values are in particular much greater than the corresponding k_{N_2} values. Inasmuch as these differences may be still further accentuated under drastically different experimental conditions, an explanation could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

perhaps be found for the discrepancies in some of the literature values of the rate constants mentioned in the Introduction, notably those of the 1,2-dialkyl ethylenes. However, definite conclusions would have to be based on systematic studies of the effect of such large variations of experimental conditions. At the moment, in comparing the rate data in the literature, invariably obtained in the presence of molecular oxygen, a potential importance of the particular conditions employed should be borne in mind.

The rate constants obtained in the presence of molecular oxygen (k_{O_2}) agree reasonably well with the previous determinations of Vrbaski and Cvetanović (3). In the earlier work some temperature increase probably did occur in the course of the reaction and it was feared that this might have affected the values of the rate constants. However, this effect could not have been large in view of the fair agreement of the rates with the present k_{O_2} values. In the present experiments, with increased amounts of diluent gases and still slower ozone introduction, no temperature increase was observed in the reaction vessels.

The yields of the products formed in the presence of molecular oxygen agree in general reasonably well with the values obtained previously (2). However, lower yields of carbon dioxide have been obtained in a number of cases. This may be due to the fact that, as pointed out, some temperature increase in the course of the reaction probably did occur in the earlier work. The yields of ketones agree well with the previous data, while those of aldehydes show some differences, perhaps in part due to different GLC column temperature used (50° in present work and 125° in the earlier work). However, such differences in the yields of the products as have been observed have evidently not resulted in large differences in the relative rate constants (k_{O_2}). This is no doubt due to the fact that in each study the experiments with single olefins and the competing olefin pairs have been done under mutually comparable conditions.

The trend in the rates of ozone–olefin reactions is very similar to that of the corresponding photochemical reactions of NO_2 with olefins in the presence of molecular oxygen. This is true both for the k_{N_2} and k_{O_2} values. A log k – log k plot of the k_{O_2} values obtained in the present work and the corresponding "maximum" rates determined by Schuck and Doyle (5, 1) for the latter reactions (k_{NO_2}) is shown in Fig. 4. The plot indicates a close similarity in the electronic and steric requirements of the electrophilic species responsible for olefin consumption in the two processes, although this does not mean that they are necessarily identical. It should be noted that isobutene deviates significantly from the linear plot and the slope is appreciably different from unity. (With the k_{N_2} values isobutene deviates much less, but the slope is again about the same and there is also a certain amount of scatter in the case of some olefins.) Considerable similarity between the two systems may be expected, since it is likely that in the photochemical reaction of NO_2 and olefins in air the reaction of the ozone generated in the process with the olefins is important (1, 6). The photochemical NO_2 reactions with olefins play a very important role in the formation of "photochemical smog" and have received considerable attention in recent years (1, 6–8). There can be little doubt that this process has much in common with the corresponding ozone reactions, although both processes are complex and their full understanding will require considerable further work.

The yields of the major products observed are invariably higher in the presence of molecular oxygen than in its absence, as is shown in Table II. It is also seen that in the presence of molecular oxygen olefin consumption is greater than stoichiometric. Under such conditions, a secondary attack on the olefins evidently takes place. The exact nature of these secondary processes and the significance of the apparently systematic trends with olefin structure shown in Table II would be difficult to ascertain on the basis of the

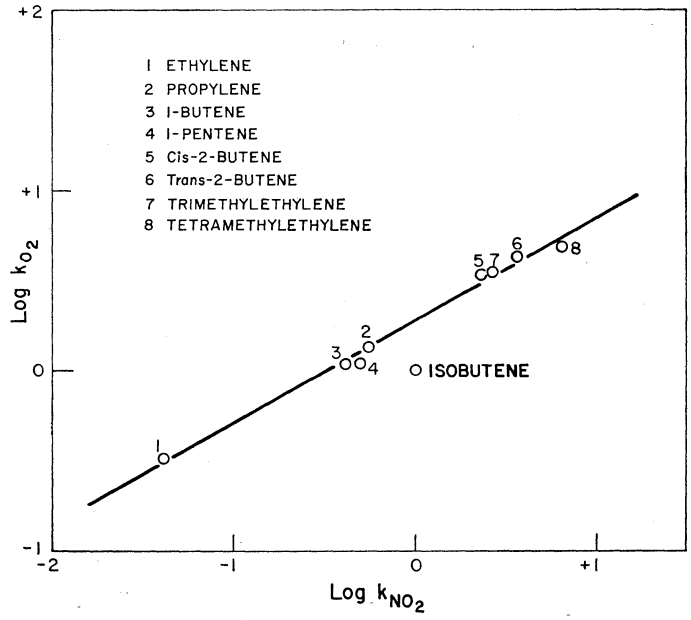

FIG. 4. Log k – log k plot for the reactions of ozone with olefins in the presence of molecular oxygen (k_{O_2}) and the photochemical reactions of NO_2 with olefins in air (k_{NO_2}). (The k_{O_2} values are those obtained in this work, the k_{NO_2} values have been taken from the data summarized in reference 1.)

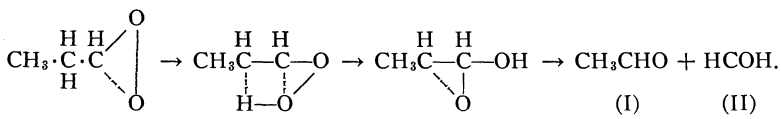
experimental information available at present. In this connection the formation of the "abnormal" carbonyl products formed in these reactions is of interest.

It was shown in the earlier work (2) that in addition to the major carbonyl compounds, i.e. the expected "normal" products of ozonolysis, smaller amounts of carbonyl compounds containing fewer carbon atoms (one or more) were also produced. These degradations were visualized as perhaps being induced by "peroxide–formate" rearrangement, or other types of rearrangement of the initially formed zwitterions, followed by decomposition, or as being due to secondary oxidation. However, it is found now that these products are not restricted to the reactions in the presence of molecular oxygen but occur also in its absence, as shown in Table I. Furthermore these products seem to fall largely into two groups, those in which the yields are smaller and those in which they are larger when molecular oxygen is present, the latter more or less following the same trend as the "normal" carbonyl products.

A unique explanation of these observations cannot be given but it may be useful to consider some tentative possibilities, subject to modifications or rejection as more extensive experimental results become available. That these degradations do not occur only as a result of secondary attack by molecular oxygen is evident, and, at least in its absence, rearrangement of zwitterions is likely to play an important role. This, again, can occur in various ways, such as single and consecutive 1,2 carbon-to-carbon shifts of H and alkyl groups or via formation of intermediate cyclic complexes. For purposes of illustration, the following example of a possible course of rearrangement of this latter kind may be given:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

By allowing internal interactions of this kind with H-atoms and alkyl groups not only on β but also on γ (etc.) carbon atoms, and assuming that the fragments (II) are as a rule not stabilized to the corresponding carbonyl compounds except in some very simple cases, formation of the degradation carbonyl products in Table I can be qualitatively explained. It seems that in most cases the yields of the degradation products formed by interaction with the substituents on the γ carbon atom decrease in the presence of molecular oxygen, while those involving β-carbon interaction increase. This would suggest that there may be an attack by molecular oxygen on β-C—H bonds of the zwitterions in competition with internal rearrangement and that this may be responsible for the increase of the yields of the degradation products formed by β-carbon interaction and the decrease of the products formed by γ-carbon interaction. Interactions of this kind involving oxygen could conceivably be also responsible for the generation of active species which induce the secondary attack on the olefins in the presence of molecular oxygen. At the same time, it should be stressed that there are some exceptions (β product yields *decreasing* in the presence of molecular oxygen) which require further refinements of this simple picture. It is also possible that degradations may be occurring as a result of internal rearrangements of zwitterions followed by molecular detachment of olefins, as discussed briefly in the earlier work (2), with simultaneous formation of zwitterions containing fewer carbon atoms. Such a mechanism, however, is not likely to be able to explain all the "abnormal" carbonyl products.

The observed increased complexity of the reaction of ozone with olefins in the presence of molecular oxygen is in agreement with some earlier conclusions by other workers (1). Smith and Eastman (9) have recently studied the reaction of ozonized oxygen with 2,3-dimethyl-2-butene in the vapor phase and have observed a consumption of about two moles of olefin per mole of ozone, in close agreement with the present findings. They suggest that two reactions occur simultaneously, attack of ozone at the carbon–carbon double bond and attack of oxygen at the allylic position of the olefin. This is similar to the tentative possibilities discussed here. However, the details of such interactions, as already stressed, must remain uncertain at present.

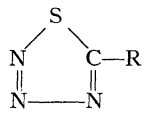
ABSTRACT

A number of 5-(*p*-substituted)phenyl-1,2,3,4-thiatriazoles have been synthesized by the diazotization of *p*-substituted thiobenzhydrazides or by the reaction of sodium thiobenzoylthioglycollates with sodium azide. The thermal decomposition of these thiatriazoles yields nitriles, nitrogen, and sulphur. 5-Alkyl-1,2,3,4-thiatriazoles are very unstable and readily decompose to nitriles. Infrared and ultraviolet absorption spectra of 5-(*p*-substituted)phenyl-1,2,3,4-thiatriazoles have been studied. Infrared spectra of several thiohydrazides have also been studied and there appears to be no thiol–thione tautomerism in these derivatives. The thiatriazole ring is found to be electron withdrawing.

INTRODUCTION

The existence of the 1,2,3,4-thiatriazole system was firmly established by Lieber and co-workers (1–5). It has been shown that the diazotization of 4-substituted thiosemicarbazides, as well as the reaction of alkyl- and aryl-isothiocyanates with hydrazoic acid, leads to 5-(substituted)amino-1,2,3,4-thiatriazoles (1, 2). The reaction product of azide ion with carbon disulphide has been shown to possess the 1,2,3,4-thiatriazoline-5-thione structure and not the acyclic azidodithiocarbonic acid structure (4). The esters of the so-called azidodithiocarbonic acid have been found to be either 5-substituted mercapto-1,2,3,4-thiatriazoles or 4-substituted-1,2,3,4-thiatriazoline-5-thiones (5). In the present communication, we report the synthesis of 5-alkyl- and 5-(substituted)phenyl-1,2,3,4-thiatriazoles (I) by two independent methods.* We have also investigated the



I

R = alkyl or *p*-substituted phenyl

thermal decomposition and infrared and near-ultraviolet absorption spectra of these thiatriazoles (I). In addition, we have studied the infrared spectra of 4-(substituted)-thiobenzhydrazides and aliphatic thiohydrazides.

EXPERIMENTAL*

Thiobenzoylthioglycolic Acid

To an ethanolic solution of potassium sulphide (equivalent of 1 mole), 97.8 g (0.5 mole) of phenyl chloroform was added slowly with stirring at about 50° C. The reaction mixture was stirred for another 15 minutes after the addition was complete (addition time 80 minutes) and was cooled to about 0° C. A solution of 62.4 g of chloroacetic acid and 38 g of sodium carbonate in 250 ml of water was then added and the temperature of the reaction mixture was maintained at about 5° C for 48 hours. The reaction mixture was then acidified with 95 ml of ice-cold aqueous sulphuric acid (50%). A dark red compound precipitated, which was washed with 200 ml of water, dried under vacuum, and recrystallized from 250 ml of benzene. The yield was 47.5 g (44.8%), m.p. 126–128° C, lit. m.p. 126.5–128° C (8, 9). Anal. Calc. for $C_9H_8O_2S_2$: S, 29.2. Found: S, 28.8.

p-Chlorothiobenzoylthioglycolic Acid

An orange crystalline solid, m.p. 118° C, was prepared starting from carbon disulphide and *p*-chlorophenylmagnesium bromide. The resulting product was treated with ice and to the aqueous layer a solution of chloroacetic acid and sodium carbonate was added. After standing for 48 hours at 5° C, the reaction mixture was acidified with ice-cold aqueous sulphuric acid. The resulting orange solid was crystallized from benzene, furnishing a yield of 24%, m.p. 117–118.5° C. Anal. Calc. for $C_9H_7O_2S_2Cl$: S, 25.9. Found: S, 25.8. This procedure is essentially the same as that of Smith and Kenny (7) but the yield in this investigation was considerably higher.

p-(N,N-Dimethylamino)thiobenzoylthioglycolic Acid

A yellowish brown solid, m.p. 168–172° C (decomp.), was prepared in 58% yield from *p*-bromo-N,N-dimethylaniline following the procedure described for the *p*-chloro analogue. Anal. Calc. for $C_{11}H_{13}O_2NS_2$: N, 5.48; S, 25.1. Found: N, 5.36; S, 24.8.

p-Methoxythiobenzoylthioglycolic Acid

To a solution of 68.1 g (0.5 mole) of *p*-anisaldehyde in 150 ml of 95% ethanol at 80° C, ammonium polysulphide solution was added dropwise with stirring. The reaction mixture was refluxed for 10 minutes and cooled to room temperature. The mother liquor was then decanted from the resinous precipitate. To the resinous precipitate in the flask was added a solution of 20 g of sodium hydroxide in 100 ml of 95% ethanol. The resulting solution was kept at 50° C for 16 hours with continuous stirring. The solution was then filtered and the precipitate washed with 50 ml of warm water. The filtrate, washings, and the mother liquor were taken in a 2-liter beaker and covered with 500 ml of ethyl ether. *p*-Methoxydithiobenzoic acid was then liberated by the slow, careful addition of 400 ml of ice-cold 6 *N* hydrochloric acid. The ether layer was extracted with 200-ml portions of 1.25 *N* potassium hydroxide. The basic extracts were treated with a solution of 62.4 g of chloroacetic acid and 38 g of sodium carbonate in 250 ml of water. This solution was kept at 5° C for 48 hours, after which the sodium salt precipitated. The solution and precipitate were acidified with 200 ml of 6 *N* hydrochloric acid. The product was crystallized from 95% ethanol to furnish 32.5 g (26.8%) of orange-yellow crystals, m.p. 125–127° C, lit. m.p. (7) 124–125° C. Anal. Calc. for $C_{10}H_{10}O_3S_2$: S, 26.5. Found: S, 26.1. Smith and Kenny (7) have prepared *p*-methoxythiobenzoylthioglycolic acid in 10% yield starting from *p*-bromoanisole and carbon disulphide.

p-Hydroxybenzoylthioglycolic Acid

A red solid, m.p. 196° C (decomp.), was prepared in 24% yield starting from *p*-hydroxybenzaldehyde, by a procedure similar to that described for the *p*-methoxy analogue. Anal. Calc. for $C_9H_8O_3S_2$: S, 28.1. Found: S, 28.2. A small amount of *p,p'*-dihydroxybenzyldisulphide was also isolated.

p-Methylthiobenzoylthioglycolic Acid

An orange-red solid, m.p. 121–122° C, was prepared in 20% yield starting from *p*-bromotoluene and carbon disulphide employing the procedure described for the *p*-chloro analogue. Anal. Calc. for $C_{10}H_{10}O_2S_2$: S, 28.3. Found: S, 28.6.

Phenylthioacetylthioglycolic Acid

A yellow solid, m.p. 77–79° C (10), was prepared in 28% yield starting from benzylmagnesium bromide and carbon disulphide by the procedure described for the *p*-chlorothiobenzoyl analogue. Anal. Calc. for $C_{10}H_{10}O_2S_2$: S, 28.3. Found: S, 28.0.

Sodium Cyclohexanethiocarbonylthioglycolate

A yellow solid, m.p. 230–245° C (decomp.), was prepared in 23% yield starting from cyclohexylmagnesium bromide. Anal. Calc. for $C_9H_{13}O_2S_2Na$: S, 26.7. Found: S, 26.4. The free acid was not prepared. Smith and Kenny (7) have obtained a 3% yield of the acid.

**All melting points are uncorrected and were determined on a Fisher–Johns apparatus. Microanalyses were by Dr. C. Weiler and Dr. F. B. Strauss, Oxford, England.*

p-Nitrobenzoylthioglycolic Acid

It was not possible to prepare this compound by any of the procedures described. Another possibility studied was the reaction of *p*-nitroethylthionbenzoate with hydrazine. However, it was found that the reaction of ethylthionbenzoate with 85% hydrazine in ethyl ether did not yield thiobenzhydrazide, as reported by Matusi (11). The only product isolated was a clear oil (b.p. 188–191° C) which contained nitrogen.

p-Substituted Thiobenzhydrazides and Aliphatic Thiohydrazides

A solution of hydrazine hydrate was added dropwise with stirring to an alkaline solution of the thioglycolic acid at 0° C. The solution was then acidified with glacial acetic acid and the product recrystallized from ethanol–water solvent. The data on all the hydrazides thus prepared are given in Table I. In the

case of the *p*-hydroxythiobenzhydrazide, acetic acid was added just to the point of neutralization since this compound does not precipitate from acidic solutions. In the preparation of thiobenzhydrazide, a small quantity of 2,5-diphenyl-1,3,4-thiadiazole, m.p. 141–142.5° C, lit. (8) m.p. 141–142° C, was isolated.

p-Nitrophenylhydrazone Derivatives

One gram of the hydrazide and 0.8 g of *p*-nitrobenzaldehyde were dissolved in 10 ml of 95% ethanol, and a drop of concentrated hydrochloric acid was added. The mixture was vigorously shaken and warmed in a hot-water bath for 10 minutes and then allowed to cool to room temperature. The *p*-nitrophenylhydrazones, 4-$NO_2C_6H_4NNHC(S)R$, thus prepared were: (1) R = $C_6H_5CH_2$, m.p. 174–176° C, red powder, 83% yield. Anal. Calc. for $C_{15}H_{13}O_2N_3S$: S, 10.2; N, 13.4. Found: S, 10.4; N, 13.6. (2) R = cyclo-C_6H_{11}, m.p. 124–126° C (lit. (7) m.p. 125–126° C), 87% yield. Anal. Calc. for $C_{14}H_{17}O_2N_3S$: S, 10.5; N, 13.8. Found: S, 10.4; N, 13.6. 1-Naphthylhydrazone Derivatives

The derivatives, $C_{10}H_7CHNNHC(S)C_6H_4R$, were obtained as white felted needles from 1-naphthaldehyde using a procedure analogous to that described for the *p*-nitrophenylhydrazones: (1) R = H, m.p. 136.5–138° C, 86% yield. Anal. Calc. for $C_{18}H_{14}N_2S$: S, 11.0; N, 9.6. Found: S, 10.8; N, 9.7. (2) R = 4-Cl, m.p. 166.5–168° C, 90% yield. Anal. Calc. for $C_{18}H_{13}N_2SCl$: S, 9.9; N, 8.6. Found: S, 9.7; N, 8.5. (3) R = 4-CH_3, m.p. 142–143.5° C, 88% yield. Anal. Calc. for $C_{19}H_{16}N_2S$: S, 10.5; N, 9.2: Found: S, 10.3; N, 9.0. (4) R = 4-OH, m.p. 174–177° C, 85% yield. Anal. Calc. for $C_{18}H_{14}ON_2S$: S, 10.5; N, 9.2. Found: S, 10.6; N, 9.4. (5) R = 4-CH_3O, m.p. 122.5–124° C, 89% yield. Anal. Calc. for $C_{19}H_{16}ON_2S$: S, 10.0; N, 9.6. Found: S, 9.6; N, 8.5.

5-(p-Substituted)phenyl-1,2,3,4-thiatriazoles

Procedure A

The *p*-substituted thiobenzhydrazide (0.01 mole) was dissolved in 22 ml of 1 N hydrochloric acid. The solution was cooled in an ice–salt bath, and a solution of 0.8 g (0.01 mole) of sodium nitrite in 25 ml of water was added dropwise with stirring. The product which separated was immediately washed with water and recrystallized from ethanol–water mixture.

Procedure B

The *p*-substituted thiobenzoylthioglycolic acid (0.01 mole) was dissolved in 20 ml of 1 *N* sodium hydroxide, and a solution of 1.3 g (0.02 mole) of sodium azide in 15 ml of water was added. The reaction mixture was agitated at room temperature for 24 hours, the compound gradually precipitating. Both procedures A

Attempted Synthesis of 5-Benzyl- and 5-Cyclohexyl-1,2,3,4-thiatriazoles

Diazotization of thiophenylacetylhydrazide and cylohexanethiocarbonylhydrazide yielded oils which showed nitrile absorption in the infrared spectra due to the decomposition of the thiatriazole. These results are similar to those of Kirmse (6) and Smith and Kenny (7). Kirmse (6), however, obtained the 5-benzyl derivative in crystalline form. While an attempt to distill the oily product was being made a mild explosion resulted, in the case of the 5-benzyl derivative.

Infrared Absorption Spectra

The infrared spectra of *p*-substituted thiobenzhydrazides, aliphatic thiohydrazides, and 5-(*p*-substituted)-phenyl-1,2,3,4-thiatriazoles were recorded on a Perkin–Elmer, Model 21-C spectrometer with rock salt optics. The samples were prepared as mulls in mineral oil.

Ultraviolet Absorption Spectra

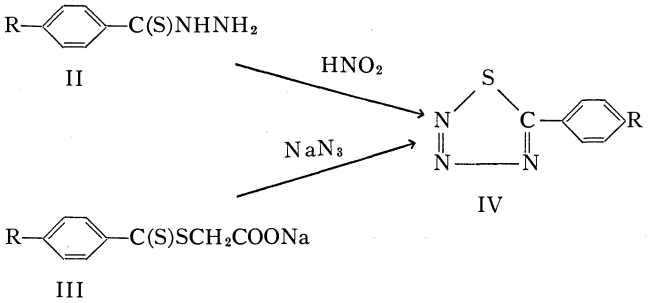
The near-ultraviolet absorption spectra of 5-(*p*-substituted)phenyl-1,2,3,4-thiatriazoles were studied in 95% ethanol using Beckman DK-1 and DK-2 spectrometers.

Thermal Decomposition Studies

Thermal decompositions of some of the 5-(*p*-substituted)phenyl-1,2,3,4-thiatriazoles were studied as a function of time using a gas volumetric apparatus. The thiatriazole (0.0015 mole) was mixed with fine, dry sand and the flask containing the mixture was lowered into an oil bath maintained at 90° C, and the decompositions were studied up to 20% completion of decomposition. The *p*-substituents studied were Cl, H, and $N(CH_3)_2$. Total decompositions were studied for most of the thiatriazoles and the expected stoichiometric quantities of nitrogen were obtained in all the cases.

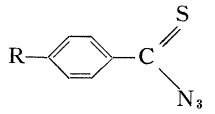
RESULTS AND DISCUSSION

Diazotization of *p*-substituted thiobenzhydrazides (II), as well as reaction of *p*-substituted thiobenzoylthioglycolic acids (III), with azide ion, produces 5-(*p*-substituted)-phenyl-1,2,3,4-thiatriazoles (IV). The infrared spectra of the products do not show the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

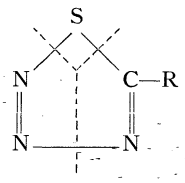
characteristic azide stretching frequencies (12), but exhibit the thiatriazole frequencies (3, 5) in the regions 1615–1515, 1300–1270, 1120–1100, and 1080–1030 cm^{-1}. Thus, the acyclic azide structure (V) for thioacyl azides, suggested by Oliveri-Mandala (13), must be eliminated from consideration.



V

Phenyl-1,2,3,4-thiatriazole (IV, R = C_6H_5) does not dissolve in dilute mineral acids. It is also inert to concentrated hydrochloric and nitric acids, but decomposes in sulphuric acid at concentrations above 55%. The decomposition products are benzonitrile, nitrogen, and sulphur. A 2% solution of IV (R = C_6H_5) in reagent carbon tetrachloride showed signs of decomposition after standing for 5 days at room temperature. Precipitation of sulphur was observed and the solution exhibited the characteristic nitrile stretching frequency in the infrared.

The 5-(*p*-substituted)phenyl-1,2,3,4-thiatriazoles are relatively stable at room temperature but decompose rapidly when heated.* The products of thermal decomposition are a nitrile, sulphur, and nitrogen. Photodecomposition, however, gives rise to isothiocyanates and nitriles (6). Studies of the thermal decomposition of IV are in good agreement with the observations of Smith and Kenny (7). The mode of thermal decomposition may be represented by VI involving heterolytic bond breaking. The instability of 5-alkyl-1,2,3,4-thiatriazoles (IV, R = alkyl) may be due to the electron-donating nature



VI

of the alkyl groups, which would be expected to decrease the stability of the ring. The identification of nitriles in the attempted syntheses of IV (R = alkyl) derivatives and the occurrence of explosions during their preparation clearly indicate that these derivatives were formed, at least momentarily. The kinetics of the thermal decomposition of IV (R = *p*-substituted phenyl), studied by a volumetric gas apparatus, showed no dependence on the *p*-substituent.

The near-ultraviolet absorption spectra of IV (R = *p*-substituted phenyl) (Table III) show an interesting trend in the position of the absorption maximum with the *p*-substituent. There is progressive bathochromic shift with increase in the electron-donating ability of the *p*-substituent. This trend is similar to that found in 5-substituted phenylamino-1,2,3,4-thiatriazoles (14) and 1-substituted phenyl-5-amino-tetrazoles (15). On the basis of the correlations of ultraviolet absorption maxima of benzenoid derivatives with electrical effects of substituents (16), it may be concluded that the 1,2,3,4-thiatriazole ring is as electronegative as a tetrazole ring. Smith and Kenny (7) have also arrived at a similar conclusion.

**A sample of IV* (R = C_6H_5) *stored for 4 months at room temperature showed no nitrile absorption in the infrared.*

CO-CATALYSIS IN FRIEDEL–CRAFTS REACTIONS

VI. POLYMERIZATION OF 2-BUTENE BY BORON FLUORIDE – METHANOL[1, 2]

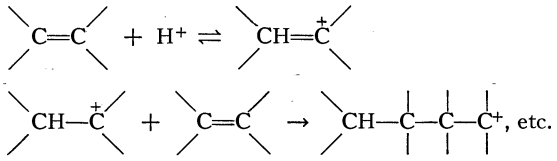
H. R. ALLCOCK[3] AND A. M. EASTHAM
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received November 26, 1962

ABSTRACT

2-Butene is polymerized by boron fluoride and methanol in ethylene dichloride solution at ordinary temperatures to give very low molecular weight polymers. The rate of polymerization shows exactly the same dependence on catalyst concentration as did the rate of isomerization of the *cis*- and *trans*-2-butenes, i.e. first order both in free boron fluoride and in the boron fluoride – methanol complex. The polymerization, however, shows a first-order dependence in olefin over a concentration range where the isomerization is, experimentally, virtually independent of the olefin concentration.

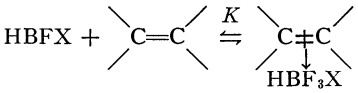
The polymerization of olefins by strong acids is generally considered to proceed by a mechanism of the type



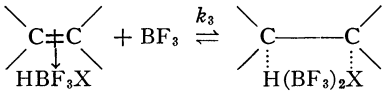
In previous work we have attempted to obtain information about the protonation step in this process by studying the acid-catalyzed equilibration of the three isomeric olefins *cis*-2-, and *trans*-2-, and 1-butene, on the assumption that the basic difference between this isomerization and a polymerization lies simply in the relative rates with which the initial carbonium ion undergoes either deprotonation or olefin addition. The *n*-butenes were chosen for this work because they do not polymerize easily and hence conditions can be found where the isomerization can be observed without serious interference from polymerization.

The results of our studies seem to show quite clearly that isomerization takes place according to the following reaction scheme (1), which is essentially a modification of the Polanyi–Evans mechanism for the polymerization of isobutene (2).

$$BF_3 + HX \rightleftharpoons HBF_3X \qquad [1]$$



[2]



[3]

Here HX, the co-catalyst, is a proton-donating material such as water, methanol, or acetic acid which reacts with the catalyst, BF_3, to form the strong acid, HBF_3X. This acid reacts rapidly with the olefin (reaction [2]) to form a labile complex (π-complex?)

[1] *Issued as N.R.C. No. 7237.*
[2] *For Part V see ref. 1.*
[3] *N.R.C. Postdoctoral Fellow, 1958–1960.*

without disrupting the olefin double bond. Isomerization occurs when this complex reacts with a molecule of free boron fluoride but the kinetics do not show whether the rearrangement occurs during the addition of this second molecule of boron fluoride or in some subsequent process such as an ionization of the complex so formed.

The rate expression for the isomerization takes the form

$$\text{rate of isomerization} = \frac{k_3[BF_3][BF_3 \cdot HX][\text{butene}]}{K + [\text{butene}]},$$

where k_3 is the rate constant for the forward process in reaction [3] (the rate-controlling step) and K is the equilibrium constant for reaction [2]. However, since the values of k_3 and K differ for each isomer, the equation in this form applies only to the initial rate of isomerization of a pure isomer. For the present purpose it is sufficient to point out that the rate is directly dependent upon the concentrations of the free boron fluoride and of the boron fluoride – methanol complex but will depend on butene concentration in a manner determined by the value of K in the ratio [butene]/K+butene. With acetic acid as co-catalyst at 20° C, K has the values 0.1, 0.4, and 0.5 mole l^{-1} respectively for the isomers *cis*-2-, *trans*-2-, and 1-butene, so the experimental order in butene varies markedly over the usual concentration range. However, in addition to this kinetic effect of changes in butene concentration, there is a medium effect which operates in the opposite direction, and the net result of the two effects is to make the observed rate virtually independent of the butene concentration over the concentration range 0.2–2.0 mole l^{-1} with either methanol or acetic acid as co-catalyst.

With the mechanism for isomerization seemingly established, it seemed worthwhile to extend the measurements to the polymerization in order to test the assumption that polymerization and isomerization are related as described above. In doing so, we have made no attempt to determine the detailed polymerization kinetics but have confined ourselves to the measurement of initial rates of monomer disappearance in ethylene dichloride solution at 0° C, using methanol – boron fluoride as the catalyst system. In order to minimize interference from the somewhat more rapid isomerization reaction we have employed as monomer a mixture of *cis*- and *trans*-2-butene in approximately the ratio they are found in the equilibrium mixture (1:3), but 1-butene, which is also a component (3%) of the equilibrium mixture, was not added because preliminary experiments indicated that the small initial fluctuations in the concentration of this monomer should not cause significant errors in the measurements.

EXPERIMENTAL

(a) Materials

Ethylene dichloride, butenes, methanol, and boron fluoride were prepared and manipulated essentially as previously described (3, 4).

(b) Rate Measurements

The rates were followed by observing the decrease in vapor pressure of butene over the reaction mixture by means of a mercury manometer closely coupled to the reaction flask. The volume of the flask and manometer was about 75 ml. For each run the methanol was distilled into the flask and was followed by 20 ml of ethylene dichloride and then by the boron fluoride. At this point the mixture was brought to 0° C, thoroughly mixed by means of a magnetic stirrer, and its vapor pressure determined as a check on its composition. It was then frozen down to remove vapor from the manometer, the manometer isolated by means of a stopcock, and the mixture again brought to 0°. The butene was rapidly vaporized into the reaction system from a small bulb attached to the reaction flask, and a few minutes allowed for equilibration of the system. The stopcock to the manometer was opened and readings taken at intervals. The readings were plotted against time, the initial rate obtained from the slope of the smoothed curve, and the results converted to concentration by means of a calibration chart prepared for the system.

For personal use only.

(c) Reaction Products

Reactions carried out with a low catalyst/monomer ratio stop short of completion because of catalyst consumption; the yield of polymer varies with the conditions but several hundred molecules of monomer are consumed per molecule of methanol. In order to obtain some information about catalyst destruction the vapor above the reaction mixture was circulated continuously through a gas cell in an Infracord infrared spectrophotometer and the strong boron fluoride band at 1500 cm^{-1} observed during the course of the polymerization. The gases were circulated rapidly through the system by means of a high-speed, magnetically driven platinum fan mounted on Teflon bearings within the system. The sodium chloride windows of the absorption cell were sealed with lead–mercury amalgam and the reference cell was filled with ethylene dichloride vapor at a pressure just sufficient to balance the absorption due to solvent vapor in the reaction cell.

In measuring the boron fluoride absorption it is necessary to make a small correction for a butene peak in the same region. Since butene disappears during the reaction the correction must be made continuously, so a manometer was introduced into the system and the pressure decrease observed. Correction was then made for butene absorption on the assumption that the pressure drop was due entirely to the decrease in butene, an assumption which may not be entirely justified but which is consistent with the change in butene absorption in other regions of the spectrum. The results thus obtained showed that the absorption due to boron fluoride remained substantially constant throughout the runs and we are satisfied that consumption of this reagent is small, perhaps well below 1% of its concentration, over the period of the rate measurements. This point is of considerable importance because the rates were followed by the fall in pressure in the system, and boron fluoride in some cases makes up a substantial part of that pressure.

Since the boron fluoride concentration seems to remain constant during the runs, we conclude that it is the co-catalyst, methanol, which is consumed, but we have been unable to devise a direct test of this point. We do know, however, that under certain rather restricted conditions, methanol can be added to butene to form the ether,

$$CH_3—CH=CH—CH_3 + CH_3OH \xrightarrow{BF_3} CH_3—CH_2—CHOCH_3—CH_3,$$

so it seems very likely that a reaction of this kind is a termination process in the polymerization (1).

No effort was made to examine the products of the rate runs but a few larger-scale runs were made for this purpose, typically as follows. Methanol (0.076 g), boron fluoride (0.22 g), and *trans*-2-butene (43 g) were added, on the vacuum line, to ethylene dichloride (700 ml) and allowed to stand 4 days at room temperature. Boron fluoride and most of the solvent was then distilled off to leave a residue of about 100 ml, which was fractionally distilled first at atmospheric and then under reduced pressure. The fractions were found, by gas chromatography, carbon and hydrogen analysis, and cryoscopy in cyclohexane, to be hydrocarbons having molecular weights below 350. Over half of the product was made up of a mixture of butene tetramers but the range included dimers to hexamers, and in all, nearly 20 different compounds. The large number of products presumably results from a mixture of 1- and 2-butene units in the polymers.

(d) Concentrations

Except in the case of boron fluoride, concentrations have been expressed in mole l^{-1} calculated from the amount of solvent and reactant measured into the reaction flask. However, since the boron fluoride has limited solubility, the concentration of this reagent in solution, $[BF_3]_{soln}$, has been used; in the present work at 0° C the dissolved boron fluoride is very close to one third of the total free boron fluoride present in the system. In calculating the concentrations it has been assumed, on the basis of earlier work (3), that methanol is always present as the 1:1 complex with boron fluoride.

RESULTS

The dependence of the rate of polymerization on the free boron fluoride concentration is shown in Fig. 1, where some typical results are plotted for a number of methanol concentrations. The dependence on methanol is obtained from the slopes of these lines and is shown in Fig. 2. There is a small and erratic "blank" in the absence of added methanol which may be due to adventitious moisture in the reagents or reaction system. It seems clear from the results that the polymerization depends on catalyst in exactly the same way as did the isomerization, i.e., directly on the concentrations of free boron fluoride and of boron fluoride – methanol complex.

The variation of rate with monomer concentration over the concentration range 0.2–1.0 mole l^{-1} is shown in Fig. 3 and is, experimentally, approximately of the first order. In the case of the isomerization reaction, under slightly different experimental conditions (1, 3), the order in butene approaches zero in this region so one is tempted to conclude

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

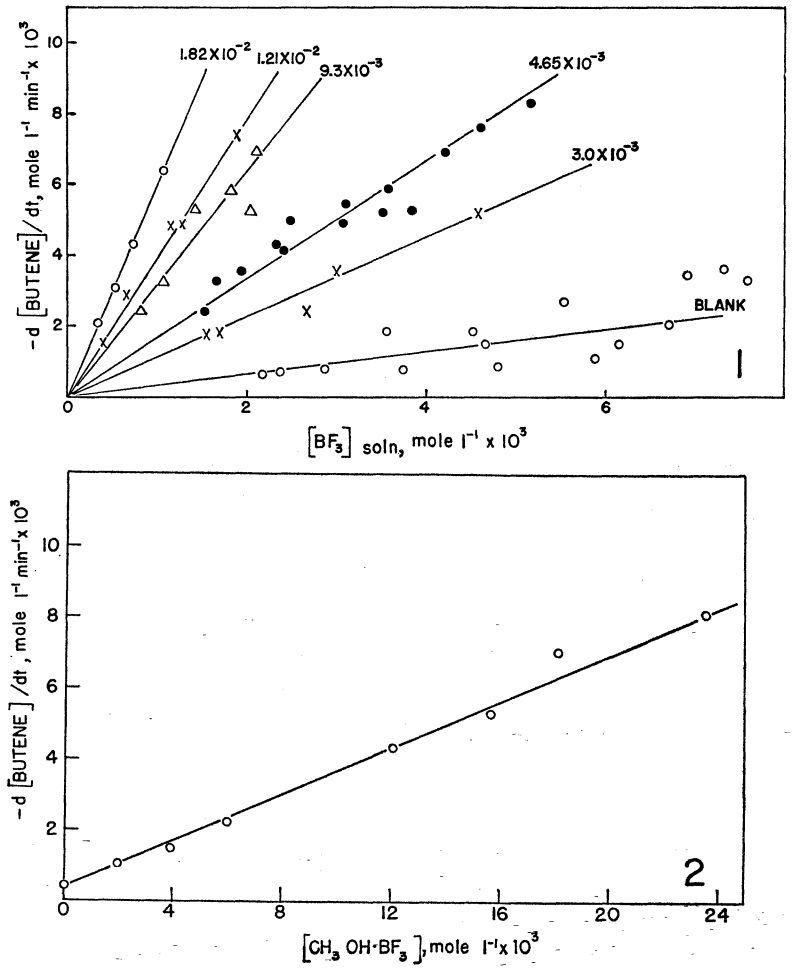

FIG. 1. Dependence of the rate of disappearance of butene on the concentration of free boron fluoride; [butene] 0.40 mole l^{-1}, [$CH_3OH \cdot BF_3$] as indicated on the curves.

FIG. 2. Dependence of the rate of polymerization on the concentration of methanol; [butene] 0.40 mole l^{-1}, $[BF_3]_{soln}$ 1.15×10^{-3} mole l^{-1}.

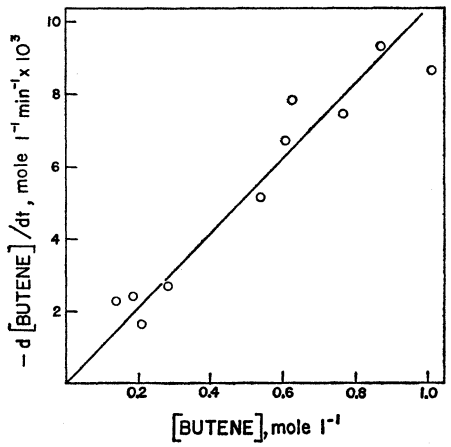

FIG. 3. Dependence of the rate of polymerization on butene concentration; [methanol] 4.65×10^{-3} mole l^{-1}, $[BF_3]_{soln}$ 4.2×10^{-3} mole l^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that in the polymerization the overall rate of disappearance of monomer is about one order higher in monomer concentration than is the rate of initiation. While this conclusion seems reasonable and may in fact be true, it is a dangerous one because the dependence of the rate of initiation (isomerization) upon monomer concentration is complex (1) and any comparison of this kind, to be valid, should be made over a much wider concentration range than the present one. Unfortunately the range of the present method is restricted by the high rates at one end of the scale and the low vapor pressure of monomer at the other, but it seems rather doubtful that it is worth pursuing the subject further with this monomer because the complexity of the system is such that there is little hope for a solution to the polymerization equation. The chains are so short that each monomer unit will probably add at a different rate to the previous one, and furthermore the monomer itself is a mixture of three isomers each presumably with its own rate of addition. We therefore conclude only that the order in butene is somewhat higher for polymerization than for isomerization.

The rate expression governing these *experimental* results is thus

$$-d[\text{butene}]/dt = k[BF_3]_{soln}[BF_3 \cdot CH_3OH][\text{butene}]$$

and k has the value 6.5×10^2 l^2 mole^{-2} min^{-1} at 0° in ethylene dichloride solution.

THE REACTION OF POLYISOPRENE WITH TITANIUM TETRACHLORIDE[1]

MORTON A. GOLUB AND JORGE HELLER
Stanford Research Institute, Menlo Park, California, U.S.A.
Received August 27, 1962

ABSTRACT

The reaction of titanium tetrachloride with hevea, balata, and synthetic *cis*-polyisoprene in benzene at 80° C has been studied. The most prominent change in the infrared spectra of these polymers is the nearly total disappearance of the 12 μ band after prolonged reaction with $TiCl_4$. The diminution of this band, associated with the loss of the original $-C(CH_3)=CH-$ units, whether cis or trans, followed pseudo-first-order kinetics, the rate varying with $[TiCl_4]^n$, where n is 1.0 in the case of the cis polymers and 1.5 in the case of the trans polymer. Contrary to previous reports, practically no cis–trans isomerization of polyisoprene occurs in the course of this reaction, the data being explained entirely by cyclization. With the help of *cis*-1,4 polymers of isoprene-3-*d* and 2-methyl-d_3-1,3-butadiene-1,1-d_2, it was concluded that cyclization, involving a $TiCl_4$-induced carbonium ion mechanism, leads to the formation of six-membered rings fused into predominantly bicyclic structures, connected by methylene groups and/or uncyclized monomer units. Each of the fused ring structures contains a single tetra-, tri-, or di-substituted double bond, the relative amounts of which are in the order tetra- > tri- > di-substituted.

INTRODUCTION

It is well known that natural rubber when treated at 60 to 80° C with strong acids such as H_2SO_4, or Lewis acids such as $SnCl_4$, BF_3, $TiCl_4$, $FeCl_3$, undergoes a progressive resinification with the formation of so-called cyclized rubber (1). Synthetic polyisoprenes also undergo cyclization quite readily (2), but polybutadienes require fairly drastic conditions (3). This reaction has been considered for some time to involve a carbonium ion mechanism, although there is a controversy as to whether the product consists of monocyclic (2, 4–8) or polycyclic (3, 9, 10) ring structures. Thus, Gordon (4–6), who studied the kinetics of cyclization of hevea latex, considered the reaction to involve the protonation of a double bond in *cis*-polyisoprene, followed by an attack of the resulting carbonium ion on an adjacent double bond, both occurring in the Markownikoff sense, to form a cyclic carbonium ion which then deprotonates to give structure I. Similar views were held by D'Ianni *et al.* (2) and various other workers. Flory (11) calculated that if monocyclic rings are formed a definite proportion (13.5%) of the isoprene units should end up as "widows", i.e., not cyclized by virtue of their neighbors having already reacted, so that the final unsaturation of the completely cyclized rubber should be about 57% of that of the original rubber instead of the 50% unsaturation indicated by structure I. This view accounted for the early unsaturation determinations on cyclized rubber by Fisher and McColm (12). On the other hand, van Veersen (9), who contends that unsaturation measurements on cyclized rubber involving iodine monochloride are not reliable because of complications due to substitution reactions, claims that cyclized rubber consists of fused cyclohexyl rings, such as II, connected by unreacted isoprene segments. Van Veersen's mechanism is similar to Gordon's except that the cyclic carbonium ion attacks still another, adjacent double bond to form a condensed ring structure, and this reaction proceeds until eventually it is terminated by a deprotonation process. According to this picture, totally cyclized rubber contains about 20 to 30% of the original unsaturation consisting of widowed double bonds as well as undetermined double bonds somewhere

I II

in the fused rings. Clearly, there is a need for further work to try to settle the controversy regarding the structure of cyclized rubber.

If the protonation step is reversible (4), some cis–trans isomerization might occur during the cyclization reaction since release of the proton from its original point of attachment would re-establish the double bond. On thermodynamic grounds, the new double bond would be expected to be predominantly trans. This is in line with the observed cis–trans isomerization of polyisoprene under the influence of such agents as sulphur dioxide or thiol acids (13, 14) or selenium (15) which can reversibly add to or complex with carbon–carbon double bonds. The possibility of isomerization accompanying cyclization was apparently not considered by Gordon nor, with the possible exception of Ferri (16), by earlier workers who investigated the cyclization of polyisoprene. Ferri showed that treatment of both hevea and balata with chlorostannic acid or titanium tetrachloride led to closely similar products which he considered had structures intermediate between the two isomeric forms of naturally occurring polyisoprene. In view of our present knowledge about the cyclizing tendencies of the materials employed, Ferri's results can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

probably best be explained in terms of the transformation of hevea and balata into essentially the same cyclized structure, rather than by cis–trans isomerization.

Recently, Dolgoplosk and co-workers (17–19) reported that natural rubber in benzene undergoes such an isomerization when treated at 80 to 90° C with titanium tetrachloride, anhydrous hydrogen chloride, or various organometallic compounds. Their results, however, are open to question on the following grounds. Firstly, they did not show the infrared spectra of the treated polymer samples over a reasonably wide range of wavelengths but confined their attention to the diminution of the 12 μ band (associated with the —$C(CH_3)$=CH— units, whether cis or trans). Although a decrease in this band could indicate cis–trans isomerization (the absorption coefficient of the trans —$C(CH_3)$=CH— unit is approximately 70% of that of the corresponding cis unit), it could also signify loss of the original double bonds through cyclization. Thus, in order to establish that cis → trans isomerization has taken place in natural rubber, it is necessary to adduce definite proof of the formation of new trans —$C(CH_3)$=CH— units. This might possibly be indicated, for example, by characteristic infrared absorption at around 7.5 μ and in the 8.5 to 10.0 μ region (13–15). Dolgoplosk and co-workers stated that they observed such characteristic absorption (18), but they neglected to present the appropriate spectra. As will be shown in this paper, the changes which do appear in these regions of the spectra of $TiCl_4$-treated polyisoprene are associated, not with the formation of trans —$C(CH_3)$=CH— units, but with the loss of unsaturation, and other structural modifications involved in cyclization. A second point of criticism is that these workers did not explain how they calculated the cis and trans content in their reacted polymers from data on the relative intensity of the 12 μ band and the residual unsaturation as determined chemically. Nor did they present such intensity data to enable the reader to see how those calculations were carried out. In fact, close examination of the data they did present (17, 18) indicates that these workers overlooked the important point that accompanying the disappearance of the original double bonds in cyclization new double bonds are formed, as in structure I or II. Thus, the relative intensity of the 12 μ band must be compared with the residual —$C(CH_3)$=CH— units, cis or trans, and not with the overall unsaturation; otherwise, one may be led into concluding that cis–trans isomerization has occurred even where it has not.

For the various reasons given above, it was considered worthwhile to reinvestigate the reaction of $TiCl_4$ with polyisoprene. Accordingly, this paper presents the results of an infrared, n.m.r., and kinetic study of the reaction of natural *cis*-, synthetic *cis*-, and natural *trans*-polyisoprenes with $TiCl_4$.

EXPERIMENTAL

Natural rubber (hevea) and balata were obtained through the courtesy of the B. F. Goodrich Company Research Center, Brecksville, Ohio; synthetic polyisoprene having a very high *cis*-1,4 structure as well as a relatively high 3,4 content was a gift of the Shell Chemical Company, Torrance, California. In addition, samples of *cis*-polyisoprene-3-*d* and *cis*-poly(2-methyl-d_3-1,3-butadiene-1,1-d_2), prepared by Dr. David Craig and Mr. Harold Tucker of the Goodrich Research Center, were kindly donated to us.

The *cis*-polyisoprenes were purified by precipitation from benzene solution using methanol as precipitant. The *trans*-polyisoprene was dissolved in refluxing hexane and allowed to crystallize out of solution at −20° C. Stock solutions were then prepared by dissolving the purified polymers in sodium-dried benzene to a polymer concentration of about 20 g/l., and stored under dry nitrogen.

Kinetic runs on the reaction of polyisoprene with $TiCl_4$ were carried out in 500-ml flasks equipped with a nitrogen inlet, stirrer, reflux condenser, and a self-sealing neoprene cap. All equipment was dried overnight in an oven at 140° C, assembled while hot, and allowed to cool under a stream of purified nitrogen. The reaction vessel was immersed in a constant-temperature bath maintained at 80±0.5° C, and 200 ml of stock solution was introduced by means of a volumetric pipette. After stirring the solution for 20 to 30 minutes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to reach the bath temperature, a measured volume of a 1 *M* solution of $TiCl_4$ in petroleum ether was injected by means of a hypodermic syringe through the neoprene cap. Aliquots were withdrawn from the reaction system at periodic intervals by means of a syringe, the reacted polymer samples precipitated with methanol, washed with additional alcohol, and dried in a vacuum oven at 60° C. The treated polymers were analyzed for chemical unsaturation by means of addition of iodine monochloride in acetic acid to the double bonds (20). Structural changes were analyzed by means of infrared absorption spectra of thin films cast from benzene solution onto rock salt plates, using a Beckman IR-4 spectrophotometer. In order to obtain spectra of the fully cyclized polymers free of benzene absorption bands, it was necessary to heat the films under vacuum for about 5 to 6 hours at 50° C. In addition, n.m.r. spectra of the cyclized perprotio and partially deuterated polyisoprenes were obtained at room temperature with a Varian HR-60 spectrometer on 5% polymer solutions in carbon tetrachloride containing 1% tetramethylsilane as an internal standard.

The reactions of the perprotio *cis* and *trans*-polyisoprenes with $TiCl_4$ were followed by measuring the decrease in the intensity of the 12 μ band relative to that of the 7.25 μ band (due to CH_3 groups) as an internal standard. The relative optical density of the 12 μ band, D, given by $O.D._{12\,\mu}/O.D._{7.25\,\mu}$, drops from about 0.79 in the case of natural rubber, 0.74 in synthetic *cis*-polyisoprene, and 0.49 in natural *trans*-polyisoprene (balata) to an ultimate D_∞ value of about 0.09 in the fully reacted *cis*- or *trans*-polyisoprene. Strictly speaking, the optical density measurements were made at 11.95 μ in the case of the cis polymers and at 11.85 μ in the case of the trans polymers. However, it has been convenient to refer to these bands in the text simply as the 12 μ band. The ratio of the extinction coefficients for the cis and trans absorption bands at 11.95 and 11.85 μ in hevea and balata, respectively, may therefore be taken to be equal to 0.79/0.49 or 1.61, which is in very good agreement with the corresponding value of 1.64 indicated by the work of Richardson and Sacher (21). Measurements were also made of the relative optical density of the 11.3 μ band, D', given by $O.D._{11.3\,\mu}/O.D._{7.25\,\mu}$, which provided a measure of the exomethylene units ($\rangle C{=}CH_2$) in the various polyisoprenes.

RESULTS AND DISCUSSION

Infrared Spectroscopy

Typical infrared spectra of the synthetic *cis*- and natural *trans*-polyisoprenes before and after reaction with $TiCl_4$ are presented in Figs. 1 and 2. The most pronounced change in the spectra of the fully reacted polymers is the nearly total disappearance of the 12 μ band. Accompanying this change in each case is a marked reduction in intensity and alteration of the shape of the various bands in the 7.5 to 10.0 μ region, bands which are characteristic of the isomeric forms of polyisoprene. At the same time, the absorption peak at 6.0 μ, corresponding to the C=C stretching vibration in an internal double bond, is greatly diminished. These facts all signify that the cis or trans $-C(CH_3){=}CH-$ units originally present in the two polymers disappear practically completely in the course of the polyisoprene–$TiCl_4$ reaction. The remaining absorption in the 7.5 to 10.0 μ region is too weak and indefinite to indicate whether the residual double bonds in either polymer comprise both cis and trans units, although under certain favorable conditions such an analysis is possible (13–15). The changes observed in the polyisoprene spectra can be accounted for entirely by cyclization without having to invoke any contribution from cis–trans isomerization, as will be confirmed later. For the present, it should be noted that the spectra of the final reaction products obtained from the two isomers of polyisoprene (Figs. 1C, 2C) are practically identical, indicating that essentially the same polymeric structures are produced. This result is in full accord with the experience of Ferri (16), who obtained very similar products on treating hevea and balata with $TiCl_4$. Moreover, the spectra in Figs. 1C and 2C are in qualitative agreement with the results of D'Ianni *et al.* (2) and others (22 and references cited therein) concerning the disappearance of the 12 μ band in polyisoprene on cyclization.

An additional feature of the spectra of the fully reacted perprotio polyisoprenes which should be mentioned is the band at 6.1 μ. This probably represents the C=C stretching vibration in an external double bond such as the exomethylene group for which direct evidence is provided by the band of medium intensity at 11.3 μ. As may be seen, the

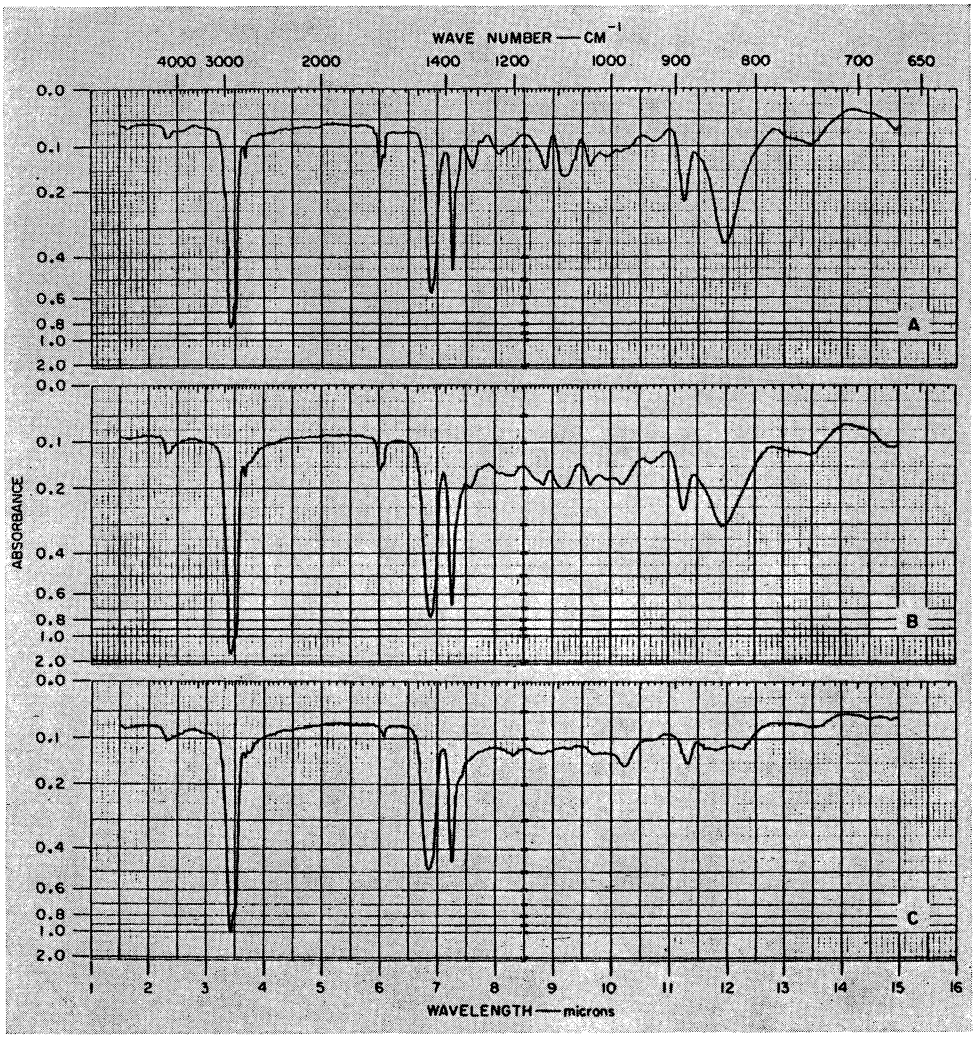

FIG. 1. Infrared spectra of synthetic *cis*-polyisoprene before and after reaction with $TiCl_4$ in benzene at 80° C. (A) Initial polymer; (B) partially cyclized polymer; (C) completely cyclized polymer.

latter band develops in the spectra of natural *trans*-polyisoprene and decreases somewhat in those of the synthetic cis polymer. Although not presented here, the spectrum of cyclized hevea was found to have an 11.3 μ band of intensity comparable to that obtained with cyclized balata. Examination of Fig. 3B reveals that this band also appears in the spectrum of cyclized *cis*-polyisoprene-3-*d* and is likewise attributed to the formation of $\diagdown C{=}CH_2$ units in this polymer.

Corresponding to the nearly complete disappearance of the 12 μ band in the perprotio polymers is the complete elimination of the 14.7 μ band in cyclized polyisoprene-3-*d* representing the loss of the original —$C(CH_3)$=CD— units in this polymer. Inspection of another infrared spectrum covering the wavelength range of 10 to 25 μ confirmed the disappearance of the 14.7 μ band in the deuterated polymer. Examination of Fig. 3B

shows also that the sharp band at 4.5 μ (C—D stretching vibration for an olefinic carbon atom) has been replaced by the broader band at 4.65 μ (C—D stretching vibration associated with a saturated carbon atom). This spectral change not only verifies the loss of the original —$C(CH_3)$=CD— units in monodeuterio polyisoprene through cyclization but it also indicates that these double bonds have become saturated to give $\rangle C(CH_3)$—CDH— and/or $\rangle C(CH_3)$—CD$\langle$ units.[2] On the basis of a monocyclic structure, these units could be found in structures III and IV. However, these structures involving tri- and di-substituted double bonds, respectively, cannot be important since there is very

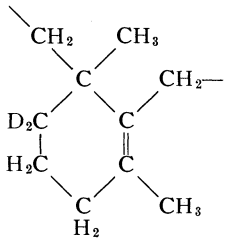
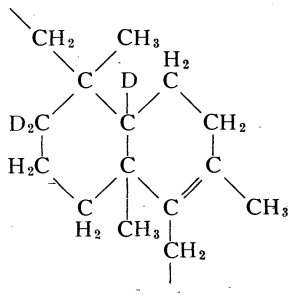
tetrasubstituted double bond, can be dismissed since it is incompatible with the nearly complete retention of deuterium in cyclized polyisoprene-3-*d*.[3] Furthermore, the alternative structure I*b*, which has the same D/H ratio as the starting polymer, would also

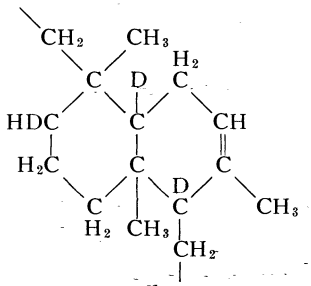


I*b*

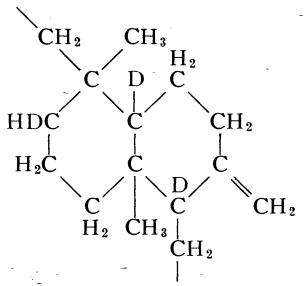
be ruled out on the grounds that whereas CD_2 groups produce a pair of absorption bands at 4.5 and 4.75 μ (23, 24), we see only a fairly symmetrical singlet at 4.65 μ in Fig. 3B. In order to rationalize the infrared results, it is necessary to postulate that cyclized polyisoprene-3-*d* consists of fused rather than monocyclic rings. As we shall see shortly, the fused ring structure is supported by n.m.r. data which point to a predominantly bicyclic structure for cyclized rubber. Thus, cyclized polyisoprene-3-*d* may be depicted by the following structures, the relative importance of which is probably in the order



V



VI



VII

V > VI > VII. The contribution of these structures, combined with that from some monocyclic rings and various other highly fused rings which perhaps also occur in cyclized rubber, gives rise to more —CDH— and tertiary C—D groups than CD_2 groups. This could account for the shape and relative intensity of the 4.65 μ band, which is probably the unresolved envelope of a weak doublet from CD_2 groups and a strong singlet from CDH and tertiary C—D groups.

The completeness with which the 14.7 μ band in Fig. 3B has disappeared compared to the incomplete removal of the 12 μ band in Figs. 1C and 2C deserves comment. In terms of a predominantly bicyclic structure for cyclized polyisoprene-3-*d*, we would expect to find some 10% of the original double bonds ending up as widows. The absence of the 14.7 μ absorption indicates that the widowed —$C(CH_3)$=CD— units have probably been replaced by —$C(CH_3)$=CH— units through a $TiCl_4$-induced double-bond shift. If this is so, there should be some residual absorption at around 12 μ instead of at 14.7 μ. Significantly, the 11.5 to 13 μ regions in the spectra of all three cyclized polyisoprenes presented in this paper are very similar in both overall shape and in relative intensity.

[3]*The deuterium content of the original polymer was 0.98 deuterium atom per isoprene unit and that of the cyclized polymer was 0.94 deuterium atom per isoprene unit, indicating only 4.3% deuterium–hydrogen exchange. The deuterium analysis was done by Mr. Joseph Nemeth, 303 Washington Ave., Urbana, Illinois.*

It may be noted that Figs. 1C and 2C, but not 3B, show a band at 10.25 μ. At first glance this band might be thought to represent the formation of some trans —CH=CH— units in ordinary polyisoprene on cyclization since such units are known to absorb at around 10.35 μ (24). However, this cannot be the case because then either the same kind of double bonds and/or the analogous —CD=CH— units would have to appear in cyclized polyisoprene-3-*d* and they do not. Thus, the absence of absorption at 10.25 to 10.35 μ in Fig. 3B rules out the former possibility while the absence of absorption at 11.2 μ (24) rules out the latter possibility. To be sure, there is a band at 11.3 μ in this figure but its shape and intensity, compared to those of the corresponding bands in Figs. 1C and 2C, clearly indicate the presence of $\diagdown\!\!\diagup C{=}CH_2$ groups. The most likely interpretation of the 10.25 μ band in cyclized polyisoprene-d_0 is that it is due to the CH_2 deformation vibrations associated with some ring structure. At the present time there is not much that can be said about such absorption other than to point out that if it involves a coordinated vibration of a number of adjacent methylene groups the absorption would be disturbed and its wavelength changed by the introduction of a CDH or CD_2 group into a sequence of CH_2 groups. This could explain why there is no 10.25 μ band in the spectrum of cyclized polyisoprene-3-*d*, the structure of which is considered to consist principally of the bicyclic rings V, VI, and VII.

To conclude the discussion of the spectrum in Fig. 3B, mention may be made of the 7.7 μ band, which is probably also related to the CDH groups (23).

Nuclear Magnetic Resonance Spectroscopy

A typical n.m.r. spectrum of the product obtained from the reaction of *cis*-polyisoprene with $TiCl_4$ is shown in Fig. 4 as the uppermost curve bounding the areas A, B, C, and D. The extensive overlapping of resonance peaks throughout the 7 to 10 τ region of this spectrum is due to the cyclic structure of the reaction product, which contains a variety

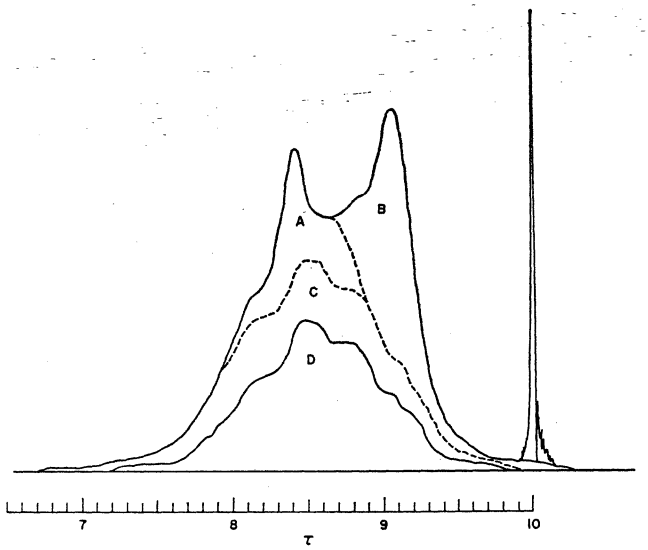

FIG. 4. Proton n.m.r. spectra of cyclized polyisoprenes at 60 Mc. The uppermost curve, comprising the envelope of the combined areas A, B, C, and D, corresponds to the cyclized perprotio polyisoprene. The curve which bounds area D corresponds to the cyclized poly(2-methyl-d_3-1,3-butadiene-1,1-d_2). For description of A, B, and C, see the text.

of non-equivalent methylene groups with different chemical shifts. Despite the obvious complexity of this spectrum, two prominent peaks stand out at around 8.4 and 9.1 τ, which correspond to protons on methyl groups attached to olefinic and saturated carbon atoms, respectively. Unfortunately, it is impossible to determine from this spectrum alone the relative amounts of the two types of methyl groups in cyclized rubber. Otherwise, we would be able to say at once that the latter material consists of mono-, bi-, tri-, or poly-cyclic rings according to whether the ratio of the methyl groups on saturated carbon atoms to the methyls on olefinic carbon atoms was one, two, three, or even higher. In an effort to resolve this question, the n.m.r. spectrum of cyclized poly(2-methyl-d_3-1,3-butadiene-1,1-d_2), viz., the curve bounding area D, was superimposed on that of the cyclized perprotio polymer. Due allowance was made for the fact that the pentadeuterio polymer has only 37.5% of the proton content of the perprotio polymer; hence, the area D was adjusted, by suitable control of the gain in the spectrometer, to 37.5% of the combined area A+B+C+D.

It is obvious from a comparison of the n.m.r. spectra of the two cyclized polymers shown in Fig. 4 that substitution of CH_3 by CD_3 resulted in the elimination of the two prominent methyl peaks. Moreover, there was a more pronounced loss in nuclear resonance in the "saturated" methyl region than in the "unsaturated" methyl region. This suggested that in the n.m.r. spectrum of cyclized perprotio polyisoprene the $CH_3-\overset{|}{\underset{|}{C}}-$peak is at least about twice as intense as the $CH_3-\underset{|}{C}=$peak. In fact, careful examination of the *differential* n.m.r. spectrum represented by the areas A, B, and C show that the most probable structure for cyclized rubber is the one consisting predominantly of bicyclic rings. Thus, if structures VIII and VIII*a* represent the cyclized perprotio and pentadeuterio polyisoprenes, respectively, it is clear that area A+B+C must represent the protons of the following groups in VIII: the three methylenes shown in bold print and also the three methyls. If we now make the reasonable assumption that these six methylene protons have essentially the same chemical shifts as the other eight methylene protons, with the one tertiary proton lying somewhere in between, we can regard C, which is drawn with the same contour as D and with an area of 6/9 or 2/3 of that of D, as representing the former six methylene protons. The methyl groups would then fall into the remaining area, A+B, which has been divided into two parts in accordance with what is known of the chemical shifts of the two types of methyl protons involved. As a result the area corresponding to the methyls on saturated carbon atoms, viz., B, is found to be about twice the area corresponding to the methyls on olefinic carbon atoms, or A. Although this

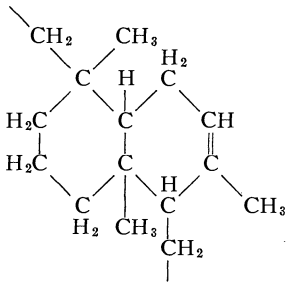
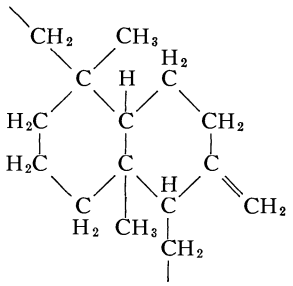
For personal use only.

analysis of the differential n.m.r. spectrum is not rigorous, it is nevertheless reliable enough to indicate that we are dealing with a predominantly bicyclic structure rather than with a predominantly monocyclic or other polycyclic structure.

Preliminary examination of the n.m.r. spectrum of cyclized polyisoprene in the 4.5 to 5.5 τ region indicated the presence of 3.4% olefinic protons distributed as follows: 1.4% in —C(CH_3)=C*H*— units, as in IX (4.7 τ); 1.2% in uncyclized —C(CH_3)=C*H*— units (4.9 τ); and 0.8% in $\diagdown$C=CH_2 groups (5.4 τ), as in X. On the basis of an exclusively bicyclic structure, we can calculate that structures IX and X would comprise 33 and 9%,



IX



X

respectively, of the isoprene units, with 10% in the form of widows, and the remaining 48% of the isoprene units contained in structure VIII. However, it may be presumed that cyclized rubber contains, in addition to a very large concentration of bicyclic rings, some monocyclic rings and some tri-, tetra-, and other poly-cyclic rings, so that the above calculations for the relative amounts of structures VIII, IX, and X can only be regarded as approximations.

In order to arrive at a fully definitive structure for cyclized rubber, the cyclization of another partially deuterated polyisoprene, —CD_2—C(CH_3)=CH—CD_2—, will be investigated. It is expected that this polymer on cyclization will yield an n.m.r. spectrum in which the two characteristic methyl peaks will be clearly resolved, thus enabling their relative areas to be determined accurately and hence also the average number of fused rings per polycyclic group.

Kinetics and Mechanism

Results of typical kinetic runs for the reaction of synthetic *cis*- and natural *trans*-polyisoprenes with $TiCl_4$ are given in Table I. The values of the optical density, D, at infinite reaction time are only approximations since the residual absorption at around 12 μ is very broad and non-specific (Figs. 1C, 2C). Thus, no particular significance can be attached to the value of 0.090 for D_∞. It was, therefore, more reasonable to calculate the percentage of residual —C(CH_3)=CH— units as $100(D-D_\infty)/(D_0-D_\infty)$ rather than as $100D/D_0$. However, for such calculations, it was not practical to follow the reactions to completion.

Attention is called to the similarity of the unsaturation values, determined both spectroscopically and chemically, for samples of *cis*- and *trans*-polyisoprenes after different periods of reaction with $TiCl_4$. The spectroscopic unsaturation values were calculated on the assumption that the disappearance of the 12 μ band is due entirely to cyclization of the polymers to bicyclic ring structures. Consider, for example, the 60-minute run for the cis polymer in which there are assumed to be 74.5% residual —C(CH_3)=CH— units.

*The plots of log $(D-D_\infty)$ vs. time were linear, giving pseudo-first-order rate constants $k' = 4.02$ and 1.83×10^{-3} min^{-1} for the *cis*- and *trans*-polyisoprenes, respectively.
†Calculated as $100(D-D_\infty)/(D_0-D_\infty)$.
‡Based on ICl titrations. For convenience in the calculations, the double bonds in the starting polymers were arbitrarily taken to be 100% —C(CH$_3$)=CH— units. The small contribution of the exomethylene units in the various polymer samples was neglected in these calculations.
§Corresponding unsaturation, based on n.m.r. results, is estimated as about 40%.

This corresponds to the loss of 25.5% of the original double bonds. On the basis of cyclization, whether to ring structure VIII, IX, or X, one-third of the 25.5% unsaturation lost, or 8.5%, would reappear as new double bonds. The resulting total unsaturation (spectroscopic), 83.0%, is only slightly less than the chemical unsaturation value of 85.7% determined by iodine monochloride titration of the polymer double bonds. The agreement between the two sets of unsaturation values is, however, somewhat poorer at the higher degrees of cyclization. This disparity is considered to arise from an inherent difficulty with the spectroscopic estimate inasmuch as there is a broadening of the 12 μ band with disappearance of the original unsaturation. This makes the value of D somewhat less than it otherwise would be. Significantly, the calculated unsaturation values were less than the corresponding chemical values by approximately the same amounts for both *cis*- and *trans*-polyisoprenes. Nevertheless, the spectroscopic and chemical unsaturation values are in close enough agreement to show that isomerization cannot be an important part of the overall reaction of polyisoprene with $TiCl_4$ as claimed by Dolgoplosk and co-workers (17–19). Accordingly, we are justified in disregarding changes in D due to possible isomerization when calculating the residual —C(CH$_3$)=CH— units in the manner shown in Table I. Finally, it should be pointed out that the chemical unsaturation of the completely cyclized *cis*- and *trans*-polyisoprenes (43 to 46%) are in good agreement with the unsaturation value indicated by n.m.r. data for a bicyclic structure for cyclized rubber, *viz.*, 40%.[4] The latter values obviously differ from the values of 56 to 58% reported by previous workers (5, 7, 12) for monocyclic structures.

Representative kinetic plots for the disappearance of the 12 μ band in the spectra of *cis*- and *trans*-polyisoprenes are shown in Figs. 5 and 6. The essential first-order character of the reaction indicates that the rate is given by a kinetic expression of the form

$$[1] \qquad -dU/dt = kUT^n = k'U,$$

[4]*Assuming 10% widowed double bonds, the consumption of 90% of the original double bonds in cyclization results in the formation of 30% new double bonds for a total unsaturation of about 40%.*

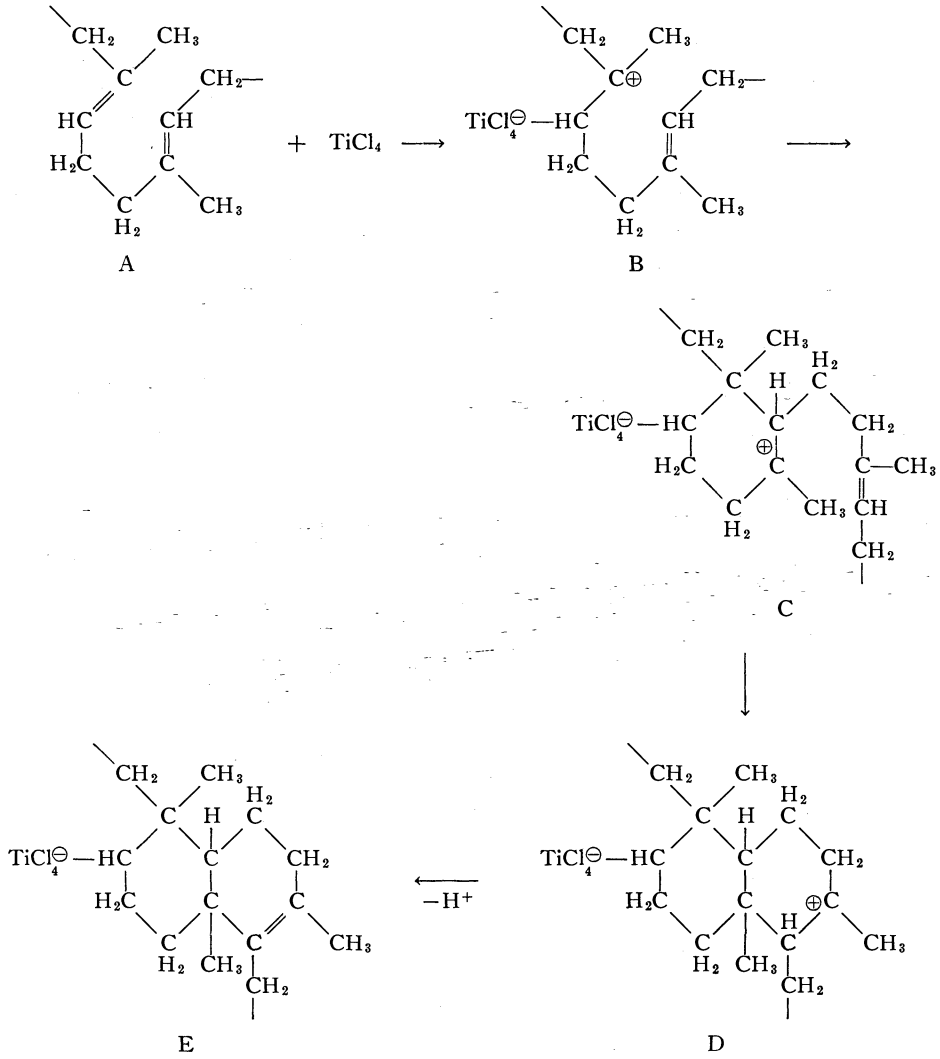
For personal use only.

where U denotes the concentration of cyclizable isoprene segments, as measured by the relative intensity of the 12 μ absorption band, T is the concentration of the effective catalyst for the reaction, and k' is the pseudo-first-order rate constant which depends on the catalyst concentration. The linearity of the semilogarithmic plots throughout the course of the reaction shows that the effective catalyst, whether the original $TiCl_4$ molecules and/or the proton by-products, maintains a steady-state concentration in the system. In analogy to the carbonium ion mechanism proposed for the acid-catalyzed cyclization to hevea latex (4, 5), but involving the formation of bicyclic rings, the overall reaction of polyisoprene with $TiCl_4$ may be written as



In this sequence of steps, for every $TiCl_4$ molecule attached to the isoprene double bond a proton is released which can either initiate further cyclization or exchange with the attached $TiCl_4$ as in E to give, finally, structure VIII and a regenerated Lewis acid catalyst. Thus, the combined concentration of free $TiCl_4$ molecules and available protons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

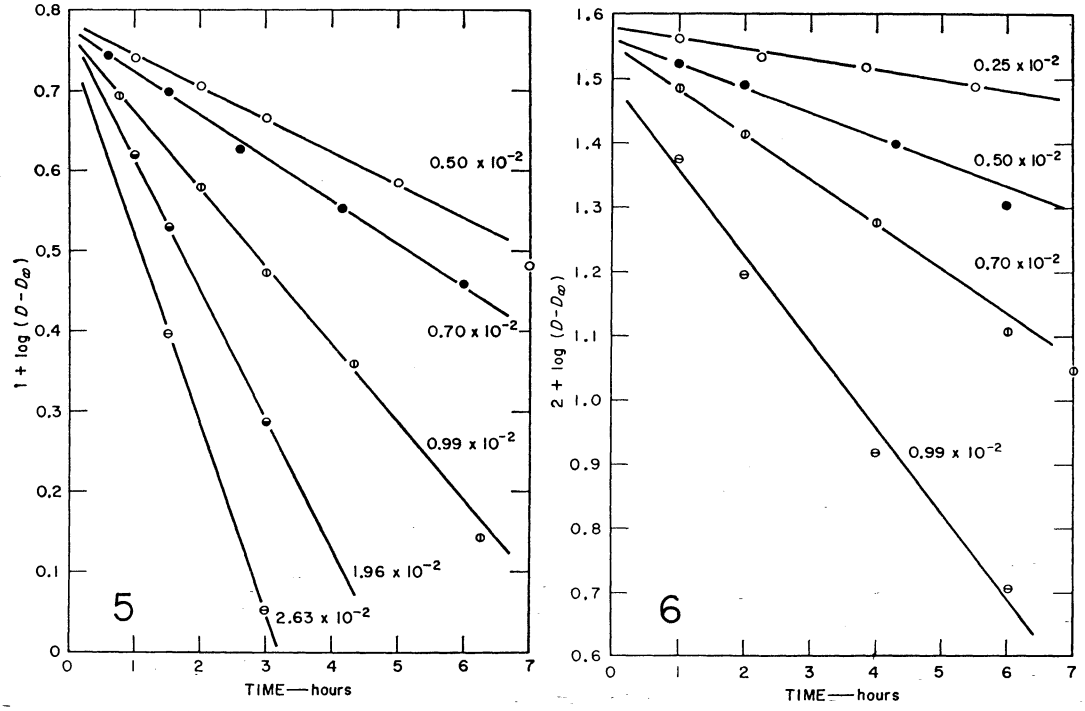

FIG. 5. Kinetic plots for the disappearance of the 12 μ band in synthetic *cis*-polyisoprene on reaction with $TiCl_4$. Concentrations of $TiCl_4$ are given in mole/l.

FIG. 6. Kinetic plots for the disappearance of the 12 μ band in natural *trans*-polyisoprene on reaction with $TiCl_4$. Concentrations of $TiCl_4$ are given in mole/l.

must remain essentially constant, and this is consistent with the first-order character of the kinetic plots. Furthermore, the proton and the $TiCl_4$ molecule must attack the isoprene double bond with comparable ease to form the carbonium ion, which is rapidly followed by cyclization of two adjacent isoprene units.

In addition to the one shown above, there are two other routes for the deprotonation of D involving hydrogens on carbon atoms adjacent to the carbonium ion site. These yield structures IX and X. Since the relative stabilities of the different possible double bonds are probably in the order tetra- > tri- > di-substituted, it is not surprising that VIII is the predominant cyclic structure, followed by IX, with only a small amount of exomethylene units, as in X, formed in the course of the cyclization reaction.

Since there is no a priori reason for the cyclization to stop after only three monomer units have been involved in forming bicyclic structures VIII to X, it is quite possible that some more highly fused rings are also formed in the polyisoprene–$TiCl_4$ reaction. However, the experimental data presented here show that for some unknown reason, probably steric in origin, most of the cyclization ceases at the bicyclic stage.

Although considerable effort was made to exclude moisture in this work, it is entirely possible that traces of water were present in the reaction system which could serve as a co-catalyst in the $TiCl_4$-induced cyclization of polyisoprene.

It should be pointed out that any reversibility to the attachment of $TiCl_4$ onto the isoprenic double bond cannot be significant since it would lead to cis–trans isomerization.

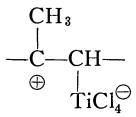
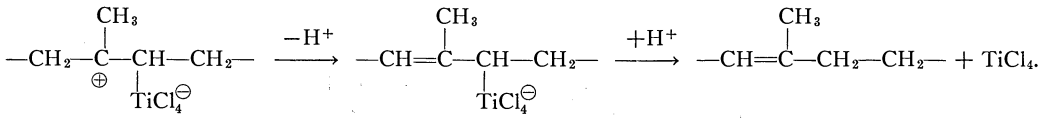
Presumably, the carbonium ion XI, as soon as it is formed, undergoes ring closure with



XI

an adjacent isoprenic double bond, if available for cyclization, before detachment of $TiCl_4$ can take place. However, in the case of a widowed double bond, where the opportunity for cyclization to monocyclic rings no longer exists, such a detachment with consequent isomerization may take place. On the other hand, it is possible for double-bond shift in a widowed segment to occur according to the process



Obviously, in the cyclization of the monodeuterio polyisoprene to form structure V, deuterons released in the "deprotonation" step proceed to initiate further cyclization, while the protons released in the formation of structures VI and VII likewise go on to induce cyclization. Since practically all the released deuterons and protons are consumed in what is essentially a "closed" chain reaction system, it would be expected that the resulting cyclized polyisoprene-3-*d* should show little or no isotope exchange. The fact that the latter polymer actually has a slightly lower deuterium content than the starting polymer may be explained by assuming that some $TiCl_4$ which is complexed to the cyclized polymer is replaced by protons from methanol in the course of precipitating the polymer from solution at the end of the cyclization reaction.

The slopes of the plots of Figs. 5 and 6, as well as those of the corresponding plots for natural *cis*-polyisoprene, multiplied by 2.3, give the pseudo-first-order constants k', which are plotted against the $TiCl_4$ concentrations in Fig. 7. The data for both synthetic and natural *cis*-polyisoprenes fall on a common line the slope of which has the value of 1.08, which determines the exponent n in equation [1]. The cyclization reaction, in addition to being first order in isoprene double bonds, is thus also first order in $TiCl_4$. On the other hand, the kinetic data for the natural *trans*-polyisoprenes fall on a different line having a slope of 1.51. We have no explanation for the apparent 1.5-order in $TiCl_4$ in the cyclization of balata.

Figure 8 shows the growth of the 11.3 μ band due to exomethylene structure in the naturally occurring *cis*- and *trans*-polyisoprenes in the course of the reaction with $TiCl_4$. There has been some controversy as to whether these polyisoprenes actually contain $\diagdown C{=}CH_2$ units. Thus, Binder and Ransaw (25) hold that 2.2% of the double bonds in hevea and 1.3% in balata are of the isopropenyl $CH_2{=}C(CH_3)-$ type, whereas Fraga (26) contends that such units are absent in these polymers, which he assumes to have an essentially 100% *cis*- or *trans*-1,4 structure. The latter point of view has been supported recently by high-resolution n.m.r. studies (27). Nevertheless, there is a band at 11.2 μ in the spectra of the naturally occurring polyisoprenes which, with the development of the 11.3 μ absorption, merges into the broad band centered at the latter wavelength.

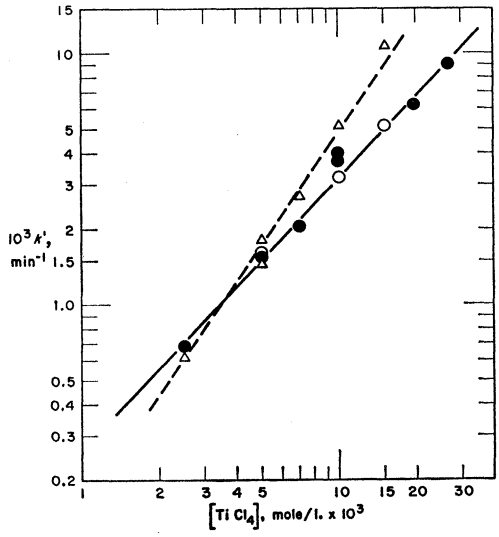

FIG. 7. Dependence of the pseudo-first-order rate constant for the disappearance of the 12 μ band in polyisoprene on the concentration of $TiCl_4$. Synthetic *cis*- (●), natural *cis*- (○), and natural *trans*- (△) polyisoprenes.

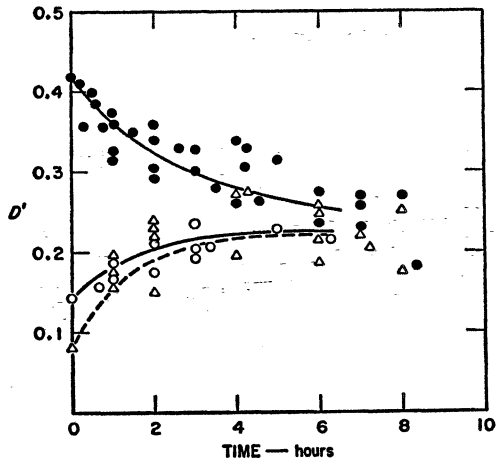

FIG. 8. Growth or decay of the 11.3 μ band in various polyisoprenes. Synthetic *cis*- (●), natural *cis*- (○), and natural *trans*- (△) polyisoprenes.

Since it is difficult to determine the relative amounts of the 11.2 and 11.3 μ components in this band, especially in the early stages of the reaction, the initial absorption intensities at 11.2 μ are treated, for convenience, just as though they were at 11.3 μ, and this is reflected in the particular values for hevea and balata indicated in Fig. 8. However, these initial values are not considered to have any special significance here. Figure 8 also shows the decay of the 11.3 μ band in a synthetic *cis*-polyisoprene containing a relatively high concentration (4.4%) of isopropenyl groups initially. As can be seen, the exomethylene content in all three polymers tends to reach a more or less equilibrium value (about 2.5%

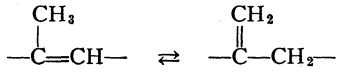
For personal use only.

of the *original* double bonds). It is not known whether this results from an isomerization of the type



or whether, as seems more likely, the processes for the formation and decay of the exomethylene units are independent. Thus, it is easy to imagine that some of the initially present $\diagdown C{=}CH_2$ units in the synthetic *cis*-polyisoprene are consumed in cyclization much like the ordinary isoprenic double bonds, while other exomethylene units are formed as a result of the cyclization.

ACKNOWLEDGMENTS

The authors wish to record their appreciation to Mrs. Harriett H. Johnson, who performed the unsaturation measurements on the various polymers, and to William R. Anderson, Jr., for providing n.m.r. data on the cyclized polyisoprenes.

THE APPARENT IONIZATION CONSTANTS OF SOME ORGANOSILYLMETHYLBENZOIC ACIDS

H. R. ALLCOCK[1]
Chemistry Department, University of Leicester, Leicester, England
Received November 27, 1962

ABSTRACT

The apparent ionization constants of several organosilylmethylbenzoic acids of formula p-$R_3SiCH_2C_6H_4CO_2H$ were measured in 39 wt% aqueous methanol using a spectrophotometric method. p-$(CH_3)_3SiCH_2C_6H_4CO_2H$ was found to be a slightly stronger acid than p-$(C_2H_5)_3SiCH_2C_6H_4CO_2H$ and p-$(n$-$C_3H_7)_3SiCH_2C_6H_4CO_2H$, but replacement of $(CH_3)_3Si$ in p-$(CH_3)_3SiCH_2C_6H_4CO_2H$ by $(C_6H_5)(CH_3)_2Si$—, $(p$-$CH_3C_6H_4)(CH_3)_2Si$—, and $(C_6H_5)_3Si$— brought about no significant change in acid strength. All the organosilylmethlybenzoic acids studied were weaker acids than p-toluic acid.

INTRODUCTION

Several investigators have attempted to correlate the dissociation constants of organosilylcarboxylic acids with the inductive and mesomeric properties of the R_3Si group (where R is alkyl or aryl). For example, Sommer *et al.* (1) reported that the dissociation constant of the acid $(CH_3)_3SiCH_2CO_2H$ was less than that of acetic acid, and Eaborn and Parker (2) found that the compounds o-, m-, and p-$(CH_3)_3SiCH_2C_6H_4CO_2H$ were weaker acids than the corresponding toluic acids. These effects were ascribed to a strong inductive electron supply by the $(CH_3)_3Si$ group.

In compounds where silicon is bonded to an aromatic ring, a mesomeric effect is also possible due to $d\pi$–$p\pi$ bonding between silicon and the phenyl group (3). Thus, Chatt and Williams (4) found that the acid p-$(CH_3)_3SiC_6H_4CO_2H$ was very slightly stronger than benzoic acid. In this compound the mesomeric electron withdrawal by the $(CH_3)_3Si$ group is presumably of greater influence than the inductive electron supply of the same group. However, successive replacement of methyl groups in this compound by phenyl groups resulted in a progressive increase in acid strength (5), which indicated that the inductive electron withdrawal by the phenyl groups in this position slightly outweighed the mesomeric electron supply to silicon.

It was of interest, therefore, to examine the dissociation constants of acids of type p-$R_3SiCH_2C_6H_4CO_2H$, in which R is methyl, ethyl, n-propyl, or aryl, since such variations would affect only the electron supply to silicon. The transmission of this effect to the carboxyl group would not be complicated by mesomeric or steric factors, and the influence of the group R should be more readily discernible.

RESULTS AND DISCUSSION

Dissociation constants of the organosilylmethylbenzoic acids and p-toluic acid were measured in 39 wt% aqueous methanol using an ultraviolet spectrophotometric method. The insolubility of the acids in water necessitated the use of an aqueous methanolic medium and, since no correction is applied for the solvent, the values obtained are considered as apparent dissociation constants. The results are shown in Table I.

The acid strength of p-$(CH_3)_3SiCH_2C_6H_4CO_2H$ is slightly lower than that of p-toluic acid. This result is in agreement with the data of other authors (2, 6), and reflects the

‡Compare with value of 1.35 obtained by the same authors.

strong inductive electron supply by the $(CH_3)_3Si$ group when separated from the benzoic acid system by a methylene group. Replacement of the $(CH_3)_3Si$ group in this compound by $(C_2H_5)_3Si$ or $(n\text{-}C_3H_7)_3Si$ brings about a further lowering of the acid strength, and this effect is consistent with the increased inductive electron supply to silicon from the ethyl and propyl groups (7). The lowering of the dissociation constants for the ethyl and propyl compounds is of particular significance in view of the separation of these groups from the carboxyl group, and provides a measure of the sensitivity of the method. The result is also of interest in view of the data of Chatt and Williams (4), who found that the acid strengths of the compounds p-$(CH_3)_3SiC_6H_4CO_2H$ and p-$(C_2H_5)_3SiC_6H_4CO_2H$ were almost equal. In these compounds, the inductive effects of the alkyl groups are probably masked by mesomeric influences resulting from the direct silicon–phenyl bonding.

Replacement of the $(CH_3)_3Si$ group in p-$(CH_3)_3SiCH_2C_6H_4CO_2H$ by $(C_6H_5)(CH_3)_2Si$, $(p\text{-}CH_3C_6H_4)(CH_3)_2Si$, or $(C_6H_5)_3Si$ brought about no significant change in the dissociation constant. Thus, the inductive electron withdrawal by phenyl groups attached to silicon (5) is not apparent in these compounds. The results suggest that, for phenyl groups in R_3Si, a mesomeric electron supply from phenyl to silicon counteracts the inductive electron withdrawal from silicon, and the overall effect approximates to that of a methyl group attached to silicon. A phenyl group attached to silicon is, therefore, weakly electron supplying. The report by Sommer *et al.* (1) that the compound $(C_6H_5)(CH_3)_2SiCH_2CO_2H$ is a weaker acid than $(CH_3)_3SiCH_2CO_2H$ can thus be attributed to the effects of electron supply to silicon by the phenyl group.

Eaborn and Parker (2) reported a bathochromic shift of the main peak in ultraviolet spectra of p-$(CH_3)_3SiCH_2C_6H_4CO_2H$ compared with p-toluic acid. This effect was attributed to an electron supply from the trimethylsilyl group by a delocalization effect. Table II lists the positions of the absorption maxima for the acids, anions, and buffered mixtures studied in the present series. Replacement of methyl groups in $(CH_3)_3Si$ by phenyl groups brought about no significant shift in the position of the absorption peak, indicating that there is little interaction between phenyl groups and other groups attached to silicon.

EXPERIMENTAL

p-(Trimethylsilylmethyl)benzoic Acid

This acid, m.p. 197° C, was prepared in 50% yield by the method described by Eaborn and Parker (8).

p-(Triethylsilylmethyl)benzoic Acid

The Grignard reagent was prepared from p-chlorobenzyl chloride (80 g) and magnesium turnings (12.5 g) in dry ether (300 ml), and was added slowly to a stirred, cooled solution of tetrachlorosilane (85 g) in ether

(222 ml). The mixture was refluxed for 3 hours and was then treated with the Grignard reagent prepared from ethyl bromide (164 g) and magnesium turnings (36 g) in ether (400 ml). This mixture was refluxed for 26 hours, and was then treated with aqueous 10% sulphuric acid. The ethereal layer was separated, washed with water, and dried (Na_2SO_4). Removal of the ether and fractionation gave an impure sample of *p-chlorobenzyltriethylsilane* (20 g, 17%), b.p. 141–143° C at 10 mm, $n_D^{20°}$ 1.5146. (Found: C, 62.3; H, 8.62%. $C_{13}H_{21}SiCl$ requires: C, 65.0; H, 8.8%.) The lithium reagent was prepared from this compound (20 g) and lithium (1.5 g) in ether (100 ml), with high-speed stirring and gentle heating during the reaction. The mixture was then poured onto a slurry of dry ice and ether, excess lithium was removed by filtration through glass wool, and the filtrate was treated with aqueous 10% sulphuric acid. The ethereal layer was separated and washed with 0.2 *N* aqueous sodium hydroxide solution, and the extracts were added immediately to aqueous hydrochloric acid (1 *N*). The precipitated solid was extracted with ether and was recrystallized from aqueous acetone and from an acetone – petroleum ether mixture to give *p-(triethylsilylmethyl)benzoic acid* (0.5 g), m.p. 235° C. (Found: C, 66.7; H, 8.82%. $C_{14}H_{22}O_2Si$ requires: C, 67.0; H, 8.85%.)

p-(Tri-n-propylsilylmethyl)benzoic Acid

This compound was prepared by essentially the same method as described for the previous acid. Tetrachlorosilane was treated with *p*-chlorobenzylmagnesium chloride and with *n*-propylmagnesium bromide to yield an impure form of *p-chlorobenzyltri-n-propylsilane*, b.p. 176–180° C at 10 mm, $n_D^{20°}$ 1.5191. (Found: C, 63.9; H, 8.61%. $C_{16}H_{27}SiCl$ requires: C, 67.8; H, 9.63%.) This compound (16 g) was converted to the lithium derivative and was carbonated to give *p-(tri-n-propylsilylmethyl)benzoic acid* (0.5 g), m.p. 197° C.

p-(Phenyldimethylsilylmethyl)benzoic Acid

A solution of phenylmagnesium bromide, prepared from bromobenzene (78.5 g) and magnesium turnings (12.5 g) in ether (300 ml), was added slowly to dimethyldichlorosilane (70 g) in dry ether (100 ml). The mixture was refluxed for 2 hours and was treated with the Grignard reagent prepared from *p*-chlorobenzyl chloride (80.5 g) and magnesium turnings (12.5 g) in ether (400 ml). The mixture was refluxed for 20 hours, hydrolyzed with aqueous 10% sulphuric acid, and the ethereal layer was washed and dried ($NaSO_4$). Distillation yielded a colorless oil, b.p. 190–200° C at 29 mm, which solidified when cooled. This material was recrystallized from petroleum ether to give *p-chlorobenzylphenyldimethylsilane* (25 g, 19%), m.p. 55° C. (Found: C, 69.1; H, 6.58%. $C_{15}H_{17}SiCl$ requires: C, 69.1; H, 6.57%.) The lithium reagent was prepared from this compound (8 g) and lithium (1 g) in ether (50 ml), and the mixture was carbonated and separated as described previously. Recrystallization from aqueous ethanol and from aqueous acetone yielded *p-(phenyldimethylsilylmethyl)benzoic acid* (2 g, 22%), m.p. 165° C. (Found: C, 71.1; H, 6.86%. $C_{16}H_{18}SiO_2$ requires: C, 71.0; H, 6.72%.)

p-(p-Tolyldimethylsilylmethyl)benzoic Acid

The Grignard reagent, prepared from *p*-chlorobenzyl chloride (40 g) and magnesium turnings (7 g) in ether (200 ml), was added slowly to a cooled, stirred solution of dimethyldichlorosilane (42 g) in ether (50 ml). The mixture was refluxed for 10 hours and was then treated with a solution of *p*-methylphenylmagnesium bromide, prepared from *p*-bromotoluene (42 g) and magnesium turnings (7 g) in ether (150 ml). After the mixture was refluxed for 50 hours it was hydrolyzed, washed, dried, and distilled to give a colorless liquid, b.p. 240° C at 10 mm, which, when fractionated, yielded *p-chlorobenzyl-p-tolyldimethylsilane* (10 g, 14%), b.p. 185° C at 6 mm, 150° C at 3 mm, $n_D^{20°}$ 1.5581. (Found: C, 72.2; H, 7.51%. $C_{16}H_{19}SiCl$ requires: C, 70.0; H, 6.96%.) This compound (8 g) was converted to the lithium derivative, was carbonated with dry ice, and the acid was isolated as described previously. Recrystallizations from aqueous ethanol and from aqueous acetone yielded *p-(p-tolyldimethylsilylmethyl)benzoic acid* (2.5 g, 27%), m.p. 174° C. (Found: C, 71.8; H, 7.01%. $C_{17}H_{20}SiO_2$ requires: C, 71.9; H, 7.10%.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

p-(Triphenylsilylmethyl)benzoic Acid

Triphenylchlorosilane (75 g) in ether (100 ml) was added slowly to the Grignard reagent prepared from *p*-chlorobenzyl chloride (40 g) and magnesium turnings (6 g) in ether (200 ml). The mixture was refluxed for 24 hours, hydrolyzed, washed, and dried. Removal of the ether yielded a mixture of *p*-chlorobenzyltriphenylsilane and triphenylsilanol. The former was extracted from the latter with petroleum ether (b.p. 40–60° C), and was recrystallized from aqueous ethanol to give *p-chlorobenzyltriphenylsilane* (5 g, 5%), m.p. 111° C. (Found: C, 78.4; H, 5.39%. $C_{25}H_{21}SiCl$ requires: C, 78.0; H, 5.50%.) This compound (2.25 g) was converted to the carboxylic acid through formation of the lithium reagent and carbonation. After isolation of the product as described previously, and recrystallization from aqueous ethanol and from an ether – petroleum ether mixture, there was obtained *p-triphenylsilylmethyl)benzoic acid* (1 g, 44%), m.p. 233° C. (Found: C, 78.8; H, 5.77%. $C_{26}H_{22}SiO_2$ requires: C, 79.2; H, 5.62%.)

Dissociation Constants

Dissociation constants were measured using an ultraviolet spectrophotometric method. The method depends on the difference in ultraviolet absorption spectra of the anion and the undissociated form of the acid, and requires that absorption measurements be taken in alkaline and acidic media, and in a buffer solution of known pH. pK_a values were calculated using the equation

$$pK_a = pH + \log_{10}[(D_{alk} - D_{buf})/(D_{buf} - D_{acid})],$$

where D_{alk}, D_{buf}, and D_{acid} are optical densities in the appropriate media. pK_a values were converted to K_a values using the equation $pK_a = -\log_{10} K_a$.

Solvent

The acids p-$R_3SiCH_2C_6H_4CO_2H$ are not sufficiently soluble in water to allow acid strength measurements to be obtained in that medium. Dissociation constants were, therefore, measured in 39 wt% water in methanol. The methanol was redistilled "Analar" grade material, diluted with carbon-dioxide-free distilled water and checked to a specific gravity of 0.896 at 15° C.

Stock Solutions

Stock solutions of the carboxylic acids were made to a concentration of 1×10^{-4} *M* in 39 wt% aqueous methanol. A 0.195 *N* sodium hydroxide stock solution was prepared by dissolving "Analar" grade sodium hydroxide pellets in 39 wt% aqueous methanol followed by standardization against potassium hydrogen phthalate solution. A 0.212 *N* sulphuric acid stock solution was prepared using the same solvent, and was standardized against standard sodium hydroxide solution. The acetate buffer stock solution was prepared from "Analar" grade sodium acetate (6.8044 g) and glacial acetic acid (10.4091 g) in 39 wt% aqueous methanol (250 ml). The pH of this solution was 5.15, and when diluted with an equal volume of 39 wt% aqueous methanol the pH was 5.29.

Experimental Procedure

Equal volumes (10 ml) of carboxylic acid stock solution and reagent stock solution were measured by pipette into a clean, dry mixing bottle and the solutions were thoroughly mixed by shaking. A portion of the mixed solution was then transferred by dropper to a 10-mm stoppered silica cell, which was placed in a thermoblock, thermostatically controlled at 25° C in the cell compartment of a Unicam S.P.500 spectrophotometer. The blank solution for the optical density measurements was prepared by mixing equal volumes (10 ml) of reagent stock solution and solvent. The cells were allowed to remain in the thermoblock for 15 minutes for temperature equilibration before the first readings were taken. In order to obtain maximum accuracy and to determine the most favorable region for spectral measurements, complete absorption spectra were plotted for acidic, alkaline, and buffered solutions from 224 mμ to 290 mμ, and a series of at least eight accurate optical density measurements was taken at different wavelengths in the most favorable region.

AZA STEROIDS

III. SYNTHESIS OF 11-AZA STEROIDS—A NOVEL CLASS OF STEROIDAL SAPOGENIN ANALOGUES

JAMES P. KUTNEY, I. VLATTAS, AND GANTI VENKAT RAO[1]

Received December 3, 1962

ABSTRACT

The cyclization of a 9,12-seco-11-nor keto acid in the hecogenin series in the presence of benzylamine and anhydrous ammonia is described. The benzylamine reaction follows an unusual course whereas the ammonia reaction proceeds normally to provide an enol lactam. The sequence represents the first synthesis of an 11-aza derivative in the steroidal sapogenin series.

In previous papers of this series (1, 2) we reported on the introduction of a nitrogen function into ring B of the steroid skeleton, and this work provided some 6-aza steroidal analogues. In extending these studies, we considered the synthesis of ring C aza steroids since these steroidal derivatives with an unexpanded C-ring system were not known (3 and references cited therein pertaining to 12*a*-aza-C-homo steroids). However, a very recent article by Engel and Rakhit (4) on the first synthesis of 11-aza steroids possessing the normal skeleton prompts us to report some of our results in this area.

In considering a synthetic sequence, it was obvious that an extension of our work in ring B should provide an entry into this series. It was therefore necessary to prepare the appropriate 9,12-seco steroidal intermediates which, in turn, could be cyclized in the presence of an amine to provide the 11-aza steroid. The most direct approach to the desired 9,12-seco steroids involved ozonolysis of a 9,11-unsaturated 12-keto steroid since this type of reaction had been successfully employed by the present authors (1, 2) and by Jacobs and Brownfield (5) in the synthesis of ring B seco derivatives and by Engel and co-workers (4, 6, 13) in the synthesis of some 9,12-seco steroids. An attractive starting material for the ring-opening reaction was 9,11-dehydrohecogenin acetate, which was readily available from hecogenin acetate (7). When we subjected this substance to ozonolysis we obtained in low yield, from the acidic fraction of the reaction product, a crystalline, high-melting compound which exhibited the expected properties of the desired 9,12-seco keto acid (I). The infrared spectrum indicated two bands in the carbonyl region (5.80 μ, 5.93 μ) and still retained the characteristic spiroketal bands (8, 9), indicating that the spiroketal side chain remained unaffected under these conditions. In spite of numerous experiments, we were not able to improve the yield in this reaction and we turned to consider another approach to this problem. An attractive alternative was the use of the Lemieux reagent (10, 11) since, just at this time, Edward (12) published his work which indicated that this reagent was superior to ozone in the instance of cholest-4-en-3-one. Consequently, 9,11-dehydrohecogenin acetate was treated with this reagent and a crystalline acidic product was obtained from this reaction. This substance was shown to be identical with the ozonolysis product (I). In addition, another crystalline compound was obtained from the acidic fraction of the reaction product which on the basis of its infrared spectrum (5.68 μ) is tentatively assigned an enol lactone structure

[1]*National Institutes of Health Postdoctoral Fellow, 1960–1961.*

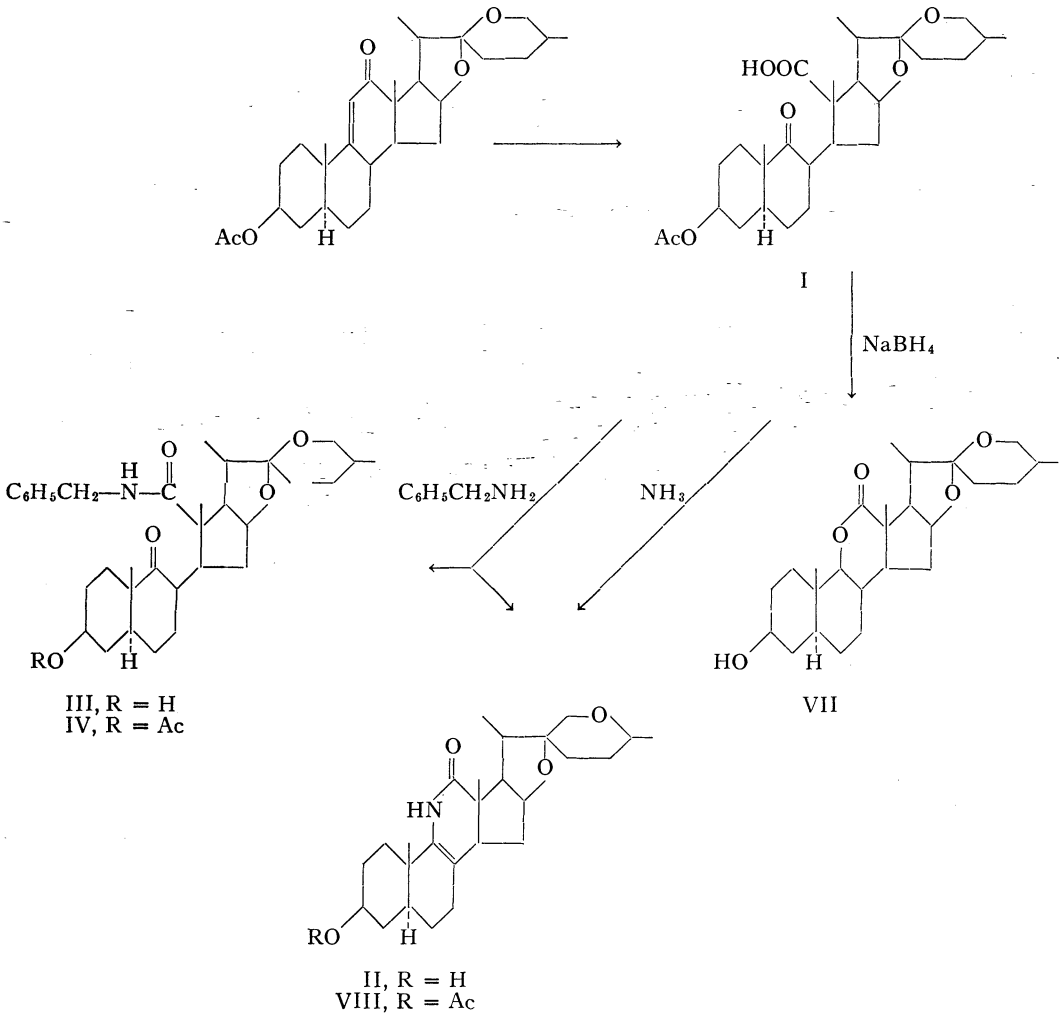
(IX). Our present evidence does not fully establish this structure and further investigation will be necessary. The overall yield of the desired keto acid (I) was substantially higher in the Lemieux reaction particularly since a large proportion of the neutral fraction in this reaction was unreacted starting material. In addition to the improved yield, it was also more convenient to utilize this reagent in large-scale preparations of I and we have used this procedure in all our subsequent preparations. After this phase of the work was completed, a detailed study of the ozonolysis of $\Delta^{9,11}$-12-keto steroids was reported by Engel (4, 13).

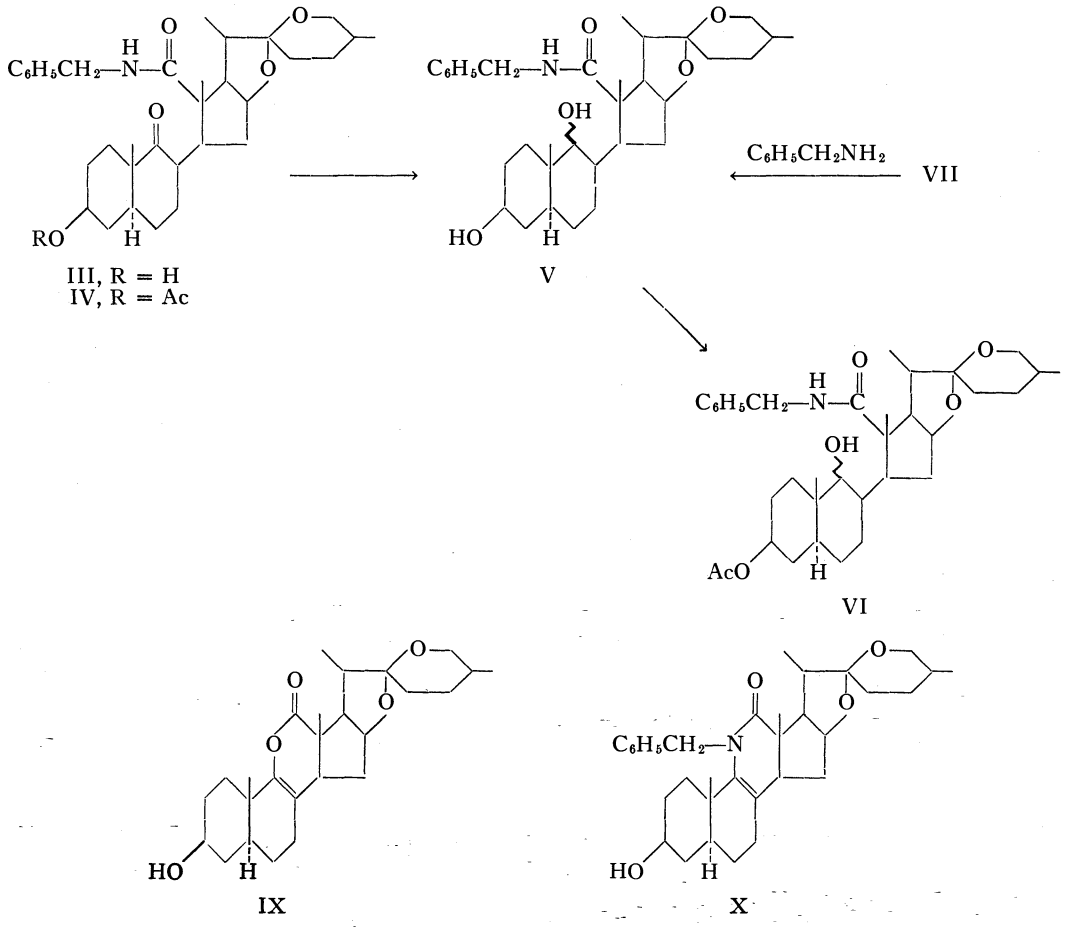
Because of our success with benzylamine in our previous work on ring B aza steroids, we decided to study the cyclization of the keto acid (I) with this amine. When the keto acid was treated with refluxing benzylamine and the reaction mixture extracted with ether, there were obtained from the neutral portion of the reaction product two crystalline compounds. The minor component was a high-melting substance which exhibited strong absorption at 6.01 μ and 6.06 μ in the infrared spectrum and also possessed an absorption maximum at 255 mμ in the ultraviolet spectrum. This spectral data led us to believe that the desired enol lactam (X) had been obtained but the subsequent analytical data was not in agreement with this structure. The structure of this product will be discussed in a later portion of this paper. The major product of the benzylamine reaction was a lower-melting crystalline compound which possessed strong carbonyl absorption in the infrared at 5.88 μ and 6.15 μ. The substance did not possess any absorption in the ultraviolet and the nuclear magnetic resonance (n.m.r.) spectrum of this material showed an intense signal in the aromatic proton region (2.75 τ). It was therefore clear that this substance did not represent a cyclic enol lactam structure but was most probably the keto amide (III). The analytical data supported this structure for the substance. In view of the apparent difference in reaction of the keto acid (I) when compared to the corresponding keto acid in the ring B series (1, 2), it was necessary to establish fully the assigned structure (III) for this keto amide. The following results provide conclusive proof of structure III.

The presence of the hydroxyl group at C_3 was readily demonstrated by the formation of a monoacetate (IV) which now showed, apart from the ketone and amide absorption, a new band at 5.80 μ in its infrared spectrum. In addition, the n.m.r. spectrum indicated a new signal for the acetate methyl group (8.0 τ). Reduction of the keto amide with sodium borohydride or with lithium aluminum hydride under mild conditions provided a dihydroxy amide (V) in good yield. Chromatographic purification of this reduction product indicated a predominance of only one isomer. The infrared spectrum of this compound indicated a disappearance of the acetate and ketone absorption but still indicated the amide band at 6.15 μ. Similarly, a disappearance of the acetate methyl signal was likewise noted in the n.m.r. spectrum for this substance. A similar reduction of the acetate, IV, with sodium borohydride provided the hydroxy acetate, VI, which in turn, was also obtained from a mild acetylation of the dihydroxy amide, V. This last reaction demonstrated that it was possible to obtain preferential acetylation at C_3 without affecting the hydroxyl function at C_9. This series of reactions served to demonstrate the functionality present in the major reaction product from the benzylamine reaction and allowed us to assign structure III to this substance.

It was now clear that the cyclization of 9,12-seco keto acids of the type indicated above could not be accomplished under the influence of refluxing benzylamine to provide N-benzyl 11-aza steroid analogues. We felt that the steric influence of the angular methyl group at C_{10} was probably the reason why the cyclization with the relatively large

N-benzyl function had failed. In order to obtain more information about the cyclization reaction we subjected the keto acid, I, to a reduction with sodium borohydride in the hope that the resulting hydroxy acid could be cyclized to provide a δ-lactone structure (VII). Indeed when we completed this reduction we obtained, as one of the reaction products, a crystalline substance which showed only one carbonyl absorption in the infrared spectrum (5.81 μ). The n.m.r. spectrum of this material showed the absence of a carboxylic proton and the analytical data was in good agreement with a lactone structure. Consequently, we tentatively assign the lactone structure VII to this reduction product, although it will be necessary to carry out a more careful study of this reaction at a later date. It is to be noted that Atwater, in his paper on oxasteroids (14), has reported a complex mixture of lactones and lactols in his work on ring B seco steroids and it would be of some interest to see whether similar results are also obtained in ring C. However, as far as the present phase of the investigation was concerned, it was merely necessary to realize that the cyclization of 9,12-seco steroids could indeed be successfully accomplished.





With the above information at hand, we treated an alcoholic solution of the keto acid, I, with anhydrous ammonia in a sealed tube at 150° C for 15 hours (5) and obtained an excellent yield of the expected enol lactam (II). This compound possessed an absorption at 255 mμ in its ultraviolet spectrum as expected for this type of chromophore (1, 2, 4, 5) and its high melting point was immediately reminiscent of the minor product which we had previously isolated in the reaction of benzylamine with I. Indeed, infrared, n.m.r., and mixed melting point comparison established beyond any doubt that the two products were *identical*. This very interesting result revealed several important aspects of the cyclization reaction. Firstly, the cyclization of 9,12-seco keto acids can be accomplished very successfully with ammonia and, most probably, with relatively small amines to generate 11-aza steroid derivatives. As already mentioned above, Engel has recently reported this reaction in another series of compounds (4), and our results amplify the generality of this type of reaction. Secondly, if a sterically larger amine such as benzylamine is employed, the reaction path takes an unusual course wherein an unexpected cyclic product is obtained. It is not known at this time whether the mechanism of the benzylamine reaction involves debenzylation at some stage or whether perhaps ammonia possibly formed by prolonged heating of the benzylamine is the actual reactant. We hope to present more evidence about this reaction in the future.

Further investigations with some of the above compounds will be the subject of future publications.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethyl alcohol on a Cary 14 recording spectrophotometer and the rotations were taken in 1% chloroform solutions except where stated otherwise. The infrared spectra were determined on a Perkin–Elmer Model 21 spectrophotometer. The n.m.r. spectra were taken at 60 Mc on a Varian A60 instrument. The values are given in the Tiers τ scale with the signal of tetramethylsilane, which was used as the internal standard, set at 10.0 τ units. Analyses were performed by Mrs. Aldridge, University of British Columbia, and by A. Bernhardt and his associates, Mulheim (Ruhr) Germany.

Ozonolysis of 9,11-Dehydrohecogenin Acetate

A solution of 9,11-dehydrohecogenin acetate (2.7 g, prepared according to the procedure of Bowers *et al.* (7)) in methylene chloride (100 ml) was ozonized at −78° C over a period of 1 hour with an ozone stream producing 0.1 mole ozone per hour. The reaction mixture was then brought to room temperature, and water (5 ml) and 30% hydrogen peroxide (5 ml) were added. The reaction mixture was stirred for 4 hours at room temperature and then the organic layer was separated. The aqueous layer was extracted with several small portions of methylene chloride and the combined organic extracts were evaporated to dryness. The residue was taken up in ether (250 ml) and washed with a saturated solution of sodium bicarbonate (100 ml) to remove acidic components. The sodium bicarbonate layer was then made acidic with dilute hydrochloric acid and extracted with ether. The ether extract was dried over anhydrous magnesium sulphate and the solvent removed to yield an insignificant amount (0.15 g) of a solid, acidic material.

The original ether extract, which had been washed with the sodium bicarbonate solution, was now washed with cold aqueous 7% sodium hydroxide to remove any remaining acidic products. The alkaline layer was then acidified with hydrochloric acid and this mixture now extracted exhaustively with ether. The ether extract was dried over anhydrous magnesium sulphate and the solvent removed to yield 0.73 g (total, 0.88 g) of crystalline, acidic product with a melting point of 262–264°. Several recrystallizations from methanol provided a pure sample (0.7 g) of 3β-acetoxy-9-oxo-9,12-seco-11-nor-25-iso-5α,22β-spirostan-12-oic acid (I), m.p. 264–265; $[\alpha]_D$ −87°; infrared (KBr): 5.80 μ, 5.93 μ. Found: C, 68.94; H, 8.89; O, 22.53. Calc. for $C_{28}H_{42}O_7$: C, 68.54; H, 8.63; O, 22.83.

Lemieux Oxidation of 9,11-Dehydrohecogenin Acetate

A solution of 9,11-dehydrohecogenin acetate (3.0 g) in a *t*-butanol – water mixture (220.6 ml, prepared from 200 ml *t*-butanol and 20.6 ml water) was treated with an aqueous solution of potassium carbonate (1.375 g) in water (39 ml). The stirred mixture was then treated with an aliquot (25 ml) of a stock solution of sodium metaperiodate (prepared from sodium metaperiodate (9.81 g) in water (123 ml)) and 0.8% aqueous potassium permanganate (2.5 ml) and the stirring was continued. The remainder of the periodate solution was added slowly to the reaction mixture over a period of 10 minutes, and after this time, another portion (2.5 ml) of 0.8% aqueous permanganate was added. The whole mixture was stirred at room temperature for another 30 minutes, a third portion (3.75 ml) of permanganate was added, and the mixture stirred at room temperature for 4 hours. The excess permanganate was destroyed by the addition of sodium bisulphite and the resultant brownish reaction mixture was concentrated on a steam cone *in vacuo* to about one-half the original volume (until most of the volatile materials had been removed). The reaction mixture was cooled in ice, acidified with ice-cold 50% aqueous sulphuric acid, and extracted with ether. The ether extract was then washed several times with cold, dilute aqueous sodium hydroxide and finally with water. The alkaline and water washings were combined and treated with concentrated hydrochloric acid until the solution was acidic and then extracted with ether. The ether extract was dried over anhydrous magnesium sulphate and the solvent was removed to provide a crystalline, acidic product (1.1 g). Several recrystallizations from methanol–chloroform (1:1) provided the pure product (0.75 g). Infrared and mixed melting point comparison established that this product was identical with the ozonolysis product (I). The mother liquors from the above crystallizations were concentrated and another crop (300 mg) of crystals was collected, m.p. 230–240°. Repeated recrystallization of this material from aqueous methanol provided a crystalline substance (200 mg) which exhibited a somewhat improved melting point (235–238°) but it was clear that this sample was not analytically pure. The infrared spectrum of this substance with only *one* strong carbonyl absorption at 5.68 μ suggests an enol lactone structure IX but further work will be necessary before any definite conclusions can be made.

The original ether extract, which had been washed with sodium hydroxide and water, was dried over anhydrous magnesium sulphate. The solvent was removed to yield 1.3 g of a crystalline, neutral product which proved to be unreacted starting material.

This procedure has been utilized in all subsequent preparations of I.

Benzylamine Reaction on Keto Acid

The keto acid (I, 2.57 g) was dissolved in benzylamine (10 ml) and refluxed for 26 hours under a nitrogen

atmosphere. The cooled reaction mixture was then taken up in ether (200 ml) and the ethereal mixture was washed several times with 5% aqueous hydrochloric acid solution, water, and finally with 5% aqueous potassium carbonate. The ether extract was dried over anhydrous magnesium sulphate and the solvent removed to provide a semisolid neutral substance (1.9 g). This material was taken up in a small amount of ether and the small quantity of white solid which remained undissolved was removed by filtration. On allowing the ether solution to stand at room temperature for 1 hour, a second crop of the white solid precipitated. Both crops of the solid were combined and weighed (0.7 g). This substance was recrystallized from benzene to provide pure, white needles (0.55 g) melting at 274–276° (with some decomposition). This compound was subsequently shown to be *identical* with the lactam, II, by means of infrared, ultraviolet, nuclear magnetic resonance, and mixed melting point comparison. The preparation and complete characterization of II is given in a later portion of this experimental part.

The ether solutions remaining after the removal of the keto amide, II, was diluted with petroleum ether and after standing overnight deposited another crop of crystals. Several more crops of crystals were obtained upon concentration of this solution and a total of 1.0 g of this compound melting at 172–174° was obtained. Two further recrystallizations from ether – petroleum ether provided an analytical sample (0.85 g) of 3β-hydroxy-9-oxo-9,12-seco-11-nor-25-iso-5α,22β-spirostan-12-N-benzylcarboxamide (III), m.p. 174–175°; $[\alpha]_D$ −143°; infrared (KBr): 5.88 μ, 6.15 μ; infrared ($CHCl_3$): 5.90 μ, 6.08 μ, and spiroketal bands at 10.19 μ, 10.85 μ, 11.11 μ, 11.50 μ (8, 9); n.m.r. ($CDCl_3$): 2.75 τ (aromatic H). Found: C, 73.32; H, 8.83; O, 15.48; N, 2.70. Calc. for $C_{33}H_{47}O_5N$: C, 73.70; H, 8.81; O, 14.88; N, 2.61.

3β-Acetoxy-9-oxo-9,12-seco-11-nor-25-iso-5α,22β-spirostan-12-N-benzylcarboxamide (IV)

The keto amide (III, 300 mg) was treated with pyridine (8 ml) and acetic anhydride (5 ml) and the reaction mixture was allowed to stand at room temperature for 24 hours. The excess anhydride was destroyed by the cautious addition of water and the reaction mixture was extracted with ether. The ether extract was first washed with 5% aqueous hydrochloric acid and then with ice-cold 5% aqueous sodium carbonate and finally dried over anhydrous magnesium sulphate. The solvent was removed and the crystalline solid (310 mg) was recrystallized from ether – petroleum ether to provide the analytical sample of the acetate (IV, 300 mg), m.p. 168–170°; $[\alpha]_D$ −132°; infrared (KBr): 5.80 μ, 6.15 μ; n.m.r. ($CDCl_3$): 2.74 τ (aromatic H), 8.0 τ ($-\overset{\overset{O}{\|}}{C}-CH_3$). Found: C, 72.09; H, 8.42; N, 2.67. Calc. for $C_{35}H_{49}O_6N$: C, 72.51; H, 8.52; N, 2.92.

3β,9ξ-Dihydroxy-9,12-seco-11-nor-25-iso-5α,22β-spirostan-12-N-benzylcarboxamide (V)

(a) By Lithium Aluminum Reduction of Keto Amide (III)

The keto amide (III, 140 mg) was dissolved in anhydrous tetrahydrofuran and refluxed for 6 hours with lithium aluminum hydride (400 mg) which was initially placed in a Soxhlet extractor and gradually brought into the vessel by the refluxing solvent. The excess hydride was destroyed by careful addition of water and the ether layer was separated. After drying the ether extract over anhydrous magnesium sulphate, the solvent was removed to yield a white solid (150 mg). This solid was recrystallized several times from ether to provide an analytical sample of dihydroxy amide, V (120 mg), m.p. 223–224°; $[\alpha]_D$ −108°; infrared (KBr): 2.86 μ, 2.91 μ, 3.01 μ, 6.15 μ; n.m.r. ($CDCl_3$): 2.75 τ (aromatic H), complete disappearance of signal at 8.0 τ present in the spectrum of IV. Found: C, 73.37; H, 9.32; N, 2.78. Calc. for $C_{33}H_{49}O_5N$: C, 73.43; H, 9.15; N, 2.66.

(b) By Sodium Borohydride Reduction of Acetoxy Keto Amide (IV)

A solution of the acetoxy keto amide (IV, 110 mg) in methanol (8 ml) was treated with a solution of sodium borohydride (65 mg) in methanol (6 ml), and the mixture was stirred at room temperature for 1 hour. After this time, more sodium borohydride (75 mg) was added to the reaction mixture and the stirring was continued at room temperature for a further 3 hours. The mixture was concentrated *in vacuo*, water was added, and the whole mixture was acidified by the addition of 10% aqueous acetic acid. The organic product was extracted from the reaction mixture with ether and the ether extract was then washed with ice-cold 5% potassium carbonate solution and finally with water. The ether layer was dried over anhydrous magnesium sulphate and the solvent removed to yield an oily product (110 mg) which did not crystallize too well. This product was taken up in benzene and chromatographed on silica gel (50 g). Elution with benzene–chloroform (1:1) provided 35 mg of the 3-acetoxy-9-hydroxy amide, VI, which is characterized below. Elution with chloroform–benzene (9:1) yielded 65 mg of another solid which was shown to be identical with the lithium aluminum hydride reduction product, V, by infrared and mixed melting point comparison.

3β-Acetoxy-9ξ-hydroxy-9,12-seco-11-nor-25-iso-5α,22β-spirostan-12-N-benzylcarboxamide (VI)

The dihydroxy amide (V, 100 mg) was dissolved in pyridine (5 ml) and treated with acetic anhydride (3 ml), and the reaction mixture was left to stand at room temperature for 24 hours. The excess anhydride was destroyed by the addition of water and the resulting reaction mixture was extracted with ether. The ether extract was washed with 5% aqueous hydrochloric acid, then with 5% aqueous sodium carbonate, and finally dried over anhydrous magnesium sulphate. Evaporation of the solvent yielded a white solid (100 mg) which on recrystallization from ether – petroleum ether provided an analytical sample of the acetate, VI

(90 mg), as white needles, m.p. 166–167°; $[\alpha]_D$ −59°; infrared (KBr): 5.80 μ, 6.17 μ; n.m.r. ($CDCl_3$): 2.78 τ (aromatic H), 8.0 τ (—C(=O)—CH_3). Found: C, 72.50; H, 8.75; N, 2.70. Calc. for $C_{35}H_{51}O_6N$: C, 72.25; H, 8.84; N, 2.41.

3β-Hydroxy-11-aza-5α,22β-spirost-8(9)-ene-12-one (II)

The keto acid (I, 500 mg) was taken up in 95% ethyl alcohol (50 ml) and anhydrous ammonia was bubbled through the solution for 1 hour at 0° C. The mixture was then heated in an autoclave kept at 150° C for 15 hours. At the end of this heating period, the mixture was allowed to come to room temperature and a small amount (50 mg) of a yellowish solid which had precipitated was removed by filtration. The filtrate was concentrated on a steam bath *in vacuo* to yield a yellowish solid (460 mg). Both crops of the solid material were combined and recrystallized from benzene to provide the enol lactam, II, as yellowish needles. Further recrystallization from benzene, after treatment with Norite, provided the pure enol lactam as white needles (450 mg), m.p. 274–276° (with some decomposition); $[\alpha]_D$ +163° (due to solubility difficulties, this rotation was taken on 1% tetrahydrofuran solution); ultraviolet: λ_{max} 255 mμ (log ϵ 3.68); infrared (KBr): 6.01 μ, 6.06 μ; Found: C, 73.11; H, 9.10; N, 3.45. Calc. for $C_{26}H_{39}O_4N$: C, 72.69; H, 9.15; N, 3.26.

3β-Acetoxy-11-aza-5α,22β-spirost-8(9)-ene-12-one (VIII)

The enol lactam (II, 100 mg) was acetylated in exactly the manner described in the preparation of VI. The white solid product (105 mg) was recrystallized from methyl alcohol to provide the pure acetate, VIII, as white needles (95 mg), m.p. 283–285° (decomp.); $[\alpha]_D$ +132° (due to solubility difficulties this rotation was taken on a 1% solution of the substance in a 1:1 mixture of methyl alcohol–chloroform); ultraviolet: λ_{max} 255 mμ (log ϵ 3.69); infrared ($CHCl_3$): 5.81 μ, 6.0 μ, and spiroketal bands at 10.18 μ, 10.85 μ, 11.11 μ, and 11.53 μ. Found: C, 71.05; H, 8.60; N, 2.85. Calc. for $C_{28}H_{41}O_5N$: C, 71.30; H, 8.76; N, 2.97.

3β-Hydroxy-11-oxa-5α,22β-spirostan-12-one (VII)

The keto acid (I, 230 mg) was dissolved in a mixture of wet methyl alcohol (18 ml) and chloroform (10 ml) and treated with a solution of sodium borohydride (150 mg) in methyl alcohol (10 ml). The reaction mixture was stirred at room temperature for 1 hour and then more sodium borohydride (300 mg) was added and stirring continued for a further 2.5 hours. After this time the solvent was removed *in vacuo* and the residue treated with a small amount of water and then acidified by the addition of 10% aqueous acetic acid. The reaction mixture was extracted with ether and the ether extract dried over anhydrous magnesium sulphate. Evaporation of the solvent left a white solid which was recrystallized from aqueous methanol to provide a first crop (150 mg) of the lactone, VII. Concentration of the mother liquors provided an additional crop (20 mg) of the same material but subsequent concentrations of the mother liquors provided small crops (total 50 mg) of solid materials which were obviously mixtures and still remain to be characterized.

The first two crops (170 mg) were combined and recrystallized from aqueous methanol to yield the pure lactone, II (140 mg), m.p. 274–276°; $[\alpha]_D$ −22°; infrared (KBr): 5.81 μ; infrared ($CHCl_3$): 5.78 μ and spiroketal bands at 10.18 μ, 10.83 μ, 11.11 μ, and 11.53 μ; n.m.r. ($CDCl_3$): complete absence of any signals for acetate methyl group and carboxylic proton. Found: C, 72.46; H, 9.20; O, 18.27. Calc. for $C_{26}H_{40}O_5$: C, 72.19; H, 9.32; O, 18.49.

Benzylamine Reaction on Lactone (VII)

The lactone (VII, 115 mg) was dissolved in benzylamine (2 ml) and refluxed for 22 hours under a nitrogen atmosphere. The cooled reaction mixture was taken up in ether and the ethereal mixture was washed with 5% aqueous hydrochloric acid and then with 5% aqueous sodium carbonate solution. After drying of the ether extract over anhydrous magnesium sulphate, the solvent was removed to yield a white solid (130 mg). Crystallization of this substance from ether yielded a pure sample (105 mg), m.p. 222–224°. Subsequent comparison of the infrared spectrum of this product with the spectrum of the dihydroxy amide, V, indicated that the two substances were identical. This identity was further confirmed by a mixed melting point determination and comparison of the nuclear magnetic resonance spectra.

ACKNOWLEDGMENTS

Financial aid from the National Research Council of Canada and from the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service, grant No. CY-5037, is very gratefully acknowledged. We would also like to thank Syntex S.A., Mexico City, for generous gifts of hecogenin acetate.

PROTON MAGNETIC RESONANCE SHIFTS AND THE ELECTRON DENSITY DISTRIBUTION IN AROMATIC SYSTEMS[1]

T. SCHAEFER[2] AND W. G. SCHNEIDER
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received October 22, 1962

ABSTRACT

The quantitative nature of the empirical linear correlation between the proton resonance shifts in aromatic molecules and the local electron density on the carbon atom to which the proton is bonded has been investigated. The application of this relationship to the determination of the electron density distribution of a variety of aromatic molecules, as well as the main limitations inherent in this application, are discussed. Electron density distributions have been derived for aniline, anisole, azulene, acepleiadylene, pyridine, pyridinium ion, and for the aromatic ions pentalenyl, indenyl, fluorenyl, triphenylmethyl cation, and azulene dianion, and are compared with those calculated by molecular orbital methods. In general there is a fairly good correspondence between the experimental and calculated density values, although for the aromatic ions the excess charge tends to be somewhat more uniformly distributed over the molecule than would be indicated by simple MO calculations.

I. THE CORRELATION BETWEEN π-ELECTRON DENSITY AND THE PROTON RESONANCE SHIFT

It has been recognized for some time that the proton resonance shift in aromatic molecules tends to reflect the π-electron density on the carbon atom to which the proton is bonded. For example in substituted benzenes, a strong electron-withdrawing substituent decreases the shielding of ring protons, whereas electron-releasing substituents cause increased shielding (1, 2, 3). The non-alternant hydrocarbon azulene provides another example; it is not possible to account for the observed proton resonance spectrum unless one invokes a contribution due to the unequal electron density at different carbon atoms (4). It is therefore of some interest to examine the possible quantitative aspects of such correlations and to what extent proton resonance shifts can provide useful information about the electron density distribution in aromatic systems.

Previous work (5, 6, 7) has provided evidence for a simple linear correlation between the proton chemical shift, δ, and the local "excess" charge, $\Delta\rho$ (located on the carbon atom), in aromatic systems; thus,

$$\delta = k\Delta\rho, \qquad [1]$$

where the constant k was found empirically to have a value near 10 p.p.m./electron. In the present work attempts have been made to examine more carefully the experimental basis of this relationship, as well as its application to a wide variety of aromatic systems. The main limitations and sources of error in evaluating π-electron densities in individual cases have also been considered.

For convenience benzene has been chosen as the reference base, both for the proton chemical shifts, δ, and for the excess charge densities, $\Delta\rho$. Thus since the π-electron density on the carbon atoms in benzene is unity, $\Delta\rho = 0$. We adopt the further convention that δ is positive for proton resonances appearing to higher field of the benzene resonance, and

negative for resonances at lower field. On this basis k is found experimentally to be a positive constant. Accordingly a negative δ, associated with decreased proton screening, corresponds to a negative $\Delta\rho$ on the carbon atom, that is, an electron deficiency relative to the carbon atoms in benzene.

The constant k can be evaluated empirically in either of two ways:

(i) by measuring δ for systems in which $\Delta\rho$ is known, and

(ii) by forming positive or negative aromatic ions

$$\mathrm{Ar} \pm \mathrm{e} = [\mathrm{Ar}]^{\pm}.$$

The total π-electron density has now been altered by exactly one unit charge. If the shifts of all protons are measured relative to benzene, the sum of these shifts must correspond to $\Delta\rho = 1$, whence $\sum\delta_1 = k$. This is essentially a normalization condition, which can also be adapted to neutral molecules.*

In applying eq. [1] to the valuation of local π-electron densities several perturbing effects are frequently encountered. These arise from contributions to the measured proton resonance shifts in addition to those caused by the altered electron density. These additional contributions are due to:

(*a*) the magnetic anisotropy of substituents or of hetero atoms in the aromatic ring,

(*b*) ring current effects of neighbor rings in polycyclic aromatic compounds,

(*c*) ion association effects of aromatic ions, and

(*d*) solvent effects.

Large contributions arising from any one of these effects seriously limit the reliability with which the electron density can be evaluated. Frequently, however, adequate corrections can be made to the measured chemical shifts, or the perturbing effect can be avoided by an appropriate choice of the experimental conditions.

The magnitude of the proton resonance shift arising from the magnetic anisotropy of substituent groups in individual molecules cannot be estimated with sufficient accuracy at present to permit a satisfactory correction to the measured shifts. Since this contribution has a $1/R^3$ dependence, it will affect primarily those protons in the molecule close to the anisotropic center. For example, in nitrobenzene there is a substantial contribution to the chemical shift of the ortho protons arising from the magnetic anisotropy of the nitro group (3). At the meta and para positions the contribution is greatly attenuated and, for the present purpose, it can be neglected. Other substituents, such as —HCO, —CH_3CO, —COCl, —SO_3, —Cl, —Br, and —I, also give rise to magnetic anisotropy effects. Hetero atoms in aromatic rings may give rise to similar effects. For example the magnetic anisotropy of the N atom in pyridine gives rise to a slight unshielding contribution to the resonance shift of the α-protons (8). An empirical evaluation of this contribution, which is undoubtedly possible, would permit extension of the present methods to a considerable number of heterocyclic aromatic molecules.

The ring current effects (9) can be dealt with more readily. Since benzene has been chosen as the basic reference, no correction is required for monocyclic (benzenoid) systems. The corrections required for 5- or 7-membered rings are small and introduce little error. For a polycyclic ring system the resonance shift of a particular ring proton must be corrected for the ring current of neighbor rings to bring the shift in line with the benzene reference. For this purpose the dipole model due to Pople (10) has been employed.

**The additivity of chemical shifts and electron charges implied here depends on the validity of eq. [1].*

For benzene itself this gives a contribution to the proton shift of magnitude

$$-\frac{e^2}{2mc^2}\frac{a^2}{R^3} \approx -1.75 \text{ p.p.m.}$$

Here a is the radius of the benzene ring and R the distance of the proton from the center of the ring. The simple dipole model evidently slightly overestimates the ring current contribution in benzene (11). An improved value of 1.5 p.p.m., used for the present work, was obtained by measuring the difference between the resonance shift of benzene and the shift of the olefinic protons in 1,3-cyclohexadiene.* With this adjustment the correction for a particular proton due to the ring current in a neighbor ring, designated δ^1, becomes

$$[2] \qquad \delta^1 = 12.0\left(\frac{a^2}{R^3}\right).$$

Here δ^1 is expressed in p.p.m.; a and R (expressed in Å units) are respectively the radius of the *neighbor* ring, and the distance of the proton being considered from the center of the neighbor ring. For bicyclic systems this correction is fairly reliable and the uncertainty is probably no greater than about 0.1 p.p.m. For larger molecules containing several fused ring systems the corrections, and hence also the errors, begin to mount. For such molecules a greater portion of the electron current circulates around the periphery of the molecule and the ring current within any one ring may differ somewhat from that of benzene.

With aromatic positive or negative ions an association with counterions in solution may be anticipated. Considered as a perturbing electric field, the counterion will cause a shift of the proton resonance of the aromatic ion being measured (12, 13, 14). With small aromatic ions, and more particularly in ions where the charge is largely concentrated at one atom in the molecule, as for example in the anilinium ion, association with the counterion occurs selectively at this point and involves a close approach, on the average, to the highly charged atom. The result is a non-averaged contribution to the resonance shifts of the ring protons, which differs in magnitude at each non-equivalent proton. In the case of anilinium ion, it has been observed (15) that these contributions to the proton resonance shift are reduced by the substitution of bulky alkyl groups on the nitrogen atom. By this means the close approach of the counterion is prevented, thus reducing the strength of the perturbing ionic field. In larger aromatic ions, and particularly those in which the excess charge is well distributed over the molecule, the effects of counterion association may be expected to be averaged out and to be much smaller in magnitude. In general such effects may be expected to be further minimized by a high degree of dilution of the ionic species with a solvent of high dielectric constant.

Closely related is the problem of residual solvent effects, which may also give rise to small contributions to the proton shifts (16). With neutral aromatic molecules this can usually be avoided by an appropriate choice of solvent, and by using a dilute solution together with a suitable internal reference. These conditions must necessarily be somewhat compromised for aromatic ions which require polar solvents. If the charge distribution in the ion is highly asymmetric, the resulting "reaction field" in the solvent may contribute to the proton shift. It is difficult to estimate the magnitude of this effect in individual cases, although when it is non-negligible it can certainly be detected and investigated by direct experimentation.

Returning now to the question of the quantitative basis for eq. [1], probably the most direct evaluation of the proportionality constant k is based on the proton resonance

Both compounds were measured as a 3 mole% solution in cyclohexane.

shifts of the symmetrical species $C_5H_5^-$, C_6H_6, $C_7H_7^+$, and $C_8H_8^=$. Although the measurements were originally made by Leto, Cotton, and Waugh (17), the most extensive ones of the first three members of the series have been carried out by Fraenkel, Carter, McLachlan, and Richards (5). The proton resonance of cyclooctatetraene dianion has been measured previously by Katz (18) and by Fritz and Keller (19) and the C^{13} resonance by Spiesecke and Schneider (7). Because of the importance of the quantitative evaluation of the constant k it was considered desirable to confirm these measurements and, in particular, to investigate the possible effects of solvent and ion association. Table I shows

TABLE I

Proton resonance shifts of monocyclic aromatic ions

	Solvent	Concentration (mole%)	δ[a] (c/s at 60 Mc/s)
$(C_5H_5)^-Na^+$	THF[b]	8	102.4±0.5
		4	100.3±0.3
		2	97.9±0.2
		1	96.1±0.3
		0.5	95.4±0.1
		0 (extrapolated)	94.5

$(C_7H_7)^+Br^-$	CH_3CN	0.2	−114.8±0.2
$(C_8H_8)^=2Na^+$	CH_3CN	3	95.9±0.2
	THF	3	95.4±0.1

[a]Relative to an internal benzene reference.
[b]Tetrahydrofuran.

the measured proton shifts of $(C_5H_5)^-Na^+$ as a function of concentration in tetrahydrofuran and of $(C_5H_5)^-Li^+$ in acetonitrile. The results for a 0.2 mole% solution of tropylium bromide in CH_3CN and of $(C_8H_8)^=2Na^+$ in tetrahydrofuran and acetonitrile are also shown.

It is apparent from the results of Table I that there is a measurable solvent dilution shift for $(C_5H_5)^-Na^+$ in tetrahydrofuran. It will be noted that the direction of this dilution shift is toward lower applied (magnetic) field, contrary to that expected for decreasing ion association with dilution. No explanation can be offered for this behavior. However, one suggestion worth considering is the possibility of complex formation of the sodium cyclopentadienide with tetrahydrofuran. A specific etherate complex, $K_2C_8H_8.THF$, has been reported (19). On the other hand $(C_5H_5)^-Li^+$ in CH_3CN shows a negligible dilution shift and, moreover, the proton shift itself is larger (relative to benzene) than that of $(C_5H_5)^-Na^+$ in tetrahydrofuran. Table II shows a comparison of some of the present measurements with the corresponding results reported by Fraenkel, Carter, McLachlan,

TABLE II

	Solvent	Concentration (mole%)	δ (p.p.m. relative to benzene) Ref. 5	Present results
$(C_5H_5)^-Na^+$	THF	2	1.72	1.63
$(C_5H_5)^-Na^+$	CH_3CN	2	1.78_5	
$(C_5H_5)^-Li^+$	CH_3CN	2		1.83

and Richards (5), who quote a measurement error in δ of ± 0.004 p.p.m. On this basis the discrepancy in the two sets of measurements for $(C_5H_5)^-Na^+$ in THF is unacceptably large. The difference between the measurements in CH_3CN is about 0.04 p.p.m., which is probably within a more realistic margin of error.

On the basis of the solvent dilution measurements shown in Table I, the results for $(C_5H_5)^-Li^+$ in CH_3CN are considered the more reliable. These have been combined with the $(C_7H_7)^+Br^-$ measurement (also shown in Table I) for the purpose of evaluating the constant k. Since the ions $C_5H_5^-$ and $C_7H_7^+$ also have six π-electrons, the aromatic ring current is taken to be the same as in benzene, and corrections, amounting to -0.10 and $+0.07$ p.p.m., respectively, were applied to allow for the effect of different ring size on the proton chemical shift. The final shifts are -1.98, 0, and $+1.73$ p.p.m. respectively for $C_7H_7^+$, C_6H_6, and $C_5H_5^-$, to be compared with differences in π-electron densities, $\Delta\rho$, of -0.143, 0, and $+0.20$. The best straight line through these points (with equal residuals) results in a value of $k = 10.7 \pm 0.2$ p.p.m./electron. Here ± 0.2 p.p.m. refers to the actual deviation of the individual points and accordingly a more realistic "error" may be in the neighborhood of ± 1.0 p.p.m.

It is difficult to give a reliable assessment of the actual precision of the above determination. In the first place the validity of eq. [1] has been assumed, which neglects possible contributions of higher-order terms. Inclusion of a square term has been suggested by Musher (20), but lacking further confirmation the use of the simple first-order term is to be preferred for the present. Moreover the application of this expression to a variety of aromatic systems, as shown in the results following, leads to a fairly satisfactory internal consistency. It should be pointed out that the measurements for $(C_8H_8)^{=}2Na^+$ were not included in the above evaluation of k. The much larger ring size and four additional π-electrons as compared to benzene would involve additional uncertainties with respect to the actual contribution of the ring current effect to the proton shift. (The measured shift relative to benzene, as shown in Table I, is actually less than that of $C_5H_5^-$ in CH_3CN.) Finally there is the question of small differences in the degree of hybridization of the carbon orbitals in the 5-, 6-, 7-, and 8-membered aromatic rings. This will undoubtedly make some contribution to the measured proton shifts, but the magnitude of this contribution cannot be reliably estimated. In any event, relative to benzene, it may be expected to be largest for the C_8H_8 dianion.

Method (ii) for the evaluation of k, mentioned earlier, involves the measurement of the proton shifts of aromatic positive or negative ions relative to those of the corresponding neutral molecule. Unfortunately there are not many compounds suitable for this purpose, but the method does provide a useful "self-consistency" check of the value of k determined by the methods already described. In their study of benzene carbonium ions MacLean and Mackor (6) derived an independent value of k equal to 13.5 p.p.m./electron. This was based on the assumption that the contribution of the "ring current" effect to the proton shift in benzene is 1.88 p.p.m. With the value 1.5 p.p.m. for this contribution used here, which we regard as a more appropriate value, the value of k based on the benzene carbonium ion shifts reported by the above authors becomes 11.8 p.p.m./electron. While this value is somewhat higher than that derived above, it nevertheless represents a satisfactory confirmation by an independent method which involves only six-membered aromatic rings. A further "self-consistency" check based on aromatic ions can be illustrated with reference to the indenyl ion as an example. (See Table III below.) This involves two aromatic rings with seven protons. The two carbon atoms joining the two rings do not contain a bonded proton, and hence their π-electron charge cannot be determined by the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

present methods. However, since the ion contains unit excess charge, an approximate value for the density at the 8,9-carbon atoms can be derived by application of the normalization condition mentioned earlier. Thus we have

$$\Delta\rho_{8,9} = \frac{1}{2}\left(1 - \sum \frac{\delta_1}{k}\right) = 0.17,$$

where δ_1 represents the shifts of individual protons bonded to the other carbon atoms, and k = 10.7 p.p.m./electron. If the indenyl negative ion had a uniform charge distribution, the π-electron density on each carbon atom would be 1.11. The value at the 8,9-positions would not be expected to differ from this by an "unreasonable" amount. The actual value, 1.17, determined in the above manner is necessarily approximate since it contains the accumulated errors of all δ_1, but the result nevertheless provides a further internal self-consistency test to the value of k.

One rather important point, however, which emerges from the experimental data presented in the next section, is that in all cases the measured proton shifts, when used in eq. [1], give the correct sign of the excess charge, $\Delta\rho$. This has also been noted in connection with measurements of benzene carbonium ions (6) and indicates that higher-order terms (which have been neglected in eq. [1]) can make but a relatively minor contribution.

The complete expression for the change in the proton screening due to a perturbing field E (here regarded as arising from the excess charge concentrated on the carbon atom) may be written (12, 14)

$$\Delta\sigma = aE + bE^2 + \ldots . \qquad [3]$$

The inclusion of the square term on the right-hand side to represent the proton shift measurements of $C_5H_5^-$ and $C_7H_7^+$ has been suggested (20) and its magnitude has been estimated.

In this connection it is of some interest to compare the proton shifts of H_3O^+ and OH^- relative to H_2O. In *both* these ions, though oppositely charged, the protons are *less* screened relative to H_2O by 10–11 p.p.m. (21, 22). To account for this it has been proposed (23) that only the square term in eq. [3] is involved. In contrast, as already mentioned, in the aromatic carbonium ions and carbanions the linear term is definitely dominant. This rather curious difference remains to be intrepreted, although the comparison may not be wholly justified. For example, the ions H_3O^+ and OH^-, when measured in aqueous solution, form hydrogen bonds and are known to undergo very rapid proton exchange. Accordingly the direct application of equation [3] to their "proton averaged" species in solution may not be appropriate.

II. APPLICATION TO ELECTRON DENSITY DETERMINATION IN AROMATIC SYSTEMS

In order to investigate further the quantitative nature of the correlation of proton resonance shifts and π-electron densities, the electron densities have been evaluated on the basis of the methods described in the preceding section, for a variety of aromatic systems. These include both neutral molecules and positive or negative aromatic ions. The value of k (cf eq. [1]) employed throughout is 10.7 p.p.m./electron. The results are summarized in Table III, where the notation

$$\delta_{corr} = \delta + \delta'$$

has been employed, δ' being given by eq. [2], and ρ ($=1+\Delta\rho$) represents the derived

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

total π-electron density. The experimental conditions employed for the proton resonance shift measurements are outlined below.

There is, unfortunately, at present no wholly reliable information on charge densities for comparison with the present derived values. The only recourse is to the various molecular orbital calculations. Depending on the type of approximation employed these often differ considerably in the individual electron density values. However, the general trend of the electron density distribution and the alternation of the densities within the molecule is broadly similar in the various approximations. (A comparison of the electron

density values calculated by various approximations for azulene, for example, is given by Streitwieser (24, p. 456).) The calculated densities included in Table III for comparison with the densities derived from n.m.r. data were either taken from the literature or else were calculated for the present purpose using simple Hückel MO methods.

(1) Aniline, Anisole

As mentioned above the main difficulty in the employment of proton resonance shifts to evaluate the electron density in substituted aromatics arises from the magnetic anisotropy of substituent groups. With substituents such as CH_3, NH_2, OH, and OCH_3, such effects are relatively small. Table III shows the π-electron densities for aniline and anisole derived from the proton resonance shifts previously reported (3). The results exhibit the anticipated excess density at the ortho and para positions and an almost negligible contribution at the meta positions.* The MO calculations for substituted benzenes are difficult, and the results depend largely on the assumptions made to take account of the electronic effects of the substituent. Three such calculations are shown for aniline. While a quantitative comparison with the n.m.r. data may not be too meaningful, the general trend of the density distributions is very similar.

(2) Non-alternant Hydrocarbons Azulene, Acepleiadylene

The electron density distribution of azulene derived from proton resonance shifts has been reported previously (25). A re-evalution of the densities of azulene is included in Table III, employing the present revised values for k and for the aromatic ring current. The proton resonance shifts employed were measured for a 3 mole% solution of azulene in cyclohexane. Accordingly solvent effects are not in question, and the main source of error in evaluating the electron densities arises from the corrections to the proton shifts, δ', due to current circulations in the "other" ring. These corrections, evaluated by eq. [2],

**The density values previously reported in ref. 5 for aniline differ significantly at the para position. This is doubtless due to a different value of the proton resonance shift employed.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are shown in the fourth column in the table. It was assumed that the currents in the 5- and 7-membered rings are equal to those in benzene, an assumption which derives some justification from a theoretical calculation due to Pople (26). The corrections are largest for the 1,3-positions and the 4,8-positions. A rather liberal estimate of the possible error in the electron density due to uncertainties in the "other" ring corrections might be ± 0.02 for the 1,3- and 4,8-positions, and probably less than ± 0.01 at the other positions. The value given in parenthesis in the table for the 9,10-positions was obtained by difference, using the normalization condition referred to earlier. Since this value is subject to cumulative errors, it will be somewhat less reliable than the other density values. It does, however, provide a useful internal self-consistency check. Of the various MO calculations for azulene included in Table III for comparison, those of Brown and Heffernan (27) (VESCF) have been adjusted to give the best agreement with the measured dipole moment of azulene. In general, the electron densities derived from n.m.r. data show a somewhat smaller variation than those evaluated by MO methods, but the density alternations around the two rings are well reproduced.

The non-alternant hydrocarbon acepleiadylene, which contains four aromatic rings in a pyrene-type structure, is less satisfactory for the present purposes than azulene. Each proton resonance shift must be corrected for current circulation in three other rings. These corrections become rather large, and no doubt also involve proportionately greater errors. The *average* density evaluated for carbons 11, 12, 13, 14, 15, and 16 was found to be 0.93. This was again obtained by taking the difference of the sum of the densities derived for all the other carbon atoms which have a bonded proton, and the total number of π-electrons (16). The low value of 0.93 for the inner carbon atoms might be interpreted to mean that the excess charge tends to be concentrated mainly on the outer perimeter of the molecule. However, in view of the possibility of accumulated errors in the "other ring" corrections this cannot be substantiated on the basis of the present results. Comparison of the charge densities derived for the remaining carbon atoms indicates a preference for the excess charge to reside in the 7-membered ring, rather than in the 5-membered ring at the opposite end of the molecule as indicated by simple Hückel MO calculations (28). This discrepancy appears to be real and outside the probable limits of the experimental uncertainties. It would also imply a direction of the molecular dipole moment opposite to that indicated by the MO calculations. The actual direction of the molecular dipole moment is not known.

(3) Pyridine, Pyridinium Ion

Pyridine and the pyridinium ion illustrate some features common to many heterocyclic aromatic systems. As already mentioned, the N atom in pyridine gives rise to a magnetic anisotropy. The presence of this anisotropy, which has been demonstrated by the nitrogen resonance measurements of Baldeschwieler and Randall (8), gives a non-negligible contribution to the screening of the α-protons in pyridine. In order to evaluate the electron density at the α-position this contribution must be subtracted out. At present a quantitative estimate of such contributions is lacking. They are very much attenuated at the β- and α-positions, and accordingly the electron densities at these positions, derived from the measured proton shifts, should be fairly reliable. They are listed in Table III together with two sets of calculated densities, with which they show a rather good correspondence.

In the pyridinium ion the magnetic anisotropy of the N atom, which now contains a bonded proton, is greatly reduced. The proton resonance shifts of the pyridinium ion have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

been reported previously (29). The derived electron densities are listed in Table III. The density shown for the N atom is again obtained by difference. If the shift of the N—H proton is employed in conjunction with that in pyrrole as a reference state, and with the same value of k as employed here for aromatic C—H bonds, the value of the density on the N atom is found to be 1.57. However, this latter procedure is very rough. The calculated results of Brown and Heffernan (30) for the pyridinium ion (Table III) show a fair correspondence with the present results.

The proton resonance measurements for pyridine were carried out in a dilute solution of cyclohexane, and solvent effects may be assumed to be absent. The pyridinium ion shifts were measured in a dilute solution (~5 mole%) in trifluoroacetic acid. Accordingly the measured proton shifts may be affected somewhat by solvent interaction and ion association.

(4) The Carbanions Pentalenyl, Indenyl, and Fluorenyl

The pentalenyl dianion has been prepared by Katz and Rosenberger (31). The proton resonance shifts (measured in a dilute solution of tetrahydrofuran) reported by these authors have been employed to evaluate the π-electron densities. These are shown in Table III together with the density values calculated by simple Hückel MO methods. There is a fairly good correspondence between the two sets of results. The experimental value in parenthesis shown for the 7,8-positions was obtained by difference and may be somewhat less reliable.

The indenyl and fluorenyl ions were prepared by reacting dilute solutions (2–5 mole%) of the parent hydrocarbons, indene and fluorene, in tetrahydrofuran with sodium. Figure 1

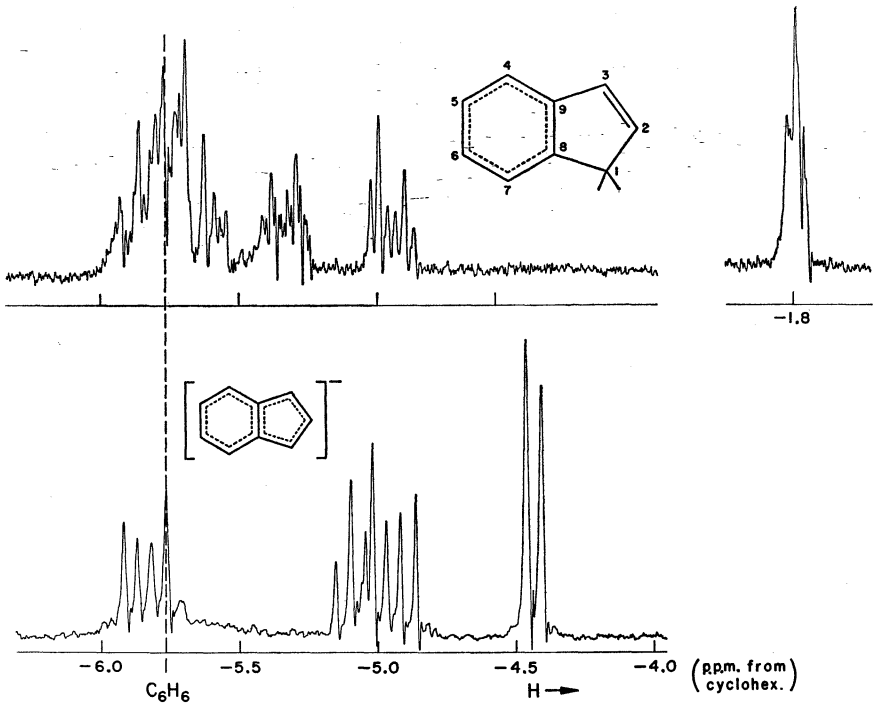

FIG. 1. Proton resonance spectrum at 60 Mc/s for indene and indenyl ion. The reference scale is in p.p.m. relative to internal cyclohexane.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

shows the proton resonance spectra (at 60 Mc/s) of both indene and the indenyl ion, on a common scale. The proton resonance of benzene on this scale is indicated by the broken line. The proton resonance spectrum of indene has been previously assigned and analyzed by Elleman and Manatt (32). Starting from the right, the signals at −1.8 p.p.m. (from cyclohexane) arise from the methylene protons at the 1-position; those centered near −4.9 from proton 2, and those centered near −5.3 from proton 3. The latter signals show additional splitting due to long-range spin-coupling with proton 4. Finally the complex pattern of signals centered near −5.7 is due to the four protons in the 6-membered ring. The assignment of the proton spectrum of the more symmetrical indenyl ion is straightforward. The three protons in the 5-membered ring give rise to an AB_2 system; the doublet at −4.4 p.p.m. is accordingly assigned to the 1,3-protons, and the triplet centered near −5.1 to the 2-proton. The four protons in the 6-membered ring form an A_2B_2 system; the lower-field half of the spectrum, centered near −5.8, has broader lines than the higher-field half centered near −4.9 p.p.m. Assuming that the broader lines are due to long-range spin-coupling with the 1,3-protons, they are accordingly assigned to the 4,7-protons. Thus, in the ion the 5,6-proton signals are shifted up field to a greater extent by the excess charge. The signals of protons 1, 2, and 3 also show a large up-field shift, but this is partly compensated by the appearance of a ring current in the 5-membered ring.

The density distribution evaluated from the proton resonance shifts (Table III) shows the largest density at the 1,3-positions and the smallest at the 4,7-positions. In this respect there is a parallel with the density distribution in azulene. The density at the 8,9-position was obtained by difference as explained above, and is accordingly subject to greater error. The densities calculated by HMO methods show a remarkably good correspondence with the n.m.r. values, and the density alternation around the rings is identical.

The proton resonance shifts in the fluorenyl ion were generally larger than those in the indenyl ion and a first-order analysis of the spectrum was adequate for the present purpose. The proton assignment was made on the basis of the spin-coupling patterns, but there remains an ambiguity, as between protons 2,7 and 3,6 and between protons 1,8 and 4,6. Of the various possible combinations of assignments, only that shown in Table III gives a reasonable pattern for the density distribution and compares favorably with that calculated by HMO. As in a number of other examples, the spread between maximum and minimum density is smaller than that in the calculated density distribution. This difference is particularly apparent at the 9-position.

(5) The Triphenyl Methyl Cation

As an example of a carbonium ion, the triphenylmethyl cation has been investigated. The proton resonance spectrum of the ion has been reported previously (33), and was repeated for the present study under conditions of higher resolution. The main problem encountered in evaluating the electron density is the assessment of the contribution to the proton shifts due to neighboring ring currents. The most reasonable assumption to make is that the molecular framework is essentially planar (i.e. carbon 1 trigonally hybridized) but with the phenyl groups tending to be tilted out of the plane like the blades of an air fan. A completely planar structure would appear to be ruled out because of strong repulsions between protons in ortho positions. If in addition the phenyl rings are assumed to librate or rotate, the contribution of the ring current to the proton shifts of a neighboring phenyl group will be largely averaged out. In any event the effect at the meta and para protons will be negligibly small, although some average residual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

contribution could be present at the ortho protons. Accordingly in evaluating the electron densities shown in Table III no corrections for neighbor ring effects were made. Comparison with the theoretically calculated values shown indicates a much closer correspondence with the SCFMO results than with those from simple Hückel molecular orbitals. The value 0.95 shown in parenthesis may be regarded as a rough indication of the average density of the 1- and 2-positions. It represents one third of the total electron density at positions 1, 2, 2′, and 2″, obtained by subtracting the sum of the density at all other positions from 18, the total number of π-electrons.

(6) The Azulene Dianion

Aromatic negative ions of a large number of compounds are readily formed by treating a dilute solution of the parent aromatic hydrocarbon in a suitable solvent with alkali metals. With most hydrocarbons the formation of a paramagnetic mononegative ion, which has the added electron in the lowest antibonding molecular orbital, is favored. Azulene on the other hand readily forms the dinegative ion on treatment with excess lithium.* Since the two electrons are paired in the same orbital the ion is diamagnetic. Its proton resonance spectrum bears a close resemblance to that of azulene itself, except that the whole spectrum is considerably displaced toward higher applied field and the signals of the 1-, 2-, and 3-protons are coalesced to a single line. This assignment of the ion was confirmed by measuring 1,3-dideuteroazulene. As an additional confirmatory check, deuterated dimethoxyethane was used as solvent. This was desirable because the spectrum of the ion, occurring at higher field, was partially overlain by the C^{13} satellite resonance peaks of the protons in the undeuterated solvent.

In evaluating the electron density distribution the assumption was made that the ring current induced by the magnetic field in the dinegative ion is similar in magnitude to that in azulene itself. Addition of two electrons to the first antibonding orbital will not increase the aromatic ring current; in fact the ring current is probably somewhat decreased (26). Certainly if all five antibonding orbitals were completely filled the induced ring current would be reduced to zero. Since the magnitude of the reduction in the ring current for the dinegative ion is not readily estimated, the above assumption is probably the best one can make under the circumstances. That this assumption cannot be far wrong is borne out by the density values derived on this basis (Table III); the value 1.29 obtained for the 9,10-positions by difference, in the usual way, is not unreasonable in the context of the overall charge distribution, particularly in view of the fact that this value will involve some accumulation of errors. Had the ring current in the dianion been very substantially reduced relative to that in azulene, the resulting value at the 9,10-positions may have been expected to deviate rather widely.

Comparison of the experimentally derived charge distribution for the dianion with that calculated from simple Hückel orbitals shows the excess charge to be more uniformly distributed, i.e. more delocalized, than would be anticipated from the calculated results. This point is perhaps more clearly demonstrated by comparing the density distribution of the dianion with auzlene itself. Table IV shows the density increments at each position for the process [azulene] $\rightarrow$ [azulene]$^{=}$. In other words, these are the density increments at each position resulting from the addition of two electrons to the lowest antibonding orbital in azulene. Discounting those at the 9,10-positions (which contain the compounded errors of both density distributions), the increments derived experimentally are moderately uniform at each position. On the other hand the calculated increments are large at the

We are indebted to Professor J. Hoijtink for pointing this out to us.

TABLE IV

Charge density increments for [azulene] → [azulene]⁼

Position	Δρ	
	Experimental	Calc. (HMO)
2	0.20	0.20
1,3	0.14	0.01
9,10	(0.32)	0.17
4,8	0.15	0.44
5,7	0.18	0.02
6	0.19	0.52

2-, 4-, and 6-positions and negligible at the 3- and 5-positions. These results, based on HMO calculations, represent, of course, a highly idealized system. In any real system it may be anticipated that an excess charge of 0.5 electron placed on any one carbon atom, as at the 6-position, would cause the molecular system to relax and part of this charge would be distributed over the neighboring carbon atoms, the 5- and 7-positions.

The greater degree of charge delocalization indicated in the charge distributions derived from n.m.r. data as compared to the MO results appears to be common also to the other aromatic ions investigated (Table III). A similar observation has also been made previously in relation to the benzene carbonium ion (6). Colpa, MacLean, and Mackor (34) have given an interpretation of this behavior in terms of π–σ interaction. As discussed above, the proton resonance responds to an altered π-electron density on a carbon atom due to an essentially electrostatic polarization of the C—H sigma bond. It is thus to be anticipated that the sigma bonds to neighboring carbon atoms will be similarly polarized, resulting in some contribution to the resonance shift of their bonded protons. Consequently the densities derived from proton resonance shifts give a measure of the combined local density alteration in both the π- and σ-electron systems. In contrast the densities calculated by simple MO theory yield an "idealized" local density for the π-electron system only. In neutral molecules, where the π-electron densities differ but slightly from unity this basic difference in the results of the two methods is not very pronounced. However, in the aromatic ions, and particularly double-charged ions, where the excess charges are greater, the disparity in the resulting density distributions is increased.

III. CONCLUSIONS

The present investigations provide strong support for a simple empirical correlation between the proton resonance shift and the local electron density on the bonded carbon atom in aromatic systems. When this relationship is applied to a variety of suitable aromatic systems a satisfactory reproduction of the electron density distribution, as indicated by chemical and theoretical methods, is obtained. The assumption that the proton screening depends linearly (to a good approximation) on the excess electron density of the bonded carbon atom appears to be well borne out. In all cases this gives the correct sign of the proton shifts, and accordingly, if square terms or higher-order interactions are involved, they must be relatively small. In favorable cases, therefore, the charge densities determined from proton shifts can be expected to be quite reliable; they are probably more accurate than those calculated by simple MO methods and compare favorably with those obtained by more refined calculations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

On the other hand many aromatic systems represent "unfavorable" cases and the determination of the electron density distribution by the present methods has serious limitations. Among these are molecules with magnetically anisotropic substituents, heterocyclic molecules, and large polycyclic molecules, for which the effects due to induced ring currents are proportionately large. The extent to which useful information on charge densities can be derived in these cases will ultimately depend on the extent to which the perturbing effects can be treated, either theoretically or empirically, in a more quantitative manner. In some cases solvent effects could give rise to additional uncertainties although these are usually less serious.

For aromatic positive or negative ions, which involve much larger excess charges than neutral molecules, the charge density distributions derived from n.m.r. data generally indicate a somewhat more uniform distribution of the excess charge than those calculated by MO methods. This may be indicative of π–σ interaction, the proton screening being thus altered by the polarized σ-orbitals as well as by the excess charge in the π-orbitals.

EXPERIMENTAL

General

The carbanions whose cations were sodium were prepared by shaking with sodium in a solvent vapor atmosphere. They were transferred to sample cells through a sintered-glass filter. The apparatus was self-contained so that contact was never made with air or water. Tetrahydrofuran (THF) had been purified by vacuum distillation after shaking with sodium and anthracene. Acetonitrile was dried over P_2O_5 and was vacuum distilled.

The carbanions whose cations were lithium were prepared from a solution of *n*-butyl lithium in hexane. After precipitation of the salt the hexane was removed by vacuum distillation and the appropriate solvent was added. Again no contact with air or water was allowed, all transfers of solvent being done on a vacuum line.

The proton resonance measurements were made at 60 Mc/s. Internal references were either benzene or cyclohexane, present in the purified solvent at a concentration between 0.5 and 1 mole%. The internal shift between benzene and cyclohexane was 351.4 c/s in THF. The same shift was found in a THF solution which had been shaken with sodium for 1 day, demonstrating the reliability of the reference positions.

Cyclopentadienyl Sodium

Separate solutions (series I) of varying concentrations were prepared from measured amounts of reactants and solvent as described above. Dicyclopentadiene was freshly distilled. A second series of dilution studies was made on an 8 mole% solution by the addition of known volumes of solvent to the initial solution in a self-contained apparatus. This arrangement precluded spinning the sample but as a check the 8 mole% solution, retrieved by vacuum removal of the correct amount of solvent, was spun, and the measurement was found to agree exactly with the original one. Table I gives the results. In the higher concentration regions (6–10 mole%) the difference in shifts between the two types of measurement differ by as much as 1.0 c/s. This is probably due to the difficulty of getting accurate concentrations with such small amounts of material (the solutions in the first series of dilution experiments were made from 1 cc of solvent). However, plots of the two series of points extrapolate to the same point at zero concentration. The shifts for the 10 mole% and 6 mole% solutions (series I) gave virtually the same peak intensities and shifts, so that a limited solubility in THF is indicated.

Cyclopentadienyl Lithium

Dilution studies were carried out from 4 mole% down to 1 mole% in acetonitrile. The dilution shift was zero to within experimental error and the shift relative to benzene was 1.83 p.p.m.

Tropylium Bromide

A 0.2 mole% solution in CH_3CN had a strong peak at -1.91 p.p.m. relative to benzene. The salt was insufficiently soluble in THF to give a resonance.

$C_8H_8{=}2Na^+$

Solutions, 3 mole%, of this compound were prepared from freshly distilled cyclooctatetraene in both THF and CH_3CN, as described above. The THF solution threw down a dark brown precipitate which partially redissolved to give a greenish-yellow solution. The CH_3CN solution was brown. The shifts were 1.60 and 1.59 p.p.m. relative to C_6H_6, respectively. A previous measurement of this ion, reported by Fritz and Keller (19), differs excessively. Our values agree with those of Katz (18).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Triphenylcarbonium Ions

Both the chloride and the carbinol of triphenylmethane dissolved to form 5 mole% orange solutions in trifluoroacetic acid. The ring proton spectra, of the A_2B_2C type, were virtually identical for the two solutions. They were analyzed to give approximate shifts (Table III). The spectra were very similar to those of Connor *et al.* for the carbinol at 40 Mc/s, allowing for the difference in spectrometer frequencies.

Crystal violet, the chloride of the symmetrically trisubstituted *p*-N,N-dimethyltriphenylmethane, gave a single broad line for the ring protons in CF_3COOH, about -0.3 p.p.m. from internal C_6H_6. Since at least partial protonation of the $N(CH_3)_2$ groups occurs, no conclusions can be drawn. Solutions in various solvents of dielectric constants as high as 65 all gave nearly the same A_2B_2 spectra for the ring protons, all a few tenths of a p.p.m. to high field of internal benzene. It was concluded that ionization was not occurring.

Experiments with $AlCl_3$ and the chloride as well as crystal violet, in an attempt to get the carbonium ion, were unsuccessful.

Triphenylmethyl sodium in THF gave a broad line at about 0.2 p.p.m. to high field of internal benzene, indicating no appreciable ionization and possibly some radical species present.

Indenyl Sodium

Freshly distilled indene gave a light orange or yellowish 5 mole% solution in THF after shaking for about a day. The spectrum of the molecule and the ion are shown in Fig. 1. The experiment was repeated at a lower concentration (~3 mole%). The shifts obtained agreed to within 0.04 p.p.m.

Fluorenyl Sodium

Solutions, 5 mole% and 3 mole%, in THF gave orange solutions after shaking with sodium for a few days. The 5 mole% solution was not completely converted to the ion but conversion was very nearly complete in the 3 mole% solution. The shifts relative to benzene in the two solutions agreed to within 0.05 p.p.m. at worst and to within 0.01 p.p.m. at one position.

Azulene Dianion

Solutions, 4 mole%, were prepared by shaking with lithium in dimethoxyethane and in deuterated dimethoxyethane, both solvents having been purified with sodium and anthracene. The solution was deep purple in color.

ACKNOWLEDGMENTS

We gratefully acknowledge our indebtedness to Mr. Y. Lupien for the preparation of samples, to Mr. J. Nicholson for technical assistance, and also to Dr. E. Mackor for providing us with his results prior to publication and to Dr. J. Martin for informative discussions.

DIFFUSION WITH MIGRATION IN THE DIFFUSE DOUBLE LAYER

S. K. RANGARAJAN
Central Electrochemical Research Institute, Karaikudi, India
Received June 12, 1962

ABSTRACT

The polarization characteristics of the concentration of the reactive species are discussed when the effects of migration in the diffuse layer are accounted for. A limiting case ($\xi_0 \rightarrow \infty$) and some particular cases ($|Z_i/Z| = 0, 1, 2, 3, 4$) are derived both for attraction and repulsion in the double layer. Linear approximations (and conditions sufficient to validate these) are presented. Some general results which relate the functional forms of the transforms of the interfacial concentrations for the cases of attraction and repulsion are also pointed out.

The effect of the diffuse double layer is usually neglected in the quantitative formulations of the problems in electrode kinetics. It is the object of the present paper to examine the polarization characteristics* of the concentrations of the reactive species when the effect of migration in the diffuse double layer is taken into account. As has been pointed out (1) the effect of the diffuse layer is mainly twofold, viz., the manner in which it affects the effective concentrations of the reactants in the plane of closest approach and the potentials for the forward and the backward reactions. Detailed investigations on the corrections that must be applied necessarily to account for the effects of the diffuse double layer have been made by various authors,† and in particular the derivations of Matsuda and Delahay (2) will be examined with reference to the expressions obtained in this paper.

1. The Formulation of the Problem and its Solution

The changes in the concentrations of the reactive species C_i(i = O, oxidant; R, reductant) in the plane of closest approach is given by the solution of the diffusion equation

$$\frac{\partial C_i}{\partial t} = D_i\left[\frac{\partial}{\partial x}\left(\frac{\partial C_i}{\partial x} + \frac{Z_iF}{RT}\frac{d\phi}{dx}C_i\right)\right] \qquad [1]$$

where the second term in the R.H.S. accounts for the "flux due to the migration effects in the diffuse double layer".

The initial condition is

$$C_i(t = 0) = C_i^{\,0}\exp\left(\frac{-Z_iF\phi}{RT}\right) \qquad [2]$$

(Z_i: valency of the species i *with sign*)

The boundary conditions are given as

$$D_i\left(\frac{\partial C_i}{\partial x} + \frac{Z_iF}{RT}\frac{d\phi}{dx}C_i\right) = \pm\frac{I}{nF} \qquad (\text{at } x = 0) \qquad [3]$$

(positive sign for i = O and negative for i = R,
if the net cathodic current is taken as positive)

**By 'polarization characteristics' of the concentrations, we mean the deviation of the final state, the concentration distribution which exists at the moment due to the application of an electric field vis-a-vis the initial state (viz. the equilibrium state).*

†For a comprehensive bibliography, see reference 1.

where n is the number of electrons transferred in the rate-determining step

$$O^{z_O} + ne \rightleftharpoons R^{z_R}$$

$$Z_O = Z_R + n$$

and

[4] $$C_i(x \to \infty) \to C_i^0.$$

It is assumed that:

(a) the diffuse double layer structure is determined entirely by a Z–Z supporting electrolyte;

(b) the potential distribution $\phi(x)$ in the layer obeys Gouy–Chapman theory, i.e.,

[5] $$\frac{d\phi}{dx} = -\left(\frac{2RT}{|Z|F}\right)\kappa \sinh\left(\frac{|Z|F\phi}{2RT}\right)$$

and

[5′] $$1/\kappa = (RT\epsilon/8\pi Z^2F^2C_t)^{1/2};$$

(c) convection is negligible; and

(d) the mobility is given by

$$\mu = \frac{Z_iD_iN}{RT}.$$

Defining the Laplace's transformation* of $f(t)$ as

$$\bar{f}(p) = p\int_0^\infty e^{-pt}f(t)dt$$

equation [1] can be transformed into an ordinary differential equation, viz.,

[6] $$D_i\frac{d}{dx}\left(\frac{d\bar{C}_i}{dx} + \frac{Z_iF}{RT}\frac{d\phi}{dx}\bar{C}_i\right) - p\left[\bar{C}_i - C_i^0\exp\left(\frac{-Z_iF\phi}{RT}\right)\right] = 0.$$

Following Matsuda and Delahay, we write

[7] $$\bar{C}_i(p) = \exp\left(\frac{-Z_iF\phi}{RT}\right)\cdot[C_i^0 - v_i(p)]$$

and

[7′] $$\xi = \exp\frac{|Z|\,F\,|\phi|}{2\,R\,T}$$

so that

[8] $$v_i \to 0 \text{ as } x \to \infty \text{ (since } \phi \to 0 \text{ as } x \to \infty).$$

By using equation [7], equation [6] can be transformed into

$$D_i\exp\left(\frac{Z_iF\phi}{RT}\right)\frac{d}{dx}\left[\exp\left(\frac{-Z_iF\phi}{RT}\right)\frac{dv_i}{dx}\right] - pv_i = 0.$$

It can be shown by using equations [5] and [7′] that

$$d\xi = -\frac{\kappa}{2}(\xi^2 - 1)dx$$

The transform variable 'p' here is not to be confused with the parameter $p = \pm|Z_i/Z| - 1$ introduced in reference 2. p of reference 2 $= (l - \frac{1}{2})$ of this paper.

and

$$[9] \qquad \xi^{(2l+1)}(\xi^2-1)\frac{d}{d\xi}\left[\xi^{-(2l+1)}(\xi^2-1)\frac{dv_i}{d\xi}\right]-\left(\frac{2}{\kappa}\right)^2 pv_i = 0$$

where $(2l+1)$ is written for $\pm|Z_i/Z|$ (the positive sign is to be taken in the case of repulsion ($Z_i\phi > 0$) and negative for attraction ($Z_i\phi < 0$). The corresponding boundary conditions are, now:

$$[10] \qquad v_i \to 0 \text{ as } \xi \to 1$$

and

$$[11] \qquad \left(\frac{dv_i}{d\xi}\right)_{\xi=\xi_0} = \mp 2\frac{\overline{I(p)}}{nFD_i\kappa}\cdot\frac{\xi_0^{(2l+1)}}{\xi_0^2-1}$$

where $\xi_0 = \exp(\{|Z|\,F\,|\phi_0|\}/2RT)$ (ϕ_0 being the potential drop across the entire diffuse double layer, i.e., $\phi(x \to 0)-\phi(x \to \infty)$).

It can be easily seen that any approximation used must be compatible with the boundary conditions; for example, it needs justification to rewrite (ξ^2-1) as ξ^2 *in the differential equation itself* (assuming $\xi^2 \gg 1$) and also use the resulting solution (which is valid only for $\xi^2 \gg 1$) to fit in with the boundary conditions at $\xi = 1$ (cf. Matsuda and Delahay (2)). Moreover, the first-order differential equation [5] is uniquely solved once the boundary condition $\phi = \phi_0$ at $x = 0$ is assumed. Actually, the solution can be written in the form

$$[5''] \qquad \frac{\xi-1}{\xi+1} = \frac{\xi_0-1}{\xi_0+1}e^{-\kappa x}$$

where κ is the *parameter* defined by equation [5']. It can easily be verified that $\xi \neq 1$ when $x = 1/\kappa$, though, of course, $1/\kappa$ gives a measure of how steep the fall is, at sufficient distances away from the electrode. (For example, at $x = 1/\kappa$, $\xi_{1/\kappa} = [\xi_0(e+1)+(e-1)]/[\xi_0(e-1)+(e+1)]$; for $\phi_0 \simeq 50$ mv and $Z = 2$, $\xi_0 = e^2$ and $\xi_{1/\kappa} \simeq 1.8$.) Also, the independent variable ξ is *not* independent of x and hence any chosen value of x leaves no choice for ξ. At the best, it can be approximated. Hence, yet another but less serious inconsistency exists while stating that $\xi = 1$ when $x = \delta$ (cf. Matsuda and Delahay). An attempt is made here to solve the equation [1] without fitting in the solutions obtained in the two different regions (viz. $0 < x \leqslant \delta_k$ and $x \geqslant \delta_k$ (cf. Matsuda and Delahay).

A fundamental method of solving this* will be to express the solution as a power series in ξ. As we are interested in the domain $1 \leqslant \xi \leqslant \xi_0$ it is but natural to express the solution of [9] as a power series in $(1 - 1/\xi^2)$. Writing $\zeta = 1 - 1/\xi^2$, the equation is transformed into

$$[12] \qquad (1-\zeta)\zeta^2 v''+\zeta[(1-\zeta)-(l+1)\zeta]v'-k^2v = 0$$

where

$$k = \frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}; \qquad [0 \leqslant \zeta \leqslant (1 - 1/\xi_0^2)].$$

The solution of this, which satisfies the boundary condition [10]; can easily be seen to be (refer to Appendix I),

$$[13] \qquad v = a_0\zeta^k F(k, k+l+1; 2k+1; \zeta)$$

**The solution of the equation [9] can be expressed in terms of hypergeometric functions by proper transformation of the variables and identifying the resulting differential equation with the Riemann P equation.*

where F is the Gaussian hypergeometric function, and a_0 is an arbitrary constant. Rewriting the boundary condition at $\xi = \xi_0$, [11], as

$$[14] \qquad \left(\frac{dv_i}{d\zeta}\right)_{\zeta=\zeta_0} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left(\frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}\right)\frac{\xi_0^{(2l+4)}}{\xi_0^2-1},$$

it is shown in Appendix I that

$$[15] \qquad a_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\frac{\xi_0^{(2l+1)}(1-1/\xi_0^2)^{-k}}{F(k+1,\, k+l+1;\, 2k+1;\, \zeta_0)};$$

$$[16] \qquad (v_i)_{\xi=\xi_0} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{(2l+1)}\frac{F(k,\, k+l+1;\, 2k+1;\, \zeta_0)}{F(k+1,\, k+l+1;\, 2k+1;\, \zeta_0)}$$

and the distribution of the concentration with x is given as

$$[17] \qquad (v_i)_\xi = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{(2l+1)}\left(\frac{1-1/\xi^2}{1-1/\xi_0^2}\right)^k\frac{F(k,\, k+l+1;\, 2k+1;\, 1-1/\xi^2)}{F(k+1,\, k+l+1;\, 2k+1;\, 1-1/\xi_0^2)}.$$

(The variable x is not explicitly present here but one can easily note that ξ is a function of x; refer to equation [5″].)

2. A Particular Case

At this stage, it may be interesting to observe how one obtains the concentration distribution for linear diffusion (with the effects due to diffuse double layer assumed negligible), as a limiting case of the equation [17].

The differential equation [1] and the condition [3] can be reduced to

$$[18] \qquad D_i\frac{\partial^2 C_i}{\partial x^2} = \frac{\partial C_i}{\partial t} \qquad \text{with} \qquad D_i\left(\frac{\partial C_i}{\partial x}\right)_{x=0} = \pm\frac{I}{nF}$$

by allowing Z_i to become zero, the other parameters, Z, ϕ_0, $1/\kappa$, etc. remaining unaltered. Hence, writing $(l+1) = \pm|z_i/z|+\frac{1}{2} = \frac{1}{2}$ in equation [17], we get

$$[19] \qquad (v_i)_\xi = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{(2l+1)}\left(\frac{1-1/\xi^2}{1-1/\xi_0^2}\right)^k\frac{F(k,\, k+1/2;\, 2k+1;\, 1-1/\xi^2)}{F(k+1,\, k+1/2;\, 2k+1;\, 1-1/\xi_0^2)},$$

which is shown to reduce identically to the well-known (3) expression

$$[20] \qquad C_i^0 - \bar{C}_i = (v_i)_\xi = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,e^{-\sqrt{(p/D_i)}x} \qquad \text{(Appendix II).}$$

Though the transform of the concentrations are obtained exactly, the process of inverse transformation is not so simple in general. Approximations may have to be made or particular cases alone chosen.

3. A Limiting Case: $\xi_0^2 \gg 1$

Interesting results are obtained when the assumption $\xi_0^2 \gg 1$ (or $1-1/\xi_0^2 \cong 1$) (*irrespective of the magnitude of other parameters like k and l*) is made. The limiting cases ($\xi_0 \to \infty$) markedly depend upon the signs of (l) and ($l+1$). The results are tabulated below (Table I) (refer to Appendix III).

But, the above limiting results are not of much significance since the condition $\xi_0^2 \gg 1$ absolutely is not of practical importance—its magnitude in relation to other parameters (particularly k) alone is of interest to us. As a matter of fact, k can be taken to be so small in many cases that any condition for an approximation made must be specified in relation to k. It will be shown later that the necessary conditions for the validity of

the first approximation, viz., expanding $(v_i)_0$ in the form $(a+bk)$ depends whether there is attraction or repulsion of the species in the diffuse layer.

Before examining the coefficient of k in the expansion of $(v_i)_0$ in its general form, some particular cases where exact expressions for $(v_i)_0$ can be obtained are also presented.

4. Particular Cases

(a) Attraction: $|Z_i| = |Z|$; $(l+1) = \pm|Z_i/Z| + 1/2 = -1/2$

$$[21] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{-1}\frac{F(k, k-1/2; 2k+1; 1-1/\xi_0^2)}{F(k+1, k-1/2; 2k+1; 1-1/\xi_0^2)}$$

It is shown in Appendix IV that

$$[22] \qquad F(k, k-1/2; 2k+1; 1-1/\xi_0^2) = \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}\frac{2k+\xi_0}{\xi_0(2k+1)}$$

and

$$[23] \qquad F(k+1, k-1/2; 2k+1; 1-1/\xi_0^2) = \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}\frac{1+2k\xi_0}{\xi_0(2k+1)}$$

so that

$$[24] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left(\frac{1+2k/\xi_0}{1+2k\xi_0}\right) = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left[1-(\xi_0-1/\xi_0)\frac{2k}{1+2k\xi_0}\right],$$

which $\rightarrow (\overline{I(p)})/(nF\sqrt{(D_i p)})$ as $|k| \rightarrow 0$ or as $\xi_0 \rightarrow 1$.

The first term represents what one would have derived had there been no perturbation due to the diffuse layer. The variation of the perturbation in the interfacial concentration with time is as that of the inverse transform of

$$\mp\frac{I(p)}{nF\sqrt{(D_i)}}\,(1-1/\xi_0^2)/(\alpha+\sqrt{(p)})$$

where $\alpha = [\kappa\sqrt{(D_i)}]/[2\xi_0]$. The inverse transform of $(v_i)_0$ is

$$[25] \qquad \frac{1}{nF\sqrt{(D_i)}}\int_0^t \frac{I(t-u)}{\sqrt{(\pi u)}}\,du - \frac{(1-1/\xi_0^2)}{nF\sqrt{D_i}}\left[\int_0^t \frac{I(t-u)}{\sqrt{(\pi u)}}\,du - \alpha\int_0^t I(t-u)e^{\alpha^2 u}\,\mathrm{Erfc}\,(\alpha u^{\frac{1}{2}})du\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The first term in the right hand side of equation [25] alone will be present if the effects due to the migration in diffuse layer are assumed negligible.

If $k = (1/\kappa)\sqrt{(p/D_i)}$ is so small that $(k\xi_0)^2 \ll 1$, $(v_i)_0$ can be written as

$$[26] \qquad \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}[1-2k(\xi_0 - 1/\xi_0)].$$

If $2k\xi_0 \gg 1$,

$$[27] \qquad (v_i)_0 \rightarrow \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{-1}\frac{1}{2k} \qquad \text{(refer to Table I).}$$

(b) Attraction: $|Z_i| = 2|Z|$; $(l+1) = -3/2$

It follows from Appendix V that

$$[28] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{-3}\frac{F(k, k-3/2; 2k+1; 1-1/\xi_0^2)}{F(k+1, k-3/2; 2k+1; 1-1/\xi_0^2)}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\frac{(3+6k/\xi_0+4k^2/\xi_0^2+2k/\xi_0^3)}{(3+6k\xi_0+4k^2\xi_0^2+2k\xi_0^3)},$$

which $\rightarrow \pm[\overline{I(p)}]/[nF\sqrt{(D_i p)}]$ as $|k| \rightarrow 0$ or as $\xi_0 \rightarrow 1$. But, if $k\xi_0^3 \gg 1$ (such that the other terms in the denominator can be neglected in comparison with $k\xi_0^3$),

$$[29] \qquad (v_i)_0 \cong \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{-3}\frac{3}{2k} \qquad \text{(refer to Table I).}$$

Expanding $(v_i)_0$ as a power series in k and neglecting coefficients of k^2 and higher powers,

$$[30] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\{1-2k[(\xi_0-1/\xi_0)+\tfrac{1}{3}(\xi_0^3-1/\xi_0^3)]\}.$$

It can be noted that (i) the coefficient of $2k$ is negative and (ii) the necessary and sufficient condition for such an expansion is $(k\xi_0^3)^2 \ll 1$ (so that it follows that k^2, $(k^2\xi_0^2)^2$, etc. are also negligible as compared with 1).

The inverse transform of $(v_i)_0$ can be expressed in integral form by making use of the convolution theorem.

(c) Attraction: $|Z_i| = 3|Z|$; $(l+1) = -5/2$

Referring to Appendix V, it can be seen that

$$[31] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\frac{F(k, k-5/2; 2k+1; 1-1/\xi_0^2)}{F(k+1, k-5/2; 2k+1; 1-1/\xi_0^2)}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\frac{f_3(k, 1/\xi_0)}{f_3(k, \xi_0)}$$

where

$$f_3(k, \xi_0) = \frac{15+30k\xi_0+24k^2\xi_0^2+(10k+8k^3)\xi_0^3+12k^2\xi_0^4+6k\xi_0^5}{(2k+1)(2k+3)(2k+5)}$$

$$\rightarrow \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \text{ as } k \rightarrow 0 \text{ or as } \xi_0 \rightarrow 1;$$

and

$$[32] \qquad \rightarrow \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{-5}\frac{5}{2k} \qquad \text{(cf. Table I)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

if $k\xi_0^5 \gg 1$ such that other terms in the denominator can be neglected. For small k, $(v_i)_0$ can be expanded as

$$[33] \qquad \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\{1-2k[(\xi_0 - 1/\xi_0)+\tfrac{1}{3}(\xi_0^3 - 1/\xi_0^3)+\tfrac{1}{5}(\xi_0^5 - 1/\xi_0^5)]\},$$

other powers in k being neglected—the condition for this being $(k\xi_0^5)^2 \ll 1$.

(d) Attraction: $|Z_i| = 4|Z|$; $(l+1) = -7/2$

In this case,

$$[34] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{-7}\,\frac{F(k, k-7/2; 2k+1; 1-1/\xi_0^2)}{F(k+1, k-7/2; 2k+1; 1-1/\xi_0^2)}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\frac{f_4(k, 1/\xi_0)}{f_4(k, \xi_0)}$$

where

$$f_4(k, \xi_0) = [105+210k\xi_0+180k^2\xi_0^2+(70k+80k^3)\xi_0^3+(104k^2+16k^4)\xi_0^4$$
$$+(42k+48k^3)\xi_0^5+60k^2\xi_0^6+30k\xi_0^7]/[(2k+1)(2k+3)(2k+5)(2k+7)]$$

$$\to \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \text{ as } k \to 0 \text{ or as } \xi_0 \to 1 \qquad \text{(refer to Appendix V)}$$

and

$$[35] \qquad \to \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{-7}\,\frac{7}{2k} \text{ for } k\xi_0^7 \gg 1.$$

For small k, an approximate expression for $(v_i)_0$, linear in k, will be

$$[36] \qquad \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\{1-2k[(\xi_0 - 1/\xi_0)+\tfrac{1}{3}(\xi_0^3 - 1/\xi_0^3)+\tfrac{1}{5}(\xi_0^5 - 1/\xi_0^5)+\tfrac{1}{7}(\xi_0^7 - 1/\xi_0^7)]\}$$

$$((k\xi_0^7)^2 \ll 1)$$

(e) Repulsion: $|Z_i| = |Z|$; $(l+1) = 3/2$

It can be proved in this case (Appendix IV) that

$$[37] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^3\,\frac{F(k, k+3/2; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+5/2; 2k+1; 1-1/\xi_0^2)}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left(\frac{1+2k\xi_0}{1+2k/\xi_0}\right),$$

which

$$[38] \qquad \to \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \text{ as } k \to 0 \text{ or as } \xi_0 \to 1.$$

Note that if one writes

$$(v_i)_0^{\text{rep}} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,w_{\text{rep}}(\xi_0),$$

and similarly define $w_{\text{attr}}(\xi_0)$,

$$w_{\text{rep}}(\xi_0)\,.\,w_{\text{attr}}(\xi_0) = 1;$$

also, refer to Section 7.

If k is small enough to satisfy the inequality $k^2 \ll 1$, $(v_i)_0$ can be expanded as

$$[39] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\{1+2k(\xi_0 - 1/\xi_0)+\text{terms in } k^2, k^3, \ldots\}.$$

For $k\xi_0 \gg 1$,

$$[40] \qquad (v_i)_0 \rightarrow \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,2k\xi_0 \qquad \text{(refer to Table I).}$$

The condition for neglecting terms in second and higher powers of k in $(v_i)_0$ is less strict in the case of repulsion. The inverse transform for $(v_i)_0$ can, of course, be expressed in this case too—as was done previously for the case of attraction.

(f) Repulsion: $|Z_i| = 2|Z|$; $(l+1) = 5/2$

$(v_i)_0$ can be written as

$$[41] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{\,5}\,\frac{F(k, k+5/2; 2k+1; 1-1/\xi_0^{\,2})}{F(k+1, k+3/2; 2k+1; 1-1/\xi_0^{\,2})}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\frac{(3+6k\xi_0+4k^2\xi_0^{\,2}+2k\xi_0^{\,3})}{(3+6k/\xi_0+4k^2/\xi_0^{\,2}+2k/\xi_0^{\,3})} \qquad \text{(Appendix V).}$$

If $k^2\xi_0^{\,2} \ll 1$ such that terms in k^2 and higher powers can be neglected,

$$[42] \qquad (v_i)_0 \cong \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\{1+2k[(\xi_0 - 1/\xi_0)+\tfrac{1}{3}(\xi_0^{\,3} - 1/\xi_0^{\,3})]\}.$$

For $k\xi_0^{\,3} \gg 1$, it is possible to express $(v_i)_0$ as

$$[43] \qquad \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{\,3}\,\frac{2k}{3} \qquad \text{(cf. Table I).}$$

(g) Repulsion: $|Z_i| = 3|Z|$; $(l+1) = 7/2$

It can easily be proved, as in the other cases, that

$$[44] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{\,7}\,\frac{F(k, k+7/2; 2k+1; 1-1/\xi_0^{\,2})}{F(k+1, k+7/2; 2k+1; 1-1/\xi_0^{\,2})}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\frac{f_3(k, \xi_0)}{f_3(k, 1/\xi_0)}$$

where

$$f_3(k, \xi_0) = \frac{15+30k\xi_0+24k^2\xi_0^{\,2}+(10k+8k^3)\xi_0^{\,3}+12k^2\xi_0^{\,4}+6k\xi_0^{\,5}}{(2k+1)(2k+3)(2k+5)},$$

which

$$\rightarrow \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \quad \text{as } k \rightarrow 0 \text{ or as } \xi_0 \rightarrow 1.$$

For large ξ_0 such that $k^2\xi_0^{\,4}$ can be neglected in comparison with 1, $(v_i)_0$ can be expressed by

$$[45] \qquad (v_i)_0 \cong \{1+2k[(\xi_0 - 1/\xi_0)+\tfrac{1}{3}(\xi_0^{\,3} - 1/\xi_0^{\,3})+\tfrac{1}{5}(\xi_0^{\,5} - 1/\xi_0^{\,5})]\}.$$

If $k^2\xi_0^{\,4} = 0(1)$, the expansion must include terms in k^2 also. For $k\xi_0^{\,5} \gg 1$, such that other terms in the numerator can be neglected,

$$[46] \qquad (v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{\,5}\,\frac{2k}{5} \qquad \text{(cf. Table I).}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(h) Repulsion: $|Z_i| = 4|Z|$; $(l+1) = 9/2$

$(v_i)_0$ can be written as

[47] $$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{9}\,\frac{F(k, k+9/2; 2k+1; 1-1/\xi_0^{2})}{F(k+1, k+9/2; 2k+1; 1-1/\xi_0^{2})}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\frac{f_4(k, \xi_0)}{f_4(k, 1/\xi_0)} \qquad \text{(Appendix V)}$$

where

$$f_4(k, \xi_0) = [105+210k\xi_0+180k^2\xi_0^2+(70k+80k^3)\xi_0^3+(104k^2+16k^4)\xi_0^4 + (42k+48k^3)\xi_0^5+60k^2\xi_0^6+30k\xi_0^7]/[(2k+1)(2k+3)(2k+5)(2k+7)]$$

which

$$\to \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \text{ as } k \to 0 \text{ or as } \xi_0 \to 1$$

and

[48] $$\to \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{7}\,\frac{2k}{7} \quad (\text{as } \xi_0 \to \infty).$$

A linear approximation in k for $(v_i)_0$ will yield

[49] $$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\{1+2k[(\xi_0 - 1/\xi_0)+\tfrac{1}{3}(\xi_0^3 - 1/\xi_0^3)+\tfrac{1}{5}(\xi_0^5 - 1/\xi_0^5) + \tfrac{1}{7}(\xi_0^7 - 1/\xi_0^7)]\}.$$

5. A Linear Expression in k for $(v_i)_0$

In general, the exact functional expressions of $(v_i)_0$ will not be simple rational functions of k. It is of interest to expand $(v_i)_0$ as a power series in k and to obtain the coefficient of k, whatever be the value of the parameter l. This coefficient alone will serve the purpose satisfactorily, as k can be assumed to be very small. It has been shown in Appendix VI that $(v_i)_0$ can be written as

[50] $$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,(1+a_i k)$$

(positive sign for the oxidant and negative for the reductant, assuming net cathodic current to be positive)

neglecting higher powers of k, where

[51] $$a_i = \int_0^{1-1/\xi_0^2} \frac{(1-z)^{-(l+1)} - (1-z)^{l}}{z}\,dz$$

$$= 2\int_1^{\xi_0} \frac{\xi^{2(l+1)} - \xi^{-2l}}{\xi(\xi^2-1)}\,d\xi$$

$$= k\int_0^{\infty}\left[\exp\left(\pm\frac{|Z_i|\,F\,|\phi|}{RT}\right) - \exp\left(\mp\frac{|Z_i|\,F\,|\phi|}{RT}\right)\right]dx$$

$$= \pm 2k\int_0^{\infty} \sinh\frac{|Z_i\phi|F}{RT}\,dx;$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

positive sign for repulsion ($Z_i\phi > 0$) and negative for attraction ($Z_i\phi < 0$) (whereas the integral

$$\int_0^\infty \exp\left[\pm(Z_iF\phi)/(RT)\right]dx$$

is divergent, a_i, as given above, can easily be proved to be convergent).

This differs from the expressions for a_i derived by Matsuda and Delahay (2). It will be shown later that the results may vary appreciably in some instances, while the order of the values as regards ξ_0 will be very much the same for $\xi_0 \to \infty$. Also $(a_i)_{rep} > 0$.

[52] $$(a_i)_{attr} < 0 \text{ and } (a_i)_{rep} = -(a_i)_{attr}$$

As illustrations, we can consider the following cases.

(i) $|Z_i| = |Z|$

[53]
$$\begin{aligned} a_i &= \pm 2\kappa \int_0^\infty \sinh\left(\frac{|Z\phi|F}{RT}\right)dx \\ &= \pm 4\kappa \int_0^\infty \cosh\frac{|Z\phi|F}{RT}\left(-\frac{|Z|F}{2RT}\frac{1}{\kappa}\frac{d\phi}{dx}\right)dx \\ &= \mp 4\int_{x=0}^{x=\infty} \cosh y\, dy \text{ where } y = \frac{|Z\phi|F}{2RT} \\ &= \pm 4 \sinh\frac{|Z|\ F\ |\phi_0|}{2RT} \text{ (since } \phi = \phi_0 \text{ at } x = 0 \text{ and } \to 0 \text{ as } x \to \infty) \\ &= \pm 2(\xi_0 - 1/\xi_0), \end{aligned}$$

as has already been proved. (The positive sign to be taken when there is repulsion and the negative when there is attraction.)

(ii) $|Z_i| = |Z|/2$; $l+1 = 1$ for repulsion and $l+1 = 0$ for attraction

[54]
$$\begin{aligned} a_i &= \pm 2\kappa \int_0^\infty \sinh\frac{|Z_i\phi|F}{2RT}dx \\ &= \mp\frac{|Z|F}{RT}\int_0^\infty \frac{d\phi}{dx}dx = \mp\frac{|Z|F}{RT}[\phi_\infty - \phi_0] \\ &= \pm\frac{|Z|F}{RT}\phi_0 \text{ or } \pm\ln \xi_0^2. \end{aligned}$$

It can be shown that the term $k(|Z|F/RT)\phi_0$ (or $k \ln \xi_0^2$) is the dominant term as regards the order of ξ_0 in the expansion of $F(k, k+1; 2k+1; 1 - 1/\xi_0^2)$ and hence in the case of repulsion ($l+1 = 1$),

$$(v_i)_0^{rep} \cong \frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\, k \ln \xi_0^2 \qquad (\text{since } k \ln \xi_0^2 \gg 1).$$

In the case of attraction, $(l+1) = 0$, and

[55] $$(v_i)_0^{attr} \cong \frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\frac{1}{k \ln \xi_0^2} \qquad \text{(cf. Table I).}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(iii) $|Z_i| = 3|Z|/2$

[56] $$a_i = \pm 2\kappa \int_0^\infty \sinh \frac{3|Z|\,F\,|\phi|}{2RT}\,dx$$

$$= \mp \int_{x=0}^{x=\infty} (2\cosh y + 1)dy \text{ where } y = \frac{|Z|\,F\,|\phi|}{RT},$$

since $\sinh 3Z = \sinh Z\,(2\cosh 2Z - 1)$

[57] $$a_i = \pm 2\left[\sinh \frac{|Z|\,F\,|\phi|}{RT} + \frac{|Z|\,F\,|\phi|}{2RT}\right]$$

$$= \pm[\xi_0^2 - 1/\xi_0^2 + \ln \xi_0^2].$$

(iv) $|Z_i| = |Z|/3$; $(l+1) = 5/6$ for repulsion and $= 1/6$ for attraction

[58] $$a_i = \pm 2 \int_1^{\xi_0} \frac{\xi^{2(l+1)} - \xi^{-2l}}{\xi(\xi^2-1)}\,d\xi$$

$$= \pm 6 \int_{1/\xi_0^{1/3}}^1 \frac{1-z^4}{1-z^6}\,dz \qquad \text{(by substituting } z^{-3} = \xi,\ d\xi = -3z^{-4}dz)$$

[59] $$= \pm\sqrt{3}\left[\pi - 2\tan^{-1}\frac{\sqrt{3}\,\xi_0^{1/3}}{\xi_0^{2/3}-1}\right]$$

$$\to \pm\sqrt{3}\,\pi \qquad \text{as } \xi_0 \to \infty.$$

Thus we see that a_i can be evaluated exactly for almost all the values (relevant to our problem) of the parameter l.

6. Validity of the Approximations

It will be of use to us to find out the range of approximation, i.e. the inequalities that the parameters are to satisfy to validate the linear approximation for $(v_i)_0$.

It is proposed to find the conditions to be satisfied in order that $(v_i)_0$ may be expressed as $(a+bk)$, (a, b, independent of k). It is proved in Appendix VI that the coefficients of k^2 in the expansion of $F(k, k+l+1; 2k+1; \zeta_0)$ and $F(k+1, k+l+1; 2k+1; \zeta_0)$ are

[60] $$S_2 = \int_0^{\zeta_0} \frac{(1-\zeta)^l S_1 - \phi_1}{\zeta}\,d\zeta \qquad \text{and}$$

$$\phi_2 = \int_0^{\zeta_0} \frac{(1-\zeta)^{-(l+1)}\phi_1 - S_1}{\zeta}\,d\zeta$$

respectively.

Table I can help us in obtaining some information about the dominant terms (i.e. for large ξ_0) in the expression for $(v_i)_0$ (the order of k being assumed to be independent of ξ_0). One can easily conclude from this and the functional forms of S_2 and ϕ_2 that the second and higher powers of k can be *confidently* neglected in the expansion of $(v_i)_0$ provided

$$\left(\frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}\right)^2 \xi_0^{2l} \ll 1 \qquad \text{(repulsion)}$$

and

$$\left[\frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}\,\xi_0^{2|l+1|}\right]^2 \ll 1 \qquad \text{(attraction)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Note that these are *confident* inequalities since a less strict condition may suffice in some cases. For example,

$$\text{for } |Z_i| = |Z| \text{ (repulsion)}$$
$$(l+1) = +3/2$$

and the condition as stated above reads

$$\left(\frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}\right)^2 \xi_0 \ll 1.$$

But, the *exact* expression for $(v_i)_0$ in this case is

$$\pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\frac{1+2k\xi_0}{1+2k/\xi_0},$$

which can be expanded as

$$\pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}(1+2k\xi_0)\left(1-\frac{2k}{\xi_0}+\frac{4k^2}{\xi_0^2}-\ldots\right), \text{ provided } (2k/\xi_0) < 1;$$

and wherein the terms in k^2 and higher powers can be neglected if

$$k^2 = \left(\frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}\right)^2 \ll 1.$$

7. Two Theorems

Some results concerning the functional forms of $(v_i)_0$ in the case of attraction and repulsion are given in the two theorems presented below.

Theorem No. 1

For a *given* Z_i, if $(v_i)_0^{\mathrm{A}}$ represents the expression of $(v_i)_0$ at the electrode surface *if there is attraction in the diffuse layer* and $(v_i)_0^{\mathrm{R}}$ the expression for $(v_i)_0$ for repulsion,

$$\frac{(v_i)_0^{\mathrm{A}}}{\pm\overline{I(p)}/nF\sqrt{(D_i p)}} \times \frac{(v_i)_0^{\mathrm{R}}}{\pm\overline{I(p)}/nF\sqrt{(D_i p)}} = 1.$$

Theorem No. 2

If $F(k, k+|Z_i/Z|+1/2; 2k+1; 1-1/\xi_0^2) = g(k, \xi_0)$, then

$$(v_i)_0^{\mathrm{A}} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{2k}\frac{g(k, 1/\xi_0)}{g(k, \xi_0)}$$

and

$$(v_i)_0^{\mathrm{R}} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{-2k}\frac{g(k, \xi_0)}{g(k, 1/\xi_0)}$$

(For proofs and discussion refer to Appendix VII.)

CONCLUSIONS

The diffusion equations for the concentration of the reactive species are solved, taking into account the migration in the diffuse double layer (Section 1).

The expression for the known solution of the diffusion equation where the effect of double layer is neglected is derived as a limiting case (Section 2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The asymptotic forms ($\xi_0 \to \infty$) of the interfacial concentrations are obtained (Section 3).

Exact functional expressions for the transforms of the interfacial concentrations in the form of rational fractions in k are given for the particular cases $|Z_i| = |Z|$, $2|Z|$, $3|Z|$, and $4|Z|$, for the cases of both attraction and repulsion (Section 4).

Under certain conditions, $(v_i)_0$ can be related linearly to k, and such a linear expansion is given, for all the values of $|Z_i/Z|$. As illustration, the double layer corrections for the cases $|Z_i| = |Z|$, $|Z|/2$, $3|Z|/2$, and $|Z|/3$ are deduced from the formulae (Section 5).

The conditions which must hold to validate such a linear expansion are discussed (Section 6).

Lastly, some results which relate the functional forms of $(v_i)_0$ for the cases of attraction and repulsion are derived (Section 7).

APPENDIX I

With the substitution $\zeta = 1 - 1/\xi^2$, equation [9] of the text, viz.,

$$\xi^{(2l+1)}(\xi^2-1)\frac{d}{d\xi}\left[\xi^{-(2l+1)}(\xi^2-1)\frac{dv_i}{d\xi}\right] - \left(\frac{2}{\kappa}\right)^2 \frac{pv_i}{D_i} = 0, \tag{A.1}$$

can be transformed into

$$(1-\zeta)^{-l}\zeta[(1-\zeta)^{l+1}\zeta v_i']' - k^2 v_i = 0; \tag{A.2}$$

(a prime indicating the differential with respect to ζ and $k = (1/\kappa)\sqrt{(p/D_i)}$).

Rewriting (A.2) as

$$(1-\zeta)\zeta^2 v'' + [(1-\zeta) - (l+1)\zeta]\zeta v' - k^2 v = 0 \tag{A.3}$$

we seek a solution which will converge at $\zeta = 0$, i.e., at $\xi = 1$ (this is equivalent to the statement: $v_i \to 0$ as $x \to \infty$). Assuming the solution to be of the form

$$\zeta^s \sum_{r=0}^{\infty} a_r \zeta^r$$

and substituting this series solution in (A.3), we obtain the indicial equation for s as

$$s^2 - k^2 = 0. \tag{A.4}$$

Hence that solution which converges at $x \to \infty$ will have $s = +k$; also

$$\sum_{r=0}^{\infty} a_r\{[(s+r)^2 - k^2] - x[(s+r)^2 + (s+r)(l+1)]\}x^{s+r} = 0, \tag{A.5}$$

which leads to the equations

$$a_r[(s+r)^2 - k^2] - a_{r-1}(s+r-1)(s+r+l) = 0; \; r = 1, 2, 3, \ldots \tag{A.6}$$

For $s = k$, (A.6) gives

$$a_r = \frac{(k+r-1)(k+r+l)}{r(2k+r)} a_{r-1}, \tag{A.7}$$

so that

$$a_1 = a_0 \frac{k(k+l+1)}{2k+1}; \qquad a_2 = a_0 \frac{k(k+l+1)(k+1)(k+l+2)}{(2k+1)(2k+2)\cdot 1\cdot 2}; \text{ etc.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It is thus seen that the required solution is

$$v_i = a_0\zeta^k\left\{1 + \frac{k(k+l+1)}{2k+1}\zeta + \frac{k(k+l+1)(k+1)(k+l+2)}{(2k+1)(2k+2)}\frac{\zeta^2}{2!} + \frac{k(k+1)(k+2)(k+l+1)(k+l+2)(k+l+3)}{(2k+1)(2k+2)(2k+3)}\frac{\zeta^3}{3!} + \ldots\right\},$$

where $\zeta = 1 - 1/\xi^2 < 1$;
In terms of hypergeometric functions, this solution is

$$v_i = a_0\zeta^k F(k, k+l+1; 2k+1; 1 - 1/\xi^2). \tag{A.8}$$

The arbitrary constant a_0 is to be found by making use of the boundary condition [11], which can be rewritten as

$$\left(\frac{dv_i}{d\zeta}\right)_{\zeta=\zeta_0} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left(\frac{1}{\kappa}\sqrt{\left(\frac{p}{D_i}\right)}\right)\cdot\frac{\xi_0^{2l+4}}{\xi_0^2-1}; \tag{A.9}$$

since it is known that

$$\frac{d}{dz}[z^a F(a, b; c; z)] = az^{a-1}F(a+1, b; c; z),$$

$$\frac{dv_i}{d\zeta} = a_0 k\zeta^{k-1}F(k+1, k+l+1, 2k+1; \zeta); \tag{A.10}$$

and hence, with the help of (A.9), we conclude that

$$a_0 = \pm[\overline{I(p)}\xi_0^{(2l+2)}/nF\sqrt{(D_i p)}](1 - 1/\xi_0^2)^k F(k+1, k+l+1; 2k+1; \zeta_0) \tag{A.11}$$

where

$$\zeta_0 = 1 - 1/\xi_0^2 \quad \text{and} \quad \xi_0 = \exp(|Z|\, F\, |\phi_0|/2RT);$$

consequently,

$$(v_i)_{\xi=\xi_0} = a_0\zeta_0^k F(k, k+l+1; 2k+1; \zeta_0) \tag{A.12}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\xi_0^{2(l+1)}\frac{F(k, k+l+1; 2k+1; \zeta_0)}{F(k+1, k+l+1; 2k+1; \zeta_0)}$$

(positive sign for the oxidant, negative for the reductant; cathodic current being taken as positive).

APPENDIX II

The equation

$$D_i\frac{\partial}{\partial x}\left(\frac{\partial C_i}{\partial x} + \frac{Z_i F}{RT}C_i\frac{d\phi}{dx}\right) = \frac{\partial C_i}{\partial t} \tag{A.13}$$

and the boundary condition

$$D_i\frac{\partial}{\partial x}\left(\frac{\partial C_i}{\partial x} + \frac{Z_i F}{RT}C_i\frac{d\phi}{dx}\right) = \pm\frac{I(t)}{nF} \qquad (\text{at } x = 0) \tag{A.14}$$

reduce to

$$D_i\frac{\partial^2 C_i}{\partial x^2} = \frac{\partial C_i}{\partial t} \quad \text{and} \quad D_i\frac{\partial C_i}{\partial x} = \pm\frac{I(t)}{nF} \tag{A.15}$$

respectively, by allowing Z_i to become zero.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The solution of equation (A.13) must, therefore, tend to that of (A.15), which is well known (3), viz.,

$$\bar{C}_i(x = 0) = C_i^0 \mp \frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} e^{-\sqrt{(p/D_i)}x}. \tag{A.16}$$

(Note: only the Laplace transform of C (with respect to t) is given instead of the original. That there is no loss of generality is ensured by the uniqueness property of a function and its Laplace transform.)

It has been proved that

$$v_i = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \xi_0^{2(l+1)} \left(\frac{1 - 1/\xi^2}{1 - 1/\xi_0^2}\right)^k \frac{F(k, k+l+1; 2k+1; \zeta)}{F(k+1, k+l+1; 2k+1; \zeta_0)} \tag{A.17}$$

and

$$(l+1) = \pm\left|\frac{Z_i}{Z}\right| + \frac{1}{2};$$

and hence $(l+1)$ becomes $= 1/2$. It is known that

$$F(k, k + 1/2; 2k+1; \zeta) = \left(1/2 + \frac{\sqrt{(1-\zeta)}}{2}\right)^{-2k} \tag{A.18}$$

and

$$F(k+1, k + 1/2; 2k+1; \zeta_0) = \left(1/2 + \frac{\sqrt{(1-\zeta_0)}}{2}\right)^{-2k} \Big/ \sqrt{(1-\zeta_0)}. \tag{A.19}$$

Substituting $\zeta = 1 - 1/\xi^2$,

$$\begin{aligned}(v_i) &= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \xi_0 \left(\frac{1 - 1/\xi^2}{1 - 1/\xi_0^2}\right)^k \left(\frac{\xi}{\xi+1}\right)^{2k} \left(\frac{\xi_0+1}{\xi_0}\right)^{2k} \frac{1}{\xi_0} \\ &= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \left(\frac{\xi-1}{\xi+1}\right)^k \left(\frac{\xi_0+1}{\xi_0-1}\right)^k; \end{aligned} \tag{A.20}$$

$$\xi = \exp\frac{|Z|\,F\,|\phi|}{2RT};$$

but

$$\frac{\xi-1}{\xi+1} = \frac{\xi_0-1}{\xi_0+1} e^{-\kappa x}$$

and hence,

$$(v_i) = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} (e^{-\kappa x})^k = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} e^{-\sqrt{(p/D_i)}x}. \tag{A.21}$$

Also

$$v_i = C_i^0 - \bar{C}_i \exp(Z_0 F\phi/RT),$$

and since $Z_0 = 0$,

$$v_i = C_i^0 - \bar{C}_i$$

or

$$\bar{C}_i = C_i^0 \mp \frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} e^{-\sqrt{(p/D_i)}x},$$

which is (A.16).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It may be mentioned, in passing, that the same limit can be attained through the path $1/\kappa \rightarrow 0$ (which also implies $\phi \rightarrow 0$ and $\xi \rightarrow 1$). By observing that

$$\xi, \xi_0 \rightarrow 1$$

but

$$\left[\left(\frac{\xi-1}{\xi+1}\right)\left(\frac{\xi_0+1}{\xi_0-1}\right)\right]^k \rightarrow e^{-\sqrt{(p/D_i)}x},$$

it can be proved that (A.16) can be regained in this case too.

APPENDIX III

To obtain the asymptotic behavior $\xi \rightarrow \infty$ (or equivalently $\zeta_0 \rightarrow 1$) of the solution, we must distinguish between the cases of attraction and repulsion and also the signs of the parameters (l) and ($l+1$).

We assume here the following limiting behavior of hypergeometric functions (4):

(a) If $(\nu-\alpha-\beta) < 0$,

$$\text{(A.22)} \qquad \underset{x\rightarrow 1-0}{\text{Limit}}\, F(\alpha, \beta; \nu; x) \div \left\{\frac{\Gamma(\nu)\cdot\Gamma(\alpha+\beta-\nu)}{\Gamma(\alpha)\cdot\Gamma(\beta)}\,(1-x)^{\nu-\alpha-\beta}\right\} \rightarrow 1.$$

(b) If $(\nu-\alpha-\beta) = 0$,

$$\text{(A.23)} \qquad \underset{x\rightarrow 1-0}{\text{Limit}}\, F(\alpha, \beta; \nu; x) \div \left\{\frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)}\,\log\frac{1}{1-x}\right\} \rightarrow 1.$$

(c) If $(\nu-\alpha-\beta) > 0$,

$$\text{(A.24)} \qquad \underset{x\rightarrow 1-0}{\text{Limit}}\, F(\alpha, \beta; \nu; x) = F(\alpha, \beta; \nu; 1) = \frac{\Gamma(\nu)\cdot\Gamma(\nu-\alpha-\beta)}{\Gamma(\nu-\alpha)\cdot\Gamma(\nu-\beta)}.$$

Also,

$$\text{(A.25)} \qquad l = \pm\left|\frac{Z_i}{Z}\right| - 1/2 \qquad l+1 = \pm\left|\frac{Z_i}{Z}\right| + 1/2$$

(positive sign to be taken in the case of repulsion and negative for attraction in the diffuse layer)

The asymptotic behavior of the hypergeometric functions $F(k, k+l+1; 2k+1; \zeta_0)$ and $F(k+1, k+l+1; 2k+1; \zeta_0)$ depends essentially on the signs of l and $(l+1)$ respectively.

It can be easily seen that $l < 0$ for attraction and $(l+1) > 0$ for repulsion, whatever be Z_i. Hence, we obtain the following:

(*a*) For attraction, in view of (A.24),

$$\text{(A.26)} \qquad F(k, k+l+1; 2k+1; \zeta_0) \cong \frac{\Gamma(-l)\cdot\Gamma(2k+1)}{\Gamma(k+1)\cdot\Gamma(k-l)} \qquad \text{(for large } \xi_0\text{)}.$$

The behavior of the denominator, namely, $F(k+1, k+l+1; 2k+1; \zeta_0)$, varies depending on whether $(l+1) > 0$, $= 0$, or < 0 (i.e. depending on whether $|Z_i/Z| < 1/2$, $= 1/2$, or $> 1/2$):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(i) $|Z_i/Z| < 1/2$; $(l+1) > 0$.
Using (A.22), one obtains,

$$\Gamma(k+1, k+l+1; 2k+1; \zeta_0) \cong \frac{\Gamma(2k+1)\cdot\Gamma(l+1)}{\Gamma(k+1)\cdot\Gamma(k+l+1)} (1-\zeta)^{-(l+1)}; \tag{A.27}$$

also by (A.12), it is seen that

$$(v_i)_{\xi=\xi_0} \cong \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \frac{\Gamma(-l)\cdot\Gamma(k+l+1)}{\Gamma(l+1)\cdot\Gamma(k-l)}. \tag{A.28}$$

(ii) $|Z_i/Z| = 1/2$; $(l+1) = 0$.
By making use of (A.23) and (A.12), it can be proved that

$$F(k+1, k+l+1; 2k+1; \zeta_0) = \frac{\Gamma(2k+1)}{\Gamma(k)\Gamma(k+1)} \ln \xi_0^2$$

and

$$(v_i)_{\xi=\xi_0} \cong \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \frac{1}{k \ln \xi_0^2}.$$

(iii) $|Z_i/Z| > 1/2$; $(l+1) < 0$
As in the above cases, the asymptotic form of v_i will be

$$\cong \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \xi_0^{-2|l+1|} \frac{|l+1|}{k}, \tag{A.29}$$

where $|l+1|$ denotes the numerical value of $(l+1)$.
(*b*) For repulsion, in view of (A.22),

$$F(k+1, k+l+1; 2k+1; \zeta_0) \cong \frac{\Gamma(2k+1)\cdot\Gamma(l+1)}{\Gamma(k+1)\cdot\Gamma(k+l+1)} \xi_0^{2(l+1)}. \tag{A.30}$$

The behavior of the numerator varies depending on whether ($l < 0$, $= 0$, or > 0 (i.e., $|Z_i/Z| < 1/2$, $= 1/2$, or $> 1/2$):

$$F(k, k+l+1; 2k+1; 1 - 1/\xi_0^2) \cong \begin{cases} \dfrac{\Gamma(-l)\cdot\Gamma(2k+1)}{\Gamma(k+1)\cdot\Gamma(k-l)}; & l < 0 \\ \dfrac{\Gamma(2k+1)}{\Gamma(k)\cdot\Gamma(k+1)} \ln \xi_0^2; & l = 0 \\ \dfrac{\Gamma(2k+1)\cdot\Gamma(l)}{\Gamma(k)\cdot\Gamma(k+l+1)} \xi_0^{2l}; & l > 0 \end{cases} \tag{A.31}$$

Hence, the behavior of $(v_i)_{\xi=\xi_0}$, in the case of repulsion, for large ξ_0 will be as

$$\frac{(v_i)_{\xi=\xi_0}}{(\pm\overline{I(p)}/nF\sqrt{(D_i p)})} \cong \begin{cases} \dfrac{\Gamma(-l)\cdot\Gamma(k+l+1)}{\Gamma(l+1)\cdot\Gamma(k-l)}; & l < 0 \\ k \ln \xi_0^2; & l = 0 \\ \xi_0^{2l} \dfrac{k}{l}; & l > 0 \end{cases} \tag{A.32}$$

The above results are tabulated in Table I.

For personal use only.

APPENDIX IV

$|Z_i| = |Z|$; for attraction,

$$l+1 = -\left|\frac{Z_i}{Z}\right| + 1/2 = -1/2$$

$$(v_i)_{\xi=\xi_0} = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{-1}\,\frac{F(k, k-1/2; 2k+1; 1-1/\xi_0^2)}{F(k+1, k-1/2; 2k+1; 1-1/\xi_0^2)}.$$

Assuming the relationship

$$F(k, k+1/2; 2k+1; \zeta_0) = \left(\frac{1}{2}+\frac{\sqrt{(1-\zeta_0)}}{2}\right)^{-2k}, \tag{A.33}$$

and the identity

$$\frac{d}{d\zeta}\left[\zeta^{c-a}(1-\zeta)^{a+b-c}F(a, b; c; \zeta)\right] = (c-a)\zeta^{c-a-1}(1-\zeta)^{a+b-c-1}F(a-1, b; c; \zeta), \tag{A.34}$$

we find that

$$F(k, k+1/2; 2k+1; 1-1/\xi_0^2) = \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k} \tag{A.35}$$

and

$$\frac{d}{d\zeta}\left[(\xi^2-1)^{k+1/2}\xi^{-2k-1}\xi\left(\frac{2\xi}{\xi+1}\right)^{2k}\right] = \frac{\xi^3}{2}\frac{d}{d\xi}\left[2^{2k}\sqrt{(\xi^2-1)}\left(\frac{\xi-1}{\xi+1}\right)^{k}\right], \tag{A.36}$$

from which we obtain that

$$F(k, k-1/2; 2k+1; 1-1/\xi_0^2) = \frac{1}{\xi_0}\left\{\frac{(2k+\xi_0)}{(2k+1)}\right\}\left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}. \tag{A.37}$$

Also

$$F(k+1, k+1/2; 2k+1; \zeta) = \left(\frac{1}{2}+\frac{\sqrt{(1-\zeta)}}{2}\right)^{-2k} \Big/ \sqrt{(1-\zeta)}\,; \tag{A.38}$$

and hence, by (A.36),

$$\frac{d}{d\zeta}\left[\zeta^{k+1/2}(1-\zeta)^{1/2}\frac{(1/2+\sqrt{(1-\zeta)}/2)^{-2k}}{\sqrt{(1-\zeta)}}\right] = \tfrac{1}{2}\zeta^{k-1/2}(1-\zeta)^{-1/2}\left(\frac{1}{2}+\frac{\sqrt{(1-\zeta)}}{2}\right)^{-2k-1}\left(1+\sqrt{(1-\zeta)}\left(k+\frac{\sqrt{(1-\zeta)}}{2}\right)\right),$$

which can be rewritten as

$$(k+1/2)\zeta^{k-1/2}(1-\zeta)^{-1/2}F(k+1, k-1/2; 2k+1; \zeta). \tag{A.39}$$

Therefore,

$$F(k+1, k-1/2; 2k+1; \zeta) = \frac{(1/2+\sqrt{(1-\zeta)}/2)^{-2k}(k+\sqrt{(1-\zeta)}/2)}{(k+1/2)},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

i.e.,

$$F(k+1, k-1/2; 2k+1; 1-1/\xi_0^2) = \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k} \frac{1+2k\xi_0}{(1+2k)\xi_0}. \tag{A.40}$$

The resulting expression for $(v_i)_{\xi=\xi_0}$ is

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\,\xi_0^{-1}\left\{\frac{(1/\xi_0)\{(2k+\xi_0)/(2k+1)\}(2\xi_0/\xi_0+1)^{2k}}{(1/\xi_0)\{(1+2k\xi_0)/(2k+1)\}(2\xi_0/\xi_0+1)^{2k}}\right\} \tag{A.41}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left(\frac{1+2k/\xi_0}{1+2k\xi_0}\right).$$

An alternate method for deriving the above expression for $F(k+1, k-1/2; 2k+1; \zeta)$ by making use of the known results for $F(k, k+1/2; 2k+1; \zeta)$ and $F(k, k-1/2; 2k+1; \zeta)$ will be to make use of the Gaussian relation among contiguous functions:

$$F(a,b;c;\zeta)+aF(a+1,b;c;\zeta)-bF(a,b+1;c;\zeta) = 0 \tag{A.42}$$

and identifying a, b, and c with k, $k-1/2$, and $2k+1$ respectively.

$$kF(k+1, k-1/2; 2k+1; \zeta) = (k-1/2)F(k, k+1/2; 2k+1; \zeta) + \tfrac{1}{2}F(k, k-1/2; 2k+1; \zeta), \tag{A.43}$$

i.e.,

$$F(k+1, k-1/2; 2k+1; 1-1/\xi_0^2) \tag{A.44}$$

$$= \frac{1}{k}\left\{(k-1/2)\left(\frac{2\xi_0}{\xi_0+1}\right)^{2k} + \frac{1}{2\xi_0}\left(\frac{2k+\xi_0}{2k+1}\right)\left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}\right\}$$

$$= \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}\cdot\frac{1}{2k}\left[(2k-1) + \frac{2k+\xi_0}{(2k+1)\xi_0}\right]$$

$$= \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}\cdot\left\{\frac{2k\xi_0+1}{(2k+1)\xi_0}\right\}.$$

APPENDIX V

We define the functions $U(k, \xi)$ and $f_n(k, \xi)$ $(n = 1, 2, 3, 4)$ as follows:

$$U(k, \xi) = \left(\frac{2\xi}{\xi+1}\right)^{2k};$$

$$f_1(k, \xi) = (1+2k\xi)/(2k+1);$$

$$f_2(k, \xi) = \frac{3+6k\xi+4k^2\xi^2+2k\xi^3}{(2k+1)(2k+3)};$$

$$f_3(k, \xi) = \frac{15+30k\xi+24k^2\xi^2+(10k+8k^3)\xi^3+12k^2\xi^4+6k\xi^5}{(2k+1)(2k+3)(2k+5)};$$

$$f_4(k, \xi) = \frac{105+210k\xi+180k^2\xi^2+(70k+80k^3)\xi^3+(104k^2+16k^4)\xi^4 + (42k+48k^3)\xi^5+60k^2\xi^6+30k\xi^7}{(2k+1)(2k+3)(2k+5)(2k+7)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Then

$$F(k, k - 1/2; 2k+1; 1 - 1/\xi^2) = U(k, \xi) \cdot f_1(k, 1/\xi)$$

and

$$F(k+1, k - 1/2; 2k+1; 1 - 1/\xi^2) = U(k, \xi) \cdot f_1(k, \xi)/\xi.$$

By repeated application of the identity

$$\frac{d}{d\zeta}[\zeta^{c-a}(1-\zeta)^{a+b-c}F(a, b; c; \zeta)] = (c-a)\zeta^{c-a-1}(1-\zeta)^{a+b-c-1}F(a-1, b; c; \zeta),$$

or by using the contiguous relationship, we can prove the following:

(A.45) $F(k, k - 3/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_2(k, 1/\xi_0);$

(A.46) $F(k+1, k - 3/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_2(k, \xi_0)/\xi_0^3;$

(A.47) $F(k, k - 5/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_3(k, 1/\xi_0);$

(A.48) $F(k+1, k - 5/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_3(k, \xi_0)/\xi^5;$

(A.49) $F(k, k - 7/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_4(k, 1/\xi_0);$

(A.50) $F(k+1, k - 7/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_4(k, \xi_0)/\xi_0^7;$

(A.51) $F(k, k + 3/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_1(k, \xi_0);$

(A.52) $F(k+1, k + 3/2; 2k+1; 1 - 1/\xi_0^2) = U(k,\xi_0) \cdot f_1(k, 1/\xi_0)\xi_0^3;$

(A.53) $F(k, k + 5/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_2(k, \xi_0);$

(A.54) $F(k+1, k + 5/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_2(k, 1/\xi_0) \cdot \xi_0^5;$

(A.55) $F(k, k + 7/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_3(k, \xi_0);$

(A.56) $F(k+1, k + 7/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_3(k, 1/\xi_0) \cdot \xi_0^7;$

(A.57) $F(k, k + 9/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_4(k, \xi_0);$

(A.58) $F(k+1, k + 9/2; 2k+1; 1 - 1/\xi_0^2) = U(k, \xi_0) \cdot f_4(k, 1/\xi_0) \cdot \xi_0^9.$

It may be of interest to mention here that the sequence of polynomials $f_r(k, \xi)$ satisfies the identity

$$(2k+2r+1)\, f_{r+1}(k, \xi) = (2r+1)f_r(k, \xi)+2k\xi^{2r+1}f_r(k,1/\xi).$$

APPENDIX VI

If $F(k, k+l+1; 2k+1; 1 - 1/\xi_0^2)$ can be expanded in the form $S_0+S_1k+S_2k^2+ \ldots$ the coefficients S_0, S_1, S_2, etc., can be found as follows.

It can be noted that $S_0 = 1$ by studying the behavior at $k = 0$ on both sides.

Expressing

(A.59) $$F(k, k+l+1; 2k+1; \zeta_0) = S_0+S_1k+S_2k^2+ \ldots$$

$$= 1 + \frac{k(k+l+1)}{2k+1}\zeta_0 + \frac{k(k+1)(k+l+1)(k+l+2)}{(2k+1)(2k+2)}\frac{\zeta_0^2}{2!} + \ldots$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

one can collect the coefficients of k in the various terms and write S_1 as

$$(l+1)\zeta_0 + \frac{(l+1)(l+2)}{2!}\frac{\zeta_0^2}{2} + \frac{(l+1)(l+2)(l+3)}{3!}\cdot\frac{\zeta_0^3}{3} + \ldots$$

so that

$$\frac{dS_1}{d\zeta_0} = (l+1) + \frac{(l+1)(l+2)}{2!}\zeta_0 + \frac{(l+1)(l+2)(l+3)}{3!}\zeta_0^2 + \ldots$$

or

$$\zeta_0\frac{dS_1}{d\zeta_0} = (l+1)\zeta_0 + \frac{(l+1)(l+2)}{2!}\zeta_0^2 + \ldots = (1-\zeta_0)^{-(l+1)} - 1,$$

which gives

$$S_1 = \int_0^{\zeta_0}\frac{(1-\zeta_0)^{-(l+1)}-1}{\zeta_0}\,d\zeta_0, \tag{A.60}$$

making use of the fact that $S_1 = 0$ for $\zeta_0 = 0$; or

$$S_1 = 2\int_1^{\xi_0}\frac{\xi^{2(l+1)}-1}{\xi(\xi^2-1)}\,d\xi. \tag{A.61}$$

Similarly expressing $F(k+1,\ k+l+1;\ 2k+1;\ \zeta_0)$ as

$$(1-\zeta_0)^{-(l+1)}\{1+\phi_1 k+\phi_2 k^2+\ldots\} \tag{A.62}$$

one can apply the identity

$$\frac{d}{dz}[z^{c-a}(1-z)^{a+b-c}F(a, b; c; z)] = (c-a)z^{c-a-1}(1-z)^{a+b-c-1}F(a-1, b; c; z),$$

which gives

$$\frac{d}{d\zeta}[\zeta^k(1-\zeta)^{l+1}(1-\zeta)^{-(l+1)}(1+\phi_1 k+\phi_2 k^2+\ldots)] = k\zeta^{k-1}(1-\zeta)^l(1+kS_1+k^2S_2+\ldots),$$

i.e.,

$$\zeta^k k\frac{d\phi}{d\zeta} + (1+k\phi_1)\frac{k}{\zeta}\zeta^k + \zeta^k k^2\frac{d\phi_2}{d\zeta} + \ldots = k\frac{\zeta^k}{\zeta}(1-\zeta)^l(1+kS_1+k^2S_2+\ldots).$$

Equating the coefficients of k, we get

$$\frac{d\phi_1}{d\zeta} + \frac{1}{\zeta} = \frac{(1-\zeta)^l}{\zeta} \quad \text{or} \quad \phi_1 = \int_0^{\zeta}\frac{(1-\zeta)^l-1}{\zeta}\,d\zeta. \tag{A.63}$$

(Note: ϕ_0 is taken as equal to 1 in the above equation, since $F(k+1,\ k+l+1;\ 2k+1;\ \zeta) \to (1-\zeta)^{-(l+1)}$ as $k \to 0$, so that comparing the terms independent of k, ϕ_0 can be identified with 1.)

It can be shown by equating the coefficients of k^2,

$$\frac{d\phi_2}{d\zeta} + \frac{\phi_1}{\zeta} = \frac{(1-\zeta)^l}{\zeta}S_1$$

so that

$$\phi_2 = \int_0^{\zeta}\frac{(1-\zeta)^l S_1 - \phi_1}{\zeta}\,d\zeta, \tag{A.64}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where the expressions for ϕ_1 are given in (A.60) and (A.63). Substituting in the identity

$$\frac{d}{dz}[z^a F(a, b; c; z)] = az^{a-1}F(a+1, b; c; z),$$

k, $k+l+1$, $2k+1$, and ζ for a, b, c, and z respectively, it is seen that

$$k\zeta^{k-1}F(k+1, k+l+1; 2k+1; \zeta) = \frac{d}{d\zeta}[\zeta^k F(k, k+l+1; 2k+1; \zeta)].$$

With the help of (A.59) and (A.62), it can be seen that

$$\frac{k}{\zeta}(1-\zeta)^{-(l+1)}(1+k\phi_1+k^2\phi_2+\ldots) = \frac{k}{\zeta}(1+S_1k+S_2k^2+\ldots) + k\frac{dS_1}{d\zeta} + k^2\frac{dS_2}{d\zeta} + \ldots$$

Comparing the coefficients of k and k^2 we obtain

$$\frac{(1-\zeta)^{-(l+1)}}{\zeta} = \frac{1}{\zeta} + \frac{dS_1}{d\zeta} \quad \text{or} \quad S_1 = \int_0^\zeta \frac{(1-\zeta)^{-(l+1)}-1}{\zeta}\,d\zeta$$

(a result that has been derived already by a different method) and

$$\frac{\phi_1(1-\zeta)^{-(l+1)}}{\zeta} = \frac{S_1}{\zeta} + \frac{dS_2}{d\zeta}.$$

Integrating one can obtain S_2 as

$$\int_0^\zeta \frac{(1-\zeta)^{-(l+1)}\phi_1 - S_1}{\zeta}\,d\zeta. \tag{A.65}$$

APPENDIX VII

For *attraction* in the diffuse layer,

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\,\xi_0^{(-2|z_i/z|+1)}\,\frac{F(k, k+1/2-|Z_i/Z|; 2k+1; \zeta_0)}{F(k+1, k+1/2-|Z_i/Z|; 2k+1; \zeta_0)}. \tag{A.66}$$

Since

$$F(a, b; c; z) = (1-z)^{c-a-b}F(c-a, c-b; c; z), \tag{A.67}$$

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\,\xi_0^{(-2|z_i/z|+1)}\,\frac{1}{\xi_0^2}\,\frac{F(k+1, k+1/2+|Z_i/Z|; 2k+1; \zeta_0)}{F(k, k+1/2+|Z_i/Z|; 2k+1; \zeta_0)}; \tag{A.68}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\,\xi_0^{-(2|z_i/z|+1)}\,\frac{F(k+1, k+1/2+|Z_i/Z|; 2k+1; \zeta_0)}{F(k, k+1/2+|Z_i/Z|; 2k+1; \zeta_0)}.$$

For *repulsion* ($l+1 = |Z_i/Z| + 1/2$)

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\,\xi_0^{(2|z_i/z|+1)}\,\frac{F(k, k+1/2+|Z_i/Z|; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+1/2+|Z_i/Z|; 2k+1; 1-1/\xi_0^2)}. \tag{A.69}$$

For a *given* Z_i, if $(v_i)_0^{\mathrm{A}}$ represents the expressions of v_i at the electrode surface *if there is attraction* in the diffuse layer, and $(v_i)_0^{\mathrm{R}}$ the expression of v_1 for repulsion

$$\left\{\frac{(v_i)_0^{\mathrm{A}}}{\pm\overline{I(p)}/nF\sqrt{(D_ip)}}\right\}\left\{\frac{(v_i)_0^{\mathrm{R}}}{\pm\overline{I(p)}/nF\sqrt{(D_ip)}}\right\} = 1. \tag{A.70}$$

This helps one in calculating the functional form of $(v_i)_0$ for the case of attraction, given the form for the case of repulsion and vice versa.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

To illustrate, let us investigate the case when $|Z_i| = |Z|$; if there is attraction,

$$\frac{(v_i)_0}{(\pm\overline{I(p)}/nF\sqrt{(D_ip)})} = \frac{1+2k/\xi_0}{1+2k\xi_0}.$$

Had there been repulsion, for $|Z_i| = |Z|$, one would therefore, have obtained

$$\frac{(v_i)_0}{(\pm\overline{I(p)}/nF\sqrt{(D_ip)})} = \frac{1+2k\xi_0}{1+2k/\xi_0},$$

a result that has been proved already. (Refer to equation [37] of the text.)

The above relationship between $(v_i)_0^{A}$ and $(v_i)_0^{R}$ is not so obvious, (nor can it be at once understood explicitly) since

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\frac{F(k, k+l+1; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+l+1; 2k+1; 1-1/\xi_0^2)}$$

and l assumes *different* values for the *same* $|Z_i/Z|$ depending on whether there is attraction or repulsion and could be seen only through the identity (A.67) relating the hypergeometric functions with different parameters.

Also, by making use of the functional relationship

$$F(a, b; c; z) = (1-z)^{-a}F(a, c-b; c; z/z-1) \tag{A.71}$$

it is seen that if

$$F(k, k+l+1; 2k+1; 1-1/\xi^2) = g(k, l, \xi), \tag{A.72}$$

$$F(k+1, k+l+1; 2k+1; 1-1/\xi^2) = \xi^{2(k+l+1)}g(k, l, 1/\xi). \tag{A.73}$$

Abbreviating, for convenience, the function $g(k, l, \xi)$ as $g(\xi)$, $(v_i)_0$ can be written in the form

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\cdot\xi_0^{-2k}\cdot\frac{g(\xi_0)}{g(1/\xi_0)}, \tag{A.74}$$

which shows that it is enough if the hypergeometric function in the numerator (or denominator) is evaluated to obtain the function $(v_i)_0$.

Also, if

$$F(k, k+|Z_i/Z|+1/2; 2k+1; 1-1/\xi^2) = g(\xi),$$

then

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\xi_0^{-2k}\frac{g(\xi_0)}{g(1/\xi_0)} \qquad \text{(for repulsion)} \tag{A.75}$$

and

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\xi_0^{2k}\frac{g(1/\xi_0)}{g(\xi_0)} \qquad \text{(for attraction)}. \tag{A.76}$$

To illustrate, let us take the particular case when $|Z_i| = |Z|$:

$$F(k, k+3/2; 2k+1; 1-1/\xi_0^2) = \left(\frac{2\xi_0}{\xi_0+1}\right)^{2k}\left(\frac{1+2k\xi_0}{1+2k}\right)$$

$$= g(\xi_0)$$

$$g(1/\xi_0) = \left(\frac{2}{1+\xi_0}\right)^{2k}\left(\frac{1+2k/\xi_0}{1+2k}\right),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

so that *for repulsion*, using (A.75), we can write,

$$(v_i)_0 = \frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \frac{g(\xi_0)}{g(1/\xi_0)}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \left(\frac{1 + 2k\xi_0}{1 + 2k/\xi_0}\right)$$

as has been shown already (equation [37] of the text). Similarly, *for attraction*, using (A.76),

$$(v_i)_0 = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \xi_0^{2k} \cdot \frac{g(1/\xi_0)}{g(\xi_0)}$$

$$= \pm\frac{\overline{I(p)}}{nF\sqrt{(D_i p)}} \left(\frac{1 + 2k/\xi_0}{1 + 2k\xi_0}\right)$$

as has been shown (equation [24] of the text).

NOTATIONS

$C_i(x,t)$	instantaneous concentration of the species i, (O for oxidant; R for reductant) at a distance x from the electrode surface
$C_i(O,t)$	instantaneous interfacial concentration of the species i
C_i^0	bulk concentration of the species i
D_i	diffusion coefficient of the species i
Z_O	valency (with sign) of the oxidant
Z_R	valency (with sign) of the reductant
Z	valency of the supporting electrolyte.
$\phi(x)$	potential distribution in the diffuse (Gouy) layer, viz., $\phi(0) - \phi(\infty)$
$I(t)$	Faradaic current
κ	Debye parameter for the reciprocal thickness of the double layer
p	transform variable (Laplace)
$\overline{C_i}(x,p)$	Laplace transform of $C_i(x,t)$
$\overline{I(p)}$	Laplace transform of $I(t)$
$F(a,b,c;Z)$	Gaussian hypergeometric function of argument Z
$\Gamma(x)$	gamma function of x
l	$\pm\lvert Z_i/Z\rvert - 1/2$ (positive sign for repulsion; negative for attraction)
$(v_i)_0 = [v_i(p)]_0$	$= C_i^0 - \overline{C_i}(0,p) \exp(Z_i F\phi/RT)$
$(v_i)_\xi = [v_i(p)]_\xi$	$= C_i^0 - \overline{C_i}(x,p) \exp(Z_i F\phi/RT)$
ξ	$\exp \lvert Z\rvert F \lvert\phi\rvert/2RT$
ξ_0	$\exp \lvert Z\rvert F \lvert\phi_0\rvert/2RT$
ζ	$1 - 1/\xi^2$
ζ_0	$1 - 1/\xi_0^2$
k	$\frac{1}{\kappa}\sqrt{(p/D_i)}$
$\cong$	asymptotically equal to

ACKNOWLEDGMENT

The author wishes to thank Professor K. S. G. Doss, Director, Central Electrochemical Research Institute, Karaikudi, for his keen interest and valuable discussions.

FARADAIC IMPEDANCE: EFFECT OF MIGRATION IN THE DIFFUSE DOUBLE LAYER

S. K. RANGARAJAN
Central Electrochemical Research Institute, Karaikudi, India

Received June 12, 1962

ABSTRACT

The expressions for the elements of the equivalent circuit are derived by making use of the modified solutions for the diffusion equation (with migration in the diffuse layer) obtained earlier. The impedance (faradaic) characteristics are discussed. Also, the results are compared with those of Matsuda and Delahay.

1. *The Steady-State Concentrations*

The study of the a-c. impedance of an electrode serves as a powerful tool in measuring the kinetic parameters of rapid electrode reactions. The conditions existing at the electrode–solution interface can be represented by an equivalent circuit whose elements R_r and C_r are given through the expressions (1)

[1] $$R_r = \frac{RT}{nF}\left\{\frac{1}{I_0} + \frac{1}{nF\sqrt{(2\omega)}}\left(\frac{1}{C_O^0\sqrt{(D_{O2})}} + \frac{1}{C_R^0\sqrt{(D_{R2})}}\right)\right\}$$

and

[2] $$\frac{1}{\omega C_r} = \frac{RT}{n^2F^2}\left\{\frac{1}{\sqrt{(2\omega)}}\left(\frac{1}{C_O^0\sqrt{(D_{O2})}} + \frac{1}{C_R^0\sqrt{(D_{R2})}}\right)\right\}$$

(R_r and C_r refer to the faradaic process only).

In obtaining these, it has been assumed that only small departures from equilibrium are of interest and diffusion is the sole mode of mass transfer.

In the above formulation, the effects due to migration in the double layer were assumed absent. It will be of importance to examine how the elements of the equivalent circuit are modified if the structure of the diffuse layer is taken into account.

Detailed investigations on this aspect have been made by Matsuda (2), based on the expressions for the interfacial concentrations obtained earlier by Matsuda and Delahay (3). It has been shown by the author (4) that the solutions derived by Matsuda and Delahay (and consequently the results of Matsuda) are to be modified. It is the object of the present paper to examine these modifications in the expressions for the elements of the equivalent circuit.

Denoting the interfacial concentration of the species i (i = O, oxidant; R, reductant) by $C_i(0,t)$ and its Laplace transform as $\bar{C}_i(0,p)$, it has been shown that

[3] $$\bar{C}_i(0, p) = \exp\left(\frac{-Z_0F\phi}{RT}\right)[C_i^0 - v_i(p)],$$

where

[4] $$v_i(p) = \pm\frac{\overline{I(p)}}{nF\sqrt{(D_ip)}}\,\xi_0^{2(l+1)}\,\frac{F(k, k+l+1; 2k+1; 1 - 1/\xi_0^2)}{F(k+1, k+l+1; 2k+1; 1 - 1/\xi_0^2)}$$

(for details, see reference 4),

$$(l+1) = \pm\left|\frac{Z_i}{Z}\right| + 1/2$$

(positive sign for the case of repulsion ($Z_i\phi > 0$) and negative sign for attraction ($Z_i\phi < 0$)), p is the transform variable, and

$$\xi_0 = \exp \frac{|Z|\ F\ |\phi_0|}{2RT}.$$

Assuming the sinusoidal component of the faradaic current as $I \cos \omega t$, it can be rigorously proved that the *steady-state* components of the concentration will assume the form

$$C_i^0 \mp \Delta C_i \cos\ (\omega t - \theta_i).$$

Hence, confining our interest only to the alternating components of the concentration, at the interface, it may be noted that

$$[5] \qquad C_i(0, t) = \exp\left(\frac{-Z_0 F\phi}{RT}\right)\left[C_i^{\,0} \mp \text{Real Part of } \frac{Ie^{j\omega t}}{nF\sqrt{(D_i\omega)}} j^{-1/2} G_i\right]$$

where $j = \sqrt{(-1)}$ and G_i stands for

$$[6] \qquad \xi_0^{\,2(l+1)} \frac{F(k_\omega, k_\omega+l+1; 2k_\omega+1; 1 - 1/\xi_0^{\,2})}{F(k_\omega+1, k_\omega+l+1; 2k_\omega+1; 1 - 1/\xi_0^{\,2})}$$

where

$$k_\omega = \frac{1}{\kappa}\sqrt{\left(\frac{j\omega}{D_i}\right)}.$$

For particular values of the parameter l, G_i takes the functional form of

$$P(k_\omega)/Q(k_\omega),$$

where $P(Z)$ and $Q(Z)$ are polynominals in Z of the same degree.

In general,

$$\frac{F(k_\omega, k_\omega+l+1; 2k_\omega+1; 1 - 1/\xi_0^{\,2})}{\Gamma(2k_\omega+1)}$$

and

$$\frac{F(k_\omega+1, k_\omega+l+1; 2k_\omega+1; 1 - 1/\xi_0^{\,2})}{\Gamma(2k_\omega+1)},$$

where

$$k_\omega = \frac{1}{\kappa}\sqrt{\left(\frac{j\omega}{D_i}\right)},$$

are entire analytic functions in k_ω, so that the only infinities of G_i are the poles, which, incidentally, are the zeros of $F(k_\omega+1, k_\omega+l+1; 2k_\omega+1; 1 - 1/\xi_0^2)$. Also observing that *no real positive* ω exists which will satisfy the equation $F(k_\omega+1, k_\omega+l+1; 2k_\omega+1; 1 - 1/\xi_0^2) = 0$, we may expand the numerator and the denominator of the function G_i in the form

$$[7] \qquad G_i = \frac{1 + k_\omega S_1(\xi_0) + (k_\omega)^2 S_2(\xi_0) + \ldots}{1 + k_\omega \phi_1(\xi_0) + (k_\omega)^2 \phi_2(\xi_0) + \ldots},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where

$$S_1(\xi_0) = 2\int_1^{\xi_0} \frac{\xi^{2(l+1)}-1}{\xi(\xi^2-1)}\,d\xi,$$

$$\phi_1(\xi_0) = 2\int_1^{\xi_0} \frac{\xi^{-2l}-1}{\xi(\xi^2-1)}\,d\xi,$$

[8]

$$S_2(\xi_0) = \int_0^{1-1/\xi_0^2} \frac{(1-\zeta)^{-(l+1)}\phi_1 - S_1}{\zeta}\,d\zeta, \quad \text{and}$$

$$\phi_2(\xi_0) = \int_0^{1-1/\xi_0^2} \frac{(1-\zeta)^{l} S_1 - \phi_1}{\zeta}\,d\zeta$$

(cf. reference 4, Appendix VI).

Conforming to the notation used by Matsuda (2), one can write

$$(-j)^{1/2}G_i = (h_i)_{\text{re}} - j(h_i)_{\text{im}},$$

where

[9]

$$(h_i)_{\text{re}} = \frac{1 + \frac{1}{\kappa}\sqrt{\left(\frac{2\omega}{D_i}\right)}S_1(\xi_0) + \left(\frac{1}{\kappa}\sqrt{\left(\frac{\omega}{D_i}\right)}\right)^2 S_1(\xi_0)\phi_1(\xi_0)}{H_i(\omega)},$$

[10]

$$(h_i)_{\text{im}} = \frac{1 + \frac{1}{\kappa}\sqrt{\left(\frac{2\omega}{D_i}\right)}\phi_1(\xi_0) + \left(\frac{1}{\kappa}\sqrt{\left(\frac{\omega}{D_i}\right)}\right)^2 S_1(\xi_0)\phi_1(\xi_0)}{H_i(\omega)},$$

and

$$H_i(\omega) = 1 + \frac{1}{\kappa}\sqrt{\left(\frac{2\omega}{D_i}\right)}\phi_1(\xi_0) + \left(\frac{1}{\kappa}\sqrt{\left(\frac{\omega}{D_i}\right)}\right)^2 \phi_1^2(\xi_0).$$

Note that $S_1(\xi_0)$ and $\phi_1(\xi_0)$ are functions of the parameter $l = \pm|Z_i/Z| - 1/2$ (positive sign for the case of repulsion ($Z_i\phi > 0$) and negative for the case of attraction ($Z_i\phi < 0$)).

Thus, the steady-state interfacial concentrations are

[11]

$$C_i(0, t) = \exp\left(\frac{-Z_0F\phi}{RT}\right)[C_i^{\,0} \mp \Delta C_i \cos(\omega t - \theta_i)],$$

where

$$\Delta C_i = \left(\frac{I}{nF}\right)(2\omega D_i)^{-1/2}[(h_i)_{\text{re}}^{\,2} + (h_i)_{\text{im}}^{\,2}]^{1/2}$$

and

$$\cot\theta_i = (h_i)_{\text{re}}/(h_i)_{\text{im}}$$

(the sign accompanying ΔC_i in the above equation is to be taken positive for the oxidant and negative for the reductant. Note that (i) the functions $(h_i)_{\text{re}}$ and $(h_i)_{\text{im}}$ defined above are only approximate, since terms in $[(1/\kappa)\sqrt{(\omega/D_i)}]^2$ and higher powers are neglected, and (ii) the functions $(h_i)_{\text{re}}$ and $(h_i)_{\text{im}}$ defined above are *different* from those given by Matsuda (2).

An interesting particular case arises for $|Z_i| = |Z|$. Under this condition, the solution of the diffusion equation shows (4) that

$$G_i = \frac{1 + 2k_\omega\xi_0}{1 + 2k_\omega/\xi_0} \quad (|Z_i| = |Z|;\ \text{repulsion},\ Z_i\phi > 0) \tag{12}$$

and

$$G_i = \frac{1 + 2k_\omega/\xi_0}{1 + 2k_\omega\xi_0} \quad (|Z_i| = |Z|;\ \text{attraction},\ Z_i\phi < 0). \tag{13}$$

These are *exact* expressions for G_i and, hence,

$$(h_i)_{re} = \frac{1 + \frac{1}{\kappa}\sqrt{\left(\frac{2\omega}{D_i}\right)}2\xi_0 + 4\left(\frac{1}{\kappa}\sqrt{\left(\frac{\omega}{D_i}\right)}\right)^2}{1 + \frac{2}{\kappa}\sqrt{\left(\frac{2\omega}{D_i}\right)}\frac{1}{\xi_0} + 4\left(\frac{1}{\kappa}\sqrt{\left(\frac{\omega}{D_i}\right)}\frac{1}{\xi_0}\right)^2} \tag{14}$$

and $(h_i)_{im}$ can be similarly expressed.

2. The Impedance Characteristics

The faradaic current $I(t)$ is related to the potential as

$$I(t) = (I_0)_{app}\left\{\frac{C_O(0,t)}{C_O^0}\exp(Z_O F\phi_0/RT)[\exp(-\alpha nF/RT)v] - \frac{C_R(0,t)}{C_R^0}\exp(Z_R F\phi_0/RT)\exp[((1-\alpha)nF/RT)v]\right\}. \tag{15}$$

Here, $(I_0)_{app}$ stands for the apparent exchange current density (Frumkin correction) and is related to $I_0 = nF\,\kappa_s C_O^{0(1-\alpha)} C_R^{0\,\alpha}$ by

$$(I_0)_{app} = I_0 \exp[(\alpha n - Z_0)F\phi_0/RT]. \tag{16}$$

Considering the a-c. impedance measurements for small deviations from the equilibrium conditions (i.e. as a relaxation method), we may linearize the exponentials in the rate equation [15] and write

$$I = (I_0)_{app}\left\{\frac{C_O(0,t)}{C_O^0}\exp\left(\frac{Z_O F\phi_0}{RT}\right) - \frac{C_R(0,t)}{C_R^0}\exp\left(\frac{Z_R F\phi_0}{RT}\right) - \frac{nFv}{RT}\right\}. \tag{17}$$

Substituting for $C_i(0,t)$ from equation [11] in [17] and identifying with

$$-v = iR_s + \frac{\int idt}{C_s} \tag{17a}$$

(the negative sign in the left hand side of [17*a*] is necessary so as to conform to the convention chosen: electrode solution potential positive and net cathodic current positive), the elements of the equivalent circuit can be derived to be

$$R_s = \frac{RT}{nF}\left\{\frac{1}{(I_0)_{app}} + \frac{1}{nF\sqrt{(2\omega)}}\left[\frac{(h_0)_{re}}{C_O^0 D_O^{1/2}} + \frac{(h_R)_{re}}{C_R^0 D_R^{1/2}}\right]\right\}, \tag{18}$$

$$\frac{1}{\omega C_s} = \frac{RT}{nF}\left\{\frac{1}{nF\sqrt{(2\omega)}}\left[\frac{(h_0)_{im}}{C_O^0 D_O^{1/2}} + \frac{(h_R)_{im}}{C_R^0 D_R^{1/2}}\right]\right\}, \tag{19}$$

where $(h_i)_{re}$ and $(h_i)_{im}$ are defined through the equations [9] and [10].

It can also be seen that

$$[20]\quad R_s - \frac{1}{\omega C_s} = \frac{RT}{nF}\left\{\frac{1}{(I_0)_{app}} + \frac{1}{nF\sqrt{(2\omega)}}\left[\left(\frac{(h_0)_{re}-(h_0)_{im}}{C_O^0 D_O^{1/2}}\right) + \left(\frac{(h_R)_{re}-(h_R)_{im}}{C_R^0 D_R^{1/2}}\right)\right]\right\}$$

$$= \frac{RT}{nF}\left\{\frac{1}{(I_0)_{app}} + \frac{S_1(\xi_0)-\phi_1(\xi_0)}{nFC_O^0 \kappa D_O H_O(\omega)} + \text{a similar term for the reductant}\right\}.$$

If the denominator of the equations [9] and [10] can be approximated as 1,

$$[21]\quad \left(R_s - \frac{1}{\omega C_s}\right) = \frac{RT}{nF}\left\{\frac{1}{(I_0)_{app}} + \frac{1}{nF}\left(\frac{a_O}{\kappa C_O^0 D_O} + \frac{a_R}{\kappa C_R^0 D_R}\right)\right\},$$

where the non-dimensional parameter a_i is given by

$$[22]\quad a_i = S_1(\xi_0) - \phi_1(\xi_0)$$

$$= \pm 2\kappa \int_0^\infty \sinh\left(\frac{Z_i F \phi}{RT}\right) dx$$

(positive sign to be taken for the case of repulsion and negative for the attraction). Recalling the classical method of measuring the exchange current density by a-c. impedance measurements, one writes

$$[23]\quad R_s - \frac{1}{\omega C_s} = \frac{RT}{nF(I_0)_{ms}},$$

where the measured exchange current density is related to $(I_0)_{app}$, and consequently to I_0, by the relationship

$$[24]\quad \frac{1}{(I_0)_{ms}} = \frac{1}{(I_0)_{app}} + \frac{1}{nF}\left(\frac{a_O}{\kappa C_O^0 D_O} + \frac{a_R}{\kappa C_R^0 D_R}\right).$$

The form of this result is identical with that derived by Matsuda, though a_O and a_R, as given here, are different from those derived therein (2, 3).

Theoretical curves $(I_0)_{ms}$ vs. ϕ_0 are drawn in Figs. 1 and 2 for some particular cases, which are compared with those of Matsuda and Delahay (3).

Under the conditions assumed in deriving equation [21], it may be seen that

$$[25]\quad R_s = R_r + \frac{RT}{n^2F^2}\left(\frac{a_O}{\kappa C_O^0 D_O} + \frac{a_R}{\kappa C_R^0 D_R}\right)$$

$$[26]\quad \frac{1}{\omega C_s} = \frac{1}{\omega C_r},$$

where R_r and C_r are the expressions obtained for the *classical case* (1).

Even if the migration in the diffuse double layer is taken into account, a linear relationship between R_s (or $1/\omega C_s$) and $1/\sqrt{(\omega)}$ is obtained. While the slopes are preserved, the intercept of the R_s vs. $1/\sqrt{(\omega)}$ plot is changed. This intercept is denoted by $RT/nF(I_0)_{ms}$ and is expressed through equation [24].

3. The Equivalent Circuits

To obtain the equivalent circuit for the case when $v_i(p)$ is written as*

$$[27]\quad \frac{\overline{I(p)}}{nF\sqrt{(D_i p)}}\left(\frac{1 + 1/\kappa\sqrt{(p/D_i)}S_1}{1 + 1/\kappa\sqrt{(p/D_i)}\phi_1}\right),$$

**Though, for simplicity, no subscript (i) is added to S_1 and ϕ_1, it must be remembered that S_1 and ϕ_1 depend on the species and are* different *for the oxidant and the reductant.*

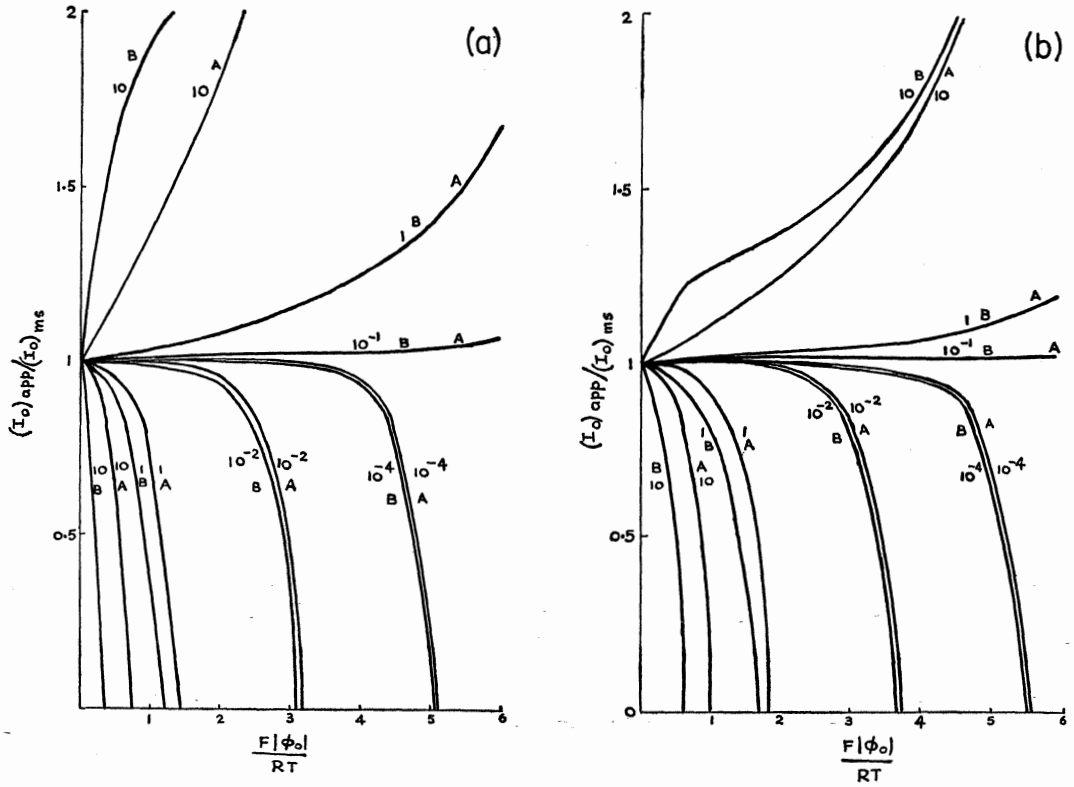

FIG. 1. Theoretical curves for the variation of $(I_0)_{app}/(I_0)_{ms}$ with the diffuse layer potential ϕ_0 (see equation [24] of the text). The numbers noted along the curves denote the values assumed for the exchange current densities. Data used: $\alpha = 0.5$; $Z_O = n = 2$; $Z_R = 0$; $C_O = 10^{-6}$ mole cm^{-3}; $D_O = 10^{-5}$ cm^2 sec^{-1}. A represents the curve obtained by calculating $(I_0)_{app}/(I_0)_{ms}$ from the equation of Matsuda and Delahay (3); B is drawn from the modified formulae derived by the author (4).
(*a*): $1/\kappa = 10^{-7}$ cm; (*b*): $1/\kappa = 3\times10^{-8}$ cm.
It may be noted that $(I_0)_{app}/(I_0)_{ms} > 1$ for the case of repulsion and <1 for the case of attraction.

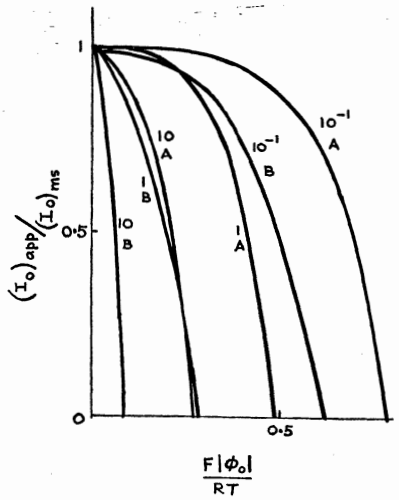

FIG. 2. Theoretical plot of $(I_0)_{app}/(I_0)_{ms}$ vs. $|\phi_0|$ (assuming *attraction* in the diffuse layer) for the case $Z_O = -3$; $Z_R = -4$; $n = 1$; $Z = 1$; $C_O = C_R = 10^{-5}$; $D_O = D_R = 10^{-6}$; $I_0 = 10$, 1, and 10^{-1} (noted along the curves); $1/\kappa = 10^{-7}$ cm. A and B calculated using the equations derived by Matsuda and Delahay (3) and the author (4), respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

we substitute for $v_i(p)$ in the linearized rate equation [17] to obtain

$$\left\{\frac{\overline{I(p)}}{(I_0)_{app}} + \frac{\bar{I}}{nF\sqrt{(D_i p)}C_i^0}\left(\frac{1+1/\kappa\sqrt{(p/D_i)}S_1}{1+1/\kappa\sqrt{(p/D_i)}\phi_1}\right) + \left\{\begin{array}{c}\text{(a similar expression corresponding}\\ \text{to the reductant)}\end{array}\right\}\right\}$$

$$\equiv -\frac{nF}{RT}v.$$

Expressing

$$\frac{RT}{n^2F^2\sqrt{(D_i p)}C_i^0}\left\{\frac{1+1/\kappa\sqrt{(p/D_i)}S_1}{1+1/\kappa\sqrt{(p/D_i)}\phi_1}\right\} \text{ as } Z_i^{d}(p)$$

we may write

[28] $$\frac{1}{Z_i^{d}} = n^2F^2C_i^0\frac{\sqrt{(D_i p)}}{RT}\left\{\frac{1+1/\kappa\sqrt{(p/D_i)}\phi_1}{1+1/\kappa\sqrt{(p/D_i)}S_1}\right\}$$

$$= \frac{n^2F^2}{RT}C_i^0\sqrt{(D_i p)} + \frac{1}{\kappa}\frac{(\phi_1 - S_1)n^2F^2C_i^0 p}{RT(1+1/\kappa\sqrt{(p/D_i)}S_1)}$$

[29] $$= \frac{1}{Z_1} + \frac{1}{Z_{2a}},$$

where

[30] $$Z_1 = \frac{RT}{n^2F^2C_i^0\sqrt{(D_i p)}} = W_i^{d}$$

and

[31] $$Z_{2a} = \frac{\kappa RT}{(-a_i)n^2F^2C_i^0}\frac{1}{p} + \frac{1}{\sqrt{(pD_i)}}\frac{RTS_1}{n^2F^2C_i^0(-a_i)}.$$

When the faradaic current is of the form $I\cos(\omega t)$, Z_1 stands for the Warburg impedance (1) and

[32] $$Z_{2a} = \frac{1}{j\omega C_i^{1}} + [W_i^{a1}]$$

with

[33] $$C_i^{1} = (-a_i)\frac{n^2F^2C_i^0}{RT\kappa}$$

and

$$W_i^{a1} = R_i^{a1} - \frac{j}{\omega C_i^{a1}}$$

$$= \frac{RTS_1}{n^2F^2C_i^0\sqrt{(2\omega D_i)}(-a_i)} - \frac{jRTS_1}{n^2F^2C_i^0\sqrt{(2\omega D_i)}(-a_i)}$$

so that

[34] $$R_i^{a1} = \frac{RTS_1}{n^2F^2C_i^0\sqrt{(2\omega D_i)}(-a_i)}$$

and

[35] $$C_i^{a1} = \frac{n^2F^2C_i^0(-a_i)}{RTS_1}\sqrt{\left(\frac{2D_i}{\omega}\right)}.$$

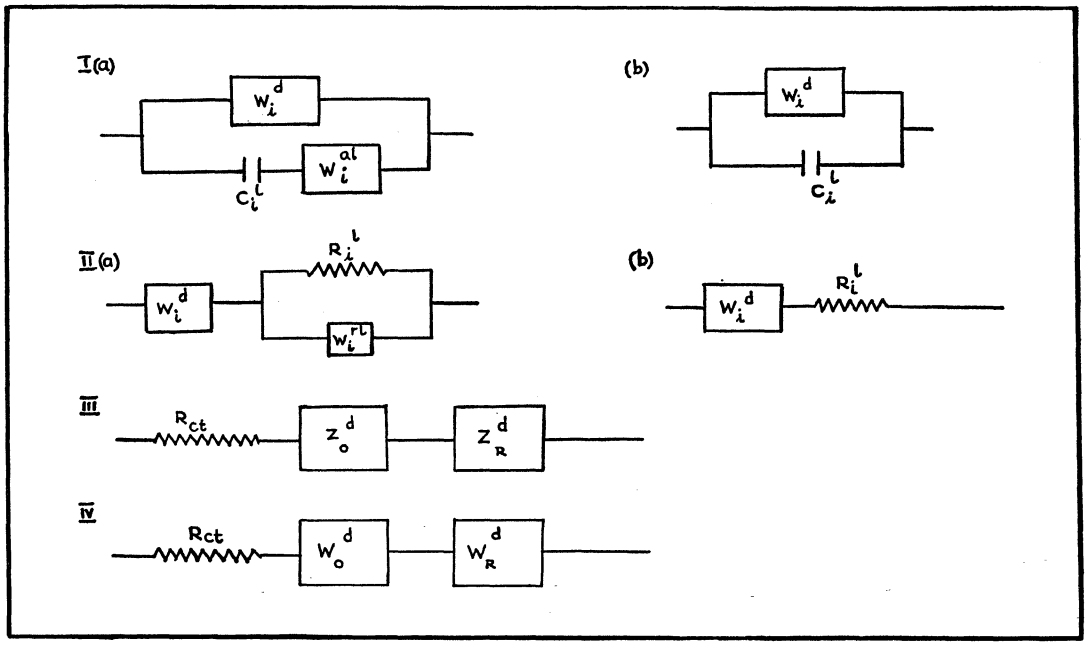

FIG. 3. Impedance characteristics—effect of migration in the diffuse layer.

Equivalent circuits for the reaction $O + ne \rightleftharpoons R$. Z_i^d: the contribution of the species i (= O, R) to the overall impedance Z (= $R_{ct}+Z_O^d+Z_R^d$); W_i^d: Warburg impedance; W_i^{al}: $[S_1/(-a_i)]W_i^d$ ($a_i < 0$); W_i^{rl}: $[a_i/\phi_1]W_i^d$ ($a_i > 0$); R_{ct}: charge transfer resistance.

I(a): formal schematic representation for Z_i^d; I(b): Z_i^d, as given by Senda and Delahay (5), for the particular condition $|(1/\kappa)\sqrt{(\omega/D_i)}S_1| \ll 1$; II($a$): Z_i^d, for the case of repulsion; II(b): Z_i^d, when $|(1/\kappa)\cdot\sqrt{(\omega/D_i)}\phi_1| \ll 1$ (see ref. 5); III: equivalent circuit for the faradaic impedance with (Z_O^d) and (Z_R^d) to be substituted from I or II depending on whether there is attraction or repulsion in the double layer; IV: the classical representation of Z (i.e. for the particular case $\phi_0 = 0$).

Hence, for the *case of attraction* (i.e. when $a_i < 0$), the impedance due to the polarization characteristics of the *species i* consists of the classical Warburg impedance in *parallel* with the impedance

$$Z_{2a} = \frac{1}{j\omega C_i^{\,l}} + R_i^{\,al} + \frac{1}{j\omega C_i^{\,al}}.$$

(Note that when the effects due to diffuse double layer are negligible, $\xi_0 \rightarrow 1$ and $a_i \rightarrow 0$ so that $R_i^{al} \rightarrow \infty$ and $C_i^{al} \rightarrow 0$.) For the case of repulsion, Z_i^d may be written as

[36] $$Z_i^{\,d} = \frac{RT}{n^2F^2\sqrt{(D_ip)}C_i^{\,0}} + \frac{a_iRT}{\kappa D_i(1 + 1/\kappa\sqrt{(p/D_i)}\phi_1)n^2F^2C_i^{\,0}}$$

$$= Z_1+Z_{2r}$$

with

[37] $$\frac{1}{Z_{2r}} = \frac{\kappa D_in^2F^2C_i^{\,0}}{RTa_i} + \frac{\sqrt{(pD_i)}\phi_1n^2F^2C_i^{\,0}}{RTa_i}$$

$$= \frac{1}{R_i^{\,l}} + \frac{1}{W_i^{\,rl}},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where

[38] $$W_i^{r1}(p) = \frac{RTa_i}{\phi_1\sqrt{(pD_i)}.n^2F^2C_i^0}$$

and

[39] $$R_i^1 = \frac{a_iRT}{\kappa D_i n^2F^2C_i^0}.$$

Thus, in the *case of repulsion* ($a_i > 0$) the impedance due to the polarization characteristics of the species i consists of the classical Warburg impedance *in series* with the impedance Z_{2r}. (Refer to Fig. 3.)

CONCLUSIONS

By making use of the modified expressions obtained recently for the interfacial concentrations $C_i(0,t)$ when the effect of the migration in the diffuse layer is taken into account, the alternating components of $C_i(0,t)$ are derived (Section 1).

With the help of the rate equation, the impedance characteristics are discussed. A comparison is made with those obtained by Matsuda (Section 2).

Equivalent circuits are derived for the cases of attraction (and repulsion) for the species i (Section 3).

ACKNOWLEDGMENT

The author wishes to thank Professor K. S. G. Doss, Director, Central Electrochemical Research Institute, Karaikudi, for his keen interest and valuable discussions.

NOTES

THE NUCLEAR MAGNETIC RESONANCE SPECTRUM OF SULPHUR TETRAFLUORIDE

J. Bacon, R. J. Gillespie, and J. W. Quail

The F^{19} n.m.r. spectrum of SF_4 has previously been described by Cotton, George, and Waugh (1) and also by Muetterties and Phillips (2). Both of these groups found the F^{19} n.m.r. spectrum to consist of one very broad line at room temperature due to rapid exchange. Upon cooling the sample, these workers observed that this line broadened further and then split into two peaks. At $-100°$ C each of these peaks was further resolved into a triplet. This spectrum is entirely compatible with the known structure of the SF_4 molecule (3).

The symmetry of the SF_4 molecule is C_{2v}. The four fluorine atoms occupy four of the corners of a trigonal bipyramid around the sulphur, the fifth position being occupied by a lone pair of electrons. All of the F—S bonds are distorted away from the lone pair by lone pair – bond pair repulsions (4).

The resolution of the SF_4 spectrum into two triplets was observed at $-60°$, a higher temperature than that previously reported. At $-90°$ C all the peaks of both triplets were observed to split into doublets. The two halves of the spectrum are symmetrical about the center, and the low-field half of the spectrum is reproduced in Fig. 1. A complete

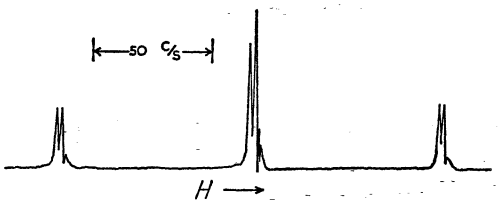

Fig. 1. Low-field half of fluorine resonance of SF_4 at $-101°$ C.

assignment of the spectrum can be achieved by treating SF_4 as an A_2B_2 system in which the two coupling constants between non-equivalent nuclei are equal.

The general theory of A_2B_2 spectra has been previously treated by Pople, Schneider, and Bernstein (5, 6). There are 24 possible transitions, of which 12 are A lines and 12 are B lines. The set of A lines is a mirror image of the set of B lines with respect to the central position, $1/2(\nu_A+\nu_B)$. Since the ratio $J/\nu_0\delta$ for SF_4 is very small, transitions giving rise to combination lines have extremely low probability and need not be considered. Because the two coupling constants between non-equivalent nuclei are equal, the spectrum is independent of the coupling constants between equivalent nuclei and depends only on the ratio $J/\nu_0\delta$. The frequency separation between transitions 1 and 3 of the n.m.r. spectrum is $2J$ and the separation between the 10,11 transition of the A spectrum and the corresponding transition of the B spectrum is $\nu_0\delta$. The values found for J and $\nu_0\delta$ at $-101°$ C are:

$$J = 76.3\pm0.3 \text{ c.p.s.}$$
$$\nu_0\delta \text{ (56.4 Mc)} = 2935\pm10 \text{ c.p.s.} = 52.1 \text{ p.p.m.}$$
$$J/\nu_0\delta = 0.0260$$

The expected spectrum of SF_4 was calculated using these values. The energies of the s_0 states have usually been obtained by perturbation methods. We obtained an explicit expression for the stationary-state energies of the s_0 levels by solving the appropriate secular determinant. It may be seen in Table I that there is good agreement between the observed and calculated spectra.

TABLE I

	Observed		Calculated	
Transition	Line position (c.p.s.)	Second-order splitting (c.p.s.)	Line position (c.p.s.)	Second-order splitting (c.p.s.)
1	−78.7±0.6	2.0±0.1	−78.3	1.9
2	−76.7±0.6		−76.4	
7	−2.0±0.1		−2.0	
6			−1.9	
10,11	0	2.0±0.1	0	1.9–2.0
3	74.2±0.6	1.9±0.1	74.3	1.9
4	76.1±0.6		76.2	

The F^{19} n.m.r. spectrum of SF_4 is an example of second-order splitting for an extremely small value of $J/\nu_0\delta$. The reason that a second-order effect is observed in this case is that the absolute values of both J and $\nu_0\delta$ are very large. The only other reported A_2B_2 spectra for which it is certain that the coupling constants between non-equivalent nuclei are equal due to the symmetry of the molecule are the SF_4 portion of the spectrum of $SF_4(SO_3F)_2$ (7) and the C^{13} satellite spectrum of allene (8). It has been suggested (9) that other n.m.r. spectra which have previously been explained as A_2B_2 with equal coupling constants between non-equivalent nuclei (β-propiolactone (10), ethyl monothiocarbonate (11), *trans*-dibromocyclopropane (12), and 2,3-dihydrofuran (12)) probably do not, in fact, have exactly equal coupling constants.

EXPERIMENTAL

The sulphur tetrafluoride used in this study was obtained from a commercial source and was contaminated with SOF_2, SCl_2, and CH_3CN. The latter two of these impurities and some of the SOF_2 were removed by fractional distillation in a vacuum line. Due to the similarity of the boiling points of SF_4 and SOF_2 it was not possible to obtain samples of SF_4 which were completely free from SOF_2. The oxyfluoride was usually present in a concentration of about 5%. Samples of SF_4 were distilled into 5 mm O.D. silica tubes, which were sealed under vacuum.

The fluorine n.m.r. spectra were obtained using a Varian high-resolution n.m.r. spectrometer and electromagnet at a frequency of 56.4 Mc and a field of 14,000 gauss. The spectra were calibrated using audio side bands generated with a D-890-A Muirhead Wigan Decade Oscillator. Peaks being measured were "bracketed" with modulation side bands from a reference peak (13). The chemical shift was measured by overlapping of the appropriate audio side bands from the A and B halves of the spectrum and recording the overlap pattern. Since the splitting between the multiplet peaks was known, $\nu_0\delta$ could be calculated.

AZOESTER–ANTHRACENE REACTIONS

C. W. HUFFMAN[1]

The known biological activity of various carbamates led us to prepare several hydrazo compounds which are a type of dicarbamate. However, none of the compounds recorded in this article were active as herbicides. An improvement in the preparation of stable ethyl azodicarboxylate and of varied labile azoester–anthracene adducts was achieved.

A recent review (1) of Diels–Alder syntheses states that the expected labile diene adduct from anthracene and ethyl azodicarboxylate cannot be isolated. This is incorrect. The labile isomer can be obtained and purified, if pure azoesters are used. The first report (2) on this reaction disclosed the preparation of labile compounds from anthracene and ethyl or methyl azodicarboxylate. These preparations have been confirmed and extended. A similar labile compound (I) was made from 2-chloroanthracene and ethyl azodicarboxylate. These labile compounds are converted to stable isomers (II) by acids. Others (3) had not been able to repeat the preparation of the labile compounds. Very likely, the azoester must be free of acid-forming by-products, to permit isolation of the labile adduct (I).

The ethyl azodicarboxylate, prepared as described, gave good yields of the labile adduct with anthracene after 21 months storage in a freezer. In his standard preparation of ethyl azodicarboxylate, Rabjohn (4) comments that chlorination by-products are formed if the reaction mixture containing ethyl hydrazodicarboxylate absorbs more than the theoretical amount of chlorine, thereby lowering the yields. His ethyl azoester yields were 81–83%. During this work it was found that appreciable quantities of unreacted ethyl hydrazodicarboxylate remained under Rabjohn's conditions. Consequently, an excess of chlorine was employed to obtain an improved azoester yield of 92%.

Alder and his co-workers (5) showed that the stable isomer from anthracene had a hydrazine structure. This means that monosubstituted anthracenes and azoesters should yield one labile ester (I), and could give two isomeric stable esters. It was surprising to find that 2-chloroanthracene gave a 74% yield of one sharply melting stable isomer (II*a* or II*b*), without prior purification of the labile ester (I). A chlorine substituent

AZOESTER–ANTHRACENE REACTIONS

C. W. HUFFMAN[1]

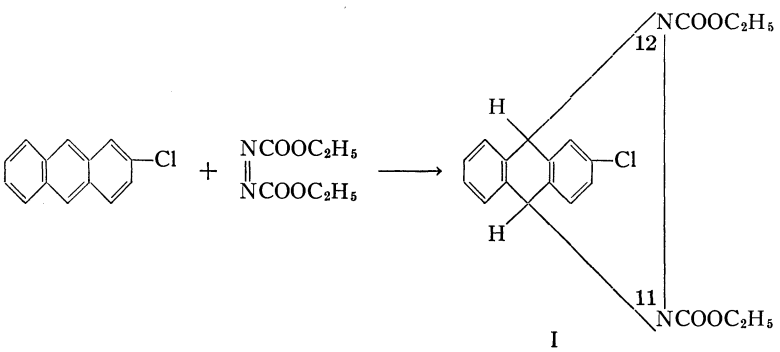
The known biological activity of various carbamates led us to prepare several hydrazo compounds which are a type of dicarbamate. However, none of the compounds recorded in this article were active as herbicides. An improvement in the preparation of stable ethyl azodicarboxylate and of varied labile azoester–anthracene adducts was achieved.

A recent review (1) of Diels–Alder syntheses states that the expected labile diene adduct from anthracene and ethyl azodicarboxylate cannot be isolated. This is incorrect. The labile isomer can be obtained and purified, if pure azoesters are used. The first report (2) on this reaction disclosed the preparation of labile compounds from anthracene and ethyl or methyl azodicarboxylate. These preparations have been confirmed and extended. A similar labile compound (I) was made from 2-chloroanthracene and ethyl azodicarboxylate. These labile compounds are converted to stable isomers (II) by acids. Others (3) had not been able to repeat the preparation of the labile compounds. Very likely, the azoester must be free of acid-forming by-products, to permit isolation of the labile adduct (I).

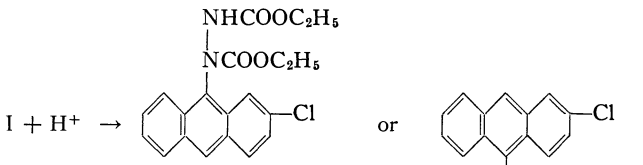
The ethyl azodicarboxylate, prepared as described, gave good yields of the labile adduct with anthracene after 21 months storage in a freezer. In his standard preparation of ethyl azodicarboxylate, Rabjohn (4) comments that chlorination by-products are formed if the reaction mixture containing ethyl hydrazodicarboxylate absorbs more than the theoretical amount of chlorine, thereby lowering the yields. His ethyl azoester yields were 81–83%. During this work it was found that appreciable quantities of unreacted ethyl hydrazodicarboxylate remained under Rabjohn's conditions. Consequently, an excess of chlorine was employed to obtain an improved azoester yield of 92%.

Alder and his co-workers (5) showed that the stable isomer from anthracene had a hydrazine structure. This means that monosubstituted anthracenes and azoesters should yield one labile ester (I), and could give two isomeric stable esters. It was surprising to find that 2-chloroanthracene gave a 74% yield of one sharply melting stable isomer (II*a* or II*b*), without prior purification of the labile ester (I). A chlorine substituent

[1]*Present address: International Minerals and Chemical Corporation, Skokie, Illinois, U.S.A.*



I
(labile)



IIa

IIb
(stable)

should stabilize intermediates which are formally related to parachlorophenyl compounds rather than the metachloro type. Furthermore, electron withdrawal by the chlorine should result in a slight increase in electrophilic attack by a proton on N-11 to give II*a* as the preferred isomer. Some II*b* should form too. Therefore, the effect of anthracene substituents (1, 2, or 9) on this ring-opening reaction warrants further study.

EXPERIMENTAL

Melting points were taken in a Hershberg-type apparatus. Initial determinations were made with ordinary 360° thermometers and the final uncorrected melting points with Anschutz thermometers.

Ethyl Azodicarboxylate

Slight modifications of the *Organic Syntheses* procedure of Rabjohn (4) gave a higher yield of stable product. Therefore, a detailed procedure is given. Ethyl hydrazodicarboxylate (4) (293 g), benzene (1470 ml), and water (1470 ml) were stirred in a 5-liter flask which was immersed in an ice bath (hood). Chlorine (cylinder on scale) was bubbled into the mixture through a plain glass tube,[2] when the reaction mixture temperature had reached 11°. A temperature of 6–7° was held constant while a total of 195 g of chlorine was added during a 1.5-hour period. The red-orange benzene layer was separated from the water layer. This water layer was extracted with 150 ml of benzene. The combined benzene solution was washed 10 times with 350-ml portions of 3% sodium carbonate before the water layer became alkaline (no doubt some of the preliminary washes could be combined). A final wash with 350 ml of 3% sodium carbonate was made, followed by two water washes with 350-ml portions of water. The final water wash was neutral. Sodium sulphate (200 g) was added to the benzene solution. The following day the sodium sulphate was removed by filtration and the benzene distilled from the solution under water-pump vacuum on the steam bath. The residue, in a 500-ml flask, was connected to a $1\frac{1}{4}\times 15$-in. column, packed half full with glass helices and wrapped with asbestos tape. An oil pump was used to maintain a pressure of 5 mm during a rapid distillation (shield). A small (4.5 g) forerun of orange-red oil was discarded. The main fraction of ethyl azodicarboxylate was orange-red, b.p. 110° at 5.0 mm, and weighed 266 g (92% yield). Most of the undistilled residue (25 g) crystallized.

[2]*Possibly an efficient gas dispersion tube would decrease the chlorine requirement. However, chlorine should be added until all the solid ethyl hydrazodicarboxylate dissolves, or the reaction mixture should be stirred until the solid dissolves (this did not take place in other experiments when the theoretical amount of chlorine was absorbed by the reaction mixture as determined by an increase in the weight of the reaction mixture).*

For personal use only.

Redistillation of one sample of ethyl azodicarboxylate from a 200-ml flask heated by a Glascol mantle proceeded satisfactorily at 122° (24 mm pressure) until about 2 ml remained in the distillation flask. At this point, the residue in the flask *exploded violently*. Consequently, the distillation flask must not be overheated. If azoesters are to be redistilled, a small amount of a high-boiling stable solvent should be added to the distillation flask, prior to the distillation.

2-Chloro-9,10-endo-(N,N'-ethylhydrazocarboxylate)-9,10-dihydroanthracene (I)

Ethyl azodicarboxylate (32.2 g, 0.183 mole, a 14% excess), toluene (110 ml), and 2-chloroanthracene (6) (34.2 g, 0.161 mole, m.p. 223°) were refluxed overnight. The clear solution was treated with Nuchar C (1.5 g) and concentrated under vacuum on the steam bath to a dark red oil. Four precipitations of this material from isopropanol solutions, by water, gave 57.8 g (93%) of dried 2-chloro-9,10-*endo*-(N,N'-ethylhydrazodicarboxylate)-9,10-dihydroanthracene, which sintered at 84° and had m.p. 100–104°. An earlier preparation, using a 10% excess of ethyl azodicarboxylate, and a 7-hour reflux period, gave a 14% recovery of unreacted 2-chloroanthracene. This run was processed to give a 64% yield of product, m.p. 99–100°. Two recrystallizations from isopropanol–water gave light yellow crystals, which sintered at 75°, and had m.p. 99–102°. Anal. Calc. for $C_{20}H_{19}ClN_2O_4$: C, 62.1; H, 4.95; Cl, 9.17; N, 7.25. Found: C, 62.3; H, 5.03; Cl, 9.27; N, 7.17.

2-Chloro-9(or 10)-(N,N'-dicarboethoxy)hydrazinoanthracene (II)

Ethyl azodicarboxylate (10.44 g, 0.06 mole), toluene (50 ml), and 2-chloroanthracene (10.6 g, 0.05 mole) were refluxed 8 hours. The clear solution was placed in a freezer overnight. A filtration gave 0.4 g (4%) of yellow flakes of recovered 2-chloroanthracene, m.p. 213–221° with sintering at 135°. The filtrate was concentrated under vacuum to an orange-red oil (21.1 g), which was dissolved in warm acetic acid (65 ml). Concentrated hydrochloric acid (6 ml) was added to the yellow filtrate. In 15 minutes a solid mass had formed. The following day, the solid was removed by filtration and slurried with acetic acid to remove the yellow color. It was dried under vacuum at 88° to give 14.3 g (74%) of cream-colored 2-chloro-9(or 10)-(N,N'-dicarbethoxy)hydrazinoanthracene, m.p. 213–214.5°, with sintering at 208°. A small sample from an earlier preparation was recrystallized several times from benzene to give white crystals which sintered at 211°, and had m.p. 213–214°. Anal. Calc. for $C_{20}H_{19}ClN_2O_4$: C, 62.1; H, 4.95; Cl, 9.17; N, 7.25. Found: C, 62.2; H, 5.06; Cl, 9.21; N, 7.33.

Water (150 ml) was added to the acetic acid filtrate above to yield 1.5 g (7.7%) of a solid which sintered at 160° and had m.p. 180–186°. This solid may contain an isomer of the stable ester which melted at 214°.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. R. C. Tallman for helpful suggestions and to Dr. S. E. Allen (Tennessee Valley Authorities Research Center, Muscle Shoals, Alabama) for conducting the herbicide tests. Analyses were performed by the Clark Microanalytical Laboratory of Urbana, Illinois.

At this point, the residue in the flask *exploded violently*. Consequently, the distillation flask must not be overheated. If azoesters are to be redistilled, a small amount of a high-boiling stable solvent should be added to the distillation flask, prior to the distillation.

2-Chloro-9,10-endo-(N,N'-ethylhydrazocarboxylate)-9,10-dihydroanthracene (I)

Ethyl azodicarboxylate (32.2 g, 0.183 mole, a 14% excess), toluene (110 ml), and 2-chloroanthracene (6) (34.2 g, 0.161 mole, m.p. 223°) were refluxed overnight. The clear solution was treated with Nuchar C (1.5 g) and concentrated under vacuum on the steam bath to a dark red oil. Four precipitations of this material from isopropanol solutions, by water, gave 57.8 g (93%) of dried 2-chloro-9,10-*endo*-(N,N'-ethylhydrazodicarboxylate)-9,10-dihydroanthracene, which sintered at 84° and had m.p. 100–104°. An earlier preparation, using a 10% excess of ethyl azodicarboxylate, and a 7-hour reflux period, gave a 14% recovery of unreacted 2-chloroanthracene. This run was processed to give a 64% yield of product, m.p. 99–100°. Two recrystallizations from isopropanol–water gave light yellow crystals, which sintered at 75°, and had m.p. 99–102°. Anal. Calc. for $C_{20}H_{19}ClN_2O_4$: C, 62.1; H, 4.95; Cl, 9.17; N, 7.25. Found: C, 62.3; H, 5.03; Cl, 9.27; N, 7.17.

2-Chloro-9(or 10)-(N,N'-dicarboethoxy)hydrazinoanthracene (II)

Ethyl azodicarboxylate (10.44 g, 0.06 mole), toluene (50 ml), and 2-chloroanthracene (10.6 g, 0.05 mole) were refluxed 8 hours. The clear solution was placed in a freezer overnight. A filtration gave 0.4 g (4%) of yellow flakes of recovered 2-chloroanthracene, m.p. 213–221° with sintering at 135°. The filtrate was concentrated under vacuum to an orange-red oil (21.1 g), which was dissolved in warm acetic acid (65 ml). Concentrated hydrochloric acid (6 ml) was added to the yellow filtrate. In 15 minutes a solid mass had formed. The following day, the solid was removed by filtration and slurried with acetic acid to remove the yellow color. It was dried under vacuum at 88° to give 14.3 g (74%) of cream-colored 2-chloro-9(or 10)-(N,N'-dicarbethoxy)hydrazinoanthracene, m.p. 213–214.5°, with sintering at 208°. A small sample from an earlier preparation was recrystallized several times from benzene to give white crystals which sintered at 211°, and had m.p. 213–214°. Anal. Calc. for $C_{20}H_{19}ClN_2O_4$: C, 62.1; H, 4.95; Cl, 9.17; N, 7.25. Found: C, 62.2; H, 5.06; Cl, 9.21; N, 7.33.

Water (150 ml) was added to the acetic acid filtrate above to yield 1.5 g (7.7%) of a solid which sintered at 160° and had m.p. 180–186°. This solid may contain an isomer of the stable ester which melted at 214°.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. R. C. Tallman for helpful suggestions and to Dr. S. E. Allen (Tennessee Valley Authorities Research Center, Muscle Shoals, Alabama) for conducting the herbicide tests. Analyses were performed by the Clark Microanalytical Laboratory of Urbana, Illinois.

INFLUENCE OF A PULSED ELECTRIC FIELD ON LUMINESCENCE IN THE RARE GASES EXCITED BY IONIZING RADIATION

Aleksander Szymanski* and Jan A. Herman

Although luminescence in gases excited by ionizing radiation has been known for a long time (1), no satisfactory interpretation of this phenomenon has yet been found. One of the points of dispute has been the relative contribution of radiative ion–electron

*Present address: Department of Chemistry, Polytechnical Institute of Lodz, Lodz, Poland.

For personal use only.

recombination to the luminescence. Contrary to what was formerly believed (2), recent work (3) indicates that such recombination does play a role in the luminescence. In this note we present some preliminary results bearing on this point.

In contrast to previous work we have measured the variation in intensity of light emission at the beginning and end of a pulsed electric field. Since the luminescence intensity in general is proportional to the number of individual processes occurring in each of the possible radiative deactivation processes undergone by atoms, molecules, or ions, it will be also proportional in the special case of dissociative recombination. To calculate this recombination as a function of time, one must know the concentration of ions and electrons at the moment of application and removal of the electric field. The following reasoning applies only to an atomic gas which does not undergo electron attachment.

The kinetic equations (neglecting diffusion) are as follows:

$$\begin{aligned} dN/dt &= q-\alpha_1 n_1 N-\alpha_2 n_2 N+\mu^- NE \\ dn_1/dt &= q-\alpha_1 n_1 N-\beta n_1-\mu_1{}^+ n_1 E \\ dn_2/dt &= \beta n_1-\alpha_2 n_2 N-\mu_2{}^+ n_2 E, \end{aligned} \qquad [1]$$

where q is the number of ions formed per cc per sec, N is the electron concentration per cc, n_1 the concentration of atomic ions, n_2 the concentration of molecular ions, α_1 the coefficient for atomic ion–electron recombination, α_2 the coefficient for dissociative recombination, μ^- the electron mobility, $\mu_1{}^+$ the atomic ion mobility, $\mu_2{}^+$ molecular ion mobility, β the rate of conversion of atomic ions into molecular ions, and E the electric field intensity in v/cm.

Adopting the following assumptions: (*a*) that E is sufficiently weak to neglect the terms $\mu^- NE$, $\mu_1{}^+ n_1 E$, and $\mu_2{}^+ n_2 E$ and (*b*) that the atomic ion–electron recombination can be neglected, α_1 being very small (4) (i.e. $\alpha_1 n_1 N \ll \alpha_2 n_2 N$, also $\alpha_1 n_1 < \beta$), then the solution of the equations [1] reduces to:

$$n_1 = q/\beta, \qquad [2]$$

$$n_2 = n_{2\,\mathrm{st}} \frac{c\sqrt{\Delta_{\mathrm{st}}}\exp(\alpha_{\mathrm{st}} t\sqrt{\Delta_{\mathrm{st}}})}{1-c\exp(\alpha_{\mathrm{st}}\sqrt{\Delta_{\mathrm{st}}})} \qquad [3]$$

$$N = n_2+q/\beta, \qquad [4]$$

where $n_{2\,\mathrm{st}}$, c ($c = (n_{2\,\mathrm{in}}-n_{2\,\mathrm{st}})/(n_{2\,\mathrm{in}}-n_{2\,\mathrm{st}}+\sqrt{\Delta_{\mathrm{st}}})$), and Δ_{st}, ($\Delta_{\mathrm{st}} = (q^2/\beta^2)-(4q/\alpha_{2\,\mathrm{st}})$) are constants and $n_{2\,\mathrm{in}}$ and $n_{2\,\mathrm{st}}$ are respectively the initial and stationary concentrations of molecular ions. Equation [3] applies both for the beginning and the end of the pulse, as it describes the transition between two states of equilibrium; these states are associated with field off and field on.

By definition the number of recombinations, $I(t)$, is given by $I(t) = \alpha n(t)N(t)$. The coefficient of dissociative recombination in general decreases with increasing electron energy (5); it will therefore decrease under an applied electric field. On the other hand, independent of this effect, the number of dissociative recombinations of molecular ions, $I(t) = \alpha_2 n_2(t)N(t)$, in a weak field may be shown to be the same as that in zero field, from which: $I_o = \alpha_{2p} n_{2p} N_p = \alpha_{2o} n_{2o} N_o$, the subscripts "o" and "p" indicating respectively values in the absence and presence of a field. Since $\alpha_{2o} > \alpha_{2p}$, then $N_o < N_p$ and $n_{2o} < n_{2p}$; in other words, there is an interdependence between a change in the recombination coefficient and a change in ion and electron density. As a result the number

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of dissociative recombinations at the beginning of the field pulse will be given by: $I(t_1) = \alpha_{2p} n_{2o} N_o < I_o$, and at the end of the field pulse by: $I(t_2) = \alpha_{2o} n_{2p} N_p > I_o$. The change in recombination at the start of the field pulse is therefore:

$$\Delta I_s = I(t_1) - I_o = (\alpha_{2p} - \alpha_{2o}) n_{2o} N_o \quad [5]$$

and at the end of the field pulse:

$$\Delta I_e = I(t_2) - I_o = (\alpha_{2o} - \alpha_{2p}) n_{2p} N_p. \quad [6]$$

Since $n_{2p} N_p > n_{2o} N_o$, then $\Delta I_e > \Delta I_s$. The change in light emission will be proportional to ΔI_s and ΔI_e at the beginning and the end of the field pulse respectively. Figure 1 expresses graphically the results given by equations [5] and [6].

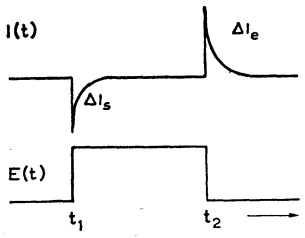

FIG. 1. Theoretical light pulse emission I, at the beginning and the end of an applied field pulse $E(t)$.

The abrupt increase or decrease in recombination rate at the beginning and end of the field pulse will be followed by a return to equilibrium rate with a decay constant given by equation [3]; however, it should be noted that the exponential in this equation is $\alpha_p qt(1+4\beta^2/q\alpha_p)^{1/2}$ at the start of the field pulse and $\alpha_o qt(1+4\beta^2/q\alpha_o)^{1/2}$ at the end of the field pulse. In addition ΔI_e depends on N_p and n_{2p}; therefore, it should diminish as the amplitude of field pulse increases.

The rare gases helium, neon, argon, krypton, xenon, and also nitrogen were studied. All, with the exception of helium and nitrogen, were spectroscopically pure. They were excited by a beam of X rays produced by a tube operated at 45 kv. The intensity was variable. The electric field was produced by a square wave generator with a rise and fall time of 8 μsec and 0.4 μsec respectively, an amplitude from 100 to 750 v/cm, pulse length of 50–500 μsec, and repetition rate of 250 to 1500 per sec. The light emitted was measured by a photomultiplier (E.M.I., type 9526-B). The output was observed on a Tetronix 545-A oscilloscope. The cell (6) contained aluminum electrodes and had a quartz window transparent to 2000 Å. Gas pressures used were from 70 to 300 mm.

In the case of helium, neon, and argon, no variation in light intensity characteristic of recombination was observed, other than that already described in the literature (2, 3, 6), and due to increased excitation by electrons accelerated by the pulsed field. Figure 2(*a*) shows the light pulse in argon; similar curves result in helium and neon. In nitrogen there is no change in luminescence that is in any way extraordinary.

However, the heavy rare gases behave differently, at the beginning of the field pulse a very weak decrease in luminescence occurs, which is almost completely masked by the increase produced by the increased excitation caused by accelerated electrons. On the other hand, at the end of the field pulse there is a large increase in luminescence (Fig. 2 (*b* and *c*)). These light pulses (peaks) can be identified without doubt with the impulses ΔI_s and ΔI_e described above. Another argument in favor of this theory is that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

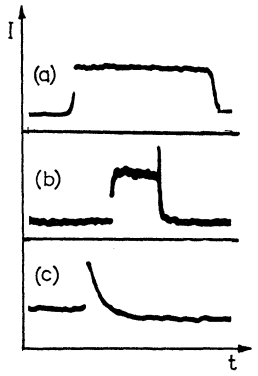

FIG. 2. (*a*) Light emission in argon; P = 224 mm Hg, E = 500 v/cm, field pulse time 0.6 msec. (*b*) Light emission in xenon: P = 664 mm Hg, E = 500 v/cm, field pulse time 0.4 msec. (*c*) Expanded trace showing peak at end of light pulse in xenon; P = 317 mm Hg, E = 400 v/cm, sweep time 20 μsec/cm.

the light pulse occurring at the end of the field pulse increases with increasing X-ray intensity, and decreases with increase in amplitude of the field pulse. Anderson (7) has observed a similar effect in the afterglow from microwave discharges in gases and assigned it to the same cause.

Similar experiments have been made using Po^{210} α-particles as the ionizing radiation; however, the large background of emission produced by ionizing radiation made it impossible to observe any changes.

The experiments described above show that in the case of krypton and xenon dissociative recombination plays an active role in the mechanism of luminescence. In the case of lighter gases either this process is less probable, or the light emitted is in a spectral region in which the photomultiplier is insensitive. In argon also, the expected phenomena were not observed, perhaps again because of experimental limitations.

The observed phenomena should permit: (*a*) measurement of recombination coefficients from the decay in the light pulse after the end of the field pulse, (*b*) relative measurements of molecular ion concentration at high pressures.

The authors would like to thank J. W. McGowan and D. G. H. Marsden for their interest in this work; and also Professor L. Kerwin, Head of the Physics Department, for the loan of equipment used in this work.

THE HYDRATES OF FLUORAL[1]

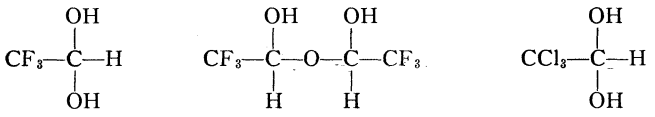
D. E. McGreer, R. Stewart, and M. M. Mocek

Fluoral has been prepared by a number of procedures (1–5) and in each report some mention is given to the formation of a hydrate from the reaction of fluoral with water. The hydrate is reported to be a solid which sublimes at 50° (1) and has a melting point of 68–70° (3, 5) but it has never been fully characterized. Fluoral hydrate is also sold commercially (Columbia Organic Chemicals Co.) as a liquid.

In connection with our studies on the permanganate oxidation of fluoral hydrate (6) we have now characterized this compound more fully and find that its analysis and physical properties more closely fit those of a hemihydrate.

Reduction of trifluoroacetic acid by the procedure of Braid, Iserson, and Lawlor (5) gave the gas fluoral, which when reacted with less than the stoichiometric amount of water yielded a white moist solid hydrate (I). This solid gave non-reproducible melting points; however, when it was dried over phosphorus pentoxide a constant melting point of 93–94° (sealed tube) was obtained. Samples could be solidified and remelted with no change in the melting point.

The elemental analysis of I (C, 22.51; H, 1.92) does not fit well for fluoral hydrate II (C, 20.68; H, 2.59) but fits better for the hemihydrate III (C, 22.40; H, 1.88). Molecular



weight determinations (m.p. depression of camphor) gave a value of 223, which also favored structure III (mol. wt. 214) over structure II (mol. wt. 116).

The proton n.m.r. spectrum of I in acetone (Fig. 1A) shows two signals, at 3.44 τ

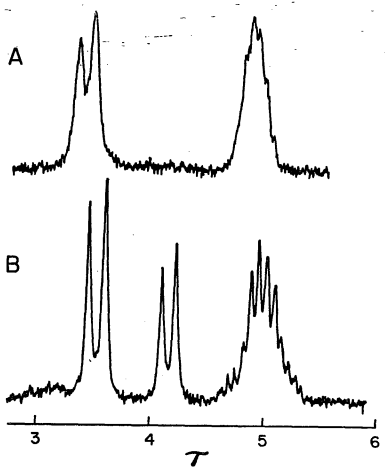


FIG. 1. A, I in acetone; B, I in acetone after standing several days in an open tube.

and 4.90 τ, with relative areas of 1:1.07. The lower-field peak, which is a doublet, J = 8.5 c.p.s., is clearly due to an OH as it is markedly shifted to higher field on the addition of water. Both structures II and III would predict a doublet for the OH but III predicts an area ratio of 1:1 whereas II predicts an area ratio of 2:1 for OH and CH. The CH peak is a complex multiplet due to coupling of the CH with the OH (J = 8.5 c.p.s.) and with the CF (J = 4.3 c.p.s.).

The proton n.m.r. spectrum of chloral hydrate (IV) (Fig. 2) in acetone, on the other hand, is quite as expected for the monohydrate. There are two peaks at 3.98 τ and

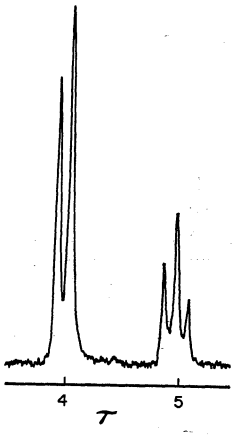

FIG. 2. Chloral hydrate in acetone.

4.96 τ with relative areas of 1.9:1. The low-field peak, which is a doublet (J = 6.7 c.p.s.) and is broadened and moves to higher field on the addition of water, is assigned to the OH. The high-field peak, which is a triplet (J = 6.6 c.p.s.), is assigned to the CH.

The fluorine n.m.r. spectrum for each of the possible structures for I would be expected to be a doublet. It is interesting therefore that the fluorine spectrum in acetone shows a number of doublets (Fig. 3). This would indicate that an acetone solution may in fact contain a number of species. This is also indicated by the fact that an acetone solution of I (Fig. 1B) which had been standing for a number of days was found to have a new but smaller doublet in the proton spectrum at 4.17 τ attributable to the OH of a second species. The development of this peak over a period of time may be due to the fact that the new species is formed slowly in the solution due to absorption of water or that on standing a reduction in the rate of exchange of the OH hydrogens (7) permits measurement of more than one species.

Addition of water in small amounts to an acetone solution of I (Fig. 3) changes the fluorine spectrum by reducing the relative area of the low-field signals with respect to the high-field signal until with excess water (mole ratio of water to I = 10:1) (Fig. 3D) the high-field peak becomes the major peak.

It is apparent from the n.m.r. evidence that in acetone there is present an equilibrium between the various hydrated fluorals. Whether this equilibrium is present in the solid I has not been determined. The major species in acetone would appear to be the hemihydrate III since the proton ratio is 1:1 and the major fluorine doublet is the second doublet from the high-field end. The high-field doublet is undoubtedly due to the hydrate II since it becomes the sole species on dilution with water. Shifts in the n.m.r. due to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

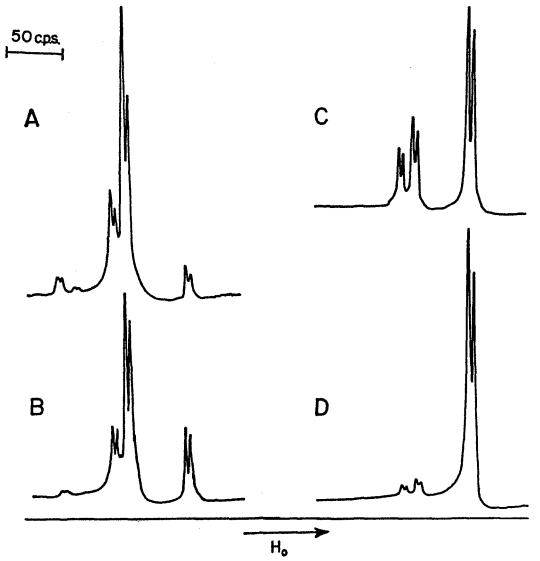

FIG. 3. A, fluorine resonance of I in acetone; addition of water gives mole ratio of water to I for B = 2:1, C = 3:1, and D = 10:1.

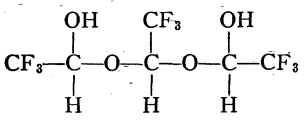
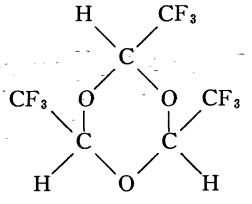
structural changes from condensation would be expected to be progressive; thus the first condensation product, III, would be expected to be the species leading to the second doublet. Other species which might exist in solution are the lower hydrates like V and the trioxane structure VI.



V



VI

EXPERIMENTAL

The proton n.m.r. spectra were obtained at 60 Mc on a Varian Associates A-60 instrument. The fluorine n.m.r. spectra were obtained at 40 Mc on a Varian Associates V4300 instrument. Reagent acetone dried over anhydrous magnesium sulphate was used as the n.m.r. solvent. The microanalyses were determined by A. Bernhardt, Mulheim, West Germany.

Fluoral Hemihydrate

Trifluoroacetic acid was reduced with the stoichiometric amount of lithium aluminum hydride by the procedure of Braid, Iserson, and Lawlor (5). The crude aldehydrol was dehydrated in a mixture of concentrated sulphuric acid and phosphorus pentoxide (5), and the fluoral which distilled was condensed at −78°. To this condensate at −78° was added less than the stoichiometric amount of water. The resulting white solid was dried over phosphorus pentoxide and gave in 43% yield a product, I, with a melting point of 93–94° (sealed tube). Calc. for $C_4H_4O_3F_6$ (III): C, 22.40; H, 1.88; mol. wt., 214 and for $C_2H_3O_2F_3$ (II): C, 20.68; H. 2.59; mol. wt., 116. Found: C, 22.51; H, 1.92; mol. wt., 223. On standing in a desiccator over phosphorus pentoxide a sample of I loses weight presumably due to slow dissociation to water and fluoral.

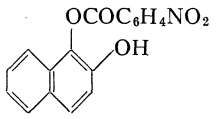
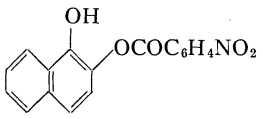
*In all cases Ar = $C_6H_4 \cdot NO_2$-*p*.

but with *α*- and *β*-naphthol crystalline phenolic products could be obtained by oxidation with *p,p'*-dinitrobenzoyl peroxide but not with benzoyl peroxide.

The structures of the phenols obtained from the substituted anilines are without doubt represented by III (Ar = $C_6H_4 \cdot NO_2$-*p*), since they show no basic properties. The oxidation product of *p*-cresol (IV; R = Me) slowly gave a green color on treatment with *p*-aminodimethylaniline and sodium hypochlorite. This color reaction is considered diagnostic of a free para position in a phenol (3), so that the oxidation product probably has the structure VI (R = Me, Ar = $C_6H_4 \cdot NO_2$-*p*), similar to that found for the product from *p*-cresol and benzoyl peroxide (3); in each case the compound V (R = Me, Ar = Ph or $C_6H_4 \cdot NO_2$-*p*) is probably formed first, but rearranges by acyl migration. On the other hand, the phenol from the reaction of *p*-bromophenol (IV; R = Br) appears from the color reaction to have no free para position, and so is probably represented by V (R = Br; Ar = $C_6H_4 \cdot NO_2$-*p*). Both *α*- and *β*-naphthol reacted with *p,p'*-dinitrobenzoyl peroxide to give the same product, which accordingly must be VII or VIII. The latter was shown



VII



VIII

to be correct, since methylation of the product with diazomethane followed by alkaline hydrolysis gave 1-methoxy-2-naphthol. Evidently the compound (VII) first formed by reaction of *β*-naphthol rearranges to VIII.

The mechanisms of the reactions of benzoyl peroxide with amines (5) and phenols (6) have been investigated recently and shown to involve nucleophilic attack of the amino or hydroxyl group on a peroxide oxygen with displacement of a benzoate ion. With the unsymmetrical peroxide, *p*-nitrobenzoyl peroxide (X), this attack may take place on the oxygen (*α*) adjacent to the benzoyl group, with expulsion of a *p*-nitrobenzoate ion (route *a*) or on the oxygen (*β*) adjacent to the *p*-nitrobenzoyl group, with expulsion of a benzoate ion (route *b*). Dibenzylamine (IX; R = CH_2Ph) attacks by route *a* in boiling

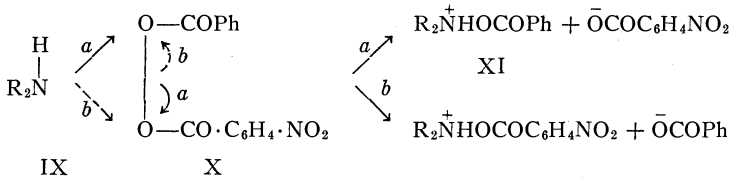
For personal use only.



chloroform (7). Diphenylamine (IX; R = Ph) might accordingly be expected to react by this route to give *o*-(*N*-phenylbenzamido)phenol (III; R = Ar = Ph) (via the intermediate XI (R = Ph) (5)) and *p*-nitrobenzoic acid. In fact, evidence could be obtained only for its reaction by route *b*. A mixture of phenolic products was obtained, from which only the nitro derivative (III; R = Ph, Ar = $C_5H_4 \cdot NO_2$-*p*) could be obtained crystalline (17% yield). Infrared and combustion analysis indicated that the uncrystallizable phenolic fraction remaining was *not* a simple mixture of the two phenols (III; R = Ph; Ar = Ph and $C_6H_4 \cdot NO_2$-*p*).

The reaction of phenols with the unsymmetrical peroxide (X) also follows a complex course. *p*-Cresol gave a mixture of benzoic and *p*-nitrobenzoic acids, and a gummy phenolic fraction from which the *p*-nitrobenzoyloxy derivative (VI; R = Me, Ar = $C_6H_4 \cdot NO_2$-*p*) could be crystallized in 13% yield, but from which the benzoyloxy derivative (VI; R = Me, Ar = Ph) was absent, since nothing could be distilled from the phenolic fraction at temperatures up to 270° at 0.1 mm pressure (cf. ref. 3). β-Naphthol also gave a complex phenolic mixture, from which only the *p*-nitrobenzoyloxy derivative (VIII) could be obtained crystalline.

It is evident that, like tributylphosphine (8) and unlike dibenzylamine (7), phenols and secondary aromatic amines attack the β oxygen of *p*-nitrobenzoyl peroxide (X), although yields are low because of competing reactions giving complex phenolic products.

EXPERIMENTAL

Reactions of Secondary Aromatic Amines with p,p'-Dinitrobenzoyl Peroxide

The peroxide (0.01 mole) was added gradually to a stirred solution of the amine (0.01 mole) in benzene (50 ml) at 20–25°. After standing overnight, the solution was worked up in the usual way (2) for acid and phenol fractions (cf. Table I). *N*-Methylaniline gave *o*-(*N*-methyl-*p'*-nitrobenzamido)phenol (III; R = Me, Ar = $C_6H_4 \cdot NO_2$-*p*), colorless needles from ethanol, m.p. 197–198°. Calc. for $C_{14}H_{12}O_4N_2$: C, 61.76; H, 4.41; N, 10.29%. Found: C, 61.92; H, 4.26; N, 10.14%. *N*-Butylaniline gave *o*-(*N*-butyl-*p'*-nitrobenzamido)-phenol (III; R = Bu, Ar = $C_6H_4 \cdot NO_2$-*p*), colorless plates from benzene, m.p. 167°. Calc. for $C_{17}H_{18}O_4N_2$: C, 64.97; H, 5.73; N, 8.91%. Found: C, 64.86; H, 5.55; N, 8.69%. Diphenylamine gave *o*-(*N*-phenyl-*p'*-nitrobenzamido)phenol (III; R = Ph, Ar = $C_6H_4 \cdot NO_2$-*p*), yellow plates from ethanol, m.p. 240°. Calc. for $C_{19}H_{14}O_4N_2$: C, 68.26; H, 4.19; N, 8.38%. Found: C, 68.08; H, 4.16; N, 8.56%.

N-Ethylaniline gave *o*-(*N*-ethyl-*p'*-nitrobenzamido)phenol (III; R = Et, Ar = $C_6H_4 \cdot NO_2$-*p*), colorless plates from 50% aqueous ethanol, m.p. 152°. Calc. for $C_{15}H_{14}O_4N_2$: C, 62.93; H, 4.89; N, 9.78%. Found: C, 62.83; H, 4.93; N, 9.63%. This phenol crystallized from other solvents with a certain amount of firmly held solvent, probably entrapped by clathrate formation, which is known to be particularly easy for phenolic compounds (9). Thus it crystallized from benzene in plates which, after being dried at 80° at 3 mm for 24 hours, melted at 90–92°, solidified, and remelted at 118°. Calc. for $C_{15}H_{14}O_4N_2 + 1/6\ C_6H_6$: C, 64.21; H, 5.01%. Found: C, 63.82; H, 4.97%. The phenol crystallized from toluene in prisms, m.p. 120°. Calc. for $C_{15}H_{14}O_4N_2 + 1/12\ C_7H_8$: C, 63.68; H, 4.99; N, 9.53%. Found: C, 63.26; H, 5.18; N, 9.60%. It crystallized from bromobenzene in prisms, m.p. 130°. Calc. for $C_{15}H_{14}O_4N_2 + 1/3\ C_6H_5Br$: C, 60.29; H, 4.63; N, 8.28%. Found: C, 60.18; H, 4.93; N, 8.18%.

Reaction of Diphenylamine with p-Nitrobenzoyl Peroxide

Diphenylamine (3.32 g) in benzene (70 ml) was treated as above with *p*-nitrobenzoyl peroxide (5.74 g). The acid fraction (3.1 g) was composed of benzoic and *p*-nitrobenzoic acids, as shown by its melting point of 193–200°. It was dissolved in alkali, filtered, and reprecipitated with mineral acid. The dried precipitate was analyzed for nitrogen, and contained 5.31%, corresponding to 37% benzoic + 63% *p*-nitrobenzoic acid.

Removal of the acid fraction from the benzene solution left a precipitate of phenolic material (0.75 g), m.p. 206–208° (decomp.). Found: C, 65.72; H, 4.41; N, 6.80%. A further 0.8 g, m.p. 202–206° (decomp.),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was removed from the benzene solution from aqueous alkali. Crystallization from acetic acid yielded *o*-(*N*-phenyl-*p*′-nitrobenzamido)phenol (III; R = Ph, Ar = $C_6H_4 \cdot NO_2$-*p*) (1.05 g, 17%), m.p. and mixed m.p. 239°. No other pure compound could be obtained from the phenolic fraction.

Reaction with Phenols with p,p′-Dinitrobenzoyl Peroxide

Solutions of the phenol (0.01 mole) and peroxide (0.01 mole) in chloroform (50 ml) were refluxed for 4–6 hours. Carboxylic acids were removed by extraction with aqueous sodium bicarbonate, and the chloroform solution dried over sodium sulphate and evaporated. The residue was dissolved in the minimum quantity of hot benzene. The solution on cooling deposited crystals of phenolic compound. In this way, *p*-cresol gave pale yellow plates of 4-*p*-nitrobenzoyloxy-*m*-cresol (VI; R = Me, Ar = $C_6H_4 \cdot NO_2$-*p*), m.p. 164°. Calc. for $C_{14}H_{11}O_5N$: C, 61.54; H, 4.03; N, 5.13%. Found: C, 61.73; H, 4.12; N, 5.20%. *p*-Bromophenol gave colorless needles of 2-*p*-nitrobenzoyloxy-4-bromophenol (V; R = Br, Ar = $C_6H_4 \cdot NO_2$-*p*), m.p. 187–188°. Calc. for $C_{13}H_8O_5NBr$: C, 46.15; H, 2.36; N, 4.14%. Found: C, 46.19; H, 2.30; N, 4.15%. α-Naphthol and β-naphthol gave yellow needles of 2-*p*-nitrobenzoyloxy-1-naphthol (VIII), m.p. 182°. Calc. for $C_{17}H_{11}O_5N$: C, 66.02; H, 3.56; N, 4.53%. Found: C, 66.14; H, 3.57; N, 4.59%.

1-Methoxy-2-p-nitrobenzoyloxynaphthalene

A solution of diazomethane in dry ether was added to a solution of 2-*p*-nitrobenzoyloxy-1-naphthol (3.11 g) in ether until a yellow color persisted. After 20 minures, excess diazomethane was destroyed with dilute hydrochloric acid. The ether solution was washed with dilute aqueous potassium hydroxide and then water, dried, and concentrated. The residue crystallized from ethanol in yellow needles, m.p. 140°, of 1-methoxy-2-*p*-nitrobenzoyloxynaphthalene (1.65 g; 51%). Calc. for $C_{18}H_{12}O_5N$: OMe, 9.59%. Found: OMe, 9.49%.

1-Methoxy-2-naphthol

A solution of 1-methoxy-2-*p*-nitrobenzoyloxynaphthalene (1 g) and potassium hydroxide (5 g) in methanol–water (9:1 v/v; 100 ml) was refluxed for 3 hours. After removal of most of the methanol by distillation, the solution was acidified. The precipitate was removed by filtration and washed with aqueous sodium bicarbonate. The residue (0.32 g) crystallized from ligroin as colorless plates of 1-methoxy-2-naphthol, m.p. 90° (reported m.p. 90.5° (10); 2-methoxy-1-naphthol has been prepared recently, and has m.p. 53.5–54.5 (11)). Calc. for $C_{11}H_{10}O_2$: C, 75.86; H, 5.75%. Found: C, 75.51; H, 5.52%. The benzoate, prepared in the usual way with benzoyl chloride in pyridine, crystallized from methanol as colorless rods, m.p. 107°. Calc. for $C_{18}H_{14}O_3$: C, 77.40; H, 5.04%. Found: C, 77.59; H, 5.17%.

Reaction of p-Cresol with p-Nitrobenzoyl Peroxide

The reaction of the peroxide (2.87 g) with *p*-cresol (1.08 g) in chloroform (50 ml) gave a mixture of benzoic and *p*-nitrobenzoic acids (1.72 g), m.p. 198–210°. This melting point corresponds to that of a mixture of 75% of *p*-nitrobenzoic acid and 25% benzoic acid. The phenolic fraction afforded 4-*p*-nitrobenzoyloxy-*m*-cresol (0.35 g; 13%), m.p. and mixed m.p. 164°, and an uncrystallizable gum (1.63 g). This was separated by chromatography on alumina into several fractions showing strong infrared bands at 3350 cm^{-1} (bonded OH) and 1745 cm^{-1} (ester CO), but none of these could be induced to crystallize.

Reaction of β-Naphthol with p-Nitrobenzoyl Peroxide

Reaction of the peroxide (5.74 g) with β-naphthol (2.88 g) in chloroform (90 ml) gave an acidic mixture (2.78 g) indicated by its melting point (188–199°) to be made up of about 65% of *p*-nitrobenzoic and 35% of benzoic acid. The phenolic fraction gave 2-*p*-nitrobenzoyloxy-1-naphthol (0.678; 11%), m.p. and mixed m.p. 182°, and a gum (3.95 g) which by chromatography on alumina gave several gummy fractions.

ALUMINUM ALKOXIDE INDUCED REARRANGEMENT DURING THE OPPENAUER OXIDATION OF CYCLOPROPYLCARBINOL

C. C. Lee and I. S. Bhardwaj*

In connection with a study in this laboratory on the radiolysis of aqueous solutions of cyclopropylcarbinol, it was necessary to synthesize cyclopropanecarboxaldehyde. This was accomplished by the lithium aluminum hydride reduction of cyclopropyl cyanide as described by Smith and Rogier (1). A possible alternative method is the Oppenauer oxidation of cyclopropylcarbinol. Smith and Rogier (1) reported that application of this oxidation, with benzil as hydrogen acceptor, failed to yield any aldehyde. However, a further investigation of the Oppenauer oxidation was undertaken as we were informed by Dr. R. H. Mazur (2) that among the unpublished results in his studies on small-ring compounds (3, 4) is the preparation of cyclopropanecarboxaldehyde from oxidation of cyclopropylcarbinol in the presence of cinnamaldehyde and a catalytic amount of aluminum isopropoxide.

About equimolar quantities of cyclopropylcarbinol and cinnamaldehyde and a catalytic amount of aluminum isopropoxide or aluminum *t*-butoxide were heated under reflux for 2 or 24 hours. The resulting mixture was distilled and the distillate analyzed by vapor phase chromatography. The results, as summarized in Table I, show the presence of some cyclopropanecarboxaldehyde as well as the formation of the rearranged alcohol, cyclobutanol. The yield of aldehyde was of the order of 20% regardless of whether the reaction mixture was refluxed for 2 or 24 hours. This is not surprising since the Oppenauer oxidation is reversible (5, 6) and no attempt was made to force the equilibrium in the forward direction by continual product removal during the reaction.

It has been well established that carbonium-ion-type reactions with cyclopropylcarbinyl derivatives will lead to mixtures of cyclopropylcarbinyl, cyclobutyl, and allylcarbinyl products (3, 7, 8). The cyclobutanol observed in the product of the Oppenauer oxidation of cyclopropylcarbinol very likely also resulted from some reaction involving intermediate carbonium ions. The metallic part of the aluminum alkoxide catalyst may act as a Lewis acid, cause formation of electron-deficient centers, and induce rearrangements typical of carbonium ions. To test this possibility, cyclopropylcarbinol was refluxed for 24 hours with either aluminum isopropoxide or aluminum *t*-butoxide under the same conditions as were used in the Oppenauer oxidation, but without any cinnamaldehyde. Vapor phase chromatographic analyses of the distillates obtained in these trials indeed showed the formation of cyclobutanol, and in amounts sufficient to account for all the cyclobutanol observed in the products of the Oppenauer oxidation (Table I). Thus, during the Oppenauer oxidation of cyclopropylcarbinol to cyclopropanecarboxaldehyde, an aluminum alkoxide induced rearrangement to cyclobutanol occurs as a side reaction. This rearrangement may be depicted by equation [1]. The intermediate cation or ion pair may be more complex in nature and probably may be better represented

Treatment with catalyst	$(t\text{-BuO})_3Al$	24	83.8	83.7	16.2	16.3		

by nonclassical structures (7, 8). However, in the absence of further data, such as isotope position rearrangements as reported by Roberts and co-workers (7, 8), a simple 1,2-shift as shown in equation [1] is adequate to account for the formation of cyclobutanol.

EXPERIMENTAL

Standard Compounds for V.P.C. Calibration

Cyclopropylcarbinol was prepared by the lithium aluminum hydride reduction of cyclopropanecarboxylic acid (1, 7). Cyclobutanol was obtained from the treatment of an aqueous solution of cyclopropylcarbinol with concentrated hydrochloric acid (8). The product obtained consisted of about 93% cyclobutanol and 7% cyclopropylcarbinol. Cyclopropanecarboxaldehyde was prepared by the lithium aluminum hydride reduction of cyclopropyl cyanide (1). The product, boiling at 97–101° C as described by Smith and Rogier (1), consisted of about 90% aldehyde and 10% unreacted cyclopropyl cyanide according to v.p.c. analysis.

Oppenauer Oxidation

A mixture of 2.0 g (0.028 mole) of cyclopropylcarbinol, 3.5 g (0.027 mole) of cinnamaldehyde, and 0.2 g of aluminum isopropoxide or aluminum *t*-butoxide was refluxed for 2 or 24 hours and then distilled through a helix-packed column. The fraction collected boiled between 90–122° C. The recoveries were of the order of 1.2 g. These distillates were analyzed with a Beckman GC-2A gas chromograph using a column filled with type A packing (diisodecyl phthalate on Chromosorb) supplied by the Perkin–Elmer Corp.

Treatment of Cyclopropylcarbinol with Aluminum Alkoxide

A mixture of 2.0 g of cyclopropylcarbinol and 0.2 g of aluminum isopropoxide or aluminum *t*-butoxide was refluxed for 24 hours and then distilled through a helix-packed column. The materials distilling below 122° C were collected and analyzed by v.p.c. as described above.

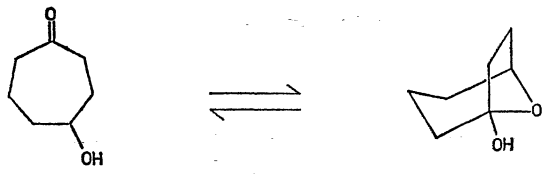
4-Benzoyloxycyclohexanone (I) (5, 6) was converted to 4-benzoyloxycycloheptanone (II) by treatment with diazomethane, generated *in situ* by addition of *N*-nitrosomethylurethane to a solution of I in methanol or ethanol containing a catalytic amount of potassium carbonate (7). The ketone II was isolated as its semicarbazone. Best results (49% yield of purified semicarbazone) were obtained when absolute ethanol was the solvent and the molar ratio of *N*-nitrosomethylurethane to I was 1.17. The substitution of methanol for ethanol resulted in a similar yield of crude product of reduced purity. Use of an increased proportion of the urethane (1.50 mole/mole of I) reduced the yield of II appreciably. The reaction proceeded at a considerably slower rate in ethanol than in methanol; a similar observation has been made by Gutsche and Peter (8) in the case of the reaction of *trans*-1-decalone with diazomethane. Purification of the semicarbazone by recrystallization was found to be greatly facilitated by prior continuous extraction with petroleum ether, which removed adhering oily by-products. The ketone II was regenerated from its semicarbazone either by treatment of the latter with sodium nitrite in acetic acid (9) or by continuous ether extraction of a solution of the semicarbazone in 8 *N* hydrochloric acid. The second process led to the better yield of II: 81% from the purified semicarbazone, i.e. 40% based on I. The genesis, infrared spectrum (*vide infra*), and reactions of this product secure the assigned structure. 4-Methoxycycloheptanone (IV) was similarly prepared from 4-methoxycyclohexanone (III) in 25% overall yield; this cycloheptanone has previously been prepared in impure form by Adamson and Kenner (10).



Va Vb

Hydrolysis of 4-benzoyloxycycloheptanone (II) with aqueous base gave 4-hydroxycycloheptanone (V). Doering and Sayigh (1) prepared this compound in high yield by the ring expansion of 4-hydroxycyclohexanone[3] and concluded on the basis of its infrared spectrum that it exists mainly as the bicyclic tautomer V*b*. We have reached the same conclusion in regard to solutions of V in carbon disulphide, since their infrared spectra show strikingly low-intensity carbonyl absorption (5.88 μ, apparent extinction coefficient less than that of the C—H stretching band). In chloroform solution, however, the carbonyl stretching band (5.90 μ) is very much more intense and it is considered that in this, more polar, solvent the hydroxy ketone tautomer V*a* is predominant. The spectra of V in either solvent possess a band at 9.82–9.83 μ, absent in the spectrum of II; the location of this band is very close to that of the C—O stretching band[4] of cycloheptanol (9.75 μ, liquid film) (12). The corresponding bands in the spectra of other saturated alicyclic secondary alcohols having three- to eight-membered rings are reported to occur at lower wavelengths (8.3–9.63 μ, liquid films) (12).

[3]*The fact that this compound gives a considerably better yield of ring-expanded product than do I and III under similar conditions lends support to the suggestion (1) that intramolecular catalysis by the hydroxyl group is involved in the former reaction.*

[4]*The vibrational assignment for this band is controversial (cf. ref. 11).*

The ethylene ketal of II, 4-ethylenedioxycycloheptyl benzoate (VI), was prepared in the usual manner (13) and was converted without purification to 4-ethylenedioxycycloheptanol (VII) by hydrolysis in aqueous methanolic base. The infrared spectrum of this compound has, in addition to O—H stretching bands at 2.82 and 2.93 μ, a band at 9.85 μ, presumably analogous to that discussed above in the case of the spectrum of V. Oxidation of VII with chromium trioxide – pyridine gave 4-ethylenedioxycycloheptanone (VIII).[5] This was characterized by conversion to the bis-2,4-dinitrophenylhydrazone of 1,4-cycloheptanedione (15). The infrared spectrum of VIII is noteworthy for the presence of bands at 2.94 and 9.87 μ, which resemble bands in the spectrum of VII associated with the presence of the hydroxyl group in that compound. The band at 2.94 μ, however, is not accompanied by a non-associated O—H stretching band at lower wavelength as is the case in the spectra of most alcohols and, in particular, of VII. Further, passage of a benzene solution of VIII over a column of activated alumina failed to change its infrared spectrum, demonstrating the absence of any hydroxylic component. It must be concluded that the band at 2.94 μ is an overtone of the carbonyl-stretching band at 5.88 μ; Stolow (2) has recently shown that bands at 2.92 μ in the spectra of 4-hydroxycyclohexanone and 4-hydroxy-4-phenylcyclohexanone have a similar origin.

Studies of the effect of ring size on the location of the carbonyl-stretching bands of cycloalkanones have indicated that these bands are shifted to slightly longer wavelengths when the ring size is increased from six to seven (16). The spectra of the four cycloheptanones prepared here (see Table I) are in accord with this conclusion.

TABLE I

Carbonyl-stretching bands of cycloheptanones and corresponding cyclohexanones

EXPERIMENTAL[6]

Mixed cis- and trans-1,4-Cyclohexanediol Monobenzoate

The method used was that of Owen and Robins (5) as modified by Jones and Sondheimer (6). With commercial reagent chloroform as diluent instead of the specified ethanol-free chloroform a 49% yield (based on the diol) of mixed *cis*- and *trans*-1,4-cyclohexanediol monobenzoate, b.p. 162.5–166.5° at 3 mm,

[5]*Compound VIII has been prepared by an alternative route (14).*

[6]*The melting and boiling points are uncorrected. Pressure values <0.1 mm are nominal. The drying agent was magnesium sulphate, unless otherwise stated. The infrared spectra were calibrated against atmospheric water vapor or polystyrene.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was obtained (reported yield 59%, b.p. 175–178° at 0.2 mm (6)). When 40% ethanol-free chloroform in dichloromethane was substituted for ethanol-free chloroform as the diluent for the pyridine and dichloromethane for ethanol-free chloroform as the diluent for the benzoyl chloride a 57% yield of distilled *cis*- and *trans*-monobenzoate was obtained.

The above procedures gave a 25–30% crude yield of the by-products, *cis*- and *trans*-1,4-cyclohexanediol dibenzoate. These remained as a distillation residue and were partially saponified to yield more monobenzoate mixture. Dibenzoate mixture (60.5 g, 0.187 mole; once recrystallized from ethanol) was dissolved in 350 ml of 95% ethanol and 50 ml of water. To this mixture at reflux was added dropwise a solution of 7.5 g (0.19 mole) of sodium hydroxide in 50 ml of water. Fifteen hours after the beginning of the sodium hydroxide addition, most of the alcohol was distilled from the refluxing mixture. Extraction of the residual liquid with chloroform afforded 19.3 g (47%) of additional *cis*- and *trans*-monobenzoate, b.p. 173–175° at 4–5 mm.

4-Benzoyloxycyclohexanone (I)

The mixture of *cis*- and *trans*-1,4-cyclohexanediol monobenzoate was oxidized with chromium trioxide in aqueous acetic acid (6) to give 73–80% of recrystallized I, m.p. 63–64.5° (lit. (17) m.p. 63–64°); infrared bands (CCl_4): 5.80, 7.89, and 9.01 μ; *semicarbazone*: white leaflets, m.p. 190–191° (lit. (5) m.p. 195–196°).

4-Benzoyloxycycloheptanone Semicarbazone

A suspension of anhydrous potassium carbonate (1.20 g, 0.0088 mole) in a solution of 4-benzoyloxycyclohexanone (I) (40.0 g, 0.184 mole) in 700 ml of absolute ethanol was cooled in an ice–salt bath. A solution of *N*-nitrosomethylurethane (18) (28.6 g, 0.216 mole) in 660 ml of absolute ethanol was added with mechanical stirring at such a rate that the temperature of the reaction mixture was maintained at −9 to −3°. The addition required 11 hours. After warming slowly to room temperature over an additional 17.5 hours, the mixture (still containing enough free diazomethane to be slightly yellow) was filtered and glacial acetic acid (1.0 ml) was added to the filtrate. The volume of the colorless solution was reduced to about 60 ml by distilling the ethanol at 60 mm, and the concentrate was added to a filtered solution of semicarbazide hydrochloride (20.5 g, 0.184 mole) and anhydrous sodium acetate (31 g) in 205 ml of water, with the use of 55–60 ml of 95% ethanol to complete the transfer. The resulting mixture was stoppered, heated in a 75° water bath for 0.5 hour, and then left in the bath to cool slowly. After about 15 hours, the mixture was cooled to 0° to give the crystalline semicarbazone (47.4 g), m.p. 143–163°. This crude product was extracted with petroleum ether (30–60°) in a Soxhlet apparatus for 2 hours. The dried, extracted 4-benzoyloxycycloheptanone semicarbazone weighed 33.5 g (63%), m.p. 158–167°. Recrystallization from 60% ethanol gave two crops: (*a*) 22.3 g, m.p. 167–170°, and (*b*) 3.69 g, m.p. 164–168°. These were pure enough for preparative purposes and represented a 49% yield. An analytical sample, m.p. 169–170°, was prepared by three recrystallizations of the product of an earlier run. Anal. Calc. for $C_{15}H_{19}N_3O_3$: C, 62.27; H, 6.62; N, 14.52. Found: C, 62.43; H, 6.74; N, 14.28.

Similar experiments carried out using absolute methanol as the solvent during the ring expansion gave a 44–47% yield of once-recrystallized product in four to six crops, the later ones having melting points down to 160–165°.

4-Benzoyloxycycloheptanone (II)

4-Benzoyloxycycloheptanone semicarbazone (21.1 g, 0.073 mole) was placed in a continuous liquid–liquid extractor and dissolved in 135 ml of 10.5 *N* hydrochloric acid by swirling at room temperature. The resulting yellowish solution was diluted with 35 ml of water and continuously extracted with ether for 30 hours. After the first 6 hours, the original ether was replaced with a fresh portion. Both portions (each of about 200-ml volume) were washed once with 40 ml of water, once with 30 ml of 1 *N* aqueous potassium carbonate, and twice with saturated aqueous sodium chloride. When dried, filtered, and stripped of ether, the first portion yielded 17.6 g and the second 3.8 g of nearly colorless liquid residue. These residues were combined and distilled from a modified Claisen flask, yielding 13.64 g (81%) of II, as a colorless oil, b.p. 145–149° at 10^{-3} mm, n_D^{20} 1.5371; infrared bands (CCl_4): 5.80, 5.84 (shoulder), 7.89, 9.01 μ (a strong band at 10.94 μ in the spectrum of I is absent in the spectrum of this product).

Liberation of the ketone with nitrous acid (9) gave a 62% yield of identical product.

Anal. Calc. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94. Found: C, 72.12; H, 7.06.

4-Methoxycyclohexanone (III)

The sample of 4-methoxycyclohexanone (III) used had b.p. 107–108.5° at 50 mm and n_D^{20} 1.4553 (lit. (19) b.p. 84–85° at 11 mm, n_D^{24} 1.4550); infrared bands (CCl_4): 5.82, 9.11, and these medium-intensity bands absent from the spectrum of 4-methoxycycloheptanone (see below): 7.68, 8.76, 9.27, and 11.05 μ. This afforded a *semicarbazone*, m.p. 179.5–181°, constant on repeated recrystallization from methanol (lit. m.p. 178° (20), 183–185° (10)); infrared bands ($CHCl_3$): 2.83, 2.94, 5.91, 6.39, and the following distinct bands not found in the spectrum of 4-methoxycycloheptanone semicarbazone: 8.66, 8.77, and 10.86 μ.

4-Methoxycycloheptanone Semicarbazone

A solution of 4-methoxycyclohexanone (III) (25.6 g, 0.200 mole) in 760 ml of absolute ethanol was cooled to −5° in an ice–salt bath. Anhydrous potassium carbonate (1.30 g, 0.0094 mole) was suspended in it, and a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solution of *N*-nitrosomethylurethane (27.9 g, 0.212 mole) in 720 ml of absolute ethanol was added with mechanical stirring at such a rate that the temperature of the reaction mixture did not exceed −1°. On completion of the addition, which required 11 hours, stirring was discontinued, and the mixture was allowed to come slowly to room temperature. Thirty-eight hours after completion of the addition, the mixture (still yellow) was filtered. Most of the ethanol was distilled *in vacuo* and the yellowish residue was dissolved in 200 ml of ether and washed with three 50-ml portions of water and two of saturated aqueous sodium chloride. The ethereal phase was dried and concentrated by distillation of the solvent. This afforded 21.0 g of yellow residual liquid. The major portion (20.8 g) was dissolved in 10 ml of 95% ethanol and mixed with a solution of semicarbazide hydrochloride (16.4 g, 0.147 mole) and anhydrous sodium acetate (24.6 g) in 155 ml of water. The mixture was heated at 75–80° for 1 hour, cooled, and scratched, when the semicarbazone began to crystallize. After standing overnight at room temperature, the mixture was cooled at 0° to give 13.3 g (33%) of 4-methoxycycloheptanone semicarbazone, m.p. 171–173° (lit. (10) m.p. 175.5°), unchanged by two recrystallizations from 60% ethanol (mixture m.p. with the semicarbazone of III 164–170.5°); infrared bands ($CHCl_3$): 2.85, 2.96, 5.91, 6.40, and a band at 11.32 μ absent from the spectrum of the lower homologue. Anal. Calc. for $C_9H_{17}N_3O_2$: C, 54.25; H, 8.60. Found: C, 54.61; H, 8.78.

4-Methoxycycloheptanone (IV)

4-Methoxycycloheptanone semicarbazone (9.34 g, 0.0469 mole) was placed in a liquid–liquid continuous extractor and dissolved in 90 ml of 8 *N* hydrochloric acid. As water (20–30 ml) was added with cooling, a colorless oil appeared on the surface of the solution. This mixture was continuously extracted with three successive 100-ml portions of ether for these respective periods: (*a*) 7 hours, (*b*) 11.5 hours, and (*c*) 11 hours. Each ethereal extract was washed with one 20-ml portion each of water, aqueous 5% sodium bicarbonate, and saturated aqueous sodium chloride and dried. The total crude product (5.65 g) obtained on distillation of the ether was evaporatively distilled at 5 mm and 45° (bath temperature), affording 5.07 g (76%, 25% overall from III) of colorless 4-methoxycycloheptanone (IV), n_D^{22} 1.4632; infrared bands (CCl_4): 5.86, 9.11, and the following weak- to medium-intensity bands absent from the spectrum of 4-methoxycyclohexanone (III): 7.95, 10.30, 11.40, and 11.74 μ. Anal. Calc. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.52; H, 9.81.

4-Hydroxycycloheptanone (V)

Crude 4-benzoyloxycycloheptanone, prepared by treatment of the semicarbazone (1.78 g, 0.0062 mole) with nitrous acid (9), was suspended in 5.0 ml of 1.8 *N* aqueous sodium hydroxide, and the mixture was heated on a steam bath for 50 minutes, and finally refluxed for 25 minutes. The mixture was neutralized with concentrated hydrochloric acid and evaporated to dryness *in vacuo*. The residue was refluxed with chloroform (40 ml) for 3 hours, and the solution was decanted. This extract afforded crude V as a brown liquid. Evaporative distillation at 60–63° (bath temperature) and 1 mm yielded 0.29 g (37% overall) of partially crystalline V, n_D^{20} 1.4903 (liquid phase); infrared bands (CS_2): 2.82, 3.00, 3.43, 5.88 μ (about same intensity as 3.00 μ band, weaker than 3.43 μ band); ($CHCl_3$): 2.80, 2.97, 3.43, 5.90 μ (strongest band in spectrum). A portion of the liquid phase was used for analysis. Anal. Calc. for $C_7H_{12}O_2$: C, 65.60; H, 9.44. Found: C, 65.68; H, 9.42.

4-Ethylenedioxycycloheptanol (VII)

4-Benzoyloxycycloheptanone (II) (4.20 g, 0.0181 mole) and *p*-toluenesulphonic acid monohydrate (18 mg) were dissolved in 50 ml of benzene. Ethylene glycol (1.20 ml, 0.022 mole) was added, and the mixture was refluxed under a water separator for 3.2 hours. The cooled mixture was washed with three 10-ml portions of aqueous 5% sodium bicarbonate and two of water. After being dried over anhydrous potassium carbonate, the solution was decolorized by passing it over 1.0 g of Merck alumina; the alumina was washed with 35 ml of benzene. The combined eluates afforded 5.98 g of crude 4-ethylenedioxycycloheptyl benzoate (VI); infrared bands (CCl_4): 5.80, 7.88, 9.04 with shoulder at 9.12 μ; there was no hydroxyl absorption in the vicinity of 3 μ, and the ketone carbonyl shoulder which appears on the benzoate carbonyl band of II was absent.

The crude VI was hydrolyzed by refluxing with a solution of potassium hydroxide (1.50 g) in 50 ml of aqueous methanol (2:3 v/v) under nitrogen for 2.5 hours. Evaporative distillation of the product at 60–70° (bath temperature) and 1 mm afforded 4-ethylenedioxycycloheptanol (VII) (2.35 g, 76% overall from II) as a colorless, somewhat viscous liquid, n_D^{20} 1.4890; infrared bands ($CHCl_3$): 2.82, 2.93, 8.78, 8.89, 9.18, 9.85 μ (a weak band at 5.91 μ could indicate the presence of a trace of ketonic contaminant). Anal. Calc. for $C_9H_{16}O_3$: C, 62.76; H, 9.36. Found: C, 62.77; H, 9.11.

4-Ethylenedioxycycloheptanone (VIII)

Reagent grade pyridine (44 ml) was placed in the 250-ml extraction chamber of a continuous liquid–liquid extractor and cooled in tap water while chromium trioxide (4.4 g) was added in small portions with swirling (21). To the resulting suspension of chromium trioxide – pyridine complex was added 4-ethylenedioxycycloheptanol (VII) (2.31 g, 0.0134 mole) in pyridine (20 ml) with vigorous swirling, and the mixture was allowed to stand at room temperature for 18 hours. Saturated aqueous sodium sulphate (100 ml) was added, and the mixture was extracted continuously with ether for 24.5 hours. The extract was dried, filtered, and concentrated *in vacuo*. The residue was evaporatively distilled at 55–60° (bath temperature) and 1 mm, yielding VIII as a colorless liquid (1.52 g, 67%), n_D^{20} 1.4852 (lit. (14) b.p. 102° at 1.5 mm; n_D^{20} 1.4828);

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

infrared bands ($CHCl_3$): 2.94, 5.88, 8.79, 8.90, 9.10, 9.87 μ; no change in the relative intensities of the bands at 2.94, 5.88, and 9.87 μ was observed after passing 15–20 mg of this product in 5–6 ml of benzene over 200 mg of Merck alumina. Anal. Calc. for $C_9H_{14}O_3$: C, 63.51; H, 8.29. Found: C, 63.58; H, 8.34.

1,4-Cycloheptanedione Bis-2,4-dinitrophenylhydrazone

1,4-Cycloheptanedione bis-2,4-dinitrophenylhydrazone was prepared from VIII by the method of Shriner and Fuson (22). Two recrystallizations from pyridine afforded a yellow-orange hemisolvated product, m.p. 242–244° (lit. (15) m.p. 242.4–242.8° decomp. (unsolvated)). Anal. Calc. for $(C_{19}H_{18}N_8O_8)_2.C_5H_5N$: C, 49.10; H, 3.93; N, 22.64. Found: C, 48.85, 49.10; H, 3.75, 3.96; N, 22.49, 22.35.

THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF SOME 2-METHYL-Δ^2-OXAZOLINES AND 2-METHYL-Δ^2-THIAZOLINES*

M. A. Weinberger and R. Greenhalgh

In connection with hydrolysis studies of 2-methyl-Δ^2-oxazoline (I) we have determined its n.m.r. spectrum and those of related compounds. An interesting feature of the spectrum of I (Fig. 1) is the coupling of the 2-methyl protons with one set of the ring methylenes.

The methylene proton spectrum was analyzable as an A_2B_2 system with equal J_{AB}'s, the upper-field half being further split by the coupling with the methyl group. Since the methyl spectrum is a triplet the two methylene protons must couple equally with the methyl protons, indicating that, unless this equality is accidental, the molecule is very likely planar. The spectrum of the 2-methyl group in 2,5,5-trimethyl-Δ^2-oxazoline (II) also shows a triplet but in the case of 2,4,4-trimethyl-Δ^2-oxazoline (III) only a single

Issued as D.R.C.L. Report No. 385.

infrared bands ($CHCl_3$): 2.94, 5.88, 8.79, 8.90, 9.10, 9.87 μ; no change in the relative intensities of the bands at 2.94, 5.88, and 9.87 μ was observed after passing 15–20 mg of this product in 5–6 ml of benzene over 200 mg of Merck alumina. Anal. Calc. for $C_9H_{14}O_3$: C, 63.51; H, 8.29. Found: C, 63.58; H, 8.34.

1,4-Cycloheptanedione Bis-2,4-dinitrophenylhydrazone

1,4-Cycloheptanedione bis-2,4-dinitrophenylhydrazone was prepared from VIII by the method of Shriner and Fuson (22). Two recrystallizations from pyridine afforded a yellow-orange hemisolvated product, m.p. 242–244° (lit. (15) m.p. 242.4–242.8° decomp. (unsolvated)). Anal. Calc. for $(C_{19}H_{18}N_8O_8)_2.C_5H_5N$: C, 49.10; H, 3.93; N, 22.64. Found: C, 48.85, 49.10; H, 3.75, 3.96; N, 22.49, 22.35.

THE NUCLEAR MAGNETIC RESONANCE SPECTRA OF SOME 2-METHYL-Δ^2-OXAZOLINES AND 2-METHYL-Δ^2-THIAZOLINES*

M. A. Weinberger and R. Greenhalgh

In connection with hydrolysis studies of 2-methyl-Δ^2-oxazoline (I) we have determined its n.m.r. spectrum and those of related compounds. An interesting feature of the spectrum of I (Fig. 1) is the coupling of the 2-methyl protons with one set of the ring methylenes.

The methylene proton spectrum was analyzable as an A_2B_2 system with equal J_{AB}'s, the upper-field half being further split by the coupling with the methyl group. Since the methyl spectrum is a triplet the two methylene protons must couple equally with the methyl protons, indicating that, unless this equality is accidental, the molecule is very likely planar. The spectrum of the 2-methyl group in 2,5,5-trimethyl-Δ^2-oxazoline (II) also shows a triplet but in the case of 2,4,4-trimethyl-Δ^2-oxazoline (III) only a single

Issued as D.R.C.L. Report No. 385.

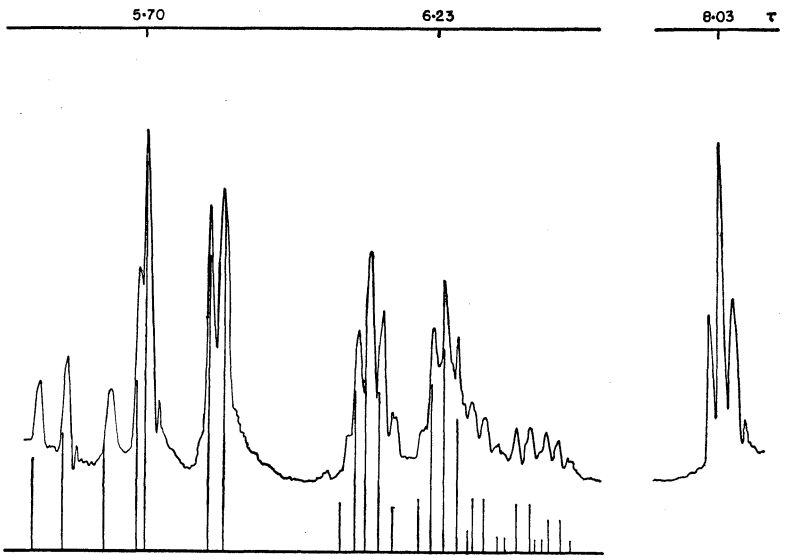

FIG. 1. The 60 Mc/s spectrum of 2-methyl-Δ^2-oxazoline in water. The theoretical spectrum for the CH_2—CH_2 portion was calculated as an A_2B_2 system with the parameters in Table I, and modified by the methyl group coupling.

peak is obtained. Thus it is the 4-position methylene protons which couple with the 2-methyl hydrogens.

The remainder of the spectrum of II consists of a low-field quartet for the methylene protons in the 4-position and a single peak for the *gem*-dimethyl protons. As expected, III only showed single peaks.

The corresponding thiazoline compounds were also investigated with similar results. 2-Methyl-Δ^2-thiazoline (IV) and 2,5,5-trimethyl-Δ^2-thiazoline (V) again show a triplet for the 2-methyl protons whilst a single peak is obtained for this set in 2,4,4-trimethyl-Δ^2-thiazoline (VI). The A_2B_2 system of IV was analyzable with $J_{AB} = J'_{AB}$, but here the half further split by the methyl protons occurs at lower field.

Long-range coupling between protons separated by five bonds has been observed previously, mainly in more highly conjugated systems (1(*a*), 2, 3). The coupling constants in our examples (1.38–1.65 c.p.s.) are comparable to that between the methyl protons of angelic acid (4), in which the trans type relationship of the groups and the degree of unsaturation are similar. In the latter cases, coupling is believed to involve hyperconjugation (1(*b*)).

Summarized in Table I are the spectral parameters together with the pK_a values for the various compounds.

The parallelism between pK_a and τ value of the N—CH_2 protons indicates that the factors which govern the electron density of the nitrogen atom similarly affect that of the hydrogen atoms. The τ values of the X—CH_2 protons depend on the electron-withdrawing character of X and are much lower for the oxazolines than for the thiazolines. In all cases substitution by *gem*-dimethyl groups increases the τ value of the unsubstituted CH_2 protons, as expected.

The τ values of the 2-methyl protons are mainly governed by X and are higher in the oxazoline series. It is believed that because of the mesomerism in oxazolines

†Reference 6.

(—O—C(CH_3)=N— ↔ —$\dot{O}$=C(CH_3)—$\bar{N}$—) there is less demand on the 2-methyl to supply electrons to the ring than in thiazolines.

In aqueous solutions of I the field positions of the 2-methyl protons are very dependent on pH, as shown in Fig. 2. This sigmoid curve, which presumably depicts the number-

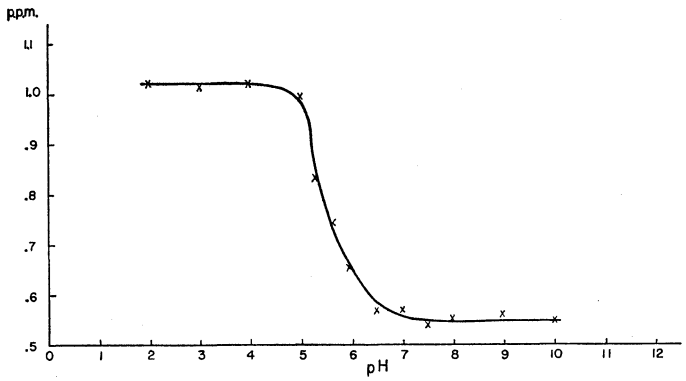

FIG. 2. Variation of chemical shift of methyl protons of 2-methyl-Δ^2-oxazoline with pH. Chemical shifts are referred to external cyclohexane.

average chemical shift of the protonated and unprotonated forms, is equivalent to a titration curve and the pK_a value deduced from it (5.5±0.1) agrees very closely with that shown in Table I. Similar chemical shift – pH curves have been reported for methyl groups attached directly to the nitrogen (7), but here the methyl protons are one atom further removed. The coupling constant $J_{CH_3-CH_2}$ also varies in an analogous manner from about 1.0 to 1.3 c.p.s. as the pH is increased.

EXPERIMENTAL

The n.m.r. spectra were determined on a Varian 4300*c* spectrometer at 60 Mc/s in CCl_4 solution (10% w/v). I was done in both H_2O (I(A), 40% w/v) and CCl_4 (I(B), 50% w/v). τ and J have standard deviations of 0.001–0.005 p.p.m. and 0.02–0.10 c.p.s. respectively.

All the compounds in Table I were prepared by the methods described by Wenker (8) and have physical properties in accord with those reported elsewhere (9, 10, 11). The pK_a values were determined in 0.1 *M* NaCl solution by titration of 2 m*M* base at 25°.

PYRIDINES FROM BASE TREATMENT OF BENZALMALONONITRILE

M. R. S. Weir, K. E. Helmer, and J. B. Hyne

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

In connection with a study of the reaction of benzalmalononitrile with basic reagents we have investigated its reaction with potassium hydroxide in methanol and ethanol.

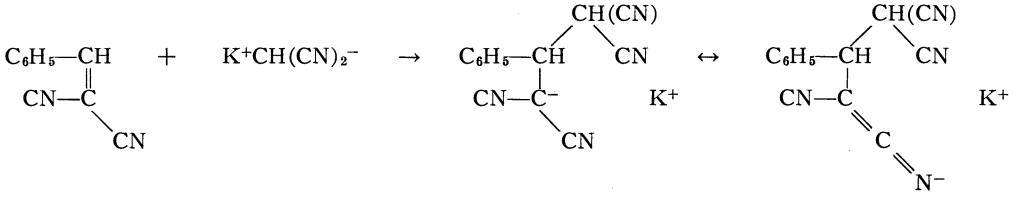
Infrared spectral analysis of the product mixture from reaction of benzalmalononitrile with molar potassium hydroxide in ethanol at room temperature gave clear indication of the presence of benzaldehyde. Isolation of the 2,4-dinitrophenylhydrazone of benzaldehyde from the reaction mixture verified that a reverse aldol condensation was taking place in the reaction. No evidence of the formation of malononitrile was found, however, and in particular the characteristic CH_2 scissoring mode absorption was absent in the infrared. The other product isolated from the product mixture was a high-melting crystalline solid obtained in 15–20% yield. The infrared spectrum of this product (Fig. 1*a*) has several striking features: a very strong absorption at 4.4 μ indicative of conjugated CN; a strong absorption in the region 2.8–3.0 μ suggesting the presence of an OH or NH_2 group; and a complex absorption pattern between 12.5 and 14.5 μ suggesting skeletal vibration modes of a ring structure other than those of the phenyl group. Addition of malononitrile to the reaction mixture resulted in a doubling of the yield of the high-melting crystalline solid.

The absence of malononitrile in the product mixture coupled with the observed increase in yield on addition of malononitrile suggested that the malononitrile entity produced in the reverse aldol reaction was undergoing further reaction with unchanged benzalmalononitrile to yield a cyclic pyridine structure.

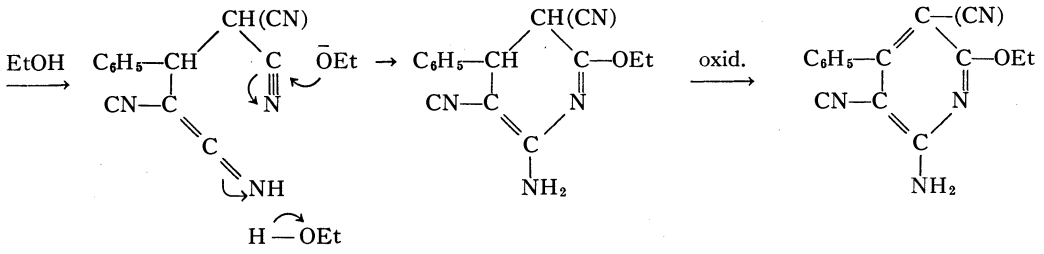
The formation of pyridines from 1,1,3,3-tetracyanopropenes by refluxing with concentrated sulphuric acid in alcohol solution has been previously reported (1). Urushibara (2) has also reported that ethoxymethylene malononitrile yields pyridines on refluxing with the sodium salt of malononitrile in alcohol. Comparison of the infrared spectrum of the high-melting crystalline product obtained from KOH treatment of benzalmalononitrile in methanol with that of an authentic sample of 2-amino-6-methoxy-3,5-dicyano-4-phenylpyridine (1) obtained by independent synthesis* showed that the two samples were identical. The n.m.r. spectra of the products from both ethanolic and methanolic KOH treatment (Figs. 1*c*, 1*d*) are in keeping with the fully substituted pyridine structures.

The experimental evidence noted above is in accord with the following proposed mechanism.

$$C_6H_5{-}CH{=}C(CN)_2 + KOH \rightarrow C_6H_5CHO + K^+CH(CN)_2^-$$



The authors are indebted to Dr. W. J. Middleton, Central Research Department, E. I. duPont de Nemours and Co., Wilmington, Delaware, for providing a sample of the fully substituted pyridine.



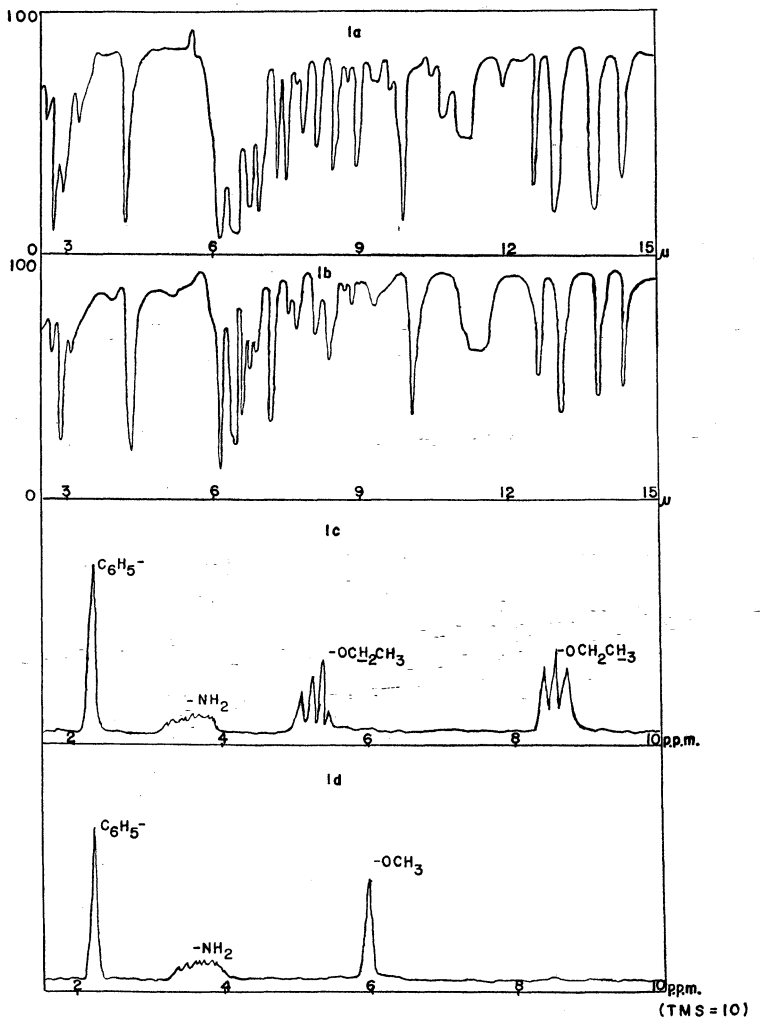


FIG. 1(*a*) The infrared spectrum of 2-amino-6-ethoxy-3,5-dicyano-4-phenylpyridine (KBr pellet).
(*b*) The infrared spectrum of 2-amino-6-methoxy-3,5-dicyano-4-phenylpyridine (KBr pellet).
(*c*) The n.m.r. spectrum of 2-amino-6-ethoxy-3,5-dicyano-4-phenylpyridine, 3–5% solution in CD_3CN. (CH_3—CN in CD_3—CN peak not shown.)
(*d*) The n.m.r. spectrum of 2-amino-6-methoxy-3,5-dicyano-4-phenylpyridine, 3–5% solution in CD_3CN. (CH_3—CN in CD_3—CN peak not shown.)

The low-field position and broadening of the NH_2 peak is due to hydrogen bonding with the CD_3—CN solvent.

The final oxidation step will obviously proceed very readily in view of the driving force to attain full aromatization of the ring. The oxidizing agent must be either aerobic oxygen or benzalmalononitrile. The latter possibility seems to be the more likely in view of the production of considerable quantities of tarry residue in the reaction probably resulting from the polymerization of the diene as it performs its role as an oxidizing agent.

It is clear from the above mechanism that variation of the solvent from methanol to ethanol will simply change the 6-alkoxy group. Both the methoxy and ethoxy pyridines were prepared and isolated, although characterization by identifying the product infrared spectrum with an authentic sample was carried out only in the methoxy case.

EXPERIMENTAL

Materials

Benzalmalononitrile was prepared by the method of Corson and Stoughton (3) by condensation of benzaldehyde with redistilled malononitrile in ethanol in the presence of catalytic amounts of piperidine. Recrystallization from ethanol gave benzalmalononitrile in 90% yield, m.p. 84.5–85° C (lit. 83.5–84° C). Reagent grade potassium hydroxide and commercial absolute ethanol and methanol were used without further purification.

Isolation of Benzaldehyde

Benzalmalononitrile (1 g, 0.0064 *M*) was stirred at room temperature for 6–8 hours in 50 ml of a molar solution of potassium hydroxide in ethanol. An aliquot of the resulting yellow solution was removed and treated with excess 2,4-dinitrophenylhydrazine reagent. This gave a solid derivative, m.p. 236–237 °C (lit. value for derivative of benzaldehyde 237° C). Mixed m.p. 236–237° C.

Isolation of Substituted Pyridine from Ethanol Solution

The remainder of the yellow product mixture solution noted above was poured into a large excess of water and the resulting precipitate filtered and recrystallized twice from 95% ethanol. The recovered pale yellow crystals were of 2-amino-6-ethoxy-3,5-dicyano-4-phenylpyridine, m.p. 235–236° C uncorr. (lit. 238–239° C). Analysis for $C_{15}H_{12}N_4O$: Calc.: C, 68.16; H, 4.58; N, 21.20. Found: C, 68.06; H, 4.50; N, 21.16. Infrared spectrum Fig. I*a*, n.m.r. spectrum Fig. I*c*.

Isolation of Substituted Pyridine from Methanol Solution

The procedure was the same as that used in the case of ethanol above but with absolute methanol as solvent. The recrystallized product had m.p. 259–260° C. Lit. value for m.p. of 2-amino-6-methoxy-3,5-dicyano-4-phenylpyridine 259–261° C. Mixed m.p. with authentic sample 260–261° C. Infrared spectrum Fig. 1*b*, n.m.r. spectrum Fig. 1*d*.

THE DECOMPOSITION OF HYDRAZINE VAPOR IN ELECTRICAL DISCHARGES[1, 2]

R. A. JONES AND S. S. BARTON

A review of work done on the vapor phase decomposition of hydrazine has been given by Audrieth and Ogg (1), who represent the stoichiometry of the decomposition reaction by the general equation

$$3N_2H_4 = 4(1-x)NH_3 + (1+2x)N_2 + 6xH_2. \quad [1]$$

Values of x range from 0.06 for thermal decomposition to 0.96 for photochemical reaction. Intermediate products have been reported by Rice and Scherber (2), who, using a high-speed flow system, at liquid nitrogen temperature, trapped ammonia and a yellow labile substance from thermally decomposed hydrazine vapor (stoichiometry of the overall reaction giving $x = 0.1$) and by Foner and Hudson (3), who detected several higher hydronitrogens as well as ammonia by mass spectrographic analysis of hydrazine vapor decomposed in an electrodeless microwave discharge.

In the investigation described in this note hydrazine vapor was decomposed by passage through an electrodeless discharge. The stoichiometry of the reaction is given by $x = 0.5$ in equation [1]. Under certain conditions small amounts of a labile yellow substance were observed.

EXPERIMENTAL

The discharge tube terminated in a cold finger trap and was pumped by a high-speed mercury diffusion pump. After leaving the discharge zone, the decomposed vapor was allowed to traverse a predetermined volume (traversed volume) before reaching the trap. The traversed volume was changed by moving the discharge zone along the tube.

A Tesla coil connected to a narrow copper band clamped around the discharge tube was used to drive the discharge. The predominant output frequency of the coil was determined by a high-speed oscilloscope to be about 0.2 Mc. By adjustment of the spark gap and input voltage, the coil could be set to give a reproducible reading on a vacuum tube voltmeter.

Hydrazine was prepared in the vacuum system by the thermal decomposition of hydrazinium phthalyl hydrazide (4), thoroughly outgassed and stored as a solid at 0°. Hydrazine flow rate into the discharge tube was fixed by a capillary tube flow control. The linear flow rate in the discharge tube was about 10 cm sec^{-1}, much smaller than that used by Rice and Scherber (2) (2900 cm sec^{-1}). Pressures were measured with a Consolidated Electrodynamics micromanometer.

At the end of the discharge period, the system was evacuated and isolated from the pumps. Then the liquid air was removed from the trap, whereupon the condensed product vaporized completely. The trap was then refilled with liquid air to recondense the vapors; at this stage there was always a residual pressure which was noted. The non-condensable gas ("evolved gas") thus measured is considered to be a measure of the amount of labile compound in the original condensed product. (Any occluded hydrogen or nitrogen will also be included in this determination.) Finally the recondensed product was distilled into a titration vessel containing an aliquot of standard hydrochloric acid. Excess acid was titrated with sodium hydroxide to give the total ammonia and hydrazine content. The titrated solution was then rapidly acidified and titrated again with standard potassium iodate for hydrazine (5).

RESULTS AND DISCUSSION

Figure 1 shows the variation with voltage of hydrazine loss and of ammonia yield at constant traversed volume for 30-minute experiments. These yields are plotted as a

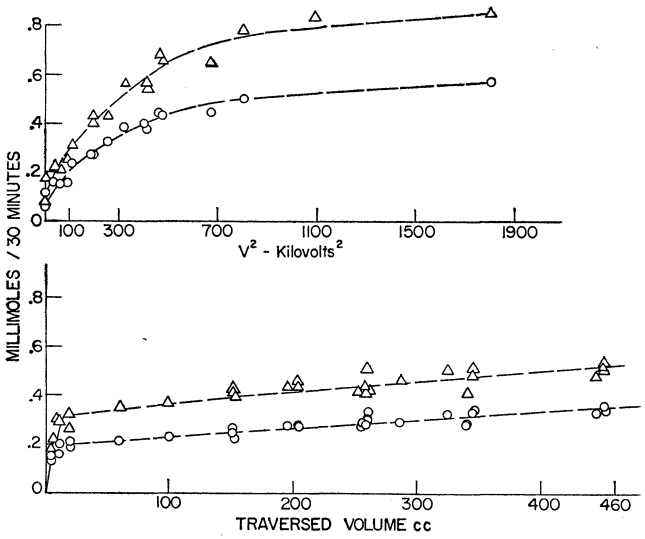

FIG. 1. Hydrazine loss and ammonia yield. Flow rate: 0.87 millimole/0.5 hr; pressure: 240±10 μ; upper figure: traversed volume = 196 cc; lower figure: voltage = 13.9 kv.

function of V^2 because Gill and Townsend found in a theoretical analysis of electrodeless discharges at electrical frequencies comparable to the molecular collision frequency of the gas (6) that the rate at which energy is transferred from the field to the gas by means of electron–molecule collisions is proportional to the square of the field strength. The apparent extent of decomposition of hydrazine for the overall reaction is about 21% for the lowest voltage to nearly 100% for the highest voltage used. The value of the ratio, millimoles ammonia produced to millimoles hydrazine lost, appears to be constant and independent of voltage over this range of percentage decomposition and is 0.69±0.03. This constant ratio is close to the value 0.67 demanded by

$$3N_2H_4 = 2NH_3 + 2N_2 + 3H_2 \text{ (i.e. } x = 0.5 \text{ in equation [1])}. \qquad [2]$$

Figure 1 also shows the variation of hydrazine loss and of ammonia yield at constant voltage with increasing traversed volume. The decomposition appears to proceed downstream away from the discharge zone in the same manner as in the discharge itself. Hydrazine is destroyed and ammonia formed in a constant ratio 0.65±0.04 independent of traversed volume up to the largest traversed volume allowed by the apparatus.

Figure 2 shows the influence of voltage and traversed volume on the production of evolved gas from the warmed product. The percentage yield of evolved gas (based on hydrazine loss) ranged from about 20% at low traversed volumes and low voltages to about 5% for the experiments done at higher traversed volumes and 13.9 kv. In the experiments done at very high voltages and 196-ml traversed volume the percentage yield approached zero. Possibly a certain amount of this evolved gas can be attributed to the presence of occluded or adsorbed nitrogen and hydrogen (7). However, this effect appears not to be significant, since the amount of gas drops to smaller values for larger apparent extent of hydrazine decomposition when the concentrations of nitrogen and hydrogen in the vapor impinging on the cold finger have higher values.

With increasing traversed volume, the amount of evolved gas suffers a rapid initial decrease followed by a much slower decrease as the traversed volume increases. The

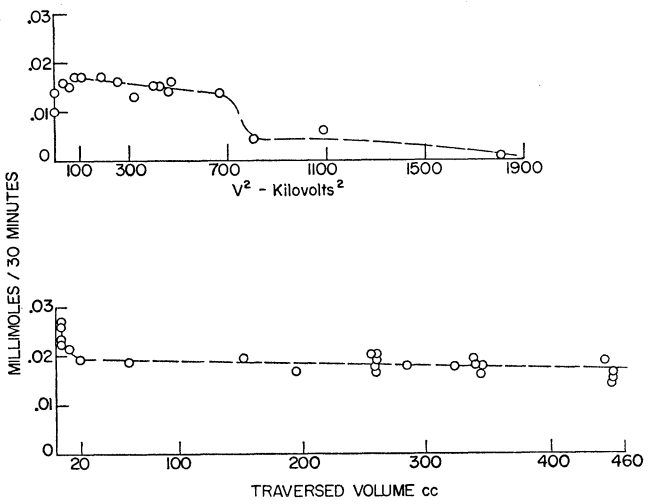

FIG. 2. Evolved gas. Flow rate: 0.87 millimole/0.5 hr; pressure: 240±10 μ; upper figure: traversed volume = 196 cc; lower figure: voltage = 13.9 kv.

condensed product was snow white in color except when formed from traversed volumes less than 10 cc, when it became straw-yellow.

The composition of the evolved gas was not systematically investigated during this work. However, one sample from an experiment done at 5.3-cc traversed volume (straw-yellow deposit) was analyzed by mass spectrometry and found to contain 16% H_2 and 84% N_2 by volume.[3]

Since the reaction in the traversed volume continues for an appreciable length of time after the gas has left the discharge, it is necessary to postulate the existence of some long-lived carriers of energy. These carriers could be activated hydrazine molecules formed by neutralization of hydrazine ions formed in the discharge, activated hydrazine molecules formed by electron collision in the discharge, or NH_2 radicals formed by the decomposition of such activated molecules. Both activated hydrazine molecules and NH_2 radicals are considered to re-form hydrazine on the cold finger. A mechanism for the reaction can be written as

$$N_2H_4^* \rightarrow 2NH_2 \qquad [3]$$

$$NH_2 + N_2H_4 \rightarrow NH_3 + N_2H_3 \qquad [4]$$

$$N_2H_3 \rightarrow N_2 + 3/2H_2. \qquad [5]$$

Reactions [3], [4], and [5] add up to give the overall stoichiometry which was observed (i.e. equation [2]). The immediate fate of the N_2H_3 radical is not clear. The vapor phase decomposition to hydrogen and nitrogen probably proceeds via the formation of other radicals and labile hydronitrogens. Rice and Scherber (2), using a high-speed flow system, regarded N_2H_3 as condensing to form their "tetrazane" (a yellow labile substance) at liquid nitrogen temperature in the thermal decomposition of hydrazine vapor:

$$2N_2H_3 \rightarrow N_4H_6. \qquad [6]$$

Tetrazane was then considered to decompose on warming according to

$$N_4H_6 \rightarrow 2NH_3 + N_2. \qquad [7]$$

With the mechanism postulated here this reaction cannot be taking place to any appreciable extent since the stoichiometric yield of ammonia has already been accounted for by reaction [4]. Foner and Hudson (3) have observed a similar yellow deposit from a microwave discharge in hydrazine vapor which vaporized to give diimide (N_2H_2) and ammonia but no nitrogen and thus was not Rice and Scherber's tetrazane.

It is possible in our case that the straw-yellow color of the deposits which yield larger amounts of evolved gas is that of N_4H_6 formed from N_2H_3 radicals on the cold wall. The disappearance of the yellow color, together with the decrease in evolved gas yield as traversed volume is increased, suggests that this radical is not present in large concentrations at higher traversed volumes.

The mechanism given above, which partially describes the observed reaction, is similar to that of Rice and Scherber's thermal decomposition mechanism except that the production of ammonia via the N_2H_3 radical is not considered to be significant. When a low flow rate is used, almost all the N_2H_3 radicals will decompose by an alternate route in the vapor phase to yield nitrogen and hydrogen. Only at very low traversed volumes do small amounts of N_2H_3 survive to reach the cold surface, where it forms tetrazane, which gives the deposit a straw-yellow color and increases the yield of evolved gas.

AN EXPLOSION WITH METHYL AZIDE[1]

C. L. Currie[2] and B. deB. Darwent

A violent explosion which occurred during the course of an investigation of the vapor-phase photolysis of methyl azide led us to investigate the cause of the phenomenon and especially the influence of impurities.

Approximately 1 liter of methyl azide gas at N.T.P., mixed with a smaller quantity of propane, had been condensed in a trap which was separated from the rest of the vacuum system by a mercury cutoff. The mixture had been warmed, until the vapor pressure was approximately 20 mm Hg, when the level of the mercury cutoff was lowered. The explosion occurred as soon as the mercury started to drop rapidly in the cutoff.

Attempts to reproduce the explosion, on a smaller scale, by causing mercury to move rapidly in a closed-arm manometer were unsuccessful whether the azide was pure or mixed with propane, stored in the dark, or exposed to the laboratory illumination. However, the explosion could be induced by the discharge of a Tesla coil. In those experiments

With the mechanism postulated here this reaction cannot be taking place to any appreciable extent since the stoichiometric yield of ammonia has already been accounted for by reaction [4]. Foner and Hudson (3) have observed a similar yellow deposit from a microwave discharge in hydrazine vapor which vaporized to give diimide (N_2H_2) and ammonia but no nitrogen and thus was not Rice and Scherber's tetrazane.

It is possible in our case that the straw-yellow color of the deposits which yield larger amounts of evolved gas is that of N_4H_6 formed from N_2H_3 radicals on the cold wall. The disappearance of the yellow color, together with the decrease in evolved gas yield as traversed volume is increased, suggests that this radical is not present in large concentrations at higher traversed volumes.

The mechanism given above, which partially describes the observed reaction, is similar to that of Rice and Scherber's thermal decomposition mechanism except that the production of ammonia via the N_2H_3 radical is not considered to be significant. When a low flow rate is used, almost all the N_2H_3 radicals will decompose by an alternate route in the vapor phase to yield nitrogen and hydrogen. Only at very low traversed volumes do small amounts of N_2H_3 survive to reach the cold surface, where it forms tetrazane, which gives the deposit a straw-yellow color and increases the yield of evolved gas.

we found the presence of a small amount of mercury to be essential to the explosion. In a large number of experiments in which mercury was carefully excluded no explosion occurred when either pure azide or azide–propane mixtures were subjected to the Tesla discharge. Explosions always occurred when mercury was added to the system and the discharge applied.

These experiments show that methyl azide, if pure, is a relatively safe substance but that a trace of mercury makes the mixture extremely treacherous. This suggests that the explosion was initiated by a shock wave set up by the detonation of minute crystals of mercury azide. The detonation of the mercury azide was possibly caused by the friction of mercury on glass.

ALKYLALUMINUM HYDRIDE TRIMETHYLAMINE COMPLEXES

F. M. PETERS, B. BARTOCHA,[1] AND A. J. BILBO

U.S. Naval Ordnance Laboratory, Corona, California, U.S.A.

Received November 19, 1962

ABSTRACT

Alkylaluminum hydride trimethylamine complexes have been obtained by several different methods: (*a*) reduction of an alkylaluminum halide trimethylamine complex with lithium hydride, (*b*) alkylation of aluminum hydride trimethylamine with dialkylmercury, (*c*) reaction of trialkylaluminum trimethylamine and aluminum hydride trimethylamine, and (*d*) reaction of dialkylaluminum chloride with lithium aluminum hydride and trimethylamine. Some physical properties of the compounds are reported, including the infrared and proton magnetic resonance spectra. Cryoscopic molecular weight determinations indicate that the compounds are associated in cyclohexane. Their possible structures are discussed.

INTRODUCTION

Trimethyldialuminum trihydride, $(Me_3Al_2H_3)_n$, and dimethylaluminum hydride, $(Me_2AlH)_n$, were originally prepared by subjecting a mixture of trimethylaluminum and hydrogen to an electric discharge (1). The latter compound was subsequently obtained from the reaction of trimethylaluminum and lithium aluminum hydride (2). Higher alkyl monohydrides have since been prepared (3, 4), but no uncomplexed dihydrides have been characterized. Since trivalent aluminum has empty $3p$ and $3d$ orbitals in addition to the three sp^2 hybrid bonding orbitals, it can further hybridize to make one or two additional orbitals available for coordination with electron donor groups. There are many examples of coordination compounds of this type, among them $AlH_3 \cdot NMe_3$, $AlH_3 \cdot 2NMe_3$, and $Et_3Al \cdot OEt_2$.

The coordinating power of aluminum suggested the possibility of stabilizing the alkylaluminum dihydrides by complex formation with a Lewis base. This was shown to be the case with the isolation of the stable trimethylamine complexes $EtAlH_2 \cdot NMe_3$ and $MeAlH_2 \cdot NMe_3$. The methylaluminum and ethylaluminum monohydride trimethylamine complexes were also prepared (5). In the following equations, which summarize the methods of synthesis, R = CH_3— and C_2H_5—. The reaction between ethylaluminum dichloride trimethylamine and lithium hydride did not yield a product free of chlorine.

$$\begin{aligned} Et_2AlCl \cdot NMe_3 + LiH &\longrightarrow Et_2AlH \cdot NMe_3 + LiCl \\ EtAlCl_2 \cdot NMe_3 + 2LiH &\longrightarrow EtAlH_2 \cdot NMe_3 + 2LiCl \end{aligned} \qquad [A]$$

$$\begin{aligned} R_2Hg + AlH_3 \cdot NMe_3 &\longrightarrow R_2AlH \cdot NMe_3 + H_2 + Hg \\ \tfrac{1}{2}R_2Hg + AlH_3 \cdot NMe_3 &\longrightarrow RAlH_2 \cdot NMe_3 + \tfrac{1}{2}H_2 + \tfrac{1}{2}Hg \end{aligned} \qquad [B]$$

$$AlH_3 \cdot NMe_3 + 2R_3Al \cdot NMe_3 \longrightarrow 3R_2AlH \cdot NMe_3$$
$$2AlH_3 \cdot NMe_3 + R_3Al \cdot NMe_3 \longrightarrow 3RAlH_2 \cdot NMe_3 \qquad [C]$$

$$R_2AlCl + LiAlH_4 \xrightarrow{NMe_3} 2RAlH_2 \cdot NMe_3 + LiCl \qquad [D]$$

EXPERIMENTAL

Apparatus

Because the alkylaluminum compounds are sensitive to air and moisture, all synthetic work was carried out either in a high-vacuum system or in a nitrogen atmosphere. Transfers were conducted in an inert atmosphere chamber.[2] For the vapor tension measurements of the triethylaluminum complex, a tensimeter was used (6).

Preparation of Starting Materials

Commercially available lithium hydride (75% pure, based on hydrogen evolution) and lithium aluminum hydride (95% pure) were obtained from Metal Hydrides, Inc. Lecture bottles of the organoaluminum starting materials were supplied by the Ethyl Corporation and Texas Alkyls, Inc. Anhydrous aluminum trichloride was obtained from Matheson Company, Inc. All other starting materials were prepared in this laboratory.

A method based on the procedure of Wiberg, Graf, and Usón (7) was used to prepare aluminum hydride trimethylamine. Lithium aluminum hydride, 32 g (0.8 mole), was refluxed in 500 ml of diethyl ether for 4 hours. After the insoluble material had settled to the bottom of the flask, the supernatant liquid was filtered into a 1-liter flask. An ether solution of 25 g (0.2 mole) of aluminum trichloride was added to the $LiAlH_4$ solution with continuous stirring. After 20 minutes, 50 ml (0.6 mole) of trimethylamine, dissolved in cold ether, was added to the reaction mixture. The product was collected by filtering the supernatant liquid of the reaction mixture, removing the ether under vacuum, and subliming the residue at 60° C (1 mm Hg). The pure $AlH_3 \cdot NMe_3$ melted at 76° C and was free of chlorine. The yield was 65% based on $AlCl_3$. Anal. Calc. for $C_3H_{12}NAl$: C, 40.44; H, 13.57; N, 15.72; Al, 30.28. Found: C, 40.42; H, 13.94; N, 15.49; Al, 30.53.

Triethylaluminum trimethylamine was made on the vacuum line, by the reaction of a hexane solution of Et_3Al and gaseous trimethylamine. The product, after purification by vacuum distillation, boiled at 38–39° C (10^{-3} mm Hg). Anal. Calc. for $C_9H_{24}NAl$: C, 62.38; H, 13.96; N, 8.09; Al, 15.57. Found: C, 62.68; H, 14.25; N, 8.30; Al, 16.03. Vapor pressure data and additional physical properties of triethylaluminum trimethylamine are shown in Tables I and II.

Ethylaluminum dichloride (9) was prepared by refluxing a mixture of aluminum trichloride (8.7 g, 0.065 mole) and Et_2AlCl (7.8 g, 0.065 mole). The purified material boiled at 54–55° C (1 mm Hg) and melted at 32° C.

Dimethylmercury and diethylmercury were prepared by reaction of an excess of alkylmagnesium bromide with mercuric chloride in ethyl ether (10).

Preparation of Reaction Intermediates

In order to understand the nature of the intermediates in the reactions of lithium hydride and alkylaluminum chlorides, the trimethylamine adducts of the alkylaluminum chlorides were prepared. Two methods led to the same products: (*a*) direct union of the reactants, and (*b*) their reaction in ethyl ether. In the presence of excess trimethylamine only the monoamine adducts were formed. The diethyl compound melted at −33 to −32° C. Anal. Calc. for $C_7H_{19}ClNAl$: Cl, 19.74; Al, 15.02. Found: Cl, 20.23; Al, 15.52. Ethylaluminum dichloride trimethylamine melted at 50–52° C. Anal. Calc. for $C_5H_{14}Cl_2NAl$: C, 32.27; H, 7.58; Cl, 38.11; N, 7.53; Al, 14.50. Found: C, 31.76; H, 7.74; Cl, 38.02; N, 7.58; Al, 14.04.

Preparation of Diethylaluminum Hydride Trimethylamine

Method A

Diethylaluminum chloride, 19.0 g (0.16 mole), was placed in 250 ml of diethyl ether in a three-necked, 500-ml flask equipped with reflux condenser and drying tube, N_2 gas inlet, and NMe_3 gas inlet. Excess trimethylamine was bubbled into the solution, which was kept at −20° C for 1 hour. After the ether solution of $Et_2AlCl \cdot NMe_3$ had reached room temperature, 1.7 g of powdered 75% LiH (0.16 mole pure LiH) was added. The reaction mixture was then maintained at reflux temperature for 9 hours. The solids were allowed to settle overnight. The clear supernatant liquid was filtered into a distilling flask, and the ether was removed in vacuum. During the slow, high-vacuum distillation that followed, the distillation flask was kept at 40° and the receiving trap at −196° C. A sample of the distillate redistilled at 63–65° C (1 mm Hg). The melting point was −28° C. Methanolysis of a 0.2643 g sample gave the following results: calc. for H_2: 40.8 ml at S.T.P., found: 39.6 ml; calc. for Al: 18.58%, found: 18.86%. The analytical data are summarized in Table III.

Method B

Aluminum hydride trimethylamine, 4.0 g (0.045 mole), was placed in a three-necked, 500-ml flask, and 250 ml of hexane was added. A hexane solution of diethylmercury, 11.6 g (0.045 mole), was added dropwise to the $AlH_3 \cdot NMe_3$ with stirring and heating. A grey precipitate of mercury was visible after 10 minutes of reaction. The system was kept at 60° C for 4 hours and then permitted to stand for 5 days at room temperature. The supernatant liquid was filtered into a distilling flask, and the solvent was removed in vacuum. Purification of the residue by high-vacuum distillation produced a liquid that boiled at 63–65° C (1 mm Hg). Methanolysis of a 0.4363-g sample gave the following results: calc. for H_2: 67.2 ml at S.T.P., found: 61.2 ml; calc. for Al: 18.58%, found: 19.19%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Method C

Triethylaluminum trimethylamine, 4.0 g (0.023 mole), and 1.0 g (0.011 mole) of $AlH_3 \cdot NMe_3$ were placed in a flask and heated with stirring for 30 minutes at 40°. Stirring was continued for 2 hours at room temperature. Distillation yielded a compound boiling at 63–64° C (1 mm Hg).

Preparation of Ethylaluminum Dihydride Trimethylamine

Method A

Several attempts to synthesize the ethylaluminum dihydride amine complex by using lithium hydride in ethyl ether were only partially successful. Although reduction took place, as indicated by the presence of an Al—H band in the infrared spectrum of the reaction mixture, no compound free of chlorine could be obtained.

Method B

The compound was prepared by Method B and gave the following hydrolytic results for a 0.4828-g sample: calc. for H_2: 184.7 ml at S.T.P., found: 181.0 ml; calc. for Al: 23.03%, found: 22.93%.

Method C

The compound was also prepared by Method C given above.

Method D

A solution of 5.9 g (0.155 mole) $LiAlH_4$ in 300 ml of ether was prepared. To this was added dropwise 18.6 g (0.155 mole) of Et_2AlCl in ether. White solids began to precipitate immediately. After the mixture had been refluxed for 20 minutes the solids were allowed to settle, the liquid was filtered into a flask, and the ether was removed in vacuum. A gelatinous material remained. A portion of the gelatinous residue was allowed to react with gaseous trimethylamine. The mixture became quite warm and liquefied while ether and some hydrogen were evolved. A grey solid, presumably metallic aluminum, also formed. When the reaction mixture was subjected to vacuum in a sublimation apparatus, a small amount of white solid collected on the cold finger. According to the melting point (88–92° C) it was $AlH_3 \cdot 2NMe_3$ (7). Fractionation under vacuum of the liquid residue yielded $EtAlH_2 \cdot NMe_3$ as well as some $Et_2AlH \cdot NMe_3$ (the latter was identified by its infrared spectrum and boiling point).

Preparation of Dimethylaluminum Hydride Trimethylamine

Dimethylaluminum hydride trimethylamine was prepared according to Methods B and C. It is interesting that dimethylaluminum chloride, following treatment with trimethylamine in ether solution, was found unreactive toward lithium hydride at 36° C.

Preparation of Methylaluminum Dihydride Trimethylamine

Successful preparation was effected by Methods B, C, and D. A variation of Method D, where the hydride was not isolated from solution prior to addition of trimethylamine, yielded only $MeAlH_2 \cdot NMe_3$. This behavior is in contrast to the corresponding ethyl reaction, where both the monohydride and dihydride were found among the reaction products.

Analytical Results

The alkylaluminum hydride trimethylamine complexes were purified by vacuum distillation and were analyzed for the elements. The analytical results,[3] melting points,[4] and boiling points of the compounds are shown in Table III. The capital-letter designations under the column heading "Anal. found" refer to the methods of synthesis used.

Molecular Weights

Molecular weights were determined cryoscopically in an airtight glass apparatus fitted with a magnetically driven stirrer.[5] The alkylaluminum hydride trimethylamine solutions in cyclohexane were prepared in the dry box. Outside the dry box the charged airtight glass vessel was placed in the ice-cooled glass jacket of the cryoscopic molecular weight apparatus and the electromagnet that drives the stirrer was attached. The freezing point of pure solvent was determined immediately prior to each solution determination. The apparent molecular weights of the alkylaluminum hydride trimethylamine complexes are given in Table IV.

Spectral Data

A model IR-5 Beckman double-beam infrared spectrophotometer with sodium chloride optics was used to record spectra. A NaCl cell with a 0.001-in. lead spacer was used for the samples. The major absorptions in the infrared of the new alkylaluminum complexes are summarized in Table V.

Proton magnetic resonance spectra of the alkylaluminum hydride trimethylamine complexes in cyclohexane solution, tabulated in Table VI, were obtained at 60 Mc, using a Varian model V-4302 nuclear magnetic resonance spectrometer.

[3]*Elemental analyses were conducted by the Schwarzkopf Microanalytical Laboratory, Woodside, New York.*

[4]*Melting points are uncorrected and were determined by the capillary method or the Stock magnetic plunger technique, depending upon the physical state of the material at room temperature.*

DISCUSSION

Synthetic Methods

The reduction of $Et_2AlCl \cdot NMe_3$ to $Et_2AlH \cdot NMe_3$ with lithium hydride was found to be more sluggish than the corresponding reaction using Et_2AlCl-etherate (3). Approximately half the calculated amount of hydride was collected after 9 hours of refluxing of the reactants in ether solution. Times up to 24 hours were used to attempt the lithium hydride conversion of $EtAlCl_2 \cdot NMe_3$ to $EtAlH_2 \cdot NMe_3$. Partial conversion was attained in numerous instances; a strong Al—H absorption repeatedly appeared in the infrared spectra of the ether-soluble fractions of the reaction mixtures. The pure dihydride, free of chlorine, was never obtained, however. In contrast to the diethyl compound, dimethylaluminum chloride trimethylamine did not react with lithium hydride in refluxing ether. Consequently, reduction of methylaluminum dichloride trimethylamine was not attempted.

Replacement of the hydrogen atoms in $AlH_3 \cdot NMe_3$ and $LiAlH_4$ by alkylmercury and arylmercury compounds has been shown to be a general reaction. A mechanism for the reaction has been proposed (11,12). Divinylmercury (13) and bisperfluorovinylmercury (14) react analogously with aluminum hydride trimethylamine, the latter reaction being violent at room temperature in ethyl ether. The partial substitution of alkyl groups for hydrogen on $AlH_3 \cdot NMe_3$ was accomplished by carefully controlling the stoichiometry of the reactants. Diethylmercury was found slightly more reactive towards $AlH_3 \cdot NMe_3$ than dimethylmercury. Hexane was found to be a better reaction medium than ether, even though the $AlH_3 \cdot NMe_3$ is insoluble in hexane, because a higher reaction temperature could be employed. A temperature of 60° C for several hours was usually required to complete the reaction. The yields of products were high since the evolution of hydrogen and the precipitation of mercury cause the equilibrium to shift continually to the right.

The mixing of stoichiometric quantities of $R_3Al \cdot NMe_3$ and $AlH_3 \cdot NMe_3$ has led to nearly quantitative yields of the alkylaluminum hydride compounds. Nuclear magnetic resonance spectra, boiling points, and cryoscopic molecular weight determinations have indicated that single compounds are formed in each case and not equilibrium mixtures containing the reactants.

Whereas reaction of Groups I and II metal alkyls with lithium aluminum hydride leads to the formation of the corresponding metal hydrides (15), the trialkyls of boron, aluminum, and gallium react according to the equation (2)

$$LiAlH_4 + R_3M \rightarrow R_2AlH + LiMRH_3.$$

It must be pointed out, however, that the reactions of Groups I and II metal alkyls with lithium aluminum hydride were carried out in diethyl ether whereas those of Group III were accomplished in the absence of solvent. To check the possibility of further exchange in the reaction of trialkylaluminum and lithium aluminum hydride, the reaction was conducted in diethyl ether using a 3:1 molar ratio of $LiAlH_4$ to Me_3Al. The product was first isolated as the etherate, and was subsequently treated with trimethylamine for easy identification. Only the monohydride was found, indicating that R_2AlH is the reaction product in the absence of or in the presence of diethyl ether. Thus, the formation of the alkylaluminum dihydride trimethylamine complexes by reaction of lithium aluminum hydride and dialkylaluminum halide with subsequent addition of trimethylamine may proceed by the following route:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$LiAlH_4 + R_2AlX \xrightarrow{Et_2O} R_2AlH + [LiAlH_3X] \downarrow LiX + AlH_3$$

$$AlH_3 + R_2AlH \rightarrow 2RAlH_2 \xrightarrow{NMe_3} 2RAlH_2 \cdot NMe_3.$$

In the case of R = methyl, the reaction product is all $MeAlH_2 \cdot NMe_3$. The corresponding reaction where R = ethyl yields a mixture of $EtAlH_2 \cdot NMe_3$, $Et_2AlH \cdot NMe_3$, and $AlH_3 \cdot 2NMe_3$, possibly indicating that the combination of AlH_3 and Et_2AlH did not proceed to completion before trimethylamine was introduced into the system. Since excess trimethylamine was used, the very stable $AlH_3 \cdot 2NMe_3$ was formed. This compound does not appear to react with either $R_3Al \cdot NMe_3$ or $R_2AlH \cdot NMe_3$.

Physical Properties

At room temperature the ethylaluminum and the monomethylaluminum hydride trimethylamine complexes are mobile liquids that can be distilled without disproportionation or dissociation under high vacuum. The dimethylaluminum complex is a low-melting solid which sublimes readily under vacuum at room temperature without change. However, the evolution of trimethylamine from each of the complexes was observed during the attempt to obtain their mass spectra at a pressure of 10^{-7} mm Hg. The complexes appear to be unstable at temperatures above 80° C.

The molecular weight determinations show that the methylaluminum and ethylaluminum hydride trimethylamine complexes are associated in cyclohexane. The degree of association appears to be a function of the number and the size of the alkyl groups attached to aluminum (Table IV). Thus, steric hindrance seems to offset the tendency for aluminum to increase its coordination number to 5 by using 3*d* orbitals in its hybridization. If the association is occurring by way of hydrogen bridges, then the hybridization of pentacoordinated aluminum must be considered. If two symmetrical bipyramids are joined on an edge by two hydrogen atoms, each aluminum atom will exhibit the sp^3d state. However, according to the estimate of the Al—H bridge distance in the aluminum hydride trimethylamine dimer by Ruff and Hawthorne (16), the Al—Al bond distance will be less than twice the normal covalent radius of aluminum in the sp^3d structure. Gillespie (17) has proposed an sp^3spd hybridization for the carbon atom which utilizes three normal sp^3 orbitals and two equivalent *spd* orbitals which are formed from the remaining sp^3 orbital and a 3*d* orbital. Ruff and Hawthorne find that a reasonable Al—Al bond distance can be calculated from the sp^3spd interpretation of the aluminum atom and their estimated Al—H bridge distance. A similar interpretation appears reasonable in the case of the analogous alkyl dimers. If the double hydrogen bridge is considered to be rigid, several isomers of each compound in the dimeric state are expected. The resulting nonequivalent alkyl groups may contribute to the methyl and methylene splitting observed in the nuclear magnetic resonance spectra of the alkylaluminum hydride amines (Table VI).[6] It must be pointed out, however, that a number of species may be present in a solution of each of the compounds in cyclohexane, since cryoscopy gives only an average molecular weight value of the species under consideration. Hence, the existence of the dimer is only postulated. The phenomenon of association may even be the result

[6]*A referee has suggested that the splitting observed may be explained in terms of an alternate structure for the dimer which involves bridging methyl or ethyl groups. Low-temperature n.m.r. studies will be required to determine the cause of the splitting.*

of dipole–dipole interactions rather than hydrogen bridging. Further studies are required to elucidate the structures and the modes of association in these electron-deficient aluminum compounds.

ACKNOWLEDGMENTS

The authors wish to thank D. W. Moore of the U.S. Naval Ordnance Test Station, China Lake, California, for the n.m.r. spectra. We desire to express our appreciation also for the continued interest of Drs. Charles P. Haber and Peter J. Slota of the Naval Ordnance Laboratory, Corona. The financial support by the Advanced Research Projects Agency through the Navy Department, Bureau of Naval Weapons, is also gratefully acknowledged.

REACTION OF CHROMYL CHLORIDE WITH SOME OLEFINS

PART I. THE PRODUCTS FROM CYCLOHEXENE, CYCLOPENTENE, 1-HEXENE, AND 2-METHYL-1-PENTENE

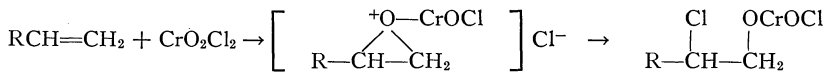
ABSTRACT

Chromyl chloride in carbon tetrachloride solution reacts in the cold with cyclohexene, cyclopentene, and 1-hexene to give the various isomeric chlorohydrins as the major products. The major product from 2-methyl-1-pentene was 2-methylpentanal. Significant amounts of α-chloro carbonyl compounds and some α,β-unsaturated carbonyl compounds were also produced. The significance of these results is discussed.

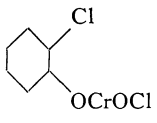
INTRODUCTION

The reaction of chromyl chloride with olefins has received little attention in contrast to the better known Étard reaction, involving the oxidation of an alkyl side chain of an aromatic hydrocarbon. Étard (1), and later Henderson and others (see references quoted in ref. 2), oxidized olefinic terpenes to obtain brown complexes containing about two atoms of chromium per molecule of olefin. On hydrolysis these complexes yield aldehydes, ketones, and chlorinated compounds that were for the most part unidentified. The first significant study of the chromyl chloride – olefin reaction was made by Cristol and Eilar (3). They reported that oxidation of cyclohexene gave *trans*-2-chlorocyclohexanol, and a series of terminal olefins yielded the chlorohydrins corresponding to anti-Markownikoff addition of hypochlorous acid. It was postulated that only 1 mole of chromyl chloride took part in the main reaction. This was later verified by Stairs (4).

From these results it was concluded that the reaction involves electrophilic attack on the double bond by an oxygen of chromyl chloride. A cyclic oxonium ion intermediate would then account for the observed positional isomerism and stereoisomerism.



More recently Sulima and Gragerov (5) have shown by use of O^{18} tracers that in the case of cyclohexene all the oxygen in the 2-chlorocyclohexanol comes from the chromyl chloride. This suggests that the most probable structure of the complex is A (or as is highly likely, a polymer of A containing cyclohexane and chlorochromate residues, possibly linked through oxygen–chromium bridges) and that hydrolysis involves the O—Cr bond of the chlorochromate IV ester.



A

Reinvestigation of the chromyl chloride – olefin reaction, using gas chromatography to separate the products, has revealed a number that were previously unreported. The nature of these products permit certain speculations regarding the mechanism of the reaction.

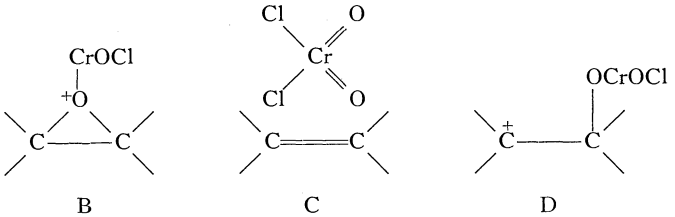
RESULTS AND DISCUSSION

Reaction of chromyl chloride with cyclohexene in carbon tetrachloride solution gave a nearly quantitative yield of a brown precipitate assumed to be $C_6H_{10} \cdot CrO_2Cl_2$. Hydrolysis with aqueous sodium bisulphite followed by distillation gave as the major fraction what was believed to be *trans*-2-chlorocyclohexanol. However, infrared spectral comparison of this product with authentic samples of *cis*- and *trans*-2-chlorocyclohexanol indicated that the product of the oxidation was a mixture of both isomers. This was confirmed by the preparation of both α-naphthylurethan derivatives, and by quantitative analysis with alkali (6). Treatment of the product mixture with α-naphthylisocyanate afforded the derivative of the trans chlorohydrin in a fairly pure state. To obtain the derivative of the cis chlorohydrin, the trans isomer was converted to cyclohexene oxide by treatment with aqueous alkali and removed from the mixture by distillation. Since this treatment was essential, the failure of Cristol and Eilar to detect the cis isomer is easily understood.

The more volatile fractions of the distillate showed infrared absorptions at 1710 and 1680 cm^{-1} which were attributed to a non-conjugated and an α,β-unsaturated ketone. Chromatography on a Bentonite–Celite column of the 2,4-dinitrophenylhydrazone obtained from this fraction resulted in separation of the 2,4-dinitrophenylhydrazones of cyclohexanone and Δ^2-cyclohexenone (7). Quantitative estimation was made of the reaction of 0.167 mole of cyclohexene with 0.160 mole of chromyl chloride. The yields (in parentheses) of the products formed were: *trans*-2-chlorocyclohexanol (21%), *cis*-2-chlorocyclohexanol (14%), cyclohexanone (5.5%), Δ^2-cyclohexenone (17%). In addition 21% of unreacted cyclohexene was recovered, and 21.5% was unidentified high-boiling material. A similar oxidation of cyclopentene yielded *trans*-2-chlorocyclopentanol (6%), *cis*-2-chlorocyclopentanol (18%), and a small amount of 2-chlorocyclopentanone.

The reaction of 1-hexene with an equimolar amount of chromyl chloride gave a liquid which was separated by preparative gas chromatography into five chromatographically pure products. These were found to be 2-chloro-1-hexanol (32.6%), 1-chloro-2-hexanol (9.3%), 2-chlorohexanal (1.7%), 1-chloro-2-hexanone (4.6%), and a 1.8% yield of a substance having an ultraviolet absorption maximum at 217 mμ in ethanol, which could be either 2-hexenal or 1-hexene-3-one. Oxidation of 2-methyl-1-pentene gave mainly 2-methylpentanal. The chlorohydrins, if they were formed at all, represented less than 10% of the major product.

The formation of cis as well as trans chlorohydrins from both cyclohexene and cyclopentene indicates that a cyclic oxonium ion intermediate, B, cannot represent the only reaction route. On the other hand, an intermediate such as C would be expected to yield entirely cis chlorohydrin. Finally, an intermediate such as D would lead to both



B C D

For personal use only.

cis and trans chlorohydrins with proportions of the isomers thermodynamically controlled. Unfortunately, the thermodynamic information is not available. The situation is complicated by the possibility of selective overoxidation of one of the isomeric chlorohydrins, either during the first step as the chlorochromate IV ester or during the hydrolysis. This is probably the origin of the α-chloro carbonyl compounds.

A further source of complication lies in the possible elimination of hydrogen chloride from both the α-chloro carbonyl compounds and from the chlorohydrins. The conjugated unsaturated compounds found among the products from cyclohexene and 1-hexene may arise in this way, and not, as we first supposed, by an Étard reaction on the allylic carbon of the olefin. That this elimination does not appear to happen with 2-chlorocyclopentanone may be due to steric difficulty in the flat cyclopentane ring. The configuration of 2-chlorocyclohexanone, on the other hand, with an axial chlorine atom (8) is very favorable for trans elimination. Elimination of hydrogen chloride from 2-methyl-2-chloropropanol has been shown to occur readily (9). If it is assumed that 2-methylpentanal, the main product from 2-methyl-1-pentene, arose in this manner, the ratio of 2-chloro-1-ol to 1-chloro-2-ol is 10:1 or greater for the 2,2-dialkylethylene, as compared to about 3:1 for the monoalkyl, i.e. 1-hexene. This is reasonable for a weak Markownikoff effect, with chlorine acting as the negative, and CrO_2Cl as the positive, part of the addend. Depending on whether the ratio is kinetically or thermodynamically controlled, this corresponds to a $\Delta(\Delta G^*)$ or $\Delta(\Delta G)$ of about 0.7 kcal/mole for 1-hexene and >1.5 kcal/mole for 2 methyl-1-pentene. This is compatible with any of the intermediates B, C, or D, though the small size of the effect favors C.

It is clearly not possible to favor any single route or particular combination of routes for the reaction on the basis of the products reported here. A kinetic study would be simpler if there were fewer products and higher yields, but it is clearly needed before the mechanism can be further discussed. Such a study is now in progress.

EXPERIMENTAL

Melting points were determined by the capillary tube method and are uncorrected. Gas chromatograms were obtained using a Burrell Model K-3 for qualitative work and a Burrell Model K-2 for preparative separations and analysis. Nuclear magnetic resonance spectra were obtained on the Varian A60 spectrometer with tetramethylsilane as external standard, this being set at 10.0 τ on the Tiers scale.

Reagents

Chromyl chloride (Allied Chemical) was purified by bubbling dry nitrogen through the liquid to remove traces of hydrogen chloride and was then distilled through a 30-cm Vigreaux column. The fraction boiling at 114–115° was retained. The reagent was protected from light during the distillation and storage and was repurified when any turbidity was noticeable. The olefins were dried and distilled before use and the purity was shown to be greater than 99% by gas chromatography using a silver nitrate – ethylene glycol column. This column efficiently separated a mixture of 1-hexene and 2-hexene prepared by the dehydration of 2-hexanol.

Reaction of Chromyl Chloride with Cyclohexene

A solution of 20.09 g (0.24 mole) of cyclohexene in carbon tetrachloride (500 ml) was treated with 38 g (0.24 mole) chromyl chloride in carbon tetrachloride (200 ml) during a 1-hour period. The temperature was maintained at 0–5°. Precipitation of the brown complex began on the addition of the first few drops of the chromyl chloride solution. The complex was hydrolyzed *in situ* by the addition of a mixture of water (200 ml), ice (100 g), and sodium metabisulphite (15 g). The mixture was stirred for 15 minutes and the organic layer was then separated, washed with saturated sodium chloride solution, dried over sodium sulphate, and the solvent removed. A gas chromatogram (115°, Apiezon T on Embacel, H_2, 55 ml/min) of crude product showed peaks with retention times of 40 seconds (solvent), 125 seconds (small), 145 seconds (medium), and 290 seconds (large). Distillation under reduced pressure through a 15-cm Vigreaux column gave the following fractions: (1) 0.30 g, b.p. 36° at 150 mm; (2) 0.66 g, b.p. 68–84° at 90 mm; (3) 1.18 g, b.p. 84–85° at 80 mm; (4) 2.26 g, b.p. 104–109° at 60 mm; (5) 2.18 g, b.p. 96–98° at 40 mm; (6) 3.15 g, b.p. 98–100° at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

36 mm; (7) 2.24 g, b.p. 92–97° at 20 mm; (8) 1.69 g, b.p. 90–92° at 20 mm; (9) 0.70 g, b.p. 92–97° at 20 mm. The following compounds were identified in the distillate.

(*a*) *Cyclohexanone and* Δ^2*-Cyclohexenone*

Gas chromatography of fraction 3 from the distillation showed two major peaks (125 and 145 seconds). The infrared spectrum of this fraction in carbon tetrachloride had absorption maxima attributed to the carbonyl absorption frequencies at 1710 and 1680 cm^{-1}. Treatment of fraction 3 with 2,4-dinitrophenylhydrazine gave a precipitate from which cyclohexanone-2,4-dinitrophenylhydrazone and Δ^2-cyclohexenone 2,4-dinitrophenylhydrazone were obtained after chromatography on a Bentonite–Celite column (7). The first eluted, a yellow band, when crystallized from ethanol, had m.p. 160–161°. The mixed melting point and infrared spectrum were identical with those of cyclohexanone 2,4-dinitrophenylhydrazone as was the retention time on gas chromatography of the original ketone. The second band on elution chromatography was a deep red-orange which when crystallized from ethanol had m.p. 162–163°. Lit. m.p. 163° (10). The infrared spectrum and mixed melting point were identical with those of an authentic sample of Δ^2-cyclohexenone 2,4-dinitrophenylhydrazone (11). Anal. Calc. for $C_{12}H_{12}N_4O_4$: C, 52.19; H, 4.38; N, 20.27. Found: C, 51.91; H, 4.25; N, 20.27.

(*b*) *cis and trans-2-Chlorocyclohexanols*

Fractions 5 to 9 showed strong infrared absorption at 3600 cm^{-1} assigned to the hydroxyl group. The spectra differed from that of authentic *trans*-2-chlorocyclohexanol prepared by the addition of hypochlorous acid to cyclohexene (12), and that of *cis*-2-chlorocyclohexanol prepared by the aluminum isopropoxide reduction of 2-chlorocyclohexanone (13), and appeared to be a composite of these. Known mixtures of these isomers were not resolved by gas chromatography under the conditions used. Treatment of the oxidation product mixture with α-naphthylisocyanate on the steam bath for 30 minutes gave *trans*-2-chlorocyclohexanol α-naphthylurethan which when recrystallized twice from hexane had m.p. and mixed m.p. 164–165°. Lit. m.p. 164° (6). Anal. Calc. for $C_{17}H_{18}NO_2Cl$: C, 67.19; H, 6.32; Cl, 11.68. Found: C, 66.70; H, 5.92; Cl, 11.40. Separation of the cis isomer from the mixture by the method of Bartlett (6) followed by treatment with α-naphthylisocyanate on the steam bath for 2 hours afforded *cis*-2-chlorocyclohexanol α-naphthylurethan, m.p. and mixed m.p. 93–94°. Lit. 93° (6). Calc. for $C_{17}H_{18}NO_2Cl$: C, 67.19; H, 6.32; Cl, 11.68. Found: C, 66.92; H, 6.34; Cl, 11.46.

Quantitative Analysis of the Cyclohexene – Chromyl Chloride Reaction

(*a*) *Unreacted Cyclohexene*

The reaction was carried out as previously outlined and the brown complex was then collected by filtration, washed with carbon tetrachloride, and dried under vacuum. Escaping vapor from both the filter flask and the vacuum desiccator were trapped in a dry ice–acetone trap and returned to the main filtrate. This filtrate was then diluted to 1000 ml with carbon tetrachloride and aliquots were titrated for cyclohexene with a standard solution of bromine according to the method of Siggia (14). The analysis was found to be accurate to within 2% when samples of known concentration were titrated.

(*b*) *cis and trans-2-Chlorocyclohexanols*

The reaction was carried out as previously described. The organic layer was extracted several times with saturated sodium chloride solution to remove any hydrochloric acid formed during the hydrolysis. The carbon tetrachloride was distilled off and the residue made up to volume with ethanol. Suitable aliquots were titrated with standard sodium hydroxide by Bartlett's method (6) for both chlorohydrins.

(*c*) Δ^2*-Cyclohexenone and Cyclohexanone*

These products were determined from their retention volumes on gas chromatography after calibration with known volumes of the pure liquids.

Reaction of Chromyl Chloride and 1-Hexene

1-Hexene (20 g, 0.24 mole) and chromyl chloride (20 ml, 0.24 mole) were reacted as described for cyclohexene. A gas chromatogram of the crude product, after removal of the solvent (125°, neopentylglycol sebacate on Embacel, He, 40 ml/min), showed five major peaks with retention times 420 seconds (small), 595 seconds (small), 730 seconds (medium), 1030 seconds (medium), 1235 seconds (large). These components were gas chromatographically separated and the various fractions condensed and collected. About 20 injections of 100 μl each were required to obtain a workable sample for the identification of the components.

(*a*) *2-Chlorohexanal*

The infrared spectrum showed absorption maxima at 1730 and 2720 cm^{-1} assigned to carbonyl and aldehyde carbon–hydrogen absorption frequencies respectively. This fraction gave positive Schiff's and Fehling's tests, and contained chlorine (Beilstein's test). Treatment with 2,4-dinitrophenylhydrazine gave yellow needles, m.p. 106–107°. An authentic sample of 2-chlorohexanal prepared by the α-chlorination of hexanal with sulphuryl chloride (15) was identical with the chromyl chloride oxidation product in every way (retention time on gas chromatography, infrared spectrum, m.p. and mixed m.p. of the 2,4-dinitrophenylhydrazone).

(*b*) *Unsaturated Carbonyl Compound*

The component with retention time 595 seconds could not be obtained in sufficient quantity for complete

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

characterization because of failure to condense in the fraction collector. However, sufficient sample was obtained for an ultraviolet spectrum, which showed a single maximum at λ_{max} 217 mμ. A value for the extinction coefficient was not obtained.

(*c*) *1-Chloro-2-hexanone*

The infrared spectrum of this oxidation product showed a carbonyl absorption at 1720 cm^{-1}. This compound failed to react with 2,4-dinitrophenylhydrazine. Analysis of the liquid for chlorine by the Schoeniger combustion method gave: Cl, 25.2. Calc. for $C_6H_{11}OCl$, 26.4. The n.m.r. signals were as follows: distorted triplet centered at 8.62 τ (terminal methyl, area = 3 H), large number of lines centered at 8.11 τ (β- and γ-methylenes area = 4 H), triplet centered at 6.08 τ (α-methylene, area = 2 H), and singlet at 5.64 τ (α-chloromethyl, area = 2 H).

(*d*) *1-Chloro-2-hexanol*

This component showed strong hydroxyl absorption in the infrared and gave a positive Beilstein's test for chlorine. Upon admixture of this product with an authentic sample prepared by the hypochlorous acid addition to 1-hexene, and gas chromatography of the mixture, a single peak was obtained. Treatment with an equivalent of α-naphthylisocyanate for 3 hours at 100° C gave the α-naphthylurethan, m.p. and mixed m.p. 86–87°. (The authentic 1-chloro-2-hexanol had to be gas chromatographically purified to remove about 10% 2-chloro-1-hexanol before a good α-naphthylurethan could be obtained.) Anal. Calc for $C_{17}H_{20}NO_2Cl$: C, 66.80; H, 6.58; Cl, 11.60. Found: C, 66.85; H, 6.65; Cl, 11.33.

(*e*) *2-Chloro-1-hexanol*

This component showed strong hydroxyl absorption in the infrared and contained chlorine. The α-naphthylurethan had m.p. 93–94°. Anal. Calc for $C_{17}H_{20}NO_2Cl$: C, 66.8; H, 6.80; Cl, 11.60. Found: C, 66.21; H, 6.90; Cl, 11.21.

(*f*) *Yields*

1-Hexene (5.0 g, 0.0591 mole) and chromyl chloride (4.8 ml, 0.059 mole) were reacted in the usual way. The carbon tetrachloride was distilled off until a volume of 30 ml was obtained as a residue. This residue was then transferred to a 50-ml volumetric flask and made up to volume with the rinse from the distilling flask. The yields of the various components were determined from the retention volumes on gas chromatography. The instrument was calibrated by obtaining retention volume versus volume injected for each of the gas chromatographically pure components.

Reaction of Chromyl Chloride with Cyclopentene

Cyclopentene (8.0 g, 0.12 mole) was oxidized with chromyl chloride (9.0 ml, 0.11 mole) in the previously described manner. A gas chromatogram (125°, neopentylglycol sebacate on Embacel, He, 40 ml/min) of the crude product showed three major peaks and one minor peak with retention times 310 seconds (small), 700 seconds (large), 950 seconds (medium), 1170 seconds (medium). These products were separated in pure fractions by the same method as applied with 1-hexene and then identified.

(*a*) *trans-2-Chlorocyclopentanol*

This fraction showed a strong infrared absorption at 3470 cm^{-1} (pure liquid) assigned to the hydroxyl group, and gave a positive Beilstein's test for chlorine. The α-naphthylurethan had m.p. 106–107°. Lit. m.p. 105° (16). Anal. Calc for $C_{16}H_{16}NO_2Cl$: C, 66.40; H, 5.57; Cl, 12.24. Found: C, 66.22; H, 5.72; Cl, 11.79. The oxidation product was found to be identical in every way (retention time on gas chromatography, infrared spectrum, m.p. and mixed m.p. of the α-naphthylurethan) with an authentic sample of *trans*-2-chlorocyclohexanol prepared by the addition of hypochlorous acid to cyclopentene.

(*b*) *cis-2-Chlorocyclopentanol*

The infrared spectrum of this component showed a strong absorption attributed to the hydroxyl group. The α-naphthylurethan had m.p. 100–101°. Anal. Calc for $C_{16}H_{16}NO_2Cl$: C, 66.40; H, 5.57; Cl, 12.24. Found: C, 66.56; H, 5.77; Cl, 11.96. This compound was identical in the infrared spectrum, in retention time on gas chromatography, and in m.p. and mixed m.p. of the α-naphthylurethan derivative with authentic *cis*-2-chlorocyclopentanol, prepared by the aluminum isopropoxide reduction of 2-chlorocyclopentanone and purification through gas chromatography.

(*c*) *2-Chlorocyclopentanone*

This product showed an infrared absorption at 1750 cm^{-1} assigned to carbonyl stretching, and it was found to contain chlorine. Authentic 2-chlorocyclopentanone, prepared by the chlorination of cyclopentanone (17), had an infrared spectrum and retention time on gas chromatography identical with those of this product.

(*d*) *Yields*

The products of the reaction of chromyl chloride with cyclopentene were determined quantitatively by the same method used for 1-hexene.

Reaction of Chromyl Chloride and 2-Methyl-1-pentene

2-Methyl-1-pentene (10 g, 0.12 mole) and chromyl chloride (9.7 ml, 0.12 mole) were reacted in the usual fashion. A gas chromatogram of the crude product showed one major product along with four very minor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

products. The infrared spectrum of the crude product showed absorption maxima at 2720 and 1720 cm^{-1} attributed to aldehyde carbon–hydrogen and carbonyl absorption respectively. Distillation of the product gave a fraction weighing 3 g, b.p. 55° at 22–26 cm, and leaving a large pot residue. The fraction distilled was identified as consisting mainly of 2-methylpentanal by a positive Fehling's test, and a 2,4-dinitrophenylhydrazone melting point of 104–105°. Lit. m.p. 102–104° (18). Anal. Calc. for $C_{12}H_{16}N_4O_4$: N, 20.0. Found: 19.8. The distilled fraction on gas chromatography had the same retention time as that of the major peak of the crude product.

THE PROTONATION OF THE CARBONYL GROUP

III. DIARYL KETONES

ROSS STEWART, M. R. GRANGER, R. B. MOODIE, AND L. J. MUENSTER
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received December 26, 1962

ABSTRACT

The basicities of 14 diaryl ketones have been determined. Except for 4,4′-bis(dimethylamino)benzophenone, which protonates on nitrogen, the pK_{BH^+} values range from −4.19 for 4,4′-dihydroxybenzophenone to −10.12 for 4,4′-dinitrobenzophenone. The basicities are not correlated well by either σ or σ^+ substituent constants and it is believed that this is due either to a variation in the degree of rotation (and hence conjugation) of the two aryl rings or to a departure of carbonyl basicities from the conventional acidity scale based on ammonia bases. The effect on the basicity of joining the ortho positions by bridges of various sizes has also been determined and the results are discussed in terms of steric and electronic effects.

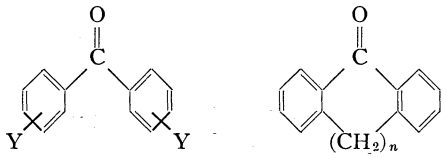
For personal use only.

Previous work in this laboratory has been concerned with the protonation of very weakly basic groups such as carbonyl (1), carboxyl (2, 3), and carboxamido (4, 5). We now wish to report the basicities of two series of diaryl ketones. In one series the para or

$$Ar_2C{=}O + H^+ \rightleftharpoons Ar_2C{=}\overset{+}{O}H$$

meta substituents in benzophenone are varied and in the other the angle of the aryl rings with the carbonyl group is varied by means of ortho–ortho bridges.



The basicities of benzophenone and anthrone have been previously measured by Handa and Koboyashi (6) and those of benzophenone and some of its alkyl derivatives by Fischer, Grigor, Packer, and Vaughan (7).

RESULTS AND DISCUSSION

The basicities and the ultraviolet spectral data for the diaryl ketones are given in Table I. Unlike the series of monoaryl ketones and aldehydes (1) whose basicities correlate quite well with the modified Hammett substituent constants, σ^+ (8), the present series (compounds I to VIII) does not give a very satisfactory fit with any of the parameters commonly used in linear free energy correlations. This may be due to the presence of two potentially conjugating rings each of which can rotate and whose actual degrees of conjugation may vary considerably with the identity of the para substituents. Another possibility to be considered is that carbonyl compounds are not following the conventional Hammett acidity function, H_0, which is based on protonation of amine bases (9, 10). The satisfactory correlations with σ^+ previously observed for benzaldehydes and acetophenones do not cover nearly the range of acidities spanned by the benzophenones. Recent work suggests that the anomalous ionization curves often obtained with carbonyl bases are due less to solvent effects on spectra than to the compounds' ionization not following the function H_0 (9). It should be pointed out in this connection that most of the

*Solvent is EtOH–H_2O (1:10).
†Solvent is 95% H_2SO_4.
‡Literature values, −5.5 (6) and −6.18 (7).
§The low solubility of this compound required the use of 95% EtOH.
‖The pK_{BH^+} of nitrobenzene is −11.26 (J. C. D. Brand, J. Chem. Soc., 997, (1950)); the nitro groups in the ketones will be less basic than this and so carbonyl, not nitro, protonation must be occurring here.
¶Solvent is 80% H_2SO_4.
**Solvent is 30% fuming H_2SO_4, nitro protonation has probably occurred here.

compounds studied in the present work gave excellent ionization curves with slopes very near unity for the logarithmic plots (Figs. 1 and 2). Following the suggestions of Professors N. C. Deno and E. M. Arnett (personal communications) we have also listed in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

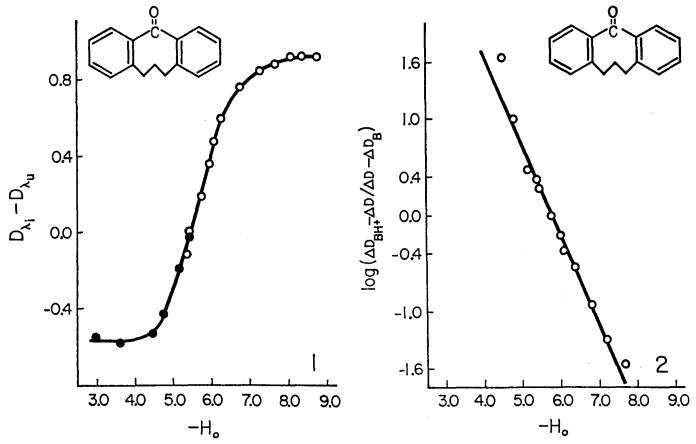

FIG. 1. The function $D\lambda_i - D\lambda_u$ plotted against $-H_0$ for 2,3;7,8-dibenzcyclooctadienone (XIII). $\lambda_i = 353$ mμ, $\lambda_u = 277$ mμ. ○, 3.93×10^{-5} *M*; ●, 4.68×10^{-6} *M*.

FIG. 2. The function log $(\Delta D_{BH^+} - \Delta D/\Delta D - \Delta D_B)$ plotted against $-H_0$ for 2,3;7,8-dibenzcyclooctadienone (XIII). ΔD, ΔD_{BH^+}, and ΔD_B are equal to $D_{353} - D_{277}$ in acid solutions in which XIII is partly ionized, completely ionized, and completely unionized, respectively.

Table I the basicities in terms of % H_2SO_4 in which the compounds are half ionized. Should it be found, in fact, that different scales are required for amine bases, carbonyl bases, etc., such an indication of a compound's basicity will still be meaningful.

Infrared Spectra of the Ketones

We have previously observed very good correlations between the basicities of substituted acetophenones and their carbonyl stretching frequencies (1). This is because the carbonyl stretching frequency and the basicity constant both tend to follow σ^+. However, when values for $\nu_{C=O}$ for diaryl ketones are plotted against both σ and σ^+ a roughly linear relation is obtained in each case. In fact, the correlation coefficients for the two lines are identical (0.978).* This probably reflects a somewhat diminished resonance effect between the carbonyl group and the para substituents in the benzophenones compared to both the acetophenone and the benzaldehyde conjugate acids, in agreement with the p*K* results.

Ultraviolet Spectra of the Cations

A red shift ($\Delta\lambda$, Table I) of roughly 100 mμ in the ultraviolet maxima results from protonation of the carbonyl group, in most cases. This is about twice as large as the shift in the case of acetophenones and benzaldehydes (1). The effect of substituents on the absorption maximum of benzophenone conjugate acid is the same as on that of the diphenylmethyl cation, $(C_5H_6)_2CH^+$ (11). The derivatives of the latter carbonium ion each absorb at about 100 mμ longer wavelength than do the corresponding protonated benzophenone ions reported herein. However, there is a marked resemblance in the shape of the spectra of the isoelectronic ions $Ar_2\overset{+}{C}OH$ and $Ar_2\overset{+}{C}CH_3$ (12).

**When a parameter gives plots with the same degree of linearity (same correlation coefficient) with both σ and σ^+ this is usually reflected in a low value of the correlation coefficient. This is not always the case, however. A plot of σ against σ^+ for the following 14 groups, p-NMe_2, p-NH_2, p-OH, p-OMe, p-C_6H_5, p-F, p-Cl, p-Br, m-F, m-I, m-Cl, m-CO_2Et, m-Br, m-CF_3, using the data of Brown and Okamoto (8), gives an excellent linear relation (correlation coefficient, 0.998). It is obvious that no decision whatever could be reached about whether σ or σ^+ was being followed if one chose only substituents in this list.*

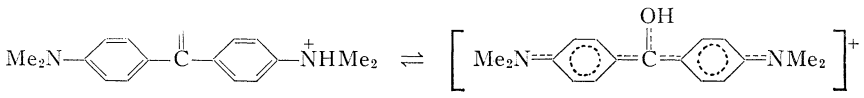
4,4′-Bis(dimethylamino)benzophenone

This compound protonates on nitrogen and the expected blue shift accompanies the formation of the doubly charged cation (348 to 251 mμ). The first and second protonation steps occur at approximately pH 3.0 and 1.2, respectively. We were interested in seeing if the presence of the resonance-stabilized cation XV, which should be in equilibrium with the ammonium monocation XIV, could be detected. By analogy with the behavior



XIV XV

of the other benzophenones we would expect the carbonyl-protonated ion, XV, to absorb at about 500 mμ with an extinction coefficient in the range $3–5\times10^4$. The monocation produced in aqueous solution has no peak in the visible and, in fact, absorbs at about 380 mμ with an extinction coefficient somewhat smaller than that of the neutral compound. This is clearly the ammonium ion, XIV. Interestingly enough, in solvents such as acidified methanol and ethanol a small peak appears at 500 mμ and this is probably due to the ion XV. As the solution is made more acidic the intensity of this peak rises and then falls again as the ammonium dication is formed. Even in these solvents, however, only a small proportion, possibly 1%, of the monocation is in the form XV. Pfeiffer *et al.* (13) prepared the crystalline mono- and di-perchlorates of 4,4′-bis(dimethylamino)benzophenone; the diperchlorate is colorless but the monoperchlorate has a yellow cast and dissolves in ethanol and acetone to give a brown-red solution. The latter color is presumably due to the presence of the ion XV in the system.

Bridged Diaryl Ketones

The basicities of these compounds are listed in Table I. There are two effects, electronic and steric, which are clearly operative in this series. Fluorenone (IX) and dibenztropone (XII) each possess special electronic features which set them apart from the other ketones. Fluorenone is a derivative of cyclopentadienone and the well-known reluctance of that ring system to donate charge is reflected in fluorenone's low basicity; this, despite the increased conjugation of the aryl rings with the protonated carbonyl group which results from the rigid planar geometry of the molecule.

Dibenztropone (XII), on the other hand, possesses the highly basic tropone unit. The pK_{BH^+} value of -5.25 shows that this compound is more basic than its saturated analogue (XI), as expected, but it is clearly many powers of 10 weaker than tropone itself. This is in agreement with its known physical and chemical properties. Unlike tropone (14) it has a normal dipole moment, its carbonyl stretching frequency (1660 cm^{-1}) (15) is similar to that of benzophenone, and it forms a 2,4-dinitrophenylhydrazone. From this evidence it has been concluded that the molecule is folded (16).

Anthrone (X) is considerably more basic than benzophenone and this must be due chiefly to the increased conjugation between the protonated carbonyl group and the two rings. Although anthrone is not actually planar it is closer to this condition than is benzophenone (17, 18).

Increasing the number of carbons in the bridge forces the aromatic rings out of the plane of the carbonyl group and this causes the decrease in basicity observed in going from X to XI to XIII. The decrease due to steric factors would probably be greater than this were it not partly compensated by the increasing inductive effect of the alkyl substituents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

That is, the ortho substituent in the case of anthrone (X) is really a benzyl group containing a carbonyl substituent. In the case of dibenzcyclooctadienone (XIII) the ortho substituent is essentially alkyl in character.

It is worth noting that the effect of two ortho methyl groups in reducing the basicity of benzophenone by lowering the planarity of the system is considerably greater than the effect of a trimethylene bridge. Thus the pK_{BH^+} value of 2,6-dimethylbenzophenone is −6.6 (7) compared to −6.2 for benzophenone and −5.8 for 2,3;7,8-dibenzcyclooctadienone (XIII).

EXPERIMENTAL

Reagents

The benzophenones which were commerically available reagents were crystallized several times to constant melting point as follows: benzophenone, 48–49°; 4-chlorobenzophenone, 75.5–76.5°; 4,4′-dimethylbenzophenone, 94–95°; 4,4′-dichlorobenzophenone, 148–149°; 4,4′-dimethoxybenzophenone, 144–145°; 4,4′-dihydroxybenzophenone, 210–212°; 4,4′-bis(dimethylamino)benzophenone, 174.5–175.5°; anthrone, 153–156°; fluorenone, 80–80.5°. 3,3′-Dininitrobenzophenone was prepared by the method of Barnett and Mathews (19). Nitration of diphenylmethane gave 4,4′-dinitrodiphenylmethane, which was oxidized with chromium trioxide to 4,4′-dinitrobenzophenone, m.p. 156–158°. 2,3;6,7-Dibenzsuberone was prepared from benzalphthalide (20) by the method of Cope and Fenton (21), b.p. 149–151° (0.3 mm). 2,3;6,7-Dibenztropone was prepared from the suberone by bromination with N-bromosuccinimide and subsequently dehydrobrominated with triethylamine (21), m.p. 88–89°. (All melting points are uncorrected.)

2,3;7,8-Dibenzcyclooctadienone

This compound was prepared from 2-(γ-phenylpropyl)benzoyl chloride (colorless oil, b.p. 153° at 0.65 mm, n_D^{20} 1.5812) by cyclization using the extreme dilution technique of Hedden and Brown (22). This procedure appears to be more successful than that used by Gutsche and co-workers (23).

To 7.5 g of aluminum chloride in 160 ml carbon disulphide was added, over a period of 10 hours, 6 g of 2-(γ-phenylpropyl)benzoyl chloride dissolved in 70 ml of carbon disulphide. The brown complex thus formed was decomposed on 200 g of crushed ice and became a cream-colored solid. The carbon disulphide was removed and the solid collected and dried in an Abderhalden pistol at 60°. The crude product was purified by sublimation (0.03 mm, 110°) followed by recrystallization from a 1:6 acetone – ethyl alcohol mixture. The colorless needles had m.p. 148–149°. Calc. for $C_{16}H_{14}O$: C, 86.46; H, 6.35. Found: C, 86.72; H, 6.65. (Thanks are due to Mr. D. Dolman for preliminary work on this preparation.)

2,4-Dinitrophenylhydrazone

The cyclooctadienone was kept for 3 weeks at 60° in a solution of 2,4-dinitrophenylhydrazine in diethyleneglycol containing a few drops of concentrated hydrochloric acid. The reaction mixture was then left for several weeks at room temperature. The crude product was recrystallized from glacial acetic acid. The obtained orange platelets turned yellow on grinding and had m.p. 195–196°. Calc. for $C_{22}H_{18}N_4O_4$: C, 65.66; H, 4.51; N, 13.92. Found: C, 65.42; H, 4.50; N, 13.67.

Oxime

White needles, m.p. 146–148°. Calc. for $C_{16}H_{15}NO$: C, 80.98; H, 6.37; N, 5.90. Found: C, 81.12; H, 6.37; N, 5.68.

Basicity Measurements

The pK measurements were made as previously described (1–4). In addition, since the absorption maxima of the neutral compounds and their conjugate acids were very far apart in most cases, a check was made by using absorption data at a single wavelength. Excellent agreement was obtained.

The ionization curve for 2,3;7,8-dibenzcyclooctadienone (XIII) using measurements at two different wavelengths is shown in Fig. 1. Low solubility of the neutral molecule required the use of two different substrate concentrations for the measurements. The logarithmic plot (3) should give a straight line of unit slope if the ionization behavior is normal. The slope of the line in Fig. 2 is close to unity, 0.94, with a correlation coefficient of 0.99.

The well-behaved character of both ionization plots in Figs. 1 and 2 may result from the fact that the absorption maxima of the neutral molecule and the cation are well separated. Tailing of the plots of $D_{\lambda i} - D_{\lambda u}$ against H_0 was not observed and it was not necessary to choose for $D_{\lambda u}$ and $D_{\lambda i}$ values which were 1.5 H_0 units away from the pK, as was done in a previous case (3).

In the case of the dinitro compounds the H_0 values of the solutions used were determined by indicator measurements. This is essential if one works with solutions whose H_0 value changes rapidly with concentration, since titration with base cannot hope to give sufficiently precise values of the acidity function.

PHTHALIDE FORMATION

IV. CONDENSATIONS WITH 5-METHOXY-3-METHYLBENZOIC ACID[1]

E. H. Charlesworth and Leon Levene
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received December 14, 1962

ABSTRACT

The products of the condensation of 5-methoxy-3-methylbenzoic acid with aqueous formaldehyde and hydrochloric acid in the presence of glacial acetic acid are dependent on the length of the heating period. A very short period of heating (2 minutes) yields 6-methoxy-4-methylphthalide and the two chloromethylphthalides of m.p. 135° and 154° C, related to the unisolated 4-methoxy-6-methylphthalide. If the period of heating is 20 minutes or longer, the above chloromethylphthalide melting at 135° is formed and in addition some of the 6-methoxy-4-methylphthalide is chloromethylated to 6-methoxy-7-chloromethyl-4-methylphthalide, melting at 179°. The orientation of all three chloromethylphthalides has been established.

INTRODUCTION

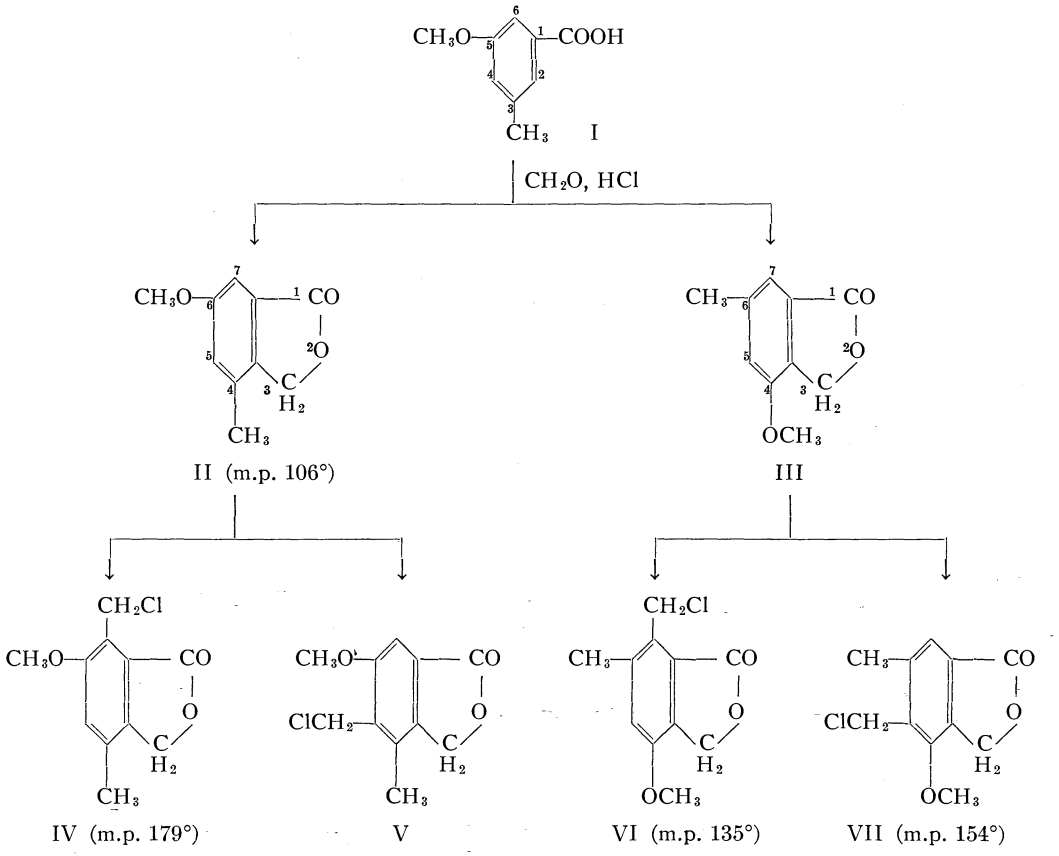
In 1945, Charlesworth *et al.* (1) reported the isolation of two products from the condensation of 5-methoxy-3-methylbenzoic acid (I) with formaldehyde and concentrated hydrochloric and acetic acids. Of these, the compound which melted at 176–178° C was established as a chloromethylphthalide, but its orientation was not proved. The present paper establishes the orientation of this and other products isolated in this reaction.

The phthalide ring may form in two ways to produce the simple phthalides II and III. On further reaction a chloromethyl group may enter positions 5 or 7 in II or 5 or 7 in III. Thus, four chloromethylphthalides (IV–VII) are theoretically possible. All condensations were carried out using the Edwards, Perkin, and Stoyle (2) method as modified by Rây and Robinson (3) by the addition of glacial acetic acid to the formaldehyde – hydrochloric acid mixture. The length of the heating period determined the number and nature of the products isolated.

When the mixture was heated for 2 minutes or less, that is, just for the length of time to put everything into solution, only the simple phthalide II and the chloromethylphthalides VI and VII were formed. The chloromethylphthalide IV, m.p. 178–179° C, of the earlier paper was not formed under these conditions. It was formed along with II and VI if the condensation time was extended to 20 minutes or more. It (IV) can also be formed alone from phthalide II in continued condensation of 20 minutes or more. Phthalide III was not isolated from any of the condensations and apparently is chloromethylated as fast as produced.

The orientation of phthalide II was established by mixed melting point and infrared spectra comparison with this phthalide produced by the Fritsch reaction. Meldrum (4) synthesized and established the orientation of both the simple phthalides by this method. When phthalide III formed by the Meldrum method was subjected to further chloromethylation VI and VII are produced, but not IV. Thus, chloromethylphthalides VI and VII have been proved to be related to phthalide III, and IV, as previously, to phthalide II. In establishing the orientation of the three isolated chloromethylphthalides it was thus necessary to determine the orientation of IV (or V) as derived from the simple phthalide II and one of the two chloromethylphthalides VI or VII as formed from simple phthalide III. Once a definite orientation could be affixed to either VI or VII the other was also known.

[1]*For Part III of this series, see Can. J. Chem.*, **32**, *941 (1954).*



A successful attack on this problem involved a synthesis of the two substituted aromatic acids VIII and X. Once these acids were available they were subjected to the normal condensation reaction to produce the corresponding phthalides IX and XI.

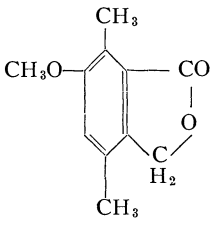
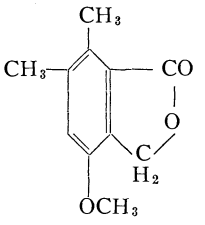
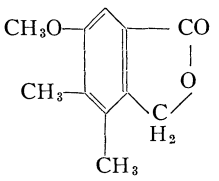
Reduction of the four theoretically possible chloromethylphthalides, IV, V, VI, and VII, derived from 5-methoxy-3-methylbenzoic acid with zinc and hydrochloric acid would yield the corresponding chlorine-free phthalides A, B, C, and D.



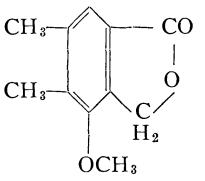
A



C



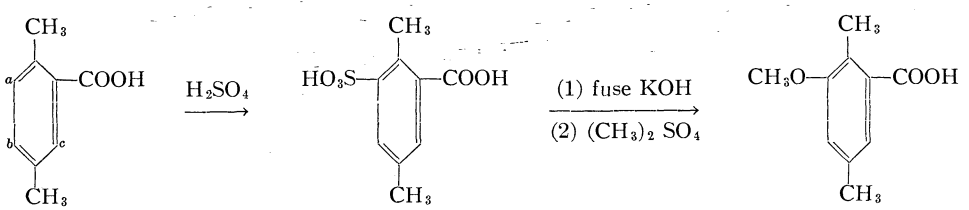
B



D

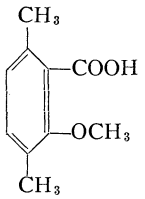
The phthalide IX prepared synthetically from 2,5-dimethyl-3-methoxybenzoic acid (VIII), whose orientation is proved below, was found to be identical with phthalide A, in turn derived from the chloromethylphthalide IV of melting point 178–179° C. In this way the orientation of IV was definitely established. Similarly, phthalide XI formed from 2,3-dimethyl-5-methoxybenzoic acid (X) was shown to be identical with phthalide C, thus definitely establishing the orientation of chloromethylphthalide (VI) of melting point 134–135° C. The remaining chloromethylphthalide melting at 152.5–154° C must by elimination have the structure VII.

The synthesis of 2,5-dimethyl-3-methoxybenzoic acid (VIII) was carried out as follows:

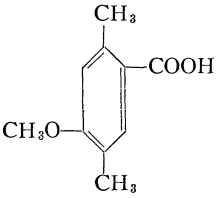


XII VIII

There are three possible positions of sulphonation in the starting molecule of 2,5-dimethylbenzoic acid (XII). If the sulphonic acid group had entered position *c* it would yield, after alkali fusion and methylation, the acid of structure XIII. It would be impossible for this acid to form a phthalide because there is no position ortho to the carboxyl group



XIII



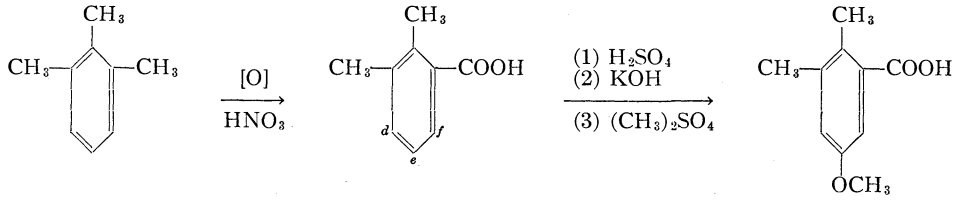
XIV

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

unsubstituted. The phenol corresponding to XIII would be expected to yield a color with ferric chloride solution. The actual acid obtained did not give a ferric chloride reaction, but does form a phthalide. Thus structure XIII can be ruled out.

If the sulphonic acid group had entered position *b* the final methyl ether would be identical with 4-methoxy-2,5-dimethylbenzoic acid (XIV), first produced by Gattermann (5) from 2,5-dimethylphenol by a Gattermann reaction, followed by methylation of the phenolic aldehyde and oxidation of the aldehyde to the corresponding acid. We have synthesized this acid by a modification of the original procedure and it is not identical with our acid (VIII), which thus must have the structure indicated.

The synthesis of 5-methoxy-2,3-dimethylbenzoic acid (X) was carried out in a similar manner from hemimellitene (XV). This was oxidized by dilute nitric acid to the acid XVI



XV XVI X

first reported by Jacobsen (6), which was then sulphonated and subjected to alkali fusion and methylation. As in the previous case, the sulphonic acid substituent can enter three possible positions. Our phenol did not give a ferric chloride reaction, but its methyl ether did form a phthalide. Position *f* is thus ruled out on both counts. It was now a relatively simple matter to establish whether carbon *d* or *e* was sulphonated. 3,4-Dimethylphenol and 2,3-dimethylphenol are solids and commercially available. Decarboxylation of our phenol formed a product identical with 3,4-dimethylphenol. Thus position *e* has been established for the sulphonation of acid XVI.

An earlier plan of attack to establish the orientation of the three isolated chloromethylphthalides (IV, VI, and VII) was oxidative attack on the reduced phthalides A, C, and D to obtain the corresponding dicarboxylic acids. These were then to have been decarboxylated and the resulting methyl ethers demethylated and compared with the commercially available solid phenols. Two of these dicarboxylic acids were isolated in the form of their anhydrides, but attempts at decarboxylation were unsuccessful.

EXPERIMENTAL

Condensation of 5-Methoxy-3-methylbenzoic Acid

The general method followed was that of Edwards, Perkin, and Stoyle (2) as modified by Rây and Robinson (3). This procedure was employed in all condensations carried out, with modifications in the period of heating, the proportion of formaldehyde, and the method of isolation of the resultants. The 5-methoxy-3-methylbenzoic acid was made from *m*-toluic acid as described in the first paper of this series (1).

Condensation Time Two Minutes or Less

5-Methoxy-3-methylbenzoic acid (4.0 g), concentrated hydrochloric acid (25.0 ml), aqueous formaldehyde (10 ml, 37%), and glacial acetic acid (25 ml) were mixed in a small flask fitted with a reflux condenser and heated on a steam bath just long enough to permit the 5-methoxy-3-methylbenzoic acid to dissolve. This usually took about 2 minutes. The flask was then cooled in ice to prevent further reaction. On standing overnight in the refrigerator a yellowish precipitate formed, which was filtered off and washed.

Isolation of 6-Methoxy-4-methylphthalide (II)

Cold water was added to the filtrate obtained above, when a white precipitate settled out. After standing the solution overnight in the cold this precipitate was filtered off and washed with water. Repeated crystallization from ethyl alcohol (95%) gave the 6-methoxy-4-methylphthalide (0.7–0.9 g), which melted at 105–106° C. Found: C, 66.9; H, 5.64%. Calc. for $C_{10}H_{10}O_3$: C, 67.4; H, 5.62%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A small amount of material insoluble in ethyl alcohol and with a melting point above 275° C was found. It was considered to be a diphenylmethane type of material and was not examined further.

Isolation of the Two Chloromethylphthalides VI and VII

The yellowish precipitate, mentioned above, obtained directly from the reaction mixture, was crystallized from alcohol (charcoal). The dry colorless crystals were washed on the filter funnel with four or five portions (5.0 ml) of boiling alcohol. This treatment dissolved the more soluble chloromethylphthalide and left the less soluble on the funnel. The latter was recrystallized from glacial acetic acid and finally from alcohol. This chloromethylphthalide, VII (0.6 g), melted at 153–154° C. Found: C, 58.2; H, 5.06; Cl, 15.4%. Calc. for $C_{11}H_{11}O_3Cl$: C, 58.3; H, 4.86; Cl, 15.7%.

The more soluble chloromethylphthalide, VI (1.0 g), was also purified by recrystallization from acetic acid and from alcohol. It melted at 134–135° C. Found: C, 58.3; H, 5.21; Cl, 15.4%. Calc. for $C_{11}H_{11}O_3Cl$: C, 58.3; H, 4.86; Cl, 15.7%.

Condensation Time Twenty Minutes or Longer

The Chloromethylphthalide IV

The procedure was as above except that the time of heating was increased to 20 minutes. The 6-methoxy-4-methylphthalide (II) was isolated as before. Two chloromethylphthalides were separated by portions of hot alcohol, the more soluble being the previously mentioned VI of melting point 134–135° C and the less soluble, IV (2.1 g) of melting point 178–179° C. Found: C, 58.4; H, 5.07; Cl, 15.6%. Calc. for $C_{11}H_{11}O_3Cl$: C, 58.3; H, 4.86; Cl 15.7%. The infrared spectrum of IV differs from that of VI and VII by not possessing characteristic peaks at 6.91 and 8.90 μ.

6-Methoxy-4-methylphthalide (II) and 4-Methoxy-6-methylphthalide (III)

These two simple phthalides were produced by the Fritsch method as reported by Meldrum (4), who also established their orientation. Mixed melting point determination and infrared spectra comparison of the simple phthalide obtained from the condensation above proved its identity with 6-methoxy-4-methylphthalide (II), m.p. 104–105° C, produced by Meldrum's directions.

Condensation of the Meldrum Phthalides II and III with Formaldehyde and Hydrochloric Acid

When 6-methoxy-4-methylphthalide II (0.85 g) was condensed with formaldehyde solution, hydrochloric acid, and glacial acetic acid for 1½ hours in the standard manner, a chloromethylphthalide (0.6 g) which melted at 178–179° C was isolated. This proved identical with the product of the same melting point isolated from the main reaction. None of the other chloromethylphthalides were found in the reaction mixture. Thus chloromethylphthalide IV must be related to simple phthalide II. If the condensation time was only 2 minutes the chloromethylphthalide was not formed, but the unchanged simple phthalide (II) could be recovered.

When the simple Meldrum phthalide III (2.0 g) was subjected to further chloromethylation for 2 minutes, a solid separated on cooling, which on crystallization from alcohol in the manner previously described gave a product (0.4 g) which melted at 153–154° C. Dilution of the reaction mixture with water and repeated crystallization of the separated product from alcohol gave the second chloromethylpthalide (0.32 g), which melted at 133–134°. These two substances were identical with the products VII and VI of the same melting points isolated from the main condensation. Thus VI and VII must be related to the simple phthalide III.

Formation of the Three Chlorine-free Phthalides (A, C, and D)

6-Methoxy-4-methyl-7-chloromethylphthalide (3.5 g) of melting point 178–179° C, zinc dust (3.7 g), concentrated hydrochloric acid (10 ml), and ethyl alcohol (75 ml, 95%) were refluxed for 15 hours. Excess hydrochloric acid was added until the zinc had completely dissolved. The solution was cooled and cold water (75 ml) added, when a thick white paste was formed. The solid was collected, washed well with water, and dried. Crystallization from ethyl alcohol produced colorless crystals (3.2 g) of 6-methoxy-4,7-dimethylphthalide (A) which melted at 169–170° C. Found: C, 68.3; H, 6.15%. Calc. for $C_{11}H_{12}O_3$: C, 68.8; H, 6.26%.

Reduction of 4-methoxy-6-methyl-7-chloromethylphthalide (VI) of melting point 134–135° C by the same method gave 4-methoxy-6,7-dimethylphthalide (C) which melted at 179–180° C. Found: C, 68.5; H, 6.29%. Calc. for $C_{11}H_{12}O_3$: C, 68.8; H, 6.26%.

Reduction of 4-methoxy-6-methyl-5-chloromethylphthalide (VII) of melting point 153–154° C gave 4-methoxy-5,6-dimethylphthalide (D) which melted at 174–175° C. Found: C, 68.5; H, 6.19%. Calc. for $C_{11}H_{12}O_3$: C, 68.8; H, 6.26%.

Formation of the Three Phthalic Acids (Anhydrides) from the Phthalides A, C, and D

6-Methoxy-4,7-dimethylphthalide (3.0 g) was dissolved in warm potassium hydroxide solution (100 ml, 6 *N*). After cooling, finely powdered potassium permanganate (3.8 g) was added slowly over a 10-minute period. The dark solution was allowed to stand at room temperature for 36 hours. The brown manganese dioxide was filtered off, leaving a green filtrate. On acidification with dilute sulphuric acid a white precipitate of 4-methoxy-3,6-dimethylphthalic acid was formed. This relatively pure product (2.1 g) was collected, washed with water, and allowed to dry. It melted at 181–182° C and effervesced vigorously with sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

bicarbonate solution. Found: C, 58.4; H, 5.41%. Calc. for $C_{11}H_{12}O_5$: C, 58.9; H, 5.36%. Crystallization from either ethyl alcohol or glacial acetic acid converted the acid into the corresponding anhydride, which melted at 185–186° C and no longer effervesced with bicarbonate solution. Found: C, 63.9; H, 5.10%. Calc. for the anhydride $C_{11}H_{10}O_4$: C, 64.1; H, 4.85%.

6-Methoxy-3,4-dimethylphthalic anhydride (1.2 g) was prepared in a similar manner from phthalide C (3.0 g). On crystallization from acetic acid it melted at 230–231° C. Found: C, 63.8; H, 4.98%. Calc. for $C_{11}H_{10}O_4$: C, 64.1; H, 4.85%.

3-Methoxy-4,5-dimethylphthalic anhydride was prepared from 4-methoxy-5,6-dimethylphthalide (D) as in the two previous cases. It melted at 174–175° C. Found: C, 63.8; H, 4.75%. Calc. for $C_{11}H_{10}O_4$: C, 64.1; H, 4.85%.

Attempts to decarboxylate the 4-methoxy-3,6-dimethylphthalic acid with copper chromite and quinoline were unsuccessful. Solid material recovered from this attempt proved to be the corresponding 4-methoxy-3,6-dimethylphthalic anhydride.

Preparation of 3-Methoxy-2,5-dimethylbenzoic Acid (VIII)

(a) Sulphonation of 2,5-Dimethylbenzoic Acid

2,5-Dimethylbenzoic acid (11.0 g, Eastman No. 7270) was heated at 110° with stirring for 2 hours with a mixture of concentrated sulphuric acid (15 ml) and fuming sulphuric acid (35 ml, 20% SO_3). After cooling, the solution was poured cautiously into ice-cold water (200 ml). After further cooling the acid was partially neutralized by the slow, careful addition of sodium bicarbonate (10 g). Sodium chloride (25 g) was added and the mixture warmed until solution was complete. The clear liquid was cooled in an ice bath, when a brown solid began to separate. This sodium salt of 2,5-dimethyl-3-sulphobenzoic acid (15 g) was collected on a sintered-glass funnel, washed well with a small quantity of saturated sodium chloride solution, and dried in an oven.

(b) 3-Hydroxy-2,5-dimethylbenzoic Acid

The above sodium salt (14 g) was fused with potassium hydroxide (80 g) in the conventional manner. The melt was dissolved in water (300 ml) and neutralized with dilute sulphuric acid. The solution was made slightly alkaline, cooled, and the precipitated potassium sulphate removed. The mother liquor was concentrated (charcoal) to about one third the original volume, filtered, cooled, and a second crop of potassium sulphate removed. On acidification with concentrated hydrochloric acid the required 3-hydroxy-2,5-dimethylbenzoic acid (5.8 g) separated. It was recrystallized from water and melted at 163–165° C. It did not give a color with ferric chloride solution. Found: C, 65.0; H, 5.99%; neut. equiv., 163. Calc. for $C_9H_{10}O_3$: C, 65.1; H, 6.03%; neut. equiv., 166.

(c) 3-Methoxy-2,5-dimethylbenzoic Acid (VIII)

3-Hydroxy-2,5-dimethylbenzoic acid (5.2 g) was methylated in the conventional manner with sodium hydroxide solution and dimethyl sulphate (10 g). The 3-methoxy-2,5-dimethylbenzoic acid (2.3 g) was crystallized from aqueous alcohol, and melted at 143–144° C. Found: C, 67.0; H, 6.74%. Calc. for $C_{10}H_{12}O_3$: C, 66.8; H, 6.68%.

6-Methoxy-4,7-dimethylphthalide (IX)

3-Methoxy-2,5-dimethylbenzoic acid (1.5 g), concentrated hydrochloric acid (11.0 ml), glacial acetic acid (11 ml), and formaldehyde solution (9 ml, 35%) were heated on a steam cone for 45 minutes. Complete solution did not take place. The flask was then cooled and the solid collected and washed with water. On crystallization from alcohol, the 6-methoxy-4,7-dimethylphthalide (1.3 g) was obtained, and melted at 169–170° C. Found: C, 68.4; H, 6.24%. Calc. for $C_{11}H_{12}O_3$: C, 68.8; H, 6.25%.

A mixed melting point of this material and the chlorine-free phthalide A of the same melting point formed by the reduction of the chloromethylphthalide IV of m.p. 179° C showed no depression. Thus the orientation of chloromethylphthalide IV has been established.

Preparation of 5-Methoxy-2,3-dimethylbenzoic Acid (X)

(a) Oxidation of 1,2,3-Trimethylbenzene

The oxidation of 1,2,3-trimethylbenzene (hemimellitene) (XV) with dilute nitric acid was first reported by Jacobsen (6). His experimental details are scanty, but the following procedure was satisfactory. It appeared impossible, however, to stop at the required monocarboxylic stage without the production of some dicarboxylic acid.

1,2,3-Trimethylbenzene (60 ml, Aldrich Chemical Co.) was refluxed with a mixture of nitric acid (50 ml, 70%) and water (140 ml) for about 20 hours, a magnetic stirrer operating throughout the heating period. The mixture was poured into cold water (400 ml). On standing in the refrigerator, the crude acid, which separated as an oil, solidified. It was separated and dissolved in sodium hydroxide solution (200 ml, 10%). The cold dark red alkaline solution was extracted with ether to remove unoxidized hemimellitene, warmed with decolorizing carbon, and filtered. The warm filtrate was acidified with dilute hydrochloric acid, when the acid separates as a brown solid. On recrystallization from ethyl alcohol (charcoal) the required 2,3-dimethylbenzoic acid (8.0 g) was obtained. It melted at 139–141° C. Jacobsen gives a value of 144° C for the melting point, but it was considered sufficiently pure for sulphonation purposes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(b) 5-Hydroxy-2,3-dimethylbenzoic Acid

The sulphonation of 2,3-dimethylbenzoic acid (12 g) was carried out exactly as described above for 2,5-dimethylbenzoic acid, and the sodium salt of the required 1,2-dimethyl-5-sulphobenzoic acid was isolated. This salt was fused with alkali as described above and the 5-hydroxy-2,3-dimethylbenzoic acid obtained. It was crystallized from water and melted at 179.0–179.5° C. Found: C, 64.6; H, 6.04%; neut. equiv., 161. Calc. for $C_9H_{10}O_3$: C, 65.1; H, 6.03%; neut. equiv., 166. This phenolic acid did not yield a color with ferric chloride solution.

(c) Decarboxylation of 5-Hydroxy-2,3-dimethylbenzoic Acid

Attempts to decarboxylate this acid by refluxing with quinoline and copper chromite were unsuccessful. However, when the acid was heated with soda lime a product was obtained which melted at 62–63° C. This did not effervesce with sodium bicarbonate solution nor give a color with ferric chloride solution. A mixed melting point with commercial 3,4-dimethylphenol gave no depression.

(d) 5-Methoxy-2,3-dimethylbenzoic Acid (X)

Methylation of 5-hydroxy-2,3-dimethylbenzoic acid (0.6 g) in the conventional manner gave 5-methoxy-2,3-dimethylbenzoic acid (0.47 g). On crystallization from aqueous ethyl alcohol it melted at 102–103° C. Found: C, 66.7; H, 6.68%. Calc. for $C_{10}H_{12}O_3$: C, 66.8; H, 6.68%.

4-Methoxy-6,7-dimethylphthalide (XI)

The above 5-methoxy-2,3-dimethylbenzoic acid, X (0.4 g), was condensed as described above for the preparation of 6-methoxy-4,7-dimethylphthalide. After crystallization from ethyl alcohol the 4-methoxy-6,7-dimethylphthalide (0.3 g) melted at 179–180° C. Found: C, 68.5; H, 6.38%. Calc. for $C_{11}H_{12}O_3$: C, 68.8; H, 6.25%. A mixed melting point of this material and the chlorine-free phthalide C, formed by the reduction of the chloromethylphthalide VI of m.p. 135° C, showed no depression. Thus the orientation of the chloromethylphthalide VI has been established.

Synthesis of 4-Methoxy-2,5-Dimethylbenzoic Acid

(a) 4-Hydroxy-2,5-dimethylbenzaldehyde

This aldehyde, m.p. 130–132° C, was synthesized from 2,5-dimethylphenol by a Gattermann reaction as modified by Adams and Montgomery (7) employing zinc cyanide and anhydrous aluminum chloride as the condensing agent.

(b) 4-Methoxy-2,5-dimethylbenzaldehyde

The aldehyde of the previous paragraph was methylated as described by Clemo *et al.* (8). It boiled at 147–179° at 12 mm and melted at 32–33° C.

(c) 4-Methoxy-2,5-dimethylbenzoic Acid

The methoxyaldehyde (23.5 g) of the previous paragraph was oxidized by boiling for 40 minutes with acetone (300 ml) containing finely powdered potassium permanganate (35 g). The hot solution was filtered and the dark solid suspended in water and treated with sulphur dioxide gas to dissolve the manganese dioxide, leaving a thick white precipitate of the 4-methoxy-2,5-dimethylbenzoic acid. A further quantity of the acid could be obtained by concentration of the acetone filtrate and dilution with water. On crystallization from aqueous acetic acid the purified acid (14.6 g) melted at 164–165° C, in agreement with the figure reported by Clemo (8). This acid is not identical with the acid VIII described above.

ABSTRACT

By measuring the initial rates of production of hydrodisulphide during reductions by sodium hydrosulphide in aqueous ethanol, it has been shown that the relative rates of reduction of a number of para-alkylated nitrobenzenes are in the order *p*-H- > *p*-*t*-butyl- > *p*-isopropyl- = *p*-cyclohexyl- > *p*-ethyl- > *p*-methyl-nitrobenzene. This is in accord with the "hyperconjugative" order of electron release by these alkyl groups.

INTRODUCTION

It has been shown that the reduction of nitrobenzene by aqueous sodium hydrosulphide (at pH ~ 9–10) first produces phenylhydroxylamine, which in turn is reduced by the hydrosulphide much more slowly than is the original nitrobenzene (1). Hydrosulphide reduction of nitrobenzene, but apparently not of phenylhydroxylamine, is accompanied by the accumulation of hydro*di*sulphide ion, which, as well as reducing nitrobenzene more quickly than does hydrosulphide ion, is capable of reducing phenylhydroxylamine 2 to 3 times more rapidly than it does the nitrobenzene. Hydro*di*sulphide reduction of nitrobenzene is accompanied by an increase in hydro*di*sulphide ion whereas in contrast the hydroxylamine apparently only *consumes* hydrodisulphide ion. In all of these reactions thiosulphate ion is produced.

Goldschmidt and Larsen (2) have found that at a pH of 8, the reduction of nitrobenzene by sodium hydrosulphide quantitatively precipitates sulphur according to the following equation:

$$C_6H_5NO_2 + 2NaSH + H_2O \rightarrow C_6H_5NHOH + 2S^0\downarrow + 2NaOH. \qquad (a)$$

At higher pH, however, the sulphur is not precipitated. For example, in the reduction by sodium sulphide (pH ~ 12.5) (3, 4), where due to hydrolysis a considerable concentration of both sulphide and hydrosulphide ion exists, the elemental sulphur produced during reaction appears as the disulphide ($S_2^=$, HS_2^-) and as $S_2O_3^=$. Nitrobenzene becomes aniline with no evidence of phenylhydroxylamine appearing during the course of the reaction. The following reactions were presented to account for this observation:

$$C_6H_5NO_2 + 3S^= + 4H_2O \rightarrow C_6H_5NH_2 + 3S^0 + 6OH^- \qquad (b)$$

$$S^0 + S^= \rightarrow S_2^= \qquad (c)$$

$$4S^0 + 6OH^- \rightarrow S_2O_3^= + 2S^= + 3H_2O. \qquad (d)$$

At pH 9–10 reduction of nitrobenzene by hydrosulphide ion produces sulphur, which also appears as hydrodisulphide and thiosulphate ions (1).

Since hydrodisulphide ion concentration increases with time during the reduction of

[1]*Taken from the thesis of O. J. Cope submitted to the Faculty of Graduate Studies of the University of Alberta in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

nitrobenzene (1) it was thought that the measurement of the rate of increase of hydrodisulphide ion, by periodically estimating its absorption at 450 mμ, might be a suitable method for determining the relative rates of reduction of a series of alkylated nitrobenzenes. The growth in concentration of hydroxyl ion, a product of the reaction (cf. equations (*a*) and (*b*)), is known to increase the rate of reduction by sodium sulphide (4) and no doubt would have the same effect in the hydrosulphide reduction presently considered. As well, change in the hydroxyl ion concentration might well increase the colorless product $S_2O_3^=$ at the expense of the HS_2^- (cf. equations (*c*) and (*d*)). In the present work, this complication was minimized by employing hydrosulphide ion in large excess and consequently for the first few minutes of the reaction at least, the hydroxyl ion concentration should remain constant due to the buffering effect of the ammonium chloride used to obtain the sodium hydrosulphide solution.

Furthermore, in the first 10 to 15 minutes of the reaction, the amounts of phenylhydroxylamine and of hydrodisulphide ion produced are both quite small relative to the concentration of nitrobenzene and hydrosulphide ion. The rate of reaction of hydrodisulphide ion with the hydroxylamine is only 2 to 3 times greater than that of hydrodisulphide with nitrobenzene, while the reaction of hydrodisulphide ion with nitrobenzene is approximately 7 times that of the hydrosulphide ion with nitrobenzene (1). Hence loss of hydrodisulphide ion by reaction with the hydroxylamine, or change of hydrodisulphide ion concentration by reaction with nitrobenzene would be negligible in this short space of time. Thus the expression $d[HS_2^-]/dt = k[HS^-][RNO_2]$ can be employed, with $k[HS^-]$ being practically constant.

Accordingly, if a series of runs are made under these conditions and as well the initial concentrations of RNO_2 are identical, then $d(HS_2^-)/dt$ will vary according to the nature of R. Thus, at least in the initial stages, $d(HS_2^-)/dt$ will provide a measure of the relative rates of reduction of various nitro compounds.

The present paper describes the application of this technique to the study of the relative rates of reduction of nitrobenzene and some of its para alkyl homologues. The particular compounds examined in addition to nitrobenzene itself were *p*-methyl-, *p*-ethyl-, *p*-isopropyl-, *p*-*t*-butyl-, and *p*-cyclohexyl-nitrobenzene.

The reduction of a nitro group is believed to occur by an attack of the negatively charged reducing species on the electron-deficient nitrogen atom of the nitro group (5) and is thus favored by electron recession from the nitrogen atom. Accordingly, it is expected and actually has been found that electron-withdrawing substituents in the position para to the nitro group in the benzene ring accelerate, while electron-donating substituents retard, the reduction processes (3, 5, 7). Since the alkyl groups cited above are electron donors, it should be possible to examine their relative electron-donating capabilities by a study of the reduction rates of the *p*-alkylnitrobenzenes, and thus gain more information concerning the controversial question of electron donation via the hyperconjugative mechanism (8–12 and references therein).

It was not possible to carry out the comparative study using sodium sulphide as the reducing agent because under the highly alkaline conditions thus involved, polysulphide oxidation of the methyl group of nitrotoluene (13, 14) interferes significantly in the normal reduction and yields products whose absorption also interferes in the spectrophotometric determination of the polysulphide. Under the buffered conditions (and consequently lower pH) prevailing during hydrosulphide reductions, a similar loss of nitrotoluene, and interference of the product in the 450 mμ region, was not detected.

EXPERIMENTAL

Reagents

Nitrobenzene.—Fisher certified reagent was purified by distillation under vacuum. The material boiling at 85–86° at 10 mm was retained.

p-Nitrotoluene.—Fisher reagent material was crystallized from ethanol and melted sharply at 51.5°. Lit. m.p., 51.8–52.0° (10).

p-Ethylnitrobenzene, p-isopropylnitrobenzene, and p-t-butylnitrobenzene.—These reagents were all prepared by nitration of the corresponding alkylbenzenes (10 and references therein). The mixtures of isomers were separated by fractional distillation until a constant refractive index was obtained. The *p-t*-butylnitrobenzene was purified further by two successive crystallizations from methanol. M.p., 28°.

p-Cyclohexylnitrobenzene.—This reagent, prepared according to published procedures (15), was crystallized twice from ethanol. M.p., 58°, lit., 58.5°.

Sodium hydrosulphide solution.—A stock solutions of 0.900 *M* sodium sulphide containing sufficient ammonium chloride to form the sodium hydrosulphide was prepared as previously described (1).

95% Ethanol.—Commercial 95% ethanol was deaerated by heating the alcohol to its boiling point and then cooling it under nitrogen.

Experimental Procedure for the Kinetic Runs

The apparatus and general method described in the previous publication (1) were used in the present work with the following minor modification. Fifty milliliters of a 0.150 *M* stock solution of nitrobenzene in 95% ethanol was added to the reaction flask containing 200 ml of the deaerated 95% ethanol. Volume measurements were made at 25°. When this solution had reached 50°, a 50-ml quantity of the sodium sulphide – ammonium chloride solution (measured at 25° then brought to 50°) was added from an automatic pipette under nitrogen pressure. An aliquot of this final solution was used to fill the absorption cell and measurements were made of hydrodisulphide concentration in terms of absorbance.

RESULTS

By conducting all of the reductions under identical conditions, and employing the same initial concentrations of reactants, it was considered a reasonable assumption that any difference in the rate of intensification of the yellow color due to hydrodisulphide formation could be ascribed to the electron-releasing ability of the para substituent. The greater reducing power of hydrodisulphide (1), frequently present as a trace impurity in hydrosulphide solutions, made it imperative that the initial concentrations of the contaminating hydrodisulphide in the various solutions of sodium hydrosulphide be identical in all determinations. This required each reduction to be carried out at least twice, and in some cases three or four times in order to obtain a comparable series. The effect of a small change in initial concentration of hydrodisulphide is demonstrated in Fig. 1 for the reduction of *p*-nitrotoluene (0.0250 *M*) by 0.150 *M* hydrosulphide. Plot I, Fig. 1, is

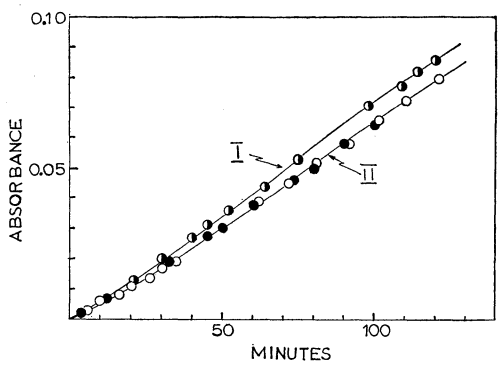

FIG. 1. The effect of initial small amounts of contaminating HS_2^- on the relative rate of reduction of 0.0250 *M* *p*-nitrotoluene with 0.150 *M* HS^- in aqueous media. Plot I—for 0.150 *M* HS^- containing HS_2^-, whose concentration is expressed by an absorbance of 0.023 (◑) at 450 mμ. Plot II—two separate reductions, with initial absorbances at 450 mμ of contaminating HS_2^-, 0.008 (○) and 0.006 (●).

that for the reduction in a solution with initial absorbance of hydrodisulphide at 450 mμ of 0.023, whereas plot II, Fig. 1, is a composite of two such reductions having initial absorbances of their solutions at 450 mμ of 0.006 and 0.008. The latter plot also demonstrates the degree of reproducibility of the measurements when all initial concentrations are practically the same.

A comparable series, obtained in the manner described above, is shown in Fig. 2. Solutions for all five runs had an initial absorbance at 450 mμ, due to contaminating

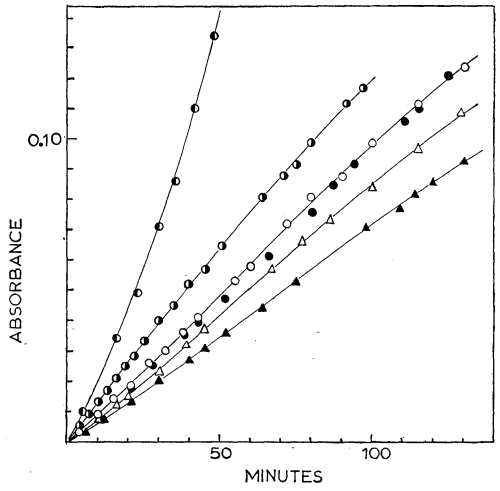

FIG. 2. The change in absorbance at 450 mμ during the reduction of the *p*-alkylnitrobenzenes (0.0250 *M*) by 0.150 *M* hydrosulphide ion in aqueous ethanol (76.5% by weight ethanol) at 50.0° C. The para substituents are H, ◐; CH_3, ▲; C_2H_5, △; *i*-C_3H_7, ○; cyclohexyl, ●; and *t*-C_4H_9, ◑.

disulphide, of 0.025±0.002. The results of the reductions of the *p*-alkylnitrobenzene, shown in Fig. 2, certainly indicate a qualitative order of electron release in the sequences methyl > ethyl > isopropyl ≈ cyclohexyl > *t*-butyl. Quantitatively, the initial slopes in each case gave a measure of the relative reduction rates of the compounds. These relative rates are shown in Table I.

TABLE I

Relative initial rates of reduction by sodium hydrosulphide of para-substituted nitrobenzenes

Relative rate	1.0	0.33	0.39	0.46	0.46	0.65

NOTE: Concentration of hydrosulphide, 0.150 *M*; of nitro compound, 0.0250 *M*. Solvent, 76.5% by weight ethanol in water. Temperature, 50°.

Previous work (3, 4) has shown that in the reduction of nitrobenzene by sodium sulphide an induction period exists wherein reduction of nitrobenzene by sulphide ion occurred very slowly with simultaneous production of disulphide ion. The much greater reducing ability of the disulphide species, compared with that of the monosulphide ion, caused a sharp acceleration of rate. This increase of rate was found to be due only to the disulphide ion produced in the reaction. Reduction of nitrobenzene by hydrosulphide ion also shows a similar but much less pronounced "induction" period because the rate of reduction of nitrobenzene by hydrodisulphide ion is only about 7 times that for hydrosulphide ion

(1). In a reaction well protected from air oxidation, the appearance of disulphide or hydrodisulphide ion occurs *only when reduction of the nitro group is taking place* (1, 3, 4). Hence any increase in hydrodisulphide concentration is a measure of the reduction occurring, at least in the initial stages of the reaction, when loss of hydrodisulphide ion by reaction with the intermediate hydroxylamine is unimportant. Thus, measurement of the production of hydrodisulphide ion at periodic intervals should give a comparison of the relative rates of reduction of the nitro group in these substituted nitrobenzenes.

The plots in Fig. 2 show the acceleration of rate of reduction as hydrodisulphide ion accumulates. The change from increasing to decreasing slope occurs as loss of this hydrodisulphide by reaction with the hydroxylamine becomes more important. The plot of unsubstituted nitrobenzene (◐) does not exhibit the decreasing slope, due to the limited size of the figure, but previous work has shown that when the reaction is continued for 50 minutes or more a similar decrease in slope does occur (1).

The composition of the solvent used was 76.5% by weight of ethanol in water. Schubert *et al.* (10), by examination of the principal band in the ultraviolet absorption spectra of *p*-alkylnitrobenzenes in various solvents as well as in the gas phase, showed that the excitation energies of these alkylnitrobenzenes in the *gas* phase and in *hydrocarbon* solvents are in the inductive order, while in other solvents (alcohols, water, amine, ethers, acids) there is a tendency towards the hyperconjugative order of electron release by alkyl groups. It was hoped in a like manner that observations could be made on the effect of change of solvent on the relative rates of reduction of the alkylnitrobenzenes. The compatibility and solubilities of both the nitro compounds and the inorganic reagents required for reduction greatly limited the choice of solvents. Hence we were confined to the use of aqueous alcoholic solutions containing not more than 51% nor less than 23% of water. Accordingly, only the two extremes of alcohol–water mixtures, compatible with the solutes, were used to show the effect of change in solvent composition on the rate of reduction. It was found that the ratio of 1.9 of the initial reduction rates of *p*-nitrotoluene and *p*-*t*-butylnitrobenzene in a solution 50.5% by weight of ethanol in water was practically identical with that found for the reductions in the solvent containing 76.5% ethanol in water.

The original concept of hyperconjugation involved a second means of electron release, in addition to the normal inductive mechanism, which was operative when the alkyl groups were subjected to a high electron demand occurring in the transition state. The phenomenon was thus considered to be electromeric (16). However, Baker, Nathan, and Shoppee (17) illustrated also the mesomeric nature of electron release in demonstrating the retardation of the sodium-ethoxide-catalyzed prototropy of benzylidene-*p*-alkylbenzylamines, a reaction facilitated by electron recession from the reaction site.

The work described in the present paper is another example of a reaction whose rate is increased by electron recession from the reaction center and again demonstrates the mesomeric character of the hyperconjugative electron release of alkyl groups in *p*-alkylnitrobenzenes. The results obtained do not assist in clarifying the *origin* of the Baker–Nathan effect—a problem which has been the subject of considerable investigation (8–12, 16–19).

SUBSTITUTED PHENYLACETYLENES. INFRARED SPECTRA

A. D. ALLEN AND C. D. COOK[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received December 4, 1962

ABSTRACT

A series of substituted phenylacetylenes has been prepared and their infrared spectra recorded. The C≡C and ≡C—H stretching frequencies are only slightly affected by substituents in the phenyl ring. Substituents in the 4-position cause a splitting of the ≡C—H band into two clearly resolved bands of similar intensity, about 10 cm^{-1} apart.

As part of an investigation into the formation of complexes between unsaturated organic molecules and transition metals, a series of substituted phenylacetylenes has been prepared and their infrared spectra recorded. Nuclear magnetic resonance spectra of these compounds have already been reported (1). In this paper we give the principal features of the infrared spectra of these compounds and the methods used for their preparation.

EXPERIMENTAL

A wide variety of substituted phenylacetylenes may be prepared by one of two general methods: (*a*) from the substituted acetophenone by chlorination followed by dehydrochlorination with alkali (2), and (*b*) from the substituted cinnamic acid by bromination followed by dehydrobromination with base.

Method (*a*) was used for the following compounds, the first four of which have not been reported previously, although Dessy (3) has described mercury acetylides derived from two of them (4-fluoro- and 3-methyl-phenylacetylene).

2-Methylphenylacetylene.—A mixture of 9.5 g phosphorus pentachloride and 5.5 g 2-methylacetophenone was maintained at 70–80° for 30 minutes. The resulting dark orange solution was distilled and the fraction boiling between 80–95° at 15 mm was collected (4.4 g). This fraction was refluxed overnight with 5 g potassium hydroxide in 15 ml absolute ethanol. After adding 150 ml iced water the solution was extracted with ether, and the extract was washed with iced water and dried over sodium sulphate. Distillation at reduced pressure gave the crude product, which was stored over potassium hydroxide pellets overnight at room temperature and then distilled from fresh pellets of potassium hydroxide. The product (1.8 g, 38%) was a colorless oil, b.p. 49–50° at 13 mm. Calc. for C_9H_8: C, 93.1; H, 6.9. Found: C, 93.0; H, 6.5.

2-Fluorophenylacetylene.—Prepared from 2-fluoroacetophenone (Pierce Chemical Co.) by the procedure used for 2-methylphenylacetylene. The product (5.8 g, 42%) was an oil, b.p. 31–32° at 10 mm. Calc. for C_8H_5F: C, 80.0; H, 4.2. Found: C, 80.0; H, 4.7.

4-Fluorophenylacetylene.—Prepared from 4-fluoroacetophenone (Pierce Chemical Co.) by the procedure used for 2-methylphenylacetylene. The product (7.5 g, 61%) was a solid, m.p. 25°, b.p. 34–35° at 10 mm, 140° at 758 mm. Calc. for C_8H_5F: C, 80.0, H, 4.2. Found: C, 80.1; H, 4.3.

3-*Methylphenylacetylene.*—Phosphorus pentachloride (83.5 g) was added to 50 g 3-methylacetophenone in 100 ml dry benzene. The mixture was cooled in ice during the initial vigorous reaction and then stirred overnight at room temperature, protected from moisture. The resulting solution was distilled at reduced pressure and the fraction boiling at 105–110° at 16 mm was collected (62 g). This fraction was refluxed for 5 hours with 75 g potassium hydroxide in 150 ml 95% ethanol. Dilution with 250 ml water, extraction with ether, drying and distillation of the ether extract gave the crude product, b.p. 75–80° at 23 mm, which was stored over potassium hydroxide pellets overnight. Distillation from fresh potassium hydroxide gave the product (16 g, 37%) as a colorless oil, b.p. 58–59° at 14 mm. Calc. for C_9H_8: C, 93.1; H, 6.9. Found: C, 92.1; H, 7.1.

4-Methylphenylacetylene.—Prepared from 4-methylacetophenone by the procedure used for 2-methylphenylacetylene. The product was an oil, b.p. 59–60° at 16 mm (lit. (2) b.p. 65–67° at 18 mm).

3-Methoxyphenylacetylene.—Prepared from 3-methoxyacetophenone by the method of Johnson *et al.* (4), b.p. 80° at 12 mm (lit. (4) b.p. 85° at 13 mm).

4-Bromophenylacetylene.—Prepared from 4-bromoacetophenone as described by Jacobs (5), m.p. 63° (lit. (2) m.p. 63.5°).

[1]*Present address: Department of Chemistry, University College, London, England.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

4-Chlorophenylacetylene.—Prepared from 4-chloroacetophenone as described by Jacobs (5), b.p. 62–63° at 13 mm, m.p. 43° (lit. (2) m.p. 43.5–44°). This compound is best purified by sublimation.

2-Chlorophenylacetylene.—Prepared from 2-chloroacetophenone by the same method as was used for 2-methylphenylacetylene, b.p. 44–45° at 11 mm (lit. (2) b.p. 71° at 18 mm).

Method (*b*) was used for the following compounds.

2-Methoxyphenylacetylene.—The following procedure is a modification of those described by Manchot (6) and Smissman (7). A solution of 48 g bromine in 200 ml dry chloroform was added during 2 hours to 50 g 2-methoxycinnamic acid in 250 ml dry chloroform. During the addition the mixture was stirred vigorously and kept between 0° and 5°. After the addition the solution was stirred for a further 30 minutes and then cyclohexene was added to remove excess bromine. The solvent was removed in a stream of dry air and the resulting crystalline mass was washed with cold carbon tetrachloride. The yield of 2-methoxy-α,β-dibromocinnamic acid was quantitative. This product was heated on a steam bath for 2 hours with 600 ml 10% sodium carbonate solution. The cooled solution was extracted with ether, and the ether extract was washed, dried, and evaporated. The residue was refluxed for 4-hours with 400 ml tertiary butanol in which 8 g potassium metal had been dissolved. Most of the solvent was then removed by distillation at reduced pressure and the residue treated with 500 ml water. Ether extraction, followed by washing, drying, and distillation of the extract, gave the crude product, b.p. 88–92° at 8 mm. This was stored overnight over pellets of potassium hydroxide and then distilled from fresh potassium hydroxide, giving a colorless liquid (12 g, 33%), b.p. 89–90° at 8 mm (lit. (8) b.p. 93° at 10 mm).

4-Methoxyphenylacetylene.—Prepared from 4-methoxycinnamic acid by the procedure used for 2-methoxyphenylacetylene, b.p. 86° at 9 mm, m.p. 29° (lit. (7) b.p. 90–95° at 10 mm).

2-Nitrophenylacetylene.—2-Nitrocinnamic acid was converted into *cis*-2-nitro-β-bromostyrene by the method of Dann *et al.* (9). The product (11.5 g) was stirred for 30 minutes at room temperature with 20 g sodium hydroxide in 250 ml 95% ethanol. The resulting solution was neutralized with glacial acetic acid, and 200 ml solvent was removed by distillation at reduced pressure. The crude product was precipitated by adding 500 ml iced water. Recrystallization from aqueous ethanol gave the pure product (3.4 g, 45%) as colorless needles, m.p. 81° (lit. (10) m.p. 81–82°).

3-Nitrophenylacetylene.—Prepared from 3-nitrocinnamic acid by the procedure used for 2-nitrophenylacetylene, b.p. 118–120 at 20 mm, m.p. 27° (lit. (11) m.p. 27°).

4-Nitrophenylacetylene.—Prepared by the method of Cristol *et al.* (12), m.p. 149–150° (lit. (12) m.p. 148–149°).

Other methods were used for the following compounds.

2-Hydroxyphenylacetylene.—Coumarilic acid (benzofuran-2-carboxylic acid) was prepared from coumarin by the method of Fuson *et al.* (13). An intimate mixture of 20 g coumarilic acid, 20 g powdered calcium oxide, and 1 g copper bronze powder was heated in a small distilling flask with a free flame until distillation stopped. The crude benzofuran (14 g) was washed with 10% sodium hydroxide solution, dried over sodium sulphate, and distilled, b.p. 170°.* A mixture of 11.8 g benzofuran, 6.9 g sodium, and 94 g pyridine (freshly distilled from potassium hydroxide) was heated in an oil bath at 190° for 4 hours. The cooled mixture was treated with pyridine and water and then acidified (to congo red) with dilute hydrochloric acid. Extraction with ether, followed by drying and distillation of the ether extract, gave the crude product, which was then dissolved in 10% aqueous potassium hydroxide. The resulting solution was extracted with ether to remove any unreacted benzofuran, and the acetylene was regenerated by the addition of dilute hydrochloric acid to the alkaline solution. The resulting acidic solution was extracted with ether, and the ether extract was washed, dried, and distilled at reduced pressure to give the pure product (3.8 g, 32%), b.p. 63° at 7 mm (lit. (8) b.p. 73–74° at 11 mm).

2-Aminophenylacetylene.—Prepared by the reduction of 2-nitrophenylacetylene as described by Schofield and Swain (10). The product was purified by precipitating the amine hydrochloride from benzene solution, and recovering the free amine by treating the precipitate with aqueous alkali. Extraction with ether, followed by washing, drying, and distillation of the ether extract, gave the product as a yellowish oil, b.p. 99–101° at 13 mm (lit. (10) b.p. 98–100° at 12 mm).

4-Aminophenylacetylene.—Prepared by reduction of 4-nitrophenylacetylene, as described by Burawoy and Critchley (14), m.p. 99–100° (lit. (14) m.p. 100°).

Phenylacetylene.—The commercial material was distilled from pellets of potassium hydroxide and the fraction boiling between 140–144° was collected and stored over potassium hydroxide. Fractional distillation gave the pure material, b.p. 44° at 23 mm (lit. (15) b.p. 140°).

Infrared Spectra

The infrared spectra of dilute solutions (ca. 5%) of the compounds in carbon tetrachloride (Fisher 'Spectranalysed') were obtained using a Perkin–Elmer 221G prism-grating spectrometer. The instrument was calibrated against indene and routinely checked against polystyrene film. The spectra were recorded at 30±1°, at a scanning speed of approximately 1 cm^{-1}/sec, in the regions of interest. Standard 221G

**Details of this method for the decarboxylation of coumarilic acid, developed by H. Gilman, were kindly provided by Professor A. G. Brook.*

settings used were: slit schedule 927, attenuator speed 11.00, amplifier gain 4.5, and scan suppression at 4–5. A 0.1-mm sodium chloride fixed cell was used and the position of the weak band at 2100 cm^{-1} was checked if necessary by using scale expansion or a 0.5-mm cell. Reproducibility was ± 1 cm^{-1}, and the precision of the band maxima is estimated to be ± 2 cm^{-1}.

DISCUSSION

Table I shows details of the C≡C and ≡C—H stretching frequencies observed for these compounds.

TABLE I

Stretching frequencies ν for compounds X—$C_6H_4C_2H$

4-Methyl	3323, 3307	2115	4-Nitro	3322, 3308	2122 (w)
3-Methyl	3313	2112	3-Nitro	3314	2126 (w)
2-Methyl	3312	2111	2-Nitro	3314	2119 (w)

The carbon–hydrogen stretching mode gives a strong absorption in all cases. The carbon–carbon stretching mode gives a much weaker absorption, the maximum observed for the series being about 10% of the ≡C—H absorption. Those compounds in which the C≡C absorption is markedly less than 10% of that of ≡C—H are shown as weak (w) in the table. It may be significant that such compounds all contain electron-withdrawing substituents.

It will be seen that there is little correlation between the electron-withdrawing or -donating ability of the ring substituent and the frequency of either stretching vibration. If the variations observed do indicate significant trends then these are that electron-withdrawing substituents tend to decrease the ≡C—H and increase the C≡C stretching frequencies.

A weak band showing up as a shoulder on the low-frequency side of the ≡C—H absorption has been reported for a variety of acetylenes by Brand *et al.* (16). They found this band to be most intense in the spectra of the aryl acetylenes studied and suggest that this absorption results from a combination tone intensified by Fermi resonance. Nyquist and Potts (17), in a more detailed examination of phenylacetylene, arrived at the same conclusion and propose that the absorption results from the summation of the first overtone of the ≡C—H bending mode (at about 1220–1250 cm^{-1}) and the C≡C stretching fundamental, the intensity being increased by Fermi resonance with the ≡C—H stretching fundamental. However recent work by West and Kraihanzel (15), which included a study of the spectrum of deuterophenylacetylene ($C_6H_5C_2D$), may invalidate the earlier proposals since these authors report that side bands also accompany the C—D stretching absorption at 2595 cm^{-1}.

We find that compounds with substituents in the 2- and 3-positions give a single, sharp band at about 3315 cm^{-1}, with perhaps a very weak unresolved shoulder, but that when the substituent is in the 4-position this band is split into two bands about 10 cm^{-1} apart. The lower-frequency band of this pair is usually of slightly lower intensity than the other,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

but only in the unsubstituted phenylacetylene is it sufficiently poorly resolved to be described as a shoulder. These spectra are complex in the 1000–1500 cm^{-1} region and in many cases it is difficult to assign a band to the first overtone of the ≡C—H bending mode, but the suggestion of Nyquist and Potts is supported by the fact that the 4-substituted compounds usually have a strong band between 1220–1230 cm^{-1}, which may be attributed to this overtone, whereas the 2- and 3-substituted compounds usually do not.

Grateful acknowledgment is made to the National Research Council of Canada for financial support and to the Shell Oil Company of Canada Limited for a fellowship (to C. D. C.).

CRITICAL PHENOMENA IN THE SYSTEM ACETIC ACID – CHLOROFORM – WATER

A. N. CAMPBELL AND E. M. KARTZMARK
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received November 30, 1962

ABSTRACT

This paper is an experimental study of (*a*) the solid–liquid equilibria at low temperatures; (*b*) equilibrium compositions at temperatures other than 25° C; (*c*) the critical phenomena, L_1–L_2, L_1–V, and L_2–V, in the acetic acid – chloroform – water system. No previous study has been made of critical phenomena in a system exhibiting partial liquid miscibility.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The system acetic acid – chloroform – water is one of the classical examples of partial miscibility in a ternary system, first studied by Wright, Thompson, and Leon in 1891 (1). Thanks to the subsequent workers Brancker, Hunter, and Nash (2), the equilibrium relations at 25° are very well known, as far as the compositions of equilibrium liquid layers are concerned. Nothing, however, is known about:

(*a*) the solid–liquid equilibria at low temperatures;
(*b*) equilibrium liquid compositions at temperatures other than 25°;
(*c*) the critical phenomena, L_1–V (L_1 = chloroform layer) and L_2–V (L_2 = aqueous layer).

So far no study has been made of critical phenomena in any system exhibiting partial miscibility in the liquid state and the results arrived at in this paper have general applicability to all systems of this kind.

A previous paper (3) has dealt with the thermodynamics of this system, as exemplified by the vapor pressures and densities. Further work is proceeding on the isobaric boiling points, dielectric constants, and heats of mixing.

RESULTS AND DISCUSSION

Because of the chemical natures of the substances named in the title, formation of compounds or of solid solutions is inherently improbable and therefore the study of the freezing point curves was expected to yield little of interest. The study was, however, carried out for the binary systems chloroform – acetic acid and chloroform – water, and for the ternary system, using a double-junction copper–constantan thermocouple, a Brown Elektronik recorder, and liquid nitrogen as a coolant. The system acetic acid – water was previously studied by various workers (4) and the eutectic found to lie at 58.1% acetic acid and −28.5 to −27.0°. The eutectic of the chloroform – acetic acid system was found to lie at 91.8% $CHCl_3$ by weight, and −67.5° (Fig. 1). In the system chloroform–water, the eutectic lies at 0.1% H_2O and −64.0°. The ternary eutectic was found to lie at −70° and 90.7% chloroform, 8.3% acetic acid, and 1.0% water. The eutectic trough leading from the acetic acid – water eutectic to the acetic acid – chloroform eutectic was determined experimentally. The results are given in Fig. 2, on which has been superimposed the partial miscibility gap for 0°.

Two types of temperatures of homogeneity are to be distinguished in this work, namely, the temperature at which two partially miscible liquids become completely miscible ($L_1 + L_2 \rightarrow L$) and the true critical temperatures ($L_1 + V \rightarrow V$ and/or $L_2 + V \rightarrow V$);

certain of the mixtures, though not all, will exhibit all three temperatures. For the determination of all three types of temperatures, the simple apparatus shown in the photograph (Fig. 3) worked very well. It consists essentially of a cylindrical block of copper, weighing about 75 lb and having a radial boring of 1-cm diameter. Slots parallel to the boring permit light to pass through. A sealed capillary tube placed in the central boring can be viewed in a telescope at a safe distance. Two heating circuits in parallel, wound around the copper cylinder, make it possible to raise the temperature to 350° in about 3 hours. An ordinary mercury-in-glass thermometer placed in a separate boring of the copper block gives the temperature. The temperature was corrected for exposed stem but with

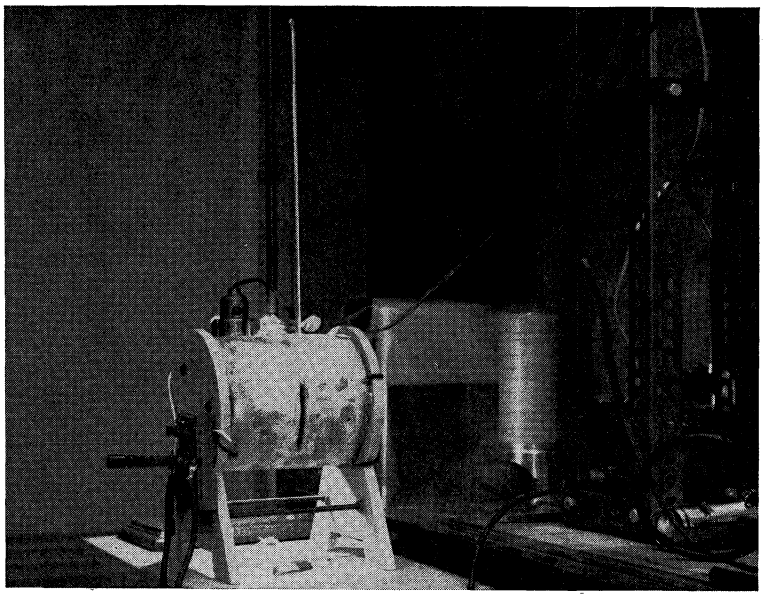

FIG. 3. Apparatus.

this relatively crude arrangement we do not believe the results to be more accurate than ±1°. We saw no reason to refine the temperature measurement, although it would have been easy to do so. Temperature was easily controlled and occasional explosions constituted no hazard to the operators.

A possible criticism of this method, as applied to L–V critical temperatures, is that, unless the amount of the mixture and the volume of the container are such as to represent the critical density, the temperature of disappearance of the meniscus is not the true critical temperature. Nevertheless, the phenomena as observed usually presented the fluctuating striae said to be characteristic of critical phenomena. It is true that the temperature of reappearance of the meniscus was frequently 5–10° lower than that of disappearance but this may be a characteristic of mixtures as distinct from pure liquids: we reproduce only the temperature of disappearance. The results were also reproducible in different experiments and the curve of critical temperature vs. composition was smooth. The explanation is, no doubt, that in the four-dimensional representation of pressure, volume, temperature, and concentration, all curves are very flat in the neighborhood of the critical point, or, in plain words, the critical temperature is not very sensitive to small changes in volume of the system. At all events, we repeat that in all cases the disappearance of the meniscus appeared to be a critical phenomenon: cases where the meniscus disappeared by exhaustion of the one or other phase were always discarded. If our figures are not true critical temperatures they are sufficiently close for the present purpose. We note that the critical temperatures of the pure liquids as determined by us are in good agreement with accepted literature values.

The critical temperatures of the homogeneous binary systems acetic acid – water and acetic acid – chloroform are reproduced graphically in Figs. 4 and 5. The critical temperatures of homogeneous ternary mixtures are given in Table I, since they cannot be expressed graphically on a plane diagram to any purpose.

Within the region of heterogeneity, as mentioned in the introduction, two, and sometimes three, temperatures of homogeneity (2 phase) have to be determined. The $L_1 - L_2 \rightarrow L$ temperature was easily determined in the apparatus described as the temperature at which one or the other liquid layer vanished by exhaustion (method of Alexejew). In order to do this accurately, it is necessary to heat very slowly in the neighborhood of the temperature of homogeneity, to remove the tube and shake vigorously to produce a fine suspension, and then to determine if the suspension persists at the temperature of the furnace.

As a preliminary to the above work, however, the isothermal area of heterogeneity was determined at such temperatures as were readily accessible, viz. 0°, 48.5°, and 91.5°. Such quantities of the three components as would give approximately equal volumes of the two layers were stirred in thermostat for 24 hours and then each layer sampled for analysis. The method of analysis was that of determining acetic acid by titration. A weighed amount of acetic acid was then added to a separate sample and the density determined. A previous calibration had been made, at 25°, of the densities of mixtures lying without the area of heterogeneity (3). These data yielded a complete analysis. We have subsequently found that the determination of refractive index gives a more sensitive determination. The results are represented graphically in Figs. 6, 7, and 8. The plait point compositions are given in Table II.

TABLE II

	Composition in wt%		
Temperature in °C	Chloroform	Water	Acetic acid
0	45.0	14.0	41.0
25.0 (Brancker, Hunter and Nash (2))	41.5	16.1	42.4
48.5	44.0	17.0	39.0
91.5	45.0	19.0	36.0

The results of the Alexejew method for the heterogeneous region are represented graphically in Figs. 9, 10, 11, 12, and 13, each of which represents a pseudobinary section of the solid model having a fixed amount of acetic acid. Some comment is necessary. In systems containing less than 20% acetic acid, the surface of heterogeneity (L_1–L_2) intersects the critical surface L_1–V, where L_1 represents the chloroform layer. This means that the chloroform layer has a constant composition when passing through the critical change L_1–V, and this change therefore takes place at a constant temperature, independent of the total composition, so long as the composition lies within the miscibility gap at the temperature of the L_1–V transition. The L_1–V transition exhibits experimentally all the characteristics of a true critical point, except that a (separate) liquid layer, the aqueous layer, remains behind and this in turn goes through the L_2–V critical transition at, however, a much higher temperature. Since, however, there is only one liquid, its composition varies with the total composition of the mixture and therefore the second critical temperature (L_2–V) is not constant but is a function of total composition.

As the concentration of acetic acid in the pseudobinary mixtures is increased, the L_1–L_2 surface separates from the L–V surface and the temperatures of L–V transition now also become a function of total composition. This is clearly shown in the pseudobinary sections Figs. 9, 10, 11, 12, and 13.

THE REACTION OF ACTIVE NITROGEN WITH METHANOL[1]

M. J. Sole and P. A. Gartaganis[2]
Chemistry Department, Ontario Research Foundation, Toronto, Ontario
Received April 30, 1962

ABSTRACT

The reaction of active nitrogen with methanol has been investigated at several temperatures in the range 30 to 480° C using a fast-flow system. The only condensable products found in appreciable amounts were water and hydrogen cyanide. The overall activation energy is 3.0 and 3.2 kcal/mole and the steric factors 1.3×10^{-3} and 2.1×10^{-3} for streamline and turbulent flow respectively.

It is postulated that the mechanism consists of the initial formation of a collision complex, $[NCH_3OH]$, which breaks down to two fragments, NCH_3 and OH, from which the two condensable products are formed,

$$N + CH_3OH \rightarrow [NCH_3OH] \rightarrow NCH_3 + OH$$

$$NCH_3 \rightarrow HCN + 2H \text{ or } H_2$$

$$OH + H \rightarrow H_2O.$$

Attack of the methanol molecules by hydrogen atoms resulting from the main reaction occurs to a lesser extent and is responsible for the production of small quantities of methane, carbon monoxide, and additional water.

INTRODUCTION

Studies of the reactions of active nitrogen, produced by electrical discharge in a low-pressure nitrogen stream, with organic compounds have been in progress for many years and have received particular attention recently through the discovery that these species exist in the upper atmosphere (1). Except for two preliminary studies on the reactions of active nitrogen with methanol, acetone, and dimethyl ether (2) and with several aromatic and aliphatic oxygenated compounds (3) and a recent study on the reactions with liquid siloxane heptamer (4), no other work has been reported on the kinetics of active nitrogen with simple oxygen-containing organic compounds. The present investigation was undertaken with a view to studying the reaction of active nitrogen with methanol.

It is now established that the major chemically active species present in active nitrogen is nitrogen atom in the ^4S ground state; recent investigations (5–7) have shown that the second active species is the $A^3\Sigma_u^+$ state of N_2.

EXPERIMENTAL

The apparatus used was similar to that described in detail by Gartaganis and Winkler (8). It consisted essentially of a condensed discharge Wood–Bonhoeffer fast-flow system with additional features for the measurement of reactants and analysis of products. The spherical reaction vessel was replaced in the present study by a 100-cm reaction tube of a 16-mm i.d. which contained thermocouple wells at regular intervals.

The duration of an experiment varied from 200 to 1600 seconds. The products were collected in traps surrounded with liquid air and were distilled at the end of each run into an absorber containing 1 *N* KOH or methanol. Hydrogen cyanide was measured by titration with 0.100 *N* $AgNO_3$ solution. Water was determined with Karl–Fischer reagent by means of a specially constructed apparatus for the direct transference of the products to the analytical system. Mass spectrometric analyses supplied information on the purity of the reagents and the nature of the non-condensable products. The ratio of water to hydrogen cyanide was established by determining their concentrations in aliquot parts withdrawn from the absorber. The

results obtained with the above techniques were verified by means of gas phase chromatography (Vapor Fractometer, Model 154, Perkin Elmer Corp.). A column comprising polyethylene glycol on teflon powder separated, in a satisfactory way, unreacted methanol, hydrogen cyanide, and water in that order.

RESULTS

The reaction of active nitrogen with methanol was accompanied by a peach-violet colored flame, similar to those observed in reactions with hydrocarbons. There was a gradual change in the flame characteristics as the flow rate of methanol and/or the temperature were increased. The atomic and the total nitrogen flow rates were 1.55 and 23.2 μmoles/sec respectively.

Hydrogen cyanide and water in approximately equal amounts were the only condensable products found regardless of methanol flow rate or temperature. Mass spectrometric analysis of non-condensable products revealed the presence of a substantial amount of hydrogen and small quantities of carbon monoxide and methane. No ammonia was detected.

The amount of hydrogen cyanide, the only nitrogen-containing product, recovered in different experiments at various flow rates and at different temperatures in the range 30 to 480° C is shown in Fig. 1.

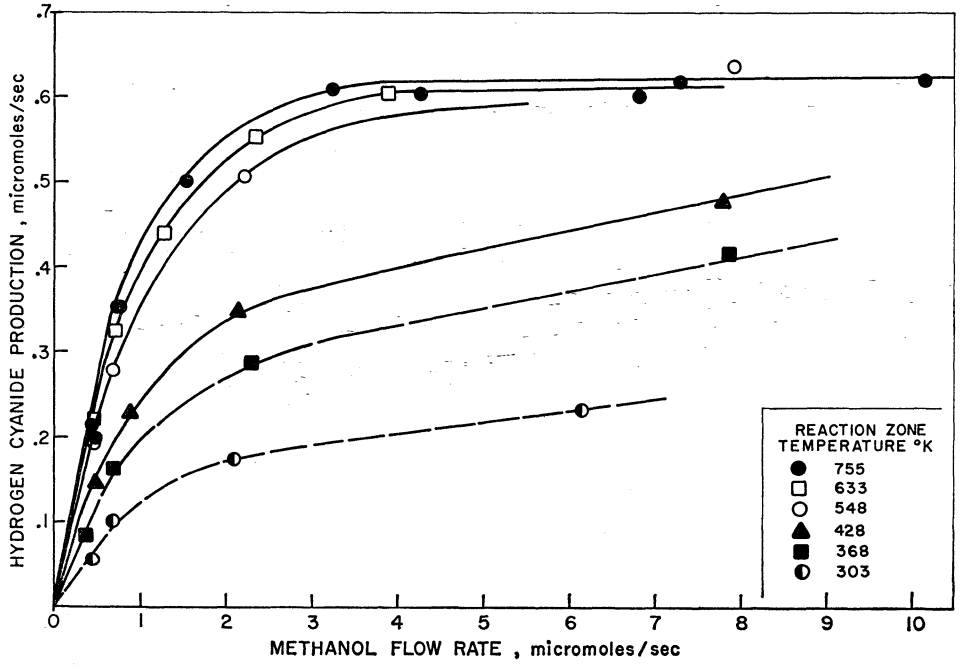

FIG. 1. Hydrogen cyanide production as a function of methanol flow rate at different temperatures in the reaction of atomic nitrogen with methanol.

It is reasonable to assume that the initial attack of the nitrogen atom on the methanol molecule is the rate-determining step of the overall reaction. If it is further assumed that pressure gradients in the reaction vessel are small and that changes in the total gas flow rate due to reaction may be neglected, second-order rate constants may be calculated from the rate of formation of hydrogen cyanide for streamline and turbulent flow (9).

According to the collision theory (10)

$$k = PZ\exp(-E/RT). \quad [3]$$

P is the steric factor and Z is the collision number, which is equal to

$$10^{-3}\sigma_{AB}^2N[8\pi RT(M_A+M_B)/M_AM_B]^{\frac{1}{2}}, \quad [4]$$

where $R = 8.3144\times10^7$ ergs/deg-mole;
M_A, M_B = molecular weights of methanol and atomic nitrogen respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The mean collision diameter, σ_{AB}, was calculated using values of 2.85 and 2.98 Å (11) for the collision diameters of methanol and atomic nitrogen respectively. Equation [3] can be written in terms of its temperature-independent part Z' and $T^{\frac{1}{2}}$, so that,

$$k = PZ'T^{\frac{1}{2}} \exp(-E/RT). \qquad [5]$$

According to equations [3] and [5] the energy of activation can be calculated from the slope of a plot of log k against $1/T$ and log $(k/T^{\frac{1}{2}})$ against $1/T$ respectively.

The calculated values and corresponding Arrhenius plots are shown in Tables II and III and Fig. 2.

DISCUSSION

Whereas the identity of the two major chemically reactive species in active nitrogen, i.e. atoms in the ^4S and molecules in the $A^3\Sigma_u^+$ state, has been firmly established, their relative concentration and its variation with experimental conditions is still under investigation (5–7). The nitric oxide "titration" in conjunction with the determination of the extent of hydrogen cyanide production from ethylene provides a measure of the concentrations of these two species. The experimental conditions adopted in this study—particularly the considerable decay time from the discharge tube to the methanol inlet—ensured the almost exclusive presence of nitrogen atoms in the active nitrogen stream. The N atom concentration was measured from the reaction with ethylene at 385° C.

The reaction of nitrogen atoms with methanol may be represented by the following mechanism:

$$CH_3OH + N \rightarrow [NCH_3OH] \rightarrow NCH_3 + OH. \qquad [6]$$

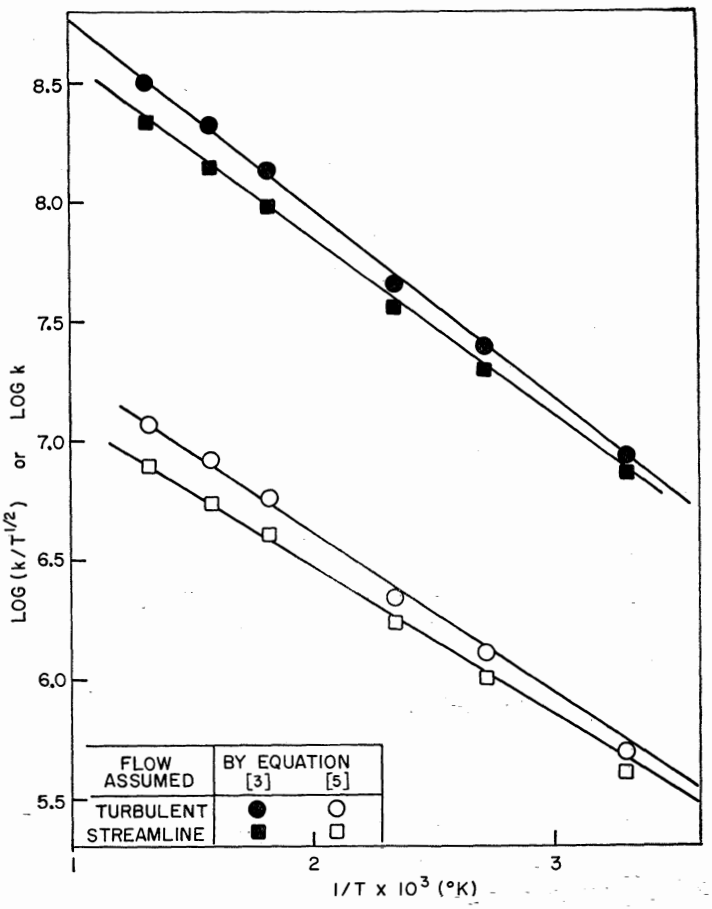

FIG. 2. Arrhenius plot of log k vs. $1/T$ and log $(k/T^{\frac{1}{2}})$ vs. $1/T$ for the reaction of atomic nitrogen with methanol.

The two fragments react further to produce hydrogen cyanide and water, which were the only two condensable products found in appreciable quantities:

$$NCH_3 \rightarrow HCN + 2H \quad [7]$$

or

$$NCH_3 \rightarrow HCN + H_2 \quad [8]$$

and

$$OH + H \rightarrow H_2O \quad [9]$$

$$OH + H_2 \rightarrow H_2O + H. \quad [10]$$

Reaction [8] is much more favorable energetically than reaction [7]; however, the latter may conserve spin while the former does not. Spin considerations are important as well as the energy relations. Reaction [9] probably requires a third body, and water production from equation [10] probably depends on prior recombination of hydrogen atoms.

Small amounts of methane and carbon monoxide were found among the products besides the three main ones, i.e. hydrogen cyanide, water, and hydrogen. In addition, a slight excess of water over hydrogen cyanide was consistently produced. Both these observations can best be explained by the direct attack on methanol by hydrogen atoms.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Indeed, Geib (12) investigated the reaction of hydrogen atoms with methanol by the discharge tube method and reported water, carbon monoxide, and methane as the main products. The small yield of CH_4 and CO can be attributed to the relatively small concentration of hydrogen atoms, which are produced according to equation [7]. Loss of hydrogen atoms results also from: (*a*) recombination of hydrogen atoms by three-body collisions with methanol molecules (13) and with nitrogen (14):

$$H + H + N_2 \rightarrow H_2 + N_2; \qquad [11]$$

(*b*) consumption of hydrogen atoms by other concomitant reactions, for instance reaction [9]. No significant amount of oxygen was found among the products, which is in accordance with the observations of Oldenberg and Rieke (15) that hydroxyl radicals react more readily with hydrogen than with themselves. Similarly, Rodebush *et al.* (16) indicated that the reaction

$$OH + OH \rightarrow H_2O + O \qquad [12]$$

does not occur.

It is noteworthy that no detectable quantities of ammonia or hydrazine were formed. Of the electronegative atomic reactants that have been studied, nitrogen atom appears to be the only one for which the direct attack is favored over hydrogen abstraction (17).

The products of the reaction of active nitrogen with methanol do not react further with the former to any significant extent. It has been established that simple hydrides, H_2, CH_4 (18), NH_3 (19) are relatively inert to atomic nitrogen; therefore, it would not be an unreasonable assumption to extend these observations to the reaction of the water molecules with active nitrogen.

The maximum yield of hydrogen cyanide (ca. 0.63 μmole/sec) does not correspond to the maximum nitrogen atom concentration indicated from the ethylene reaction (ca. 1.55 μmoles/sec). It would seem, therefore, that the consumption of nitrogen atoms does not proceed exclusively according to equation [6]. Reactions leading to nitrogen atom "wastage" must also be considered. The simplest explanation for the consumption of more than half the atomic nitrogen with no product formation in the presence of methyl alcohol is the reaction

$$N + N + CH_3OH \rightarrow N_2 + CH_3OH, \qquad [13]$$

where the alcohol is an efficient third body. According to Geib (12) there is evidence of catalytic recombination of hydrogen atoms in the presence of methyl alcohol. Alternatively the "wastage" could result from intermediate formation of NO or NOH. On the basis of the available data it is rather difficult to decide which approach to a mechanism of nitrogen atom wastage would be the best. It is hoped that pertinent information from the reactions of active nitrogen with other simple alcohols will elucidate this interesting phenomenon.

CONCLUSION

On the basis of the available evidence the mechanism of the reaction of active nitrogen with methanol appears to consists of an initial formation of a collision complex, $[NCH_3OH]$, which breaks down to two fragments, NCH_3 and OH, according to reaction [6]. These two fragments produce directly by reactions [7], [8] and [9], [10] the only two condensable products present in appreciable amounts, i.e. hydrogen cyanide and water, in a 1:1 ratio. Concomitant attack of the methanol molecule by hydrogen atoms is responsible for the production of small amounts of carbon monoxide, methane, and additional water.

THE RADIOLYSIS OF HCl–HBr MIXTURES

R. C. Rumfeldt and D. A. Armstrong
Department of Chemistry, University of Alberta, Calgary, Alberta
Received August 7, 1962

ABSTRACT

Bromine was the only halogen formed in irradiated mixtures of HCl and HBr. A study of its effect on the hydrogen yield from HCl showed that it reacted with the first hydrogen-forming species (or its precursor), and indicated the same yield for this species as did the earlier experiments with chlorine. The results were consistent with thermal hydrogen atoms, formed in the reaction

$$e + H—Cl \cdots H—Cl \rightarrow H + Cl—H \cdots Cl^-,$$

as the first hydrogen-forming species, and hot hydrogen atoms, resulting from the dissociation of excited HCl molecules, as the second species.

The hydrogen yield from liquid HBr at −79° C was a factor of two larger than that from liquid HCl at the same temperature, and in mixtures of the two the hydrogen yield increased gradually from a value characteristic of pure HCl ($G_{H_2} = 6.5$) to one characteristic of pure HBr ($G_{H_2} = 12.4$). The smaller yield from HCl cannot be explained by radical combinations:

$$H + Cl + M \rightarrow HCl + M$$

$$H + H + M \rightarrow H_2 + M$$

in the radiation tracks and must be attributed either to differences in the ion-combination reactions in the two liquids or to a genuinely greater yield of ions and/or dissociative excited molecules in HBr. The hydrogen yield from solid HBr at −196° C was $G_{H_2} = 10.5$.

INTRODUCTION

A recent publication (1) from this laboratory described a study of the radiolysis of liquid and solid hydrogen chloride. This paper reports the results of a similar study of the radiolysis of hydrogen bromide, and also presents further evidence for the existence of two hydrogen-forming species in irradiated hydrogen chloride. Because the decomposition yield of hydrogen bromide was found to be twice that of hydrogen chloride, hydrogen and halogen yields in mixtures of the two were also studied in the hope that a reason for the difference in radiation sensitivity of the two compounds would become apparent.

EXPERIMENTAL

Materials

Hydrogen chloride and hydrogen bromide were obtained from the Matheson Co. and purified by the preirradiation procedure already described. Reagent grade bromine was thoroughly dried by treatment with $CaCl_2$ and subjected to several bulb-to-bulb distillations. It was stored over P_2O_5 at −80° C.

Apparatus

The apparatus and technique used for the preparation of samples and measurement of hydrogen yields were essentially as previously described. In this study a spectroscopic technique was also employed to observe the halogen production in the irradiated mixtures. Optical cells, which were shielded from the direct Co^{60} beam during irradiations, were attached to the pyrex irradiation cells. On completion of an irradiation the hydrogen halide – halogen solution was transferred to the optical cell, where its spectrum over the range 3000–5000 Å was taken with a Beckman D.U. spectrometer fitted with a cell compartment for use at −80° C. This consisted of an aluminum block machined to receive the optical cell and to permit passage of the light beam. The block was insulated with styrofoam on all sides and attached to two plates, which were bolted to the monochromator and photocell of the D.U. spectrometer. Quartz plates isolated the cell compartment from the D.U. spectrometer and it was purged by streams of dry nitrogen. The temperature of the compartment was maintained within a few degrees of −80° C by means of a liquid nitrogen cooling bath. Optical densities were measured relative to air as blank. The optical density of the cell over the wavelength range used with liquid HCl or HBr in it at −80° C was the same, within experimental error, as that

of the cell with water at room temperature. This is in accord with expectation, as HCl and HBr do not absorb appreciably above 2500 Å (2). For the pure hydrogen halides changes in optical density on irradiation may be associated with the halogen generated by the radiolysis.

Dosimetry

Dose rates were calculated in units of ev per gram per minute from measurements of ferrous–ferric conversion in the Fricke dosimetry solution. Corrections for differences in the number of electrons per gram in liquid HCl, liquid HBr, and the dosimetry solution were made on the basis of the Compton scattering process alone. The scattering cross sections per electron were assumed to be identical in all three liquids. In mixtures of HCl and HBr the total dose was taken as the sum of the individual doses calculated separately.

RESULTS

The hydrogen yields from pure liquid and solid HBr have been presented in Table I. Within experimental error they were independent of dose over the range used. Hydrogen

yields from liquid mixtures of HCl and HBr have also been given in Table I and have been plotted in Fig. 1 as a function of the "electron fraction" of HBr. The effect of bromine on hydrogen yields from HCl is shown in Table II.

0.345	5.03	1.50			

Measurement of the halogen yields by the spectroscopic technique described served as a check on the purity of the hydrogen halides. It was in fact the use of this technique which led to the development of the preirradiation procedure, and irradiated samples of either hydrogen halide exhibited absorption bands other than those of the corresponding halogen unless this procedure was employed. The absorption spectra of Br_2 and Cl_2 generated by irradiation in the liquid hydrogen halides (see Fig. 2) were very similar to their spectra

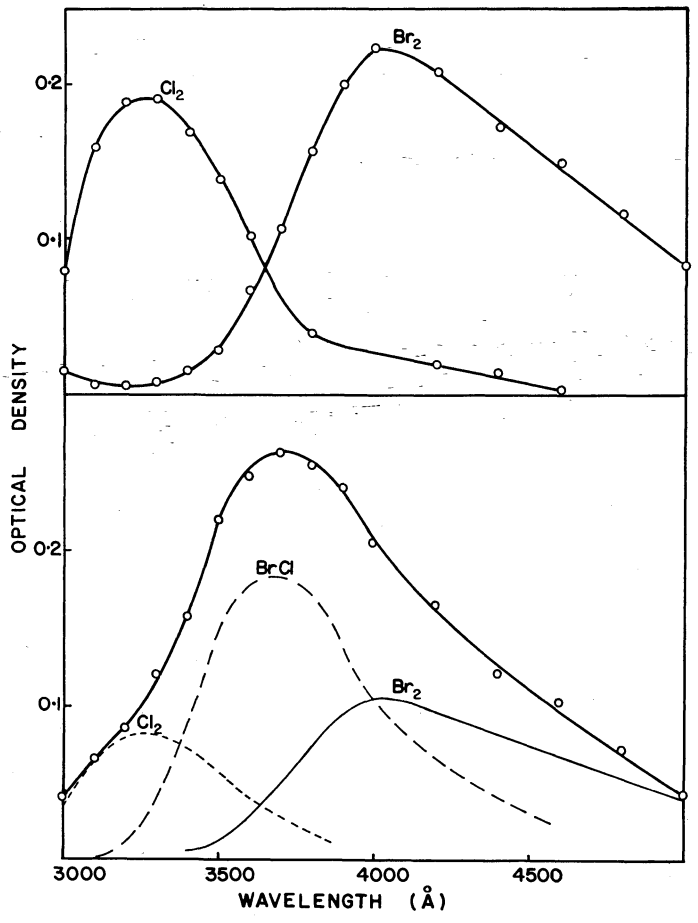

FIG. 2. Top: typical spectra of Cl_2 and Br_2 in the liquid hydrogen halides at $-79°$ C; bottom: spectrum of an irradiated 0.004 M solution of HBr in liquid HCl at $-79°$ C after complete oxidation of the HBr.

obtained under more normal conditions (3, 4). The optical densities at 3300 Å taken after successive irradiations of a sample of HCl, which had been purified by preirradiation, have been plotted as a function of dose in Fig. 3, line A. After this data had been obtained

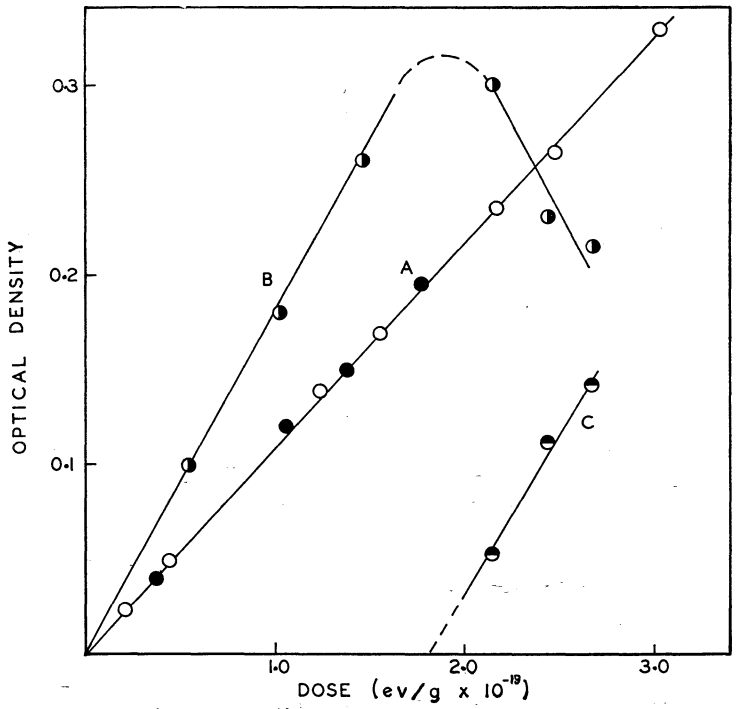

FIG. 3. Optical density – dose plots for irradiated HCl solutions. These plots illustrate: A: ● optical density at 3300 Å of Cl_2 produced in an irradiated sample of pure HCl, ○ same experiment repeated; B: ◑ optical density at 4000 Å of Br_2 produced in the irradiation of a 0.004 *M* solution of HBr in HCl; C: ◓ optical density at 3700 Å of BrCl produced in the irradiation of a 0.004 *M* solution of HBr in HCl.

the sample was distilled into the vacuum line, purified from chlorine, replaced in the irradiation cell, and then subjected to a second set of irradiations. After each of these the optical density at 3300 Å was again taken. The optical densities for both sets of irradiations have been included in Fig. 3, line A. Bromine yields from preirradiated HBr were similarly linear with dose. Extinction coefficients for solutions of the halogens in their respective hydrides were calculated from the slopes of the optical density – dose plots on the assumption that the hydrogen and halogen yields were identical. The values obtained at the absorption maxima (viz. ϵ_{Br_2} at 4000 Å = 198 in HBr; ϵ_{Cl_2} at 3300 Å = 88 in HCl) were slightly lower than those observed in carbon tetrachloride (viz. ϵ_{Br_2} at 4110 Å = 206; ϵ_{Cl_2} at 3300 Å = 97) (3, 4), but such a trend is in accordance with the behavior of these molecules in polar acidic solvents (4). From these figures and the observed linearity of the optical density – dose plots it may be concluded that the preirradiation procedure was effective in removing the impurities which interfered with halogen formation in the hydrogen halide samples not subjected to this procedure.

In mixtures of the hydrogen halides containing more than 1 mole% HBr bromine was the only halogen detected after irradiation. In dilute solutions of HBr in HCl, however, bromine was produced until all of the HBr had been oxidized, and then on further irradiation the absorption maximum of the solution began to shift toward shorter wavelengths,

indicating the formation of bromine monochloride and chlorine. The spectra of these solutions can be resolved as is the one in Fig. 2 (bottom). A plot of the contribution of bromine to the total optical density at 4000 Å of an irradiated 0.004 *M* HBr solution in HCl is shown in Fig. 3, curve B. The optical density rose until the HBr had been consumed, and thereafter decreased. Production of BrCl (see C in Fig. 3) commenced at the point where the bromine concentration passed through a maximum. From the spectrum taken after the final irradiation (see Fig. 2, bottom) it would appear that Cl_2, Br_2, and BrCl exist in equilibrium, as they do at room temperature. In support of this it was found that the value of the equilibrium constant for the reaction

$$Cl_2 + Br_2 \rightleftharpoons 2ClBr \qquad [1]$$

calculated from the present data agreed with the work of Buckles and Mills (4).

As nothing is known about the rates of the reactions which may occur between the halogens and HBr under these conditions, viz:

$$BrCl + HBr \rightarrow HCl + Br_2 \qquad [2]$$

$$Cl_2 + HBr \rightarrow HCl + BrCl, \qquad [3]$$

a solution of bromine monochloride (in equilibrium with smaller amounts of chlorine and bromine) in liquid HCl was prepared and frozen at liquid nitrogen temperature in an optical cell. A slight excess of HBr was then frozen on the surface of this. Spectroscopic examination carried out immediately after melting of this mixture showed that the bromine monochloride and chlorine oxidized the HBr to bromine, the above reactions being complete in a few minutes. Since these spontaneous reactions would have occurred prior to spectroscopic examination of the irradiated samples, the failure to observe Cl_2 and BrCl in the dilute solutions of HBr in HCl does not mean that all of the chlorine atoms escaped from the radiation tracks to undergo the reaction

$$Cl + HBr \rightarrow HCl + Br. \qquad [4]$$

There should in fact be a "molecular yield" of chlorine similar to the "molecular yield" of H_2O_2 observed in irradiated water.

DISCUSSION

The earlier paper from this laboratory showed that two hydrogen-forming species, which were scavenged with different efficiencies by chlorine, were present in irradiated HCl. The results with bromine confirm the presence of two species, and a plot of $1/\Delta G_{H_2}$ versus $1/[Br_2]$ has been presented in Fig. 4 in accordance with equation (i) of reference 1. The *G* value for the formation of the first hydrogen-forming species and the ratio of its rate constants for reaction with bromine and HCl as deduced from this plot have been presented in Table III together with the corresponding data obtained from the work

TABLE III

	Cl_2		Br_2	
	G	k_{HCl}/k_{Cl_2}	*G*	k_{HCl}/k_{Br_2}
First species	2.3	1.7×10^{-3}	2.4	7.9×10^{-4}
Second species	4.2	0.10	4.1	—

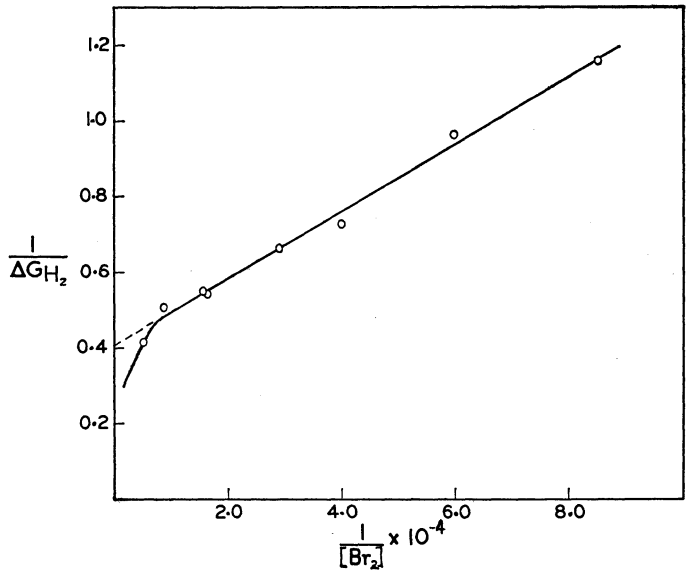

FIG. 4. The reciprocal of the reduction in the hydrogen yield ($1/\Delta G_{H_2}$) plotted against the reciprocal of the bromine concentration ($1/[Br_2]$) measured in moles/g.

with chlorine. Unfortunately the low solubility of bromine in liquid HCl at −80° C (approximately 3×10^{-4} mole/g) precluded experiments at higher concentrations, where the scavenging of the second species should have occurred. The ratio of its rate constants for reaction with bromine and HCl could not therefore be evaluated.

In view of the fact that added bromine reduced the hydrogen yields from HCl, one might suggest that its accumulation in the irradiated mixtures could have reduced the decomposition yield as the irradiations proceeded. However, since the concentration of bromine generated in the mixtures of HBr and HCl (and also in pure HBr) was always at least an order of magnitude less than the lowest concentration of bromine listed in Table II, and since HBr reacts more rapidly both with hydrogen atoms and electrons than does HCl (see below), it may be concluded that scavenging of the first hydrogen-forming species would have been unimportant at the doses used in the present work. The dose independence of the hydrogen yields in Table I leads to the same conclusion and we may assume that they are true initial yields. Similar considerations do not apply to an earlier study (5) of the radiolysis of liquid HBr, in which much larger doses were given and much lower yields obtained. In view of this and the more extensive study reported here, we feel that the present results are more trustworthy.

Although in the initial study it was not clear whether chlorine was scavenging electrons or hydrogen atoms, it seemed probable that the first (or more readily scavenged species) was the thermal hydrogen atom and the second species the "hot" hydrogen atom. Recent mass spectrometric investigations (6, 7) have shown that the energy thresholds of the electron capture reactions

$$e + Cl_2 \rightarrow Cl + Cl^- \quad [5]$$

$$e + HCl \rightarrow H + Cl^- \quad [6]$$

$$e + Br_2 \rightarrow Br + Br^- \quad [7]$$

are respectively 1.6_0, 0.6_5, and 0.0_0 ev. Since electrons are thermalized very rapidly in liquid media (8), reaction [5] could not have competed with reaction [6] unless chlorine molecules were present in such high concentrations (ca. 10 mole%) that a significant number of electrons would have collided with them prior to falling below the threshold energy. Identification of the first species as the thermal hydrogen atom is thus supported. Further, bromine, as well as reacting with these hydrogen atoms, would have been an efficient scavenger for electrons at or just above the thermal energy range, and at the concentrations used (0.1 to 1 mole%, see reference 9) reaction [7] should have competed with reactions [8*a*] and [8*b*]:

$$e + H_2Cl^+ \rightarrow H^* + HCl \qquad [8a]$$

$$e + H_2Cl^+ \rightarrow H_2 + Cl \qquad [8b]$$

for electrons which were not captured in reaction [6]. Thus the fact that it indicated the same yields of the two hydrogen-forming species as did chlorine is an indication that reactions [8*a*] and [8*b*] are not the major source of the second (or less readily scavenged) component of the hydrogen yield. In fact for reasons already stated (1) it is highly likely that the threshold energy for electron capture in liquid HCl is much lower than that in the gas phase, and that all electrons are captured* in a process which is best represented by the equation

$$e + H—Cl\cdots H—Cl \rightleftharpoons H + Cl—H\cdots Cl^-. \qquad [6a]$$

Highly energetic electrons undergoing this reaction could conceivably produce a number of hot hydrogen atoms. However, the rapid rate of energy loss for electrons and the fact that the capture process is restricted to a fairly narrow energy range (see ref. 7) would operate against this. Reaction [9]:

$$HCl \text{—}\!\!\sim\!\!\rightarrow HCl^* \rightarrow H^* + Cl, \qquad [9]$$

is therefore postulated as the major source of hot hydrogen atoms in this system.

Since the energy threshold for capture of electrons by HBr molecules is lower than that for HCl molecules (0.22 ev and 0.65 ev for HBr and HCl respectively (7)) and the capture cross section higher (10), we conclude, as did Eyring, Hirschfelder and Taylor (11), that the analogous reaction will also be the predominate fate of electrons in irradiated HBr. Because of hydrogen bonding effects, the liquid capture reaction should be written:

$$e + H—Br\cdots H—Br \rightarrow H + Br—H\cdots Br^-. \qquad [10]$$

Although positive fragment ions (Br^+ and Br^{++}) are more frequent in the mass spectrum of HBr than of HCl (12), they are not likely to be formed in great abundance in the liquid phase, where the excited molecule–ions from which they arise should be rapidly stabilized. The parent ions, HBr^+ and HCl^+, should therefore be the predominate ionic species resulting from ionization in both compounds:

$$HCl \text{—}\!\!\sim\!\!\rightarrow HCl^+ + e \qquad [11]$$

$$HBr \text{—}\!\!\sim\!\!\rightarrow HBr^+ + e. \qquad [12]$$

The analogous ion–molecule reactions:

$$HCl^+ + HCl \rightarrow H_2Cl^+ + Cl \qquad [13]$$

and

$$HBr^+ + HBr \rightarrow H_2Br^+ + Br \qquad [14]$$

*NOTE ADDED IN PROOF: *This argument has been substantiated by more recent experiments and for reasons which will be presented elsewhere we do not believe that an alternative non-dissociative electron capture by the halogen molecules to form the negative molecule–ions* Cl_2^- *and* Br_2^- *recently discussed in some detail by Person (J. Chem. Phys.* **38**, *109 (1963)) competes with reaction [6] in liquid* HCl.

occur with roughly equal rate constants (13), and in the liquid phase should be complete within about 10^{-13} seconds of formation of the parent ions. Because conventional electrochemical studies (14) have shown that pure liquid HCl undergoes autoprotolysis, it has been inferred (1) that neutralization of the H_2Cl^+ and Cl—H - - Cl^- ions formed in it by radiation will proceed via the reverse of the autoprotolysis reaction:

$$H_2Cl^+ + Cl—H - - Cl^- \rightleftharpoons 3HCl, \quad [15]$$

and that this will be a relatively slow process. Though the electrochemistry of HBr has not been studied as extensively, the similar dielectric constants (D.C. of HCl = 10; D.C. of HBr = 7 at −80° C (15)) and generally analogous electrochemical properties (16) of the two liquids suggest that the corresponding process:

$$H_2Br^+ + Br—H - - Br^- \rightleftharpoons 3HBr, \quad [16]$$

should occur in HBr. On this basis one hydrogen atom, resulting from the electron capture processes [6*a*] and [10], would be formed per ionization in both HCl and HBr, and the difference in hydrogen yield could not be attributed to differences in ionic reactions. However, the possibility of alternative neutralization reactions in HBr, such as reaction [17]:

$$H_2Br^+ + Br—H - - Br^- \rightarrow H + Br + 2HBr, \quad [17]$$

cannot be overlooked. Since this would produce a second hydrogen atom per ionization, we offer it as a possible explanation for the higher hydrogen yield from HBr.

The free-radical reactions which H and Br atoms are likely to undergo in irradiated HBr are analogous to those already discussed for the corresponding atoms in HCl. In both liquids hot atoms should react rapidly with hydrogen halide molecules. On the basis of existing kinetic knowledge from conventional gas phase studies the ratio of the rate constants for the thermal hydrogen atom reactions

$$H + HCl \rightarrow H_2 + Cl \quad [18]$$

$$H + HBr \rightarrow H_2 + Br \quad [19]$$

$$H + H + M \rightarrow H_2 + M \quad [20]$$

$$H + Cl + M \rightarrow HCl + M \quad [21]$$

$$H + Br + M \rightarrow HBr + M \quad [22]$$

at −80° C can be estimated to be about 10^{-4}: 10^{-1}: 1: 1: 1 respectively (17). Thus in pure HCl the probability of reactions [20] and [21] competing with reaction [18] would be somewhat greater than that of the corresponding competition in liquid HBr. However, since the *G* value for thermal hydrogen atoms determined from the chlorine experiments was only 2.4, it is very unlikely that more than half of this number undergo combination in the tracks. In fact, since they probably are produced in reaction [6*a*], they would be formed at some distance from the track centers and the possibility of reactions [20] and [21] occurring would be even less. Analogy with water, which should have a similar ion density and for which Dyne and Kennedy (18), Kupperman (19), and others have computed estimates of the track combination reactions at different scavenger concentrations, supports these conclusions. Furthermore a much steeper initial slope would have been observed at the lower HBr concentrations in Fig. 1 had reactions [20] and [21] been very important in pure HCl. Hydrogen atom combination in the HCl tracks could at the most, therefore, account for only one *G* unit of the rather large difference in the hydrogen yields from HCl and HBr. The only explanation for this difference, other than the one offered above, would be that the primary yield of ions and/or dissociating

excited molecules is much larger in HBr than in HCl. Since the ionization potentials of the two molecules are similar (I_{HCl} = 12.8 ev, I_{HBr} = 12.0$_4$ ev (20)) large differences in the ion yields are not to be expected, and it may well be that fast electron excitation produces a greater number of dissociative excited molecules in HBr than in HCl.

THE STEREOCHEMISTRY OF MALEOPIMARIC ACID AND THE LONG RANGE SHIELDING EFFECT OF THE OLEFINIC BOND[1]

W. A. AYER AND C. E. MCDONALD

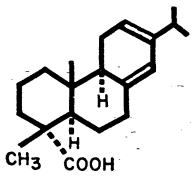
Received October 9, 1962

ABSTRACT

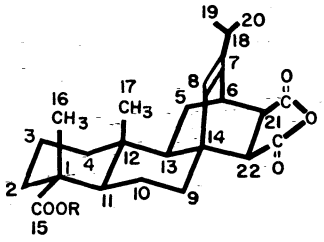
Nuclear magnetic resonance studies of methyl maleopimarate and closely related derivatives clearly establish the stereochemistry of methyl maleopimarate and, consequently, levopimaric acid. An extension of this study to other related compounds, 22 in all, provides evidence, on the basis of an intercomparison of the chemical shifts for the angular methyl protons, to support the original suggestion by Jackman (Applications of NMR in organic chemistry. Pergamon, New York. 1959. Chap. 7) that the long range shielding effect of the olefinic linkage is analogous to that of the carbonyl double bond. Coupling constants and chemical shifts for some of the protons of the bicyclo[2.2.2]octene system present in these compounds are also discussed.

INTRODUCTION

Levopimaric acid (I) reacts quantitatively with maleic anhydride in benzene at room temperature (1) to yield an adduct, maleopimaric acid, which has recently been assigned the stereochemistry shown in II (R = H) (2). This assignment was based mainly on



I



II

studies of molecular models coupled with the observation that a single isomer is formed in the reaction (2). At that time the configuration at C-13 in levopimaric acid had not been definitely established and, in fact, Klyne (3), using the method of molecular rotation differences, had assigned the β-configuration. Recent chemical (4) and rotatory dispersion (5) evidence has supported the α-orientation at C-13. We wish to report some proton magnetic resonance studies on methyl maleopimarate (II, R = CH_3) and related compounds which confirm structure II, and hence the α-orientation at C-13 in levopimaric acid. We have examined the N.M.R. spectra of a series of 22 compounds derived from II, and an intercomparison of *all* of these data leads to the conclusion that these compounds have the α-orientation at C-13. The compounds examined, prepared in connection with

double bond at the 7,18-position; and C (XVII–XX), those with no carbon–carbon double bond. These results provide evidence that an olefinic linkage exhibits a long range shielding effect similar to that of the carbonyl grouping (6, 7), and therefore, tends to shield nuclei above or below the plane of the trigonal carbons and to deshield nuclei in or close to this plane. This interpretation of the long range effect of the olefinic group was suggested some time ago (8), but little evidence bearing on this point was available. More recently an alternative model which predicts that the region of maximum shielding will be on the transverse axis *in the plane* of the double bond has also been discussed (9). The conclusion that the former model is the more appropriate for the interpretation of the long range effect of the double bond (i.e. that it is analogous to that of the carbonyl group) has been reached by other workers from studies of other cyclic systems (10, 11) since this study was initiated.

EXPERIMENTAL

N.M.R. Spectra

All spectra were determined at 60 Mc/s using either a Varian DP-60 or an A-60 spectrometer. With the former instrument, the peak positions were measured by the usual audio side-band method. The chemical shift data are given in p.p.m. relative to an internal tetramethylsilane (TMS) signal, and the precision is estimated to be within ±0.01 p.p.m. for the chemical shifts and ±0.2 c/s for the coupling constants. For most cases, the solute concentrations were approximately 10% (w/v) in either carbon tetrachloride or deuterochloroform. To check for differences between these two solvents, 10 of the examples were examined in both.

Materials[2]

Methyl maleopimarate (II, R = CH_3) was prepared by esterification of commercial (Distillation Products Industries) maleopimaric acid. The triester III was prepared as previously described (12) or more conveniently by treatment of a methanolic solution of maleopimaric acid with ethereal diazomethane. Compound IV was obtained by refluxing maleopimaric acid with methanolic potassium hydroxide followed by esterification (CH_2N_2) of the tricarboxylic acid thus obtained, or by the addition of fumaric acid to abietic acid (13) followed by esterification. The assignment of the C-21 exo, C-22 endo configuration rests mainly on the observation that the oxidation of the C-15 monoester corresponding to IV (prepared by the addition of fumaric acid to methyl abietate) with lead tetracetate in pyridine yields the γ-lactone XVI. A second product of this oxidation was the $\Delta^{21,22}$ compound corresponding to X, which on hydrogenation over platinum yielded X. The alcohol V was prepared by sodium borohydride reduction of the acid chloride of maleopimaric acid. Dissolution of V in methanolic diazomethane yielded the diester VI. Reduction of the C-15 monoester corresponding to IV with lithium–ammonia–alcohol followed by esterification gave the diester VII, which was also obtained by equilibration (methanolic KOH) of VI. The ketone XI was prepared by ozonolysis of III as previously described (14). Treatment of XI with methanolic KOH followed by esterification of the resulting acid gave XII. The anhydride VIII was prepared by addition of maleic anhydride to abieta-7,14(9)-diene. Methanolic diazomethane transformed VIII to IX and ozonolysis of IX gave the ketone XIII.

The lactone XVII was prepared by the method of Brus and co-workers (15). The acid XVIII was prepared by partial saponification of XVII, and the hydroxy compound XIX was obtained by treatment of XVII with hot 1 *N* sodium hydroxide for 96 hours followed by esterification. The tricarboxylic acid corresponding to XIX failed to lactonize or readily form an anhydride. Dehydration of XIX with phosphorus oxychloride – pyridine yielded the isopropylidine compound XIV, contaminated with a small amount (less than 10% by N.M.R. analysis) of the endo isomer IV. Compound XV was obtained by alkaline permanganate oxidation of maleopimaric acid (16). The structure of this oxidation product has recently been established independently by Zalkow, Ford, and Kutney (17). The oxide XX was prepared by ozonization of XV.

Compounds XXI and XXII resulted from the lead tetraacetate – pyridine oxidation of maleopimaric acid, followed by (in the case of XXI) methanolysis and esterification with diazomethane. The configuration at C-1 in XXII rests on the observation that the C-17 protons are not shifted relative to methyl maleopimarate (II, R = CH_3). If the acetoxyl group were β, a downfield shift of the C-17 protons would be expected (18).

The ketone XXIII was kindly provided by Professor L. H. Zalkow, Oklahoma State University.

[2]*Complete details of the preparation of all new compounds and of the structural assignments will be presented in a separate communication. All new compounds reported gave satisfactory analytical results.*

RESULTS

In the N.M.R. spectra of this series of compounds, there are two principal types of information provided. First, there are the chemical shift data for the various kinds of methyl protons and these are collected in Table I. Secondly, in a number of cases a critical examination of the region from 110 to 200 c/s from TMS allows a determination of the chemical shifts and coupling constants for the protons at C-6, C-21, and C-22, and thus provides evidence for the relative configuration of substituents on C-21 and C-22. The data for these protons are given in Table II.

DISCUSSION

General Features

To illustrate the gross features of the N.M.R. spectra for the three basic formulations, A, B, and C, some typical curves are reproduced in Figs. 1(*a*) and (*b*), and 2(*a*) and (*b*). In these figures, two examples of type A (II, R = CH_3 and III), and one example of each of B (XIV) and C (XIX) are included, and the line positions are given in c/s from TMS. It can be seen that marked differences occur in the C-methyl region (<100 c/s) as the double bond is changed in position or is removed. The number of separately resolved peaks in the carbomethoxyl region (~220 c/s) appears to depend on the double bond position as well as on the relative configuration of these groups. A third general feature to be noted is the variation in the appearance of the spectral pattern in the region 100–200 c/s for these structural modifications.

Stereochemistry of Maleopimaric Acid, II

If one examines the spectrum of the parent compound, methyl maleopimarate (II, R = CH_3), Fig. 1(*a*), in more detail, a number of the signals can be assigned directly. The single olefinic proton must give rise to the slightly broadened peak at 332 c/s (5.53 δ), while the carbomethoxyl protons absorb as a singlet at 220 c/s (3.67 δ) and the C-methyl groups appear as four equally intense peaks near 36, 56, 63, and 70 c/s. The highest-field peak can be assigned to the angular methyl group, C-17, (0.59 δ), on the basis of a published survey of the N.M.R. spectra of some resin acids (19) and from the results discussed below. Since the separations between the three remaining signals are approximately equal and since one would expect the isopropyl methyl protons to appear as a doublet with a coupling constant of ca. 7 c/s (19), two assignments are possible. The C-16 protons absorb at either 56 or 70 c/s. The more reasonable choice is that the lower-field peak arises from these protons (1.16 δ). Thus, the C-19 and C-20 protons, which are equivalent, absorb at 1.00 δ with J = 6.9 c/s. Support for this assignment is provided by the spectrum of III, Fig. 1(*b*), in which the relative intensities of the C-methyl peaks clearly show the C-16 protons to be at 68.8 c/s (1.14 δ), overlapping one band of an isopropyl methyl doublet (the isopropyl methyls are clearly non-equivalent in this case). Again, the angular methyl protons appear at highest field, 0.62 δ.

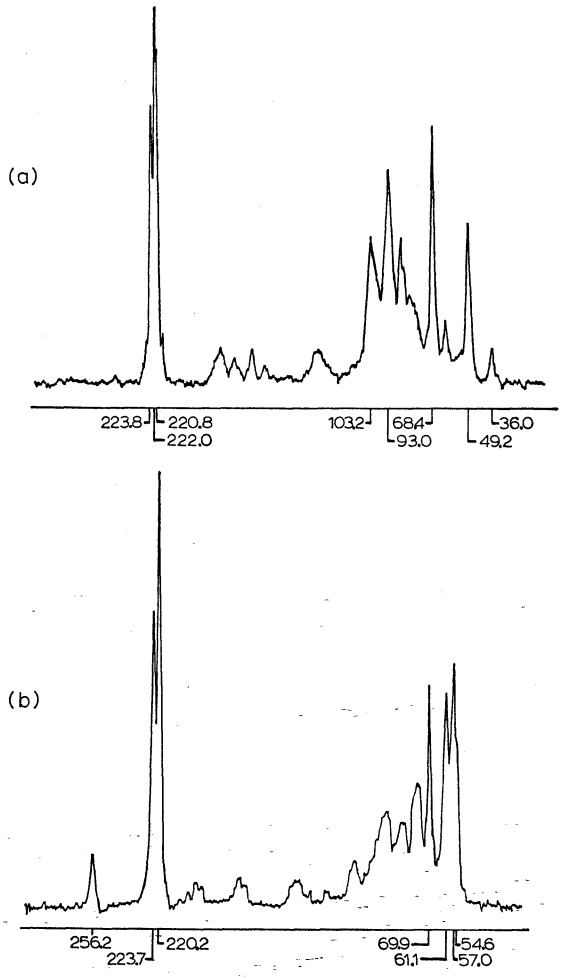

FIG. 2. Spectra at 60 Mc/s (in $CDCl_3$) of compounds (*a*) XIV and (*b*) XIX, having the B and C type skeletons, respectively. Line positions are given in c/s from TMS. (In (*a*), a small amount of IV is also present, as shown by the peak at 36 c/s.)

The virtually constant position of the angular methyl group at $0.60\pm0.03\ \delta$ for the closely related compounds II–X (see Table I) clearly indicates that the C-17 protons are strongly shielded by some similar means. Although four possible isomeric structures may be envisaged for the parent compound, maleopimaric acid, only two of these possibilities, II and its exo isomer, provide a common mechanism which could explain the similar shifts of the angular methyl protons for all the compounds II–X. It is apparent from the data in Table I that the carbonyl functions on C-21 and C-22 do not contribute to this shift, since not only is the shift independent of the change anhydride to diester but it is unchanged even when the carbonyl groups are replaced by hydrogen as in X. Proof that the C-15 substituent is without effect on the angular methyl shift is provided by the data for the same series, in which the C-15 grouping is changed from $—COOCH_3$ (II–IV, X) to $—CH_2OH$ (V–VII), to $—CH_3$ (VIII, IX), or to $—OCOCH_3$ (XXII). The only common feature potentially capable of producing the observed high-field shift is the C-7, C-8 double bond in compounds II–X and XXII. It follows, therefore, that this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

bond must be responsible for the observed effect and, furthermore, it must be relatively close to C-17. These facts require the α-configuration at C-13 in maleopimaric acid and, since the reaction conditions for its formation (in benzene at room temperature (1)) would not be expected to epimerize levopimaric acid (I) at C-13, the recent assignment of the 13α-H configuration in I (4, 5) is confirmed.[3]

The remaining uncertainty concerns only the configuration of the anhydride group in II. This problem, however, has been answered by the observation (17, 20) that a number of lactones may be prepared from II, for example, XV, XVII, XVIII, and XX. The formation of these derivatives requires an interaction of the anhydride grouping and the double bond, and only in the endo isomer, II, are these groups suitable oriented. Further support for this assignment from the N.M.R. spectrum is presented in a later section of this paper. It should be noted that the stereochemistry as now established is exactly that which would be predicted on the basis of mechanistic arguments and molecular models.

Long Range Shielding Effect of the Olefinic Bond

A definitive, qualitative evaluation of the long range effect of a carbon–carbon double bond due to its diamagnetic anisotropy should be possible from the results of this study because of two important factors. (*a*) All of the methyl protons in the compounds of the entire series give rise to sharply defined signals which can be assigned unequivocally. (*b*) The orientation of each of these methyl groups relative to the double bond position can also be assigned, in the majority of the cases, with certainty. A critical examination of the trends exhibited by the chemical shifts of these protons in similar positions should, therefore, provide evidence as to the spatial characteristics of the shielding effect of the olefinic bond. To this end, the observed shifts for each of the various types of methyl groups are discussed in the following.

(a) C-17 Angular Methyl Protons

As already mentioned, the chemical shift of the angular methyl protons is found to be virtually independent of the functional groups on C-21 and C-22 and at C-15 as shown by the data for compounds II–X and XXII (Table I). A small increase in the shielding of ca. 0.1 p.p.m., however, is observed when the isopropyl grouping is replaced by a methyl ketone function (on C-7). The data for three examples, XI–XIII, are included in Table I. Again, no significant effect is noted for a change either at C-15 from —$COOCH_3$ to —CH_3 or for configurational differences of the carbomethoxyl groups on C-21 and C-22 (XV and XVI). The origin of this enhanced shielding in the methyl ketones, however, is obscure.

An examination of molecular models (Dreiding) indicates that the expected effect of the carbonyl group would tend to deshield the C-17 protons slightly, assuming either an S-cis or S-trans conformation for the α,β-unsaturated carbonyl system; but this effect should be small, since the average distance between these protons and the carbonyl bond is large (ca. 4 Å). The effect of the isopropyl grouping cannot be estimated reliably, since the long range shielding effects of carbon–carbon single bonds are not clearly established. Although some successful semiquantitative evaluations of the shielding effects of carbon–carbon single bonds have appeared using the point-dipole approximation (21, 22, 23, 24) in each case, rather limited systems were examined. A recent systematic

[3]*After the completion of this manuscript, a preliminary communication (W. L. Meyer and R. W. Hoffman. Tetrahedron Letters, No. 16, 691 (1962)) appeared in which conclusions similar to ours were reached, but on the basis of less extensive evidence.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

study of the shielding effects of the methyl group in an extensive series of closely related compounds, 36 methylated cyclohexanols, has shown the weakness of this approach for single bonds (25). At any rate, the present results indicate that the isopropyl group may be *deshielding* the angular methyl protons, since the angular methyl shift is up-field when the isopropyl group is replaced by an acetyl group which has a carbonyl bond at C-18. An additional complexity is that the effect of changing the polarization of the C-7, C-8 double bond cannot be predicted with any degree of certainty. The fact remains that the C-17 protons absorb at relatively high field in all compounds having the C-7, C-8 double bond as a common feature.

One other example, having the basic skeleton A, requires comment. Compound XXI differs from the others in that C-15 and C-16 are replaced by an exo methylene group. The N.M.R. spectrum of XXI clearly shows these protons at 4.48 and 4.85 δ as well as the C-8 proton at 5.46 δ. The positions of the carbomethoxyl and isopropyl methyl signals are virtually unchanged from those in III, as expected. The angular methyl peak, however, appears at 0.49 δ, showing an increased shielding of 0.13 p.p.m. relative to III. Part of this change, if not all, may be attributed to the loss of the C-16 methyl group, since it has been shown in the steroid series (26) that the C-19 protons are deshielded by 0.05–0.10 p.p.m. by a 6β-methyl, a 1,3-diaxial arrangement comparable to the C-16, C-17 positions in the present series. Since the observed shift is slightly larger, we have an indication that the exocyclic double bond at C-1 may exert a small shielding effect on the C-17 protons.

Turning now to the compounds having the B skeleton, with an exocyclic double bond at C-7, C-18 (XIV–XVI), it can be seen that the angular methyl group appears at lower field than in the A series, namely, 0.70–0.81 δ (Table I). The spectrum of a typical example, XIV, is shown in Fig. 2(*a*). It is reasonable to assume that the effect of the C-15 and C-21 carbomethoxyls and the C-16 methyl group is the same as above, II–IV and X–XII, and, hence, the downfield shift relative to these must be attributed to the change in position of the double bond to C-7, C-18. Apparently, an additional effect enters into two of these cases, XV and XVI, in which C-8 bears an oxygen of a lactonic link to C-22. It is not surprising that such an effect is observed since an oxygen atom will be closer to the C-17 protons than in any of the previous examples. A closely related compound, XXIII, shows the angular methyl group at 0.84 δ, in good agreement with the position of this peak for XIV. The key feature in each of these cases is the common location of a double bond at C-7, C-18, and it appears that the effect of the carbonyl bond in XXIII is qualitatively similar to that of the carbon–carbon double bond in XIV–XVI.

For the third group, the members of which have the basic skeleton C, with no double bond, XVII–XX, it can be seen from Table I that the angular methyl protons absorb at the lowest field of any so far discussed. The general appearance of the spectra of these compounds is illustrated in Fig. 2(*b*) (compound XIX). The virtually constant position of the C-17 signals at 0.95 ± 0.01 δ clearly shows that these compounds lack some shielding factor present in the others (i.e., the double bond). As before the shift of the angular methyl group is independent of the nature of the functional groups at C-21 and C-22. There is a possibility that an oxygen atom on C-7 or C-8 influences this shift in some manner, but all that can be concluded from the present results is that this effect is similar for both positions since each of the examples has this feature.

It can also be noted that the angular methyl protons for all examples absorb at a similar field (within 0.02 p.p.m.) in either solvent.

(b) C-16 Methyl Protons

The chemical shift of the C-16 protons throughout this series is found to depend only on the nature of the C-15 group. In those cases in which there is a carbomethoxyl group at C-15, the C-16 protons appear near 1.14 δ in chloroform and 1.10 δ in carbon tetrachloride solution. This small difference is probably due to an association of chloroform with the carbonyl group of the substituent. An indication that this is indeed the case is given by the fact that the shift of the C-16 protons is *not* solvent dependent when C-15 is a methyl (VIII, IX, and XIII) or a hydroxymethyl group (V–VII). In all cases the shifts are unexceptional.

As mentioned before, the relative configuration at C-1 in XXII was assigned from the N.M.R. spectrum, since the alternative configuration of the acetoxyl group would tend to deshield the angular methyl protons by ca. 0.1 p.p.m. and this is not observed.

(c) Carbomethoxyl Protons

The protons of the various carbomethoxyl groups present in this series of compounds give rise to signals in the range 3.52–3.76 δ, and an examination of these data reveals some consistent trends for the shifts of these groups in the different environments. From the positions of these protons in II, X, and XVIII, in which the assignment is straightforward, together with the previous observation that the C-16 protons are unaffected by structural changes at C-21 and C-22, it is possible to assign the appropriate peak for the C-15 carbomethoxyl groups in the rest of the series. The data in the last two columns of Table I indicate certain chemical shift changes with structure for these groups at C-21 and C-22. For compounds III, VI, IX, and XXI, having a C-7, C-8 double bond and the cis $COOCH_3$ groups in the endo configuration, the methoxyl protons are equivalent and appear at relatively high field, but when one $COOCH_3$ group is exo (IV and VII) these groups are non-equivalent and absorb at lower field. In XI and XIII, the two carbomethoxyl groups, although cis and endo, are no longer equivalent but these peaks are also at relatively high field. Furthermore, in a saturated example, XIX, the trans C-21 and C-22 carbomethoxyl protons are equivalent and appear at lower field than the examples above. One can conclude, therefore, that the protons of an endo carbomethoxyl group at C-21 and C-22 tend to absorb at slightly higher field than those of an exo carbomethoxyl because of the shielding effect of the endocyclic double bond.

(d) Other Methyl Groups

The chemical shifts of the other various types of methyl protons encountered in this series of compounds are listed in Table I. All of the data are unexceptional. A downfield shift of the methyl protons is observed in chloroform relative to carbon tetrachloride solution when a carbonyl grouping is adjacent. Presumably this is a result of an association of chloroform with the carbonyl grouping.

The Diamagnetic Anisotropy of the Carbon–Carbon Double Bond

On the basis of the chemical shift results for the methyl groups in these compounds, it is apparent that the olefinic bond exerts an appreciable effect on those protons which lie close to it (<3 Å). The effect is most striking for the angular methyl protons (on C-17) particularly in the A series with the C-7, C-8 double bond, and it is definitely a shielding contribution. A smaller shielding effect is observed for the angular methyl protons in those compounds having the exocyclic double bond (C-7, C-18, series B), and in fact, the shift of these protons in XXIII (7-keto) was found to be comparable. These observations clearly support the original suggestion by Jackman (8) that the anisotropy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of the carbon–carbon double bond is analogous to that of the carbonyl double bond. In terms of the McConnell point-dipole approximation (27) for the carbonyl group, the anisotropic effect can be considered to produce a 'shielding cone' whose axis is centered on the C=O bond (or, at the electrical center of gravity) and is orthogonal to the trigonal plane and whose apical angle is approximately 70°. The shielding effect at a given nucleus near the carbonyl bond depends on the distance, R, between that nucleus and the center of the bond and the angle, θ, described by R and the bond axis. This model predicts a maximum shielding for $\theta = 90°$ and a zero effect at $\theta = 54°44'$; while a minimum shielding (i.e., maximum deshielding) would be expected at $\theta = 0°$. Although this is an idealized model, the limitations of which have been discussed in detail (8), it is qualitatively valid and a number of examples of its use in stereochemical studies have appeared (8, 28, 29, 30). By analogy, therefore, protons lying above the trigonal plane of an olefinic bond will experience a shielding effect and those in this plane will be deshielded. Although the shielding is appreciable in the present system one would expect a still larger effect for a suitably located proton if that proton were fixed. Presumably, the shifts are reduced for the angular methyl protons as a result of free rotation of the methyl group.

On the basis of the point-dipole approximation (27), the contribution of the anisotropic double bond to the total shielding of a given proton, $\Delta\sigma$, may be related in terms of R and θ by the expression $\Delta\sigma = (1/R^3)(1 - 3\cos^2\theta)\Delta\chi$, where $\Delta\chi$ is the difference between the longitudinal and transverse magnetic susceptibilities which defines the diamagnetic anisotropy of a group of electrons. Although, in principle, three susceptibilities are required to express the anisotropy of the double bond, two will suffice if one is significantly larger than the others. From models with an assumed staggered conformation for the angular methyl group it is possible to evaluate the terms for R and θ in this expression for these protons in the A and B type skeletons and so calculate the ratio $\Delta\sigma_A/\Delta\sigma_B$ for the two structures. This calculation yields the value 2.9. An experimental determination of this ratio from the observed shifts for compounds IV, XIV, and XIX, using the expression $\Delta\sigma_A/\Delta\sigma_B = (\delta_{XIX}-\delta_{IV})/(\delta_{XIX}-\delta_{XIV})$, leads to the value 2.8, which is in good agreement with the theoretical, and thereby provides further support for our conclusion regarding the diamagnetic anisotropy of the double bond.

Stereochemistry at C-21 and C-22

In all of the spectra of these compounds, II–XXIII, patterns of varying complexity are observed in the region 130–200 c/s and while some of the spectra defy analysis in this region, others are much simpler and can be analyzed in detail. As an example of the latter, the 140–200 c/s region of the spectrum of XI is reproduced in Fig. 3(*a*). The integral curve showed that these peaks are due to two protons and the absorption pattern appears to be of the AB type, one half of which is further split by coupling with another nucleus with spacings of 11.0 and 1.7 c/s. In XI, only those protons at C-6, C-21, and C-22 would be expected to absorb in this region and the observed pattern eliminates the C-6 proton as a possibility. Since the integral curve clearly shows 10 protons in the carbomethoxyl region, the bridgehead proton probably absorbs near 210 c/s. The AB pattern, therefore, arises from the C-21 and C-22 hydrogens, with the former showing additional coupling with the bridgehead proton. Since Anet (31) has shown that 1,3-coupling involving a bridgehead proton is not observed in the bicyclo[2.2.1]heptane system, it is reasonable to assume that this is also the case in the present bicyclo[2.2.2]-octene system. It follows that the vicinal coupling of the cis-oriented protons gives the larger splitting, of 11 c/s, a value which is considerably larger than that predicted by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

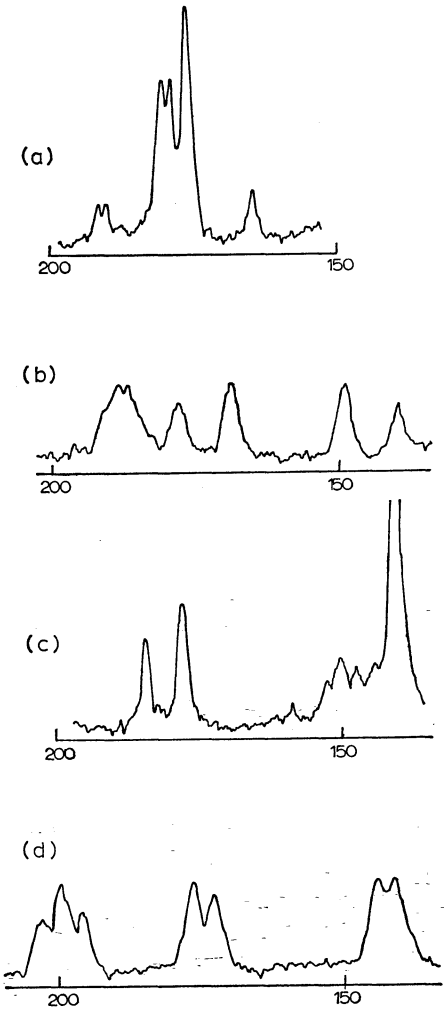

FIG. 3. Intermediate-field region (130–210 c/s from TMS) for the following compounds: (*a*) XI, (*b*) XV, (*c*) XII, and (*d*) XIX.

Karplus (32). It can be noted that recent reports of coupling constants of comparable magnitude have appeared for other fused ring systems (12, 14, 33, 34) having protons in a similar orientation and also for vicinal cases in which there are small dihedral angles of ca. 20° (35, 36).

To illustrate some of the variations in these patterns, portions of the spectra for XV, XII, and XIX are shown in Figs. 3(*b*), (*c*), and (*d*), respectively. Since a few of the observed patterns can be analyzed as the AB portions of ABX systems, it is possible to determine the chemical shifts and coupling constants for the C-21 and C-22 protons in a number of the examples. In all cases, the bridgehead proton gives a broad, unresolved multiplet, the center of which has been taken as the approximate chemical shift. These data are collected in Table II.

It is clear that a large coupling is observed for those cases in which the protons on C-21 and C-22 are in a cis and exo orientation. The nature of the ring system requires that the dihedral angle for these vicinal protons must be close to 0°. Small variations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

in this coupling are observed for structural changes which would be expected to alter the dihedral angle. For example, the coupling constant is 11.0 c/s for the diesters, XI and XIII, and decreases to 10.0 c/s in the lactone esters, XV and XX. It is reasonable that the formation of the lactone would alter the C-21, C-22 dihedral angle and, since a maximum coupling is expected for 0° (32), an increase in the dihedral angle would tend to decrease the coupling, as is observed. The concomitant change in the coupling of the bridgehead and C-21 protons is a further indication that the skeletal geometry is indeed different from that of the diesters and that the dihedral angle between the bridgehead and C-21 protons increases upon formation of the lactone relative to the diesters. Qualitatively, the general behavior of these coupling constants is that predicted by Karplus (32) but the magnitude of the constants for very small dihedral angles is significantly larger than the calculated values.

An indication of the magnitude of the trans vicinal coupling between the C-21 and C-22 protons is given by the spectra of XII and XIX (Figs. 3(*c*) and (*d*)). In each of these cases, a well-defined doublet appears near 175 c/s which can be assigned to the C-22 proton from the results in the cis examples discussed above. The spacing of these doublets, 6 and 4 c/s, respectively, will be approximately equal to the trans vicinal coupling constant and these values are of the order expected for dihedral angles near 120° (32). Since the coupling constant is much more sensitive to changes in the dihedral angles of this magnitude, the observed difference is not unexpected because of the marked difference in flexibility, between the bicyclo[2.2.2]octene ring system and its saturated analogue. The coupling between the bridgehead and the C-21 protons is also changed from the cis cases and appears to be approximately 3–4 c/s. Again, the agreement with theoretical predictions is reasonable.

For the examples discussed above, there are some interesting changes in the chemical shifts of the C-21, C-22, and bridgehead (C-6) protons. In the doubly unsaturated compounds, XI–XIII, the bridgehead proton absorbs at the lowest field of the three, ca. 3.5 δ. Presumably this shift is a result of the combined effects of the two neighboring double bonds since, in the most favorable conformation, the C-6 proton is in the plane of both (i.e., the region of maximum deshielding). This proton is shifted up-field in XV, in which only one double bond is adjacent, and a further shift to higher field is observed upon removal of the double bond as in XIX and XX. A part of the high-field shift observed for the bridgehead proton in XX may arise from a shielding contribution by the neighboring epoxide ring. Since it has been shown recently (37) that this grouping tends to deshield nuclei near the plane of the three-membered ring, it follows that a shielding effect may be operative in the region above this plane. In general, however, the changes in shift for the C-21 and C-22 protons are in agreement with those expected on the basis of the anisotropic nature of the double bond as discussed earlier. A marked shielding effect is observed for the change from the exo to the endo configuration in compounds with the endocyclic double bond (cf. XI and XII). This change can be attributed to the anisotropic olefinic grouping since, in the endo orientation, the C-21 proton would be in the shielding region of the C-7, C-8 bond.

These assignments are based on the observed splittings and on the intensities (i.e., the skewed nature of the bands), and, although not unequivocally, clearly indicate that there is a marked dependence of the shift on the orientation of the protons in the vicinity of anisotropic groups. Further work is planned, using simpler model compounds, to test these assignments and to study the coupling constants in this bicyclic system in more detail.

C-8 Protons

In the series of compounds containing the endocyclic double bond at C-7, C-8, the proton on C-8 appears in the characteristic olefinic region and exhibits minor variations in chemical shift with structural changes. In the C-21, C-22 diesters this band appears at $5.40\pm0.03\ \delta$ ($CDCl_3$) and $5.34\pm0.02\ \delta$ (CCl_4). This peak is shifted to lower field in the anhydrides and is found at $5.57\pm0.03\ \delta$ ($CDCl_3$). As is usual, an additional deshielding is experienced by this proton when it is beta to a carbonyl group (e.g., XI–XIII) and the peak appears at $6.90\pm0.03\ \delta$ ($CDCl_3$) and $6.81\pm0.03\ \delta$ (CCl_4). Finally, for compounds XV and XVI, in which C-8 is part of a lactone ring to C-22, the C-8 proton appears at $5.00\ \delta$ ($CDCl_3$).

THE INFRARED SPECTRA OF TRIMETHYLAMINE OXIDE SALTS[1]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received January 2, 1963

ABSTRACT

Several salts of trimethylamine oxide have been prepared. A species common to all these salts, the $(CH_3)_3NOH^+$ ion, has been inferred from the infrared spectra of the solids, but with varying degrees of interaction in the hydrogen bond O—H · · · X, depending on the anion. These variations have been investigated in detail, and with the help of deuterium replacement, confident assignments for the OH stretching, bending, and torsional modes have been made. A splitting of about 80 cm^{-1} in the bending mode has been noted, and has been ascribed to correlation field coupling. With one exception, the assignments are in good agreement with those previously determined by Giguère and Chin.

INTRODUCTION

An analysis of the vibrational spectrum of trimethylamine oxide, its dihydrate, and its hydrochloride has recently been published by Giguère and Chin (1). The earlier work was summarized by them. The structure of the hydrochloride has also been determined by Rérat using the techniques of X-ray diffraction (2).

The present work complements the existing data, for while the general assignments were satisfactory, the definition of the OH group modes needed further elaboration. This has been achieved by the study of several hydrohalides and also more complex salts of trimethylamine oxide, using deuterium substitution to aid identification of bands due to the hydroxyl hydrogen atom.

This work forms part of an attempt to determine donor characteristics of functional groups for both Lewis acids and protonating acids. The interaction of donors with the latter category yields salts whose XH stretching modes are of little diagnostic use but whose bending modes show promise of becoming useful group frequencies.

RESULTS

The spectrum of the HBr salt is shown in Fig. 1. Bands from all the spectra are listed in Table I and those bands arising from vibrations of the OH group are summarized in Table II.

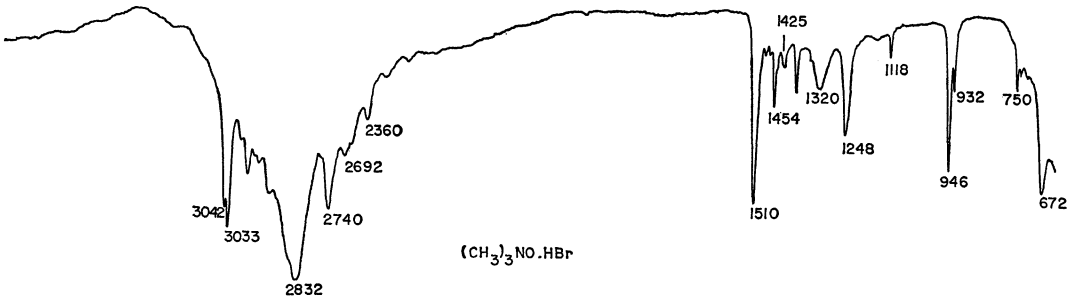

FIG. 1. Infrared spectrum of trimethylamine oxide.HBr.

DISCUSSION

Hydrogen Stretching Modes

The strong band designated ν_{OH} in the tables has been assigned to the OH stretching vibration. This varies from a strong, broad band with much structure centered at 2628 cm^{-1}, for the HCl salt, to a slightly narrower band in the HPF_6 salt at about 3450 cm^{-1}. In the analogous deuterated salt the vibration is found at a lower frequency which bears a ratio to the hydrogen stretching frequency varying from about 1.28 in the HCl salt to about 1.35 in the HPF_6 salt. The half-widths in the deuterated salts are also smaller.

This behavior is characteristic of protonated species and has been observed for the salts of pyridine (3), γ-pyrones (4), γ-pyridones (5), etc. It has been suggested that the structure in many XH stretching vibrations is due to a combination of a fundamental (or possibly two, if splitting occurs) with a low-lying lattice mode and its overtones, i.e. $\nu_{XH} \pm n\nu_L$, where ν_L is a lattice mode. Raman shifts due to some of these lattice modes in crystalline acids have been measured recently by Gross (6) near 200 cm^{-1}. These lattice modes also showed some fine structure, a series of small peaks with a separation increasing from 10 to 20 cm^{-1} being observed.

Similar behavior has been noted in the OH stretching band in the HPF_6 salt of trimethylamine oxide. This salt has one strong, broad absorption band at 3450 cm^{-1} ($\Delta\nu_{1/2} \sim 115$ cm^{-1}) in the H salt and at 2552 cm^{-1} ($\Delta\nu_{1/2} \sim 80$ cm^{-1}) in the D salt. The contours of the band suggest a series of shoulders which are spaced approximately 10 cm^{-1} apart on both sides of the main peak. Inspection of one of the salts with low ν_{OH}, for example, the HCl salt, shows the displacements of the satellites from the main peak to be larger, of the order of 35 to 40 cm^{-1}. Consequently the resolution of these bands in the spectra of such compounds is greater. On deuteration the usual shift to lower frequency occurs. The structure in the salts with low ν_{OD}, for example, the DCl salt, is better resolved than in the H salt, but in the DPF_6 salt the shoulders are still not resolved.

Hydrogen Bending Modes

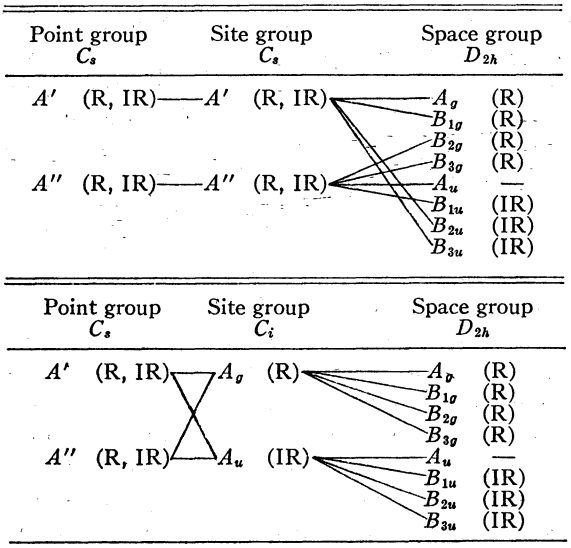
The in-plane hydrogen-bending mode, δ_{OH}, is, by contrast, a relatively sharp band ($\Delta\nu_{1/2} \sim 20$ cm^{-1}). It occurs near 1500 cm^{-1} (see Table II) and is always split with another

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

component near 1430 cm^{-1}. This second component is generally somewhat weaker than the other. The deuteration shifts are normal, giving ratios of about 1.33 and 1.37 for each component respectively. The splitting of this mode recalls a similar splitting in salts of γ-pyrones (4) and γ-pyridones (5), where the values were $\sim$1300 and 1210 cm^{-1}, and $\sim$1300 and 1230 cm^{-1} respectively. Some light can be thrown on the origin of the splitting in the present case as the structure of trimethylamine oxide hydrochloride is known (2).

The crystals belong to the space group *Pnam*, have orthorhombic symmetry, and contain four molecules per unit cell. The structure is made up of layers consisting of alternating rows, each molecule in each row being related to the other by an S_2 symmetry operation. The layer above is similarly constituted except that the O—H . . . Cl bonds point in the reverse direction. Cohesive forces between layers are due to coulombic interaction between Cl^- and N^+. Two site symmetries are involved; some molecules are related by a center of symmetry and have site group C_i (two molecules from different layers) while others (in the same layer) have C_s site symmetries (7). There can be no site group splitting, therefore, since the ion symmetry is C_s (the H, O, N, and one C atom are in the same plane). The space group, however, D_{2h}^{16} being isomorphous with the irreducible representation D_{2h}, will permit some splitting, the number of components being determined by the species of the site group involved. For the C_s site group the A' modes of the ion would be split with two components, while the A'' modes would show no splitting in the infrared spectrum. For the C_i site group, however, both A' and A'' modes should be split in the Raman and infrared spectra into three components (see Table III).

TABLE III



The actual behavior in the infrared spectrum seems to be more in keeping with splitting due to the C_s site symmetry. Two components have been observed in the OH in-plane bending mode (A') for all the compounds studied, the magnitude of the splitting decreasing somewhat as the hydrogen bond gets weaker in the salts with larger anions (see Table II). The detailed structure of the OH stretching band in some of the salts with low ν_{OH} may be due to splitting from such coupling. Although this structure disappears in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

salts with more complex anions, the band is still broad enough to accommodate two components. A larger splitting would be expected in the hydrohalides which have stronger hydrogen bonds and would be more strongly coupled. The out-of-plane hydrogen deformation does not seem to be split. Although the low-frequency region is somewhat inaccessible, only one band has been observed between 450 and 750 cm^{-1} in the HCl salt, and probably in the HBr salt, that shifts on deuteration. It seems unlikely that splitting of this mode could be as much as 300 cm^{-1}.

The presence of these bands in the infrared spectrum seems to show that the site group symmetry responsible for the splitting is C_s, and the coupling is between molecules lying on zigzag chains running in the direction of the *c* axis, or in almost linear chains making an angle of about 45° with the *c* axis. In terms of intermolecular contacts the OH groups of molecules on these chains are probably close enough to permit this coupling (the oxygen atoms are 4.4 Å apart; compare 5.4 Å between those in the same plane, and 7 Å for those related by the center of symmetry).

Dilute isotopic solid solutions have been used previously to distinguish between static field and correlation field effects (8, 9). The vibration of the bond containing the dilute isotope is then uncoupled from those of its neighbors, and its frequency should then be the average of all correlation field components. This type of behavior has been confirmed for dilute solutions of $(CH_3)_3NO.HX$ in $(CH_3)_3NO.DX$. The two coupled components near 1500 and 1420 cm^{-1} practically disappear, leaving two small shoulders, and a band at about 1465 cm^{-1} that is not present in the HX salt appears strongly. Occasionally this band can only be observed as an enhancement of a band already present. The frequency of the uncoupled vibration is sufficiently close to the mean value of the two components to make it reasonably certain that these are the only infrared-active components. Dilute solutions of the D salt in the H salt have not given unambiguous results, since the presence of the 1123 cm^{-1} band in the H salt, close to the mean of the two bending components ($1/2(1148+1055) = 1102$ cm^{-1}), has interfered with the observation of weak new bands. A small shoulder, however, at 1112 cm^{-1}, has been observed in such solid solutions. This is further support for the view that the site group symmetry responsible for the splitting is C_s. Without the Raman shifts, though, this cannot be proved.

Torsional Modes

The symmetric CN stretching vibration was assigned by Giguère and Chin (1) to the strong band at 752 cm^{-1} in the hydrochloride. This band, however, disappears in the deuterated salt (a very small component at 745 cm^{-1} remains, see below), and is probably due to the out-of-plane (or torsional) mode. A similar band, which also disappears on deuteration, is at 672 cm^{-1} in the HBr salt, at 585 cm^{-1} in the HI salt, and at 622 cm^{-1} in the $HClO_4$ salt. These bands do not appear to be split, in accordance with the selection rules for the solid. The trend in these frequencies to lower values with weaker hydrogen bonds duplicates that for the in-plane hydrogen-bending mode, though in this case, too, the relationship between ν_{OH} and γ_{OH} is far from precise. Wavelength limitations prevented observation of γ_{OD} so no value of the ratio γ_{OH}/γ_{OD} can be determined. However, it must be greater than $752/550 = 1.37$ since 550 cm^{-1} is the low-frequency cutoff of the spectrometer used.

Several other bands which shift on deuteration are seen at 1458, 1320, and 1155 cm^{-1} in the HCl, HBr, and HI salts respectively; the deuterated materials have bands at 1070, 962, and 840 cm^{-1}. They are weak bands and are plausibly assigned to the overtone of the out-of-plane hydrogen deformation. The isotopic ratios are 1.36, 1.37, and 1.38 respec-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tively for these three salts. No band in the appropriate region has been found for the other salts.

In all the salts there is a weak band at about 1120 cm^{-1} which disappears on deuteration. It seems unlikely that this can be a fundamental, partly on account of its intensity, partly since all the OH fundamentals have been assigned. Neither is it likely to be another component of the in-plane hydrogen-bending mode. It can be accounted for by a combination tone of the NO stretching mode (or the CN asymmetric stretching mode), and a low-lying lattice mode, thus 950+170 = 1120. If on deuteration the lattice mode is displaced by a factor 1.37 to lower frequency then the combination tone should be seen at 950+(170/1.37) = 950+124 = 1054. Since δ_{OD}, the low-frequency component of the bending mode, absorbs near 1050 cm^{-1}, one would have to assume that the combination tone is obscured by δ_{OD}, an unsatisfactory assumption, but with little plausible alternative.

Other Vibrational Modes

Although the strong band at 752 cm^{-1} in the HCl salt is not due to the symmetric CN stretching vibration as suggested by Giguère and Chin (1), there is in the DCl salt, and in all the other salts, a weak band at about 745 cm^{-1} which is probably due to this vibration. Its weakness is a little surprising but becomes more reasonable when it is appreciated that the greater part of the dipolar structure resides in the NO bond.

The doublet near 950 cm^{-1} has been assigned to the NO stretching mode and the CN asymmetric stretching mode. In many of the salts studied further structure in this doublet was observed as a high-frequency shoulder. This is probably the splitting of ν_{CN}, which is doubly degenerate in $(CH_3)_3NO$. This should be apparent too for the OCN bending mode, previously (1) assigned to the 472 cm^{-1} band. Wavelength limitations do not permit observation below the 460 cm^{-1} band, presumably the high-frequency component of the doublet.

EXPERIMENTAL

Materials

Trimethylamine oxide dihydrate and hydrochloride were obtained from the K and K Laboratories. Other salts were made by adding the requisite amount of aqueous acid to the dihydrate and allowing the salt to crystallize. The following exceptions were made. The HBr salt was prepared by passing HBr gas through a solution of the dihydrate in a little methanol with excess ether. The solid so formed was recrystallized from methanol. The tetraphenylboron compound was precipitated when aqueous solutions of the hydrochloride and sodium tetraphenylboron were mixed. Deuterium exchange of the labile proton was achieved by dissolving the salt in excess D_2O and removing the latter by evacuation, except that the insoluble tetraphenylboron salt was made from D_2O solutions in the manner described.

Spectra

The spectra were those of emulsions of the finely ground solid in nujol and fluorolube. They were recorded on a Perkin–Elmer 221 prism-grating spectrometer with NaCl optics over the range 4000 to 650 cm^{-1}, and from 650 to 550 cm^{-1} on a Perkin–Elmer 421 double-grating spectrometer. A KBr prism-grating spectrometer (10) was used to record the spectra of two of the salts down to 450 cm^{-1}.

ACKNOWLEDGMENTS

The assistance of Miss C. D. Anderson in preparing some of the salts and recording their spectra is gratefully acknowledged. The facilities of the Perkin–Elmer 421 spectrometer and the KBr prism-grating spectrometer were kindly made available by Mr. D. G. Barnes and Dr. W. J. Potts, Jr. (The Dow Chemical Company, Midland, Michigan, U.S.A.) respectively.

THE STABILITY OF METALLIC COMPLEXES OF TWO DIMETHYLPHENANTHROLINES

D. A. BRISBIN[1] AND W. A. E. MCBRYDE[1]
Department of Chemistry, University of Waterloo, Waterloo, Ontario
Received November 26, 1962

ABSTRACT

The stepwise formation constants for the complexes formed by 5,6-dimethyl- and 4,7-dimethyl-1,10-phenanthroline with bivalent iron, cobalt, nickel, copper, and zinc were determined by a partition method. The measurements were made at 25° C and in aqueous solutions having an ionic strength maintained at 0.1. The enhanced basicity of the ligands compared to the parent phenanthroline is paralleled by increased stability of the metallic complexes. The abnormally high formation constants of the cobalt complexes suggest oxidation to cobalt (III).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A number of studies to determine the stability of metal complexes of the phenanthrolines have been published (1–8), among the most complete of which are those of Irving and co-workers (2, 4). In an extension of these studies the present investigation has sought formation curves, and hence formation constants, for the complexes formed by 5,6- and 4,7-dimethyl-1,10-phenanthroline with a selected group of ions of the first transition series.

The inductive effect of substituent methyl groups in increasing the basic strength of phenanthroline is apparent from the data of the following table:

Compound	pK_a	Investigators	Compound	pK_a	Investigators
1,10-Phenanthroline	4.96	Ref. 6	2,9-Dimethylphenanthroline	5.85	Ref. 2
	4.93	This work		5.79	This work
	5.0	Ref. 2			
2-Methylphenanthroline	5.42	Ref. 2	5,6-Dimethylphenanthroline	5.60	This work
5-Methylphenanthroline	5.28	Ref. 3	4,7-Dimethylphenanthroline	5.95	This work
	5.23	Ref. 7			
	5.26	Ref. 8			

From these data it is seen that the basic strength of these compounds is enhanced by the presence of each methyl group in the conjugated ring system, and that the extent of this enhancement is related to the propinquity of the methyl groups to the nitrogen atoms. In agreement with expectations, the increased basicity of the compounds investigated is paralleled by an increase in stability of the complexes investigated except, as noted elsewhere, when steric hindrance to coordination about the metal atom occurs (5).

METHOD

The experimental method used was based on partition of the ligand between an aqueous solution and a solvent immiscible with water. The principle of the method is old, but its extension to the study of formation of complexes involving stepwise equilibria was first suggested by Kolthoff *et al.* (9), and subsequently extended and refined by Irving and co-workers (2). A measured volume of a solution of the ligand of known concentration in a selected solvent was shaken with a measured volume of aqueous solution containing

[1]*Formerly of the Department of Chemistry, University of Toronto, where most of the experimental work was done.*

the metal (and also buffer and indifferent electrolyte sufficient to maintain constant ionic strength) until a steady state was reached. The initial and final optical densities of the solution of free ligand were measured, and, as necessary, the pH of the aqueous solution. The distribution of unbound ligand was assumed to follow the distribution law, and after allowance had been made for any protonated ligand that might have formed, the amount bound to metal was found by difference. This quantity, divided by the number of moles of metal taken, yields the degree of complex formation, $\bar{n}$, while the concentration of ligand in the aqueous phase furnishes a corresponding value of pL. Thus, for equal volumes of the two liquid phases,

$$[1] \qquad \bar{n} = \frac{C_L - C_L' - C_L'(1 + H/K_a)q^{-1}}{C_M}$$

$$[2] \qquad pL = \log q - \log C_L',$$

in which C_L = initial concentration of ligand in solvent,
C_L' = final concentration of ligand in solvent,
C_M = total concentration of metal in aqueous phase,
q = partition coefficient for free ligand,
H = antilog (−pH),
K_a = dissociation constant for protonated ligand.

Each distribution experiment thus yields a point on the formation curve ($\bar{n}$ vs. pL).

An assumption implicit in the use of this method for studying complex formation is that no species other than free ligand occurs in the solvent phase throughout the distribution experiment. A ready check on this can be made by examining the absorption spectrum of the solvent phase after shaking with an aqueous solution containing metal; in the case of iron (II) the intense color of the metallic complexes would readily disclose the presence of any metal in the organic solvent. Except for the cases noted below, no evidence was found for the presence of any species other than ligand in the organic solvent.

The range of pL that could be encompassed by a single solvent was limited by practical upper and lower limits in C_L'. The lower limit in this case was set by the smallest optical density that could be measured with precision, the upper limit by the necessity to define accurately the difference $C_L - C_L'$. The upper limit in C_L was fixed in some solvents by the solubility of the ligand; in another (chloroform) by the number of dilutions required to produce a solution whose optical density could be measured in a 1-cm cell. For the investigation of all ranges of pL appropriate to the formation curves of the complexes examined chloroform and carbon tetrachloride were selected as solvents, but some experiments were performed with a mixed solvent consisting of these two substances mixed in such proportions as to give a convenient value of q between those of the single solvents.

EXPERIMENTAL

The two dimethylphenanthrolines were purchased from the G. F. Smith Chemical Co. and purified before use. Some of the material was recrystallized from warm benzene, and some by dissolving in dilute hydrochloric acid and reprecipitating by the addition of dilute aqueous sodium hydroxide. The latter method produced a whiter crystalline product than the former, although both melted sharply. The melting points and analyses showed that whereas the 4,7-dimethyl derivative crystallized from aqueous solution as the monohydrate, the 5,6-dimethyl analogue was obtained as the anhydrous compound.

The solutions of the metallic ions were made up from reagent-grade salts; and in any instance where the composition of the salt was in doubt, for instance as a result of deliquescence, the solutions were standardized by familiar gravimetric methods. Chloroform and carbon tetrachloride, of U.S.P. grade, were distilled in all-glass apparatus before use as solvents for the ligands.

Measurements of ultraviolet absorption were made in 1-cm covered silica cells with a Beckman Model DU spectrophotometer. The cell compartment was flanked by thermospacers through which water, maintained thermostatically at 25° C, was circulated. When spectra over a wide range of wavelengths were desired these were measured by a Beckman Model DK-1 spectrophotometer. The pH of aqueous solutions was measured by a Beckman Model G meter fitted with the manufacturer's small electrodes. The circuit was calibrated with freshly prepared buffer solutions as follows: 0.05 *M* potassium hydrogen phthalate (pH 4.00); 0.01 *M* potassium tetroxalate (pH 2.15); a suitable dilution of Radiometer concentrated buffer (pH 6.50). All distribution experiments were carried out in 40-ml glass-stoppered tubes; these were shaken in a water bath maintained at 25° for a minimum of 20 hours.

Acidity Constants of Ligands

The pK_a values for the protonated forms of the ligands were obtained absorptiometrically. Solutions of a suitable concentration of ligand containing buffer and indifferent electrolyte to give ionic strength of 0.1 were prepared to have pH values ranging from 2 to 12. The optical densities of these at various selected wavelengths were plotted against pH, and at the points of inflection on the resulting skew-shaped curves the pH was noted and identified with pK_a. The values found in this way are listed above.

Partition Coefficients

Measured volumes of a solution of ligand in non-aqueous solvent and of an aqueous solution containing various amounts of hydrochloric acid and potassium chloride sufficient to yield an ionic strength of 0.1 were shaken together in a thermostat, and analysis of the ligand solution carried out as described above in connection with measurement of $\bar{n}$. The partition coefficient was given by the equation

$$q = \frac{D_2V_2}{(D_1-D_2)V_1}(1 + H/K_a), \qquad [3]$$

in which D_1 = optical density of ligand solution before shaking,
D_2 = optical density of ligand solution after shaking,
V_1 = volume of the organic solvent solution,
V_2 = volume of the aqueous solution,
and the remaining terms apply as above.

FORMATION CONSTANTS

Formation curves depicting the relationship between $\bar{n}$ and pL were drawn from the experimental results. Except as noted below for cobalt and iron (II), the formation constants were obtained from these by a system of approximations suggested by Bjerrum (10).

This procedure did not work for the iron (II) or the cobalt data. The curves were peculiarly steep, as the iron (II) curve also is with orthophenanthroline. In the latter case the steepness is due to the value of K_3 being appreciably larger than those for K_1 and K_2. To a first approximation the iron (II) curves can be represented by the equation

$$\bar{n} = \frac{3\beta_3[L]^3}{1+\beta_3[L]^3}, \qquad [4]$$

in which

$$\beta_3 = K_1K_2K_3.$$

The formation curve can, therefore, give little information about the constants K_1 and K_2. This is illustrated in Table I, in which values of $\bar{n}$ calculated by the above equation are compared with values from the experimental formation curves for these two ligands reacting with iron (II). The values of β_3 for the calculations were those found to give the best fit to the experimental curves.

For establishing values of K_1 recourse was made to the procedure of Kolthoff *et al.* (11). In this, solutions containing a molar excess of iron (II) over reagent ($\bar{n}$ = 0.1 to 0.3) and

NOTE: β function 1 = $(3\beta_3[L]^3)/(1+\beta_3[L]^3)$, β function 2 = $(K_1[L]+3\beta_3[L]^3)/(1+K_1[L]+\beta_3[L]^3)$; the values of K_1 and β_3 used are those shown in Table III.

adjusted to pH $\sim$ 5 were prepared, and their optical densities measured at the wavelength of maximum absorption by the tris-complex. The following relationships apply:

$$K_1 = \frac{[FeL]}{[Fe][L]} \quad [5]$$

$$\beta_3 = \frac{[FeL_3]}{[Fe][L]^3} \quad [6]$$

$$[L]_T = 3[FeL_3]+[FeL]+[L](1 + H/K_a) \quad [7]$$

$$[Fe]_T = [FeL_3]+[FeL]+[Fe]. \quad [8]$$

We have assumed, as did Kolthoff, that no significant concentration of FeL_2 is present in these solutions and that the final term in equation [7] is negligible compared with the first two. The second assumption can subsequently be verified when values of [L] have been obtained. From the measured optical density and $[L]_T$ we obtain [Fe] by equation [8], and thence [L] with equation [6]. For each solution prepared this way, $\bar{n}$ and pL are known, and a value of K_1 may be calculated. Such measurements provide additional points at the lower end of the formation curves for the iron (II) complexes. Concerning K_2 no more can be said than that its value cannot lie above 10^7; values much greater than this would produce a detectable difference in the middle and lower parts of the formation curves from the values obtained by equation [4].

RESULTS AND DISCUSSION

The characteristic absorption of the ligands in the three solvents used, and the partition coefficients for the ligands between these solvents and dilute aqueous solutions are given in Table II.

The formation curves are shown in Figs. 1 and 2. The circles show the experimental points; the solid lines are calculated from the formation constants derived as explained in the previous section. These formation constants are given in Table III.

Certain anomalies, not encountered in similar studies with the simpler phenanthrolines, came to light in this work. For instance, in the partition experiments with iron (II) or nickel and 4,7-dimethylphenanthroline, where chloroform was the solvent, evidence was

observed that some of the metallic complex had entered the solvent phase. This was plainly visible in the case of the colored iron complex, and in both cases was detected by a marked shift of the points for the experimental formation curve along the pL axis. Fortunately

*Average of four determinations made spectrophotometrically.

this effect was not observed in distributions with the 3:7 mixed solvent, and most of the formation curves could be obtained with this solvent. The formation curve for nickel with this ligand is incomplete, and the value of K_1 given in Table III has been estimated on the assumption that the formation curve would continue parallel to that of the 5,6-dimethyl analogue.

A second difference is shown by cobalt; here oxidation has undoubtedly occurred with formation of a more stable cobalt (III) complex. This oxidation had been noted previously with the simpler phenanthrolines, but could be prevented by the addition of hydroxylamine (2). The steeper cobalt formation curves and the large values for β_3 in these cases suggest that very stable complexes with large values of K_3 have been formed in a manner similar to the iron (II) complexes with which they are isoelectronic. However, the results must be interpreted with some care in this case, since no proof of the reversibility of the reactions by which these postulated cobalt (III) complexes were formed can be given; it might be better to regard the values of β_3 etc. derived from these curves as "apparent" formation constants.

The results reported here, taken with those for 1,10-phenanthroline and its 5-methyl derivative, provide a good example of the correlation between the stability of metallic complexes and the proton affinity of the ligands. This is portrayed in Fig. 3 in which

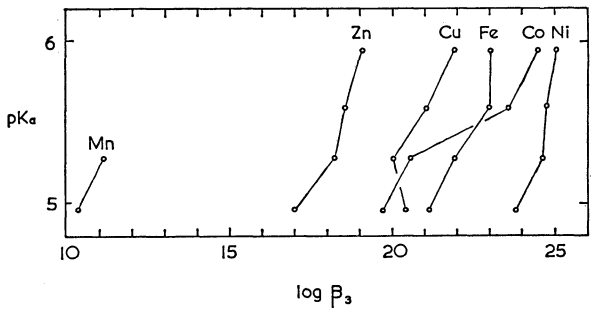

FIG. 3. Correlation between log β_3 of metallic complexes and pK_a of phenanthrolines. Data for orthophenanthroline from reference 2, for 5-methylphenanthroline from reference 3, for the dimethylphenanthrolines from this paper.

log β_3 for the indicated metallic complexes is compared with pK_a of the ligand. The exceptional behavior of the cobalt complexes noted in the previous paragraph is also

evident. A similar representation of log K_1 plotted against pK_a shows the same trend except that the relative positions of iron (II) and copper are different. As has been noted elsewhere (1, 12) the large β_3 of the iron (II) complexes resides mainly in the abnormally large K_3. Copper (II), on the other hand, shows a large K_1 (see the Irving–Williams order of stability) but this is not carried over into the β_3 owing to the reluctance on the part of copper to accept ligands beyond a coordination number of four.

ACKNOWLEDGMENTS

This investigation was supported by grants from the National Research Council of Canada, for which the authors record their appreciation. We also wish to thank Professor H. M. Irving of the University of Leeds for helpful discussions.

THE ORIGIN OF CARBON ATOMS 4, 5, AND 6 OF RICININE[1]

Received January 4, 1963

ABSTRACT

Degradations to isolate the carbon atoms at positions 4, 5, and 6 of the alkaloid ricinine from *Ricinus communis* L. are described. Tracer experiments with glycerol-1-^{14}C and glycerol-2-^{14}C suggest that glycerol or a closely related metabolic compound is a biosynthetic precursor of these carbon atoms.

Previous studies (1, 2) on the biosynthesis of ricinine (I) from *Ricinus communis* L. implicated succinic acid or a closely related four-carbon dicarboxylic acid found in the Krebs tricarboxylic acid cycle as the source of the carbon atoms at positions 2, 3, and 7. Also, the distribution of radioactivity in ricinine from feeding experiments with sodium acetate-1-^{14}C and sodium acetate-2-^{14}C was consistent with the initial formation of appropriately labelled succinic acid via the Krebs cycle.

The fact that carbon atoms 4, 5, and 6 were not significantly labelled by either acetate-^{14}C or succinic acid-^{14}C indicated that these three carbon atoms arose from a precursor or precursors not contained in the Krebs cycle and not derived under the experimental conditions used from the Krebs cycle. Consequently glycerol-1-^{14}C and glycerol-2-^{14}C were fed in separate experiments (1) to young *Ricinus* plants. Both precursors were incorporated into ricinine to almost the same extent as the acetate and succinic acid, but an appreciable proportion of the activity was concentrated on the carbon atoms of the methyl groups and nitrile group. Some of the glycerol may have been converted to acetate through glycolysis. Significant incorporation of activity into ricinine from labelled glycerol-^{14}C feeding experiments has been reported by other workers (3) but the location of the activity within the α-pyridone ring was not determined. Further progress was hampered by the lack of suitable degradative procedures for isolating the carbon atoms under study.

It is the object of this present paper to describe the individual isolations of carbon atoms 4, 5, and 6 of the ricinine molecule and to report and discuss the results obtained from the labelled acetate, succinic acid, and glycerol feeding experiments. A brief account of this work has already been reported (4).

Carbon 4 of ricinine (I) was isolated as the carbon of the carboxyl group of benzoic acid by the scheme outlined in Fig. 1. Ricinine was converted by hydrolysis followed by

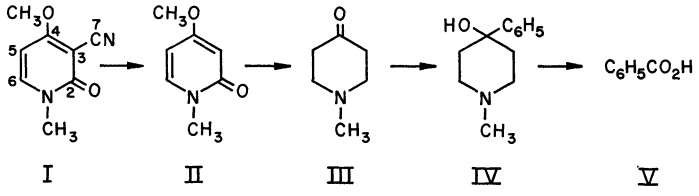

FIG. 1. Isolation of C-4 of ricinine.

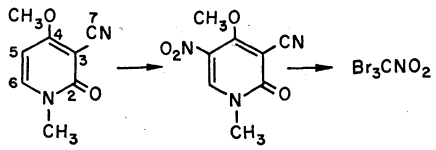
decarboxylation (5) to 4-methoxy-1-methyl-2-pyridone (II), which on treatment with lithium aluminum hydride followed by an acid work-up gave 1-methyl-4-piperidone (III). Reaction of this ketone with phenyllithium provided the known 4-hydroxy-1-methyl-4-phenylpiperidine (IV), which on oxidation with potassium permanganate gave benzoic acid (V), the carboxyl carbon of which originated at C-4 of ricinine.

Use was made again of the 'bromopicrin split' (2, 6) for the isolation of carbon 5 of ricinine. Electrophilic substitution of the nucleus of N-methyl-2-pyridones occurs in the 3- and 5-positions (7, 8). A methoxyl group at position 4 will activate position 3 for electrophilic substitution. A nitrile group at position 3 will deactivate position 6 for electrophilic substitution. Ricinine (I) readily underwent nitration to a mononitro derivative with the orientation of the incoming group being, necessarily, to the 5-position (Fig. 2). Treatment of the 5-nitroricinine (VI) with calcium hypobromite liberated carbon 5



I VI VII

FIG. 2. Isolation of C-5 of ricinine

of ricinine as the carbon atom of tribromonitromethane (bromopicrin) (VII). The liquid bromopicrin was purified by gas–liquid chromatography.

A degradative procedure for the isolation of carbon atom 6 of ricinine has already been described by Tamir and Ginsburg (9). These authors claimed that ozonolysis of 4-methoxy-1-methyl-2-pyridone (II), followed by an oxidative decomposition of the resulting ozonides, gave methyl hydrogen oxalate, N-methyloxamic acid, and one equivalent of carbon dioxide. The carbon dioxide was assumed to have arisen from carbon 6 of ricinine. In our hands application of this degradative procedure gave initially between two and four equivalents of carbon dioxide. Part of the carbon dioxide obtained was shown to have arisen from attack of ozone upon the solvent used in the reaction. By employing techniques designed to eliminate this source of error, approximately one equivalent of carbon dioxide was eventually obtained from the pyridone. However, the activity at carbon 6 of ricinine from the succinic acid-2,3-^{14}C feeding experiment (1, 2) by this method was found to be 31% of the total activity of the ricinine, when 95.7% of the activity had already been accounted for (2) on carbons 2, 3, 7 and the methyl carbons.

In order to check the usefulness of this ozonolysis procedure for carbon 6, a sample of ricinine-6,7-^{14}C (VIII), equally labelled on each of the two carbon atoms, was synthesized by the route outlined in Fig. 3. The scheme is based on a synthesis of ricinine first described by Schroeter, Seidler, Sulzbacher, and Kanitz (10).

Removal of the nitrile group from this synthetic ricinine (VIII) gave 4-methoxyl-1-methyl-2-pyridone (II) specifically labelled at position 6. Ozonolysis of this pyridone with oxidative cleavage of the resulting ozonides gave approximately one equivalent of carbon dioxide, which was isolated as barium carbonate. Instead of the expected activity of 50% of the total activity of the parent ricinine, carbon 6 was experimentally found to account for only 1.8%. Clearly most of the carbon dioxide from this degradation comes from some source other than carbon 6, probably from carbon 2 or 3 if the result obtained

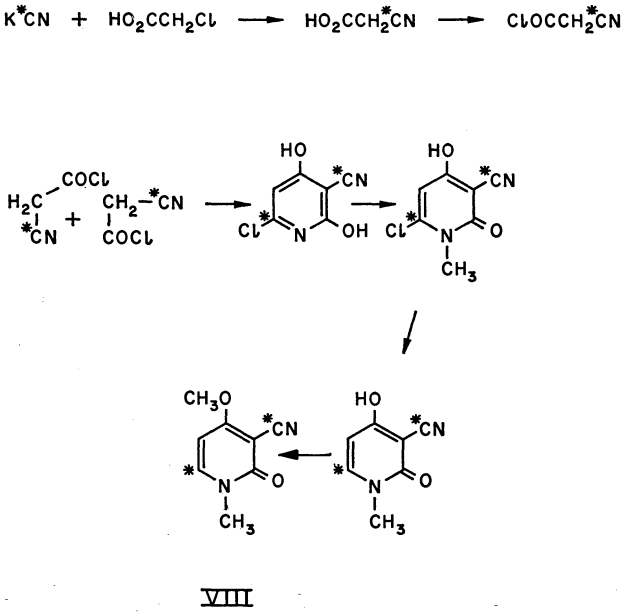

FIG. 3. Synthesis of ricinine-6,7-^{14}C. *C signifies ^{14}C.

from the ozonolysis degradation of ricinine from succinic acid-2,3-^{14}C is taken into account. More important, the degradative procedure must be rejected as a method of isolating carbon 6 of ricinine.

Carbon 6 was eventually isolated by the procedure outlined in Fig. 4 as formaldehyde

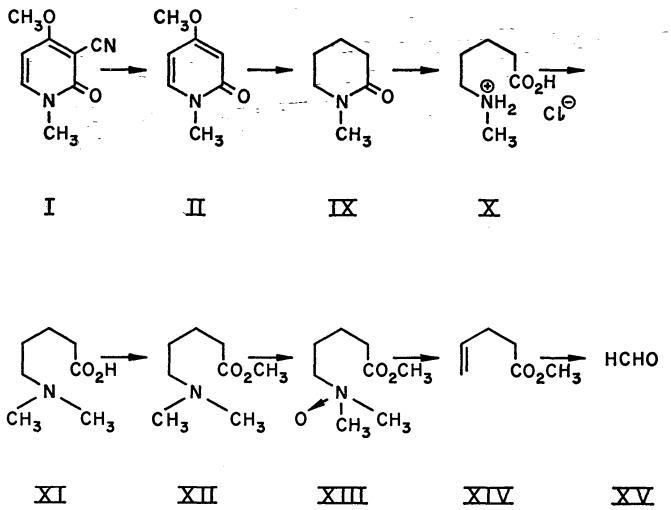

FIG. 4. Isolation of C-6 of ricinine.

characterized as its dimedone derivative. Conversion of ricinine (I) to 4-methoxy-1-methyl-2-pyridone (II) has been described above. In a previous paper (2) it was reported that the only product obtained from treatment of the pyridone (II) with hydrogen and

For personal use only.

Adams' catalyst in methanol was 4-methoxy-1-methyl-2-piperidone. Subsequently it has been found impossible to repeat this result under the conditions stated. The main product now obtained, under similar conditions but using a fresh batch of catalyst, is 1-methyl-2-piperidone (IX) with only ca. 10% of the 4-methoxy-1-methyl-2-piperidone. By addition of a trace of hydrochloric acid to the reaction mixture, it is possible to obtain almost complete hydrogenolysis. The 1-methyl-2-piperidone was hydrolyzed with concentrated hydrochloric acid to the corresponding amino acid (X), which was readily converted to the dimethylamino derivative (XI) on treatment with formaldehyde, formic acid, and sodium formate. The order of addition of the N-methylation reagents to the free amino acid (X) was found to be important if rapid recyclization was not to occur. Esterification of XI with diazomethane gave methyl dimethylaminovalerate (XII). The amine (XII) was converted to its N-oxide (XIII) with 98% hydrogen peroxide. Pyrolysis of the N-oxide yielded the methyl ester of allylacetic acid (XIV), the identity of which was confirmed by comparison with a sample prepared by esterification of allylacetic acid (11) with diazomethane. The olefin was cleaved by the action of sodium periodate in the presence of a catalytic amount of osmium tetroxide, and the liberated formaldehyde (XV), containing carbon 6 of ricinine, was isolated as the dimedone derivative (12).

The degradative procedures described above were applied to samples of ricinine obtained from the acetate-2-^{14}C, succinic acid-2,3-^{14}C, glycerol-1-^{14}C, and glycerol-2-^{14}C feeding experiments (1). Samples of ricinine, benzoic acid, bromopicrin, and the dimedone derivative of formaldehyde were separately converted by combustion to carbon dioxide, which was collected in barium hydroxide solutions as barium carbonate. All radioactivity measurements were made on barium carbonate samples. The percentages of the incorporated activity located at carbon atoms 4, 5, and 6 for the various samples are recorded in Table I.

TABLE I

Location of radioactivity in ricinine

Precursor	Percentage of activity of ricinine		
	C-4	C-5	C-6
Acetate-2-^{14}C	0.0	0.3	*
Succinic acid-2,3-^{14}C	0.0	0.0	*
Glycerol-1-^{14}C	25.8	2.2	19.7
Glycerol-2-^{14}C	2.2	38.8	0.0

*Activity not determined.

As was to be expected, carbon atoms 4 and 5 from ricinine obtained from the acetate-2-^{14}C and succinic acid-2,3-^{14}C feeding experiments showed little or no activity, since in both cases nearly 100% of the total incorporated activity already had been accounted for (2). The activities at carbon 6 in these two samples were not determined due to insufficient material.

From the results reported previously for glycerol-1-^{14}C and glycerol-2-^{14}C (1) it was apparent that there was considerable breakdown of the glycerol molecule to simpler units prior to incorporation, since the nitrile, N-methyl, and O-methyl carbon atoms of both samples of ricinine were all significantly labelled. However, the fact that carbon 5 of ricinine from the glycerol-2-^{14}C feeding experiment holds an appreciable percentage of the total activity of the ricinine molecule, whilst very little activity is located at carbons 4 and 6, suggests that some of the glycerol was incorporated intact into the ricinine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

molecule. The high activity at both carbons 4 and 6 and the low activity at carbon 5 after the feeding of glycerol-1-^{14}C lend support to this suggestion.

It is now proposed that carbon atoms 4, 5, and 6 of ricinine are derived from a three-carbon unit such as glycerol or a closely related metabolic compound. The slight inequality of activity at carbons 4 and 6 from the glycerol-1-^{14}C experiment points to the possibility that the actual precursor, unlike glycerol, is chemically non-symmetrical. If glycerol itself were the only source of this non-symmetrical intermediate, then the latter should be labelled equally at the terminal carbon atoms. However, with the rather long time lapse (3 days) between the feeding of the labelled glycerol and the harvesting of the plants, some of the actual non-symmetrical precursor could have been synthesized from the previously mentioned breakdown products of glycerol, with unequal labelling of the terminal carbons. In this connection further tracer experiments with labelled glycerol with a much shorter time interval between feeding and harvesting the plants are being carried out.

It has already been suggested (2) that carbon atoms 2 and 3 of the pyridine nucleus of nicotine are derived from the same source as carbon atoms 2 and 3 of the α-pyridone nucleus of ricinine. Recently Byerrum and his co-workers (13, 14) have reported the incorporation of activity derived from labelled glycerol into the pyridine ring of nicotine. Although only a small fraction of the activity (8%) was located at C-3 it could well be that at least part of the glycerol was incorporated intact into positions 4, 5, and 6 of the pyridine ring of the nicotine molecule. Hence it is possible that the carbon atoms of the α-pyridone ring of ricinine and the pyridine ring of nicotine are derived from the same basic units. This is not so surprising if it is remembered that nicotinic acid occupies an important position towards the end of the biosynthetic pathways of both molecules.

It should be noted that Ortega and Brown have proposed (15), although with little experimental proof, that resting cells of *Eschericia coli* synthesize nicotinic acid by an initial reaction between a three-carbon compound (either glycerol or a compound closely related to glycerol) and a four-carbon dicarboxylic acid.

Further studies are now required to determine more precisely the precursors of the carbon atoms of ricinine, and to determine the route by which the ring nitrogen atom (16) enters the molecule.

EXPERIMENTAL

Melting points were determined on a Kofler block and corrected. Radioactive samples were counted as thin layers on aluminum planchets in either a Radiation Counter Laboratories internal sample proportional counter or a Baird-Atomic end window proportional counter, as indicated in the text. Appropriate corrections were made for background count and sample self-absorption. Glycerol-1-^{14}C and glycerol-2-^{14}C were supplied by the California Corporation for Biochemical Research. Potassium cyanide-^{14}C was supplied by Merck, Sharp and Dohme of Canada Ltd.

Growth of Ricinus Plants and Administration of the Tracers

Plants of *R. communis* L. were grown and the tracers fed as described previously (1, 2). The glycerol-1-^{14}C (1.53 mg) in water (0.5 ml) was fed to 42 plants, and had a total activity of 2.22×10^8 d.p.m. The glycerol-2-^{14}C (2.13 mg) in water (0.8 ml) was fed to 50 plants, and had a total activity of 2.22×10^8 d.p.m.

Isolation of Ricinine

The ricinine was isolated and purified as described previously (1, 2).

Ricinine (418 mg), m.p. 202° (17), with radioactivity of 20,500 d.p.m./mg (Radiation Counter Laboratories instrument, previously reported (1) in c.p.m./mg) was obtained from the plants fed glycerol-1-^{14}C, which represents an incorporation of 3.9%.

Ricinine (470 mg), m.p. 202°, with radioactivity of 12,900 d.p.m./mg (Radiation Counter Laboratories instrument, previously reported (1) in c.p.m./mg) was obtained from the plants fed glycerol-2-^{14}C, which represents an incorporation of 2.7%.

Ricinine from Succinic Acid-2,3-^{14}C and Acetate-2-^{14}C Feeding Experiments

The same two samples of active ricinine which were used in the isolations of carbon atoms 2, 3, 7 and the N-methyl and O-methyl carbons (2) were also used in the isolations of the carbon atoms at positions 4 and 5, as described below.

Successful Degradation Procedures for Carbon Atoms 4, 5, and 6

The degradation of the ricinine from the glycerol-2-^{14}C feeding experiment will be taken as typical. The Baird-Atomic Counter was used in all the following experiments.

Carbon 4

The radioactive ricinine (I) (40 mg) was diluted with pure, inactive ricinine by a factor of approximately 30. The active ricinine was cocrystallized with the inactive sample. A small sample of the diluted ricinine was sublimed and then converted by combustion to carbon dioxide, which was collected in a barium hydroxide solution as barium carbonate. The barium carbonate had an activity of 36.5 d.p.m./mg.

4-Methoxy-1-methyl-2-pyridone (II)

The diluted ricinine (1.25 g) was hydrolyzed and decarboxylated (5) with 57% sulphuric acid solution to 4-methoxy-1-methyl-2-pyridone (820 mg). The product was purified by sublimation at 80° at 5×10^{-4} mm and had m.p. 114–116°.

1-Methyl-4-piperidone (III)

A solution of the pyridone (II) (820 mg) in hot, dry tetrahydrofuran (8 ml) was added, with stirring, to an excess of lithium aluminum hydride in dry ether (30 ml) and the mixture heated under reflux for 5½ hours. The excess lithium aluminum hydride was destroyed with water, and the complex decomposed with 10% hydrochloric acid. The mixture was shaken well and the aqueous layer separated, made alkaline, and extracted with chloroform. The solvent was removed from the extract, and 1-methyl-4-piperidone (116 mg) was distilled from the residue as a colorless oil, air-bath temperature 55–60° at 12 mm (18). An inactive sample of the piperidone (III), prepared from inactive ricinine as above, formed a hydrochloride derivative (18), m.p. 164–166°, and was identified with an authentic sample of 1-methyl-4-piperidone by comparison of infrared and n.m.r. spectra.

4-Hydroxy-1-methyl-4-phenylpiperidine (IV)

A solution of the ketone (III) (116 mg) in dry ether (10 ml) was added, with cooling and shaking, to a suspension of an excess of phenyllithium in ether (15 ml). The reaction mixture was stirred at room temperature for 2 hours, then poured onto ice and 10% hydrochloric acid. After shaking well, the aqueous layer was separated, made alkaline with sodium hydroxide, and extracted with ether. Evaporation of the dried extracts left an oily solid which was purified by sublimation at 80–85° at 5×10^{-4} mm to afford 4-hydroxy-1-methyl-4-phenylpiperidine (71 mg) as colorless prisms, m.p. 115–116° (19) undepressed on admixture with an authentic synthetic sample.

Benzoic Acid (V)

A solution of the carbinol (IV) (71 mg) in water (25 ml) was heated under reflux with an excess of potassium permanganate (0.5 g) for 2½ hours. The excess permanganate was destroyed by the addition of ethanol and the precipitated manganese dioxide removed by filtration. The filtrate was acidified and extracted with ether. Evaporation of the dried ether extracts left a residue which was purified by repeated sublimation at 100–105° at 12 mm to yield benzoic acid (10 mg), m.p. 121–122° with no depression on admixture with a pure authentic sample. The benzoic acid was converted to carbon dioxide by combustion, and the carbon dioxide collected in a barium hydroxide solution as barium carbonate which had a specific activity of 0.9 d.p.m./mg.

Similar Degradations

The activity at carbon 4 of ricinine from the glycerol-1-^{14}C, succinic acid-2,3-^{14}C, and acetate-2-^{14}C feeding experiments was determined likewise. The results are recorded in Table II.

TABLE II

Precursor	Activity of $BaCO_3$ from diluted ricinine, d.p.m./mg	Activity of $BaCO_3$ from benzoic acid, d.p.m./mg
Glycerol-1-^{14}C	77.3	10.2*
Succinic acid-2,3-^{14}C	24.0	0.0
Acetate-2-^{14}C	142.0	0.0

*In the degradation involving the glycerol-1-^{14}C experiment, it was necessary to dilute the intermediate, radioactive 4-hydroxy-1-methyl-4-phenylpiperidine with a pure synthetic and inactive sample, by a factor of 31.3/14.0. This factor has to be taken into account in calculating the percentage of activity (25.8, Table I) at C-4 in the ricinine derived from glycerol-1-^{14}C.

For personal use only.

Carbon 5

The radioactive ricinine (20 mg) from the glycerol-2-^{14}C feeding experiment was diluted with inactive ricinine by a factor of approximately 18, as described for carbon 4. The barium carbonate obtained by combustion of the diluted ricinine had an activity of 62.5 d.p.m./mg.

5-Nitroricinine (VI)

The diluted ricinine (300 mg) was dissolved in a solution of concentrated sulphuric acid (5 ml) and 90% nitric acid (1.0 ml) and the solution allowed to stand at room temperature for 2 hours. The solution was poured onto ice, and sodium hydroxide added until the solution was just acid. Chloroform extraction of the aqueous solution yielded 5-nitroricinine (275 mg), which was recrystallized from methanol as pale yellow needles, m.p. 163–164°. Found: C, 45.94; H, 3.39; N, 20.19. Calc. for $C_8H_7O_4N_3$: C, 45.94; H, 3.37; N, 20.09%.

Tribromonitromethane (Bromopicrin) (VII)

The bromopicrin was produced from the 5-nitroricinine (275 mg) by treatment with calcium hydroxide and bromine as described for the preparation of bromopicrin from 4-methoxy-1-methyl-3-nitro-2-pyridone (2). The purified bromopicrin was identified by comparison of its infrared spectrum with that of an authentic sample prepared from picric acid (20). Gas–liquid chromatography (2) of a small sample of the purified material showed only one component with a retention time almost identical with that obtained for authentic bromopicrin. The pure bromopicrin was converted by combustion to carbon dioxide, which was collected in a barium hydroxide solution as barium carbonate. The barium carbonate had an activity of 194.0 d.p.m./mg.

Similar Degradations

The activity at carbon 5 of ricinine from the glycerol-1-^{14}C, succinic acid-2,3-^{14}C, and acetate-2-^{14}C feeding experiments was determined likewise. The results are recorded in Table III.

TABLE III

Precursor	Activity of $BaCO_3$ from diluted ricinine, d.p.m./mg	Activity of $BaCO_3$ from bromopicrin, d.p.m./mg
Glycerol-1-^{14}C	84.0	15.0
Succinic acid-2,3-^{14}C	29.5	0.5
Acetate-2-^{14}C	229.0	4.65

Carbon 6

The radioactive ricinine (60 mg) from the glycerol-2-^{14}C feeding experiment was diluted with inactive ricinine by a factor of approximately 13, as described for carbon 4. The barium carbonate from the diluted ricinine had an activity of 84.0 d.p.m./mg.

4-Methoxy-1-methyl-2-pyridone (II)

The diluted ricinine (750 mg) was hydrolyzed and decarboxylated (5) with 57% sulphuric acid solution to 4-methoxy-1-methyl-2-pyridone (536 mg). The product was purified by sublimation at 80° at 5×10^{-4} mm and had m.p. 114–116.°

1-Methyl-2-piperidone (IX)

A solution of the pyridone (II) (536 mg) in methanol containing drops of concentrated hydrochloric acid was shaken in an atmosphere of hydrogen with Adams' catalyst at room temperature and under pressure of a small head of mercury, until no further uptake of hydrogen was observed. The catalyst and methanol were removed and the residue dissolved in water which was made basic with sodium hydroxide. Chloroform extracts of the aqueous solution yielded an oil which was distilled over a short path at 12 mm. 1-Methyl-2-piperidone (IX) (360 mg) distilled at an air-bath temperature of 100–105° (21). An inactive sample prepared from inactive ricinine as above formed a mercuric chloride derivative, m.p. 117–120° (21), and was identified with an authentic sample by comparison of their infrared spectra.

5-Methylaminovaleric Acid Hydrochloride (X)

A solution of 1-methyl-2-piperidone (IX) (360 mg) in concentrated hydrochloric acid (6 ml) was heated under reflux for 55 hours. The solvent was removed by heating on a steam bath at 25 mm. A small quantity of methanol was added to the residue and removed in the same way. The residue was heated with a lamp while under vacuum on the steam bath, and 5-methylaminovaleric acid hydrochloride (515 mg) crystallized on cooling as clusters of needles (21). The salt is hygroscopic.

Methyl 5-Dimethylaminovalerate (XII)

The 5-methylaminovaleric acid hydrochloride was dissolved in 98% formic acid (1.2 ml) and 37% formaldehyde (0.5 ml). Sodium formate (197 mg) was added and the mixture heated on the steam bath for 3 hours. Very little undissolved material remained at this point. The solvents were removed by distillation at 25 mm on the steam bath and a solution of hydrogen chloride in anhydrous methanol added to the residue.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A white crystalline precipitate formed. The methanol and excess acid were removed by heating at 25 mm and were flushed out by adding fresh methanol to the residue and distilling again. The residue was treated successively with three portions of methanol (5 ml). Each portion was decanted from an insoluble white salt. The combined methanolic extracts were treated with a solution of diazomethane in ether, when an additional quantity of the white solid precipitated. Excess diazomethane was destroyed with acetic acid, the solution was decanted from the solid, and the solvents removed at atmospheric pressure on the steam bath. The residue was distilled at 25 mm, air-bath temperature 90–130°, and was identified as methyl 5-dimethylaminovalerate (247 mg) by comparison of its infrared spectrum with that of an authentic sample prepared by the methods described above from inactive synthetic 1-methyl-2-pyridine. The authentic methyl 5-dimethylaminovalerate had b.p. 90° at 20 mm (22) and formed a methiodide, m.p. 140–141°. Found for the methiodide: C, 35.89; H, 6.81; N, 4.77; I, 42.02. Calc. for $C_9H_{20}O_2NI$: C, 35.88; H, 6.69; N, 4.65; I, 42.13%. In several preparations, the yield of the ester was 50–55%.

Methyl Allylacetate (XIV)

The methyl 5-dimethylaminovalerate (XII) (247 mg) was dissolved in anhydrous methanol (1.0 ml), cooled in water at 23°, and treated with 98% hydrogen peroxide (ca. 150 mg). The reaction mixture was kept at 22–24° until a negative test with phenolphthalein was obtained (5 hours). The excess peroxide was destroyed by the addition of a small quantity of platinum black. The initial reaction was violent and the solution was cooled in water at 18–20°. The solution was allowed to stand overnight at room temperature, when a negative test with moistened lead sulphide paper showed no peroxide. The solution was filtered to remove platinum and the methanol removed at 45° at 25 mm. The residue was extracted with chloroform (2 ml). The chloroform was removed at 25 mm whilst the heating bath temperature was gradually raised to 50°. The temperature was gradually raised again until a product distilled at 130–155°. The product, which was collected in a receiver cooled in a dry ice – butyl cellosolve bath, was treated with carbon disulphide (0.5 ml) and water (1.0 ml). The carbon disulphide was removed and the aqueous layer re-extracted four times with fresh solvent. The combined carbon disulphide extracts were dried (sodium sulphate). An infrared spectrum of this solution (3.0 ml) showed the presence of methyl allylacetate (ca. 48 mg) by comparison with an infrared spectrum of authentic inactive methyl allylacetate. The latter, b.p. 127–128° at 760 mm, was synthesized by alkylating malonic ester with allyl bromide, hydrolysis, decarboxylation of the product to allylacetic acid (11), and treatment of the allylacetic acid with diazomethane. Found: C, 63.3; H, 8.86. Calc. for $C_6H_{10}O_2$: C, 63.13; H, 8.83%. Methyl iodide (0.2 ml) was added to the solution of methyl allylacetate from the degradation of the ricinine, and the mixture allowed to stand at 5° for 30 minutes. The small amount of methyl 5-dimethylaminovalerate methiodide which precipitated was removed by filtration of the mixture through a short column of anhydrous magnesium sulphate. The carbon disulphide was removed from the filtrate by distillation. The residue was treated with dry pentane, and the solution decanted from a small amount of solid residue. Removal of the pentane left a liquid residue (59 mg) consisting mainly of methyl allylacetate. It was identified with the synthetic sample by comparison of their infrared absorption spectra.

Formaldehyde (XV)

The sample of methyl allylacetate prepared above was dissolved in dioxane (2 ml) containing osmium tetroxide (11 mg). Water (3.0 ml) was added and the solution stirred at 27° for several minutes. Sodium metaperiodate (189 mg) was added in one portion, and the slurry stirred for 90 minutes. To this slurry was added water (10 ml) and concentrated sulphuric acid (3 ml). The mixture was heated at 30° at 30 mm, when an orange-yellow distillate was obtained and discarded. The mixture was then heated with continual stirring to 60° at 30 mm until approximately 10 ml of distillate had been collected. This distillate was brought to pH 4.5 with sodium acetate and acetic acid, then warmed on a steam bath and treated with 5,5-dimethyl-1,3-cyclohexandione (dimedone reagent). After 5 minutes the mixture was cooled in ice and the solid collected, washed well with water, and dried briefly at 105°. The grey material (50 mg) was purified by sublimation at 130–135° at 0.01 mm to give a colorless cubic crystalline product, m.p. 191–192° undepressed on admixture with a dimedone derivative prepared from authentic formaldehyde (12). The formaldehyde dimedone derivative was converted by combustion to carbon dioxide, which was collected in barium hydroxide solution as barium carbonate. The barium carbonate was inactive.

Carbon 6 from Glycerol-1-^{14}C

The radioactive ricinine from the glycerol-1-^{14}C feeding experiment was diluted with inactive ricinine by a factor of approximately 20, as described for carbon 4. The barium carbonate from the diluted ricinine had an activity of 75.6 d.p.m./mg. The degradation of the diluted ricinine was carried out as described above. The barium carbonate from the dimedone derivative of formaldehyde had an activity of 7.0 d.p.m./mg.

Synthesis of Ricinine-6,7-^{14}C

Cyanoacetyl Chloride-^{14}CN

Potassium cyanide-^{14}C (3.2 mg of total activity 5.9×10^8 d.p.m.) was diluted with inactive potassium cyanide (20 g). The diluted $K^{14}CN$ was allowed to react (23) with chloracetic acid to give cyanoacetic acid-^{14}CN. Treatment of the cyanoacetic acid with phosphorus pentachloride (23) gave cyanoacetyl chloride-^{14}CN.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Ricinine-6,7-^{14}C (VIII)

The labelled ricinine (3 g) was prepared from the dimerization of the cyanoacetyl chloride-^{14}CN by a method similar to that described for a synthesis of inactive ricinine from inactive cyanoacetyl chloride by Schroeter *et al.* (10). The ricinine-6,7-^{14}C was purified by alternate crystallization from methanol and by sublimation at 180° at 5×10^{-4} mm.

Ozonolysis Degradative Procedure for Carbon 6

Active ricinine from the succinic acid-2,3-^{14}C feeding experiment (1, 2) and the synthetic ricinine-6,7-^{14}C were separately degraded by a method similar to that described by Tamir and Ginsburg (9).

Ricinine from Succinic Acid-2,3-^{14}C

The active ricinine was diluted with inactive ricinine by a factor of approximately 20 as described previously. A sample of barium carbonate from the diluted ricinine had an activity of 29.5 d.p.m./mg.

4-Methoxy-1-methyl-2-pyridone (II)

The diluted ricinine from above was converted to 4-methoxy-1-methyl-2-pyridone as described previously.

Ozonolysis of 4-Methoxy-1-methyl-2-pyridone

Ozonized oxygen was passed through a solution of the pyridone (II) (110 mg) in methylene chloride (7 ml), cooled by a solid carbon dioxide – acetone bath, until the solution turned blue. Pure oxygen was passed through until the solution was colorless. The solution, in an atmosphere of oxygen, was allowed to warm to room temperature, and oxygen bubbled through the solution for a further 20 minutes. Hydrogen peroxide (30%, 3 ml) was added to the tube containing the reaction solution, and the tube connected to a trap containing a barium hydroxide solution. Pure oxygen was passed through the system until no further precipitate was obtained in the trap (3–4 hours). The precipitated barium carbonate (ca. 90% of one equivalent based on the pyridone) had an activity of 73.0 d.p.m./mg.

A blank experiment, run as above but without the pyridone, gave a negligible precipitate. A precipitate was continuously formed when a blank experiment was run with the barium hydroxide trap connected to the reaction vessel while the ozonized oxygen was being passed through the reaction vessel. Experiments with inactive pyridone gave between two and four equivalents of barium carbonate after 3–4 hours when the barium hydroxide trap was connected during the passage of the ozonized oxygen.

Ricinine-6,7-^{14}C (VIII)

A small sample of the synthetic ricinine was converted by combustion to carbon dioxide, which was collected in a barium hydroxide solution as barium carbonate. The barium carbonate had an activity of 2670 d.p.m./mg. The synthetic ricinine was treated as described above for ricinine from the succinic acid-2,3-^{14}C experiments. The barium carbonate isolated from the ozonolysis reaction had an activity of 384.0 d.p.m./mg.

ACKNOWLEDGMENTS

The authors are indebted to Dr. L. C. Leitch and Mr. N. Kraut for the synthesis of ricinine-6,7-^{14}C. Thanks are also due to Mr. H. Seguin for the microanalysis and sample combustions.

THE REACTION OF CHLOROSULPHATE ESTERS OF SUGARS WITH PYRIDINE

H. J. Jennings and J. K. N. Jones
Department of Chemistry, Queen's University, Kingston, Ontario
Received November 26, 1962

ABSTRACT

Hexoside and hexitol derivatives with vicinal chlorosulphate ester groups in different configurations were treated with pyridine. The corresponding cyclic sulphate esters were produced except in the case of the diaxial configuration, which gave an anyhdro derivative. The axial–equatorial configuration gave in addition a keto-deoxy compound. The structures of the cyclic sulphate esters and of other reaction products are proposed and their mode of formation is discussed.

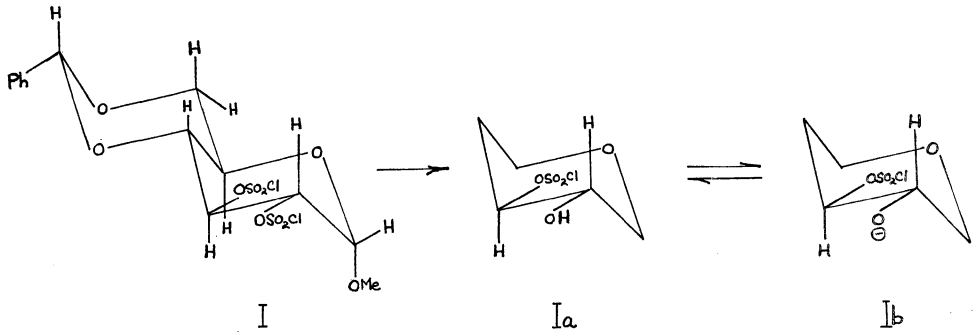
INTRODUCTION

Sulphuryl chloride is the only reagent which has been reported to yield cyclic sulphate ester derivatives of carbohydrates (1–5) and although other methods of forming diol cyclic sulphates are known they do not seem to be applicable in this field (6). Helferich and co-workers first isolated cyclic sulphate derivatives of methyl α- and methyl β-D-glucopyranoside, of mannitol, and of trehalose (1–3) and this work has been extended more recently (4, 5). The cyclic sulphate ester groups were shown to bridge adjacent hydroxyl groups on C_2 and C_3 of the glycopyranosides and possibly across C_3 and C_4 of the D-mannitol derivative (4, 5). Comparison of the reaction conditions which yielded the cyclic sulphate esters (1, 4) with more recent work which described the preparation of 2,3-dichlorosulphate ester derivatives of reducing sugars (7) showed that the ratio of pyridine to sulphuryl chloride had been approximately halved in the latter series of reactions. Therefore the effect of excess pyridine on the chlorosulphate esters of model compounds of different configurations was investigated, with particular emphasis on the 2,3-dichlorosulphate esters. This led to a new synthesis of cyclic sulphate esters in sterically favorable cases.

DISCUSSION

The reactions of pyridine on the 2,3-dichlorosulphate esters in the equatorial–equatorial configuration were carried out using derivatives of methyl α-D-glucopyranoside. Methyl α-D-glucopyranoside when treated with sulphuryl chloride gave a syrupy product which was dechlorosulphated (sodium iodide) to yield crystalline methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside (4). This evidence indicated that the initial reaction product was methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-dichlorosulphate. The syrupy dichlorosulphate ester when reacted with pyridine gave methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-cyclic sulphate (4). Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside when similarly treated gave a crystalline compound which was identified as the 2,3-dichlorosulphate ester (I) by isolation of the initial reactant after dechlorosulphation with sodium iodide. Treatment of the dichlorosulphate ester with pyridine in the cold yielded crystalline methyl 4,6-*O*-benzylidene-α-D-glucopyranoside 2,3-cyclic sulphate (4). When this reaction was carried out at 60° no cyclic sulphate derivative was formed and methyl α-D-glucopyranoside and its 4,6-*O*-benzylidene derivative were isolated.

The reaction of methanolic sodium methoxide on the 2,3-dichlorosulphate ester produced no cyclic sulphate ester and a poor yield of methyl 4,6-*O*-benzylidene-2,3-anhydro-α-D-alloside (9) was isolated. This evidence indicates that the basicity of the reagent is an important factor in the formation of the cyclic sulphate ester. The reactions probably proceed by the basic hydrolysis of the chlorosulphate ester on C_2 of I as in the case of the formation of the 2,3-anhydro derivatives from the ditosylate esters (9, 11), and the mechanism can be represented by the partial formulae (I, I*a*, and I*b*) (cf. ref. 10).



I Ia Ib

Sodium methoxide produced the 2,3-anhydro derivative due to the large concentration of oxide ion (I*b*), whereas in the less basic reagent (pyridine) the concentration of I*b* would be much smaller, enabling the formation of the cyclic sulphate from I*a* to take place.

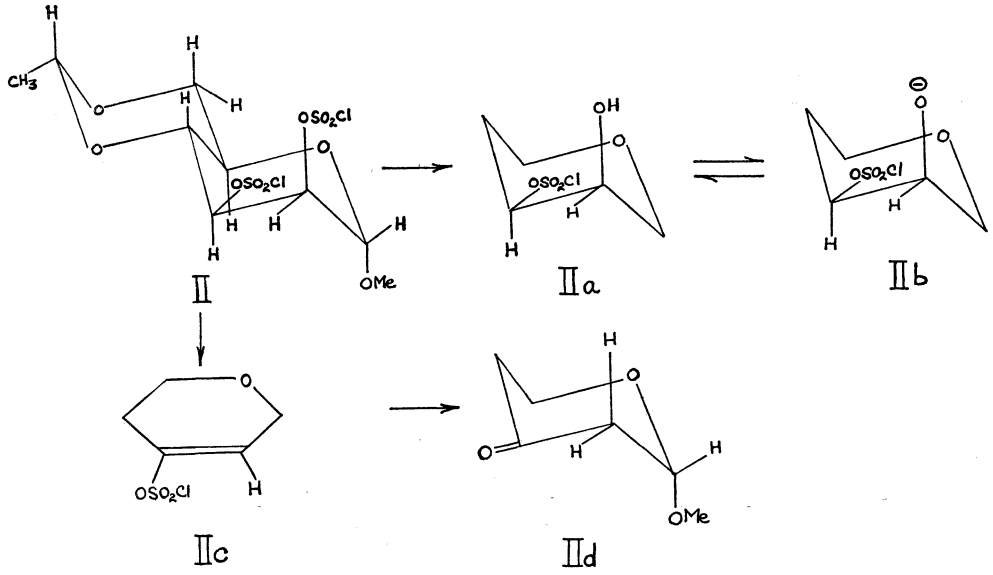
The reaction of pyridine on the 2,3-dichlorosulphate ester in the axial–equatorial configuration was carried out using the 2,3-dichlorosulphate derivative of methyl 4,6-*O*-ethylidene-α-D-mannopyranoside (II), the structure of which was proved by the isolation and identification of the following reaction products. The dichlorosulphate ester was treated with pyridine to give two crystalline products identified as methyl 4,6-*O*-ethylidene-α-D-mannopyranoside 2,3-cyclic sulphate, and methyl 4,6-*O*-ethylidene-2-deoxy-3-keto-α-D-*erythro*-hexoside. The structure of the cyclic sulphate derivative was indicated by its analysis and desulphation followed by hydrolysis (4) to give syrupy D-mannose (identified as the crystalline phenylhydrazone).

The structure of the 2-deoxy-3-keto compound was confirmed by sodium borohydride reduction of the 3-keto group and hydrolysis of the reduced product to give 2-deoxy-D-*ribo*-hexose (13). This reduction appears to be stereospecific in absolute ethanol and practically so in ethanol–water (1:1). Although 2-deoxy-D-glucose was detected when ethanol–water (1:1) was used it seems that solvent effects of the type reported by Eliel (14) are insignificant and that the main factor is steric hindrance of the reducing species. Models of the 2-deoxy-3-keto compound (II*d*) indicate possible interaction between the axial glycosidic group on C_1 of the molecule and the axial approach of the borohydride complex (14) needed for reduction of the keto group on C_3 to form an equatorial hydroxyl group. The bulky group would therefore be expected to approach from the less hindered equatorial side of the molecule, producing a hydroxyl group in the axial configuration (15).

The reaction of the axial–equatorial vicinal chlorosulphate ester groups with pyridine to give the cyclic sulphate and 2-deoxy-3-keto derivatives can be explained by the same mechanism as proposed previously and is represented by the partial formulae II, II*a*, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

II*b*. The formation of the 2-deoxy-3-keto compound using pyridine indicates that hydrolysis of the chlorosulphate ester group on C_2 of II must take place slowly for diaxial



elimination (16), with the subsequent formation of the transient compound (II*c*). This compound (II*c*) in the basic medium would be rapidly converted to the 2-deoxy-3-keto compound (II*d*) via an intermediate enolate. Sodium methoxide produced no keto-deoxy compound because the hydrolysis of II to II*a* was rapid. The formation of the cyclic sulphate derivative probably takes place via II*a* using pyridine and II*b* using sodium methoxide, as the formation of a 2,3-anhydro compound from II*b* is sterically unfavorable.

The reaction of pyridine on the 2,3-dichlorosulphate esters in the axial–axial configuration was carried out using the 4,6-*O*-benzylidene derivative of methyl α-D-altroside. Methyl 4,6-*O*-benzylidene-α-D-altropyranoside was treated with sulphuryl chloride to give a crystalline dichlorosulphate ester derivative (III), which decomposed rapidly and could not be analyzed. When a chloroform solution of the compound was allowed to evaporate to dryness another crystalline derivative was obtained which had lost the benzylidene group and which was indicated by analysis to be methyl α-D-altropyranoside 2,3-dichlorosulphate. The removal of the benzylidene group was probably facilitated by the presence of traces of acid caused by the partial decomposition of the chlorosulphate ester groups. The 4,6-*O*-benzylidene dichlorosulphate ester was treated immediately with pyridine to give crystalline methyl 4,6-*O*-benzylidene 2,3-anhydro-α-D-mannopyranoside (11).

The formation of the 2,3-anhydro derivative from III using pyridine indicates that the small concentration of III*b* is in a sterically more favorable position to react than III*a*. Models show that the distance between the groups on C_2 and C_3 of III*a* is much greater than for the equatorial–equatorial and axial–equatorial configurations, which gave cyclic sulphate derivatives with ease. Also the trans–axial configuration of III*b* is the most preferred configuration for nucleophilic attack of the oxide ion on C_3 to give the 2,3-anhydro derivative.

The reactions of pyridine on vicinal dichlorosulphate esters in the open chain form were carried out on derivatives of D-mannitol. D-Mannitol when treated with sulphuryl

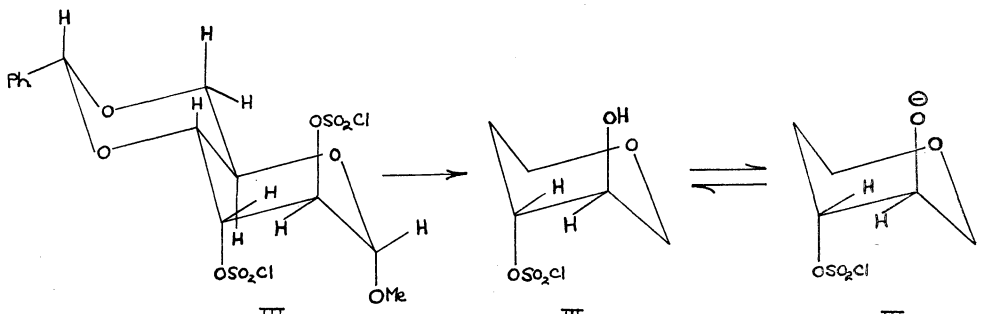
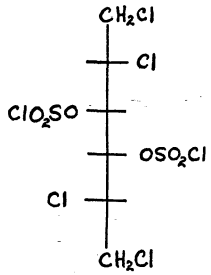
For personal use only.



III IIIa IIIb

chloride gave a crystalline tetrachlorotetradeoxy dichlorosulphate ester (IV). The ester (IV) when treated with pyridine gave a crystalline derivative which was shown by analysis to be a tetrachlorotetradeoxy cyclic sulphate ester (2, 4). This evidence indicates that the chlorosulphate groups in the original compound (IV) must have been vicinal. There is also some evidence that they are situated on C_3 and on C_4, as 1,2:5,6-di-*O*-isopropylidene mannitol gave an unstable dichlorosulphate ester which with pyridine yielded a crystalline cyclic sulphate derivative.



IV

Because of the free rotation of the bond between C_3 and C_4 of IV it is possible for the two chlorosulphate groups to approach each other closer than is possible for structures I, II, and III. It might therefore be expected that the reaction of pyridine on the vicinal dichlorosulphate ester would form the cyclic sulphate derivative with ease. The fact that sodium iodide also produced the cyclic sulphate derivative is unusual as the same treatment of the 2,3-dichlorosulphate esters in the equatorial–equatorial configuration (7) has so far resulted in dechlorosulphation to give the 2,3-dihydroxy compound. A possible explanation for this could be that the proximity of the two groups is favorable for cyclic sulphate formation in this case.

1,2:5,6-Di-*O*-isopropylidene-D-glucose when treated with sulphuryl chloride gave a crystalline monochlorosulphate ester as shown by analysis and dechlorosulphation (sodium iodide) to form the starting product. The monochlorosulphate ester when treated with pyridine also gave 1,2:5,6-di-*O*-isopropylidene-D-glucose, which indicates that pyridine can hydrolyze the chlorosulphate ester.

EXPERIMENTAL

Optical rotations were measured at 21±3°. Melting points were determined on a Kofler hot stage and were uncorrected. All solutions were concentrated under reduced pressure below 50°. Paper chromatography

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was carried out by the descending method on Whatman No. 1 filter paper using the following solvent systems (v/v): (*a*) butan-1-ol, ethanol, water (3:1:1), (*b*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4), and (*c*) 2-butanone, acetic acid, saturated aqueous boric acid (9:1:1). Reducing sugars were located on chromatograms by *p*-anisidine hydrochloride (17) or alkaline silver nitrate (18) spray reagents and keto-sugars by orcinol – trichloracetic acid spray reagent (19); the rates of movement are quoted relative to that of D-xylose (R_x). Paper electrophoresis was performed using Whatman 3MM filter paper impregnated with 0.05 *M* borate buffer and the sugars were detected on the electrophoretograms by *p*-anisidine hydrochloride spray reagent (17). The rates of movement of compounds on paper electrophoretograms are given relative to that of D-glucose (M_g). Infrared spectra were measured in chloroform solution (unless otherwise stated) using a Perkin–Elmer Model 21 spectrophotometer.

The reactions with sulphuryl chloride and the isolation of the chlorosulphate esters were carried out by the method described in a previous communication ("general method") (7), except that in most cases the reaction mixture was homogeneous.

Methyl 4,6-Dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-Dichlorosulphate

Methyl-α-D-glucoside (10 g) was treated with sulphuryl chloride (26 ml) and pyridine (40 ml) in chloroform solution (7). Concentration of the chloroform extracts gave a yellow syrup (12 g, 55%) which had $[\alpha]_D$ +115° (*c*, 1.2 in chloroform) and gave a positive test with aniline–pyridine (7). The syrup showed strong absorption frequencies in the infrared spectrum at 1427 cm^{-1} and 1195 cm^{-1}.

Dechlorosulphation of Methyl 4,6-Dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-Dichlorosulphate

The above syrup (10 g) was dissolved in methanol (150 ml), and a solution of sodium iodide (8 g dissolved in 20 ml of methanol–water (1:1)) was added, producing an immediate formation of iodine and the evolution of sulphur dioxide. The solution was neutralized with barium carbonate, filtered, and concentrated to a semicrystalline mass, which was dissolved in water. Following the addition of a few crystals of sodium thiosulphate to remove traces of iodine, the aqueous solution was continuously extracted with chloroform. Concentration of the chloroform solution gave a crystalline mass which was recrystallized from chloroform – light petroleum (b.p. 40–60°) to give colorless needle-shaped crystals (4.5 g, 82%) of $[\alpha]_D$ +179° (*c*, 2.0 in water) and m.p. 158°, undepressed on admixture with authentic methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside (4).

Methyl 4,6-Dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-Cyclic Sulphate

The syrupy 2,3-dichlorosulphate (9.7 g) was dissolved in redistilled pyridine (40 ml) and the solution was kept at 60° for 8 hours. The resultant dark brown solution, which still gave a positive test with aniline–pyridine (7), was poured into water and extracted (×2) with chloroform. The chloroform solution was washed with dilute sulphuric acid (5%), saturated sodium bicarbonate solution, and distilled water before being dried over anhydrous sodium sulphate. The chloroform solution was treated with charcoal, filtered, and concentrated to a pale yellow syrup (5 g, 76%). The syrup crystallized on standing, and the crude crystals gave a negative test with aniline–pyridine (7) and showed absorption frequency in the infrared spectrum at 1412 cm^{-1}. No strong absorption was detected in the 1200 cm^{-1} region as with the chlorosulphate esters (7). Recrystallization from ether – light petroleum (b.p. 40–60°) gave large needles (3 g, 46%) of $[\alpha]_D$ +139° (*c*, 1.75 in methanol) and m.p. 103–104°, undepressed on admixture with authentic methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-sulphate (4).

Methyl 4,6-O-Benzylidene-α-D-glucopyranoside 2,3-Dichlorosulphate

Methyl 4,6-*O*-benzylidene-α-D-glucoside (8) (5 g) was treated with sulphuryl chloride (13 ml) and pyridine (20 ml) in chloroform solution (7). Concentration of the chloroform extracts gave a syrup (8 g, 94%) which crystallized immediately. Recrystallization from chloroform – light petroleum (b.p. 60–80°) gave large colorless crystals of m.p. 133–136° (decomp.) and $[\alpha]_D$ +41.5° (*c*, 1.5 in chloroform). The crystals gave a positive test with aniline–pyridine (7) and showed strong absorption frequencies in the infrared spectrum at 1415 cm^{-1} and 1190 cm^{-1}. Analysis: Calc. for $C_{14}H_{16}O_{10}Cl_2S_2$: C, 35.1; H, 3.3; Cl, 14.8; S, 13.4. Found: C, 35.0; H, 3.3; Cl, 14.5; S, 13.2.

Dechlorosulphation of Methyl 4,6-O-Benzylidene-α-D-glucopyranoside 2,3-Dichlorosulphate

The crystals (3 g) were dechlorosulphated by the method described previously in the dechlorosulphation of methyl 4,6-dichloro-4,6-dideoxy-α-D-galactoside 2,3-dichlorosulphate except that barium carbonate (8 g) was stirred into the methanol solution before the addition of the sodium iodide (3 g). This kept the solution neutral and prevented the removal of the benzylidene group. The solution was filtered, concentrated to small volume, and, on the addition of water, the reaction product was precipitated. The precipitate was filtered from the solution and recrystallized from acetone–water to give crystals of m.p. 165°, undepressed on admixture with authentic methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (8).

Methyl 4,6-O-Benzylidene-α-D-glucopyranoside 2,3-Cyclic Sulphate

The crystals of the dichlorosulphate ester above (5 g) were dissolved in pyridine and kept at 0° for 8 hours, after which time the solution still gave a positive test with aniline–pyridine (7). The product was isolated as described previously for the 4,6-dichlorodideoxy cyclic sulphate derivative to yield a syrup which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

crystallized on standing and gave a negative test with aniline–pyridine (7). Recrystallization from chloroform – *n*-hexane gave needles (2 g, 72%) which had m.p. 103–106° (decomp.) and $[\alpha]_D$ +69° (*c*, 2.28 in chloroform). The crystals showed a strong absorption frequency in the infrared spectrum at 1405 cm^{-1} and a weak absorption frequency at 1203 cm^{-1}. Analysis: Calc. for $C_{14}H_{16}O_8S$: C, 48.8; H, 4.7; S, 9.3. Found: C, 48.8; H, 4.7; S, 9.4. This compound was isolated previously by Bragg *et al.* (4).

When the above reaction was carried out at 60° as with the 4,6-dichlorodideoxy derivative, methyl 4,6-*O*-benzylidene-α-D-glucopyranoside and methyl α-D-glucoside were isolated and characterized as the only products.

Methyl 4,6-O-Benzylidene-2,3-anhydro-α-D-alloside

Methyl 4,6-*O*-benzylidene-α-D-glucoside 2,3-dichlorosulphate (0.25 g) was treated with 4.8 moles of sodium methoxide (1 ml of 2.5 *N* solution in methanol) by the method of Richtmyer and Hudson (20). It was observed that the chloroform solution gave a negative test with aniline–pyridine (7) immediately after the addition of the sodium methoxide. Therefore the chloroform solution was washed with distilled water, dried (anhydrous $NaSO_4$), and concentrated to a crystalline solid (0.032 g, 23.2%). Recrystallization from methanol gave needles of m.p. 200–201°, undepressed on admixture with authentic methyl 4,6-*O*-benzylidene-2,3-anhydro-α-D-alloside (9).

Methyl 4,6-O-Ethylidene-α-D-mannopyranoside 2,3-Dichlorosulphate

Methyl 4,6-*O*-ethylidene-α-D-mannoside (12) (4.2 g) was treated with sulphuryl chloride (10 ml) and redistilled pyridine (16 ml) in chloroform solution (7). Concentration of the chloroform extracts gave a brown syrup which was redissolved in chloroform and treated with charcoal. Filtration and concentration of the solution gave a yellow syrup which slowly crystallized (7.2 g, 90%). Recrystallization from light petroleum (b.p. 60–80°) gave colorless crystals (5 g, 63%) of m.p. 94–96° and $[\alpha]_D$ −10° (*c*, 1.8 in chloroform). The crystals gave a positive test with aniline–pyridine (7) and showed strong absorption frequencies in the infrared spectrum at 1417 cm^{-1} and 1200 cm^{-1}. Analysis: Calc. $C_9H_{14}O_{10}Cl_2S_2$: C, 25.9; H, 3.4; Cl, 17.0; S, 15.4. Found: C, 25.7; H, 3.3; Cl, 17.0; S, 15.2.

Methyl 4,6-O-Ethylidene-α-D-mannopyranoside 2,3-Cyclic Sulphate

The crystals above (4 g) were treated with redistilled pyridine (40 ml) by the same method as used previously with methyl 4,6-dichloro-4,6-dideoxy-α-D-galactopyranoside 2,3-dichlorosulphate. After treatment with charcoal the chloroform solution was filtered and concentrated to a light yellow syrup (1.5 g) which partially crystallized and gave a negative test with aniline–pyridine (7). The strong absorption frequencies shown by the product in the infrared spectrum at 1740 cm^{-1} and 1405 cm^{-1} indicated that it was a mixture containing a keto compound and a cyclic sulphate derivative. The presence of the keto compound was further substantiated by chromatographic analysis of the mixture in solvents (*a*) and (*b*), which showed the presence of one component at R_x 4.0 with *p*-anisidine hydrochloride (brown) and orcinol – trichloracetic acid (green) sprays. The cyclic sulphate ester was obtained by repeated crystallizations from methanol as colorless plates (0.35 g, 12%) of m.p. 163–164° (slow decomp.) and $[\alpha]_D$ −23° (*c*, 1.2 in chloroform). Analysis: Calc. for $C_9H_{14}O_8S$: C, 38.3; H, 5.0; S, 11.4. Found: C, 38.4; H, 5.5; S, 11.3.

Methyl 4,6-O-Ethylidene-2-deoxy-3-keto-α-D-erythro-hexoside

The mother liquors from the reaction above were concentrated to a syrup and dissolved in a small quantity of ether from which solution crystallization occurred. The crystals were recrystallized from ether – *n*-hexane, giving colorless needles (0.25 g, 14.5%) of m.p. 103–104° and $[\alpha]_D$ +155° (*c*, 1.23 in methanol). Analysis: Calc. for $C_9H_{14}O_5$: C, 53.4; H, 6.9. Found: C, 53.0; H, 6.6.

Reaction of Methyl 4,6-O-Ethylidene-α-D-mannopyranoside 2,3-Dichlorosulphate with Sodium Methoxide

The crystals of the 2,3-dichlorosulphate ester (2 g) were dissolved in methanol (25 ml) and treated with 3.8 moles of sodium methoxide (64 ml of 0.2 *N* solution in methanol). Both the solutions were previously cooled in an ice bath before mixing and the reaction mixture was kept at 0° for 16 hours. Excess sodium methoxide was decomposed by the addition of solid carbon dioxide and the methanol solution was concentrated to a syrup, which was dissolved in chloroform. The chloroform solution was washed with dilute sulphuric acid (10%) in order to disperse a gel formation and then with saturated sodium bicarbonate solution and distilled water. The chloroform solution was dried (anhydrous Na_2SO_4) and concentrated to a syrup (0.9 g) which gave a negative test with orcinol – trichloracetic acid (19) and showed the absence of carbonyl absorption in the infrared spectrum. Crystallization of the syrup occurred from ether – light petroleum (b.p. 40–60°) and two recrystallizations from methanol gave colorless plates (0.05 g) of m.p. 162–163° (decomp.) and $[\alpha]_D$ −26.5° (*c*, 1.25 in chloroform). Mixed melting point with the cyclic sulphate derivative obtained previously by the reaction of pyridine on the dichlorosulphate ester of methyl 4,6-*O*-ethylidene-α-D-mannoside was 159–164° (decomp.). The two cyclic sulphate esters also gave identical infrared spectrums (0.8% in potassium bromide).

Desulphation of Methyl 4,6-O-Ethylidene-α-D-mannopyranoside 2,3-Cyclic Sulphate

The crystals of the cyclic sulphate ester (0.35 g) were desulphated by the method of Bragg *et al.* (4) using methanolic ammonia and sulphuric acid to yield a syrup (0.15 g). Chromatographic examination of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

syrup in solvents (*a*) and (*b*) indicated that it was a reducing sugar which co-chromatographed with D-mannose. The phenylhydrazone derivative of the syrup had m.p. 186–187° (decomp.), undepressed on admixture with authentic D-mannose phenylhydrazone.

*Reduction of Methyl 4,6-O-Ethylidene-2-deoxy-3-keto-α-*D-erythro-*hexoside with Sodium Borohydride*

The crystals of the 2-deoxy-3-keto compound (0.35 g) were dissolved in ice-cold absolute ethanol (20 ml). Sodium borohydride (0.35 g) was added at 0° and the solution was stirred continuously until it gave a negative test with orcinol – trichloracetic acid (19) (40 hours). Acetone was then added to the solution to destroy the excess sodium borohydride. The solution was deionized (Amberlite IR.120 (H form) ion exchange resin) and the eluate was concentrated to a syrup, which was co-distilled with methanol to constant weight in order to remove boric acid. The resultant pale yellow syrup (0.33 g), which could not be obtained crystalline, was dissolved in 0.2 *N* sulphuric acid and the solution was heated at 60° for 14 hours. The solution was neutralized with barium carbonate, filtered, and passed through Amberlite IR.120 (H form) and Duolite A.4 (OH form) ion exchange resins and concentrated to a syrup (0.27 g, 88%) which crystallized on standing. Chromatographic analysis of the crystals in solvent (*c*) indicated one component at R_x 1.7 which chromatographed with 2-deoxy-D-allose (2-deoxy-D-*ribo*-hexose). Electrophoresis showed one component at M_g 0.64 which ran at the same speed as 2-deoxy-D-allose and a faint unidentified spot at M_g 0.77. Recrystallization from ethanol–ether gave colorless needles of $[\alpha]_D$ +57° (*c*, 0.76 in water) and m.p. 138°, undepressed on admixture with authentic 2-deoxy-D-allose (13).

The reduction was repeated using ethanol–water (1:1) as the solvent and crystalline 2-deoxy-D-allose was again isolated as the main product. In this case chromatographic analysis in solvent (*c*) did indicate a faint spot at R_x 1.5 which was found to chromatograph with authentic 2-deoxy-D-glucose, and this was confirmed by electrophoresis as it showed a trace of material at M_g 0.33 which ran at the same speed as 2-deoxy-D-glucose. However, 2-deoxy-D-glucose was not present in sufficient quantities to allow its isolation.

*Reaction of Methyl 4,6-O-Ethylidene-α-*D-*mannopyranoside 2,3-Cyclic Sulphate with Pyridine*

The crystals of the cyclic sulphate were treated with redistilled pyridine at 60° by the same method previously used with the dichlorosulphate ester of methyl 4,6-*O*-ethylidene-α-D-mannopyranoside (12). The pyridine solution gave a negative test with orcinol – trichloracetic acid spray (19) and the chloroform-soluble crystalline product was recrystallized from methanol and gave colorless plates of m.p. 163°, undepressed on admixture with the starting material.

*Methyl 4,6-O-Benzylidene-α-*D-*altropyranoside 2,3-Dichlorosulphate*

Methyl 4,6-*O*-benzylidene-α-D-altroside (20) (1.2 g) was treated with sulphuryl chloride (3.2 ml) and redistilled pyridine (5 ml) in chloroform solution (7). Concentration of the chloroform gave a syrup which rapidly crystallized. Recrystallization from chloroform – light petroleum (b.p. 30–60°) gave colorless needles (1.65 g, 82%) of m.p. 105–108° (slow decomp.) and $[\alpha]_D$ +25.5° (*c*, 1.2 in chloroform). The crystals gave a positive test with aniline–pyridine (7) and showed strong absorption frequencies in the infrared spectrum at 1410 cm^{-1}, 1192 cm^{-1} (chlorosulphate ester), 3010 cm^{-1}, and 1605 cm^{-1} (aromatic) and no hydroxyl absorption. The substance began to decompose rapidly and it was therefore quickly dissolved in chloroform. A fraction (A) of the chloroform solution was kept and the remainder was concentrated to a crystalline solid (B) and was treated with pyridine.

*Methyl α-*D-*Altroside 2,3-Dichlorosulphate*

The chloroform was allowed to evaporate slowly from fraction A, leaving a comparatively stable crystalline compound. Recrystallization from chloroform–ether gave colorless needles of the 2,3-dichlorosulphate of m.p. 120–122° (decomp.) and $[\alpha]_D$ +44° (*c*, 1.09 in dioxane). The crystals showed strong absorption frequencies at 3550 cm^{-1}, 3315 cm^{-1} (hydroxyl), 1410 cm^{-1}, and 1192 cm^{-1} (chlorosulphate ester) and no aromatic absorption in the infrared spectrum. Analysis: Calc. for $C_7H_{12}O_{10}Cl_2S_2$: C, 21.5; H, 3.0; Cl, 18.2; S, 16.4. Found: C, 21.3; H. 3.0; Cl, 18.5; S, 16.2.

*Reaction of Methyl 4,6-O-Benzylidene-α-*D-*altropyranoside 2,3-Dichlorosulphate with Pyridine*

The crystalline mass (B) from above (1 g) was dissolved in pyridine and left at 0° for 16 hours. The chloroform-soluble component was isolated as described in previous reactions with pyridine, and gave a negative test with aniline–pyridine (7). The solution was concentrated to a crystalline mass which was recrystallized from methanol–water to give needles (0.33 g, 60%) of m.p. 146° and $[\alpha]_D$ 107° (*c*, 0.98 in chloroform). Analysis: Calc. for $C_{14}H_{16}O_5$: C, 63.6; H, 6.1. Found: C, 63.5; H, 5.9. The physical constants and the analysis are consistent with those of methyl 4,6-*O*-benzylidene-2,3-anhydro-α-D-mannopyranoside (11). Chromatographic analysis of the methanol–water mother liquors in solvents (*a*) and (*b*) showed the presence of a component R_x 3.7 which gave a faint green color with orcinol – trichloracetic acid (19). The infrared spectrum of the residue from the mother liquors also showed a weak absorption frequency at 1700 cm^{-1} indicating the presence of a ketonic compound. However, it was not present in sufficient quantities for isolation.

Tetrachlorotetradeoxyhexitol Dichlorosulphate

D-Mannitol (10 g) was treated with sulphuryl chloride (26 ml) and pyridine (40 ml) in chloroform solution

(7). The chloroform extract was treated with charcoal, filtered, and concentrated to a yellow syrup, which slowly crystallized (16.7 g, 67%). Recrystallization from chloroform – light petroleum (b.p. 40–60°) gave colorless crystals of the dichlorosulphate derivative of m.p. 134° and $[\alpha]_D$ +41° (*c*, 1.07 in chloroform). Analysis: Calc. for $C_6H_8O_6Cl_6S_2$: C, 15.9; H, 1.8; Cl, 47.0; S, 14.1. Found: C, 15.9; H, 1.8; Cl, 47.8; S, 14.2.

Tetrachlorotetradeoxyhexitol Cyclic Sulphate

The crystalline hexitol derivative (3 g) was dissolved in pyridine (26 ml) and allowed to stand at ambient temperature for 24 hours. The chloroform-soluble product was isolated from the reaction mixture as described in previous reactions with pyridine. The chloroform extract was concentrated to a syrup (1.7 g, 80%) which crystallized on standing. Two recrystallizations from chloroform – light petroleum (b.p. 40–60°) gave yellow plates (0.5 g, 23%) of the cyclic sulphate derivative of m.p. 105° and $[\alpha]_D$ +104° (*c*, 1.0 in methanol). Analysis: Calc. for $C_6H_8O_4Cl_4S$: C, 22.6; H, 2.5; Cl, 44.7. Found: C, 22.6; H, 2.4; Cl, 44.8. The infrared spectrum of the compound showed a strong absorption frequency at 1410 cm^{-1} and a weak one at 1197 cm^{-1} (cyclic sulphate ester), and the physical constants and analysis indicate that it is identical with the compound isolated by Helferich *et al.* (2).

An attempt was made to dechlorosulphate the tetrachlorotetradeoxyhexitol dichlorosulphate (12 g) with sodium iodide (5 g) by the method used previously in the dechlorosulphation of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside 2,3-dichlorosulphate. The resultant chloroform solution was treated with charcoal, filtered, and concentrated to a syrup (4.2 g, 50%) which crystallized on standing. Recrystallization from ether – light petroleum (b.p. 40–60°) gave pale yellow plates of $[\alpha]_D$ +103° (*c*, 1.06 in methanol) and m.p. 105°, undepressed on admixture with the tetrachloro cyclic sulphate ester derivative obtained above.

1,2:5,6-Di-O-isopropylidene-D-mannitol 3,4-Cyclic Sulphate

1,2:5,6-Di-*O*-isopropylidene-D-mannitol (21) (6.5 g) was treated with sulphuryl chloride (13 ml) and pyridine (26 ml) in chloroform solution (7). The chloroform extract was concentrated to a syrup (10 g, 82%) which gave a positive test with aniline–pyridine (7) and which began to decompose rapidly. The syrup was dissolved in pyridine (40 ml) and left at ambient temperature for 8 hours and the chloroform-soluble product was isolated as described in previous reactions with pyridine. The resultant chloroform solution was concentrated to a syrup (3.5 g, 48%) which crystallized on standing. Successive recrystallizations from ether, methanol, and light petroleum (b.p. 30–60°) gave long colorless needles of m.p. 114–118° and $[\alpha]_D$ +41° (*c*, 0.6 in chloroform). Analysis: Calc. for $C_{12}H_{20}O_8S$: C, 44.4; H, 6.2; S, 9.9. Found: C, 44.6; H, 6.1; S, 9.8.

1,2:5,6 Di-O-isopropylidene-D-glucose 3-Chlorosulphate

Diacetone glucose (10 g) (22) was treated with sulphuryl chloride (26 ml) and pyridine (40 ml) in chloroform solution (7). Concentration of the chloroform extract gave a syrup which crystallized immediately and recrystallization from light petroleum (b.p. 60–80°) gave colorless needles (10 g, 72%) which had m.p. 92° and $[\alpha]_D$ −40° (*c*, 1.36 in chloroform). Analysis: Calc. for $C_{12}H_{29}O_8ClS$: C, 40.2; H, 5.3; Cl, 9.9; S, 8.9. Found: C, 40.2; H, 5.7; Cl, 9.9; S, 8.9. It was found to decompose rapidly in the atmosphere but could be kept for a longer period of time under vacuum over phosphoric oxide.

Dechlorosulphation of 1,2:5,6-Di-O-isopropylidene-D-glucose 3-Chlorosulphate

The crystals above (2 g) were dechlorosulphated using sodium iodide (2 g) as described previously for the dechlorosulphation of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside 2,3-dichlorosulphate. The barium carbonate was filtered from the methanol solution and the filtrate was concentrated to a syrup, which was dissolved in water and extracted with ether. Concentration of the ethereal extract gave a crystalline mass, which was recrystallized from light petroleum (b.p. 40–60°) to give needles (0.6 g, 41%) of m.p. 107–108°, undepressed on admixture with authentic 1,2:5,6 di-*O*-isopropylidene-D-glucose (22).

When the monochlorosulphate ester of di-*O*-isopropylidene-D-glucose was dissolved in pyridine and the solution was kept at 0° for 8 hours, di-*O*-isopropylidene-D-glucose was isolated in good yield (melting point undepressed on admixture with an authentic sample).

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council (N.R.C. T-19) and the Ontario Research Foundation for grants which made this work possible. They also thank Dr. T. Reichstein for a gift of 2-deoxy-D-*ribo*-hexose (2-deoxy-D-allose) and Dr. E. Buncel for helpful discussion on the reaction mechanisms.

THE MECHANISMS OF PERMANGANATE OXIDATION

VII. THE OXIDATION OF FLUORAL HYDRATE[1, 2]

ROSS STEWART AND MICHAEL M. MOCEK[3]
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received December 26, 1962

ABSTRACT

The kinetics of the permanganate oxidation of fluoral hydrate have been examined over a very wide range of acidities. In the region between pH 2 and pH 8 the reaction is extremely slow but as the basicity is increased the reaction rate rises and can be correlated with the increasing concentration of the anions $CF_3—\underset{|}{\overset{O^-}{C}}HOH$ and $CF_3CHO_2^-$. The latter is oxidized extremely rapidly. The mechanism is discussed in terms of hydride ion or hydrogen atom transfer from the anions to permanganate. Large isotope effects are observed in the oxidation of $CF_3CD(OH)_2$.

In strong acid the oxidation rate rises again and this is interpreted in terms of a reaction between neutral fluoral hydrate and neutral permanganic acid. The acidity constant for the latter has been determined.

Previous work on the mechanism of the permanganate oxidation of alcohols gave strong indication that the reactive species were the alkoxide ions and that the rate-controlling step was a hydride transfer from alkoxide ion to permanganate ion (1, 2). In order to investigate this type of reaction more closely we have examined the permanganate oxidation of fluoral hydrate to trifluoroacetic acid:

$$CF_3CH(OH)_2 \xrightarrow{Mn^{VII}} CF_3CO_2H.$$

This is a useful model system since the first ionization occurs in only mildly basic solution and the effect on the reaction rate of the substrate's charge can be conveniently determined.

EXPERIMENTAL

Materials

Fluoral hydrate and its deuterio derivative were prepared by the reduction of trifluoroacetic acid by lithium aluminum hydride and deuteride essentially by the procedure of Braid, Iserson, and Lawlor (3). The white solid materials which were obtained were found to be not monomeric and the details of the structure proof of these compounds are presented elsewhere (4, 5). In aqueous solution it is clear that fluoral hydrate exists as the monomer, however.

Kinetic Methods

Both titration and spectrophotometric methods were used and these have been previously described (1, 6). The molar ratio of permanganate to reductant used was 2:1 above pH 12 and 2:3 below pH 11 because of the different stoichiometries. Typical rate plots are shown in Fig. 1.

In the experiments in sulphuric acid solution complications arose because of the decomposition of the permanganate and because of the heat of mixing of the reacting solutions. Blank experiments helped correct for the first problem and the following procedure for the second. The acid solution was momentarily cooled in ice and the aqueous permanganate solution was added. The substrate was then added and the volume of the solution adjusted quickly to the mark with sulphuric acid of the appropriate concentration. Since the substrate did not mix immediately with the remainder of the solution the reaction could be conveniently started by agitating the mixture. Since the temperature of the reaction mixture was slightly below the temperature of the run the heat of mixing could be used to bring the temperature close to the desired value.

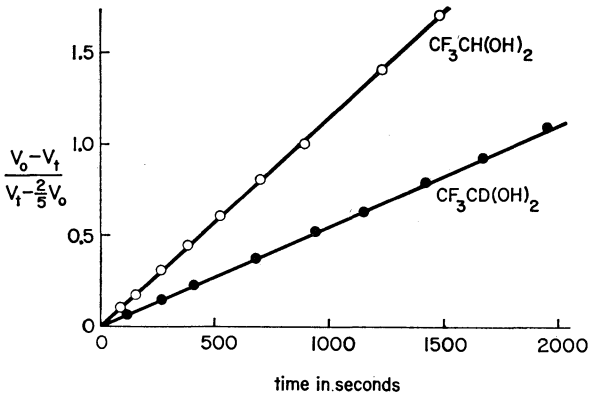

FIG. 1. Rate plots for the permanganate oxidation of fluoral hydrate and fluoral-1-*d* hydrate at pH 10.20. (Multiply units on ordinate by 2 and on abscissa by 5 for the latter.) $T = 25°$.

The solution was then thermostated. With practice it was found that the initial temperature could be brought to within a degree of the desired reaction temperature.

Acidity Constant of Fluoral Hydrate

The method which was employed makes use of the glass electrode and was similar to that previously described (7). The results of pK_a measurements at different ionic strengths are shown in Table I. The

TABLE I

Acidity constants of fluoral hydrate and fluoral-1-*d* hydrate in water at 25°

	$CF_3CH(OH)_2$		$CF_3CD(OH)_2$	
Ionic strength	$K\times10^{11}$	pK	$K\times10^{11}$	pK
0.01	6.17	10.21	6.03	10.22
0.05	6.46	10.19		
1.00	9.78	10.01	9.33	10.03

difference in the acidity of the protio and deuterio compounds is within experimental error (±0.02 pK units) but suggests that the deuterio acid may be slightly weaker than the protio acid. This would be in the same direction as that found by Halevi for carboxylic acids (8).

The enthalpy of ionization for the protio compound was measured by the same means and found to be approximately 6.2 kcal mole^{-1}. This is somewhat higher than the value for aliphatic acids (9, 10) but is in accord with the findings of other investigators (11, 12, 13).

Acidity Constant for Permanganic Acid

This was determined spectrophotometrically in sulphuric acid essentially as previously described (14) except that the substrate was added as the salt ($KMnO_4$) in aqueous solution. The absorption measurements for permanganate ion were made at 525 mμ and for permanganic acid at 458 mμ, near the absorption maxima. Symons has previously determined the pK_a to be −2.25 in aqueous perchloric acid (15).

The plot of optical densities (at 458 and 525 mμ) versus the H_- function showed, except for one point, the behavior of typical ionization curves (Fig. 2). The pK_a was calculated from the data at 525 and 458 mμ and then by modified Davis-Geissman method (14), using optical data at both wavelengths (Fig. 3). Since the plot of log $\{(\epsilon_{B^-}-\epsilon_{\lambda 525})/(\epsilon_{\lambda 525}-\epsilon_{BH})\}$ versus H_- did not show a slope of unity, the logarithms of the extinction coefficients were also plotted against the H_0 and H_R (J_0) functions in order to determine whether the dependence on the H_- function is real. It was found that the slope was essentially the same when H_0 or H_- function was used. This is not surprising, since both functions are almost parallel in the region studied. The slope, using H_R function was, however, much less than unity. The optical data used in the calculations are shown in Table II and the pK_a's summarized in Table III. The pK_a calculated with the aid of the H_R function was rejected on the basis of the small slope. The pK_a calculated with the H_- function appears to be the most satisfactory. The low slope (using data at 525 mμ) is perhaps due to interference of the ionization (16),

$$HMnO_4 + H^+ \rightleftharpoons MnO_3^+ + H_2O.$$

RESULTS

Stoichiometry and Kinetics

Since fluoral hydrate is subject to hydrolytic cleavage in basic solution it was important to show that the oxidation reaction being followed was not that of the hydrolysis product, formic acid. The rate of the latter's reaction over the entire pH range is known and it was easy to show that the fluoral hydrolysis is much slower than its oxidation. This was done by allowing fluoral hydrate to stand in 0.15 *M* sodium hydroxide for 30 minutes (about 34 half-lives for the oxidation at this basicity), then quenching the hydrolysis by adding acid and buffering the solution to pH 6.5 and titrating the amount of formic acid formed with permanganate. At this pH the oxidation of formic acid is fast and of fluoral hydrate very slow. At most, 2% of the fluoral hydrate had been hydrolyzed during the period.

Similar experiments with chloral hydrate showed that the hydrolysis seriously interfered with the oxidation reaction even though chloral hydrate appears to be oxidized somewhat faster than fluoral hydrate (4).

In the alkaline solution the stoichiometry of the reaction is given by the equation

$$2MnO_4^- + CF_3CH(OH)_2 + 3OH^- \rightarrow 2MnO_4^= + CF_3CO_2^- + 3H_2O.$$

The manganate which accumulates in the reaction mixture oxidizes fluoral hydrate only about 1/64th as fast as permanganate in 0.1 *M* sodium hydroxide and hence it would not interfere with the kinetics until a very late stage of the oxidation.

Below approximately pH 12 the manganate disproportionates to permanganate and manganese dioxide and the stoichiometry becomes

$$2MnO_4^- + 3CF_3CH(OH)_2 + OH^- \rightarrow 2MnO_2 + 3CF_3CO_2^- + 5H_2O.$$

Figure 2 shows the results for two typical kinetic runs, one of which is taken to about 75% completion. Excellent fits with second-order kinetics were obtained except in the region pH 11 to 12.5 where the manganate disproportionation rate becomes comparable to the oxidation rate. Neither a 2:1 nor a 2:3 ratio of reactants is satisfactory in this region.

Variation of Oxidation Rate with Acidity

Figures 4 and 5 show the effect of changing acidity on the oxidation rate of fluoral hydrate. The paucity of points near pH 11 in Fig. 5 is caused by the difficulties with manganese (VI) disproportionation referred to earlier.

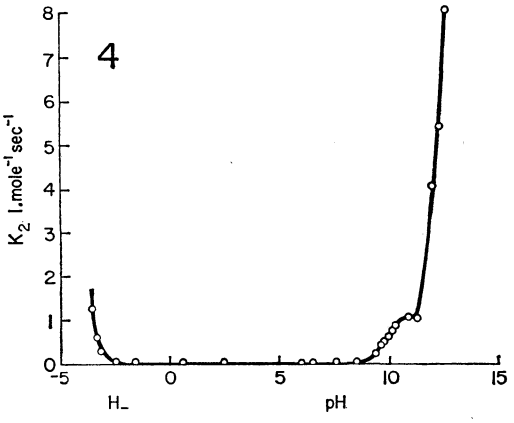

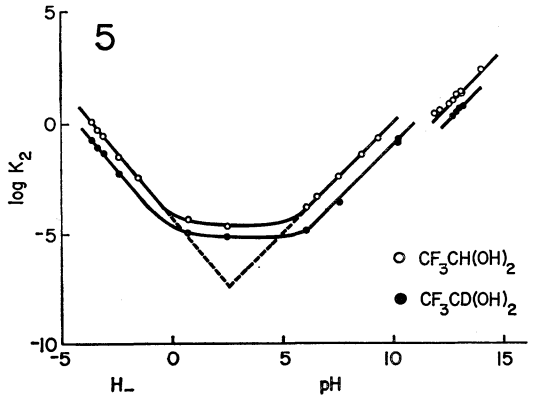

FIG. 4. Rate of the permanganate oxidation of fluoral hydrate as a function of the acidity of the medium.
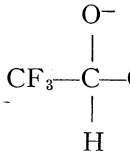
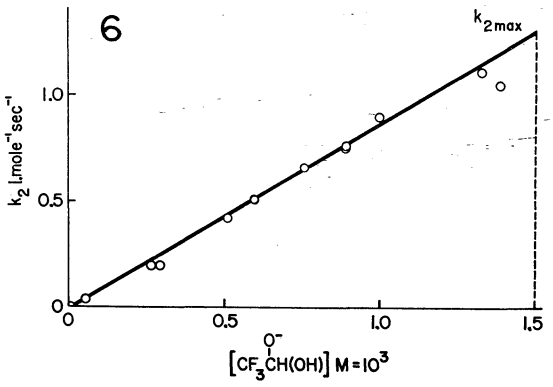
FIG. 5. The logarithm of the rate of the permanganate oxidation of fluoral hydrate as a function of the acidity of the medium.

Between pH 6 and pH 11 the oxidation rate of fluoral hydrate rises by a factor of about 10^4. Using the pK_a of 10.01 determined for fluoral hydrate one can show that the reaction rate in this region is linearly dependent on the concentration of the monoanion,



$CF_3CH(O^-)OH$, (Fig. 6). As the concentration of monoanion nears its maximum the rate



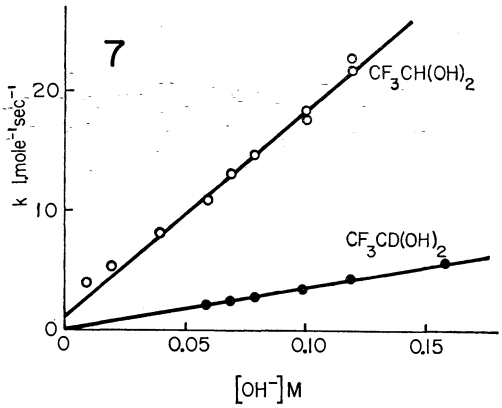


FIG. 6. The permanganate oxidation rate as a function of the fluoral hydrate monoanion concentration.
FIG. 7. Rate dependence on hydroxyl ion concentration.

levels off but soon rises again much more sharply as the much more reactive dianion begins to form. The first-order dependence of the rate on the hydroxyl ion concentration above pH 12 (Figs. 7 and 5) shows that the rate in this region becomes directly proportional to the concentration of the dianion, $CF_3CHO_2^=$. The reaction rate in 0.1 *N* NaOH is increased by a factor of more than three when the ionic strength is raised from 0.1 to 1.0. This is outside the region where the Debye–Hückel treatment can be applied but it is clearly in accord with the reactants possessing like charges.

In the weakly acidic region, pH 2 to 3, the oxidation of fluoral hydrate is extremely slow but one can detect a reaction which is some 100 times faster than that due to the minute amount of anion present at these acidities. This is presumably the oxidation of the neutral fluoral hydrate molecule by permanganate ion.

As the acidity is increased the rate of oxidation rises once more and becomes dependent on the acidity function again (Fig. 5). In this region, up to 46% sulphuric acid, the H_- function is used to denote the latter quantity. The oxidation in this region is believed due to the reaction of the neutral fluoral hydrate molecule with permanganic acid, $HMnO_4$. The latter is a strong acid which is about half dissociated in 60% sulphuric acid. The determination of the pK_a of this acid is described in the Experimental section.

Activation Parameters

The effect of the reactants' charge on the activation parameters of the oxidation is shown in Table IV. Figure 8 shows the effect of changing temperature on the oxidation rate

TABLE IV
Activation parameters

Oxidant	Substrate	Acidity	$\Delta H^{\ddagger}$ (kcal mole^{-1})	$\Delta S^{\ddagger}$ (e.u.)
MnO_4^-	$CF_3-C(O^-)(O_-)-H$	$[OH^-] = 0.07\ M$	6.6	−31.4
MnO_4^-	$CF_3-C(O^-)(O_-)-D$	$[OH^-] = 0.07\ M$	7.5	−31.8
MnO_4^-	$CF_3-C(O^-)(OH)-H$	pH = 10.20	12.4	−18.4
MnO_4^-	$CF_3-C(O^-)(OH)-D$	pH = 10.20	14.3	−16.7
$HMnO_4$	$CF_3-C(OH)(OH)-H$	41.8% H_2SO_4	12.9	−17.8

of the monoanion. The rate constants used to calculate the activation parameters for the monoanion oxidation are true bimolecular rate constants corrected for incomplete ionization but in the case of the dianion oxidation and in the case of the permanganic acid oxidation they necessarily include the pre-equilibrium step. The true enthaplies of activation for the rate-controlling step may be either somewhat larger or somewhat smaller than those listed; the entropies of activation are certainly more negative for these two reactions.

The effect of the reactants' charge type is entirely reasonable. The greatly increased rate of oxidation of the dianion results from a greatly lowered activation enthalpy, which more than overcomes the unfavorable entropy term. The latter results from the repulsion between the anionic oxidant and the dianionic reductant.

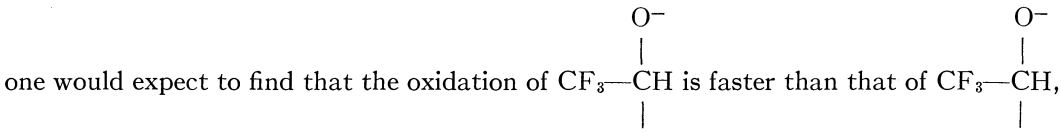
of making accurate measurements for these very slow reactions. However, an isotope effect clearly exists for this reaction also, which we presume is that between permanganate ion and neutral fluoral or its hydrate.

The discrepancy in the isotope effect of 10.1 and 13.6 observed at pH's 10.2 and 7.6 is not easily accounted for since they are both presumed to refer to the reaction between permanganate ion and fluoral hydrate monoanion. The fact that they are larger than the "normal" value of 7, which corresponds to complete loss of the C—H stretching mode in the transition state at 25°, occasions no surprise since large isotope effects had been previously observed for the permanganate oxidation of fluoroalcohols (2). (An isotope effect of close to 20 has been observed in the permanganate oxidation of $(CF_3)_2CDOH$ (17).) Experiments were conducted at a much higher temperature in order to throw some light on the possibilities of proton tunnelling as a cause of the high isotope effects at room temperature. A non-classical penetration of the reaction barrier should also result in a curved Arrhenius plot and this has been observed by Hullett in at least one case (18). The present work showed no deviation from linearity in the Arrhenius plots but as a check a rate experiment was conducted at 78°. We found an isotope effect of 6.3 at this temperature. This is the exact value calculable from the activation parameters of the protio and deuterio compounds obtained at the lower temperatures. It appears as if proton tunnelling is not the cause of the large isotope effect. Changes in the bending modes in the transition state could account for the present results and this may be associated with the fact that the reactants bear a similar charge and, as a consequence of this repulsion, will tend to be further apart in the transition state. The reaction between the dianion and permanganate, which should exhibit this effect more strongly, actually has a smaller isotope effect. The activation enthalpy for this reaction is very small, however, and the transition state must resemble the reactants rather closely, suggesting that the C—H bond is only slightly stretched in the transition state of the dianion–permanganate reaction. We have observed in other work that the isotope effect in the oxidation of structurally related compounds tends to decrease as the reaction rate increases (19). It should be pointed out that the C—H and C—D stretching vibrations in fluoral hydrate are unexceptional (2980 cm^{-1} and 2220 cm^{-1}).

DISCUSSION

Except for one feature of the reaction the present results can be explained quite satisfactorily in terms of a hydride transfer from the reductant to the oxidant. On this basis



one would expect to find that the oxidation of $CF_3—CH(O^-)—O^-$ is faster than that of $CF_3—CH(OH)—O^-$, which is faster than that of $CF_3—C(OH)_2—H$, and that oxidation by $HMnO_4$ is faster than that by MnO_4^-. This is indeed what is observed.

The profound effect of charge on the oxidizability of the substrate is shown in Table VI. The surprising aspect of these results is the relatively small effect of group polarities on the reaction rate. That is, such groups as $—CF_3$ and —H, with vastly different inductive

*Ionic strength not constant, rate values rounded off.

effects, produce only a fivefold rate difference when directly attached to the reacting C—H group. (The very low rho value in the permanganate oxidation of $Ar—\underset{|}{\overset{O^-}{\overset{|}{C}}}HCF_3$ is similar and has been commented on before (2).) If a hydride ion is expelled from $Z—\underset{|}{\overset{O^-}{\overset{|}{C}}}HCF_3$ a drastic change in rate would be expected when the electronic properties of the substituent Z are varied. It is true that when Z is the strongly electron-donating group $—O^-$ the rate soars but this again seems to indicate the importance of negative charge on the reductant. The increased charge results in a greater electrostatic repulsion between the reactants and this shows up in the less favorable activation entropy for the fluoral hydrate dianion – permanganate reaction but this is much more than compensated for by the lowered activation enthalpy.

In view of the above discussion it is worth examining a hydrogen atom abstraction mechanism. There appears little doubt that the rate-controlling step is between the alkoxide and permanganate ions and the following step can be considered.

$$CF_3—\underset{|}{\overset{O^-}{\overset{|}{C}}}—H + MnO_4^- \rightarrow CF_3—\underset{|}{\overset{O^-}{\overset{|}{C}}}\cdot + HMnO_4^-$$

$$\underset{|}{\overset{O^-}{\overset{|}{C}}}\cdot \xrightarrow[\text{fast}]{Mn^{VI} \text{ or } Mn^{VII}} CF_3CO_2H$$

The driving force for such a reaction would be the greater stability of Mn(VI) (compared to Mn(V) formed by hydride transfer) and the fair stability of the ketyl type radical–anion, $CF_3\underset{|}{\overset{O^-}{\overset{|}{C}}}\cdot$. Moreover, recent work by Halpern and Candlin (20) on the permanganate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

oxidation of the formate – Co(III) complex can only be interpreted in terms of a hydrogen atom abstraction by permanganate.

Further work is required to determine whether hydride ion or hydrogen atom abstraction from the fluoral hydrate anion is occurring. The reaction in strong acids, on the other hand, appears to be between neutral fluoral or its hydrate and permanganic acid.

FLUORIDE COMPLEXES OF GERMANIUM (IV) IN AQUEOUS SOLUTION[1]

R. L. BENOIT AND J. PLACE
Department of Chemistry, University of Montreal, Montreal, Que.
Received December 21, 1962

ABSTRACT

The germanium (IV) – fluoride species in various acid media have been investigated by solvent extraction, solubility, and potentiometric methods. The results are interpreted in terms of a series of mononuclear fluorohydroxygermanium (IV) species in which the number of fluorides bound per germanium tends to a maximum value of 5. The formation curve in 0.50 *M* perchloric acid is explained in terms of stability constants of species $GeF_4(OH)_i^{i-}$ and $GeF_5(OH)_i^{(i+1)-}$.

INTRODUCTION

The chlorogermanium (IV) species in acid media have recently been investigated (1, 2), and this work is now extended to the fluorogermanium (IV) species.

$H_2(GeOF_4).2H_2O$ and $H_2(GeF_6).2H_2O$ have been shown to exist as solid phases in the system GeO_2–HF–H_2O (3) at high HF concentrations, but information on the nature and stability of the species in solution is meagre. An approximate method for comparing the stabilities of various fluoride complexes (4) indicated that the germanium complexes were very weak, and conductance data relating to GeF_6^{2-} have been interpreted in terms of partial hydrolysis (5). Adsorption of Ge(IV) from mixed HF–HCl solutions on an anionic resin revealed the presence of negatively charged fluorogermanic species (6).

In this work three methods have been employed to investigate the equilibria involving fluorogermanium (IV) species, each method being useful at certain levels of acidity. The solvent extraction method (1) has been first used to study the distribution of Ge (IV) between CCl_4 and HCl (8–11 molal) as a function of added hydrofluoric acid. In the second place, the solubilities of GeO_2 in HF (0–1 *M*), and, as functions of HF added, in $HClO_4$ (5.7 and 7.0 molal) and HCl (4.5 molal) were measured. The solubility data were supported by measurements of pH and fluoride concentrations. Finally, a potentiometric method, the so-called "ferri" method (7), was used to investigate the fluorogermanium (IV) species in 0.50 *M* perchloric acid.

EXPERIMENTAL

Reagents

Chemicals used were of reagent grade. Germanium dioxide, of 99.9% purity, was used to make up stock solutions. Potassium fluorogermanate was prepared according to the procedure of Müller (8) and was recrystallized from hot water in polythene vessels. The preparation of stock solutions for the "ferri" method has been described by Hepler *et al.* (9).

Apparatus coming into contact with hydrofluoric acid was either made of polythene or protected by paraffin wax. Volumetric apparatus, of glass or polythene, was calibrated before use.

Procedure

Solvent Extraction

The procedure followed was similar to that for the experiments on the chlorogermanium (IV) system (1). The phases were shaken in a tightly sealed polythene bottle at 23±1° C and separated by decantation. The aqueous phase was also analyzed for germanium when the distribution ratio D was high ($\log D \geqslant +0.5$), and when the total germanium added was small because traces of germanium were found to be adsorbed by the polythene. Analysis for germanium was by the phenylfluorone method (10); a Beckman DU spectrophotometer was used.

[1]*Part of this work was carried out at the Department of Chemistry, Laval University, Quebec, Que.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Solubility Experiments

The aqueous and solid phases were shaken together in polythene bottles for 4 days at room temperature, 25±1° C. The solid phase was then allowed to settle (several hours) and aliquots of the clear liquid were removed by pipette. After dilution of the sample, analysis for germanium was made by the phenylfluorone method (10); the data of the solvent extraction experiments were used to ensure that sufficient HCl was added to give adequate separation in the presence of fluoride.

Hydrogen ion concentrations were determined by means of the quinhydrone electrode, and fluoride by the "ferri" method.

Potentiometric Measurements

A Radiometer pH meter 4c was used, and potentials were read to ±0.1 mv. Electrodes were of bright platinum wire or foil; a calomel–saturated KCl electrode served as the reference electrode.

The setup for the "ferri" method was based on that described by Hepler *et al.* (9), the chief difference being that the potential of the Fe^{2+}/Fe^{3+} system was measured against a calomel reference electrode. An atmosphere of nitrogen was maintained over the solution, and stirring was by means of a stream of nitrogen. The salt bridge for the experiments at ionic strength 0.5 was of 0.5 *M* $NaClO_4$ in 3% agar-agar; one end of the bridge and the reference electrode dipped into saturated NaCl. The temperature of the reaction vessel was maintained at 25.0±0.1° C in a water bath. The salt bridges for the experiments in 5.70 and 7.00 molal $HClO_4$ media were of perchloric acid of the same concentrations, connection to the reaction vessel being made by narrow, flexible polythene tubing with a platinum wire clip and to the reference electrode by a solution of saturated NaCl.

EXPERIMENTAL RESULTS

Solvent Extraction

Preliminary experiments showed that the amounts of hydrofluoric acid extracted from concentrated hydrochloric acid by carbon tetrachloride were negligible at the concentrations involved: at 10.2 molal HCl, the HF distribution coefficient $(HF)_{CCl_4}/(HF)_{aq}$ is about 2×10^{-4}.

Irvine *et al.* (11) have reported small changes in relative volumes on equilibrating equal volumes of concentrated HCl solutions and CCl_4; however, under the present conditions the volumes of the two phases were found to be unchanged within 0.5% provided that clean separations were ensured.

It has been shown that germanium is extracted by CCl_4 from germanium solutions in concentrated HCl media and that addition of HF lowers the germanium distribution ratio (2). The variation of the distribution ratio with the HF concentration can be interpreted in terms of solution equilibria involving fluorogermanium species if mixed fluoro–chloro species $GeF_i(OH)_jCl_m$ are unimportant.

Assuming first that hydrated $GeF_i(OH)_j$ is the only fluorogermanium (IV) species present in a given concentration interval, calling K_{ij} the mass action constant for the equilibrium, and ignoring the charge of the fluorogermanium (IV) species,

$$GeCl_4 + i\,HF + j\,H_2O \rightleftarrows GeF_i(OH)_j + 4Cl^- + (i+j)H^+,$$

the following expression is found:

$$D_{ij} = \frac{P}{K_{ij}} \times \frac{|Cl^-|^4 |H^+|^{i+j}}{|HF|^i \, |H_2O|^j} \times f_{ij}, \qquad [1]$$

where

$$D_{ij} = \frac{(GeCl_4)_{CCl_4}}{(GeF_i(OH)_j)}, \qquad P = \frac{(GeCl_4)_{CCl_4}}{|GeCl_4|_{aqueous}},$$

vertical rules designate activity, parentheses concentration, and f_{ij} is the activity coefficient of $GeF_i(OH)_j$.

For personal use only.

If activity coefficients and water activity are kept constant equation [1] gives:

$$\left[\frac{d \log D_{ij}}{d \log (HF)}\right]_{(H^+),(Cl^-)} = -i. \qquad [2]$$

Assuming now that various mononuclear $GeF_i(OH)_j$ and $GeCl_m(OH)_n$ species are present simultaneously, the distribution ratio becomes

$$\frac{1}{D} = \sum \frac{1}{D_{ij}} + \sum \frac{1}{D_{mn}}.$$

Taking the derivatives with respect to log (HF),

$$\frac{d \log D}{d \log (HF)} = D \sum \frac{1}{D_{ij}} \times \frac{d \log D_{ij}}{d \log (HF)}. \qquad [3]$$

Combining equations [2] and [3],

$$\left[\frac{d \log D}{d \log (HF)}\right]_{(H^+),(Cl^-)} = \sum \frac{-iD}{D_{ij}}.$$

For the fluorogermanium species the average number of F bound per Ge atom is:

$$\bar{i} = \frac{\sum i(GeF_i(OH)_j)}{\sum (GeF_i(OH)_j)} = \frac{C_{Ge}}{\sum (GeF_i(OH)_j)} \sum \frac{iD}{D_{ij}},$$

where C_{Ge} is the total germanium concentration in the aqueous phase. Finally

$$\left[\frac{d \log D}{d \log (HF)}\right]_{(H^+),(Cl^-)} = -\bar{i} \frac{\sum (GeF_i(OH)_j)}{C_{Ge}}.$$

In other words, the plot of log D against log (HF) at constant (H^+) and (Cl^-) gives $\bar{i}$, the average number of fluoride bound per germanium, when the chloride species are in negligible concentration, i.e. $\sum (GeF_i)(OH)_j)/C_{Ge} \simeq 1$. When chloride species are also present, $\bar{i}$ is obtained by multiplying the slope by $C_{Ge}/\sum (GeF_i(OH)_j)$; this correction factor is taken as being equal to $D_0/(D_0-D)$, where D_0 is the distribution ratio for (HF) $=0$.

At the levels of acidity involved, 8–11 molal HCl, HF is practically undissociated and the concentration of the species F^- and HF_2^- is negligible (12). The values of the equilibrium concentration (HF) were calculated from the added concentration C_{HF} by subtracting a correction term for fluoride bound to germanium, $\bar{i} \sum (GeF_i(OH)_j)$. $\sum (GeF_i(OH)_j)$ was calculated from the values of C_{Ge} and D_0, and $\bar{i}$ was obtained, by using successive approximations, from the corrected value of the slope of log D against log (HF). Germanium distribution and $\bar{i}$ are plotted as functions of (HF) in Figs. 1 and 2 respectively.

The Potentiometric Method

In the so-called "ferri method" the redox potential of the ferric–ferrous system is used to indicate the equilibrium HF concentration present in an acid solution (9).

A run was first made with ferrous and ferric ions and the potential measured with a platinum electrode was plotted on a graph as a function of added HF. Then a run was made under identical conditions but with germanium added and the potentials read off as a measure of free HF; a correction for the fluoride bound to Fe^{3+}, $\sum x(FeF_x)$, was calculated from the equilibrium constants for the ferric fluoride system (9). The concentration of fluoride bound to germanium was obtained as $C_F - [(HF) + \sum x(FeF_x)]$, where C_F is the total concentration of HF added.

Experiments were carried out in a perchlorate medium with $(H^+) = 0.497\ M$ and the ionic strength was made up to 0.500 with $LiClO_4$. The temperature of the thermostat was 25.0±0.1° C. The initial volume for each run was 25.17 ml, the initial concentrations of ferrous and ferric ion were $4.91\times10^{-4}\ M$ and $2.82\times10^{-4}\ M$ respectively, and runs were made at initial germanium concentrations of $1.00\times10^{-2}\ M$ and $2.16\times10^{-3}\ M$. The results of several runs are consolidated in Table I. In calculating the ionic strength of the solutions, the contributions of GeO_2 and HF were neglected although the formation of ionic germanium species will have some effect as more HF is added. At this level of acidity the predominant hydrofluoric species is HF since $(F^-)/(HF) = 2.5\times10^{-4}$ (13).

The formation curve is plotted in Fig. 3 in the form of $\bar{\imath}$ against log (HF), where

$$\bar{\imath} = \frac{C_F - [(HF) + \sum x(FeF_x)]}{C_{Ge}}.$$

The values of $\bar{\imath}$ tend to a maximum of 5. Further information on the nature and stability of the species formed can be obtained by finding the minimum number of parameters necessary to fit the formation curve satisfactorily. As GeO_2, probably hydrated, is present in non-complexing acid media (14), addition of HF to the Ge (IV) solution leads to equilibria such as

$$GeO_2 + i\,HF + (j-2)H_2O \rightleftarrows GeF_i(OH)_j + (i+j-4)H^+ \qquad [4]$$

ignoring the charges of the fluorogermanium (IV) species.

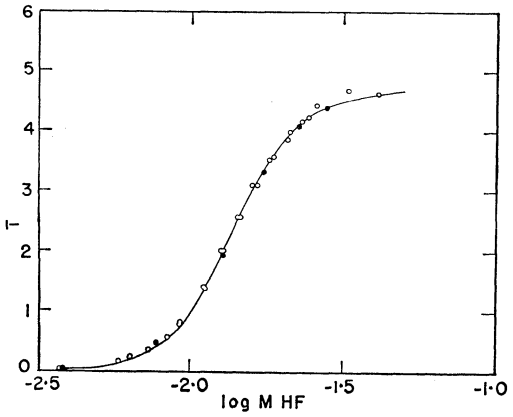

FIG. 3. Complexity of the germanium (IV) – fluoride system at $(H^+) = 0.50$ M: ○ (Ge) initial = 1.076×10^{-2} M; ● (Ge) initial = 2.16×10^{-3} M. The curve is calculated from $\beta_4' = 2.0\times10^7$, $\beta_5' = 8.8\times10^8$.

The overall stoichiometric stability constant, β_{ij}, for this equilibrium is

$$\beta_{ij} = \frac{(GeF_i(OH)_j)(H^+)^{(i+j-4)}}{(GeO_2)(HF)^i}.$$

When (H^+) is held constant at a particular level, a constant β_{ij}' may be defined such that

$$\beta_{ij}' = \frac{(GeF_i(OH)_j)}{(GeO_2)(HF)^i}. \qquad [5]$$

If N is the maximum coordination number of Ge (IV), constants β_i' may be determined under the particular conditions of ionic strength and acidity, where

$$\beta_i' = \sum_{j=0}^{j=N-i} \beta_{ij}' = \frac{\sum_{j=0}^{j=N-i} (GeF_i(OH)_j)}{(GeO_2)(HF)^i}. \qquad [6]$$

A graphical extrapolation method of Rossotti and Rossotti (15, p. 110) using the function

$$\frac{\bar{i}(HF)^{-5}}{5-\bar{i}} = \beta_5' + \beta_4' \frac{4-\bar{i}}{5-\bar{i}}(HF)^{-1} + \sum_{i=1}^{i=3} \frac{i-\bar{i}}{5-\bar{i}} \beta_i'(HF)^{i-5}$$

gave the following values:

$$\beta_5' = 8.8(\pm0.2)\times10^8,\ \beta_4' = 2.0(\pm0.3)\times10^7,\ \beta_3' \leqslant 10^4.$$

The approximate limits of error quoted were estimated from the graphs used to evaluate the constants. Satisfactory agreement between the experimental and calculated formation curves was obtained by using β_5' and β_4' only, as can be seen in Fig. 3.

To check whether the maximum value of i is in fact 5, a plot was made of $[\beta_4' + \beta_5'(HF)]$ against (HF); this gave a linear relation over the explored range of (HF), implying that complexes in which $i > 5$ are not present in appreciable concentration under these conditions (15, p. 116).

Solubility Measurements

Solubility of GeO_2 in HF at Constant Levels of Acidity and Molality

Stability constants are easily obtained from solubility measurements when added and

For personal use only.

free ligand can to a first approximation be regarded as equal (16), i.e. when the solubility remains low.

Determinations of GeO_2 solubility were carried out for solutions containing increasing HF concentrations at 4.50 molal HCl, 5.70 molal $HClO_4$, and 7.00 molal $HClO_4$. By working at constant and high acidity one of the variables of the system is eliminated with the further advantage that the GeO_2 solubility is appreciably depressed by a salting-out effect (14). Results are given in Table II and the values of C_{Ge} are plotted against C_F in Fig. 4.

	0.261	0.0800	0.0182	3.04	3.10

The equation

$$(C_{Ge}-S_0)\mathbf{a} = C_F, \qquad [7]$$

where $\mathbf{a} = 3.3\pm0.1$ and S_0 is the solubility when $C_F = 0$, accounts for the results at all three levels of acidity over the range $C_F = 0$ to $C_F = 0.3$ molal. With $\bar{\imath}' = [C_F-(HF)]/[C_{Ge}-S_0]$, the results set an upper limit of $\mathbf{a} = 3.3$ for $\bar{\imath}'$ which is the average number of fluoride bound per germanium for species other than GeO_2. A further interpretation of these data, according to the method described in reference 16, is not feasible and as the rise in solubility in relation to C_F is considerable another approach must be found.

Solid GeO_2 is in equilibrium with dissolved GeO_2, so, with (GeO_2) and (H^+) constant, from [6],

$$\sum (GeF_i(OH)_j) = \sum \beta_i' S_0 (HF)^i.$$

Thus, taking into account the experimental relation [7],

$$\mathbf{a} \sum \beta_i' S_0 (HF)^i = (HF) + \sum i\beta_i' S_0 (HF)^i. \qquad [8]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

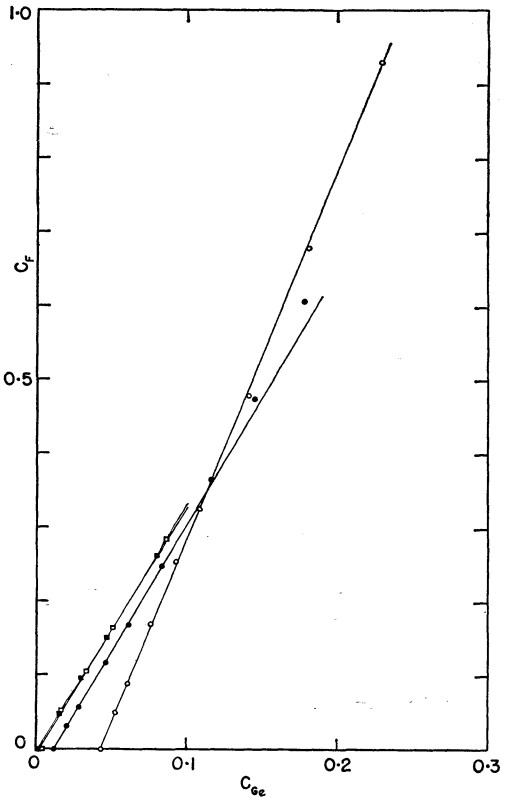

FIG. 4. The solubility of GeO_2 in HF in various media: C_{Ge} as a function of C_F. ○ in HF (in molarities); ● in 4.50 molal HCl (in molalities); □ in 5.70 molal $HClO_4$ (in molalities); ■ in 7.00 molal $HClO_4$ (in molalities).

A set of solutions to this equation is obtained if (HF) is negligible, i.e. (HF) $\ll C_F$, and all the values of β_i' except one are nil: e.g. with $\beta_i' = \beta_2' = \beta_4' \ldots = 0$ and $\beta_3' \neq 0$,

$$\mathbf{a}_3 = \frac{3\beta_3' S_0(\mathrm{HF})^3}{\beta_3' S_0(\mathrm{HF})^3} = 3.$$

Thus by assuming the presence of only $GeF_3(OH)_j$ species in addition to GeO_2 and a small free ligand concentration, it is possible to account for the experimental relation [7]. However, approximate solutions can also be found for equation [8]: a nearly linear relation with $\mathbf{a} = 3.3$ is obtained by choosing two arbitrary constants β_3' and β_4' such that the ratio $\beta_3'/\beta_4' = 50$ and varying (HF) but little around 10^{-2} molal. Therefore in order to obtain less ambiguous information on the nature of the fluorogermanium (IV) species in these solutions, some measurements of (HF) were made by the "ferri" method, allowing the direct calculation of $\bar{\imath}$. These data are given in Table II.

The interpretation given by Kleiner for the rise of solubilities of stannic (17) and antimonous (18) oxides in fluoride solutions involved an expression of the type log $(M(OH)_{N-i}F_i) = i$ log (HF) + constant, neglecting or correcting for S_0. On this basis the data of Table II would have been interpreted in terms of the formation of species where $i = 1$. Consequently this simplified treatment of such solubility data would seem to be misleading.

Solubility of GeO_2 in HF (0–1 M)

The measurements of the solubility of GeO_2 in HF up to 1 M are listed in Table III, expressed in molarities. C_{Ge} as a function of C_F is plotted in Fig. 4. Near 1 M HF the solubility values agree with the results of Tananaev and Avduevskaya (3), which start at $C_F = 1$ M. The solubility is represented up to $C_F = 1$ M by the relation [7], $(C_{Ge} - S_0)\mathbf{a} = C_F$, with $\mathbf{a} = 5.0$.

Some supporting measurements of (H^+) were made by comparing the quinhydrone electrode potentials given by the germanium (IV) – HF solutions and a series of standard hydrochloric acid solutions. This implied that equimolar germanium and HCl solutions would be of comparable ionic strength. The results are given in Table III. (H^+) can be related to the solubility increase $C_{Ge}-S_0$ as

$$(H^+) = (F^-)+(HF_2^-)+\bar{n}(C_{Ge}-S_0),$$

where $\bar{n}$ is the average negative charge of the $GeF_i(OH)_j$ species other than GeO_2. As (F^-) and (HF_2^-) are low, $\bar{n} \simeq (H^+)/[C_{Ge}-S_0]$, and this ratio is seen to be near 1.

DISCUSSION

In the solvent extraction experiments the concentration of Ge was varied by factors of 10 and 100 without significant deviation from the distribution ratio (Fig. 1), and in the potentiometric investigations a fivefold variation in Ge concentration had no effect on the formation curve (Fig. 3), so polynuclear germanium species are unimportant in the range of variables studied, as implicitly assumed above.

The formation curve in 0.50 M perchloric acid was satisfactorily interpreted by using only the overall stability constants β_4' and β_5', corresponding to species $GeF_4(OH)_j^{j-}$ and $GeF_5(OH)_j^{(j+1)-}$. The relative abundances of the fluorogermanium (IV) species over the range of (HF) studied are illustrated in Fig. 5. This formation curve was the only one to cover a satisfactory range of $\bar{\imath}$ and (HF) values with sufficient accuracy to warrant the determination of stability constants.

In the experiments concerning the solubility of GeO_2 in HF at constant acidity, the (HF) values as measured by the "ferri" method varied over only a small range, as did the values of $\bar{\imath}$. As indicated in Table II the average number of F bound per Ge for species other than GeO_2, $\bar{\imath}' = [C_F-(HF)]/[C_{Ge}-S_0]$, is in the region 2.5–3.3. It is also apparent that the range of C_F studied corresponds to a limited range of (HF). Under these circumstances the value of **a** obtained from the linear variation of the solubility with added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

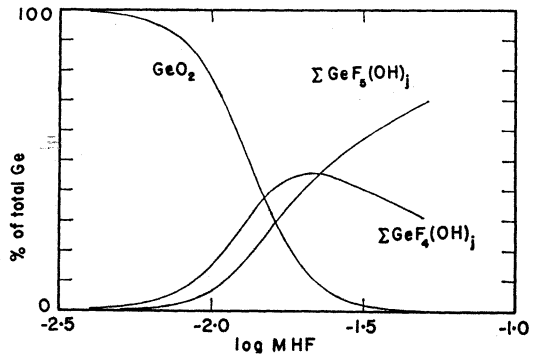

FIG. 5. The percentages of species in the germanium (IV) – fluoride system at $(H^+) = 0.50\ M$.

HF can give no more than a maximum value for $\bar{\imath}'$. The solubility method as used here was of little value as such since the free ligand concentration had to be measured to resolve ambiguity in the interpretation.

Considering the solubility of GeO_2 in HF alone, it is interesting that the solubility still varies linearly with added HF even though (H^+) and the ionic strength vary. The value of **a** again gives a maximum for $\bar{\imath}'$, since some free HF is present and "S_0" may decrease somewhat with increasing ionic strength. This ratio remains close to 5, not only in the range studied here but up to 3 molal added HF (3), subsequently decreasing to 4.2 when the added HF is about 30 molal with respect to the added H_2O and when the solid phase is still GeO_2. The value of **a** suggests that $GeF_4(OH)_j$ and $GeF_5(OH)_j$ species play a prominent part at these low acid levels, as they do when $(H^+) = 0.5\ M$. In this connection it was calculated that, using the values of β_4' and β_5' obtained for the medium 0.50 M $HClO_4$, the solubility of GeO_2 would also vary nearly linearly with added HF according to relation [7] with **a** = 4.6 up to at least 0.3 M added HF, provided that the very considerable effect of the germanium (IV) – fluoride species on the ionic strength was ignored. The average charge $(\bar{\imath}+\bar{\jmath}-4)$ of the $GeF_i(OH)_j$ species other than GeO_2, deduced from a comparison of the solubility increase and (H^+), is approximately -1; this would lead to species of the nature $GeF_4(OH)^-$ and GeF_5^-.

The formation curves obtained at the highest levels of molality and acidity by the distribution method (Fig. 2) show qualitatively that $\bar{\imath}$ again tends towards a maximum value of 5. The more flattened nature of these curves compared with the curve obtained in 0.5 M perchloric acid suggests greater participiation of complexes with $i < 4$ at higher levels of acidity, and a similar effect was observed in the solubility experiments. The replacement of about 18% of the H^+ of the medium by Li^+ at the highest level of molality (11.12 molal) had little effect on either the measured distribution (Fig. 1) or formation (Fig. 2) curves. Investigation of the number of bound hydroxy groups would have required a much wider variation in (H^+), to which the methods used did not lend themselves.

Equilibrium in the system at 8.12 molal HCl was achieved rapidly whether the germanium was added as GeO_2 or as K_2GeF_6; in other words there is no very slow step in the equilibria and GeF_6^{2-} is much more labile than, for example, AsF_6^- (20) or BF_4^- (21). This is confirmed by the fact that K_2GeF_6 and similar salts of GeF_6^{2-} are readily recrystallized from their aqueous solutions whose acidity (pH $\simeq$ 3) indicates hydrolysis. Thus the trend to decreasing lability in the isoelectronic series $AlF_6^{3-} > SiF_6^{2-} > PF_6^- > SF_6$ (22) is followed to the extent that $GeF_6^{2-} \gg AsF_6^-$.

For personal use only.

In conclusion, the fluorogermanium (IV) species in acid media are much more stable than the chlorogermanium (IV) species, which are only formed at high HCl concentrations (1), although quantitative comparisons cannot be made. It has not been possible to demonstrate conclusively the presence of fluorogermanium (IV) species with $i > 5$ in aqueous solution, just as complete formation of $GeCl_6^{2-}$ in acid media was not obtained (1). Comparisons with other metal–fluoride systems (23) are difficult owing to the hydrolyzed nature of the complexed and uncomplexed metal species and to the unknown stability of the first Ge–F complex.

THE INFRARED ABSORPTION OF SOME CRYSTALLINE INORGANIC FORMATES

K. B. HARVEY, B. A. MORROW,[1] AND H. F. SHURVELL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received January 2, 1963

ABSTRACT

The infrared absorption of some polycrystalline alkali metal and alkaline earth formates has been measured in the region of 500 cm^{-1} to 3000 cm^{-1}. The observed crystal splitting of the formate fundamentals is discussed in terms of a vibrational analysis under the factor group.

INTRODUCTION

Apart from some Raman studies of aqueous solutions (1, 2, 3) little has been reported concerning the vibrational spectrum of the formate ion. We have therefore undertaken the investigation of the infrared absorption spectra of a number of crystalline inorganic formates. The present report concerns a preliminary survey of the infrared absorption of polycrystalline samples.

EXPERIMENTAL

Those formates not directly obtainable were prepared from formic acid and the corresponding carbonate. All materials used were reagent grade and the salts were further purified by recrystallization from aqueous solution. The lithium and potassium salts are quite hygroscopic and a certain amount of care was necessary in their manipulation.

The spectra were obtained on a Perkin–Elmer, Model 421, double-beam grating spectrometer. All of the samples were polycrystalline and were suspended, in the usual manner, in KBr pellets. Under the scanning conditions employed the accuracy would be of the order of ± 2 cm^{-1} and the resolution 2 cm^{-1} or better.

RESULTS AND DISCUSSION

Assignments

The frequencies of the observed absorption peaks are summarized completely in Tables I and II and representative spectra are shown in Figs. 1 and 2. The vibrational

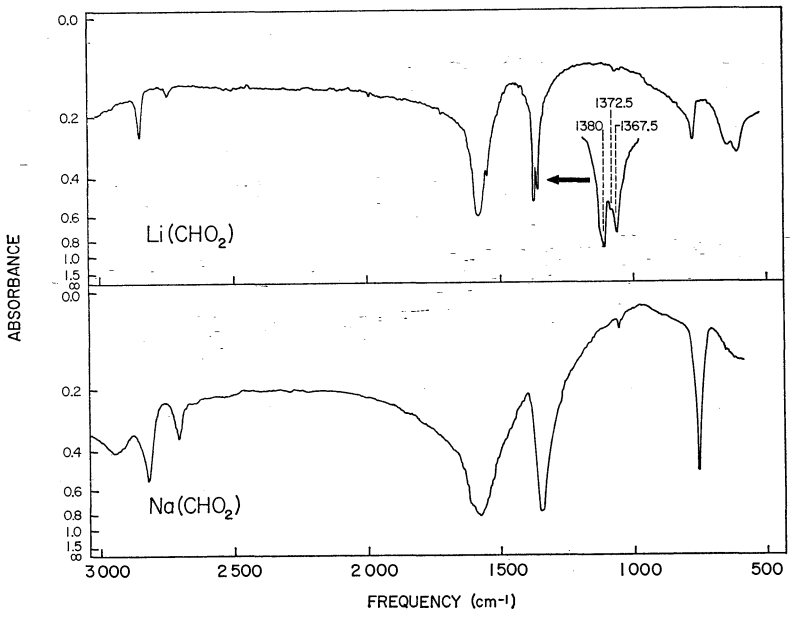

FIG. 1. Infrared absorption spectra of lithium and sodium formates.

analysis of Fonteyne (3), employing a Urey–Bradley potential function, was used as a basis for the assignments. For the most part, the assignments are straightforward but some ambiguities exist, especially in the assignment of the overtones and combinations. Thus, two fundamentals, ν_1 and ν_5, fall in the region 1340 cm^{-1} to 1400 cm^{-1}. In the spectra of the formates of divalent cations, the assignment of these two fundamentals would appear to be straightforward, with two strong, easily resolved absorption bands

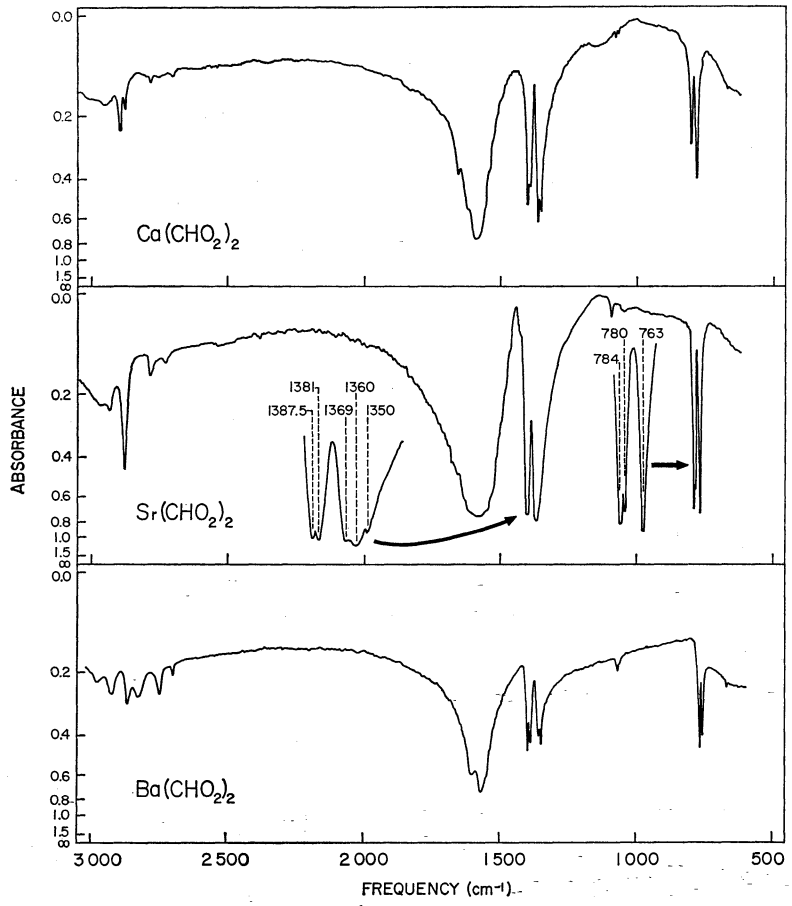

FIG. 2. Infrared absorption spectra of some alkaline earth formates.

being observed in each case. The spectrum of lithium formate also exhibits this feature but those of the sodium and potassium salts differ rather markedly in this region. Presumably this results from the different crystal structure of the formates of potassium and sodium (Table III). Similar ambiguities exist in the assignment of $2\nu_5$. On a frequency basis this would appear to be the only plausible assignment, especially for the 2017 cm^{-1} peak of the $Na(DCO_2)$ spectrum, but in view of the weak fundamental it is surprising that the overtone is observed. That it is seen in every case must be the result of Fermi resonance with the fundamental ν_2. Such an explanation also provides a means for rationalizing the variations in the difference between the observed and calculated values for the frequency of $2\nu_5$.

Fine Structure of the Absorption Bands

Since the C_{2v} symmetry of the free formate ion precludes any degeneracy, the fine structure of the absorption due to the formate, internal vibrations may be ascribed to crystal-field splitting. That such fine structure is to be expected can be seen from the factor group analyses summarized in Tables IV, V, and VI. These tables and the correlation table (Table VII) were prepared by the well-known procedure described by

Bhagavantum (4) and Halford (5). In addition to the character table, giving the symmetry of the vibrations, the tables list the following:

n_i, the total number of optically active vibrations of the symmetry species i under the factor group analysis;

n_i (T), the number of purely translational modes of symmetry species i;

n_i (T′), the number of lattice modes of translational origin of symmetry species i;

n_i (R′), the number of lattice modes of rotational origin of symmetry species i;

n_i', the number of internal formate vibrations of symmetry species i.

The crystal structures on which these analyses are based have been summarized in Table III. It should be noted that while the number of molecules (Z) in the conventional unit cell of sodium formate is four, the primitive cell will contain only two molecules.

In the case of the formates of divalent cations the factor group analysis is almost trivial because, in each case, the atoms all lie on general positions. The unit cell of $Ca(HCO_2)_2$, for example, contains 16 formate ions composed of two sets of 8 crystallographically equivalent units. A set of eight formate ions, each member of which is executing the same normal vibration, gives rise to eight different combinations with the ions vibrating in phase or 180° out of phase relative to one of their number arbitrarily chosen; each combination corresponds to one of the irreducible representations. The other set of ions will exhibit eight identical combinations but, since the two sets are not related by symmetry, in-phase or out-of-phase combinations of the two sets are of the same symmetry species. Thus a single internal formate vibration has 16 components in the spectrum of the crystal. Only vibrations of three symmetry species are active, however, so that, if completely resolved, the infrared spectrum should reveal each internal vibration to be

split into six components, two each of species b_{1u}, b_{2u}, and b_{3u}. Examination of Table II shows that in most cases only a doublet is observed, so that one might tentatively assume that each component of the doublet is composed of three unresolved absorption peaks corresponding to vibrations of symmetry b_{1u}, b_{2u}, and b_{3u}.

Similar considerations apply in the case of the formates which have the space group $D_2^4(P2_12_12_1)$. Each formate internal vibration will have eight components in the crystal spectrum but only six of these are infrared active, two each of species b_1, b_2, and b_3. Again, most of the internal vibrations are split into doublets, so that one is tempted to propose that each component of the doublet is composed of three unresolved absorption peaks corresponding to vibrations of symmetry b_1, b_2 and b_3.

In the case of sodium formate each internal formate vibration should give rise to two components, one of which is infrared active. In addition, because the twofold axes of the ions are coincident with those of the crystal, there is a correspondence between the a_1 modes of the free ion and the a_u modes of the crystal, and the b_1 and b_2 modes of the free ion and the b_u modes of the crystal (Table VII). These conclusions would appear to be in agreement with the observed spectrum.

It will be apparent from the above discussion that a study of single crystals of these materials using polarized radiation would be of considerable assistance in deciding the origin of the observed fine structure. Such an investigation of barium formate is nearly completed and will be reported upon shortly. In the case of lithium formate, a single crystal study would likely permit specific characterization of the space group and reveal whether or not the formate ions lie on special positions. In addition, because of the light cation, it is probable that many of the lattice modes will be in regions which are experimentally accessible.

PREMELTING PHENOMENA IN LONG-CHAIN FATTY ACIDS

M. R. BARR, B. A. DUNELL, AND R. F. GRANT[1]
Chemistry Department, University of British Columbia, Vancouver, British Columbia
Received October 25, 1962

ABSTRACT

Nuclear magnetic resonance spectra and the infrared absorption between 700 and 750 cm^{-1} have been observed at temperatures near the melting points of the even-numbered fatty acids from C_{18} to C_{10}. The results are interpreted as indicating breakdown of crystalline character and onset of liquid-like motion at scattered points in the solid structure several degrees below the melting point, and increasing in extent as the melting point is approached.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

A proton magnetic resonance study of anhydrous stearic acid (1) gave some quantitative indication of liquid-like molecular motion occurring in part of an otherwise rigid lattice at temperatures several degrees below the melting point. It seemed appropriate to look for this behavior, which was considered to be a premelting phenomenon (2), in other fatty acids and by other methods. Acids with an even number of carbon atoms from palmitic (C_{16}) to capric (C_{10}) have been examined by nuclear magnetic resonance, and the change with temperature of the shape of the infrared absorption band at about 720 cm^{-1} has been studied for the even-numbered acids from stearic (C_{18}) to lauric (C_{12}). This infrared band, which is characteristic of hydrocarbon chains $(CH_2)_n$ with $n \geqslant 4$, is frequently a doublet below the melting points of the compounds showing it, and a singlet above the melting point or for the compound in solution. It has been assigned to the CH_2 rocking mode (3, 4). A series of higher normal modes of CH_2 rocking has been identified in the spectra of *n*-paraffins in the range 720–1050 cm^{-1} (4). These bands are of much lower intensity than the first mode at 720 cm^{-1}, and their number depends on the length of the methylene chain. Stein has used the strong absorption of the first mode in an investigation of the crystallinity of polyethylene (5), attributing the component of the doublet at 720 cm^{-1} equally to crystalline and amorphous parts of the polymer and the component at 730 cm^{-1} exclusively to crystalline parts. The splitting of the band was explained by the perturbation of the CH_2 rocking vibration by the interaction of nearest-neighbor methylene chains in the crystalline array. It was shown (6) that the crystal field shifted the frequency of the out-of-phase rocking mode only slightly to higher energy and that the frequency of the in-phase mode was moved much further to higher energy. In an amorphous substance (solid, liquid, or solution) the unperturbed band occurs at essentially the same frequency as the out-of-phase mode in the crystalline substance. Changes with temperature in the intensity of this band have also been used to study phase transitions in waxes (7). In the work reported here, the variation with temperature of the integrated intensity of the components of the doublet has been examined as a possible indication of loss of crystalline character in fatty acids below the melting point.

EXPERIMENTAL

The acids used in this investigation were all Eastman Kodak white label grade that were further purified by repeated recrystallizations from acetone following the method of Brown and Kolb (8). Melting points were run on a hot stage microscope using a heating rate of about 0.2° C/min, and freezing points were obtained from the plateau of a time–temperature cooling curve. Values obtained are compared in Table I with those quoted by Markley (9).

*54.4 quoted by Francis and Piper, J. Am. Chem. Soc., **61**, 577 (1939).

Broad line n.m.r. spectra were obtained with a marginal oscillator spectrometer operating at 28 Mc/sec and a 6-in. Varian electromagnet. This spectrometer and the arrangements for temperature control have been described previously (1).

Infrared spectra were run on a Perkin–Elmer 21B double-beam spectrometer. Samples were prepared as solid films from a melt between sodium chloride plates and as pellets pressed with potassium bromide. Compensation was provided in the reference beam with a double-thickness sodium chloride plate or a pure potassium bromide pellet. The sample was heated with a standard Perkin–Elmer heating unit or cooled with vapor from liquid nitrogen flowing over the face of the NaCl plates, the sample and beam path being enclosed in a box. Temperature was measured with a copper–constantan thermocouple mounted in a small notch between the NaCl plates, and extending into the beam, or soldered into a well set into the KBr pellet holder. Temperature gradients around the KBr pellet were such that the thermocouple temperature in that case was probably good only to within 3°. For the samples between NaCl plates, temperatures are probably reliable to within 0.5°. Preliminary studies of the full spectrum of stearic acid from 4000 to 600 cm^{-1} were made at several temperatures from 30° C to 20° above the melting point. Expanded spectra (50 cm per 100 cm^{-1}) were then run in the range 750 to 700 cm^{-1}. Expanded runs for each acid were commenced at about 30°, made at successive temperatures down to about 60° below the melting point, then at increasing temperatures to some 20° above melting and back to 30° C.

RESULTS

The n.m.r. spectra of these acids are all comparable to those of stearic acid as their melting points are approached. A narrow line, whose width is determined on the broad line spectrometer by the depth of modulation at any temperature, can be resolved from the broad line. As the melting point of an acid is approached the intensity of the narrow component increases relative to the intensity of the rest of the line. The qualitative nature of this behavior has been shown in Fig. 1 of reference 1 for stearic acid. The derivative curves for n.m.r. absorption can be resolved very readily, and the relative integrated areas under the component absorption curves determined. The fraction, area under narrow component/area under both components, equals the fraction of protons involved in very rapid and extensive motion, corresponding to a liquid-like condition. This fraction is plotted in Fig. 1 as a function of $T_M - T$ for the acids studied, where T_M is the melting point of the acid, and T the temperature at which the spectrum was taken.

The infrared spectra of the acids all showed two peaks of the CH_2 rocking mode very clearly resolved at temperatures sufficiently below the melting points. This is illustrated by the four spectra of Fig. 2, all taken near 0° C and between 750 and 700 cm^{-1}. In addition, a third peak at frequency higher than the other two is very distinctly resolved in palmitic acid; it sometimes appears as a resolved peak and sometimes as a shoulder in lauric acid, and is seen as a shoulder in stearic acid, the more clearly the higher the temperature to within a couple of degrees of the melting point. There is some indication that myristic acid behaves like stearic but its shoulder at higher frequency is not as distinct, and no attempt was made to resolve it. These low- to medium-intensity

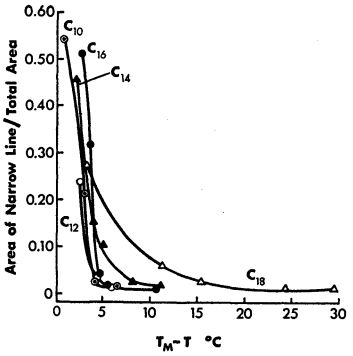

FIG. 1. Fraction of protons in rapid motion as obtained from n.m.r. study.

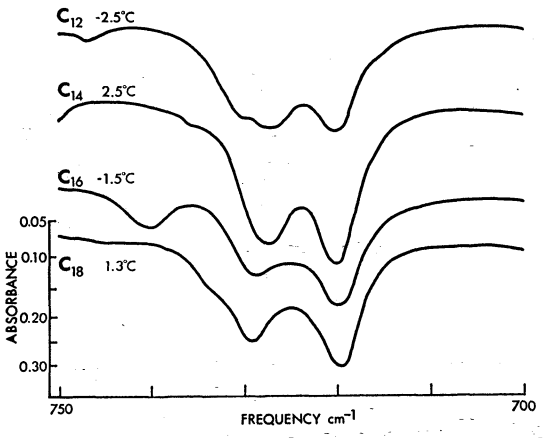

FIG. 2. Spectra of lauric, myristic, palmitic, and stearic acids near 0° C in the range 700–750 cm^{-1}. For each spectrum the absorbance at 750 cm^{-1} is 0.07. For convenience the ordinate has been displaced for each spectrum.

absorptions at about 735 cm^{-1} must arise from higher normal modes of the CH_2 rocking motion (4).

Graphical resolution of the whole band from 745 to 700 cm^{-1} was attempted in order to obtain the integrated intensity for each of the two principal peaks. Maximum transmission for the whole of the range 4000 to 600 cm^{-1} occurs near 750 cm^{-1} for these acids, and it was assumed that absorbance was zero at 750 cm^{-1} or at the point of maximum transmission close to 750 cm^{-1} for myristic and lauric acids. Absorbance was plotted on a linear scale against frequency (cm^{-1}) and it was assumed, for the purpose of resolving the bands, that absorbances were additive, that each peak was symmetrical about its maximum, and that no appreciable portion of a band was included in a long tail (4). Table II shows the frequencies of the peaks that were thus resolved for the solid acids.

Since the observed absorbances were all less than 0.35 (for 100% transmission at approximately 750 cm^{-1}), the difference between observed and true absorbance attributable to non-uniformity of sample thickness in those samples prepared from a melt cooled between sodium chloride plates was minimal and can probably be ignored without significant error (10).

TABLE II

Frequencies of resolved peaks in the infrared band for the CH_2 rocking mode in solid fatty acids

Acid	Frequencies (cm^{-1})		
Stearic (C_{18})	719.5	726–729*	733.5–736
Palmitic (C_{16})	720	726–728.5*	740.5
Myristic (C_{14})	720	726.5–728*	
Lauric (C_{12})	720	724–727*	731

*The frequency of the middle peak decreased as the melting point was approached.

The change in the appearance of the two lower-frequency peaks of the observed band with change in temperature is similar for all four acids studied, and is shown for stearic acid in Fig. 3. The behavior with changing temperature of the shoulder or peak at about

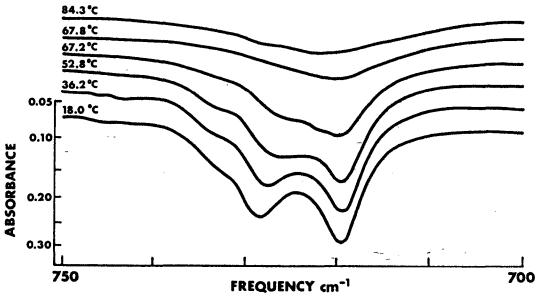

FIG. 3. Spectrum of stearic acid in the range 700–750 cm^{-1} at various temperatures. For each spectrum the absorbance at 750 cm^{-1} is 0.07. For convenience the ordinate has been displaced for each spectrum.

735 cm^{-1} varies considerably from one acid to another. At and above the melting point of each acid, resolution could only be made on the basis of asymmetry of the total band about its maximum, which now appears at approximately 720.5 cm^{-1}. The significance of such resolution as might be made is very questionable. One sample of myristic acid behaved irregularly by showing two just distinguishable peaks even at temperatures above the melting point. Determination of the integrated intensity above the melting point is also of doubtful significance because the peak is broadened to such an extent that it is very difficult to determine the shape of the wings, which apparently extend beyond 700 and 750 cm^{-1}, overlapping with other bands. A general increase in absorbance in the wings of the curve, both with film samples between NaCl plates and with samples pressed in KBr disks, may be in part due to change in scattering by the sample when the melting point is passed.

The spectra obtained from samples pressed in KBr pellets were qualitatively the same as those obtained from films of the acids. Three peaks could be resolved for each of the acids except myristic, which again showed a small, not easily resolvable shoulder near 735 cm^{-1}. The ratio of integrated areas under each peak did not agree with those obtained from film samples, although the progressive decrease in sharpness of resolution of the 727 cm^{-1} peak could be followed clearly as the melting point was approached. Lack of quantitative agreement between the two forms of sample might correspond with the observation of Kirkland that the absorptivity of bands associated with crystalline character is affected by particle size in the KBr pellet technique of sampling (11). probably, however, the effect is the result of preferential orientation in the sample film between the NaCl plates.

The variation in the integrated intensity under each of the 720 and 727 cm^{-1} peaks is shown as a function of temperature for four of the acids in Figs. 4 to 7. The intensities

are in arbitrary units, unrelated from one acid to another, and are taken from spectra obtained from film samples between NaCl plates. A hysteresis loop is found for each acid because of differences in behavior as the temperature is raised twoard the melting point or lowered from it. Using the notation of Stein and Sutherland from their work on the crystallinity of polyethylene (5), one can say that if x is the fraction of the sample which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is crystalline, or well ordered, and I_{720} and I_{727} are the integrated intensities in the 720 and 727 cm^{-1} bands,

$$\frac{I_{727}}{I_{720}} = \frac{xB_c}{xA_c+(1-x)A_a},$$

where A_a is the integrated intensity of the 720 cm^{-1} band for a completely amorphous sample, A_c is the same for a completely crystalline sample, and B_c is the integrated intensity of the 727 cm^{-1} band for a completely crystalline sample. Snyder (4) has indicated that the integrated intensities of the two bands need not be the same in a crystalline substance, and if we assume that the fatty acids are approaching a completely crystalline condition at low temperature, we can consider that B_c/A_c equals the low-temperature limiting value of the ratio of integrated intensities of 727 and 720 cm^{-1} bands, $(I_{727}/I_{720})_0$. If the ratio A_a/A_c is represented by ρ,

$$x = \frac{(I_{727}/I_{720})\rho}{(I_{727}/I_{720})_0+(I_{727}/I_{720})(\rho-1)}.$$

It is difficult to arrive at a value for the parameter ρ. Even if A_a is taken as the integrated absorption of the 720 cm^{-1} band above the melting point and A_c the corresponding quantity at lowest temperature, there is still difficulty in determining A_a. Resolution of the absorption curve above and just below the melting point is difficult, but one can construct a symmetrical band about 720 cm^{-1}. The remainder of the liquid phase absorption is a fairly symmetrical peak centered at about 735 cm^{-1}, corresponding, presumably, to a higher normal mode of the CH_2 rocking motion (4). Small variation in the optical density at the edges of the CH_2 rocking absorption (at 750 cm^{-1} and 700 cm^{-1}) as one passes through the melting point may be due to changes in scattering of radiation with the change of phase. Such changes in optical density which move the whole band make a significant increment in the integrated intensity. In spite of these uncertainties, and failing a better method of determining ρ, we have estimated ρ by taking the ratio of the integrated intensity of a resolved 720 cm^{-1} peak above the melting point to that of the 720 cm^{-1} peak at the lowest temperatures. Values of ρ of 0.57, 0.60, 0.42, and 0.46 have been obtained from the curves of Figs. 4 to 7 for stearic, palmitic, myristic, and lauric acids, respectively. Stein and Sutherland (5) estimate ρ to be in the range 1.4 to 2 for long-chain hydrocarbons. Such a large value of ρ appears, however, to be inconsistent with the observed decrease of the integrated intensity of the 720 cm^{-1} band with increasing temperature in fatty acids. From the relation

$$I_{720} = A_a+x(A_c-A_a)$$

it is seen that if x decreases with increasing temperature and I_{720} is to decrease with increasing temperature, $A_c > A_a$, which requires that $\rho < 1$. The quantity $1-x$, measuring the extent of disorder in the alignment of the CH_2 chains, is plotted using the appropriate value of ρ for each of the acids as a function of temperature difference from the melting point, T_M-T, in Fig. 8.

DISCUSSION

It is not considered that the fraction, $1-x$, of disordered material as obtained from the infrared study should be directly comparable to the fraction of protons in rapid, liquid-like motion as measured by the area of the narrow n.m.r. absorption peak divided

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

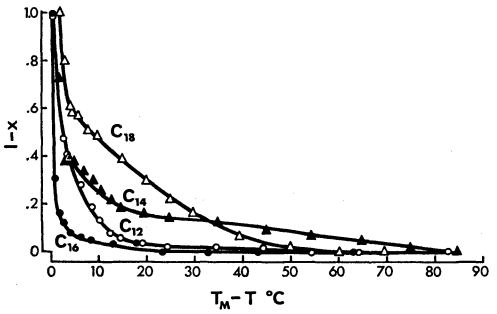

FIG. 8. Fraction of the lattice which is disordered, $1-x$, as a function of the temperature interval from the melting point, $T_M - T$, for stearic, palmitic, myristic, and lauric acids.

by the total area under the n.m.r. absorption curve. Apart from the uncertainties inherent in the calculation of x, the two quantities may not agree because it is quite possible that disordered chains may be rigid as far as n.m.r. observations are concerned (reorientations less frequent than approx. $\gamma\Delta H = 4(10^5)$ cycles/sec), and consequently contribute to decreasing x, but not to the area of the narrow n.m.r. signal. The n.m.r. results show that in all the fatty acids studied a significant fraction of the protons are in liquid-like motion at least 4° C below the melting point of the acid, and the fraction increases as the melting point is approached. Since 1% of palmitic acid impurity in stearic acid has been found to lower the freezing point of stearic acid by 0.24° C (12), it is probable that none of the acids contains more than 1% impurity, and most samples much less. Thus one can in no case attribute the narrow line of the n.m.r. spectrum solely to motion of impurities, although the impurities may serve as centers at which disordering of the main lattice may occur below its melting point. It is presumed (1) that liquid-like regions appear at defect or impurity centers in the crystal and spread from there as the melting point is closely approached. A study of the effect on this phenomenon of introducing known amounts of impurity is indicated, and preliminary results point to the existence of a larger amount of liquid-like motion at lower temperatures when the sample is more impure. Variation from acid to acid of the percentage of protons in liquid-like motion as a function of temperature interval to the melting point may be dependent only on the purity of the samples, except in the case of stearic acid, for which the purity is considered to be very high. If this is correct, the unusually large amounts of liquid-like motion in stearic acid must be dependent on the crystal structure of stearic acid rather than on a high impurity content.

The infrared results suggest that lack of crystalline order appears well below the melting points of the fatty acids and as the melting point is approached increases rather more rapidly in extent than does the liquid-like motion evidenced by the n.m.r. behavior. It is possible that disordering of the crystal lattice around imperfection sites, without significantly rapid chain motion accompanying the disorder, precedes the appearance of the liquid-like regions. The infrared studies of Davison and Corish on polyesters (13) and dicarboxylic acids (14) indicate, contrary to the review by Bellamy (3), that the 720 cm^{-1} peak in the compounds they studied is virtually eliminated upon melting and they conclude that the extended trans configuration of the methylene chain is virtually absent from the molten state of these substances. Bradbury, Elliott, and Fraser (15) find that the 720 cm^{-1} band is greatly reduced in intensity with increasing temperature in polyethylene and polyethylene suberate, but that it does not disappear. From this and other

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

evidence they conclude that there are many configurations of the hydrocarbon chain which, in amorphous material, do not contribute to the 720 cm^{-1} CH_2 rocking band. If it is supposed that the fraction of the CH_2 groups which is in disordered configurations which do not contribute to the 720 cm^{-1} peak remains effectively constant within the temperature range involved in this study, then the factor ρ includes the necessary compensation for the failure of certain conformations to contribute to the observed band. The measure $1-x$ of the extent of disordering of hydrocarbon chains should be, then, reliable to within the extent to which ρ is correctly evaluated, and to which the fraction of non-contributing disordered conformations is independent of temperature.

An alternative approach (16) also assumes that the sample is 100% crystalline (or of ordered configuration) at low temperature and that the distribution of chain conformations in the liquid just above the melting point is the same as the distribution in the regions of disorder below the melting point. Then if C is integrated intensity of the whole doublet at low temperature ($C = A_c+B_c$), and A is the integrated intensity of the 720 cm^{-1} band just above the melting point (where the 727 cm^{-1} band has disappeared; $A = A_a$), and I_T is the integrated intensity of the doublet at intermediate temperature T ($I_T = I_{720}+I_{727}$), the fraction of chains undergoing melting is

$$f = \frac{C-I_T}{C-A}.$$

The fraction f is plotted in Fig. 9 as a function of T_M-T, having been calculated from the results shown in Figs. 4–7 as

$$f = \frac{(I_{720}+I_{727})_0-(I_{720}+I_{727})_T}{(I_{720}+I_{727})_0-A_a}.$$

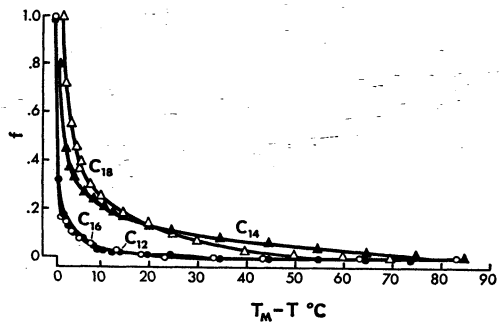

FIG. 9. The fraction f of chains which are disordered as calculated from total integrated intensity of both components of the doublet is plotted as a function of temperature interval from the melting point for stearic, palmitic, myristic, and lauric acids.

In terms of the previous assumptions, namely, $I_{720} = xA_c+(1-x)A_a$, and $I_{727} = xB_c$, the right-hand side of this expression reduces to $1-x$. The curves of Figs. 8 and 9 for $1-x$ and f, respectively, as functions of T_M-T are not identical, but are very close to one another for palmitic and myristic acids and are sufficiently alike for stearic and lauric acids that they lead to the same qualitative picture of the premelting behavior in these acids. Such discrepancy as exists may be due to failure of the assumption that the distribution of conformations in the disordered portions is independent of temperature or to difficulties associated with preferential orientation in the film samples between NaCl

plates. The infrared results do, however, support the n.m.r. evidence for the existence of premelting behavior well below the accepted melting points of these fatty acids.

THE PHOTOLYSIS OF TRIFLUOROACETIC ACID VAPOR[1]

A. M. MEARNS[2] AND R. A. BACK
Division of Pure Chemistry, National Research Council of Canada, Ottawa, Canada

Received December 22, 1962

ABSTRACT

The photolysis of CF_3COOH vapor has been studied at temperatures between about 90 and 190° C, using light of wavelengths between 2000 and 2200 Å. The major products were CO_2 and C_2F_6, with smaller amounts of CO, H_2, and CF_3H. A marked reduction in the yields of CO_2, CO, and H_2 with increasing pressure of added isobutane or 1-butene has been interpreted to imply the presence of free COOH radicals in the system, which is supported by the tentative identification of formic and oxalic acids as products of the photolysis. It is thought that the reaction

$$CF_3COOH + h\nu \rightarrow CF_3 + COOH$$

represents the main primary photolytic process, with the minor processes

$$CF_3COOH + h\nu \rightarrow CF_3 + CO_2 + H$$

and

$$CF_3COOH + h\nu \rightarrow CF_3 + CO + OH$$

accounting for no more than 27 and 7% respectively of the total at 165° C.

Some tentative conclusions have been drawn about the reactions of COOH radicals. In the present system, the disproportionation reaction,

$$2COOH \rightarrow CO_2 + HCOOH,$$

appears to predominate, with the decomposition reaction,

$$COOH \rightarrow CO_2 + H,$$

apparently of minor importance at 165° C.

INTRODUCTION

Previous studies of the vapor-phase photolysis of acetic acid have indicated a mechanism, partly intramolecular and partly free radical, which was complicated by secondary reactions of radicals with the parent compound (1, 2, 3). It was thought that the photolysis of trifluoroacetic acid should be very much simpler, by analogy with the perfluoroketones, and might yield some useful information about the primary photolysis process in carboxylic acids, and about the stability and reactions of the COOH radical.

EXPERIMENTAL

The photolysis vessel was a quartz cylinder, 10 cm long and 5 cm in diameter, with plane windows at both ends, whose temperature was controlled to ±0.5° C with an air thermostat. The light source was a medium-pressure Hanovia S-500 mercury arc, used without a filter, and collimated to give approximately uniform illumination throughout the vessel. The absorption spectrum of the acid vapor showed a strong, apparently continuous absorption beginning at about 2200 Å, so that the light effective in the photolysis was of wavelength between 2200 and 2000 Å. In a few experiments in which it was desired to selectively photolyze perfluoroacetone in mixtures with CF_3COOH, Corning filter 9700 was used to eliminate light with wavelengths below 2600 Å. In almost all the experiments, the time of irradiation was about 200 minutes.

In the first series of experiments, the reaction vessel was attached through a metal diaphragm valve (Hoke 413) to conventional high-vacuum preparation and analytical lines. When it became evident that non-volatile products were accumulating in the reaction vessel, and were decomposing to yield CO and CO_2, a different technique was adopted. Before each experiment, the photolysis vessel was fitted with a break-seal and attached to the preparation line through a constricted Pyrex lead, and was baked overnight at 350° C under vacuum. The reagent vapors were then metered out and condensed in the vessel at −196° C, and after evacuation to a pressure of 10^{-5} mm, the vessel was sealed at the constriction, removed from the preparation

For personal use only.

line, and mounted in a reproducible position in the air thermostat. After irradiation, the vessel was removed again, and attached through the break-seal to the analytical line. This technique was found to give consistent and reproducible results, and was used in all but the first few preliminary experiments.

The products of the reaction were condensed at −196° C, and CO and H_2 were removed through a trap at −210° C, measured in a gas burette, and analyzed by combustion on copper oxide. Mass-spectrometric analysis showed that H_2 and CO were the only gases non-condensable at −210° C. The remaining products were transferred to two low-temperature stills in series, and C_2F_6, CF_3H, and CO_2 were removed at −145° C and measured in a gas burette. This fraction was then analyzed by gas chromatography, using a 2-m column of silica gel at 76° C. In some experiments, an analysis was made for higher-boiling products. Isobutane, when present, was removed at −125° C, and the remaining material analyzed by gas chromatography, using a column with 20% glyceryl monooleate on firebrick.

Trifluoroacetic acid was obtained from three different sources. The acid itself was purchased from both the Minnesota Mining and Manufacturing Co., and the Columbia Chemical Co. The acid was then distilled at atmospheric pressure, a middle fraction being collected, which was treated with anhydrous sodium sulphate, and distilled again on a Vigreaux-type column. The vapor was dried again over sodium sulphate in the vacuum line, was degassed thoroughly by the usual methods, and stored at −80° C. The third source of acid was its preparation by the addition of water to an excess of the acid anhydride, which was obtained from Matheson, Coleman and Bell, the excess anhydride being distilled off. Acid from all three sources gave identical results, and no impurities were detectable by gas chromatography.

Hexafluoroacetone was obtained from Merck and purified by methods described elsewhere (4). Perfluorobutane was obtained from Minnesota Mining and Manufacturing Company, while isobutane and 1-butene were Phillips' research-grade, all used without further purification.

RESULTS

Preliminary experiments in the fixed reaction vessel at 150° C showed that CO_2, C_2F_6, and CO were the main products of the photolysis, with much smaller amounts of CF_3H and H_2. In a series of experiments, a single sample of acid was irradiated three times, volatile products being removed after each irradiation, and it was observed that the yields of CO_2 and CO increased progressively by about 30% between the first and the third experiments, while the C_2F_6 yield remained almost constant. Subsequently it was found that irradiating the "empty" reaction vessel, or heating it to 200° C, caused the evolution of appreciable quantities of CO and CO_2, and it was concluded that a very slightly volatile material, possibly oxalic acid, or perhaps some higher product of the photolysis, was condensed on the walls of the vessel, and decomposed either thermally or by photolysis to give CO and CO_2 in approximately equal quantities. It proved very difficult to eliminate these effects in the fixed reaction vessel, so that finally a detachable vessel, which could be thoroughly baked out between experiments, as previously described, was adopted, and used in all subsequent experiments.

In Table I are shown the gaseous products of the photolysis at 165° C, at several pressures of CF_3COOH, and in Fig. 1, values of $CO + CO_2$ and of $CF_3H + 2C_2F_6$ are

TABLE I

Products of the photolysis of CF_3COOH at 165° C

CF_3COOH pressure (mm)	Rates of product formation (μmoles/min×100)				
	C_2F_6	CF_3H	CO_2	CO	H_2
10.5	0.219	0.047	0.666	0.133	0.021
28.0	0.610	0.071	1.645	0.252	0.044

98.0	1.520	0.150	3.500	0.463	0.162

plotted against the pressure of acid. Several features are evident from these data. The yield of C_2F_6 was much greater than that of CF_3H, indicating that abstraction of hydrogen from the acid by CF_3 radicals was very inefficient, and also that the intramolecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

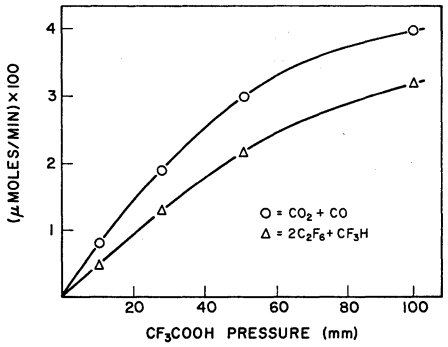

FIG. 1. Products of the photolysis vs. pressure of CF_3COOH vapor, showing the deficit of CF_3-containing products.

formation of CF_3H and CO_2 was not an important primary process. The yield of CO_2 was much greater than that of CO, and the ratio CO_2/CO increased from 5.0 to 7.6 with increasing pressure of acid. The material balance evident in Fig. 1 indicates an apparent loss of CF_3 radicals which varied from about 40% to 20% with increasing pressure of acid. There was also a marked shortage of hydrogen in the gaseous products, with the H_2 and CF_3H accounting for only about 9 to 13% of the yield of CO_2. The general pressure dependence of the yields of gaseous products (Fig. 1) appears to parallel approximately the absorption of light in the system, although because the light was not monochromatic, no precise measurement of the absorption was possible.

A series of experiments was made at 165° C with a constant pressure of CF_3COOH and varying amounts of isobutane added to see whether the yield of CF_3-containing products might be improved by providing a substrate for the abstraction of hydrogen. The results are shown in Figs. 2 and 3. As expected, the yield of C_2F_6 fell rapidly to zero

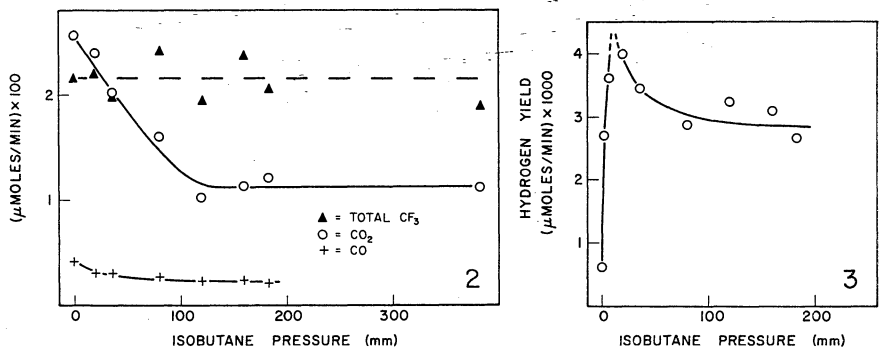

FIG. 2. The effect of added isobutane on the products of the photolysis at 165° C, with an acid pressure of 50.7 mm.

Fig. 3. The effect of added isobutane on the hydrogen yield from the photolysis at 165° C, with an acid pressure of 50.7 mm.

with increasing isobutane pressure, while the yield of CF_3H rose accordingly. However, the final rate of production of CF_3H at high isobutane pressure was, within a rather large experimental scatter, just equal to twice that of C_2F_6 in the pure acid, so that the total yield of CF_3-containing products was unchanged. The isobutane, however, had a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

marked effect on all the other products. The yield of H_2 rose sharply, passed through a maximum of about 20 mm pressure of isobutane, and decreased again at higher pressures of isobutane. The yields of CO_2 and CO were both reduced to about one-half their original values by the addition of isobutane.

In order to determine whether the effect of isobutane might be due simply to collisional deactivation, some experiments were made with added C_4F_{10}, both with and without isobutane present (Table II). Like isobutane, the C_4F_{10} appeared to have little effect on

the yield of CF_3-containing products. There was a slight decrease in the yield of CO_2, both with and without isobutane also present, but C_4F_{10} was about 10 times less effective than isobutane in reducing the yield.

In Fig. 4 is shown the effect of temperature on the products of the photolysis, with 50

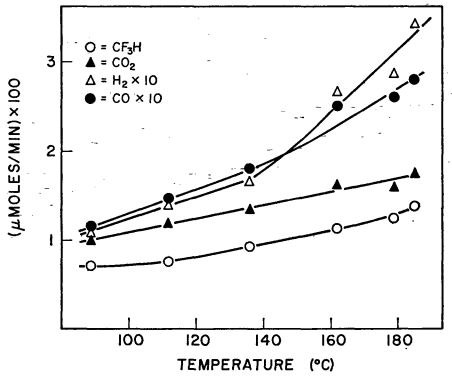

FIG. 4. The effect of temperature on the photolysis of CF_3COOH, at a constant pressure of 50.7 mm of acid and 80 mm of isobutane.

mm pressure of CF_3COOH and 80 mm of isobutane. All the products increased with increasing temperature, H_2 the most markedly and CF_3H the least. The light intensity was somewhat less than for the experiments in Figs. 1 and 2, so that the data are not exactly comparable.

In Table III is shown the effect of 1-butene on the photolysis of CF_3COOH. The only products observed in the presence of the olefin were CO_2 and CO, and these were reduced to about one-third and one-half respectively of their original yields.

DISCUSSION

Molecular Association in CF_3COOH Vapor

Trifluoroacetic acid, like other carboxylic acids, is known to be partially associated into hydrogen-bonded dimer molecules in the vapor phase (5), and the effect of such association on the photolysis must be considered. The degree of association depends upon both temperature and pressure. Most of the present results were obtained at 165° C and a pressure of 50.7 mm, and from the data of Taylor and Templeman (5), one may calculate a monomer/dimer ratio of 144. It seems unlikely that acid dimers present in such low concentration played any important role in the photolysis mechanism. At 90° C, the lowest temperature used, with a pressure of 50.7 mm, the monomer/dimer ratio was about 6. The lack of any profound changes in the products of the photolysis with changing pressure and temperature suggests that the presence of dimer molecules had little effect in the present experiments.

Primary Processes

The experimental evidence suggests that the main primary process in the photolysis was

$$CF_3COOH + h\nu \rightarrow CF_3 + COOH. \qquad [1]$$

While this reaction presumably proceeded through some excited state of CF_3COOH, the almost negligible effect of C_4F_{10}, the relatively small effect of temperature, and the nature of the dependence of the product yields on the pressures of acid, isobutane, and 1-butene all indicate that any such excited intermediate was too short lived under the experimental conditions to suffer appreciable deactivation before decomposing. This is not surprising in view of the energy of 130 to 140 kcal/einstein of the absorbed light.

The formation of free CF_3 radicals in the photolysis seems beyond doubt. The production of C_2F_6 in the pure acid, its replacement by CF_3H in the presence of isobutane, and the complete suppression of both products by 1-butene can only be explained by reactions of free CF_3 radicals, and it appears that the intramolecular production of CF_3-containing products, in particular the formation of CF_3H and CO_2, played no part in the photolysis. This is in contrast to the photolysis of CH_3COOD, in which intramolecular formation of CH_3D and CO_2 was thought to be a minor ($\sim$10%) primary process (1).

The evidence for the presence of free COOH radicals in the system is less certain, but still fairly convincing. The ability of isobutane to reduce by about one-half the yields of CO_2 and CO, without seriously affecting the production of CF_3-containing products, strongly suggests the removal, by reaction, of some precursor of CO_2 and CO. This view is confirmed by the effect of 1-butene on the yields of CO_2 and CO. The effect of isobutane on the yield of H_2 suggests that hydrogen atoms were formed in the photolysis, which,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in the pure acid, disappeared, probably by reaction with the acid, without forming H_2. These hydrogen atoms reacted efficiently with added isobutane, and the H_2 production rose sharply (Fig. 3). The subsequent decrease in hydrogen production as more isobutane was added approximately parallelled the decreases in CO_2 and CO, and suggests that a common precursor of CO_2, CO, and H was being removed by reaction with isobutane. The carboxyl radical is the most probable such precursor. The suppression by 1-butene of the CO_2 and CO yields to approximately the same extent as caused by isobutane indicates that the precursor can also disappear by reaction with 1-butene, while the complete suppression of hydrogen production suggests that all the hydrogen was formed by reactions of hydrogen atoms or carboxyl radicals.

There is some additional supporting evidence for the presence of free carboxyl radicals. In two experiments at 117° C with 50.7 mm of acid and 88 mm of isobutane, appreciable amounts of formic acid were detected in the products by gas chromatography. In three similar experiments at 166° C, and in one other experiment at 117° C, however, formic acid was not found. This rather capricious behavior was probably due to the difficulties in detecting micromolar amounts of formic acid in a large excess of CF_3COOH, which tended to flood the chromatographic column, so that formic acid appeared as a small peak superimposed on a large "tail". In the experiments at 117° C, the reaction vessel was also fitted with a second break-seal, so that after removal of all the volatile products in the usual way, the vessel was sealed again and baked overnight at 300° C. Several micromoles of gas were produced which was found to consist of CO and CO_2 in almost equal amounts, of water vapor, and of traces of H_2 and C_8-hydrocarbon, perhaps a dimer of butyl radicals. The formation of CO, CO_2, and water in the observed proportions suggests that oxalic acid may have been the involatile compound which was deposited on the walls of the vessel, and which decomposed thermally. Similar deposition of a compound which yielded CO and CO_2 on heating or on photolysis had also been observed in the fixed reaction vessel used in preliminary experiments. The formation of formic and oxalic acids in the system is most simply explained as resulting from abstraction and dimerization reactions of free carboxyl radicals.

The continued production of some CO and CO_2 in the presence of 1-butene suggests the occurrence of two other primary processes,

$$CF_3COOH + h\nu \rightarrow CF_3 + CO_2 + H \quad [2]$$

and

$$CF_3COOH + h\nu \rightarrow CF_3 + CO + OH, \quad [3]$$

which from the data in Table III may be estimated to represent 27 and 7% respectively of the primary photolysis process, with reaction [1] accounting for the remainder.

In this estimate, no account was taken of carboxyl radicals which reacted to form products other than CO and CO_2. It is also possible that some of the CO_2, and perhaps the CO, formed in the presence of 1-butene came from disproportionation reactions of COOH with hydrocarbon radicals. For these reasons, the values of 27 and 7% for reactions [2] and [3] should be regarded as upper limits.

Reactions of CF_3 Radicals

In the pure acid, from 90 to 95% of the CF_3 radicals found in the products were accounted for by C_2F_6, which was almost certainly formed by simple dimerization. The remainder was CF_3H, and this apparently did not arise by abstraction of hydrogen from CF_3COOH. This was shown by several experiments in which CF_3 radicals were generated by the selective photolysis of perfluoroacetone in the presence of CF_3COOH, and no CF_3H

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was observed. The most probable source of CF_3H in the photolysis of the acid is the disproportionation reaction

$$CF_3 + COOH \rightarrow CF_3H + CO_2. \quad [4]$$

The material balance of the volatile products, shown in Fig. 1, indicated a considerable loss of CF_3 radicals in the photolysis of the pure acid. This loss was most likely due to an addition reaction,

$$CF_3 + CF_3COOH \rightarrow (CF_3)_2\dot{C}—OH, \quad [5]$$

followed by further reactions of the resulting radical to form higher-weight products. Such addition of perfluoro radicals to carbonyl double bonds has been observed previously (6, 7).

When the experiments with added isobutane were done, it was thought that the reaction

$$CF_3 + C_4H_{10} \rightarrow CF_3H + C_4H_9 \quad [6]$$

would effectively scavenge all the CF_3 radicals, so that the limiting rate of production of CF_3H at high isobutane pressure would be a measure of the CF_3 radicals initially formed. It has since become evident that this simple condition cannot in practice be attained with isobutane (8). At a very early stage in the reaction, isobutene, formed by disproportionation of butyl radicals, begins to compete effectively with isobutane for CF_3 radicals,

$$CF_3 + C_4H_8 \rightarrow CF_3C_4H_8—. \quad [7]$$

Olefin is used up in the process, and rapidly reaches a very low steady-state concentration, which because of the relatively high value of the ratio k_7/k_6 is achieved after less than 0.1% reaction. The $CF_3C_4H_8$ radicals probably undergo further reactions, resulting in CF_3-containing compounds with 5 to 10 carbon atoms. Under certain conditions, reaction of CF_3 radicals with C_4H_9 or other radicals may also compete with reaction [6]. The net result of these complications is that, for example, in the photolysis of hexafluoroacetone in the presence of isobutane at 120° C, a limiting rate of production of CF_3H at high isobutane pressure corresponded to only about 70% of the CF_3 radicals formed (8). It appears almost certain that in the photolysis of CF_3COOH there was a similar loss of CF_3 radicals in the presence of isobutane, the exact extent depending on a number of parameters of the system. Thus in the pure acid, CF_3 radicals were probably lost by addition to the carbonyl double bond, while with isobutane added, they disappeared chiefly by addition to the isobutene which was present in a low steady-state concentration. The loss by these two mechanisms appears to have been fortuitously about the same, within the rather large experimental scatter.

Reactions of COOH Radicals

There is some uncertainty about the thermochemistry of the carboxyl radical. Most previous workers have assumed that the reaction

$$COOH \rightarrow CO_2 + H \quad [8]$$

was endothermic by only a few kilocalories, and that the carboxyl radical decomposed rapidly in this way even at room temperature. However, there are at present two sets of conflicting data. Gorden and Ausloos (9) have estimated reaction [8] to be almost thermoneutral; this estimate was based on Glockler's values for the dissociation energies of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

C—C bond in acetic acid (93 kcal) and the C—H bond in formic acid (99.9 kcal), which were calculated from a correlation of bond length with bond energy (10), and which lead to $\Delta H_f(\text{COOH}) = -43$ kcal. On the other hand, Back and Sehon have estimated, from a toluene-carrier measurement of the bond-dissociation energy of phenylacetic acid (11), that $\Delta H_f(\text{COOH}) = -62$ kcal/mole, which would make reaction [8] about 20 kcal endothermic, and which would lead to dissociation energies of about 85 and 78 kcal for the C—H and C—C bonds in formic acid and acetic acid respectively. These latter bond energies seem slightly low, and those estimated by Glockler rather high, by comparison with similar C—C and C—H bonds, and an intermediate value for $\Delta H_f(\text{COOH})$ is perhaps most probable, as there are considerable uncertainties in both estimates. Thus an endothermicity of 10 ± 10 kcal may be assigned to reaction [8], which, combined with a probable activation energy for the reverse reaction of at least 10 kcal, suggests that carboxyl radicals may well be stable enough to undergo a variety of reactions in the present system. The alternative decomposition,

$$\text{COOH} \rightarrow \text{CO} + \text{OH}, \qquad [9]$$

is well established to be 25 kcal more endothermic than reaction [8], and should certainly be unimportant by comparison at the temperatures of the present study.

In the photolysis of the pure acid, several combination and disproportionation reactions are possible:

$$2\text{COOH} \rightarrow (\text{COOH})_2 \qquad [10]$$
$$\rightarrow \text{CO}_2 + \text{HCOOH} \qquad [11]$$
$$\rightarrow 2\text{CO}_2 + \text{H}_2 \qquad [12]$$
$$\rightarrow \text{CO}_2 + \text{CO} + \text{H}_2\text{O}. \qquad [13]$$

In the presence of isobutane, the situation is somewhat complex. The simplest way to account for the reduced yields of CO_2, CO, and H_2 is by the reaction

$$\text{COOH} + \text{C}_4\text{H}_{10} \rightarrow \text{HCOOH} + \text{C}_4\text{H}_9. \qquad [14]$$

The thermochemistry of this reaction is in some doubt due to the uncertainty in the C—H bond in formic acid, and it may or may not be exothermic. It also seems probable, as discussed earlier, that in the trifluoroacetic acid – isobutane system there was a low steady-state concentration of olefin formed by disproportionation of isobutyl radicals, and reaction with this olefin may account for a considerable part of the loss of COOH radicals. The effect of 1-butene on the photolysis shows that olefins can remove carboxyl radicals very efficiently, probably by an addition reaction followed by further reactions of the resulting radicals, leading eventually to higher carboxylic acids.

From the products of the photolysis, and assuming a mechanism involving reactions [1] to [14], some simple stoichiometric estimates may be made of the relative importance of the several possible reactions of carboxyl radicals. The rates of product formation were all measured at a temperature of 165° C and 50.7 mm pressure of acid, and are expressed in units of μmoles/min$\times$100.

$R_2 = H_2$ production at high isobutane pressure = 0.30

$R_3 =$ CO production at high pressure of isobutane or butene = 0.20

$R_4 = CF_3H$ production in pure acid = 0.11

R_8+R_{12} = reduction in H_2 yield (from a rather arbitrary maximum value of 0.46 estimated from Fig. 3) caused by removal of COOH at high pressures of isobutane = 0.16

$R_{12} = H_2$ production from pure acid = 0.06

R_{13} = reduction in CO production at high pressures of isobutane or butene = 0.22

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rate of reaction [2] estimated above is too low, perhaps by about a factor of 2, because of loss of hydrogen atoms by addition to the olefin generated in the system, as discussed earlier, and 0.60 is probably a better estimate for R_2. This may be compared with the yield of CO_2 of 0.80 in the presence of 1-butene, which should also be a measure of reaction [2]. The excess CO_2, and the much larger excess at high isobutane pressure ($R_{CO_2} = 1.10$) could be due to disproportionation reactions between COOH and hydrocarbon radicals,

$$COOH + R \rightarrow CO_2 + RH, \qquad [15]$$

which may be very favorable because of the relatively weak COO—H bond.

The decrease in CO_2 production on the addition of 1-butene should have equalled the sum $R_4+R_8+2R_{12}+R_{13}+R_{11}$. The first four terms, from the estimates above, can account for a total of 0.55, leaving a yield of 1.25 to be formed by reaction [11] to make up the observed total decrease of 1.80. Thus reaction [11] apparently represented the predominant fate of carboxyl radicals in the photolysis of the pure acid, with the reactions of carboxyl in order of importance being 11 (1.25), 13 (0.22), 4 (0.11), 8 (0.10), and 12 (0.06). The extent of occurrence of reaction [10] is difficult to estimate. The simple decomposition of carboxyl (reaction [4]) appears to be relatively unimportant under the present experimental conditions, which would tend to support the higher value for the COO—H bond strength. This behavior is in contrast to that in the photolysis of formic acid (9), in which the carboxyl radical apparently decomposed rapidly, so that added olefin had almost no effect on the yields of CO and CO_2. Excess energy from the primary photolytic process may account for this difference in behavior, as the carboxyl radical would undoubtedly carry away more of the excess energy from formic acid than from the larger CF_3COOH molecule with its additional degrees of freedom.

The suggested mechanism appears to account fairly well for the observed results, but in the absence of more complete product analysis it must be regarded as tentative. All the calculations above apply to the photolysis of the acid at 165° C and 50.7 mm pressure. The temperature dependence of the products (Fig. 4), from the photolysis in the presence of isobutane, requires some comment. The increasing yields of CO_2, CO, and H_2 suggest that primary processes [2] and [3] are favored by the higher temperatures. The increase in CF_3H, and part of the sharp increase in H_2, may reflect a more efficient scavenging of CF_3 and H by isobutane.

In summary, the photolysis of CF_3COOH appears to proceed by three concurrent primary processes, the most important being the simple decomposition into CF_3 and COOH. The carboxyl radicals so formed were apparently stable enough to undergo a variety of reactions before decomposing, and some tentative conclusions about these reactions have been drawn. The main fate of COOH in the photolysis of the pure acid appears to have been a mutual disproportionation reaction yielding CO_2 and formic acid. A more detailed product analysis, particularly of heavier products, would be required for a full understanding of the photolysis mechanism.

The authors wish to thank Dr. K. O. Kutschke for his interest and useful suggestions throughout the course of this work.

THE REACTIONS OF ELECTRONICALLY EXCITED NITRIC OXIDE MOLECULES WITH HYDROCARBONS[1]

O. P. STRAUSZ AND H. E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received November 9, 1962

ABSTRACT

The reactions of $NO(^4\Pi)$ molecules, generated by Hg $6(^3P_1)$ photosensitization, with methane, ethane, propane, neopentane, and benzene have been studied at room temperature in a circulatory system. In the case of ethane the following reaction products were identified: N_2, N_2O, H_2O, NO_2, CO, CO_2, C_2H_4, acetaldehyde, nitroethane, ethyl nitrite, ethyl nitrate, nitroethylene, nitromethane, methyl nitrite, methyl nitrate, formaldehyde. For hydrocarbon consumption, under comparable conditions, the following quantum yield values were established: $\Phi_{-(C_6H_6)} < 0.04$, $\Phi_{-(CH_4)} > 0.045$, $\Phi_{-(C_2H_6)} > 0.063$, $\Phi_{-(\text{neopentane})} \simeq 0.1$ mole/einstein. The most probable primary process may be represented by the sequence

$$Hg^* + NO \rightarrow Hg + NO(^4\Pi)$$
$$NO(^4\Pi) + RH \rightarrow NO + R + H.$$

Alkyl free radicals catalyze the chain disproportionation of nitric oxide at room temperature according to the stoichiometric equation

$$4NO\ (+ R) \rightarrow N_2 + 2NO_2\ (+ R).$$

A minimal value of 12 was established for the average chain length.

INTRODUCTION

It was shown in a previous paper (1) that the Hg $6(^3P_1)$-photosensitized decomposition of nitric oxide proceeds via the formation of an electronically excited species, very likely in the $(^4\Pi)$ state (2) and its subsequent reactions with ground-state molecules. On this basis it appeared instructive to obtain additional information concerning the reactivity of $NO(^4\Pi)$ molecules with other species, since this type of reaction would involve both atomic and molecular photosensitization and as such is of special interest in itself. In addition, nitric oxide has been used extensively as a free-radical trap in reaction kinetics, and recently the possibility of an attack of nitric oxide on substrate molecules has been considered (3). In the present study, the reactions of $NO(^4\Pi)$ molecules with methane, ethane, propane, neopentane, and benzene are reported.

EXPERIMENTAL

The static reaction system used will be described in another publication (4). The circulatory reaction system consisted of a rotary pump of commercial design (Precision Glass), a differential manometer, a U-trap, a Pirani gauge, and a cylindrical reaction cell made of optical quartz, 50 mm in diameter and 40 mm in length. The cell was attached to the system by standard tapers. The entire system was equipped with mercury float valves. The reaction cell was positioned in a water thermostat in such a fashion that its plane windows were opposite ports of Vycor 7910 glass in the sides of the thermostat. Radiation at 2537 Å was taken from a Hanovia SC-2537 mercury resonance source.

The methane, ethane, propane, neopentane (all Phillips Research Grade), nitric oxide (Matheson), trideuteroethane (Merck), and benzene (Fisher, Reagent Grade) were purified by standard low-temperature distillation techniques. Their purity was checked by gas–liquid partition chromatography (G.L.P.C.). The reaction products were fractionated by low-temperature distillation and the various fractions analyzed by G.L.P.C. The following columns were used: 6 ft of Burrell, 13X molecular sieves; 6 ft of Burrell, medium activity silica gel; 10 ft of Carbowax 600–6% by weight on "Celite".

The product identifications were performed by mass spectrometry and confirmed against predetermined retention time values in the G.L.P.C. analysis.

RESULTS

Preliminary experiments had shown that the addition of a small amount of a hydrogen-containing compound to pure nitric oxide which was undergoing mercury photosensitization resulted in a marked increase in the nitrogen and nitrous oxide yields. The results of some experiments, carried out under static conditions, are tabulated in Table I. A more

the reactions were further investigated in the circulatory apparatus to avoid depletion of mercury vapor in the cell through reaction with NO_2.

The quantum yield of N_2 formation ($\Phi_{(N_2)}$) as a function of the total pressure, with $P_{(C_2H_6)}/P_{(NO)} = 1.11$, is shown in Fig. 2. This curve, after an initial steep rise, seems to

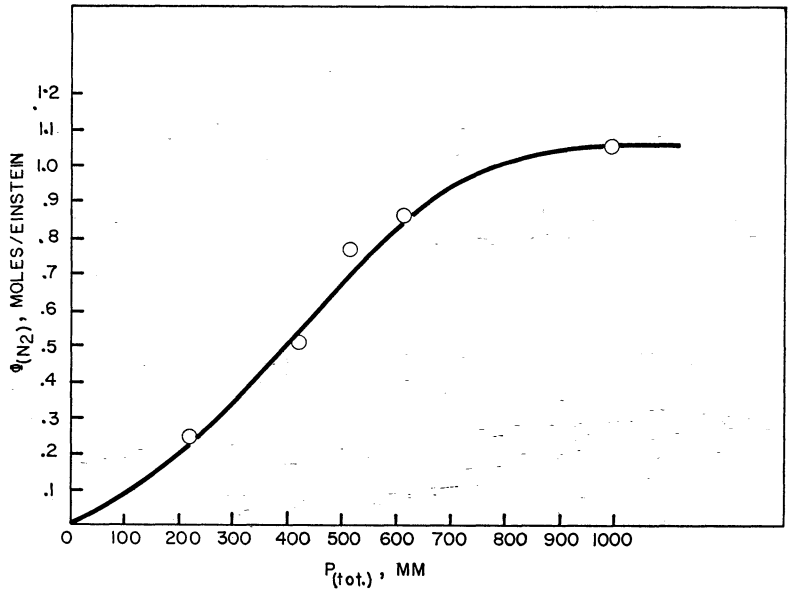

FIG. 2. The quantum yield of nitrogen formation as a function of total pressure, for $P_{(C_2H_6)}/P_{(NO)} = 1.11$.

level off at a pressure of ca. 1000 mm. The highest measured value of $\Phi_{(N_2)}$ at 30° was 1.06 moles/einstein at a total pressure of 995 mm.

It was also found that nitrogen formation continued in the reaction mixture even after termination of the photochemical reaction. The apparent $\Phi_{(N_2)}$ values, as a function of the dark reaction time following 12-minute exposures, are given in Fig. 3. At a total pressure of 430 mm and a $[C_2H_6]/[NO]$ ratio of 1.10, $\Phi_{(N_2)}$ increased from 0.51 mole/einstein, when the analysis was started immediately after the lamp was shut off, to a value of 1.27 moles/einstein, when the analysis was delayed 6 hours. This dark reaction was found to be much less pronounced at longer exposures as shown by the data of Table III. The decrease of $\Phi_{(N_2)}$ at longer exposures is not due to a mercury depletion in the system, since the quantum yield of the condensable products increased rather than decreased with longer exposure periods. It will be shown later that a more plausible explanation of this effect

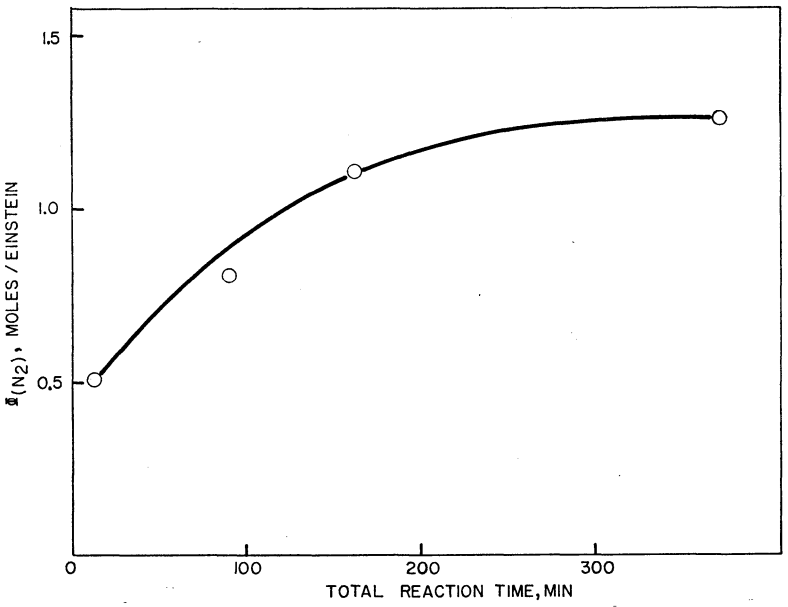

FIG. 3. The apparent quantum yield of nitrogen formation as a function of total dark reaction time, following 12-minute exposures at $P_{(C_2H_6)}/P_{(NO)} = 1.10$, and a total pressure of 430 mm.

TABLE III

The effect of exposure duration, and post-irradiation dark period on the apparent quantum yield of nitrogen in the reaction of NO($^4\Pi$) molecules with ethane

$P_{(tot)}$		Exposure duration	Dark Period	$\Phi_{(N_2)}$
mm	$[C_2H_6]/[NO]$	min		moles/einstein
430	1.11	12	360	1.27
438	1.12	33	680	0.73
466	1.10	50	180	0.50
430	1.14	12	150	1.12

is that the nitrogen-producing reaction between alkyl free radicals and nitric oxide is a chain reaction in which the most likely chain-terminating step is the combination reaction of an alkyl radical with NO_2 or NO_3. Since the concentration of NO_2 increases progressively with increasing exposure time, the relative rate of chain propagation to chain termination will progressively decrease. Since nitrogen is a chain product, the apparent $\Phi_{(N_2)}$ will have lower values with longer exposure periods.

In connection with the quantum yield measurements for C_2H_6 consumption, the experimental difficulties encountered should be briefly mentioned. First of all, one of the major reaction products was NO_2, and this product reacted rapidly with mercury to form $HgNO_2$. The amount of NO_2 formed was in almost all cases several times that of the C_2H_6 consumed; that is, the corrosion of the mercury surface and the depletion of mercury vapor was disproportionately faster than the reaction under study. This necessitated the use of a comparatively large reaction volume. Furthermore, it was necessary to confine the study to high nitric oxide concentrations at high total pressure, in order to

ensure that the ethane decomposition resulted from NO($^4\Pi$) photosensitization. Thus there was always a large excess of the reactants present in the reaction mixtures, which prevented the quantitative determination of some of the products.

To illustrate the procedure for the estimation of $\Phi_{-(C_2H_6)}$ a representative run will be considered, for which the quantum yield data are listed in Table IV. The total condensables at −130° C amounted to 35.92 μmoles, excluding the higher nitrogen oxides which

TABLE IV

Quantum yield data for a representative run in the reaction of NO^4(II) molecules with ethane

Product formed	μmoles	Φ moles/einstein
N_2	136.8	0.50

$C_2H_5ONO_2$	2.27	0.84×10^{-2}
C_2H_5ONO	2.32	0.86×10^{-2}
$C_2H_5NO_2$	1.18	0.44×10^{-2}
CH_3NO_2	0.18	0.07×10^{-2}
$CH_2{=}CHNO_2$	~0.1	
CH_2O }	<0.6	
CH_3ONO }		

NOTE: I_a = 5.42 μeinstein/min; exposure time = 50 minutes; temperature = 30° C; $P_{(C_2H_6)}$ = 244 mm; $P_{(NO)}$ = 222 mm; dark period following exposure = 180 minutes.

were previously absorbed by mercury. The total yields of C_1 and C_2 compounds were 0.29 and 11.93 μmoles respectively, and in this oxidation of ethane, 9.53 μmoles of water must have formed. The sum of the condensables is therefore 21.75 μmoles, leaving 35.92 − 21.75 or 14.17 μmoles of condensables unaccounted for. Now each mole of unrecovered product, condensable at −130°, could represent, at the most, 1 mole of ethane consumed where the oxidation yields ethylene and water, and in the least, one-third of a mole of ethane consumed where all of the hydrogen in the ethane is converted to water. Therefore the minimum and maximum values for $\Phi_{-(C_2H_6)}$ will be $(12.22 + 14.17/3)/(5.42\times50) = 0.063$, and $(12.22+14.17)/(5.42\times50) = 0.098$ mole/einstein respectively. Since both CO_2 and C_2H_4 were detected in the products the true quantum yield value should be about 0.08–0.09 mole/einstein. In either case the actual value is considerably higher than the quantum yield for the reaction between C_2H_6 and Hg $6(^3P_1)$ atoms, corrected for quenching by NO, for which an effective value of <0.005 mole/einstein is obtained.

The analytical data for a number of runs performed under various conditions are given in Table V. It is apparent from the table that the total C_2 yield found was in each case only a fraction of the condensable products and well below the stoichiometric ratio. This ratio was considerably higher at longer exposure times.

The effect of temperature was studied in the short range, 30–77° C. The data obtained seem to suggest a small positive activation energy for the reaction forming condensable products, and a small negative activation energy for the N_2-producing reaction. A plot of $\ln \Phi_{(cond.)}$ against $1/T$ gave a satisfactory straight line, as can be seen from Fig. 4, and from the slope a value of 2.0 kcal/mole was obtained for ΔE_a. A similar plot for $\Phi_{(N_2)}$ showed a strong curvature, thus indicating some complexity in the reaction mechanism.[2]

[2]*Only a part of the reaction system was temperature regulated, therefore the* $\Phi(N_2)$ *values at elevated temperature have only qualitative significance.*

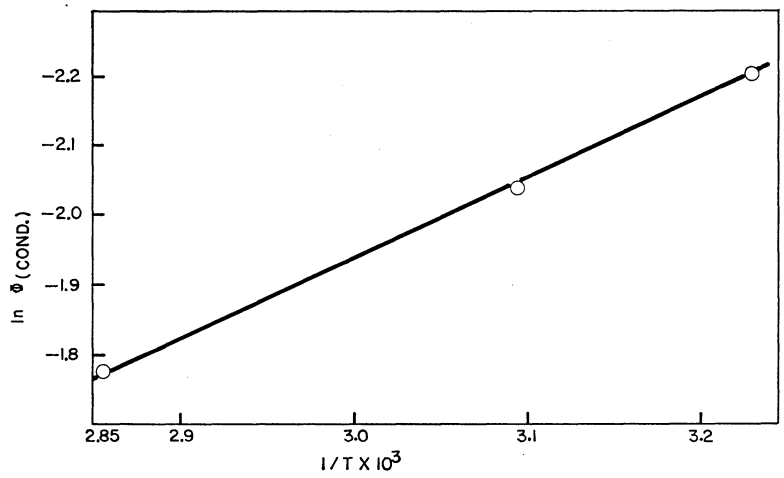

FIG. 4. Plot of ln $\Phi_{(cond.)}$ versus $1/T$.

To study the isotope effect on the reaction, one run was performed with 1,1,1-trideuterioethane. The quantum yield data for this run are given in Table VI, together with

TABLE VI

Quantum yield data for the CH_3CD_3 + NO($^4\Pi$) reaction

Product	Φ mole/einstein	Product	Quantity μmoles
N_2	0.58	Nitroethane	~1.4
Condensables	0.17	Nitromethane	~0.4
Acetaldehyde	0.021	Methyl nitrate	
$CH_3CD_2ONO_2$	0.007	H_2O	Very large
$CD_3CH_2ONO_2$	0.005		
CH_3CD_2ONO	0.006		
CD_3CH_2ONO	0.004		

NOTE: $\Phi_{(min.)}$ for ethane disappearance = 0.077 mole/einstein; $\Phi_{-(CH_3CD_3)}$ calculated on a competitive quenching basis was <0.005 mole/einstein; CH_3CD_2/CD_3CH_2 = 1.4 as determined from the ethyl nitrate, ethyl nitrite, and nitroethane products by mass spectrometric analysis; I_a = 5.42 μeinstein/min; exposure time = 61 minutes; temperature = 30°; $P_{(CH_3CD_3)}$ = 236 mm; $P_{(NO)}$ = 211 mm; dark period = 0.

the isotopic composition of the products as obtained from mass spectrometric analysis. It is interesting to note the increase in the quantum yield for CH_3CD_3 consumption compared to that for C_2H_6. The corresponding minimum values are $\Phi_{-(C_2H_6)} = 0.063$ and $\Phi_{-(C_2H_3D_3)} = 0.077$, which represent approximately a 22% increase in reactivity for the deuterated compound. The isotopic analysis data suggested that the reactivity of CD_3 with respect to NO($^4\Pi$) molecules is about 40% higher than that of the CH_3 in CH_3CD_3. Combining this result with the quantum yield values, it follows that the reactivity of CH_3 in C_2H_6 and CH_3CD_3 is about the same.

One more qualitative run, carried out under static conditions, should be mentioned. In this run (27 mm C_2H_6 and 39 mm NO), after completion of the exposure, 172 mm NO was added to the reaction mixture. Within a few minutes a deep brown color developed in the cell. No color formation could be observed in similar experiments omitting the addition of a further amount of nitric oxide. This experiment suggests the presence of

For personal use only.

some reactive species in the reaction mixture capable of combining with NO if the concentration of the latter is sufficiently high. At this point it appeared to be instructive to examine the reaction of some other hydrocarbon with NO($^4\Pi$) molecules.

The quantum yield data for three runs performed with methane are given in Table VII. The non-condensable fraction, in addition to N_2 and unreacted CH_4 and NO, contained a small amount of H_2. The middle fraction was composed of N_2O and CO_2 and the condensable fraction contained water, formaldehyde, methyl nitrite, methyl nitrate, nitromethane, and some other unidentified compounds. For the disappearance of CH_4 a minimum quantum yield value of 0.045 mole/einstein was obtained, while the one calculated on a competitive quenching basis is negligibly small.

NOTE: $\Phi_{(min.)}$ for CH_4 disappearance = 0.045 mole/einstein; I_a = 5.42 μeinstein/min; temperature = 30°.

One qualitative run was also done using nitrosomethane dimer and nitric oxide. No reaction was observed at room temperature in several hours. It was concluded that the nitrosomethane dimer is much less reactive than the monomer (5, 6).

The products identified in the reaction of propane with NO($^4\Pi$) molecules along with the corresponding quantum yield data are listed in Table VIII. The ratio of *n*-propyl/*i*-propyl in the products was 0.86.

TABLE VIII

Quantum yield data for the $C_3H_8 + NO(^4\Pi)$ reaction

The data from one run performed with benzene are given in Table IX. The low quantum yields of N_2 and N_2O indicate that this reaction is very slow.

The results of five runs with neopentane are shown in Table X. The highest measured quantum yield for N_2 production was 1.75 moles/einstein. The quantum yield of the

condensable products was also high and varied between 0.17 and 0.21 mole/einstein. The quantum yield data for N_2O in the table are high since they include the CO_2 which was formed in the reaction, the amount of which varied between 10 and 20 mole%.

In common with the ethane and methane systems, a dark reaction was also observed in this system, as is evident from the data in Table X. The condensables contained at least 18 compounds, among them trimethylacetaldehyde and water.

DISCUSSION

The hydrocarbon molecules selected for this study are characterized by their low reactivity with respect to Hg $6(^3P_1)$ atoms, due either to their low quenching or low quantum efficiencies, or both. The corresponding σ_Q^2 and Φ values are listed in Table XI.

TABLE XI

Quenching cross section and quantum yield values for Hg $6(^3P_1)$-photosensitized reactions

Substrate	σ_Q^2 Å^2	Φ mole/einstein	References
CH_4	0.059	0.008 (98°)	7, 8
C_2H_6	0.11; 0.10	1.0	9, 10, 11
$(Me)_4C$	1.5	0.004	9, 12
C_6H_6	41.9	0.00	7, 13
NO	24.7	0.002	7, 1

In the case of two substrate molecules, the fraction of each that quenches the sensitizer atoms is determined by the formula $F_A = 1/[1+(Z_BP_B)/(Z_AP_A)]$, where Z_A and Z_B are the collision numbers and P_A and P_B are the pressures of components A and B respectively. Possessing the values of the quenching cross sections and quantum yields, one can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

calculate, using the above formula, the amount of each substrate disappearing in the reaction. The computed values are as follows: $\Phi_{(CH_4)} < 0.001$, $\Phi_{(C_2H_6)} < 0.005$, $\Phi_{(neopentane)} < 0.001$, which can be compared to the measured values of 0.045, 0.063, and 0.1 mole/einstein respectively for the minimum Φ value obtained in this study. The case of neopentane is of special interest. For the Hg $6(^3P_1)$-photosensitized decomposition of this molecule, under conditions similar to those prevailing in this study, a quantum yield value of 0.004 mole/einstein has been reported (12). When, however, an approximately equal amount of NO is added, the quantum yield increases about 25-fold, even though the amount of energy transferred directly from the Hg $6(^3P_1)$ atoms to neopentane has decreased by ca. 25-fold. This fact, taken in conjunction with the quantum yield data for the NO–CH_4 and NO–C_2H_6 systems, can best be explained by the formation and subsequent reactions of NO($^4\Pi$) molecules in these systems according to the following sequence:

$$Hg + h\nu_{(2537)} \rightarrow Hg^* \quad [1]$$

$$Hg^* + NO \rightarrow NO(^4\Pi) + Hg \quad [2]$$

$$NO(^4\Pi) + RH \rightarrow NO + R + H. \quad [3]$$

The role of NO as a photosensitizer is evident from this mechanism.

The results obtained from the CH_3CD_3 study are also in agreement with and lend further support to the proposed mechanism. Recent investigations of the Hg $6(^3P_1)$-photosensitized reactions of partially and fully deuterated saturated hydrocarbon molecules (14–18) have concordantly shown that replacement of H-atoms in the molecule by D-atoms led to a more or less marked decrease in the reactivity of the molecule with respect to Hg $6(^3P_1)$ atoms. In the present instance, however, a marked increase appeared in the minimum quantum yield from 0.063 to 0.077. Furthermore, in the Hg $6(^3P_1)$ reaction, the C—H bond rupture in all cases predominates over C—D bond scission, contrary to the inverted isotope effect of 1.4 favoring C—D rupture found here. It should also be noted that the reactivity of hydrocarbons with respect to Hg $6(^3P_1)$ atoms follows the order $CH_4 < (Me)_4C < C_2H_6$, while for NO($^4\Pi$)-photosensitization the reactivity sequence is $CH_4 < C_2H_6 < (Me)_4C$.

The measured quantum yield values are of the order of one tenth. Naturally, unit efficiency cannot be expected, owing to the activation energy required (2.0 kcal for the C_2H_6 + NO system) and because of the deactivating effect of the nitric oxide on the NO($^4\Pi$) species (1), which is likely very efficient.

The ratio of primary to secondary C—H bond cleavage in the reaction of NO($^4\Pi$) molecules with propane is 0.86 (Table VIII), nearly identical with the value obtained in the Hg $6(^3P_1)$-photosensitized reaction (14, 15).

The alkyl free radicals produced in reaction [3] react with nitric oxide to form the corresponding nitroso compounds (19–25):

$$R + NO \rightarrow RNO. \quad [4]$$

This reaction is likely to be second order for ethyl and the higher alkyl radicals (the corresponding reaction with O_2 is second order (26)). The reaction of H-atoms with NO will be discussed in another publication (4). The subsequent reactions of the alkyl nitroso monomers are complex and not fully understood. Generally, there are three possible ways for their disappearance: (1) dimerization leading to the formation of the stable, solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

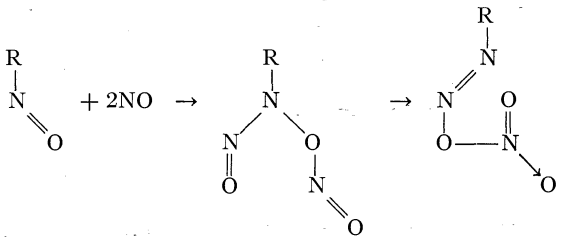
alkyl nitroso dimers as shown in step [5]; (2) isomerization to the corresponding oxime (reaction [6]); (3) further reaction with nitric oxide (reaction [7]):

$$2RNO \rightarrow (RNO)_2 \quad [5]$$

$$RNO \rightarrow R{=}NOH \quad [6]$$

$$RNO + 2NO \rightarrow RNO\cdot(NO)_2. \quad [7]$$

Reaction [5] is slow (5, 6, 27) and the dimer formed is not capable of further reactions (5, 6). The isomerization reaction, [6], has an activation energy of 39 kcal in the case of nitrosomethane (6) but it may proceed rapidly in ultraviolet light or in the presence of an active surface (6, 28). Reaction [7], under the conditions of this study (high pressure of nitric oxide, room temperature), must be considerably faster than [5] and [6], since neither oxime nor nitroso dimer was found in the products. That nitroso monomers react with NO was first shown by Bamberger (29), who obtained phenyldiazonium nitrate from nitrosobenzene and NO in the liquid phase. More recently Burkhard *et al.* (30) have reported on the reaction of hydrocarbons with nitric oxide. Brown (31, 32) studied a number of reactions involving various hydrocarbons and nitric oxide. With isobutylene, 45 liquid and solid organic fractions were isolated from the crude product. This author has proposed that the reaction occurs via a diazo nitrate, the formation of which can be visualized as



[8]

It was further proposed that this intermediate diazo nitrate can decompose by either homolytic or heterolytic bond rupture. The homolytic process regenerates the original radical and hence accomplishes a simple disproportionation of the NO into N_2 and NO_2, which is a thermodynamically feasible reaction ($\Delta F = -59.6$ kcal):

$$R\cdot + 3NO \rightarrow RN_2ONO_2 \quad [9]$$

$$RN_2ONO_2 \rightarrow R\cdot + N_2 + NO_3\cdot \quad [10]$$

$$NO_3\cdot + NO \rightarrow 2NO_2 \quad [11]$$

$$4NO \rightarrow N_2 + 2NO_2 \quad [12]$$

The heterolytic route yields sequentially diazonium nitrate, carbonium nitrate, nitroolefin, and nitric acid. A conversion of NO to NO_2 is also achieved but less efficiently than by the homolytic route:

$$NO_2 + \text{olefin} \rightarrow R'\cdot \quad [13]$$

$$R'\cdot + 3NO \rightarrow R'N_2ONO_2 \quad [9a]$$

$$R'N_2ONO_2 \rightarrow [R'N_2^+\cdot NO_3^-] \rightarrow [R'^+\cdot NO_3^-] + N_2 \quad [14]$$

$$[R'^+\cdot NO_3^-] \rightarrow \text{nitroolefin} + HNO_3 \quad [15]$$

$$HNO_3 + 0.5NO \rightarrow 0.5H_2O + 1.5NO_2 \quad [16]$$

$$\text{olefin} + 3.5NO \rightarrow \text{nitroolefin} + 0.5H_2O + 0.5NO_2 + N_2, \quad [17]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

where R′· is a nitroalkyl free radical. Donaruma and Carmody (33) have studied the reaction of nitric oxide with bisnitrosocyclohexane. They obtained cyclohexyl nitrate, nitrocyclohexane, and cyclohexyl nitrite as the major reaction products. Their kinetic findings—a rate equation zero order in NO pressure, a high activation energy coupled with a high positive entropy of activation, along with the spectroscopic and thermochemical evidence for the association complex formation—were interpreted in terms of Brown's (31, 32) mechanism. In order to account for the final reaction products the following reactions between R and NO_2, formed in reactions [10] and [11], were suggested:

$$R + NO_2 \rightarrow RNO_2^* + RONO^* \quad [18]$$

$$RNO_2^* + M \rightarrow RNO_2 + M \quad [19]$$

$$RONO^* \rightarrow RO + NO \quad [20]$$

$$RONO^* + M \rightarrow RONO \quad [21]$$

$$RO + NO_2 \rightarrow RONO_2. \quad [22]$$

Burrell (5) has also measured the specific rate constant for the reaction of nitric oxide with nitrosocyclohexane monomer. The results and their interpretation are in line with those of Donaruma and Carmody (33).

There is also evidence in the literature from gas phase kinetic studies which gives support to the above mechanism. Levy (34) found that in the thermal decomposition of *t*-butyl nitrite the HCN product is replaced by nitromethane when the reaction is carried out in the presence of NO. The explanation advanced was that the HCN originated from the thermal decomposition of nitrosomethane by the equation

$$CH_3NO \rightarrow CH_2{=}NOH \rightarrow HCN + H_2O \quad [23]$$

while CH_3NO_2 originated from the reaction of CH_3NO with NO. Indeed, separate experiments showed that the reaction of nitrosomethane with nitric oxide produced nitromethane (35). Christie (27) found that CH_3NO reacts with nitric oxide in the ratio of 1:2 to give a product which is stable in the gas phase at room temperature, but decomposes on freezing and rewarming. Batt and Gowenlock (6) have also reported that nitrosomethane monomer in the gas phase reacts with NO. The reaction product could be condensed at liquid air temperatures but decomposed on standing to give a mixture of gases about one-half of which was condensable in liquid air. They suggested the mechanism

$$CH_3{-}\underset{\underset{N{=}O}{|}}{N}{-}O{-}N{=}O \rightarrow CH_3N_2^+ \cdot NO_3^- \rightarrow CH_3ONO_2 + N_2, \quad [24]$$

which is essentially identical with the heterolytic route [14] proposed by Brown (32). Finally, McMillan (36) reported very recently that when diisopropyl peroxide is decomposed in the presence of nitric oxide, at room temperature, the products include methyl nitrate and nitrogen among others. The formation of these products was explained on the basis of Batt and Gowenlock (6) and Christie's (27) experimental observations of the reaction between methyl free radicals and nitric oxide.

In conclusion it may be stated that all the publications which have appeared in the literature in connection with the reactions between alkyl and aryl nitroso compounds and nitric oxide appear to be in favor of the mechanism first proposed by Brown (31, 32). The results of the present work may also be conveniently explained in terms of this mechanism and, as such, lend additional support to its validity.

It is likely that in the gaseous phase the homolytic process predominates over the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

heterolytic route. The proposed mechanism to account for the products found in this work is as follows:

$$RNO + 2NO \rightleftarrows R{-}N(O{-}N{=}O)(N{=}O) \quad [25]$$

$$R{-}N(O{-}N{=}O)(N{=}O) \rightarrow R{-}N{=}NONO_2 \quad [26]$$

$$R{-}N{=}NONO_2 \rightarrow R + N_2 + NO_3 \quad [10]$$

$$R{-}N{=}NONO_2 \rightarrow [RN_2^+ \cdot NO_3^-] \quad [27]$$

$$[RN_2^+ \cdot NO_3^-] \rightarrow [R^+ \cdot NO_3^-] + N_2 \quad [28]$$

$$[R^+ \cdot NO_3^-] \rightarrow \text{olefin} + HNO_3 \quad [29]$$

$$NO_3 + NO \rightarrow 2NO_2 \quad [11]$$

$$HNO_3 + 0.5NO \rightarrow 1.5NO_2 + 0.5H_2O \quad [16]$$

$$R + NO_2 \rightarrow RNO_2^* \quad [18a]$$

$$\rightarrow RONO^* \quad [18b]$$

$$RNO_2^* + M \rightarrow RNO_2 + M \quad [19]$$

$$RONO^* \rightarrow RO^* + NO \text{ or } R'CHO + HNO \quad [30]$$

$$RONO^* + M \rightarrow RONO + M \quad [21]$$

$$RO^* + NO \rightarrow R'CHO + HNO \quad [31]$$

$$RO^* + M \rightarrow RO + M \quad [32]$$

$$RO + NO_2 \rightarrow RONO_2 \quad [22]$$

$$R'CHO + h\nu \text{ (or Hg* or NO}(^4\Pi)) \rightarrow R' + CHO \quad [33]$$

$$CHO + NO \rightarrow CO + HNO \quad [34]$$

$$R' + NO + M \rightarrow R'NO + M. \quad [35]$$

The N-nitroso-N-alkyl-hydroxylamine nitrite intermediate formed in reaction [25] appears to be in equilibrium with the nitrosoalkyl monomer, in agreement with Burrell's (5) but contrary to Donaruma and Carmody's (33) proposal. This view is supported by our observation that the reaction mixture, after the excess NO was distilled off at −183° C, releases nitric oxide on standing at room temperature. The rate-determining step is the isomerization of this intermediate to the corresponding diazonium nitrate, [26], the latter then rapidly decomposes, mainly homolytically, [10], to regenerate the alkyl radical, and simultaneously a small fraction cleaves heterolytically, [29], to yield olefin. Donaruma and Carmody (33) obtained a value of 47,700 cal/mole for $\Delta H^{\ddagger}$ and 77.9 e.u. for $\Delta S^{\ddagger}$ in the reaction of bisnitrosocyclohexane with nitric oxide in cyclohexane solution. This value for $\Delta H^{\ddagger}$ may be compared to the small negative activation energy found for the nitrogen-producing reaction in this work and also to the results of Batt and Gowenlock (6), for the gas-phase reaction of nitrosomethane monomer with nitric oxide, which indicate that there is little effect of temperature upon the reaction rate. The following reason can be advanced to explain this discrepancy, which far exceeds the experimental error. Donamura and Carmody (33) measured the rate of dimer disappearance by determination of its absorption band at 8.28 μ. Now it is apparent from Burrell's (6) work that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the rate of dissociation for the dimer is about two orders of magnitude slower than the rate of the monomer reaction with nitric oxide at the nitric oxide pressures encountered in their experiments. The half-period of reaction at 25° was found to be 0.23 sec for the nitric oxide and 13.5 sec at 51° for the dissociation reactions. The rate-controlling step is obviously the dissociation of the dimer, which reaction has a high activation energy. Donaruma and Carmody incorrectly assigned this activation energy and the related entropy of activation to the subsequent reactions with nitric oxide. The view that the activation energy is due to the dissociation process is further substantiated by Burrell's (6) qualitative observation that chloronitrosocyclohexane in cyclopentane solution reacts rapidly at −80° with nitric oxide, indicating a low activation energy process leading to the formation of nitrate. Chloronitrosocyclohexane is known to be monomeric in solution. It may be mentioned here that for an association reaction leading to equilibrium, a low activation energy would be expected also on theoretical grounds. If, however, the activation energy is very low, the entropy of activation, in contrast to Donaruma and Carmody's value, ca. 80 e.u., should rather have a negative value, since the reaction rate is comparatively slow. A negative value for the entropy of activation may be expected if the molecule in the activated state contains more bonds than the original molecule (37), or, in other words, if the isomerization of N-nitroso-N-alkyl-hydroxylamine nitrite intermediate to the alkyl diazonium nitrate occurs via a cyclic activated complex as was originally proposed by Brown (32). It also follows from this line of reasoning that the rate-determining step is this isomerization reaction, the slowness of which is related to the low probability of formation of the activated complex.

Reaction [18*a*] illustrates the autoinhibited character of the reaction. Under favorable conditions, when the NO to NO_2 ratio is kept sufficiently high, long chains could probably build up. Some calculated values of the average chain lengths, from the ethane – nitric oxide system, are given in the last column of Table V. The minimum and maximum values were obtained by dividing the nitrogen quantum yields by the maximum and minimum values respectively of the estimated quantum yield of ethane consumption. As can be seen from the table, an increase in NO pressure or dark reaction time causes an increase in the average chain length.

The significant difference between gas and liquid phase reactions as far as the final product distribution is concerned lies in the fact that in the latter case only nitration occurs whereas in the former case, both nitration and oxidation products are formed (32), with oxidation assuming major importance. This deviation may be explained in terms of the cage effect, which favors nitrate formation, and the more efficient collisional deactivation of excited species in the liquid phase.

The aldehyde is formed from the decomposition of RONO (38), either through excited alkoxy radicals, in reactions [30] and [31], or directly from RONO* [30]. Some alkoxy radicals have to be present in the gas phase system since the formation of the nitrate product directly from R and NO_3 is very unlikely. If RONO* dissociates, the excess energy of about 20 kcal/mole likely remains in the newly formed C—O bond.

The nitroethylene, which was tentatively identified by a peak at mass 73 in the mass spectrum of the condensable products, may arise from the secondary reactions of C_2H_4 by the heterolytic process, as suggested by Brown (32).

The discussion of such secondary reactions as the photolytic and oxidative decomposition of the primary products leading to CO and CO_2 formation will be omitted here.

Finally, as will be shown in another publication (4), both the nature of the products and the kinetics of the reaction of hydrogen atoms with nitric oxide molecules seem to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be in favor of a reaction between nitroxyl molecule and nitric oxide in close analogy with alkyl and aryl nitroso compounds and nitric oxide. This reaction, however, according to the quantum yield data is not a chain process. Therefore it is assumed that during the isomerization of the nitrosohydroxylamine nitrite intermediate to diazonium nitrate a proton shift from the nitrogen to the oxygen occurs and the reaction yields directly N_2 and HNO_3 without going through the diazonium nitrate state. Alternately hydrogen diazonium nitrate may be formed, and decompose via the heterolytic route [29].

CONCLUSIONS

Electronically excited nitric oxide molecules, most likely in the ($^4\Pi$) state, produced in Hg $6(^3P_1)$ photosensitization, react with hydrocarbons. The primary step is a carbon–hydrogen split. The rate of reaction follows the order benzene < methane < ethane < neopentane. In the case of the CH_3CD_3 molecule an inverted isotope effect appears. Propane yields normal and isopropyl radicals in nearly equal quantities.

Monomeric alkyl nitroso compounds in the gas phase react with nitric oxide. These reactions lead to an alkyl-radical-catalyzed chain disproportionation of nitric oxide into nitrogen and nitrogen dioxide at room temperature. Nitrogen dioxide inhibits the chain propagation.

ACKNOWLEDGMENTS

The authors wish to express their deep appreciation to Mr. Gene Fried for his assistance in some of the experimental work and to Mr. R. K. Taylor for the mass spectrometric analysis.

THE METHYL 2-O-(BENZYLTHIO)CARBONYL DERIVATIVE AS A PRECURSOR TO PARTIAL ESTERS OF METHYL α-D-GLUCOPYRANOSIDE

J. J. WILLARD,[1] JOANNE SADOWSKI,[2] AND WILLIAM VITALE[2]
Cellulose Research Institute, State University of New York College of Forestry, Syracuse, N.Y., U.S.A.

Received December 26, 1962

ABSTRACT

The utility of the thiocarbonyl group for blocking the C_2 hydroxyl in methyl glucosides has been demonstrated. Methyl 2-*O*-(benzylthio)carbonyl-α-D-glucopyranoside has been synthesized in good yield and its structure proved. Use of this 2-*O*-thiocarbonyl derivative in conjunction with acid-labile blocking groups has permitted the first syntheses of the following esters of methyl α-D-glucopyranoside: 3-*O*-benzoyl-, 3,4-di-*O*-benzoyl-, and 3,4,6-tri-*O*-benzoyl-, and the crystalline 2-*O*-(*p*-toluene)sulphonate derivative of each.

INTRODUCTION

In a previous communication (1) the synthesis of methyl 2,3-di-*O*-(benzylthio)-carbonyl-α- and -β-D-glucopyranosides and the use of these compounds for the synthesis of methyl 4,6-di-*O*-benzoyl-α- and -β-D-glucopyranosides were described. Thiocarbonate derivatives of carbohydrates are conveniently prepared, are stable to mild aqueous acid conditions, but are readily decomposed by oxidation with hydrogen peroxide in glacial acetic acid or by reduction with Raney nickel, conditions which do not generally disturb other ester groups. Thus, a (benzylthio)carbonyl derivative can be used in conjunction with acid-sensitive blocking groups to furnish several classes of partial ester derivatives of the methyl glucosides.

It has been found that crystalline methyl 4,6-*O*-benzylidene-2-*O*-(benzylthio)carbonyl-α-D-glucopyranoside (III), as seen in Fig. 1, can be isolated in 58% yield after treating

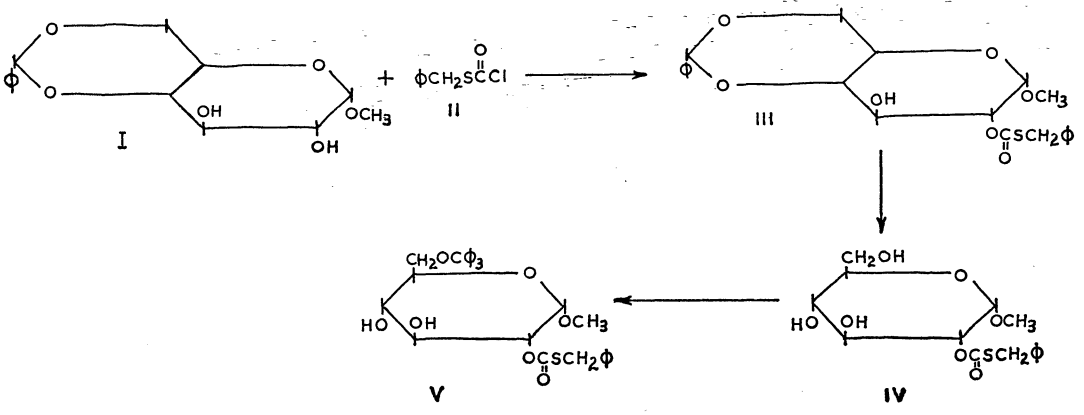

FIG. 1.

methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) with 1 mole of (benzylthio)carbonyl chloride (II) in pyridine solution. Removal of the benzylidene group by mild acid

hydrolysis gave, in 98% yield, a crystalline product which was shown to be methyl 2-*O*-(benzylthio)carbonyl-α-D-glucopyranoside (IV). These compounds serve as useful intermediates in the synthesis of 3-, 3,4-di-, and 3,4,6-tri-*O*-substituted derivatives of methyl α-D-glucopyranoside in the following ways: (i) esterification of III followed by removal of the benzylidene and (benzylthio)carbonyl groups provides 3-*O*-substituted methyl glucosides, (ii) esterification of IV and subsequent removal of the (benzylthio)-carbonyl group gives 3,4,6-tri-*O*-substituted derivatives, and (iii) formation of the triphenylmethyl (trityl) ether of IV provides a compound (V) which is suitable for the formation of 3,4-di-*O*-substituted methyl glucosides. This is the first general synthetic route to each of these three classes of partial ester derivatives of methyl α-D-glucopyranoside.

This article describes the proof of structure of methyl 4,6-*O*-benzylidene-2-*O*-(benzylthio)carbonyl-α-D-glucopyranoside (III) and the syntheses of each of the above classes of partial esters as benzoates of methyl α-D-glucopyranoside; crystalline 2-*O*-(*p*-toluene)-sulphonates of each partially benzoated derivative were prepared.

DISCUSSION

Problems encountered in the use of previously reported blocking groups for the synthesis of partial esters of carbohydrates (namely the trifluoroacetate (2), the dichloroacetate (3), and the tosylate groups (4)) are largely overcome by making use of the thiocarbonate radical. The latter is stable under a wide range of conditions but is readily decomposed, when desired, by oxidative or reductive cleavage. It is now possible to synthesize a large number of previously inaccessible partial ester derivatives of the sugars.

There is ample evidence that the hydroxyl groups at C_2 and C_6 in methyl α-D-glucopyranoside are more reactive than those at C_3 and C_4 (5–7). Similarly, in methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) the hydroxyl at C_2 is more reactive in substitution reactions than that at C_3 (8–11). When I was treated with 1 mole of (benzylthio)-carbonyl chloride in pyridine solution, the 2-thiocarbonate derivative was isolated in 58% yield together with 10% of the disubstituted product, methyl 4,6-*O*-benzylidene-2,3-di-*O*-(benzylthio)carbonyl-α-D-glycopyranoside. These two products are readily separated by fractional crystallization from ethanol. Attempts to isolate another product from the mother liquors which might be the 3-thiocarbonate derivative were not successful. The 2-thiocarbonate gave a crystalline acetate, phenylcarbamate, and benzoate derivative.

In order to establish the position of substitution of the thiocarbonate group in III, use was made of its benzoate derivative, VI, Fig. 2, since removal of the thiocarbonate group would furnish one of the isomeric monobenzoate derivatives of I, both being well characterized (2). Attempts to remove the thiocarbonate group from VI by oxidation with hydrogen peroxide in glacial acetic acid resulted in loss of the benzylidene group. It was found, however, that the thiocarbonate radical is decomposed by treatment with Raney nickel in boiling ethanol. In order to accomplish this desulphurization, it was discovered that it is essential to shake the ethanol solution of VI with Raney nickel at room temperature for at least 24 hours prior to refluxing for 3 hours. Omission of this step resulted in the recovery of mostly starting material, in low yield, together with small amounts of other products which were difficult to separate from VI. Under the above conditions, a mixture of the isomeric monobenzoates was obtained containing 24% of the C_2 benzoate (VII) and 56% of the C_3 benzoate (VIII); in another experiment the yield of VIII was 71%. Both monobenzoates were characterized as their tosylates, IX and X. Replacement of the (benzylthio)carbonyl group in VIII yielded a product indistinguishable from that (VI)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

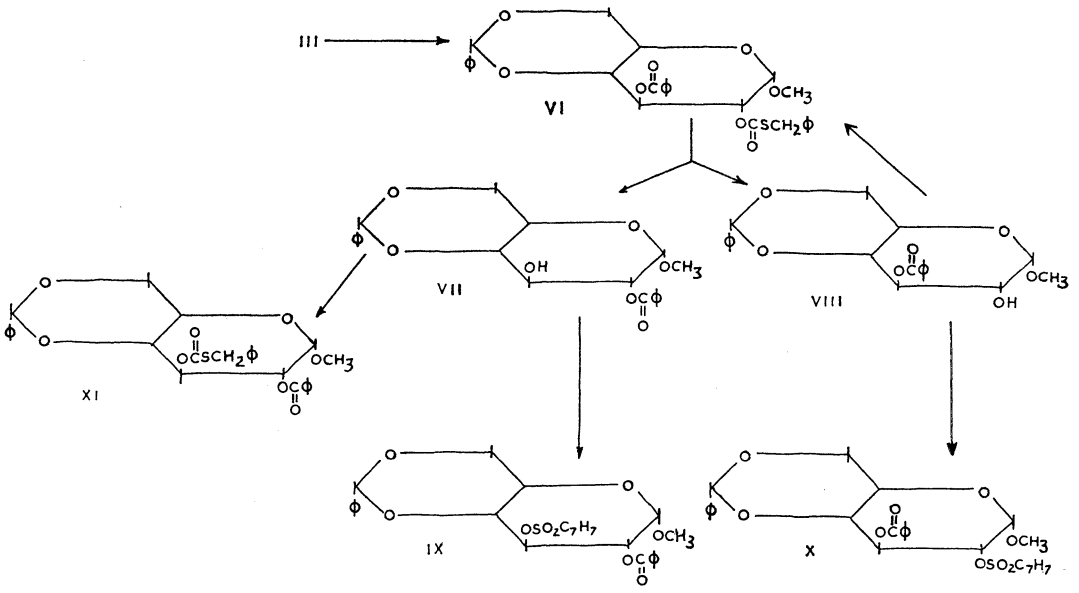

FIG. 2.

obtained by benzoylation of III. Since VIII and its tosylate (X) are well characterized as having the benzoyl group on C_3, the structure of VI must be as shown. Resubstitution of the (benzylthio)carbonyl group in VII yielded a product (XI) quite different from VI in melting point and specific rotation. The occurrence of VII as a product of Raney nickel desulphurization of VI must therefore have resulted from migration of the benzoyl group from the C_3 to the C_2 hydroxyl, possibly catalyzed by traces of alkali still present in the Raney nickel.

The migrations of ester groups in sugar derivatives are assumed to occur through orthoester intermediates (12) but factors which influence the direction of migration are not clearly understood. In derivatives of I there are reports of both C_3 to C_2 (2) and C_2 to C_3 (2, 13) migrations of ester groups; the present work provides another example of a C_3 to C_2 migration in these derivatives.

Benzoylation of IV gave a sirupy product XII, Fig. 3, which on treatment with hydro-

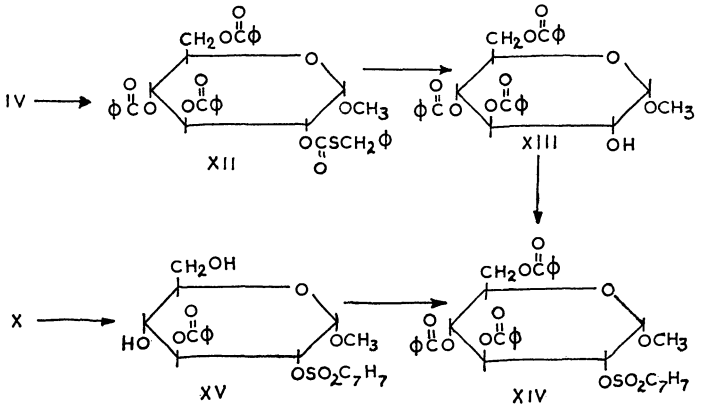

FIG. 3.

For personal use only.

gen peroxide in glacial acetic acid gave 72% of the new crystalline tribenzoate of methyl α-D-glucopyranoside (XIII); this compound yielded a crystalline tosylate (XIV). The same tosylate was obtained from the known compound X by removal of the benzylidene group to give XV and benzoylation to yield methyl 3,4,6-tri-*O*-benzoyl-2-*O*-(*p*-toluene)-sulphonyl-α-D-glucopyranoside (XIV). Compound XIII was therefore proved to be methyl 3,4,6-tri-*O*-benzoyl-α-D-glucopyranoside.

The trityl derivative V of IV gave on benzoylation, XVI, Fig. 4. Detritylation to XVII followed by oxidative removal of the thiocarbonate group gave an amorphous solid,

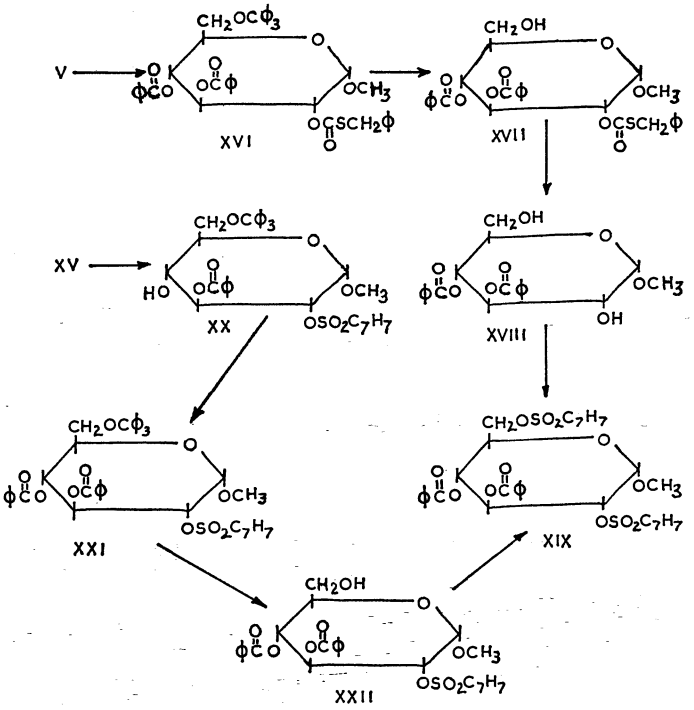

FIG. 4.

XVIII, which, however, gave a crystalline ditosylate derivative, XIX. To prove the structure of this compound, the known compound X was converted through three new crystalline products to an identical ditosylate dibenzoate derivative of methyl α-D-glucopyranoside. Contrary to the usual experience found in this laboratory with sugars having a free primary hydroxyl group, XV did not react with trityl chloride (1 mole) during 2 days at room temperature in pyridine solution. However, when the reaction mixture was warmed on the steam bath for 2 hours, a 93% yield of the crystalline trityl derivative XX was obtained. Benzoylation of the C_4 hydroxyl gave XXI, which was detritylated to give the crystalline 2-tosylate derivative of methyl 3,4-di-*O*-benzoyl-α-D-glucopyranoside. Tosylation of XXII gave a product indistinguishable from XIX obtained from XVIII. Thus, the structure of XVIII was also established.

Removal of the benzylidene group from the known 3-*O*-benzoyl derivative VIII furnished, in 70% yield, an hydroscopic amorphous solid, methyl 3-*O*-benzoyl-α-D-glucopyranoside. Its purity was established when the resynthesis of the benzylidene derivative, VIII, was accomplished in 93% yield.

These reactions confirm the assignment of structure to the monothiocarbonate derivative III as methyl 4,6-*O*-benzylidene-2-*O*-(benzylthio)carbonyl-α-D-glucopyranoside and to the compound IV, methyl 2-*O*-(benzylthio)carbonyl-α-D-glucopyranoside. Furthermore, the synthesis of the three new partial benzoate derivatives in good yield further demonstrates the use of the thiocarbonate group as a valuable blocking group for carbohydrate reactions.

EXPERIMENTAL[3]

Methyl 4,6-O-Benzylidene-2-O-(benzylthio)carbonyl-α-D-glucopyranoside (III)

Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) was prepared by a standard method (14), as was (benzylthio)carbonyl chloride (15). To 15.0 g of I in 30 ml of anhydrous pyridine was added dropwise 9.0 ml of II during ½ hour, the solution being cooled with an ice bath. The mixture was kept an additional half hour at room temperature and was then poured into 300 ml of ice water. The sirupy product was extracted into 100 ml of chloroform, and the latter solution was extracted successively with 100 ml of *N* hydrochloric acid, *N* sodium hydroxide, and water. The chloroform layer was dried over magnesium sulphate. The sirup obtained by evaporation of the chloroform was dissolved in 150 ml of hot ethanol. When cooled to room temperature, this solution gave after 3 hours 3.1 g (10%) of methyl 4,6-*O*-benzylidene-2,3-di-*O*-(benzylthio)carbonyl-α-D-glucopyranoside (1), which was recrystallized from ethanol; there was thus obtained 2.7 g of product with m.p. 133–134°. The original ethanol solution was cooled overnight at −5° and furnished 14.4 g of product having m.p. 118–121°. After recrystallization from 1 liter of ligroin there was obtained 13.3 g (58%) of fine needles, m.p. 121–122°. The melting point was not changed after recrystallization from ethanol, and this product showed $[\alpha]_D^{22}$ +80.60° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{22}H_{24}O_7S$: C, 61.06; H, 5.77; S, 7.37. Found: C, 61.21; H, 5.41; S, 7.45.

In some instances, a third product, m.p. 42.5–44° and optically inactive, was obtained, which cocrystallized with III from ethanol. It was isolated by recrystallization of the mixture from ligroin, coming down last from that solvent. Its infrared spectrum and elemental analysis indicated that this compound was di(benzylthio)carbonyl, $(C_6H_5CH_2S)_2CO$, reported (16) previously as an oil. This same compound was sometimes encountered in low yield during the preparation of II from phosgene and benzylmercaptan, and can be distilled under high vacuum. Its formation during the synthesis of III can be attributed to a reaction of II with water, followed by loss of carbon dioxide to give benzylmercaptan, which reacts in turn with another mole of II. The use of strictly anhydrous pyridine was found to be essential for high yields of III. Anal. for di(benzylthio)carbonyl: Calc. for $C_{15}H_{14}OS_2$: C, 65.69; H, 5.12; S, 23.38. Found: C, 65.33; H, 5.23; S, 23.29.

Derivatives of III

The following derivatives of III were synthesized by standard procedures in pyridine solutions.

Methyl 3-O-Acetyl-4,6-O-benzylidene-2-O-(benzylthio)carbonyl-α-D-glucopyranoside

Yield: 59%; m.p. 135–136°; $[\alpha]_D^{22}$ +74.30° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{24}H_{26}O_8S$: C, 60.75; H, 5.48; S, 6.74. Found: C, 59.61; H, 5.62; S, 6.99.

Methyl 4,6-O-Benzylidene-2-O-(benzylthio)carbonyl-3-O-phenylcarbamoyl-α-D-glucopyranoside

Yield: 84%; m.p. 120–121°; $[\alpha]_D^{22}$ +99.15° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{29}H_{29}O_8NS$: C, 63.16; H, 5.26; S, 5.78; N, 2.54. Found: C, 63.68; H, 5.36; S, 5.78; N, 2.59.

Methyl 3-O-Benzoyl-4,6-O-benzylidene-2-O-(benzylthio)carbonyl-α-D-glucopyranoside (VI)

Yield: 87%; m.p. 138–139°; $[\alpha]_D^{25}$ +44.5° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{29}H_{28}O_8S$: C, 64.92; H, 5.23; S, 5.97. Found: C, 64.87; H, 5.21; S, 6.08.

Methyl 2-O-(Benzylthio)carbonyl-α-D-glucopyranoside (IV)

To 1.0 g of III dissolved in 40 ml of acetone was added 12 ml of 0.2 *N* hydrochloric acid, and the solution was refluxed for 2 hours. After neutralization with excess barium carbonate and filtration, the solution was evaporated to dryness and the residue was extracted with several portions of warm ether, the insoluble barium chloride being removed by filtration. On cooling, the ether solution gave 0.78 g (98%) of product as large needles, m.p. 135–137°. After recrystallization from acetone – petroleum ether the product had m.p. 136–137° and $[\alpha]_D^{22}$ +112.2° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{15}H_{20}O_7S$: S, 9.30. Found: S, 9.18.

Methyl 2-O-(Benzylthio)carbonyl-3,4,6-tri-O-phenylcarbamoyl-α-D-glucopyranoside

Compound IV was treated with phenyl isocyanate in pyridine solution by the usual procedure. The product had m.p. 192.5–193° and $[\alpha]_D^{22}$ +107.6° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{36}H_{35}O_{10}N_3S$: C, 61.62; H, 4.99; N, 5.99; S, 4.57. Found: C, 60.95; H, 5.08; N, 6.01; S, 4.64.

Methyl 2-O-(Benzylthio)carbonyl-6-O-triphenylmethyl-α-D-glucopyranoside (V)

To 1.0 g of IV in 5 ml of anhydrous pyridine was added 0.81 g of triphenylmethyl chloride. The solution

[3]*Melting points are uncorrected. Solvents were removed in vacuo at 50°.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

stood for 2 days at room temperature, with protection from moisture, and was then poured into ice water. The product was extracted into chloroform and isolated in the usual way. The sirup obtained on evaporation of the chloroform turned to a glass on standing over phosphorus pentoxide, but failed to crystallize. It had $[\alpha]_D^{22}$ +46.7° (*c* 1, $CHCl_3$).

Reaction of Methyl 3-O-Benzoyl-4,6-O-benzylidene-2-O-(benzylthio)carbonyl-α-D-glucopyranoside with Raney Nickel

A solution of 5.4 g of VI in 500 ml of ethanol was treated with 8 g of Raney nickel (suspension in ethanol). The mixture was shaken for 24 hours at room temperature and then was refluxed for 3 hours. After filtering the hot solution, 100 ml of water was added. After concentrating this solution to 250 ml and cooling it at −25° for 3 hours, 2.2 g (56%) of product, m.p. 210–212°, was obtained. After recrystallization from acetone – petroleum ether the product had m.p. 216–217° and $[\alpha]_D^{25}$ +34.0° (*c* 1, $CHCl_3$). Reported for VIII: m.p. 217–218° and $[\alpha]_D^{19}$ +33.5° (*c* 2.6, $CHCl_3$).

Further concentration of the original solution gave two additional crops totaling 0.94 g, m.p. 160–163°. After recrystallization from acetone – petroleum ether this product had m.p. 166–168° and $[\alpha]_D^{25}$ +106° (*c* 2, $CHCl_3$). Reported (2) for VII, m.p. 165–166° and $[\alpha]_D^{15}$ +109.5° (*c* 2.1, $CHCl_3$). A mixed melting point with I (m.p. 163–164°) was depressed to 133–150°.

In a separate experiment, 50 mg of VI was shaken for 3 days at room temperature with 200 mg of Raney nickel prior to refluxing for 3 hours. Isolation as above gave, on cooling the ethanol solution, 26 mg (71%) of VIII, m.p. 217–218°.

Methyl 3-O-Benzoyl-4,6-O-benzylidene-2-O-(p-toluene)sulphonyl-α-D-glucopyranoside (X)

To 100 mg of VIII in 2 ml of anhydrous pyridine was added 58 mg of (*p*-toluene)sulphonyl chloride. After being left to stand overnight, the solution was poured into 50 ml of ice water. A solid product was obtained which was recovered by filtration and washed with water. It crystallized from ethanol, giving 125 mg (91%), m.p. 213–214° and $[\alpha]_D^{25}$ +52.4° (*c* 0.8, $CHCl_3$). Reported for X: m.p. 212–213°, $[\alpha]_D^{15}$ +51.6° (*c* 2.9, $CHCl_3$).

Methyl 2-O-Benzoyl-4,6-O-benzylidene-3-O-(p-toluene)sulphonyl-α-D-glucopyranoside (IX)

Compound VII (200 mg) was tosylated as described above except that 4 days' reaction time was required. The yield of IX was then 50%; the product, crystallized from ethanol, had m.p. 185–186° and $[\alpha]_D^{25}$ +78.9° (*c* 2.8, $CHCl_3$). Reported (2): m.p. 184–186° and $[\alpha]_D^{15}$ +83.8° (*c* 4.2, $CHCl_3$).

Resynthesis of VI from VIII

To 240 mg of VIII dissolved in 1 ml of anhydrous pyridine was added 140 mg of II. After 10 hours at room temperature, the product was isolated by the usual procedure. Evaporation of the chloroform gave a sirup which crystallized from ethanol, giving 220 mg (73%) after recrystallization from that solvent. This product had m.p. 138–139° and $[\alpha]_D^{25}$ +45.0° (*c* 2, $CHCl_3$). Found before: the same m.p. and $[\alpha]_D^{25}$ +44.5°. The melting point was not depressed after admixture with VI obtained by benzoylation of III.

Methyl 2-O-Benzoyl-4,6-O-benzylidene-3-O-(benzylthio)carbonyl-α-D-glucopyranoside (XI)

To 196 mg of VII in 1 ml of anhydrous pyridine was added 186 mg of II. The solution stood for 3 hours at room temperature (drying tube), and was then poured into 50 ml of ice water, giving a solid which was recovered by filtration. Two crystallizations from ethanol gave 130 mg (48%) of product as needles having m.p. 133–135° and $[\alpha]_D^{25}$ +107° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{29}H_{28}O_8S$: C, 64.93; H, 5.23; S, 5.97. Found: C, 65.37; H, 5.43; S, 5.73.

Methyl 3,4,6-Tri-O-benzoyl-2-O-(benzylthio)carbonyl-α-D-glucopyranoside (XII)

To 0.5 g of IV in 5 ml anhydrous pyridine was added 1 ml of benzoyl chloride. Isolation in the usual way gave a sirup with $[\alpha]_D^{25}$ +28.0° (*c* 2, $CHCl_3$) which failed to crystallize.

Methyl 3,4,6-Tri-O-benzoyl-α-D-glucopyranoside (XIII)

The product XII from above was dissolved in 10 ml of glacial acetic acid containing 1 ml of chloroform. Sodium acetate (150 mg) and 2 ml of 30% hydrogen peroxide were added and the solution was kept for 5 days at room temperature. The solution was then poured into 200 ml of ice water containing sufficient sodium bicarbonate to neutralize the acetic acid. The product was extracted into chloroform, and the latter was dried and evaporated, leaving a sirupy product which crystallized from ligroin. After recrystallization from ligroin there was obtained 391 mg (72%) of product as needles having m.p. 103–105° and $[\alpha]_D^{25}$ +75.5° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{28}H_{26}O_9$: C, 66.40; H, 5.14. Found: C, 66.52; H, 5.09.

Methyl 3,4,6-Tri-O-benzoyl-2-O-(p-toluene)sulphonyl-α-D-glucopyranoside (XIV)

To 100 mg of XIII in 1 ml of pyridine was added 100 mg of (*p*-toluene)sulphonyl chloride. After being left to stand overnight, the solution was poured into 50 ml of ice water; a solid product was obtained which crystallized from ligroin. There was obtained after recrystallization from that solvent 103 mg (79%) of product having m.p. 158–159° and $[\alpha]_D^{25}$ +67.2° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{35}H_{32}O_{11}S$: C, 63.64; H, 4.85; S, 4.85. Found: C, 63.50; H, 5.35; S, 4.91.

For personal use only.

Methyl 3-O-Benzoyl-2-O-(p-toluene)sulphonyl-α-D-glucopyranoside (XV)

Compound X (125 mg) was treated as described before for the synthesis of IV. After two crystallizations from acetone – petroleum ether, the product (82 mg, 80%) was obtained as large needles having m.p. 192–193° and $[\alpha]_D^{25}$ +114° (*c* 2, acetone). Anal. Calc. for $C_{21}H_{24}O_9S$: C, 55.77; H, 5.32; S, 7.08. Found: C, 55.40; H, 5.66; S, 6.78.

Benzoylation of 15 mg of XV by the usual procedure gave 11 mg of product having $[\alpha]_D^{25}$ +66.5° (*c* 0.2, $CHCl_3$) and m.p. 157–158°. Admixture of this product with XIV synthesized from XIII did not depress the melting point.

Methyl 3,4-Di-O-benzoyl-2-O-(benzylthio)carbonyl-α-D-glucopyranoside (XVII)

One gram of IV was tritylated as described before and 1.2 ml of benzoyl chloride was added to the pyridine solution after 2 days. After a third day, the product was isolated by the usual procedure and was obtained as a glass having $[\alpha]_D^{25}$ +19° (*c* 2, $CHCl_3$). This product was dissolved in 6 ml of glacial acetic acid, and 1 ml of acetic acid saturated with hydrogen bromide was added, the solution being kept cool with an ice bath. The triphenylmethyl bromide (0.75 g) was recovered by filtration, and the solution was poured into 100 ml of ice water containing 1 g of sodium bicarbonate. The water was decanted from the sirup, and the latter was then dissolved in chloroform. After washing, drying, and evaporating the chloroform, there was obtained a sirup with $[\alpha]_D^{25}$ +13° (*c* 2, $CHCl_3$).

Methyl 3,4-Di-O-benzoyl-α-D-glucopyranoside (XVIII)

The product from the above reaction was dissolved in 10 ml of glacial acetic acid containing 3 ml of chloroform. Sodium acetate (275 mg) and 3 ml of hydrogen peroxide were added and the solution was kept for 4 days at room temperature. It was then poured into 200 ml of ice water containing sufficient sodium bicarbonate to neutralize the acetic acid. Evaporation of the chloroform left the product as a solid suspended in the water. This product was recovered by filtration and washed thoroughly with water. It could not be induced to crystallize. The yield was 0.69 g (59% based on IV) and the amorphous product had $[\alpha]_D^{25}$ +32° (*c* 0.5, acetone). Anal. Calc. for $C_{21}H_{22}O_8$: C, 62.68; H, 5.48. Found: C, 61.83; H, 5.61.

Methyl 3,4-Di-O-benzoyl-2,6-di-O-(p-toluene)sulphonyl-α-D-glucopyranoside (XIX)

To 60 mg of XVIII in 1 ml of anhydrous pyridine was added 200 mg of (*p*-toluene)sulphonyl chloride. After 3 days the solution was poured into 50 ml of ice water; a solid product was obtained, which was recovered by filtration. After two crystallizations from ligroin, there was obtained 51 mg of product (48%) as needles which had m.p. 189–190° and $[\alpha]_D^{25}$ +25.9° (*c* 1, $CHCl_3$). Anal. Calc. for $C_{35}H_{34}O_{12}S_2$: C, 59.16; H, 4.78; S, 9.02. Found: C, 60.29; H, 5.06; S, 9.41.

Methyl 3-O-Benzoyl-2-O-(p-toluene)sulphonyl-6-O-trityl-α-D-glucopyranoside (XX)

To 300 mg of XV in 5 ml anhydrous pyridine was added 240 mg of triphenylmethyl chloride. While being protected with a drying tube, the solution was warmed on the steam bath for 2 hours, after which it was poured into ice water. The solid product thus obtained was recovered by filtration and crystallized from ethanol, giving 429 mg (93%), m.p. 174–176°. Recrystallization from ligroin did not change the melting point of the product, which had $[\alpha]_D^{25}$ +90.0° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{40}H_{38}O_9S$: C, 69.16; H, 5.48; S, 4.61. Found: C, 69.39; H, 5.37; S, 4.64.

Methyl 3,4-Di-O-benzoyl-2-O-(p-toluene)sulphonyl-6-O-trityl-α-D-glucopyranoside (XXI)

To 330 mg of XX in 3 ml of anhydrous pyridine was added 120 mg of benzoyl chloride and this solution was heated for 1 hour on the steam bath (drying tube). The addition of ice water (50 ml) gave a solid product, which was crystallized from ethanol and then ligroin; there was thus obtained 210 mg (61%) of product in a low-melting crystalline form (m.p. 89–91°). Recrystallization from ligroin gave large needles, m.p. 179–181° and $[\alpha]_D^{25}$ +38.0° (*c* 1, $CHCl_3$). Anal. Calc. for $C_{47}H_{42}O_{10}S$: C, 70.67; H, 5.27; S, 4.01. Found: C, 70.56; H, 5.25; S, 4.30.

Methyl 3,4-Di-O-benzoyl-2-O-(p-toluene)sulphonyl-α-D-glucopyranoside (XXII)

Compound XXI (140 mg) was detritylated as previously described; there was obtained 50 mg (52%) of product which was crystallized twice as fine needles from ligroin. The product had m.p. 70–72° and $[\alpha]_D^{25}$ +18.0° (*c* 0.5, $CHCl_3$). Anal. Calc. for $C_{28}H_{28}O_{10}S$: C, 60.43; H, 5.04; S, 5.76. Found: C, 60.80; H, 5.07. For an unexplained reason, sulphur analyses were high, 6.7 and 7.1

This product (24 mg) was tosylated as previously described, giving 16 mg of product, which after two crystallizations from ligroin had m.p. 190–192°. The m.p. was not depressed after admixture with XIX obtained from tosylation of XVIII.

Methyl 3-O-Benzoyl-α-D-glucopyranoside

This compound was synthesized from 0.5 g of VIII by a method previously described. The product was obtained as an amorphous solid having $[\alpha]_D^{25}$ +169° (*c* 2, $CHCl_3$). Anal. Calc. for $C_{14}H_{18}O_7$: C, 56.37; H, 6.04. Found: C, 55.71; H, 6.34.

To 100 mg of this product dissolved in 1 ml of benzaldehyde was added 100 mg of anhydrous zinc chloride. After the mixture was shaken for 3 hours, it was treated with ice water and petroleum ether; the product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was thus obtained as a solid, which was recovered by filtration and crystallized twice from ethanol. There was obtained 120 mg (93%) of product having m.p. 216–217° and $[\alpha]_D^{25}$ +34.0° (*c* 1, $CHCl_3$). The melting point was not depressed after admixture with VIII.

ACKNOWLEDGMENT

This investigation was carried out during the tenure of a Postdoctoral Fellowship supported by the National Science Foundation.

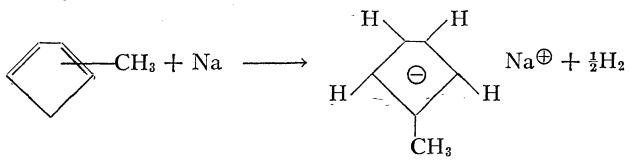
NOTES

THE NUCLEAR MAGNETIC RESONANCE SPECTRUM OF SODIUM METHYLCYCLOPENTADIENIDE

STEWART MCLEAN AND PETER HAYNES

The nuclear magnetic resonance spectrum of sodium cyclopentadienide in several solvents has already been described (1). Our results, obtained with a *colorless* 4 mole% solution of sodium cyclopentadienide in tetrahydrofuran, confirm the previous report that the proton spectrum consists of a single line (at 4.38 τ in our system) and that addition of free cyclopentadiene to the solution produces a spectrum that is a simple superimposition of those of the two components, showing that proton exchange between cyclopentadiene and cyclopentadienide anion is a relatively slow process.

The distillate obtained on thermal cracking of methylcyclopentadiene dimer consists principally of a mixture of 1- and 2-methylcyclopentadienes in the ratio of 1:1.2 (2, 3). The mixture can be converted to a single sodium methylcyclopentadienide by several methods, including treatment with sodium sand in a suitable medium.



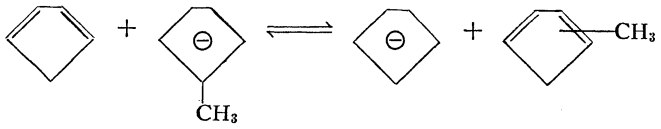
The n.m.r. spectrum of a colorless 4 mole% solution of sodium methylcyclopentadienide in tetrahydrofuran consisted of only two peaks other than those from the solvent: one at 4.58 τ (relative area 4) due to the ring protons, and the other at 7.87 τ (relative area 3) due to the methyl protons. The peaks, which had widths at half height of 1.0 and 1.3 c.p.s. respectively, showed no resolvable fine structure. Two pairs of non-equivalent protons are present on the ring and it must be presumed that the negative charge on the ring produces a "levelling" effect on their environment. The spectrum was relatively insensitive to changes of concentration in the range 4 to 15 mole% sodium methylcyclopentadienide, the shift to higher field at the higher concentration being 5.4 c.p.s. for the ring protons and 3.9 c.p.s. for the methyl protons.

Although it is obvious that throughout the study of these systems a thorough analysis cannot ignore completely the influence of the cation associated with the ring system, it is interesting to note that the introduction of a methyl substituent on the cyclopentadienide anion shifts each of the ring protons 12 c.p.s. to higher field, giving a total effect of +48 c.p.s. for the four protons; this is almost exactly the value obtained by Reddy and Goldstein (4) for the effect of a methyl substituent on the ring proton chemical shifts in a number of uncharged aromatic systems.

The spectrum of the mixture of methylcyclopentadienes is, needless to say, very complex; we merely note at this stage that a solution of our material in tetrahydrofuran gave rise to characteristic spectral patterns at 3.6 to 4.2 τ (vinyl protons), 7.02 to 7.25 τ (methylene protons), and 7.97 to 8.07 τ (methyl protons). Addition of this mixture of isomers to a solution of sodium methylcyclopentadienide produced a spectrum that was

a simple superimposition of the spectra of the components. Once again proton exchange must be a slow process on the scale of nuclear relaxation times.

The addition of methylcyclopentadiene to sodium cyclopentadienide or of cyclopentadiene to sodium methylcyclopentadienide allows proton exchange to be examined on a considerably expanded time scale since products and reactants are no longer indistinguishable. When fractions of an equivalent of cyclopentadiene were added stepwise to a solution of sodium methylcyclopentadienide in tetrahydrofuran, it was possible to observe the growth of the peak attributed to the cyclopentadienide anion at the expense of the methylcyclopentadienide peaks, and it was convenient to use the areas of the peaks associated with ring protons to calculate the relative concentrations of the two anions.* When a full equivalent of cyclopentadiene had been added, the spectrum of the solution did not change appreciably on longer standing. From a comparison of the peak areas associated with the anionic species it is possible to deduce that the equilibrium



lies to the right and that the methylcyclopentadienide ion is an appreciably stronger base than the cyclopentadienide anion. We are as yet unable to express this quantitatively, and a refinement of technique will be necessary before we can do so. The spectrum obtained on addition of methylcyclopentadiene to sodium cyclopentadienide confirmed that the equilibrium could be approached from either direction.

We were interested to observe that the spectrum of the mixture of methylcyclopentadienes produced from sodium methylcyclopentadienide and cyclopentadiene was identical with that of the material obtained by cracking the dimer. Thermal cracking of the dimer must, therefore, lead to the equilibrium mixture of methylcyclopentadienes, as we had suspected from other evidence.

EXPERIMENTAL

Cyclopentadiene and *methylcyclopentadiene* were prepared by thermally cracking the appropriate dimer (at 170° and 200° respectively).

Sodium cyclopentadienide and *sodium methylcyclopentadienide* solutions of the required concentration were prepared by adding a calculated amount of the corresponding diene to a stirred suspension of sodium sand in dry tetrahydrofuran (distilled from $LiAlH_4$ and stored over sodium wire) under an atmosphere of dry, oxygen-free nitrogen. When the reaction was complete, the colorless solution was transferred via a side arm incorporating a sintered-glass filter into the n.m.r. sample tube, which was then sealed. A stream of nitrogen was used to drive the solution through the side arm and the whole apparatus was blanketed with another stream of nitrogen. The concentration of the filtered solution was determined by adding an aliquot to an excess of standard HCl solution and back-titrating (pH meter) with standard NaOH solution.

Nuclear magnetic resonance spectra were obtained at 22° using a Varian DP 60 high-resolution spectrometer operating at 60 Mc/sec and equipped with a field stabilizer. A precision bore (5 mm) spinning tube with a gas-tight ground-glass stopper was used. Operations requiring the addition of a further component to the solution in the tube were carried out under nitrogen. Chemical shifts (τ values (5)) were determined using tetramethylsilane (1–2%) as an internal reference and utilizing the audio side-band technique; a preliminary check showed that the addition of tetramethylsilane did not change the character of the spectrum.

**It is of interest that when the two peaks were of equal height, the width at half height of the methylcyclopentadienide peak was 1.8 c.p.s. while that of the cyclopentadienide peak was 0.9 c.p.s., indicative of unresolved coupling in the former case.*

ORGANIC PEROXIDES
V. OXIDATION OF ARYLLITHIUM COMPOUNDS TO PHENOLS

H. S. Chang and J. T. Edward

Low yields of phenols are obtained by the oxidation of arylmagnesium halides with molecular oxygen, but they may be improved by carrying out the oxidation in the presence of an aliphatic Grignard reagent (1). The reasons for this improvement have been discussed by Walling and Buckler (2). Aryllithium compounds are also oxidized to phenols by molecular oxygen in low yields (3, 4), and we have carried out the oxidation in the presence of butyllithium in the hope of improving the yield. This hope proved illusory, as shown by the results in Table I. Better yields were obtained when oxidation was effected by *t*-butyl hydroperoxide (cf. ref. 4), but were still sometimes low. The oxidations of the α-furyllithium compounds were suggested by the successful oxidation of α-thienyllithium (5), and expected to yield the unsaturated lactones tautomeric with the α-furanols (6); in the event, only intractable, high-boiling tars were obtained.

TABLE I

Yields (%) of phenols from the oxidation of aryllithium compounds with different oxidizing agents

EXPERIMENTAL

Oxidation with Molecular Oxygen

The preparations of phenyllithium (7), *p*-biphenylyllithium (7), α-furyllithium (8), and 5-methyl-2-furyllithium (8) were carried out according to the literature; 2-methoxy-1-naphthyllithium was prepared in 80% yield (estimated by titration) from 1-bromo-2-methoxy naphthalene by the conventional procedure (7). Dry oxygen was bubbled through the ether solutions of the organolithium compounds for several hours. This represents a large excess of oxygen over that stoichiometrically required; in separate experiments it was shown that use of the stoichiometric quantity offered no advantage. The ether solutions were then worked up in the usual way.

Phenol, extracted from the ether solution with aqueous sodium hydroxide, was estimated in the extract by titration (9); this accounts for yields slightly higher than those reported (3, 4), which were based on the isolation of the product. *p*-Hydroxybiphenyl was isolated as a crystalline solid, m.p.161°, identified by mixed m.p. The phenolic fraction from the oxidation of 2-methoxy-1-naphthyllithium (0.014 mole) was obtained as a brown gum (0.58 g), which was chromatographed on Woelm alumina (activity II–III) in hexane solution. Elution with hexane–benzene 4:1 (v/v) gave 2-methoxy-1-naphthol as a gummy solid, crystallizing from hexane as colorless needles (0.17 g; 7%), m.p. 53.5–54.5°. Calc. for $C_{11}H_{10}O_2$: C, 75.86; H, 5.75%. Found: C, 75.70; H, 5.78%. Infrared spectrum: $\nu_{max}^{CCl_4}$ in cm^{-1}: 3530 (m), 3040 (m), 2940 (m), 2820 (m), 1650 (m), 1600 (m), 1490 (s), 1410 (m), 1380 (m), 1360 (s), 1280 (s), 1200 (m), 1180 (w), 1100 (s), 1060 (s), 905 (s). Treatment of this compound with benzoyl chloride in pyridine gave an oily product. The oil in benzene solution was washed with aqueous alkali, dried over magnesium sulphate, and recovered by evaporation. It was then taken up in hexane and chromatographed on Woelm alumina (activity II–III). Elution with hexane–benzene 4:1 (v/v) gave 2-methoxy-1-naphthyl benzoate, crystallizing from hexane in colorless rods, m.p. 104–105°. Calc. for $C_{18}H_{14}O_3$: C, 77.69; H, 5.03%. Found: C, 77.48; H, 4.93%. Infrared spectrum: $\nu_{max}^{CCl_4}$ in cm^{-1}: 3050 (w), 3020 (w), 2985 (w), 2860 (w), 1750 (s), 1645 (m), 1609 (m), 1515 (w), 1485 (w), 1459 (m), 1385 (m), 1353 (w), 1318 (w), 1280 (s), 1247 (s), 1190 (m), 1175 (s), 1155 (m), 1150 (m), 1100 (s), 1080 (s), 1067 (s), 1023 (s), 923 (w), 695 (m). Chakravarti and Pasupati (10), who oxidized 2-methoxy-1-naphthylmagnesium bromide with molecular oxygen, did not isolate the napthol, but converted it to 2-methoxy-1-naphthyl benzoate, m.p. 110°, in low, unspecified overall yield.

Oxidation with t-Butyl Hydroperoxide

Commercial hydroperoxide (84% by titration; 1 mole) in anhydrous ether was added slowly to a stirred ether solution of the aryllithium compound (2.2 moles). Stirring was continued for 2–3 hours, and the mixture then poured into ice water and worked up in the usual fashion. Crystallization from hexane of the gummy phenolic fraction obtained from 2-methoxy-1-naphthyllithium gave white crystals (7% yield) decomposing above 288°, presumably of *4,4′-dihydroxy-3,3′-dimethoxy*-1,1′-*binaphthyl* (cf. ref. 11), although a satisfactory analysis could not be obtained for the compound. Calc. for $C_{22}H_{18}O_4$: C, 76.30; H, 5.20%. Found: C, 75.39; H, 5.02%. (Chakravarti and Pasupati (10) reported obtaining in unspecified yield from the oxidation of 2-methoxy-1-naphthylmagnesium bromide with molecular oxygen a solid melting above 300°, which they did not analyze.) However, the *dibenzoate*, obtained by treatment of the binaphthol with benzoyl chloride in pyridine, crystallized from benzene in colorless rods, m.p. 346–348°, of satisfactory purity. Calc. for $C_{36}H_{25}O_6$: C, 77.97; H, 4.67%. Found: C, 77.98; H, 4.88%. The mother liquors from 4,4′-dihydroxy-3,3′dimethoxy-1,1′-binaphthyl were chromatographed as before to yield 2-methoxy-1-naphthol (Table I).

Symposium on Organometallic Compounds

The papers that follow were presented at a symposium held at the University of British Columbia, Vancouver, British Columbia, on September 4, 5, and 6, 1962, under the joint auspices of the Inorganic Chemistry Division of the Chemical Institute of Canada, and the Department of Chemistry of the University of British Columbia.

THE EFFECT OF SUBSTITUENTS ON THE STABILITIES OF COMPLEXES OF PLATINUM WITH ARYL ACETYLENES AND PHOSPHINES[1]

A. D. Allen and C. D. Cook
Department of Chemistry, University of Toronto, Toronto, Ontario

Received October 29, 1962

ABSTRACT

Compounds of platinum (0) with aryl phosphines are stabilized by electron-withdrawing substituents. A maximum coordination number of three is observed in such cases, suggesting that platinum tetracarbonyl cannot be prepared. Compounds in which one phosphine is replaced by an aryl acetylene are also stabilized by electron withdrawal by the acetylene and quantitative data are given on the relative stabilities of these compounds. These data indicate that a two-coordinated diphosphine platinum (0) compound might be stable if an appropriate substituted phosphine is used. The effect of substituents on the stabilities of these compounds is discussed.

Ligands which stabilize zero oxidation states of the transition metals are generally those which are capable of donating electrons to and accepting electrons from the metal atom. The clearest example of this is carbon monoxide in the metal carbonyls. It follows that the ability of the metal atom to accept and donate electrons is an important factor in the formation of such compounds. The stabilities, occurrence, and absence of carbonyls of the various transition metals have been the subject of much speculation (1), and in particular the absence of carbonyls of palladium and platinum, in contrast to the ready formation of nickel carbonyl, has been related to the higher ionization potential of the d^{10} spin-paired state of these two elements (1). Although no tetracarbonyls of palladium or platinum have been prepared, mixed derivatives containing carbon monoxide and ligands such as phosphines (2), amines, and halogens (3) exist, presumably because these other ligands are stronger electron donors and weaker electron acceptors than carbon monoxide and thus do not compete so strongly for the metal *d* electrons. No compound with more than two molecules of carbon monoxide attached to platinum has been prepared. Even for nickel carbonyl there is evidence (4) that loss of one carbon monoxide occurs readily, leaving a relatively stable tricarbonyl intermediate.

It appears that the requirement for ligands which are most likely to stabilize the zero oxidation state of platinum is that they should be slightly better electron donors and weaker electron acceptors than carbon monoxide. Phosphines, arsines, sulphides, and unsaturated hydrocarbons are obvious possibilities, and various compounds containing these ligands have been prepared (5). These ligands form an ideal system for study, since their donor and acceptor properties can be modified by introducing suitable substituents, particularly if an aromatic nucleus is attached to the bonding atoms.

[1]*Presented at the Symposium on Organometallic Compounds, Vancouver, British Columbia, September 4–6, 1962, sponsored by the Inorganic Chemistry Division, Chemical Institute of Canada, and the Department of Chemistry, University of British Columbia, with the support of the National Research Council, Ottawa, in cooperation with the University Extension Department.*

Malatesta and Cariello (5) observed that triphenylphosphine forms compounds with platinum (0) containing three and four phosphines. Recently Chopoorian, Lewis, and Nyholm (6) have reported that these compounds should be regarded as hydrides of bivalent platinum. We have found (7) that the triphenylphosphine–platinum system is complicated and that both hydrides and non-hydrides are formed under different conditions, but that the products are difficult to characterize adequately, the composition changing during purification procedures. Malatesta and Cariello also found that not more than three tri-*p*-chlorophenylphosphine ligands could be attached to platinum (0). We find the same behavior with tri-*p*-fluorophenylphosphine and have demonstrated (8) that the very stable three-coordinated compound formed is not a hydride. These results indicate that triphenylphosphine is just too weak an electron acceptor to give very stable platinum (0) compounds, but that when electron-withdrawing groups are introduced the substituted phosphine strongly stabilizes the three-coordinated compound. Since there is no steric change on going from triphenylphosphine to the substituted compound, failure to obtain the four-coordinating compound must be attributed to the nature of the bonding involved. Monodentate ligands which can accept electrons sufficiently strongly apparently do stabilize the zero oxidation state of platinum, but only three such ligands can then be attached. Thus it is extremely unlikely that platinum tetracarbonyl could form, and it seems that carbon monoxide depends too strongly on electron acceptance even to form a stable tricarbonyl. A platinum dicarbonyl might be kinetically unstable, but there is some evidence from our work with acetylenic complexes that a relatively stable reaction intermediate is formed with only two triphenylphosphines attached to platinum. The possibility of increasing the stability of the two-coordinated compound by using bulky substituents on the phosphines is currently being investigated.

Towards platinum (0), aryl acetylenes behave in a manner very similar to that of the aryl phosphines. Compounds of the general formula $(Ph_3P)_2Pt\cdot ac$, where ac is a substituted acetylene, were first reported by Chatt, Rowe, and Williams (9) in 1957. These may be regarded as tricoordinated compounds in which the triple bond of the acetylene occupies one position. The most stable compound reported was that of di-*p*-nitrophenylacetylene, showing that electron withdrawal by aryl groups attached to the triple bond stabilizes the compound. We have now made a detailed study of the effect of substituents on the stabilities of these compounds (10). The ligand exchange reaction: $(Ar_3P)_2Pt\cdot ac + ac' \rightleftarrows (Ar_3P)_2Pt\cdot ac' + ac$, proceeds smoothly at room temperature in an inert solvent such as cyclohexane, and we have been able to determine spectrophotometrically both the equilibrium position and the kinetic form of the reaction for a wide range of substituted aryl acetylenes and diaryl acetylenes. As an example of the effects observed the results obtained with a series of para-substituted phenyl acetylenes are given in Table I.

The equilibrium constants show clearly that electron-withdrawing substituents stabilize these complexes relative to phenylacetylene. Confirmation of this is given by the kinetic measurements. The initial rates of both the forward and backward reactions are independent of the nature and concentration of the reagent, and are first order with respect to the complex. The rate-determining step thus appears to be the breaking of the metal–acetylene bond, and the rate of the reaction provides a measure of the relative strength of this bond. The complex with the slowest rate of reaction is that of *p*-nitrophenylacetylene and so we may conclude that the bond is strengthened by the strongly electron-withdrawing nitro group.

TABLE I

First-order rate coefficients (k_1) and equilibrium constants (K) for the reactions, in cyclohexane at 28°,

$$(Ph_3P)_2Pt\text{-}p\text{-}X\text{-}C_6H_4CCH + PhCCH \underset{k_1}{\overset{K}{\rightleftharpoons}} (Ph_3P)_2PtPhCCH + p\text{-}X\text{-}C_6H_4CCH$$

p-X-	10^4k_1 (sec^{-1})	$1/K$
p-Nitro-	1.5	105
p-Bromo-	5	10
p-Chloro-	7	10
p-H-	15	1
p-Methoxy-	19	~1

A more detailed examination of the kinetics of these, and other related reactions, particularly when more than one acetylene is present in the reaction mixture, indicates that the intermediate formed in the rate-determining step, $(Ar_3P)_2Pt$, has a significant stability, there being a small activation energy for its reaction with the available acetylenes which varies with the nature of the acetylene, e.g. is less for p-nitrophenylacetylene than for phenylacetylene.

The reaction steps may be written:

$$(Ph_3P)_2Pt\cdot ac \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (Ph_3P)_2Pt + ac$$

$$(Ph_3P)_2Pt + ac' \xrightarrow{k_2} (Ph_3P)_2Pt\cdot ac'.$$

If we assume a steady state for the intermediate $(Ph_3P)_2Pt$, the rate expression for the initial forward reaction is:

$$v = k_1[(Ph_3P)_2Pt\cdot ac]/\left(\frac{k_{-1}}{k_2}\frac{[ac]}{[ac']}\right)+1.$$

In the absence of added acetylene ac, the initial concentration [ac] is zero and a simple first-order expression is obtained, $v = k_1[(Ph_3P)_2Pt\cdot ac]$. If ac is added at a concentration equal to ac′, the denominator becomes $(k_{-1}/k_2)+1$. The effect on the rate of reaction of addition of ac thus depends on the relative magnitudes of k_{-1} and k_2. If both are very large, as would be the case with a very reactive intermediate, k_{-1}/k_2 would approach unity and the denominator would approach a value of 2. Thus for a reactive intermediate we would expect the rate to be approximately halved when [ac] = [ac′]. If k_{-1} is much greater than k_2 a strong retardation of rate will be observed, but if k_2 is much greater than k_{-1} there will be little, if any, inhibition. We find that the rate of the reaction of the phenylacetylene complex with p-nitrophenylacetylene is virtually unaffected by added phenylacetylene, but that the reverse reaction is strongly inhibited by small amounts of added p-nitrophenylacetylene. Thus the intermediate reacts at different rates with different acetylenes, showing that the process involves some activation energy.

The limited availability of the metal d electrons and the competition for them that exists between the various ligands is illustrated by a comparison between complexes of substituted phenyl phosphines. Under the same conditions the phenylacetylene complex with tri-p-fluorophenylphosphine reacts about twice as rapidly, and that with tri-p-tolylphosphine about twice as slowly as the triphenylphosphine complex. Electron

For personal use only.

donation by the methyl groups in tri-*p*-tolylphosphine will reduce the acceptor properties of the phosphorus and hence allow the acetylene to increase the degree of double bonding between it and the metal. This strengthens the metal–acetylene bond and reduces the rate of reaction. The opposite occurs with tri-*p*-fluorophenylphosphine.

The rather delicate balance between the ability of these ligands to stabilize the zero oxidation state of platinum is illustrated by their methods of preparation. Treatment of a suspension of *cis*-dichlorobis(triarylphosphine)platinum (II) in alcohol with hydrazine gives a clear solution which reacts further in a way which depends on the substituent in the aryl phosphine, as shown below:

Substituent in phosphine	Clear solution at room temp. gives	Heating to 70° for 5 minutes gives
p-Methoxy	No product	No product
p-Methyl	No product	No product
p-H	No product	$(Ph_3P)_nPtH_m$?
p-Fluoro	$((p\text{-F—Ph})_3P)_3Pt$ rapidly	—
p-Chloro	$((p\text{-Cl—Ph})_3P)_3Pt$ rapidly	—

Thus electron-donating groups inhibit the formation of the phosphine complexes, and electron-withdrawing groups facilitate their formation. When the clear solution resulting from the reduction of the dichloro complex with hydrazine is treated with excess phenylacetylene, the tri-*p*-methoxy-, tri-*p*-totyl-, and triphenyl-phosphine compounds give the acetylene complexes, the ease and rapidity of formation increasing in the above sequence. With the tri-*p*-fluoro- and tri-*p*-chloro-phenylphosphine compounds the trisphosphine is formed too rapidly to permit the preparation of the acetylene complex in this way. If, however, an excess of the acetylene is added before reduction with hydrazine, the *p*-fluorophenylphosphine compound gives the acetylene complex, but the *p*-chlorophenylphosphine compound still gives only the trisphosphine of platinum (0). We have been unable to prepare an acetylene complex from the *p*-chlorophenylphosphine compound.

These reactions show that by the use of suitable substituents the tendency of this type of ligand to stabilize platinum (0) compounds can be significantly modified. Preliminary results with substituted aryl sulphides indicate that these ligands behave in a similar manner.

ORGANOTIN CHEMISTRY

II. THE REACTION OF DIORGANOTIN OXIDES WITH PHENOLS[1, 2]

WM. J. CONSIDINE, J. J. VENTURA, A. J. GIBBONS, JR., AND A. ROSS
Research Laboratory, Metal and Thermit Corp., Rahway, New Jersey, U.S.A.

Received October 29, 1962

ABSTRACT

The reaction of diorganotin oxides with many compounds containing active hydrogen proceeds to the formation of di-derivatives. With phenols the reaction stops at the distannoxane stage. The synthesis and characterization of several 1,3-diphenoxydistannoxanes is described. On the basis of molecular weights and other evidence, a structure is proposed for these compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The literature (1) reports the reaction of diorganotin oxides with acids, phenols, alcohols, and mercaptans. In the case of phenols the expected product, the diorganotin diphenoxide, would be formed according to reaction [1]. Compounds of structure I have

$$R_2SnO + 2ArOH \rightarrow R_2Sn(OAr)_2 + H_2O \qquad [1]$$

I

been reported in the literature (1 and references cited therein, 2) but without any description of their synthesis or analytical, or other, data to support the claims.

We reacted dibutyltin oxide with 4-methoxyphenol and 4-*tert*-butylphenol. Toluene was used as solvent and the water of reaction was removed by azeotropic distillation and collected in a Dean–Stark trap. The final, constant amount of water isolated never equalled that predicted by [1] and the product which crystallized from the reaction mixture was the starting phenol.

These results caused us to reconsider the applicability of [1] to the reaction of diorganotin oxides and phenols. The insufficiency of water produced and the recovery of starting phenol both suggested that reaction [2] might be an accurate description of the reaction. Compounds of structure II have been disclosed in the patent literature (3) but have never been described in any detail.

$$2R_2SnO + 2ArOH \rightarrow (R_2SnOAr)_2O + H_2O \qquad [2]$$

II

In order to decide between [1] and [2] as the course of the reaction, we reacted a variety of diorganotin oxides and phenols according to the stoichiometries of [1] and [2]. For example, when 2 moles of phenol itself was reacted in toluene with 1 mole of dibutyltin oxide, only 56% of the amount of water required by [1] could be isolated. When equimolar quantities of the two were reacted, the amount of water predicted by [2] was isolated and the compound tetrabutyl-1,2-diphenoxydistannoxane (II, R = *n*-C_4H_9; Ar = C_6H_5) was isolated in a 95% yield.

To give more examples, dimethyl- and diphenyl-tin oxide were reacted with phenol, and dibutyltin oxide was reacted with 4-methoxyphenol, 4-*tert*-butylphenol, 4-nitrophenol,

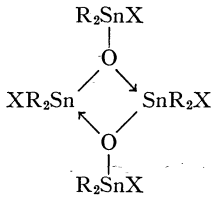
[1]*Presented at the Symposium on Organometallic Compounds, Vancouver, British Columbia, September 4–6, 1962, sponsored by the Inorganic Chemistry Division, Chemical Institute of Canada, and the Department of Chemistry, University of British Columbia, with the support of the National Research Council, Ottawa, in cooperation with the University Extension Department.*

[2]*Part I: Wm. J. Considine and J. J. Ventura. Chem. Ind. In press.*

β-naphthol, hydroquinone, and 2,2-bis(4-hydroxyphenyl)propane (bisphenol A). In every case, when 2 moles of the phenol was reacted with 1 mole of the oxide, only about 50% of the water required by [1] was isolated. When equimolar amounts of reactants were used, high yields of water, according to [2], and the corresponding distannoxanes were isolated. The distannoxanes from hydroquinone and bisphenol A were apparently polymeric in nature. No reaction was observed between dibutyltin oxide and 2,6-di-*tert*-butyl-4-methylphenol due to the steric hinderance of the bulky *tert*-butyl groups.

Tetrabutyl-1,3-diphenoxydistannoxane was isolated as white prisms; m.p. 137–139.5°. The molecular weights, by the Rast procedure, both in camphor and cyclopentadecanone, gave values corresponding to a monomer. When the molecular weight was determined in benzene or carbon tetrachloride solutions at 37.5° in a thermistor osmometer, the results clearly showed a dimer to be present. These observations require a structure which is a dimer, but which allows for an easy thermal dedimerization at the higher temperatures of the Rast determination.

Okawara (4), on the basis of X-ray analysis, has determined the structure of tetramethyl-1,3-bis(trimethylsiloxy)distannoxane as III. Alleston, Davies, and Figgis (5) were unable to choose between IV and V, as structures for tetrabutyl-1,3-dichlorodistannoxane



III, R = CH_3, X = $(CH_3)SiO$ V, R = *n*-C_4H_9, X = Br
IV, R = *n*-C_4H_9, X = Cl VI, R = *n*-C_4H_9, X = OC_6H_5

and tetrabutyl-1,3-dibromostannoxane, and related structures in which the halogens were only on the exocyclic tin atoms. Their conclusions were based on dimeric molecular weights and the occurrence of two overlapping peaks of approximate area, and with chemical shifts close to those of the corresponding dibutyl dihalides, in the ^{119}Sn magnetic resonance spectra of IV and V.

We propose VI as the structure of tetrabutyl-1,3-diphenoxydistannoxane. The molecular weight data is accommodated by the unique four-membered ring. It would be reasonable to expect that the strength of the coordinate bond could be offset by thermal energy and the dimer would revert to the monomers. This dimeric structure also is supported by the melting point behavior of the diphenoxydistannoxanes. Most of the members of this class have a constant, but broad, melting point due to the fact that the phase change observed is not a simple melting point, but rather a dedimerization. The same melting behavior is shown by the nitroso compounds, which are also dimers.

We have not considered any alternates to VI in which the exocyclic tins each bear two phenoxy groups. Dibutyltin diphenoxide (6) is extremely sensitive to hydrolysis, whereas the distannoxane is quite indifferent to water. For this reason it does not seem reasonable to advance a structure which has two phenoxy groups on the same tin.

VI was independently synthesized by reaction [3].

$$[([n\text{-}C_4H_9]_2ClSn)_2O]_2 + 4C_6H_5OH + 4(CH_3CH_2)_3N \rightarrow [([n\text{-}C_4H_9]_2C_6H_5OSn)_2O]_2 + 4(CH_3CH_2)_3N.HCl \quad [3]$$

Mention was made of the extreme sensitivity of the diphenoxide to hydrolysis. It is our view that this fact explains the failure of the diphenoxydistannoxanes to react further

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

with phenols. The further reaction of phenol, to form dibutyltin diphenoxide, would produce water. This water then would hydrolyze the product back to the distannoxane. Dibutyltin oxide does react with, for example, 4-*tert*-butylthiophenol to form dibutyltin di-4-*tert*-butylthiophenoxide in toluene. However, the Sn—S bond is much more resistant to hydrolysis (7) than is the Sn—O bond so the water of reaction does not destroy the product in this case.

EXPERIMENTAL

All melting points are uncorrected.

In the reactions of diorganotin oxides with various phenols described below, the reactions were run under two conditions. In condition A the ratio of moles diorganotin oxide to *equivalents* of the phenol was 1:2. In condition B this ratio was 1:1.

Reactions of Bu_2SnO with Phenol

A (1:2). Phenol (47.1 g, 0.5 mole) was added to a stirred suspension of dibutyltin oxide (67.2 g, 0.25 mole) in 500 ml of anhydrous toluene contained in a 1-liter three-necked flask equipped with a Dean–Stark apparatus, a mechanical stirrer, a reflux condenser, and a drying tube. After 3 hours' refluxing, a constant volume of only 2.5 ml water (0.14 mole, 56%) collected in the trap.

Tetrabutyl-1,3-diphenoxydistannoxane

B (1:1). Phenol (47.1 g, 0.5 mole) was reacted as in A, above, with dibutyltin oxide (124.5 g, 0.5 mole). After 2 hours' reflux a constant volume of 4.5 ml water (0.25 mole, 100%) had been collected. The hazy solution was filtered and the toluene removed by vacuum distillation to give 159.0 g (0.12 mole; 95%) of a yellow oil which set to a light tan solid. Repeated recrystallizations from hexane gave white prisms; m.p., 137–139.5° constant. Anal. Calc. for $C_{56}H_{62}O_6Sn_4$: C, 50.34; H, 6.94; Sn, 35.54; M.W., 1336.10. Found: C, 50.36; H, 6.96; Sn, 35.48; M.W., 661, 682 (Rast, cyclopentadecanone); 675, 692 (Rast, camphor); 1291, 1374 (thermistor osmometer, carbon tetrachloride); 961, 982, 985 (thermistor osmometer, benzene).

Reactions of Bu_2SnO with p-Methoxyphenol

A (1:2). In this example, 78% of the theoretical amount of water could be isolated. The crude reaction product was dissolved in benzene. Upon the addition of pentane, *p*-methoxyphenol was obtained in a recovery of 29%. Its identity was established by a mixed melting point determination, after recrystallization from hexane.

Tetrabutyl-1,3-bis(4-methoxyphenoxy)distannoxane

B (1:1). Water was isolated in the theoretical amount. Removal of the solvent gave the crude product as a solid in 101% yield. Three recrystallizations from pentane gave crystalline material with a constant melting point of 86–89°. Anal. Calc. for $C_{60}H_{100}O_{10}Sn_4$: Sn, 32.61; C, 49.48; H, 6.92. Found: Sn, 32.57, 32.61; C, 49.82, 49.68; H, 6.97; 6.91.

Reactions of Bu_2SnO with p-tert-Butylphenol

A (1:2). Water was isolated in 59% of theory. Recrystallization of the crude product gave *p-tert*-butylphenol as shown by a mixed melting point determination.

Tetrabutyl-1,3-bis(4-tert-butylphenoxy)distannoxane

B (1:1). Water was isolated in the theoretical amount and removal of the solvent gave the product in a yield of 97%. Three recrystallizations from pentane gave white crystals with a constant melting point of 139–142°. Anal. Calc. for $C_{72}H_{122}O_6Sn_4$: Sn, 30.43; C, 55.41; H, 8.01. Found: Sn, 30.15; C, 55.20, 55.19; H, 8.02, 8.11.

Reactions of Bu_2SnO with p-Nitrophenol

A (1:2). Only 53% of the calculated amount of water was obtained.

Tetrabutyl-1,3-bis(4-nitrophenoxy)distannoxane

B (1:1). Water was isolated in 100% yield and the product was obtained directly as a yellow powder by filtration of the reaction mixture, in which it was insoluble. The yield was 99%. The melting point of the crude product, 247–248°, was unchanged when a small portion was recrystallized from toluene. The crude product was dried at 100° and a pressure of 1 mm Hg for 6 hours before analysis. Anal. Calc. for $C_{56}H_{88}N_4O_{14}Sn_4$: C, 44.08; H, 5.61; N, 3.72; Sn, 31.32. Found: C, 43.92; H, 5.71; N, 3.80; Sn, 31.55.

Reactions of Bu_2SnO with β-Naphthol

A (1:2). Only 49% of the theoretical amount of water was isolated.

For personal use only.

Tetrabutyl-1,3-bis(β-naphthoxy)distannoxane

B (1:1). Water was obtained in 100% yield. Removal of the toluene by vacuum distillation gave the product as a brown oil which solidified to a brown solid upon cooling. The yield of the crude product was 104%. Repeated recrystallizations from pentane, including charcoal clarification, gave the product as light tan crystals with a constant melting point of 94–100°. Anal. Calc. for $C_{12}H_{100}O_6Sn_4$: C, 56.29; H, 6.56; Sn, 30.91. Found: C, 56.39, 56.11; H, 6.61, 6.65; Sn, 30.68.

Reactions of Bu_2SnO with Hydroquinone

A (1:1). Only 58% of the calculated amount of water was obtained.

B (1:0.5). Water was obtained in 100% of calculated yield. The reaction mixture was a thick slurry of a white solid which was separated from the toluene by filtration. The product, when dry, was a brown, friable powder, insoluble in toluene, ether, or methanol, which decomposed, without melting, at 310°. It was obtained in 100.5% yield. Anal. Calc. for $(C_{22}H_{40}O_3Sn_2)_x$: Sn, 40.24. Found: Sn, 40.68.

Reactions of Bu_2SnO with 2,2-Bis(p-hydroxyphenyl)propane

Dibutyltin oxide (248.8 g, 0.1 mole) and 2,2-bis(*p*-hydroxyphenyl)propane were added to 200 ml of benzene contained in a three-necked flask equipped with a mechanical stirrer, a Dean–Stark apparatus, and a reflux condenser with a drying tube. During stirring, the reaction mixture was heated to, and held at, the reflux temperature for 3 hours. Two milliliters of water (0.08 mole; 80%) was collected in the trap. The reaction mixture was filtered, while hot, and allowed to cool.

Overnight, white solids formed, which were isolated by filtration and air-dried; yield 20 g (66%). Washing of the crude product with cold methanol caused a weight loss of 1 g and gave material with m.p. 268–274°. Recrystallization from toluene raised the melting point to 302–305° (decomp.). Anal. Calc. for $(C_{31}H_{50}O_3Sn_2)_x$: Sn, 33.53; C, 52.57; H, 7.12. Found: Sn, 32.87; C, 52.59; H, 7.18.

Reactions of Diphenyltin Oxide with Phenol

A (1:2). Only 50% of the theoretical amount of water was obtained.

Tetraphenyl-1,3-diphenoxydistannoxane

B (1:1). The reaction mixture was a very thick, pasty, white mass, and an additional 250 ml of anhydrous toluene had to be added to get efficient stirring. The water isolated amounted to 83% of the theoretical amount. The crude reaction product was insoluble in toluene and it was isolated by filtration in a yield, when dry, of 89%. The melting point of the crude material was broad and centered around 250°. Attempts to recrystallize the material were unsuccessful due to its extreme insolubility in all of the solvents tried. It was analyzed without further purification. Anal. Calc. for $C_{72}H_{60}O_6Sn_4$: Sn, 31.74. Found: Sn, 33.12.

Reactions of Dimethyltin Oxide with Phenol

A (1:2). Under these conditions only 53% of the theoretical amount of water could be isolated.

Tetramethyl-1,3-diphenoxydistannoxane

B (1:1). Water was isolated in the theoretical yield. Removal of the solvent gave a 94% yield of the product as a white solid. Recrystallizations from both hexane and cyclohexane gave a crystalline product with a constant, but broad, melting range of 190–197° C. Anal. Calc. for $C_{32}H_{22}O_6Sn_2$: Sn, 47.51. Found: Sn, 48.24, 48.28, 48.21.

Reactions of Bu_2SnO with 2,6-Di-tert-butyl-p-methylphenol

A (1:2). This reaction was not run under condition A.

B (1:1). After 12 hours' reflux the water isolated was only a constant 2.5% of the theoretical.

Synthesis of Tetrabutyl-1,3-diphenoxydistannoxane from Tetrabutyl-1,3-dichlorodistannoxane

Phenol (0.1 g; 107 mmoles) and tetrabutyl-1,3-dichlorodistannoxane (28.3 g, 27 mmoles) were dissolved in 100 ml of anhydrous benzene. During stirring, triethylamine (10.8 g, 107 mmoles) was added over a period of 5 minutes. The temperature rose from ambient to 42° and a white precipitate formed. Stirring was continued for 2 hours.

The reaction mixture was washed with a 100-ml and a 50-ml portion of water to remove triethylamine hydrochloride. The organic layer dried over anhydrous magnesium sulphate and was freed of benzene to give 33.0 g (24 mmoles, 89%) of off-white crystals with a melting point of 137.5–139°, undepressed when admixed with the material prepared as above. The infrared spectra of the materials prepared by both methods were congruent.

After recrystallization from hexane, the X-ray powder pattern of the product was identical with that of the material prepared as above.

Treatment of Tetrabutyl-1,3-diphenoxydistannoxane

Tetrabutyl-1,3-diphenoxydistannoxane (33.4 g, 25 mmoles) and phenol (9.4 g, 100 mmoles) were dissolved in 50 ml of anhydrous toluene and the solution was heated to reflux in a flask fitted with a Dean–Stark apparatus, a reflux condenser, and a drying tube. After 48 hours' reflux, 0.2 ml of water (11 mmoles, 22%) had collected in the trap. After an additional 48 hours of reflux no more water had collected.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The toluene was removed by distillation, at atmospheric pressure, to a pot temperature of 160°. The stripped residue was subjected to vacuum distillation and 2.9 g (31 mmoles, 31%) passed over at 63° at 5 mm. These white needles were identified as phenol by their melting point of 37–41°, undepressed when admixed with authentic material.

The distillation residue, a brownish crystalline solid, weighed 38.3 g. Recrystallization from hexane raised the melting point considerably but pure tetrabutyl-1,3-diphenoxydistannoxane could not be recovered. The infrared spectra showed the presence of an —OH band which points to phenol as the difficultly removable contaminant.

Synthesis of Dibutyltin Di-p-tert-butylthiophenol

Dibutyltin oxide (106.2 g, 427 mmoles) and *p-tert*-butylthiophenol (142.0 g, 854 mmoles) were added to 500 ml of anhydrous benzene contained in a 1-liter three-necked flask fitted with a mechanical stirrer, a Dean–Stark apparatus, a reflux condenser, and a drying tube. During stirring the mixture was heated to ithe reflux and held there for 3½ hours, during which period 7.7 ml of water (427 mmoles, 101%) was collected n the trap. Removal of benzene left 229 g (406 mmoles, 95%) of a hazy yellow liquid. Fractionation gave material boiling at 191–200° at 0.1 mm Hg, N_D^{29} 1.5744. Anal. Calc. for $C_{28}H_{44}S_2Sn$: Sn, 21.07; S, 11.40. Found: Sn, 20.72, 20.66, 20.83; S, 11.61.

ACKNOWLEDGMENTS

The analyses were performed by Mr. H. Corbin and his associates with the exception of C, H determinations, which were done by Spang Microanalytical Laboratory, Ann Arbor, Michigan. The molecular weights and spectra were determined by Mr. I. Simmons and his associates.

ORGANOGERMANIUM COMPOUNDS

PART II. INFRARED SPECTRA OF SOME ACETOXYGERMANES AND THE RELATIVE INDUCTIVE EFFECTS OF TRIMETHYLSILYL AND TRIMETHYLGERMYL GROUPS[1, 2, 3]

T. N. SRIVASTAVA[4] AND M. ONYSZCHUK

Inorganic Chemistry Laboratory, McGill University, Montreal, Que.

Received October 29, 1962

ABSTRACT

The infrared spectra of GeH_3OCOCH_3 and $(CH_3)_3GeOCOCH_3$ have been measured in the gas phase over the range 650–3800 cm^{-1}. Assignments for the principal bands have been made and their values compared with those of analogous alkyl, methylsilyl, methyltin, and methyllead acetates. Carbonyl absorption bands shift to lower frequencies and carbon–oxygen (skeletal) absorptions to higher frequencies as M changes from C to Si to Ge in the series of acetates represented by $(CH_3)_3MOCOCH_3$. These results suggest that the Ge—O bond is more polar than the Si—O bond and that the order of electron release in acetate derivatives is $(CH_3)_3Ge > (CH_3)_3Si > (CH_3)_3C$, which is consistent with the electronegativity order: C > Si > Ge.

INTRODUCTION

The infrared spectra of all but the germanium compound in the series of acetates with general formula $(CH_3)_3MOCOCH_3$, where M is a Group IV*b* element, have now been reported. Okawara, Webster, and Rochow (1) examined the infrared spectra of several methylsilicon and methyltin acetates, and they concluded, on the basis of the positions of the carbonyl stretching bands, that the Si—O bonds in the former are covalent while the Sn—O bonds in the latter are ionic. Later, Okawara and Sato (2) interpreted the infrared spectrum of trimethyllead acetate as the superimposition of absorptions due to the acetate anion and the trimethyllead cation.

We have examined the infrared spectra of acetoxygermane, GeH_3OCOCH_3, and trimethylacetoxygermane, $(CH_3)_3GeOCOCH_3$, with the object of determining the nature of the Ge—O bond. These new compounds have been prepared recently in this laboratory in connection with our interests in the preparation and properties of germyl (3) and trimethylgermyl (4, 5) compounds.

EXPERIMENTAL

The interaction of silver acetate with monobromogermane and trimethylbromogermane in a vacuum was used for the preparation of acetoxygermane (3) and trimethylacetoxygermane (5), respectively. Both compounds were purified by fractional distillation in a vacuum and tensimetrically pure samples were used for infrared spectral measurements (vapor pressures were 9.7 mm at 0° for GeH_3OCOCH_3 and 7.1 mm at 15° for $(CH_3)_3GeOCOCH_3$). The spectrum of *tert*-butyl acetate (Eastman Kodak, redistilled) was also recorded because we were unable to find its spectrum in the chemical literature.

Spectra were recorded on a Perkin–Elmer, Model 21, double-beam spectrometer equipped with a NaCl prism and calibrated with CO_2 and H_2O. In the range 650 to 2000 cm^{-1} wave numbers are accurate to ± 3 cm^{-1}, and to ± 10 cm^{-1} above 2000 cm^{-1}. Samples were examined as liquids in capillary film or in carbon tetrachloride solution, and/or as gases contained at measured pressures in glass cells of 10-cm length and 5-cm diameter fitted with 5 mm thick NaCl end plates.

RESULTS AND DISCUSSION

The spectra of acetoxy- and trimethylacetoxy-germane are shown in Fig. 1, and the frequency assignments are summarized in Table I; these assignments are discussed separately as follows.

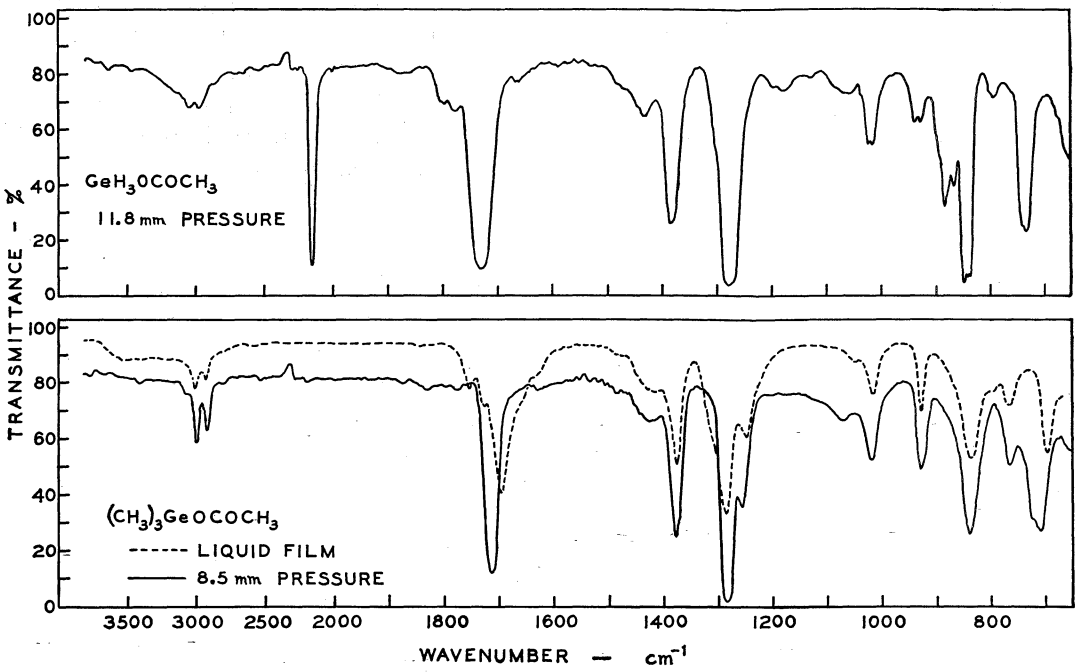

FIG. 1. Infrared spectra of GeH_3OCOCH_3 and $(CH_3)_3GeOCOCH_3$.

TABLE I

Vibrational assignments for gaseous GeH_3OCOCH_3 and $(CH_3)_3GeOCOCH_3$

GeH_3OCOCH_3 bands (cm^{-1})	$(CH_3)_3GeOCOCH_3$ bands (cm^{-1})	Assignment
3045 w	2995 w	C—H asym. stretching (CH_3—C)
2970 w	2920 w	C—H sym. stretching (CH_3—C)
2150 vs	—	Ge—H asym. and sym. stretching (GeH_3—)
1727 vs	1715 vs	C=O stretching
1432 w	1426 w	C—H asym. deformation (CH_3—C & CH_3(—Ge))
1383 s	1376 s	C—H sym. deformation (CH_3—C)
1275 vs	1285 vs	Skeletal (C—CO—O—)
—	1257 s	C—H sym. deformation (CH_3(—Ge))
1065 w	1072 w	Combination or CH_3 rocking (CH_3—C)
1017 m	1018 m	Skeletal (C—CO—O—) coupled with CH_3 rocking
932 w	927 m	Skeletal (C—CO—O—) coupled with CH_3 rocking
880 m 862 m 842 s		Ge—O stretching, skeletal (C—CO—O—) coupled, and GeH_3 deformation
	837 s	Ge—O stretching, skeletal (C—CO—O—) coupled, and CH_3(—Ge) rocking
790 w		Combination
730 s	707 s	Skeletal (C—CO—O—) coupled with Ge—O stretching

NOTE: w = weak; m = medium; s = strong; v = very.

C—H Stretching Vibrations

The two distinct weak bands which occur at 3045 and 2970 cm^{-1} in the spectrum of acetoxygermane are attributed to the asymmetrical and symmetrical C—H stretching vibrations of the methyl carboxyl group (CH_3—C), respectively. In methyl acetate (6) the same vibrations are about 10 times weaker than those of the ester methoxy group (—OCH_3). Two weak bands appear at 2995 and 2920 cm^{-1} in the spectrum of trimethylacetoxygermane; they are probably also due to C—H stretching modes of the methyl carboxyl group. However, these bands are remarkably similar in position, shape, and relative intensity to those exhibited by trimethylgermyl halides and pseudohalides (5), in which they are entirely due to C—H stretching vibrations of methyl groups bonded to germanium (CH_3(—Ge)). This strongly suggests that these vibrations also contribute appreciably to the absorptions at 2995 and 2920 cm^{-1} in trimethylacetoxygermane.

Ge—H Stretching Vibrations

In germyl halides (7) and pseudohalides (8) the Ge—H stretching vibrations of the GeH_3 group produce strong and sharp bands in the range 2110–2140 cm^{-1}. The strong and sharp band at 2150 cm^{-1} in acetoxygermane is definitely due to this vibration, but the symmetrical and asymmetrical modes were not resolved by the NaCl prism.

C=O Stretching Vibrations

In acetoxygermane the C=O stretching absorption band is very strong and appears at 1727 cm^{-1}, which is 44 cm^{-1} lower than the corresponding band in gaseous methyl acetate (9). In trimethylacetoxygermane this vibration occurs at 1715 cm^{-1} in the gaseous phase, at 1696 cm^{-1} in the liquid phase, and at 1695 cm^{-1} in carbon tetrachloride solution. These values are significantly lower than those observed for *tert*-butyl acetate and trimethylacetoxysilane as evident from the comparisons made in Table II. The significance of these differences is discussed in a separate section.

TABLE II

Comparison of some vibrational frequencies of Group IV*b* acetates

R (in $ROCOCH_3$)	C=O stretching (cm^{-1})	C—CO—O— skeletal (cm^{-1})	CO—O asymmetric stretching (cm^{-1})	CO—O symmetric stretching (cm^{-1})	Ref.

*This compound has not yet been prepared.

C—H Deformation Vibrations

The weak band at 1432 cm^{-1} and the stronger one at 1383 cm^{-1} in acetoxygermane are due respectively to asymmetrical and symmetrical deformation vibrations of the methyl carboxyl group. Bands of similar shape and relative intensity occur at 1426 and 1376 cm^{-1} in trimethylacetoxygermane, which contains two types of methyl groups, CH_3—C and

CH_3(—Ge), the C—H deformation vibrations of which undoubtedly overlap. In methyl acetate, absorptions near 1430 and 1370 cm^{-1} have been assigned to CH_3—C asymmetrical and symmetrical C—H deformation vibrations, respectively (6, 9). The corresponding C—H deformation modes of CH_3(—Ge) methyl groups in trimethylgermyl halides and pseudohalides (5) appear near 1415 and 1250 cm^{-1}, respectively. These comparisons lead us to suggest that in trimethylacetoxygermane: (i) the 1426 cm^{-1} band results from superimposition of asymmetrical C—H deformation vibrations of CH_3—C and CH_3(—Ge) methyl groups, (ii) the 1376 cm^{-1} band is due only to symmetrical C—H deformation mode of the CH_3—C methyl group, and (iii) the 1257 cm^{-1} band arises from symmetrical deformation vibrations of CH_3(—Ge) methyl groups.

"C—O Stretching Vibrations"

The intense band between 1280 and 1150 cm^{-1} in alkyl carboxylic esters was first assigned to a stretching vibration of the C—O bond adjacent to the carbonyl bond, but it was later shown to involve coupled vibrations of C—C and C—O bonds and is better described as a skeletal stretching vibration of the acetoxy group (C—CO—O—) (10). The strong bands at 1275 and 1285 cm^{-1} in acetoxy- and trimethylacetoxy-germane, respectively, are attributed to this skeletal vibration. These bands are at significantly higher frequencies than the corresponding ones in analogous methyl, *tert*-butyl, and trimethylsilyl acetates (Table II).

Absorption Bands in the Range 1100–650 cm^{-1}

There is much confusion in the literature about assignments of absorption bands below 1100 cm^{-1} in spectra of alkyl acetates. Methyl rocking, C—C stretching, C—O stretching, and acetoxy skeletal vibrations are expected in this region and considerable overlapping and coupling of vibrations is possible. This region is further complicated in acetoxy- and trimethylacetoxy-germane by the presence of Ge—O stretching, GeH_3 deformation, and CH_3(—Ge) rocking vibrations.

The weak bands at 1065 and 1072 cm^{-1} in acetoxy- and trimethylacetoxy-germane, respectively, may be due to combination tones or to CH_3—C methyl rocking vibrations. Stronger bands are observed at 1017 and 1018 cm^{-1} in acetoxy- and trimethylacetoxy-germane, respectively. Similar bands have been reported at 1060 cm^{-1} in methyl acetate (9), at 1046 cm^{-1} in ethyl acetate (11), at 1016 cm^{-1} in methyl laurate (12), and in the range 1020–995 cm^{-1} in a variety of saturated methyl esters (13). Wilmshurst (9) assigned the 1060 cm^{-1} band in methyl acetate to the C—O stretching of the methoxy group, but this has been questioned by Katritzky *et al.* (13) and by Jones (12). Jones suggests that it is more reasonable to regard this band, like the one between 1280 and 1150 cm^{-1}, as a skeletal stretching vibration of the C—CO—O— linkage system. On this basis we assign the bands at 1017 and 1018 cm^{-1} in acetoxy- and trimethylacetoxy-germane, respectively, to C—CO—O— skeletal stretching modes.

Acetoxy- and trimethylacetoxy-germane also exhibit similar bands at 932 and 927 cm^{-1}, respectively. The corresponding band in methyl acetate occurs at 980 cm^{-1} and Wilmshurst (9) has assigned it to a CH_3—C methyl rocking vibration, while Katritzky *et al.* (13) regard it as due to coupling of methyl rocking and C—CO—O— skeletal modes. The latter assignment appears to be more realistic and is proposed for the 932 and 927 cm^{-1} bands in the two acetoxygermanes.

The strongest band in the 800–900 cm^{-1} region of acetoxygermane occurs at 842 cm^{-1} and is undoubtedly due to deformation vibrations of the GeH_3 group, since these occur between 830 and 875 cm^{-1} in germyl halides (7). Two other weaker bands at 880 and 835

cm^{-1} are more difficult to assign. The band at 880 cm^{-1} is attributed to the Ge—O stretching vibration, which occurs near 880 cm^{-1} in alkylgermanium oxides (14). The band at 862 cm^{-1} probably corresponds to a band at 846 cm^{-1} in methyl acetate (13) which, like the band at 980 cm^{-1}, has been assigned to a coupling of methyl rocking and C—CO—O— skeletal vibrations.

The absorption band at 837 cm^{-1} in trimethylacetoxygermane probably results from overlap of the Ge—O stretching vibration, the coupling of methyl rocking with C—CO—O— skeletal vibrations, and rocking vibrations of methyl groups bonded to germanium, all of which are known to occur near 850 cm^{-1}. Since CH_3(—Ge) methyl rocking vibrations also give a band near 750 cm^{-1} in trimethylgermyl halides and pseudohalides (5), it is likely that the band at 767 cm^{-1} in trimethylacetoxygermane is associated with this vibration. The weak band at 790 cm^{-1} in acetoxygermane is probably a combination band. The strong bands at 730 and 707 cm^{-1} in acetoxy- and trimethylacetoxygermane, respectively, are probably due to C—CO—O— skeletal vibrations coupled with the polar Ge—O bond.

Polarity and Relative Inductive Effects

The positions of the carbonyl and carbon–oxygen (skeletal) stretching vibrations are of particular interest because, as Okawara *et al.* (1) have pointed out, they reflect the type of bonding between the acetate group and the group attached to it. Carbonyl stretching vibrations near 1750 cm^{-1} are indicative of covalent bonding, while values near 1570 and 1425 cm^{-1} are characteristic of ionic bonding. This differentiation has been questioned recently by Beattie and Gilson (15),* who examined the effect of acetate bridging on the infrared spectra of some metal acetates. They concluded that there is "no simple way of distinguishing between a discrete acetate ion and a bridging acetate group". If this is true, the positions of carbonyl stretching vibrations cannot be used to distinguish between covalent and ionic bonding in acetates in their solid phase.

The comparisons made in Table II reveal that acetoxy- and trimethylacetoxy-germane resemble alkyl and methylsilyl acetates more than they do sodium, trimethyltin, and trimethyllead acetates. Therefore, it seems reasonable to conclude that the Ge—O bond in acetoxygermanes, like the C—O and Si—O bonds in alkyl and methylsilyl acetates, respectively, is predominantly covalent. The carbonyl stretching frequency is 44 cm^{-1} lower in acetoxygermane than in methyl acetate; there is also a significant decrease from top to bottom in the series of methyl-substituted acetates (Table II). The shift to lower frequencies is probably associated with increasing polarity of the metal–oxygen bond; thus the Ge—O bond is more polar than the Si—O and C—O bonds in acetate derivatives.

Hartwell *et al.* (17) concluded, after a thorough examination of the infrared spectra of a variety of alkyl acetates and related compounds, that variations in carbonyl stretching frequencies are not due to mass effects but mainly to electronic effects induced by attached groups. In support of this Freeman (18) has shown that electronegative groups attached to the α-oxygen atom of carboxylic acid derivatives raise the carbonyl stretching frequency by 15–70 cm^{-1}. This he attributes to inductive effects, although these cannot be differentiated from direct field effects. We found that substitution of a *tert*-butyl group for the methyl group in methyl acetate lowers the carbonyl stretching frequency by 21 cm^{-1} (Table II). This is probably due mainly to the greater positive inductive effect (+I) of

**We are grateful to Dr. R. J. O'Brien of The University of British Columbia for drawing our attention to this paper.*

the *tert*-butyl group, which decreases the electron density at the carbonyl bond thereby decreasing its vibrational frequency. Similarly, the lowering of carbonyl stretching frequencies in methyl-substituted acetates (Table II) is attributed to decreasing electron release in the order $(CH_3)_3Ge > (CH_3)_3Si > (CH_3)_3C$. The positive inductive effect of the first two groups in this series is opposed by a negative inductive effect (−I) resulting from electron release from oxygen to silicon or germanium through supplementary d_π–p_π bonding. If the latter effect were predominant, carbonyl stretching frequencies of trimethylsilyl and trimethylgermyl acetates would be higher than that of *tert*-butyl acetate, contrary to the observed trend.

The order of electron release suggested by our results differs from the following order established by nuclear magnetic measurements on tetramethyl Group IV*b* compounds (19, 20): $(CH_3)_3Si \approx (CH_3)_3Sn > (CH_3)_3Ge \gg (CH_3)_3Pb > (CH_3)_3C$. The interpretation of these measurements has been disputed (21). Our order supports the results described recently by Bott *et al.* (22). They concluded from the rates of some cleavage reactions that towards a methylene group the trimethylgermyl group is slightly more electron releasing than the trimethylsilyl group, which implies that silicon is slightly more electronegative than germanium, contrary to the new electronegativity scale proposed by Allred and Rochow (19). Seyferth and Kahlen (23) suggested that the shift to lower frequencies of N=C stretching vibrations in $RN{=}C{-}Fe(CO)_4$ compounds might be due to decreasing electron release in the series $R = (CH_3)_3Sn \approx (CH_3)_3Ge \approx (CH_3)_3Si > (CH_3)_3C > CH_3$. Apparently the N=C stretching vibrations in these compounds are not sufficiently sensitive to the small differences which undoubtedly exist in the inductive effects of the trimethyl-substituted groups. More work is obviously necessary to clarify the relative inductive effects of these groups.

ACKNOWLEDGMENTS

We thank the National Research Council for a Postdoctoral Fellowship (to T. N. S.) and for an Annual Grant (to M. O.). We are grateful to Mr. J. P. Guertin and Mr. J. M. Miller for technical assistance, and to Dr. R. N. Jones for helpful discussions.

RECENT DEVELOPMENTS IN THE ORGANOMETALLIC CHEMISTRY OF TECHNETIUM. PREPARATION AND PROPERTIES OF A POLYNUCLEAR TETRACARBONYL[1,2,3]

H. D. KAESZ AND D. K. HUGGINS
Department of Chemistry, University of California, Los Angeles, California, U.S.A.
Received October 29, 1962

ABSTRACT

A polynuclear tetracarbonyl of technetium, constituting a novel class of carbonyls for the manganese subgroup metals, is formed during the treatment of the pentacarbonyl, $Tc_2(CO)_{10}$, with sodium amalgam and subsequent acidification. The new derivative is characterized, and its possible structure is discussed.

INTRODUCTION

In a recent synthesis of the pentacarbonyl hydride of technetium (1) the less volatile residues were observed to contain infrared absorption bands due both to technetium pentacarbonyl, $Tc_2(CO)_{10}$, as well as some additional product(s) not then identified. It is significant that in the preparation of the intermediate, $Na^+Tc(CO)_5^-$, from the treatment of the carbonyl with sodium amalgam, appreciable evolution of carbon monoxide and a reddish coloration of the solution had occurred in competition with the normal cleavage of the metal–metal bond in $Tc_2(CO)_{10}$ (2). We now wish to report a new carbonyl of technetium, $[Tc(CO)_4]_n$, which we have isolated from the above-mentioned reaction mixture, which is not observed in similar treatment of the pentacarbonyls of manganese or rhenium.

EXPERIMENTAL

The following procedures were carried out in an atmosphere and with materials rigorously freed of oxygen.

In a typical experiment, $Tc_2(CO)_{10}$ (2) (0.500 g, 1.05 mmole) in 15 ml of tetrahydrofuran (THF) was treated with 100 g of 0.5% sodium amalgam (containing 22 mg-atom of Na). The mixture was agitated at room temperature for 15 hours, resulting in a dark red coloration of the THF solution, and evolution of 6.9 cc at S.T.P. (0.31 mmole) of CO gas. The THF solution was separated from the excess amalgam by decantation and washing, under inert atmosphere. The solvent was stripped off under vacuum, and 30 ml of cyclohexane was distilled onto the remaining red solids, which were insoluble in that medium. Infrared spectrophotometric examination of the cyclohexane at this point revealed no absorptions in the carbonyl stretching region, indicating that no unreacted $Tc_2(CO)_{10}$ had remained.

The contents of the flask were gradually treated with a solution of 5 ml of H_3PO_4 in 20 ml of H_2O at 0° C. The flask was warmed to room temperature, and the immiscible solid and liquids were agitated over a 24-hour period, with provision for release of the H_2 gas which was formed (1). An aliquot of cyclohexane was withdrawn at this point, and dried over $CaSO_4$. This displayed a multitude of bands in the carbonyl stretching region of the infrared, given in the center spectrum, Fig. 1. The maxima were measured[4] at the following positions (cm^{-1}): $2093._3$ (m), $2064._3$ (m), 2052 (m), $2036._5$ (s), $2020._8$ (s), $2016._8$ (s), $2014._4$ (s), $1989._6$ (m), and $1984._2$ (m). By contrast, the cyclohexane solution resulting from a completely analogous treatment of the carbonyls of manganese and rhenium displayed only the absorptions of the respective pentacarbonyl hydrides (1), as shown on the upper and lower traces in Fig. 1.

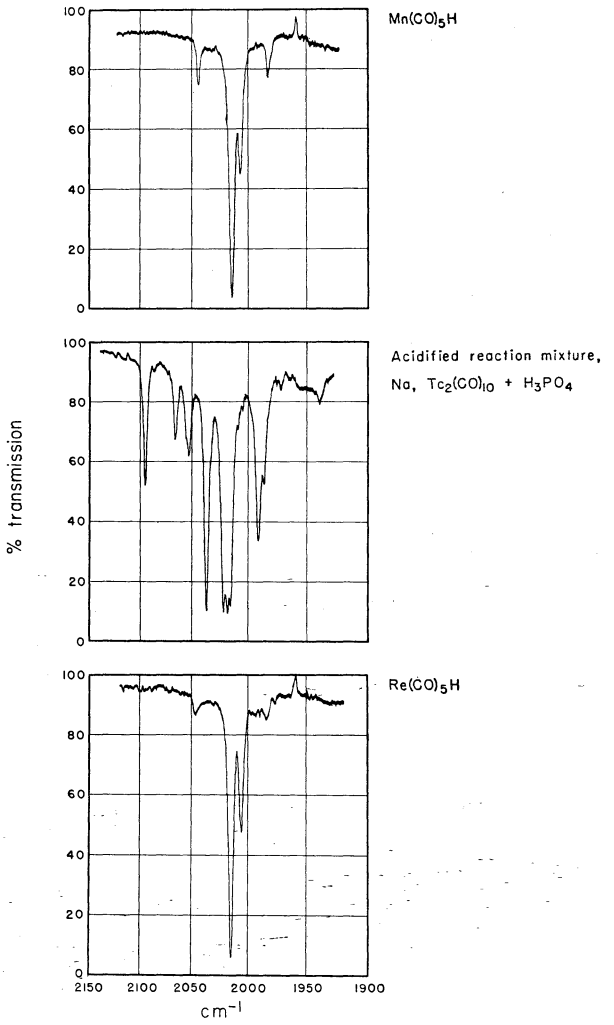

FIG. 1. Comparison of the high-resolution infrared absorption spectra in the carbonyl stretching region after acidification of the reaction mixtures resulting from the treatment of Group VII*b* metal carbonyls with sodium amalgam. LiF prism, cyclohexane solutions.

The small amount of $Tc(CO)_5H$ present in the reaction mixture of the compounds of technetium may be identified by the presence of the band at $2020._8$ cm^{-1} (1), and is removed by stripping off a quantity of cyclohexane at reduced pressure (15–20 mm Hg). When diethyl ether is used in place of cyclohexane during the acidification step, the solids are dissolved and the yield of $Tc(CO)_5H$ is much higher and, also, almost none of the new derivative reported here could be observed.

The less volatile residues were extracted with 10 portions of 8 ml each of cyclohexane, and the combined solutions evaporated to dryness in a stream of nitrogen at room temperature. The extracted solids were subjected to sublimation at 50° C and 0.05 mm Hg, with the probe cooled to 0° C. After 6 hours, $Tc_2(CO)_{10}$, which was present in the gross reaction product, was removed and identified by the bands at $2064._3$ (m), $2016._8$ (s), and $1984._2$ (m) cm^{-1} (also present in the pattern shown in Fig. 1). A cyclohexane extract of the residue displayed four prominent absorptions, at $2093._3$ (m), $2036._5$ (s), $2014._4$ (s), and $1989._6$ (s) cm^{-1}, as shown in Fig. 2. The four bands, taken together with those for $Tc(CO)_5H$ and $Tc_2(CO)_{10}$, account for all but one of the bands observed in the gross reaction mixture above (Fig. 1), that of medium intensity at 2052 cm^{-1}. This band was observed to decrease slowly in relative intensity and to finally disappear, over a period of 3 or 4 hours, from the solution stored in the infrared cell. It is due to some less robust species which we have as yet not identified.

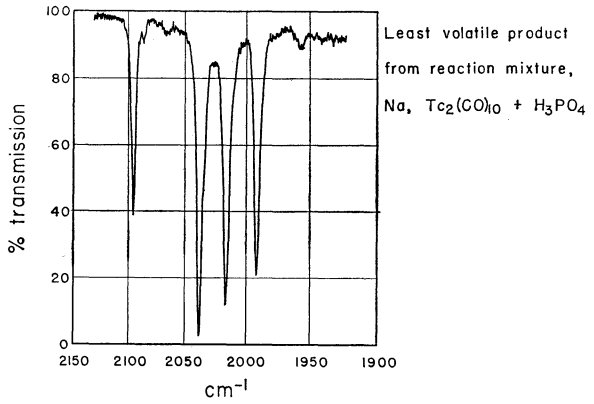

FIG. 2. High-resolution infrared absorption spectrum in the carbonyl stretching region of the least volatile product isolated from the acidified reaction mixture resulting from the treatment of technetium carbonyl with sodium amalgam. LiF prism, cyclohexane solvent.

The sublimation residue was extracted with five portions of 5 ml each of cyclohexane, which were combined and concentrated to a volume of 1 ml in a stream of nitrogen, in a 12-ml centrifuge tube. Solids, consisting mostly of the product giving rise to the four absorptions shown in Fig. 2, crystallized from solution. Precipitation was brought to a maximum by cooling the tube to 0° C, and then allowing it to warm up just enough to melt the cyclohexane. The tube was quickly centrifuged, and the reddish filtrate discarded. The solids in the centrifuge tube were washed with two succeeding 1-ml portions of cyclohexane, and finally recrystallized from 5 ml of solvent by essentially the same cooling and centrifugation procedure mentioned above. A light tan, flocculent product (I) consisting of small platelets was obtained, weighing approximately 25 mg. Analysis[5] yielded 47.0% Tc, 23.35% C, and 0.0% H; required, for $[Tc(CO)_4]_n$, 46.9% Tc, 22.8% C.

The product (I) appeared to be quite stable in air as the solid. Its solutions in cyclohexane (giving the infrared absorptions shown in Fig. 2) appeared to decompose only slowly in contact with the atmosphere. Treatment of the product (I) with dilute solution of Br_2 in cyclohexane resulted in a solution in which only the bands of $[Tc(CO)_4Br]_2$ could be observed, namely, 2117 (m), 2046 (s), 2013 (s), and 1975 (s), which compared exactly with those of an authentic sample in this solvent (a previous report lists the bands observed in CCl_4 (1), in which the maxima were only slightly shifted from these results). By comparison, bromination under identical conditions of $Tc_2(CO)_{10}$ yields $Tc(CO)_5Br$, initially (1), which slowly loses CO over *several days'* standing in solution at room temperature to give mixtures also containing $[Tc(CO)_4Br]_2$. It is reasonable to assume then that bromination of I indicates the presence of $Tc(CO)_4$ and absence of $Tc(CO)_5$ groups in that compound.

The product (I) could be converted to $Tc_2(CO)_{10}$ by carbonylation in an autoclave, in which the products were handled in a Von Grosse tube, as already described (1). The carbonylation occurred at 220° C, for 17 hours, initial pressure of 3100 p.s.i. CO at room temperature, which rose to 5300 p.s.i. at the reaction temperature. Conversion to $Tc_2(CO)_{10}$ was complete; the infrared spectrum showed no evidence for any other compound.

A molecular weight of the product was determined with a Mechrolab Vapor Pressure Osmometer[6] (Mechrolab Inc., Mountain View, Calif.), using cyclohexane as a solvent and $Re_2(CO)_{10}$ as standard. Because of relative low solubility of (I), the concentration of the standard and unknown solutions were of the order of 0.0016 *M*. The average of eight determinations of the molecular weight was 625, with a standard deviation of 37.

DISCUSSION

Analytical data and the results of bromination indicate that I is a tetracarbonyl of technetium. This is further supported by the fact that I is produced only under conditions where cleavage of a carbonyl group from the pentacarbonyl has occurred. The four infrared absorptions of I are extremely similar to the tetracarbonyl halide dimers of technetium (4) in which each Tc atom is octahedrally surrounded by four CO groups, and

two (cis) bridging halogen atoms (C_{2v} local symmetry). When the absorptions of I are compared to those of the tetracarbonyl halides, Fig. 3, it is seen that a uniform progression in the positions of the bands are observed. Those of $[Tc(CO)_4Cl]_2$ are the most

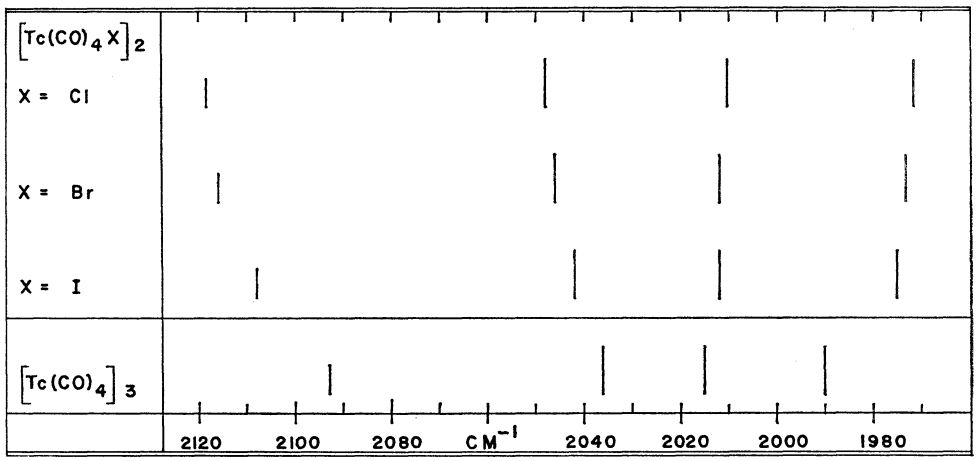

FIG. 3. Comparison of the infrared absorption spectra in the carbonyl stretching region of the series of derivatives $[Tc(CO)_4X]_2$ and $[Tc(CO)_4]_3$.

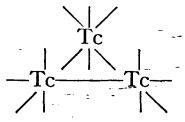
widely spaced, with a minimum reached in the bands of I. This is in keeping with a similar local symmetry for each Tc atom in this series of compounds, where in I metal–metal bonds have replaced the bridging halogen atoms in the tetracarbonyl halides. The molecular weight indicates that we have isolated a trimer: found 625 (see above); required for $[Tc(CO)_4]_3$, 633, and in that case would possess the structure shown in I*a*. This structure would then be extremely similar to that recently determined for $[Os(CO)_4]_3$ (5).



I*a*

Both of these possess C_{2v} local symmetry for each metal, and overall symmetry of D_{3h}, for which four infrared-active carbonyl stretching modes would be expected.[7]

A reliable determination of the magnetic susceptibility of the product has been hindered by the low solubility of the compound in suitable solvents and, also, by the lack of sufficient sample, so far. A preliminary attempt to determine the magnetic properties of I was carried out, using the n.m.r. method of Evans, adapted to coaxial sample tubes as previously described (2). Measurement of the proton resonance of solvent of a saturated solution of I in cyclohexane (0.0093 molal) in the inner tube gave a separation of 19.5 c.p.s. (at 60 Mc) from the resonance of the methyl protons of toluene in the annular space. Neat cyclohexane yields essentially the same separation under these conditions. We assume this to indicate diamagnetism for I. This conclusion must be held as only tentative at this time since the observed value is not sufficiently separated from that which might be expected from a paramagnetic complex. A trimer containing one unpaired electron,

[7]*Six, rather than four, prominent carbonyl stretching absorptions have been reported (6) for* $Os_3(CO)_{12}$. *We have redetermined the spectrum of a sample of that compound purified by elution chromatography, and observed only four prominent bands, as expected: 2068 (s), 2034.5 (s), 2014 (m), and 2002 (m)* cm^{-1}, *in cyclohexane.*

For personal use only.

for instance, would be expected to yield a separation of approximately 18 c.p.s. under these conditions, assuming no factors restricting paramagnetism are in operation. We are therefore presently engaged in obtaining more definitive magnetic data.

If the trimer is diamagnetic, however, as appears most likely at this time, some moiety such as an H atom or CH or OH group would be required in the complex in addition to the odd number of $Tc(CO)_4$ units. Any one of the three above-mentioned additional groups, if present, would not markedly affect the analytical results, and furthermore, if placed symmetrically in the center of the trimeric structure drawn above (I*a*), would not greatly perturb the local symmetry of the $Tc(CO)_4$ units. No evidence is yet available about whether such an additional group does exist, and the search for this would be predicated on more reliable magnetic measurements. It is of course possible to account for a diamagnetic species of polymers containing only $Tc(CO)_4$ units, but then in an even total number. Such might also have been synthesized in the above-mentioned reaction sequence. Further work is in progress to answer these and other questions about the new derivative of technetium. It is also our intent to ascertain whether similar species of manganese and rhenium[8] may be obtained, though requiring perhaps, different preparative routes.

ELEMENTAL ORGANIC COMPOUNDS

VI. SIGNIFICANCE OF π-RADICAL HYBRIDIZATION: NEW SYNTHETIC METHOD FOR BIS-ARENE π-COMPLEXES[1,2]

MINORU TSUTSUI AND GEORGE CHANG
New York University, Departments of Chemical Engineering and Chemistry, New York, N.Y., U.S.A.

Received October 29, 1962

ABSTRACT

The hypothesis of the existence of π-radical hybridization in aryl (M. Tsutsui. Ann. N.Y. Acad. Sci. **93**, 133 (1961)) and vinyl (M. Tsutsui. Abstracts of Papers, 141st Meeting of the American Chemical Society, Washington, D.C. March, 1962. p. 3-O) coupling reactions has led us to a further investigation of the reactivity of highly active transition metal atoms in the so-called "radical state". As a result, a new synthetic method for bis-benzene-type π-complexes of transition metals has been discovered.

The following methods (1) for the preparation of bis-arene π-complexes have been reported previously.

(1) Grignard Method (2)

The reaction of an aryl Grignard solution and a transition metal halide in ether or tetrahydrofuran yields arene π-complexes. This method, at present, is limited to the preparation of chromium π-complexes.

$$RMgX + MCl_n \rightarrow \text{bis-arene } \pi\text{-complexes}$$

(R is limited to a phenyl or tolyl group; M = transition metal; n = 2 or 3)

(2) Reductive Friedel–Crafts Method (3)

Heating of a mixture of a transition metal halide, arene, aluminum metal powder, and aluminum chloride under atmospheric pressure or increased pressure affords arene π-complexes. This method seems to be widely applicable. It has, however, been shown to be non-usable for certain elements and arenes.

$$3MCl_3 + 2Al + AlCl_3 + 6C_6H_6 \rightarrow 3M(C_6H_6)_2^+ \cdot (AlCl_4)^-$$

(3) Cyclic Polymerization of Disubstituted Acetylenes by Organotransition Metals (4)

The reaction of an organotransition metal and disubstituted acetylene yields an aromatic hydrocarbon, a trimer of the acetylene, and a bis-arene π-complex. This method has afforded manganese and cobalt π-complexes which could not be prepared via the reductive Friedel–Crafts method.

(4) Cyclic Polymerization of Disubstituted Acetylenes with a Transition Metal Halide and Trialkylaluminum (5)

Except for the reductive Friedel–Crafts method, all the methods involve the reduction of either di- or tri-valent chromium to the zerovalent state. In the case of the reductive Friedel–Crafts method, chromium seems to be reduced from trivalent to monovalent. The question whether chromium is reduced from trivalent to monovalent or from trivalent
