From these results the following conclusions may be drawn: (i) a fully methylated polysaccharide may be obtained but a much more prolonged treatment was required than is usual for the majority of natural polysaccharides; (ii) the fully methylated polysaccharide had an unusually high solubility in petroleum ether; (iii) of the terminal glucose units about 20% of them were furanose; (iv) some of the internal glucose units were also furanose but the predominant linkage appeared to be $1 \rightarrow 6$-glucopyranose although evidence for $1 \rightarrow 2$, $1 \rightarrow 3$, and $1 \rightarrow 4$ linkages were also found; (v) those sugar glycosides having a free hydroxyl group on C_6 may be readily separated from mixtures as their water-insoluble trityl ethers. In summary, it is clearly shown that the synthetic glucan is extremely highly branched and composed of a high proportion of glucofuranose units. This is in marked contrast to natural glucans but is in agreement with an earlier study of this material by periodate oxidation (1).

EXPERIMENTAL

Paper chromatographic separations were carried out using the descending technique and butanone–water azeotrope as the developing solvent. Electrophoresis was carried out in 0.1 *M* sodium borate at 1000 v. The sugars on paper chromatograms were detected by use of *p*-anisidine–trichloroacetate spray reagent.

Evaporations were carried out under reduced pressure at a bath temperature of 40–45° C. Optical rotations recorded are equilibrium values at 21±2° C. Melting points quoted are uncorrected.

Methylation of the Glucan

A sample (7.5 g) of the synthetic glucan was methylated in the usual manner with the Haworth reagents to yield a water-insoluble amorphous product. This substance was further methylated by the procedure of Kuhn (2) to give a pale yellow, amorphous glass which contained 43% methoxyl. The product was consequently treated four times with Purdie's reagents over extended intervals (96 hours each) on a steam bath to yield finally a brittle glass (8.1 g), $[\alpha]_D$ 72.5° in $CHCl_3$, 71.8° in methanol (*c*, 3.1), which showed no OH band in the infrared spectrum and contained 45.35% methoxyl (theory 45.6%). The methylated glucan was suspended in petroleum ether (30–60°), 3% (by volume) chloroform added, and the milky solution allowed to stand 12 hours. The clear solution was decanted and evaporated to yield a pale yellow amorphous glass (7.75 g).

Hydrolysis of Methylated Glucan

The methylated glucan was dissolved in 72% cold sulphuric acid to yield a thick syrup to which was added cold water to give approximately a 2 *N* H_2SO_4 solution. This solution was boiled for 10 hours, neutralized ($BaCO_3$), deionized, and evaporated to a colorless, mobile syrup. Chromatographic examination of the hydrolyzate showed the presence of tetra- (multi-colored spot suggesting the presence of furanose isomer), tri- (elongated spot), di-, and mono-*O*-methylglucoses and glucose (present in minor amount).

For personal use only.

Cellulose Column Chromatography

The mixture was passed through a cellulose–hydrocellulose column using butanone–water azeotrope solvent in approximately 900-mg aliquots. The contents of tubes consisting of a mixture, for example of tetra- and tri-*O*-methyl sugars, were rechromatographed.

Fraction	Weight (g)	Molar ratio
4. Tetra-*O*-methyl-glucose	2.082	4.9
3. Tri-*O*-methyl-glucose	2.002	5.0
2. Di-*O*-methyl-glucose	1.078	2.9
1. Mono-*O*-methyl-glucose	0.352	1
	0.025	—

Fraction 4

The mixture showed $[\alpha]_D$ 64° (*c*, 8.1 in water). The reported rotation for 2,3,4,6-tetra-*O*-methyl-D-glucose is 84° in water (equilibrium value), while the 2,3,5,6-tetra-*O*-methyl isomer has a rotation of −11° (7). The fraction of the 2,3,5,6-tetra-*O*-methyl isomer present in the mixture is therefore about 21% or approximately 420 mg. The mixture was dissolved at room temperature in dry methanol containing 1% hydrogen chloride and the change in rotation at room temperature followed. When no further change was observed, the solution was neutralized (Ag_2CO_3), evaporated, and passed through a cellulose–hydrocellulose column. The eluate immediately appearing after the solvent front and until 2,3,4,6-tetra-*O*-methyl-D-glucose appeared was combined and evaporated to a syrup (180 mg). Hydrolysis of this non-reducing substance (20 ml 0.1 *N* H_2SO_4, 3 hours on steam bath), followed by neutralization ($BaCO_3$) of the solution and evaporation, gave a syrupy product (175 mg), $[\alpha]_D$ −9.5° (*c*, 3.5 in water), which had an R_f slightly greater than that of authentic 2,3,4,6-tetra-*O*-methyl-D-glucose. The syrup was dissolved in water and the sugar oxidized with bromine in the usual fashion. The acid was heated under vacuum to effect lactone formation and the syrupy product showed $[\alpha]_D$ 52° (*c*, 1.6 in MeOH). The lactone was dissolved in dry methanol containing ammonia, the solution left for 72 hours, and the solvent evaporated. The syrupy product, $[\alpha]$ 39.5° in water (*c*, 1.5 in water), was dissolved in acetone, ether and pet. ether (30–60°) were added, whereupon partial crystallization took place. Removal of some crystals followed by washing with cold ether and drying on a porous plate gave a substance which melted at 86–89° C; reported (7) m.p. for 2,3,5,6-tetra-*O*-methyl-D-gluconamide is 91° C.

A portion (188 mg) of the reducing sugar obtained from the above separation of the furanoside from the pyranose isomer showed $[\alpha]_D$ 74° (*c*, 1.9 in MeOH). The sugar was treated with *p*-nitrobenzoyl chloride in the usual manner to give the water-insoluble *p*-nitrobenzoate. After recrystallization from an acetone – ethyl acetate solvent mixture, the 2,3,4,6-tetra-*O*-methyl-1-*O*-*p*-nitrobenzoyl-D-glucose had m.p. 98–100° C; reported (8) melting point is 102° C.

Identification of 2,3,4- and 2,4,6-Tri-O-methyl-D-glucose

A portion (250 mg) of fraction 3 was rechromatographed on the cellulose–hydrocellulose column and the effluent collected in five distinct fractions. A small quantity (about 15 mg) of fast-migrating material was not further investigated. The second fraction (66 mg), having an R_f similar to that of 2,3,4-tri-*O*-methyl-D-glucose, showed $[\alpha]_D$ 75° (*c*, 0.7 in acetone). Treatment of the sugar with *p*-nitroaniline (9) gave needle-like crystals which upon recrystallization from an ethanol–ether solvent mixture had m.p. 221–224° C, $[\alpha]_D$ −245° (*c*, 0.1 in pyridine); reported (9) m.p. for 2,3,4-tri-*O*-methyl-*N*-(*p*-nitrophenyl)-D-glucosylamine is 224–225° C, $[\alpha]_D$ −251° in pyridine.

The slowest fraction (22.5 mg), $[\alpha]_D$ 71° (*c*, 0.3 in MeOH), crystallized upon standing. Removal of some crystals followed by washing with cold ether and drying on a porous plate gave a substance which had m.p. 116–120° C. The compound was treated with aniline to give the *N*-phenylglucosylamine, $[\alpha]_D$ −109° (*c*, 0.3 in MeOH), which had m.p. 158–160° C; reported (10) m.p. for 2,4,6-tri-*O*-methyl-*N*-phenyl-D-glucosylamine is 162–166° C, $[\alpha]_D$ −113° in MeOH.

Treatment of Fraction 3 with Methanol–HCl

The bulk (1.75 g) of fraction 3 (trimethylglucoses) was dissolved in dry methanol (25 ml) containing 1% hydrogen chloride. When no further change in rotation was observed, the solution was neutralized (Ag_2CO_3) and evaporated. The syrupy product was passed through a cellulose–hydrocellulose column. The effluent was collected as described in the separation procedure for the tetramethyl mixture. The yield of furanoside (component 3F) was about 420 mg. Hydrolysis of a small portion (60 mg) with sulphuric acid and chromatography of the hydrolyzate gave evidence for the presence of substances with R_f values of 0.74, 0.66, and 0.57. The slower-moving substance was presumed to be 2,3,6-tri-*O*-methyl-D-glucose.

Periodate Oxidation of Trimethylglucofuranose Mixture (3F)

A portion (40.7 mg or 0.1815 mmole) of the furanose mixture from the above hydrolysis was dissolved in water (20 ml), and a solution (5 ml) of sodium borohydride (25 mg) added. The reduction was allowed to proceed for 48 hours at room temperature. The solution was neutralized with acetic acid, and sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

periodate (5 ml 0.5 *M* solution) was added. After 5- and 8-hour intervals, formaldehyde was determined (11). Formaldehyde (0.0369 mmole) would originate from 0.0369 mmole 3,5,6-tri-*O*-methyl-D-glucitol, or about 20% of the original mixture was 3,5,6-tri-*O*-methyl-D-glucose. A total of 0.1490 mmole of periodate was consumed; therefore 0.1815 − 0.1490 or 0.0325 mmole (18%) of 2,3,5-tri-*O*-methyl-D-glucose was present since the corresponding hexitol would be the only hexitol immune to periodate attack. The remainder (62%) of the mixture would be 2,3,6- or 2,5,6-tri-*O*-methyl-D-glucose or a mixture of both.

Further Resolution of Component 3F

The remainder (365 mg) of the tri-*O*-methylfuranosides was dissolved in dry pyridine (10 ml), and trityl chloride (0.5 molar equivalent) was added and the solution left at room temperature for about 48 hours. Water was added to the mixture, whereupon the insoluble tritanol and trityl derivative (3FTr) precipitated. Of the possible furanosides (2,3,5-, 2,3,6-, 2,5,6-, 3,5,6-tri-*O*-methyl), only methyl 2,3,5-tri-*O*-methyl-D-glucoside would form the water-insoluble 6-trityl derivative. The precipitate was dissolved in methanol (15 ml) containing 1% HCl and the solution boiled for 1 hour. Water (50 ml) was added and the solution boiled for an additional 2 hours to regenerate the free sugar. The solution was neutralized ($PbCO_3$), filtered, and deionized. Evaporation of the effluent gave a syrup, 22 mg, $[\alpha]_D$ 15° (*c*, 0.75 in MeOH), which had an R_f 0.59–0.61. The sugar was oxidized with bromine in the usual fashion. The acid (25 mg) gave a neutralization equivalent of 260, theoretical is 240. After the acid was heated under vacuum to effect lactone formation, a few milligrams of product was subjected to the Weerman test (6). The negative result indicated that C_2 of the sugar was substituted. To the lactone, in boiling ether, was added phenylhydrazine. The small amount of insoluble phenylhydrazide was collected, washed with ether, and after drying had m.p. 150–154° C; reported (12) m.p. for 2,3,5-tri-*O*-methyl-D-gluconophenylhydrazide is 156–157° C.

Component 3F6

From the previous experiment, the furanosides which could not form 6-*O*-trityl ethers were subjected to acid hydrolysis to give the free sugars. This mixture should now be composed of 2,3,6-, 2,5,6-, and 3,5,6-tri-*O*-methyl-D-glucoses. The syrup (300 mg) was dissolved in 0.15 *M* periodic acid (100 ml) and left at 5° C for 24 hours. The solution was neutralized ($BaCO_3$), deionized, and evaporated to a syrup. Chromatography revealed three components with R_f values of (*a*) 0.49 (2,3,6-tri-*O*-methyl-D-glucose), (*b*) 0.59 (2,5,6-tri-*O*-methyl-D-glucose), and (*c*) 0.80 (presumed to be 2,4,5-tri-*O*-methyl-*aldehydo*-D-arabinose arising from periodate cleavage of 3,5,6-tri-*O*-methyl-D-glucose). The mixture was resolved by cellulose column chromatography. *Component (a)*, 55 mg, $[\alpha]_D$ 73° (*c*, 0.5 in water), was treated with *p*-nitrobenzoyl chloride in the usual manner. The product after recrystallization from acetone–ether had m.p. 188–190° C, $[\alpha]_D$ −32° (*c*, 0.4 in $CHCl_3$); reported (13) m.p. for di-*p*-nitrobenzoate of 2,3,6-tri-*O*-methyl-D-glucose is 189–190° C, $[\alpha]_D$ −33° in $CHCl_3$. *Component (b)*, 31 mg, had $[\alpha]_D$ 12.5° (*c*, 0.6 in water), 19° (*c*, 0.6 in MeOH), and was presumed to be 2,5,6-tri-*O*-methyl-D-glucose (14). The sugar was oxidized with bromine and the acid converted to the lactone by the usual techniques. A small portion (5 mg) of the amide was subjected to the Weerman test (6). The negative result indicated that the C_2-hydroxyl was substituted. Treatment of the lactone, in boiling ether, with phenylhydrazine gave a solid which after washing with ether and pet. ether (30–60°) and drying had m.p. 157–161° C. *Component (c)*, 184 mg, showed $[\alpha]_D$ 17.5° (*c*, 1.9 in MeOH), and was presumed to be 2,4,5-tri-*O*-methyl-*aldehydo*-D-arabinose. The substance gave a positive Schiffs test. A small portion (10 mg) was oxidized and converted to the amide, which gave a negative Weerman test, indicating that the C_2-hydroxyl of the aldehydo sugar was substituted. An attempt to prepare the 2,4-dinitrophenylhydrazone failed.

Tri-O-methyl-D-glucopyranose Constituents (3P)

The tri-*O*-methylglucoses which did not form furanosides in the treatment with methanolic hydrogen chloride at room temperature (see previous section) were presumed to consist of 2,3,4-, 2,3,6-, 2,4,6-, and 3,4,6-tri-*O*-methyl-D-glucoses. The mixture (1.2 g) was boiled with methanol containing 1.5% hydrogen chloride. The product was tritylated as described before to give the water-insoluble *O*-trityl ether of methyl 2,3,4-tri-*O*-methyl-D-glucoside (3PTr) and the unreacted water-soluble methyl glycosides (3P6) of 3,4,6-, 2,3,6-, and 2,4,6-tri-*O*-methyl-D-glucoses. *Component 3PTr*, 400 mg, had $[\alpha]_D$ of detritylated free sugar 72° (*c*, 1.2 in acetone). Treatment of a portion (80 mg) of the free sugar with *p*-nitroaniline gave the corresponding 2,3,4-tri-*O*-methyl-*N* (*p*-nitrophenyl)-D-glucosylamine (9), m.p. 221–224° C, $[\alpha]_D$ −248° (*c*, 0.1 in pyridine). A portion (175 mg) of the sugar was reduced ($NaBH_4$) and the glucitol oxidized with periodic acid, whereby a syrupy pentose (110 mg), $[\alpha]_D$ −17° (*c*, 0.5 in water), was obtained. Treatment with *p*-nitrobenzoyl chloride gave 2,3,4-tri-*O*-methyl-1-*O*-*p*-nitrobenzoyl-L-xylose (8, p. 517), m.p. 134–135° C, $[\alpha]_D$ −73° (*c*, 0.4 in $CHCl_3$). The free sugar had R_f 0.79. *Component 3P6*: The water-soluble material (750 mg) from the previous tritylation experiment was presumed to be composed of methyl 2,4,6-, 3,4,6-, and 2,3,6-tri-*O*-methyl-D-glucosides. The mixture was boiled (10 hours) in *N* sulphuric acid (25 ml) and after neutralization ($BaCO_3$) a syrup (710 mg) was obtained. A small portion of this syrup was reduced ($NaBH_4$), oxidized with periodate, and the formaldehyde measured (11). The result indicated that about 15% of the original mixture was 3,4,6-tri-*O*-methyl-D-glucose. Periodate oxidation of the bulk of the syrup followed by chromatographic examination of the product (645 mg) gave evidence for three components: (*a*) R_f 0.81, presumed to be 2,3,5-tri-*O*-methyl-D-arabinose from periodate cleavage of 3,4,6-tri-*O*-methyl-D-glucose, (*b*) R_f 0.51, presumed to be 2,3,6-tri-*O*-methyl-D-glucose, and (*c*) R_f 0.46, presumed to be 2,4,6-tri-*O*-methyl-D-glucose. The mixture was resolved

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

on a cellulose column in the usual manner. *Component (a)*, 85.5 mg, showed $[\alpha]_D$ 38.5° (*c*, 0.8 in water), 47° (*c*, 0.8 in MeOH). The sugar was oxidized with bromine and converted to the lactone (73 mg), $[\alpha]_D$ 23° (*c*, 1.2 in water). The lactone was treated with methanolic ammonia (30 ml), left 48 hours, and the solvent evaporated. The amide (70 mg), which did not crystallize, showed $[\alpha]_D$ −20° (*c*, 1.5 in EtOH), −15° (*c*, 1.5 in water) and gave a negative Weerman test. Reported rotation of 2,3,5-tri-*O*-methyl-L-arabinolactone, −45 → −24° in water; of amide, +16° in water and +21° in EtOH (15). *Component (b)*, 229 mg, $[\alpha]_D$ 72° (*c*, 0.7 in water), was presumed to be 2,3,6-tri-*O*-methyl-D-glucose. The syrupy substance was treated with *p*-nitrobenzoyl chloride in the usual manner to give 2,3,6-tri-*O*-methyl-1,4-di-*O*-*p*-nitrobenzoyl-D-glucose (8, p. 533) which after recrystallization from acetone–ether mixture had m.p. 186–188° C, $[\alpha]_D$ −32° (*c*, 2.1 in $CHCl_3$). *Component (c)*, 126 mg, $[\alpha]_D$ 71° (*c*, 1.3 in water) was believed to be 2,4,6-tri-*O*-methyl-D-glucose. This sugar was identified previously. Treatment with *p*-nitrobenzoyl chloride gave a thick semisolid which did not crystallize.

Attempted Resolution of Di-O-methyl-D-glucoses

The mixture of di-*O*-methylglucoses was treated with methanolic hydrogen chloride as previously described and the product passed through a cellulose column to yield the furanoside fraction (component 2F) and the pyranose fraction (2P). The 2P-component (460 mg), presumed to consist of a mixture of 2,4-, 3,4-, and 4,6-di-*O*-methyl-D-glucoses, was boiled with methanolic hydrogen chloride and the methyl glycoside mixture treated with trityl chloride as described before. The water-insoluble substance was presumed to be a mixture of the methyl 6-*O*-trityl-2,4-, and 3,4-di-*O*-methyl-D-glucosides and tritanol (component 2PTr). This material was hydrolyzed to recover the free sugars and the mixture (198 mg) oxidized with periodic acid. The product, isolated in the usual manner, was tentatively shown to contain a dimethylglucose, R_f 0.21, presumed to be 2,4-di-*O*-methyl-D-glucose, a dimethylpentose, R_f 0.27, presumed to be 2,3-di-*O*-methyl-D-arabinose, and two unknown components, R_f 0.79 and 0.84. The mixture was not investigated further. The water-soluble material (213 mg) (component 2P6) recovered from the above tritylation treatment was hydrolyzed and the syrupy product (205 mg), R_f 0.22, presumed to be 4,6-di-*O*-methyl-D-glucose, analyzed by electrophoresis. Two components in apparently equal quantities were found to be present.

Attempted Resolution of Component 2F

This syrupy substance (505 mg) was treated with trityl chloride as described before to give the trityl fraction (component 2FTr, 75 mg) and the non-tritylated fraction (component 2F6, 265 mg). The two fractions were subjected to the following treatments: *Component 2F6* was unintentionally treated with periodate. Since 2,6-, 3,6-, and 5,6-di-*O*-methyl-D-glucoses were presumed to be present, the distillate from the evaporation of the neutralized ($BaCO_3$) oxidation mixture was bubbled through a solution of sodium borohydride to catch and reduce any volatile aldehyde fragments that might have been formed. The distillate was acidified, evaporated, borate removed (MeOH–HCl), and the small quantity (25 mg) of product chromatographed and found to contain one Tollens-positive substance with an R_f greater than glycerol (R_{xylose} 2.95 in EtOAc:HOAc:H_2O (8:2:2)). A portion (10 mg) of the syrup was oxidized with periodic acid (20 ml, 0.1 *M*) and after 30 and 60 minutes, 2.65 mg formaldehyde had been produced (theoretical yield 2.84 mg based on 1-*O*-methylglycerol), and 0.0881 mmole of periodate had been consumed (theoretical consumption of 1-*O*-methylglycerol is 0.0944). The remainder (15 mg) of the syrup was dissolved in 48% hydrobromic acid (3–4 ml) and refluxed on a steam bath for about 20 minutes, the solution was neutralized ($PbCO_3$), and the product (11 mg) was examined chromatographically. Glycerol was identified with a trace of faster-moving material, and the oily product was treated with *p*-nitrobenzoyl chloride to give glycerol tri-*O*-*p*-nitrobenzoate, m.p. and mixed m.p. 186–189° C. Only 2,6-di-*O*-methyl-D-glucose will furnish 1-*O*-methylglycerol upon periodate oxidation and its presence is thus established.

The non-volatile mixture from the periodate oxidation described above was chromatographed and found to contain some (major quantity) unreacted di-*O*-methylglucose (R_f 0.23), a dimethylpentose in smaller amount and presumed to be 2,5-di-*O*-methyl-D-arabinose (R_f 0.55), and at least four substances with R_f ranging from 0.70 to 0.88. This mixture was resolved chromatographically and electrophoresis of the di-*O*-methylglucose fraction showed that it was composed of two major components and one in lesser quantities. A component (13 mg) with R_f 0.79–0.81 was analyzed as described above for 1-*O*-methylglycerol. A portion (4.3 mg) of the substance upon periodate oxidation gave about 94% of the theoretical amount of formaldehyde and the periodate consumption was 96% of theory (assuming that the substance was 3,4-di-*O*-methyl-D-erythritol, which would have arisen from the periodate cleavage of 5,6-di-*O*-methyl-D-glucose). The remainder (10.7 mg) of the substance was demethylated and erythritol identified chromatographically as the major component.

Component 1

The syrupy mixture of mono-*O*-methyl-D-glucoses was shown by chromatography to contain a negligible amount of the 5-*O*-methyl isomer. Electrophoresis showed that the mixture contained 3-*O*-methyl, M_g 0.86, 6-*O*-methyl, M_g 0.78, 2-*O*-methyl, M_g 0.31, each identical with authentic material; and 4-*O*-methyl, M_g 0.24. The ratio of the sugars was determined by the phenol – sulphuric acid method (16) and found to be 5:2:3:1 respectively.

D-*Glucose*

The syrup, $[\alpha]_D$ 51° (*c*, 0.75 in water), crystallized spontaneously. After washing with ethanol, the solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

had m.p. and mixed m.p. 143–145° C. Treatment of the sugar with phenylhydrazine hydrochloride in aqueous ethanol gave D-glucose phenylosazone, m.p. and mixed m.p. 205–208° C.

ACKNOWLEDGMENTS

This investigation was supported by a research grant (RG 7652) from the Division of General Medical Sciences, Public Health Service (U.S.A.), to whom we express our thanks. We are also indebted to Miss J. Hunter for skillful technical assistance.

ABSTRACT

The problem of current distribution at an electrode of linear geometry having a significant ohmic resistance is examined for conditions where the ohmic potential drop along the electrode material is of the same order of magnitude as the metal–solution potential difference. This problem is of practical significance in primary and secondary cells at high current drains and in certain types of fuel cell electrodes. The current distribution and metal–solution potential profiles are calculated as limiting cases of a general theory. The true and apparent current–potential relations are compared theoretically.

I. INTRODUCTION

In recent years, current distribution problems in electrolysis processes have become of of renewed importance in certain applications involving high current drains in batteries, palladium hydrogen diffusion anodes operating at elevated temperatures, and in anodic electrolytic machining. General problems of current density distribution were recognized in early work on electroplating and throwing-power (1, 2) and renewed interest in this and related kinds of problems has recently been apparent (3, 4). In the above work, the inhomogeneous current density distribution is treated largely in terms of the finite resistance of the electrolyte. The corresponding problem, in which the *electrode resistance* effect is significant at high current drains, has not previously been examined, except in the case of thin-film light modulators (5) where film resistance and solution conductance effects have been simultaneously considered as a special problem. Co-conduction effects longitudinally through the solution (6) and through the double layer (7) parallel to a thin wire electrode have been considered for cases where the electrode resistance was not negligible compared with the electrolyte solution resistance. Such studies can lead to information about adsorption in the double layer (7) and the electrode potential distribution in the case of a wire in a solution with contacts at each end to an external electric circuit (6).

In the present work, we examine the general theory of current density and overpotential distribution for a thin wire or tubular diffusion electrode having significant ohmic resistance and immersed in an electrolyte with contact to the external circuit at one end; relations are also obtained for the true and apparent Tafel slope for an electrode process occurring at the wire under such conditions.

II. CALCULATION OF POTENTIAL AND CURRENT PROFILES

1. Model

We consider the model for a cylindrical electrode of length L, radius r, and specific

[1]*Present address: John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia 4, Pennsylvania.*

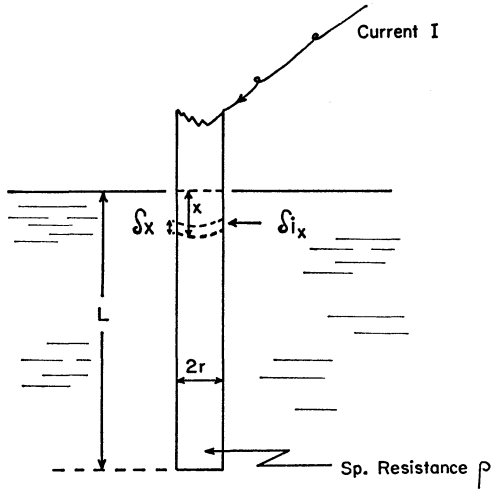

FIG. 1. Schematic diagram of the model considered in the current distribution problem at a cylindrical electrode, showing some of the quantities involved in the treatment.

resistance ρ, shown in Fig. 1. The electrode may be a thin wire or a thin tube, as in the case of palladium hydrogen diffusion anodes where significant electrode resistance can arise. An element of current di_x is regarded as passing across an element of area $2\pi r dx$ at a position x below the top of the electrode (taken as the level of immersion of the electrode in the electrolyte). The total current passing into, or out of, the electrode is written as I and the overvoltage which would determine the rate of the electrode reaction if ρ were negligible is expressed as V_0. The normal current density i passing in the absence of ohmic effects is related to the exchange current density by the Tafel equation in exponential form as

$$i = i_0 \exp [\alpha V_0 F/RT] = i_0 \exp [V_0/b].$$

We assume the current density passing at any point x along the electrode is determined by the overvoltage V_0 (arising from an impressed voltage, or from a galvanic potential difference in the case of a battery or fuel cell) less the ohmic drop ΔV_x existing at the position x down the electrode from the top. This potential drop will be determined by the current passing in the cylinder from the top to x and by the specific resistance ρ of the electrode. The current passing will not be uniform and will decrease down the electrode. At any given point, the current density will be exponentially related to the overpotential and hence the metal–solution p.d. existing at that point, i.e. to $V_0 - \Delta V_x$.

2. Formulation of Equations

At x, the element of actual anodic* current passing across an area ds equal to $2\pi r \cdot dx$ is

$$[1] \qquad di_x = i_0 \exp [\alpha(V_0 - \Delta V_x)F/RT] \cdot 2\pi r \cdot dx,$$

where i_0 is the usual exchange *current density* for the electrode process concerned and α the transfer coefficient characteristic of the rate-determining process.

The potential drop ΔV_x in the conductor is a function of length but is not simply linearly related to it since the current in the conductor is not uniform but decreases down the

**For convenience, we write the kinetic expression for an anodic reaction involving a one-electron transfer as in the H ionization case.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

cylinder. The quantity ΔV_x will hence increase with x but as some function x^n where $0 < n < 1$, and n may be a function of x.

In the element of the electrode surface of area $2\pi r \cdot dx$, at the position x, the potential drop dV down the element is given by

$$dV = i_x \rho dx/\pi r^2,$$

where i_x is the total current in the conductor crossing a plane perpendicular to the electrode axis at a position x along the electrode determined by the sum of all current elements entering the electrode from $x = L$ to the representative position $x = x$.

The total potential drop ΔV_x from the top of the electrode to x is then

[2]* $$\Delta V_x = \int_0^x dV = \frac{\rho}{\pi r^2} \int_0^x i_x \cdot dx.$$

But i_x is already the integral of di_x over the length $x = L$ to a position x which involves ΔV_x from equation [1], i.e.,

[3] $$i_x = i_o \exp\left[\frac{\alpha V_o F}{RT}\right] 2\pi r \int_x^L \exp -\left[\frac{\alpha \Delta V_x F}{RT}\right] dx$$

and ΔV_x in equation [3] is given by the integral equation [2] which itself involves i_x. The mathematical problem is thus a particularly complex one and an explicit solution is not obtainable without some simplification.

3. Linear Approximation

Equation [3] can be linearized under two conditions:

(*a*) if the current densities along the electrode do not exceed approximately 1.7 i_o (the condition for linear current – potential behavior in the basic rate expression), or

(*b*) if $\Delta V_x < RT/\alpha F$; this latter condition only obtains at moderately low c.d. or fairly low ohmic resistance of the conductor such as is the case in most practical problems.

In either case, we could write approximately for the forward (anodic) current, e.g. in H ionization,

[4] $$i_x = i_o \exp\left[\frac{\alpha V_o F}{RT}\right] 2\pi r \int_x^L \left[1 - \frac{\alpha \Delta V_x F}{RT}\right] dx$$

and the equation then becomes with [2] and $i = i_o \exp [\alpha V_o F/RT]$

[5] $$i_x = 2\pi r i \int_x^L dx - 2\pi r i \int_x^L \left[\frac{\alpha \Delta V_x F}{RT}\right] dx,$$

which can be written

[6] $$i_x = K_1 - K_2 x - K_3 \int_x^L \left[\int_0^x i_x dx\right] dx,$$

where K_1, K_2, and K_3 are constants, the significance of which follows by reference to equation [5]. We may write equation [6] conveniently in differential form as

[7] $$di_x/dx = -K_2 + K_3 \int_0^x i_x dx$$

**In this and other related equations, the term $\rho/\pi r^2$ will become $\rho/\pi(r^2 - [r-a]^2)$ for the case of a tubular electrode of radius r and annular thickness a.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and

$$[8] \qquad d^2i_x/dx^2 = K_3 i_x = \frac{2\rho i\alpha F}{rRT} i_x.$$

4. Evaluation of ΔV_x as a Function of x and Determination of the Profile of i_x as a Function of x

The general solution of the differential equation [8] is

$$[9] \qquad i_x = A \exp(-K_3^{1/2}x) + B \exp[K_3^{1/2}x].$$

The constant B is set equal to zero since i_x must always decrease with increasing x, i.e.

$$[9a] \qquad di_x/dx = K_3^{1/2}[-A \exp(-K_3^{1/2}x) + B \exp(K_3^{1/2}x)] < 0$$

and the above inequality will be satisfied for all values of x only if $B = 0$. Also, at $x = 0$, we have

$$i_x = I = A.$$

Hence we obtain the following specific solution to the differential equation [8]:

$$[10] \qquad i_x = I \exp -(K_3^{1/2}x) = I \exp -\left(\frac{2\rho i\alpha F}{rRT}\right)^{1/2} x.$$

The current density distribution may then be obtained as

$$[11] \qquad -\frac{di_x}{ds} = -\frac{1}{2\pi r}\frac{di_x}{dx} = \frac{1}{2\pi r} K_3^{1/2} I \exp -(K_3^{1/2}x)$$

and the current density at x is

$$[11a] \qquad -\frac{di_x}{ds} = \frac{K_3^{1/2}}{2\pi r} i_x.*$$

The evaluation of ΔV_x as a function of x may then be carried out as follows. Substituting i_x from equation [10] into equation [2] we have

$$[12] \qquad \Delta V_x = \frac{\rho}{\pi r^2}\int_0^x i_x dx = \frac{\rho}{\pi r^2} I \int_0^x \exp[-K_3^{1/2}x]dx,$$

i.e.,

$$\Delta V_x = -\frac{\rho I}{\pi r^2 K_3^{1/2}}[e^{-K_3^{1/2}x} - 1] = \frac{\rho I}{\pi r^2 K_3^{1/2}}[1 - \exp(-K_3^{1/2}x)]$$

so that, upon substituting the value of K_3, we have

$$[12a] \qquad \Delta V_x = \left(\frac{\rho RT}{2\pi^2 r^3 i\alpha F}\right)^{1/2} I\left[1 - \exp\left(-\frac{2\rho i\alpha F}{rRT}\right)^{1/2} x\right].$$

We may note that i_x is the total current entering the electrode from the bottom up to a position x, while ΔV_x is the potential drop along the electrode measured from the top. Accordingly we find that i_x decreases with increasing x (equation [10]) and ΔV_x increases with increasing x (equation [12*a*]).

**The negative sign arises here on account of the manner in which i_x is defined. In any case the c.d. must have the same sign as the total current and this is satisfied above since the derivative of i_x with respect to x is negative (equation [9a]).*

III. CALCULATION OF THE APPARENT CURRENT – POTENTIAL RELATION

1. Conditions and Model

We now consider the relation between the apparent and real current – potential behavior at an electrode of length L and specific resistance ρ, as defined in Section II. The model is the same as that considered above but the electrode is regarded as divided into a large number n of segments Δx in length ($n\Delta x = L$) and Δi_j is taken as the actual current passing from a representative j'th segment into the solution.

2. Formulation of Equations

For convenience in the mathematical development, we treat the problem now in terms of summations. From the definitions above, we may write

$$\sum_{j=1}^{n} \Delta i_j = I. \tag{13}$$

If the ohmic resistance of the electrode is not negligible, conditions will be as in the previous calculation (Section II) and the current density will decrease down the electrode. Let it be assumed that each segment is small enough for the ohmic p.d. within it to be, to a *first* approximation, negligible and that the potential operative at the j'th segment depends on the potential V_0 applied to the electrode less the ohmic potential drop down the $j-1$ preceding segments, as in the previous calculation. At the middle of the first segment the current passing is taken as

$$\Delta i_1 = i_0 2\pi r \Delta x \exp [V_0/b]. \tag{14}$$

At the corresponding position in the second segment, the potential operative in determining the current will be less than V_0 by the ohmic potential drop in segment one, i.e.

$$\begin{aligned}\Delta i_2 &= i_0 2\pi r \Delta x \exp \frac{1}{b}\left[V_0 - \frac{\rho}{\pi r^2} \Delta x (I - \Delta i_1) \right] \\ &= i_0 2\pi r \Delta x \exp \frac{V_0}{b}\left[1 - \frac{\rho}{\pi r^2} \frac{\Delta x}{V_0} (I - \Delta i_1) \right].\end{aligned} \tag{15}$$

Similarly

$$\begin{aligned}\Delta i_3 &= i_0 2\pi r \Delta x \exp \frac{1}{b}\left[V_0 - \frac{\rho}{\pi r^2} \Delta x (I - \Delta i_1) - \frac{\rho}{\pi r^2} \Delta x (I - \Delta i_1 - \Delta i_2) \right] \\ &= i_0 2\pi r \Delta x \exp \frac{V_0}{b}\left[1 - \frac{\rho}{\pi r^2} \frac{\Delta x}{V_0} (2I - 2\Delta i_1 - \Delta i_2) \right]\end{aligned} \tag{16}$$

and

$$\begin{aligned}\Delta i_4 &= i_0 2\pi r \Delta x \exp \frac{1}{b}\left[V_0 - \frac{\rho}{\pi r^2} \Delta x (2I - 2\Delta i_1 - \Delta i_2) - \frac{\rho}{\pi r^2} \Delta x (I - \Delta i_1 - \Delta i_2 - \Delta i_3) \right] \\ &= i_0 2\pi r \Delta x \exp \frac{V_0}{b}\left[1 - \frac{\rho}{\pi r^2} \frac{\Delta x}{V_0} (3I - 3\Delta i_1 - 2\Delta i_2 - \Delta i_3) \right]\end{aligned} \tag{17}$$

and, in general, for the current at the j'th element

$$\begin{aligned}\Delta i_j &= i_0 2\pi r \Delta x \exp \frac{1}{b}\left[V_0 - \frac{\rho}{\pi r^2} \Delta x \{ (j-1)I - (j-1)\Delta i_1 - (j-2)\Delta i_2 \right. \\ &\qquad \left. - (j-3)\Delta i_3 - (j-k)\Delta i_k \} \right] \\ &= i_0 2\pi r \Delta x \exp \frac{V_0}{b} \exp -\left[\frac{\rho}{\pi r^2} \frac{\Delta x}{b} (j-1) I \right] \exp \frac{\rho}{\pi r^2} \frac{\Delta x}{b}\left[\sum_{k=1}^{j-1} (j-k)\Delta i_k \right].\end{aligned} \tag{18}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The total current is

$$I = \sum_{j=1}^{n} \Delta i_j.$$

The latter summation cannot be evaluated analytically since it is a sum of exponentials having different arguments. However, if the variation of current density along the electrode is not too large, the procedures given below can be adopted as an approximation.

Here, let it be assumed that the arithmetic mean of the current over the n elements can be approximated by the geometric mean. That is

[19] $$\frac{1}{n}\sum_{j=1}^{n} \Delta i_j = (\overset{j}{\Pi}\, \Delta i_j)^{1/n}$$

and hence

[20] $$I = n\,(\overset{j}{\Pi}\, \Delta i_j)^{1/n}.$$

Taking logarithms of the terms in equation [18] for Δi_j gives

[21] $$\ln \Delta i_j = \ln (i_0 2\pi r \Delta x) + \frac{V_0}{b} + \frac{1}{b}\left[-\frac{\rho}{\pi r^2}\Delta x(j-1)I + \frac{\rho}{\pi r^2}\Delta x \sum_{k=1}^{j-1}(j-k)\Delta i_k\right];$$

then since

[22] $$\ln [\overset{j}{\Pi}\, \Delta i_j] = \sum_{j=1}^{n} \ln [\Delta i_j]$$

we obtain

[23] $$\sum_{1}^{n} \ln \Delta i_j = n \ln (i_0 2\pi r \Delta x) + \frac{nV_0}{b} - \frac{1}{b}\frac{\rho}{\pi r^2}\Delta x I \sum_{j=1}^{n}(j-1) + \frac{\rho}{\pi r^2}\frac{\Delta x}{b}\sum_{j=1}^{n}\sum_{k=1}^{j-1}(j-k)\Delta i_k$$

or

[24] $$\frac{1}{n}\sum_{j=1}^{n} \ln \Delta i_j = \ln (i_0 2\pi r \Delta x) + \frac{V_0}{b} - \frac{1}{nb}\frac{\rho}{\pi r^2}\Delta x I \frac{n(n-1)}{2} + \frac{\rho}{\pi r^2}\frac{\Delta x}{nb}\sum_{j=1}^{n}\sum_{k=1}^{j-1}(j-k)\Delta i_k.$$

Now

$$\ln (I/n) = \ln [\overset{j}{\Pi}\, \Delta i_j]^{1/n} = \frac{1}{n}\sum_{j=1}^{n} \ln [\Delta i_j],$$

so that

$$\ln (I/n) = \text{r.h.s. of [24]}$$

or

[25] $$\frac{I}{n} = i_0 2\pi r \Delta x \exp\left[\frac{V_0}{b}\right]\exp\left[-\frac{\rho I \Delta x}{\pi r^2 b}\frac{(n-1)}{2}\right]\exp\left[\frac{\rho \Delta x}{\pi r^2 n b}\sum_{j=1}^{n}\sum_{k=1}^{j-1}(j-k)\Delta i_k\right].$$

If we make the simplification that $n-1 = n$ since n can be made arbitrarily large, and with $n\Delta x = L$, we have

[26] $$I = i_0 2\pi r L \exp\left[\frac{V_0}{b}\right]\exp\left[\frac{\rho L}{\pi r^2}\frac{I}{2b}\right]\exp\left[\frac{\rho L}{\pi r^2}\frac{1}{n^2 b}\sum_{j=1}^{n}\sum_{k=1}^{j-1}(j-k)\Delta i_k\right].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Since the resistance of the whole electrode is given by $\mathscr{R} = \rho L/\pi r^2$ and its total surface area is $S = 2\pi rL$, we can rewrite equation [26] as

$$[27] \qquad I = i_0 S \exp(V_0/b) \exp(-\mathscr{R}I/2b) \exp\left[\frac{\mathscr{R}}{n^2 b} \sum_{j=1}^{n} \sum_{k=1}^{j-1} (j-k)\Delta i_k\right].$$

We shall now examine the physical significance of the various terms in equation [27]. The term

$$i_0 \exp[V_0/b]$$

is obviously the value of I/S when $\rho = 0$, i.e. when no finite resistance of the electrode is considered and is the theoretically significant quantity since its value and, in particular, its variation with V_0 are characteristic of the kinetics of the electrochemical reaction occurring at the electrode. In fact, it is the purpose of these calculations to relate this "ideal" current density to the mean overall value which would be experimentally measured, viz. I/S.

The second term in equation [27], $\exp[-RI/2b]$, is effectively a correction factor which takes into account a linear potential drop along the electrode due to its ohmic resistance; the last term on the r.h.s. of equation [27] is a second-order correction factor which takes into account the departure from linearity of this potential drop arising from the exponential variation of reaction resistance with electrode potential. The double sum in the last term can be represented in tabular form as shown below:

Terms in the double sum in equation [27]

k \ j	1	2	3	4	5 ..... j
1	0	Δi_1	$2\Delta i_1$	$3\Delta i_1$	$4\Delta i_1$ ..... $(j-1)\Delta i_1$
2	0	0	Δi_2	$2\Delta i_2$	$3\Delta i_2$ ..... $(j-2)\Delta i_2$
3	0	0	0	Δi_3	$2\Delta i_3$ ..... $(j-3)\Delta i_3$
4	0	0	0	0	Δi_4 ..... $(j-4)\Delta i_4$
5	0	0	0	0	0 ..... $(j-5)\Delta i_5$
⋮					
k	0	0	0	0	0 ..... $(j-k)\Delta i_k$

Since the term involving the summation in equation [27] constitutes a second-order correction, we may make the approximation

$$[28] \qquad \Delta i_k = \Delta i_{k+1} = I/n,$$

so that the last term in equation [27] becomes

$$\exp\frac{\mathscr{R}}{b}\cdot\frac{1}{n^2} \sum_{j=1}^{n} \sum_{k=1}^{j-1} (j-k)\Delta i_k = \exp\frac{\mathscr{R}I}{b}\cdot\frac{1}{n^3} \sum_{j=1}^{n} \sum_{k=1}^{j-1} (j-k).$$

It can be shown that

$$[29] \qquad \lim_{n\to\infty}\left[\frac{1}{n^3} \sum_{j=1}^{n} \sum_{k=1}^{j-1} (j-k)\right] = 1/6,$$

so that, combining equations [27] and [29],

$$[30] \qquad I/S = i \exp\left[-\frac{\mathscr{R}I}{2b}\right] \exp\left[\frac{\mathscr{R}I}{6b}\right] = i \exp\left[-\frac{\mathscr{R}I}{3b}\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

or

$$i = (I/S) \exp [\mathscr{R}I/3b]. \quad [31]$$

Equation [31] has been derived for convenience for an anodic process; it is obviously applicable generally for any electrode process since $I/b > 0$ in all cases.

Apparent Tafel Slope

The observed Tafel slope $dV/d \ln I$ will be related to the mechanistically significant Tafel slope $dV/d \ln i$ through the equation

$$dV/d \ln i = (dV/d \ln I)(d \ln I/\mathrm{d} \ln i) \quad [32]$$

from equation [31]

$$(d \ln i/d \ln I) = 1 + \frac{\mathscr{R}I}{3b}. \quad [33]$$

Hence

$$dV/d \ln i = dV/d \ln I(1+\mathscr{R}I/3b)^{-1}. \quad [34]$$

We note, therefore, that a finite electrode resistance will cause a decrease in the overall current density from that predicted by the corresponding Tafel equation: also the observed apparent Tafel slope will be larger than the real one (b in equation [34]) and will tend to increase with current density.

Since equation [34] was derived assuming that RI, although not negligible, was relatively small, the true Tafel slope can be obtained from a measured value of $dV/d \ln I$ and the known specific resistance of the electrode at a given total current I. The result can be further improved, if required, by a series of successive approximations. It is of interest to note also that the current–potential behavior at electrodes at which a given reaction is proceeding with a high value of b will be relatively less affected by electrode resistance effects than that for reactions associated with low Tafel slopes.

The above calculations have been made in order that at electrodes of significant resistance where internal ohmic potential drops are not negligible at high current densities, the true, mechanistically significant Tafel slopes can nevertheless be evaluated from the observed current-potential relation for high-load conditions, and the current-density distribution can also be calculated. We also note that, since there is a drop of potential down the electrode, significant longitudinal ionic currents may arise in the solution. Such effects will be small when the solution resistance is not too low and ρ is not high.

THE REACTION OF METHYL RADICALS WITH METHYL ALCOHOL

T. W. SHANNON AND A. G. HARRISON
Department of Chemistry, University of Toronto, Toronto, Ontario
Received May 13, 1963

ABSTRACT

The photolysis of acetone in the presence of methyl alcohol and of methyl-d_3 alcohol has been studied between 406 and 472° K. The rates and Arrhenius parameters for the following abstraction reactions have been determined:

$$CH_3 + CH_3OH \rightarrow CH_4 + \begin{cases} CH_3O \\ HOCH_2 \end{cases} \quad [a]$$

$$CH_3 + CD_3OH \rightarrow CH_4 + CD_3O \quad [b]$$

$$\rightarrow CH_3D + CD_2OH. \quad [c]$$

At 182° C the rate of reaction [*b*] is found to be approximately four times greater than the rate of reaction [*c*].

INTRODUCTION

There now exists a large body of data on the hydrogen abstraction reactions of methyl radicals and some correlation between molecular structure and reactivity are apparent (1). In many cases, however, there is uncertainty as to which hydrogen is abstracted by the methyl radical. Although the reaction of methyl radicals with methyl alcohol has been studied (2, 3) it is not clear from the results whether the methyl or the hydroxyl hydrogen is abstracted. The present work reports a study of the reaction of methyl radicals, produced by the photolysis of acetone, with methyl-d_3 alcohol to determine the relative importance of the two possible abstraction processes.

EXPERIMENTAL

The photolyses were carried out in a cylindrical pyrex reaction vessel of 157 cc capacity maintained to ±1° C in an aluminum block furnace. Corex-D windows on the cell removed radiation below 2800 Å. The light source was a B.T.H. type ME/D 250 watt mercury discharge lamp. The light beam was roughly collimated by a quartz lens and filled the whole reaction cell. Photolyses were carried out for periods from 700 to 1200 seconds, corresponding to 2 to 3% decomposition of the acetone.

The reaction products were passed through traps at 142° K and the volatile products transferred by a Toepler pump to a calibrated gas burette and thence to sample flasks for analysis with an A.E.I. MS-2 mass spectrometer.

The acetone was Fisher spectranalyzed grade dried and distilled *in vacuo* before use. Fisher certified reagent methanol was found to contain trimethyl borate impurity. This was removed by refluxing with water followed by fractional distillation. The methyl-d_3 alcohol was obtained from Merck, Sharp and Dohme, Montreal. Mass spectrometric analysis showed hexadeuterodimethyl ether as the only impurity. This was easily removed by pumping at low temperature. Low-energy analysis showed less than 1% isotopic impurity. The CH_3OH and CD_3OH were stored in quartz containers connected to the vacuum line by metal valves.

RESULTS

Photolysis of Acetone

The main features of the photolysis of acetone are well established (4). Above 100° C the formation of the products methane and ethane can be described by the following scheme:

$$CH_3COCH_3 + h\nu \rightarrow 2CH_3 + CO \quad [1]$$

$$2CH_3 \rightarrow C_2H_6 \quad [2]$$

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3, \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

leading to the following rate expression

$$R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[Ac] = k_3/k_2^{\frac{1}{2}}. \quad [I]$$

In the present work the photolysis of acetone alone was studied between 415 and 499° K to check the accuracy of the experimental techniques and to establish values for $k_3/k_2^{\frac{1}{2}}$ pertaining to the present system. From a least squares plot the best straight line fitting the experimental data is given by the equation

$$13 + \log k_3/k_2^{\frac{1}{2}} \text{ (cc}^{\frac{1}{2}} \text{ molecule}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}) = 5.80(\pm 0.05) - 2.021(\pm 0.023)10^3/T.$$

Using $k_2 = 2.2 \times 10^{13}$ cc mole^{-1} sec^{-1} (5) and $E_2 = 0$, this relationship gives log A_3 (cc mole^{-1} sec^{-1}) = 11.35±0.05 and $E_3 = 9.3 \pm 0.1$ kcal mole^{-1}. This is in satisfactory agreement with previous values of 11.5 and 9.7 (6), 11.5 and 9.6 (7), and 11.35 and 9.5 (8) for log A_3 and E_3 respectively.

Photolysis of Acetone – Methyl Alcohol Mixtures

When acetone is photolyzed in the presence of methyl alcohol the following reaction leading to methane formation must be added to the reaction scheme given above:

$$CH_3 + CH_3OH \rightarrow CH_4 + \begin{Bmatrix} CH_2OH \\ CH_3O \end{Bmatrix} \quad [4]$$

The following equation may be derived:

$$R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[CH_3OH] = k_4/k_2^{\frac{1}{2}} + k_3/k_2^{\frac{1}{2}} \cdot [Ac]/[CH_3OH]. \quad [II]$$

Since $k_3/k_2^{\frac{1}{2}}$ is known from experiments with acetone alone $k_4/k_2^{\frac{1}{2}}$ may be determined. Photolyses of acetone – methyl alcohol mixtures were carried out in the temperature range 406 to 472° K. From a least squares analysis the best straight line fitting the experimental data is given by the equation

$$13 + \log k_4/k_2^{\frac{1}{2}} \text{ (cc}^{\frac{1}{2}} \text{ molecule}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}) = 5.20(\pm 0.07) - 1.90(\pm 0.032)10^3/T,$$

leading to $E_4 = 8.7 \pm 0.2$ kcal mole^{-1} and log A_4 (cc mole^{-1} sec^{-1}) = 10.76±0.07. Phibbs and Darwent (2) obtained log $A_4 = 10.49$ and $E_4 = 8.2 \pm 0.5$ while Trotman-Dickenson and Steacie (3) obtained log $A_4 = 10.53$ and $E_4 = 8.2 \pm 0.2$. Both the A factor and the activation energy obtained in the present work are somewhat higher; however the values for k_4 at 182° C are in excellent agreement for all three studies.

Photolysis of Acetone – Methyl-d_3 Alcohol Mixtures

The following reactions are proposed to explain the formation of CH_4, CH_3D, and C_2H_6 when acetone is photolyzed in the presence of CD_3OH at temperatures above 100° C:

$$2CH_3 \rightarrow C_2H_6 \quad [2]$$

$$CH_3 + CH_3COCH_3 \rightarrow CH_4 + CH_2COCH_3 \quad [3]$$

$$CH_3 + CD_3OH \rightarrow CH_4 + CD_3O \quad [5]$$

$$CH_3 + CD_3OH \rightarrow CH_3D + CD_2OH. \quad [6]$$

From this reaction scheme the following equations may be derived:

$$R_{CH_4}/R_{C_2H_6}^{\frac{1}{2}}[Ac] = k_3/k_2^{\frac{1}{2}} + k_5/k_2^{\frac{1}{2}} \cdot [CD_3OH]/[Ac] \quad [III]$$

$$R_{CH_3D}/R_{C_2H_6}^{\frac{1}{2}}[CD_3OH] = k_6/k_2^{\frac{1}{2}} \quad [IV]$$

$$R_{CH_4}/R_{CH_3D} = k_5/k_6 + k_3/k_6[Ac]/[CD_3OH]. \quad [V]$$

The photolyses of acetone–CD_3OH mixtures were carried out at five temperatures between 427 and 477° K with the ratio of CD_3OH to acetone being varied from 0.3 to 3.0. The results are given in Table I. In addition to the expected products mass spectrometric analysis showed small amounts of products having parent masses of 33 and 19,

presumably CD_3CH_3 and CD_3H. The proportion increased with increasing temperature, reaching 5% of the $CH_4 + C_2H_6$ product at the highest temperature. These products suggest the formation of CD_3 radicals; however it was not possible to obtain concrete evidence concerning the mechanism of formation owing to the small amounts involved. In any event the formation of these products should not invalidate the kinetic scheme proposed above for the major products.

The values obtained for $k_6/k_2^{\frac{1}{2}}$ via equation [IV] (column 9, Table I) are constant, within experimental error, for each temperature. The average values are given in Table II,

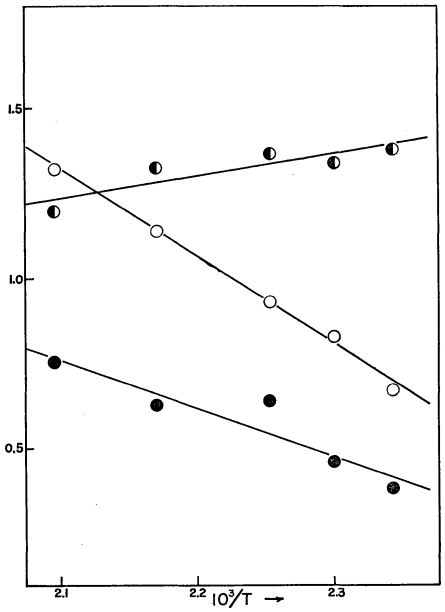

FIG. 1. Arrhenius activation energy plot: ○ 14 + log $k_6/k_2^{\frac{3}{2}}$; ● 13 + log $k_5/k_2^{\frac{3}{2}}$; ◐ log k_3/k_6.

while an Arrhenius plot of the data is shown in Fig. 1. The least squares line gives log A_6 (cc mole^{-1} sec^{-1}) = 11.25±0.28 and E_6 = 11.7±0.6 kcal mole^{-1}, using Shepp's value for k_2.

The experimental data are plotted in the form of equation [III] in Fig. 2. The intercept of the straight lines obtained should give values for $k_3/k_2^{\frac{3}{2}}$. The best straight line fitting the experimental intercepts is given by equation

$$13 + \log k_3/k_2^{\frac{3}{2}} = 5.77(\pm 0.23) - 2.017(\pm 0.10)10^3/T,$$

in excellent agreement with the equation obtained above from the photolysis of acetone alone.

From the slopes of the lines in Fig. 2 the values of $k_5/k_2^{\frac{3}{2}}$ reported in Table II are obtained. The Arrhenius plot of this data (Fig. 1) leads to log A_5 (cc mole^{-1} sec^{-1}) = 9.25 ±0.3 and E_5 = 6.4±0.7 kcal mole^{-1}.

The experimental data is plotted in the form of equation [V] in Fig. 3. The values of k_5/k_6 and k_3/k_6 obtained from the intercepts and slopes of the least squares lines are given in Table II. The values of k_5/k_6 show irregular variations and do not give a satisfactory Arrhenius plot. The amounts of CH_3D and CH_4 formed by reactions [5] and [6] are quite small and analytical errors will have a much larger effect on the intercept than the slope. The plot of log k_3/k_6 vs. $1/T$ (Fig. 1) leads to $E_6 - E_3$ = 3.0±1.0 kcal mole^{-1}. Using E_3 = 9.3 this gives E_6 = 12.3±1.1 kcal mole^{-1}, in agreement with the value of 11.7 ±0.6 kcal mole^{-1} obtained above.

DISCUSSION

The above results indicate that the reaction of methyl radicals with CH_3OH previously written as reaction [4] is the sum of two reactions:

$$CH_3 + CH_3OH \rightarrow CH_4 + CH_3O \quad [5']$$
$$\rightarrow CH_4 + HOCH_2 \quad [6']$$

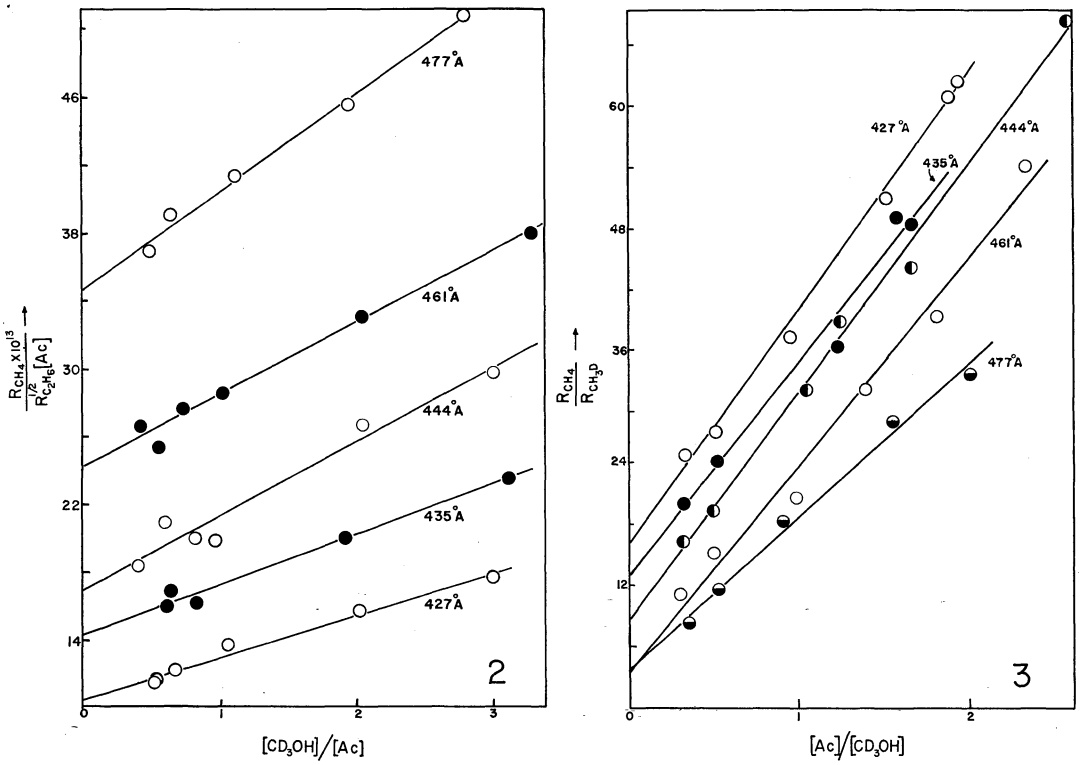

FIG. 2. Photolysis of acetone with methyl-d_3 alcohol. Experimental plot of equation [III].
FIG. 3. Photolysis of acetone with methyl-d_3 alcohol. Plot of equation [V]. (Scale for plots from 461 to 427° A raised 3 units successively.)

It follows that $k_4/k_2^{\frac{1}{2}}$ obtained above is given by the following relation:

$$k_4/k_2^{\frac{1}{2}} = k_{5'}/k_2^{\frac{1}{2}} + k_{6'}/k_2^{\frac{1}{2}}. \qquad [VI]$$

If we assume that the rate of abstraction of the hydroxyl hydrogen is independent of hydrogen–deuterium substitution of the methyl we may equate $k_{5'}/k_2^{\frac{1}{2}}$ with $k_5/k_2^{\frac{1}{2}}$ and solve equation [VI] for $k_{6'}/k_2^{\frac{1}{2}}$. The values thus obtained are recorded in Table II and are best represented by the equation

$$13 + \log k_{6'}/k_2^{\frac{1}{2}} = 5.82 - 2.28110^3/T.$$

This leads to $E_{6'} = 10.4$ kcal mole^{-1} and log $A_{6'}$ (cc mole^{-1} sec^{-1}) $= 11.38$. These values contain relatively large errors due to the accumulation of errors in the ratios from which they were calculated. The difference in activation energy for D vs. H abstraction is thus given by $E_6 - E_{6'} = 1.3$ kcal mole^{-1}. Using the stretching frequencies for C—H and C—D bonds in CH_3OH and CD_3OH, 2845 and 2094 cm^{-1} respectively (9), the difference in zero-point energies is calculated to be 1.1 kcal mole^{-1}. Rice and Vanderslice (10) have reported activation energy differences for D and H abstraction from various alkanes to be in the region 0.6 to 2.3 kcal mole^{-1} while Ausloos and Steacie (11) have reported 1.1 kcal mole^{-1} difference for abstraction from acetaldehyde. The present result therefore appears reasonable.

A summary of the rate constants and Arrhenius parameters of the reactions studied in

TABLE III
Summary of results

Reaction	E (kcal mole^{-1})	$k\times10^{-6}$ (182° C) (mole^{-1} cc sec^{-1})	$A\times10^{-11}$ (mole^{-1} cc sec^{-1})	$p\times10^{4}$
3	9.3±0.1	7.87	2.13	6.2
4	8.7±0.2	3.90	0.575	1.7
6	11.7±0.6	0.43	1.79	7.2
6′	10.4	2.4	2.4	7.2
5′ (or 5)	6.4±0.7	1.52	0.0179	0.054

the present work is given in Table III. The steric factors were calculated using collision diameters for CH_3, CH_3OH, and CH_3COCH_3 of 3.5 (3), 5.0 (2), and 5.1 Å (6) respectively. Reaction [6] was assigned the same steric factor as reaction [6′].

The outstanding feature of the present results is the low activation energy and low A factor for abstraction of the hydroxyl hydrogen. Although the A factor for methyl hydrogen abstraction is similar to that normally found for methyl radical reactions the A factor for hydroxyl hydrogen abstraction is a factor of 100 lower. Furthermore the activation energy $E_{5'}$ is quite low considering the strength of the bond being broken. Two lines of evidence can be presented which indicate that the present result is not likely to be in serious error.

$E_{5'}$ = 6.4 kcal mole^{-1} when combined with $D(CH_3O—H)$ = 100 kcal mole^{-1} (12) and $D(CH_3—H)$ = 102 kcal mole^{-1} (13) leads to E = 8.4 kcal mole^{-1} for reaction [7].

$$CH_3O + CH_4 \rightarrow CH_3OH + CH_3 \qquad [7]$$

Bercés and Trotman-Dickenson (14) have reported an activation energy of 7.1 kcal mole^{-1} for methoxy radical abstraction from ethane. Considering the difference in bond strength between methane and ethane the value calculated for E_7 appears quite reasonable. It is interesting to note that $E_{6'}$ = 10.4 kcal mole^{-1} when combined with $D(HOCH_2—H)$ = 90 kcal mole^{-1} (15) and $D(CH_3—H)$ leads to E_8 = 22 kcal mole^{-1}. Although there is

$$HOCH_2 + CH_4 \rightarrow HOCH_3 + CH_3 \qquad [8]$$

little information available on the reactions of hydroxy-methyl radicals they do not appear to be particularily reactive.

Of particular interest with regard to the present results are the results obtained by Thynne (16) for the reaction of methyl radical with CH_3NH_2. Thynne obtained log A = 11.15±0.12 and E = 9.3±0.2 kcal mole^{-1} for abstraction of the methyl hydrogen and log A = 9.34±0.34 and E = 5.26±0.66 kcal mole^{-1} for abstraction of the amino hydrogen. The general trend of the results is identical with that found for methyl alcohol. Abstraction of the methyl hydrogen, which involves the weakest bond, occurs with a relatively high activation energy and a normal A factor, while abstraction of the amino or hydroxyl hydrogen occurs with a low activation energy and a low pre-exponential factor. The reasons for the low A factors are not apparent and further work is planned to determine if this is a general phenomenon for alcohols.

While this manuscript was in preparation Cher (17) reported a study of the reaction of CD_3 radicals with methyl-d_3 alcohol in the liquid phase at 30° C. He found the rate of abstraction of the methyl deuterium to be approximately five times faster than abstraction of the hydroxyl hydrogen. This should correspond to the ratio k_6/k_5 of the present work. The results in Table III give k_6/k_5 = 0.28 at 182° C and extrapolate to k_6/k_5 = 0.06 at 30° C. This apparent discrepancy can be explained by the logical assumption that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

hydrogen bonding in the liquid phase has greatly reduced the reactivity of the hydroxyl hydrogens.

ACKNOWLEDGMENTS

DINITROPHENYL PEPTIDES

I. PREPARATION AND PROPERTIES OF SOME DINITROPHENYL GLYCYL DIPEPTIDES

J. H. LOUDFOOT AND J. E. KRUGER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received February 15, 1963

ABSTRACT

Some dinitrophenyl glycyl peptides have been prepared from dipeptides and from dinitrophenyl glycyl chloride, and the products suitably characterized. Electrophoresis gave good separation of those differing by more than two carbon atoms.

Dinitrophenyl peptides prepared from protein or peptide hydrolyzates by Sanger's method (1) are usually characterized by chromatographic identification of their hydrolysis products. Where direct comparison with authentic dinitrophenyl peptides has been made, this was based only on chromatographic behavior (2, 3, 4). Comparison on the basis of other physical properties, such as melting point, specific rotation, etc., would require the synthesis of authentic dinitrophenyl peptides, preferably by several independent methods, and determination of their physical properties. Rhinesmith (5) has recently reported the synthesis of dinitrophenyl-DL-valyl peptides from dinitrophenyl-DL-valyl chloride, but did not report their physical properties or compare them with products from any other preparative method. Also, yields were calculated from spectral data, and analysis was based on chromatographic and spectral estimation of the hydrolysis products.

We have therefore undertaken a systematic study of the preparation and properties of dinitrophenyl peptides, in particular the dinitrophenyl derivatives of glycylglycine, glycyl-L-alanine, glycycl-L-valine, and glycyl-L-leucine by two procedures found to be the most suitable. Separation of these peptide derivatives from one another and from dinitrophenyl glycine by electrophoresis is also reported.

EXPERIMENTAL

Dinitrophenyl Glycine

This compound was prepared by the method of Levy and Chung (6) using sodium bicarbonate instead of sodium carbonate as condensing agent.

Dinitrophenyl Glycyl Chloride

Dinitrophenyl glycine (1 g) and thionyl chloride (10 ml) were heated 1 hour under reflux, and the excess thionyl chloride removed by distillation under vacuum. The yellow crystalline residue was heated under reflux with carefully dried benzene to complete solution; on cooling, the product crystallized as large yellow needles. Yield 1 g (92.5% theory), m.p. 129–130°. Anal. Calc. for $C_8H_6N_3O_5Cl$: C, 36.96, H 2.33, N 16.17, Cl 13.66. Found: C 37.42, H 2.62, N 15.29, Cl 12.57. The preparation of this compound was studied previously (5) but lower yields were obtained and its melting point was not reported.

Dinitrophenyl Peptides

The dinitrophenyl peptides made directly from the dipeptides and from the acid chloride were identical, and distinct from dinitrophenyl glycine, as established by mixed melting point determination. When they were made from dinitrophenyl glycyl chloride, little if any racemization occurred, and sodium hydroxide was unsuitable as acid binder.

A. From the Dipeptides

The dipeptide and 2,4-dinitrofluorobenzene (equimolar quantities) were added to 15% (w/v) sodium bicarbonate solution (8.7 ml/mmole of peptide), and the mixture stirred 2 hours at room temperature. Immediate acidification with hydrochloric acid precipitated the product as a yellow solid, which was filtered and washed with water.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

B. From Dinitrophenyl Glycyl Chloride

A solution of the acid chloride (1 mmole) in dry benzene (6–8 ml) was added slowly with stirring to an ice-cold solution of the amino acid (1 mmole) in 3.5% (w/v) aqueous sodium carbonate (18 ml) during 2 hours. The stirring was continued for a further 2 hours at ice-bath temperature, whereupon the benzene layer was removed and the aqueous layer acidified with hydrochloric acid to precipitate the dinitrophenyl peptide. With all the peptides except glycyl glycine, a darker-colored impurity appeared during the initial stages of acidification, before precipitation of the product. This impurity was easily removed by careful addition of acid until no further impurity separated, followed by decantation; the remainder of the acid was then added immediately.

Dinitrophenyl Glycylglycine

The solid was recrystallized by dissolving in ethanol and adding just enough water for crystals to form, which were filtered and dried 4 hours at 104°. *Method A*—91–92% yield, m.p. 194–195°, optically inactive in 95% ethanol. *Method B*—54–55% yield, m.p. 194–195°, optically inactive in 95% ethanol. Anal. Calc. for $C_{10}H_{10}N_4O_7$: C 40.03, H 3.38, N 18.8, equiv. 298.14. Found: C 39.44, H 3.64, N 16.72, equiv. 299.4.

Dinitrophenyl Glycyl-L-alanine

Method A—Recrystallization and drying were as described for dinitrophenyl glycylglycine; 75–76% yield, m.p. 175–176.5°, $[\alpha]_D^{21}$ −23.4±2° (2.77% in 95% ethanol). *Method B*—Recrystallization had to be as described for dinitrophenyl glycyl-L-valine; drying was as for method A; yield 44–45%, m.p. 175–176.5°, $[\alpha]_D^{21}$ −23.4±2° (2.75% in 95% ethanol). Anal. Calc. for $C_{11}H_{12}N_4O_7$: C 42.31, H 3.87, N 17.98, equiv. 312.27. Found: C 41.73, H 3.77, N 18.01, equiv. 317.1.

Dinitrophenyl Glycyl-L-valine

This compound was recrystallized by dissolving in ethanol,* diluting with a large volume of water, evaporating to small bulk at room temperature,† and repeating the entire process as often as necessary to reach a constant melting point; it was dried 4 hours at 90°.

Method A—44–45% yield, m.p. 132–134°, $[\alpha]_D^{22}$ −21.2±2° (1.18% in 95% ethanol). *Method B*—44–45% yield, m.p. 131–132°, $[\alpha]_D^{22}$ −20.4±2° (1.22% in 95% ethanol). Anal. Calc. for $C_{13}H_{16}N_4O_7$: C 45.59, H 4.74, N 16.38, equiv. 340.3. Found: C 45.29, H 4.96, N 14.9, equiv. 337.0.

Dinitrophenyl Glycyl-L-leucine (Monohydrate)

Recrystallization was as for the glycyl-L-valine derivative, and it was dried overnight at room temperature over phosphorus pentoxide. *Method A*—46–47% yield, m.p. 98–100°, $[\alpha]_D^{22}$ −29.8±2° (1.01% in 95% ethanol). *Method B*—57–58% yield, m.p. 96–98°, $[\alpha]_D^{22}$ −29.1±2° (1.03° in 95% ethanol). Anal. Calc. for $C_{14}H_{20}N_4O_8$: C 45.16, H 5.41, N 15.05, equiv. 373.32. Found: C 45.82, H 5.24, N 15.11, equiv. 364.3–369.1.

Carbon, hydrogen, and nitrogen analyses were by Geller Laboratories, Bardonia, N.Y.

Electrophoresis

A Reco model E 800-2 open strip apparatus was used, at 300 v and 5 ma for 20 hours at 21°, with 0.02 *M* borate buffer (pH 9.11) and Whatman No. 1 paper, 50×20 cm. A bridge support was placed under the paper near the positive plate, to ensure that the compounds (in anionic form) would be migrating on a rising incline. The initial spots were placed near the opposite end, avoiding the part of the paper held to the cooling surface by unavoidable capillary action.

The movements of dinitrophenyl glycine and of the products, separately and in various admixtures with one another, were studied. The glycine derivative moved much further than the dipeptide derivatives, and the latter showed good separation of those differing by more than two carbon atoms. Distances moved by the dinitrophenyl derivatives of glycine, glycylglycine, glycyl-L-alanine, glycyl-L-valine, and glycyl-L-leucine were 17.5, 14, 13.2, 10.7, and 10.5 cm respectively.

ACKNOWLEDGMENT

Financial support for this work, including a Summer Assistantship (for J. E. K.), was made available by the National Research Council of Canada.

THE SULPHURIC ACID SOLVENT SYSTEM

PART V. SOLUTIONS OF SOME ORGANOSILICON COMPOUNDS

R. H. FLOWERS, R. J. GILLESPIE,[1] AND E. A. ROBINSON[2]
Department of Chemistry, University College, London, England
Received May 27, 1963

ABSTRACT

The cryoscopic and conductimetric behavior of solutions of hexamethyldisiloxane, trimethylethoxysilane, dimethyldiethoxysilane, methyltriethoxysilane, and tetraphenylsilane in 100% sulphuric acid has been investigated. The measurements show that stable non-electrolytes such as $(CH_3)_3Si\cdot HSO_4$ and $(CH_3)_2Si(HSO_4)_2$ are formed from the tri- and di-alkyl compounds. Species such as $CH_3Si(HSO_4)_3$, which are presumably formed in the reaction of monoalkyl compounds, and $Si(HSO_4)_4$, which it is reasonable to suppose is the initial product from the cleavage of tetraphenylsilane, are unstable and polymerize to give polymers containing Si—O—Si bridging groups. No evidence was obtained for the formation of siliconium ions or for the formation of compounds containing silicon with a coordination number greater than four.

INTRODUCTION

The reactions of organosilicon compounds with sulphuric acid are of interest in view of the use of sulphuric acid as an equilibrating agent in the preparation of silicones (1) and in cleavage reactions of complex organosilicon compounds (2). There have consequently been several investigations of the cryoscopic behavior of organosilicon compounds (2–4), although no previous conductimetric studies have been reported.

In this paper the results of cryoscopic and conductimetric studies of solutions of hexamethyldisiloxane, trimethylethoxysilane, dimethyldiethoxysilane, methyltriethoxysilane, and tetraphenylsilane are reported. Ethyl silicate, triphenylsilanol, trinaphthylsilanol, silicon tetraacetate, and diphenylsilanediol were found to be insoluble in sulphuric acid and they reacted slowly to give gelatinous solids.

EXPERIMENTAL

Cryoscopic measurements were carried out using the Beckmann method of cryoscopy as described previously (5). Solid-stem mercury in glass thermometers which had been calibrated against a platinum resistance thermometer was used for temperature measurements. Conductivities were measured at 25° C (6). In each case addition of a small quantity of the strong base potassium sulphate to the solution of the silicon compound at the end of an experiment led to an increase in the specific conductance, showing that all the compounds ionize as bases.

Hexamethyldisiloxane, trimethylethoxysilane, dimethylethoxysilane, and methyltriethoxysilane were obtained from the Midland Silicone Company and were at least 99% pure as supplied. They were distilled through a column and the middle fraction of constant boiling point collected in each case. (Boiling points: $[(CH_3)_3Si]_2O$, 99.5°; $(CH_3)_3SiOEt$, 75–76°; $(CH_3)_2Si(OEt)_2$, 112–113°; $CH_3\cdot Si(OEt)_3$, 141–142°). Tetraphenylsilane was prepared according to the method of Gilman and Jones (7) from triphenylchlorosilane and phenyllithium. It had a melting point of 236°.

The sulphuric acid solvent was prepared from 'AnalaR' sulphuric acid and sulphur trioxide and adjusted to the composition 100% H_2SO_4 by means of its freezing point or specific conductivity (5, 6).

RESULTS

The results of the cryoscopic and conductimetric measurements are shown in Tables I, II, and III and the conductivities are compared with the conductivities of solutions of the strong base water in Fig. 1. In the case of the cryoscopic measurements corrections

undissociated sulphuric acid (10.625°), m is the stoichiometric concentration of the solute, and m_d is the total concentration of the self-dissociation species. The osmotic coefficient ϕ was taken as unity: thus the ν-values obtained are only approximate as no allowance is made for non-ideality effects. Earlier workers who used slightly aqueous sulphuric acid as solvent expressed their cryoscopic results in terms of the vant'Hoff i-factor, $i = \theta/6.12m$. Values of γ, which is approximately equal to the number of moles of hydrogen sulphate ion produced by the ionization of 1 mole of solute, were obtained by comparison of the specific conductance with that of a standard electrolyte such as water (6).

DISCUSSION

Trialkylsilanols and Derivatives

Our cryoscopic measurements on hexamethyldisiloxane, ($\nu = 4.1$), are in agreement with those of Newman, Craig, and Garrett (4) ($i = 4.1$), and Price (3) ($i = 4.3$), who suggested that trimethylsilicon hydrogen sulphate is formed according to the equation

$$[(CH_3)_3Si]_2O + 3H_2SO_4 = 2(CH_3)_3Si\cdot HSO_4 + H_3O^+ + HSO_4^-.$$

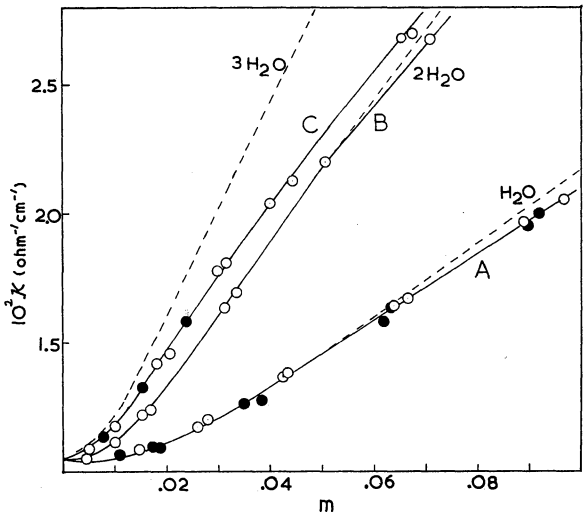

FIG. 1. Conductivities of solutions of some silicon compounds: A, ○ hexamethyldisiloxane, ● trimethylethoxysilane; B, dimethyldiethoxysilane; C, ○ methyltriethoxysilane, ● tetraphenylsilane.

Our conductivity results give $\gamma = 1.0$, which provides confirmation of this suggested reaction. It may be noted that the values of ν are slightly greater than the expected value of 4.0; this may be attributed to non-ideality of the solutions (9). The high i-factors obtained by Newman and co-workers (4) and by Price (3) can, at least partly, be accounted for in a similar manner. Also, these earlier measurements were made in sulphuric acid containing a little water and it has been shown that some non-electrolytes and weak electrolytes such as nitro compounds (10, 11) give anomalously large freezing-point depressions, probably because of a 'salting-out' effect. If, as seems probable, the alkylsilicon hydrogen sulphates behave similarly this would provide an additional reason for the high i-values. There is no evidence that the trimethylsilicon hydrogen sulphate is further ionized either to give a 'siliconium' ion $[(CH_3)_3Si]^+$ as suggested by Price (3) in order to account for his i-factors, or by acting as a weak proton acceptor. Any such additional ionization would be expected to give a conductivity somewhat greater than that of water, i.e. $\gamma > 1$. Actually the observed conductivity coincides with that of water at low concentrations of solute and is a little less than that of water at higher concentrations. This is consistent with the presence of the non-electrolyte $(CH_3)_3Si \cdot HSO_4$ since non-electrolytes are known to decrease the conductivity of sulphuric acid slightly (6, 12).

Our results for trimethylethoxysilane ($\nu = 4.0$, $\gamma = 1.0$), and those of Newman, Craig, and Garrett (4) for triethylethoxysilane ($i = 4.3$) and triethylsilanol ($i = 3.0$), can be similarly accounted for in terms of the formation of trialkyl hydrogen sulphates according to the equations

$$R_3SiOEt + 3H_2SO_4 = R_3Si \cdot HSO_4 + EtHSO_4 + H_3O^+ + HSO_4^-$$

and

$$R_3SiOH + 2H_2SO_4 = R_3Si \cdot HSO_4 + H_3O^+ + HSO_4^-.$$

Dialkylsilanols and Their Derivatives

Our results for dimethyldiethoxysilane ($\nu = 7.3$, $\gamma = 2.0$) suggest that it reacts to form dimethylsilicon di(hydrogen sulphate) according to the equation

$$(CH_3)_2Si(OEt)_2 + H_2SO_4 = (CH_3)_2Si(HSO_4)_2 + 2EtHSO_4 + 2H_3O^+ + 2HSO_4^-.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

This is consistent with Price's i-value of 12.6 for the tetramer $[(CH_3)_2SiO]_4$ which he accounted for in terms of the reaction

$$[(CH_3)_2SiO]_4 + 12H_2SO_4 = 4(CH_3)_2Si(HSO_4)_2 + 4H_3O^+ + 4HSO_4^-.$$

The rather high values of ν and i may be attributed to non-ideality of the solutions.

Monoalkylsilanols and Their Derivatives

Methyltriethoxysilane differs from the compounds discussed above in that both ν and γ show quite a definite concentration dependence: ν decreases from 8.4 to 7.7 while γ decreases from 2.8 to 2.2 over the concentration range 0.01 to 0.06 molal. In this case values of γ were obtained by comparison of the conductivity with that of $(CH_3)_2Si(OEt)_2$ which approximately corrects for the effect on the conductivity of the non-electrolytes formed in the reaction. For the formation of methylsilicon tri(hydrogen sulphate) values of $\nu = 10$ and $\gamma = 3$ would be expected:

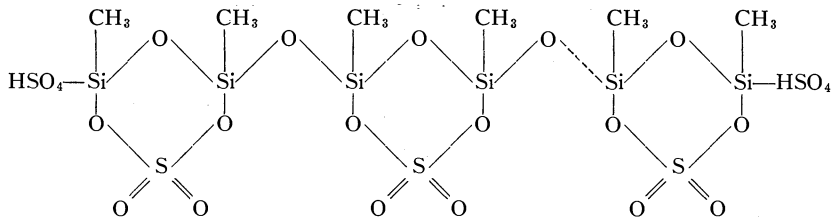
$$CH_3Si(OEt)_3 + 9H_2SO_4 = CH_3Si(HSO_4)_3 + 3EtHSO_4 + 3H_3O^+ + 3HSO_4^-.$$

Presumably the low observed values of ν and γ and their concentration dependence are due to polymerization of the methylsilicon tri(hydrogen sulphate). The general equation for the formation of linear polymers may be written

$$CH_3Si(OEt)_3 + (6 + 3/n)H_2SO_4 = 1/n\left[HSO_4\text{—}Si(CH_3)(SO_4H)\text{—}O\text{—}\left(Si(CH_3)(SO_4H)\text{—}O\right)_{n-2}\text{—}Si(CH_3)(SO_4H)\text{—}SO_4H\right] + 3EtHSO_4 + (2 + 1/n)H_3O^+ + (2 + 1/n)HSO_4^-$$

	n	$\nu = (7n+3)/n$	$\gamma = (2n+1)/n$
dimer	2	8.5	2.5
trimer	3	8.0	2.3
tetramer	4	7.75	2.25

It is possible that these polymers are better formulated as containing six-membered rings with bridging sulphate groups formed by elimination of sulphuric acid from the linear polymer:



This is consistent with the structures recently proposed for complex sulphato compounds of boron (13) and arsenic (14). The formation of a mixture of these polymers would account satisfactorily for the experimental observations. The i-factors of between 8.5 and 8.0 obtained by Price (3) for the compound $[(CH_3)_3SiO]_3Si\cdot CH_3$ are consistent with the formation of the same linear polymers:

$$[(CH_3)_3SiO]_3SiCH_3 + (6 + 3/n)H_2SO_4 = 1/n\left[HSO_4\text{—}Si(CH_3)(SO_4H)\text{—}O\left(Si(CH_3)(SO_4H)\text{—}O\right)_{n-2}\text{—}Si(CH_3)(SO_4H)\text{—}SO_4H\right] + 3(CH_3)_3Si\cdot HSO_4 + (2 + 1/n)H_3O^+ + (2 + 1/n)HSO_4^-$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

for which $\nu = 7+3/n$. The formation of analogous cyclic polymers as suggested by Price (3) is not in such good agreement with the experimental results. For example,

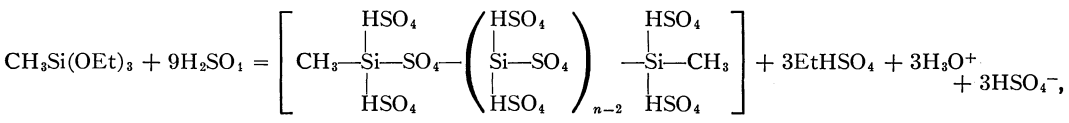
$$CH_3Si(OEt)_3 + 6H_2SO_4 = 1/n[CH_3Si(SO_4H)O]_n + 3EtHSO_4 + 2H_3O^+ + 2HSO_4^-$$

and

$$[(CH_3)_3SiO]_3 + 6H_2SO_4 = 1/n[CH_3Si(SO_4H)O]_n + 3(CH_3)_3SiHSO_4 + 2H_3O^+ + 2HSO_4^-.$$

For the former reaction $\nu = 7+1/n$ and $\gamma = 2$ while for the latter $\nu = 7+1/n$.

The possibility of the formation of other types of polymers was also considered but no agreement with the experimental results could be obtained. For example the formation of polymers containing sulphate bridges,



would give $\nu = 9+1/n$ and $\gamma = 3$.

Tetraphenylsilane

A cryoscopic study of this compound and also tetrabenzylsilane and hexaphenyldisiloxane has been previously carried out by Szmant, Devlin, and Brost (2). They found that their results could only be accounted for if it was assumed that complete cleavage of the Si—C bonds occurs with the formation of the corresponding arylsulphonic acid; they were able to isolate these sulphonic acids from the sulphuric acid solutions.

The cleavage of C—Si bonds is well known to be caused by a variety of both acidic and basic reagents and kinetic studies have been made of the cleavage of phenyltrimethylsilane by sulphuric acid (15). However the simple formation of $Si(HSO_4)_4$ or of the anions $Si(HSO_4)_5^-$ or $Si(HSO_4)_6^{2-}$ is not in agreement with the cryoscopic results:

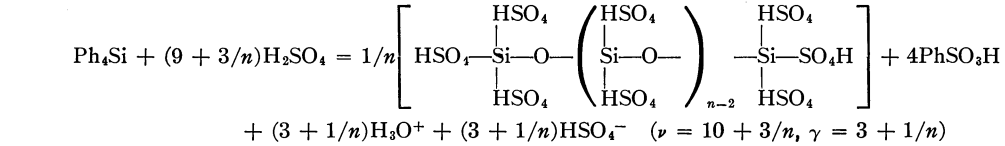
$$Ph_4Si + 12H_2SO_4 = Si(HSO_4)_4 + 4PhSO_3H + 4H_3O^+ + 4HSO_4^- \quad (\nu = 13, \gamma = 4),$$

$$Ph_4Si + 12H_2SO_4 = Si(HSO_4)_5^- + 4PhSO_3H + 4H_3O^+ + 3HSO_4^- \quad (\nu = 12, \gamma = 3),$$

$$Ph_4Si + 12H_2SO_4 = Si(HSO_4)_6^{2-} + 4PhSO_3H + 4H_3O^+ + 2HSO_4^- \quad (\nu = 11, \gamma = 2).$$

Our ν values are somewhat higher than the i-values obtained by Szmant, Devlin, and Brost and unlike their values they show a definite decrease with increasing concentration. This decrease in ν and the corresponding decrease in γ with increasing concentration indicate clearly that some form of polymerization is occurring. Szmant *et al.* (2) explained their results in terms of the cyclic polymers $[Si(HSO_4)_2O]_n$ first proposed by Price (3); however, our results cannot be explained fully by either cyclic or linear polymers, mainly because neither can give a γ-value less than 3.0:

$$Ph_4Si + 9H_2SO_4 = 1/n[Si(HSO_4)_2O]_n + 4PhSO_3H + 3H_3O^+ + 3HSO_4^- \quad (\nu = 10 + 1/n, \gamma = 3.0)$$



$$+ (3 + 1/n)H_3O^+ + (3 + 1/n)HSO_4^- \quad (\nu = 10 + 3/n, \gamma = 3 + 1/n)$$

The best explanation of the conductimetric results appears to be obtained by postulating the formation of a three-dimensional polymer as first proposed by Price for the related compound $Si[OSi(CH_3)_3]_4$ (3):

$$Ph_4Si + 15/2H_2SO_4 = 1/2n[Si_2(HSO_4)_2O_3]_n + 5/2H_3O^+ + 5/2HSO_4^- + 4PhSO_3H \quad (\nu = 9 + 1/2n, \gamma = 2.5)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The fact that the observed ν-values are a little higher than predicted can be reasonably attributed to non-ideality. Probably the predominant species at low concentrations are small cyclic polymers, which are replaced at higher concentrations by an increasing amount of the three-dimensional polymer, which eventually separates out, even from quite dilute solutions, as a gelatinous precipitate. The somewhat less accurate cryoscopic results of Szmant and co-workers (2) on tetrabenzylsilane and hexaphenyldisiloxane, and Price's results (3) on the compound $[(CH_3)_3SiO_4]Si$, can be accounted for in an exactly analogous manner.

NUCLEAR MAGNETIC RESONANCE MEASUREMENTS OF PROTON EXCHANGE IN ALCOHOL–WATER SYSTEMS

PART II. n-C_3H_7OH–H_2O AND i-C_3H_7OH–H_2O[1]

W. G. PATERSON[2]

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received April 4, 1963

ABSTRACT

Recent methods of analysis of exchange-broadened n.m.r. multiplets are used to make measurements of multiplet spacings and line widths in the n.m.r. spectra of n-C_3H_7OH–H_2O and i-C_3H_7OH–H_2O solutions. The data are interpreted in terms of the proton exchange reaction ROH + HOH* $\rightleftharpoons$ ROH* + HOH (R = n-C_3H_7 and i-C_3H_7) for which rate constants k = 1.7±0.3 (R = n-C_3H_7) and 0.35±0.06 (R = i-C_3H_7) l.mole^{-1} sec^{-1} at 42±1° are suggested. Possible exchange mechanisms are discussed.

INTRODUCTION

The n.m.r. spectrum of a liquid or solution may undergo striking changes if the molecules concerned are participating in rate processes. Since its discovery several years ago, interest in this phenomenon has become widespread (4). In particular, much attention has been given to intermolecular proton exchange.

Previous n.m.r. studies of proton exchange in alcohol–water solutions[3] have been confined principally to the system C_2H_5OH–H_2O, with widely varying results being reported. Qualitative measurements of proton exchange in the systems n-C_3H_7OH–H_2O and i-C_3H_7OH–H_2O appeared recently (5), and in this paper results of a more quantitative nature are presented. This paper is the second of a series dealing with proton exchange in alcohol–water systems.

EXPERIMENTAL

The n.m.r. spectra were measured on a Varian A-60 n.m.r. spectrometer operating at 60 Mc/s. Through the use of a copper–constantan thermocouple, the temperature of the solutions, in the spectrometer, was found to be 42±1°. Calibration of the instrument was achieved by the customary side-band technique (6), using a Hewlett–Packard Model 200AB audio-oscillator and a Hewlett–Packard Model 521C frequency counter. The precision in the n.m.r. measurements varied from 0.02 c.p.s. to 0.1 c.p.s. depending on signal shape. Nearly all measurements were an average of at least five determinations. Transverse relaxation times (T_2) were measured as previously described (1). The degree of resolution of the n.m.r. spectrometer was deliberately made poorer than usual in order that T_2 be governed chiefly by magnetic field inhomogeneities (7).

All glassware which was used either in the purification of materials or in the rate measurements was cleaned with the following substances in the order given, and then heated for several hours at 120°: Fisher "Sparkleen" detergent, distilled water, dilute hydrochloric acid, distilled water, dilute ammonia, distilled water. The rinsings with distilled water were done 10–20 times.

Anhydrous n-propyl alcohol was prepared from Fisher Certified Reagent Grade material by the method quoted by Fieser (8) for anhydrous ethyl alcohol. A 30 in Vigreux fractionating column and a Kjeldahl spray trap were used in the distillation, and air was excluded from the apparatus by passing a very slow stream of dried, carbon dioxide free nitrogen through it. A middle fraction was collected (n_D^{25} = 1.3832; Brunel (9) gives n_D^{25} = 1.3835). Vapor-phase chromatography indicated the presence of trace impurities only. No water peak was observed in the n.m.r. spectrum run at high recorder gain. The alcohol —OH signal was a sharp triplet with spacings which varied in different preparations from 5.14±0.04 c.p.s. to 5.16±0.05 c.p.s. (average of 10 determinations). These variations should have a negligible effect on the

results quoted, since any set of measurements on *n*-propyl alcohol – water solutions was compared to the purified *n*-propyl alcohol prepared for that set.

Nichols Reagent Grade isopropyl alcohol was refluxed over calcium oxide for 4 hours in an atmosphere of dry, carbon dioxide free nitrogen, decanted into a clean flask, refluxed over sodium metal for 2 hours in a nitrogen atmosphere, and distilled as described above for *n*-propyl alcohol. The middle cut had $n_D^{25} = 1.3755$ (Brunel (9) reports 1.3749). No water peak could be detected in the n.m.r. spectrum run at high gain. The alcohol —OH signal was a sharp doublet with spacing 4.29±0.02 c.p.s. (average of 10 determinations).

Pure water was prepared in two different ways as described previously (1), by distillation from alkaline permanganate and by ion exchange. Two different preparations gave $n_D^{28} = 1.3323$ and $n_D^{25.5} = 1.3325$. Literature values (10) are $n_D^{28} = 1.3322$ and $n_D^{25.5} = 1.3325$. The pH of water thus prepared varied between 6.7 and 7.0, corresponding to $[H^+] = 2\times10^{-7}$ mole/l. or less. Alcohol–water solutions, approximately 40% v/v, gave similar pH readings. A single measurement also showed that a *n*-propyl alcohol – water solution had a very low conductivity. Identical rate plots, within experimental error, were obtained using water prepared by the two methods. The alcohol–water solutions were prepared by weight and the concentrations in moles/l. calculated from published density data (11).

All flasks and n.m.r. tubes which were used in sample preparation were flushed with dried, carbon dioxide free nitrogen before use. Since the solutions slowly leach impurities from the glass (1, 2), it was found necessary to do a given set of n.m.r. measurements on the same day that the materials were distilled.

Further experimental details are obtainable elsewhere (1, 2).

RESULTS AND DISCUSSION

The simplest interpretation of the kinetic data is obtained if it is assumed that the only reaction of kinetic significance in the alcohol–water solutions is

$$ROH + HOH^* \rightleftharpoons ROH^* + HOH, \qquad [1]$$

where R = *n*-C_3H_7 or *i*-C_3H_7. This assumption is probably valid in view of the extremely small ionic concentrations in neutral alcohol–water solutions (12, 13), and the fact that there is no observable proton exchange in the pure alcohols (see Experimental). Since the average lifetime τ_{ROH} of a hydroxyl proton on an alcohol molecule ROH before exchange with a proton on a different site (1, 12) is

$$\tau_{ROH} = \frac{[ROH]}{d[ROH]/dt} = \frac{1}{k[H_2O]}, \qquad [2]$$

where k is the rate constant for reaction [1], a plot of τ_{ROH}^{-1} vs. $[H_2O]$ should be a straight line with slope k passing through the origin. Figures 1 and 2 suggest that this is approxi-

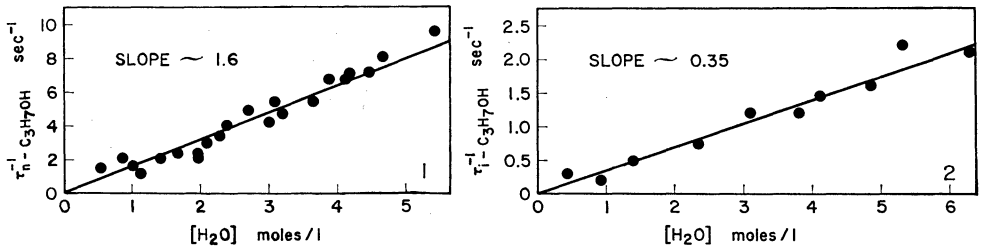

FIG. 1. Variation of $\tau_{n\text{-}C_3H_7OH}^{-1}$ with $[H_2O]$.
FIG. 2. Variation of $\tau_{i\text{-}C_3H_7OH}^{-1}$ with $[H_2O]$.

mately true. The point scatter is probably due to minute traces of impurities, to which the exchange process is very susceptible (1, 2, 12).

Since $\tau_{ROH} = \tau_{H_2O}$ for reaction [1], where τ_{H_2O} is the average lifetime of a proton on a water molecule before exchange with a proton on an alcohol molecule, a plot of $\tau_{H_2O}^{-1}$ vs. $[H_2O]$ should also be a straight line with the same slope k passing through the origin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

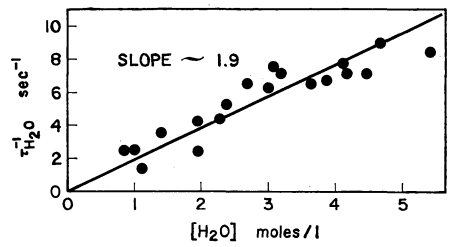

FIG. 3. Variation of $\tau^{-1}_{H_2O}$ with $[H_2O]$.

(Fig. 3). Although there is a severe point scatter, the previous observation (1) of a linear plot with zero intercept for the system ethyl alcohol – water lends support to a similar interpretation of Fig. 3. No reliable data of this nature were obtainable from the spectra of isopropyl alcohol – water solutions due to interference from the methine proton signal. It may be significant that the slope of the plot $\tau^{-1}_{H_2O}$ vs. $[H_2O]$ is slightly greater than that of τ^{-1}_{ROH} vs. $[H_2O]$ for both the systems C_2H_5OH–H_2O and n-C_3H_7OH–H_2O. However, this feature has thus far been ignored and the slopes have been averaged to obtain the apparent rate constant.

The values of $\tau^{-1}_{n\text{-}C_3H_7OH}$ and $\tau^{-1}_{i\text{-}C_3H_7OH}$ were obtained from the transverse relaxation time, T_2, and the spacings of the triplet and doublet —OH signals, respectively, using analytical methods previously discussed (1–3). Values of $\tau^{-1}_{H_2O}$ were obtained from the expression (12, 14, 15) $\tau^{-1}_{H_2O} = \pi\Delta\nu_{\frac{1}{2}} - T_2^{-1}$ where $\Delta\nu_{\frac{1}{2}}$ is the full width of the water signal at half-maximum amplitude. Typical —OH and H_2O signals are presented in Figs. 4 and 5.

The average of the slopes of Figs. 1 and 3 yields a rate constant k for reaction [1] (R = n-C_3H_7) equal to 1.7±0.3 l. mole^{-1} sec^{-1} at 42±1°. The slope of Fig. 2 yields a

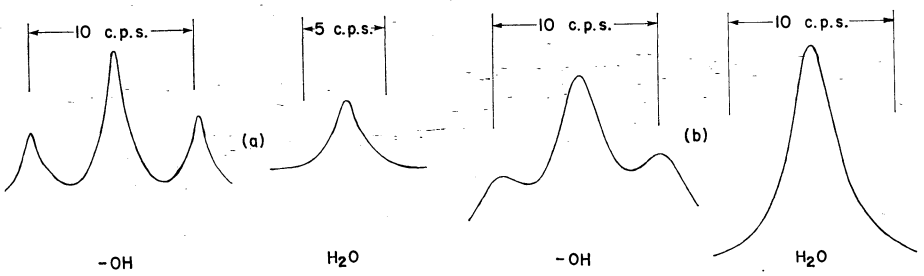

FIG. 4. Typical —OH and H_2O signals in the n.m.r. spectra of n-C_3H_7OH–H_2O solutions. (*a*) $[H_2O]$ = 1.12 moles/l.; (*b*) $[H_2O]$ = 3.89 moles/l. The —OH and H_2O signals were recorded at different recorder gain settings.

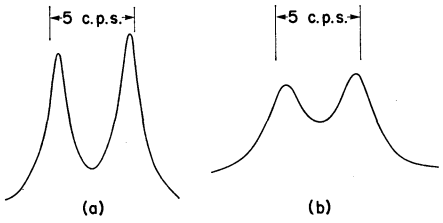

FIG. 5. Typical —OH signals in the n.m.r. spectra of i-C_3H_7OH–H_2O solutions. (*a*) $[H_2O]$ = 2.34 moles/l. (*b*) $[H_2O]$ = 6.28 moles/l.

value 0.35 ± 0.06 l. mole^{-1} sec^{-1} at $42\pm1°$ as the rate constant k for reaction [1] (R = i-C_3H_7). The errors quoted are somewhat arbitrary. A summary of the data is given in Table I. It could be argued that these rate constants are upper limits, since proton-

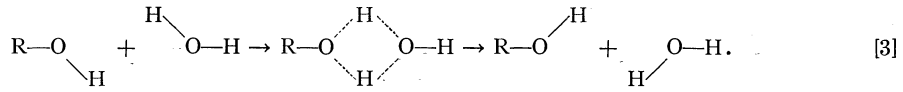
TABLE I

Rate constants for proton exchange in neutral alcohol–water solutions

Alcohol	k (l. mole^{-1} sec^{-1})	Temperature (°C)
C_2H_5OH	$2.7\ \pm0.4$ (1)	42 ± 1
	0.8 (12)	22 ± 2
n-C_3H_7OH	$1.7\ \pm0.3$	42 ± 1
i-C_3H_7OH	0.35 ± 0.06	42 ± 1

transfer reactions involving ionic mechanisms have very large rate constants (12), of the order of 10^6–10^8 l. mole^{-1} sec^{-1} at room temperature.

If the exchange reaction [1] is bimolecular, as suggested by the experimental data, several mechanisms are feasible. One of these (5) could involve the interaction of —OH dipoles via a four-center transition state



[3]

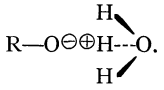
Others might involve a slow ionization reaction to a pair of ions followed by a rapid recombination reaction, e.g.,

$$ROH + H_2O \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} RO^- + H_3O^+ \qquad [4]$$

$$ROH + H_2O \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} ROH_2^+ + OH^-. \qquad [5]$$

The reverse reactions must be very fast since the recombination of H_3O^+ and OH^- ions in aqueous solution (16) has a rate constant $k = (1.4\pm0.2)\times10^{11}$ l. mole^{-1} sec^{-1}. Reactions [4] and [5] are perhaps more feasible than reaction [3] since the orientation conditions during collision are less stringent. Variable-temperature studies of the exchange rates would permit an evaluation of the entropy of activation from which one might be able to decide between the possibilities.

It has been known for a long time that water behaves as a base in ethanolic solutions (13), and if the same is true for aqueous solutions of n-propyl alcohol and i-propyl alcohol, reaction [4] is preferable to reaction [5]. On the basis of inductive effects, the relative order of acidity of the three alcohols thus far investigated is $C_2H_5OH > n$-$C_3H_7OH > i$-C_3H_7OH. If equation [4] represents the exchange mechanism, then in the three systems studied, the rates of proton exchange should be in the order C_2H_5OH–$H_2O > n$-C_3H_7OH–$H_2O > i$-C_3H_7OH–H_2O. As this was the observed order, the experimental data are therefore consistent with equation [4] rather than equation [5] as the exchange mechanism. Further, the relative extents of autoprotolysis (17) in the pure alcohols are in the same order. The pair of ions formed in reaction [4] can be envisaged as



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

After formation of the pair of ions, the three protons become equivalent, and since any one of them may return to the alkoxide ion, proton exchange between the alcohol and water molecules is thereby effected. If the same proton returns, there is no change in the spectrum. If another proton with different spin returns, broadening of the n.m.r. signals will be observed.

It should be emphasized that the foregoing discussion of the exchange mechanism is highly speculative. Further results on other alcohol–water systems will be published shortly (18).

ACKNOWLEDGMENTS

This work was supported in part by the National Research Council of Canada, whose financial assistance is greatly appreciated. The author is indebted to Mr. R. Mermelstein, Dr. C. C. Bigelow, Dr. R. N. O'Brien, and Mr. A. Patil for assistance and advice concerning the experimental work, and to Dr. D. Darwish for helpful suggestions about the manuscript. The author also wishes to thank Mr. R. N. Swindlehurst and Mr. R. Kadlecz for careful maintenance of the n.m.r. apparatus.

NUCLEAR MAGNETIC RESONANCE MEASUREMENTS OF PROTON EXCHANGE IN ALCOHOL–WATER SYSTEMS

PART III. *n*-, *i*-, *s*-, AND *t*-C_4H_9OH–H_2O

W. G. PATERSON[1] AND H. SPEDDING
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received May 24, 1963

ABSTRACT

Measurements of exchange-broadened n.m.r. signals are analyzed by recent methods to yield proton exchange rates of the reaction ROH + H*OH ⇄ ROH* + HOH, where R = *n*-, *i*-, *s*-, and *t*-C_4H_9. The rate constants suggested are 0.95 (44°), 0.90 (42°), 0.60 (46°), and 0.25 (46°) l. mole^{-1} sec^{-1}, respectively. The trend in rate constants for these four systems, and the C_2H_5OH–, *n*-C_3H_7OH–, and *i*-C_3H_7OH–H_2O systems examined in Parts I and II (W. G. Paterson, Can. J. Chem. **41**, 714, 2472 (1963)), is discussed in terms of the nature of the alkyl groups in each alcohol.

INTRODUCTION

The work described below is an extension of Parts I and II (1, 2), and is based on the same theoretical analyses (1, 3, 4) used therein. Data have now been accumulated for the eight alcohol–water systems from CH_3OH–H_2O through *t*-C_4H_9OH–H_2O. It is shown that the results form a consistent pattern when they are interpreted in terms of the inductive nature of the alkyl groups in each alcohol.

EXPERIMENTAL

Spectroscopic Measurements

The n.m.r. spectra were measured on a Varian A-60 spectrometer operating at 60 Mc/s. The temperature of the samples, in the spectrometer probe, was measured by means of a copper–constantan thermocouple. It varied between 42° and 46° over the course of the measurements; the individual temperature for each of the four alcohol–water systems is given in Table I. The customary side-band technique (5) was used to

chiefly by magnetic field inhomogeneities (6). The line widths of these two substances were checked at intervals during the measurements on each system.

For —OH triplet (*n*- and *i*-C_4H_9OH) and doublet (*s*-C_4H_9OH) signals, the lifetime τ before exchange of the hydroxyl proton was estimated from the multiplet spacing (1–4). In the case of *t*-C_4H_9OH, where the —OH signal is a singlet, this lifetime was estimated from the half band-width of the hydroxyl proton signal in the manner previously described for H_2O signals (1, 2). All spacings and half band-widths were an average of at least five determinations.

Glassware

All the glassware used in the purification of the alcohols and water and in the subsequent measurements was cleaned as described previously (2). In addition, however, the n.m.r. sample tubes were given a further conditioning treatment. Before they were used at all, and again between runs, all the tubes were filled with concentrated nitric acid (16 normal) for 10 minutes, emptied, rinsed 25 times with distilled water, dried at ~120° (for convenience), and then baked overnight at 580°. This treatment was found necessary in order to obtain reproducible and sensible results with two of the alcohols, and was therefore adopted as a standard procedure. (Some additional qualitative experiments suggested that the nitric acid cleaning might not have been necessary. The annealing, however, was essential.) All flasks and n.m.r. tubes that were used for the alcohol–water solutions were flushed beforehand with dried, carbon dioxide free nitrogen.

Materials

Water was purified by passing distilled water from the tap through a Barnstead "Bantam Demineralizer" ion-exchange column, and then bubbling carbon dioxide free nitrogen through it to remove carbon dioxide. This was one of the two methods used previously (1). The pH of water prepared in this manner corresponded to $[H^+] = (1–2)\times10^{-7}$ moles/l. Such water was always used on the same day that it was prepared.

Purified *n*-butanol was prepared from Fisher Certified Reagent Grade material by the method of Lund and Bjerrum (7). The distillation apparatus and procedure were the same as those used in Parts I and II (1, 2). The —OH signal was a sharp triplet with spacing 5.11±0.02 c.p.s.; $n_D^{25} = 1.3980$ (lit. value (8): 1.3974). No water peak was observed in the n.m.r. spectrum of any of the alcohols run at high recorder gain.

Purified *i*-butanol was prepared by refluxing Fisher Certified Reagent Grade material over small lumps of reagent grade calcium oxide for 20 hours in an apparatus protected from atmospheric moisture, and then distilling from the same calcium oxide as previously described. $n_D^{25} = 1.3947$ (lit. value (9): 1.3939). The —OH signal was a sharp triplet with spacing 5.35±0.03 c.p.s.

Purified *s*-butanol was prepared from Eastman Kodak Reagent Grade material in the manner described for *i*-butanol. $n_D^{20} = 1.3982$ (lit. value (9): 1.3978). The —OH signal was a sharp doublet with spacing 4.88±0.03 c.p.s.

Purified *t*-butanol was prepared from Eastman Kodak Reagent Grade material by the method described for *i*-butanol. $n_D^{28.5} = 1.3832$ (lit. values at 25° (9, 10): 1.3823 and 1.3845).

The alcohol–water solutions were prepared by weight, and their molar concentrations were calculated from published density data (11 or reference therein).

RESULTS AND DISCUSSION

The interpretation of the kinetic data is based on the same assumptions discussed in Parts I and II (1, 2). The influences of the various complicating factors that were discussed there, such as trace impurities and uncertainty about T_2, were also operative in the present work. The effect of the latter factor is more pronounced in the exchange rates estimated from band widths than in those based on multiplet spacings because of the nature of the calculations involved (1). Furthermore, the effect of any error in the value taken for T_2 becomes more pronounced the slower the exchange rate, because the latter is obtained as the difference between the observed half band-width and T_2^{-1}. That the approximation of the half band-width of water and cyclohexane for T_2^{-1} in all the alcohols is a reasonable one is suggested by the satisfactory agreement found in the case of *t*-butanol, the only instance where T_2^{-1} was directly obtainable on account of the hydroxyl peak being a singlet.

In all the four alcohol–water systems examined here both the hydroxyl and water signals were free from interference by overlap. The results are given in Table I and Figs. 1–8 along with new data for the systems CH_3OH–H_2O and *i*-C_3H_7OH–H_2O, as well as the

FIG. 7. Variation of $\tau^{-1}_{t\text{-}C_4H_9OH}$ with [HOH] in the system t-C_4H_9OH–H_2O.
FIG. 8. Variation of τ^{-1}_{HOH} with [HOH] in the system t-C_4H_9OH–H_2O.

results obtained previously (1, 2). In the previous papers, for the systems C_2H_5OH–H_2O and n-C_3H_7OH–H_2O, $\tau^{-1}_{H_2O}/[H_2O]$ was slightly greater than $\tau^{-1}_{ROH}/[H_2O]$; no comparison was possible in the system i-C_3H_7OH–H_2O. The present results show that this difference probably has little if any significance and presumably is due to experimental error. A few measurements on solutions where the water concentration was much less than 1 mole/l showed marked deviations from the plots given in Figs. 1–8; the reason for this is not known.

The results in Table I show that substitution of a methyl group for a hydrogen atom in the alcohols studied leads to a reduction in the apparent rate constant k in every instance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

but one; in the latter (i-C_3H_7OH to s-C_4H_9OH), there is no perceptible change. The effect of substitution is illustrated below. A graphical summary of all the rate data is given in

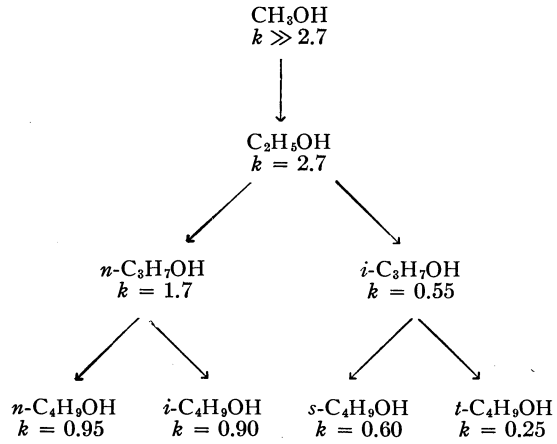

Fig. 9. The pattern is a remarkably consistent one—especially if one includes the CH_3OH–H_2O system where the apparent rate constant, given by $k = \tau^{-1}/[H_2O]$, is too great to permit an accurate evaluation by the present method.

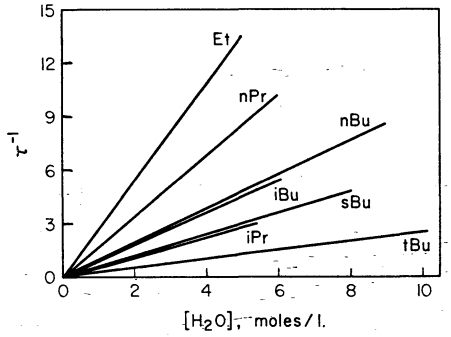

FIG. 9. Variation of τ^{-1} with $[H_2O]$ (average values) in the systems ROH–H_2O. τ is the average lifetime of a hydroxyl proton on an alcohol molecule before exchange with a water molecule.

It is tempting to ascribe the observed changes in apparent rate constant to the greater inductive (+I) effect, or greater polarizability, of the methyl group (as compared to hydrogen) retarding the reaction $ROH + H_2O \rightarrow RO^- + H_3O^+$ by rendering the loss of the alcoholic proton more difficult (2). However, there are many examples, provided by the study of the effect of structure on reactivity (12), where a similar trend would be expected but is not realized. Instead, several different trends are to be found, showing that other factors (steric hindrance, solvation, etc.), whose relative importance varies according to the reaction type involved, are also operating. In the present instance, an explanation based on steric effects and the alcohols behaving as bases ($ROH + HOH \rightleftarrows ROH_2^+ + OH^-$) is a possible alternative. It is, however, a less likely one because (*a*) ethanol is known to act as the acid in ethanol–water solutions (2), and (*b*) it is hard to see how the large changes observed along the series ethanol, n-propanol, and n-butanol could be ascribed to steric opposition, by methyl groups that are well removed from the hydroxyl group, to the acceptance of a water proton.

REARRANGEMENT STUDIES WITH C^{14}

XVI. REARRANGEMENTS INDUCED BY γ-IRRADIATION OF 2-PHENYLETHYL-1-C^{14} BROMIDE OR 2-*p*-METHOXYPHENYLETHYL-1-C^{14} BROMIDE

D. P. THORNHILL[1] AND C. C. LEE

Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received April 22, 1963

ABSTRACT

Irradiation of 2-phenylethyl-1-C^{14} bromide with up to 133 million rads of Co^{60} γ-rays gave 2-phenylethyl-2-C^{14} bromide with a mean G_r of 0.30 ± 0.01. Similar studies with 2-*p*-methoxyphenylethyl-1-C^{14} bromide resulted in 2-*p*-methoxyphenylethyl-2-C^{14} bromide with a mean G_r of 0.46 ± 0.04. Monomeric, liquid organic products were found to be benzene, ethylbenzene, and styrene, or the analogous *p*-methoxy derivatives, from the irradiation of 2-phenylethyl bromide or 2-*p*-methoxyphenylethyl bromide, respectively. Possible mechanisms for the radiation-induced isotope position rearrangements are discussed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

As an extension of studies in this laboratory on the γ-irradiation-induced rearrangement of 2-phenylethyl-1-C^{14} iodide to 2-phenylethyl-2-C^{14} iodide (1) and of ethyl-1-C^{14} iodide to ethyl-2-C^{14} iodide (2), this communication reports findings on isotope position rearrangements resulting from irradiation of 2-phenylethyl-1-C^{14} bromide (I) or 2-*p*-methoxyphenylethyl-1-C^{14} bromide (II) with Co^{60} γ-rays.

The bromides, I and II, were prepared from treatment of 2-phenyl- or 2-*p*-methoxyphenyl-ethyl-1-C^{14} *p*-toluenesulphonate with lithium bromide in acetone. Such a method of preparation is expected to cause no rearrangement in the desired products (3) and this was confirmed by degradation of I and II, respectively, to essentially inactive benzoic acid and anisic acid. It is of interest to note that treatment of 2-phenylethanol-1-C^{14} with phosphorus tribromide resulted in I containing about 1.5% of the C^{14} in the C-2 position (4).

Three gram samples of I or II were irradiated at ambient temperature in the same manner as described for the irradiation of 2-phenylethyl-1-C^{14} iodide (1), with the exception that a 1000 c Co^{60} γ-cell,* instead of a 90 c unit, was used as radiation source. Under the conditions employed in these experiments, the dose rates were about 78,000 rads/hr. Irradiation was carried up to an absorbed dosage of 133 million rads. Degradation of I and II, before and after irradiation, was effected in the same way as in the study with 2-phenylethyl-1-C^{14} iodide (1). Through carbonation of the corresponding Grignard reagents, I and II were converted, respectively, to hydrocinnamic acid (III) and *p*-methoxyhydrocinnamic acid (IV). Alkaline permanganate oxidation of III and IV resulted in benzoic acid and anisic acid whose activities gave measures to the extents of rearrangement of the C^{14} from the C-1 to the C-2 positions of I and II. The results, together with the calculated G_r values, representing the number of molecules of I rearranging to 2-phenylethyl-2-C^{14} bromide, or II rearranging to 2-*p*-methoxyphenylethyl-2-C^{14} bromide, per 100 ev absorbed, are summarized in Table I.

The active benzoic acid or anisic acid derived from various irradiated samples was combined and decarboxylated by heating with soda lime. The liquid products, benzene or anisole, were found to contain no activity as expected.

	125.5	"	15.2	1.20	0.43

*Radioactivity was measured in a liquid scintillation counter as previously described (12). Counting efficiency was determined by measuring known C^{14} standards so that specific activity in mμc/mmole may be calculated.

From Table I, it may be noted that, as in previous studies with iodides (1, 2), the extent of rearrangement increases with increasing dosage of radiation. The mean G_r value of I is 0.30±0.01, and of II is 0.46±0.04. These values may be compared with the G_r of 0.50±0.05 for the γ-induced rearrangement of 2-phenylethyl-1-C^{14} iodide to 2-phenylethyl-2-C^{14} iodide (1).

Ordinary samples of I and II, which were not labeled with C^{14}, were examined by vapor phase chromatography after irradiation. From I, the monomeric, liquid organic products were found to be benzene ethylbenzene, and styrene, with a trace of toluene. The yields are given in Table II.* Qualitatively, anisole, *p*-methoxyethylbenzene, and *p*-methoxy-

TABLE II

Monomeric, liquid organic products from radiolysis of 2-phenylethyl bromide

Absorbed dosage (megarads)	Product	Yield % by wt. in sample	Yield G
65.3	Benzene	0.10	0.19
	Ethylbenzene	0.45	0.63
	Styrene	0.40	0.57
112.0	Benzene	0.20	0.22
	Ethylbenzene	0.83	0.67
	Styrene	0.11	0.09

styrene were obtained after irradiation of II, but quantitative measurements were not carried out (see Experimental). Addition of 1 mole% of iodine to II before irradiation essentially eliminated the chromatogram peaks corresponding to these three compounds.

It may be of interest to note that in the photolysis of 2-phenylethyl bromide solutions in the glassy state at low temperature, styrene was reported as a primary product (5). In the radiolysis of liquid I, a more complex mixture of products arising from secondary processes is to be expected. The chief monomeric materials detected, ethylbenzene and

These results were obtained by I. S. Bhardwaj.

For personal use only.

styrene, may be explained as resulting from hydrogen abstraction and disproportionation of the 2-phenylethyl radical produced during irradiation. The lower net yield of styrene at the higher absorbed dosage (Table II) is likely related to its ability to undergo further reaction, such as polymerization (6, pp. 77–85). The fact that added iodine could practically prevent the formation of *p*-methoxyethylbenzene, *p*-methoxystyrene, and anisole during irradiation of II also suggested the involvement of radicals which were scavenged by iodine, giving rise to organic iodides which were not detectable under the conditions used for the v.p.c. analyses.

Returning to the results summarized in Table I, it is evident that a net 1,2-aryl shift has occurred upon irradiation or either I or II. The exact nature of the process responsible for the observed rearrangements, however, is not clear. One might simply say that irradiation of I or II led to some excited state which collapses to give the rearranged products. On the other hand, free-radical rearrangements have been postulated as the explanation for the γ-induced isomerization of *n*-butyl to *s*-butyl, and *i*-butyl to *t*-butyl halides (7, 8). The formation of 1-phenylethyl radical in the photolyses of 2-phenylethanol in a rigid medium at low temperature was suggested as having resulted from isomerization of the 2-phenylethyl radical (5). As it is generally accepted that, with the exception of the carbon–fluorine bond, the carbon–halogen bond is ruptured preferentially during radiolysis of organic halides (6, pp. 111–116), and in view of the fact that ethylbenzene and styrene, or the *p*-methoxy analogues, were obtained as radiolysis products in the present studies, it is reasonable to assume that 2-phenylethyl or 2-*p*-methoxyphenylethyl radicals are produced during irradiation of I or II, respectively. 1,2-Aryl shifts in these radicals could then lead to the observed isotope position rearrangements.

In a recent paper, Neddenriep and Willard (9) listed a number of reasons for expecting differences in the radiolysis of alkyl iodides and bromides. Among these is that the carbon–iodine bond is weaker than the carbon–bromine bond. Although Porter and Strachan (5) have pointed out that bond dissociation energies in the liquid state are largely unknown, if the relative order of bond energies is not reversed in changing from the vapor to the liquid state for the carbon–bromine bond in I and the carbon–iodine bond in 2-phenylethyl iodide, the lower G_r in the irradiation of bromide I, as compared to the results from studies with 2-phenylethyl-1-C^{14} iodide (1), may be associated with the less ready formation of the 2-phenylethyl radical from the bromide.

The introduction of a *p*-methoxy group increased the G_r value from 0.30 for I to 0.46 for II. It is known that substitution of the *p*-hydrogen by a methoxy group enhances the migratory aptitude of the aryl group in carbonium ion processes (10–12), while in free-radical reactions, the migratory ratio of *p*-methoxyphenyl to phenyl has been reported to be 0.35 (13, 14). However, Zimmerman and Sandel (15) pointed out very recently that in organic photochemistry, the electronic distribution in the excited state may be quite unlike that of its ground-state progenitor and that there is no assurance that ground-state experience would extend to excited states. It was shown with monosubstituted benzenes that the electronic effects of substituents, such as the methoxy group, on the excited state are quite different from such effects on the ground state (15). Thus the *p*-methoxyphenyl to phenyl migratory ratio of 0.35 obtained from the decarbonylation of β-arylisovaleraldehydes (13, 14) may not necessarily hold in free-radical rearrangements induced by γ-irradiation of I and II. Upon irradiation of I or II, it is possible that excitation is followed by dissociation to 2-arylethyl radicals or formation of 2-arylethyl cations which may undergo 1,2-aryl shifts, leading eventually to isotopically rearranged I or II.

EXPERIMENTAL

Preparation of 2-Phenylethyl-1-C^{14} Bromide (I)

2-Phenylethyl-1-C^{14} *p*-toluenesulphonate (16) was treated with a 20% excess of anhydrous lithium bromide in dry acetone in a manner analogous to that described for the reaction of this sulphonate with sodium iodide in acetone (16). The yield of 2-phenylethyl-1-C^{14} bromide (I), b.p. 90° C at 9 mm (lit. (3) b.p. 110–113° C at 17 mm), was 65%. Conversion of a sample of I to the Grignard reagent followed by reaction with carbon dioxide gave a 74% yield of the solid derivative, hydrocinnamic acid (III), m.p. 48–49° C (lit. (3) m.p. 48–49° C).

Preparation of 2-p-Methoxyphenylethyl-1-C^{14} Bromide (II)

2-*p*-Methoxyphenylethanol-1-C^{14} was prepared according to the method of Lee, Newman, and Thornhill (12). This alcohol was converted to 2-*p*-methoxyphenylethyl-1-C^{14} *p*-toluenesulphonate (11) which, in turn, was treated with anhydrous lithium bromide in dry acetone to give a 79% yield of 2-*p*-methoxyphenylethyl-1-C^{14} bromide (II), b.p. 90° at 1 mm (lit. (17) b.p. 79° C at 0.5 mm). Anal. Calc. for $C_9H_{11}OBr$: C, 50.25; H, 5.15; Br, 37.15. Found: C, 50.09; H, 5.18; Br, 37.76. Reaction of the Grignard from II with carbon dioxide gave a 77% yield of *p*-methoxyhydrocinnamic acid (IV), m.p. 104–105° C (lit. (12) m.p. 104–105° C). Anal. Calc. for $C_{10}H_{12}O_3$: C, 66.70; H, 6.71. Found: C, 67.06; H, 6.85.

Irradiation

Three gram samples of I or II were placed in 4 ml glass vials, stoppered and sealed with wax, and then irradiated at room temperature in fixed positions in a gamma cell originally containing 1000 c of Co^{60}. The dose rate was determined by measuring the ferric ions formed on irradiating solutions of ferrous ammonium sulphate (18) and correcting for the difference in electron densities of the organic sample and dosimeter solution. Irradiation was continued for periods of up to about 2.5 months. Allowance was made for the decay of the Co^{60} in calculating the total absorbed dosage.

Degradation of I and II

Aliquots of the irradiated samples of I or II were converted to the corresponding Grignard reagents and treated with carbon dioxide to give hydrocinnamic acid (III) or *p*-methoxyhydrocinnamic acid (IV), respectively. Alkaline permanganate oxidation (3) of III or IV gave benzoic acid or anisic acid whose activities measured the extents of rearrangement. Similar degradations carried out on I and II before irradiation gave inactive benzoic and anisic acids.

Vapor Phase Chromatography Analyses

Ordinary, unlabeled samples of I or II were irradiated and then examined by a Beckman GC-2A chromatograph, using a column of apiezon L (25%) on firebrick. For irradiated samples of I, using a column temperature of 150° C, helium pressure of 20 p.s.i., and filament current of 200 ma, benzene, ethylbenzene, and styrene were identified and measured quantitatively after calibration with authentic compounds. Higher-boiling materials were removed by prolonged sweeping with helium while the column was maintained at 190° C. For irradiated samples of II, anisole, *p*-methoxyethylbenzene, and *p*-methoxystyrene were also identified. Because of technical difficulties arising from the requirement of higher inlet and column temperatures, irradiated samples of II were not analyzed extensively nor quantitatively.

THE THERMAL CIS–TRANS ISOMERIZATION OF CROTONONITRILE

JAMES N. BUTLER[1] AND ROBERT D. MCALPINE
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received May 22, 1963

ABSTRACT

The thermal cis–trans isomerization of crotononitrile has been studied in the gas phase at pressures from 0.2 to 20 mm and temperatures from 300° C to 560° C. For the equilibrium cis → trans, $\Delta H = 0.17 \pm 0.12$ kcal/mole, and $\Delta S = -0.39 \pm 0.19$ cal/mole °K. The isomerization is a homogeneous, unimolecular, reversible first-order reaction, the rate constant for the reaction cis → trans being given by

$$k_1 = 10^{11.0 \pm 1.0} e^{-51.3 \pm 3.7 \text{ kcal}/RT}.$$

The only side reaction with appreciable rate was a surface polymerization.

INTRODUCTION

The cis–trans isomerization of 2-butene (1) has been shown to be a unimolecular reaction at low pressures in the gas phase, but the cis–trans isomerization of dichloroethylene (2) appears to be a free-radical reaction. An intermediate case which might be interesting to study is dicyanoethylene, but its vapor pressure is too low to make a gas-phase study practicable. Crotononitrile, CH_3—CH=CH—CN, has an appreciable vapor pressure at room temperature, however, so a study of its cis–trans isomerization in the gas phase appeared promising.

EXPERIMENTAL

Materials

Crotononitrile was obtained from the Columbia Organic Chemical Company, Columbia, South Carolina, and was found to contain about 40% of the trans isomer and 60% of the cis isomer, together with small amounts of allyl cyanide, methacrylonitrile, and the various isocyanides. The cis and trans isomers were identified by comparison of their n.m.r. spectra with published spectra (3), and purified by gas chromatography. The purified *cis*-crotononitrile contained about 1% of trans isomer, and the purified *trans*-crotononitrile contained about 2% of the cis isomer.

Procedure

The apparatus used has been described previously (4). A sample of either *cis*- or *trans*-crotononitrile was admitted to the 100 ml reactor by expansion of its vapor from a storage vessel. When the reaction had proceeded for the desired length of time, the products were condensed into a side tube of 0.2 ml volume, and sealed off. No non-condensable products were observed.

Analysis

Analysis was performed on a Perkin–Elmer model 226 gas chromatograph using a 150 ft capillary column coated with polypropylene glycol (type R). A flame ionization detector was used. The sample tube was frozen in liquid nitrogen and broken open. Fifty microliters of ether was added immediately, and the solution was thoroughly stirred. Five to ten microliters of this solution was injected into the gas chromatograph and analyzed. Quantitative analysis was performed by measuring peak heights. Calibrations were made by analysis of known mixtures of approximately the same composition. The results of successive analyses on the same sample agreed to within ±5%.

EQUILIBRIUM

Although a detailed spectroscopic analysis of *trans*-crotononitrile has been performed (5) and the thermodynamic functions of this compound have been tabulated, no study has been made of the temperature dependence of the cis–trans ratio. Since this information

[1]*To whom all correspondence should be addressed, at TYCO Laboratories, Inc., Bear Hill, Waltham 54, Mass.*

was necessary in order to calculate the rate constants for the cis–trans isomerization, a study of the equilibrium was undertaken.

Samples of *cis*-crotononitrile, *trans*-crotononitrile, and mixtures of the two were pyrolyzed at temperatures from 300° C to 500° C. The low-temperature experiments were performed in sealed tubes with a small amount of iodine present as a catalyst (6, 7, 8). High-temperature experiments were performed in the gas phase with no catalyst present. The results are presented in Table I. Each value is the average of the results of three experiments.

TABLE I

Equilibrium data for crotononitrile

Temp. (°C)	Equilibrium cis/trans ratio
Sealed tube, I_2 catalyst	
303	1.40
362	1.39
400	1.39
455	1.35
Gas phase, no catalyst	
479	1.20
520	1.38
560	1.54

Although the high-temperature results scatter much more widely than the low-temperature results, they seem to be consistent. By fitting the more precise low-temperature data with a least-squares straight line, the following thermodynamic functions were calculated for the reaction cis → trans:

$$\Delta H = 0.17 \pm 0.12 \text{ kcal/mole}$$

$$\Delta S = -0.39 \pm 0.19 \text{ cal/mole °K.}$$

Crotononitrile is similar to difluoroethylene (8) and dichloroethylene (9, 10) in that the cis isomer is more stable than the trans isomer. For the dihaloethylenes, this results from a large positive value of ΔH, which has been attributed (11) to the high electronegativity and small size of the halogen atoms. In crotononitrile, ΔH is positive but rather small, and the stability of the cis isomer is primarily due to the negative value of ΔS.

The negative value of ΔS which has been observed in 2-butene has been explained (12) in terms of the potential barrier to hindred rotation of a methyl group. A similar explanation can be invoked for crotononitrile. In the cis isomer, with the methyl group in its low-energy conformation, the repulsion between the cyano group and the nearest two hydrogens of the methyl group is greater than that for the low-energy conformation of the trans isomer, where the two hydrogens of the methyl group interact only with a hydrogen on the other side of the double bond. In the high-energy conformation of either isomer the repulsion will be nearly the same between the single hydrogen of the methyl group and either the cyano group or the hydrogen on the other side of the double bond. The result is that the barrier to internal rotation has approximately the same maximum energy in both cis and trans isomers, but the minimum energy is higher in the cis isomer, and hence the internal rotation in the cis isomer can occur more freely. This could account for the higher entropy of the cis isomer.

KINETICS OF THE CIS–TRANS ISOMERIZATION

The kinetics of the isomerization of crotononitrile was studied in the gas phase at pressures from 0.7 to 20 mm and temperatures from 400° C to 560° C. Very little low-boiling side-reaction products were observed, although extensive charring and polymerization occurred, blackening the walls of the vessel. On the walls of the tube connecting the vessel with the vacuum system was found a red-brown tarry deposit, which apparently had such a low vapor pressure that none of it distilled into the sample tube.

This polymerization was rapid enough at 600° C to prevent equilibrium from being attained. If a sample of pure *cis*-crotononitrile was pyrolyzed for a sufficiently long time, a steady value of the cis/trans ratio was obtained, approximately 2.0, which was somewhat larger than the equilibrium value, 1.35, extrapolated from lower temperatures. Similarly, if a sample of pure *trans*-crotononitrile was pyrolyzed a steady state was reached in which the cis/trans ratio was 1.05, smaller than the extrapolated equilibrium value. Under these conditions, however, almost no side-reaction products were detected in the boiling point range from 80° C to 150° C. The competing reaction which prevented the attainment of equilibrium appeared to be polymerization. Although polymerization affected the equilibrium runs, it was unimportant at the short times used for the kinetic runs.

At lower temperatures and for shorter reaction times, however, the results showed the isomerization to be a simple reversible first-order reaction:

$$\text{cis} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{trans},$$

and the rate constants were calculated using the conventional integrated rate equation for this mechanism (see, for example, reference 13).

The rate constants listed in Table II were calculated from experiments at 480° C using

TABLE II

Variation of rate constant with time at 480° C

Starting material	Time (sec)		$k_1 \times 10^5$ (sec^{-1})
Cis (22 mm pressure)	100		13.7
	300		14.7

both *cis*- and *trans*-crotononitrile as starting materials, and varying the time of reaction by a factor of 80. No trend is apparent with either time of reaction or direction from which equilibrium is approached.

The rate constant was measured as a function of temperature from 393° C to 560° C, and the results are summarized in Table III. A least-squares straight line fitted to the

Arrhenius plot of this data gave the following parameters:

$$E_a = 51.3 \pm 3.7 \text{ kcal/mole}$$

$$\log A = 11.0 \pm 1.0.$$

The activation energy is lower than the 65 kcal/mole observed for 2-butene (2), and dideuteroethylene (14) but higher than the 46 kcal/mole observed for cyanostyrene (15). The fact that crotononitrile falls between the conjugated styrene system and the unconjugated ethylene system lends support to the hypothesis that conjugation in the side groups makes the activation energy for isomerization lower. The pre-exponential factor is almost exactly the same as the log $A = 11.6$ observed for cyanostyrene, and the similar entropy of activation implies that the transition state configuration in the two cases is similar.

The rate of reaction was unaffected by the addition of up to 1% of oxygen or by packing the reaction vessel with glass wool. This evidence, together with the hgh frequency factor and activation energy, suggests that the reaction is a truly homogeneous unimolecular one.

Further evidence for the unimolecular nature of this reaction is provided by the dependence of the rate constant on pressure. Figure 1 shows the rate constant as the pressure

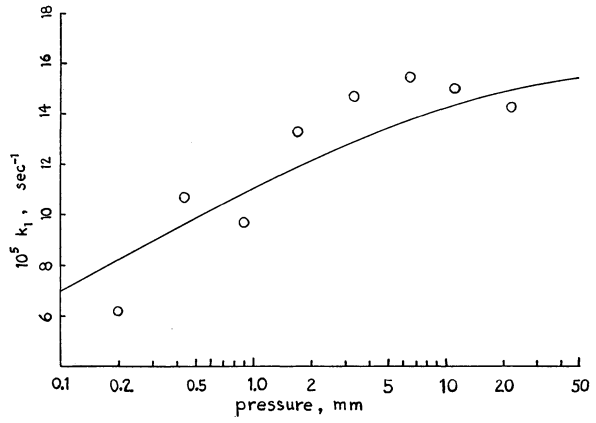

FIG. 1. Pressure dependence of rate constant.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

was varied from 0.2 to 20 mm at 480° C. Although the scatter in the data is large, due principally to the method of analysis, the rate constant can be seen to decrease by about a factor of 2 over this range of pressure.

The curve in Fig. 1 was drawn using the Kassel (16) equation with the following parameters: Infinite-pressure rate constant 1.60×10^{-4} sec^{-1}, collision diameter 5.5 Å, and fall-off parameter $s = 9$. Although by analogy with 2-butene and dideutereothylene (2) we might expect s to be in the range from 15 to 25, this value is not unreasonable.

THE THERMAL CIS–TRANS ISOMERIZATION AND DECOMPOSITION OF METHYL CROTONATE

JAMES N. BUTLER[1] AND GERALD J. SMALL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received May 22, 1963

ABSTRACT

Methyl crotonate undergoes a homogeneous, unimolecular cis–trans isomerization in the gas phase at temperatures from 400° C to 560° C. The rate constant for the cis → trans reaction was found to be

$$k_1 = 10^{13.2\pm0.3}e^{-57.8\pm1.5 \text{ kcal}/RT}$$

independent of pressure in the range from 0.1 mm to 10 mm. The equilibrium trans/cis ratio is approximately 4.5, independent of temperature, from 200° C to 500° C. Simultaneous free-radical reactions also occur, the most important of which are the isomerization to methyl vinylacetate, and the decomposition to give carbon dioxide and the various butene isomers. Side reactions gave carbon monoxide, methane, propylene, numerous other hydrocarbons, and various ethers.

INTRODUCTION

The cis–trans isomerization of butene-2 was for a long time thought to have an anomalously low frequency factor and activation energy, but a recent study at low pressures using gas chromatography for analysis (1) showed that both the frequency factor ($10^{13.8}$) and the activation energy (62.8 kcal) were normal. The availability in this laboratory of the cis isomer of methyl crotonate, CH_3—CH=CH—$COOCH_3$, suggested that an investigation of the cis–trans isomerization of methyl crotonate at low pressures using gas chromatography might be interesting.

Some brief experiments conducted in sealed tubes (2) indicated that methyl vinylacetate, CH_2=CH—CH_2—$COOCH_3$, was formed from methyl crotonate. Part of the purpose of this study was to investigate whether methyl vinylacetate was formed in the gas phase, and if so, by what mechanism.

EXPERIMENTAL

Materials

trans-Methyl crotonate was obtained from K and K Laboratories, Inc., New York, and purified by gas chromatography. The purified material contained approximately 0.1% of the cis isomer, and approximately 0.1% of methyl vinylacetate. *cis*-Methyl crotonate was provided by Dr. D. E. McGreer of the University of British Columbia, who prepared it by the thermal decomposition of 3-carbomethoxypyrazoline (2). The sample was purified by gas chromatography, and the purified material contained approximately 0.2% of *trans*-methyl crotonate, and approximately 3% of methyl vinylacetate.

Procedure

Experiments were conducted in a vacuum system entirely free from stopcock grease. Metal diaphragm valves (Hoke) were used, and were connected to the glass parts of the apparatus with epoxy resin cement. The reaction vessel was of 100 ml volume, and was kept at constant temperature by an electrically heated air bath. The temperature was controlled by operating the furnace from a variac and voltage-regulating transformer, and enclosing the furnace in an insulated copper drum which was cooled by tap water at 8° C circulating through coils fastened to its outside. The temperature could be maintained to within 0.5° C for periods of up to 1 hour in the temperature range from 300° C to 600° C. A sample of either *cis*- or *trans*-methyl crotonate was admitted to the reactor by expansion from a storage vessel. Normally, the pressure in the reactor was the vapor pressure of the material at room temperature: 10 to 14 mm for both the trans and cis isomers.

When the reaction had proceeded for the desired length of time, the material in the reactor was pumped

[1]*To whom all correspondence should be addressed, at TYCO Laboratories, Inc., Bear Hill, Waltham 54, Mass.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

through a trap cooled in liquid nitrogen. Normally all non-condensable gases were discarded. The condensable material was distilled into a side tube of volume 0.2 ml, and sealed off.

Routine Analysis

Analysis was performed on a Perkin–Elmer model 226 gas chromatograph, using a 50 m capillary column coated with polypropylene glycol (type R), and a flame ionization detector. The contents of the sample tube was dissolved in anhydrous ether and injected in the gas chromatograph. Peak height ratios were measured and calibrated with known mixtures of approximately the same composition. The results of successive analyses of the same sample agreed to within about ±5%.

Analysis for Side-reaction Products

In order to establish the nature and extent of the side reactions which proceeded at the same time as the cis-trans isomerization, a nearly complete separation of the products of the reaction was desirable. Under the normal conditions of analysis, only the compounds boiling in the range from 80° C to 150° C were detected.

To detect the intermediate-range compounds, the temperature of the 50 m capillary column was initially held at 0° C, and was raised during the course of the analysis to 120° C. *n*-butyl ether (b.p. 147.2–147.3° C, purified by gas chromatography) was used as a solvent, so that peaks for all the products boiling up to 145° C except CO and CO_2 (to which the detector did not respond) appeared on the chromatogram. Peaks from C_4 up were well resolved. A packed silica gel column (type J) at room temperature resolved CO, CH_4, CO_2, and C_2H_6. A tetraisobutylene column (type D) separated all the products up through the butenes except for CO and CH_4, which appeared as a single peak. A polypropylene glycol column (type R) was used to confirm the identification of the various peaks, but it did not separate propylene from allene, methylacetylene, and dimethyl ether.

EQUILIBRIUM MEASUREMENTS

Although the entropy and enthalpy changes for a number of cis–trans isomerizations have been determined, methyl crotonate is not among these. We therefore undertook a study of the temperature dependence of the equilibrium trans/cis ratio. *cis*-Methyl crotonate, *trans*-methyl crotonate, and mixtures of the two of varying composition were pyrolyzed both in the gas phase at 14 mm pressure and in sealed tubes using I_2 as a catalyst (3, 4, 5).

At temperatures above 450° C, the decomposition of methyl crotonate occurred so rapidly that if a sample of pure trans was heated, the trans/cis ratio would fall to some value which was higher than the equilibrium value, remain there for some time, and then begin to increase again. Similarly, if a sample of pure cis was heated, the trans/cis ratio would increase to a steady-state value which was less than the equilibrium value. In order to achieve equilibrium it was necessary to start with a mixture which was near the equilibrium composition and to pyrolyze it for a sufficiently short time that decomposition was not extensive. At temperatures above 500° C, the results were so irreproducible that they were discarded.

The results obtained are listed in Table I. Although the results are not very precise, the trans/cis ratio can be seen to be approximately 4.5, independent of temperature, over the temperature range from 200° C to 500° C. A least-squares fit of the data gave the following thermodynamic functions for the reaction cis → trans:

$$\Delta H^0 = -0.2 \pm 0.4 \text{ kcal/mole}$$

$$\Delta S^0 = +2.7 \pm 0.7 \text{ cal/mole °K.}$$

KINETICS OF THE CIS–TRANS ISOMERIZATION

Because of the extensive formation of side products, it was necessary to account for them in the calculation of the rate constant. The method of analysis used made measurement of product ratios more precise than measurement of the absolute amounts of products, and therefore the expression for the rate constant was cast into this form.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

TABLE I

Equilibrium trans/cis ratios

Temperature (°C)	Equilibrium trans/cis ratio	Predominant isomer of starting material
Sealed tubes, I_2 catalyst		
204.8	4.88	Cis
244.0	4.98	Cis
266.8	5.20	Cis
280.0	4.58	Cis
280.0	4.20	Trans
357.0	4.40	Cis
358.5	4.44	Trans
358.5	4.02	Trans
Gas phase, 14 mm, uncatalyzed		
425.5	4.54	Trans
437.6	4.96	Trans
447.5	4.24	Trans
448.5	4.25	Trans
450.2	4.88	Cis
478.0	4.82	Cis

The mechanism followed was assumed to be a reversible first-order reaction with a parallel, irreversible side reaction:

$$\text{cis} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{trans}$$

$$\text{cis} \rightarrow \text{side products.}$$

If the cis–trans isomerization is first order, the rate of formation of trans is

$$[1] \qquad \frac{d[T]}{dt} = k_1[C]-k_2[T],$$

where $[T]$ is the partial pressure of *trans*-methyl crotonate, and [C] is the partial pressure of *cis*-methyl crotonate. Let $[S]$ represent the partial pressure of *cis*-methyl crotonate which has formed side products, the sum of methyl vinylacetate, propylene, and butene being a good approximation. A material balance gives

$$[2] \qquad [C]+[T]+[S] = [\mathrm{C}]_0+[T]_0+[S]_0,$$

where the subscript zero indicates the partial pressures in the starting material. Substituting [2] in [1] and integrating gives

$$[3] \qquad \ln\left\{\frac{k_1([C]_0+[S]_0-[S])-k_2[T]_0}{k_1[C]-k_2[T]}\right\} = (k_1+k_2)t.$$

Introducing the equilibrium constant $[T]_{eq}/[C]_{eq} = k_1/k_2$, and approximating $[S]/[C]_0 = [S]/[C]$, [3] may be expressed entirely in terms of product ratios:

$$[4] \qquad \ln\left\{\frac{\left[\frac{k_1}{k_2}\left(1+\frac{[S]_0}{[C]_0}-\frac{[S]}{[C]}\right)-\frac{[T]_0}{[C]_0}\right]\left[1+\frac{[T]}{[C]}+\frac{[S]}{[C]}\right]}{\left[\frac{k_1}{k_2}-\frac{[T]}{[C]}\right]\left[1+\frac{[T]_0}{[C]_0}+\frac{[S]_0}{[C]_0}\right]}\right\} = (k_1+k_2)t.$$

An expression is obtained from the isomerization of *trans*-methyl crotonate, which is the same form as [4] except that $[C]$ and $[T]$, k_1 and k_2, are interchanged. The results of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

series of experiments at 10 mm pressure and 480° C, starting with pure *trans*-methyl crotonate, are listed in Table II. The calculated rate constant k_1 for the cis → trans

TABLE II

isomerization showed no trend as the time was varied by a factor of 40. Apparently the mechanism described represents the data satisfactorily.

Addition of up to 1% oxygen or packing the vessel with glass wool had no effect on the rate of the cis–trans isomerization.

The rate constant was also found to be independent of pressure. In Table III are listed

TABLE III

the values of k_1 obtained by pyrolyzing *trans*-methyl crotonate for approximately 10 minutes at 478° C and at pressures ranging from 11 mm down to 0.1 mm. No trend is apparent with pressure.

The number of vibrational modes in methyl crotonate is 39, and by analogy with 2-butene (1) one might expect that nearly all of these would be effective in the Slater (6) model for a unimolecular isomerization. This would imply that a unimolecular falloff in rate constant should be about 30% at a pressure of 0.01 mm, which is well below the pressure of our lowest measurement. These results indicate that the cis–trans isomerization is a truly homogeneous, unimolecular reaction.

The temperature dependence of the rate constant at 10 mm pressure was studied from 350° C to 550° C, using both *trans*-methyl crotonate and *cis*-methyl crotonate as starting material. The results are summarized in Table IV. A least-squares fit to the Arrhenius

474.0	19	2

plot of these data gave the parameters

$$E = 57.8 \pm 1.5 \text{ kcal/mole}$$

$$\log A = 13.2 \pm 0.3.$$

No curvature was detectable in the Arrhenius plot.

Examination of Table IV will show that, within the experimental errors, the same values were obtained for k_1 whether the starting material was cis or trans. This further confirms the proposed mechanism, and the value measured for the equilibrium constant.

The values of the activation energy and frequency factor are very similar to those obtained in the known unimolecular isomerization of 2-butene (1). For methyl crotonate, the frequency factor is $10^{13.2}$; for 2-butene, the frequency factor is $10^{13.78}$. Since methyl crotonate is unsymmetrical and 2-butene is symmetrical, we might expect that the frequency factor for 2-butene would be a factor of 2 larger than for methyl crotonate. This is true within the experimental errors. The activation energy for methyl crotonate is 57.8 kcal, which is only slightly lower than that for 2-butene: 62.8. This 5 kcal lowering could be rationalized by considering some conjugative effect due to the highly electronegative oxygen atoms so close to the double bond.

A compound which we might also expect to be similar to methyl crotonate in its behavior is dimethyl maleate. The thermal cis–trans isomerization of dimethyl maleate (7) was followed by freezing point depression. As was shown in the case of 2-butene (1), small amounts of side reaction can introduce systematic errors in a rate constant measured by this technique.

The frequency factor (10^5) and activation energy (26 kcal) for the isomerization of dimethyl maleate are both extremely low compared to methyl crotonate and 2-butene, even though the temperature at which a comparable rate occurs is not very much lower. Furthermore, both 2-butene and methyl crotonate show a pressure dependence of the rate constant which is consistent with nearly all the normal modes of the molecule taking part in the reaction. The pressure dependence of the rate of isomerization of dimethyl maleate, if explained by the theory of unimolecular reactions, implies that only 1 normal mode of vibration out of the possible 42 normal modes is active in the reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Although we cannot conclude from these comparisons alone that the rate constant for dimethyl maleate is in error, it certainly seems reasonable that the isomerization of dimethyl maleate should be reinvestigated at low pressures using gas chromatography for analysis.

KINETICS OF THE FORMATION OF METHYL VINYLACETATE

One of the major side reactions in the thermal cis–trans isomerization of methyl crotonate is the formation of methyl vinylacetate:

$$CH_3—CH=CH—COOCH_3 \xrightarrow{k_3} CH_2=CH—CH_2—COOCH_3.$$

Unfortunately, the rate of this reaction was not nearly so reproducible as the rate of the cis–trans isomerization: variations in k_3 of a factor of 10 occurred in experiments under supposedly the same conditions. Nevertheless, some approximate results were obtained.

The formation of methyl vinylacetate appears to be first order, since the rate constant k_3 shows no noticeable trend with pressure, or with time of reaction. The rate is not affected by the addition of small amounts of oxygen or by packing the vessel with glass wool. The temperature dependence of the rate constant gave the Arrhenius expression

$$k_3 = 10^{8.7\pm1.5}e^{-43\pm5 \text{ kcal}/RT}.$$

Approximately the same values of k_3 were obtained whether the starting material was cis or trans.

The isomerization of methyl crotonate to methyl vinylacetate might appear at first to be a homogeneous unimolecular reaction. However, the large amounts of other products of free-radical decomposition, and the extreme irreproducibility of the results, imply that the reaction proceeds by a free-radical mechanism. Furthermore, the low frequency factor and activation energy imply that the mechanism is not a simple unimolecular one. An ionic reaction on the surface of the vessel is ruled out by the fact that packing the vessel does not affect the rate appreciably.

The decomposition of methyl crotonate (next section) gives a large number of free radicals, and it is conceivable that abstraction and displacement reactions occurring between these radicals and methyl crotonate result in the shift of a hydrogen atom in methyl crotonate. A possible scheme might involve a radical which is stabilized by allylic resonance (8):

$$R\cdot + CH_3—CH=CH—COOCH_3 \rightarrow RH + \cdot CH_2—CH=CH—COOCH_3$$

$$\cdot CH_2—CH=CH—COOCH_3 \leftrightarrow CH_2=CH—\dot{C}H—COOCH_3$$

$$RH + CH_2=CH—\dot{C}H—COOCH_3 \rightarrow R\cdot + CH_2=CH—CH_2—COOCH_3,$$

but experiments using isotopic tracers would be required to elucidate the mechanism more definitely.

DECOMPOSITION REACTIONS

Extensive decomposition of methyl crotonate occurs at the temperatures where the *cis–trans* isomerization proceeds at a measurable rate. A nearly complete analysis of a typical product mixture is given in Table V. In addition to the trans isomer and methyl vinylacetate, pyrolysis of *cis*-methyl crotonate gave carbon monoxide, carbon dioxide, methane, propylene, butenes, and 20 or more minor products ranging in boiling point from −30° C to over 150° C.

TABLE V

Side-reaction products in the pyrolysis of methyl crotonate*

Product	Relative amount	Product	Relative amount
cis-Methyl crotonate	400	A peak occurring near propylene, probably allene + dimethyl ether	8
trans-Methyl crotonate	100	A peak occurring near the butenes, probably methyl acetylene	5
Carbon dioxide	60	4 closely spaced peaks following the butenes, compounds boiling in the 20–30° C range	1
Carbon monoxide	30	4 closely spaced peaks, compounds boiling in the 35–45° C range, perhaps $C_3H_5OCH_3$	3
Methane	23	3 closely spaced peaks boiling in the 80–90° C range, perhaps 2,4-hexadienes	9
Methyl vinylacetate	20	7 peaks of nearly the same height, boiling in the 140–150° C range	4
Propylene	9		
trans-2-Butene	9		
cis-2-Butene	6		
1-Butene	4		
Ethane	3		
Methyl methacrylate	1		
Methanol	0.2		
1,5-Hexadiene	<0.1		

*This analysis reports the approximate amounts of the products formed when *cis*-methyl crotonate was pyrolyzed for 40 minutes at 480° C.

The decomposition of methyl crotonate to give CO_2, CO, and various hydrocarbons and ethers proceeded at a rate which was only slightly slower than the rate of cis–trans isomerization. A probable mechanism involves an initial split to give propenyl radicals:

$$CH_3—CH=CH—COOCH_3 \rightarrow CH_3—CH=CH\cdot + CO_2 + CH_3\cdot$$
$$\rightarrow CH_3—CH=CH\cdot + CO + CH_3O\cdot.$$

The recombination of propenyl and methyl radicals produces 2-butene. Isomerization of propenyl to allyl, and subsequent recombination with methyl, would give 1-butene. Propylene, allene, and methylacetylene can be formed by abstraction of hydrogen from methyl crotonate. Polymeric materials as well as the high-boiling products can be formed by addition of the various radicals to methyl crotonate.

The presence of CO in the products makes it almost certain that CH_3O radicals are present in the reaction scheme. These radicals might be expected to form methanol by abstraction of a hydrogen atom from methyl crotonate. Only a barely detectible trace of methanol was found in the products, which implies that methoxyl radicals are being consumed by some other process, possibly by addition to the double bond of methyl crotonate or recombination with other radicals. The recombination of methoxyl with allyl or propenyl radicals would give ethers of the form $C_3H_5OCH_3$, which might account for the peaks having boiling points in the 35–45° C range. If dimethyl ether were formed by recombination of methoxyl with methyl, it would appear in the same peak as propylene.

A direct unimolecular elimination of CO_2 to form butene is unlikely, since all three butene isomers were formed. Furthermore, pyrolysis of *cis*-methyl crotonate, *trans*-methyl crotonate, and methyl vinylacetate all gave roughly the same distribution of butene isomers.

The presence of allyl radicals (9, 10, 11) would be expected to give 1,5-hexadiene as a product, but no trace of this material could be found in the pyrolysis of either *cis*- or *trans*-methyl crotonate. Pyrolysis of methyl vinylacetate gave a trace (about 0.5% of products) of 1,5-hexadiene, but not nearly as much as might be expected. Apparently allyl radicals are being consumed by other reactions much more rapidly than they are being recombined with each other.

On the other hand, the appearance of three peaks of almost equal height in the correct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

boiling point region implies the presence of moderate amounts of the three isomers of 2,4-hexadiene in the products. These would be formed by recombination of propenyl radicals. On such tentative evidence it is difficult to draw any definite conclusion, but it would appear that propenyl radicals recombine much more rapidly than do allyl radicals, possibly because of the resonance stabilization of allyl radicals.

A small amount of methyl methacrylate observed in the products increases by about a factor of 10 when the pyrolysis is conducted in a packed vessel, whereas the other free-radical decomposition products are formed at approximately the same rate as in the unpacked vessel. This implies that the methyl group shift occurs on the surface, probably by an ionic mechanism (12, 13).

METHYLATION OF SUGAR DITHIOACETALS

V. D-MANNOSE DIETHYL DITHIOACETAL

G. G. S. DUTTON AND Y. TANAKA[1]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received June 17, 1963

ABSTRACT

Partial methylation of D-mannose diethyl dithioacetal in tetrahydrofuran with methyl iodide and silver oxide yielded 2-, 3-, and 6-*O*-methyl-D-mannose in the ratio of 12:1:1, respectively. The major component, 2-*O*-methyl-D-mannose, was characterized as the phenylhydrazone and the other isomers identified by electrophoresis. The M_g values of these mono-*O*-methyl ethers were recorded.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In Part I of this series it was demonstrated that various sugar dithioacetals could be successfully methylated in tetrahydrofuran with methyl iodide and silver oxide (1). Subsequent papers have reported the nature of the mono-*O*-methyl ethers obtained by partial methylation of the diethyl dithioacetals of L-arabinose (2), D-galactose (3), and D-xylose (4). The present paper reports the mono-*O*-methyl ethers obtained by methylation of D-mannose diethyl dithioacetal under similar conditions and is a continuation of our study on the relative reactivities of hydroxyl groups in sugar dithioacetals.

Preparation of D-mannose diethyl dithioacetal by Fischer's method (5) was found to give unreliable results since on several occasions the crude product decomposed on washing with ice water. It was found preferable to neutralize with barium carbonate and dilute with methanol whence the dithioacetal could be obtained by evaporation of the filtered solution.

The dithioacetal was shaken in tetrahydrofuran at room temperature with an appropriate amount of silver oxide and methyl iodide to give a reasonable yield of the mono-*O*-methyl ethers, after hydrolysis. The mono- and di-*O*-methyl ethers were separated from the unchanged and poly-*O*-methylated D-mannoses by chromatography in butanone–water azeotrope.

Electrophoresis in 0.05 *M* borate showed that the mixture of mono-*O*-methyl ethers contained three isomers, one of which was predominant judging from the size and intensity of the spots. These three components had M_g values of 0.38, 0.54, and 0.63, and were shown to be 2-, 3-, and 6-*O*-methyl-D-mannose, respectively, by concurrent electrophoretic examination with synthetic samples of these isomers. 2-*O*-Methyl-D-mannose gave the strongest and largest spot, and the others were weak and small. The mixture of di-*O*-methyl ethers, which might contain the 5-*O*-methyl ether, was also examined by electrophoresis but only a very slowly migrating component was detected, suggesting no 5-*O*-methyl ether was present.

The phenol – sulphuric acid method (6) of quantitative analysis on the mixture of mono-*O*-methyl-D-mannoses gave a ratio of 12:1:1 for 2-, 3-, and 6-*O*-methyl-D-mannose, respectively.

The mixture of mono-*O*-methyl-D-mannoses was separated on Whatman No. 3MM paper by electrophoresis and the area corresponding to the 2-*O*-methyl-D-mannose was extracted with water. The extract was deionized and evaporated to a sirup, which was

[1]*Present address: Department of Chemistry, Queen's University, Kingston, Ontario.*

then treated with methanol many times in order to destroy possible borate complexes (7). The residue was condensed with phenylhydrazine in warm ethanol to give the phenylhydrazone, m.p. 161–163° C.

Authentic 2-, 3-, and 6-*O*-methyl-D-mannose were prepared by reported procedures. 2-*O*-Methyl-D-mannose was synthesized by the method of Curtis and Jones (8), except that the diethyl dithioacetal was used. This ether was also prepared by the method of Aspinall and Zweifel (9). The synthesis according to their procedure showed, however, that the product was accompanied by a small amount of the 3-*O*-methyl ether.

3-*O*-Methyl-D-mannose was also prepared by the method of Aspinall and Zweifel (9). Following their procedure, methyl 4,6-*O*-ethylidene-α-D-mannopyranoside was partially *O*-nitrated in acetic anhydride, but the infrared spectrum of the product showed the bands of *O*-acetate at 5.75 and 8.13 μ as well as the bands of *O*-nitrate at 6.10 and 7.85 μ, indicating partial acetylation during the nitration. Bell and Synge (10) have successfully deacetylated methyl 2,6-di-*O*-acetyl-3,4-di-*O*-nitro-β-D-glucopyranoside in a mixture of methanol and chloroform with sodium. Application of this method on the partially acetylated product gave a sirup which showed no band of *O*-acetate in its infrared spectrum. Completion of Aspinall and Zweifel's process with this deacetylated product showed, however, that the final product was accompanied by a small amount of 2-*O*-methyl-D-mannose.

Waters, Hockett, and Hudson (11) have reported the synthesis of 6-*O*-methyl-D-mannose. Due to acetyl migration the use of this method resulted in only a very small yield of this compound, which was separated from the mixture by chromatography.

The results reported here demonstrate the preferential reactivity of the 2-position of D-mannose diethyl dithioacetal to methylation, in marked contrast to the D-galactose isomer where the 2-, 3-, and 6-position showed similar reactivity. A discussion of these and other related results is planned.

EXPERIMENTAL

All evaporations were carried out *in vacuo* at a bath temperature not exceeding 40° C. Chromatograms were run by the descending technique in butanone–water azeotrope and the same solvent was used for column separations. Electrophoretic separations were carried out in 0.05 *M* borate at 950–1050 v, 25–30 ma.

Preparation of D-*Mannose Diethyl Dithioacetal*

D-Mannose (15 g) was mixed with concentrated hydrochloric acid (15 g) in an ice-water bath. Ethane thiol (10 g) was added portionwise with vigorous shaking. After all the ethane thiol was added, the mixture was shaken mechanically for 20 minutes. The clear solution thus obtained was partially neutralized with barium carbonate, and then completely neutralized with excess barium carbonate after addition of methanol (100 ml) to the mixture. Barium chloride and excess barium carbonate were removed by filtration, and evaporation of the filtrate gave a sirupy residue which was separated from inorganic impurities by extraction with cold absolute ethanol (ca. 150 ml). The solvent was evaporated and the residue was recrystallized from ethanol–ether. Yield 14.2 g (60%). Melting point and mixed melting point with a sample prepared by Fischer's method were 132–134° C.

Methylation of D-*Mannose Diethyl Dithioacetal*

To a solution of D-mannose diethyl dithioacetal (1.00 g) in tetrahydrofuran (100 ml), silver oxide (1.50 g), Drierite (3 g), and methyl iodide (10.0 ml) were added, and the mixture was shaken mechanically at room temperature for 12 hours. After another 10.0 ml of methyl iodide was added, the mixture was shaken similarly for a further 12 hours. The mixture was filtered and the inorganic substances were washed with tetrahydrofuran (20 ml). The filtrate and washing were concentrated to a sirup, which was redissolved in chloroform (20 ml) in order to remove inorganic impurities in the sirup by filtration. A light brown sirup (1.157 g) obtained by evaporation of the filtered chloroform solution was hydrolyzed for 5 hours in a boiling mixture of ethanol (10 ml) and 2 *N* sulphuric acid (5 ml). Evaporation of the deionized hydrolyzate (Duolite A-4 resin) gave a sirup (528 mg) which showed the following spots by paper chromatography: R_f 0.34, 0.22, 0.07, and a few spots of high R_f values. The spot of R_f 0.07 was strong in its intensity and the others weak.

From the same quantities of reactants, another sirup (508 mg) of methylated D-mannoses was obtained and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

paper chromatography showed the following spots: R_f 0.43, 0.29, 0.11, 0.03 and a few spots of high R_f values. The spots of R_f 0.11 and 0.03 were strong and the others weak.

These combined sirups (528+508 mg) were separated on a cellulose–hydrocellulose column (solvent flow: 10 ml/20 mins), and the component of R_f 0.07 (or R_f 0.11) was detected in tubes No. 80–200, whereas the components of R_f 0.22 and 0.35 (or R_f 0.29 and 0.43) were found in tubes No. 40–70 (10 minute fractions) but without clear separation. The yield of these fractions was 115.7 mg and 21.3 mg respectively.

Methylation using the same quantities of reactants was performed twice more, and two sirups (484 mg and 419 mg) of *O*-methyl-D-mannoses were obtained. These sirups were chromatographed together in a similar manner as described above and mixtures of mono- and di-*O*-methyl ethers (70.5 mg and 11.7 mg, respectively) were obtained.

The two fractions of mono-*O*-methyl ethers were amalgamated and treated with charcoal in hot water and an electrophoretic examination of the recovered sirup (170 mg) showed three spots, M_g 0.32 (strong), 0.48 (weak), and 0.60 (weak), which corresponded to authentic samples of 2-, 3-, and 6-*O*-methyl-D-mannose, respectively.

The two di-*O*-methyl fractions were also examined by electrophoresis under the same conditions, and one large spot (two or three components (?)) of M_g 0.14–0.15 was detected in both sirups.

The phenol – sulphuric acid method (6) was used to estimate the ratio of mono-*O*-methyl ethers in the sirupy mixture. A ratio of 12:1:1 for 2-, 3-, and 6-*O*-methyl-D-mannose was obtained.

Identification of 2-O-Methyl-D-mannose

The mixture (170 mg) of mono-*O*-methyl-D-mannoses was separated by electrophoresis (950–1050 v, 50 minutes in 0.05 *M* sodium borate solution) on three 15 cm wide Whatman No. 3MM sheets, and 2-*O*-methyl-D-mannose was located on the guide strips. The appropriate areas of the sheets were extracted with cold water (30 ml×3), the solution was deionized, and the residue obtained by evaporation of the extracts was treated with cold methanol (about 5 ml) and the solvent was then evaporated. After this treatment was repeated about 20 times, a sirupy residue (28.7 mg) of 2-*O*-methyl-D-mannose was obtained.

Absolute ethanol (2 ml) and phenylhydrazine (16.0 mg) in absolute ethanol (0.1 ml) were added to the residue and after the mixture was warmed for 20 minutes petroleum ether was added. The precipitated phenylhydrazone which was separated by centrifugation and recrystallized from ethanol – petroleum ether had m.p. 161–163° C. Admixture with synthetic 2-*O*-methyl-D-mannose phenylhydrazone showed no depression of the melting point.

Preparation of 2-O-Methyl-D-mannose

(I) The published procedure (8) was used starting with D-mannose diethyl dithioacetal, and the deionized hydrolyzate of the completely methylated di-*O*-isopropylidene dithioacetal showed by paper chromatography a strong spot (R_f 0.07) of mono-*O*-methyl-D-mannose as well as a medium spot of unchanged mannose and a series of weak spots of poly-*O*-methylated D-mannoses. The following components were detected on a paper chromatogram run for 48 hours: R_{mannose} 2.50 (strong), 1.40 (weak), and 1.00 (medium). Chromatographically and electrophoretically pure 2-*O*-methyl-D-mannose (M_g 0.38) was obtained as a sirup by chromatography on a cellulose–hydrocellulose column and it was characterized as its phenylhydrazone, m.p. 161–163° C. Lit. (8) m.p. 161–163° C.

(II) A preparation from methyl 4,6-*O*-ethylidene-α-D-mannopyranoside (1.33 g) following the method of Aspinall and Zweifel (9) gave a sirup (190 mg) of methylated mannoses with components of R_{mannose} 3.32, 2.54, and 1.00. Column separation yielded the component with R_{mannose} 2.54 (78 mg) identical with the 2-*O*-methyl-D-mannose prepared from the dithioacetal, although neither sample crystallized.

Preparation of 3-O-Methyl-D-mannose

This was prepared by the published procedure (9) except that during the nitration of methyl 4,6-*O*-ethylidene-α-D-mannopyranoside with nitric acid in acetic anhydride some acetylation also occurred. The crude product was deacetylated with sodium in methanol–chloroform before tosylation. A mixture of methylated mannoses was finally obtained which contained components with R_{mannose} 3.34 (weak), 2.50 (strong), and 1.00 (medium). Separation on Whatman 3 MM yielded a sirup of 3-*O*-methyl-D-mannose (M_g 0.54). Chromatography on paper of this sirup in butanone–water saturated with borax showed a small amount of the 2-*O*-methyl isomer as a contaminant (R_{mannose} 2.22, strong; 2.40, weak).

The sirup (14.3 mg) was dissolved in 20% acetic acid to which phenylhydrazine (26.5 mg) in absolute ethanol (0.15 ml) was added. The mixture was heated in boiling water for several hours and on cooling the osazone precipitated. After recrystallization from ethanol–water the osazone melted at 165° C (lit. (9) 165–166° C) and gave no depression with 3-*O*-methyl-D-glucose phenylosazone.

Preparation of 6-O-Methyl-D-mannose

The published procedure (11) gave a mixture of mono-*O*-methyl-D-mannoses due to acyl migration, and an electrophoretically pure sirup (M_g 0.63) was obtained by column chromatography but in very poor yield.

The pure sirup (10 mg) was dissolved in 20% acetic acid (2 ml) and was heated for 5 hours in boiling water with phenylhydrazine (20 mg) in absolute ethanol (0.11 ml) and a little sodium bisulphite. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

phenylosazone which precipitated on cooling melted at 171° C, lit. (11) m.p. 172° C, after recrystallization from ethanol–water.

Full details of the syntheses of these three mono-*O*-methyl-D-mannoses are given elsewhere (12).

DIRECT CARBONYLATION OF THE BENZOPHENONE SEMICARBAZONES AND BENZOPHENONE AZINE USING DICOBALT OCTACARBONYL[1]

ALEX ROSENTHAL AND S. MILLWARD
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received April 29, 1963

ABSTRACT

Benzophenone semicarbazone (I) reacted with carbon monoxide at about 4000 p.s.i. and at 235–245° in the presence of preformed dicobalt octacarbonyl as catalyst to yield 3-phenylphthalimidine (II), 3-phenyl-2-(N-benzhydrylcarboxamido)phthalimidine (V), N,N′-dibenzhydrylurea (VI), and N-benzhydrylurea (VII). At 200–220° substance I gave compound VII, benzophenone azine (VIII), and benzophenone 4-benzhydrylsemicarbazone (IX). When the reaction temperature was further reduced to 175–185°, compound I did not produce the carbonylation product obtained in the second experiment but only the degradation and reduction products VIII, and IX, respectively. Carbonylation of benzophenone azine at 235–245° produced 3-phenylphthalimidine, whereas that of benzophenone 4-benzhydrylsemicarbazone at the same temperature yielded 3-phenylphthalimidine and 3-phenyl-2-(N-benzhydrylcarboxamido)phthalimidine.

Independent syntheses of the last compound and of benzophenone 4-benzhydrylsemicarbazone are described.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

We have previously reported the synthesis of phthalimidines and N-carboxyanilide derivatives of phthalimidines by the direct incorporation of one and two carbon monoxide units into aromatic ketoximes and phenylhydrazones, respectively (1, 2). Because the kind of products obtained was dependent on temperature, we hoped to obtain information on the mechanism of the cyclization reaction by a further study of the direct carbonylation of other substrates containing the imino group (but containing different substituents on the nitrogen).

In this paper we report the results of a study of the carbonylation of aromatic imino compounds containing the ureido (—$NHCONH_2$), ureylene (—NHCONH—), and imino groups attached to the nitrogen of the C=N group. In particular, benzophenone semicarbazone, benzophenone 4-benzhydrylsemicarbazone, and benzophenone azine were carbonylated under a variety of reaction conditions. The last substance was included in this study since it is known that benzophenone semicarbazone decomposes above its melting point to yield benzophenone azine (3).

Benzophenone semicarbazone reacted with carbon monoxide at about 4000 p.s.i. and at 235–245° in the presence of preformed dicobalt octacarbonyl to give a mixture of reduction and carbonylation products (the latter are shown in Chart I) which were separated by chromatography on alumina. Most of the product directly crystallized out of the reaction mixture as a blue crystalline material (designated as A in experimental). This material was extracted with ethanol and then chromatographed to yield N,N′-dibenzhydrylurea (VI) and 3-phenylphthalimidine (II). The structures of both of these substances were established by direct comparison with authentic samples of N,N′-dibenzhydrylurea (4) and 3-phenylphthalimidine (5).

The filtrate remaining after the removal of the blue material A was evaporated to dryness and the residue (B) then fractionated by alumina chromatography. Diphenylmethane (7% yield) and 1,1,2,2-tetraphenylethane (2%) were isolated from the residue

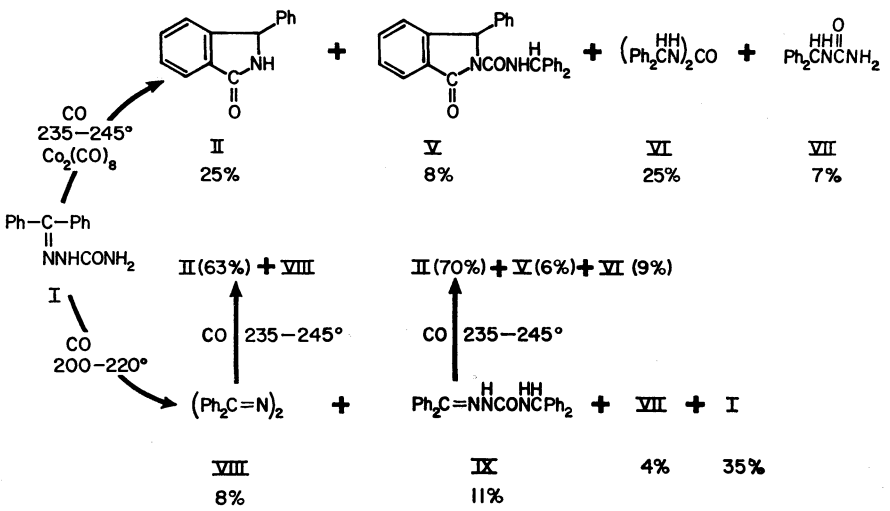

CHART I

Carbonylation of benzophenone semicarbazones and benzophenone azine

B and characterized by direct comparison (m.p. and infrared) with authentic samples of these substances. The fact that these compounds were present indicated that the high-purity carbon monoxide (containing about 0.01% hydrogen) acted as a reducing agent.

Compound V was unequivocally assigned the structure of 3-phenyl-2-(N-benzhydryl-carboxamido)phthalimidine on the following bases: (*a*) infrared analyses showed the presence of two carbonyls at 1684 and 1700 cm^{-1}, in excellent agreement with the spectrum of the previously reported N-carboxyanilide of 3-phenylphthalimidine (2); (*b*) refluxing compound V in 99% deuterium oxide gave a substance the infrared spectrum of which indicated the presence of an N—D grouping (see Experimental); (*c*) proton magnetic resonance analyses of the compound suggested a structure similar to that of 3-phenylphthalimidine-N-carboxyanilide (absorption at δ equal to 6.09 and 6.20 indicated the presence of the two benzylic hydrogens; comparison of the n.m.r. of compound V with that of 3-phenylphthalimidine-N-carboxyanilide established that the peak at 6.20 was due to the CH of the HC(Ph)=N group). The structure of V was then confirmed by direct comparison with an authentic sample of 3-phenyl-2-(N-benzhydrylcarboxamido)-phthalimidine, prepared by the condensation of 3-phenylphthalimidine with benzhydryl-isocyanate according to established procedures previously described (2, 6, 7).

Compound VII was directly compared with an authentic sample of N-benzhydrylurea (8), prepared by the condensation of benzhydrylisocyanate with ammonia, and shown to be the same.

When the reaction temperature was reduced to 175–180°, benzophenone semicarbazone did not cyclize with carbon monoxide but pyrolyzed and was reduced to yield two major products, one of which was readily characterized as benzophenone azine (VIII). This assignment of structure is in accord with that of Borsche and Merkivitz (3), who first reported that the thermal decomposition of benzophenone semicarbazone yielded benzophenone azine. On the bases of elemental, infrared, and proton magnetic resonance

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

studies it appeared that the second product (compound IX in Experimental) was benzophenone 4-benzhydrylsemicarbazone. Confirmation of this assignment of structure was obtained by condensing benzhydrylamine with benzophenone semicarbazone to yield ammonia and benzophenone 4-benzhydrylsemicarbazone (identical in m.p. and infrared with compound IX).

At an intermediate temperature of 200–220°, benzophenone semicarbazone afforded the same reduction products as obtained at 175–185°, and in addition N-benzhydrylurea. It is noteworthy that these reactions therefore indicate that carbonylation of the semicarbazone to yield a urea takes place between 180–220°.

Although the mechanism of formation of benzophenone 4-benzhydrylsemicarbazone from benzophenone semicarbazone is obscure, it is probable that a portion of the latter substance was reduced by the carbon monoxide via some type of hydrogen-transfer process, as envisaged by Natta, Pino, and Ercoli (9), to yield benzhydrylamine which then condensed with the remaining portion of benzophenone semicarbazone to yield compound IX.

The fact that benzophenone azine and benzophenone 4-benzhydrylsemicarbazone were present in the product of the 200-220° experiment but were not in that of the higher temperature one suggested that one or both of these substances might be the reactive intermediates in the direct ring closure reactions to yield the phthalimidines. In order to test this hypothesis, both of these substances were carbonylated at 235–245°. Benzophenone azine yielded only 3-phenylphthalimidine, whereas benzophenone 4-benzhydrylsemicarbazone afforded both 3-phenylphthalimidine and 3-phenyl-2-(N-benzhydrylcarboxamido)phthalimidine. Since some unreacted benzophenone azine remained after it had been treated with carbon monoxide at 235–245° but none was present when benzophenone semicarbazone or benzophenone 4-benzhydrylsemicarbazone was carbonylated at the same temperature for the same time one might assume that stronger complexing had occurred between the semicarbazones and the catalyst than between benzophenone azine and the catalyst which facilitated the cyclization reaction to yield the phthalimidines.

The fact that diphenylmethane and 1,1,2,2-tetraphenylethane were present in the reaction product suggests strongly that benzhydryl free radicals were produced by thermal decomposition of the azo tautomer of the semicarbazone. Evidence for a similar tautomerization of arylhydrazones has been recently noted by Connor (10). The homolytic cleavage of the azo tautomer of the semicarbazone might be expected to yield nitrogen and benzhydryl free radicals. Abstraction of hydrogen from the substrate might then be expected to yield diphenylmethane. On the other hand one might envisage that benzophenone semicarbazone might be reduced by the small quantity of hydrogen present in the gas to benzhydrylamine and the latter might then undergo hydrogenolysis to yield diphenylmethane.

EXPERIMENTAL

General Considerations

(*a*) The high-pressure equipment has been described previously (1).

(*b*) In every carbonylation experiment preformed dicobalt octacarbonyl (11) was used, and high-purity carbon monoxide supplied by the Matheson Co., East Rutherford, N.J., was added to an initial pressure of about 2100 p.s.i. at room temperature.

(*c*) The aluminum oxide (calcined) "Analar" was procured from the British Drug Houses (Canada) Ltd., Toronto 14.

(*d*) All melting points were obtained on a Leitz heating stage and are uncorrected. The infrared analyses were done on a Perkin–Elmer spectrophotometer, Model 21, using a sodium chloride crystal. Microanalyses

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

were done by Dr. A. Bernhardt, Mikroanalytisches Laboratorium, im Max-Planck Institut fur Kohlenforschung, Mulheim (Ruhr), Germany, and by Mrs. Aldridge of this department. The n.m.r. spectra were obtained on a Varian A-60 instrument using tetramethylsilane as the internal standard (set at $\delta = 0$).

Carbonylation of Benzophenone Semicarbazone at 235–245°

To a mixture of 10.0 g of benzophenone semicarbazone (0.04 mole) in 45 ml of dry purified benzene were added 3.0 g of preformed dicobalt octacarbonyl and 2100 p.s.i. of carbon monoxide. The mixture was heated to 235–245° (at about 4000 p.s.i.) for 150 minutes. The bomb was then cooled overnight (the pressure drop at room temperature was 40 p.s.i., equal to 0.019 mole of carbon monoxide) and vented. The vented gas contained no basic material. The reaction product consisted of 7.4 g of a blue solid (A) and a brown liquid (essentially free of catalyst) which on evaporation yielded 4.6 g of a brown solid (B).

3-Phenylphthalimidine (from Blue Solid A)

The blue solid (A) was extracted with ethanol for 24 hours in a Soxhlet apparatus, yielding 4.3 g of crystalline material. Chromatography of 0.105 g of this substance on alumina using benzene–chloroform (5:1) as developer yielded 0.019 g (10%) of N,N′-dibenzhydrylurea. Further elution of the column with chloroform afforded 0.054 g (25%) of solid which on recrystallization from ethanol had a melting point of 222–224°. The mixed melting point of the latter substance (II) and an authentic sample of 3-phenylphthalimidine (5) was 222–224°. The infrared spectra of the two compounds were identical.

Separation of Substances in Solid B

Solid B was separated into five components by thin-layer chromatography (12) on silica gel using chloroform as a developer and concentrated nitric acid – sulphuric acid as a detector.

A 2.17-g portion of material B dissolved in a minimum of benzene was chromatographed on an alumina column (133×54 mm diameter). The following developers were then added consecutively with elutions as indicated: (1) 600 ml of benzene – petroleum ether (30–60°) (1:1) eluted 0.283 g (8%) of liquid III; (2) 300 ml of benzene eluted 0.050 g (2%) of solid IV; (3) 400 ml of benzene yielded no material; (4) 600 ml of benzene eluted a trace; (5) 800 ml of benzene gave 0.328 g (8%) of solid V; (6) 1200 ml of benzene–ethanol (99:1) eluted nothing; (7) 500 ml of benzene–ethanol (98:2) yielded 0.595 g (15%) solid VI; (8) 300 ml of benzene–ethanol (98:2) gave no material; (9) 400 ml of benzene–ethanol (5:1) gave 0.312 g (7%) sirup VII.

Characterization of Fractions

Diphenylmethane (III)

Fraction III was purified by vapor phase chromatography using a silicone column at 270° C. Scratching of the liquid induced crystallization, m.p. 25°; mixed melting point with an authentic sample of diphenylmethane was 24–25°. The infrared spectrum of compound III was identical with that of an authentic sample of diphenylmethane.

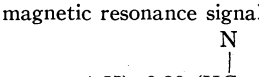
1,1,2,2-Tetraphenylethane (IV)

Compound IV was recrystallized from ligroin, m.p. 215–217°. Anal. Found: C, 93.69; H, 6.40. Calc. for $C_{26}H_{22}$: C, 93.40; H, 6.64. The infrared spectrum of compound IV was identical with that of an authentic sample of 1,1,2,2-tetraphenylethane (13), prepared by the reduction of tetraphenylethylene.

3-Phenyl-2-(N-benzhydrylcarboxamido)phthalimidine (V)

Compound V was recrystallized twice from benzene – petroleum ether (b.p. 30–60°); m.p. 200–201°; mixed m.p. of compound V with an authentic sample of 3-phenyl-2-(N-benzhydrylcarboxamido)phthalimidine, 199–200°.

Infrared spectrum of compound V (KBr): 3260 (w), 3050 (w), 3020 (w), 2930 (w), 1700 (s), 1684 (s), 1607 (w), 1593 (w), 1582 (w), 1528 (s), 1493 (m), 1465 (w), 1453 (w), 1359 (m), 1340 (m), 1324 (m), 1295 (w), 1236 (m), 1201 (w), 1185 (m), 1158 (w), 1137 (m), 1090 (w), 1083 (m), 1024 (w), 894 (w), 849 (w), 770 (m), 762 (m), 750 (s), 738 (s), 727 (s), 697 (s). Nuclear magnetic resonance signals (given in δ units; spectra



obtained in deuterated chloroform): 6.09 (HC—Ph_2, area = 1 H), 6.20 (HC—Ph, area = 1 H), 7.20 (aromatic H, area = 15 H), 7.48 (phenylphthalimidine, aromatic H, area about 4 H), 9.45 (N—H, doublet, area 1 H). Anal. Found: C, 80.8; H, 5.29; N, 6.58. Calc. for $C_{28}H_{22}N_2O_2$: C, 80.35; H, 5.30; N, 6.70.

Exchange Reaction of 3-Phenyl-2-(N-benzhydrylcarboxamido)phthalimidine with D_2O

3-Phenyl-2-(N-benzhydrylcarboxamido)phthalimidine was refluxed for 17 hours in 10 ml of D_2O containing 0.05 g of K_2CO_3. The product was obtained in the usual way. The infrared spectrum showed a strong N—D band at 2430 cm^{-1} and a lowering of the carbonyl band to 1695 cm^{-1}.

Synthesis of Authentic 3-Phenyl-2-(N-benzhydrylcarboxamido)phthalimidine

Diphenylacetic acid was first converted into diphenylacetyl chloride according to the procedure of Stollé and Wolf (7). Diphenylacetyl chloride (5.0 g), dissolved in 35 ml of acetone, was added dropwise through a separatory funnel into a well-stirred solution of sodium azide (2.9 g) in 10 ml of water at such a rate that the temperature did not exceed 15°. Stirring was continued for a further 75 minutes; then 20 ml of cold aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

sodium bicarbonate (10%) was added. The reaction mixture was poured into 50 ml of ice-cold water and extracted with three 40-ml portions of cold ethyl ether. The combined extract was washed with cold aqueous sodium bicarbonate (10%) and then with cold water, dried over anhydrous magnesium sulphate, filtered into 100 ml of dry benzene, and warmed to 65° for 90 minutes. Removal of the benzene *in vacuo* yielded 3.32 g (73% of theoretical) of the crude isocyanate, which was subsequently distilled at 112° and 0.08 mm Hg, n_D^{26} 1.5765. The infrared spectrum showed the characteristic strong absorption at 2270 cm^{-1} and a medium absorption at 2130 cm^{-1}. The benzhydrylisocyanate (0.48 g) was then condensed with 3-phenylphthalimidine (0.48 g) following the procedure previously described (2) to yield 0.89 g (93% of theoretical) of 3-phenyl-2-(N-benzhydrylcarboxamido)phthalimidine; m.p. 198–199°; Anal. Found: C, 80.37: H, 5.41. Calc. for $C_{28}H_{22}N_2O_2$: C, 80.35; H, 5.30.

N,N′-Dibenzhydrylurea (VI)

Compound VI was rechromatographed on alumina using benzene–chloroform (4:1). The first fraction from this column was decolorized with norite and recrystallized from ethyl acetate; m.p. 289–290°. Infrared spectrum of purified compound VI in KBr: 3290 (m), 3050 (w), 3020 (w), 2890 (w), 1623 (s), 1568 (s), 1490 (m), 1451 (m). As this spectrum suggested that compound VI was a urea, an authentic sample was prepared by allowing benzhydrylisocyanate to react with the moisture in the air. The product recrystallized from acetone had a melting point of 291–291.5°; mixed melting point of compound VI and authentic N,N′-dibenzhydrylurea, 290–291°. The literature melting point for this compound is 269–270° (4). Anal. Found: C, 82.81; H, 6.47; N, 6.95. Calc. for $C_{27}H_{24}N_2O$: C, 82.61; H, 6.16; N, 7.14.

N-Benzhydrylurea (VII)

Compound VII was recrystallized from benzene and then from hot water; m.p. 148–149°. The mixed melting point of an authentic sample of N-benzhydrylurea, prepared from benzhydrylisocyanate and ammonia, was 148–149° (literature m.p. is 143° (8)). Anal. (compound VII): Found: C, 73.89; H, 6.45; N, 12.33. Calc. for $C_{14}H_{14}N_2O$: C, 74.28; H, 6.23; N, 12.38.

Carbonylation of Benzophenone Semicarbazone at 200–220°

A 2.2-g aliquot of the product obtained from the carbonylation of benzophenone semicarbazone at 200–220° for 2.5 hours was chromatographed on alumina and yielded the following: 0.071 g of diphenylmethane (4%), 0.28 g (8%) of benzophenone azine (VIII), 0.85 g of benzophenone semicarbazone (35%), 0.45 g (11%) of a substance (IX) having a melting point of 179–181°, and 0.09 g of N-benzhydrylurea (4%).

Anal. (Compound IX): Found: C, 79.60; H, 5.67; N, 10.58; O, 4.11; mol. wt., 369 (Rast). Calc. for $C_{27}H_{23}N_3O$: C, 79.97; H, 5.72; N, 10.36; O, 3.95; mol. wt., 405. Nuclear magnetic resonance signals (deutereochloroform) of compound IX: 6.25 (HC—Ph_2, doublet, area 1 H), 6.95 (NH, area = 1 H), 7.32 (aromatic H, area = 20 H), 7.72 (NH, area = 1 H). Infrared spectrum (KBr): 3410 (m), 3150 (w), 3060 (w), 1668 (s), 1580 (m), 1495 (s), 1445 (m), 1365 (w), 1325 (w), 1230 (w), 1180 (m), 1105 (s), 1065 (m), 1025 (m), 945 (w), 910 (w), 862 (w), 835 (w), 782 (m), 753 ()s, 735 (m), 695 (s). The infrared spectrum of benzophenone semicarbazone showed peaks at 3460, 3190, and 1700 cm^{-1}.

Hydrolysis of compound IX with dilute sulphuric acid yielded benzophenone (isolated as benzophenone 2,4-dinitrophenylhydrazone).

Synthesis of Benzophenone 4-Benzhydrylsemicarbazone

A mixture of 0.38 g of benzophenone semicarbazone and 0.47 g of benzhydrylamine was heated at 120° for 4 hours. The reaction was accompanied by the evolution of ammonia. The residue was recrystalized from 25 ml of ethanol; yield, 0.47 g (74%), m.p. 179.5–180.5°; mixed melting point with compound IX was 179–180°. The infrared spectra of both compounds were the same.

Carbonylation of Benzophenone Semicarbazone at 175–180°

Similarly, 15.3 g of benzophenone semicarbazone was dissolved in chlorobenzene and treated with carbon monoxide at 175–180° for 2.5 hours. Chromatography of 3.3 g of the product on alumina yielded 0.11 g of diphenylmethane, 0.05 g of 1,1,2,2-tetraphenylethane, 1.0 g of benzophenone azine (35%), 0.75 g of substance IX (24%), and 1.4 g of unreacted starting material.

Carbonylation of Benzophenone Azine

Benzophenone azine was carbonylated at 235–245° for 2.5 hours under conditions similar to those used in the first experiment. Chromatography of the product yielded 63% of 3-phenylphthalimidine and unreacted starting material.

Carbonylation of Benzophenone 4-Benzhydrylsemicarbazone

The benzene solution obtained from the carbonylation of 0.47 g of benzophenone 4-benzhydrylsemicarbazone at 235–245° for 2.5 hours was boiled for 30 minutes to destroy the catalyst, filtered, and evaporated to dryness under vacuum. Chromatography of this residue on alumina as described previously yielded 0.044 g of diphenylmethane (11%), about 0.015 g of benzophenone (about 7%), 0.030 g of 3-phenyl-2-(N-benzhydrylcarboxamido)phthalimidine (6%), 0.04 g of N,N′-dibenzhydrylurea (9%), and 0.170 g of 3-phenylphthalimidine (70%). The yields are based on mole quantities possible from each moiety of the starting material.

POLAROGRAPHY OF VANADIUM (II) COMPLEXES

WENDELL J. BIERMANN AND WEN-KUEI WONG
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received March 6, 1963

ABSTRACT

Polarograms taken in solutions of vanadium (II) perchlorate, 0.10 *N* with respect to perchloric acid and at an ionic strength of 0.20, indicate that vanadium (II) exists predominately as a dimer in the concentration region of 5 millimolar. Oxidation of one of these ions appears to make the second relatively inert towards oxidation until labilized by further oxidation of the first to vanadyl ion.

No indication of complex formation of vanadium (II) was found with sulphate, chloride, iodide, or bromide ions. The existence of fluoro and thiocyanato complexes was noted, the vanadium (II) complexes having lower formation constants than the corresponding vanadium (III) complexes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The coordination chemistry of the lower oxidation states of vanadium should contain interesting examples of the effects of ligand field stabilization energies. As the ligand field strength increases, it would seem likely that there would be an increased stability of the complexes of divalent vanadium, as compared to corresponding complexes of trivalent vanadium. Experimental difficulties in working with these strongly reducing solutions seem to have discouraged investigation of these systems to the point that little is known about the coordination compounds of divalent vanadium (1, 2).

The absorption spectra of complexed vanadium (II) were too similar to that of the aquated species for this to be of use in investigating formation constants. Similarly the use of a metal – metal salt electrode to obtain free ligand concentrations was not possible because of reduction of the metal salt by vanadium (II) in a variety of electrodes tried.

The dropping mercury electrode has been used in vanadium (II) solutions and found, by Lingane and Meites (3, 4, 5), to be well behaved. The present work may be viewed as a continuation of these earlier investigations. As only the oxidation process can be studied in this case, it was not possible to obtain formation constants, but only to establish ratios between the formation constants of vanadium (II) and vanadium (III) for the same number of ligands.

EXPERIMENTAL

Solutions were prepared from a crystalline vanadium (II) sulphate heptahydrate. This was prepared according to the method of Jones and Colvin (6), reducing reagent grade vanadium pentoxide, suspended in concentrated sulphuric acid, by sulphur dioxide to vanadyl sulphate. This, in turn, was reduced electrolytically at a mercury cathode, using a platinum anode, to the vanadium (III) and vanadium (II) states, successively. Crystallization of the vanadium (II) sulphate was accomplished by placing the reduced solution under a layer of 95% ethyl alcohol, which, by slow diffusion, brought about the separation of well-crystallized vanadium (II) sulphate heptahydrate.

Five different batches of the divalent vanadium salt were prepared and analyzed. Sulphate was determined as barium sulphate and vanadium was precipitated with ammonium benzoate and weighed as vanadium pentoxide, following the procedure of Shemyakin (7, 8). Water was determined by difference. The following average values were obtained, the theoretical values for $VSO_4.7H_2O$ being given in parenthesis for comparison: vanadium 18.64±0.02% (18.65%), sulphate 35.14±0.03% (35.17%), water 46.23%.

The solid vanadium (II) sulphate and solutions of divalent vanadium were stored in an atmosphere of flowing oxygen-free hydrogen, and transfers of these were made in an inert atmosphere chamber filled with purified nitrogen. Standardization of vanadium (II) solutions was done by permanganate titration.

Various solid reagents employed were reagent grade chemicals, further purified by recrystallizing twice from conductivity water.

All measurements reported here were made at a constant ionic strength of 0.20 with a perchloric acid concentration of 0.10 formal. The ionic strength was adjusted to the 0.20 figure by addition of the calculated amount of 1.00 formal sodium perchlorate solution. As the possibility of forming a sulphate complex had not been eliminated prior to the investigation of the oxidation of the aquated vanadium (II) ion, these investigations were carried out in solutions containing perchlorate as the only anion. In these cases vanadium (II) sulphate was treated with an equivalent amount of barium perchlorate solution, to give a vanadium (II) perchlorate solution.

Figure 1 shows the titration-type polarographic cell used in this work. Four hundred milliliters of solution

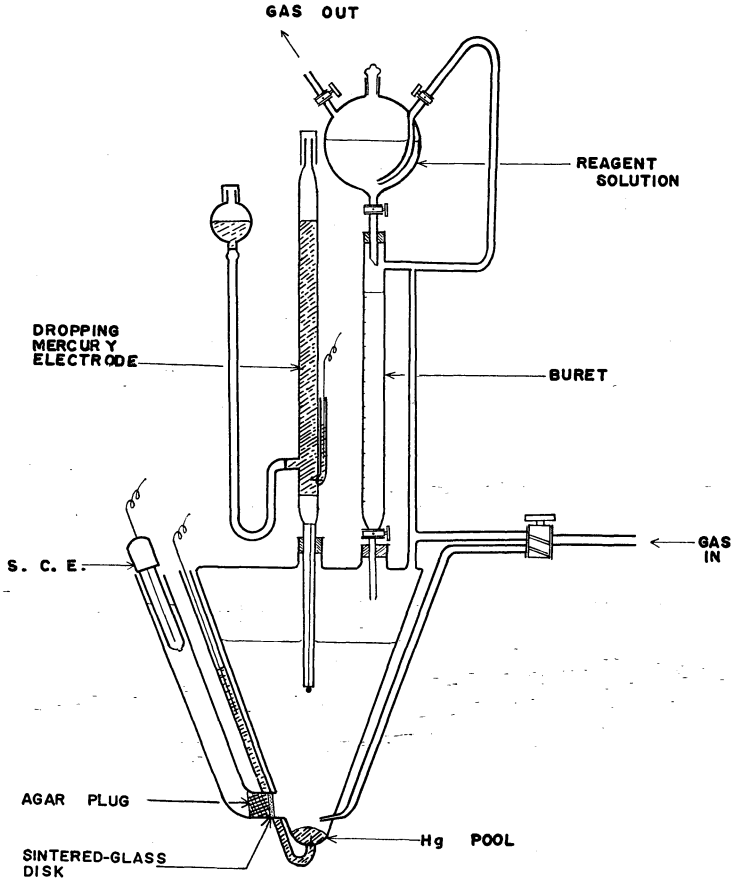

FIG. 1. Titration-type polarographic cell used in this work.

was used in this cell and the gas passed through was purified hydrogen. The applied voltage was taken from a Sargent–Heyrovsky model XII polarograph and the polarograms recorded on a Moseley X-Y recorder, using the potential drop across a precision 10,000 ohm resistor as a measure of current. A variable capacitor in parallel with the resistor was used to damp the current oscillations. The cell was thermostatted at 25.0±0.1° C.

DATA AND RESULTS

The Polarography of Vanadium (II) in 0.10 N Perchloric Acid

In Fig. 2 are shown typical polarograms obtained over a range of concentrations of vanadium (II) in 0.20 ionic strength perchlorate solution, including 0.10 *N* perchloric acid. Table I contains a series of observed half-wave potentials and diffusion currents over

a concentration range of divalent vanadium 0.80 to 7.5 mM. Also included are the calculated diffusion current constants and the slopes of $E_{d.e.}$ vs. log $(i)/(i_d-i)$ for each of these waves.

At concentrations below about 2.5 mM, the polarograms show several ill-defined steps with diffusion current constants somewhat less than the constant value reached at higher concentrations. Plots of the dropping mercury electrode potential, $E_{d.e.}$, against log $(i)/(i_d-i)$ do not give slopes capable of simple interpretation. Above 2.5 mM the test slope becomes reasonably constant and in acceptable agreement with the theoretical slope of 118.4 mv which would be predicted for a reversible, average half-electron transfer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The explanation offered for these observations is that above 2.5 mM vanadium (II), in the solvent environment employed, the vanadium species present is a dimeric form, probably a hydrated $(V_2O)^{2+}$, which is initially oxidized by a one-electron transfer to $(V_2O)^{3+}$. Below this concentration the polynucleation process is presumably incomplete and the two waves which begin to appear are probably due to oxidation of hydrated V^{2+} and VOH^+ ions. Meites and Lingane (4), who did most of their work in 1.0 N acid, commented on the "irreversibility" at lower acid concentrations and also proposed that hydrolysis was taking place.

Above about 7 mM the behavior of the system suggests that important amounts of more complex polynuclear species are beginning to be formed.

Because of the difference in ionic strength and acidity, a comparison of the half-wave potentials found in this work with those of Lingane is not possible. Jones and Colvin (6), however, have shown that in 0.10 N sulphuric acid the half potential of the V (II) → V (III) oxidation could be expressed as $E_{1/2} = 0.2025+0.0820(C_3+C_2)$ v versus a normal hydrogen electrode, C_3 and C_2 being the molar concentrations of V (III) and V (II), respectively. Taking C_3+C_2 as 0.005 moles/liter and adding −0.246 v, a half-wave potential of −0.449 v versus the saturated calomel electrode is predicted, which is the value obtained in this work in the concentration region [V (II)] = 5 mM.

Further support of an initial oxidation process involving the loss of one electron from an entity containing two V (II) ions was obtained by titrating a solution of vanadium (II) sulphate in 0.10 N perchloric acid with 0.100 N potassium permanganate and taking polarograms at intervals during the titration. These data are tabulated in Table II, which

TABLE II

Half-wave potentials and diffusion currents of vanadium in the potassium permanganate titration

6.49	12.81	—	—	—	1.178	24.70	19.02

gives the total molarity of vanadium in terms of the concentration of V (II) placed in the titration cell and the amount of permanganate added in terms of the normality it would show if diluted to the volume of solution in the cell at that point in the titration. An anodic and cathodic diffusion current are shown for each step of the titration, computed from the wave which is characterized by a half-wave potential of about 0.5 v, these presumably being proportional to the concentrations of V (II) and V (III).

When the anodic wave has been reduced to half its original value (i.e. half the V (II) has been oxidized) a second cathodic wave with a half-wave potential of 1.2 v appears, as shown in the sixth and seventh columns of Table II. This is the same potential as reported by Jones and Colvin (6) for the process

$$VO^{2+} + 2H^+ + e = V^{3+} + H_2O,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

which was found to be reversible. As shown in the right-hand columns of Table II, the diffusion current for this latter wave is about twice that of the first anodic wave for a given vanadium concentration, suggesting that further oxidation of the $[V_2O]^{3+}$ formed in the first step involves the formation of VO^{2+}, with simultaneous labilization and oxidation of the remaining V (II) ion, giving a net transfer of one electron per vanadium ion, as observed.

Complex Formation

As the preparation of vanadium (II) perchlorate would be unnecessary if it could be demonstrated that the sulphato complex was very weak, this possibility was examined. The half-wave potentials of 5 mM VSO_4 solutions, 0.10 formal in $HClO_4$ and with various sulphate concentrations (ionic strength kept constant at 0.20 with sodium perchlorate), were measured. These were constant at -0.449 v, indicating that no significant formation of sulphato complex takes place.

Fluoride Complex

Table III shows the variation of half-wave potential as a function of excess fluoride

TABLE III

Half-wave potential of vanadium (II) fluoride complex ion as a function of the fluoride concentration (Concentration of vanadium (II) sulphate was 0.005 to 0.0045 M)

NaF in excess (mM)	Log C_{F^-}	$-E_{1/2}$ vs. S.C.E. (v)	NaF in excess (mM)	Log C_{F^-}	$-E_{1/2}$ vs. S.C.E. (v)
3.3	−2.48	0.476	31.3	−1.50	0.518
6.6	−2.18	0.489	45.5	−1.44	0.529
9.8	−2.01	0.492	59.0	−1.23	0.530
13.0	−1.89	0.497	71.8	−1.14	0.529
16.1	−1.79	0.501	89.6	−1.05	0.532
23.7	−1.63	0.514	100.4	−0.99	0.528

ion, approximated on the assumption that a monofluoro complex is formed. The slope of a plot of the half-wave potential as a function of log C_F, where C_F is the molar concentration of free fluoride ions, is a measure of the difference of the coordination number in the lower oxidation state ("p") and in the higher oxidation state ("q") through the relationship (9, p. 218)

$$(E_{1/2})_C - (E_{1/2})_S = E_C^0 - E_S^0 - \frac{(p-q)}{a} 0.0591 \log C_X,$$

where the subscripts C and S refer to the complexed and aquated forms, respectively, C_X is the concentration of free ligand X, and a is the number of electrons transferred per vanadium ion. The slope becomes 0.00 when the fluoride ion concentration exceeds 0.045 M, indicating that $p = q$ above this concentration.

The formation constants of the oxidized and reduced forms:

$$K_{ox} = \frac{[(V_2OF_q)^{3-q}]}{[(V_2O)^{3+}][F^-]^q}$$

and

$$K_{red} = \frac{[(V_2OF_p)^{2-p}]}{[(V_2O)^{2+}][F^-]^p},$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

can be best compared in the concentration region where $p = q$ by means of the relationship (9, p. 222)

$$(E_{1/2})_C - (E_{1/2})_S = \frac{0.0591}{a} \log \frac{K_{red}}{K_{ox}} - \frac{(p-q)}{a} 0.0591 \log C_X.$$

It is found that $K_{ox}/K_{red} = 23.4$, indicating that the higher oxidation state leads to a substantially more stable fluoro complex.

Thiocyanate Complex

Table IV shows the variation of half-wave potential as a function of excess thiocyanate

TABLE IV

Half-wave potential of vanadium (II) thiocyanate complex ion as a function of the thiocyanate concentration (Concentration of vanadium (II) sulphate was 0.005 to 0.0045 *M*)

NH_4CNS in excess (m*M*)	Log C_{CNS^-}	$-E_{1/2}$ vs. S.C.E. (v)	NH_4CNS in excess (m*M*)	Log C_{CNS^-}	$-E_{1/2}$ vs. S.C.E. (v)
3.15	−2.50	0.467	43.54	−1.36	0.514
7.81	−2.11	0.478	56.43	−1.25	0.516
15.39	−1.81	0.489	68.64	−1.16	0.516
22.74	−1.64	0.494	91.11	−1.04	0.517
29.88	−1.53	0.498	120.93	−0.92	0.515
36.80	−1.43	0.503			

ion. Again, above a free ligand concentration of 0.045 *M* the coordination numbers in the two oxidation states becomes equal, and the ratio of formation constants $K_{ox}/K_{red} = 13.70$. This lowering of the ratio of formation constants is to be anticipated because of the higher field associated with the thiocyanate ion, giving additional ligand field stabilization of the lower oxidation state.

Other Halide Ions

The half-wave potential was found to be independent of the concentrations of chloride, bromide, or iodide ions, indicating that only very weak complexing could take place.

NUCLEAR REACTIONS INDUCED IN TANTALUM BY PROTONS OF ENERGY UP TO 84 MEV[1]

C. L. RAO[2] AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.
Received April 19, 1963

ABSTRACT

Nuclear reactions induced in tantalum by protons of energy up to 84 Mev have been studied and excitation functions obtained for products formed by (*p*,*xn*), (*p*,*pxn*), (*p*,2*pxn*), and (*p*,3*pxn*) reactions. Radiation characteristics of the products were redetermined. Previously unreported γ-rays with energies 90 to 1050 kev have been found for W^{176}, and 113 kev for W^{177}. A new half-life of 2.7 ± 0.1 hr for W^{176} is reported. The cross sections for the (*p*,*xn*) reactions were compared with the values predicted by Jackson's schematic model and found to be in reasonable agreement. More complex reactions are discussed in the light of current nuclear theories.

INTRODUCTION

Nuclear reactions induced by protons and other particles of kinetic energies up to a few tens of Mev in medium heavy-weight elements have been chiefly interpreted in terms of the compound nucleus (1). However, significant deviations from the predictions of this model, as observed in the large inelastic scattering cross sections and the anisotropy of the emitted particles, prompted the introduction of a direct interaction mechanism (2, 3) as an alternative to the compound nucleus mechanism. The investigation of the excitation functions of a neutron-excess nucleus with high atomic number offers a convenient method of differentiating reactions that proceed through compound nucleus formation from those reactions, like (*p*,*pn*), which take place via other non-compound-nucleus processes.

The present study pertains to the investigation of the nuclear reactions induced in tantalum by protons in the energy range 8–84 Mev. In this energy range, these reactions are not greatly complicated by fission or other exotic processes. Tantalum was chosen for this study for the following reasons:

(1) The element is available in a very pure form commercially as a foil in different thicknesses, and it is essentially monoisotopic.

(2) The detailed study of the spallation reactions in this mass region ($150 < A < 200$) and energy range (8–90 Mev) is not extensive. A literature survey is given by Miller and Hudis (4) covering the work carried out up to 1959. At higher energies nuclear reactions on tantalum have been studied, among which the studies with 340 Mev (5) and 5.7 Bev (6) protons are the most comprehensive. An extension of these data to lower energies would be informative.

(3) It was also felt desirable to investigate the gamma spectra of neutron-deficient nuclides of W, Ta, Hf, and Lu, since these are poorly identified.

Even though a large number of stable nuclides would be formed in several reactions on tantalum, which cannot be studied radiochemically, a limited comparison with the total reaction cross section, as derived from the continuum theory or from the optical model, can be obtained at a few energies.

EXPERIMENTAL PROCEDURES

(a) Target Assembly

Tantalum metal, used as the target foil, was available in two thicknesses (84.3 mg/cm² and 21 mg/cm²). The thinner foil was used in the study of (*p*,*xn*) and (*p*,*pxn*) reactions and the thicker foil for the study of (*p*,2*pxn*) and (*p*,3*pxn*) reactions.* Spectrographic analysis of the tantalum foil indicated that no detectable impurities would cause any interference in the present study. The monitor foil was a 'spec pure' copper foil 0.002 in. thick obtained from Johnson, Matthey and Co. A study to determine the recoil losses in the monitor foil was made by irradiating a copper foil and a pure aluminum foil as a catcher foil at two energies, 50 Mev and 85 Mev. The recoil losses of Cu^{64} were found to be less than 0.25% of the total Cu^{64} activity at both the above energies and were therefore neglected. The recoil losses from tantalum were not measured and it was assumed that they would be negligible. Hence no guard foils were used for the monitor or target foil during irradiations.

The tantalum foils were cleaned with concentrated nitric acid and rinsed with distilled water. The copper foils were cleaned with acetone and distilled water. The two foils, each of about 2 cm² in area, were carefully aligned and fixed to the target holder in such a way that the beam of protons first struck the monitor foil. It was necessary to ensure that equal areas of the monitor and the target foils intercepted the beam. Before bombardments, the sides of the foils were trimmed with a pair of scissors and examined under a magnifying glass to make sure that the foils were uniformly cut and the leading edge was perfectly aligned. After bombardments, the foils were again sheared at about 4 mm from the leading edge, such that, after being weighed, equal areas of the target and monitor foils were processed for activity determination.

(b) Irradiations

The target holder was fixed to the probe of the McGill Synchrocyclotron and the probe set at the desired radii, thus letting the target intercept the internal circulating proton beam at various energies. The calibration curve for radial distance vs. proton energy by Kirkaldy (7) was used. Energy degradation of the proton beam at all energies at which irradiations were carried out was estimated from the range-energy values of Sternheimer (8) and was found to be negligible within the energy spread of the proton beam (~2 Mev). The irradiation period was about one hour in most of the experiments.

(c) Chemical Procedures

The elements that are expected to be formed in the spallation of Ta in the present study are W, Ta, Hf, Lu, and possibly Yb. Depending upon the energy of the bombardment, either all or some of these elements would be formed. The formation of any product formed by secondary reactions was neglected on account of the thin targets employed in this work. In copper, zinc, copper, nickel, cobalt, and iron would be formed as spallation products. It was found convenient to separate in one series of experiments throughout the energy range only Ta and W, and in another series Hf and Lu, from the spallation products of Ta. The formation of Yb was neglected. The existing chemical procedures for the separation of the spallation products of Ta (5) and Cu (9) were slightly modified to suit the present experimental conditions in order to achieve a high degree of decontamination.† Tantalum was dissolved in the minimum amount of concentrated nitric and hydrofluoric acids in the presence of W, Zr (for Hf), and La (for Lu) carriers in a platinum crucible by gently warming the mixture on a steam bath for a few minutes. Briefly, Ta was separated by extraction with diisopropylketone from the acid medium twice, and finally back-extracted from the ketone layer into 50% tartaric acid solution. Tungsten was precipitated as $CoWO_4$ followed by complexing with thiocyanate and recovery of the tungsten in ammoniacal solution. Similarly, zirconium, used as a carrier for Hf, was precipitated as barium zirconyl fluoride and later extracted with TTA in xylene and, finally, Zr(Hf) was recovered in 5 *M* hydrochloric acid. Lanthanum, used as carrier for Lu, was precipitated as fluoride and later as hydroxide, and finally recovered in 4 *M* hydrochloric acid. Copper was separated from its spallation products by suitable adaptation of anion exchange methods.

All the solutions containing the purified elements were made up to a certain volume, and an aliquot of each was pipetted into a standard screw-cap glass vial in order to measure the radiation characteristics and decay rates. Aliquots of the above solutions were analyzed spectrophotometrically for chemical yield determinations; Ta as a phenylfluorone complex (10), W as a thiocyanate complex (11), Zr (Hf) as a thoron complex (12), La (Lu) as an alizarin red S complex (11), and Cu as diethyldithiocarbamate complex (13).

(d) Beam Intensity Measurement

In order to measure the absolute cross sections, it was necessary to know the number of protons that had passed through the target foils. Copper was used as the monitor foil for the proton beam. For low-energy bombardments, the monitor reaction $Cu^{63}(p,n)Zn^{63}$ was utilized, and the cross-section values from the excitation function given by Ghoshal (14) for this reaction were used. At higher energies (above 15 Mev),

**The nomenclature used in indicating all these reactions is not intended to imply any particular reaction mechanism.*

†*A detailed account of the chemical procedures, measurement techniques, and resolution of decay curves may be found in the thesis of Lakshman Rao Chervu, McGill University, Montreal, Que., 1962.*

the reaction $Cu^{65}(p,pn)Cu^{64}$ was utilized, for which the cross-section values were obtained from Meadows (15). The cross sections for the monitors at the various energies are given in Table I.

TABLE I

30	—	440	74	—	217
36	—	360	84	—	183

(e) Activity Measurements

All the samples were measured by a calibrated 3 in.×3 in. sodium iodide crystal (16) coupled to a photomultiplier tube in conjunction with a 100-channel pulse-height analyzer. This γ-ray spectrometer was used for the measurement of the intensity of γ-rays and *K* X-rays in every sample. The energy calibration was made with a number of well-known γ-ray emitters.

(f) Treatment of Data

The areas of the prominent photopeaks were converted into photon-emission rates by applying the photopeak counting efficiency in the crystal and the resolution losses as observed on the pulse analyzer. A plot of the photon-emission rate as a function of time gave the radioactive decay curve. The *K* X-ray photopeak decay curves of the samples were graphically analyzed into several components, depending upon the energy at which the irradiation was made, in order to separate the contributions from the different isotopes of each element. In those cases where some of the decaying species had radioactive daughter species growing in the fraction after radiochemical purification, graphical analysis of the multicomponent decay curve was too difficult. If an easily observed γ-ray of known energy and abundance was emitted by the parent or its daughter, the photon-emission rate of the species was obtained without resolving the *K* X-ray decay curve for that particular nuclide. In those cases where it was not possible to follow any specific γ-ray, the *K* X-ray decay curve was analyzed for the longer-lived daughter components only, from which the parent activities were estimated.

For the calculation of the disintegration rates at the end of bombardment for each nuclide observed, the corrections applied to the photon-emission rates were the following: decay during the period between the end of bombardment and the measurement time, chemical yield of the sample and dilution factor, γ-ray and *K* X-ray abundance (17, 18) per disintegration of each nuclide detected. In the case of positron emitters, the intensity of the annihilation γ-rays was measured and a factor of 2 included in the calculation of disintegration rates to allow for the emission of two quanta.

Finally, the cross sections for the formation of the nuclide were calculated by means of the following equation:

$$\sigma_p = \sigma_m \cdot \frac{D_0^p}{D_0^m} \cdot \frac{n_m}{n_T} \cdot \frac{(1-e^{-\lambda_m t})}{(1-e^{-\lambda_p t})}$$

where σ_p and σ_m = formation cross sections of product and monitor respectively;
D_0^p and D_0^m = disintegration rates of product and monitor respectively at end of bombardment;
n_m and n_T = number of atoms of monitor and target respectively;
λ_m and λ_p = disintegration constants of monitor and product respectively;
t = time of irradiation.

In the case of those nuclides which are not shielded, if the parent half-lives and formation cross sections are known, corrections for the formation from the precursors was applied to obtain independent cross sections; when the precursor half-lives are too short that they decayed away into the daughter nuclide before any chemical separation was effected, cumulative cross sections only were given.

RESULTS

*(a) Radiation Characteristics**

(i) W^{176}

This nuclide has previously been reported only by Wilkinson (19), who assigned a half-life of 80 min to it and a γ-ray of about 1.3 Mev in energy. In the present work two

**The error in gamma-ray energy values quoted is ±5% unless otherwise indicated.*

For personal use only.

γ-rays of energies 90 kev and 1050 kev were found attributable to W^{176}. They decayed with a half-life of 2.7±0.1 hr over four half-lives. The mass assignment was made both on the basis of excitation functions for the $Ta^{181}(p,6n)$ reaction and the observed growth of the Ta^{176} daughter (half-life 8 hr) which was consistent with having a 2.7-hr parent.

(ii) W^{177}

This nuclide was produced by the reaction $Ta^{181}(p,5n)$. It had previously been reported only by Wilkinson (19), who found a half-life of 2.17±.05 hr for it and assigned γ-rays of energies 450 and 1200 kev to it. In the present work we found γ-rays of 113, 450, and 1050 kev decaying with a half-life of 2.2±0.1 hr over five half-lives.

(iii) W^{178}, W^{179}, W^{181}

These nuclides were prepared by the $(p,4n)$, $(p,3n)$, and (p,n) reactions respectively on Ta^{181}. The half-lives found, viz. 22±0.5 days, 40±2 min, 140±2 days, agreed well with the literature values (17). The values were derived by resolution of the X-ray curves. Ta^{178} (9.3-min half-life), in secular equilibrium with W^{178}, has a prominent γ-ray at 1.35 Mev energy and 511 kev annihilation radiation due to a 2% positron branching. Both decayed with the 22-day parent half-life.

(iv) Ta^{173}

This nuclide was produced by the $(p,p8n)$ reaction on Ta^{181} and by decay of the short-lived W^{173} formed by the $(p,9n)$ reaction on Ta^{181}. The half-life for Ta^{173} was found to be 3.7 hr, in agreement with that reported by Faler and Rasmussen (20). Ta^{173} was observed by the growth of an intense photopeak due to Hf^{173} (24 hr) in the separated tantalum fraction. Harmatz *et al.* (21) have proposed a half-life of 2.5 hr for Ta^{173}. In Fig. 1 are

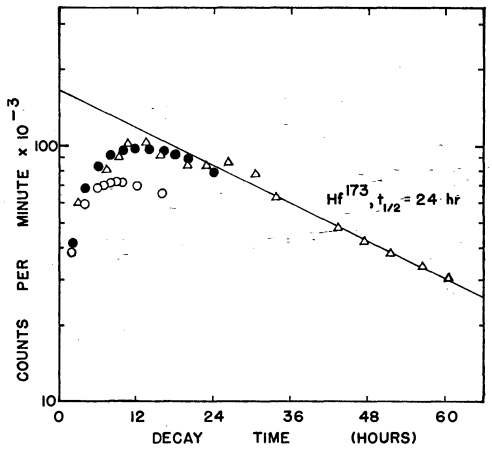

FIG. 1. Growth of 24-hr Hf^{173} from Ta^{173}: △ experimental points; ● theoretical growth curve assuming a half-life of 3.7 hr for Ta^{173}; ○ theoretical growth curve assuming a half-life of 2.5 hr for Ta^{173}.

shown the experimental data and the theoretical growth curves for both a 2.5-hr and a 3.7-hr parent feeding a 24-hr daughter. The data are consistent with the latter value.

(v) Ta^{174}

This nuclide was formed by the reaction $Ta^{181}(p,p7n)$ and by decay of short-lived W^{184} produced by the reaction $Ta^{181}(p,8n)$. The 511-kev annihilation radiation peak decayed with a half-life of 1.3±0.1 hr, in agreement with that found by Faler and Rasmussen (20).

(vi) Ta^{175}

The formation of this nuclide was recognized by the growth of the characteristic 340 kev γ-ray due to Hf^{175}. Gamma rays of energies 125, 205, 265, and 350 kev were found attributable to Ta^{175}. Due to the complexity of the spectrum, the abundance of Ta^{175} was calculated from the growth of Hf^{175}.

(vii) Ta^{176}

This is produced by decay of W^{176} and from the reaction $Ta^{181}(p,p5n)$. Gamma rays at 202, 1160, and 1700 kev were observed to decay with a half-life of 8 hr, in agreement with previous work. In all, about 60 transitions of energies up to 2 Mev (21) have been reported for this nuclide. The resolution of the decay curve yielded an 8-hr component, a mixture of Ta^{176} and Ta^{180m}, and thus no yield determinations of Ta^{176} were made.

(viii) Ta^{177}

This is produced by the decay of W^{177} and from the reaction $Ta^{181}(p,p4n)$. Resolution of the X-ray curves gave a half-life of 56 ± 1 hr for this nuclide, in good agreement with the work of Mann *et al.* (22).

(ix) Ta^{178}

This nuclide was formed by the reaction $Ta^{181}(p,p3n)$. Gamma rays of energies 213, 330, and 427 kev were found decaying with a half-life of 2.2 ± 0.1 hr. These γ-rays originate (17) mainly from the 4.8-sec Hf^{178m} state in equilibrium with Ta^{178}.

(x) Ta^{179}

This was formed from the reaction $Ta^{181}(p,p2n)$ and by decay of W^{179}. No prominent γ-rays were observed and measurements were made by resolution of the X-ray photopeak. A half-life of about 600 days (19) has been reported for Ta^{179}. Measurements made over a period of one half-life were consistent with this value.

(xi) Ta^{180m}

The formation cross section of this nuclide, produced by the reaction $Ta^{181}(p,pn)$, was measured by the X-ray photopeak. A half-life of 8.1 ± 0.1 hr was obtained, in good agreement with previous data (17). At higher energies, production of Ta^{176} made measurements in this fashion impossible.

(xii) Hf^{171}

The γ-ray spectrum of separated Hf fractions at higher energies was very complex. Gamma rays at 680, 880, and 1100 kev were found attributable to Hf^{171} as these were not found at bombarding energies where Hf^{173} alone was produced. Although the spectrum was too complex for decay-curve analysis, the decay of these peaks was consistent with a 16-hr half-life (17). The growth of the 740 kev photopeak due to the Lu^{171m} daughter (21) was used to measure the formation cross section.

(xiii) Hf^{172}

This nuclide (half-life $\sim$ 5 yr) was identified and measured with the help of the high-energy photopeaks due to Lu^{172} (6.7 day) in secular equilibrium with the parent nuclide.

(xiv) Hf^{173}

Very intense photopeaks at 120 and 300 kev decayed with a half-life of 24 ± 0.5 hr. This nuclide was observed both as a direct spallation product and, at high energies, by decay of its precursors.

(xv) Hf^{175}

The very intense 340 kev photopeak attributable to this nuclide decayed with a half-life of 70 ± 2 days. Hf^{175} was formed directly at 42 Mev proton bombarding energies.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

This did not result from decay of Ta^{175} since the formation of the latter was not observed at proton energies less than 64 Mev. At these energies the production of Hf^{175} from its precursors was observed.

(xvi) Hf^{180m}

This nuclide was first observed at a proton bombarding energy of 42 Mev. Characteristic γ-rays at energies of 216, 340, 440, and 500 kev were found. The 216 kev peak decayed with a half-life of 5.5±0.1 hr, in excellent agreement with the result of Burson *et al.* (23).

(xvii) Lu^{171m}

This was identified by the characteristic photopeak (21) at 740 kev. The decay of this photopeak gave a half-life of 7.7±0.2 days, measured over a period of four half-lives, shorter than that of 8.2 days reported by Bonner *et al.* (24).

(xviii) Lu^{172}

Gamma rays at energies of 113, 180, 200, 300, 370, and 1090 kev were observed. The decay of the most intense peak was followed for seven half-lives and gave a value of 6.7±0.1 days, in very good agreement with the literature values (17).

(xix) Lu^{176m}

The decay of the 90 kev gamma peak reported (17) for this nuclide gave a half-life of 3.8 hr, in good agreement, with literature values (17).

(xx) Lu^{177}

This was detected as a very weak β^- activity observed in lutetium fraction decaying with a half-life of approximately 7 days. The gamma spectrum indicated weak peaks at 113 and 208 kev due to Lu^{177}.

(b) Experimental Cross Sections

The radiation characteristics used to determine the formation cross sections are given in Table II. The cross sections found experimentally are listed in Table III. The estimated accuracy quoted for each cross-section value is the standard deviation calculated by

TABLE II

taking into account the errors in obtaining the disintegration rates and saturation factors. No allowance was made for the uncertainty in the monitor cross-section values or for that in the radiation abundance values used.

DISCUSSION

The formation cross sections presented in Table III indicate the general behavior expected in the spallation of a medium-weight element, in the energy range 8–84 Mev, namely production of neutron-deficient nuclides up to of the order of a few mass numbers below that of the target nucleus.

(a) (p,xn) Cross Sections

The individual excitation functions for the (*p,xn*) reactions, forming W isotopes, all exhibit sharp peaks separated from each other by about 12 Mev, as shown in Figs. 2–6.

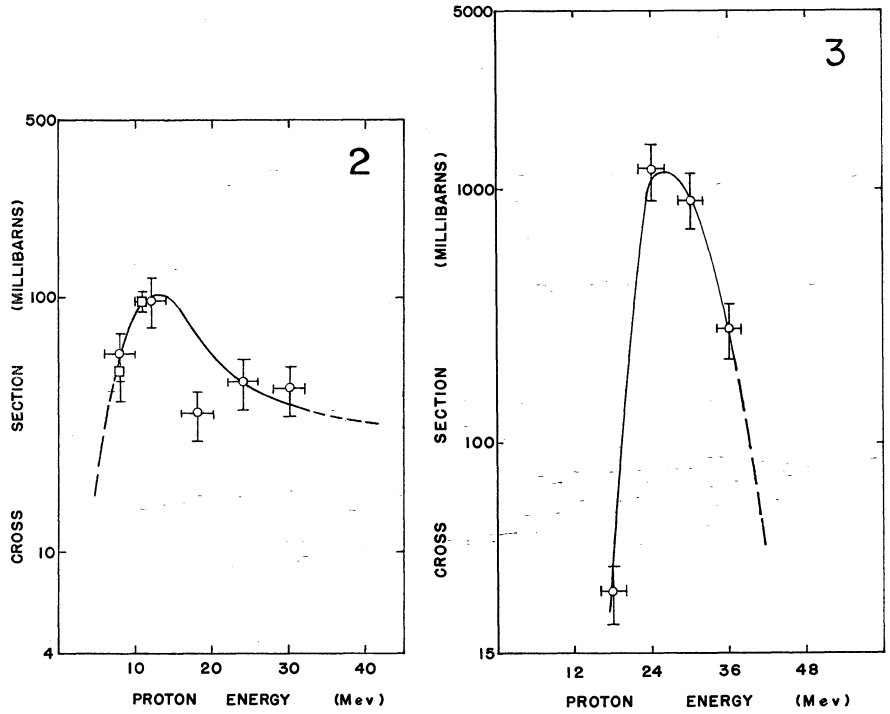

FIG. 2. Excitation function for the $Ta^{181}(p,n)W^{181}$ reaction: ○ present work; □ Hansen *et al.* (34).
FIG. 3. Excitation function for the $Ta^{181}(p,3n)W^{179}$ reaction.

These are typical of reactions proceeding at lower energies through the formation of a compound system with the subsequent decay governed by statistical considerations. The tailing off of each of these excitation functions at higher energies indicates that the nucleon–nucleon internal cascade mechanism (27) is becoming important.

In order to calculate the cross section for the (*p,xn*) reaction proceeding primarily through a compound nucleus mechanism in heavy non-fissile elements at these energies, an application of the statistical model was made by Jackson (28). He combined the Monte Carlo calculations of McManus *et al.* (29) for the prompt knock-on cascade process with a simplified evaporation model in order to calculate the excitation functions for the

(p,xn) reaction up to 100 Mev. In the energy range up to 50 Mev, the knock-on cascade process enters as a minor correction, since the incident protons that enter the nuclear core will probably lead to compound nucleus formation. Hence the Jackson model was applied in the present work assuming only the compound nucleus mechanism.

The probability that a nucleus with initial excitation energy E will evaporate exactly x neutrons is given by:

$$P(E,x) = I(\Delta_x,2x-3)-I(\Delta_{x+1},2x-1),$$

where $I(z,n)$ is Pearson's incomplete gamma function,

$$\Delta_x = (E - \textstyle\sum_i^x B_i)/T.$$

B_i is the binding energy of the ith neutron, and Δ_x is the energy (in units of T, the nuclear temperature) above the threshold for the emission of x neutrons. The nuclear temperature is given by the relationship

$$\Delta E = \bar{B}+2T.$$

ΔE in Mev is the energy separation between the successive peaks of the (p,xn) excitation functions (12 Mev) which corresponds closely to the average energy carried off by the successive neutrons. $\bar{B}$, the average neutron binding energy, was calculated as 8.1 Mev from the neutron binding energies given by Seeger (30). A nuclear temperature of 1.95 Mev was thus deduced. The $P(E,x)$ values for several values of x were obtained from Pearson's Incomplete Gamma Function Tables (31) and individual neutron binding energies from Seeger's Mass Tables.

If the mechanism is assumed to be entirely that of compound nucleus formation, then

$$\sigma(p,xn) = \sigma_c(E_0)P(E,x),$$

where $\sigma_c(E_0)$ is the cross section for compound nucleus formation at an incident proton energy of E_0. The values of $\sigma_c(E_0)$ were calculated from the continuum theory of Shapiro (32) for a nuclear radius of $R = 1.3\times10^{-13}\ A^{1/3}$cm. The experimental and calculated excitation functions are given in Fig. 7.

As is evident from the results, the agreement is good only at some energies for all the reactions. The theoretical curves fall slightly to the right of those experimentally determined. A smaller value for the nuclear temperature would shift the predicted curves to slightly lower energies, but that alone would not give any better agreement with the experimental values. A more detailed account of the properties of the nucleus, combined with the excitation distribution appropriate to each of the prompt processes and evaporation steps, would perhaps better predict these cross-section values.

A comparison with the (p,xn) excitation functions (33) for Bi and Pb with those of Ta shows that the Ta curves are shifted to lower energies, since the incident proton binding energy is 6.6 Mev for Ta^{181} as compared to 5 Mev for Bi^{209} and 3.3 Mev for Pb^{206}. At low energies, at 8 Mev and 12 Mev, the cross section for the (p,n) reaction reported here, 60 and 98 millibarns respectively, are comparable to the values given by Hansen *et al.* (34) for the same reaction, 52 and 90 millibarns at the corresponding energies. At the highest bombarding energy, 84 Mev, the cross-section values for $(p,4n)$, $(p,5n)$, and $(p,6n)$ reactions are 64, 98, and 73 millibarns as compared to the values for these reactions at 340 Mev by Nervik and Seaborg (5), which are 65, 30, and 65 millibarns. The cross section for the $(p,6n)$ reaction product W^{176} by Nervik and Seaborg will be nearly halved in view of the new half-life of 2.7 hr reported for this nuclide in the present work as compared to the earlier value of 1.3 hr.

(b) (p,pxn), (p,2pxn), and (p,3pxn) Cross Sections

The data for the (p,pxn) reactions are shown in Figs. 8–11. The excitation functions

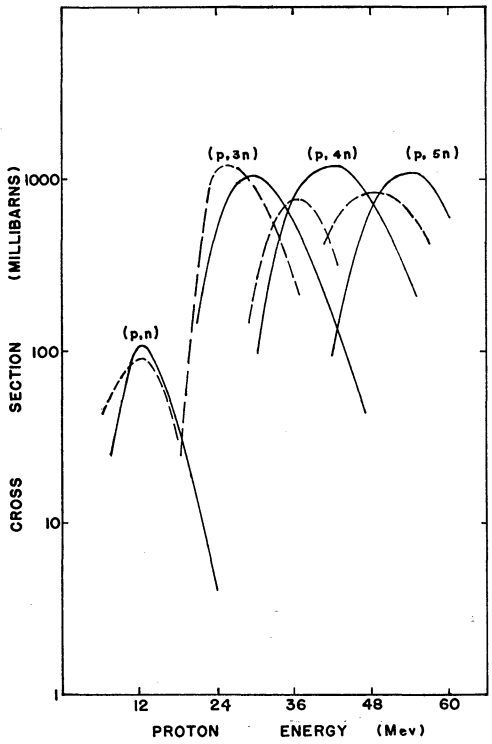

FIG. 7. Comparison of experimental excitation functions with those predicted by the Jackson model: - - - experimental; — Jackson model.

of these reactions, as well as the more complex ones, increase rapidly above the threshold. Some of these reach a maximum value and then decrease slowly with increasing energy, while others increase monotonically up to the highest bombarding energy (84 Mev). Reactions of this type are expected to have negligibly small cross sections compared with the (p,xn) cross section in medium-heavy target nuclei like Ta on the basis of statistical theory, since they are inhibited by the Coulomb barrier in both the entrance and exit channels. The experimental cross sections for these reactions are, however, quite large and the alternative mechanism proposed, that might lead to these reactions at low and medium energies, is the direct interaction (2, 3) process. The difference between the direct interaction mechanism at low energies and at high energies proposed by Serber (27) is that at low energies the knock-on process is assumed to occur with the nucleons in the surface of the target nucleus, while at higher energies direct interaction occurs in the interior of the nucleus with a sharp boundary. Internal direct processes at low energies account for only a very small fraction of the (p,$xpxn$) cross sections and hence are relatively unimportant (28, 35). Monte Carlo calculations of the cascade–evaporation phases of the high-energy interactions (35–38), based on the Serber model, assume a sharp cutoff nuclear boundary, and the cross sections predicted (26, 39) for the (p,$xpxn$) reactions at high energies are smaller than the experimental values. Further, these calculations do not take into account any interaction in the knock-on phase with the incoming particle of aggregates of nucleons and thus cascade emission of complex units as deuterons, tritons, or alphas is neglected. In the light of these remarks, the spallation yields of (p,$xpxn$) reactions on Ta are discussed below in the order of increasing complexity.

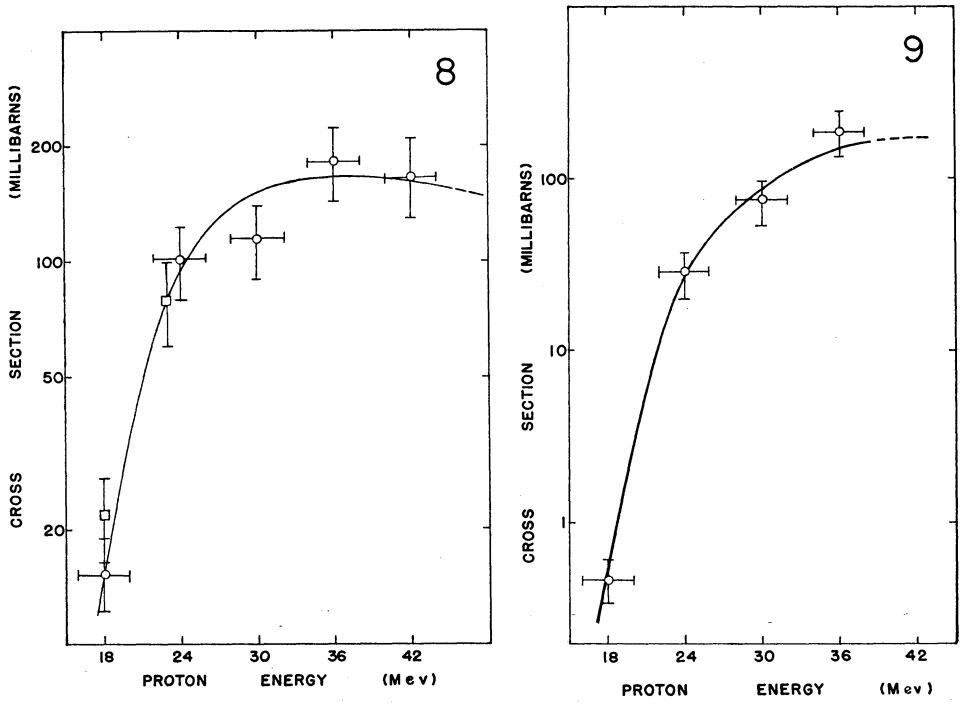

FIG. 8. Excitation function for the $Ta^{181}(p,pn)Ta^{180m}$ reaction: ○ present work; □ Cohen *et al.* (43).
FIG. 9. Excitation function for the $Ta^{181}(p,p2n)Ta^{179}$ reaction.

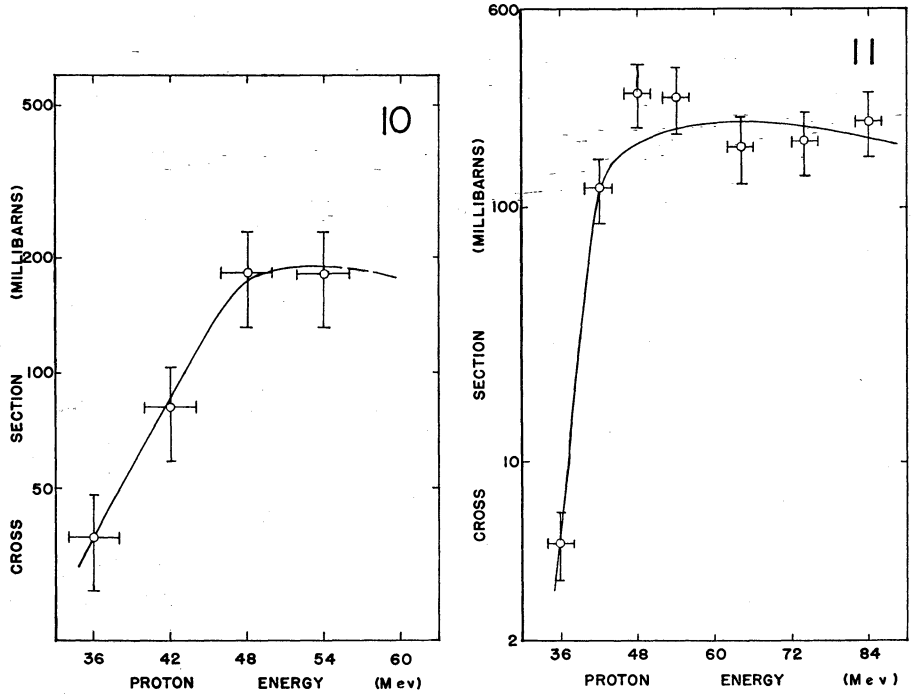

FIG. 10. Excitation function for the $Ta^{181}(p,p3n)Ta^{178}$ reaction.
FIG. 11. Excitation function for the $Ta^{181}(p,p4n)Ta^{177}$ reaction.

(i) (p,pn) and (p,2p) Cross Sections

These two reactions lead partially to isomeric states and partially to the stable ground states of Ta^{180} and Hf^{180} respectively. It is not known what percentage goes to the ground states and hence any comparison of cross sections for Ta^{180m} and Hf^{180m} indicates only the nature of the reaction paths favoring one reaction over the other. The possible mechanisms for these two reactions in this energy range are:

(*a*) direct interaction process involving collision of the incident proton with a neutron or a proton in which both collision partners escape from the nucleus;

(*b*) direct inelastic scattering of the incident proton followed by evaporation of a particle;

(*c*) for the (*p*,*pn*) reaction, the emission of deuterons by the well-known pickup process, i.e. the (*p*,*d*) reaction, which is another case of direct interaction important at low energies.

A comparison of the cross section for the (*p*,2*p*) reaction forming Hf^{180m} at 42 Mev, 0.03 millibarn, with the cross section for the (*p*,*pn*) reaction forming Ta^{180m} at the same energy, 170 millibarns, indicates how the several reaction paths favor the production of Ta^{180m} in contrast to that of Hf^{180m}. For the formation of Hf^{180m}, only mechanism (*a*) is significant. The fact that the cross sections for (*p*,2*p*) reactions below 54 Mev are extremely small is consistent with the Monte Carlo calculations (35, 36), indicating that, below about 100 Mev, absolute values of cross sections for multiple particle cascades are small. The yields for both Hf^{180m} and Ta^{180m} could not be studied up to the highest bombarding energy available. The probability for the (*p*,2*p*) reaction may increase due to an increase in the knock-on process, while the (*p*,*pn*) cross section may level off or gradually drop due to the decreasing importance of mechanism (*c*) among other factors (26, 40). The excitation function for Ta^{180m} compares well with those obtained for the same reaction on Ir^{193} reported by Grant (41) and on Au^{197} by Kavanagh and Bell (42) in the energy range where the investigations overlap. Cohen *et al.* (43) report a value of 80 millibarns at 23 Mev for the same reaction on Ta^{181}, in close agreement with the present work.

(ii) (p,p2n), (p,p3n), and (p,p4n) Cross Sections

These reactions occur by the same mechanism as discussed above. The excitation energy of the residual nucleus after the direct interaction event must be appropriate to evaporate the required number of neutrons. The pickup process, e.g. (*p*,*t*) reaction, may also contribute to these cross sections. After reaching a maximum cross-section value, the excitation functions level off or decrease slowly with increasing bombarding energy. The maximum cross-section values are about the same for all these reactions, including the previously discussed (*p*,*pn*) reaction. It may be mentioned that the Ta^{178} yield represents only a part of the Ta^{181}(*p*,*p*3*n*) cross section, so that the yields for all these reactions are quite large.

The cross-section value for the (*p*,*p*3*n*) reaction at 54 Mev, 180 millibarns, may be compared with the cross-section value of 152 millibarns reported by Nervik and Seaborg at 340 Mev (5). The cross section for Ta^{177}, formed by the (*p*,*p*4*n*) reaction at 84 Mev, is 220 millibarns and at 340 Mev, 27 millibarns, as reported by the same authors.

(iii) (p,2pxn) and (p,3pxn) Cross Sections

The direct interaction mechanism suggested for the (*p*,*pxn*) reactions involving inelastic scattering of the proton followed by particle evaporation cannot possibly account for the formation yields of the (*p*,2*pxn*) and (*p*,3*pxn*) reactions observed from 42 Mev onwards with appreciable cross sections. If the direct interaction occurs with only one particle, the residual excitation energy may be insufficient to evaporate even a number of neutrons. For example, at 42 Mev, Hf^{175} formed by (*p*,2*p*5*n*) reaction has a cross section of 6.0

For personal use only.

millibarns and Lu^{177} produced by the $(p,3p2n)$ reaction has a value of 0.05 millibarn. The threshold energies ($-Q$ values) calculated from Seeger's mass tables (30) for formation of these nuclides, formally written as $(p,2pxn)$ and $(p,3pxn)$ reaction products, are listed in Table IV.

TABLE IV
Threshold calculations

Product nuclide	Reaction mechanism	$-Q$ (Mev)
Hf^{175}	$(p,2p5n)$	42.7
Hf^{173}	$(p,2p7n)$	58.4
Hf^{172}	$(p,2p8n)$	64.5
Hf^{171}	$(p,2p9n)$	74.6
Lu^{177}	$(p,3p2n)$	26.7
Lu^{176}	$(p,3p3n)$	34.6
Lu^{172}	$(p,3p7n)$	63.5
Lu^{171}	$(p,3p8n)$	71.0

It has been known that the (p,α) reactions in medium heavy elements proceed through direct interaction of the incoming proton with an alpha particle or by a triton pickup reaction (44, 45). This process must be assumed to occur only at the nuclear surface, instead of throughout the nuclear volume, because of the small mean free path of the α-particles in nuclear matter (46). A nucleon, in the peripheral region of the nucleus, spends a substantial fraction of its time, probably about one-third to one-half, in an 'alpha particle' as concluded by Hodgson (45) at 40 Mev and at higher energies by Ostroumov and Filov (47). The (p,α) cross section in Ta^{181} at 23 Mev is 6 millibarns (48) and it probably increases at higher energies. According to Lindner and Turkevich (39), the yields of the products of the reactions, formally written as $(p,3pxn)$, are considerably higher than predicted by the cascade–evaporation model (35, 36), and they state that such products are perhaps produced by the reaction of the $(p,\alpha pxn)$ type in which the α-particle is knocked out of the nucleus during the cascade step, since the evaporation stage seems hardly likely to provide enough charged-particle emission in heavy elements bombarded with 340 Mev proton. Similarly, at lower energies below 70 Mev, Foreman *et al.* (49) suggest that $(\alpha,xpxn)$ reactions are formed by direct interaction with complex particles emitted in preference to a series of protons and neutrons. Thus at low energies below 100 Mev, the large yields of the $(p,2pxn)$ and $(p,3pxn)$ reaction products in Ta^{181} can best be explained by direct interaction of the incoming particle with aggregates of nucleons, like H^3, He^3, He^4, He^6, Li^5, Li^6, Li^7, etc., followed by evaporation of an appropriate number of neutrons, rather than by multiple emission of particles, unless an appreciable reduction of the Coulomb barrier, proposed only at high energies of excitation (50, 51), occurs even at low excitation energies (48) permitting the evaporation of charged particles. However, it has been shown theoretically that barrier penetrability should remain roughly constant up to 30 Mev of excitation energy (52).

The $(p,2pn)$, $(p,2p2n)$, $(p,2p3n)$, and $(p,2p4n)$ reactions lead to Hf^{179}, Hf^{178}, Hf^{177}, and Hf^{176}, respectively which are stable and their yields cannot be determined radiochemically. The $(p,2p5n)$ reaction product, Hf^{175}, would probably result from a $(p,Hexn)$ reaction, with the proton–helium isotope knockout mechanism, followed by neutron evaporation at 42 Mev and above. Its isobar, Ta^{175}, formed either through the decay of W^{175} or independently through a $(p,p6n)$ reaction, was observed only at bombarding energies above 64 Mev, which might be explained on the basis that no alternative reaction paths are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

available for its formation, except by neutron evaporation from an excited nucleus after proton inelastic scattering. It may also be pointed out that the two reaction products, Ta^{178} formed by the $(p,p3n)$ reaction and Hf^{175} produced by the $(p,\alpha 3n)$ reaction, were observed at about the same energy, the former at 36 Mev and the latter at 42 Mev, suggesting a similarity of the two reaction processes. The drop in the excitation function for Hf^{175} at higher energies is somewhat puzzling and further experiments alone would clarify this point. The independent yields of Hf^{173}, formed by the $(p,2p7n)$ reaction, may also be explained by the same mechanism of helium isotope surface knockout, followed by neutron evaporation. Its formation in comparable yield to that of Hf^{175} indicates a greater deposition of energy in the residual nucleus with increasing bombarding energy favoring evaporation of many neutrons, which may be one of the reasons for the gradual decrease in the yields of Hf^{175} at higher energies.

The $(p,3pxn)$ reaction products have been observed at about 42 Mev. The $(p,3p2n)$ reaction at 42 Mev, leading to Lu^{177}, has a low cross section, 0.05 millibarn, indicating the low probability even for its alternative reaction path, $(p,\alpha p)$ mechanism, in which both collision partners escape the target nucleus, as explained for the $(p,2p)$ reaction. Lu^{176} formed by a $(p,3p3n)$ reaction cannot be determined radiochemically, and the yield determined for Lu^{176m} represents only a fraction of the total yield for this reaction. The yields are low, 0.2 millibarn at 64 Mev, indicating the low probability for the reaction to occur via a $(p,\alpha d)$, $(p,\alpha pn)$, or (p,Li^5n) reaction, the last reaction being more probable than the others. Lu^{172} and Lu^{171m}, produced by $(p,3p7n)$ and $(p,3p8n)$ reactions at 84 Mev, have cross sections of 3.7 and 2.6 millibarns respectively, and they are likely to be formed by surface interaction with a lithium isotope or a helium isotope followed by particle evaporation.

A comparison of the cross-section values for the $(p,2pxn)$ and $(p,3pxn)$ reactions in Ta^{181} with those of similar reactions induced in erbium isotopes (53) and iridium isotopes (41) does show that the high yields for these reactions indeed occur in the medium heavy elements even in the energy range of present interest.

(c) The Total Reaction Cross Section

At low energies (<12 Mev) the measurement of the (p,xn) cross section gives direct information about the proton reaction cross section, since the contribution from the proton inelastic scattering cross section is negligible. Experimentally, it was found in the present study that the (p,pn) reaction did not occur at 12 Mev, in agreement with Cohen *et al.* (43), who determined a value of about 0.5 millibarn at 13.5 Mev for this reaction. Thus, at 8 Mev and 12 Mev, the total reaction cross section is the sum of the cross sections for (p,n) and $(p,2n)$ reactions, the others like (p,γ) being negligible. The experimentally determined values for the (p,n) reaction at 8 Mev and 12 Mev in this work are 60 and 98 millibarns. The $(p,2n)$ reaction leading to stable W^{180} has calculated (34) cross-section values of 6 and 400 millibarns at 8 Mev and 12 Mev respectively. Thus the total reaction cross-section values of 66 millibarns at 8 Mev and 500 millibarns at 12 Mev compare well with the values computed with the optical model using a surface absorption potential (34). The proton capture cross sections at these energies, calculated by Shapiro (32) with $R = 1.5\times10^{-13}A^{1/3}$, correspond to 60 and 470 millibarns, which also agree with the above total reaction cross-section values, again pointing out that the (p,n) interaction proceeds via the compound nucleus at these low energies and direct interaction interference is negligible.

The theoretical proton total reaction cross section at 31.5 Mev given by Melkanoff *et al.* (54) for Ta is 1830 millibarns, which may be compared with the value, 1650 ± 360

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

millibarns, obtained at 30 Mev in the present work. The experimental value includes the (p,p') cross section for Ta at 31 Mev (2) and also the $(p,2n)$ cross section at 30 Mev (55) for Bi^{209}. The (p,α) cross sections are not significant. A similar experimental value of 1600 millibarns was given (42) for the total reaction cross section of a medium heavy nucleus like Au^{197} or Bi^{209}. Gooding (56) reported a value of 1775 millibarns for Pb as the total proton reaction cross section at 34 Mev, obtained by beam attenuation measurements. A similar comparison cannot be extended to higher energies because of the large number of competing undetermined cross sections.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Dr. R. E. Bell for making the facilities of the Radiation Laboratory so readily available to us.

One of us (C. L. R.) wishes to express his appreciation to the Canadian Universities Foundation and to the Ministry of Scientific Research and Cultural Affairs, Government of India, under whose joint auspices a Canadian Commonwealth Scholarship was held.

THE SPALLATION OF IRIDIUM WITH PROTONS OF ENERGIES 9–87 MEV[1]

G. R. GRANT[2] AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.
Received May 8, 1963

ABSTRACT

Iridium metal has been bombarded with protons varying in energy from 8 to 87 Mev. The spallation products were radiochemically separated and decay characteristics and formation cross sections were determined. It was confirmed that both Pt^{187} and Pt^{186} have half-lives of about 3 hr, and a half-life of 13.3±0.2 days was found for Ir^{189}. An isomeric state of Ir^{186} with half-life 2.0±0.5 hr has been found. Fair agreement was obtained between excitation functions for (*p,xn*) reactions determined experimentally and those predicted by the Jackson model. The (*p,pn*) yield at 84 Mev has been compared with that calculated from Monte Carlo cascade data combined with evaporation theory and found to be too high by a factor of 4.

INTRODUCTION

The purpose of the present investigation was twofold: (*a*) to investigate half-lives and other decay characteristics of the spallation products of iridium that were observed by bombarding iridium with protons of up to ~87 Mev energy, and (*b*) to determine excitation functions for these products. The energy range covered is an interesting one since it is in this region that the mechanism of nuclear reactions is believed to change from a compound nucleus type to one which is predominantly a knock-on cascade reaction, followed by nucleon evaporation.

To date, there have been relatively few studies of a similar nature in this particular mass region, but a few notable exceptions are the following: (*p,xn*) reactions on isotopes of lead and bismuth (1) where *x* is the number of neutrons emitted, the alpha and deuteron bombardment of bismuth and lead (2), the proton bombardment of gold (3), and recently the proton bombardment of tantalum (4).

EXPERIMENTAL

(a) Preparation and Irradiation of Targets

The targets were prepared by loading approximately 10–15 mg of an intimate mixture of 'spec-pure'* iridium sponge and 'spec-pure'* copper powder (both metals were of normal isotopic abundance) into thin-walled aluminum tubing (2S purity). The target was fastened to the end of the cyclotron probe and inserted to the proper radius, depending upon the energy desired.

The reactions $Cu^{63}(p,n)Zn^{63}$ and $Cu^{65}(p,pn)Cu^{64}$ were used to monitor the proton beam intensity. There are some discrepancies in the published cross sections for both of these reactions. However, there seems to be reasonable agreement between Ghoshal (5), Linder and James (6), and Howe (7) for the former reaction and Ghoshal's results have been used for bombarding energies of less than 15 Mev. For higher proton energies, Meadows' results (8) for the $Cu^{65}(p,pn)Cu^{64}$ reaction were used. The monitor cross sections are shown in Table I.

(b) Dissolution of Target

After irradiation the target (aluminum tubing, plus copper and iridium mixture) was placed in a thick-walled pyrex combustion tube along with ~1 ml 12 *M* hydrochloric acid to dissolve the aluminum and 1 drop of 30% hydrogen peroxide to speed the solution of the copper powder. The mixture was heated gently for a few minutes to remove dissolved gases and then cooled to liquid-air temperature. About 0.04 g of sodium chlorate was added as oxidant and the end of the pyrex tube was sealed prior to placing it inside a stainless

TABLE I

Monitor cross sections

Proton energy (Mev)	$\sigma_{Zn^{63}}$ (millibarn)	$\sigma_{Cu^{64}}$ (millibarn)	Proton energy (Mev)	$\sigma_{Cu^{64}}$ (millibarn)
9	370		47	280
12	520		57	250
16		110	67	230
23		510	77	210
30		420	84	190
38		330	87	190

steel pressure vessel. The steel vessel was heated for 1 hour at 300° C in a muffle furnace to dissolve the iridium sponge (9). The high internal pressure of the pyrex vessel was counterbalanced by placing a weighed amount of 'dry ice' inside the steel vessel, thus keeping breakages to a minimum.

It was found most convenient to add osmium carrier before dissolution of the iridium, while all the other necessary carriers were added after dissolution of the target. However, essentially complete removal of the spallation products from the pyrex tube was verified by means of gamma-ray spectroscopy.

(c) Chemical Separations and Chemical Yields

Depending upon the energy at which the target was irradiated, the target solution may have contained activities of a few or all of the following elements: Pt, Ir, Os, Re—from the iridium target; Zn, Cu, Ni, Co, Fe—from the copper monitor, and Al, Na, F—from the aluminum tubing.

Osmium and fluorine were distilled from an all-glass distilling apparatus (10) and collected in ice-cold 6 *N* sodium hydroxide. The osmium was then purified by slightly acidifying the distillate with hydrochloric acid and extracting the osmium tetroxide twice with carbon tetrachloride (11). The osium tetroxide was then back-extracted into 1 *N* sodium hydroxide and the osmium complexed with 1,2,3-benzotriazole (12).

The remaining elements were separated on a column of Dowex-1, using the data of Kraus and Nelson (13) as a guide. After distillation of the osmium and fluorine, the residue was made 0.5 *M* in hydrochloric acid and applied to the top of a column of Dowex-1 (100 to 200 mesh, ×8%). The diameter of the column was 5 mm and the resin bed was 6 cm deep.

Copper and its spallation products were first washed from the column by eluting with water. The monitor (Zn^{63} or Cu^{64}) was then separated from the other copper spallation products at a convenient time after the bombardment. For this purpose a second column of Dowex-1 was used following a modification of the procedure outlined by Kraus and Moore (14).

Iridium was removed from the first column by reducing the Ir(IV) to Ir(III) by passing a few milliliters of aqueous hydroquinone solution through the column and then washing it with about 15 ml 6 *M* hydrochloric acid.

About 30 ml 9 *M* hydrochloric acid was sufficient to elute the Re(VII), but it was usually contaminated with trace amounts of iridium and platinum. Therefore the Re(VII) was further purified by distilling rhenium heptoxide from a perchloric acid medium and trapping it in ice-cold 6 *N* sodium hydroxide.

Since Pt(IV) is adsorbed very strongly at all hydrochloric acid concentrations (13), about 20 ml of 35% perchloric acid was used as eluant (15).

The various samples were analyzed to determine the chemical yields in the separations after the activities had decreased substantially. The methods of analyses used were taken from the literature with some simplifications introduced because of the previous separations performed. The analytical procedures used were:

zinc—volumetric titration with ethylenediaminetetracetic acid (EDTA) (16);
copper—volumetric titration with EDTA (16) or colorimetrically with diethyldithiocarbamate (17);
platinum—colorimetrically with potassium iodide (11);
iridium—potentiometric titration with Fe(II) (18) or spectrophotometrically with EDTA (19);
osmium—gravimetrically with 1,2,3-benzotriazole (12);
rhenium—colorimetrically with thiocyanate and Sn(II) (11).

(d) Radiation Measurements

Aliquots of the separated samples were made up to 2 ml in small, glass, screw-cap vials and the gamma activity of the samples was measured with a 3 in.×3 in. NaI(Tl) crystal in conjunction with a 100-channel pulse-height analyzer. The crystal was calibrated experimentally for photopeak efficiency using several sources which had been standardized using a 4π β-proportional counter. Since the gamma-ray spectra of most of the spallation products were generally quite complicated, the sources were usually measured on a shelf no closer to the detector than about 6 cm in order to reduce summing effects.

RESULTS AND DISCUSSION

(a) Radiation Characteristics

The Pt–Ir–Os system is exceedingly complex since the half-lives of many of the nuclides are so similar and the decay schemes very complex and in some cases virtually unknown (23).

(i) Pt^{191}.—Gamma rays of 130, 355, 410, and 540 kev energies were found attributable to Pt^{191}. These decayed with a half-life of 2.9±0.2 days, measured over four half-lives.

(ii) Pt^{189}.—Two γ-rays of energies 550 and 720 kev were observed in the decay of Pt^{189}. Their intensities decayed with a half-life of 9±1 hr, somewhat shorter than the values found recently by Anderson and Ringh (20) and Albouy *et al.* (21) (11.1±0.4 and 11.5 hr respectively). The relative intensities of the 550 and 720 kev γ-rays were determined to be 100 and 56 respectively. From more recent data (22), it would appear that the 550 kev peak observed is in reality a mixture of 545 kev and 608 kev γ-rays.

(iii) Pt^{188}.—A 633 kev γ-ray was found which showed the characteristic growth and decay of a 10-day parent decaying to a 41-hr daughter, i.e. $Pt^{188} \rightarrow Ir^{188}$. This energy corresponds to one of the known energy levels in Os^{188} (23).

(iv) Pt^{187} and Pt^{186}.—Recently Malysheva *et al.* (24) reported that both Pt^{187} and Pt^{186} have half-lives of 2.2±0.5 hr. This similarity in half-lives for the two isotopes has been substantiated in the present investigation. Figure 1 shows the two excitation functions

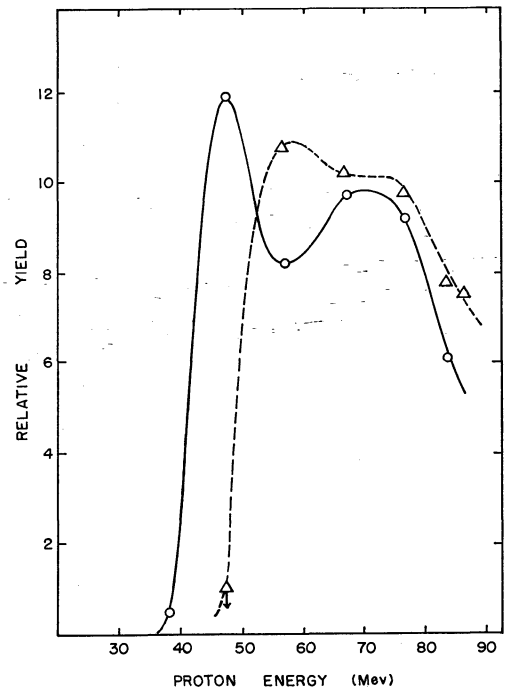

FIG. 1. Excitation functions of Pt^{187} and Pt^{186}: ○ 2100 kev γ-ray from Pt^{187}; △ 670 kev γ-ray from Pt^{186}.

found for this pair of isotopes. The solid curve is attributed to Pt^{187} on the basis of the energies at which the excitation functions $Ir^{191}(p,5n)Pt^{187}$ and $Ir^{193}(p,7n)Pt^{187}$ reach

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

their maxima. The formation cross sections for Pt^{187} were based on a 3.1±0.5 hr component of the γ-ray spectrum at 2.15 Mev energy. Cameron's mass formula (25) also lends support to this assignment since it predicts an available decay energy of 2.16 Mev for Pt^{187} and only 0.76 Mev for Pt^{186}. The excitation function for Pt^{186}, shown as a broken curve in Fig. 1, was based on a very broad γ-peak at 670 kev energy. This activity decayed with a half-life of 3.0±0.3 hr measured over a period of four half-lives. The yield curve is consistent with $(p,6n)$ and $(p,8n)$ reactions on Ir^{191} and Ir^{193} respectively.

(v) Ir^{192}.—This nuclide is produced independently by the reaction $Ir^{193}(p,pn)Ir^{192}$. Gamma rays of energies 140, 315, 470, 605, and 790 kev were found decaying with a half-life of 74±1.2 days (measured over two half-lives) in good agreement with that of Kastner (26).

(iv) Ir^{190m} *and* Ir^{190g}.—Gamma rays of 190, 365, and 510 kev energies were found decaying with the half-lives of both the metastable and ground state. The half-life of Ir^{190m} was found to be 3.0±0.2 hr, measured over nine half-lives, while that of the ground state was 11±1 days.

(vii) Ir^{189}.—Ir^{189} was not found as a primary spallation product. It undoubtedly was produced, but could not be resolved in the presence of the complicated spectra of Ir^{190} (with similar half-life) and Ir^{192}. Ir^{189} was, however, observed as a daughter of Pt^{189} in a separated Pt fraction. Smith and Hollander (27) have assigned a half-life of 11±2 days to Ir^{189}. We have remeasured the half-life by purifying a platinum sample and then separating the iridium daughter from this several days later. The only activity present was Ir^{189} since, under the bombardment conditions, the only radioactive platinum isotopes formed would be Pt^{191} and Pt^{189}, and Pt^{191} decays to a stable iridium isotope. A half-life of 13.3±0.2 days (measured over five half-lives) was found. This is in agreement with a recent value by Lerohl (28) of 13.3±0.1 days.

(viii) Ir^{188}.—Most of the known γ-rays of Ir^{188} were observed in both purified platinum and iridium fractions, i.e. 155, 475, 633, 830, 1200, 1440, 1700, and 2100 kev. The last three peaks appeared to be complex. In the iridium fraction Ir^{188} decayed with a half-life of 41±1 hr, while the growth and decay of Ir^{188} peaks in the platinum fractions were consistent with 41-hr Ir^{188} in equilibrium with 10-day Pt^{188}.

(ix) $Ir^{187, 186, 185}$.—These three isotopes present a situation which is very difficult to handle experimentally since they all have very similar half-lives, viz. 13 to 16 hr (29). As a result of this, and because of the complex gamma spectra, the only one of the three directly observed was 15-hr Ir^{186}. It was identified by gamma peaks at 135, 295, 630, 770, and 950 kev. These γ-ray energies for 16-hr Ir^{186} correspond closely to those reported by Diamond and Hollander (29), who also reported possible gamma rays up to 1.099 Mev in energy. In the present work, additional gamma rays of energies 1700 and 2100 kev have been observed, which are believed to follow the decay of Ir^{186}. All of the gamma rays of Ir^{186} showed a shorter-lived component of 2±0.5 hr half-life. This has been taken as evidence for the existence of a shorter-lived metastable state of Ir^{186}. It is considered unlikely that this activity could be attributed to the short-lived neutron-deficient iridium isotopes (Ir^{184}—3.2 hr, or Ir^{183}—53 min) recently reported by Diamond *et al.* (30). The 2-hr activity was first observed at a bombarding energy of 57 Mev, and it is unlikely that it was energetically possible to produce Ir^{183} or Ir^{184} at that energy. Recently Bonch-Osmolovskaya *et al.* (31) have isolated an iridium fraction from a gold target irradiated with 660 Mev protons. They observed that the γ-ray at 137 kev attributed to Ir^{186} had a shorter-lived component of 1.7±0.2 hr which they proposed belonged to an isomer of Ir^{186},

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in agreement with this work. Ir^{185}, while not observed directly, was found by means of the growth of its daughter 94-day Os^{185} in a separated iridium sample.

(x) Os isotopes.—A 16-day component in the X-ray decay curve of a separated osmium sample was assigned to Os^{191}, although the characteristic 129 kev γ-ray of this nuclide was not observed due to the complexity of the spectrum in that region. Os^{185} was identified by its 645 kev γ-ray, the intensity of which decayed with a half-life of 94 days. A 382 kev γ-ray, characteristic of Os^{183}, was observed, the intensity of which decayed with half-lives of 12 and 14 hr in samples of separated osmium from bombardments at 77 and 84 Mev respectively, resulting from different admixtures of Os^{183} and Os^{183m}. Os^{182} was identified by the 510 kev γ-ray which decayed with a half-life of 20 ± 0.2 hr (over six half-lives).

(xi) Re isotopes.—Re^{181} was found in a separated rhenium fraction as evidenced by the decay of its 365 kev γ-ray. A half-life of 18 ± 1 hr was found, measured over six half-lives.

(b) Formation Cross Sections

In order to determine the cross sections of the individual spallation products, it was necessary to know the decay schemes of the nuclides concerned. For some of the nuclides observed these data are not yet available and only a lower limit to the cross section could be obtained by assuming a branching ratio of 100%.

The nuclear characteristics used to determine the formation cross sections are given in Table II and the cross sections found experimentally are shown in Table III. At the time

this work was being done enriched iridium isotopes were not readily available. All of the nuclides given in Table II, with the exception of Ir^{192}, could be produced by reactions on both Ir^{191} and Ir^{193}. For purposes of calculation iridium was assumed to be monoisotopic. Many of the experiments were run twice at the same energy to check reproducibility.

NOTE: I* = independent yield from Ir^{193}; I = independent yield from both Ir isotopes; C = cumulative yield.

The two results showed a spread of about 10%. The estimated error in each of the determinations was obtained from the square root of the sum of the squares of errors in the various operations which included photopeak areas (±10%), photopeak efficiency (±5%), chemical yields (±2% to ±5%), pipetting and dilution (±1%), ratio of number of atoms in monitor to target (±6%), giving overall errors of ±20% to ±25%. No allowance has been made for errors in monitor cross sections or in values chosen for the nuclear characteristics of the radiations used.

All of the (*p,xn*) reactions observed have the same general features, i.e. two peaks separated by about 20 Mev as expected from the contributions from the two isotopes of the target which are separated by two mass numbers. These are shown in Figs. 1–4

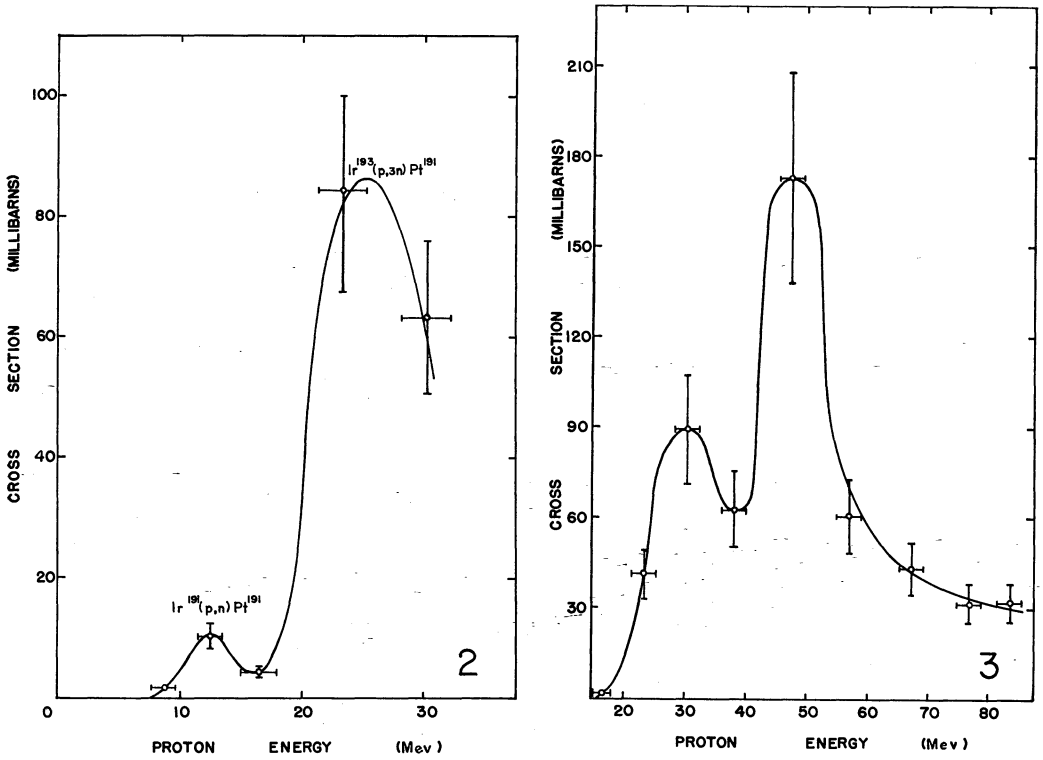

FIG. 2. Excitation functions for the reactions $Ir^{191}(p,n)Pt^{191}$ and $Ir^{193}(p,3n)Pt^{191}$.
FIG. 3. Excitation functions for the reactions $Ir^{191}(p,3n)Pt^{189}$ and $Ir^{193}(p,5n)Pt^{189}$.

inclusive. The (*p,pxn*) and (*p,2pxn*) reactions show excitation functions which increase rapidly above the threshold. Some reach a maximum value and decrease only slowly with increasing energy, while others increase monotonically to the highest bombarding energy available in the McGill synchrocyclotron. At these energies the yields of (*p,pxn*) and (*p,xn*) products are roughly equal, while those formed by (*p,2pxn*) reactions have yields roughly an order of magnitude lower. At an energy corresponding to a peak in a (*p,xn*) excitation function the yield is many times higher than that corresponding to the isobar formed by the corresponding (*p,pxn*) reaction. For example, at a bombarding energy of 38 Mev, $\sigma_{Pt^{188}}/\sigma_{Ir^{188}} \approx 30$, as shown in Fig. 4.

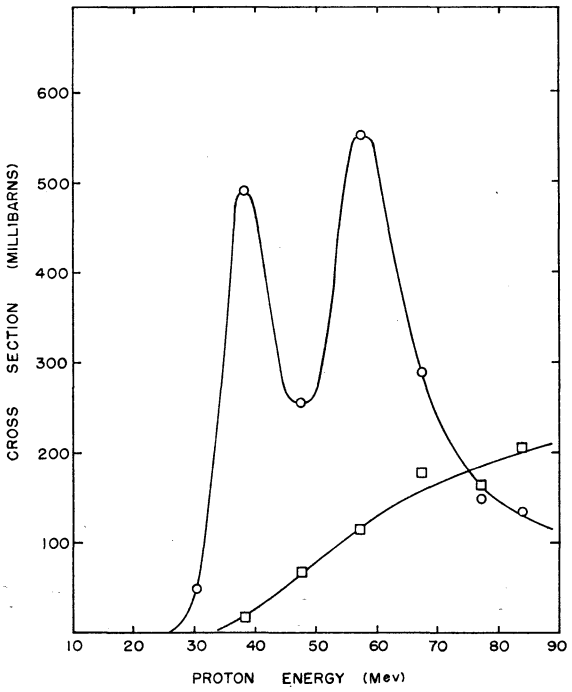

FIG. 4. Excitation functions for the production of Pt^{188} and Ir^{188}: ○ Pt^{188}; □ Ir^{188}.

The (p,xn) excitation functions show the characteristics of the two main mechanisms by which nuclear reactions in this energy range are thought to proceed. Compound nucleus formation accounts for the rapid rise above the threshold to a maximum yield followed by a rapid decrease in yield as other reactions begin to compete. However, the yields do not fall to negligible values at higher energies, showing that the knock-on reactions are making a contribution.

Even though iridium is not monoisotopic, it has been possible to compare the results of the $Ir^{191}(p,n)Pt^{191}$, $Ir^{193}(p,3n)Pt^{191}$, and $Ir^{191}(p,4n)Pt^{188}$ reactions with the model for (p,xn) reactions suggested by Jackson (33). Jackson made the assumptions that neutron emission occurred whenever energetically possible, proton evaporation was neglected, and the evaporated neutron energy spectrum was proportional to $E \exp(-E/T)$, where E is the excitation energy and T the nuclear temperature, which is taken to be constant. The cross section for a particular reaction is then given by

$$\sigma_{(p,xn)} = \sigma_c(E_0)[I(\Delta_x,2x-3) - I(\Delta_{x+1},2x-1)],$$

where

$$\Delta_x = (E - \textstyle\sum_i^x B_i)/T.$$

The term $\sigma_c(E_0)$ is the cross section for compound nucleus formation which, for our calculations, was taken from Shapiro's (34) tabulations, using a nuclear radius $r = 1.3\times10^{-13}A^{1/3}$. The term in the square brackets is the difference of two Pearson incomplete gamma functions, giving the probability for the emission of exactly x neutrons. The individual neutron binding energies, B_i, were taken from Cameron's tables (25) and a constant nuclear temperature of 1.8 Mev was used.

The calculated excitation functions for (p,n), $(p,3n)$, and $(p,4n)$ reactions on an iridium target are shown by the solid curves in Fig. 5. In order to compare some experimental yields with those predicted by the model, it was necessary to make certain assumptions.

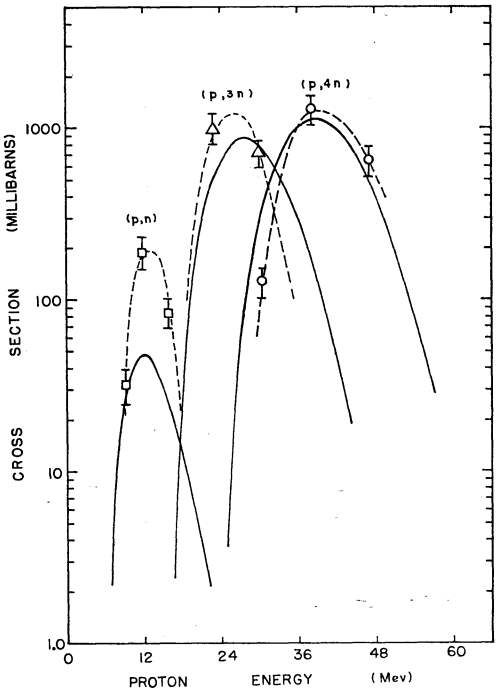

FIG. 5. Comparison of experimental excitation functions with those predicted from the Jackson model: - - - experimental; — theoretical.

In the production of Pt^{188} it has been assumed that below ~50 Mev proton energy a $(p,6n)$ reaction on Ir^{193} is negligible compared to a $(p,4n)$ reaction on Ir^{191}, and the measured cross sections below ~50 Mev were corrected for isotopic abundance of the target. Similarly, in the production of Pt^{191} we have corrected our results for the isotopic abundance of Ir^{191} and assumed the $Ir^{191}(p,n)Pt^{191}$ reaction to be predominant below ~17 Mev proton energy and the $Ir^{193}(p,3n)Pt^{191}$ reaction to be predominant above this energy.

There is fair agreement between the experimental and predicted cross sections. Use of a larger nuclear radius at low bombarding energies, as suggested by Bell and Skarsgard (1), would give better agreement with the experimental results.

In Fig. 6 is shown the excitation functions for the two Ir^{190} isomers which are formed independently. The ground state, which is the low-spin isomer in this case, is preferred in the reaction.

In this work Ir^{192} is formed by a (p,pn) reaction on Ir^{193}. The excitation function is shown in Fig. 7. The experimental cross section for this reaction was compared with that predicted from the Monte Carlo data* of Metropolis *et al.* (35) at a proton energy or 82 Mev on Bi^{209}, by combining with them the contribution from nuclear evaporation af was done by Yule and Turkevich (36). The experimental cross section was about fous times higher than that predicted by theory. A similar discrepancy has been found by other workers (35, 36, 37).

REACTIONS PRODUCED ON ERBIUM BY PROTONS OF ENERGIES BETWEEN 6 AND 87 MEV[1]

G. V. S. RAYUDU[2] AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.
Received May 17, 1963

ABSTRACT

Erbium was bombarded with protons of energies varying between 6 and 87 Mev. Nuclear characteristics and excitation functions were studied for isotopes of Tm, Er, Ho, and Dy, formed by various (p,xn) and $(p,xpxn)$ reactions. Bombardment of enriched Er isotopes helped elucidate some of the excitation functions. A comparison has been made of the experimental (p,xn) cross sections with those predicted by the Jackson model and reasonable agreement has been found. Holmium was bombarded with α-particles to produce the compound nucleus Tm^{169*} and the ratios $\sigma(p,n):\sigma(p,2n) = \sigma(\alpha,n):\sigma(\alpha,2n)$ were found to hold.

The aim of the present study was twofold. First, it was desired to bombard a medium heavy element with protons of energies in the region where the compound nucleus type of reaction begins to be replaced by a direct nucleon–nucleon type of interaction characteristic of higher-energy processes. Secondly, the development of rapid ion exchange processes for lanthanide separations and the recent availability of isotopically enriched lanthanides would enable the characterization of the nuclear properties of known and new radioactive nuclides in this region.

EXPERIMENTAL

(a) Targets

The targets were a mixture of 'spec-pure' erbium oxide and copper oxide which had been obtained from Johnson, Matthey and Co. The reactions $Cu^{63}(p,n)Zn^{63}$ and $Cu^{65}(p,pn)Cu^{64}$ were used to monitor the proton beam at energies below and above 13 Mev respectively. The cross sections used are those of Meadows (1), and are shown in Table I. Isotopically enriched erbium oxide was used in some of the later bombardments

TABLE I

Monitor cross-section values used

Proton energy (Mev)	$\sigma_{Zn^{63}}$ (millibarn)	$\sigma_{Cu^{64}}$ (millibarn)	Proton energy (Mev)	$\sigma_{Cu^{64}}$ (millibarn)
6	200		40	320
10	380		47	280
13	400		57	250
16		150	67	230
22		480	77	210
28		500	87	180
34		360		

to verify isotopic assignments and to clarify the assignment of excitation functions. The target and monitor were mixed mechanically. At low energies (6, 10, and 13 Mev) an atom ratio of erbium to copper of 1:1 was used, while at higher energies the atom ratio was 1:2. About 10 to 15 mg of powdered mixture was placed in a thin aluminum tube which was fastened to the probe, inserted to intercept the circulating beam of the McGill proton synchrocyclotron. Targets were irradiated for periods ranging from 15 minutes to 2 hours. The uncertainty in proton energy, due to the spread of the beam was ± 2 Mev. Slight corrections ($\sim$0.5 Mev) were made to the three lowest energy values used to correct for beam attenuation due to the sample.

For personal use only.

Several irradiations* were made with alpha particles in order to study Ho(α,xn) reactions. The targets of holmium oxide were prepared by a method developed by Dodson *et al.* (2). A known amount of holmium oxide (>99.9% pure) was dissolved in concentrated nitric acid, evaporated almost to dryness, and the holmium nitrate dissolved in a 1% zapon solution (0.4 cc zapon, obtained from Glidden Paint Co., Ohio, as syrup of aquanite, 6 cc ethyl acetate, and 28 cc of 95% ethanol). The concentration of holmium in this mixture was 6 mg/cc. A piece of aluminum foil, 6.69 mg/cm², carefully flattened, was used as the target backing. The foil was placed on a glass plate which was put on the turntable of a record player. A quantity of the mixture was painted on to the foil with a fine camel hair brush while the foil was rotating. The mixture was air-dried and then the aluminum foil dropped onto the surface of a hot plate (400° C). This process was repeated several times, the surface of the foil being carefully smoothed with lens paper and by ironing after each application. With practice, very uniform targets would be prepared in this way. Circular targets were punched out of the foil and affixed to the target holder with sufficient aluminum absorbers (3) to degrade the energy to the required values. The α-particle energy of the Cyclotron was 39.8±0.5 Mev. The integrated current was measured by a Faraday cup. Seven targets were irradiated simultaneously by the stacked-foil technique.

(b) Chemical Separations

No chemical separations were necessary for the targets irradiated at low proton energies (6–13 Mev inclusive) since the activities were readily separable by the use of a multichannel analyzer as described later. The target mixture was dissolved in concentrated hydrochloric acid, made up to a known volume, and an aliquot taken for activity measurements.

At higher proton energies the target was dissolved in a minimum amount of concentrated hydrochloric acid and then transferred to the top of a column containing Dowex 1×8 (100 mesh) anion exchange resin which had been preconditioned with concentrated hydrochloric acid. The separation was based on the work of Kraus and Moore (4). The lanthanides and nickel were eluted with concentrated hydrochloric acid, leaving copper and any other spallation products on the column. Manganese and cobalt were eluted with 4 *M* hydrochloric acid, and copper with 1.5 *M* hydrochloric acid. The copper was made up to volume and an aliquot taken for activity measurements.

To the concentrated hydrochloric acid eluate about 2 mg of nickel was added as holdback carrier, and the lanthanides were precipitated as hydroxides by the addition of 6 *M* ammonium hydroxide, leaving the nickel in solution. The combined hydroxides were washed, dissolved in hydrochloric acid, and made up to volume.

From this stock solution an aliquot was taken for activity measurements. To a further aliquot known amounts (~4 mg) of Tm, Ho, Dy, and Tb were added and this mixture, after repeated evaporation with 0.06 *M* hydrochloric acid, was carefully pipetted onto the top of a heated (87° C) column (5) of 400 mesh 12% cross-linked Dowex 50 cation exchange resin. It was found empirically that the addition of a small amount of Na^+ ion helped improve the separation of Tm and Er, so that a small amount (~0.5 mg) was added with the loading mixture. The resin had been carefully graded and preconditioned by repeated treatment with 6 *M* ammonium hydroxide, hot distilled water, hydrochloric acid, and finally stored as the ammonium form in degassed distilled water. The elutriant solution used was 0.2 *M* α-hydroxyisobutyric acid at pH = 4.1. The commercial grade of the acid was purified by repeated recrystallization from ether. The flow rate was 0.6 ml/min, and the entire separation was concluded in 70 minutes. The fractions were collected into centrifuge cones, those which were known to contain a particular element combined, the lanthanide precipitated as the hydroxide, washed, dissolved in dilute hydrochloric acid, and made to volume from which aliquots were taken for activity measurements.

No chemical separations were done on the holmium targets which had been bombarded by α-particles. The targets were separated, dissolved in 0.1 ml hydrogen peroxide and 0.5 ml concentrated hydrochloric acid, and made up to a known volume from which aliquots were taken for activity measurements.

(c) Chemical Yield Determinations

Chemical yields were determined by means of standard spectrophotometric methods. Copper was determined by means of diethyldithiocarbamate (6) and the lanthanides with Alizarin Red-S (7).

(d) Activity Measurements

Gamma-ray measurements were made using a 3 in. × 3 in. sodium iodide thallium-activated scintillation detector coupled to a 100-channel pulse-height analyzer. The energy scale was calibrated by the use of well-known γ-emitters and the geometrical efficiency in the various positions was obtained by using sources of known disintegration rate calibrated by a 4π β-proportional counter. Beta radiation was measured by a 2π-flow proportional counter.

RESULTS

(a) Radiation Characteristics

The nuclides observed and their radiation characteristics observed are discussed below.

We are grateful to Dr. J. Hudis for arranging these irradiations with the Brookhaven Cyclotron.

For personal use only.

(i) Tm^{170}

Tm^{170}, produced by the reaction $Er^{170}(p,n)$, was found only in small amounts due to its long half-life. The decay of the 80 kev γ-ray was followed after subtracting the contribution due to 86-day Tm^{168}. The latter was produced by a $(p,3n)$ reaction on natural erbium at 30 Mev, where the (p,n) reaction cross section to produce Tm^{170} is negligibly small and products formed from reactions on other erbium isotopes are relatively short-lived. A half-life of 128 ± 10 days, measured over two half-lives, was observed, in good agreement with the values of Bonner *et al.* (8), Caldwell (9), and Ketelle (10), who obtained values of 125, 120, and 129 days respectively.

(ii) Tm^{168}

Tm^{168} was produced by the reactions $Er^{168}(p,n)Tm^{168}$ and $Er^{170}(p,3n)Tm^{168}$, and $Ho^{165}(\alpha,n)$. Gamma rays at 80, 100, 200, 270, 490, 750, 800, 1280, and 1450 kev were observed. The γ-ray energies are in accord with those measured by Kochevanov *et al.* (11) and Jacob *et al.* (12). The decay curve of the 200 kev γ-ray was followed over a period of five half-lives and gave a value of 86 ± 3 days, in good agreement with that of Wilkinson and Hicks (13), and Handley and Olson (14), who obtained values of 85 and 87 days respectively, but lower than the value of 93 days obtained by Bonner *et al.* (8).

(iii) Tm^{167}

Tm^{167} was produced by the reactions $Er^{167}(p,n)$, $Er^{168}(p,2n)$, $Er^{170}(p,4n)$, and $Ho^{165}(\alpha,2n)$. Gamma rays of energies 110, 200, 510, and 710 kev, as well as a K X-ray, were found attributable to Tm^{167}. The 200-kev X-ray was followed over a period of six half-lives to give a value of 9.6 ± 0.2 day half-life. The half-life is in good agreement with the values of Wilkinson and Hicks (13), Handley and Olson (14), and Bonner *et al.* (8), while the observed gamma peaks are in accord with those found by Narasimhaih and Pool (15).

(iv) Tm^{166}

Tm^{166} was produced by the reactions $Er^{177}(p,n)$, $Er^{167}(p,2n)$, $Er^{168}(p,3n)$, and $Er^{170}(p,5n)$. The γ-ray peaks observed at 10, 180, 800, 790, 1200, 1850, and 2050 kev agree with those published recently by Pool and Wilson (16). The decay of the 2050 kev photopeak was followed for eight half-lives and gave a value of 7.7 ± 0.1 hr, in agreement with the value of Wilkinson and Hicks (13), Michel and Templeton (17), and Wilson and Pool (16).

(v) Tm^{165}

Tm^{165} was produced by the reactions $Er^{166}(p,2n)$, $Er^{167}(p,3n)$, $Er^{168}(p,4n)$, and $Er^{170}(p,6n)$. Photopeaks were observed at 220, 300, 830, 1160, and 1380 kev, in agreement with the work of Handley and Olson (18), and Gorodinskii *et al.* (19). The half-life determined in the present work by observation of the 1160 kev photopeak over a period of six half-lives was found to be 28 ± 1.5 hr compared with values of 24.5 and 29 hr obtained by Handley and Olson, and Gorodinskii *et al.* respectively. Gamma rays at 200, 800, 1160, and 1400 kev were observed.

(vi) Tm^{164}

When this work was begun, this isotope of thulium was unknown. Tm^{164} was identified by irradiations of naturally occurring erbium and of erbium enriched in mass 164. Irradiations were of the order of 2 minutes with 7 Mev protons, and the decay of the X-ray was followed immediately without chemical separation. A half-life of 1.8 ± 0.1 min was assigned to Tm^{164}. This is in very good agreement with that found recently by Wilson and Pool (20). The existence of this isotope was also confirmed by Abdurazakov *et al.* (21), who established the existence of the decay chain

$$Yb^{164} \xrightarrow{75\text{ min}} Tm^{164} \xrightarrow{2\text{ min}} Er^{164}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(vii) Tm^{163}

Tm^{163} was produced by the reaction $Er^{164}(p,2n)$ with natural erbium and erbium enriched in mass 164. The decay of the 110-kev γ-ray gave a half-life of 1.8±0.1 hr, followed over a period of four half-lives. This agrees well with the values of Harmatz *et al.* (22), who established the existence of the decay chain

$$Tm^{163} \xrightarrow{2\text{ hr}} Er^{163} \xrightarrow{75\text{ min}} Ho^{163} \xrightarrow{0.8\text{ sec}} Dy^{163},$$

and Bjørnholm *et al.* (23), who recently obtained a value of 1.8±0.1 hr.

(viii) Tm^{162}

Tm^{162} was unknown when this work commenced. Erbium, enriched in mass 162, was bombarded with 7 Mev protons for about 2 hours. The *K* X-ray curve was resolved into three components with half-lives 90±10 min; 7.7 hr, Tm^{166}; and 9.6 days, Tm^{167}. The first component has been attributed to Tm^{162}. Pool and Wilson (20) recently reported a half-life of 77 min obtained by irradiating erbium, enriched in Er^{162}, with 6 Mev protons.

(ix) Tm^{161}

This isotope was produced by a 20 Mev proton irradiation of erbium enriched in Er^{162}. The presence of Er^{161} (3.1 hr) in a separated thulium fraction indicated a half-life of 20–30 min for Tm^{161}, although the initial growth of the Er^{161} daughter was obscured by the other activities present.

(x) Er^{169}

Er^{169} was produced by the reaction $Er^{170}(p,pn)$. The half-life was obtained by following the decay of the β^--activity. A half-life of 9.0±0.1 days, measured over six half-lives, was obtained, in agreement with that of Butement's (24) value of 9 days but slightly lower than the values of Ketelle and Peacock (25) and Pavlotskaia and Lavrukhina (26) of 9.4 and 9.5 days respectively.

(xi) Er^{165}

Er^{165} was produced by the reactions $Er^{166}(p,pn)$, $Er^{167}(p,p2n)$, $Er^{168}(p,p3n)$, and $Er^{170}(p,p5n)$, and by decay from the parent Tm^{165}. The half-life was determined accurately by an auxiliary radiation to get the $Ho^{165}(p,n)$ reaction. This produced pure Er^{165}. The decay of the *K* X-ray was followed for 10 half-lives, giving a half-life of 10.4±0.1 hr, in good agreement with 10.5 hr by Grigorev *et al.* (27). In agreement with several other authors (28), no gamma rays ascribable to Er^{165} were found.

(xii) Er^{161}

Er^{161} was produced by (p,pxn) reactions on all the erbium isotopes and by decay of Tm^{161} (*vide supra*). Photopeaks were found at 200, 300, 820, 1160, 1400, 1700, and 2000 kev. The decay of the activity of the 820 kev photopeak was followed for six half-lives, giving a half-life of 3.1±0.1 hr for Er^{161}, in very good agreement with 3.01 hr by Nervik and Seaborg (29) but lower than the values given by Handley and Olson (30) and Michel and Templeton (17) of 3.6 and 3.5 hr repectively.

(xiii) Er^{160}

Er^{160} was produced by (p,pxn) reactions on all the erbium isotopes and by decay of short-lived Tm^{160}. A half-life of 29.5±0.5 hr was obtained by following the decay of the activity of the *K* X-ray, in good agreement with previously determined values (28).

(xiv) Ho^{161}

Ho^{161} was produced by $(p,xpxn)$ reactions on all the erbium isotopes and by decay of Er^{161}. The half-life obtained from the decay curve of the *K* X-ray was 2.5±0.2 hr, measured over four half-lives, in good agreement with previous values (28).

TABLE III

Formation cross sections for nuclides formed in proton bombardments

Nuclide	Proton energy (Mev): 6	10	13	16	22	28	34	40	47	57	67	77	87	Type of yield	Error (%)
	σ (millibarn)														
Tm^{170}		95	170	24										I	±20
Tm^{168}		71	120	24	520	620	260							I	±15
Tm^{167}		57	180	1200	680	380	430	510	160	110	94	59	48	I	±15
Tm^{166}	0.3	9.3	25	95	99	98	54	36	47	21	22	13	13	I*	±15
Tm^{165}				1.5	1.2	8.4	8.0	9.7	6.0	3.3				I*	±15
Tm^{163}							1.6	23	29	41	34	17	0.4	I*	±15
Er^{169}				3.6	4.3	5.9	29	46	69	120	110	89	62	I	±10
Er^{165}					1.5		50	41	120	190	390	230	230	I	±15
Er^{161}							8.5		17	120	400	300	260	C	±15
Er^{160}										42	80	190	240	I	±15
Ho^{161}										45	93		80	I	±20
Ho^{160m}										3.8	17	17	25	I	±20
Dy^{159}											5.2	33	33	C	±20
Dy^{157}											1.7	5.3	7.1	C	±20
Tm^{167*}				550	1700	4.0	120							I	±20

NOTE: I = independent yield; I* = lower limit for independent yield (branching ratio assumed to be 1.00); C = cumulative yield. Tm^{167*}—obtained on the basis of enriched isotope experiments.

(xv) Ho^{160m}

Ho^{160m} was produced by (*p*,*xpxn*) reactions on all the erbium isotopes and by decay of Er^{160}. Photopeaks were observed at 87, 190, 650, 730, 890, and 970 kev. The decay of the *K* X-ray activity gave a half-life of 5±0.2 hr, measured over a period of five half-lives, in good agreement with previous values (28).

(xvi) Dy^{159}

Dy^{159} was produced in very low yield both by (*p*,*xpxn*) reactions on the erbium isotopes and by decay of Ho^{159}. The decay of the *K* X-ray activity gave a half-life of 138±5 days, measured over two half-lives, in reasonable agreement with previous values (28).

(xvii) Dy^{157}

Dy^{157} was produced by (*p*,*xpxn*) reactions on the lighter erbium isotopes as well as by decay of Ho^{157} (unknown). The half-life, found by following the decay of the 320 kev photopeak, of 8.2±0.2 hr, measured over six half-lives, is in good agreement with previous work (28).

(b) Formation Cross Sections

The radioactive characteristics used in determining the formation cross sections for the spallation products are given in Table II, and the cross sections found for the various proton bombardments are shown in Table III. In Table IV are given the formation cross sections determined in the α-bombardments.

TABLE IV

Cross sections for the reactions $Ho^{165}(\alpha,n)Tm^{168}$ and $Ho^{165}(\alpha,2n)Tm^{167}$

	Energy (Mev):						
	15	20	25	30	35	39	Error (%)
	σ(millibarn)						
(α,*n*)	6.8	39	5.6				±15
(α,2*n*)		25	480	450	110	60	±15

In general, the formation cross sections were calculated by means of the following equation:

$$\sigma_p = \sigma_m \cdot \frac{D_p^0}{D_m^0} \cdot \frac{W_{Cu}}{W_{Er}} \cdot \frac{A_{Er}}{A_{Cu}} \cdot \frac{(1-e^{-\lambda_m t})}{(1-e^{-\lambda_p t})},$$

where the subscripts p and m refer to the product and monitor respectively, and σ = cross section, D^0 = disintegration rate at end of bombardment, W_{Cu} = weight of copper monitor, W_{Er} = weight of erbium target, A_{Er}/A_{Cu} = ratio of atomic weight of erbium to copper, λ = disintegration constant, t = time of bombardment.

In the cross-section calculations of Tm^{166}, Tm^{165}, Tm^{163}, Er^{165}, Er^{163}, Er^{160}, Ho^{161}, Ho^{116m}, Dy^{159}, and Dy^{157}, the total weight of erbium recovered has been assumed to be W_{Er}. In the case of the Tm^{170} and Er^{169} calculations, the natural isotopic abundance of Er^{170} was used (14.9%) since these nuclides could be produced only by reactions on Er^{170}. For the production of Tm^{168}, the isotopic abundance of Er^{168} (29.1%) was taken as the target weight for the reactions with protons up to 16 Mev in energy, since only the (*p*,*n*) reaction was contributing. For the proton energies between 16 and 34 Mev, the target weight was considered to be that due only to Tm^{170}, since now only the (*p*,3*n*) reaction was contributing. In the Tm^{167} calculations, the weight of target has been arbitrarily taken as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

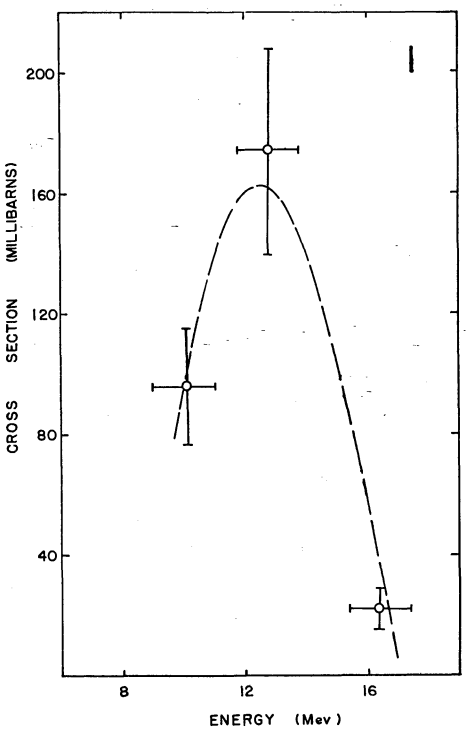
66.9% of the erbium used, since only Er^{170}, Er^{168}, and Er^{177} can contribute to the production of Tm^{167}. However, two irradiations were made on erbium enriched in mass 168 at proton energies of 22 and 28 Mev. It was assumed that the Er^{167} (p,n) would not contribute at these energies and that any contribution from Er^{170} (1.5% abundance in this target) would be negligible. The weight of Er^{168} was taken as the target weight in these two experiments. Data for this $(p,2n)$ reaction at 16 and 34 Mev were obtained by solving two simultaneous equations obtained from the irradiation of natural erbium and erbium enriched in mass 168. The results are shown in the last line of Table III.

In the case of the alpha radiations, the same equation as above was used with the appropriate values for holmium inserted. Holmium is monoisotopic, so that there is no question as to what weight to use in the calculations.

The errors quoted in Tables III and IV are the standard deviations obtained by compounding the errors involved in the individual terms used to calculate the cross sections. No estimate of error in the monitor cross section is included.

DISCUSSION

The excitation functions for the (p,xn) reactions follow, at low energies, the behavior predicted by the compound nucleus theory. Several of these are shown in Figs. 1–3



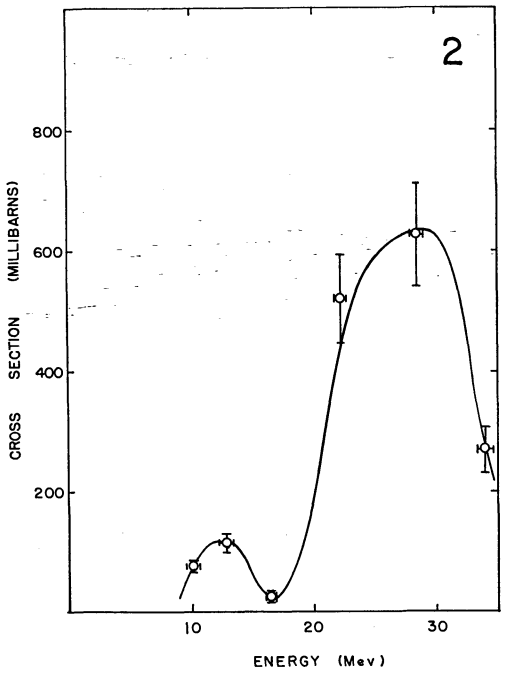


FIG. 1. Excitation function for the $Er^{170}(p,n)Tm^{170}$ reaction.
FIG. 2. Excitation functions for the $Er^{168}(p,n)Tm^{168}$ and $Er^{170}(p,3n)Tm^{168}$ reactions.

inclusive. Elucidation is made easier by virtue of the fact that Er^{168} and Er^{170} are stable and will contribute to (p,xn) reactions, but Er^{169} which is unstable will not, thus leaving a gap. The (p,pxn) reactions do not fall to zero, but show signs of levelling off. A typical

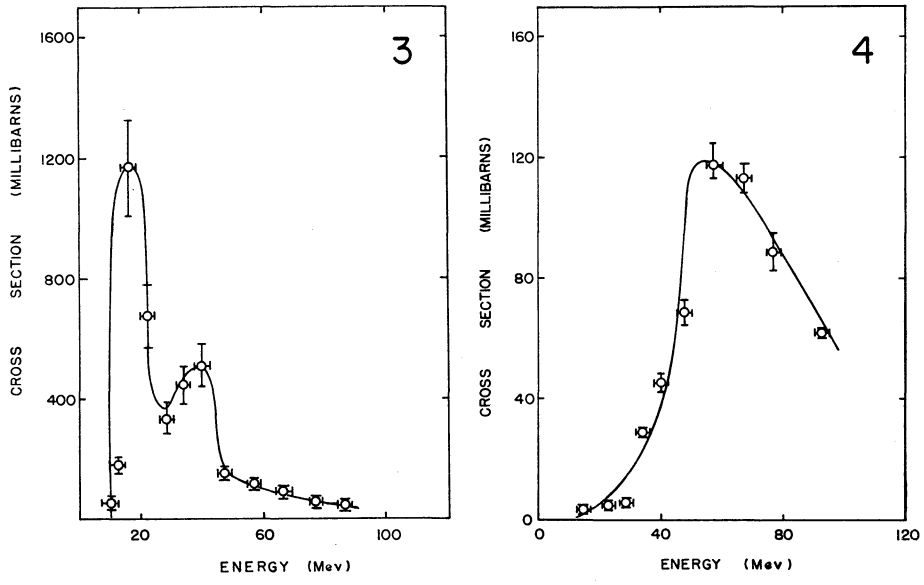

FIG. 3. Excitation functions for the $Er^{167}(p,n)Tm^{167}$, $Er^{168}(p,2n)Tm^{167}$, and $Er^{170}(p,4n)Tm^{167}$ reactions.
FIG. 4. Excitation function for the $Er^{170}(p,pn)Er^{169}$ reaction.

curve is that for the $Er^{170}(p,pn)Er^{169}$ reaction given in Fig. 4, showing that at higher energies the knock-on process is now contributing.

The cross sections of $(p,2pxn)$ reactions were found to be an order of magnitude lower than those of the corresponding (p,pxn) reactions. The former increased monotonically with energy, since it was not possible to reach the curve maxima with the cyclotron energies available.

The multi-isotopic nature of the erbium target limits the possibilities of comparison of experimentally and theoretically determined cross sections. A limited comparison can be made, however, for the reactions $Er^{170}(p,n)Tm^{170}$, $Er^{168}(p,n)Tm^{168}$, $Er^{168}(p,2n)Tm^{167}$, and $Er^{170}(p,3n)Tm^{168}$ with the theoretical (p,xn) calculations of Jackson (35). Jackson combined the Monte Carlo results of McManus *et al.* (36) for the nuclear cascade with a simplified evaporation theory in order to calculate formation cross sections. Jackson showed that the probability that a nucleus with initial excitation energy E will evaporate x neutrons is given by:

$$P(E,x) = I(\Delta_x,2x-3)-I(\Delta_{x+1},2x-1),$$

where the values of I are obtained from Pearson's incomplete gamma functions (37). The term

$$\Delta_x = \left(E - \sum_i^x B_i\right) \Big/ T,$$

where B_i is the binding energy of the ith neutron and T is the nuclear temperature. The average binding energy of the neutrons in this region was taken from Cameron's (38) tables to be 7.4 Mev. An approximate nuclear temperature, T, was calculated from the expression

$$\Delta E = \bar{B}+2T,$$

where ΔE represents the energy separation in Mev between successive peaks of (p,xn)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

excitation functions (~13 Mev for $Z = 69$) and the average binding energy per nucleon, $\bar{B}$, was taken as 8.2 Mev, giving $T = 2.4$ Mev.

In the range of bombarding energies where all the interactions of the bombarding particle with the target nucleus involve the initial formation of a compound nucleus followed by neutron evaporation, the formation cross sections can be given by simple functions of the type

$$\sigma(p,xn) = \sigma_c(E_0)P(E,x),$$

where $\sigma_c(E_0)$ is the cross section for compound nucleus formation at incident energy E_0. The values of $\sigma_c(E_0)$ have been taken from Shapiro (39). His curve has been extrapolated to 50 Mev and a nuclear radius $R = 1.3\times10^{-13}A^{1/3}$ cm has been used.

The comparison between the experimental (broken) curves and the calculated (solid) curves is shown in Fig. 5. The measured cross sections for the reaction $Er^{168}(p,n)Tm^{168}$

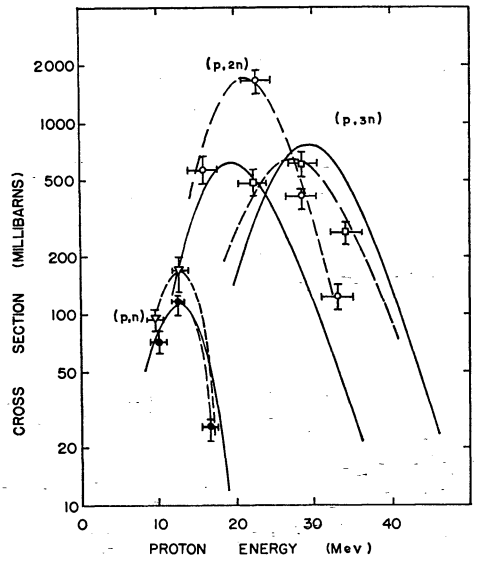

FIG. 5. Comparison of experimentally determined excitation functions with those predicted by the Jackson model: — theoretical; --- experimental; ▽ $Er^{170}(p,n)Tm^{170}$; ● $Er^{168}(p,n)Tm^{168}$; ○ $Er^{168}(p,2n)Tm^{167}$; □ $Er^{170}(p,3n)Tm^{168}$.

agreed well with the calculated values, whereas the calculated values for the reaction $Er^{170}(p,n)Tm^{170}$ were about 30% too low. In the case of the $Er^{168}(p,2n)Tm^{167}$ results, the calculated values were only about half the experimental values. The calculations for the reaction $Er^{170}(p,3n)Tm^{168}$ agreed well with the experimental values. Some of the discrepancies mentioned above may, of course, be due to uncertainties in the decay schemes used.

Yule and Turkevich calculated (p,pn) reaction cross sections at various energies by combining the cascade results with a simplified evaporation theory. For $A = 169$ they calculated a formation cross section of 30 millibarns for the (p,pn) reaction. This is to be compared with our experimental value of 60 millibarns. This type of discrepancy has been noticed by other authors (40–42) and it has been ascribed to the use of too sharp a nuclear boundary in the calculations, giving an incorrect number of low-energy depositions.

An attempt was made in the present work to check the compound nucleus mechanism

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

by a Ghoshal-type (44) of experiment, i.e. production of the same compound nucleus by two different nuclear reactions and comparison of the excitation functions. The reactions were the following:

$$_{67}Ho^{165} + \alpha \rightarrow {}_{69}Tm^{169*} \rightarrow Tm^{168} + {}_{0}n^{1} \qquad (a)$$
$$_{68}Er^{168} + p \rightarrow {}_{69}Tm^{169*} \rightarrow Tm^{168} + {}_{0}n^{1}$$

$$_{67}Ho^{165} + \alpha \rightarrow {}_{69}Tm^{169*} \rightarrow Tm^{167} + 2{}_{0}n^{1} \qquad (b)$$
$$_{68}Er^{168} + p \rightarrow {}_{69}Tm^{169*} \rightarrow Tm^{167} + 2{}_{0}n^{1}.$$

The ratios of the excitation functions have been calculated at the same excitation energy, which was determined in the following way. The α-bombardment energy to produce Tm^{169} is equal to the proton bombardment energy to produce Tm^{169} plus the proton binding energy (5.900 Mev) minus the α-binding energy (-0.534 Mev) (38). Thus 6.434 Mev has to be added to the proton bombarding energy to produce Tm^{169} at the same excitation energy as that produced by the alpha bombardments. (The small factor involved in changing from center-of-mass to laboratory coordinates has been neglected.) The excitation functions are plotted in Fig. 6 and the data are given in Table V.

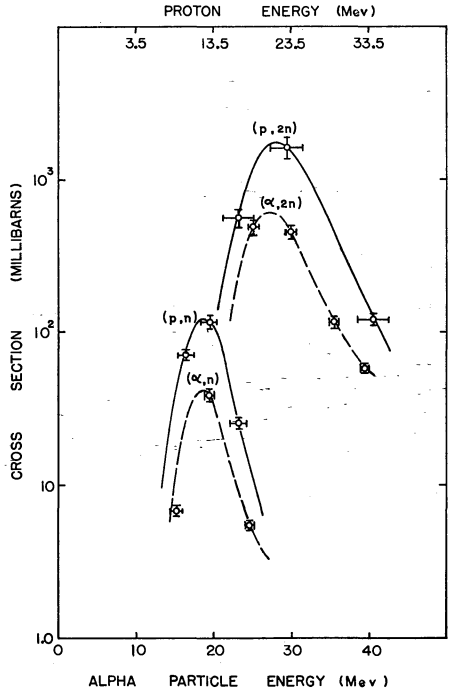

FIG. 6. Comparison of excitation functions for $Ho^{165} + \alpha$, and $Er^{168} + p$ reactions: --- $Ho^{165}(\alpha,xn)$; — $Tm^{168}(p,xn)$.

The formation cross sections for the proton reactions were interpolated from the previous excitation functions. The two excitation function sets matched when the proton energy scale was shifted by 6.5 ± 1 Mev, in good agreement with the threshold calculations. Ghoshal (44) was able to superimpose the excitation functions and observe the following ratio to hold true for the compound nucleus Zn^{64}:

$$\sigma(p,n):\sigma(p,2n):\sigma(p,pn) = \sigma(\alpha,n):\sigma(\alpha,2n):\sigma(\alpha,pn).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

TABLE V

Ratio of cross sections for reactions induced by protons and alpha particles

Proton energy (Mev)	Alpha energy (Mev)	$\frac{\sigma(p,n)}{\sigma(\alpha,n)}$	$\frac{\sigma(p,2n)}{\sigma(\alpha,2n)}$
8.5	15	2.9	
13.5	20	2.9	
18.5	25	2.5	2.9
23.5	30		3.4
28.5	35		3.6
32.5	39		3.0

John (45) was similarly able to superimpose excitation functions for the compound nucleus Po^{210} and found the following ratio to hold true:

$$\sigma(p,2n):\sigma(p,3n):\sigma(p,4n) = \sigma(\alpha,2n):\sigma(\alpha,3n):\sigma(\alpha,4n).$$

In our experiments superimposition was not possible (again perhaps due to decay scheme difficulties) but the ratio

$$\sigma(p,n):\sigma(p,2n) = \sigma(\alpha,n):\sigma(\alpha,2n)$$

held true. Similar results have been found by Gibson (46), who studied the compound nucleus Am^{241}.

TARTRATE COMPLEXES OF THE RARE-EARTH ELEMENTS

I. THE *d*-, *dl*-, AND meso-TARTRATE COMPLEXES OF Tb AND Eu[1]

P. G. MANNING[2]

Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received May 21, 1963

ABSTRACT

Solvent extraction and radiotracer techniques have been applied to the study of metal – tartrate ion association in water at 25° C. Trace concentrations of the radioisotopes Tb^{160} and $Eu^{152/154}$ were equilibrated between aqueous sodium tartrate solutions and organic phases of thenoyltrifluoroacetone in toluene. The ionic strength (0.0597) and the pH (4.53) of the aqueous phase were kept constant by means of sodium perchlorate and sodium acetate.

Metal complexing with the *d*-, *dl*-, and meso isomers of the ligand was examined. For all isomers two complex species were identified with metal:ligand ratios of 1:1 and 1:2, and stability constants for both stages of ion association have been estimated. No third (1:3) complex was detected.

Metal coordination numbers and the formation of tartrate–tartrate hydrogen bridges in the 1:2 complex are discussed.

INTRODUCTION

The application of organic acids to the separation of rare earths by successive elution from ion-exchange resins has, in recent years, stimulated research into the chemistry of these elements in solutions of carboxylic acids. Data as to the nature, number, and stabilities of the complexes formed are, however, limited to the simpler α- or β-hydroxycarboxylic acids and some multidentate aminopolycarboxylic acids.

That at least two tartrate ions will associate with a single lanthanide ion is evident from the fact that the addition of the ammonium salt of the racemic acid to an aqueous solution of a rare earth gives, initially, a precipitate, which dissolves in excess of reagent (1). Mattern (2), from spectrophotometric measurements, similarly concluded that at least two stages of ion association were involved, but the experimental accuracy was such that quantitative data in the form of stability constants were unobtainable. Manning and Monk (3) used the solvent extraction – radiotracer method to show that, in solutions of racemic tartaric acid, EuL^+ and EuL_2^- are formed (where L = ligand), and the sole reported stability constants appear to be those of these workers.

Recent publications on the complex chemistry of the lanthanides have suggested that metal coordination numbers of eight are possible. Thus the synergic extraction of the lanthanides by mixtures of acidic (HX, e.g. thenoyltrifluoroacetone) and neutral (S, e.g. tributyl phosphate) extractants proceeds through the formation of the species MX_3S_2 (4–6). If the S molecules are coordinated to the metal ion, then coordination numbers of eight must be proposed, as thenoyltrifluoroacetone is a bidentate chelating agent. Sonesson (7) and Choppin and Chopoorian (8) have shown that four glycolate ions will associate with a single metal ion, but it is possible that some of the ligands are of monodentate character. Thompson and Loraas (9) explained their results on the addition of ethylenediaminediacetic acid to 1:1 lanthanide-N-hydroxyethylethylenediaminetriacetic acid chelates on the basis of coordination numbers of greater than six. As tartrate is, potentially, a tetradentate ligand, and since ML_2^- forms, a study of lanthanide–tartrate ion-pair formation could well shed light on the problem of rare-earth coordination numbers.

The association of carboxylic acids, and other oxygenated organic molecules, in solution, has been attributed to the formation of intermolecular hydrogen bonds of the type O—H- - -O (10), and one of the aims of this work has been to determine whether ligand–ligand hydrogen bonds can form in the rigid structures of the higher complexes of metal carboxylates. Although the existence of such an intracomplex bridging phenomenon has not been reported in the literature, its presence should be manifested in the enhanced stability of the complexes. Tartaric acid seemed a promising complexing agent as it contains two carboxyls and two hydroxyls, groups that readily form hydrogen bonds.

EXPERIMENTAL

The *d*- and *dl*-tartaric acids were British Drug Houses Analytical Reagent. *l*-Tartaric acid was purchased from K and K Laboratories, Jamaica 33, New York. Molecular weight determinations by alkalimetry gave values within 0.2% of calculated. meso-Tartaric acid (K and K Laboratories) possessed a molecular weight of 167.5 (calculated for the monohydrate 168.1) and a melting point of 139° C (literature 140° C). The *d*- and *l*-isomers gave equal and opposite optical rotations, and synthetic *dl*-solutions were inactive. Stock solutions of sodium tartrate were prepared by 80% neutralization, with carbonate-free NaOH, of weighed amounts of the acids. Sodium perchlorate, used to maintain a constant ionic strength, was prepared and standardized as described in a previous publication (3). Thenoyltrifluoracetone (HTTA), obtained from the Fisher Scientific Company Ltd., was recrystallized from hexane, and stock solutions in thiophene-free toluene prepared by weight. Succinic and malic acids were Fisher Certified and Highest Purity reagents respectively.

pH constancy in the aqueous phase was ensured by the introduction of a 0.0040 *M* sodium acetate – acetic acid mixture, both these reagents being of Analytical Reagent grade. pH measurements of the aqueous phase were effected with an Electronic Instruments Ltd. (Richmond, England) Model 23A pH meter. This same instrument was also used in the determination of the p*K* values for the tartaric acids.

The radioisotopes were purchased from the Radiochemical Centre, Amersham, England. In all experiments the total metal concentration was $\sim 10^{-7}$ *M*; this ensured that extractant and ligand concentrations remained essentially constant. The γ-emitting isotopes were assayed using a NaI(Tl) scintillation detector coupled to a Nuclear-Chicago automatic sample changer.

Distribution measurements were performed by agitating 10.00 ml of both phases in ground-glass-stoppered Erlenmeyer flasks fitted with polytetrafluoroethylene (PTFE) sleeves. The flasks were suspended in a constant-temperature water bath (25.0±0.2° C) from the arms of a variable-amplitude wrist-action shaker. Three hours' shaking was ample for equilibration. All organic phases were pre-equilibrated.

THEORY

The distribution coefficient of a nuclide is

$$[1] \qquad K = \frac{\text{concentration of nuclide in organic phase}}{\text{concentration of nuclide in aqueous phase}}.$$

Adopting the convention of Sonesson (7), the overall (β) and successive (b) stability constants are

$$[2] \qquad \beta_n = \frac{[ML_n^{(3-2n)+}]}{[M^{3+}][L^{2-}]^n}$$

$$[3] \qquad b_n = \frac{[ML_n^{(3-2n)+}]}{[ML_{n-1}^{(5-2n)+}][L^{2-}]},$$

where M and L represent metal and ligand.

Since it is well established that lanthanide–ClO_4^- complexing in water is negligible (at least at $[ClO_4^-] \simeq 0.06$ *M*), then when $[L^{2-}] = 0$, from equation [1]

$$[4] \qquad K^o = \frac{[M(TTA)_3]_o}{\{[M^{3+}]+[MA^{2+}]+[MA_2^{+}]+\ldots\}_w},$$

where A^- represents the acetate ion, and "o" and "w" are organic and water phase species respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In the presence of tartrate ion,

$$[5] \qquad K = \frac{[M(TTA)_3]_o}{\{[M^{3+}]+[MA^{2+}]+\ldots+[ML^{+}]+[ML_2^{-}]+\ldots\}_w}.$$

From equations [2], [4], and [5], it can be shown (3)

$$[6] \qquad \frac{\{(K^\circ/K)-1\}}{[L^{2-}]} = \frac{\{\beta_1+\beta_2[L^{2-}]+\beta_3[L^{2-}]^2+\ldots\}}{\{1+\beta_1'[A^-]+\beta_2'[A^-]^2+\ldots\}},$$

where β and β' are stability constants for the lanthanide–tartrate and lanthanide–acetate complexes respectively.

Since only one lanthanide–acetate complex (MA^{2+}) forms under these experimental conditions (3), putting $1+\beta_1'[A^-] = D$ we get

$$[7] \qquad \frac{D\{(K^\circ/K)-1\}}{[L^{2-}]} = \beta_1+\beta_2[L^{2-}]+\beta_3[L^{2-}]^2+\ldots.$$

D is a correction factor for metal–acetate interaction, and is constant under given experimental conditions for any one lanthanide.

It follows from equation [7] that a plot of $D\{(K^\circ/K)-1\}/[L^{2-}]$ against $[L^{2-}]$ is horizontal if only ML^+ forms (whence β_1 = intercept when $[L^{2-}] = 0$), linear with positive slope if ML^+ and ML_2^- form (whence β_1 and β_2 are intercept and slope respectively), and curved (of ever-increasing curvature) if ML_3^{3-} also forms.

Stability constants have been calculated from these plots using the least mean squares analysis.

RESULTS

The pK_1 and pK_2 values for the different tartaric acids, determined by potentiometric titration (11), are given in Table I.

TABLE I

pK values for the tartaric acids at 25° C

	Isomer		
	d-	*dl-*	Meso
pK_1	2.935	2.89	3.17
pK_2	4.21	4.09	4.68

At the pH = 4.53 employed in these experiments, much of the tartrate is present as the protonated ligand HL^-. Free-ligand concentrations, $[L^{2-}]$, have, therefore, been computed from the expression

$$[8] \qquad C_L/[L^{2-}] = 1+[H^+]f_{H^+}f_{L^{2-}}/K_2,$$

where C_L is the total sodium tartrate concentration, and f_{H^+} and $f_{L^{2-}}$ are activity coefficients calculable from the Debye–Hückel expression (12)

$$[9] \qquad -\log f = 0.509z^2\{I^{\frac{1}{2}}/(1+I^{\frac{1}{2}})\}-0.2I,$$

where z is the ionic charge and I is the ionic strength. Similar calculations have been performed to estimate $[A^-]$ for the determination of D (equation [7]). The β_1' values of Kolat and Powell (13) at $I = 0.1$ have been corrected to $I = 0.0597$ using equation [9]. Also, $pK_{HA} = 4.76$ (14). For Eu and Tb, $D = 1.436$ and 1.255 respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Although a third term involving $[H^+]^2$ and K_1K_2 has been ignored in equation [8], the error introduced in $[L^{2-}]$ by so doing ($<1\%$) is much smaller than the reproducibility of the distribution coefficients ($\pm 2\%$). Also, the validity of equation [9], when used to calculate f_{H^+} and $f_{L^{2-}}$ under the present experimental conditions, must be considered. Davies (12) has shown that equation [9] is valid for 1:2 electrolytes (in the present work, HL^-) to within 2% up to $I = 0.1$. However, the aqueous phase in the present work is not pure water: it is, in fact, a mixed solvent, and activity coefficients in mixed solvents can differ appreciably from those in pure water. Manning and Monk (15) used the solvent extraction method to study cobalt–dicarboxylate complexing, and showed that the values of the parameters $\mathring{a}$ and b in the equation

$$[10] \qquad -\log f = 0.509z^2\left\{\frac{I^{\frac{1}{2}}}{1+B\mathring{a}I^{\frac{1}{2}}} - bI\right\}$$

were 4.0–4.5 and 0.15 respectively. These values agree with those of McCauley and Nancollas (16), who carried out a potentiometric examination of the same system. Also, equation [9] has been applied successfully to the analogous Eu–SO_4 system (3). We may conclude, therefore, that equations [8] and [9] are applicable to the present work.

Lanthanide–Tartrate Systems at 25° C

In Table II are listed metal distribution coefficients at different ligand concentrations.

*l-Tartaric acid.
†Synthetic *dl*-tartaric acid.
‡See text for explanation.

The *d*- and *l*-isomers were checked against each other, and a synthetic *dl*-solution against the B.D.H. racemic compound.

Plots of $\{(K^\circ/K)-1\}/[L^{2-}]$ against $[L^{2-}]$ are linear in all instances, indicating that two complexes, ML^+ and ML_2^-, are formed. Calculated values of β_1 and β_2, together with b_1:b_2 ratios, are presented in Table III. The estimated error in β_1 and β_2 is generally less than 10%.

To show that lanthanide–HL^- complexing may be ignored, a "run" was carried out with europium and *dl*-tartaric acid at a pH = 5.02, whence $C_L/[L^{2-}] = 1.050$ and $D = 1.715$. When $[L^{2-}] = 0$, $K_{Eu}^\circ = 42.0$, and when $[L^{2-}] = 6.50\times10^{-4}$ M, $K_{Eu} = 4.81$. From these figures, $D\{(K^\circ/K)\}-1/[L^{2-}] = 2.05\times10^4$. The corresponding value of $D\{(K^\circ/K)\}-1/[L^{2-}]$ at a pH = 4.53, using the information of Table II marked ‡, is 2.15×10^4. As the

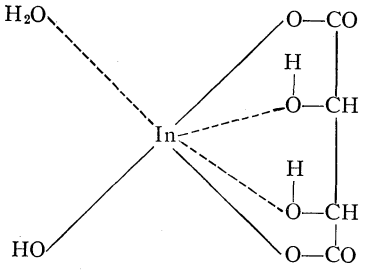
DISCUSSION

That the hydroxyl groups of the tartrate ion coordinate to the central metal ion is readily apparent from a comparison of the β_1 values of the europium complexes of succinate (1.5×10^3), malate (4.5×10^3), and tartrate ($11.8\text{–}60\times10^3$). These figures show that β_1 increases as the number of —OH groups in the ligand increased, which suggests that both the —OH groups of the tartrate ion coordinate in the ML^+ complex. An identical trend in stabilities is exhibited by the corresponding complexes of Ca, Ba, Sr, and Co (15, 17–21).

Cozzi and Vivarelli (22) have prepared a complex tartrate of indium, to which chelate they assigned the structure (with a tetradentate tartrate)



The greater stabilities of the Tb and Eu chelates of meso-tartaric acid over those of *d*- or *dl*-tartaric acid are attributable to the more favorable spatial arrangement of the hydroxyl groups of the meso-isomer. It is apparent from Fig. 1 that, unless steric crowding

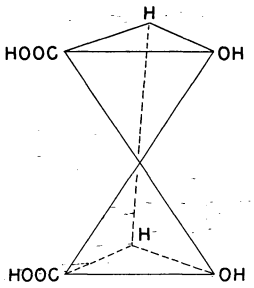


FIG. 1. Configuration of meso-tartaric acid.

around the metal ion becomes of importance, both —OH groups will bind if chelation occurs at all. It has been demonstrated for lanthanide–EDTA (ethylenediaminetetraacetic acid) complexes, that five, if not six, of the available groups coordinate to the metal ion (23, 24). It would seem that steric crowding of groups in the ML^+ complex may be insignificant.

Assuming coordination numbers of either six or eight for the rare-earth ions, the possible bonding contributions of the ligands (two tartrates and water) to the coordination number of the metal ion are shown in Table VI. For example, in scheme Y, the first tartrate to

TABLE VI

Possible bonding contributions of the ligands

Scheme	L′	L″	H_2O	Coord. No.
W	4	2	0	6
X	4	2	2	8
Y	4	3	1	8

For personal use only.

coordinate (L′) functions as a tetradentate ligand, the second (L″) as a tridentate ligand, while a molecule of water also coordinates to give a coordination number of eight. The possibility that L″ might not be tetradentate must be considered, as Betts and Dahlinger (24) suggested that the discontinuity in many of the properties of lanthanide complexes at Gd might be due to a change in configuration, e.g., in the case of EDTA, the change is one from hexa- to penta-coordination. Since, in the present work, $\beta_1(\mathrm{Eu}) > \beta_1(\mathrm{Tb})$ for all the different tartrates, it is likely that the "Gd break" effect is present in the tartrate systems also. It is unlikely, however, that the "Gd break" is a manifestation of differences in configuration, since the discontinuity is more pronounced for such simple monodentate ligands as acetate (13) and chloride (25)—where effects due to configurational differences should be at a minimum—than it is for multidentate ligands such as EDTA. Moreover, the partial molal entropies of the ion pairs, TbL′ and $\mathrm{EuL_1}'$, are approximately equal, indicating that the Eu and Tb chelates are structurally similar (26).

The relative coordinating power of L″ is reflected in the magnitude of b_1/b_2. For statistical reasons, there being fewer coordination sites available, $b_1/b_2 > 1$. On the basis of lanthanide coordination numbers of six, Bjerrum (26) has shown that for simple chelating agents, e.g. glycolate,

$$b_1:b_2:b_3 = 12:2:0.33.$$

The theoretical value of b_1/b_2 for a lanthanide glycolate would therefore be six. The average experimental value is 4.1 (7), which suggests that coordination numbers greater than six are possible. While the second glycolate ion to associate has a choice of two coordination sites out of four on the basis of a metal coordination number of six (two out of six, if eight), the choice available to L″ is limited: two from two or four from four depending on the configuration of the metal. The statistical factor demands, therefore, for lanthanide–tartrate complexes, that $b_1/b_2 \gg 4.1$ (whether the metals exert coordination numbers of six or eight). The b_1/b_2 values for the 1:2 M–*d*–*d* and M–*d*–*l* tartrate complexes of Eu and Tb range from 9.7 to 4.3, values which are incomprehensible on the basis of the Bjerrum treatment. It is apparent that a mechanism must be in operation in the second stage of ion association that confers increased stability on the ML′L″ complexes (omitting charges).

Another factor that will influence b_1/b_2 will be the number of groups of L″ coordinating to the metal ion. If neither —OH group of L″ binds, L″ is approximately equivalent to a succinate, and if one hydroxyl binds, a malate. Now b_2 (europium malate) $= 3\times10^2$, and this value gives us an upper limit to b_2 for the addition of a malate-type ion to a EuL′ complex (where L′ = meso-tartrate). Since b_1 (europium meso-tartrate) $= 60\times10^3$, then, if only one —OH group of L″ coordinates, $b_1/b_2 \simeq 200$. If neither —OH group of L″ coordinates, the value of $b_1/b_2 \gg 200$. The experimentally determined values of b_1/b_2 are 40 and 41 for Tb and Eu respectively (Table III), indicating that L″ is also of tetradentate identity. Coordination numbers of eight are, therefore, possible for the rare-earth ions.

The most striking feature of these results are the remarkably low b_1/b_2 values for the M–*d*–*d* and M–*d*–*l* complexes. The b_2 values listed in Table III show that it is more difficult for a second meso-tartrate to coordinate to Tb than it is for a *d*- or an *l*-tartrate to coordinate to a 1:1 *d*-tartrate chelate: an unexpected result considering the more favorable configuration of —OH groups in the meso-isomer. The low values of b_1/b_2 in *d*- and *dl*-tartrate systems cannot be brought about by steric hindrance, or by L′ being tetradentate and L″ being tridentate, as both these effects would lead to larger-than-expected b_1/b_2 values. Because the *d*- and *l*-isomers of tartaric acid are mirror images, a potential binding metal ion cannot distinguish between them (β_1 values Table III).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Similarly, the identical β_2 values for the M–*d*–*d* and M–*d*–*l* complexes indicate that the 1:1 *d*-tartrate chelate cannot do so either. Since the b_1/b_2 values for the meso-tartrate complexes are reconcilable with the theoretical Bjerrum treatment (27), it would seem that the enhanced β_2 values for the M–*d*–*d* and M–*d*–*l* species are linked with the orientation of the —OH groups of the tartrates. To explain these results, therefore, it is necessary to postulate tartrate–tartrate hydrogen bridging in the M–*d*–*d* and M–*d*–*l* chelates. The orientation of the active groups must, from a comparison of the stability constants listed in Table III, be identical in the metal chelates of *d*- and *dl*-tartaric acid, while the configuration of the M–meso–meso complex is such that hydrogen bridging is absent or very weak.

Three bridging models are possible, depending on the active groups involved and the nature of the hydrogen bond formed. For example, in one model O—H - - - O hydrogen bridging occurs via the —OH groups of L′ and the —OH groups of L″, while a similar type of bridge could be formed between the —OH and the —COO^- of different ligands. Another mode of orientation of L′ and L″ could induce bridging between the —OH of one ligand and C—H of the other ligand, but evidence for the existence of C—H - - - O bonds is scant (10).

Insufficient experimental data are available at the present time to warrant giving a detailed picture of the molecular configurations in the three models, but it is hoped to present a theoretical treatment to account for these results in a future publication in this series.

CONCLUSIONS

Two tartrate ions (whether *d*-, *dl*-, or meso-), functioning as tetradentate ligands, coordinate with a central lanthanide ion, conferring on the latter a coordination number of eight.

The trends in stabilities for the two stages of ion association are

$$M^{3+} + L^{2-} = ML^{+};\ \text{meso} > d = dl$$

$$ML^{+} + L^{2-} = ML_2^{-};\ \text{meso} \leqslant d = dl.$$

A suggestion has been made that ligand–ligand hydrogen bridging may be responsible for the extra stability of ML_2^- complexes of *d*- and *dl*-tartaric acid.

TARTRATE COMPLEXES OF THE RARE-EARTH ELEMENTS

II. THE *dl*- AND meso-TARTRATE COMPLEXES OF La, Ce, Pm, Tm, AND Y[1]

P. G. MANNING[2]

Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada

Received June 10, 1963

ABSTRACT

The liquid–liquid distribution method has been used to measure the stability constants of the *dl*-tartrate complexes of La^{3+}, Ce^{3+}, Pm^{3+}, Tm^{3+}, and Y^{3+}, and the meso-tartrate complexes of Ce^{3+} and Tm^{3+}. Thenoyltrifluoroacetone was the organic phase extractant, and the aqueous phase, acetate buffered (pH = 4.53), was maintained at a constant ionic strength (0.0597) by means of sodium perchlorate.

The order of stabilities for the two stages of ion association are

$$M^{3+} + L^{2-} = ML^{+};\ \text{meso} > dl$$

$$ML^{+} + L^{2-} = ML_2^{-};\ \text{meso} < dl.$$

The b_1/b_2 values, where b is a stepwise stability constant defined as

$$b_n = [ML_n^{(3-2n)+}]/[ML_{n-1}^{(5-2n)+}][L^{2-}],$$

are lower (by factors of 4–8) for the *dl*-tartrates than for the meso-tartrate complexes. The b_1/b_2 ratios decrease as the ionic radius of the metal ion decreases, and for the *dl*-tartrates of Tb^{3+}, Y^{3+}, and Tm^{3+}, the b_1/b_2 values are 5.3, 5.0, and 4.3 respectively. The enhanced stabilities of the 1:2 (ML_2^-) *dl*-tartrate chelates have been interpreted in terms of ligand–ligand hydrogen bridging in the 1:2 complex.

INTRODUCTION

In Part I of this series (1), it was proposed that the enhanced stabilities of the 1:2 chelates of Tb and Eu with *d*- and *dl*-tartaric acid were attributable to ligand–ligand hydrogen bridging. In the present paper we report additional results for *dl*-tartrate complexing with La^{3+}, Ce^{3+}, Pm^{3+}, Tm^{3+}, and Y^{3+}, and also meso-tartrate complexing with Ce^{3+} and Tm^{3+}.

A qualitative account of three possible hydrogen bridging models, depending on the groups involved and the nature of the hydrogen bond formed, is presented.

EXPERIMENTAL

The experimental details are identical with those described in Part I of this series (1).

Carrier-free La^{140} was "milked" from a Ba^{140}/La^{140} fission product mixture by extraction with thenoyltrifluoroacetone (HTTA) at pH = 4.53, followed by back extraction of any traces of Ba^{140} with an aqueous phase of identical composition. The other (β-emitting) radioisotopes, of high specific activity, were purchased from the Radiochemical Centre, Amersham, England. The β-emitters were assayed using a conventional Geiger–Müller counter, and the La^{140} using a NaI(Tl) scintillation detector.

The temperature was maintained at 25.0±0.2° C.

THEORY

The distribution coefficient of a given nuclide is

$$[1] \qquad K = \frac{\text{concentration of nuclide in organic phase}}{\text{concentration of nuclide in aqueous phase}}.$$

[1]*Crown copyright reserved.*

[2]*National Research Council of Canada Postdoctoral Fellow.*

The overall (β) and stepwise (b) stability constants are

[2] $$\beta_n = [ML_n^{(3-2n)+}]/[M^{3+}][L^{2-}]^n$$

and

[3] $$b = [ML_n^{(3-2n)+}]/[ML_{n-1}^{(5-2n)+}][L^{2-}]^n.$$

The theoretical deviation of the equation,

[4] $$D\{(K^\circ/K)-1\}/[L^{2-}] = \beta_1+\beta_2[L^{2-}]+\beta_3[L^{2-}]^2+\ldots$$

has been described in greater detail in previous publications (1, 2). Here, $K^\circ = K$ when $[L^{2-}] = 0$, and D ($= 1+\beta_1'[Ac^-]$, where β_1' represents the stability constants for the 1:1 lanthanide acetate complex) is a correction factor for metal–acetate interaction. The D values, evaluated using the β_1' values of Kolat and Powell (3), are given in Table I. The

TABLE I

D values for lanthanide–acetate complexing

Metal	La	Ce	Pm	Tm	Y
D	1.177	1.210	1.287	1.176	1.159

method of calculation of free ligand concentrations has also been described previously (1).

It follows from equation [4], therefore, that a plot of $D\{(K^\circ/K)-1\}/[L^{2-}]$ against $[L^{2-}]$ is horizontal if ML^+ forms, linear with positive slope if ML^+ and ML_2^- form, and curved if ML_3^{3-} also forms.

RESULTS

In Table II are presented metal distribution coefficients at different ligand concentrations. The K values were generally reproducible to $\pm 3\%$.

For all the metals studied, and for both stereoisomeric forms of tartaric acid, plots of $D\{(K^\circ/K)-1\}/[L^{2-}]$ against $[L^{2-}]$ were linear, indicating that ML^+ and ML_2^- are formed. The estimated values of β_1, β_2, b_2, and b_1/b_2 are collected in Table III. The estimated errors in β_1 and β_2 are $\pm 10\%$. The least mean squares analysis was applied to the plots.

DISCUSSION

If the β_1 values for the Tb and Eu chelates (measured in Part I of this series, ref. 1) are included for comparison, it is observed that the spectrum of β_1 values for the lanthanide

*Part I of this series (1).

tartrates (both *dl*- and meso-) conforms with the trend exhibited by rare-earth complexes generally. β_1 values increase with decreasing ionic radius from La to Eu, but at this point a discontinuity occurs, and $\beta_1(\text{Tb}) < \beta_1(\text{Eu})$. From Tb to Lu, stabilities again increase with decreasing ionic radius.

The β_1 value for the *dl*-tartrate complex of Y is close to that of Ce, giving Y a lanthanide atomic number equivalent of 58. From consideration of ionic radii (4), one would expect Y (r = 0.90 Å) to be closest in its chemical properties to Ho (r = 0.89 Å) or Dy (r = 0.91 Å), bestowing upon Y a lanthanide atomic number equivalent of 67.6. However, the b_1/b_2 values, when correlated with ionic radius, place Y between Tb and Tm (Z = 65 and 69 respectively). In its chemical properties generally, the position of Y on this atomic number scale is extremely nomadic, and in very few instances, e.g., the extraction by tributyl phosphate (5) from strong nitric acid solutions, does the lanthanide atomic number equivalent of Y equal 67.6. Usually, Y behaves as a lanthanide of $Z < 67.6$, while for ionic complexes with, e.g., acetate (3) and sulphate (6), Y cannot be placed on the atomic number scale at all, i.e., $Z < 57$. In most of its reactions, therefore, Y behaves like a rare earth of effective ionic radius greater than that of Ho or Dy, suggesting that Y retains its hydration shell to a much greater extent than do either Ho or Dy. Moreover, Schwarzenbach (7) has shown that the properties of Y are closest to those of Ho and Dy when it forms strong complexes. These complexes are generally formed by association with powerful chelating or coordinating agents, e.g., ethylenediaminetetraacetic acid or tributyl phosphate, reagents that readily displace hydration sheaths (8). The nomadic behavior of Y on the rare-earth atomic number scale could, conceivably, be due to hydration effects, Y forming, in its weaker complexes "outer sphere" ion pairs. The b_1/b_2 value for the *dl*-tartrate chelate suggests that, in the 1:2 complex, the hydration sheath has been displaced to the same degree as for Ho and Dy.

In Part I of this series (1) it was shown that the b_1/b_2 values for the *d*- and *dl*-tartrate complexes of Tb and Eu were irreconcilable with the Bjerrum statistical treatment (9), and it was concluded that a mechanism was present in the second stage of ion association whereby the stability of the ML_2^- species (hereafter denoted as ML'L'', where L' designates the first tartrate ion to coordinate, and L'' the second) was increased. The b_1/b_2 values for the corresponding meso-tartrates were greater than those for the *d*- or *dl*-complexes by factors of 4–8, indicating that the effect responsible for the increased stability of the 1:2 M–*d*–*d* (i.e., ML'L'' where L' = L'' = *d*-tartrate) and M–*d*–*l* chelates is either absent, or very weak in the 1:2 M–meso–meso complexes. The low b_1/b_2 values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(Table III) measured for the *d*- and *dl*-tartrate chelates were attributed to hydrogen bridging in the 1:2 complex.

As Table III shows, b_1/b_2 values for the 1:2 M–meso–meso species decrease with decreasing ionic radius of the central metal ion. It would seem, therefore, that either steric hindrance is negligible or that hydrogen bridging, although comparatively weak, is, nevertheless, strong enough to overcome steric obstruction.

In solutions of *dl*-tartaric acid, the species M–*d*–*d*-, M–*l*–*l*, M–*d*–*l*, and M–*l*–*d* will be formed, but the structures M–*d*–*d* and M–*l*–*l* are equivalent, as are also M–*d*–*l* and M–*l*–*d*. The equivalence in complexing power of *d*- and *dl*-tartaric acid (1) indicates that the orientation of the bridging groups of L′ relative to those of L″ must be identical in the M–*d*–*l* and M–*d*–*d* complexes.

Tartaric acid is well endowed with carboxyl and hydroxyl groups, each of which is a potential bridging site. Three bridging models have been considered, two of which are based on O—H - - - O hydrogen bridging, in the first instance via the —OH groups of L′ and L″, and in the second via the —OH of one ligand and the COO^- of the other. A third model would involve C*—H - - - O bridging via the —OH of one ligand and the C*—H of the other. C* represents an asymmetric C atom.

Model A: O—H - - - O Bridging via —OH of L′ and L″

Figures 1(*a*)–1(*c*) represent the structural configurations of *d*-, *l*-, and meso-tartaric

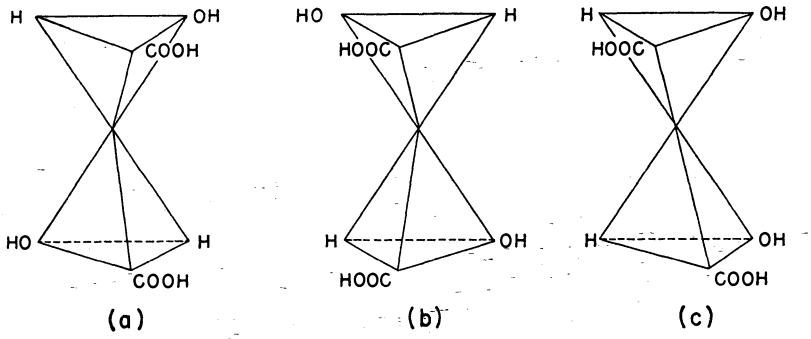

FIG. 1. Configurations of the tartaric acids: (*a*) *d*-tartaric acid; (*b*) *l*-tartaric acid; (*c*) meso-tartaric acid.

acids. For pictorial clarity the tetrahedral space formula for tartaric acid has been used.

Let us, first of all, consider metal complexing in solutions of *d*-tartaric acid, and, more specifically, the two-stage reaction (omitting ionic charges)

$$M + L' = ML'$$
$$ML' + L'' = ML'L''$$

where L′ = L″ = *d*-tartrate. Further, let us consider the probable position of the metal ion in relation to the coordinating groups of L′. Since all four groups of L′ coordinate (1), the metal ion (dotted line in Fig. 2) will be symmetrically placed relative to them. It should be stressed that this and following figures are purely diagrammatic, and serve to give a qualitative picture only. It is difficult to construct atomic models with any geometrical precision, as it is certain that some geometrical distortion of the ligands will occur on complexing. It is possible, for example, that the C*—C* bond axis will attain some curvature, the degree of which depends on how close the ions approach each other.

If we compare the b_1/b_2 values for the *d*- and *dl*-tartrates with those for meso-tartrates,

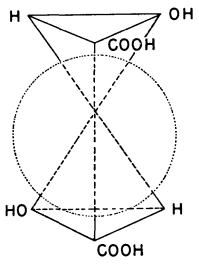

FIG. 2. Configuration of the 1:1 *d*-tartrate complex.

it is evident that hydrogen bridging occurs in the 1:2 *d*- and *dl*-tartrate complexes of all the metals studied. The strengths of the hydrogen bridges in the M–*d*–*d* and M–*d*–*l* complexes will naturally increase as the ionic radius of the metal ion decreases, thus explaining the trend in the b_1/b_2. Since La and Tm have ionic diameters of 2.16 and 1.74 Å respectively (4), it is apparent that some latitude in the geometrical dimensions of the reacting ions in Fig. 2 is permissible. Figure 2 seems a reasonable representation when we consider that C*—C*, C*—C, and C*—OH bond lengths are all of the order of 1.5 Å (10).

The next step to be considered is the addition of L″ to ML′. Rotating Fig. 1(*a*) on its base through an angle of 180° and superimposing directly on Fig. 2, it is evident that the —H and —OH attached to the C* of L′ are, respectively, immediately opposite the —OH and —H of L″. By further rotating L″ on an axis perpendicular to the plane of the paper, it is possible to align the two —OH groups of L″ with those of L′, an orientation conducive to the formation of hydrogen bridges across the M–*d*–*d* complex. Figure 3(*a*) depicts the type of structure conceived, the hydrogen bridges being depicted by arrows.

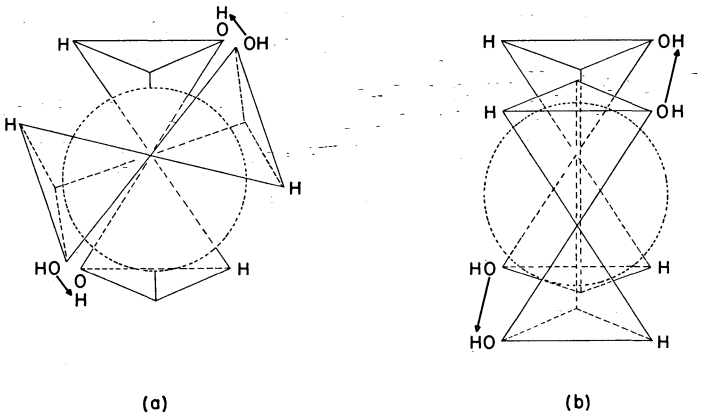

FIG. 3. (*a*) Configuration of ML′L″ (O—H - - - O bridging); L′ = L″ = *d*-tartrate. (*b*) Configuration of ML′L″ (O—H - - - O bridging); L′ = *d*-tartrate, L″ = *l*-tartrate.

Since *d*- and *dl*-tartaric acids give complexes of similar stabilities, the bridging mechanism must, perforce, be in operation in the 1:2 M–*d*–*l* complexes also. The configuration of Fig. 3(*a*) does not, however, represent the system where L′ = *d*-tartrate and L″ = *l*-tartrate, as the —OH groups would no longer be adjacent. If Fig. 1(*b*) is rotated on its base through an angle of 180° and superimposed directly on Fig. 2, the configuration for optimum hydrogen bridging is again achieved (Fig. 3(*b*)).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Model A has some disadvantages, however. Thus the O atoms of the hydroxyls are already coordinated to three other atoms, and it is reasonable to propose that steric crowding around the O atom may be sufficiently important to prevent its taking part in a hydrogen bond. Moreover, it has been assumed that L′ and L″ are able to orientate themselves, after coordination to the metal ion, in order to make the O—H - - - O bond lengths in the M–*d*–*d* and M–*d*–*l* complexes equal.

Model B: C—H - - - O Bridging*

The possibility exists that four C*—H - - - O hydrogen bridges, involving the —OH groups of L′ and the H atoms attached to the C* of L″ (and vice versa), could be formed in the ML′L″ complex. For complexes with racemic acid, if we rotate Fig. 1(*b*) (*l*-isomer) through 180° on its base and through 45° on an axis perpendicular to the plane of the paper, then superposition on Fig. 2 brings into alignment four (C*—H) hydrogen atoms and four —OH groups. The resultant complex, stabilized by four hydrogen bridges, resembles a Maltese cross (Fig. 4). Again, when L′ = L″ = *d*-tartrate, the rotation of

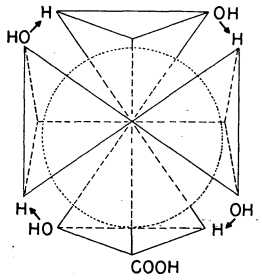

FIG. 4. Configuration of ML′L″ (C—H - - - O bridging); L′ = *d*-tartrate, L″ = *l*-tartrate.

Fig. 1(*a*) through 180° on its base and superposition on Fig. 2 could also bring about hydrogen bonding. However, in only one system, the association of chloroform with strong bases such as pyridine, has conclusive evidence been obtained that a C*—H group can function as a H-bonding acid (11). Since hydrogen bonding in the chloroform–pyridine system is facilitated by the activating influence of three Cl atoms, and since O is more electronegative than C, it would seem that C*—H - - - O bridging in the 1:2 complexes of metal tartrates is comparatively unlikely.

Model C: O—H - - - O Bridging via —OH and —COOH

A hydrogen bridging structure that seems to be the most likely is one involving the —OH groups of one ligand and the C=O of the carboxyl groups of the other ligand. Such a model has one great advantage over models A and B, in that less emphasis is placed on the relative orientation of L′ and L″. In models A and B, it was postulated that the bridging groups (—OH and C*—H) were positioned "off-center" with respect to the metal ion, and to explain the similar stabilities of the M–*d*–*d* and M–*d*–*l* complexes, it was necessary to assign fixed, but different, orientations for L′ and L″ (Figs. 3(*a*), 3(*b*), and 4). It was pointed out in Part I of this series (1) that an ML′ chelate cannot differentiate between a potential binding *d*-tartrate and an *l*-tartrate. Now a —COO^- group of L′ cannot distinguish between a *d*- or an *l*-tartrate either, since the difference would be one between identical groups being to its left and to its right. It follows, therefore, that whatever the relative orientation of L′ and L″, hydrogen bridging, through the —COO^- of L′ and the —OH of L″, will be identical in the M–*d*–*d* and M–*d*–*l* complexes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

On the basis of an electrostatic model for hydrogen bonding, one would expect that the strength of an O—H - - - O bond formed between —OH and —COOH groups would be greater than that for a similar bond formed via two —OH groups, due to the greater dipole moment of the carboxyl oxygen. Coulson (12) has pointed out, however, the absence of correlation between dipole moment and the strength of a hydrogen bond, indicating that a hydrogen bond has appreciable covalent character. According to Coulson and Danielsson (13), the degree of covalent character associated with a hydrogen bond depends on the bond length; the shorter the bond length the greater the covalency. As the hydrogen bond length is unknown in the 1:2 metal chelates, and since hydrogen bond lengths between similar groups can vary appreciably, it is not possible to presume, on the basis of dipole moments, that hydrogen bridging through the C=O group is favored.

The configurations of the M–*d*–*d* and M–*d*–*l* complexes have not been drawn diagrammatically, as model C imposes no restrictions on the relative orientations of L′ and L″. Presumably, L′ and L″ are positioned at random with respect to each other, and the extreme positions would be represented by the configurations of Figs. 3(*a*) and 4, although hydrogen bridging would occur through the —OH and —COO^- groups.

From the magnitudes of the b_1/b_2 values, bridging must be much weaker in the M–meso–meso complexes. Let us suppose that Fig. 5 represents the 1:1 meso-tartrate chelate, and let us consider the extreme ligand positions whereby hydrogen bridging in the 1:2 complex is first at a maximum, and then at a minimum. Thus the rotation of Fig. 1(*c*) through 45°, anticlockwise, on its base, and superposition of Fig. 5 brings into alignment the carboxyls

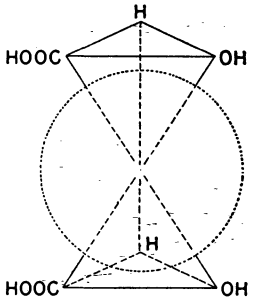

FIG. 5. Symmetrical structure of 1:1 meso-tartrate complex.

and hydroxyls of different ligands, a criterion for strong hydrogen bonding. Also, by rotating Fig. 1(*c*) through 45° clockwise, inverting end-over-end, and then superimposing on Fig. 5, it is evident that the —COO^- and —OH groups of L′ are, respectively, opposite their counterparts of L″. In this configuration, hydrogen bridging would be at a minimum. Statistically, therefore, the degree of hydrogen bridging in the M–meso–meso complexes should be of the same order of magnitude as that in the M–*d*–*d* and M–*d*–*l* chelates. The much greater b_1/b_2 values for the 1:2 meso-tartrates (indicating weaker hydrogen bridging) suggest that a model in which the two —OH and the two —COOH groups have an "equal share" of the cation is incorrect, and that an unsymmetrical configuration, as depicted in Fig. 6, might be a better representation of the 1:1 meso-tartrate chelate. The coordination of L″ to ML′ results in a "staggered" configuration (Fig. 7), in which hydrogen bridging is considerably weakened. Figure 7 indicates that the two coordinated ligands are in fixed orientation relative to each other, but if the unsymmetrical configuration of ML′ (Fig. 6) is correct, then it is conceivable that electronic distortion of the cation renders the "staggered" structure for the M–meso–meso complex the most stable.

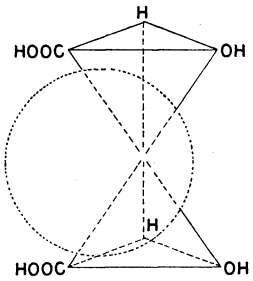

FIG. 6. Unsymmetrical structure of 1:1 meso-tartrate complex.

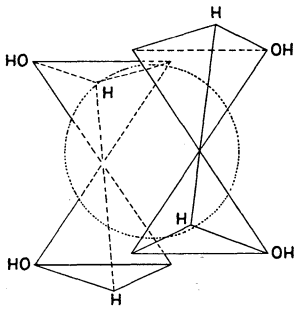

FIG. 7. Staggered configuration of ML'L''; L' = L'' = meso-tartrate.

The approximate dimensions of the 1:2 M–*d*–*d* and M–*d*–*l* complexes may be gauged from the fact that hydrogen bond lengths are normally of the order of 2.5–3 Å. Depending on the degree of geometrical distortion of the ligands, this would suggest an upper limit of about 5 Å for the "diameter" of the complex along the L'—M—L'' axis. Manning and Monk (14) showed that the mean distance of approach of Co and tartrate ions was 4.0 Å, indicating that in the M–*d*–*d* and M–*d*–*l* complexes bonding is covalent in character, or that the ions are stripped of their hydration sheaths and are in contact.

It is interesting to compare our results with those of Fronaeus (15) for complexing between Cu^{2+} and *d*- or *dl*-tartaric acids. This worker found that β_1(Cu *d*-tartrate) > β_1(Cu *dl*-tartrate), while β_2(Cu *d*-tartrate) = β_2(Cu *dl*-tartrate). Four tartrates coordinated to a single Cu^{2+}, and β_3(Cu *d*-tartrate) < β_2(Cu *d*-tartrate), indicating that structural changes, brought about by the coordination of L''', have resulted in a weaker complex.

CONCLUSION

The increased stability of the ML_2^- complexes of lanthanide ions with *d*- and *dl*-tartaric acid has been ascribed to ligand–ligand hydrogen bridging. Three different hydrogen bridging models have been described. It is proposed that O—H - - - O bridging occurs via the —COO^- groups of one ligand and the —OH groups of the other.

Some light could be shed on this problem of hydrogen bridging in metal chelates, by examining the infrared and Raman spectra of Th(tartrate)$_2$, and some work along those lines is in progress.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to the National Research Council of Canada for the award of a Fellowship, and to Dr. G. G. Eichholz for many stimulating discussions.

PROTONATED CARBONYL GROUPS

II. γ-PYRIDONE SALTS[1]

DENYS COOK

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received June 10, 1963

ABSTRACT

The salts of 1,2,6-trimethyl-4-pyridone and 1-ethyl-2,6-dimethyl-4-pyridone and mineral acids and their deuterated analogues have been prepared and their spectra recorded. The spectra are consistent with protonation at the carbonyl oxygen atom, not the nitrogen atom. Many similarities with the spectra of γ-pyrone salts (D. Cook. Can. J. Chem. **41**, 505 (1963)) have been observed. ν_{OH} varies from 2495 cm^{-1} in the HCl salt to 3470 cm^{-1} in the HPF_6 salt. The deformation mode, ν_{OH}, is much more constant in frequency and is doubled, near 1300 and 1230 cm^{-1}, probably due to correlation field splitting. A few of the more strongly hydrogen-bonded salts have torsional modes around 800 cm^{-1}.

Many of the salts can also be prepared in a hydrated form which contains the same organic cation, probably hydrogen bonded to chains of water molecules.

In one case a salt containing 2 molecules of the base to 1 of acid ($HAsF_6$) has been prepared. The spectrum contains a very broad, strong band, near 1300 cm^{-1}, probably due to the species $[B\cdots H\cdots B]^+AsF_6^-$.

INTRODUCTION

The vibrational spectra of γ-pyrones (1) and γ-pyridones (2, 3) and their complexes with Lewis acids (4, 5) have recently been recorded. The latter were consistent with the view that the donor site was the carbonyl oxygen atom. Several protonated γ-pyrones revealed interaction at the same site (6).* Though there was a wide variation in the frequency of the OH stretching vibration, ν_{OH}, depending on the nature of the anion, O—H···X⁻, the bending mode, δ_{OH}, was much more constant (±18 cm^{-1}) while the torsional mode, γ_{OH}, was not observed.

Since the γ-pyridones are structurally very similar to the γ-pyrones, and are made from them by simple reactions, it was of interest to see if the spectroscopic behavior of protonated γ-pyridones was similar to that of γ-pyrones.

Previous work on the n.m.r. spectra of γ-pyridone salts in solution led to the conclusion that oxygen protonation took place (7). However, the vibrational spectrum of 4-pyridone.HCl was interpreted on the basis of a protonated nitrogen atom (8).

RESULTS

The frequencies of the absorption bands have been abstracted from the spectra and are shown in Tables I and II for 1-ethyl-2,6-dimethyl-4-pyridone and 1,2,6-trimethyl-4-pyridone salts respectively. The bands due to the stretching vibrations of the protonating hydrogen and deuterium atoms are collected in Table III, and those due to the in-plane deformations in Table IV.

The spectrum of a representative 1-ethyl-2,6-dimethyl-4-pyridone salt is shown in Fig. 1, the solid line being that of the H_2SnCl_6 salt, the broken line being that of the deuterated salt. The 1,2,6-trimethyl-4-pyridone salts have very similar spectra except for differences in absorptions due to the nitrogen alkyl group vibrations.

DISCUSSION

Anhydrous 1:1 Salts

Most of the important features in the spectra of the γ-pyrone salts (6) are duplicated in those of the γ-pyridone salts. These include the strong absorption with multiple peaks centered near 2495 cm^{-1} in the HCl salt, moving and narrowing as the anionic influence weakens to 3470 cm^{-1} in the HPF_6 salt. In the deuterated salts the expected shifts to lower frequency occur, the isotopic ratios being between 1.29 and 1.35 (see Table III).

The in-plane hydrogen-bending mode is doubled, and at a similar frequency in the

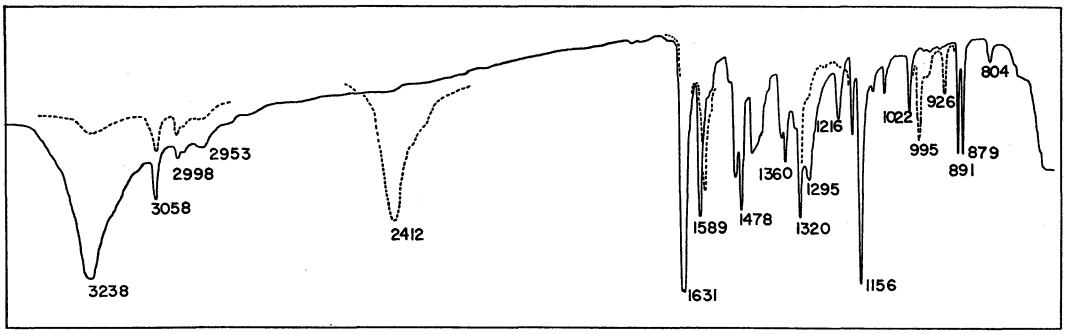

FIG. 1. Infrared spectrum of (1-ethyl-2,6-dimethyl-4-pyridone)$_2$.H_2SnCl_6, solid line; deuterated salt, broken line.

two sets of compounds. In the γ-pyridone salts there is a doublet near 1300 and 1230 cm^{-1} with slight variation in the different salts. A plot of ν_{OH} against δ_{OH} reveals a trend to higher deformation frequencies as the stretching frequency lowers. This is in keeping with the view (9) that stronger hydrogen bonds have higher δ_{OH} and lower ν_{OH}, but the plot is very scattered with a poor correlation. The higher-frequency component of the doublet is the more intense, but part of this may be due to another strong band close to it near 1320 cm^{-1}. On deuteration these bending modes give absorption bands near 1000 and 930 cm^{-1}, of comparable intensity, with isotopic ratios near 1.30.

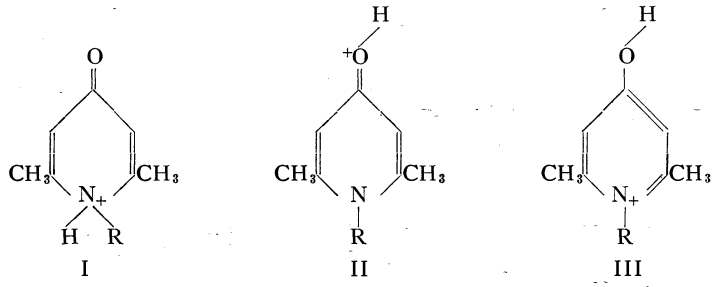
The splitting of the in-plane hydrogen-deformation mode into two components near 1300 and 1230 cm^{-1} recalls similar doubling in γ-pyrone salts (6), which was attributed to correlation field splitting. The similarity of the splittings both in frequency and separation suggests that a very similar space group will be involved in the structural arrangements in these γ-pyridone salts. The N-alkyl groups, which constitute the sole difference between the γ-pyridones presently considered and the γ-pyrones, would be expected to play a minor part in the determination of the crystal structure, the hydrogen bond having a dominant role. Other possible causes for the doubled bending mode have been sought but none is as satisfactory as correlation field splitting. Fermi resonance of a single bending mode with an overtone or a combination tone can be discounted in view of the isotope shifts, except if a torsional mode having a constant frequency also involving an isotopic shift were involved. This again can be rejected because of the large variation in position of the torsional modes (862, 800, and 745 cm^{-1} respectively in the HCl, HBr, and HI salts of 1-ethyl-2,6-dimethyl-4-pyridone). Two distinctly different crystallographic environments could cause splitting; but as the largest and smallest values of δ_{OH} differ by 28 cm^{-1} it seems unlikely that the observed splittings (average 76 cm^{-1}) can be explained in this way.

All these bands (with the exception of those due to the torsional mode) are so similar to those in γ-pyrone salts that a strong presumption of a similar protonation site is present. Further evidence can be derived from the carbonyl and ring stretching frequencies. All the salt spectra show a very strong band at about 1630 cm^{-1}, a weaker one at about 1480 cm^{-1}, and a still weaker one near 1583 cm^{-1}. In 1-ethyl-2,6-dimethyl-4-pyridone itself these bands are at 1638, 1566, and 1547 cm^{-1} respectively. In the Lewis acid complexes (5) only one band at 1566 cm^{-1} showed any change in position, and this in a progressive manner to lower frequency as the Lewis acid strength increased. This band was assigned to the carbonyl stretching vibration. In the protonated salts the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

band at 1480 cm^{-1} is to be associated with the carbonyl frequency, and the two bands at 1630 and 1580 cm^{-1} with the ring modes. Again, this behavior follows very closely that of the protonated γ-pyrones. Furthermore, the spectra of salts of 1-ethyl-2,6-dimethyl-4-thiopyridone, while showing a strong band near 1620 cm^{-1} and a weaker one near 1560 cm^{-1}, have no band near 1480 cm^{-1}, which strengthens the assignment of the protonated carbonyl group stretching vibration to the 1480 cm^{-1} band.

Evidence is thus accumulating that a protonated carbonyl group has in-plane hydrogen-bending frequencies near 1260 cm^{-1} (mean value of split components), for example, the salts of 1-ethyl-2,6-dimethyl-4-pyridone, 1261 cm^{-1}; 1,2,6-trimethyl-4-pyridone, 1246 cm^{-1}; 2,6-dimethyl-4-pyrone, 1253 cm^{-1} (6); 4-pyrone, 1273 cm^{-1} (6); N,N dicyclohexylacetamide, 1287 cm^{-1} (10); antipyrine, 1260 cm^{-1} (11). (The N,N-dicyclohexylacetamide value may be slightly affected by coupling, in that the ratio of the hydrogen and deuterium deformation frequencies is 1.18, whereas in all the other salts listed it is near 1.31.) It has been pointed out before (6) that these deformation frequencies are very different from those of protonated tertiary (sp^3) amines, which are close to 1400 cm^{-1}, for example, $(CH_3)_3N$ salts, 1420 cm^{-1} (12, 13); triphenylamine salts, 1390 cm^{-1} (13); N-alkylpiperidine salts, 1400 cm^{-1} (14); NH_4^+ salts, ν_4, 1390 cm^{-1} (15, 16). These values are so well founded that it is possible to assert with some confidence that a structure such as I is not consistent with the experimental data, while structure II is.



Experimental evidence is also accumulating that a protonated carbonyl group results in a carbonyl stretching frequency in the region 1400–1500 cm^{-1}, for example, the salts of 1-ethyl-2,6-dimethyl-4-pyridone, 1475 cm^{-1}; 1,2,6-trimethyl-4-pyridone, 1485 cm^{-1}; 2,6-dimethyl-4-pyrone, 1480 cm^{-1} (6); 4-pyrone, 1490 cm^{-1} (6); N,N-dicyclohexylacetamide, 1400 cm^{-1} (10). The last value may be slightly affected by coupling.

It could be suggested that since the salts with weak hydrogen bonding between the OH group and the anion have high values of ν_{OH} (close to values for phenols) III would represent a realistic description of the structure of the cation. This would neglect the rather high stretching frequency of the CO bond. At about 1480 cm^{-1} this is somewhat higher than in phenols. A CO bond distance appropriate to this stretching frequency has been derived (ref. 17 and unpublished work) of about 1.28 Å. This is a good deal smaller than the CO bond distance in some phenols, for example, 4-isopropylideneaminophenol, 1.38 Å (18), α-resorcinol, 1.35 Å (19), indicating a significant contribution from π-electron binding in the CO bond in the pyridone salts. This contribution must be sensibly constant too in all the salts considered, since the position of all bands other than those due to the OH group are remarkably constant in frequency.

Anhydrous 2:1 Salts

It is possible to prepare a salt of 1-ethyl-2,6-dimethyl-4-pyridone and $HAsF_6$ containing 2 moles of base to 1 of acid. Its spectrum is significantly different from those

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the 1:1 salts (see Fig. 2) and is characterized by lack of absorption in the region above 2500 cm^{-1}, but has a strong, broad absorption near 1300 cm^{-1}.

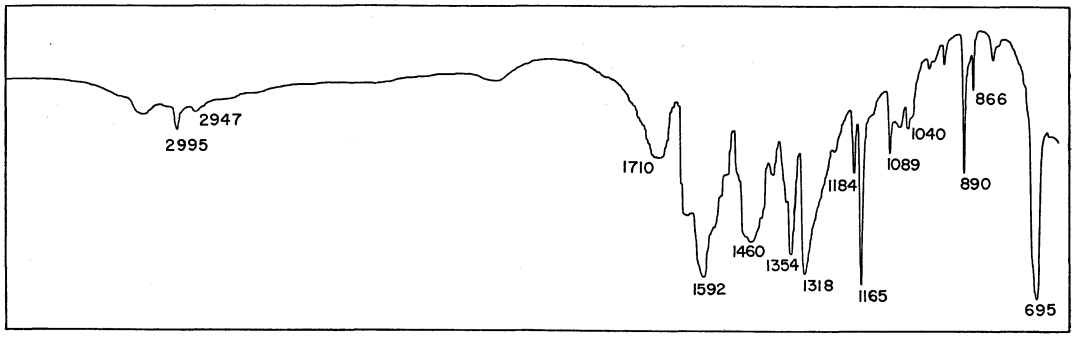


FIG. 2. Infrared spectrum of (1,2,6-trimethyl-4-pyridone)$_2$.$HAsF_6$.

Similar complex acids have been found to give anomalous 2:1 salts with pyridine-1-oxides (20), and the suggested structure was $[C_5H_5NO\cdots H\cdots ONC_5H_5]^+MX_n^-$. Other bases which have been found to give 2:1 salts are trimethylamine oxide, triethylamine oxide, 2,6-dimethyl-4-pyrone, 1-methyl-2-pyridone, and 1-methyl-2-quinolone (21).

The high intensity, low frequency, and great breadth of the bands due to the proton in these 2:1 salts are associated with very short, probably symmetrical, hydrogen bonds as was described by Albert and Badger (22) and Takei (23) for acetamide hemihydrochloride, by Kutzelnigg and Mecke for other acetamide salts (24) and some urea salts (25), and by Hadzi for salts of various oxide bases (26).

Hydrated 1:1 Salts

The hydrated salts incorporate 1 molecule of water into the lattice for each molecule of base. This alters the absorption bands above 2000 cm^{-1} but makes little difference to those below this region. In particular, the bands at 1630, 1580, and 1480 cm^{-1} are unchanged. The in-plane hydrogen-deformation vibration still gives rise to a doubled absorption near 1230 and 1300 cm^{-1}. The pyridone cation is therefore present, which makes it likely that the hydrate structure is $(BaseH)^+.X^-.H_2O$ rather than $Base.H_3O^+.X^-$. The OH stretching vibrations above 2000 cm^{-1} show some unusual splittings and are being investigated further.

EXPERIMENTAL

1-Ethyl-2,6-dimethyl-4-pyridone

This was prepared as described previously (5).

HCl Salt

The preparation has been previously described (5).

HBr Salt

A chloroform–ether solution of the anhydrous pyridone was treated with anhydrous HBr, depositing the anhydrous salt; m.p. 234–235°. Found: HBr, 34.1%. Calc. for $C_9H_{13}NO.HBr$: HBr, 34.8%.

HI Salt

The same technique was used with anhydrous ethereal HI (from aqueous HI, by shaking with ether then drying with anhydrous Na_2SO_4), giving the anhydrous salt; m.p. 208–210°. Found: HI, 45.3%. Calc. for $C_9H_{13}NO.HI$: HI, 45.8%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

H_2SiF_6 Salt

The anhydrous pyridone (0.76 g) and aqueous (30%) H_2SiF_6 (1.2 g) were mixed and the excess water removed *in vacuo*; m.p. 150–151°. Found: H_2SiF_6, 32.2%. Calc. for $(C_9H_{13}NO)_2.H_2SiF_6$: H_2SiF_6, 32.2%.

$HClO_4$ Salt

Crystals of the hydrated salt were deposited when 1.03 g of the pyridone trihydrate in 2 ml water was mixed with aqueous (60%) $HClO_4$ (0.7 g). The anhydrous salt was obtained by removal of water *in vacuo*; m.p. 208–210°. Found: $HClO_4$, 39.4%. Calc. for $C_9H_{13}NO.HClO_4$: $HClO_4$, 39.8%.

H_2SnBr_6 Salt

The pyridone HBr salt (2.32 g) in water (2 ml) gave a copious precipitate of the anhydrous salt when treated with $SnBr_4$ (3.4 g) in aqueous (48%) HBr (2 ml); m.p. 202–204°. Found: H_2SnBr_6, 67.6%. Calc. for $(C_9H_{13}NO)_2.H_2SnBr_6$: H_2SnBr_6, 66.6%.

H_2PtCl_6 Salt

Aqueous (5%) $H_2PtCl_6.6H_2O$ (15.5 g) and the pyridone HCl salt (1.2 g) on being mixed gave a clear solution which quickly precipitated out the hydrated salt; m.p. 221–222°. Found: C, 29.55%; H, 3.97%; N, 3.73%. Calc. for $(C_9H_{13}NO)_2.H_2PtCl_6.H_2O$: C, 29.27%; H, 4.09%; N, 3.79%. The anhydrous material was obtained by dehydration *in vacuo*; m.p. 218–219°. Found: H_2PtCl_6, 58.0%. Calc. for $(C_9H_{13}NO)_2.H_2PtCl_6$: H_2PtCl_6, 57.6%.

H_2SnCl_6 Salt

The pyridone HCl salt (0.94 g) in H_2O (3 ml) on being mixed with $SnCl_4$ (1.22 g) in conc. HCl (3 ml) deposited the anhydrous salt; m.p. 256–259°. Found: H_2SnCl_6, 53.5%. Calc. for $(C_9H_{13}NO)_2.H_2SnCl_6$: H_2SnCl_6, 52.5%.

HBF_4 Salt

The pyridone (1.51 g) was slurried with H_2O (1 ml), and aqueous (50%) HBF_4 (1.78 g) added, giving crystals of the hydrated salt; m.p. 68–70°. Found: C, 42.26%; H, 5.64%; N, 5.37%; HBF_4, 33.3%; H_2O, 6.83%. Calc. for $C_9H_{13}NO.HBF_4.H_2O$: C, 42.05%; H, 6.27%; N, 5.45%; HBF_4, 34.2%; H_2O, 7.01%. The water of crystallization was removed *in vacuo*, giving the anhydrous salt; m.p. 164–168°.

$HAsF_6$ Salt

The pyridone (1.51 g) slurried in H_2O (2 ml) followed by the addition of aqueous (65%) $HAsF_6$ (2.79 g) gave crystals of the 1:1 anhydrous salt after a few hours; m.p. 199–200°. Found: $HAsF_6$, 56.1%. Calc. for $C_9H_{13}NO.HAsF_6$: $HAsF_6$, 55.7%. Subsequent efforts to prepare this salt resulted only in the 2:1 salt; m.p. 183–184°. Found: C, 44.05%; H, 5.16%; N, 5.84%; As, 13.3%. Calc. for $(C_9H_{13}NO)_2.HAsF_6$: C, 43.91%; H, 5.53%; N, 5.69%; As, 15.2%. (Two crystal modifications seem to exist for this compound.)

HPF_6 Salt

The pyridone (1.51 g) and water (2 ml) were treated with aqueous (65%) HPF_6 (2.25 g). The excess water was removed *in vacuo*, giving the anhydrous salt; m.p. 165–168°. Found: C, 36.27%; H, 4.78%; N, 4.68%. Calc. for $C_9H_{13}NO.HPF_6$: C, 36.37%; H, 4.75%; N, 4.71%.

1,2,6-Trimethyl-4-pyridone

This was prepared as previously described (5).

HCl Salt

The preparation has been described previously (5).

HBr Salt

The same procedure as that used for the 1-ethyl derivative was followed, giving a compound with m.p. 272–273° (decomp.) Found: HBr, 37.0%. Calc. for $C_8H_{11}NO.HBr$: HBr, 37.1%.

HI Salt

The same procedure as that used for the 1-ethyl derivative was followed, giving a compound with m.p. 252–253°. Found: C, 35.82%; H, 4.57%; N, 5.09%; HI, 47.2%. Calc. for $C_8H_{11}NO.HI$: C, 36.24% = H, 4.56%; N, 5.28%; HI, 48.3%.

$HAsF_6$ Salt

The hydrated 1:1 salt was deposited on mixing 1.37 g of the anhydrous pyridone and 2.90 g aqueous (65%) $HAsF_6$; m.p. 124–126°. Found: As, 19.6%; H_2O, 4.79%. Calc. for $C_8H_{11}NO.HAsF_6.H_2O$: As, 21.7%; H_2O, 5.22%. The anhydrous salt was obtained by warming slightly *in vacuo*; m.p. 151° (decomp.).

$HSbCl_6$ Salt

The pyridone in $CHCl_3$ was treated with $SbCl_5$ in $CHCl_3$ saturated with HCl, resulting in a precipitate of the anhydrous salt; m.p. 239–240°. Found: C, 20.71%; H, 2.59%; N, 2.82%. Calc. for $C_8H_{11}NO.HSbCl_6$: C, 20.33%; H, 2.56%; N, 2.96%.

HPF_6 Salt

Aqueous (65%) HPF_6 (1.94 g) was added to the anhydrous pyridone (1.18 g) in warm water (14 ml). On cooling, hydrated crystals formed; m.p. 118–119°. Found: H_2O, 4.79%. Calc. for $C_8H_{11}NO.HPF_6.H_2O$: H_2O, 5.22%. The anhydrous salt was obtained by warming slightly *in vacuo*; m.p. 150–155°.

The deuterated materials were prepared by exchange with an excess of D_2O, except the DBr salts, which were made from gaseous DBr using a $CDCl_3$ solution of the pyridone. The DBr was generated from D_2O and phosphorus tribromide. The D_2O was 99.77% pure and was purchased from Atomic Energy of Canada Ltd.

All melting point measurements were made in sealed tubes and are not corrected. The metal analyses were determined by X-ray fluorescence, and the acids were estimated titrimetrically.

A Perkin–Elmer model 221 prism-grating spectrometer was used to record the spectra, from 4000 to 650 cm^{-1}, of emulsions of the finely ground solids in nujol and fluorolube. Sensitive materials, and all the deuterated compounds, were prepared *in vacuo* and subsequently handled in a dry box.

ACKNOWLEDGMENTS

The assistance of Miss C. D. Anderson in preparing many of the compounds and recording their spectra is gratefully acknowledged. The metal analyses were obtained through the kind cooperation of Mr. D. G. Barnes. Mr. K. Sketris (Dow Chemical of Canada, Limited) and Dr. L. E. Swim and associates (The Dow Chemical Company, Midland, Michigan, U.S.A.) are thanked for the microanalyses.

ANALOGUES OF PSILOCIN AND LYSERGIC ACID DIETHYLAMIDE

I. CHLORO, NITRO, AND AMINO DERIVATIVES OF 3-SUBSTITUTED INDOLES

J. B. McKay, R. M. Parkhurst, R. M. Silverstein, and W. A. Skinner[1]

Physical and Life Sciences Divisions, Stanford Research Institute, Menlo Park, California, U.S.A.

Received June 5, 1963

ABSTRACT

A number of indole derivatives structurally related to either psilocin or lysergic acid diethylamide (LSD) were synthesized. The following structural analogues of psilocin are reported: 4-chloro-3-dimethylaminoethylindole, 4-nitro-3-dimethylaminoethylindole, 4-nitro-3-aminoethylindole, 4-amino-3-dimethylaminoethylindole, and 4-amino-3-aminoethylindole. Compounds structurally related to LSD that were synthesized are: 3-[β-carboxyethylaminoethyl]-4-nitroindole and 4-nitro-3-[N-methyl-N-(N′,N′-diethylcarboxamidoethyl)-aminoethyl]indole. Several 3,5- and 3,6-disubstituted indoles are also reported.

A number of compounds possessing the indole structure have aroused considerable interest because of their hallucinogenic reactions in man. Two of the more potent of these hallucinogens are lysergic acid diethylamide (LSD) and psilocin, 3-dimethylaminoethyl-4-hydroxyindole. Both of these compounds are 3,4-disubstituted indoles. This paper reports the synthesis of a number of 3,4-disubstituted indoles structurally related to psilocin and LSD (1). Also included are several 3,5-disubstituted indoles, used as models for synthesis, and several 3,6-disubstituted indoles which were obtained together with the 3,4-compounds from Fischer ring closures.

XIX: $R_2 = NH_2$; $R = CH_2CH_2NH_2$
XX: $R_1 = NH_2$; $R = CH_2CH_2NH_2$

Conditions which were suitable for reaction of indole (2) with oxalyl chloride gave virtually no product with 4-chloroindole. However, carrying out the reaction in refluxing ether solution for 15 hours yielded 4-chloro-3-indolylglyoxylchloride (II) in 73% yield. Treatment of a suspension of II in ether with dimethylamine for 6 hours gave 4-chloro-3-indolyl-N,N-dimethylglyoxamide (III) in 82% yield. Reduction of III with lithium aluminum hydride in refluxing tetrahydrofuran afforded the desired 4-chlorodimethylaminoethylindole (IV) in 97% yield. Treatment of IV with cuprous cyanide under a wide

[1]*To whom inquiries should be addressed.*

For personal use only.

variety of conditions (3), however, failed to yield isolable amounts of 4-cyano-3-dimethylaminoethylindole.

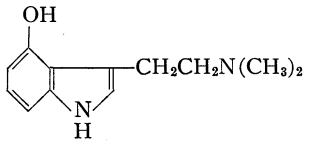
Attempts to utilize 4-bromoindole (4) in the same reaction sequence failed owing to its low reactivity toward oxalyl chloride; steric hindrance may be partly responsible since it was later found that 5-bromoindole reacts readily with oxalyl chloride.

Fischer cyclization (5) of γ-chlorobutyraldehyde gave a mixture of 3-chloroethyl-4-nitroindole (V) and 3-chloroethyl-6-nitroindole (VI). Isomer separation by column chromatography was clean, and isomer identification by n.m.r. was straightforward. Reaction of the separated 3-chloroethyl isomers with dimethylamine yielded 3-dimethylaminoethyl-4-nitroindole (VII) and 3-dimethylaminoethyl-6-nitroindole (VIII), and reaction with ammonium hydroxide yielded 3-aminoethyl-4-nitroindole (IX) and 3-aminoethyl-6-nitroindole (X).

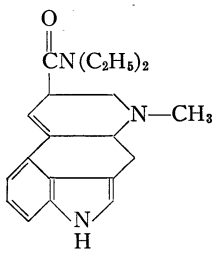
Model studies were carried out on the 3-nitrophenylhydrazone of butyraldehyde, closure of which yielded the readily separated isomers 3-ethyl-4-nitroindole (XI) and 3-ethyl-6-nitroindole (XII).

A brief investigation of the synthesis of γ-chlorobutyraldehyde disclosed that Rosenmund reduction (6) of commercially available γ-chlorobutyryl chloride with sulphur-quinoline poisoned palladium on barium sulphate (3) was the method of choice; the yield was 92%.

Reaction of 3-chloroethyl-4-nitroindole (V) with the sodium salt of β-alanine in aqueous ethanol for 12 days at room temperature gave 3-[β-carboxyethylaminoethyl]-4-nitroindole (XIII), isolated as the hydrochloride. Similar treatment of 3-chloroethyl-6-nitroindole (VI) gave 3-[β-carboxyethylaminoethyl]-6-nitroindole (XIV). Reaction of V with β-methylamino-N,N-diethylpropionamide (from methylamine and diethylacrylamide) gave 4-nitro-3-[N-methyl-N-(N′,N′-diethylcarboxamidoethyl)-aminoethyl]indole (XV), isolated as the picrate. Similar treatment of VI gave 6-nitro-3-[N-methyl-N-(N′,N′-diethylcarboxamidoethyl)-aminoethyl]indole (XVI), isolated as the hydrochloride. The side chain at the 3-position of compounds XIII, XIV, XV, and XVI was designed to resemble part of the molecule of LSD.



Psilocin



Lysergic acid diethylamide (LSD)

Reduction of the nitro group to an amino group with sodium dithionite was studied utilizing the readily prepared model compound (5), 3-ethyl-5-nitroindole. This method of reduction was successfully used for the preparation of 5-amino-3-ethylindole, 4-amino-3-dimethylaminoethylindole (XVII), 6-amino-3-dimethylaminoethylindole (XVIII), and 3-aminoethyl-6-aminoindole (XIX), but failed in the attempted preparation of 3-aminoethyl-4-aminoindole (XX). This latter compound was prepared in excellent yield by catalytic reduction of the corresponding nitro compound with platinum oxide at atmospheric pressure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Several attempts to replace the diazotized amino group of the model compound, 5-amino-3-ethylindole, with a cyano or a mercapto group demonstrated the lack of utility of the amino compounds as intermediates.

EXPERIMENTAL

4-Chloro-3-indolyl-N,N-dimethylglyoxamide (III)

To a solution of 3.84 g (0.025 mole) of fractionally distilled 4-chloroindole (Aldrich, b.p. 144–145° at 10.5 mm, n_D^{22} 1.6272) in 20 ml ether (distilled from lithium aluminum hydride) stirred at room temperature under nitrogen was added 6.62 g (0.0521 mole) of oxalyl chloride in 30 ml dry ether. After addition, the mixture was refluxed for 15 hours. The yellow precipitate was filtered and washed with ether; it weighed 4.5 g (73%). This product was suspended in 60 ml ether, 6.5 g (0.144 mole) of anhydrous dimethylamine dissolved in 50 ml of ether was added, and the mixture was stirred for 6 hours. The ether and excess dimethylamine were removed under reduced pressure, and the residue was treated with water. This mixture was filtered and the precipitate was washed with water, then dried under reduced pressure at room temperature for 64 hours. It weighed 3.83 g (82%), m.p. 223.5–224.5° corr., λ_{max}^{Nujol} (μ) 3.25 (NH); 6.05 (C=O, keto); 6.20 (C=O, amide). Anal. Calc. for $C_{12}H_{11}ClN_2O_2$: C, 57.5; H, 4.42; Cl, 14.1; N, 11.2. Found: C, 57.8; H, 4.99; Cl, 13.9; N, 10.9.

4-Chloro-3-dimethylaminoethylindole (IV)

To a slurry of 13.00 g (0.344 mole) of $LiAlH_4$ in 150 ml of tetrahydrofuran (THF), freshly distilled from $LiAlH_4$, was added a solution of 14.2 g (0.0568 mole) of 4-chloro-3-indolyl-N,N-dimethylglyoxamide (III) in 1 liter of dry tetrahydrofuran (THF). The mixture was refluxed for 3 hours, then cooled, and 110 ml of methyl alcohol – THF 1:1 mixture was added, followed by 30 ml of saturated sodium sulphate. The mixture was concentrated under reduced pressure almost to dryness, then dissolved in 200 ml of ether. This solution was extracted three times with 20-ml portions of 5% HCl solution, dried over anhydrous sodium sulphate, and evaporated to dryness under reduced pressure. The residue of nonbasic material weighed less than 0.4 g. The combined acid extracts were made basic with cold 50% sodium hydroxide and extracted with chloroform. The combined chloroform extracts were dried over sodium sulphate and evaporated to dryness under reduced pressure. The residue of crude basic product weighed 12.25 g (97%). Repeated recrystallization from cyclohexane afforded an analytical sample, m.p. 136.5–138° corr., λ_{max}^{Nujol} (μ) 3.30 (NH); absence of C=O bands at 6.06, 6.20. Anal. Calc. for $C_{12}H_{15}ClN_2$: C, 64.7; H, 6.79; N, 12.6; Cl, 15.9. Found: C, 64.7; H, 6.75; N, 12.6; Cl, 15.9.

3-Ethyl-4- and -6-nitroindoles (XI and XII)

A solution of 10 g (0.0484 mole) of *n*-butyraldehyde-3-nitrophenylhydrazone in 200 ml of concentrated hydrochloric acid and 200 ml of benzene was stirred for 3 hours at room temperature. The benzene was replaced with fresh benzene for another 3 hours. The combined benzene fractions were washed with water, dried over sodium sulphate, and chromatographed on acid-washed Merck alumina (3×25 cm).

The first major fraction from the column, an orange crystalline solid, m.p. 109.5–112°, was found to be the 3-ethyl-4-nitroindole by its n.m.r. spectrum.

The second major fraction, yellow needles, melting at 87–89°, was found to be the 6-isomer. The overall yields were about 0.55 g (6%) and 0.18 g (2%), respectively.

The infrared absorption spectra of the 4- and 6-nitro isomers were very similar. 3-Ethyl-4-nitroindole: λ_{max}^{Nujol} (μ) 2.95 (NH); 6.63, 7.60 (NO_2); 7.91, 8.86, 9.36, 10.2, 10.4, 12.1, 12.6, 13.8. 3-Ethyl-6-nitroindole: λ_{max}^{Nujol} (μ) 2.95 (NH); 6.63, 7.65 (NO_2); 8.15, 9.05, 9.40, 11.4, 11.9, 12.3, 12.7, 13.3, 13.7.

The n.m.r. spectra made possible assignment of structures to the two isomers. 3-Ethyl-4-nitroindole: CH_3 (triplet, 8.80 τ); CH_2 (quartet, 7.15 τ); 2 H and 6 H (2.78 τ); 7 H (2.36 τ); 5 H (doublet, 2.24 τ, additional meta coupling); 1 H (1.43 τ). 3-Ethyl-6-nitroindole: CH_3 (triplet, 8.65 τ); CH_2 (quartet, 7.23 τ); 2 H (2.63 τ); 4 H (doublet, 2.40 τ); 5 H (doublet, 1.98 τ, additional meta coupling); 7 H (doublet, 1.65 τ); 1 H (1.40 τ).

3-Ethyl-4-nitroindole: λ_{max}^{EtOH} 2400 Å, ϵ = 8650; 3-ethyl-6-nitroindole: λ_{max}^{EtOH} 2525 Å, ϵ = 8930; 2680 Å, ϵ = 8530.

Anal. Calc. for $C_{10}H_{10}N_2O_2$: C, 63.1; H, 5.31; N, 14.7. Found 4-NO_2: C, 63.5; H, 5.57; N, 14.6. Found 6-NO_2: C, 62.9; H, 5.20; N, 14.7.

γ-Chlorobutyraldehyde by Rosenmund Reduction

A mixture of 153 g (1.085 moles) of γ-chorobutyryl chloride, 16 g palladium on barium sulphate catalyst, 1.66 ml of sulphur-quinoline poison (7), and 900 ml of toluene was refluxed and vigorously stirred while hydrogen was passed through; the effluent gas was bubbled through water. After 6.5 hours, the evolution of hydrogen chloride ceased. The mixture was filtered and the filtrate washed with water, sodium bicarbonate solution, and water. After drying over sodium sulphate, the toluene was removed by distillation under reduced pressure through a Vigreux column. The yield of crude product was 99.7 g (92%), b.p. 28–29° at 2.0 mm; 2,4-dinitrophenylhydrazone, m.p. 130–131°, lit. 130–131°.

γ-Chlorobutyraldehyde-3-nitrophenylhydrazone

A solution of 10 g (0.1 mole) of crude γ-chlorobutyraldehyde and 20 g (0.132 mole) of 3-nitrophenylhydrazine dissolved in a minimum amount of hot ethanol containing 10% of acetic acid was allowed to stand on the steam bath for 1 hour. The mixture was cooled, and water was added until a dark red oil started to separate out. Because attempts to crystallize this oil failed, the alcohol was evaporated *in vacuo*, the water was decanted off, and the crude oil used directly in the next step.

3-[β-Chloroethyl]-4- and -6-nitroindoles (V and VI)

A solution of 29 g of the crude 3-nitrophenylhydrazone of γ-chlorobutyraldehyde in 300 ml of concentrated hydrochloric acid and 200 ml of benzene was stirred rapidly for 3 hours. The benzene was replaced with fresh benzene, and stirring was continued for another 4 hours. The combined benzene fractions were washed with water, dried over anhydrous sodium sulphate, and evaporated *in vacuo* to about 35 ml. The solution was placed on a column of alumina (3×25 cm) and eluted with benzene. The two major fractions were 3-[β-chloroethyl]-4-nitroindole, 1.89 g (7%), and 3-[β-chloroethyl]-6-nitroindole, 2.19 g (8%). Several recrystallizations from benzene – petroleum ether gave products which melted at 134–135°, golden yellow plates, in the case of the 4-nitro, and 108–110°, canary yellow needles, in the case of the 6-nitro compound.

The infrared absorption spectra of the two isomers were similar. 3-[β-Chloroethyl]-4-nitroindole: λ_{max}^{Nujol} (μ) 3.00 (NH); 6.60, 7.60 (NO_2); 8.95, 10.03, 10.2, 12.4, 12.6, 13.7. 3-[β-Chloroethyl]-6-nitroindole: λ_{max}^{Nujol} (μ) 2.90 (NH); 6.25 (aryl); 6.55, 7.45 (NO_2); 9.10, 9.45, 11.3, 13.3, 13.7, 14.0.

3-[β-Chloroethyl]-4-nitroindole: CH_2CH_2Cl (triplet, 6.62 τ); CH_2CH_2Cl (triplet, 6.25 τ); 2 H (2.80 τ); 6 H (2.63 τ); 7 H (doublet, 2.34 τ, *m*-coupled); 5 H (doublet, 2.09 τ, *m*-coupled); 1 H (1.40 τ). 3-[β-Chloroethyl]-6-nitroindole: CH_2CH_2Cl (triplet, 6.73 τ); CH_2CH_2Cl (triplet, 6.22 τ); 2 H (2.57 τ); 4 H (doublet, 2.39 τ); 5 H (doublet with additional *m*-coupling, $J \sim 2$ c.p.s., 1.97 τ); 7 H (doublet 1.62 τ); 1 H (1.22 τ).

3-[β-Chloroethyl]-4-nitroindole: λ_{max}^{EtOH} 2375 Å, $\epsilon = 7480$. 3-[β-Chloroethyl]-6-nitroindole: λ_{max}^{EtOH} 2525 Å, $\epsilon = 8290$; 2650 Å, $\epsilon = 7900$.

Anal. Calc. for $C_{10}H_9ClN_2O_2$: C, 53.5; H, 4.04; Cl, 15.8; N, 12.5. Found 4-NO_2: C, 53.3; H, 4.26; Cl, 15.5; N, 12.4. Found 6-NO_2: C, 53.5; H, 4.28; Cl, 15.9; N, 12.5.

3-Dimethylaminoethyl-4-nitroindole (VII)

A solution of 356.8 mg (1.59 mmoles) of 3-[β-chloroethyl]-4-nitroindole in 20 ml of alcohol and 20 ml of 34.3% aqueous dimethylamine was left at room temperature for 7 days. The alcohol was removed *in vacuo*, and the orange-yellow crystalline material was filtered; the crude yield was 300 mg (81%). The material was dissolved in dilute hydrochloric acid, filtered, and precipitated with dilute sodium hydroxide. Recrystallization from alcohol–water mixtures gave orange needles melting at 115–116°. Anal. Calc. for $C_{12}H_{15}N_3O_2$: C, 61.8; H, 6.48; N, 18.0. Found: C, 61.6; H, 6.39; N, 18.3.

3-Dimethylaminoethyl-6-nitroindole (VIII)

A solution of 485.7 mg (2.16 mmoles) of 3-[β-chloroethyl]-6-nitroindole in 20 ml of ethanol was treated with aqueous dimethylamine as in the case of the 4-isomer above. The crude yield was 423 mg (85%). The recrystallized product appeared as yellow plates melting at 171.5–172.5°. Anal. Calc. for $C_{12}H_{15}N_3O_2$: C, 61.8; H, 6.48; N, 18.0. Found: C, 61.2; H, 6.47; N, 17.8.

3-Aminoethyl-4-nitroindole (IX)

A solution of 1.0 g (4.46 mmoles) of 3-[β-chloroethyl]-4-nitroindole, 50 ml of concentrated NH_4OH, and 75 ml of ethyl alcohol was kept in a stoppered flask for 10 days. The alcohol was removed under reduced pressure, and the precipitate was filtered. The crude product was dissolved in hydrochloric acid and the solution filtered with Celite. After precipitation with dilute sodium hydroxide, the product was collected and recrystallized from ethanol–water; yield, 0.587 g (64.5%), m.p. 145–147°. Anal. Calc. for $C_{10}H_{11}N_3O_2$: C, 58.5; H, 5.40; N, 20.5. Found: C, 58.0; H, 5.61; N, 20.1.

3-Aminoethyl-6-nitroindole (X)

A solution of 2.0 g (8.92 mmoles) of 3-[β-chloroethyl]-6-nitroindole, 150 ml of concentrated ammonia, and 150 ml of ethyl alcohol was kept at room temperature for 9.5 days. The solvent was evaporated under reduced pressure, and the residue was dissolved in 10% hydrochloric acid. The acid solution was filtered with Celite, made basic, and the precipitated amine was filtered and recrystallized from ethyl acetate – petroleum ether (60–110°). Yield 1.37 g (71.5%). Another recrystallization yielded an analytical sample, m.p. 185–186° (decomp.). Anal. Calc. for $C_{10}H_{11}N_3O_2$: C, 58.5; H, 5.4; N, 20.5. Found: C, 58.5; H, 5.5; N, 20.4.

3-[β-Carboxyethylaminoethyl]-4-nitroindole Hydrochloride (XIII)

A solution of 1.0 g (4.46 mmoles) of 3-[β-chloroethyl]-4-nitroindole, 0.15 mole of β-alanine sodium salt in 75 ml of water, and 75 ml of ethyl alcohol was kept in a stoppered flask at room temperature for 12 days. The solvent was removed under reduced pressure and the residue triturated with benzene. The benzene-insoluble precipitate was dissolved in water, precipitated with HCl, and the crude product was collected and recrystallized from water; yield 3-[β-carboxyethylaminoethyl]-4-nitroindole, 0.20 g (28.6%), m.p. 210°. The hygroscopic orange product was dried *in vacuo* to constant weight. Anal. Calc. for $C_{13}H_{15}ClN_3O_4$: C, 49.8; H, 5.14; Cl, 11.3; N, 13.4. Found: C, 49.8; H, 5.35; Cl, 11.3; N, 13.5.

For personal use only.

3-[β-Carboxyethylaminoethyl]-6-nitroindole Hydrochloride (XIV)

A solution of 374 mg (1.67 mmoles) of 3-[β-chloroethyl]-6-nitroindole in 25 ml of alcohol and a solution of 0.1 mole of β-alanine sodium salt in 25 ml of water were mixed and allowed to stand at room temperature for 10 days. Evaporation of the alcohol and addition of hydrochloric acid caused the precipitation of a green solid weighing 300 mg (57%). The infrared spectrum of this material shows a strong band at 5.80 μ. The light green hydrochloride was recrystallized from water four times, dried to constant weight, m.p. 220° (decomp.). Anal. Calc. for $C_{13}H_{16}ClN_3O_4$: C, 49.8; H, 5.14; Cl, 11.3; N, 13.4. Found: C, 49.6; H, 5.84; Cl, 11.2; N, 13.3.

β-Methylamino-N,N-diethylpropionamide

To a solution of 26 g (0.84 mole) of methylamine in 80 ml of absolute ethyl alcohol was added, with cooling, 25.5 g (0.20 mole) of diethylacrylamide. The solution was allowed to stand in a freezer (−15°) for 45 hours. The solvent and excess methylamine were removed under reduced pressure, and the residue was distilled. One fraction was collected, b.p. 76–80° at 0.6 mm, n_D^{20} 1.4617. This material was redistilled through a spinning band column; one fraction of b.p. 62–63° at 0.40 mm, weight 16.6 g, n_D^{23} 1.4609 was collected. The hydrochloride was precipitated from ether with anhydrous HCl; m.p. 84.5–86°. Anal. Calc. for $C_8H_{19}ClN_2O$: C, 49.3; H, 9.84; Cl, 18.2; N, 14.4. Found: C, 49.1; H, 9.74; Cl, 17.3; N, 13.9.

6-Nitro-3-[N-methyl-N-(N',N'-diethylcarboxamidoethyl)-aminoethyl]indole (XVI)

A solution of 0.5 g (2.23 mmoles) of 3-β-chloroethyl-6-nitroindole in 3.0 ml of β-methylamino-N,N-diethylpropionamide was allowed to stand at room temperature for 10 days. The solution was poured into water, and the insoluble oil was isolated by centrifugation. The oil was dissolved in dilute acid, filtered with Celite, the solution made basic, and the product extracted into chloroform. The solution was dried ($MgSO_4$), and the solvent was removed under reduced pressure. The residue crystallized on scratching. Yield 0.67 g (87%). An analytical sample was obtained by repeated recrystallization from benzene – petroleum ether mixture; m.p. 93–94°. Anal. Calc. for $C_{18}H_{26}N_4O_3$: C, 62.4; H, 7.56; N, 16.2. Found: C, 62.3; H, 7.46; N, 16.2.

4-Nitro-3-[N-methyl-N-(N',N'-diethylcarboxamidoethyl)-aminoethyl]indole (XV)

A solution of 0.290 g (1.29 moles) of 3-[β-chloroethyl]-4-nitroindole in 6 ml of β-methylamino-N,N-diethylpropionamide was allowed to stand at room temperature for 14 days. The solution was poured into water and the oil which formed was isolated by centrifugation. The oil was dissolved in dilute hydrochloric acid, filtered, the solution made basic, and the product extracted into chloroform. The chloroform extracts were dried over anhydrous magnesium sulphate, and the solvent was removed under reduced pressure. Because the residue (0.187 g, 58%) could not be crystallized, the picrate was made. An analytical sample of the picrate was obtained by recrystallization from ethyl acetate; m.p. 205–208°. Anal. Calc. for $C_{24}H_{29}N_7O_{10}$: C, 50.1; H, 5.08; N, 17.0. Found: C, 50.0; H, 4.98; N, 16.7.

6-Amino-3-dimethylaminoethylindole (XVIII)

To a solution of 1.0 g (4.3 mmoles) of 3-dimethylaminoethyl-6-nitroindole in 75 ml of alcohol and 20 ml of *N* sodium hydroxide at 50° was added a solution of 6 g of sodium dithionite in 30 ml of 0.2 *N* sodium hydroxide. The mixture was filtered hot and the filtrate evaporated to dryness. The residue was dissolved in 5% hydrochloric acid solution, filtered, and made basic with cold 30% sodium hydroxide. The basic solution was extracted with ether, and the light purple ether solution was evaporated to dryness. The purple solid residue weighed 0.66 g (75%), m.p. 93–96°. Two sublimations at 110° at 0.1 mm gave a white crystalline product; m.p. 98–99°. Anal. Calc. for $C_{12}H_{17}N_3$: C, 70.9; H, 8.43; N, 20.7. Found: C, 70.5; H, 8.95; N, 20.5.

4-Amino-3-dimethylaminoethylindole (XVII)

To a solution of 0.52 g (2.2 mmoles) of 3-dimethylaminoethyl-4-nitroindole in 35 ml of ethyl alcohol and 10 ml of *N* sodium hydroxide at 50° was added a solution of 3 g of sodium dithionite in 15 ml of 0.2 *N* sodium hydroxide. The mixture was filtered hot and the filtrate evaporated to dryness. The residue was dissolved in acid, filtered, made basic, and extracted into ether. The residue from evaporation of the ether weighed 0.21 g (47.5%), m.p. 129–131°, and sublimed at 125–130° at 0.1 mm. The sublimate weighed 0.182 g, m.p. 130.5–131.5°. Anal. Calc. for $C_{12}H_{17}N_3$: C, 70.9; H, 8.43; N, 20.7. Found: C, 71.4; H, 7.72; N, 20.8.

3-Aminoethyl-6-aminoindole (XIX)

A solution of 3.0 g of sodium dithionite in 15 ml of 0.5 *N* sodium hydroxide solution was added to a solution of 0.50 g of 3-aminoethyl-6-nitroindole in 35 ml ethyl alcohol and 10 ml *N* sodium hydroxide solution at 50° C. The mixture was then filtered hot, and the filtrate was evaporated to dryness, 0.27 g (63.5% yield). The viscous oil residue was sublimed at 130° at 0.1 mm. The noncrystalline sublimate was partially dissolved in ether and cooled in a dry ice – acetone bath. Crystallization was induced by scratching with a glass rod. The ether was removed under reduced pressure and the residue, m.p. 102–105°, was sublimed twice at 110–120° at 0.015 mm, m.p. 105.5–107.5°. Anal. Calc. for $C_{10}H_{13}N_3$: C, 68.5; H, 7.48; N, 24.0. Found: C, 68.0; H, 7.54; N, 24.0.

3-Aminoethyl-4-aminoindole (XX)

A mixture of 0.232 g (1.13 mmole) of 3-aminoethyl-4-nitroindole, 0.0165 g (0.07 mmole) of platinum oxide, and 25 ml of absolute ethanol was stirred in an atmospheric hydrogenation apparatus. The reaction ceased after 50 minutes at 95% completion. The solution was filtered and the filtrate evaporated to dryness under reduced pressure. The oily residue was crystallized by cooling an ether solution in a dry ice – acetone bath and scratching the flask wall with a glass rod. The ether was removed under reduced pressure. The light purple product (0.18 g, 90%, m.p. 106–113°) was sublimed twice (100° at 0.01 mm, m.p. 116°). Anal. Calc. for $C_{10}H_{13}N_3$: C, 68.5; H, 7.48; N, 24.0. Found: C, 68.2; H, 7.81; N, 24.1.

ACKNOWLEDGMENT

The authors wish to express their appreciation to the United States Army Chemical Center Research and Development Command for support of this research under contract RFP-147, DA 18-108-405-CML-839.

A VAPOR PRESSURE STUDY OF THE ALLOYS OF MANGANESE WITH COPPER[1]

B. F. PETERS[2] AND D. R. WILES[3]
Department of Mining and Metallurgy, University of British Columbia, Vancouver, British Columbia
Received August 15, 1960

ABSTRACT

The Knudsen effusion method has been applied in a study of the vapor pressures of manganese in equilibrium with copper–manganese alloys at high temperatures. The amount of manganese effused was determined by the use of radioactive Mn^{54}. The odd behavior noted in this system at 20–30% Mn, observed in a number of studies of various physical properties, has been observed once more in the apparent activity of manganese. Some discussion is given of the Knudsen effusion method, particularly regarding some possible sources of error.

INTRODUCTION

A number of studies have been made in recent years of the copper–manganese alloy system, and all results point to its being of great interest. A study of high-temperature magnetic susceptibilities led Myers (1) to suspect that the number of electrons contributed by manganese to the conduction band is a function of composition. Somewhat different studies by Scheil and Wachtel (2) and by Valentiner and Becker (3) of the magnetic susceptibilities at somewhat lower temperatures brought out the suggestion of short-range order. Neutron diffraction studies by Meneghetti and Sidhu (4) supported this latter view, and antiferromagnetic ordering was suggested. Specific heat studies by Kussmann and Wollenberger (5) showed ordering below 270° C.

The copper–manganese system is one of the few in which two quite dissimilar metals show solid solubility over an appreciable composition range. (The phase diagram (6) is given in Fig. 1.) The properties of the γ-phase of this system are therefore of considerable interest in throwing light on the structure of such alloys. This is especially so in view of the fact that the sizes of the copper and manganese atoms are not greatly different, so that these studies may shed some light on the effects of such factors as electronegativity and electronic structure.

This paper reports on measurements of the vapor pressures of manganese over a series of Cu–Mn alloys.

Of the two components in the copper–manganese system, manganese is known to have the higher vapor pressure and consequently this work involves a study of the partial pressures of manganese alone. Determination of this vapor pressure was done by the Knudsen effusion method (7, 8) because of its ready applicability to the determination of very low pressures.

The Knudsen equation for the calculation of vapor pressures is given as equation (I)

$$p = \frac{m}{tAf}\sqrt{\left(\frac{2\pi RT}{M}\right)}, \qquad \text{(I)}$$

where p is the pressure in dynes/cm^2, m is the weight of material of molecular weight M collected after having effused for t seconds through an orifice of area A, where f is the

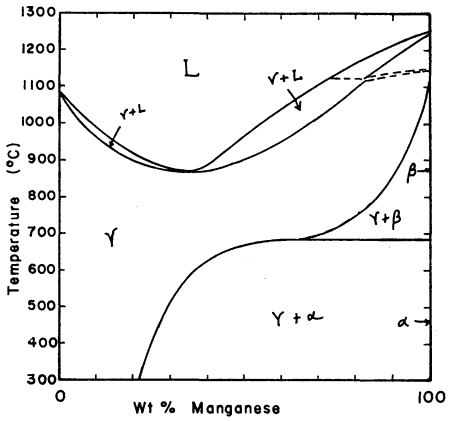

FIG. 1. Phase diagram for the copper–manganese system.

fraction of the effused material which is collected. R and T represent, as usual, the gas constant and temperature, respectively. The activity and other thermodynamic functions can be calculated by well-known methods. It is important to note that in the use of this method we must assume that (*a*) the vapor is monatomic (i.e. that $M = 54.9$) and (*b*) all atoms which strike the collecting surface remain there. These assumptions will be discussed later.

EXPERIMENTAL

The Knudsen effusion apparatus used is shown schematically in Fig. 2. The cell itself was made of molybdenum, which had been shown by McCabe and Hudson (9) not to dissolve in nor react with manganese at high temperatures. The orifice was a circular hole drilled in 0.003 in. molybdenum. The diameter of the hole was varied from about 1 to 3 mm without effect on the pressure values obtained. The furnace was of Kanthal strip wound on machined lava block.

Temperatures were measured with two chromel–alumel thermocouples inserted into the cell as shown in Fig. 2—one deep inside the cell wall, the other in a shallow hole in the bottom. The thermocouples were calibrated at the boiling point of water and at the melting point of aluminum. The temperatures given by the two thermocouples differed by about 3°, that in the shallow hole showing the lower temperature.* The effective temperature of the cell was assumed to be 1° lower than that shown by the thermocouple in the cell wall. Temperature readings were made by means of a Tinsley Type 3387B potentiometer.

Temperature control was effected by means of a control thermocouple located close to the furnace windings, and connected to a Minneapolis-Honeywell Controller, operating an on, 3/4-on furnace circuit. Variations in the temperature at equilibrium amounted to ±0.5°. The absolute error in the effective temperature is estimated to be not greater than 2° C.

The effused manganese vapor was collected on water-cooled manganese-coated aluminum disks. Precoating of the disks with manganese was found necessary to provide an unvarying surface on which to collect the vapor. The disks were arranged in a sample changing device to make possible several measurements on a given alloy without breaking the vacuum. The same device made it possible to specify accurately the time and temperature at which each sample was collected. The pressure under operating conditions was about 10^{-5} mm Hg.

The measurement of the quantity of effused manganese collected was done using radioactive manganese-54 as tracer. The radioactive manganese was obtained carrier free, in HCl solution, from Nuclear Science and Engineering Corp. Measurements were made with an end-window proportional counter, counting the conversion electrons from the 0.84 Mev γ-ray. For a single vapor pressure determination several samples were collected for different lengths of time, and intercompared to eliminate possible non-statistical errors. Agreement was generally very good among samples.

The manganese was 99.9% pure electrolytic manganese obtained from the Electromanganese Corp. of America. The copper was Fisher Reagent metal of 99.7% purity.

**This deviation persisted through a number of changes and interchanges of the thermocouples, and is thus real. It seems likely that heat was being lost from the bottom of the cell because of inadequate thermal shielding.*

D. Collimator	S. Location of sample

The radioactive manganese metal, and the labelled alloys, were made in the following way: A few drops of carrier-free Mn^{54} solution were evaporated on the surface of a manganese chip, and this melted together with more, inactive, manganese by induction heating in a closed argon-filled system. The manganese melt was contained in a Norton RA84 silica crucible. The alloys were made by melting together weighed amounts of copper and radioactive manganese, using a molybdenum crucible. The melts were rapidly cooled under argon. Subsequent microscopic examination revealed no inhomogeneity. The manganese content of the alloys was determined spectrophotometrically as permanganate. The specific activity of the stock manganese was determined by using very small aliquots of a nitric acid solution of the active manganese. These were evaporated on aluminum disks similar to the vapor-collection disks. Several different-sized aliquots of the manganese solutions were used, and the observed activity was seen to be a linear function of the size of the aliquot used. The calibration curve was checked by dissolving collected manganese off a disk and analyzing this spectrophotometrically.

EVALUATION OF ERRORS

A number of sources of error were found which, although consistent throughout the experiments, tend to cast some doubt on the absolute accuracy of the values.

The orifice plate was observed visually to be somewhat cooler than the inside of the cell and some manganese was observed to condense on its under side. Using an optical pyrometer, it was estimated that the difference in temperature was about 25°. Since all discussions of the Knudsen method emphasize that the orifice must be no cooler than the rest of the cell, we feel obliged to make some comments of justification.

The extreme case—that of partial clogging of the orifice with condensed atoms—was never observed. The effect to be expected, then, is a decrease in the flux of atoms in the downward direction because of condensation of some atoms on the orifice plate. This would have some effect on the concentration of atoms on the bottom surface, and consequently on the flux of atoms moving upward toward the orifice. The magnitude of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

effect was estimated through a direct experiment (10) in which the amount of manganese condensed on the inside of the orifice plate was found to be 16% of that striking the plate. Considering that the orifice plate subtends approximately 18% of the total solid angle it may be estimated with some confidence that the error in absolute vapor pressures resulting from this effect is not more than 5%, as long as the rate of evaporation is much higher than the rate of effusion. Good agreement with the values obtained by McCabe and Hudson for pure manganese gives confidence that the evaporation rate is adequate to ensure equilibrium. For the alloys this condensation was never observed.

Oxidation was a problem in the case of pure manganese. It was observed (10) that after only a short time at high temperatures the manganese samples were coated with a loosely adherent green layer, even at the best vacuum obtained. This layer was identified from its X-ray diffraction pattern as MnO. It was found, however, that on prolonged heating this layer became very porous, spalling off to expose large areas of what appeared to be bare metal. Vapor pressure studies made on such samples showed an interesting behavior as a function of time, which tend to substantiate this last observation. These results are shown in Fig. 3.

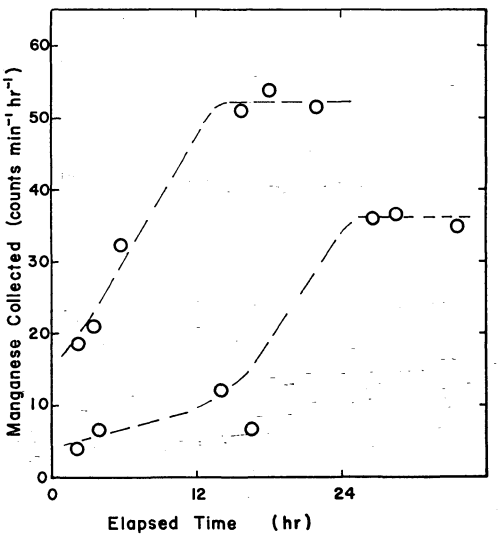

FIG. 3. Apparent vapor pressures of pure manganese measured at various times showing the effect of oxidation. Upper curve: 862° C; lower curve: 832° C.

It was concluded from these experiments that after a 'soaking' time of 20–30 hours, depending on the temperature, the manganese surface was no longer blocked by the adherent oxide layer, and the vapor pressures observed were, in fact, those of pure manganese. For this reason all experimental runs on pure manganese were made after an initial 24 hour heating period.

Collection of the effused vapor was found to be fraught with some initial difficulties. It was found that the collection efficiency varied as a function of time, when aluminum disks were used for collecting the vapor. Other substrates, e.g. silver, copper, were found to be no better. This variation is shown by curve 3 in Fig. 4. This behavior was corrected when the aluminum disks were given a thick coating of non-radioactive manganese prior to use, as is seen in curve 1 of Fig. 4. This delayed deposition was observed a long

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

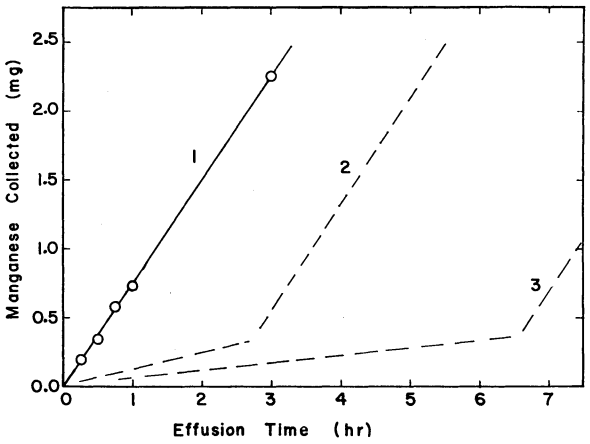

FIG. 4. Collection of manganese for various times on various substrates, showing the necessity for having clean manganese for good collection. Curve 1: disk precoated with Mn just prior to use; curve 2: disk precoated with Mn and kept in air for 72 hours before use; curve 3: clean Al disk.

time ago by Wood (11), Estermann (12), and others. It is explained as resulting from the fact that manganese atoms are held strongly only when they condense on a clean manganese surface, while when they strike any other surface, the condensation is inefficient until a manganese layer is built up. This is true even when the collecting layer is mildly oxidized manganese, as is seen in curve 2 of Fig. 4. In all experiments the aluminum collection disks were thickly coated with non-radioactive manganese prior to use and kept under high vacuum.

All experiments were done so as to collect several samples representing different exposure times. These were checked for linearity in time (as in curve 1, Fig. 4) and the rate of effusion per unit time computed from the average.

A more fundamental source of error is the assumption that the vapor is monatomic (i.e. that M in equation (I) is equal to 54.9). Although on the average the vapor is likely very nearly monatomic, there is no certainty of this. Moreover, any error arising from this assumption will be temperature dependent and lead to false values of the heat of sublimation. At any one temperature, this error would be independent of composition.*

Errors in the radioactive measurements were small and random.

An assessment of the magnitude of the errors is very difficult in this case, where many sources of non-random errors exist. By holding these errors constant, as described, the relative errors were held to a minimum, and the authors are confident that the measurements are internally consistent to within about 10%, at any temperature.

The accuracy and reproducibility of measurements made using this technique are conveniently checked by comparing the results obtained for pure manganese with those reported by McCabe and Hudson (9). The absolute values of the manganese vapor pressure are found to agree quite well. There is, however, a considerable difference between the values for the heat of sublimation, and our value of 92 kcal/mole, determined from the slope of the curve of ln P vs. $1/T$, in Fig. 5, is in poor agreement with theirs of 67 kcal/mole. Since the present work was done over such a narrow range of temperatures, we feel that our value is not reliable, and does not offer a challenge to the earlier value.

**This independence of composition would no longer be true in the case of direct evaporation from a metal surface into a vacuum.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

From this comparison, we deduce that the pressure values obtained are internally consistent, when considered at a single temperature, but that the ΔH values, while probably consistent, may not be sufficiently reliable to warrant their being used in detailed thermodynamic calculations. The discussion to follow, then, is based on the interpolated values at 820° C.

One serious uncertainty may arise in attempting to prove that the vapor collected from alloy samples reflects their true equilibrium pressure. It is possible, for example, that the extent of depletion of manganese in the surface was controlled by the rate of diffusion of manganese from the body of the sample to the surface.*

Since no regular variation in evaporation rate was ever noted as a function of either sample area or length of heating time, it seems unlikely that this deviation from equilibrium would be significant. However, it is not at present possible to rule out this possibility. and we will refer to "apparent" pressures, "apparent" activities, and so on, so as to emphasize this uncertainty.

RESULTS AND DISCUSSION

The results of measurements on the copper–manganese system are given in Table I, and plotted as a function of reciprocal temperature in Fig. 5. As explained earlier, these data will be discussed at a single temperature only—820° C—using values obtained from Fig. 5 by interpolation. The interpolated values at 820° C are given in Table II.

TABLE I

Primary vapor pressure data for manganese and copper–manganese alloys*

*Activity and activity coefficient data are computed as relative to γ-Mn, because the alloys studied are in the γ-phase.

activity from that to be expected from Raoult's Law. Although the data allow no conclusion to be made, one may speculate that the behavior of manganese in dilute solution in copper follows Henry's law, in which the apparent activity coefficient, though differing from unity, is constant. In the second region—from 30% up to 87%, where β-manganese forms a second phase at 820° C—the deviation from ideality is quite large, and it is clear that neither Raoult's nor Henry's law could correlate the results.

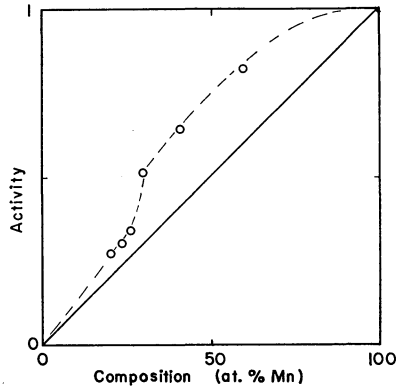

FIG. 6. Apparent activity of manganese in copper–manganese alloys at 820° C (relative to γ-Mn).

The same results are shown in Fig. 7 in the form of the apparent activity coefficients. Here the transition from the one region to the other is quite abrupt. The same data in the form of the excess free energy ($\Delta F^x = RT \ln \gamma$) fall on a very similar curve, which need not be presented here. The abruptness of the change between 26% and 29% is somewhat startling, and may well be exaggerated as it is drawn in Fig. 7.

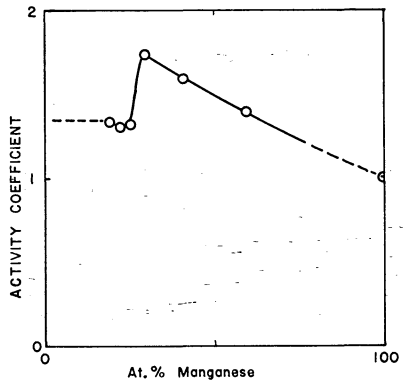

FIG. 7. Apparent activity coefficients of manganese in copper–manganese alloys at 820° C (relative to γ-Mn).

The results indicate a considerable change in the structure of the alloy—a sudden increase of the lattice spacing, an abrupt change in electronegativity difference, or perhaps a "clustering" of the manganese atoms. (It is to be noted that should the apparent vapor pressures reflect a diffusion-controlled evaporation rate, the anomalous values once more point to a marked change in the nature of the lattice.) A detailed interpretation of these data can scarcely be made without accurate heat and entropy data and, as was discussed earlier, we do not feel that our temperature range was wide enough to give the required accuracy in view of our other experimental uncertainties.

Perhaps the most significant point in the present work, to which attention is now directed, is that the observed discontinuity in the apparent activity occurs in the same region as those found in the magnetic properties. Myers' measurements (1) at 800° showed a distinct, if not sharp, break in the magnetic susceptibility at about 30 at% manganese.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Similar measurements by Scheil and Wachtel (2) on alloys quenched from 800° C to 100–200° C showed a very pronounced maximum in the magnetic susceptibility between 20% and 25% manganese. Likewise values of the magnetic susceptibility obtained at −188° C by Valentiner and Becker (4) showed a strong maximum between 20% and 30% manganese.

Although several workers (2–5) have suggested magnetic ordering as the cause of the phenomena observed, Myers' suggestion (1) of an electronic change in the alloy from a localized d^6s^1 configuration of the manganese to a delocalized d-band common to both copper and manganese seems to offer a more reasonable explanation of the present results. Indeed it may be that this valence change underlies all of the anomalies observed.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the able assistance of Mr. R. G. Butters in the design and construction of the apparatus, and to the National Research Council for financial assistance. Several discussions with Dr. E. A. Flood, Dr. M. J. Dignam, and Dr. C. S. Samis have been very stimulating and helpful.

TOXIC FLUORINE COMPOUNDS

XIX. ω-FLUOROALKYNES[1]

F. L. M. PATTISON AND R. E. A. DEAR
Department of Chemistry, University of Western Ontario, London, Ontario
Received June 3, 1963

ABSTRACT

Some ω-fluoroalkynes have been prepared and shown to be valuable intermediates in the synthesis of rare long-chain ω-fluoro compounds; successful representative reactions, in all of which the C—F bond remained intact, included Grignard reactions, partial and total catalytic hydrogenation, halogenation, and miscellaneous coupling reactions.

The potential value of ω-fluoro-1-alkynes for the synthesis of unusual long-chain ω-fluoro compounds has been recognized for several years. Early work was not encouraging (2), because loss of fluorine occurred under the reaction conditions employed. More recent improvements in techniques involving acetylenic intermediates led us to re-examine the problem. In the course of the work, improved procedures for preparing ω-fluoro-1-alkynes were developed, and the importance of these compounds as intermediates was established. In illustration of their usefulness, the synthesis of two naturally occurring compounds (ω-fluoro-oleic acid and ω-fluoropalmitic acid) has already been described (1).

The preparations of the ω-fluoro-1-alkynes have been discussed (1, 2). The method of choice involves the reaction of an ω-fluoroalkyl chloride or bromide (3) with lithium acetylide stabilized as the ethylenediamine complex; the optimum reaction temperature for chlorides was 25° and for bromides 5–10°. The use of this complex obviates the need for gaseous acetylene and results in a higher yield of product. This is the only method which gives high yields of 1-alkynes directly from chlorides. Previous objections (1) to the use of alkyl chlorides, arising from the presence of unreacted chloride in the product, have been overcome by slowly warming the reaction mixture to 60° after the initial brisk reaction has ceased. This final step ensures complete reaction both of chlorides and of bromides. (Alkyl fluorides apparently do not react with the complex under the reaction conditions employed.) Yields of ω-fluoro-1-alkynes as high as 92% have thus been obtained. Physical constants are shown in Table I. The reactions which follow were undertaken to study the stability of the C—F bond under widely varying experimental conditions.

The first reactions of the ω-fluoro-1-alkynes to be studied were those involving Grignard reagents. Previous work using ethylmagnesium bromide had resulted only in fluorine-free mixtures (2). However, by using ethylmagnesium chloride under carefully controlled conditions, normal reactions occurred. The resultant Grignard reagents formed the corresponding N-α-naphthyl-ω-fluoro-2-alkynoamides with α-naphthyl isocyanate, and the corresponding ω-fluoro-2-alkynoic acids with carbon dioxide; in this work, the studies of Hollingsworth, Wotiz *et al.* (4, 5, 6) were of assistance. The first of these reactions is of value for characterizing the ω-fluoro-1-alkynes as crystalline derivatives. The second is interesting as an example of a "forced" Grignard reaction, wherein the reacting species are respectively diethylmagnesium and the di-(ω-fluoroalkynyl)magnesiums; to this end, the use of dioxane as solvent forced the Schlenk equilibrium in the desired direction.

$$F(CH_2)_nC{\equiv}CMgCl \xrightarrow{C_{10}H_7NCO} F(CH_2)_nC{\equiv}CCONHC_{10}H_7 \quad \text{(yields: 72–88\%)}$$

$$(F(CH_2)_nC{\equiv}C)_2Mg \xrightarrow{CO_2} F(CH_2)_nC{\equiv}CCOOH \quad \text{(yields: 51–95\%)}$$

Partial catalytic hydrogenation of the ω-fluoro-1-alkynes was next examined. The usual procedure, employing an alkali metal in liquid ammonia, gave fluorine-free products. However, by using hydrogen in the presence of Lindlar catalyst (7; 8, p. 200), high yields (75–86%) of the corresponding ω-fluoro-1-alkenes were obtained; uptake of hydrogen ceased abruptly after the addition of 1 mole. Oxygen-containing solvents caused total hydrogenation to the 1-fluoroalkanes; it is therefore important to use hydrocarbon solvents, such as *n*-pentane, for the reaction.

Halogenation of the acetylenic hydrogen was accomplished using sodium hypobromite, or by treating the lithium derivative with *p*-toluenesulphonyl chloride. The bromination reaction was based on the work of Straus *et al.* (9). For the lower members, the reaction proceeded well in the aqueous medium; but the low solubility of the higher members made the use of dioxane as solvent, and a higher reaction temperature, necessary for satisfactory yields. Yields of 1-bromo-ω-fluoro-1-alkynes ranged from 67–87%. The chlorination reaction was examined only in the case of 8-fluoro-1-octyne. Extending the observations of Truchet (10), who advocated the use of the sodium or potassium derivative of a 1-alkyne, we found that the preparation of the lithium derivative, using *n*-butyllithium in a hydrocarbon solvent, was more convenient, because it avoided the use of liquid ammonia; the subsequent reaction with *p*-toluenesulphonyl chloride proceeded smoothly to give 1-chloro-8-fluoro-1-octyne in an overall yield of 42%.

$$F(CH_2)_nC{\equiv}CH + NaOBr \rightarrow F(CH_2)_nC{\equiv}CBr + NaOH$$

$$F(CH_2)_6C{\equiv}CLi + CH_3C_6H_4SO_2Cl \rightarrow F(CH_2)_6C{\equiv}CCl + CH_3C_6H_4SO_2Li$$

Attempts were then made to prepare 1-fluoro-1-alkynes by reaction of metal derivatives of 1-alkynes with perchloryl fluoride. It is known that the fluorine atom in this compound displays, under appropriate conditions, electrophilic reactivity towards many types of carbanions. However, reaction of alkynyl anions, formed from 1-alkynes and *n*-butyllithium, with perchloryl fluoride gave only a low yield (16.5%) of the symmetrical diyne, $RC{\equiv}C{\cdot}C{\equiv}CR$. The reactions of alkynyl anions with various aromatic sulphonyl fluorides were equally unsuccessful in forming 1-fluoro-1-alkynes.

Of greater importance to the overall objective of preparing long-chain compounds were various coupling reactions. ω-Fluoro-1-alkynes, in the presence of lithium amide, formed *in situ* in liquid ammonia, reacted with ω-fluoroalkyl iodides to form α,ω-difluoroalkynes. ω-Chloroalkyl iodides similarly gave the corresponding α-chloro-ω-fluoroalkynes (1), which were then utilized in the synthesis of ω-fluoro-oleic and ω-fluoropalmitic acids. Yields in these simple couplings were good (65–89%). Successful couplings between the dilithium derivative of diacetylene (11) and ω-fluoroalkyl iodides have also been carried out; the former is conveniently prepared *in situ* from 1,4-dichloro-2-butyne and four equivalents of lithium amide in liquid ammonia. Overall yields fell in the range 40–50%. The diacetylene route is of value only for forming symmetrical diynes. The method of Chodkiewicz (12) was therefore employed for preparing unsymmetrical diynes; this involves the reaction of 1-alkynes with 1-bromo-1-alkynes in the presence of a cuprous salt and a primary amine. Yields were good (55–71%).

$$F(CH_2)_nC{\equiv}CLi + I(CH_2)_mF \rightarrow F(CH_2)_nC{\equiv}C(CH_2)_mF + LiI$$

$$2F(CH_2)_nI + LiC{\equiv}C{\cdot}C{\equiv}CLi \rightarrow F(CH_2)_nC{\equiv}C{\cdot}C{\equiv}C(CH_2)_nF + 2LiI$$

$$F(CH_2)_nC{\equiv}CH + BrC{\equiv}C(CH_2)_mF \rightarrow F(CH_2)_nC{\equiv}C{\cdot}C{\equiv}C(CH_2)_mF + HBr$$

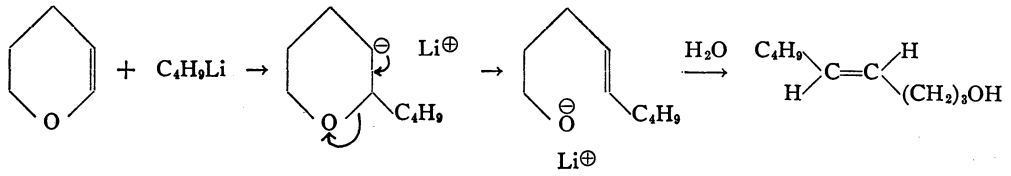
Catalytic hydrogenation of the conjugated diynes using platinum gave the α,ω-difluoroalkanes in about 60% yield; ethanol was found to be a much better solvent for this than ethyl acetate. Previous preparations of α,ω-difluoroalkanes have usually involved anodic couplings, giving members containing an even number of carbon atoms. The acetylenic route is equally satisfactory for the even members, and provides a ready means of preparing the less accessible odd members.

One related reaction is of general interest. Paul and Tchelitcheff (13) have shown that dihydropyran on treatment with *n*-amylsodium forms 5-hydroxy-1-pentyne, a useful intermediate in this work. When we substituted *n*-butyllithium for *n*-amylsodium in this reaction, *trans*-1-hydroxy-4-nonene was formed in 73% yield. Thus the reaction had not followed the normal ring opening, but instead the dihydropyran had undergone addition of *n*-butyllithium followed by ether cleavage. This represents the simplest and best preparation of this unsaturated alcohol yet found.



Toxicities of some representative ω-fluoroalkynes have been given in earlier reports (1, 2). The LD_{50} results listed in Table I do not add much to the current knowledge concerning the metabolism of the alkyne grouping. The two new ω-fluoro-1-alkynes conform to the toxicity pattern previously established. The results of the three ω-fluoro-2-alkynoic acids suggest that the presence of an α,β-acetylenic bond does not affect the ultimate fate of ω-fluorocarboxylic acids; that is, the unsaturation has little effect on the toxicity. Similar observations have been made previously with ω-fluoro-2-alkenoic acids, $F(CH_2)_nCH{=}CHCOOH$ (14), and with their metabolites such as ω-fluoro-β-hydroxyacids, $F(CH_2)_nCH(OH)CH_2COOH$ (15) and ω-fluoro-β-ketoacids, $F(CH_2)_nCOCH_2COOR$ (16). The alternation of toxicity in the 1-bromo-ω-fluoro-1-alkyne series is similar to, but less pronounced than that given by the ω-fluoroalkyl halide series (3). No particular trend is apparent in the α,ω-difluoro series containing non-terminal mono- and di-yne functions.

The interpretation of the results obtained with the ω-fluoro-1-alkenes remains as obscure as ever (2). The three new α,ω-difluoroalkanes gave toxicity results in line with those described in earlier work (3).

The most important conclusion from the work described in this paper is that ω-fluoro-1-alkynes may be prepared conveniently and in good yield from ω-fluoroalkyl halides (including chlorides), and that the acetylenic function undergoes further reactions, under a wide range of experimental conditions, without loss of fluorine. The ω-fluoro-1-alkynes are thus well established as important intermediates in the synthesis of biologically active aliphatic fluorine compounds.

EXPERIMENTAL

Many of the reactions described herein were followed by gas chromatography and infrared spectroscopy. Physical constants and analytical data for all new compounds are given in Table I. The preparations described below represent typical examples of each procedure; obvious variations for obtaining different members have not been included. Melting points (uncorrected) were determined on a Kofler hot stage, and densities with a Fisher-Davidson gravitometer. Infrared spectra were obtained with Beckman IR-7 and IR-5 infrared spectrophotometers. Analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, 77, N.Y. The presence of the ω-fluorine atom has previously been shown by nuclear magnetic

¶The following toxicities of ω-fluoro-1-alkynes have been reported (2): $F(CH_2)_4C{\equiv}CH$, 5.7; $F(CH_2)_5C{\equiv}CH$, 53; $F(CH_2)_6C{\equiv}CH$, 7.5; $F(CH_2)_7C{\equiv}CH$, 79.
**For comparison, the toxicity of two 1-halo-1-alkynes was determined: $CH_3(CH_2)_3C{\equiv}CBr$, >100; $CH_3(CH_2)_3C{\equiv}CCl$, >100; this lack of toxicity does not bear out the statement that "the lower 1-chloroalkynes are extremely toxic" (Raphael (8, p. 57)).

resonance spectroscopy, and the significance of the spectra discussed (1). The lithium acetylide (stabilized as the ethylenediamine complex) and the *n*-butyllithium solution were purchased from Foote Mineral Co., Route 100, Exton, Pa. Ethylmagnesium chloride solution was purchased from Arapahoe Chemicals, Inc., Boulder, Colorado. The 1,4-dichloro-2-butyne was kindly presented by Antara Chemicals, General Aniline and Film Corporation, 435 Hudson Street, New York 14, N.Y.

ω-Fluoro-1-alkynes

Two methods for preparing the ω-fluoro-1-alkynes have already been described (1). By the sodium acetylide route in xylene–DMF were prepared 8-fluoro-1-octyne (from 6-fluorohexyl bromide in 50.0% yield) and 10-fluoro-1-decyne (from 8-fluoro-octyl bromide in 60.1% yield). By the lithium acetylide route were prepared the following: 5-fluoro-1-pentyne (from 3-fluoropropyl bromide in 21.4% yield[2]); 6-fluoro-1-hexyne (from 4-fluorobutyl chloride in 74.8% yield); 7-fluoro-1-heptyne (from 5-fluoropentyl chloride in 91.8% yield); 8-fluoro-1-octyne (from 6-fluorohexyl chloride in 76.4% yield); and 9-fluoro-1-nonyne (from 7-fluoroheptyl bromide in 76.4% yield). The optimum reaction temperature for the alkyl chlorides is 25° and for alkyl bromides 10°. It was previously noted (1) that incomplete reaction rendered chlorides unsuitable as starting materials, owing to the similarities in boiling points and refractive indices between the chlorides and resultant alkynes. By slowly warming the reaction mixture to 60°, after reaction at the initial low temperature has ceased, both chlorides and bromides may be caused to react completely. Unreacted starting material thus ceases to be a problem.

N-α-Naphthyl-9-fluoro-2-nonynoamide

Ethylmagnesium chloride (5.15 ml of 3 *M* solution; 0.0156 mole) was placed in a dry 100-ml three-necked flask fitted with a nitrogen inlet, a dropping funnel, a precision-bore stirrer, and a condenser. A nitrogen atmosphere was maintained throughout. 8-Fluoro-1-octyne (2 g, 0.0156 mole) in ether (10 ml) was added slowly with stirring. The ether refluxed and the dark brown color of the original Grignard suspension lightened considerably. When gas evolution had ceased, a solution of α-naphthyl isocyanate (2.6 g, 0.0154 mole) in dry ether (10 ml) was added slowly with stirring; fast addition results in urea formation. When refluxing had ceased, the mixture was poured onto crushed ice and extracted with ether. The extract was washed with water and dried over calcium sulphate. Removal of the ether gave the amide (3.31 g, 72.2%). Recrystallization from ether – petroleum ether, followed by drying *in vacuo* at 40°, gave the pure material.

The following were prepared similarly: *N-α-naphthyl-10-fluoro-2-decynoamide* (87.6%); *N-α-naphthyl-11-fluoro-2-undecynoamide* (75.3%); and *N-α-naphthyl-2-heptynoamide* (77.0%).

Principal infrared bands of the three fluorinated amides ($CHCl_3$, cm^{-1}): 3378 and 3257 (free N—H) w; 3049 and 2985 (aromatic C—H) w; 2933 and 2857 (aliphatic C—H) m; 2232 (C≡C) m; 1664 (C=O) s; 1524 (combination N—H and C—N) s; 1488 s; 1350 m; 1256 m; 1046 and 990 (C—F) w.

9-Fluoro-2-nonynoic Acid

Precautions were observed to exclude moisture and oxygen, as in the previous procedure; the apparatus was the same. Ethylmagnesium chloride (14.5 ml of 3 *M* solution; 0.042 mole) and dry ether (29 ml) were added to the flask, thus giving a 1 *M* solution. This was stirred and heated under reflux, and dioxane (sodium dried; 3.78 g, 0.042 mole) was added. The resulting suspension was refluxed and stirred for 5 hours. 8-Fluoro-1-octyne (5 g, 0.039 mole) was added slowly, and the mixture was stirred without heating for 1 hour. It was then poured onto a mixture of powdered dry ice (150 g) suspended in dry ether (60–70 ml), and stirred for 1 hour. The mixture was hydrolyzed with saturated ammonium chloride solution and then acidified with dilute hydrochloric acid. The ether layer was extracted with sodium carbonate solution. Removal of the ether allowed recovery of unreacted alkyne. The aqueous extract was acidified and extracted with ether. Washing, drying ($CaSO_4$), and distillation gave the acid (3.39 g, 50.5%).

The following were prepared similarly: *10-fluoro-2-decynoic acid* (94.6%) and *11-fluoro-2-undecynoic acid* (75.0%).

Principal infrared bands of the three acids (CCl_4, cm^{-1}): 3521 (free O—H) w; 3077, 2660, and 2532 (bonded O—H) m; 2941 and 2865 (C—H) s; 2242 (C≡C) s; 1689 (C=O) s; 1466 (C—H) m; 1412 and 1279 (C—O and O—H) s; 1050 and 1013 (C—F) m; 919 (O—H) m.

7-Fluoro-1-heptene

Lindlar catalyst (7, 8) (200 mg) was suspended in *n*-pentane, and 5% synthetic quinoline in *n*-pentane (1 ml) was added. Upon saturation with hydrogen at room temperature and atmospheric pressure, no noticeable uptake of hydrogen occurred. 7-Fluoro-1-heptyne (4.56 g, 0.04 mole) in *n*-pentane (20 ml) was added, and hydrogenation was started. The theoretical amount of hydrogen was absorbed in just under 3 hours, after which no further uptake was observed. The catalyst was filtered off and washed with *n*-pentane. The filtrate was washed with dilute hydrochloric acid and then with water, dried ($CaSO_4$), and distilled to give the alkene (3.56 g, 80.4%).

The following were prepared similarly: *8-fluoro-1-octene* (86.0%); *9-fluoro-1-nonene* (79.8%); and *10-fluoro-1-decene* (74.9%).

[2]*The low yield is explained by the very high volatility of the product. Suitable variations in technique would undoubtedly raise the yield to that of the other members.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Principal infrared bands of the fluoroalkenes (CCl_4, cm^{-1}): 3067 (olefinic C—H) w; 2907 and 2857 (C—H) s; 1642 (C=C) m; 1464, 1445, and 1416 (C—H) m; 1052 and 1018 (C—F) m; 952 (olefinic C—H) m; 912 (olefinic C—H) s; 722 (C—H) w.

1-Bromo-6-fluoro-1-hexyne

Sodium hydroxide (10 *N*, 37 ml, 0.367 mole) was cooled in a flask surrounded by ice. Water (23 ml) was added, followed by dropwise addition of bromine (17.2 g, 0.108 mole). 6-Fluoro-1-hexyne (10 g, 0.100 mole) in ether (5 ml) was added with vigorous stirring. The mixture was then stirred overnight at room temperature. The heterogeneous mixture was poured into water and extracted with ether. The extracts were washed, dried ($CaSO_4$), and distilled to give the bromoalkyne (15.47 g, 86.4%).

The following were prepared similarly: *1-bromo-7-fluoro-1-heptyne* (86.6%), and *1-bromo-8-fluoro-1-octyne* (73.8%). The same procedure, but using dioxane (10 ml) in place of the ether and a temperature of 35°, gave: *1-bromo-9-fluoro-1-nonyne* (64.9%) and *1-bromo-10-fluoro-1-decyne* (86.4%). The 1-bromo-1-alkynes must all be distilled at reduced pressure to avoid decomposition.

Principal infrared bands (CCl_4, cm^{-1}): 2933 and 2865 (C—H) s; 2222 (C≡C) w; 1468 and 1433 (C—H) m; 1380 w; 1330 w; 1110 w; 1053 and 1012 (C—F) m; 722 (C—H) w.

1-Chloro-8-fluoro-1-octyne

The reaction was carried out in an atmosphere of dry nitrogen. 8-Fluoro-1-octyne (3.84 g, 0.03 mole) was dissolved in *n*-pentane (25 ml), and the solution was freed of any dissolved oxygen by refluxing in a stream of nitrogen for 15 minutes. *n*-Butyllithium (11.45 g of 15.2% w/w solution; 1.74 g C_4H_9Li; 0.0272 mole) in hexane was added slowly with stirring. The alkynyllithium separated. The mixture was warmed to ensure completion of the reaction. After no more butane was evolved, sodium-dried dioxane (5 ml) was added, thus dissolving most of the solid. *p*-Toluenesulphonyl chloride (freshly distilled and recrystallized, 5.7 g, 0.0298 mole) was added in dioxane, and the orange-yellow lithium sulphinate was deposited. The mixture was stirred for 15 minutes and then was poured onto crushed ice. Separation of the organic layer, ether extraction of the aqueous layer, washing, drying ($CaSO_4$), and distillation gave the chloroalkyne (2.05 g, 41.8%). Principal infrared bands (CCl_4, cm^{-1}): 2933 and 2857 (C—H) s; 2232 (C≡C) w; 1464 and 1431 (C—H) m; 1391 w; 1330 w; 1078 m; 1048 and 1012 (C—F) m.

Attempted Preparation of 1-Fluoro-1-octyne

1-Octynyllithium was prepared from 1-octyne (12.1 g) as described in the previous procedure. Dioxane was added to dissolve the solid and perchloryl fluoride was passed in at 0°. An exothermic reaction occurred and a white precipitate was deposited. Working up the mixture in the usual way gave only recovered 1-octyne (3.94 g) and 7,9-hexadecadiyne (1.35 g, 16.5%). A reaction analogous to the preparation of 1-chloro-8-fluoro-1-octyne, using *p*-toluenesulphonyl fluoride, gave no fluoroalkyne.

1,12-Difluoro-6-dodecyne and 1,14-Difluoro-7-tetradecyne

These were prepared in yields of 65.0% and 77.0% by the procedure described for 1-chloro-17-fluoro-8-heptadecyne (1). The infrared spectra of these two compounds were similar to those of the chlorofluoroalkynes (1), except that no C—Cl bands were present and the C—F bands were stronger.

1,12-Difluoro-5,7-dodecadiyne

Liquid ammonia (200 ml) was introduced into a 500-ml three-necked flask fitted with a stirrer, a dropping funnel, and a dry-ice condenser. Anhydrous ferric chloride (0.1 g) and small pieces of lithium (1.85 g, 0.264 g-atom) were added. At the end of 10 minutes, a grey suspension of lithium amide was present. 1,4-Dichloro-2-butyne (8.1 g, 0.066 mole) was added slowly. The ensuing dehydrochlorination was rapid and exothermic, being complete in about 1 minute. 4-Fluorobutyl iodide (3) (26.83 g, 0.132 mole) was added slowly, and the mixture was stirred for 4.5 hours. Ammonium chloride was added to neutralize any unreacted amide, and the ammonia was allowed to evaporate. The brown residue was extracted with ether, and the extracts were washed, dried ($CaSO_4$), and distilled, giving recovered 4-fluorobutyl iodide (3.16 g) and the required symmetrical diyne (4.83 g, 40.8%).

1,14-Difluoro-6,8-tetradecadiyne was prepared similarly in 47.8% yield.

1,11-Difluoro-4,6-undecadiyne

A 250-ml flask was fitted with a gas inlet tube, a dropping funnel, a stirrer, and a condenser. The flask was purged with nitrogen, and 5-fluoro-1-pentyne (2.88 g, 0.0335 mole) in absolute methanol (25 ml) was added. To this solution was added 10 ml of a 33% v/v solution of *n*-propylamine in methanol (i.e. ca. 0.06 mole of amine), cuprous chloride (70 mg), and hydroxylamine hydrochloride (0.2 g). The mixture was cooled to 0° and a methanolic solution of 1-bromo-6-fluoro-1-hexyne (6 g, 0.0335 mole) was added dropwise and with vigorous stirring. Small crystals of hydroxylamine hydrochloride were added from time to time to maintain the copper in the reduced state. The reaction was complete after about 1 hour. The copper was complexed by the addition of sodium cyanide (1 g). The mixture was diluted with water, extracted with ether, and the extracts were washed, dried ($CaSO_4$), and distilled, yielding the unsymmetrical diyne (3.36 g, 54.6%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1,13-Difluoro-5,7-tridecadiyne was prepared similarly in 71.4% yield.

Principal infrared bands of the four diynes (CCl_4, cm^{-1}): 2933 and 2857 (C—H) s; 2257 and 2155 (C≡C?) vw; 1477, 1458, and 1431 (C—H) m; 1391 m; 1351 w; 1326 m. The next six bands must be due to C—F, because none of them are present in the nonfluorinated analogues; all are strong: 1066, 1044, 1019, 1006, 986, and 959.

1,11-Difluoroundecane

Platinum dioxide (250 mg) was reduced in ethanol to finely divided platinum black. 1,11-Difluoro-4,6-undecadiyne (1.99 g, 0.0108 mole) in ethanol was added; hydrogenation proceeded smoothly until the theoretical quantity of hydrogen had been taken up. The catalyst was removed by filtration, and the ethanol by distillation, to give the difluoroalkane (1.98 g). Distillation gave the pure material (1.33 g, 64.0%).

1,13-Difluorotridecane was prepared similarly in 53.2% yield.

trans-1-Hydroxy-4-nonene

A 500-ml flask, fitted with a gas inlet tube, a dropping funnel, a precision-bore stirrer, and a condenser, was purged with nitrogen. *n*-Butyllithium (163 g of a 15.2% w/w solution; 24.6 g C_4H_9Li; 0.385 mole) was introduced, and dihydropyran (17.7 g, 0.19 mole based on 90% purity) was added over a period of 30 minutes. The temperature rose from 26° to 34°. The mixture was heated under reflux for 3 hours and then cooled. Excess *n*-butyllithium was destroyed by the slow addition of water, with cooling. The layers were separated and the aqueous layer was extracted with ether. Drying ($CaSO_4$) and distillation yielded the product (19.8 g, 73.0%) of b.p. 209–210° and n_D^{25} 1.4465; lit. (17) b.p. 103–104° at 14 mm, n_D^{20} 1.4494. Principal infrared bands (CCl_4, cm^{-1}): 3610 (free O—H) w; 3322 (bonded O—H) m; 2959, 2924, and 2857 (C—H) s; 1468, 1458, 1439, and 1381 (C—H) m; 1058 (C—O and O—H) s; 970 (*trans*-RCH=CHR′) s.

A MASS SPECTROMETRIC STUDY OF THE OXIDATION OF HYDROGEN SULPHIDE

PART I. OBSERVATION AND IDENTIFICATION OF SOME INTERMEDIATES

D. G. H. MARSDEN
Department of Chemistry, Laval University, Quebec, Que.
Received May 29, 1963

ABSTRACT

The oxidation of hydrogen sulphide has been followed mass-spectrometrically by direct sampling from a reaction vessel having a small leak. In the neighborhood of the third explosion limit, there is a period of 8–12 seconds of accelerating reaction before the explosion; during this time peaks are observed to grow, disappearing after explosion. By using $D_2S/^{16}O_2$ and $H_2S/^{18}O_2$ mixtures, it has been shown that these peaks arise from the ions H_2^+, S_2O^+, H_2SO^+, S_2^+, and $H_2S_2^+$. It is evident that the first two ions represent the intermediate formation of hydrogen and disulphur monoxide; the parents of the last three ions are discussed, and it is concluded that the most likely possibilities are H_2SO_2, S_2, and H_2S_2. Only during the explosion itself is there any evidence for SO radical.

INTRODUCTION

The oxidation of hydrogen sulphide was first studied in the 1930's. The first investigations (1–5) showed that the reaction was preceded by an induction period, was autocatalytic, and at sufficiently high pressures and temperatures led to an explosion. The explosion limit was at first thought to represent part of an explosion peninsula, but Jacovlev and Schantarovitsch (6) showed later that this limit was a third limit, the true explosion peninsula lying at considerably lower pressures, as would have been expected. Previous workers had not noticed it for two reasons; firstly, their manometers were not sufficiently sensitive, and secondly, the explosion was feeble and took place after a considerable amount of slow reaction, even in the middle of the peninsula. The induction period and autocatalytic reaction were observed in the whole press.–temp. plane; as the pressure was raised above the upper limit the induction period was shortened and the acceleration more marked, leading eventually to the third explosion limit. It appeared that the third limit was a thermal one; Frank-Kamenetskii calculated the position of this limit, and found good agreement with the experimental value, using the maximum rate of reaction during the acceleration period as a basis for the calculation of self-heating (7).

The facts that the reaction was autocatalytic, that the final products, SO_2 and water, were without influence on the kinetics, and that the maximum rate of reaction occurred at 10–15% conversion indicated that an intermediate product was formed which could give rise to degenerate branching; however, the intermediate was evidently less stable than the peroxides in hydrocarbon oxidation, since the reaction was complete in a matter of minutes.

Semenov and Emanuel (8, 9) were able to demonstrate the presence of the intermediate in the following manner. They found that if a mixture were partially reacted at a certain temperature and pressure and then transferred to a second reactor at a different temperature and pressure, the induction period in this second reactor was reduced considerably, or even eliminated, depending on the length of time the mixture had remained in the first reactor; this indicated that the intermediate survived the transfer from one reactor to another. It was then found that if, before introduction to the second reactor, the partially

reacted mixture were diluted with fresh mixture, the induction period was again lengthened, evidently due to dilution of the intermediate; it was found that there was a direct relation between induction period and dilution. They were able, thus, to use the induction period in the second reactor to measure relative concentrations of intermediate after various times of reaction in the first reactor. It was found that the intermediate was produced right from the start, i.e. even during the induction period (no pressure change), and rose to maximum concentration at the point of inflection of the pressure–time curve. Experiments also showed that the intermediate lasted for some hours at room temperature, but decayed faster in the presence of water vapor.

To identify the intermediate, Emanuel (9) took ultraviolet absorption spectra of cooled, partially reacted mixtures; new bands were observed and identified with those of Schenk's sulphur monoxide (10). In addition it was noticed that on cooling partially reacted mixtures there was an abnormal pressure decrease. Emanuel concluded that the intermediate was SO, but that on cooling it dimerized to S_2O_2; thus Schenk's sulphur monoxide as prepared and observed in ultraviolet absorption at room temperature was in fact S_2O_2. The same conclusion had also been reached earlier by Kondratiev and Kondratieva (11) for energetic reasons. The pressure decrease was then used to obtain absolute concentrations of SO; it appeared that in the early stages of reaction up to 75% of the H_2S consumed appeared as SO.

Later work by Jones (12) appeared to confirm the formula S_2O_2 at room temperature, since two infrared absorption bands were found. However, recently Myers (13, 14) has reinvestigated the compound and has shown conclusively by means of stoichiometry, molecular weight determination, mass spectrometry, and microwave spectroscopy that the correct formula is in fact S_2O, the thioanalogue of SO_2. Thus the compound prepared by Schenk, the intermediate observed by Emanuel at room temperature, and the end product observed in the flash-photolysis of H_2S/O_2 mixtures at room temperature by Norrish and Zeelenberg (15, 16) must all be considered as S_2O, disulphur monoxide.

It was therefore considered that it would be of interest to study the thermal oxidation by means of mass spectrometry in order to determine whether S_2O or SO were the important intermediate at the temperature of reaction, and to see if any other intermediates were formed. The region of the third limit was chosen, for three reasons. First, the induction period is negligible and the rate of reaction at its fastest, so that concentrations of intermediate would be expected to be relatively large. Secondly, the time scale is short, explosion taking place after 8–12 seconds; a relatively large sampling leak may be used in the reaction vessel, thus increasing sensitivity, without sensibly diminishing the pressure during the time interval of interest. Thirdly, there was the possibility of observing intermediates during the explosion itself. All experiments were carried out on stoichiometric mixtures.

EXPERIMENTAL

The mass spectrometer has recently been described in detail (17). It is essentially a 60° sector instrument with fast electrostatic scanning, having a large vacuum chamber at the source end, which holds a reaction vessel with surrounding furnace. The reaction vessel has a small leak from which the escaping gas passes directly through the ion source and is pumped away. The cylindrical reaction vessel used in this work was 40 mm in diam. and 120 mm long; the leak was 30 μ in diam., giving a leak rate of 2%/min at 100 mm pressure.

The ions are collected by an ion-electron multiplier and peaks displayed on a Tektronix 545A oscilloscope synchronized with the ion-voltage scan. The mass spectra were recorded on a Bolex H16 cinecamera, which triggered the oscilloscope so as to give one mass spectrum per frame; the time of scan was 0.01 second, and the framing rate either 8 or 7 1/2 frames per second.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Gases were obtained as follows:

Hydrogen sulphide, from a cylinder; purified by passage over iodine, ice-cold baryta solution; dried over P_2O_5, finally bulb-to-bulb distilled.

Oxygen, from a cylinder, 99.6% pure; dried over P_2O_5.

Deuterium sulphide, reaction of D_2O on freshly prepared aluminum sulphide (using degreased aluminum powder). To obtain a pure product it was necessary to degas the sulphide at 1200° C *in vacuo*; the reactants were sealed in ampoules which were broken inside an evacuated 5 *l* flask. The product was bulb-to-bulb distilled twice.

Oxygen-18, from the Weizman Institute, Israel; purity ^{18}O 98.73%, ^{17}O 0.36%, ^{16}O 0.91%, randomly distributed isotopically. Exchange with a silica surface at the temperatures used has been shown to be negligible (25).

Disulphur monoxide, prepared after Schenk (10) by passing a mixture of sulphur dioxide and sulphur vapor through a discharge tube (aluminum electrodes, 15 kv neon-sign transformer). The product was probably 50% diluted with unchanged SO_2.

Experimental Method

In the case of H_2S or D_2S mixtures with $^{16}O_2$ the gases were mixed at appropriate pressures in a large flask and the mixture expanded to a smaller flask, at a known pressure, whence it was expanded into the reaction vessel through a quick-opening lever valve; pressures were equalized in 1/4 second. All pressures were measured with a silica bourdon gauge nulled against a mercury manometer.

With the mixtures of H_2S and $^{18}O_2$ it was necessary to eliminate as much dead space as possible, in view of the small quantity available (150 cc $^{18}O_2$ at NTP). In this case, a vessel of appropriate size was glass-blown to the break-seal-equipped ampoule containing $^{18}O_2$ and filled with hydrogen sulphide to give a stoichiometric mixture at as high pressure as possible. After the seal was broken, the gases were allowed to mix for 3 days. A small Toepler pump was used to transfer the mixture to a small sampling volume attached to the bourdon gauge, from which it was expanded to the reaction vessel.

In an experimental run the reaction mixture was let into the reaction vessel and the camera started simultaneously. In certain cases the oscilloscope sensitivity was switched manually during a run (8–12 seconds) to observe rapidly changing peaks with greater precision.

In the runs with added S_2O, the discharge tube was allowed to run a few minutes while connected to the pumps. Then the evacuated reaction vessel was connected to the pump-line, allowing some S_2O to enter; after evacuating the line, the reaction mixture was then admitted to the reaction vessel, the camera being started simultaneously.

All electron energies quoted are relative and do not take into account surface potentials, etc.; where several experiments were done at different electron energies, they were done in succession, to minimize as much as possible changes in source conditions.

EXPERIMENTAL RESULTS

The third and upper explosion limits for stoichiometric mixtures found in this work are shown in Fig. 1, together with those found by Jacovlev and Schantarovitsch (6) for a

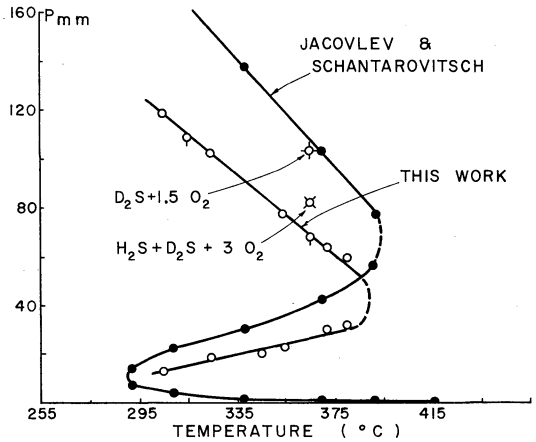

FIG. 1. Explosion limits in stoichiometric H_2S/O_2 mixtures. Points with tails represent determinations after an interval of 6 months.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

vessel of the same diameter. The limits were reproducible, as shown by points taken after an interval of several months; the difference between the curves may be due to some non-uniformity in the temperature of the reaction vessel. A point on the third limit is also shown for D_2S/O_2 stoichiometric mixture, and for a 50–50 $H_2S/D_2S/O_2$ stoichiometric mixture. It is of interest to note the considerable rise in the limit.

At the third limit the explosion takes place after a period of 8–12 seconds, during which peaks at mass 18 and 64 grow right from entry of the mixture into the reaction vessel, the rate accelerating up to the moment of explosion. During this time a peak is observed to grow at mass 80, which disappears after the explosion. This peak could be due to either the ion SO_3^+ or S_2O^+. The previous work suggested that it was probably S_2O^+, since it is known (13) that S_2O has a parent peak; this was borne out also by the abnormal height of the isotopic peak, mass 82. Confirmation was obtained using $^{18}O_2$; Fig. 2 shows some

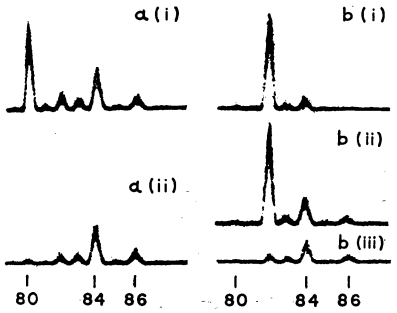

FIG. 2. Identification of S_2O: *a*(i) $H_2S/^{16}O_2$/Kr mixture just before explosion; *a*(ii) Kr alone before entry of reactants; *b*(i) $H_2S/^{18}O_2$ mixture; *b*(ii) $H_2S/^{18}O_2$/Kr mixture, both just before explosion; *b*(iii) Kr alone, before entry of reactants. Pressure, temperature: *a*, 95 mm, 340° C; *b*, 105 mm, 350° C. Electron energy 50 v.

oscilloscopic traces of these peaks, alone and in the presence of Kr as marker. It is observed that with $^{18}O_2$ the peaks are shifted to mass 82 and 84 and there is no peak at mass 86 ($^{32}S^{18}O_3^+$).

During the acceleration reaction peaks also grow at mass 2 and 48. The peak at mass 2 was shown to be due to hydrogen, since its growth was observed at electron energies too low for it to be formed as a fragment ion from H_2O or H_2S. After explosion it disappeared, while if the mixture were below the third limit it continued to grow (Fig. 3). The peak at mass 18 is necessarily due to water, but the peaks at mass 48 and 64 could arise from various species. Mass 48 was shown to be due to SO^+ and not O_3^+, since no peak at mass 54 was found using $^{18}O_2$, but the SO^+ ion could be formed in several ways: (*a*) by fragmentation of SO_2 or S_2O; (*b*) by fragmentation of some other SO-containing molecule; (*c*) by direct ionization of SO radical. Mass 64 could be SO_2^+ ion, formed from (*a*) SO_2, by direct ionization, or (*b*) some SO_2-containing species, by fragmentation; it could also be S_2^+ ion formed by (*a*) direct ionization of S_2 molecule, or (*b*) fragmentation of S_2O or some other S_2-containing species.

As noted in the introduction, Emanuel (9) considered that SO was the active intermediate and was formed in a larger amount than SO_2 at the beginning of reaction. To see if this were so, the ratio of peaks 64 to 48 was measured during the acceleration period and compared with the value after explosion, when the only species present is SO_2; the measurements were taken at various electron energies (Fig. 4). It may be seen that at

40 v the ratio is effectively constant during the acceleration period and unchanged after explosion, while at the two lower electron energies, the ratio 64/48 increases during the acceleration period and is lower than the value after explosion. This might be considered as evidence that SO radical was being formed in greater quantity at the beginning of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

reaction, the proportion of SO_2 increasing during the acceleration period. However, it will be noted that at corresponding times the actual value of the ratio 64/48 is bigger at lower electron energies; therefore if it is assumed that at low energies the 48 peak represents SO radical, then the 64 peak must be largely due to S_2^+ at the beginning of reaction. In fact, there is a considerable contribution from S_2^+ ion, as will be seen, but nevertheless the quantity of SO radical must be small, since there is no change in ratio at 40 v. Further experiments were made at energies below the appearance potential of SO from SO_2, as measured on a sample of SO_2 introduced into the reaction vessel. There was no evidence for any peak at mass 48 during the acceleration period. However, during the explosion itself a transient growth and decay was observed; Fig. 5 is a time exposure showing the transient taken with the mass spectrometer focused on mass 48 and the oscilloscope sweep running free, the electron energy being below A.P. $SO^+/(SO_2)$. It is of interest that the ultraviolet spectrum of SO has recently been observed in the flash-photolysis of H_2S/O_2 mixtures under adiabatic conditions (18).

It would therefore appear that SO radical is formed in very small amount, if at all, during the acceleration period. The fact that the 64/48 ratio grows during the acceleration period at low electron energies may be explained by supposing that SO^+ is being formed not only from SO_2, but also from S_2O or other intermediates. Since I.P. S_2O is undoubtedly lower than I.P. SO_2 (31), and the S—S bond weaker than the S—O bond, the contribution to mass 48 will come more and more from S_2O as the electron energy is lowered; as the reaction proceeds, 64 will grow not only from S_2^+, but also from SO_2^+ contributions, faster than 48, since, as will be seen, SO_2 grows faster than S_2O; after the explosion the ratio will be larger, since all the contribution to mass 48 is now from SO_2. At high electron energies, the increased cross section for ionization and fragmentation of SO_2 masks the effects of S_2O fragmentation, so that at 50 v SO_2 is the main contributor to peaks 48 and 64.

In observing the growth of peaks 48 and 64 at low energies, it was noted that the ^{34}S isotopic peaks at masses 50 and 66 were higher in proportion to the main peaks before the explosion than after. Since this effect was only observed at low energies, it was thought that some intermediate was being formed in small quantity at the same mass number. Fig. 6A(i and ii), recorded just before and after the explosion, show the effect at mass 50; similarly Fig. 6B(i and ii) show the effect at mass 66. Using D_2S, peaks were observed at mass 52 and 68 before the explosion, disappearing after the explosion (Fig. 6A(iii and iv); B(iii and iv)). The peak at mass 66 (68) could be due to either $H_2S_2^+$ ($D_2S_2^+$) or $H_2SO_2^+$ ($D_2SO_2^+$), while the peak at mass 50 (52) can only be ascribed to H_2SO^+ (D_2SO^+); this ion has recently been observed by Henglein (26).

To decide between these possibilities, $H_2S/^{18}O_2$ mixtures were reacted. First, it was verified that the isotopic anomaly at mass 52 ($H_2S^{18}O^+$) was still present at low electron energies. The results are shown in Fig. 7, where it may be observed that peak 52 is larger in relation to peak 50 before the explosion, *a*, than after, *b*. The large peak at mass 48, which would at first sight indicate gross contamination by ^{16}O, is in fact due to $C^{18}O_2^+$ produced by reaction with the filament; this may be inferred from the fact that it remains at almost the same height before and after the explosion, and that on raising the electron energy to 50 v after the explosion, *c*, it becomes much smaller in relation to peak 50; the purity of the oxygen-18 was confirmed by mass spectrometric analysis after the series of experiments was finished.

When the series of peaks from mass 64 to 70 was examined, indications were found that the $H_2S/^{18}O_2$ mixture that had been made up was richer than stoichiometric. First, there

For personal use only.

was a deposit of sulphur in a short section of cold tubing leading from the reaction vessel to its inlet valve; secondly, the peak at mass 64 after explosion was too large to be attributed to isotopic impurity in SO_2, and disappeared more slowly than the peak at mass 68 on pumping out; thirdly, a small peak at mass 82 was present after the explosion (S_2O may be synthesized by incomplete combustion of sulphur (19)). It was felt that these effects could not be accounted for by the presence of mercury vapor in the Toepler, for two reasons. Firstly, there was no such effect during trial runs with stoichiometric $H_2S/^{16}O_2$ mixtures; secondly, mercury vapor would tend to lower the sulphur content, forming hydrogen and non-volatile HgS.

Attempts were made to reduce the H_2S content by partial condensation in a capillary cold finger, and it was possible to suppress almost entirely the sulphur deposit and residual S_2O peak after explosion. It was felt that even if the mixture was still slightly richer than stoichiometric, essentially the same intermediates should be formed before the explosion, since during this time only 10–15% reaction occurred. Some oscilloscopic traces of masses 64–70 are shown in Fig. 8, *a* and *b* being taken near the beginning and end of the acceleration period respectively; *c* after explosion, all at low electron energy; *d* was taken after

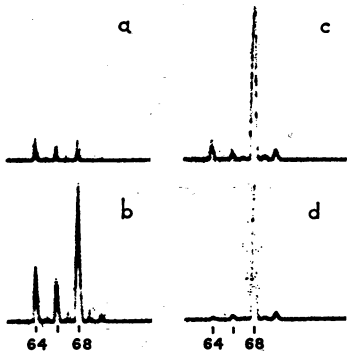

FIG. 8. Peaks at masses 64–70 using $H_2S/^{18}O_2$ mixture; *a*, at beginning of acceleration reaction; *b*, just before explosion; *c*, after explosion, all at low electron energy; *d*, after explosion at 50 v electron energy (scale change of 500).

the explosion at high electron energy. In *a* and *b* it may be observed that peaks 64, 66, and 68 are all of the same order of magnitude, 68 increasing toward the end of the acceleration period. It may be deduced immediately that the ions S_2^+, $H_2S_2^+$, and SO_2^+ are present. Mass 68 must be largely $S^{18}O_2^+$ since the contribution of $H_2\ ^{34}S^{32}S^+$ would be only 9% of the 66 peak; similarly 66 must be largely $H_2S_2^+$, since the contribution from $^{34}S^{32}S^+$ would be only 9% of the 64 peak. It is clear that peaks 64 and 66 belong to one or more intermediate compounds. The presence of sulphur after the explosion is shown also by Table I, where the experimental 50 v analysis after the explosion is compared with that expected; the 64 peak is too large, and increases at low electron energies (I.P. S_2 < I.P. SO_2).

The Effect of Added S_2O

When S_2O, produced by the discharge tube, was admitted to the reaction vessel before the reaction mixture, the period of acceleration could be reduced by one half or more, depending on the amount of S_2O produced by the discharge and the time elapsed before the reaction mixture was added; the same effect was observed by Emanuel (9). The explosion limit was unaffected. Figures 9–12 show growth of peaks 80, 64, 48, 18, 20 (D_2O^+),

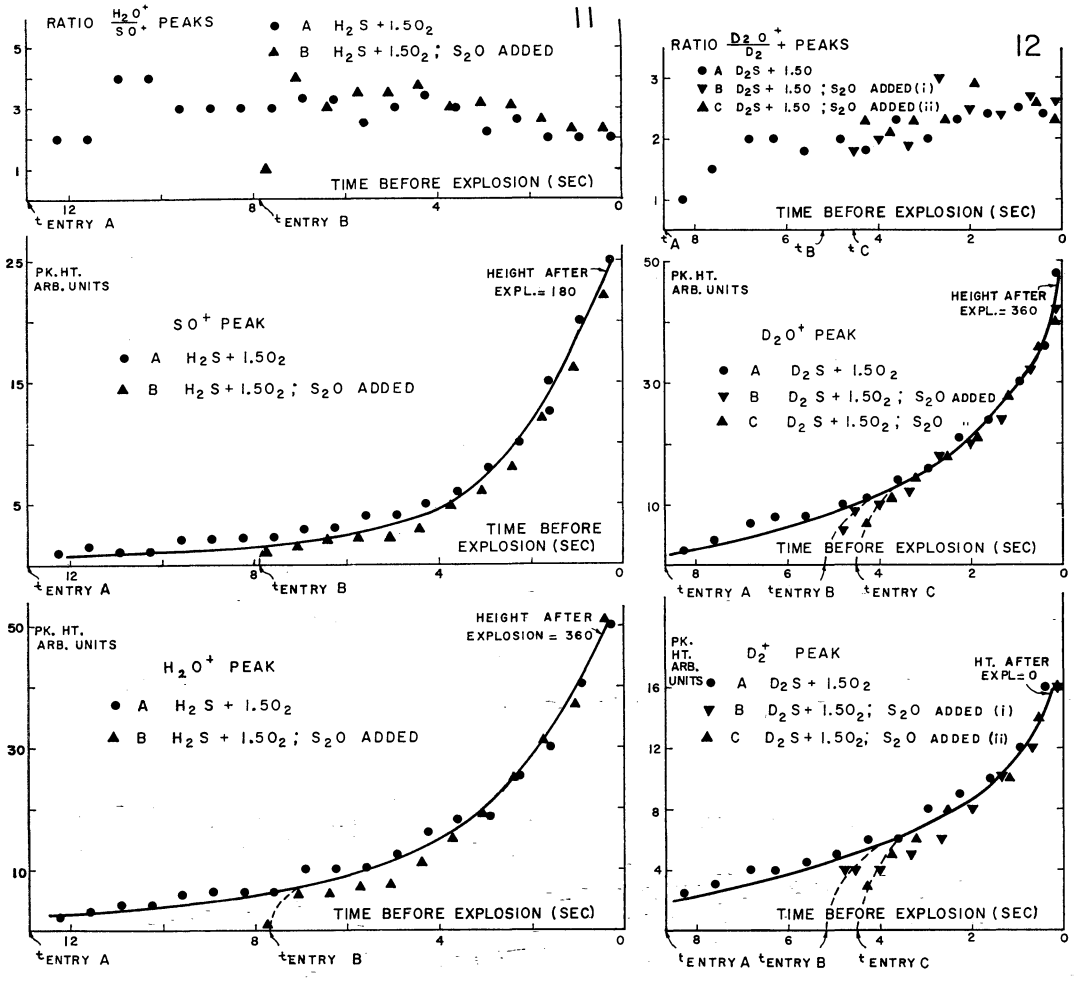

FIG. 11. Growth of SO^+ and H_2O^+ and variation of peak height ratio with time in the presence and absence of added S_2O; 50 v electron energy.

FIG. 12. Growth of D_2 and D_2O and variation of peak height ratio with time; $D_2S/^{16}O_2$ mixture, electron energy reduced sufficiently to eliminate contribution to D_2^+ peak from D_2O and D_2S.

represent the relative growth of S_2O^+, SO_2, H_2O, and H_2. However, in order that peak heights be proportional to concentrations, it is necessary that there be molecular flow through the reaction vessel leak; in the present case this is not so, for reasons of sensitivity (17), and the flow is in the transition region between molecular and viscous. Nevertheless, since only 10–20% of reaction occurs during the acceleration period, the viscosity may be assumed to be reasonably constant, so that peak heights are a fair indication of concentration.

Figures 10–12 show ratios of peaks 80/64, 48/18, and 20/4 during the acceleration period, the last two with and without added S_2O; the ratio 80/64 is also independent of added S_2O, as shown by Fig. 9. It may be seen that within the statistical scatter (largest at the beginning of the acceleration period, due to the small number of ions formed) H_2, H_2O, and SO_2 all grow at the same relative rate, while S_2O grows more slowly.

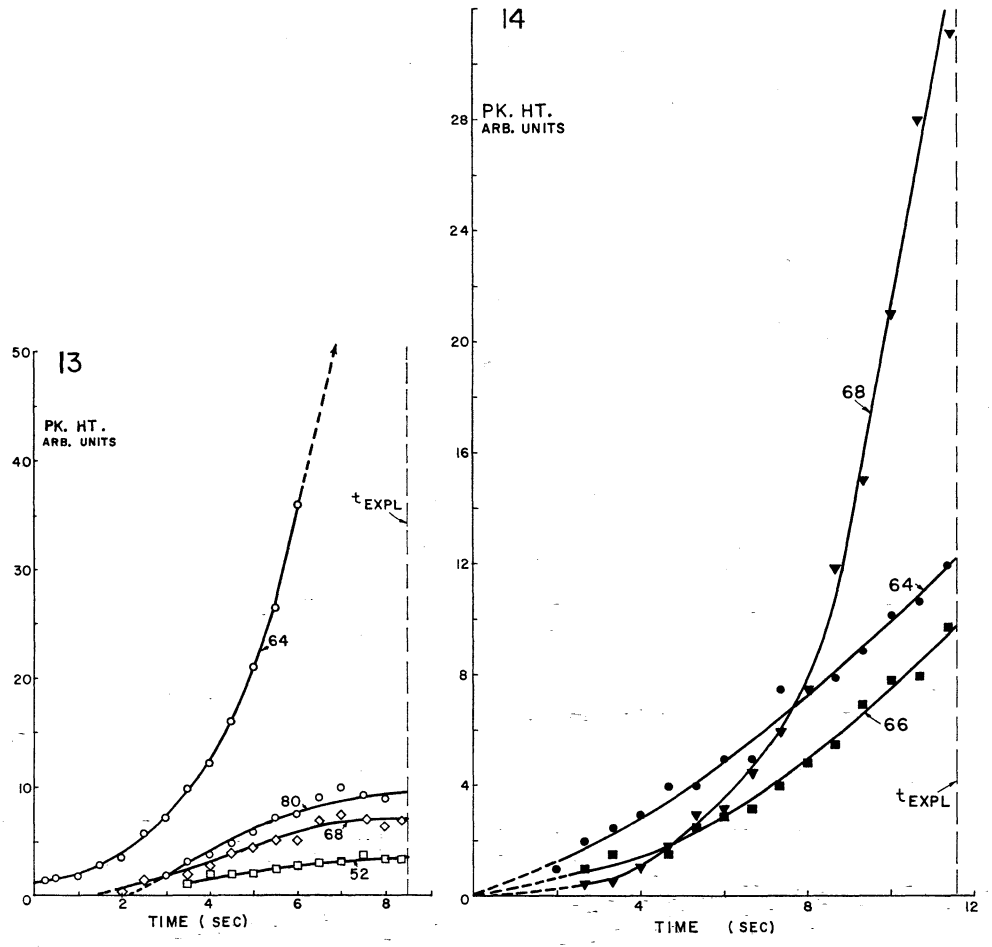

FIG. 13. Variation with time of peaks 52, 64, 68, 80; $D_2S/^{16}O_2$ mixture.
FIG. 14. Variation with time of peaks 64, 66, 68; $H_2S/^{18}O_2$ mixture; low electron energy.

Figures 13 and 14 show the growth of peaks 52, 68, 80 ($D_2S/^{16}O_2$) and the growth of peaks 64, 66, 68 ($H_2S/^{18}O_2$). It is to be noted, especially from Fig. 14, where the contribution to mass 68 can only be from SO_2^+, that peaks 52, 64, and 66, as well as peak 80, grow considerably more slowly than SO_2. Due to the smallness of the peaks it was impossible to measure with any accuracy differences between the rate of growth of peaks 50 (52), 64, 66 (68), and 80 (82); certainly no marked difference was observed.

Experiments on S_2O

Numerous experiments were carried out on reactions of S_2O, produced by the discharge tube; oxygen, H_2S or D_2S, H_2O or D_2O, H_2 or D_2, and various mixtures of these at different temperatures and pressures were added to see if the intermediates already found could be detected. Alone, i.e. at a pressure of a few mm and mixed with unchanged SO_2 from the discharge tube, S_2O is observable for several minutes at 350° C, and indefinitely at room temperature. In the presence of small quantities of oxygen it disappears faster, and above a critical pressure, immediately; the critical oxygen pressure is lower the higher the temperature, as has also been noted by Kondratiev and Kondratieva (20). No precise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

measurements were made, as the efficiency of the discharge tube in producing S_2O was was variable, but it was established that S_2O was destroyed immediately if the same pressure of oxygen was added that would be present in an H_2S/O_2 mixture at the third limit. No evidence for SO radical was obtained during the decomposition in the presence of oxygen.

In the presence of D_2O vapor at 350° C, the disappearance of S_2O was somewhat faster than in its absence, but the difference was not nearly as marked as Emanuel observed at room temperature (9); he found, however, that the reaction had a negative temperature coefficient. During the decomposition, no peak was observed at mass 68 ($D_2O \rightarrow D_2S_2^+$), but a small peak appeared at mass 36, shifting to mass 34 when H_2O was used, thus indicating the formation of H_2S. Addition of H_2S had no effect on the decomposition; mixtures of $H_2O + H_2S$ or $H_2O + O_2$ produced no other intermediate substances. Further experiments were made with $SO_2/H_2(D_2)$ and $SO_2/H_2O(D_2O)$ mixtures; again no reaction occurred and no intermediates were observed.

DISCUSSION

It appears certain that the S_2O^+ ion may be identified with the compound S_2O; if S_2O_2 does exist and is present during the acceleration period, it must lack a parent peak (no other peaks being found up to mass 150). In addition, the absorption spectra observed by Emanuel and by Norrish are certainly due to S_2O; if S_2O_2 were formed during the oxidation its absorption spectrum should have been observed, in addition to that of S_2O.

The identification of the compound or compounds giving rise to the ions H_2SO^+, S_2^+, and $H_2S_2^+$ is more difficult. It is hard to imagine that a compound $H_{2+x}S_{2+y}O_z$ could exist at the temperature of experiment, since such compounds as the thio acids are relatively unstable even at room temperature. H_2S_2 is the most stable of the polysulphides (21), and the simplest molecule able to give this peak. The ion H_2SO^+, again, would be more likely to arise from a compound $H_{2+x}SO_{1+y}$ than one containing several sulphur atoms. There are no obvious compounds containing more than two hydrogen atoms, so that the simplest choice would be one of the series H_2SO_{1-5}. Of this series the only known compounds are H_2SO_4 and H_2SO_5, H_2SO_3 being probably non-existent (22). H_2SO_5 is only formed under extreme oxidizing conditions, is unstable, and therefore unlikely to be formed under the experimental conditions. If H_2SO_4 were formed, it is surprising that no peak was observed at mass 86 ($^{32}S^{18}O_3^+$) or higher; it would also have been expected that sulphuric acid would condense in the cool reaction vessel inlet and give rise to persistent residual peaks. Of the two remaining possibilities H_2SO_2 might be formulated as the unknown parent compound of (*a*) the sulphoxylates, (*b*) the sulphinic acids, or (*c*) the sulphones. From the thermal stabilities of the known examples of these compounds, formulation (*c*) would be expected to be most stable (23). It is to be noted also that this form would be isoelectronic with the ion $H_2PO_2^-$. Some inconclusive evidence for its existence lies in the reaction of hydrogen atoms with sulphur dioxide at low temperatures; it was reported (24) that the rate of consumption of H and SO_2 corresponded with the stoichiometry H_2SO_2, though the products on warming up were complex. If the compound exists, it must lack a parent peak, since no isotopic anomaly was observed at mass 70, using $^{18}O_2$.

If H_2SO^+ is the parent ion, then the analogous known compounds are the sulphenates and the sulphoxides, of which the latter are by far the more stable, though considerably less so than the sulphones (23).

The peak S_2^+ could arise (*a*) as a fragment from sulphur vapor (S_{4-8}); (*b*) as a fragment

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

from S_2O or H_2S_2; or (*c*) from S_2 itself. The first possibility may be ruled out, since no peaks higher than 80 were observed, while they are known to exist in the mass spectrum of sulphur vapor (27).

Case (*b*) is difficult to establish, since values of I.P. S_2 exist between 8.3 v and 11.0 v (27–31), while the only published value of I.P. H_2S_2 (10.2 v) has been obtained indirectly (30). It is impossible to choose a particular selection of these values such that the series I.P. S, S_2, H_2S, H_2S_2 falls into line with the series I.P. O, O_2, H_2O, H_2O_2, though such comparisons have been used to justify the correctness of values obtained (27, 30).

An experiment was done using $H_2S/^{18}O_2$ mixture under the same conditions as the experiment illustrated by Figs. 8 and 14, but at an electron energy 2 v lower. Peaks 64, 66, and 82 were smaller, but in the same relation to each other, while 68 was relatively considerably smaller than before, as expected, since it is known that I.P. S_2 < I.P. SO_2 (31). In addition it was observed that peak 80 always disappeared at 11–12 v indicated electron energy, using S_2O produced either during the oxidation of hydrogen sulphide or synthetically; using the values found by Hagemann (31) for I.P. S_2O and A.P. $SO^+(S_2O)$, it may be concluded that S_2^+ is unlikely to arise from S_2O. The possibility of S_2^+ arising from H_2S_2 cannot be excluded, since calculation of A.P. $S_2^+(H_2S_2)$ using $\Delta H_f(H_2S_2)$, $\Delta H_f(S_2)$, and I.P. S_2 would give A.P. $S_2^+(H_2S_2) \geqslant 9.5$–12.2 v. If the value reported (30) for I.P. H_2S_2 is correct, then it is unlikely that A.P. $S_2^+(H_2S_2)$ is less than 10.2 v, since it is unusual for $D(H—X^+)$ to be negative in value; in fact, two bonds are broken, so that A.P. $S_2^+(H_2S_2)$ would be expected to be somewhat higher.

If the true electron energy can be assumed to about 1–2 v lower than the indicated value, as a comparison of I.P. S_2O measured in this work with that obtained by Hagemann would suggest, one would expect that the ratio 64/66 should change markedly on going from 16 v to 14 v indicated electron energy, if mass 64 were a fragment from H_2S_2; in fact it did not change, suggesting that S_2^+ is not a fragment ion.

To sum up, it is clear that hydrogen is an intermediate in this reaction, and it is almost certain that the intermediate giving rise to the peak at mass 80 is S_2O; the most plausible species likely to give rise to the ions H_2SO^+, $H_2S_2^+$, and S_2^+ are H_2SO_2, H_2S_2, and S_2.

THE WATER-SOLUBLE POLYSACCHARIDES OF DERMATOPHYTES

II. A GLUCAN FROM MICROSPORUM QUINCKEANUM[1]

ABSTRACT

A levorotatory glucan with a minimum degree of polymerization of 36 has been isolated from the water-soluble polysaccharides of the dermatophyte *Microsporum quinckeanum*. Hydrolysis of the methylated glucan yielded the following *O*-methyl-D-glucoses: 2,3,4,6-tetra- (10.2 mole%); 2,3,4-tri- (57.7 mole%); 2,4,6-tri- (22.2 mole%); 2,4-di- (8.2 mole%); and 2-mono- (1.6 mole%). The glucan consumed 1.53 moles of periodate with production of 0.70 mole of formic acid per mole anhydroglucose. Reduction and hydrolysis of the periodate-oxidized glucan yielded glycerol, erythritol, and D-glucose in a molar ratio of 72.3:0.6:27.1. The results showed that the glucan consisted of β-D-glucopyranose units joined in straight chains by $1 \rightarrow 6$ (57%) and $1 \rightarrow 3$ (24%) linkages. Approximately 3 in every 37 glucose residues constitute branch points in the glucan with branches occurring at the C_6 and C_3 positions of the same glucose unit. The glucan bears some resemblance to the yeast glucans of *Saccharomyces cerevisiae* and *Candida albicans* but differs from them in the relative number of $1 \rightarrow 6$ and $1 \rightarrow 3$ linkages and in the degree of branching.

It has been shown (1) that water-soluble polysaccharides form an essential part of antigenic material from cultures of dermatophytes and are therefore of considerable immunochemical importance. Preliminary examination of the polysaccharides isolated from five dermatophytes indicates that each has a similar pattern of water-soluble polysaccharides, specifically, two galactomannans and a glucan. The immediate objective of this program is to determine the main structural features of these polysaccharides by periodate oxidation and methylation procedures to see if they can be related to species differences and immunological properties. More detailed structural investigations are being reserved until these relationships are clear. The first paper (2) in this series described the purification and gross structural features of a galactomannan from *Trichophyton granulosum* Sabouraud, 1909. The present publication describes the isolation and constitution of a glucan from *Microsporum quinckeanum* (Zopf) Guiart and Grigorakis, 1928.

The polysaccharides were extracted in 4.7% yield from powdered cells of *M. quinckeanum* as described previously for *T. granulosum* (2). The product was a tan-colored powder containing significant amounts of ash and nitrogen and yielding mannose, glucose, and galactose on hydrolysis. Moving-boundary electrophoresis of this material in borate buffer (3) showed the presence of three migrating components. The mixture was separated into four fractions by chromatography on diethylaminoethyl (DEAE) cellulose (4). The first fraction eluted from the column contained no nitrogen and no ash, yielded only glucose on hydrolysis, and gave a single symmetrical peak ($\mu = 3.45 \times 10^{-5}$ cm²/volt sec) on moving-boundary electrophoresis. The other three fractions were mixtures, two of them still containing some protein.

The specific rotation of the glucan changed from $-27 \pm 1°$ to $53 \pm 1.5°$ on hydrolysis,

indicative of a predominance of β-glycosidic linkages. Isolation of a crystalline derivative confirmed the identity of the constituent monosaccharide as glucose and showed that it was present as the D-enantiomorph. The methylated glucan had a molecular weight of 8000 (degree of polymerization, 36) as shown by osmometry; this must be regarded as a minimum because some degradation of the glucan may have occurred during methylation.

The methylated glucan (OCH_3, 44.3%) was hydrolyzed and *O*-methyl glucoses in the hydrolyzate were isolated and estimated by preparative paper chromatography and by gas–liquid chromatography of their methyl glycosides (5). Figure 1 shows the separation

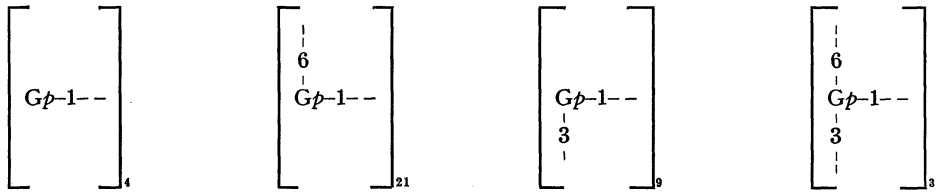
obtained by the latter method; the separated components were identified by comparison of their retention volumes (R_v) with those of authentic samples and by isolation of crystalline derivatives after separation of the free sugars by preparative paper chromatography. Table I shows the quantitative data obtained by the two methods; the results were in excellent agreement. Preparative paper chromatography showed the presence of a small amount of 2-*O*-methyl-D-glucose which was not sufficiently volatile to be estimated in the presence of the other components by gas–liquid chromatography.

The results in Table I show that the repeating unit of the glucan is made up of the following residues in the approximate ratios shown:



I II III IV

Thus, most of the β-D-glucopyranose units are joined in straight chains by 1 → 6 (II) and 1 → 3 (III) linkages. There are approximately three branch points in every 37 units, each branch being formed by linkages through C-6 and C-3 of a single glucose unit (IV). All chains are terminated by D-glucopyranose residues (I). In any study of polysaccharide structure by the methylation procedure the significance of 2–3% or less of a hydrolysis product is questionable because it may have arisen from incomplete methylation or from demethylation during hydrolysis. Although the 2-*O*-methyl-D-glucose (Table I) may represent a triple branch point in the glucan, the amount present (1.6%) was too small to be certain about this point.

A glucan made up of units I–IV should consume 1.35 moles of periodate with production of 0.68 mole of formic acid per anhydroglucose unit. The oxidized glucan, after reduction and hydrolysis (6), should yield glycerol and D-glucose in a ratio of 25:12. The values found were 1.53 moles of periodate and 0.70 mole of formic acid per mole anhydroglucose and a glycerol to D-glucose ratio of 25:9 in the reduced, hydrolyzed product. The periodate-oxidized, reduced glucan also yielded a small amount (0.6 mole%) of erythritol on hydrolysis. This may represent a 1 → 4 linkage in the polysaccharide but, as with the 2-*O*-methyl-D-glucose, the amount was too small to be certain of its significance. The results of periodate oxidation were thus in reasonable agreement with the main structural features deduced from the methylation data.

The structural units shown (I–IV) could be joined together in a number of ways. For example, short side chains of 1 → 3-linked units could be attached at intervals, through the C_3 positions, along a basic chain of 1 → 6-linked residues. Another possible structure could be a straight chain of 1 → 6- and 1 → 3-linked residues with single-unit side chains. Distinction between these or other possible structures requires the isolation of oligosaccharide fragments by partial hydrolysis of the periodate-oxidized, reduced glucan (7) and of the glucan itself.

The glucan from *M. quinckeanum* differs from glucans that have been isolated from other microorganisms. It is clearly distinguished by its negative rotation from the dextrorotatory bacterial dextrans (8) and from *pullulan*, a glucan from the yeast-like fungus *Pullularia pullulans* (9). In this respect it more closely resembles the levorotatory yeast

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

glucans isolated from *Saccharomyces cerevisiae* (10, 11) and from *Candida albicans* (12). A further similarity between these yeast glucans and that from *M. quinckeanum* is the almost exclusive occurrence of $1 \rightarrow 6$ and $1 \rightarrow 3$ linkages. Differences arise in the relative amounts of these two linkages and in the degree of branching in the polysaccharides. Thus, the glucan from *S. cerevisiae* was shown to be a linear polysaccharide in which 10–20% of the linkages were β-1 $\rightarrow$ 6, the remainder being β-1 $\rightarrow$ 3 (11). The glucan from *C. albicans* contained only β-1 $\rightarrow$ 6 linkages in the linear portions of the molecule with branches (23%) being formed by β-1 $\rightarrow$ 3 bonds (12). The glucan from *M. quinckeanum* contains both β-1 $\rightarrow$ 6 (57%) and β-1 $\rightarrow$ 3 (24%) linkages in the linear portions of the polysaccharide, and branch points, involving the same linkages, constitute only some 8% of the molecule.

EXPERIMENTAL

Paper chromatograms were run by the descending method using the following solvent systems (v/v):
(A) pyridine:ethyl acetate:water—1:2.5:2.5 (upper phase);
(B) butan-1-ol:ethanol:water—3:1:1;
(C) butan-1-ol:pyridine:water—6:4:3;
(D) butanone saturated with water.

Sugars were detected on chromatograms by the *p*-anisidine hydrochloride spray reagent (13) or by silver nitrate – sodium hydroxide sprays (14). A Tiselius-type, Spinco model H apparatus was used for moving-boundary electrophoresis in 0.05 *M* borate buffer (3). A Pye Argon Chromatograph and an F and M Model 500 Chromatograph were used for gas–liquid chromatography (5). Evaporations were done at 35–40° C under diminished pressure; melting points are corrected; specific rotations are equilibrium values unless otherwise specified. R_g values represent movement relative to 2,3,4,6-tetra-*O*-methyl-D-glucose on paper chromatograms.

Preparation of Water-soluble Polysaccharides

Microsporum quinckeanum, isolated from a scutulum of a mouse, was cultured and polysaccharides were extracted from the dried mycelium as described previously for *T. granulosum* (2). The preparation thus obtained was a light brown powder which contained 0.52% nitrogen and 4.91% ash and amounted to 4.7% of the dried mycelium. A sample (5 mg) of this preparation was hydrolyzed by *N* sulphuric acid (1.5 ml) at 97° C in a sealed tube for 12 hours. Paper chromatography of the hydrolyzate in solvent A showed the presence of mannose, glucose, and galactose. Another sample (150 mg) of the water-soluble polysaccharides was dissolved in 0.05 *M* sodium tetraborate (15 ml), equilibrated with the buffer by dialysis for 20 hours, and examined by moving-boundary electrophoresis (3). Although resolution was not complete, three components could be detected.

Isolation of Glucan

A portion (500 mg) of the mixture of water-soluble polysaccharides obtained above was resolved on a column (32×3 cm) of diethylaminoethyl (DEAE) cellulose by successive elution with 0.01 *M* sodium tetraborate, 0.05 *M* sodium tetraborate, 0.02 *N* sodium hydroxide, and 0.1 *N* sodium hydroxide (4). Fractions (20 ml each) were collected automatically every 15 minutes. Aliquots (1 ml) of each fraction were mixed with 2 ml of anthrone reagent (200 mg anthrone in 100 ml of 95% sulphuric acid) and the optical densities at 625 mμ were read on a colorimeter to give the relative amounts of polysaccharide in each fraction. The relative amounts of protein in the fractions were determined from the optical densities of the eluates at 280 mμ. Four polysaccharide fractions were eluted successively, one in each of the solutions described above. The eluates containing the first two polysaccharide fractions (eluted by 0.01 *M* and 0.05 *M* sodium tetraborate respectively) were passed over Amberlite IR-120 ion exchange resin and evaporated to dryness. Boric acid was removed from the residues by repeated addition and evaporation of methanol. Polysaccharide fractions 1 and 2 were then washed with ether and dried. The eluates containing polysaccharide fractions 3 and 4 (eluted by 0.02 *N* and 0.1 *N* sodium hydroxide respectively) were dialyzed and freeze-dried. These procedures yielded polysaccharide fractions 1 (62.4 mg); 2 (26.0 mg); 3 (270.0 mg); and 4 (41.6 mg): recovery, 400 mg, 80%. The losses were accountable in part by the 5% of each fraction of eluate used for the anthrone test and in part by the irreversible absorption of highly pigmented impurities on the DEAE cellulose. The recovered polysaccharides were ash-free, water-soluble powders. The optical densities at 280 mμ showed that fractions 3 and 4 contained protein; fractions 1 and 2 were protein free. The polysaccharide fractions yielded the following sugars on hydrolysis as revealed by paper chromatography (solvent A): 1—glucose; 2—glucose with smaller amounts of mannose and galactose; 3—mannose and galactose with a trace of glucose; 4—glucose, mannose, and galactose. Subsequent work has shown that fraction 3 could be resolved into two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

galactomannans by fractional precipitation with Fehling's solution and the same procedure showed that fraction 4 was a mixture of polysaccharides. In view of these results it seemed likely that fraction 2 was a mixture of a glucan and at least one galactomannan. Fraction 1 was the only homoglycan obtained in the separation and it also showed a single, symmetrical peak on electrophoresis with a mobility, μ, equal to 3.45×10^{-5} cm²/volt sec.

The separation was repeated a sufficient number of times (12 g of crude polysaccharide on a column (29×9 cm) of DEAE cellulose, 240 g) to yield 4.5 g of polysaccharide fraction 1, the glucan on which the balance of this work was done.

Properties of Glucan

The polysaccharide had $[\alpha]_D^{26}$ $-27\pm1°$ (*c*, 1% in water) changing to $[\alpha]_D^{26}$ $+53\pm1.5°$ (*c*, 1% in *N* hydrochloric acid) after hydrolysis in *N* hydrochloric acid at 97° C for 12 hours. The hydrolyzate was neutralized (Amberlite IR-45 ion exchange resin), evaporated to dryness, and the residue was heated with *p*-nitroaniline in methanol solution for 40 minutes. The solution was cooled and the crystals which separated were recrystallized from methanol to yield N-(*p*-nitrophenyl)-D-glucopyranosylamine dihydrate (15), m.p. 183° C, $[\alpha]_D^{26}$ $-199\pm1°$ (*c*, 1% in pyridine). The minimum degree of polymerization of the glucan was 36 as determined for its methylated derivative by osmometry.

Periodate Oxidation

The glucan (200 mg, 1.235 mmoles) was dissolved in 0.02 *M* sodium periodate (200 ml). Reagent blanks were also prepared and the oxidation was allowed to proceed at 5° C in the absence of light. At intervals samples were removed for estimation of formic acid by iodometric titration and of periodate by the excess arsenite procedure (16). The results, in moles per mole anhydroglucose, were as follows:

Time (hr)	Formic	Periodate
23	0.52	0.14
47	0.70	1.52
71	0.70	1.50
95	0.69	1.56
173	0.71	1.53

After the oxidation was complete iodate and excess periodate were precipitated by addition of 0.5 *M* barium acetate and the precipitate was filtered. The filtrate was deionized by Amberlite ion exchange resins IR-120 and IR-45 and then potassium borohydride (100 mg) was added. After 48 hours the solution was neutralized with acetic acid and deionized again. The solution was then evaporated to dryness and last traces of boric acid were removed from the residue by repeated evaporation with methanol. The residue was dissolved in water (5 ml) and an aliquot (1 ml) was hydrolyzed by 2 *N* sulphuric acid at 97° C for 12 hours. Paper chromatography (solvent B) showed the presence of two components that were identical with authentic samples of glycerol and glucose run on the same paper strips. The hydrolysis products from another aliquot of the polyol were acetylated by pyridine – acetic anhydride (1:1) and the reaction mixture was examined directly by gas–liquid chromatography (5, 17). Four components were found having retention volumes corresponding to those of authentic samples of glycerol triacetate, erythritol tetraacetate, α-D-glucose pentaacetate, and β-D-glucose pentaacetate. The molar ratio of glycerol to erythritol to glucose was 72.3:0.6:27.1, as determined from the relative areas under the peaks.

Methylation of Glucan

The glucan (3.5 g) was methylated 10 times by dimethyl sulphate and 30% sodium hydroxide (18) and 5 times by silver oxide and methyl iodide (19) to yield a product (OCH_3, 42.1%) showing weak hydroxyl absorption in its infrared spectrum. One further methylation by dimethyl sulphate and powdered sodium hydroxide in tetrahydrofuran (20) yielded the fully methylated glucan; 1.8 g; $[\alpha]_D^{22}$ $-30\pm1°$ (*c*, 1.5% in chloroform); OCH_3, 44.3%, calc. 45.6%; molecular weight by osmometry, 8000.

Hydrolysis Products from Methylated Glucan

The methylated glucan (1.8 g) was hydrolyzed by sulphuric acid under the conditions described by Croon *et al.* (21) as causing minimum degradation and demethylation. The neutralized (Amberlite IR-45) hydrolyzate was evaporated to dryness and a portion of the residue was boiled under reflux for 6 hours with 2% methanolic hydrogen chloride. Acid was removed by silver carbonate and the methyl glucosides in the solution were examined by gas–liquid chromatography. The conditions used and the separation obtained are shown in Fig. 1. The quantitative data given in Table I were obtained from the areas under the peaks as measured by a planimeter. The compounds giving the individual peaks (Fig. 1) were identified by comparison of their retention volumes with those of authentic samples under the same conditions.

To confirm the identities of the *O*-methyl-D-glucoses the remainder of the hydrolyzate was fractionated by

preparative paper chromatography on Whatman 3 MM paper (solvent D) to yield the following products:

2,3,4,6-tetra-*O*-methyl-D-glucose	125 mg
2,3,4-tri-*O*-methyl-D-glucose	711 mg
2,4,6-tri-*O*-methyl-D-glucose	274 mg
2,4-di-*O*-methyl-D-glucose	101 mg
2-*O*-methyl-D-glucose	20 mg

2,3,4,6-Tetra-O-methyl-D-glucose

This product showed the same chromatographic mobility in solvents B, C, and D as an authentic sample (R_g 1.00). The compound crystallized from light petroleum (30–60° C) and was recrystallized from *n*-hexane to yield 2,3,4,6-tetra-*O*-methyl-D-glucose (21), m.p. 93–94° C, unchanged on admixture with an authentic sample, $[\alpha]_D^{24}$ +83° (*c*, 1% in water).

2,3,4-Tri-O-methyl-D-glucose

The sirupy product had R_g values of 0.88 and 0.85 in solvents B and D respectively. Anilide formation yielded a crystalline product that was recrystallized from ether to give *N*-phenyl-2,3,4-tri-*O*-methyl-D-glucosylamine (22), m.p. 145° C, $[\alpha]_D^{25}$ +70° (*c*, 1% in ethanol).

2,4,6-Tri-O-methyl-D-glucose

On paper chromatograms the compound gave the same color reaction with *p*-anisidine hydrochloride and the same R_g values (0.86 and 0.79 in solvents B and D respectively) as 2,4,6-tri-*O*-methyl-D-glucose. The sirupy product was extracted with boiling ether and the extract was evaporated to a small volume. The crystals which separated were recrystallized from ether to yield 2,4,6-tri-*O*-methyl-D-glucose (23), m.p. 122° C, $[\alpha]_D^{25}$ +71° (*c*, 1% in water).

2,4-Di-O-methyl-D-glucose

The compound from preparative paper chromatography showed the same R_g values in solvents B, C, and D, and the same color reaction with *p*-anisidine hydrochloride as 2,4-di-*O*-methyl-D-glucose. The sample was boiled under reflux with 2% methanolic hydrogen chloride for 6 hours. The anomeric methyl glycosides were then separated by gas–liquid chromatography and were collected separately from the effluent gas stream. Both glycosides crystallized in the collecting tubes and were recrystallized from ether – light petroleum (30–60° C) to yield methyl 2,4-di-*O*-methyl-α-D-glucoside (24), m.p. 79–80° C, $[\alpha]_D^{24}$+160° (*c*, 0.2% in acetone), and methyl 2,4-di-*O*-methyl-β-D-glucoside (24), m.p. 123–124° C, $[\alpha]_D^{24}$ −18° (*c*, 0.1% in acetone).

2-O-Methyl-D-glucose

The compound showed the same chromatographic behavior in solvents B and C as 2-*O*-methyl-D-glucose. Reduction by sodium borohydride followed by acetylation yielded a mono-*O*-methyl-penta-*O*-acetyl-D-glucitol which had the same retention time on gas–liquid chromatography as 2-*O*-methyl-1,3,4,5,6-penta-*O*-acetyl-D-glucitol (25). The product crystallized and had m.p. 53–54° C, unchanged on admixture with an authentic sample.

ACKNOWLEDGMENT

The authors wish to thank Mr. F. P. Cooper for assistance with the gas–liquid chromatography.

STUDIES WITH A PERFLUOROALKYL–SILICON COMPOUND

H. C. CLARK, J. T. KWON, AND D. WHYMAN
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received June 3, 1963

ABSTRACT

Some detailed chemical studies are described of dimethylbis(perfluoropropyl)silane (I), prepared from *n*-perfluoropropyllithium and dimethyldichlorosilane. The hydrolytic stability of (I) towards base is described, and pyrolyses in the temperature range 185–295°, leading to the formation of dimethyldifluorosilane, $(CH_3)_2SiF_2$, and fluorocarbons, are discussed. Chlorination of (I) leads to stepwise chlorination of the CH_3 groups, and even excess chlorine does not cause cleavage. Bromine does not react with (I). The reaction of (I) with iodine and catalytic amounts of aluminum in boiling toluene causes rapid cleavage of C_3F_7 as C_3F_7I. The mechanisms of some of these reactions are discussed.

INTRODUCTION

A number of reports appear in the literature describing the preparation of perfluoroalkyl–silicon compounds. The passage of perfluoroiodoalkanes over a heated mixture of silicon and copper at 400–500° is said to produce bis(perfluoroalkyl)silicon dihalides (1), while compounds such as trifluoro(trifluoromethyl)silane, CF_3SiF_3, are reported (2) to be formed on the passage of fluorine and silicon tetrafluoride over calcium carbide at 300°. No further details of these reactions have appeared in the literature and there is some doubt as to their reliability. Compounds such as CF_3SiCl_3 and $(CF_3)_2SiCl_2$ have been described briefly by other workers (3), but details of the preparative method and of their properties have not been given. Even less information has appeared concerning the chemical behavior of perfluoroalkyl–silicon compounds, and several conflicting statements have been made. Thus, Rochow (4) has stated that CF_3 groups are cleaved from silicon by cold water, while Haszeldine and Marklow (3) contend that the CF_3—Si bonds of CF_3SiCl_3 and $(CF_3)_2SiCl_2$ are not broken on treatment with water, although reaction with dilute aqueous alkali is said to liberate fluoroform rapidly.

Diethylbis(perfluoropropyl)silane, $(C_2H_5)_2Si(C_3F_7)_2$, has been prepared (5) from methyllithium, perfluoroiodopropane, and diethyldichlorosilane. The compound is reported to be stable towards 3 *N* sulphuric acid at 100°, and towards methanolic sodium hydroxide below 75°, but other chemical properties are not described. Recently, we have shown (6) that perfluoro-*n*-propyllithium can be prepared directly from perfluoroiodopropane and lithium metal; this provides a more direct synthetic route to perfluoro-*n*-propyl derivatives and has allowed us to prepare and examine in some detail a perfluoropropyl–silicon compound.

DISCUSSION

The compound chosen for study, dimethylbis(perfluoro-*n*-propyl)silane, $(CH_3)_2Si(C_3F_7)_2$, (hereafter referred to as (I)) was prepared directly in ethereal solution from dimethyldichlorosilane and perfluoro-*n*-propyllithium:

$$(CH_3)_2SiCl_2 + 2n\text{-}C_3F_7\text{-}Li \rightarrow (CH_3)_2Si(C_3F_7)_2 + 2LiCl.$$

(I) is a colorless liquid which boils at 124° and which is stable to air and water. Treatment of (I) with 50% aqueous potassium hydroxide causes rapid cleavage of C_3F_7 as C_3F_7H. This was not quantitative under conditions which required heating at 110° for 18

For personal use only.

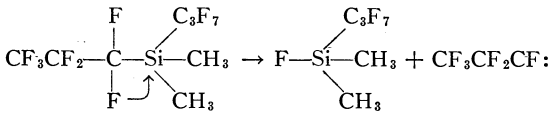
hours, so that the rate of hydrolysis seems comparable to that observed for heptafluoropropyl–phosphorus compounds (7).

Decomposition of (I) was appreciable at 185°, and above 250° was almost complete. In the present investigation, the aim was to determine the general decomposition scheme and it was apparent, from the nearly quantitative formation of $(CH_3)_2SiF_2$ from each pyrolysis, that this could be represented by the equation

$$(CH_3)_2Si(C_3F_7)_2 \xrightarrow{\Delta} (CH_3)_2SiF_2 + x[(C_3F_6)].$$

Complete identification of the fluorocarbon fragments was not possible, largely because comparisons could not be made with samples from a complete set of known fluorocarbon compounds, particularly for fluorinated cycloalkane derivatives.

Our results indicate that the fluorocarbon products are largely C_3 or C_6 compounds, that some unsaturated C_3 products are formed, and that both cyclic and straight-chain C_6 compounds may also be produced. It has been proposed (8) that the thermal breakdown of polyfluoroalkyl–silicon compounds containing fluorine in the α-position occurs by an α-elimination of fluorine. Such a mechanism probably operates also for (I), again initiated by an internal nucleophilic attack on silicon by the α-fluorine atom:



A similar second step involving the second C_3F_7 group will give the final product, $(CH_3)_2SiF_2$, in agreement with the experimental results, and two CF_3CF_2CF: radicals. The latter must undergo considerable rearrangement and dimerization (9) leading to $CF_3CF{=}CF_2$, perfluorocyclopropane, hexanes, and cyclohexanes, the latter three presumably resulting from possible formation of $\cdot CF_2CF_2CF_2\cdot$. From the infrared spectra and molecular weights of the fluorocarbon mixtures, and from the observed formation during pyrolysis of small quantities of SiF_4 and C_3F_7H, it is clear that secondary reactions are occurring which may well involve reaction of hydrocarbon groups and hydrogen abstraction. However, the evidence certainly indicates the above type of thermal decomposition leading to the formation of the difluorodimethylsilane.

In an attempt to ascertain more clearly the nature of the fluorocarbon products, a pyrolysis of (I) in the presence of tetrafluoroethylene was performed. It was hoped that any carbene such as CF_3CF_2CF: would add preferentially to the C_2F_4 to give a more readily identifiable product. However, no such addition seemed to occur and only the decomposition products of (I) seemed to be formed.

The reactions of (I) with the halogens are of considerable interest since cleavage of either methyl or perfluoropropyl groups is possible, or alternatively halogenation of the CH_3 groups may occur. Information may thus be obtained concerning the relative ease of cleavage of alkyl, and perfluoroalkyl, groups. Chlorination of (I) takes place readily although a temperature of 110° is required to complete the reaction. The major volatile product is hydrogen chloride, showing that chlorination of the CH_3 groups occurs in preference to cleavage. Reactions were carried out in which the ratio of chlorine to (I) was 1:1, 2:1, 4:1, 6:1, and 8:1. In the first case, as can be seen in Table II, 50% of (I) was recovered unchanged from the reaction, and the yield of hydrogen chloride was in accord with the equation

$$(CH_3)_2Si(C_3F_7)_2 + 2Cl_2 \rightarrow (CH_2Cl)_2Si(C_3F_7)_2 + 2HCl.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

However, since it has been shown (10) that a Si—CH_2Cl group is more readily chlorinated than a Si—CH_3 group, it is possible that the final product is $(CH_3)(CHCl_2)Si(C_3F_7)_2$. As the ratio of chlorine to (I) is increased, further chlorination of the methyl groups occurs, till in the 6:1 case six equivalents of hydrogen chloride are released, and the remaining involatile silicon compound contains no C—H bonds. Even with excess chlorine (8:1 ratio of Cl_2:(I)), no cleavage occurs and the excess chlorine is recovered from the reaction. In all these chlorinations, side reactions also occurred but only to a small extent (approx. 5%), as evidenced by the separation of small quantities of compounds such as $CClF_3$, and CCl_2F_2. In no case was there evidence of the formation of CH_3Cl. This inability of chlorine to cleave either the CH_3 or C_3F_7 groups of (I) is in agreement with earlier observations (11, p. 126) on the cleavage of silicon–alkyl bonds.

The reaction of (I) with bromine did not lead to cleavage, or to bromination of the CH_3 group. This is also in agreement with the fact that bromine alone does not react with Si—CH_3 groups (11, p. 381).

The cleavage of silicon–alkyl bonds by iodine in the presence of aluminum iodide as catalyst is well known (11, p. 126), and in this case such a reaction provides a method of determining the relative ease of cleavage of Si—CH_3 and Si—C_3F_7 groups. The reaction of (I) with iodine and catalytic amounts of aluminum powder in refluxing toluene caused rapid cleavage of C_3F_7 as C_3F_7I. As has also been shown in other cases (11, p. 126), this

$$(CH_3)_2Si(C_3F_7)_2 + 2I_2 \rightarrow [(CH_3)_2SiI_2] + 2C_3F_7I$$

reaction is actually catalyzed by aluminum iodide which we have observed is formed by the direct reaction of iodine and aluminum in toluene. Because of its reactivity and great ease of decomposition, the diiodosilane, $(CH_3)_2SiI_2$, was not itself characterized, but it was readily shown that the reaction residue contained no C_3F_7 groups. No CH_3I was formed.

For hydrocarbon groups, the ease of cleavage falls in the order Ph $\gg$ Me $>$ Et $>$ *n*-Pr (12). Since phenyl groups are readily cleaved from silicon by bromine (11, p. 152), whereas C_3F_7 is not, it seems that a probable order of ease of cleavage, including the C_3F_7 group, is: Ph $>$ C_3F_7 $>$ Me $>$ Et $>$ *n*-Pr. It is therefore not possible to obtain perfluoropropyl–silicon halides by direct halogenation of compounds such as (I).

EXPERIMENTAL

The techniques and procedure used in the preparation of perfluoro-*n*-propyllithium have been described previously (6) and some further reactions of halides of group IIIA–VA elements with perfluoro-*n*-propyllithium will be reported elsewhere (13).

Dimethylbis(perfluoro-*n*-propyl)silane was obtained, in a typical preparation, from perfluoroiodopropane (46.3 g), lithium metal containing 2% sodium (2.4 g), and dimethylsilicon dichloride (12.9 g) in dry diethyl ether (30 ml) at −40°. Fractionation *in vacuo* of the reaction mixture followed by two distillations at 760 mm gave a final yield of 5.4 g (20%) of I, b.p. 124±1.0°, M.W. 382±10 (calc. M.W. for $(CH_3)_2Si(C_3F_7)_2$: 396). (Calc. for $C_8H_6F_{14}Si$: C, 24.3; H, 1.53; F, 67.1. Found: C, 24.8; H, 1.81; F, 65.1.) A vapor phase chromatographic examination of I, using a Beckman GC-2A gas chromatograph fitted with a dinonyl phthalate – Chromosorb column at 70°, with helium as carrier gas, showed the presence of approximately 6–7% of a more volatile impurity which presumably accounts for slight deviations in the analytical results. This parallels the results of Pierce *et al.* (5), who found that along with $(C_2H_5)_2Si(C_3F_7)_2$, the monochloro compound, $(C_2H_5)_2SiCl(C_3F_7)$, was also formed in small amounts and that the latter could not be satisfactorily purified. In the present case, therefore, the impurity was probably $(CH_3)_2SiCl(C_3F_7)$ and since the presence of such an impurity would not affect the reactions being studied, no further purification was attempted.

Hydrolysis

(I) (0.2935 g) was treated with 50% aqueous potassium hydroxide in a sealed tube at 110° for 18 hours to give 0.1594 g of C_3F_7H, identified spectroscopically. This corresponds to 79.8% hydrolysis, and oily droplets of unreacted I, which is immiscible with water, remained after the completion of the experiment.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

A second experiment under the same conditions also gave approximately an 80% yield of C_3F_7H. Hydrolysis of (I) occurred readily with ethanolic potassium hydroxide but the difficulty of completely separating the C_3F_7H from ethanol prevented a quantitative measure of the degree of hydrolysis.

Pyrolysis

Samples of (I) were heated at various temperatures in the range 185–295° in sealed tubes for 20 hours. The reaction products were separated by trap-to-trap distillation in a conventional vacuum apparatus and each product was identified by measurements of its molecular weight and vapor pressure, and by its infrared spectrum. From each experiment, fractions were obtained which, in order of increasing volatility, condensed at −23°, −64°, −96°, −125°, and −196°. That at −23° was shown to be unreacted (I). The −125° fraction contained just one compound, which was identified by its infrared spectrum (14) and molecular weight (calc. 96, observed values 96–100) as difluorodimethylsilane, $(CH_3)_2SiF_2$. It is of interest that, while Kriegsmann's spectrum of $(CH_3)_2SiF_2$ shows a broad unresolved band at 900–1000 cm^{-1} due to Si—F stretching, the present spectra all showed excellent and reproducible resolution so that maxima were observed in this region at 900, 910, 937, 948, 958, and 980 cm^{-1}. The −196° fractions had molecular weights of approximately 100 and all observed infrared bands could be assigned (15) to SiF_4 and to C_3F_7H. The −64° and −96° fractions were complex mixtures; in fact, a gas chromatographic examination of a −64° fraction showed the presence of two major and two minor components. Because of the difficulty of obtaining a sufficiently wide range of known fluorinated compounds for comparison, it was not possible to identify each component of these mixtures. However, the −96° fractions gave molecular weights in the range 210–280, and their infrared spectra showed them to contain C_3 compounds such as perfluorocyclopropane and $CF_3CF{=}CF_2$, as well as compounds containing C—H bonds, in view of the weak absorptions at 2900–3000 cm^{-1}. The less volatile −64° fractions gave molecular weights in the 310–330 region, and together with their infrared spectra, this clearly indicated that fluorinated C_6 compounds were present (e.g. the major absorptions for C_6F_{14} were observed). At the higher pyrolysis temperatures (250–295°), the spectrum of this −64° fraction always showed a characteristic triplet at 1280, 1315, and 1345 cm^{-1} which occurs in a number of fluorinated cyclohexane derivatives (15, 16), and also in unsaturated C_5 and C_6 fluorocarbons (15). However, since the spectrum showed that this fraction contained no C=C group, this triplet is considered to be due to six-membered cyclic components. Since a very weak C—H absorption was observed at 2900 cm^{-1}, these components may be only partially fluorinated cyclohexanes. The effect of temperature on the approximate distribution of products between the various fractions is shown in Table I.

TABLE I

Pyrolysis experiments

Pyrolysis temp. (°C)	Wt. sample (g)	% recovered	Wt.% of products* in: −64° fraction	−96° fraction	−125° fraction	−196° fraction
185	1.564	85.0	6.6	6.5	1.3	0.2
225	0.890	18.3	23.5	28.5	26.0	1.1
255	1.183	7.0	39.7	21.0	24.7	1.8
295	0.865	3.0	21.8	43.0	25.3	1.5

*As a percentage of the total weight of material in the experiment.

In a further effort to identify some of the fluorocarbon components, all of the −96° fractions were combined and subjected to further fractionation. Most of the material was condensed at −78°, gave a molecular weight of 260±10, and had an infrared spectrum showing absorptions expected for perfluorocyclopropane, C=C groups, and C—H groups. Individual components could not be further characterized.

Reaction of (I) with C_2F_4

Tetrafluoroethylene (0.232 g, 2.32 mmole) and (I) (0.846 g, 2.13 mmole) were heated in a sealed tube for 20 hours at 255°. Fractionation of the reaction mixture gave: (I) (0.092 g) identified spectroscopically; a −64° fraction (0.164 g), M.W. 320±30, whose infrared spectrum was very similar to that of *n*-C_6F_{14} and which did not show the spectroscopic features of a cyclohexane group; a −96° fraction (0.210 g) whose infrared spectrum was identical with that of the similar fractions obtained from pyrolysis of (I); a −125° fraction (0.306 g), M.W. 110, shown spectroscopically to consist largely of $(CH_3)_2SiF_2$ together with a smaller amount of C_2F_4; and a −196° fraction (0.026 g), M.W. 110, whose spectrum clearly showed the major components to be SiF_4, C_2F_4, and C_3F_7H. In addition 0.12 g of a white, involatile residue remained in the reaction tube, this residue having an infrared spectrum showing the presence of only C—F and C—C groups. The residue was hence polymerized tetrafluoroethylene.

Chlorination

Samples of (I) were reacted with chlorine in varying molar ratios, in sealed tubes under ultraviolet irradiation. To ensure completion of the reactions, tubes were finally heated for several hours at 110°. The results are shown in Table II.

TABLE II

Chlorination reactions

Reactants				Wt. of products (g) in:				
Chlorine		(I)		−10°	−23°	−96°	−125°	−196°
g	mmole	g	mmole	fraction	fraction	fraction	fraction	fraction
0.183	2.55	1.010	2.55	0.533	0.502	0.024	0.016	0.110
0.178	2.50	0.495	1.25	0.541	0.050	0.025	0.009	0.098
0.326	4.60	0.454	1.15	0.596	—	—	0.010	0.168
0.510	7.18	0.466	1.18	0.484*	—	0.007	0.010	0.294

*Incomplete recovery due to absorption on grease.

In some reactions, a portion of (I) was recovered unchanged as a fraction which condensed at −23° and which could be identified by its vapor pressure, molecular weight, and infrared spectrum. A major product in each chlorination was a colorless liquid of very low volatility, which condensed at −10° or remained in the reaction tube. Because of the low vapor pressure, molecular weights could not readily be obtained, but infrared studies showed the $>Si(C_3F_7)_2$ portion of (I) to be present in these products, and marked changes occurred in the 700 and 800 cm^{-1} regions, which are associated with the $>Si(CH_3)_2$ group (17, pp. 336–337), and also with C—Cl linkages (17, p. 330). Moreover, as the molar ratio of (I) to chlorine was increased from 1:2 to 1:4 to 1:6, the intensity of the C—H absorption at 2900–3000 cm^{-1} decreased and was completely absent from the spectrum of the involatile colorless liquid obtained from the 1:6 reaction.

The other major product was a gas which condensed at −196° and which was identified (observed molecular weights for these fractions fell in the range 37–42) as hydrogen chloride. The infrared spectra of these fractions showed slight contamination by C_2F_4 (~2–4%), SiF_4 (~2%), and also an unknown component (<5%) which gave strong absorption at 2300 cm^{-1} and in the 1150–1350 cm^{-1} region, suggesting some type of fluorinated C≡C linkage. Minor products condensed at −96° and −125°. Those at −96° had molecular weights of the order of 125–150 and were shown spectroscopically to contain compounds such as CCl_2F_2, CH_2Cl_2, $CClF_3$, and CCl_3F. The −125° fractions gave molecular weight of 190–210 and contained C_3F_7Cl and $CF_3CF{=}CF_2$.

In none of the chlorination reactions was there any evidence of methyl chloride as a product.

In another experiment, the ratio (I):chlorine was 1:8. The products were identical with those obtained in the reactions of Table II, with the addition that 25% of the chlorine was recovered unchanged.

Reaction of (I) with Bromine

Samples of (I) with bromine in a 1:6 and 1:2 molar ratio were reacted under the same conditions as used for chlorination. In both cases, at least 95% of the bromine was recovered, together with approximately 80% of unreacted (I). Small quantities of fluorocarbons produced by the decomposition of (I) were also separated.

Reaction of (I) with Iodine

Iodine (0.625 g, 2.48 mmole) and (I) (0.454 g, 1.15 mmole) were refluxed in 20 ml of toluene, with a trace of aluminum powder. After 1 hour, only a faint iodine color remained, and refluxing was continued for a further hour to ensure complete reaction. Fractionation of the reaction mixture left a tarry, black involatile residue which fumed slightly in air and whose infrared spectrum showed the complete absence of fluorocarbon groups. The chief volatile product, condensing at −78°, was identified spectroscopically as C_3F_7I (0.450 g, 67% yield).

In a reaction in which (I) and iodine were heated in a sealed tube at 135° for 60 hours in the absence of a solvent but with a trace of aluminum powder, 50% of (I) was recovered unchanged.

NUCLEAR ISOMERS $Hg^{197m,g}$, $Hg^{195m,g}$, AND $Au^{196m,g}$ FORMED BY BOMBARDMENT OF GOLD WITH PROTONS OF ENERGIES FROM 8 TO 60 MEV[1]

Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.

Received April 22, 1963

ABSTRACT

Gold has been bombarded with protons of energies from 8 to 60 Mev to study excitation functions and isomer yield ratios for the formation of the isomeric pairs $Hg^{197m,g}$, $Hg^{195m,g}$, and $Au^{196m,g}$. For $Hg^{197m,g}$ and $Hg^{195m,g}$, the ratio of the yield of the metastable state to that of the ground state, σ_m/σ_g, was found to increase with increasing proton bombarding energy up to 20 and 35 Mev respectively, whilst that for $Au^{196m,g}$ showed a maximum at about 40 Mev.

INTRODUCTION

The study of the formation of nuclear isomeric pairs in nuclear reactions may be used as an aid in the investigation of the mechanism of nuclear reactions. At low energies (less than about 30 Mev) nuclear reactions are believed to proceed by a compound nucleus mechanism. The compound nucleus de-excites by emission first of particles (while there is sufficient excitation energy available) to give a residual excited nucleus, and then by γ-ray emission to a product nucleus. If the product nucleus can exist in two isomeric states of definite angular momentum, the ratio of the yields for formation of the two isomers will reflect the angular momentum states of the compound residual nuclei. The yield ratio of high-spin to low-spin isomer would be expected to increase regularly with increasing bombarding energy.

Above approximately 30 Mev (for nuclear reactions in the heavy-mass region) the compound nucleus mechanism is believed to give way to a direct interaction mechanism in which not all the energy of the bombarding particle is transferred to the target nucleus. The yield ratio of high-spin to low-spin isomers might then not continue its regular increase, but would level off or even peak and decrease before coming to a steady value. Thus a change in the yield ratios might serve as a sensitive indicator as to the extent of the two types of processes.

Gold was chosen as target material, since, on bombardment with protons over the available energy range (8 to 80 Mev), it should produce cleanly three isomeric pairs with convenient half-lives. The nuclear reactions giving rise to these nuclear isomers occur over different energy ranges such that the isomer yield ratios should form a critical test of the different nuclear mechanisms operating.

EXPERIMENTAL

(a) Target Preparation

Gold powder, in a sealed aluminum tube, was used as target material. The sealed aluminum tube was a precautionary measure to ensure that no mercury would be lost by evaporation during bombardments.

Copper powder, mixed with the gold, was used to monitor the proton beam. The monitor reactions used were $Cu^{63}(p,n)Zn^{63}$ at low energies and $Cu^{65}(p,pn)Cu^{64}$ at all higher energies, and the cross sections used are shown in Table I. Those for the first reaction were taken from the work of Ghoshal (1) while those for the second are from the work of Meghir (2).

TABLE I
Monitoring cross sections

Proton energy (Mev)	$\sigma_{Zn^{63}}$ (millibarn) (1)	$\sigma_{Cu^{64}}$ (millibarn) (2)	Proton energy (Mev)	$\sigma_{Cu^{64}}$ (millibarn) (2)
8	300		28	345
10	450		31	320
11	480		34	290
12	520		37	275
13	530		40	260
14.5	490		46	240
16		100	52	210
20		300	60	190
24		370		

For bombardments, about 10 mg of gold and 10 mg of copper powders were weighed separately into a 2S aluminum tube (about 3.5 cm long and 1/16 inch internal diameter and 0.003 inch wall thickness) which was crimped at one end. The other end of the tube was then closed and the weighed gold and copper powders thoroughly mixed by shaking. The mixing of the powders was tested previously by shaking them together in a glass tube of the same dimensions as the aluminum tube, when it was seen that the powders mixed together quite homogeneously. The aluminum tube containing the mixture was mounted in the target holder for bombardment in the circulating beam of the cyclotron.

Corrections were made for proton energy degradation by the target. The range-energy data of Sternheimer (3) were used for this correction, and it was found to be approximately 1 Mev at a proton energy of 20 Mev.

(b) Chemical Procedures

After bombardment, the aluminum tube and its contents were dissolved in aqua regia. For most runs the following chemical separations were made. Carriers of 10.0 mg Hg^{++}, about 5 mg each of Pt^{++}, Ni^{++}, Zn^{++}, Co^{+++}, and Na^{+} were added and the nitric acid destroyed by repeated evaporation with concentrated hydrochloric acid. The volume of the solution was made up to about 20 ml with concentrated hydrochloric acid and gold extracted with isoamyl acetate. The isoamyl acetate extract was washed with 6 *M* hydrochloric acid and the washing combined with the acid layer, since otherwise some copper would be extracted with the gold. The gold was back-extracted from the organic layer with water, made up to known volume with dilute hydrochloric acid, and an aliquot taken for activity measurement.

Mercury was precipitated from the aqueous phase as mercurous chloride by reduction with stannous chloride solution, and repurified by distillation as mercurous chloride. The chloride was then dissolved in aqua regia, made up to volume, and an aliquot taken for activity measurement.

The remaining solution was evaporated to about 2 ml in volume and copper separated from nickel, cobalt, zinc, and sodium by means of Dowex 1 anion exchange resin based on the method of Kraus and Moore (4). The ion exchange column, 10 cm long and 7 mm in diameter, was washed with concentrated hydrochloric acid, and the solution containing the elements to be separated, in 2 ml of concentrated hydrochloric acid, was mixed with a little of the resin and transferred to the top of the column. The column was then eluted with 1.5 *M* hydrochloric acid until the first few drops of blue solution indicated the presence of copper in the eluate. The eluate was collected until the blue copper color had almost disappeared (between 2 and 5 ml were sufficient), made up to volume, and an aliquot taken for activity measurement. The column was eluted with a further 5 ml of 1.5 *M* hydrochloric acid to remove copper completely and then eluted with water to remove zinc which could be collected and an aliquot taken for measurement, if required.

Examination of the separated samples by gamma ray spectroscopy and half-life measurements was used as a check on the radiochemical purity of the samples. In the accepted runs, the half-lives for the monitors never varied by more than 2% from the literature values.

(c) Chemical Yield Determinations

The chemical yield of each element separated was determined so that absolute cross sections could be calculated for the various nuclear reactions. All chemical yield determinations, with the exception of that for zinc, were based on standard spectrophotometric methods using a Beckman DU spectrophotometer and 1 cm Pyrex cells. Mercury was determined as mercury dithizonate in chloroform (5), gold by means of its complex ion $[AuBr_4]^-$ (6), and copper by means of the diethyldithiocarbamate complex in isoamyl alcohol (7). Zinc was determined volumetrically, using disodium ethylenediaminetetraacetic acid and eriochrome black T as the indicator (8).

(d) Activity Measurements

The 511 kev annihilation radiation was used to measure the Zn^{63} and Cu^{64} activities. A 3in.×3 in. sodium iodide (Tl activated) crystal and photomultiplier tube assembly were used as the detector. The pulses from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

this were fed into a 100-channel pulse-height analyzer assembly. It was determined in auxiliary experiments that complete annihilation of the positrons from both Zn^{63} and Cu^{64} occurred in the liquid source and glass vial, so that no correction factor for this effect had to be introduced. The mercury and gold activities were also measured by the scintillation detector. Corrections for the overall detector efficiency were made to the counting data from empirical efficiency curves available in our laboratory.

(e) Calculation of Cross Sections

The cross sections for formation, σ_A, were calculated from the equation

$$[1] \qquad \sigma_A = \sigma_m \cdot \frac{D_A}{D_m} \cdot \frac{n_m}{n_A} \cdot \frac{(1-e^{-\lambda_m T})}{(1-e^{-\lambda_A T})},$$

where A refers to the product and m refers to the monitor, and σ = cross section, D = disintegration rate at end of bombardment, n = number of atoms in target, λ = disintegration constant, T = time of bombardment.

In cases where the ground-state isomer was formed by decay of the upper state, the disintegration rate, D_A, was corrected for that which had grown in during the bombardment. In general, the cumulative disintegration rate of a daughter at the end of bombardment is given by

$$[2] \qquad D_d' = D_d + \frac{D_p}{1-e^{-\lambda_p T}}\left[1 - \frac{\lambda_p e^{-\lambda_d T} - \lambda_d e^{-\lambda_p T}}{\lambda_p - \lambda_d}\right],$$

where the subscripts p and d refer to parent and daughter respectively, and D_d and D_p are the amounts formed directly. D_d can be calculated, substituted for D_A in equation [1], and the formation cross section of the independently formed daughter thus calculated.

RESULTS

(a) $Au^{197}(p,n)Hg^{197m,g}$

Photon peaks at 75 and 134 kev were observed in the γ-spectrum from the mercury fraction in the low-energy (8–20 Mev) runs. The peak at 134 kev decayed with a half-life of 24±1 hr measured over six half-lives. It is due to Hg^{197m} and occurs in 97% of the disintegrations (9). A conversion coefficient $\alpha_T = 2.1$ (9) has been used in the cross-section calculations. The peak at approximately 75 kev decayed with a half-life of 65±2 hr, measured over a period of six half-lives. The peak is a combination of the K X-ray and a 77 kev γ-ray from the first excited state of Au^{197}. It was assumed, for purposes of calculation, that 1 K X-ray corresponded to 1 disintegration of Hg^{197g}. The K X-ray fluorescence yield was taken to be 0.945 (10).

Since Hg^{197m} decays 97% by isomeric transition to Hg^{197g}, the cross section thus calculated for Hg^{197g} (σ_g*) actually represents the cross section for the independent formation of Hg^{197g} plus 0.97 of the cross section for the formation of Hg^{197m}. By making this subtraction, the cross section for the independent formation of Hg^{197g} was obtained (σ_g). The data are given in Table II and shown in Figs. 1 and 2. These results agree reasonably

(b) $Au^{197}(p,pn)Au^{196m,g}$

Photopeaks of 150 and 190 kev, due to Au^{196m}, were observed to decay with a half-life of 9.5±0.5 hr, measured over a period of three half-lives. Since the conversion coefficients of the γ-rays from Au^{196m} have not been measured, the disintegration rate was taken from the *K* X-ray peak, assuming one X-ray per disintegration. The half-life of the metastable state obtained from the X-ray decay curve was always slightly longer than that obtained from the γ-ray photopeaks, in conformity with observations made previously (13). At bombarding energies of 52 and 60 Mev, contributions from 39-hr Au^{194} were subtracted from the decay curve. Above a bombarding energy of 60 Mev, the formation of 17-hr Au^{193} interfered with the resolution of the curve and limited the presentation of the data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A well-defined peak at 350 kev, due to Au^{196g}, decayed with a half-life of 6.1±0.1 days measured over six half-lives, in good agreement with recent values (9). The decay of Au^{196g} is well established and the curves of the photopeaks from three neighboring γ-rays, 333, 356, and 426 kev, were summed to obtain disintegration rates. From recent data (9), the total conversion coefficients, α_T, for the 333 kev (26.9% branching ratio), the 356 kev (66.7%), and the 426 kev (6%) peak were calculated to be 0.084, 0.063, and 0.035 respectively. The area under the composite peak was multiplied by 1.12 to allow for branching ratio and internal conversion corrections.

TABLE IV

subtraction from σ_T, the total cross section. The cross-section ratio, σ_m/σ_T can be obtained, using the ratio of counting rates at the end of bombardment rather than disintegration rate, so that errors in chemical yield and sampling factors do not affect the result. From $\sigma_m/\sigma_T = \sigma_m/(\sigma_m+\sigma_g)$ the ratio σ_m/σ_g can be calculated and is given in Table IV. The results are shown graphically in Figs. 3 and 4. The values of σ_T compare favorably with the values

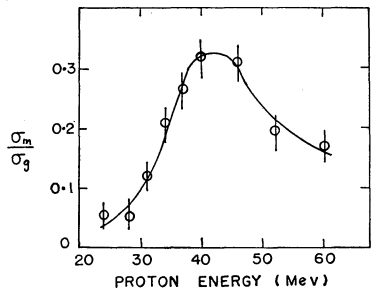

FIG. 4. Variation of isomer yield ratios with proton bombarding energy for the reactions $Au^{197}(p,pn)Au^{196m,g}$.

of the cross section for formation of Au^{196} as measured by Kavanagh and Bell (15). The displacement of the two excitation functions is about 4 Mev in terms of proton bombardment energy which may be compared with the ±2 Mev uncertainty in the proton energy.

(c) $Au^{197}(p,3n)Hg^{195m,g}$

The decay scheme of $Hg^{195m,g}$ is very complicated. The γ-ray spectrum obtained from the chemically separated and purified mercury fraction showed a prominent X-ray peak, and peaks at 185 and 260 kev which decayed with half-lives of 6.5 and 42 hr respectively. The peak at 260 kev is due to Au^{195} and occurs in 26% of the decays of Hg^{195m}. The peak at 185 kev showed a half-life (6.5 hr) far removed from the 9.5 hr associated with Hg^{195g}. The X-ray peak was nicely resolvable into three components—a long-lived tail, 40 hr, and 9.5 hr, and this peak was used to measure the counting rates of the metastable and ground states. Disintegration rates were calculated assuming a fluorescence yield of 0.945 (10) and that each disintegration yielded one X-ray. The cross-section values are given in Table V and are shown in Fig. 5. Figure 6 shows the ratio σ_m/σ_g.

ERRORS

A standard deviation of ±18% in the absolute cross sections for formation of the metastable states has been calculated. For the ground-state isomers whose disintegration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

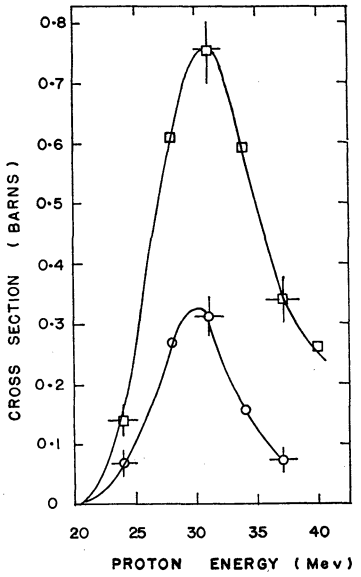

FIG. 5. Excitation functions for the reactions $Au^{197}(p,3n)Hg^{195m,g}$: □ σ_m; ○ σ_g.

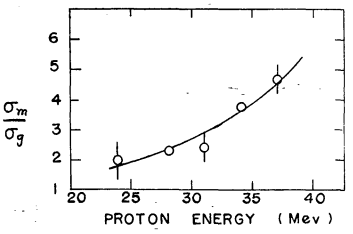

FIG. 6. Variation of isomer yield ratios with proton bombarding energy for the reactions $Au^{197}(p,3n)Hg^{195m,g}$.

rates at the end of bombardment had to be corrected for that which had grown in during the bombardment, the standard deviation in the absolute values rose to ±25%.

If the external errors are neglected, i.e. errors in the monitor cross-section values, the standard deviations in this work range between ±10% and ±16%, and these are the vertical error bars shown in the figures. The uncertainty in the proton bombarding energy (±2 Mev) is indicated by horizontal bars.

The errors involved in the calculation of the isomer cross-section ratios are smaller, since the cross section of the monitor, the chemical yield factors, and sampling factors all cancel in the expression for σ_m/σ_g. For $Hg^{197m,g}$, the standard deviation in the cross-section ratio varied between 10 and 15%, for $Au^{196m,g}$ between 10 and 20%, and for $Hg^{195m,g}$ between 7 and 15%. Due to uncertainties in the decay schemes and incomplete knowledge of the conversion coefficients, there may be systematic errors here which have not been taken into account. However, the relative values of the σ_m/σ_g values and the shape of the curves of σ_m/σ_g against energy would not be affected.

DISCUSSION

The shapes of the (p,n) and $(p,3n)$ excitation functions, as expected, show the effect of the operation of the compound nucleus mechanism. The probability for forming the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

compound nucleus increases sharply above the threshold energy to a maximum at the optimum energy of the reaction, and then falls steeply as the next competing reaction becomes energetically possible.

The (p,pn) excitation functions (Fig. 3) also show a sharp initial rise as the energy of the proton beam increases above the threshold value. The excitation functions reach a maximum and fall off slowly with increasing proton energy, in contrast to those for the (p,n) and $(p,3n)$ reactions. This shape of the (p,pn) excitation functions is in agreement with the work of Bell and Kavanagh (14) and Meadows *et al.* (15) and shows that the (p,pn) reaction involves a larger percentage of direct interactions than the (p,n) or $(p,3n)$ reactions.

The isomer yield ratios for the (p,n) and $(p,3n)$ reactions increase with energy over the energy range studied, whilst the yield ratio for the (p,pn) reaction passes through a maximum at about 40 Mev. Several attempts have been made to calculate expected isomer yield ratios for low-energy nuclear reactions assuming the compound nucleus mechanism (11, 16, 17). In the present work this type of calculation is applicable only to the (p,n) reaction, since this occurs at sufficiently low energies for the compound nucleus mechanism only to apply. However, no values for the transmission coefficients for protons in gold, which are required in the calculation, are available. The calculations are very lengthy, and for these reasons have not yet been attempted.

The $(p,3n)$ and $(p,4n)$ reactions occur over too high an energy range for the above calculations to be valid, as a considerable percentage of the initial events is direct interaction in which only a fraction of the energy and angular momentum of the projectile are transferred to the compound nucleus. It is expected that direct interactions will favor the production of the isomer whose spin is closer to the target spin. This effect is noticed for the σ_m/σ_g ratios for Au^{196} where the ground-state isomer ($I = 2$) becomes favored above 40 Mev, compared to the metastable state ($I = 12$). The spin of the target Au^{197} is 3/2.

NUCLEAR MAGNETIC RESONANCE STUDIES OF THE PROTONATION OF WEAK BASES IN FLUOROSULPHURIC ACID

II. AMIDES, THIOAMIDES, AND SULPHONAMIDES[1]

T. BIRCHALL AND R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ontario
Received May 27, 1963

ABSTRACT

The proton magnetic resonance spectra of solutions of amides in fluorosulphuric acid confirm previous results which indicated that protonation of amides occurs on the carbonyl oxygen. A similar study of solutions of thioacetamide, thioacetanilide, thiourea, and *N*-methylthiourea provides conclusive evidence that the sulphur atom is protonated in these bases. In the case of *N*-methyl- and *N,N'*-dimethyl-*p*-toluenesulphonamide and sulphamide protonation occurs on nitrogen rather than on oxygen. It was not possible to obtain any conclusive evidence on the site of protonation of urea and *N,N'*-dimethylurea. Evidence is presented which indicates that thiourea and *N*-methylthiourea are diprotonated in solution in strong acids such as fluorosulphuric acid, and diprotonation of urea and *N,N'*-dimethylurea under the same conditions also seems very likely.

For personal use only.

In Part I (1) it was shown that a new peak appears at approximately −10 p.p.m. from an external tetramethylsilane reference in the proton magnetic resonance spectrum of certain amides in fluorosulphuric acid at low temperatures. It was shown that this peak can be attributed to the $C{=}\overset{+}{O}{-}H$ group. The low basicity of the solvent and the low temperature (approx. −80°) are together sufficient to reduce the rate of proton exchange between the conjugate acid of the amide and the solvent so that they give rise to separate peaks in the n.m.r. spectrum. Hence it was established unambiguously that acetamide and formamide and their *N,N*-dimethyl derivatives protonate on the carbonyl oxygen and not on nitrogen. The same conclusion has also been reached somewhat less directly by other workers from measurements of the areas of the NH or NH_2 peaks in the n.m.r. spectra of neutral and acid solutions of formamide, acetamide, benzamide, and their *N*-methyl derivatives (2–5). We have now extended our previous measurements to include the *N*-methyl derivatives of formamide and acetamide and also benzamide and its *N*-methyl and *N,N*-dimethyl derivatives. We have also studied thioacetamide, thioacetanilide, urea, *N,N'*-dimethylurea, thiourea, *N*-methylthiourea, sulphamide, and *N*-methyl- and *N,N*-dimethyl-*p*-toluenesulphonamide in order to determine the site of protonation.

RESULTS AND DISCUSSION

Amides

The results of our measurements are summarized in Table I. In every case at a sufficiently low temperature the signal from the $C{=}\overset{+}{O}{-}H$ proton is observed at approximately −10 p.p.m. from the external reference of tetramethylsilane and it is clear therefore that protonation occurs on the carbonyl oxygen. In each case (except *N,N*-dimethylbenzamide) this peak is somewhat broad even at −85°, indicating that even at this low temperature there is a slow proton exchange between the solvent and the conjugate acid of the amide. If the basicity of the solvent is reduced by the addition of antimony pentafluoride the

[1]*Reference 1 is regarded as Part I of this series.*

*Solution in 10 mole% SbF_5 in fluorosulphuric acid.

$C{=}\overset{+}{O}{-}H$ line width decreases, indicating a further reduction in the rate of proton exchange and in the case of *N*-methyl formamide splitting of the $C{=}\overset{+}{O}{-}H$ peak into a doublet is then observed which can be attributed to spin–spin coupling with the formyl proton (J = 3.5 c/s).

Thioamides

As some previous workers have presented evidence for protonation on sulphur (6–9) while others have concluded that protonation occurs on nitrogen (10–11) we have examined the proton magnetic resonance spectra of solutions of thioacetamide and thioacetanilide in fluorosulphuric acid. The results given in Table II clearly establish that protonation occurs on sulphur.

The spectrum of the thioacetamide solution at 25° contained, in addition to the solvent and tetramethylsilane peaks, three peaks A, B, and C of relative areas 1.98:0.9:3.0 which may be assigned to the NH_2, $C{=}SH^+$, and CH_3 groups respectively (Fig. 1). It is interesting to note that the $C{=}SH^+$ peak (B) is quite sharp, indicating that proton exchange with the solvent is quite slow even at 25°. The NH_2 peak (A) is a broad triplet due to N^{14}—H coupling. Reduction of the temperature causes this triplet to collapse to a single line as has also been found to occur in the case of acetamide and formamide (1).

A solution of thioacetanilide in acetone gives a spectrum with three peaks, in addition to the solvent and reference peaks, that may be attributed to the NH, C_6H_5, and CH_3 protons. In fluorosulphuric acid at 25° an additional peak appears that may be assigned to the $C{=}\overset{+}{S}H$ group. The spectrum at −40° (Fig. 2) is essentially the same except that the NH peak is sharper and is more clearly resolved from the solvent peak: the four peaks A, B, C, and D may be attributed to the NH, C_6H_5, $C{=}SH^+$, and CH_3 groups respectively.

at 25° indicates that proton exchange is very much slower than for the C═OH^+ group under the same conditions.

Thiourea and N-Methylthiourea

The results for these substances are shown in Table III. The spectrum of thiourea in water or trifluoracetic acid contains only one line due to the NH_2 group in addition to the solvent peak. The fact that the trifluoracetic acid peak is quite broad suggests that although protonation occurs in this medium proton exchange is rapid at 25°. In the more acidic (and less basic) medium sulphuric acid a new peak appears in the spectrum at approximately −5 p.p.m. that can be attributed to the C═SH^+ group, and the NH_2 peak disappears. In fluorosulphuric acid the spectrum is essentially the same except that the C═SH^+ peak is somewhat narrower, indicating that proton exchange with the solvent is slower than in sulphuric acid. Decreasing the temperature causes a further narrowing of this line as expected. At the same time the solvent peak increases in width with decreasing temperature. This observation and the disappearance of the NH_2 peak can only be reasonably interpreted as being due to diprotonation, the first proton being attached to sulphur and exchanging only very slowly with the solvent and the second proton being attached to nitrogen and exchanging rather rapidly with the solvent.

The behavior of *N*-methylthiourea is similar. In water and trifluoracetic acid the spectrum consists of three peaks A, B, and C, due to the NH, NH_2, and N—CH_3 groups respectively. The latter peak is a doublet due to spin–spin coupling with the NH proton (J = 4 c/s) (Fig. 3). Area measurements gave a ratio (A+B):C = 2.8:3.0. Figure 4

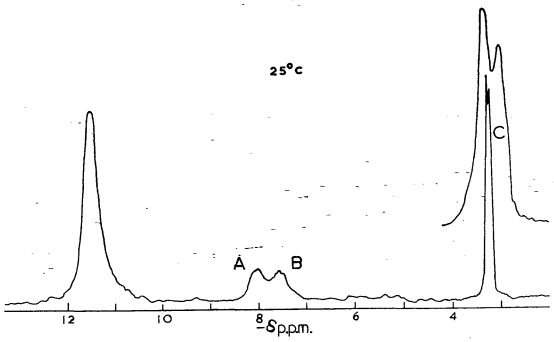

FIG. 3. *N*-Methylthiourea in trifluoracetic acid.

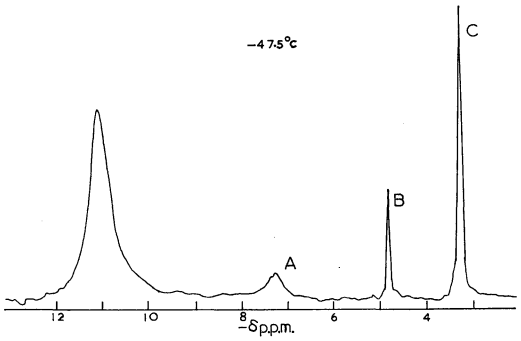

FIG. 4. *N*-Methylthiourea in fluorosulphuric acid.

shows the spectrum of a fluorosulphuric acid solution at −47.5°. A C=SH^+ peak (B) has appeared, the NH peak has disappeared, and the N—CH_3 peak (C) has collapsed to a single line. The relative areas were found to be A:B:C = 1.81:0.95:3.00. It must be concluded that a second protonation occurs on the nitrogen of the $NH \cdot CH_3$ group but proton exchange between the $\overset{+}{N}H_2 \cdot CH_3$ group and the solvent is quite rapid even at −80°. By using a less basic SbF_5–HSO_3F mixture as solvent it was found possible to reduce the rate of this exchange sufficiently that at −67° a new peak was observed in the spectrum at −8.19 p.p.m. which can presumably be attributed to the two protons on the methylated nitrogen atom. The N—CH_3 peak was found to have a width of 15 c/s which must be at least partly due to slow proton exchange: in the absence of exchange this peak would be expected to be a triplet due to coupling with the $\overset{+}{N}H_2$ protons. At low temperatures these solutions became very viscous and this is also partly responsible for the broadness of the signals.

Our conclusion that protonation of thiourea and its *N*-methyl derivative occurs first on sulphur is in agreement with ultraviolet and infrared spectroscopic studies (6, 7) and wide line n.m.r. (9) studies on thiourea salts. It appears that a second protonation occurs on the nitrogen atom in very strong acid solution.

Urea and N,N′-Dimethylurea

In dilute aqueous solution the spectrum or urea consists of an NH_2 peak. In sulphuric and fluorosulphuric acids this peak disappears and no peak was observed for urea in fluorosulphuric acid even at −86° or in fluorosulphuric acid containing 10% SbF_5 at −88°. However, in both these latter cases the solvent peak was quite broad, indicating that proton exchange is fairly slow but not slow enough for a separate peak from the conjugate acid of urea to be observed.

We observed only a single peak due to the N—CH_3 group in the spectrum of a 6 mole% solution of *N,N*-dimethylurea in water. Thus it appears that in this case the NH protons exchange with the solvent even in dilute aqueous solution. Redpath and Smith (9) however, observed both an NH peak (width = 23 c/s) and a doublet due to the $N \cdot CH_3$ group (J = 4.3 c/s) in a 0.6 weight fraction of the *N,N′*-dimethylurea in water. This doublet collapses in sulphuric acid solution. Although, as in the case of urea, the solvent peak became very broad at low temperatures, it was not possible to slow down exchange sufficiently even at −88° in HSO_3F containing 10% SbF_5 to observe peaks due to NH_2^+ or C=OH^+. Unfortunately our present results do not enable us to draw any definite conclusions concerning the site of protonation in urea and *N,N*-dimethylurea. In simple amides by decreasing the basicity of the solvent the rate of proton exchange with the solvent can be decreased sufficiently that a separate n.m.r. signal from the conjugate acid can be observed. However, in the case of urea and its derivatives decreasing the basicity (and therefore increasing the acidity) of the solvent probably leads to a second protonation of the amide and the diprotonated species exchanges more rapidly with the solvent than the conjugate acids of simple amides. Evidence for the diprotonation of tetraethylurea has been obtained from freezing-point measurements in 100% sulphuric acid (14). Evidence that the site of the first protonation is on the oxygen atom is given by the results of an X-ray diffraction study (15) of the crystal structure of *N*-methylurea nitrate in which a short hydrogen bond was found between the carbonyl oxygen and an oxygen of the nitrate ion. Redpath and Smith (9) have also obtained evidence from the line widths in the n.m.r. spectra of various crystalline urea salts that the conjugate acid of urea has a proton on the carbonyl oxygen. The infrared and ultraviolet spectra of urea

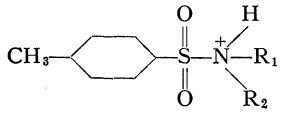
hydrochloride have also been interpreted (7) on the basis of protonation on the carbonyl oxygen.

Sulphonamides

Our results are summarized in Table IV. The conjugate acids of these bases undergo

TABLE IV

Chemical shifts of sulphamide and some sulphonamides in fluorosulphuric acid



Sulphonamide	Temperature (°C)	−δ (p.p.m.) from external T.M.S. Phenyl	N—H	N—CH_3	C—CH_3	J (c/s)

extremely slow proton exchange with the solvent even at room temperature. Figure 5 shows the spectrum of *N*-methyl-*p*-toluenesulphonamide in fluorosulphuric acid at −5°: A is assigned to the C_6H_4 and $\overset{+}{N}H_2$ protons, B to the N—CH_3 group, and C to the *p*-CH_3 group. This assignment is confirmed by the relative areas of the peaks, which were found to be A:B:C = 6.13:3.05:3.00, and the fact that B is a poorly resolved triplet due to spin–spin coupling with the NH_2 protons. Figure 6 shows the spectrum of *N*,*N*-dimethyl-*p*-toluenesulphonamide in fluorosulphuric acid at 25°. A is assigned to the C_6H_4 and $\overset{+}{N}H$ protons, B to the N—CH_3 group, and C to the *p*-CH_3 group. This assignment is confirmed by the relative areas of the peaks, which were found to be A:B:C = 4.87:6.30:3.00, and the fact that B is a doublet due to spin–spin coupling with the $\overset{+}{N}H$ proton. It is clear that in both these cases protonation is on nitrogen.

Sulphamide

A solution of sulphamide in fluorosulphuric acid at 25° gave the spectrum shown in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

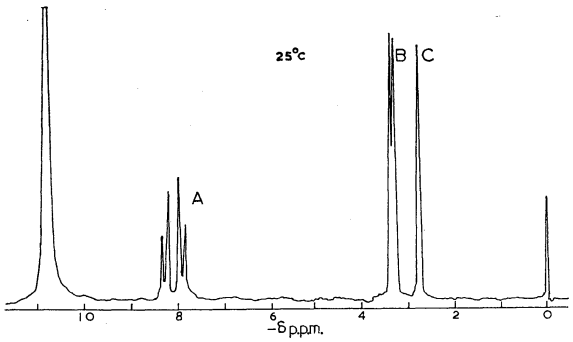

FIG. 6. *N,N*-Dimethyl-*p*-toluenesulphonamide in fluorosulphuric acid.

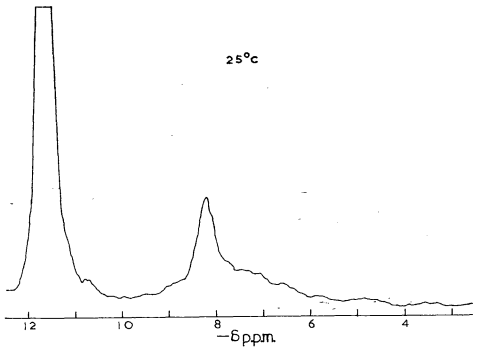

FIG. 7. Sulphamide in fluorosulphuric acid.

Fig. 7, consisting of a moderately broad peak superimposed on a very broad peak. The former is assigned to the NH_3^+ group and the latter to the NH_2 group in the conjugate acid of sulphamide $O_2S(NH_2)(NH_3^+)$. No peaks other than the solvent peak were visible in the spectrum of a sulphuric acid solution at room temperature presumably because of relatively rapid proton exchange between the conjugate acid of sulphamide and the solvent.

EXPERIMENTAL

The solutes were all commercial samples except for the *p*-toluenesulphonamides, which were prepared from *p*-toluenesulphonyl chloride and the corresponding amine. All the solids were recrystallized before use. Other experimental details have been described in Part I (1).

THE INCORPORATION OF PUTRESCINE INTO HYOSCYAMINE[1]

J. KACZKOWSKI[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received July 3, 1963

ABSTRACT

Putrescine-1,4-^{14}C was fed to the excised root cultures of *Datura metel* L., and the alkaloids subsequently isolated. These consisted of hyoscyamine, hyoscine, and a base of undetermined constitution designated as alkaloid X. All three bases were radioactive. Degradation of the hyoscyamine revealed that ca. 8% of the radioactivity was present in the tropic acid moiety, but that all the radioactivity of the tropine moiety was located in the pyrrolidine ring. The implications of these results are discussed.

INTRODUCTION

Earlier attempts to ascertain whether putrescine was a precursor of hyoscyamine failed (1) although it has been established that ornithine is the precursor of the pyrrolidine ring of that alkaloid in *Datura stramonium* L. (2). Since preliminary experiments carried out by one of us (J. K.) seemed, however, to indicate that root cultures of *Datura metel* L. when fed unlabelled putrescine produced a slightly higher yield of alkaloid, it was decided to repeat the experiments with labelled putrescine.

MATERIALS AND METHODS

Since the biosynthesis of tropane alkaloids is known to take place mostly if not exclusively in the roots (3), isolated root cultures of *D. metel* L. grown in a nutrient as described by Robbins and Bartley Schmidt (4) were used in all the experiments. The cultures were developed from one seed as previously described by Kaczkowski *et al.* (5).

The nutrient solution in which the roots had grown was removed after 30 days and replaced by fresh nutrient solution containing putrescine-1,4-^{14}C, purchased from New England Nuclear Corporation. The times of incubation in contact with the radioactive putrescine in different experiments were 2, 4, 6, and 4 days respectively.

After the incubation period the roots were removed from the nutrient solution, washed thoroughly with water, and dried at 60°. The dried roots, mixed with sodium carbonate, were ground and extracted with chloroform for 12 hours in a Soxhlet apparatus. The crude extract was purified, and an aliquot was chromatographed on paper. The alkaloids which separated on the chromatogram were determined by a nephelometric micromethod, all as previously described by Kaczkowski and Reifer (6). Three alkaloids were thus detected, i.e., hyoscyamine, hyoscine, and an unidentified third base which has been reported previously (7) and will be designated alkaloid X. The radioactivity of the alkaloids eluted from the paper strips was measured with a Baird Atomic end-window gas flow counter against a blank prepared by elution of a paper strip cut from a space on the chromatogram between alkaloid spots.

The bulk of the radioactive alkaloids was separated by thin-layer chromatography on silica gel G (Merck) using a mixture of chloroform, cyclohexane, diethylamine, and acetone in the ratio 5:3:1:1. The hyoscyamine eluted from the silica gel was diluted with inactive hyoscyamine to 600 mg and degraded by hydrolysis and then oxidation with chromic acid as previously described (2). The very small quantity of radioactive hyoscyamine obtained did not permit a higher dilution and consequently the degradation could not be taken further than the formation of N-methylsuccinimide. The diluted hyoscyamine, as well as the products of its degradation were, before counting, ignited to carbon dioxide which was collected as barium carbonate. In each case the radioactivity was determined with an efficiency of ca. 20% and an average background of 10 c.p.m.

RESULTS AND DISCUSSION

Four different experiments were carried out with four different lots of roots, each being fed a different concentration of labelled putrescine and each being allowed a different incubation period. The data concerning these experiments are given in Table I.

TABLE I

Expt. No.	Wt. of roots (mg)	Time of incubation (days)	Amt. of putrescine (mg)	Sp. activity of putrescine (d.p.m./mmole)	Amt. of alkaloid (μg)		
					Hyoscyamine	Hyoscine	Alkaloid X
I	84	2	2.64	4.84×10^8	74	295	267
II	132	4	3.79	9.42×10^8	148	261	213
III	232	6	4.92	7.76×10^8	119	253	269
IV	186	4	5.28	1.32×10^9	129	223	133

TABLE II

Expt. No.	Specific activities of alkaloids (d.p.m./mmole$\times10^6$)		
	Hyoscyamine	Hyoscine	Alkaloid X
I	16.6	1.18	10.4
II	19.0	4.90	18.8
	20.6	3.42	19.5
Ave.	19.8	4.16	19.2
III	40.0	6.90	21.2
	39.2	5.78	22.9
Ave.	39.6	6.34	22.0
IV	95.0	23.7	91.3
	96.5	24.0	93.0
Ave.	95.7	23.9	92.2

Table II contains the specific radioactivities of the isolated alkaloids. In all cases, the activity of the blank was only 1–2 c.p.m. In the first experiment this figure represents but 2% of the activity of hyoscine and a much smaller proportion of the activity of the other two alkaloids. Hence it has not been taken into account in the calculations concerning the remaining experiments.

The results given in Table II show that putrescine-1,4-^{14}C was incorporated into the alkaloids.[3] The extent of incorporation was highest in hyoscyamine and lowest in hyoscine while it was intermediate in base X. This could indicate that the last base, of unknown constitution, might be an intermediate product in the transformation of hyoscyamine into hyoscine, rather than the direct precursor of hyoscyamine as previously suggested (7). In the mature *D. stramonium*, however, it has been shown that when hyoscyamine is being synthesized, hyoscine no longer is being formed (2, 8). Hence either the biosynthesis of the alkaloids in *D. metel* under the conditions used follows a different pattern than in *D. stramonium* or, in the latter, the synthesis of hyoscine gradually decreases as that of hyoscyamine increases so that at maturity the synthesis of hyoscine no longer takes place, although it still does in the isolated root system of *D. metel.*

The values of the specific activities of the alkaloids isolated in the four experiments do not vary regularly with regard to concentration or incubation time, and this irregularity may be attributable to the sensitivity of the root cultures towards small changes in experimental conditions, as well as to the different ages of the subcultures of roots used in each experiment.

The specific activities of hyoscyamine and its degradation products listed in Table III indicate that the incorporation of labelled putrescine is largely specific. Almost all the activity was present in the tropine moiety of hyoscyamine. Furthermore, all the specific

[3]*In a footnote in a recent review of the biosynthesis of alkaloids (K. Mothes and H. R. Schütte. Angew. Chem.* **75,** *268 (1963)), Professor Mothes states that he has found that putrescine-1,4-*^{14}C *is incorporated into hyoscyamine in D. metel.*

TABLE III

Compound	Amt. (mg)	Specific activity (d.p.m./mmole×10⁴)		M.p. (°C)
Hyoscyamine	600	1.34		
Tropine	245	1.20	51	63 (lit.)
Picrate			293	290–295 (lit.)
Tropic acid	260	0.11	115	117 (lit.)
N-Methylsuccinimide	21	1.22	65	66 (lit.)

activity of the tropine was present in the N-methylsuccinimide derived from it. Although paucity of material did not permit further degradation it is most probable that the label was located at positions 1 and 5 of the tropane skeleton.

About 8% of the total activity of hyoscyamine was located on the tropic acid moiety. This is explainable only by the breakdown of some of the putrescine to simpler products before incorporation into the alkaloids.

The results obtained do not agree with those of Diaper, Kirkwood, and Marion (1), who fed putrescine-1,4-^{14}C (by hydroponic solution) to 7-, 8-, and 9-month-old *D. stramonium* plants kept in the darkness, and found very little radioactivity in the isolated hyoscyamine. There is reason to believe, however, that this finding may not be reliable.[4] On the other hand, ornithine-2-^{14}C fed to mature *D. stramonium* plants is incorporated into hyoscyamine (2) and all of the activity is located on one only of the bridgehead carbons (9). Hence the biosynthetic pathway cannot involve an intermediate which is symmetrical. Putrescine, therefore, does not appear to represent an intermediate step in the incorporation of ornithine-2-^{14}C into the pyrrolidine ring of hyoscyamine since symmetrical putrescine-1-^{14}C (i.e., the product of the decarboxylation of ornithine-2-^{14}C) should produce labelling at both bridgeheads.

It appears probable, then, that although putrescine when fed to the plant can be a precursor of hyoscyamine, it does not represent an intermediate step in the normal incorporation of ornithine into the alkaloid.

LYCOPODIUM ALKALOIDS

XIII. MASS SPECTRA OF REPRESENTATIVE ALKALOIDS[1]

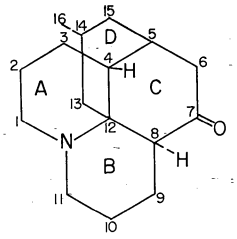
D. B. MacLean
Department of Chemistry, McMaster University, Hamilton, Ontario
Received April 29, 1963

ABSTRACT

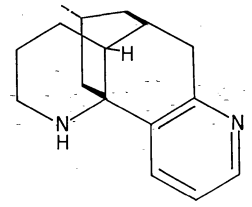
The mass spectra of a number of *Lycopodium* alkaloids are recorded and schemes proposed for their fragmentation. The loss of the bridge dominates the fragmentation process in the structural types examined.

The *Lycopodium* alkaloids have been the subject of many studies in the past few years, but there are still many alkaloids of unknown constitution. Those alkaloids whose structures have been elucidated are, for the most part, the most abundant while those whose structure still await solution have been found in smaller quantity. The mass spectrometric method, which has been used in many recent investigations, is particularly well suited to structural studies on substances available in small amount.[2] It was of interest, therefore, to record the spectra of the *Lycopodium* alkaloids of known structure and to study their fragmentation in order that the information so obtained might be applied to the study of those alkaloids whose structures are yet unresolved and to those alkaloids yet to be isolated.

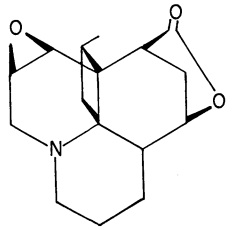
The *Lycopodium* alkaloids which are now known may be conveniently classified for the purposes of this discussion into four groups: those related in skeletal structure to lycopodine (2), by far the largest group; those related in skeletal structure to lycodine (3, 4),



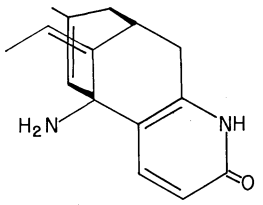
Lycopodine



Lycodine



Annotinine



Selagine

[1]*This work was carried out in the laboratories of Professor K. Biemann, where the author spent the academic year 1962–1963 as a guest of the Department of Chemistry, Massachusetts Institute of Technology.*

Financial support of this work from a grant to Professor Biemann from the Petroleum Research Fund of the American Chemical Society is gratefully acknowledged.

[2]*The reader is referred to the recent book by Biemann (1) for a review of the application of the mass spectrometric method to structural problems.*

the next most abundant group; annotinine (5, 6); and selagine (7, 8). At the time of writing, annotinine and selagine are the sole reported representatives of their groups. The alkaloids whose spectra are discussed in this paper are mostly from the lycopodine group and comprise, besides lycopodine and simple derivatives of it, some alkaloids carrying substituents on the bridge and others with substituents on ring C. From an examination of the spectra of these alkaloids it has been possible to formulate a fragmentation mechanism which applies to the lycopodine group and which, with minor modifications, may be applied to the other groups.

The spectra of lycopodine, dihydrolycopodine (2, 9), anhydrodihydrolycopodine (2, 9), and acetyldihydrolycopodine (2, 9) are shown in Fig. 1. A common feature of all these

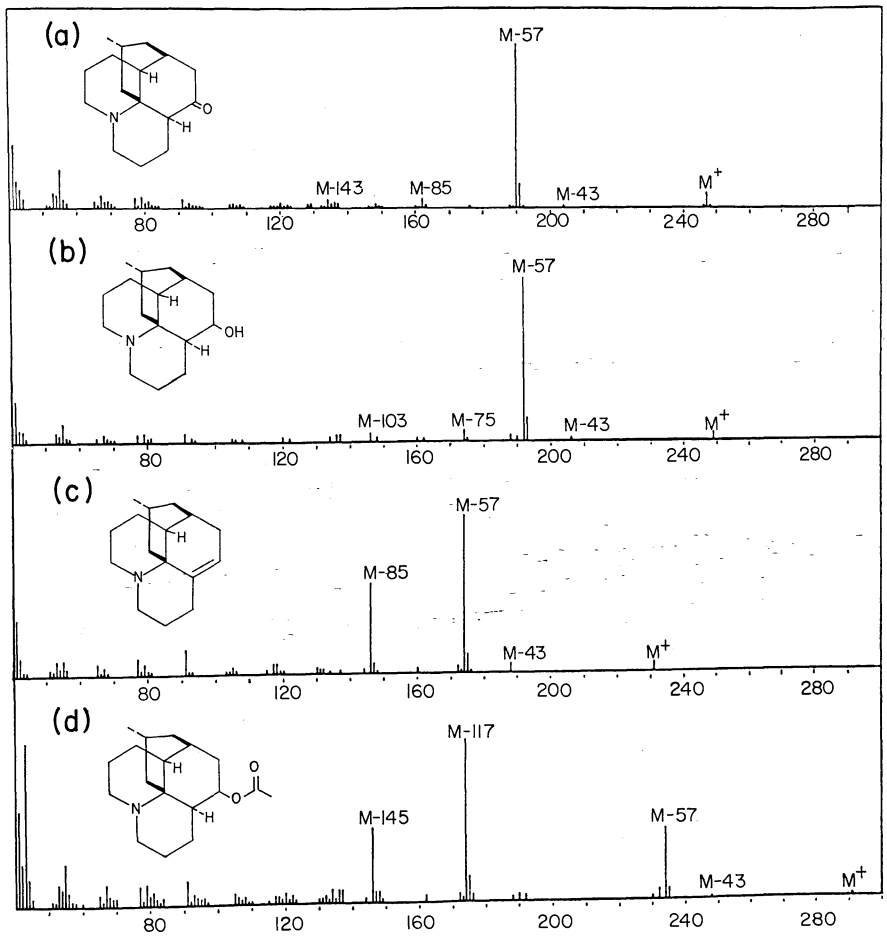


FIG. 1. Mass spectra of lycopodine and simple derivatives of it: (*a*) lycopodine, (*b*) dihydrolycopodine, (*c*) anhydrodihydrolycopodine, (*d*) acetyldihydrolycopodine. Peaks with an intensity $\geqslant$ 2% of the most intense peaks are shown in this and subsequent spectra.

spectra is the presence of a peak at M-57, which corresponds to loss of the bridge plus a hydrogen atom. With the exception of the acetyldihydrolycopodine spectrum, this peak is the strongest in the spectrum. In addition, a peak is found in all the spectra at M-43, the origin of which is adumbrated from the labeling experiments and will be discussed in a

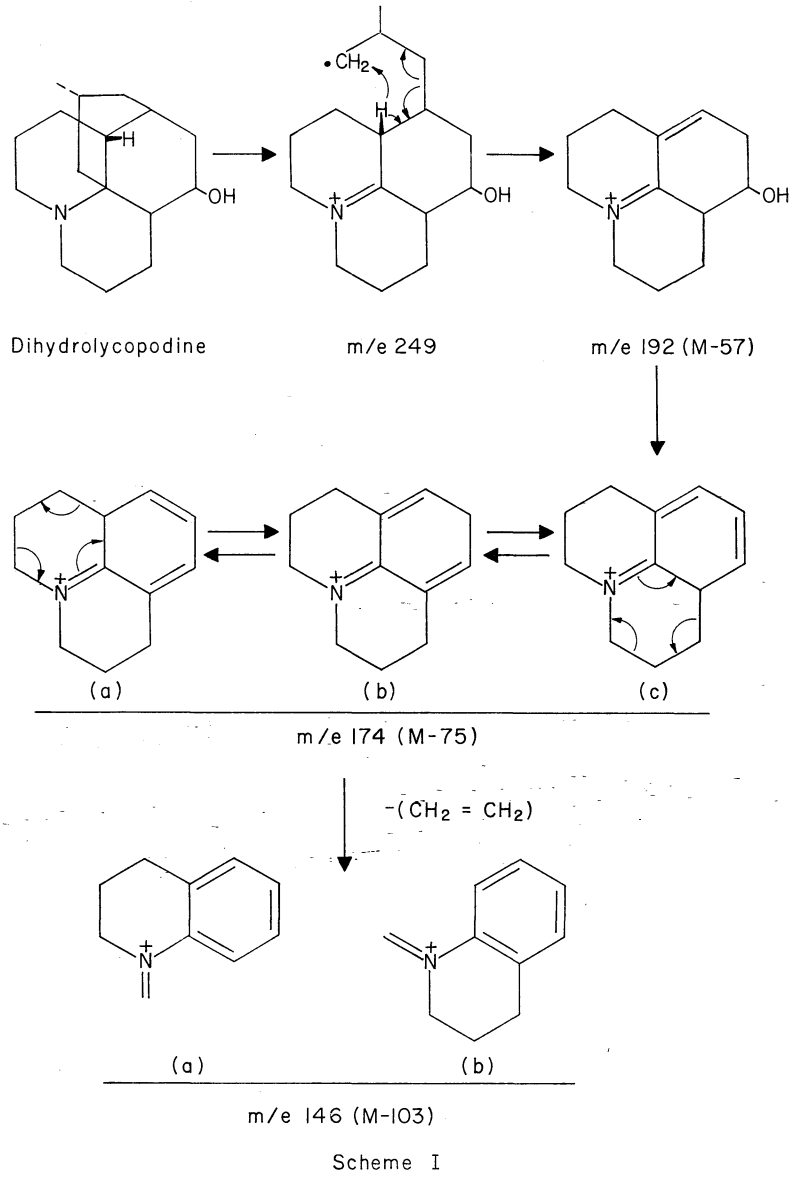
For personal use only.

later section. It will be noted with the exception of lycopodine the spectra all show a peak at *m/e* 146. A fragmentation scheme, compatible with these findings, is shown in Scheme I for dihydrolycopodine.[3] The neutral fragment eliminated in the transformation



Scheme I

m/e 249 to *m/e* 192 is postulated to be $(CH_3)_2CHCH_2$. In the case of acetyldihydrolycopodine, a molecule of acetic acid rather than one of water is lost, and in anhydrodihydrolycopodine the double bond is already present in the 7,8-position. In the ion of *m/e* 174 it is unlikely that the double bonds are fixed, but instead may assume any of the positions shown in formulas *a*, *b*, and *c*. Thus, a fluid rather than static situation

with respect to the unsaturation is considered to pertain. The loss of ethylene to yield the ions of *m/e* 146 may proceed as shown by the arrows. Ions *a* and *b* of mass 146 are identical as written but a distinction would arise if ring A or B carried a label.

Lycopodine, which cannot form the double bond at the 7,8-position, shows peaks at *m/e* 190, 162, and 134, corresponding to the loss of 57, 85, and 113 mass units, respectively. The consecutive losses of 28 mass units are very likely associated with the loss of carbon monoxide and of ethylene, but the order in which they are lost cannot be ascertained by this method although the question could be resolved by a high-resolution spectrum.

In Table I the observed positions of the metastable peaks[4] associated with the loss of

TABLE I

Metastable peaks in the spectra of lycopodine and its derivatives

	m^*_{obs}	m^*_{calc}	
Lycopodine	147.0	247 → 191	147.7
		247 → 190	146.2
Dihydrolycopodine	148.5	249 → 193	149.6
		249 → 192	148.0
Acetyldihydrolycopodine	189.5	291 → 235	189.8
		291 → 234	188.2
Anhydrodihydrolycopodine	131.5	231 → 175	132.6
		231 → 174	131.1
Lycopodine-d_3	150.0	250 → 194	150.5
		250 → 193	149.0

the bridge are recorded along with the values calculated for a loss of 56 and 57 mass units from the molecular ions. In all cases, including that of lycopodine-d_3, the position of the metastable peak is in agreement with the loss of 57 rather than of 56 mass units, and a concerted rather than a stepwise process apparently pertains. A stepwise process in which the molecular ion first loses hydrogen and then isobutylene cannot be ruled out with the data available. It seems less likely, however, because of the low intensity of the ions at M-1 in the five examples discussed.

In Scheme I the hydrogen lost with the bridge is postulated to come from C_4. No direct evidence is at hand to support this postulate, but its origin from C_6, the other likely position for its abstraction, is precluded by a labeling experiment with lycopodine. The spectrum of lycopodine-d_3, in which the C_6- and C_8-hydrogens have been exchanged for deuterium, was examined. It was found that the major peak in the spectrum fell at *m/e* 193, corresponding to loss of 57 mass units from the molecular ion at *m/e* 250. The more intense peak at *m/e* 192 in the deuterated compound, relative to the peak at *m/e* 189 in the undeuterated lycopodine, arises from some lycopodine-d_2 present in the sample. Calculation shows that no more than 5% of the peak at *m/e* 192 can be ascribed to loss of 58 mass units from the molecular ion. Table II records the relative intensities of the peaks in the region of M-57 and of the molecular ion in the spectra of deuterated and undeuterated lycopodine.

In the spectra of dihydrolycopodine and acetyldihydrolycopodine metastable peaks are

[4]*Metastable peaks are observed in a spectrum when ions of mass m_1 decompose in the accelerating region near the exit slit to ions of mass m_2. The approximate value of m/e, m*, at which such ions are recorded in the spectrum may be calculated by applying the relation $m^* = (m_2)^2/m_1$ (10). In practice, in the type of instrument used in this study, the observed values are higher, but usually by not more than one mass unit, than those calculated by the relation above. The metastable peaks are observed as broad peaks of low intensity and it is the intensity maximum which is reported. The presence of a metastable peak is evidence that the transformation m_1 to m_2 is a concerted rather than a stepwise process. In the text following, the symbolism $m_1 \rightarrow m_2$ will be used to denote such a transformation.*

TABLE II

Relative intensity vs. *m/e* of deuterated and natural lycopodine

	Intensity			Intensity	
m/e	Lycopodine	Deuterated lycopodine	*m/e*	Lycopodine	Deuterated lycopodine
251	—	2.0	194	—	14.0
250	—	10.5	193	—	100.0
249	—	2.3	192	1.0	12.0
248	1.8	0.3	191	15.0	1.4
247	9.0	—	190	100.0	0.4
246	1.8	—	189	0.8	—
195	—	2.0			

present corresponding to the loss of water and of acetic acid, respectively, from the fragment ions. Thus, in dihydrolycopodine a metastable peak is found at *m/e* 159.5 (*m** calc. (192 → 174) = 157.7), and in acetyldihydrolycopodine at *m/e* 131 (*m** calc. (234 → 174) = 129.4). A strong metastable peak is present in each of spectra 1*b*, 1*c*, and 1*d* at *m/e* 124. The loss of 28 mass units from the ion 174 is common to all these spectra, but the calculated position for a metastable peak corresponding to this change is 122.5. The observed value is higher than expected, but there is no other fragmentation process which can give rise to this strong metastable peak.

Three alkaloids–lofoline (11, 12), clavolonine (12, 13), and annofoline (14, 15)—each bearing a substituent on the bridge as well as at position 7, are now examined. The spectra of the three alkaloids, shown in Fig. 2, may be interpreted along the same lines as those outlined in Scheme I. In clavolonine (Fig. 2) the major peak occurs at M-73, corresponding to the loss of the bridge plus hydrogen. This is followed by loss of 28 mass units yielding a peak at *m/e* 162 (M-101) and a further loss of 28 mass units yielding a peak at *m/e* 134 (cf. Fig. 1*a*). The spectrum of lofoline, Fig. 2*b*, resembles that of acetyldihydrolycopodine (Fig. 1*d*), from, which it differs by virtue of the presence of a hydroxyl group on the bridge. Major peaks occur in the spectrum at *m/e* 234 (M-73), 174 (M-133), and 146 (M-161), corresponding, respectively, to the loss of the bridge plus hydrogen, followed by loss of acetic acid and of ethylene.

The fragmentation of annofoline (Fig. 2*c*) follows the same pattern, with peaks appearing at M-71, M-89, and M-117, corresponding respectively to the loss of the bridge plus hydrogen, followed by loss of water and of ethylene. The annofoline spectrum, however, has additional features commented upon later.

The most significant feature of the three spectra of Fig. 2 is the fact that the substituents on the bridge do not alter appreciably the fragmentation pattern exhibited by lycopodine and its derivatives. Both the presence and the nature of the substituents on the bridge are immediately evident from an examination of the spectra. In the investigation of new alkaloids, it will be of great advantage to obtain such information readily and with very little material.

Returning now to the annofoline spectrum, it is observed that the peak at *m/e* 193 (M-70) is somewhat stronger than expected of a normal isotope peak. The fragment ion contributing to this peak may arise by loss of methylcyclopropanone from the molecular ion to give the ion–radical shown below. Alternatively, the bridge might be lost as carbon monoxide and propylene. The ion–radical (M-70) may lose a hydroxyl radical with hydrogen migration to give the ion observed at *m/e* 176 (M-87). Perhaps the most striking

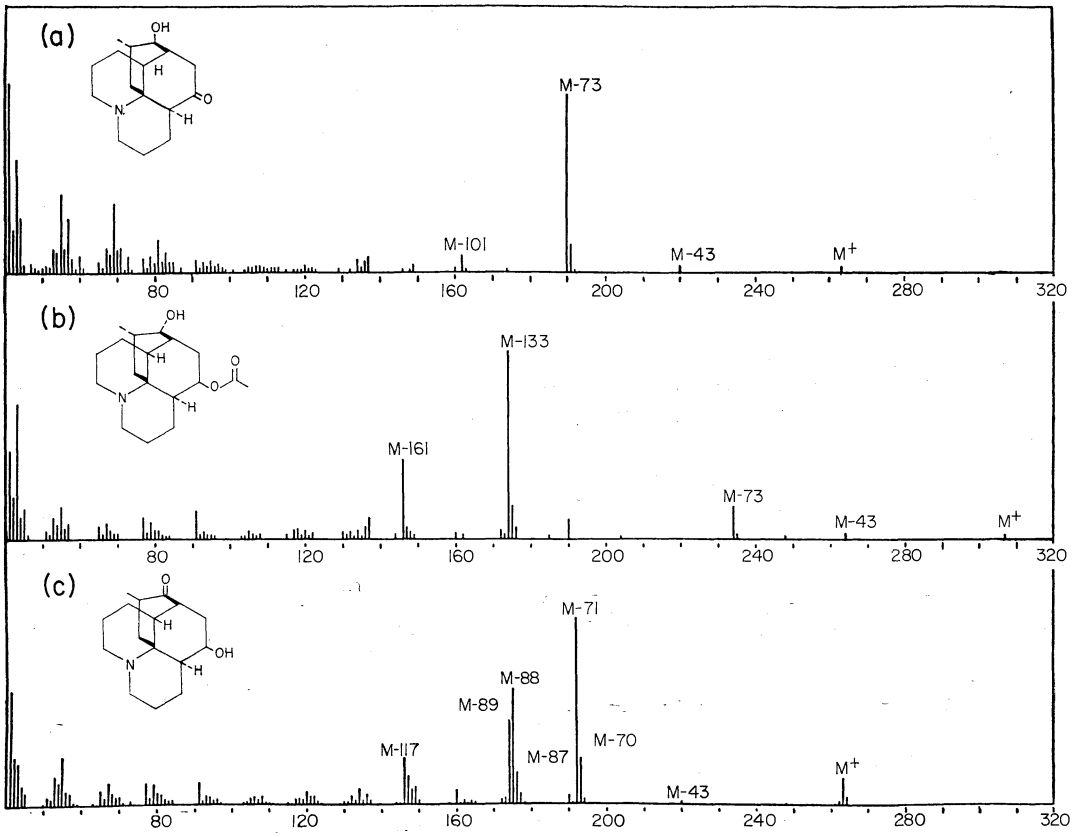

FIG. 2. Mass spectra of alkaloids of the lycopodine group with a substituent on the bridge: (*a*) clavolonine, (*b*) lofoline, (*c*) annofoline.

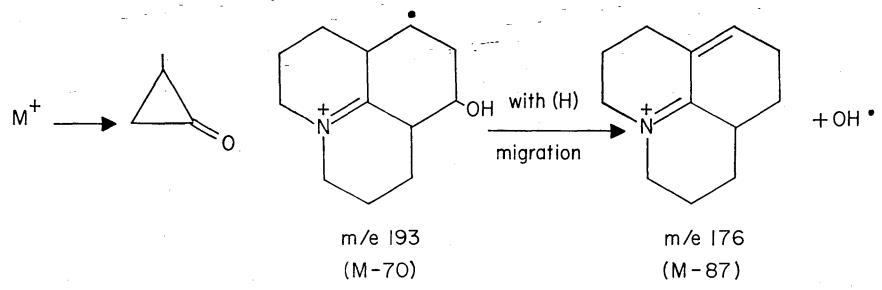
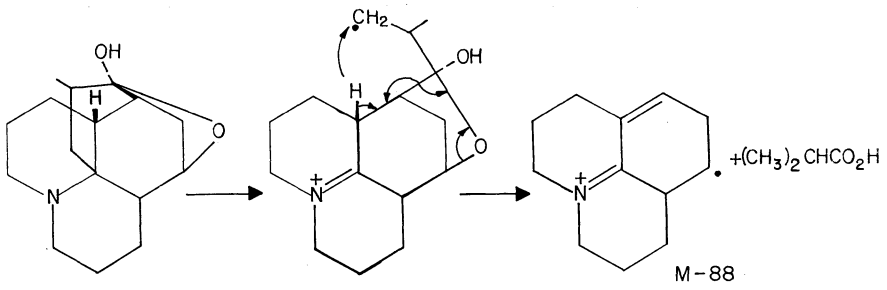


feature in the spectrum of annofoline is the enhanced intensity of the peak at *m/e* 175 (M-88) relative to that at *m/e* 174 (M-89). The ion of *m/e* 174 must arise, at least partly, by loss of water from the ion of *m/e* 192. It is conceivable that the ion of *m/e* 175 arises by loss of OH from the ion of *m/e* 192 although this pattern is not observed in the fragmentation of dihydrolycopodine. It seems more likely that it forms directly from the molecular ion. Annofoline is known to exist as an equilibrium mixture of hemiketal and hydroxy ketone (14, 15), and a mechanism for formation of the fragment M-88 from the hemiketal form is postulated below:



A metastable peak at m/e 117.0 (m^* calc. (263 → 175) = 116.4) is in accord with this postulate. The conversion of 175 → 174 by loss of hydrogen is also supported by a metastable peak at m/e 173.5. Besides the metastable peaks noted above, others are observed at m/e 141 and 124, corresponding, respectively, to the transformations 263 → 192 and 174 → 146.

The spectrum of deuterated annofoline corroborates the findings above and yields information regarding the origin of the M-43 peak. Details of the exchange of annofoline and the recording of the spectrum of deuterated annofoline are found in the experimental section, but it should be pointed out here that the two hydrogens alpha to the carbonyl group differ greatly in behavior, as might be expected. The hydrogen at C_5 exchanges relatively slowly with deuterium but once introduced is stable. The hydrogen at C_{14} exchanges rapidly but surprisingly is lost to a large extent in the heated inlet system of the spectrometer. Only when the inlet system is given a prior treatment with CH_3OD is a satisfactory spectrum of the fully deuterated compound obtained, and even then the intensity of the peak at m/e 265 owing to the dideuterated species decreases rapidly, as Table III illustrates.

TABLE III

Deuterated annofoline; relative intensity vs. m/e at different times

	Intensity				Intensity		
m/e	$t = 0$	$t \approx 30$ min	$t \approx 60$ min	m/e	$t = 0$	$t \approx 30$ min	$t \approx 60$ min
266	8	6	3	191	3	6	10
265	15	14	12	178	8	10	9
264	10	17	16	177	24	26	26
263	3	4	5	176	100	100	100
195	16	14	12	175	68	75	77
194	78	67	60	174	12	16	17
193	95	114	115	173	3	6	8
192	15	17	17				

The major fragment peaks in the spectrum of deuterated annofoline appear at m/e 193, 176, 175, and 147, one mass unit higher than in the undeuterated species, and correspond to loss of 72, 89, 90, and 118 mass units from the molecular ion at m/e 265. Thus one deuterium atom is lost with the bridge and one is retained in the fragment ions. Metastable peaks corresponding to the changes 265 → 193, 265 → 176, and 175 → 147 are observed and lend support to the fragmentation mechanism already proposed. The M-43 peak appearing at m/e 220 in annofoline becomes an M-44 peak appearing at m/e 221 in the spectrum of dideuterated annofoline. One must infer that the bridge carbons are responsible for this peak in the annofoline spectrum and possibly are responsible for it or

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

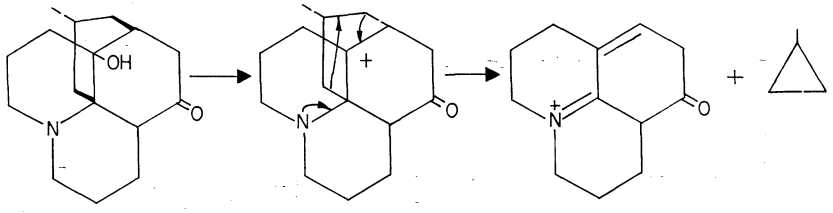
contribute to it in the spectra of the other alkaloids of the lycopodine group where an M-43 peaks is invariably present.

We come now to two alkaloids which have a functional group instead of a hydrogen atom at C_4 and which might, therefore, be expected to differ in their fragmentation from those already examined if the postulated fragmentation be correct. The first of these to be discussed is the alkaloid lycodoline (16), which differs in structure from lycopodine by virtue of the presence of a hydroxyl group at C_4, but its stereochemistry is the same. The spectrum is shown in Fig. 3*a* and it is observed to undergo a more complex fragmentation than other alkaloids previously examined. The molecular ion peak is now the most intense peak while the peak at M-57 is less intense than several others in the spectrum. It is worthy of mention that the peak at M-56 has approximately 50% the intensity of M-57, a reflection of the lack of hydrogen at C_4. The M-17 and M-28 peaks most likely arise by loss of hydroxyl and carbon monoxide, respectively. An M-43 peak is present as in the other spectra examined, but in this case for the first time is more intense than the M-57 peak. The M-71 peak is probably due to loss of 28 mass units from the ion M-43 while that at M-73 may be attributed to loss of the bridge plus the hydroxyl group. Scheme II depicts a possible fragmentation mechanism for two of the fragment ions. The formation of the M-73 fragment is considered to proceed in a stepwise rather than a concerted manner, although the latter possibility cannot be excluded from the evidence at hand.



Scheme II

The overall result agrees with the proposition that the hydrogen removed with the bridge is normally derived from the C_4-position. When a hydrogen is absent at C_4, a hydrogen is lost from another position in the molecule, but the particular fragmentation proceeds much less readily.

Acrifoline (17), with a $\Delta^{3,4}$-double bond, is another example of a system lacking a hydrogen at C_4, and an examination of its spectrum, Fig. 3*b*, again shows a divergence from the normal fragmentation pattern. The spectrum exhibits two intense peaks at M-70 and M-87 and has peaks of lesser intensity at M-28, M-43, M-71, and M-89. The M-28 peak may be attributed to loss of carbon monoxide while the M-43 peak is characteristic of this group of alkaloids and may come from the bridged atoms, as previously noted. The M-71 and M-89 peaks are expected and the mechanism shown for their formation in Scheme III[5] needs no further elaboration. The greater intensity of M-70 (loss of bridge) than M-71 (loss of bridge + H) is unique among the spectra examined. (An M-70 peak is present in the spectrum of annofoline, but it is weak in comparison to the M-71 peak and in lycodoline the peak at M-56 is still only 50% as intense as that at M-57.) In acrifoline a hydrogen is not available at C_4 for a concerted elimination, and it is postulated that

[5]*The double bond in the ion distinguished by * may occupy a 5,6- or 6,7-position as indicated by the broken line.*

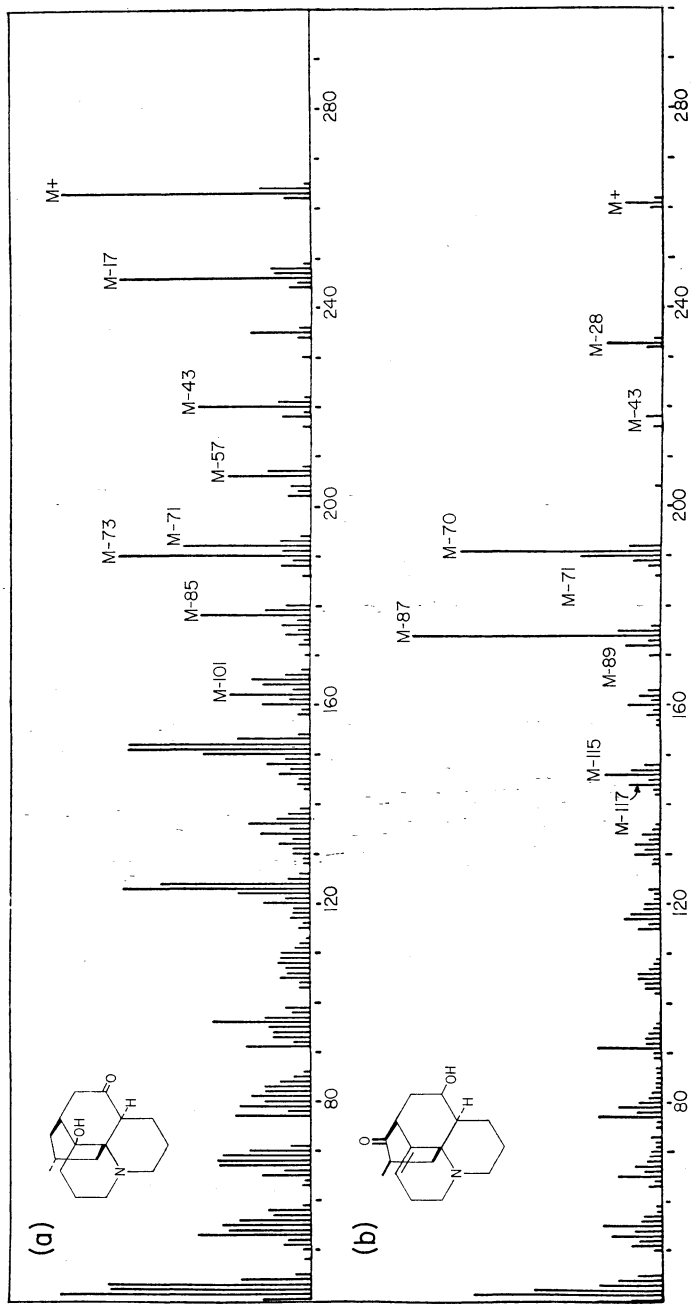

FIG. 3. Mass spectra of alkaloids of the lycopodine group with a functional group at C_4: (*a*) lycodoline, (*b*) acrifoline.

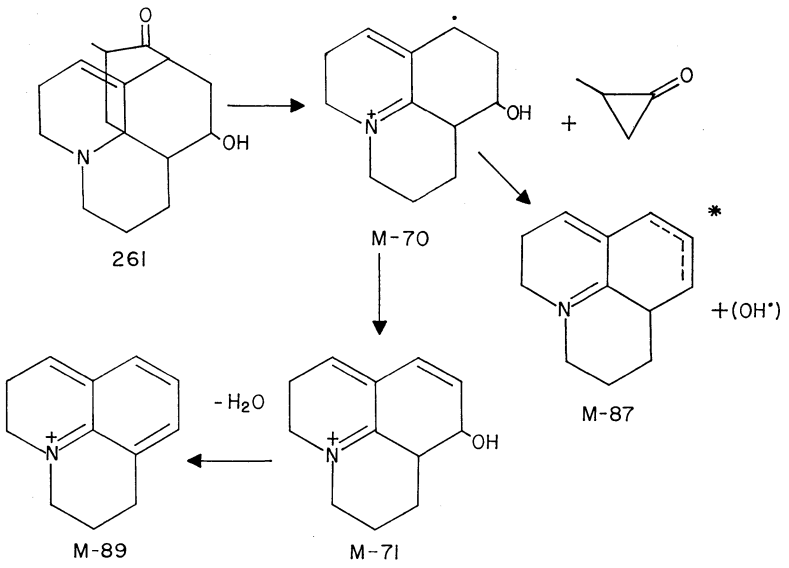
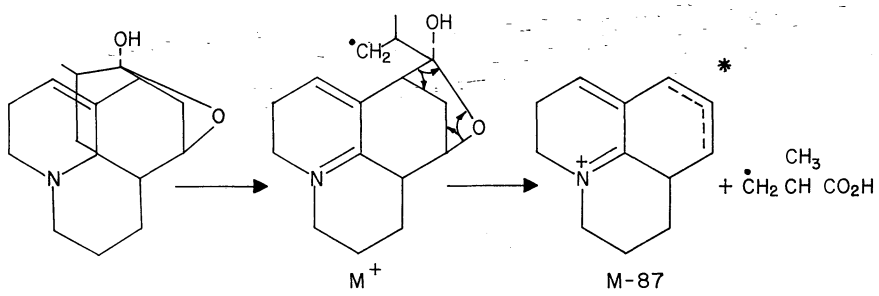


Scheme III

the bridge is lost as methylcyclopropanone or as carbon monoxide and propylene from the molecular ion to leave the stable conjugated ion–radical 191 (M-70). The peak at M-87, the most intense in the spectrum, may be due to an ion formed by loss of hydroxyl radical from the ion *m/e* 191, or alternately may form directly from the molecular ion. Acrifoline like annofoline is an equilibrium mixture of hydroxyketone and hemiketal isomers (17). A concerted elimination from the molecular ion involving the hemiketal form is shown below:[5]



Metastable peaks at *m/e* 159.0 corresponding to the transformation 191 → 174 (m^*_{calc} = 158.5) and at 117.0 corresponding to the transformation 261 → 174 (m^*_{calc} = 116.0) imply that the ion of M-87 may form by both pathways.

The acrifoline spectrum demonstrates again that the absence of a hydrogen at C_4 results in a departure from the fragmentation pattern normally observed.

Two alkaloids, flabelliformine (18) and lycoclavine (19) with oxygen functions at C_7 and C_8 and at C_6 and C_7, respectively, will now be discussed. The spectrum of flabelliformine (Fig. 4*a*) follows the expected fragmentation with peaks at M-57, M-75, and M-103 as well as a weak M-43 peak. In addition to these peaks, there is a peak of high intensity at M-99 which is not observed in other spectra and which is, therefore, characteristic of this

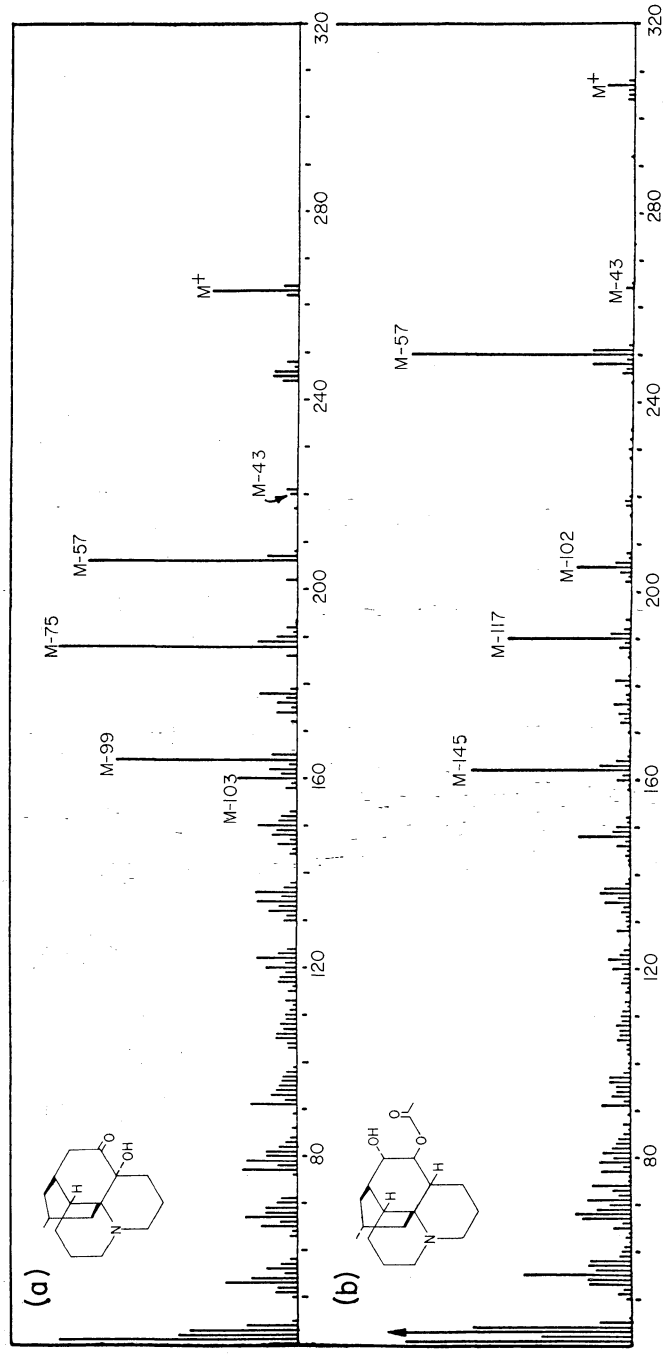

FIG. 4. Mass spectra of alkaloids of the lycopodine group with a substituent in ring C: (*a*) flabelliformine, (*b*) lycoclavine.

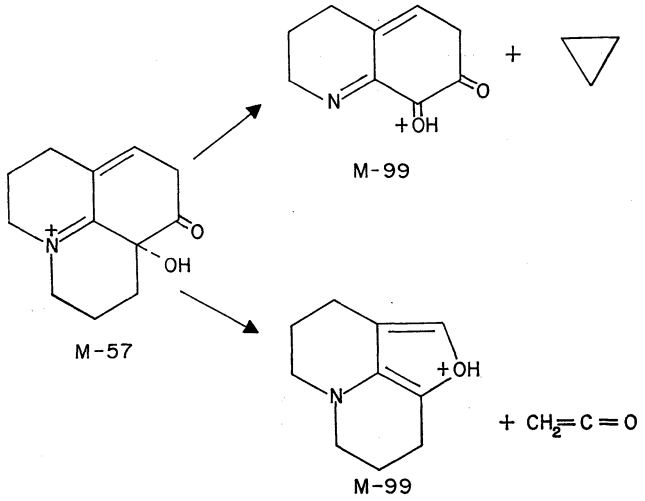
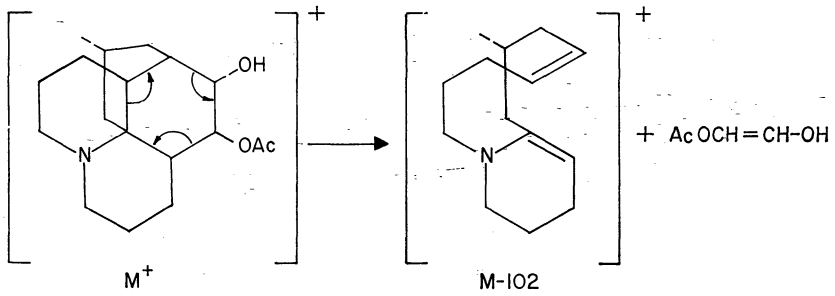
compound. A mechanism accounting for the formation of the ion (M-99) is offered below:



Lycoclavine (Fig. 4*b*) fragments in the expected manner with the peaks at M-57, M-117, and M-145 dominating the spectrum. With the exception of the peak at M-102, the spectrum of lycoclavine is very similar to that of acetyldihydrolycopodine (Fig. 1*d*), from which it differs in structure only by the presence of a hydroxyl group at C_6. The only major difference between the two is the peak at M-102, which is not found in other spectra examined and which is characteristic of this compound. A possible route whereby it might be formed from the molecular ion is shown below:



In summary it can be said that the alkaloids of the lycopodine group undergo a fragmentation which is dominated by loss of the bridge atoms and that substituents on the lycopodine skeleton have very little effect on the fragmentation process except when they are situated at C_4. The mass spectrometric method, therefore, should prove valuable in the study of new alkaloids of this group.

The second most abundant group of alkaloids are those related in structure to lycodine. In this category are found lycodine, its N-methyl derivative (20), α- and β-obscurine (20), and de-N-methyl-α-obscurine (20). The spectra of two of these are shown in Fig. 5. The fragmentation of the two substances is very similar with major peaks appearing at M-43, M-57, and M-85. The M-57 and M-85 peaks undoubtedly arise by a mechanism similar to that shown for dihydrolycopodine in Scheme I. The spectra of β-obscurine and of de-N-methyl-α-obscurine were recorded and follow the same fragmentation pattern. For the sake of clarity a fragmentation mechanism for α-obscurine is shown in Scheme IV.

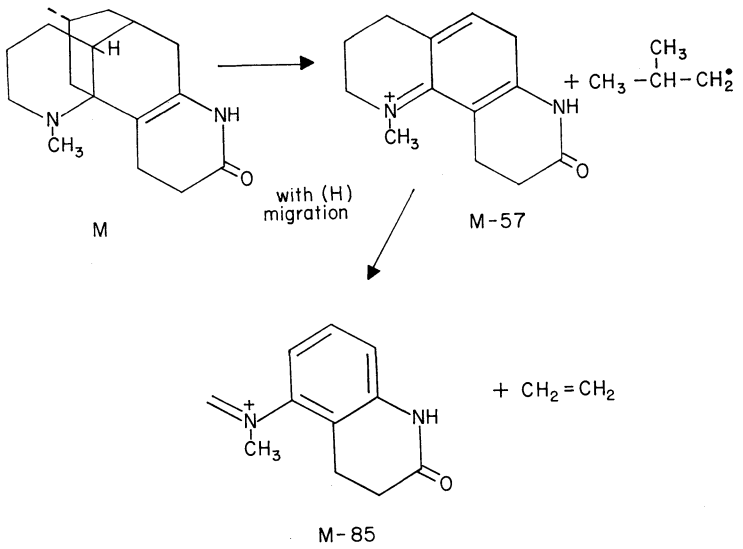

Scheme IV

The most noteworthy feature of these spectra is their very remarkable resemblance to those of the lycopodine group. The bridge is the dominant structural feature affecting the fragmentation in both ring systems. Its loss leads to the major fragment ions, and other modes of fragmentation are usually of minor importance. Although alkaloids of the two ring systems yield very similar spectra, the alkaloids with two nitrogen atoms can be easily differentiated because their molecular weight is always an even number. Confusion can arise only when the lycopodine skeleton carries a nitrogenous substituent group.

Substituted alkaloids of the lycodine group are not known, but if encountered they might be expected to fragment along lines similar to their analogues in the lycopodine group.

Annotinine differs from the other *Lycopodium* alkaloids in that the bridge carries one less carbon and forms a four-membered rather than six-membered ring. It has, however, the hexahydrojulolidine system characteristic of the lycopodine group and might be expected to show some similarity to this group in its fragmentation. The spectrum of annotinine and of a derivative of it, deoxodihydroannotinine (21), are shown in Figs. 6*a* and 6*b*, respectively. Figure 6*b* is simple and can be interpreted by assuming that fragmentation proceeds by expulsion of the bridge to give the ion at M-42. Loss of CO_2 then gives the ion at M-86, which loses hydrogen to yield the fragment M-87. Loss of 28 mass units leads to the ion of *m/e* 146 (M-115). Metastable peaks associated with the changes 219 → 175, 175 → 174, 174 → 146 are observed at *m/e* 141.0, 173.5, and 124.0 (m^*_{calc} = 139.8, 173.0, and 122.5) respectively. It is interesting to note here that the same fragment ions of *m/e* 174 and 146 are derived from deoxodihydroannotinine as from annofoline, lofoline, dihydrolycopodine, anhydrodihydrolycopodine, and acetyldihydrolycopodine, and that in all of the spectra a strong metastable peak appears at 124.0.

In contrast to its deoxo derivative, the spectrum of annotinine, Fig. 6*a*, is much more complex, and a detailed interpretation of it would require a more detailed study. The appearance of peaks at M-42, M-86, M-87, and M-115 is clearly evident, corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

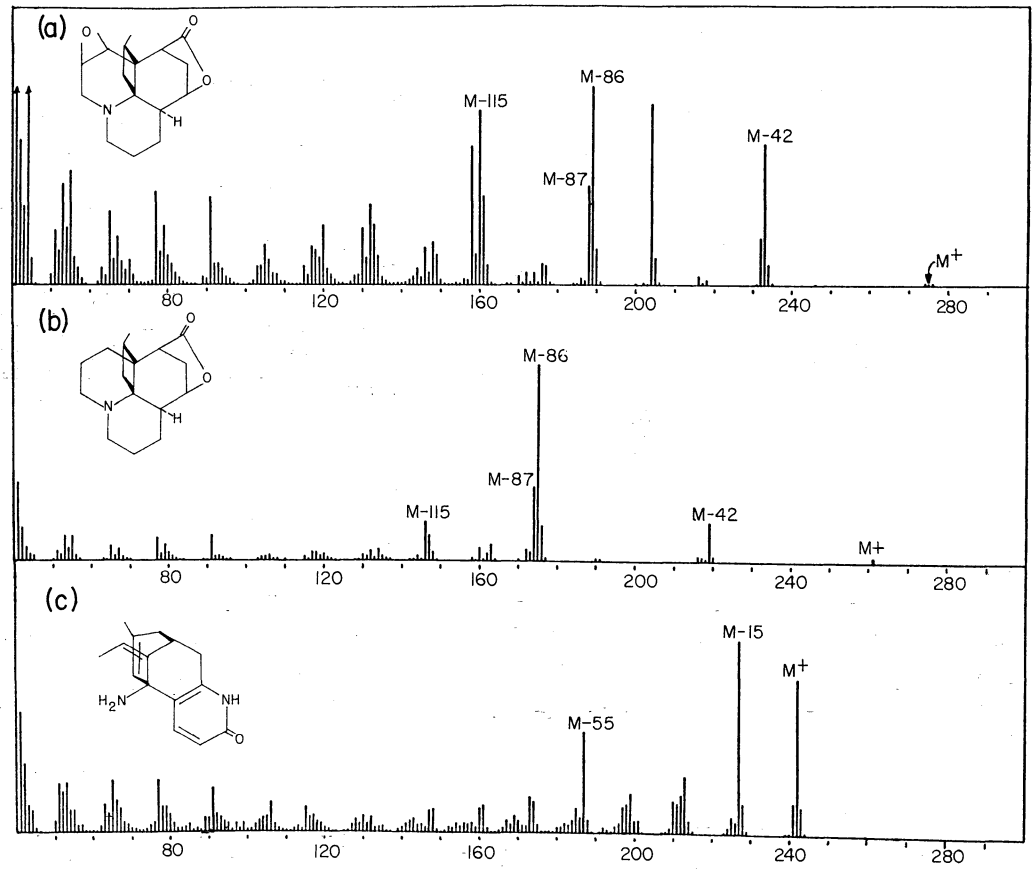

FIG. 6. Mass spectra of alkaloids of the annotinine and selagine groups: (*a*) annotinine, (*b*) deoxodihydroannotinine, (*c*) selagine.

to the changes chronicled above. The M-42 peak is the most significant from the structural viewpoint since it differentiates this structural type from the other two types examined before.

A comparison of the spectrum of annotinine and of deoxodihydroannotinine provides a striking example that the removal of a single functional group greatly simplifies the spectrum.

The selagine spectrum is recorded in Fig. 6*c*. Since it is the only example of its class and since no derivatives of it were at hand for study, a detailed interpretation of its spectrum will not be attempted. It is worthwhile to note, however, the peak at M-55 which arises from the ion formed by loss of the bridge + H. In this respect, at least, the spectrum of selagine is characteristic of *Lycopodium* alkaloids.

This study has shown that the mass spectrometric method can be of considerable value in establishing the structural group to which a *Lycopodium* alkaloid belongs and in the case of alkaloids of the lycopodine group in aiding in the location of a substituent group. The mechanisms for fragmentation which have been proposed must be considered tentative. A more detailed study with specifically labeled compounds would be required to test the mechanistic proposals.

EXPERIMENTAL

Apparatus, Methods, and Materials

The mass spectra were determined on a CEC-103C mass spectrometer at an ionizing potential of 70 ev and an ionizing current of 50 μa. Samples were introduced through the heated inlet system, which was maintained at 140°. Annotinine, selagine, and α-obscurine, when introduced by this method, gave complex spectra in the low-mass region, probably owing to pyrolytic decomposition. Accordingly, the spectra recorded for these compounds were taken with samples introduced directly into the ion source through a vacuum lock system.

The alkaloids, with the exception of selagine and lycoclavine, were taken from samples isolated in the author's laboratory over the past few years. Their infrared spectra and melting points were in accord with those reported in the literature. The sample of selagine was supplied by Dr. Z. Valenta and that of lycoclavine by Dr. W. A. Ayer, to each of whom my thanks are extended.

Deuterium Exchange Experiments

(a) Lycopodine.—A solution of sodium methoxide in deuteromethanol was prepared by dissolving approximately 50 mg of sodium in 1 ml of CH_3OD. To this solution, 30 mg of lycopodine was added and the mixture heated under reflux for 4 hours. The deuteromethanol was evaporated under reduced pressure, the residue treated with 1 ml of D_2O and extracted with ether. The dried ether extract was evaporated to dryness and the solid residue subjected to a second exchange exactly as above. The residue from the second exchange was recrystallized from dry petroleum ether (30–60°) before its mass spectrum was recorded.

(b) Annofoline.—The exchange was carried out in the same fashion as that described above for lycopodine. The crystalline product was used without further recrystallization.

The Spectrum of Deuterated Annofoline

When the deuterated annofoline prepared above was introduced into the heated inlet system and its spectrum recorded, the most intense peak in the molecular ion region was observed at *m/e* 264 and not at *m/e* 265, as expected. It seemed at first that exchange had not been complete, but closer examination of the spectrum showed that this could not be the case since peaks corresponding to almost complete exchange of deuterium for hydrogen at the bridgehead carbon were present. It appeared more likely that exchange of the deuterium on the bridge with moisture in the inlet system occurred very rapidly. Accordingly the inlet system was given a prior treatment with CH_3OD, the sample introduced, and the spectrum scanned repetitively over the mass region of *m/e* 160 to 270. The results of this experiment are shown in Table III, where the relative intensity of the major peaks in the spectrum of deuterated annofoline are shown at the time of introduction, after approximately 30 minutes, and after approximately 1 hour.

The peak at *m/e* 176 is assigned an arbitrary intensity of 100 and other peaks related to it. The peak at *m/e* 176 was selected as a standard of reference since the ion has no hydroxyl function and its intensity, unlike that of peaks in the region of mass 190 and of the molecular ion, will not be affected by the relative proportion of hydroxyl to deuteroxyl groups in the sample of annofoline.

Table III shows that the intensity of the peak of *m/e* 266 decreases rapidly and, after 60 minutes, it is only slightly stronger than expected of a normal isotope peak, indicating that virtually all of the —OD originally present has reverted to —OH. The peak of *m/e* 265 diminishes rapidly in intensity, too. Initially it is the most intense peak in the molecular ion region but is less intense than the 264-peak after 30 minutes and continues to decrease in intensity relative to the 264-peak.

These results are in accord with the proposition advanced above that the deuterium at C_{14} is easily exchanged but that the deuterium at the bridgehead position is stable in the inlet system.

Deoxodihydroannotinine

This substance was prepared by the method of Betts and MacLean (21).

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Professor Klaus Biemann for the hospitality of his laboratory and for many helpful suggestions in the prosecution of this work and in the preparation of the manuscript. The granting of a year's leave of absence by McMaster University and the award of a Senior Research Fellowship by the National Research Council are gratefully acknowledged.

THE REDUCTIVE CLEAVAGE OF 1,3-OXATHIOLANES WITH LITHIUM ALUMINUM HYDRIDE IN THE PRESENCE OF ALUMINUM CHLORIDE OR BORON TRIFLUORIDE[1]

B. E. LEGGETTER AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received May 10, 1963

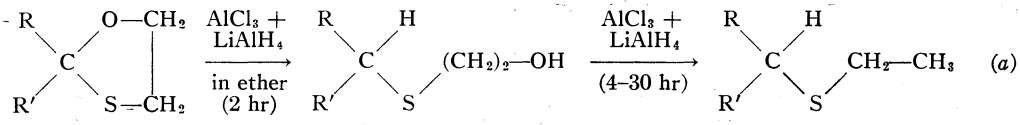
ABSTRACT

A number of 1,3-oxathiolanes and 1,3-dithiolanes were subjected to reduction in ether solution by lithium aluminum hydride in the presence of either aluminum chloride or boron trifluoride. Both of these Lewis acids not only isomerized 1,3-oxathiolanes but also catalyzed their hydrogenolysis to the hydroxy thioethers. Under the same conditions neither aluminum chloride nor boron trifluoride had any effect upon 1,3-dithiolanes. However, in methylene chloride solution, 1,3-dithiolanes are isomerized by both Lewis acids although their hydrogenolysis was not achieved, probably due to the insolubility of the hydride in methylene chloride.

A mechanistic interpretation is discussed to explain the results obtained.

INTRODUCTION

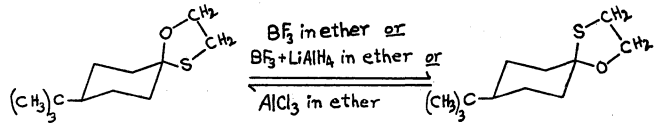
Recently Eliel and co-workers (1, 2) reported the reduction of 13 cyclic hemithioacetals and ketals (1,3-oxathiolanes) with a mixture of lithium aluminum hydride and aluminum chloride in ether solution. They found that in every case cleavage of only the carbon–oxygen bond occurred. Extended reaction times gave further reduction of the hydroxy thioether to the dialkyl sulphide (equation (*a*)).



(*a*)

Attempts by the same authors to reduce a hemithioketal with a mixture of *boron trifluoride* and lithium aluminum hydride were unsuccessful, resulting in practically complete recovery of the hemithioketal.* Thus, boron trifluoride – lithium aluminum hydride reduction of 4-*t*-butylcyclohexanone ethylene hemithioketal gave, in 2 hours, less than 1% of the hydrogenolyzed product, whereas the combination of aluminum chloride and lithium aluminum hydride, under otherwise identical conditions, yielded 85 to 90% of the hydrogenolyzed products, which consisted mainly of the hydroxy thioether along with some dialkyl sulphide.

Although *reduction* of the 4-*t*-butylcyclohexanone ethylene hemithioketal failed to occur with the BF_3–$LiAlH_4$ combination, *isomerization* of the two individual isomers of this ketal *did* take place readily and cleanly with the mixture BF_3–$LiAlH_4$ *or* with BF_3 etherate alone (equation (*b*)). Such isomerization was also obtained by $AlCl_3$ alone in ether solution but accompanied by some further decomposition (1).



(*b*)

[1]*Taken in part from the thesis of B. E. Leggetter submitted to the Graduate School, University of Alberta, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

Reduction of a dioxyketal (a 1,3-dioxolane) with* BF_3–$LiAlH_4$*, however, is readily accomplished (Note 18 in ref. 1). Compare also A. R. Abdum-Nur and C. H. Issidorides, J. Org. Chem.,* **27, *67 (1962).*

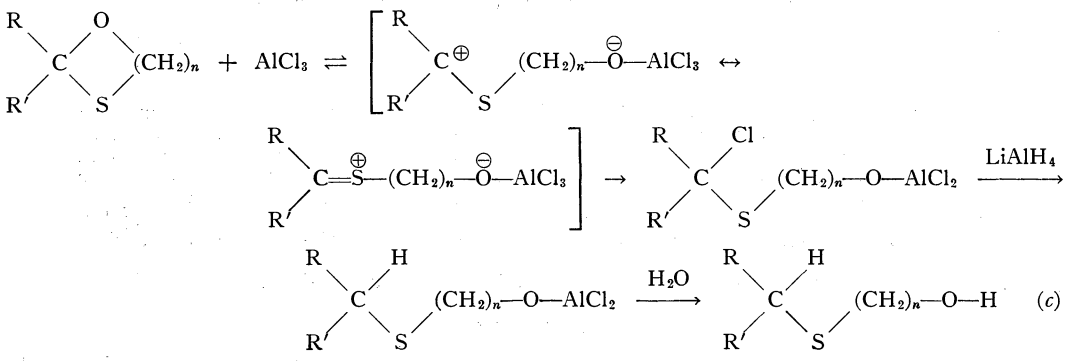
For personal use only.

On the basis of this information, a mechanism for the hemithioketal reduction was proposed (1) involving first the formation of the resonance-stabilized sulphocarbonium ion *which could not be reduced by the hydride but did permit isomerization.* Reaction of this ion with the more nucleophilic chloride ion from the aluminum chloride, but not with the less nucleophilic fluoride ion from BF_3, gave the α-halo thioether which in turn could be reduced easily by the hydride to the hydroxy thioether (equation (*c*)).



As part of a program of research in this laboratory it had become necessary to examine the selective cleavage of 1,3-dioxolanes (ketals or acetals), and 1,3-oxathiolanes (hemithioketals or acetals) using as one of the reducing agents lithium aluminum hydride along with a Lewis acid. This paper reports the results obtained and gives data which cast some doubt on the mechanism of reductive cleavage suggested by Eliel (1).

RESULTS AND DISCUSSION

A number of 1,3-oxathiolanes in ether solution were treated with the combination of lithium aluminum hydride – aluminum chloride or lithium aluminum hydride – boron trifluoride. The results of these experiments are shown in Table I.

Cleavage of C—O but not C—S Bonds

Our results corroborate the findings of the previous workers (1, 2) that in the reduction of 1,3-oxathiolanes the C—O but not the C—S bond is ruptured. No base-soluble mercaptans were isolated. Analyses by v.p.c. and infrared spectroscopy of the individual products as well as the mixtures of products failed to reveal evidence of the presence of the mercapto group. Furthermore, 1,3-*di*thiolanes failed to reduce at all even when the normal reduction time of 2 hours was extended to 48 hours. Only unchanged 1,3-dithiolanes were recovered, and these nearly quantitatively (experiments 6–9).

Hydrogenolysis with BF_3–$LiAlH_4$

As clearly shown in Table I, boron trifluoride *will* catalyze the reductive cleavage of 1,3-oxathiolanes by lithium aluminum hydride in diethyl ether solution (experiments 10–12, 14–15). However, the yield of reduction products is dependent upon the mode of addition of the reagents and upon the physical state of the hydride. In previous work on the reduction of dioxolanes and oxathiolanes using aluminum chloride as catalyst, we have found that when the Lewis acid is added to an ether solution of the dioxolane or oxathiolane *prior* to the addition of hydride, some resinous material was obtained, resulting in a reduced yield of the hydroxy ether. The same occurred but to a much lesser extent when BF_3 was used as the Lewis acid. Our experience in the reduction of these acetals and ketals with $LiAlH_4$–$AlCl_3$ mixture has been that this loss due to resin formation

*Unless otherwise stated, equimolar mixtures of $LiAlH_4$, Lewis acid, and oxathiolane or dithiolane in ether were used. The Lewis acid was added slowly over a period of 5 minutes to an ether solution of oxathiolane and hydride and then the mixture was stirred 2 hours. After work-up the products were analyzed by distillation and/or v.p.c.

†The solution was stirred for 3.5 hours before work-up.

‡The same result was obtained when the solution was allowed to stand 48 hours.

§The BF_3 etherate was added to the solution of hydride and oxathiolane and then the mixture stirred 3 hours.

‖Solid, finely ground $LiAlH_4$ was added to the stirred solution of BF_3 and oxathiolane in ether and the mixture stirred 3 hours.

¶Some resinous product formed. Here solid lumps of hydride in an ether suspension were added to the stirred ether solution of oxathiolane and BF_3.

**Here a solution of the oxathiolane was added to a stirred ether solution of $LiAlH_4 + BF_3$ as in Eliel's procedure (1), except that equimolar proportions of reagents were used. Eliel used a 4:1 ratio of BF_3:$LiAlH_4$. Our reduction time was 3 hours.

††Total product recovery includes both the recovered oxathiolane (or dithiolane) *and* the thioether.

‡‡Much resinous (polymeric) material remained in the flask after removal of volatile products.

could be avoided, and good control of reduction along with quite satisfactory results could be achieved by careful addition of an ether solution of the Lewis acid to the stirred ether solution of the dioxolane or oxathiolane containing the requisite amount of hydride.* Accordingly this procedure was employed initially in the BF_3-catalyzed reductions of the oxathiolanes. It was found that when equimolar quantities of the oxathiolane and lithium aluminum hydride were treated with ethereal BF_3, 39% of the total isolated product was the hydroxy thioether and the remainder (61%) was unchanged material (experiment 10). However, further investigation showed that if the BF_3 and oxathiolane were mixed *first* and then the hydride added in a finely divided state, a greater proportion of the product was found to be the reduced material (experiment 11). If the hydride was added as in experiment 11, but in the form of small lumps, an even greater proportion of the product was the hydroxy thioether (experiment 12). In both experiments 11 and 12, wherein the oxathiolane and BF_3 were first mixed together, somewhat better reduction did occur, though now with resin formation, than by the method of Lewis acid addition to the

**Addition of an ether solution of the ketal or acetal to a mixture of* $LiAlH_4$ *and* $AlCl_3$ *in ether was the procedure employed by Eliel et al. (1, 2).*

For personal use only.

mixture of hydride and oxathiolane—the procedure found to be much the better when $AlCl_3$ was the Lewis acid.* Finally, a repetition of the procedure used by Eliel and co-workers in the reduction of 4-*t*-butylcyclohexanone ethylene hemithioketal (1), in which 0.05 mole of oxathiolane in ether was added to a 4:1 mixture of BF_3 etherate and $LiAlH_4$ in ether which had been stirred for 5 minutes, gave less than 1% of the reduction product and 99% of the starting material, thus duplicating these authors' results.

The failure of a previously prepared 4:1 mixture, in ether, of BF_3–$LiAlH_4$ to effect reductive cleavage of the oxathiolane might be due to destruction of the reducing species before the oxathiolane could be attacked. The work of Shapiro *et al.* (3) on the preparation of diborane indicates that the addition of excess BF_3 to $LiAlH_4$ in ether produces diborane and aluminum fluoride according to the overall reaction given by equation (*d*). Because

$$3LiAlH_4 + 4BF_3 \xrightarrow{\text{ether}} 2B_2H_6 + 3LiF + 3AlF_3 \qquad (d)$$

of its low solubility in diethyl ether, diborane is evolved (4), and in fact the collection of diborane was used as a measure of the rate of formation of diborane (3) from these reagents.

The practically complete loss of the hydride as diborane from the ether solution thus would account for the absence of significant reduction as reported (1),* and as found in the present work when similar experimental conditions were employed.

Shapiro and co-workers (3) observed that no diborane was evolved until the ratio of BF_3 added to $LiAlH_4$ was greater than 1:1, thus indicating a two-step sequence shown by equations (*e*) and (*f*). Complete failure of reduction found in our experiment (No. 13)

$$BF_3 + LiAlH_4 \rightarrow LiBH_4 + AlF_3\downarrow \qquad (e)$$

$$BF_3 + 3LiBH_4 \rightarrow 2B_2H_6 + 3LiF\downarrow \qquad (f)$$

wherein the ratio of BF_3 to $LiAlH_4$ was only 1:1 could thus be attributed to the total conversion of BF_3 to AlF_3. Since the insolubility of AlF_3 makes it an ineffective Lewis acid (5), no reduction of the oxathiolane would occur even though the reducing species, lithium borohydride, was present (equation (*e*)).

In the addition of BF_3 etherate to a mixture of 1,3-oxathiolane and $LiAlH_4$, a competitive reaction must take place between the acetal and the hydride for the Lewis acid. Coordination of the Lewis acid with the oxathiolane would result in subsequent hydrogenolysis while reaction with the hydride would lead to the formation of AlF_3 and B_2H_6. Such a competitive reaction might explain the variability in reduction due to the physical condition of the hydride.

The much faster reduction of 1,3-dioxolanes as compared to that of the 1,3-oxathiolanes (see latter portion of this discussion), and the concept of competition of the dioxolane (or oxathiolane) with the lithium aluminum hydride for the Lewis acid, BF_3, could explain why 1,3-dioxolanes are quite readily reduced by BF_3–$LiAlH_4$ in ether (see first footnote in this paper) but 1,3-oxathiolanes reduce with more difficulty (1) and depend much more upon the order of addition of the reagents than do the dioxolanes.

**It is interesting that a new batch of* $LiAlH_4$, *which was quite finely divided and appeared light grey in color as compared with the darker grey color and lumpy texture of the batch of hydride used for all our experiments, gave reduction to the hydroxy thioether comparable to that of the darker grey material when the hydride was added to a mixture of the 1,3-oxathiolane and* BF_3 *etherate, but gave only unchanged material if the* BF_3 *was added to the previously mixed hydride and oxathiolane in ether.*

**The small amount of reduction, <1%, reported (1) could be due to the residual* B_2H_6 *remaining in the ether solution or to the presence of some unreacted hydride.*

Comparison of the Ease of Reduction of 1,3-oxathiolanes and 1,3-dioxolanes

A number of reductions were carried out with 2-*n*-propyl-1,3-dioxolane and 2-*n*-propyl-1,3-oxathiolane. Equimolar proportions of reagents were employed and conditions were identical in all cases except for the length of time that each experiment was allowed to proceed. The results are shown in Table II.

TABLE II

Comparison of the ease of reduction of 2-*n*-propyl-1,3-dioxolane and 2-*n*-propyl-1,3-oxathiolane by $LiAlH_4$ in the presence of $AlCl_3$ (solvent, diethyl ether)

Expt. No.	Total reduction time, min	Total recovery,* %	Yield of β-hydroxy thioether, %	Amount of recovered unreacted acetal, %
		For 2-*n*-propyl-1,3-oxathiolane		
1	20	89	51	49
2	40	84	81	19
3	60	91	91	9
4	210	80	>99.8	<0.2
		For 2-*n*-propyl-1,3-dioxolane		
5	20	88	100	0

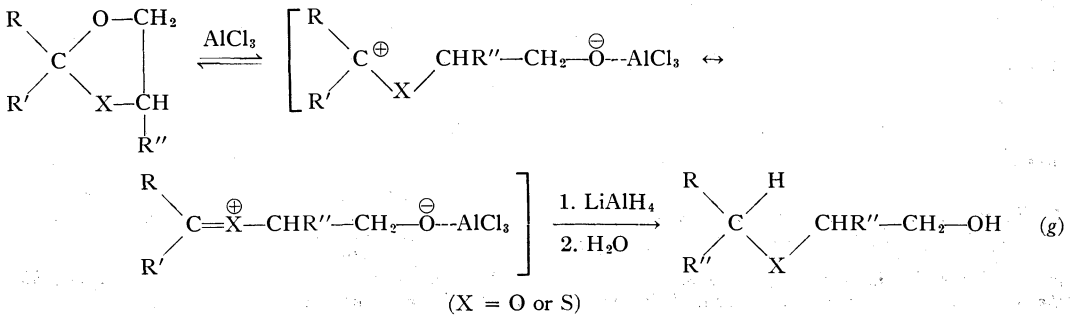
*Total recovery includes the unreacted acetal *and* the β-hydroxyalkyl thioether reduction product. The dialkyl thioethers which Eliel found on continued reduction of the hydroxyalkyl thioethers apparently were not formed during the time of our reduction since v.p.c. analyses failed to reveal their presence.

It is clear that under identical conditions 2-*n*-propyl-1,3-dioxolane is reduced considerably faster than is 2-*n*-propyl-1,3-oxathiolane. The dioxolane had disappeared completely within 20 minutes and it is quite likely that the time for complete reduction is less than this. On the other hand, the oxathiolane was approximately 50% hydrogenolyzed in 20 minutes.

Mechanistic Interpretation

Any mechanistic scheme to explain the reductive cleavage, in ether solution, of these acetals or ketals by lithium aluminum hydride in the presence of a Lewis acid must account for: (i) the direction of ring opening of cyclic acetals (6, 7); (ii) the cleavage of the C—O bond but not the C—S bond in oxathiolanes; (iii) the slower rate of cleavage of oxathiolanes as compared with that of the dioxolanes; (iv) the complete failure of reductive cleavage of dithiolanes.

The two reasonable mechanisms which have been advanced (1, 7, 8) are: (A) direct reduction of the initially formed resonance-stabilized oxocarbonium or sulphocarbonium ion as in equation (*g*).



(*g*)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(B) formation of the α-halo ether from the oxo- or sulpho-carbonium ion followed by reduction of the α-halo ether by the hydride as in equation (*c*).

In view of our observation that BF_3–$LiAlH_4$ causes reduction as does $AlCl_3$–$LiAlH_4$, the argument used as the support for the necessary formation of the α-halo ether is no longer valid. However, this does not mean that the concept of prior α-halo ether formation is disproved. It still *may* be, but is not *necessarily*, the pathway of the reaction.

It is noteworthy that both isomers of 4-*t*-butylcyclohexanone ethylene hemithioketal, when reduced by $AlCl_3$–$LiAlH_4$, were found to give a high (86 to 92%) yield of the same isomer, *trans*-4-*t*-butylcyclohexyl β-hydroxyethyl sulphide (1). This indicates that if α-halogenation were in fact a preliminary step, then *either* the α-halo ether must lose the halogen to become a carbonium ion, a common intermediate from both isomers, which is then reduced stereospecifically, *or* a rapid equilibration of the oxathiolanes occurs (cf. equation (*b*) wherein approximately a 1:1 mixture was found at a slowly attained equilibrium (1)) from which only one of the isomeric α-chloro ethers is formed, and this nearly quantitatively, which is then reduced stereospecifically. In the latter case, if the α-halo ether reacts with $LiAlH_4$ via an S_N1 mechanism, as is likely in view of the known S_N1 character of the solvolysis reactions of α-halo ethers (9),* then initial cleavage of the C—Cl bond must occur to form the readily reducible sulphocarbonium ion.

In view of the fact that the sulphocarbonium ion formation is necessary in the isomerization of the oxathiolane, in the formation of the preferred α-halo ether and also in the reduction (S_N1) of the α-halo ether, it is more logical to assume that prior α-halogenation isn't necessary and that the initially formed sulphocarbonium ion (made with the assistance from the Lewis acid) is the species reduced. The α-halogenation might then occur only as a competitive reaction, with the transient α-halo ether being immediately reduced. No evidence has been obtained in our work (cf. Table II) in the partial reduction of oxathiolanes of α-halo ether formation. No carbonyl compound was found in the products after work-up under alkaline conditions, suggesting α-halo ether formation.

As pointed out by Eliel, Pilato, and Badding (1) "only those functional groups are subject to hydrogenolysis (by $LiAlH_4$) which upon departure leave a stabilized carbonium ion". By and large this seems to be the guiding principle in nearly all the reductive cleavages of 1,3-dioxolanes or 1,3-oxathiolanes encountered in our laboratory. The very few exceptions can be rationalized within the framework of the above statement. This, and other aspects of the problem will be reported upon in a subsequent publication.

Regarding the Selective Cleavage of the C—O Bond Rather than the C—S Bond

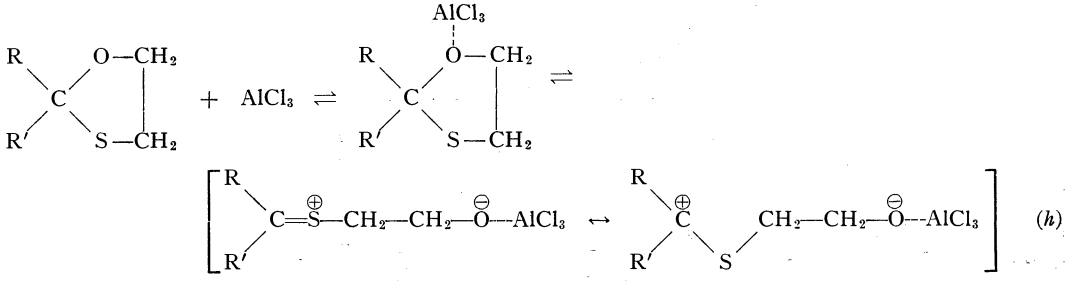
There is considerable evidence that association of $AlCl_3$ with thioethers is more difficult than similar association of $AlCl_3$ with oxygen ethers. Harnish and Tarbell found in their study of the cleavage of ethers (10–12) that thioethers are more resistant to cleavage by acidic reagents than are their oxygen analogues. Suter and Hanson (13) found that alkyl *p*-methoxyphenyl thioethers were cleaved by an acetic acid solution of HBr to form only alkyl *p*-hydroxyphenyl thioethers with no evidence of cleavage of the C—S bond. Furthermore, when dry aluminum bromide was added to pure phenyl benzyl sulphide, cleavage occurred to give thiophenol and benzyl bromide, but when electron donor solvents such as ethers or nitrobenzene were used as diluents for this reaction, aluminum bromide failed

**The reviewer kindly pointed out that α-halo ethers can also react very rapidly by the S_N2 mechanism (P. Ballinger, P. B. D. de la Mare, G. Kohnstam and B. M. Prestt, J. Chem. Soc. 3641 (1955). However, since the work done by Ballinger et al. involved* primary *alkyl halides in the α-halo ether structure, while our work concerned itself with* secondary *and* tertiary *alkyl halides of α-halo ether structure, and as well involved the presence of aluminum chloride which could promote dissociation of the halogen as the halide ion, we prefer to consider the S_N1 reaction of our α-halo ethers as being more likely, even in the ether solutions employed.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to cause any cleavage of the thioether (10). The explanation offered was that of preferential coordination of the $AlBr_3$ with the electron donor solvents.

For diethyl ether solutions of 1,3-dioxolanes the acetal oxygen atom can compete quite effectively with the solvent oxygen atoms for the Lewis acid, thus leading to Lewis acid catalysis of the reduction with $LiAlH_4$. Dithiolanes in diethyl ether solution would fail to experience effective association between the Lewis acid and the sulphur atoms and hence would be resistant to $LiAlH_4$ reduction, as has been found. If then the *first* and *necessary* step in the reductive cleavage of the 1,3-oxathiolanes is coordination of the oxathiolane with the Lewis acid, then one must have the reaction shown in equation (*h*) in which the sulphocarbonium ion is formed. This could then undergo isomerization accompanied by some polymerization or be reduced if $LiAlH_4$ is present.



(*h*)

Support for the concept of the inability of the Lewis acid to associate with the sulphur atom of the oxathiolane or dithiolane in diethyl ether solution is obtained from the observation that the high-melting isomer *cis-* (or *trans-*) 4-chloromethyl-2-phenyl-1,3-dithiolane* treated with either BF_3 or $AlCl_3$ in *ether solution* did not isomerize detectably even when the solution was allowed to stand at room temperature for as long as 20 hours. On the other hand, in the solvent methylene chloride, in which the Lewis acids and the dithiolane were quite soluble, equilibration occurred quite readily. Boron trifluoride gave complete equilibration within 90 minutes unaccompanied by polymerization, but aluminum chloride gave equilibration accompanied by extensive gum formation. Detection of isomerization was easily accomplished by n.m.r. analysis of the individual isomers and the mixtures produced, since the signal for the lone proton on C_2 of the dithiolane occurred as a sharp singlet at $\tau = 4.48$ for the low-melting isomer (m.p. 60–62°) and at $\tau = 4.43$ for the high-melting isomer (m.p. 68–69°).

On the assumption that if reduction is to occur there must be prior association of the Lewis acid with the dithiolane, and now knowing that isomerization of dithiolanes does occur in CH_2Cl_2 solution through the agency of a Lewis acid, we attempted to reduce several 1,3-dithiolanes at our disposal. However, the failure of $LiAlH_4$ to dissolve in the CH_2Cl_2 thwarted attempts in this direction and there were obtained only the unchanged dithiolanes. That failure of reduction can be attributed to the insolubility of the $LiAlH_4$ in CH_2Cl_2 is borne out by complete lack of reduction of 2,2,4-trimethyl-1,3-dioxolane in CH_2Cl_2 by the mixture $LiAlH_4$ and $AlCl_3$. This dioxolane is very readily reduced under these conditions if the solvent is ether.

It is possible to explain the more rapid reduction of the dioxolanes as compared with the oxathiolanes. The formation of the stabilized oxocarbonium ion is easier because of the better overlap of the *p*-orbitals of the oxygen atom with the vacant *p*-orbital of the carbonium ion. Similar stabilization of the sulphocarbonium ion in the oxathiolane occurs

*See Note in the experimental section on the preparation of the chloromethyl compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

by the less facile overlap of the *d*-orbitals of the sulphur atom. The *formation* of the stabilized carbonium ion then must be involved in the rate-controlling step or steps of the reaction.

EXPERIMENTAL

All compounds mentioned were made by authentic and reported procedures or were newly prepared and characterized. Except where otherwise stated, all v.p.c. analyses were done with a Burrell K-2 Kromotog using a 2-m column packed with 25% of carbowax 20 M on gas-chrom P as the solid stationary phase. Helium, at a flow rate of approximately 80 ml/min was the carrier gas. The column temperature was dependent upon the boiling point of the products. Products were identified by comparison of their retention times with those of authentic samples, and/or by means of infrared spectroscopy as well as n.m.r. analyses with a Varian A-60 spectrometer. Quantitative measurements were made by comparison of v.p.c. peak areas with those obtained from known quantities of authentic reagents.

Typical Reduction Procedure. Reduction of 2-Phenyl-1,3-oxathiane

The compound, 2-phenyl-1,3-oxathiane, was prepared according to published directions (1). However, the boiling point reported was 166° at 1.2 mm while that found by us is 92° at 1.0 mm. Elemental analysis of our preparation agreed closely for the assigned structure.

To a stirred mixture of 2-phenyl-1,3-oxathiane (12.0 g, 0.067 mole) and lithium aluminum hydride (2.7 g, 0.067 mole) in ether (150 ml) at room temperature was added, over a period of 5 minutes, a solution of dry aluminum chloride (8.9 g, 0.067 mole) in 100 ml of ether. The exothermic reaction which took place during the addition required the slow admixture of the $AlCl_3$. The resulting mixture, first stirred 2 hours, was then cautiously diluted with cold water to destroy the aluminum chloride complexes and the excess hydride. In all cases the excess hydride was employed deliberately so that on treatment with water the solution remained basic at all times to avoid isomerization or hydrolysis of any unreacted acetal. The inorganic material was removed by filtration and the ethereal filtrate was dried over magnesium sulphate. Removal of the ether and distillation of the oil under reduced pressure gave a total yield of 6.5 g (54%) of material boiling at 126° at 1.6 mm. Lit. b.p., 185° at 19 mm (14). The infrared spectrum of this material was identical with that of a sample of benzyl γ-hydroxy-*n*-propyl sulphide prepared from benzyl chloride and 3-mercaptopropan-1-ol (14).

The oxathiolanes reduced by this procedure, along with authentic reduction products and their yields, are shown in Table III.

TABLE III

1,3-Oxathiolanes reduced by $LiAlH_4$ and $AlCl_3$ and product yields

1,3-Oxathiolane	Ref.	Reduction product	% yield	Ref.
2-Phenyl-1,3-oxathiolane	15	Benzyl β-hydroxyethyl sulphide	72	18
2-*n*-Propyl-1,3-oxathiolane	(See expt.)	*n*-Butyl β-hydroxyethyl sulphide	89*	18
2,2-Dimethyl-1,3-oxathiolane	16	*i*-Propyl β-hydroxyethyl sulphide	87	1
2,2-Diphenyl-1,3-oxathiolane	17	Diphenylmethyl β-hydroxyethyl sulphide	73	19

*The reaction time in this case was 210 minutes rather than the usual 2 hours.

Attempted Reduction of 2-Phenyl-1,3-dithiolane

To a stirred mixture of 2-phenyl-1,3-dithiolane (18.3 g, 0.1 mole) (20) and lithium aluminum hydride (1.9 g, 0.05 mole) in ether (120 ml) at room temperature was added a solution of dry aluminum chloride (13.4 g, 0.1 mole) in 60 ml of ether over a period of 3 to 5 minutes. The mixture was then stirred for 2 hours. Following treatment of the mixture as for the 1,3-oxathiolanes or 1,3-oxathiane above, there was obtained, by fractional distillation, 17.5 g (96%) of material whose infrared spectrum was identical with that of the original 2-phenyl-1,3-dithiolane.

A second attempt at reduction using the same conditions but with twice the amount of hydride and also with a reaction time of 48 hours gave 96% recovery of the original material. No evidence of reduction was found.

The 1,3-dithiolanes whose reductive cleavage was attempted by the above procedure are shown in Table IV.

Comparative Rates of Reduction of 2-n-Propyl-1,3-dioxolane and 2-n-Propyl-1,3-oxathiolane

The following specific procedure was used for *four* separate reductions of 2-*n*-propyl-1,3-oxathiolane and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

TABLE IV

1,3-Dithiolanes subjected to reduction by $LiAlH_4$ and $AlCl_3$

1,3-Dithiolane	Ref.	Recovered 1,3-dithiolane, %	Reduction product, %
2,2-Dimethyl-1,3-dithiolane	21	96	0
2,4-Dimethyl-1,3-dithiolane	(See expt.)	92	0
2-Phenyl-4-methyl-1,3-dithiolane	22	78*	0

*The low recovery was due to accidental loss.

one for 2-*n*-propyl-,13-dioxolane. These differed only in the length of time that the reaction was allowed to proceed after admixture of all reagents. Times of 20, 40, 60, and 210 minutes were chosen for the oxathiolane experiments while a 20-minute reduction time was allowed for the dioxolane.

To a stirred mixture of acetal (0.05 mole) and lithium aluminum hydride (0.05 mole) in 70 ml of ether was added at room temperature over a period of *one* minute a solution of aluminum chloride (0.05 mole) in ether (30 ml). The mixture was then stirred for the requisite time at room temperature and then diluted carefully with cold water. After removal of the inorganic material by filtration, the ether extract was dried ($MgSO_4$). The residual oil obtained on removal of the ether was analyzed by v.p.c. The results are shown in Table II.

2-n-Propyl-1,3-oxathiolane was prepared according to modifications of the general procedure recommended in the literature (16) by condensation of *n*-butyraldehyde with 2-mercaptoethanol. *n*-Butyraldehyde (40 g) and 36 g of 2-mercaptoethanol were dissolved in 200 ml of dry benzene. To this was added 0.3 g of *p*-toluenesulphonic acid and 20 g of anhydrous magnesium sulphate. The solution, which became warm upon the addition of these reagents, was allowed to stand for 20 hours and then poured into aqueous sodium carbonate. The organic layer was separated and dried ($MgSO_4$) and then fractionally distilled. There was obtained 50 g (82%) of 2-*n*-propyl-1,3-oxathiolane boiling at 84° at 34 mm. Calc. for $C_6H_{12}OS$: C, 54.54; H, 9.09; S, 24.24. Found: C, 54.63; H, 9.17; S, 24.01.

2,4-Dimethyl-1,3-dithiolane was prepared according to the above procedure by condensation of acetaldehyde with 1,2-dimercaptopropane. Yield 77%. B.p. 81° at 25 mm. Calc. for $C_5H_{10}S_2$: C, 44.78; H, 7.46; S, 47.76. Found: C, 44.55; H, 7.47; S, 47.91.

n-Butyl β-hydroxyethyl thioether was prepared according to the procedure of Klamann and Bertsh (18). B.p. 68° at 3 mm. Lit. b.p. 106–107° at 14 mm.

Reduction of 1,3-Oxathiolanes with $LiAlH_4$–BF_3

In these reductions 2,2-dimethyl-1,3-oxathiolane (16) was used as starting material for experiments 10–13 and was prepared most conveniently in 86% yield by condensation of 2-mercaptoethanol and acetone in the presence of anhydrous magnesium sulphate and a catalytic amount of *p*-toluenesulphonic acid. Excess acetone was removed and the residual oil fractionally distilled, affording 2,2-dimethyl-1,3-oxathiolane. B.p. 57° at 45 mm; lit. b.p. 70° at 65 mm (16).

(a) Experiment 10

A mixture of 2,2-dimethyl-1,3-oxathiolane (0.15 mole) and finely divided lithium aluminum hydride (0.05 mole) in 75 ml of anhydrous ether was stirred while boron trifluoride etherate (0.05 mole) was added dropwise. After the addition, the solution was stirred for 3 hours at room temperature. After cautious addition of water, followed by removal of inorganic precipitate, the ether layer was separated and dried ($MgSO_4$). Removal of the ether left an oil (95% yield) which v.p.c. analysis showed to consist of 39% *i*-propyl β-hydroxyethyl sulphide and 61% of unchanged 2,2-dimethyl-1,3-oxathiolane.

(b) Experiment 11

In this experiment, a mixture of 2,2-dimethyl-1,3-oxathiolane (0.05 mole) and boron trifluoride etherate (0.05 mole) in ether (75 ml) was stirred whilst powdered hydride (0.05 mole) was added in small batches. The remainder of the procedure followed that for experiment 10. Total yield of material was 73%, of which 50% was the hydrogenolized product, *i*-propyl β-hydroxyethyl sulphide, and 50% the unchanged oxathiolane. The low yield (73%) was due to the occurrence of considerable resinous material.

(c) Experiment 12

The same procedure as in experiment 11 was followed except that the hydride was added in the form of lumps. The overall total yield was 75%, 56% of which was *i*-propyl β-hydroxyethyl sulphide and the remainder (44%) unreacted starting material. Here again the formation of resinous material lowered the yield.

(d) Experiment 13

The procedure of Eliel *et al.* (1) was used to reduce 2,2-dimethyl-1,3-oxathiolane with the modification that equimolar proportions of reagents were employed and the reaction time extended to 3 hours. During the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mixing of the hydride and boron trifluoride a vigorous evolution of gas took place. This had not been noted in the previous experiments. Presumably the gas was B_2H_6. The overall yield of recoverable material was 90%, of which <1% was the hydroxy sulphide and the remainder unchanged oxathiolane.

(e) Experiment 14

A quantity of 2-phenyl-1,3-oxathiolane was reduced by the procedure used in experiment 12. All of the product (29% yield) was benzyl β-hydroxyethyl sulphide. The residual material in the flask was resinous. No starting material was recovered. Analyses by v.p.c. were done with a 2-m column of 25% silicone rubber on Gas-Chrom P at a temperature of 250°. The n.m.r. spectrum agreed with the structure.

(f) Experiment 15

Reduction of 2-phenyl-1,3-oxathiolane by the procedure used in experiment 10 gave a 80% yield of material of which 73% was benzyl β-hydroxyethyl sulphide and 27% was starting material.

Preparation of cis- and trans-2-Phenyl-4-chloromethyl-1,3-dithiolane.

The method of Roberts and Cheng (22) was employed to prepare the 3,5-dinitrobenzoate of 4-hydroxymethyl-2-phenyl-1,3-dithiolane. The method of separation of the cis and trans isomers of this ester devised by Roberts and Cheng proved to be unsatisfactory. However, good separation was achieved by fractional crystallization from benzene. The higher-melting isomer, 118–119° (lit. 112–113° (22)), precipitated, leaving the lower-melting isomer, 99–100° (lit. 100–101° (22)), in solution. Concentration of the mother liquor afforded the latter in 15% yield based upon the hydroxymethyldithiolane used. A 33% yield was obtained for the 118–119° melting isomer.

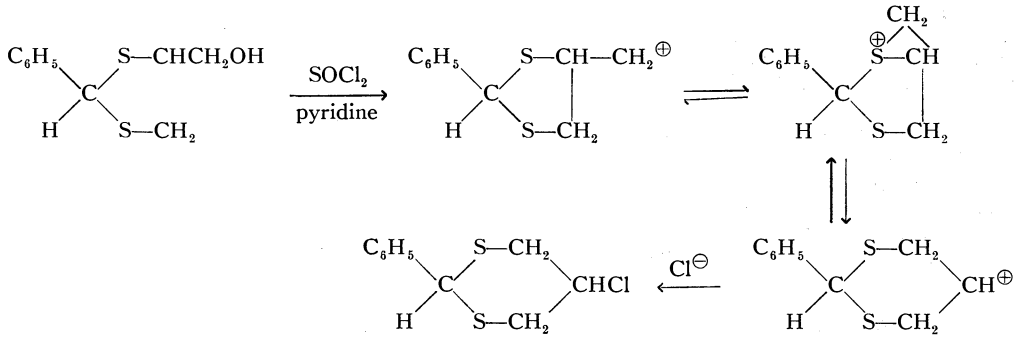
Both isomeric 3,5-dinitrobenzoates were hydrolyzed to the *cis*- and *trans*-4-hydroxymethyl-2-phenyl-1,3-dithiolanes most satisfactorily by refluxing the esters for 45 minutes in a 1:1 mixture of aqueous ethanol containing 8% of potassium hydroxide. Use of only aqueous KOH as advocated by Roberts and Cheng gave less satisfactory results since much of the material remained unhydrolyzed. The high-melting isomeric ester gave a 77% yield of crude alcohol which was purified by chromatography on alumina with ether as eluant. Subsequent crystallization from benzene–skellysolve afforded the pure alcohol, m.p. 90°; lit. m.p. 88.5–89° (22). The low-melting ester gave a 74% yield of crude alcohol which after purification as above melted at 88°. Lit. m.p. 87.5–88° (22).

Conversion of the 4-hydroxymethyl-2-phenyl-1,3-dithiolane to the 4-chloromethyl-2-phenyl-1,3-dithiolane was accomplished by treatment of the alcohol with an equivalent quantity of thionyl chloride in the presence of a catalytic amount of pyridine, all in refluxing diisopropyl ether. Removal of the ether and other volatile substances gave a pale yellow solid which was purified by chromatography on alumina using skellysolve as eluant. Crystallization from skellysolve gave an analytical sample.

The isomeric alcohol melting at 90° gave the 4-chloromethyl-2-phenyl-1,3-dithiolane in 46% yield based on the alcohol used. An analytical sample melted at 68–69°. Calc. for $C_{10}H_{11}ClS_2$: C, 52.06; H, 4.77; Cl, 15.40; S, 27.77. Found: C, 51.74; H, 4.52; Cl, 15.17; S, 28.01.

The isomeric alcohol melting at 88° gave, by the same procedure, a 58% yield of the 4-chloromethyl-2-phenyl-1,3-dithiolane, melting at 60–62°. Calc. for $C_{10}H_{11}ClS_2$: C, 52.06; H, 4.77; Cl, 15.40; S, 27.77. Found: C, 51.80; H, 4.64; Cl, 15.61; S, 27.61. The n.m.r. spectrum in CS_2 with tetramethylsilane as reference compound supported the structure assigned and gave a sharp singlet for the C_2 proton at $\tau = 4.48$.

(Note: The possibility arises that during the conversion of the 4-hydroxyethyl-2-phenyl-1,3-dithiolanes to the chloromethyl compounds, expansion of the 1,3-dithiolane ring may occur as illustrated by the following scheme.



However, it is significant that the two isomeric hydroxymethyl-dithiolanes afforded different chloro derivatives upon treatment with thionyl chloride. This observation would argue against ring expansion. The n.m.r. spectrum also favors the 5-membered ring structure. *Absolute* identification however must await the synthesis of authentic 6-membered ring structures for comparison. However, the main point of the use of these dithiolanes is not affected.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The unresolved mixture of *cis*- and *trans*-4-hydroxymethyl-2-phenyl-1,3-dithiolane gave a 65% yield of a mixture of *cis*- and *trans*-chloromethyl compounds which melted over the broad range of 57–62°. Elemental analysis of this mixture gave the following results. Calc. for $C_{10}H_{11}ClS_2$: C, 52.06; H, 4.77; Cl, 15.40; S, 27.77. Found: C, 51.83; H, 4.44; Cl, 15.59; S, 27.90. The integrated areas for proton absorption in the n.m.r. spectrum obtained in CS_2 supported the structural designation. The signal position of the C_2-proton, using tetramethylsilane as internal standard, indicated the expected mixture of the two isomers by the presence of the two singlets at 4.44 τ and 4.49 τ. The relative areas of these two signals indicated a 4:1 ratio of high-melting isomer to low-melting isomer which had occurred as result of a 3-fold crystallization from skellysolve. Further crystallization from the same solvent decreased the content of low-melting isomer in the mixture.

Attempted Reduction of 1,3-Dithiolanes by $LiAlH_4$–$AlCl_3$

A mixture of the dithiolane (0.05 mole) and lithium aluminum hydride (0.05 mole) in 60 ml of dry ether was stirred while a solution of aluminum chloride (0.05 mole) in 20 ml of ether was added dropwise. The reaction mixture was then stirred under nitrogen until a total reaction time of 2 hours had elapsed. Decomposition and subsquent treatment of the reaction mixture in the usual manner afforded only the original unchanged material in at least 90% yield. No alkali-soluble materials were obtained. Vapor phase chromatographic analyses gave no indication of a product other than starting material. Increase in reaction time to 24 hours also failed to yield any hydrogenolyzed products. The compounds subjected to this treatment are shown in Table I, experiments 6–9, and in Table IV.

Equilibration of cis- and trans-4-Chloromethyl-2-phenyl-1,3-dithiolane

In Diethyl Ether as Solvent

A solution of 230 mg of the isomer melting at 68–69° in 20 ml of ether was treated with 135 mg of anhydrous aluminum chloride in 10 ml of ether. The reaction mixture was allowed to stand at room temperature for 20 hours and then poured into aqueous sodium bicarbonate. The ether layer was separated and dried. Evaporation of the solvent afforded 100 mg of product melting sharply at 67–68°. Nuclear magnetic resonance analyses indicated that no equilibration had occurred since only one sharp singlet occurred at $\tau = 4.43$ characteristic of the C_2-proton of the high-melting isomer.

When boron trifluoride etherate was used as the Lewis acid, the same results were obtained.

In Methylene Chloride as Solvent

A quantity (290 mg) of the isomer melting at 68–69° was dissolved in methylene chloride previously dried for 48 hours over $CaCl_2$. Anhydrous boron trifluoride was bubbled into the solution for several minutes and the resulting solution allowed to stand for 90 minutes. The solution was then poured into aqueous sodium bicarbonate. The organic layer was separated, washed with aqueous bicarbonate, then with water, and finally dried (Na_2CO_3). Evaporation of the solvent gave 225 mg of material melting at 51–54°. An n.m.r. spectrum (CS_2) of this product indicated a mixture of *cis*- and *trans*-4-chloromethyl-2-phenyl-1,3-dithiolane in which the high-melting isomer predominated slightly over the low-melting isomer as determined by the integrated areas and by visual inspection of the two singlets at $\tau = 4.43$ and 4.48.

The same reaction was carried out using $AlCl_3$ as the catalyst rather than BF_3, and allowing the reaction mixture to stand for 20 hours. When the mixture was worked up as before, a resinous material was obtained. An n.m.r. spectrum of this substance indicated extensive decomposition and nothing definite concerning isomerization.

A repetition of the reaction with $AlCl_3$ as catalyst, but for a period of 4 hours, gave a resinous oily product whose n.m.r. spectrum showed a somewhat broader and poorly resolved signal at 4.46 τ, indicating that isomerization had occurred along with decomposition.

INVESTIGATION OF THE SELF-ASSOCIATION OF PHENOLS AND ANILINES BY ULTRAVIOLET SPECTROSCOPY

J. C. DEARDEN[1]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Newfoundland

Received February 25, 1963

ABSTRACT

Equations are derived for the calculation of the extent of self-association from ultraviolet absorption spectra. The spectra of a number of phenols and anilines have been taken over wide concentration ranges, and are discussed in terms of association. Association constants for four of the compounds have been calculated. An explanation of the spectral effects of self-association is offered.

INTRODUCTION

A compound capable of forming a hydrogen bond may associate either with itself or with another hydrogen bonding compound, and such association manifests itself in the ultraviolet absorption spectrum of the compound. The electronic spectral effects of hydrogen bonding between unlike molecules have been widely studied (1), but ultraviolet spectroscopic investigation of self-association has been limited, partly because of the difficulty of obtaining spectra of highly concentrated solutions. Qualitative ultraviolet studies of self-association have recently been made by Ungnade and Lamb (2) on benzoic acids, Forbes *et al.* on benzoic acids (3) and phenols and anilines (4), Rao and Murthy (5) on phenol, Arvan and Zaitseva (6) on dyes, and Lippert and Oechssler (7) on acetic acids. Attempts to determine degrees of association by ultraviolet spectroscopy have been made by von Keussler (8) on phenol, Ito (9) on substituted phenols, and Kaye and Poulson (10) on methanol. Levshin *et al.* (11, 12) have calculated degrees of association and hydrogen bonding energies in dyes, from measurements of the concentration and temperature dependences of their spectra.

In the present paper, equations representing monomer–dimer, monomer–trimer, and monomer–polymer equilibria have been developed.

THE ASSOCIATION OF PHENOL

The evidence for the mode of association of phenol is conflicting. Various workers consider that it forms a dimer (13) or a cyclic dimer (9), a trimer (14, 15), or a polymer (9, 16).

The formation of a cyclic dimer is unlikely for two reasons. Firstly, the hydrogen bonds in such a structure would be strained; secondly, further association would be inhibited, since approach to the proton-accepting sites in the dimer would be sterically hindered. Now, it has been shown (17) that the apparent molecular weight of phenol increases continually with concentration; it is therefore probable that phenol associates first into open dimers and then into open trimers and polymers with increasing concentration (see also ref. 18).

The method developed below for the calculation of the monomer fraction (α) from ultraviolet spectra requires prior knowledge of the relation between the association constant (K) and α, and necessitates the assumption of constant K.

[1]*Present address: "Shell" Research Limited, Thornton Research Centre, P.O. Box 1, Chester, England.*

THE CALCULATION OF MONOMER FRACTION

Three equations are considered, each of which involves a single association constant K:

(i) $$K = \frac{1-\alpha}{2\alpha^2 C}$$ representing dimer formation,

(ii) $$K = \frac{1-\alpha}{3\alpha^3 C^2}$$ representing trimer formation,

(iii) $$K = \frac{1-\sqrt{\alpha}}{\alpha C}$$ representing polymer formation (16),

where C denotes molar concentration.

Ito (9) has shown that, in a spectrum containing monomer and dimer bands, the apparent molar absorptivity ϵ at any wavelength is given by:

(iv) $$\epsilon = \epsilon_M\alpha + \tfrac{1}{2}\epsilon_D(1-\alpha),$$

where ϵ_M and ϵ_D are the true molar absorptivities of monomer and dimer, respectively.

From (iv)

(v*a*) $$\epsilon_1 = \epsilon_M\alpha_1 + \tfrac{1}{2}\epsilon_D(1-\alpha_1)$$

and

(v*b*) $$\epsilon_2 = \epsilon_M\alpha_2 + \tfrac{1}{2}\epsilon_D(1-\alpha_2),$$

where subscripts 1 and 2 refer to concentrations C_1 and C_2.

From (v*a*)

$$\alpha_1 = \frac{\epsilon_1 - \frac{1}{2}\epsilon_D}{\epsilon_M - \frac{1}{2}\epsilon_D}$$

so that

(vi*a*) $$1-\alpha_1 = \frac{\epsilon_M - \epsilon_1}{\epsilon_M - \frac{1}{2}\epsilon_D}.$$

Similarly, from (v*b*)

(vi*b*) $$1-\alpha_2 = \frac{\epsilon_M - \epsilon_2}{\epsilon_M - \frac{1}{2}\epsilon_D}.$$

Combination of (vi*a*) and (vi*b*) gives

(vii) $$\frac{1-\alpha_1}{1-\alpha_2} = \frac{\epsilon_1 - \epsilon_M}{\epsilon_2 - \epsilon_M} = Q, \text{ say.}$$

Similarly, from (i)

(viii) $$\frac{1-\alpha_1}{\alpha_1^2 C_1} = \frac{1-\alpha_2}{\alpha_2^2 C_2}.$$

From (viii)

(ix) $$\alpha_2 = \pm\alpha_1\sqrt{(C_1/QC_2)}.$$

Substituting (ix) in (vii),

$$Q = \frac{1-\alpha_1}{1\pm\alpha_1\sqrt{(C_1/QC_2)}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Hence

$$Q \pm \alpha_1 \sqrt{(QC_1/C_2)} = 1-\alpha_1.$$

This is rearranged to give

$$\alpha_1 = \frac{1-Q}{1 \pm \sqrt{(QC_1/C_2)}}.$$

However, only the solution

(x) $$\alpha_1 = \frac{1-Q}{1-\sqrt{(QC_1/C_2)}}$$

is valid, since α must lie between 0 and +1.*

A similar expression for α_1 is obtained if monomer–trimer equilibrium is assumed. In this case, (iv) is replaced by

$$\epsilon = \epsilon_M \alpha + \tfrac{1}{3}\epsilon_T(1-\alpha),$$

where ϵ_T is the true molar absorptivity of the trimer. The expression for α_1 is then given by

$$\alpha_1 = \frac{1-Q}{1-\sqrt[3]{(Q^2C_1^2/C_2^2)}}.$$

The case of monomer–polymer equilibrium cannot be so easily solved; treatment as above yields a complicated expression containing α^6. A simple graphical solution may, however, be obtained as follows. From (iii)

$$\frac{1-\sqrt{\alpha_1}}{\alpha_1 C_1} = \frac{1-\sqrt{\alpha_2}}{\alpha_2 C_2}.$$

Arbitrary values of α_1 and α_2 between 0 and +1 are substituted in $(1-\sqrt{\alpha_1})/\alpha_1 C_1$ and $(1-\sqrt{\alpha_2})/\alpha_2 C_2$ respectively, using the experimental values of C_1 and C_2. From plots of α_1 versus $(1-\sqrt{\alpha_1})/\alpha_1 C_1$ and of α_2 versus $(1-\sqrt{\alpha_2})/\alpha_2 C_2$ corresponding values of α_1 and α_2 are obtained for a range of values of $(1-\sqrt{\alpha_1})/\alpha_1 C_1$. The intersect of a plot of α_1 versus α_2 with the line

(xi) $$\alpha_2 = 1 - \frac{1-\alpha_1}{Q}$$

derived from (vii) yields both α_1 and α_2.

Equation (xi) involves the assumption that the molar absorptivities of all complexes are equal. This is probably only approximately true; as will be shown later, each complex probably has a slightly different spectrum.

RESULTS AND DISCUSSION

The ultraviolet spectra of several phenols and anilines in cyclohexane solution have been obtained over wide concentration ranges. The results have been published previously (4) and so only the spectral curves for phenol are reproduced here (Fig. 1). (Spectral data for the other compounds studied can, if required, be obtained from the author.)

**Ito (9) obtains the equation*

$$1-\alpha = \frac{C_2-C_1}{QC_2-C_1} \pm \sqrt{\left(\frac{(3Q+1)C_1C_2}{QC_2-C_1}\right)},$$

which appears to be incorrect.

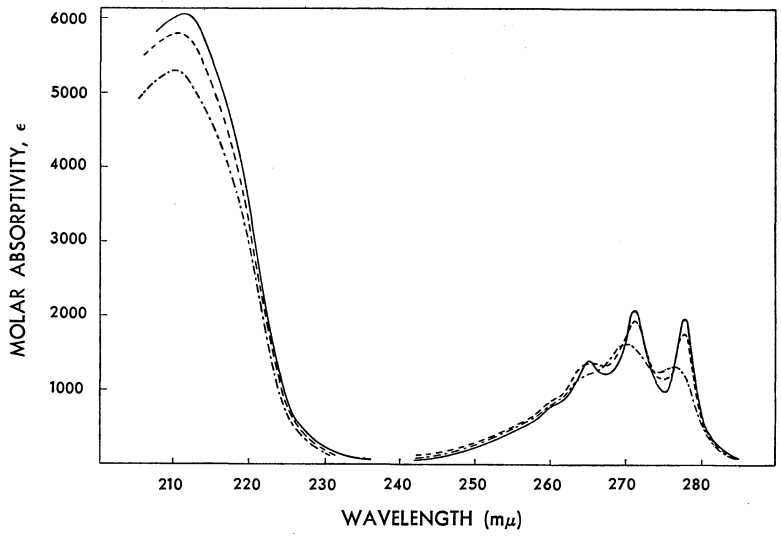

FIG. 1. The spectrum of phenol in cyclohexane at various concentrations. *K*-Band: 0.924×10^{-4} *M* (—); 2.88×10^{-2} *M* (- - -); 0.499 *M* (-·-). *B*-Band: 2.31×10^{-4} *M* (—); 0.104 *M* (- - -); 2.44 *M* (-·-).

The spectra of these compounds show upon self-association slight hypsochromism and hypochromism in both the *K*- and *B*-bands,* together with loss of fine structure in the latter.

Isosbestic points do not occur in the spectra. Ito (9) also observed this, but believed it to be due to experimental inaccuracies, and corrected his spectra so as to obtain isosbestic points. However, it is here considered that the absence of isosbestic points in the spectra is real and is caused by the existence of a number of different complexes, each with its own spectrum (cf. refs. 12, 19).

Phenol

There is wide disparity between the present results for the concentration dependence of the phenol spectrum and those of von Keussler (8) and Ito (9). The present results agree closely, however, with those of Rao and Murthy (5). The spectrum of anisole, which compound is incapable of self-association through hydrogen bonding, also shows a hypochromic effect with increasing concentration. It does not, however, display a hypsochromic shift; such a shift may therefore be taken as evidence of hydrogen bonding. Anisole probably associates slightly (see ref. 20) through dipole–dipole interaction, but this in no way affects the validity of the calculation of α as described above, since the mechanism of association is immaterial to the calculation.

From the spectra obtained, the variation of α with concentration, and the association constant *K*, have been calculated for the cases of dimer, trimer, and polymer formation. The values of *K* are shown in Table I, and of α in Fig. 2. These values are the means of values calculated at several wavelengths. Agreement amongst individual values was reasonably good. In Fig. 2 a comparison is made with the data of Mecke (16) in carbon tetrachloride solution. Since carbon tetrachloride is a weak proton acceptor, it would be expected that self-association in this solvent would be less than in cyclohexane. Hence the values of α determined in the present work are rather high, and those of *K* rather low,

**Referred to in ref. 4 as B- and C-bands, respectively.*

TABLE I

Association constants of the self-association of phenols and aniline, calculated from ultraviolet spectra

Compound	Assuming dimer formation (liters/mole)	Assuming trimer formation (liters²/mole²)	Assuming polymer formation (liters/mole)
Phenol	1.28	15.4	1.45
m-Cresol	1.87	30.7	2.68
p-Cresol	1.93	34.0	2.30
Aniline	2.02	80.0	2.71

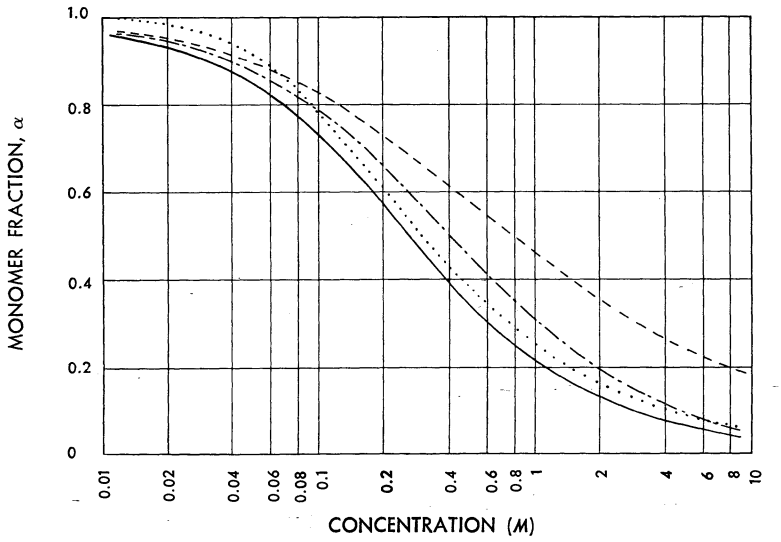

FIG. 2. The change of monomer fraction of phenol in cyclohexane with concentration, assuming dimeric (- - -), trimeric (· · ·), and polymeric (-·-) association, and the data of Mecke in carbon tetrachloride (—).

due probably to experimental error (see Experimental). However, it is important to note that Mecke's curve shows a marked disparity in shape with the dimer curve, but quite good agreement with the trimer and polymer curves, with the latter having the best overall fit.

The effect of association on the *B*-band of phenol is shown in Fig. 3; the polymer spectrum was calculated assuming $\alpha = 0.1$ at a concentration of 2.44 M in cyclohexane. The value of $\alpha = 0.1$ is rather less than that calculated from the present ultraviolet data, and was estimated from Mecke's value of $\alpha = 0.11$ in carbon tetrachloride. The polymer spectrum has slightly more pronounced fine structure, and a slightly smaller band width, than has von Keussler's (8) spectrum of pure liquid phenol. These features are consistent with the concept of the size of the associated molecule increasing continually with concentration.

The Cresols

The present results for the concentration dependence of the spectrum of *o*-cresol were not sufficiently accurate for values of α and K to be calculated. The values of K for *m*- and *p*-cresol are given in Table I, and the variation of α with concentration in Figs. 4 and 5.

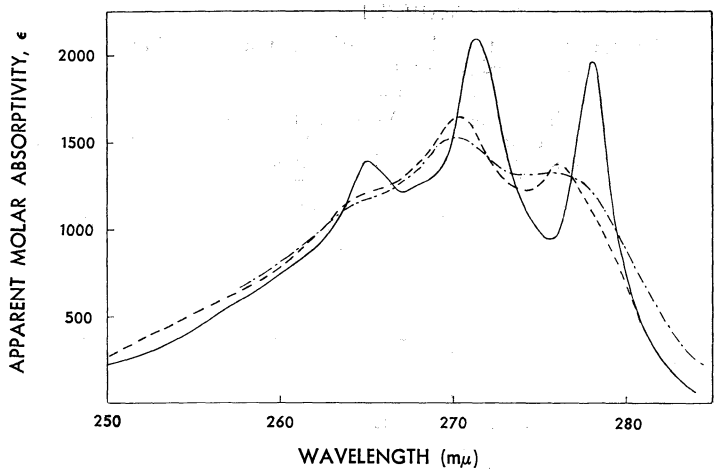

FIG. 3. The *B*-band of phenol in cyclohexane: monomer (—), polymer at 2.44 *M* (- - -) and the data of von Keussler for pure liquid (···).

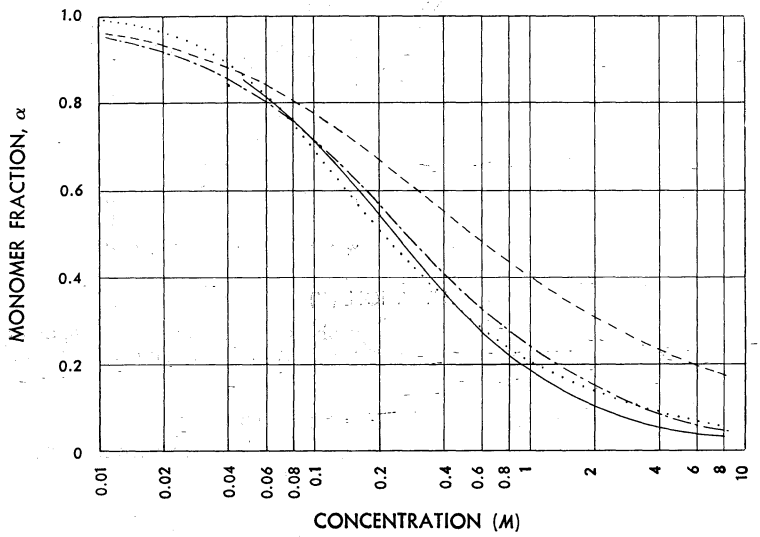

FIG. 4. The change of monomer fraction of *m*-cresol in cyclohexane with concentration, assuming dimeric (- - -), trimeric (···), and polymeric (-·-) association, and the data of Azimi-Pour in carbon tetrachloride (—).

Figure 4 also includes the data of Azimi-Pour (21) for *m*-cresol in carbon tetrachloride, determined by infrared spectroscopy. The data are seen to be in fair agreement, with the present α values again slightly high. The same may be said of the present results for *p*-cresol (Fig. 5) compared with those of Bono (22) from infrared spectra. For both these compounds the assumption of a monomer–trimer or monomer–. . .–polymer equilibrium gives a much better fit with the infrared data than does that of a monomer–dimer equilibrium.

2,6-Di-tert-butylphenol

There appears to be no significant concentration dependence of the spectrum of this compound (4), save for a slight hypsochromic shift at high concentrations. This is consistent with the concept of the very bulky *tert*-butyl groups' preventing the formation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

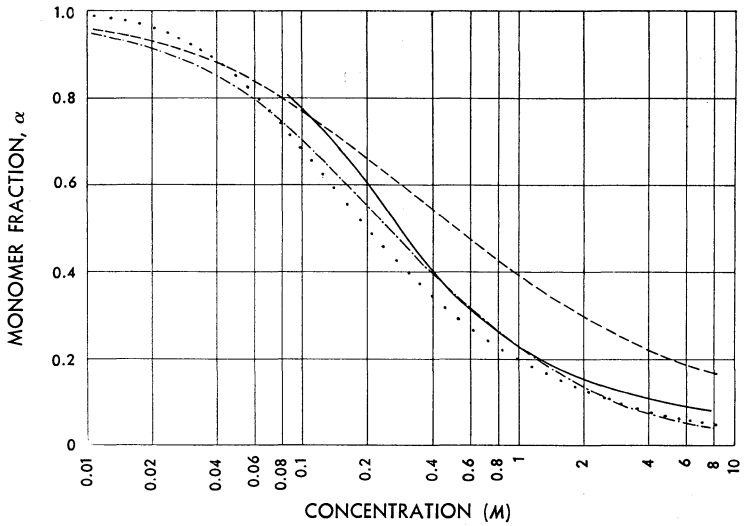

FIG. 5. The change of monomer fraction of *p*-cresol in cyclohexane with concentration, assuming dimeric (- - -), trimeric (· · ·), and polymeric (-·-) association, and the data of Bono in carbon tetrachloride (—).

of an intermolecular hydrogen bond. This phenomenon has been demonstrated in infrared studies by Bellamy and Williams (23), who have shown that the compound is monomeric even as a pure liquid.

Aniline

The *B*-band of aniline displays no appreciable concentration dependence (4), in contrast to the *K*-band, whilst no significant effect is observed on either band in N,N-dimethylaniline. Since the *K*-band of aniline is well clear of any strong high-frequency band absorption, an attempt was made to calculate α and K for aniline from its change in molar absorptivity (see Table I and Fig. 6). The results give α values which are too low, since

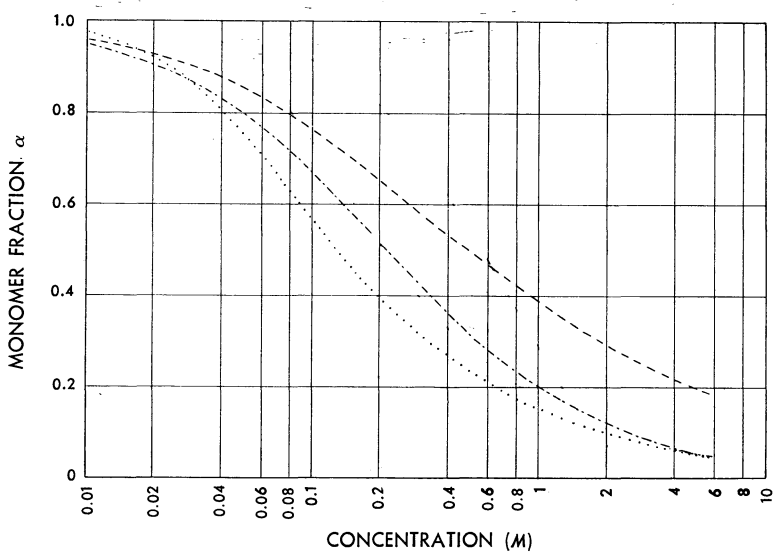

FIG. 6. The change of monomer fraction of aniline in cyclohexane with concentration, assuming dimeric (- - -), trimeric (· · ·), and polymeric (-·-) association.

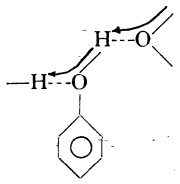
it is well known that aniline associates to a lesser degree than, say, phenol. So far as is known, no data have previously been published giving α as a function of concentration for aniline. Fuson *et al.* (24) attempted to determine this by infrared methods but obtained inconclusive results.

THE NATURE OF THE HYPSOCHROMIC SHIFT

Pimentel (25) has differentiated between the spectral effects of two types of hydrogen bond in the case of a compound such as a substituted benzene in which the substituent is ortho,para-directing. A bathochromic shift occurs when the absorbing species acts as proton donor, and a hypsochromic shift occurs when it acts as proton acceptor. In the self-association of phenol (and aniline) both types of hydrogen bonding occur, whether cyclic or open polymers are involved, and so it is difficult to say a priori whether the spectra should shift to longer or shorter wavelengths.

The hydroxyl group in phenol is an electron-donating group, and in the monomeric molecule electron migration is into the ring. When the hydroxyl group acts as proton donor, migration into the ring is increased. Conversely, when the groups acts as proton acceptor, migration into the ring is decreased. If the group acts as both proton donor and proton acceptor, as in I, increased migration, not to the ring, but to the adjacent hydrogen bond,



I

will occur, which incidentally may have the effect of strengthening that bond. Thus the shift of the spectrum of I will be similar to that of the spectrum of phenol behaving only as a proton acceptor. Although this latter spectrum has not been isolated, it probably corresponds closely to that of phenol in water. Evidence for this comes from the 1 mμ hypsochromic shift of the phenol spectrum on going from cyclohexane to water solution (26), and from the almost complete absence of K-band absorption corresponding to proton donating molecules, in water solution (4). The shift caused by self-association (1–2 mμ) is thus, as predicted above, similar to that caused by phenol's acting as proton acceptor.

EXPERIMENTAL

Spectra were obtained in spectroanalyzed cyclohexane (Fisher) at ca. 25° C on a Unicam SP 500 spectrophotometer, with a wavelength accuracy of ca. $\pm$0.5 mμ and repeatability of ca. 0.1 mμ in the relevant spectral region. For determinations at high concentrations, two specially constructed cells (Research and Industrial Instruments Co., London, England) were used, with path lengths of 25.1 μ and 2.91 μ. These lengths were measured by the manufacturers to an accuracy of $\pm$1%. However, the spacers in the cells were made of "Teflon", which compresses under load, and so it is probable that the path lengths were slightly different each time the cells were assembled, which would cause slight errors in the determination of apparent molar absorptivity.

The compounds used were commercial materials, and were purified by vacuum distillation or recrystallization.

ACKNOWLEDGMENTS

The author wishes to thank Professor W. F. Forbes, of the University of Waterloo, Ontario, and Drs. W. T. Thorneycroft and E. G. Vaal, of Thornton Research Centre, for helpful discussion.

NOTES

π-BONDING IN INORGANIC COMPOUNDS
PART 5. DELOCALIZATION OF *d*-ORBITALS IN K_2RuCl_6 AND K_2OsCl_6

A. D. WESTLAND

In a previous article it was shown that the molar magnetic susceptibility of K_2OsCl_6 is much increased when it is diluted with K_2PtCl_6 (1). This was interpreted as a consequence of spin–spin interaction operating by the delocalization of metal *d*-orbitals through ligand *p*-orbitals (2). A similar behavior was observed by Johannesen and Candela for $(NH_4)_2OsBr_6$ dissolved in $(NH_4)_2PtBr_6$ (3). These authors related the spin coupling in a variety of chloro- and bromo-osmates to the mean distance between nearest osmium atoms.

As the bond system of K_2RuCl_6 differs from that of K_2OsCl_6 only in such respects as may be affected by the principal quantum numbers of the metal orbitals and, moreover, as the two compounds possess the same geometry with very nearly the same interatomic distances, it was considered of interest to examine the magnetic behavior of the mixed-crystal system K_2RuCl_6/K_2PtCl_6.

Measurements of the magnetic susceptibility of K_2RuCl_6 have yielded values which are considerably higher than the corresponding values for K_2OsCl_6 (3, 4). This seems to indicate that there is less spin coupling in the case of the ruthenium compound but dilution experiments are required to verify this.

Theoretical estimates of χ have been made by several workers. In 1949, Kotani examined the effect of spin–orbit coupling on calculations of magnetic susceptibility and derived an expression for strong field $(t_{2g})^n$ complexes assuming *inter alia* that coulomb energies are much stronger than spin–orbit coupling (5). This predicts for $(t_{2g})^4$ a singlet ground state with a large intraconfigurational temperature-independent paramagnetism provided that $\zeta \gg kT$ where ζ is the spin–orbit coupling constant. Figgis and his collaborators have shown that this description is not very satisfactory for $OsCl_6^{2-}$ for it leads to a value of ζ_{5d} which is much too large (6). Also they noted that assuming *jj*-coupling overcompensates for the discrepancy. The susceptibility of K_2RuCl_6 was found to exhibit some temperature dependence. Griffith improved the calculation for Ru^{4+}, Os^{4+}, and Ir^{5+} by assuming intermediate coupling (7). He obtained good agreement with experiment by employing the spin–orbit coupling constant and the Racah parameters $3B+C$, obtained from spectroscopic data for the free ions. Kamimura and co-workers came independently to the same result (8). These calculations did not take into account the possibility of spin–spin interaction and since this was shown in the preceding papers of this series to have a very great influence, the agreement between theory and experiment is somewhat deceptive. We proceed also to show that previous work on K_2RuCl_6 was in error.

EXPERIMENTAL

Magnetic measurements were carried out using the Gouy method. Corrections for diamagnetism were based on the measured value for K_2PtCl_6 prepared in a manner identical with that followed for the ruthenium samples.

The solid solutions were prepared by mixing solutions of H_2RuCl_6 and H_2PtCl_6 in various proportions,

the solutions at no time being allowed to become less acid than 9 *N* in HCl. The ruthenium solution was prepared as described by Howe (9) by the oxidation of H_2RuCl_5OH with chlorine in strongly acid (HCl) solution. An equal volume of a saturated solution of KCl in 8 *N* HCl was added to the first solution. Mixed crystals varying in color from black to red-brown, depending upon the ratio of the components, appeared rapidly. These were separated on a fritted-glass filter, washed with 9 *N* HCl and sucked as dry as possible. The products so obtained were dried in a stream of dry hydrogen chloride gas at 35° C. Analysis for K_2RuCl_6: Calc.: Cl, 54.27; Ru, 25.89. Found: Cl, 54.1; Ru, 26.01. Drying at 100° C resulted in hydrolyzed products even when a hydrogen chloride atmosphere was employed. Evidence of hydrolysis was obtained from the infrared absorption spectrum obtained from a nujol mull. Absorption in the region ~3600 cm^{-1}, taken to be due to O—H stretching, was associated with a low magnetic susceptibility. A similar absorption band was exhibited by K_2PtCl_5OH and $K_4Ru_2Cl_{10}O \cdot H_2O$.

X-Ray powder diffraction photographs did not indicate any detectable inhomogeneity.

The preparations were analyzed by distillation and gravimetric estimation of the ruthenium following the method of Thiers *et al.* (10). Platinum was precipitated with zinc after distillation of the ruthenium. Chlorine was determined gravimetrically as silver chloride after treatment of a separate sample with magnesium.

RESULTS AND DISCUSSION

Values of the molar magnetic susceptibility of K_2RuCl_6 in solid solution with K_2PtCl_6 are presented in Table I. The data for the pure salt are in close agreement with those of

TABLE I

Johannesen and Candela (3). The values given by Earnshaw *et al.* are somewhat lower (4). We found that low values were obtained unless the samples were dried at a low temperature in a stream of dry hydrogen chloride gas (see experimental section).

It is apparent that the results for mixed crystals are not appreciably dependent upon concentration of ruthenium.

This is a sharp contrast to the behavior of K_2OsCl_6, where there is nearly a doubling of the room-temperature susceptibility upon diluting to ~5 mole%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

It must be concluded that there is no significant degree of spin superexchange in K_2RuCl_6 despite the fact that it is isoelectronic and isostructural with K_2OsCl_6. It follows that there is much less pronounced p_π–d_π orbital overlap between chlorine and ruthenium than between chlorine and osmium. It may be argued instead that there is less overlap between the chlorine atoms of neighboring $RuCl_6^{2-}$ groups than between chlorines in $OsCl_6^{2-}$ groups. This would be the case if the Cl—Cl distance were greater. This possibility cannot be ruled out, as sufficiently accurate X-ray diffraction data are not available. However, as the lattice constants of K_2RuCl_6 and K_2OsCl_6 are nearly identical, there are strong grounds for supposing that all corresponding interatomic distances are very nearly the same in both compounds.

Our evidence for greater *d*-orbital extension in the osmium compound is in accord with other evidence of a pronounced difference in the bonding to members of the second and third transition series, respectively. For example, back coordination of metal *d*-electrons to vacant *d*-orbitals on ligand atoms is apparently more extensive for third-row elements. As an instance of this we note the stability of the sulphoions of Os, Ir, and Pt while the corresponding ions of Ru, Rh, and Pd are not formed. Similarly, complexes containing organic sulphides or phosphines etc. and elements of the former group of metals are generally more stable than corresponding complexes of the latter group.

Griffith's estimate of the low-temperature susceptibility of K_2RuCl_6, viz. $\chi_M = 3650\times10^{-6}$ c.g.s. units/mole, is rather low compared to our value of $\chi_M = 4100\times10^{-6}$ obtained by extrapolation of the data to 0° K. An improved estimate would include the effect of orbital reduction. The theory for this was worked out by Griffith although it was not made use of by him in the case of ruthenium as existing experimental data did not seem to require it. He gives

$$\chi_M = \frac{2N\beta^2(1+\cos\theta)(k+2)^2}{3\delta(1/4\sqrt{2}\tan\theta - 1 + \sec\theta)} \qquad [1]$$

where $\delta = 1/2(15B+5C+\zeta)k$ and $\tan\theta = \sqrt{2}\zeta/\theta$. The parameters B, C, and ζ refer to the free ion and k allows for electron delocalization onto the ligands. When our value for the susceptibility at 0° K is inserted into equation [1], a value $k = 0.74$ is obtained. Allowance was made for the temperature-independent paramagnetism of about 60×10^{-6} c.g.s. units/mole which arises from elements outside the ground configuration. This value of k is in close agreement with that, $k = 0.7_6$, found previously for K_2IrCl_6 (11). There is no reason to suppose that k should be nearly identical for various hexachloro complexes, but an approximate agreement is at least reasonable.

An examination of the temperature dependence provides an independent verification of the treatment. Earnshaw and co-workers (4) provide the relation

$$\chi = \chi^0 \tanh(a/2kT), \qquad [2]$$

where χ^0 is the limiting susceptibility at zero temperature, and a is the energy separation of the ground and first higher level. If we assume that the free ion parameters are reduced by the factor 0.74 and insert these into the expressions of Kamimura and co-workers for the levels concerned (labelled by them W_1 and W_3), a separation $a = 625$ cm^{-1} is obtained. The best fit of the experimental values of χ is provided by $a = 570$ cm^{-1}. This reasonably good agreement is considered strong support for the correctness of the theories of Griffith and Kamimura and his co-workers for Ru^{4+}. We cannot, however, account quantitatively for the behavior of Os^{4+} using these theories.

DESULPHURIZATION WITH RANEY NICKEL
III. BENZYL N-ALKYL-N-BENZENESULPHONYLCARBAMATES[1,2]

George R. Pettit and Raymond E. Kadunce

Alkylation of sodium saccharin followed by Raney nickel desulphurization has been found useful for converting certain alkyl halides to N-alkylbenzamides or N-alkylcyclohexylcarboxamides. In addition, Raney nickel desulphurization of N-alkylated dibenzenesulphonamides has been briefly considered for converting alkyl halides to amines. However, alkylation of sodium dibenzenesulphonamide generally proved inefficient, and this route was not further investigated.[1]

The present study was undertaken to evaluate benzyl N-alkyl-N-benzenesulphonylcarbamates (I) as amine precursors. The anion derived from benzyl N-benzenesulphonylcarbamate (I*a*) was predicted[3] to be a stronger nucleophilic agent than its dibenzenesulphonamide counterpart. Alkylation of sodium salt I*b* by normally reactive alkyl

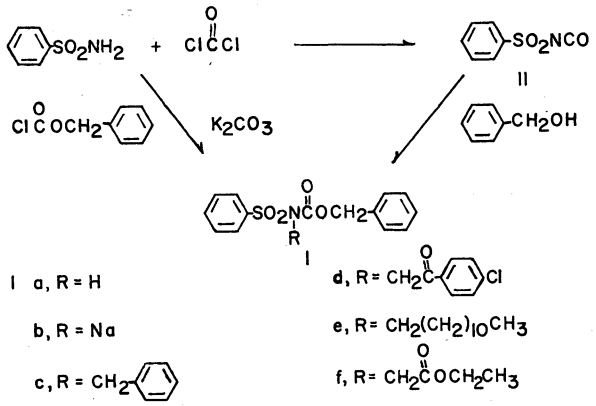
DESULPHURIZATION WITH RANEY NICKEL
III. BENZYL N-ALKYL-N-BENZENESULPHONYLCARBAMATES[1,2]

George R. Pettit and Raymond E. Kadunce

Alkylation of sodium saccharin followed by Raney nickel desulphurization has been found useful for converting certain alkyl halides to N-alkylbenzamides or N-alkylcyclohexylcarboxamides. In addition, Raney nickel desulphurization of N-alkylated dibenzenesulphonamides has been briefly considered for converting alkyl halides to amines. However, alkylation of sodium dibenzenesulphonamide generally proved inefficient, and this route was not further investigated.[1]

The present study was undertaken to evaluate benzyl N-alkyl-N-benzenesulphonylcarbamates (I) as amine precursors. The anion derived from benzyl N-benzenesulphonylcarbamate (I*a*) was predicted[3] to be a stronger nucleophilic agent than its dibenzenesulphonamide counterpart. Alkylation of sodium salt I*b* by normally reactive alkyl



[1]*Part II, G. R. Pettit and R. E. Kadunce, J. Org. Chem.* **27**, *4566 (1962).*
[2]*Abstracted in part from the Master of Science thesis submitted by R. E. Kadunce to the Graduate School, University of Maine, June, 1961.*
[3]*Compare Part II, footnote 7.*

halides was, therefore, expected to proceed satisfactorily. Subsequent cleavage of the N-alkyl derivative with hydrogen bromide (1) or by concomitant desulphurization and hydrogenolysis using Raney nickel might then yield the corresponding amine.

Synthesis of carbamate I*a* was accomplished by condensing (e.g., ref. 2) benzenesulphonamide with carbobenzoxy chloride or, more conveniently and in good yield (91%), by treating benzenesulphonyl isocyanate (II) with benzyl alcohol. The isocyanate was prepared (cf. ref. 3) from benzenesulphonamide and phosgene. Generally, the carbobenzoxy chloride procedure led to carbamate I*a* (72%) accompanied by benzyl N-benzenesulphonyl-N-benzylcarbamate (I*c*). The N-benzyl derivative apparently arises from N-alkylation of initially formed carbamate (I*a*) by benzyl chloride, already present, or generated (4) during partial decomposition of carbobenzoxy chloride. Comparison of the N-benzyl derivative (I*c*) with a specimen prepared from benzyl chloride and the sodium salt of benzyl N-benzenesulphonylcarbamate (I*b*)[4] confirmed the structural assignment.

In contrast to our prior experience with dibenzenesulphonamide, the sodium salt of carbamate I*a*, in dimethylformamide, was easily N-alkylated by *p*-chlorophenacyl bromide, *n*-dodecyl bromide, and ethyl bromoacetate. Interestingly, the principal products (I*d-f*, 68 to 87% yield) were usually accompanied by small quantities of another N-alkyl derivative: subsequently identified as benzyl N-benzenesulphonyl-N-benzylcarbamate (I*c*). Formation of N-benzyl derivative I*c* apparently proceeds by competitive intermolecular condensation of carbamate I*b*.

Both the N-dodecyl (I*e*) and N-α-acetate (I*f*) carbamates were selected for cleavage studies. Treating the N-dodecyl (I*e*) derivative with Raney nickel (W-4) under mild conditions (70° in dioxane) afforded only the product of hydrogenolysis, N-dodecylbenzenesulphonamide. A variety of more vigorous desulphurization techniques (5) also proved unsatisfactory. These experiments led to mixtures of nitrogen-containing products bonded to the nickel residues. Isolation required continuous extraction with benzene and/or dissolution of the nickel components in hydrochloric acid. Raney nickel desulphurization of N-α-acetate I*f* was similarly unrewarding. However, carbamates I*e* and I*f* were readily converted by hydrogen bromide in acetic acid to, respectively, *n*-dodecylamine and glycine ethyl ester hydrobromides.

Although hydrogen bromide cleavage of N-alkyl-N-benzenesulphonylcarbamates appears to offer a practical route to amines, concurrent N-benzylation of carbamate I*b* during the alkylation step limits the overall usefulness of this approach.[5]

EXPERIMENTAL

Before evaporation, all solvent extracts were dried over magnesium or sodium sulphate. Melting points are uncorrected and were observed employing a silicone oil bath and open Kimble glass capillaries. Reaction products were shown to be identical with known specimens by mixture melting point determination and infrared spectral comparison (in potassium bromide). Dr. R. A. Hill of this laboratory recorded the infrared spectra and Dr. A. Bernhardt, Max-Planck Institute, Mülheim, Germany, provided the microanalyses.

Benzenesulphonyl Isocyanate (II)

Phosgene (38 ml) was condensed in a dry-ice trap and then slowly distilled into a refluxing solution of benzenesulphonamide (41 g) in 1,2,4-trichlorobenzene (85 ml). Heating and stirring (in a nitrogen atmosphere) was continued 2 hours. The reaction mixture was next swept with dry nitrogen and distilled through an 8-in. Vigreux column. The fraction boiling at 69–75° (0.5 mm) weighed 31 g and was sufficiently pure for subsequent work. Billeter (6) reported a b.p. of 129.6° at 9 mm.

[4]*Benzenesulphonyl isocyanate may occasionally be a useful reagent for separating alcohols from neutral substances, since reaction between the isocyanate and alcohols may yield carbamates soluble in aqueous base.*

[5]*For example, selection of t-butyl N-benzenesulphonylcarbamate for alkylation might improve this alkyl halide → amine sequence.*

Benzyl N-Benzenesulphonylcarbamate (Ia)

A. From Benzenesulphonyl Isocyanate

In a typical experiment, benzenesulphonyl isocyanate (3.3 g) was added to benzyl alcohol (2 g) and the mixture was allowed to remain 2 hours at room temperature, in a flask protected from moisture. The viscous oil was triturated with petroleum ether and the colorless needles (m.p. 90–96)° which separated were collected; yield, 4.8 g (91%). Purification was achieved by reprecipitation (at pH 6 using dil. hydrochloric acid) of the amide from 15% sodium hydroxide solution and then recrystallization from chloroform – petroleum ether. A pure colorless crystalline sample of carbamate I*a* melted at 104.5–105.5°; ν_{max} 3290, 1750, 1720, 1350, and 1165 cm^{-1}. Anal. Calc. for $C_{14}H_{13}NO_4S$: C, 57.72; H, 4.47; N, 4.81; S, 11.01. Found: C, 57.78; H, 4.52; N, 4.78; S, 10.72.

B. From Benzenesulphonamide

Carbobenzoxy chloride (14 g, 0.08 mole) was added to a mixture of benzenesulphonamide (10 g, 0.06 mole) and anhydrous potassium carbonate (25 g) in dry acetone (100 ml). Following an overnight period of stirring and heating at reflux the mixture was cooled and filtered. Solid material was treated with 10% hydrochloric acid (200 ml) and extracted with benzene (2×100 ml). Concentration of the benzene extract to ca. 25 ml and dilution with petroleum ether gave 12.5 g (72%) of colorless crystals, m.p. 102.5–105°. Recrystallization from benzene – petroleum ether raised the melting point to 104.5–106°. The carbamate (I*a*) prepared by this method was identical with the substance descibed in procedure A.

Diluting the filtrate (acetone solution), from the original reaction mixture, with water gave 3.4 g, m.p. 106–109°, of benzyl N-benzenesulphonyl-N-benzylcarbamate (I*c*). Six recrystallizations from chloroform – petroleum ether yielded a pure specimen as colorless prisms, m.p. 111.5–112.5°; ν_{max} 1725, 1365, and 1170 cm^{-1}. Anal. Calc. for $C_{21}H_{19}NO_4S$: C, 66.13; H, 5.02; N, 3.67; S, 8.41. Found: C, 65.94; H, 5.01; N, 3.93; S, 8.49.

The benzyl derivative (I*c*) was identical with an authentic specimen obtained by the following method:

Benzyl N-Benzenesulphonyl-N-benzylcarbamate (Ic)

A solution of sodium methoxide in ethanol was added to an equivalent quantity of benzyl N-benzenesulphonylcarbamate in a minimum quantity of absolute ethanol. The sodium derivative (I*b*) which separated was collected and washed with benzene; 95% yield, colorless crystals, d.p. 298–300°. One recrystallization from dimethylformamide – ethyl ether gave microcrystals decomposing at 299–300°.

A mixture of the sodium salt of benzyl N-benzenesulphonylcarbamate (I*b*, 3.14 g, 0.01 mole), benzyl chloride (1.25 g, 0.01 mole), and dimethylformamide (25 ml) was heated (steam bath) 45 minutes. Solvent was removed *in vacuo* and the residue washed with chloroform and filtered. The filtrate was evaporated to a yellow solid (1.6 g, 42%) melting at 110–112°. Recrystallization from acetone – petroleum ether gave large colorless prisms, m.p. 110.5–113°. The product (I*c*) was characterized as noted above (cf. I*a*, procedure B).

Benzyl N-Benzenesulphonyl-N-(p-chlorophenacyl)carbamate (Id)

The preceding experiment was repeated using *p*-chlorophenacyl bromide (1.23 g, 0.05 mole), excess carbamate (I*b*, 2.5 g, 0.08 mole) and a 1.5-hour reaction period. The product recrystallized from benzene – petroleum ether as colorless needles; yield 2.0 g, m.p. 136–140°. Several recrystallizations from the same solvent raised the melting point to 141.5–143°; $\nu_{max}^{CHCl_3}$ 1730, 1705, 1355, 1220, and 1170 cm^{-1}. Anal. Calc. for $C_{22}H_{18}ClNO_5S$: C, 59.51; H, 4.09; S, 7.22. Found: C, 59.12; H, 4.00; S, 7.34.

Benzyl N-Benzenesulphonyl-N-dodecylcarbamate (Ie)

The experimental procedure described for synthesis of N-benzylcarbamate I*c* was repeated using dodecyl bromide (2.49 g, 0.01 mole) in place of benzyl chloride. In this case, a 2-hour reaction period was employed. A petroleum ether solution of the crude oily product slowly (24 hour) deposited benzyl N-benzensulphonyl-N-benzylcarbamate (I*c*, 0.15 g), m.p. 108–110.5°, which was identified by comparison with an authentic specimen. Concentrating and cooling the filtrate led to a waxy solid (2.8–3.4 g, 50–68%) melting at 40–46°. Five recrystallizations from ethyl ether provided an analytical sample of benzyl N-benzenesulphonyl-N-dodecylcarbamate as colorless needles, m.p. 47.5–49.5°; $\nu_{max}^{CHCl_3}$ 1712, 1355, and 1175 cm^{-1}. Anal. Calc. for $C_{26}H_{37}NO_4S$: C, 67.94; H, 8.12; N, 3.05; S, 6.98. Found: C, 67.44; H, 7.89; N, 3.30; S, 6.95.

Cleavage of Benzyl N-Benzenesulphonyl-N-dodecylcarbamate (Ie)

A. By Raney Nickel

A mixture of carbamate I*e* (0.50 g), Raney nickel (4 ml, W-4, 2 weeks old, ref. 7), and dioxane (25 ml) was stirred for 50 minutes at 70±2°. After collecting residual nickel the filtrate was concentrated (*in vacuo*) to 0.15 g of colorless solid, m.p. 45–53°. Recrystallization from methanol–water yielded a pure specimen of N-dodecylbenzenesulphonamide melting at 57–58.5° (ref. 8, m.p. 59°). The product was identical with an authentic specimen prepared from dodecylamine and benzenesulphonyl chloride.

A variety of more vigorous experimental conditions using dioxane as solvent and variously aged samples of W-2 and W-4 Raney nickels gave unsatisfactory results. The mixtures (evidenced by thin-layer chromatograms) obtained were not considered of further interest.

For personal use only.

B. By Hydrogen Bromide (8)

A solution composed of carbamate I*e* (1.4 g), 35% hydrogen bromide in acetic acid (12 ml), and phenol (0.7 g) was allowed to remain at room temperature 48 hours. Dilution with ethyl ether precipitated 0.31 g (74%) of *n*-dodecylamine hydrobromide, d.p. 190° (sintering from 140°). Both the hydrobromide and *p*-toluenesulphonamide (m.p. 74–75°, ref. 9) derivatives were identical with authentic specimens.

Ethyl α-Aminoacetate Hydrobromide

The sodium salt of benzyl N-benzenesulphonylcarbamate (5.5 g) in dimethylformamide (20 ml) was alkylated with ethyl α-bromoacetate (2.9 g) as described using benzyl chloride (cf. I*c*). In this example, a 1-hour reaction period was employed and the crude reaction residue was extracted with benzene. Following removal of benzene, *in vacuo*, a petroleum ether solution of the resulting oily product (6.3 g) was maintained at room temperature 2 days. The benzyl N-benzenesulphonyl-N-benzylcarbamate (0.2 g, m.p. 103–109°) which separated was recrystallized (to m.p. 111–112°) from acetone–water and shown to be identical with an authentic sample (I*c*). Concentrating the petroleum ether filtrate afforded an impure specimen of N-benzenesulphonyl-N-carbobenzoxyglycine ethyl ester. A portion (0.70 g) of the crude oily mixture was treated with 35% hydrogen bromide in acetic acid (7 ml, containing 0.5 g of phenol) as reported using *n*-dodecylcarbamate I*e*. The crude semisolid hydrobromide of glycine ethyl ester weighed 0.22 g. Four recrystallizations from ethanol – ethyl ether led to colorless needles decomposing at 177–178°. Comparison with an authentic specimen of ethyl α-aminoacetate hydrobromide (d.p. 175–176°, ref. 10) confirmed the structural assignment.

NUCLEAR SPIN–SPIN COUPLING CONSTANTS INVOLVING THE GROUP IV ELEMENTS

L. W. Reeves and E. J. Wells

Consideration of correlations involving coupling constants between different nuclei has been mostly confined to those involving C^{13} and hydrogen (1–4). The interest has centered around the following topics: dependence of $J_{C^{13}-H}$ on *s* character (1–4), the variation of $J_{C^{13}-H}$ in molecules of the type CHXYZ (5–8), and the use of $J_{C^{13}-H}$ in conjunction with chemical shift data to indicate diamagnetic anisotropy (9). $J_{Si^{29}-H}$ coupling constants have been measured (16) but these are influenced by polar effects besides being dependent on hybridization (6). Long range $J_{C^{13}-C-H}$ and $J_{C^{13}-C-C-H}$ coupling constants have been

measured in both enriched compounds (10, 11) and in natural abundance (12). The unfavorable magnetic properties of Ge^{73} make it unlikely that parameters will be available for germanium (17). Recent reports of coupling constants for Sn^{119}, Sn^{117}, and Pb^{207} (13–20) are available for comparison with measurements made by us recently (21). As a minor point we find coupling constants measured in reference 13 to be 3% lower than ours in dimethyltin dihydride.

In the accompanying table are listed coupling constants involving group IV elements

Coupling constant J	Value, c.p.s.	Compound measured	References	J/μ
C^{13}—H	125	Many sp^3 type	1, 3	178
Si^{29}—H	202.5	SiH_4	16	289
Sn^{119}—H	1797	$(CH_3)_2SnH_2$	21	1727
Pb^{207}—H	2380	$(CH_3)_3PbH$	13	4075
C^{13}—C—H	3.8	$(C_2H_5)_3COH$	11	5.4
Si^{29}—C—H	6.57	$(CH_3)_4Si$	15	11.8
Si^{119}—C—H	60.2	$(CH_3)_2SnH_2$	21	57
Pb^{207}—C—H	66.7	$(CH_3)_3PbH$	13	114
C^{13}—F	257	CF_4	14	366
Si^{29}—F	274.8	$SiHF_3$	16	495
C^{13}—C—F	38.5	CF_3CH_2Br	14	54.8
Sn^{119}—C—F	251	$(CH_3)_2Sn(C_2F_4H)_2$	21	239

in situations where hybridization is near sp^3 for the group IV elements. The neighboring atoms are also chosen so as to eliminate the possibility of back donation of charge into the unfilled d orbitals of a group IV atom.

In order to eliminate the contribution to $J_{NN'}$ arising from nuclear constants it is necessary to divide by the dissimilar magnetogyric ratios. In the series C^{13}, Si^{29}, Sn^{119}, and Pb^{207} all have spin 1/2 properties so division by the nuclear moment in nuclear magnetons is sufficient. It is to be noted that $\mu_{C^{13}}$ and $\mu_{Pb^{207}}$ are positive and $\mu_{Si^{29}}$ and $\mu_{Sn^{119}}$ are negative.

The underlying prerequisite of the present discussion is a knowledge of the electronic contribution to J_{X-H} and this is represented in column 5 of the table. We will presume that $J_{C^{13}-H}$ and $J_{Pb^{207}}$ have opposite sign to $J_{Si^{29}-H}$ and $J_{Sn^{119}-H}$ merely because of a change in the sign of the gyromagnetic ratio of the group IV nucleus. This assumption has yet to be tested. Since we assume the electronic contribution to J_{X-H} has the same sign down the group we shall use for our purpose $|J/\mu|$. Discussions regarding absolute magnitudes of coupling constants should compensate for nuclear dependence.

We have found a most satisfactory linear correlation of $\sqrt{|J_{X-H}/\mu_X|}$ with the atomic number Z_X for group IV element X, with the conditions specified earlier. This is shown in Fig. 1. A similar relationship $\sqrt{|J_{X-C-H}/\mu_X|}$ versus Z_X also holds and is shown in Fig. 1. Data for long-range couplings $J_{X-C-C-H}$ are too sparse but the data for J_{X-F} (14–16) is partially available as are some values of J_{X-C-F} (14, 21). The square root law can be tested in this case by taking values of $\sqrt{(J_{X\ldots F}\times\mu_{C^{13}}/J_{C^{13}\ldots F}\times\mu_X)}$ versus atomic number. Three available points give good linear relationship. This is shown in Fig. 2.

The above correlations may be represented analytically:

$$[1] \qquad \sqrt{|J_{X-H}/\mu_X|} = 0.676\,Z_X+8.0$$

$$[2] \qquad \sqrt{|J_{X-C-H}/|\mu_X|} = 0.107\,Z_X+1.95$$

$$[3] \qquad \sqrt{(J_{X\ldots F}\times\mu_{C^{13}}/J_{C^{13}\ldots F}\times\mu_X)} = 0.0245\,Z_X+0.84.$$

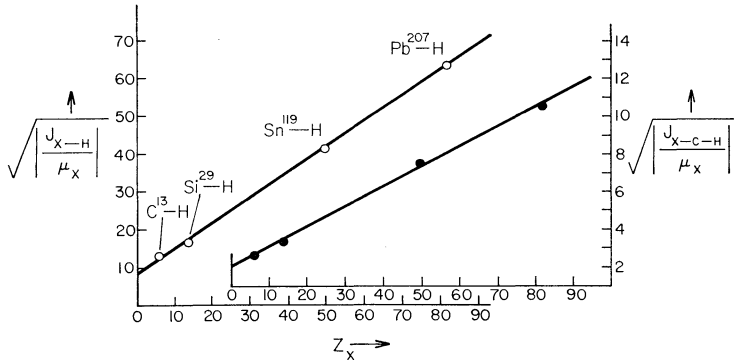

FIG. 1.

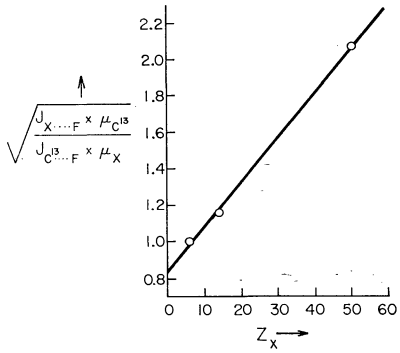

FIG. 2.

In a recent paper using the valence bond approach, Gutowsky and Juan (6) have formulated the contact contribution to J_{X-H} (X = C^{13} or Si^{29}) in sp^3 molecules of the type we are considering. Their expression can be generalized, in their notation, as:

$$[4] \qquad J_{X-H} = \frac{\gamma_H \gamma_X}{h\Delta E_X}\left(\frac{16\pi\beta\hbar}{3}\right)^2 \eta_X^2 \alpha_H^2 |ns_X(0)|^2 |1s_H(0)|^2.$$

The assumptions are that the contact term is the dominant one as has already been shown for C^{13} (22), that the perfect pairing approximation may be used for all the ground-state wave functions down the group, and that the product of the contact matrix elements over all excited triplet states may be replaced by the diagonal element over the ground state, coupled with a mean triplet excitation energy, ΔE_X. The terms which depend on the group IV atoms X are ΔE_X, the normalization term η^2, and the atomic s electron charge density at the nucleus $|ns_X(0)|^2$. An estimate of the dependence of this latter on Z may be obtained from the hyperfine splitting of the ^2S ground states of the atomic alkali metals, where the only **I.S** interaction mechanism is through the scalar contact term. The most accurate hyperfine splitting energies are from atomic microwave measurements and have been tabulated by Ramsey (23, p. 89). The hyperfine structure separation for a single s electron ($L = 0$) is (23, p. 10; 24)

$$[5] \qquad \Delta E = \frac{8\pi\beta}{3}\mu_X |ns_X(0)|^2 \frac{(2I_X+1)}{I_X}.$$

Thus the contact charge density of the alkali metals may be obtained from knowledge of the splittings ΔE, the nuclear magnetic moments, and the nuclear spins I_X. Figure 3

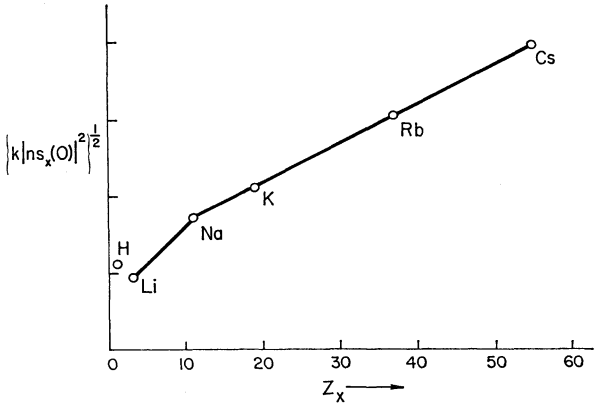

FIG. 3.

shows the correlation of the square root of the contact charge against the atomic number.

Although this correlation fails for small Z values, it is sufficient to allow a qualitative explanation of the J_{X-H} dependence in terms of equation [4]. In moving from group I of the alkalis to group IV*b* without increasing the principal quantum number, we should tend to increase the slope of Fig. 3, and also to iron out the Li–Na irregularity. The conclusion is that most of the Z dependence noted in J_{X-H} is contained in $|ns_X(0)|^2$. Were the atomic wave functions hydrogenic, this dependence would be as Z^3, but is reduced to approximately Z^2 by the inner filled shells. It appears reasonable that the screening by the increasing number of core electrons should leave ΔE_X roughly independent of Z. Thus any Z dependence in η_X^2 caused by the changing ionicity of the X—H bond must be slight.

MERCURY PHOTOSENSITIZED DECOMPOSITION OF LIQUID CYCLOHEXANE*

CORNELIUS E. KLOTS AND R. H. JOHNSEN

A statement in the recent literature (1) to the effect that alkyl radicals do not undergo normal disproportionating reactions in condensed media gained superficial support from the calculations of Bradley (2) which were compatible with a dimer-like structure to the transition state. The exothermic dissociation to disproportionation products would presumably be quenched by rapid collisional cooling. This model is not inevitable from the calculations, however (3), and the liquid phase disproportionation of ethyl radicals has since been demonstrated (4). The extent to which the larger alkyl radicals disproportionate is crucial in the elucidation of radiation chemistry mechanisms. We have thus adapted the technique of mercury photosensitization as a means of investigating their reactions in condensed phases.

EXPERIMENTAL

Several grades of liquid cyclohexane were used either as received or after washing with sulphuric acid followed by drying over sodium carbonate. Five milliliter samples were saturated with mercury, thoroughly degassed in a Vycor tube equipped with constrictions and break-off seals, thermostatted in water at room temperature, and photolyzed with an AH-4 mercury lamp. In the absence of dissolved mercury no decomposition ensued. The presence of mercury, however, does permit photosensitization via its medium-broadened resonance line (5). Gaseous products were measured manometrically and identified by uptake on hot copper oxide or by gas–solid chromatography as hydrogen. Liquid products were measured, using 4 λ injections on columns similar to those described by Dyne (6), with a flame ionization detector. At conversions less than 0.02% (about ½ hour illumination) only cyclohexene and dicyclohexyl were obtained. Calibration standards were prepared from genuine materials or, conveniently, by X-irradiation of pure cyclohexane using published G-values (6). The two classes of standards were in excellent agreement.

RESULTS AND DISCUSSION

We assume the following mechanism adequately encompasses our results:

$$\mathrm{Hg^* + C_6H_{12} \rightarrow C_6H_{11} + H + Hg}$$

$$\mathrm{H + C_6H_{12} \rightarrow H_2 + C_6H_{11}}$$

$$\mathrm{2C_6H_{11} \xrightarrow{k_c} C_{12}H_{22}}$$

$$\mathrm{2C_6H_{11} \xrightarrow{k_d} C_6H_{10} + C_6H_{12}}$$

In Fig. 1 the yield of cyclohexene is presented as a function of the dicyclohexyl obtained.

$$\xrightarrow{k_d} C_6H_{10} + C_6H_{12}$$

In Fig. 1 the yield of cyclohexene is presented as a function of the dicyclohexyl obtained.

*This work was supported in part by the U.S. Atomic Energy Commission under Contract AT-(40-1)-2001.

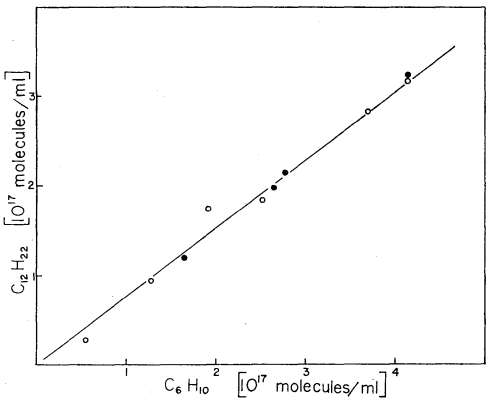

FIG. 1. Yield of cyclohexene as a function of dicyclohexyl. Filled circles obtained with highly purified cyclohexane.

The data, *en toto*, indicate a value of $k_d/k_c = 1.31 \pm .04$. Filled circles represent experiments using Phillips Research Grade cyclohexane with acid treatment, for which an excellent mass balance with the hydrogen yield was obtained. Other materials gave up to 15% too little of the hydrocarbon products but the same apparent k_d/k_c. This speaks against the possible significant role of hydrogen atom – cyclohexyl cage disproportionation producing cyclohexene and non-scavengeable hydrogen gas. There are other indications in the literature that hydrogen atoms are sufficiently mobile so as not to be subject to cage restrictions.

At higher conversions, cyclohexene yields are decreased and cyclohexylcyclohexene appears as a secondary product, as in X-irradiation (6). This is most simply attributed to addition of a cyclohexyl radical to cyclohexene followed by sterically favored disproportionation. Thus, while comparison with gas phase studies of the disproportionation–combination reactions of cyclohexyl radicals is invited, the often-quoted value $k_d/k_c \sim 0.5$ is almost certainly vitiated by the degree of conversion obtained (7). Similar considerations probably also apply to the single previously reported condensed phase adaptation (in *n*-decane) of the mercury photosensitization technique (5).

Prior to the completion of this work we learned of similar studies in other liquid aliphatic media by Professor Gilbert Mains (8). He finds a quantum yield of unity for hydrogen production and draws mechanistic conclusions similar to ours. We are grateful to him for access to his results before their publication. The relevance of our present data to the interpretation of radiation chemistry yields (6) will be discussed, along with additional results, in another place.

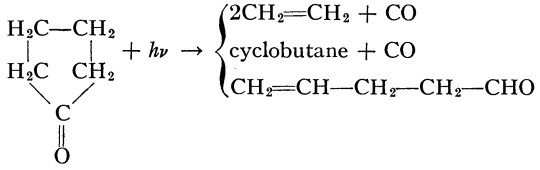
SECONDARY PROCESSES IN THE PHOTOLYSIS OF CYCLOPENTANONE: THE PHOTOLYSIS OF 4-PENTENAL

JAMES N. BUTLER,[1] ARTHUR T. DRAKE, J. CHRISTOPHER MITCHELL, AND PRITAM SINGH

The primary processes in the photolysis of cyclopentanone have been studied extensively (1). Srinivasan (2) has presented evidence that three primary processes of decomposition occur from different vibrational levels of the same excited singlet state of cyclopentanone:



In an attempt to detect the possible isomerization of vibrationally excited cyclobutane molecules to ethylene, we have performed some experiments at very low pressures.

Cyclopentanone (Eastman Kodak), which had been purified by gas chromatography, was photolyzed at room temperature with 3130 Å radiation to approximately 1% decomposition. The pressure ranged from 7 mm to 0.003 mm. The products were analyzed by gas chromatography on a silica gel column at 100° C. The results are listed in Table I.

TABLE I

Variation of ethylene/cyclobutane ratio with pressure in the photolysis of cyclopentanone

Pressure (mm)	Ethylene/cyclobutane ratio	Pressure (mm)	Ethylene/cyclobutane ratio
7.07	2.32	0.24	2.98
2.96	2.29	0.022	3.25
1.30	2.53	0.015	3.38
0.55	2.73	0.003	3.10

It can be seen that the ethylene/cyclobutane ratio increases as the pressure is decreased. A plot of the ethylene/cyclobutane ratio as a function of reciprocal pressure would be expected to give a straight line if part of the ethylene was being formed by isomerization of excited cyclobutane. However, such a plot showed a marked curvature, the slope decreasing as pressure decreased. While it might be possible to interpret this by a complex deactivation mechanism, it seemed much more likely that a systematic error was causing the variation of the ratio with pressure.

The reaction vessel was constructed with the lamp immersed in a well in a 5 liter flask. At high pressure most of the light was absorbed near the central well and relatively little was absorbed at the outer portions of the flask. At low pressure, however, absorption took place throughout the vessel. Although the degree of decomposition could not be accurately estimated in the small samples, it was probably greater at low pressures than at high pressures, even though the time of exposure was the same.

TABLE II

Variation of ethylene/cyclobutane ratio with degree of decomposition, in the photolysis of cylopentanone (pressure 6–10 mm)

Degree of decomposition (%)	Ethylene/cyclobutane ratio	Degree of decomposition (%)	Ethylene/cyclobutane ratio
0.025	3.41	0.25	2.96
0.075	3.17	0.34	2.35
0.14	2.83	0.75	2.32
0.17	2.86		

The effect of degree of decomposition was studied at pressures from 6 to 10 mm. The results are listed in Table II. The ethylene/cyclobutane ratio decreases as the degree of decomposition increases. Thus, the increasing degree of decomposition at low pressures cannot completely explain the pressure dependence, but could possibly account for the curvature observed in the plot. A different reaction vessel geometry which does not cause the absorbed intensity to change with pressure might give better results.

An alternative explanation is that the other primary product, 4-pentenal, is itself undergoing photolysis, and is also producing ethylene. 4-Pentenal was prepared by the thermal isomerization of vinyl allyl ether (3, 4), and was photolyzed to about 3% decomposition under the same conditions that cyclopentanone had been studied. The major portion (94.5%) of the products of decomposition was produced by the reaction

$$CH_2{=}CH{-}CH_2{-}CH_2{-}CHO \rightarrow 2C_2H_4 + CO.$$

In addition, approximately 1.5% of 1-butene, 0.75% of *cis*-2-butene, and 0.25% of *trans*-2-butene were formed. The remaining 3% of the material was not accounted for, and presumably polymerized. Less than 0.05% of ethane or propylene was formed, which seems to rule out the participation of methyl or allyl radicals in the reaction. 1-Butene may be formed in the primary process if a cyclic transition state is invoked, and similar transition states can be devised to produce the 2-butenes (5).

The quantum yield for the decomposition of 4-pentenal was not measured accurately, but was approximately the same as the quantum yield for the decomposition of cyclopentanone. Thus, the secondary photolysis of 4-pentenal could account for at least part of the ethylene produced from cyclopentanone, even at small degrees of decomposition. However, this predicts that the ethylene/cyclobutane ratio would increase with increasing degree of decomposition, which is contrary to the results given in Table II. Possibly this ratio is influenced by the reactions of free radicals formed in the photolysis of cyclopentanone or 4-pentenal.

The photolysis of cyclopentanone to about 20% decomposition shows a very large number of secondary products. Using a 150 ft capillary column coated with polypropylene glycol, at 0° C, and a flame ionization detector, many of the products of such a photolysis were separated. In addition to ethylene, cyclobutane, and carbon monoxide, which are produced in the primary process, small amounts of 1-butene and smaller amounts of *cis*- and *trans*-2-butene were observed. These presumably resulted from the secondary photolysis of 4-pentenal. More than 40 other products also appeared, including ethane, propane, propylene, acetaldehyde, and numerous C_4, C_5, and C_6-hydrocarbons. Flowers and Frey (6) have reported the formation of cyclohexane when cyclopentanone is photolyzed in the presence of a large excess of ethylene. We observed no appreciable amount of cyclohexane

under the conditions of our experiment. Clearly, many simultaneous free-radical reactions are taking place in this system, and could account for some of the ethylene formed.

In summary, the secondary processes in cyclopentanone photolysis have been shown to be extremely complicated, and no simple explanation for the pressure dependence of the ethylene/cyclobutane ratio is readily apparent.

DETERMINATION OF RELATIVE SIGNS OF H—F COUPLING CONSTANTS IN FLUOROBENZENES BY NUCLEAR MAGNETIC DOUBLE RESONANCE

W. G. PATERSON* AND H. SPEDDING

The discovery (1–3) that the relative signs of n.m.r. coupling constants could be ascertained by nuclear magnetic double resonance has proved to be a valuable aid in the analysis of high-resolution spectra of liquids. This communication summarizes double-resonance experiments with 2,3-difluoro-5,6-dibromonitrobenzene (I), 2,4-dichloro-3,5-difluoronitrobenzene (II), and 2-chloro-4,5-difluoronitrobenzene (III), which yield the relative signs of J_{HF}^{o}, J_{HF}^{m}, and J_{HF}^{p}. The F^{19} n.m.r. spectra of these compounds at 94.1 Mc/s are first order, and the relative signs of the H—F coupling constants were determined by the method of Freeman (3). The decoupling apparatus is such that no other relative signs could be obtained (4). The n.m.r. parameters of the single-resonance spectra are listed in Table I.

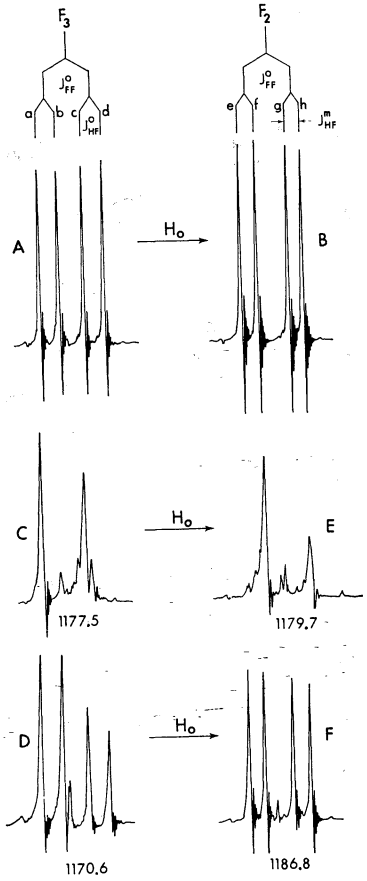

FIG. 1. F^{19} spectra of I dissolved in acetone. The separations in c.p.s. between H_1 and H_2 are shown below the double-resonance spectra. The magnetic field increases from left to right for all spectra. A. Single-resonance spectrum of F_3. B. Single-resonance spectrum of F_2. C. Double-resonance spectrum of F_3 with irradiation at $\frac{1}{2}(f+h)$ with "like-signs" arrangement. D. Double-resonance spectrum of F_3 with irradiation at $\frac{1}{2}(e+g)$ with "opposite-signs" arrangement. E. Double-resonance spectrum of F_2 with irradiation at $\frac{1}{2}(a+c)$ with "like-signs" arrangement. F. Double-resonance spectrum of F_2 with irradiation at $\frac{1}{2}(a+c)$ with "opposite-signs" arrangement.

The F^{19} spectrum and typical double-resonance spectra of I are shown in Fig. 1. Irradiation with a moderately weak r.f. field at a frequency $\frac{1}{2}(a+c)$ in the F_3 spectrum should collapse lines e and g in the F_2 spectrum if J_{HF}^{o} and J_{HF}^{m} are of the same sign, or collapse lines f and h if they are of opposite sign. Analogous arguments apply to irradiation at frequencies $\frac{1}{2}(b+d)$, $\frac{1}{2}(e+g)$, and $\frac{1}{2}(f+h)$. The possibilities are summarized in Table II.

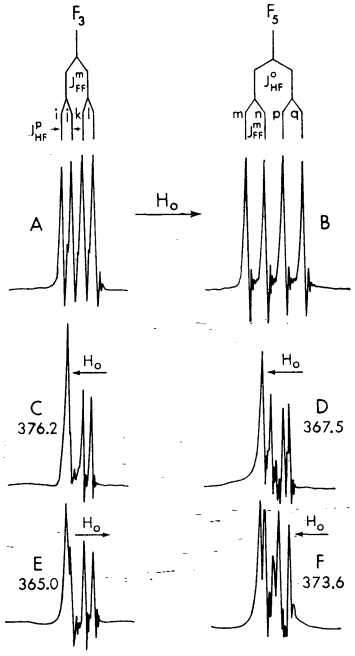

FIG. 2. F^{19} spectra of II as neat liquid. The separations in c.p.s. between H_1 and H_2 are shown beside the double-resonance spectra. The double-resonance spectra, which are all of F_5, were recorded at a substantially faster sweep rate than the single-resonance spectra. The direction of increasing magnetic field is shown for each spectrum. A. Single-resonance spectrum of F_3. B. Single-resonance spectrum of F_5. C. Double-resonance spectrum of F_5 with irradiation at $\frac{1}{2}(i+k)$ with "opposite-signs" arrangement. D. Double-resonance spectrum of F_5 with irradiation at $\frac{1}{2}(i+k)$ with "like-signs" arrangement. E. Double-resonance spectrum of F_5 with irradiation at $\frac{1}{2}(j+l)$ with "opposite signs" arrangement. F. Double-resonance spectrum of F_5 with irradiation at $\frac{1}{2}(j+l)$ with "like-signs" arrangement.

Typical spectra are shown in Fig. 1. It is clear that optimum collapse of the signals is obtained when a decoupling frequency is used which corresponds to like signs for J_{HF}^{o} and J_{HF}^{m}.

The F^{19} spectrum and representative double-resonance spectra of II are shown in Fig. 2. Irradiation at a frequency $\frac{1}{2}(i+k)$ in the F_3 spectrum should collapse lines m and n in the F_5 spectrum if J_{HF}^{o} and J_{HF}^{p} are of the same sign, or collapse lines p and q if they are of opposite sign. Analogous arguments apply to irradiation at frequencies $\frac{1}{2}(j+l)$, $\frac{1}{2}(m+n)$,

TABLE III

Separations between r.f. fields H_1 and H_2 required for determination of relative signs of J_{HF}^{o} and J_{HF}^{p} in II

	Location in spectrum of H_2	Separation (c.p.s.) between H_1 and H_2 required for collapse of:	
		m and n	p and q
Like signs	$\frac{1}{2}(i+k)$	367.8	—
" "	$\frac{1}{2}(j+l)$	—	374.0
Opposite signs	$\frac{1}{2}(i+k)$	—	376.2
" "	$\frac{1}{2}(j+l)$	365.3	—

and $\frac{1}{2}(p+q)$. A summary of the different arrangements is given in Table III, and experimental spectra are shown in Fig. 2. The data suggest convincingly that J_{HF}^{o} and J_{HF}^{p} are of opposite sign, which implies that J_{HF}^{m} and J_{HF}^{p} are also of opposite sign. These conclusions are in agreement with those obtained from studies of single-resonance spectra (5).

Further experiments of the type just described were also done with compound III, for which each F^{19} multiplet consisted of eight lines. Although the decoupling patterns were complex, the regions of the spectra which were perturbed in the double-resonance measurements left no doubt that all H—F coupling constants in III were of the same sign.

EXPERIMENTAL

The H^1 and F^{19} n.m.r. spectra were obtained with a Varian spectrometer operating at 100 Mc/s and 94.1 Mc/s respectively. The spectra were calibrated by the usual side-band method (6), using a Hewlett–Packard Model 200AB audio-oscillator and a Hewlett–Packard Model 521C frequency counter. The double-resonance experiments were carried out as described by Johnson (4). With the center-band signal phased out, the first modulation side band H_1 of the V3521 Integrator is used to record the n.m.r. spectrum while a second, stronger side band H_2, provided by an audio-oscillator, is applied to the system under investigation such that $|\omega_2-\omega_1|$ is equal to the separation required for the double-resonance experiment. The oscillator output is critical (3). The ratios of the chemical shifts to the coupling constants in the present instance were large enough that second-order corrections to the modulation frequency were unnecessary (7). The frequency of the first modulation side band (nominally 2 kc/s) of the Integrator varied slightly from day to day and was checked before each experiment. Measurements of the foregoing type have been previously reported (8). The compounds were very kindly supplied by Dr. G. C. Finger of the Illinois State Geological Survey, Urbana. The samples were thoroughly degassed by the nitrogen bubbling technique prior to the n.m.r. measurements.

ACKNOWLEDGMENTS

The financial support of the National Research Council of Canada is gratefully acknowledged. The authors wish to thank Mr. G. Bigam for his careful maintenance of the n.m.r. equipment.

THE MIXED COMPLEXES OF COPPER(II) AND NICKEL(II) WITH NITRILOTRIACETATE AND GLYCINATE AND THE FORMATION CONSTANT OF THESE AND OTHER MIXED COMPLEXES

Y. J. Israéli

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

We found previously that the nitrilotriacetates of copper(II) and nickel(II) can react with other bidentate ligands and form mixed complexes with them (1).

The composition of the mixed complexes formed by the reaction of glycine with the nitrilotriacetates of copper(II) or nickel(II) was determined by Job's method of continuous variations (2). The measurements were taken at several pH values and at the λ_{max} of the solutions containing equimolecular amounts of cation (Me), of nitrilotriacetate (X), and of glycinate (Glyc). At pH = 9 the solutions containing nickel(II) have maxima at 385 mμ and at 590 mμ and the corresponding copper solutions have a single maximum at 685 mμ. For the copper(II) solutions additional measurements were made at 625 mμ. The results of the Job experiments are shown in Fig. 1.

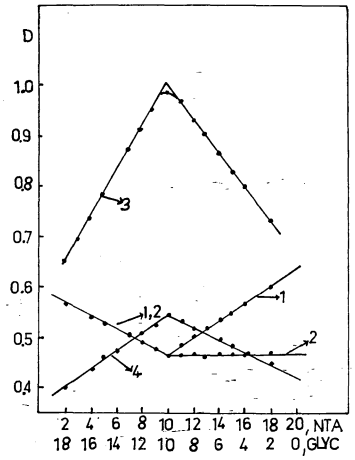

FIG. 1. Composition of the solutions: 5 ml Cu (2×10^{-2} M) + x ml NTA (1×10^{-2} M) + (20−x) ml Glyc (1×10^{-2} M): (1) pH = 10, λ = 685 mμ, (2) pH = 6, λ = 625 mμ; 5 ml Ni (1×10^{-1} M) + x ml NTA (5×10^{-2}) M + (20−x) ml Glyc (5×10^{-2} M): (3) pH = 7, λ = 385 mμ, (4) pH = 9, λ = 590 mμ.

From the curves of Fig. 1 we concluded that, at all the pH values measured, only one complex is formed of composition MeXGlyc.

The formation constant of the mixed complexes, formed by the reaction of nitrilotriacetate of copper(II) or nickel(II) (MeX) with bidentate ligands (BH), was determined by the Martell–Chaberek method (3). The bidentate ligands were glycine (Glyc), sodium salycilate (Salyc), and pyridine aldoxime (PA).

The reaction leading to the formation of the mixed complexes is:

$$MeX + BH \rightarrow MeXB + H^+ \qquad [1]$$

and the formation constant of the mixed complex is:

$$K_f = \frac{[MeXB]}{[MeX][B]}. \qquad [2]$$

To determine K_f, a solution containing equimolecular amounts of cation, trisodium nitrilotriacetate, and bidentate ligand (BH) was titrated with NaOH. All titrations were carried out at an ionic strength of 0.5, kept constant with $NaNO_3$.

In the following equations, a is the number of moles of NaOH added per mole of bidentate ligand (BH):

$$C_A = [MeX]_t = [MeX]+[MeXB] \quad [3]$$

$$C_B = [BH]_t = [HB]+[B^-]+[MeXB] \quad [4]$$

$$C_A = C_B \quad [5]$$

$$aC_B = [B]+[MeXB]+[OH]-[H]. \quad [6]$$

From equations [4], [5], and [6] it follows that:

$$[B] = \frac{K\{(1-a)C_B+[OH]-[H]\}}{[H]}, \quad [7]$$

where K is the acid dissociation constant of the bidentate ligand (BH). For glycine, pK = 9.7 (see ref. 4). For the other bidentate ligands the pK values were redetermined and found to be:

pK of NaSalyc = 11.6; pK of pyridine aldoxime = 9.9.

From equations [3] and [4] it follows that:

$$[MeX] = [B]\left\{1+\frac{[H]}{K}\right\} \quad [8]$$

$$[MeXB] = C_A-[MeX]. \quad [9]$$

From equations [2], [7], [8], and [9] it is easy to calculate K_f.

Table I shows a selection of data obtained in two typical titrations. Table II shows the formation constants of other mixed complexes.

We assert the hypothesis that in these complexes the cation is probably hexacoordinated.

THE OCCURRENCE OF D-*glycero*-D-*manno*-HEPTOSE IN THE EXTRACELLULAR POLYSACCHARIDE PRODUCED BY AZOTOBACTER INDICUM

J. K. N. Jones, M. B. Perry, and W. Sowa

Knight and his co-workers (1) showed that *Azotobacter indicum* produced an extracellular polysaccharide containing D-glucose, uronic acid, and an unidentified aldoheptose. In an earlier study of this organism it was found that a fructoglycan was produced when sucrose was used as a substrate, but a polysaccharide containing D-glucose and uronic acid was produced when D-glucose was used as a substrate (2). The occurrence of aldoheptoses in bacterial polysaccharides is well established (3); however, little is known about the fine structure of such polysaccharides or of the sereological specificity of the component aldoheptoses. This note records the identification of D-*glycero*-D-*manno*-heptose in the extracellular polysaccharide produced by *A. indicum* and some preliminary structural investigations.

A. indicum (syn. *Beijerinckia indica* Starket and De) was grown in shake culture on a 5% D-glucose medium supplied with peptone and mineral salts to give after 38 days' growth a 4.5% yield of a crude polysaccharide which was obtained by acetone precipitation from the culture medium. Moving-boundary electrophoresis showed the preparation to be at least a two component mixture containing a major electrophoretically mobile component and an immobile minor fraction. The major component was an acidic glycan which was isolated from the mixture by Cetavlon precipitation (4) leaving a neutral glycan composed of glucose, mannose, rhamnose, and arabinose.

The acidic glycan had an equivalent weight of 1030 corresponding to a uronic anhydride content of 17.1% and was shown to be essentially homogeneous by electrophoresis in veronal buffer (pH 8.6) and in phosphate buffer (pH 7.4).

Hydrolysis of the acidic glycan followed by chromatographic fractionation of the neutral and acidic sugars afforded D-glucose characterized as its *N*-*p*-nitrophenylglycosylamine derivative, D-mannose characterized as its phenylhydrazone derivative, and D-*glycero*-D-*manno*-heptose which was characterized as its acetate and by its reduction to give crystalline D-*glycero*-D-*manno*-heptitol. Chromatographic examination of the uronic acid monosaccharide fraction indicated it to be composed mainly of glucuronic acid and a small amount of galacturonic acid. On reduction of the methyl ester, methyl glycoside preparation from this fraction with borohydride, and hydrolysis of the resulting methyl glycosides, paper chromatography revealed the presence of glucose and small amounts of galactose and a sugar tentatively identified as gulose. The presence of this latter sugar indicates the possible occurrence of small amounts of guluronic acid in the polysaccharide. Quantitative analysis of the uronic acid in the polysaccharide by the

THE OCCURRENCE OF D-*glycero*-D-*manno*-HEPTOSE IN THE EXTRACELLULAR POLYSACCHARIDE PRODUCED BY AZOTOBACTER INDICUM

J. K. N. Jones, M. B. Perry, and W. Sowa

Knight and his co-workers (1) showed that *Azotobacter indicum* produced an extracellular polysaccharide containing D-glucose, uronic acid, and an unidentified aldoheptose. In an earlier study of this organism it was found that a fructoglycan was produced when sucrose was used as a substrate, but a polysaccharide containing D-glucose and uronic acid was produced when D-glucose was used as a substrate (2). The occurrence of aldoheptoses in bacterial polysaccharides is well established (3); however, little is known about the fine structure of such polysaccharides or of the sereological specificity of the component aldoheptoses. This note records the identification of D-*glycero*-D-*manno*-heptose in the extracellular polysaccharide produced by *A. indicum* and some preliminary structural investigations.

A. indicum (syn. *Beijerinckia indica* Starket and De) was grown in shake culture on a 5% D-glucose medium supplied with peptone and mineral salts to give after 38 days' growth a 4.5% yield of a crude polysaccharide which was obtained by acetone precipitation from the culture medium. Moving-boundary electrophoresis showed the preparation to be at least a two component mixture containing a major electrophoretically mobile component and an immobile minor fraction. The major component was an acidic glycan which was isolated from the mixture by Cetavlon precipitation (4) leaving a neutral glycan composed of glucose, mannose, rhamnose, and arabinose.

The acidic glycan had an equivalent weight of 1030 corresponding to a uronic anhydride content of 17.1% and was shown to be essentially homogeneous by electrophoresis in veronal buffer (pH 8.6) and in phosphate buffer (pH 7.4).

Hydrolysis of the acidic glycan followed by chromatographic fractionation of the neutral and acidic sugars afforded D-glucose characterized as its *N*-*p*-nitrophenylglycosylamine derivative, D-mannose characterized as its phenylhydrazone derivative, and D-*glycero*-D-*manno*-heptose which was characterized as its acetate and by its reduction to give crystalline D-*glycero*-D-*manno*-heptitol. Chromatographic examination of the uronic acid monosaccharide fraction indicated it to be composed mainly of glucuronic acid and a small amount of galacturonic acid. On reduction of the methyl ester, methyl glycoside preparation from this fraction with borohydride, and hydrolysis of the resulting methyl glycosides, paper chromatography revealed the presence of glucose and small amounts of galactose and a sugar tentatively identified as gulose. The presence of this latter sugar indicates the possible occurrence of small amounts of guluronic acid in the polysaccharide. Quantitative analysis of the uronic acid in the polysaccharide by the

colorimetric carbazole method (5) and analysis of the neutral sugars by the gas–liquid partition chromatographic method (6) indicated the composition of the polysaccharide to be: uronic acid 18.8%; D-*glycero*-D-*manno*-heptose 15.9%; D-glucose 32.8%; D-mannose 25.6%; and unidentified components 6.9%.

A spray reagent for the tentative identification of aldoheptoses on paper chromatograms is described. The test is based upon the condensation of the formaldehyde, released by the oxidation of the aldoheptose with buffered (pH 3.6) metaperiodate solution, with acetylacetone in the presence of ammonium salts to form the yellow highly fluorescent 3,5-diacetyl-1,4-dihydrolutidine (7). Under the oxidation conditions used, aldoheptoses liberate 1 mole formaldehyde per mole sugar whereas aldohexoses do not liberate formaldehyde and do not therefore give a positive reaction with the acetylacetone – ammonium acetate spray reagent. The difference in behavior of the aldoheptoses and aldohexoses noted above allows aldoheptoses to be detected on chromatograms even when they overlap with aldohexoses. The reagent is not specific since some other compounds (e.g. glycitols and ketoses) can also liberate formaldehyde on treatment with acidified metaperiodate solution; however, despite the lack of specificity of the test, its application has in several cases shown the presence of aldoheptoses in mixtures where they would otherwise have been overlooked or been identified as aldohexoses.

EXPERIMENTAL

Paper chromatography was performed by the descending method on Whatman No. 1 filter paper, using the following solvent systems: (A) ethyl acetate – acetic acid – formic acid – water (18:3:1:4 v/v); (B) butan-1-ol–ethanol–water (3:1:1 v/v); (C) butan-1-ol–pyridine–water (10:3:3 v/v); and (D) ethyl acetate – pyridine – water (10:4:3 v/v).

The following sprays were used to detect the compounds on the paper chromatograms: (A) 2% solution of *p*-anisidine hydrochloride in butan-1-ol; (B) 1% solution of silver nitrate in acetone, followed by 2% ethanolic sodium hydroxide; and (C) heptose spray—the chromatograms were first lightly sprayed with 0.03 *M* sodium metaperiodate in pH 3.6, 0.2 *M* acetate buffer followed after 1 minute by a 1% aqueous solution of inositol. The chromatograms were next sprayed with a solution of ammonium acetate (15 g), acetic acid (0.2 ml), and acetylacetone (1 ml) in methanol (50 ml) and the papers were examined after standing at room temperature for 30 minutes. The heptoses were located as yellow spots which were intensified when examined under ultraviolet light. The lower limit for the detection of aldoheptoses was found to be 1 γ/sq. cm in daylight and 0.5 γ/sq. cm under ultraviolet light.

Production of the Extracellular Polysaccharide

A. indicum (National Research Council Culture Collection) was kept in subculture on agar slopes having the same composition as the medium used for the liquid growth. The organism was grown at 25° in shake culture and 1 liter conical flasks each containing 300 ml of a medium having the following composition: D-glucose (50 g), peptone (1 g), dipotassium hydrogen phosphate (0.5 g), magnesium sulphate hydrated (0.2 g), sodium chloride (0.2 g), calcium sulphate (0.1 g), ferric chloride (trace), and calcium carbonate (20 g), in water 1 liter. The yield of crude extracellular polysaccharide based on the D-glucose supplied was: 2% (6 days), 2.3% (14 days), 7.5% (19 days), 17.8% (27 days), 18.3% (36 days), and 27.6% (9 months). The main bulk of the culture medium was harvested after 38 days' growth, and after adjustment to pH 4 with acetic acid, the crude polysaccharide was precipitated by pouring the solution into 6 volumes of acetone. The polysaccharides were collected by centrifugation and then precipitated four times in the same way. The polysaccharides were deionized by passage through columns of IR 120 (H^+) and IR 45 (OH^-) ion-exchange resins and the concentrated solution was freeze-dried to give the product in 4.5% yield based on the D-glucose supplied.

Some Properties of the Polysaccharide Preparation

Tiselius electrophoresis of the polysaccharide preparation (1% w/v) in veronal buffer (pH 8.6, $\mu = 0.1$) and in phosphate buffer (pH 7.4, *M*/20) indicated that it was a mixture of a major electrophoretically mobile fraction and a minor immobile fraction. Trial small-scale experiments showed that the polysaccharide preparation could be fractionated into the two electrophoretically identified components by precipitation of the major component with either cetyltrimethylammonium bromide (Cetavlon) or with barium hydroxide solution.

The polysaccharide preparation (10 g) was fractioned by treating its aqueous solution (4 l.) with Cetavlon (80 ml, 10% w/v) to give an insoluble complex of the major component which was collected by centrifugation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and dissolved in dilute acetic acid (500 ml, 50% w/v); the polysaccharide was then obtained by pouring the solution into ethanol (4 l.). The polysaccharide was twice further precipitated with Cetavlon and regenerated in the same way to give the acidic glycan which was freeze-dried from its aqueous solution (4.66 g).

The supernatant (4 l.) from the first Cetavlon treatment of the original polysaccharide preparation was concentrated to ca. 100 ml and since it did not give any further precipitate on treatment with Cetavlon it was poured into ethanol (1 l.) to give a precipitate of the electrophoretically immobile polysaccharide which contained glucose, mannose, rhamnose, and a trace of arabinose.

Some Properties of the Acidic Glycan

The acidic glycan had $[\alpha]_D^{19}$ +38° (*c*, 0.4 water). Anal. sulphate ash 1.3%; N, 0.2%. It gave a highly viscous solution in water and had a neutralization equivalent of 1030 determined by titration with standard sodium hydroxide solution. Tiselius electrophoresis examination of 1% w/v solution of the glycan in phosphate buffer (pH 7.4, *M*/20) gave a single sharp peak corresponding in behavior to the mobile peak observed in the electrophoresis of the original polysaccharide preparation.

Component Sugars of the Acidic Glycan

A portion of the glycan (20 mg) was hydrolyzed by heating its solution in *N* sulphuric acid (8 ml) at 100° for 10 hours. The hydrolyzate was neutralized ($BaCO_3$), filtered, and the concentrated filtrate was examined by paper chromatography in solvent systems A, B, C, and D and detection was made using the three spray reagents described previously. The polysaccharide hydrolyzate was indicated to contain uronic acid, heptose, glucose, and mannose in the visual ratio 1:1:2:2 together with trace amounts of arabinose and rhamnose.

The acidic glycan (8.6 g) was hydrolyzed with 0.5 *N* sulphuric acid (450 ml) at 100° for 9 hours. The cooled hydrolyzate was neutralized ($BaCO_3$) and ethanol was added to the concentrated filtrate to precipitate the barium uronates (3.3 g) which were removed by filtration. The filtrate was deionized by passage through IR 120(H^+) and IR 45(OH^-) ion-exchange resins and the effluent and washings containing the neutral sugars were concentrated to a syrup (2.7 g).

The neutral sugars (2.5 g) were fractionated by cellulose column chromatography using propan-1-ol – ethyl acetate – water (7:2:1 v/v) as the mobile phase. The isolated sugars were characterized as follows: D-Glucose, $[\alpha]_D^{23}$ +51.6° (*c*, 1.2 water), which gave *N*-*p*-nitrophenylglucosylamine having m.p. and mixed m.p. 182–183°; D-mannose, $[\alpha]_D^{23}$ +9.5° (*c*, 1.1 water), which gave a crystalline phenylhydrazone derivative having m.p. and mixed m.p. 186–187°; D-*glycero*-D-*manno*-heptose, a syrup which had $[\alpha]_D^{20}$ +21.4° (*c*, 2.8 water) and was chromatographically indistinguishable from an authentic specimen of the heptose in all the solvent systems used. The heptose had $R_{glucose}$ 0.90 (solvent A) and $R_{glucose}$ 0.82 (solvent B). The heptose (60 mg) was acetylated in acetic anhydride (6 ml) containing sulphuric acid (0.1 ml) to give hexa-*O*-acetyl-D-*glycero*-α-D-*manno*-heptose which after two recrystallizations from ether – petroleum ether (b.p. 40–60°) had m.p. 135–136° and did not depress the melting point of the authentic acetate on admixture with it (m.p. 138–139°). The derivative and an authentic specimen of the acetate had identical X-ray diffraction patterns. Reduction of the heptose (40 mg) with aqueous sodium borohydride solution afforded D-*glycero*-D-*manno*-heptitol which had m.p. and mixed m.p. 154° and an infrared spectrum (KBr disk) indistinguishable from that of an authentic specimen of the heptitol.

The barium uronates (3.3 g) were dissolved in water and passed down a column of IR 120(H^+) ion-exchange resin. The concentrated solution was fractionated by cellulose column chromatography using solvent A as the mobile phase. A portion of the monosaccharide fraction (50 mg) was treated with 1% w/v methanolic hydrogen chloride solution in a sealed tube at 100° for 3 hours. The cooled solution was neutralized with a solution of diazomethane in ether and the solution was left in contact with a slight excess of diazomethane at 5° overnight to complete the esterification of the acid groups. The concentrated solution was dissolved in 0.4 *M* boric acid (1 ml), and sodium borohydride (50 mg) in 0.4 *M* boric acid (10 ml) was added to the cooled solution followed after 1 hour by sodium borohydride (100 mg) in water (10 ml). The excess borohydride was destroyed by the addition of acetic acid, the solution was deionized by passage through columns of IR 120(H^+) and IR 45(OH^-) ion-exchange resins, the boric acid was removed from the dried solution as methyl borate by repeated distillations with methanol. Examination of the residue by paper chromatography revealed spots corresponding to glucose, galactose, and gulose having $R_{glucose}$ 1.00, 0.83, and 1.26 (solvent B) and 1.00, 0.84, and 1.18 (solvent C) respectively. The components corresponding to galactose and gulose were present in very minor amounts. The original uronic acid monosaccharide fraction on paper chromatography showed a minor component corresponding to galacturonic acid, a large elongated spot corresponding to glucuronic acid, and a large spot corresponding to glucuronolactone.

Quantitative Analysis of the Component Sugars of the Acidic Glycan

The uronic acid content of the acidic glycan determined by the Dische (5) colorimetric carbazole method was found to be 18.8%. The composition of the neutral sugars was determined after complete hydrolysis of the glycan (17.3 mg) with *N* sulphuric acid (7 ml) at 100° for 10 hours. D-Xylose (3 mg) was added to the hydrolyzate as an internal standard and the solution was neutralized ($BaCO_3$), filtered, and the filtrate was treated with sodium borohydride (30 mg) to reduce the aldoses to their corresponding glycitols. The acidified (acetic acid) reaction mixture was concentrated to dryness and the glycitols were acetylated by heating them with acetic anhydride (5 ml) containing sulphuric acid (0.1 ml) at 40° for 5 hours. The resulting

PREPARATION AND PROPERTIES OF ISOMERIC 2,4-DINITROPHENYL DERIVATIVES OF ALPHA–EPSILON DIAMINOPIMELIC ACID[1]

D. JUŠIĆ, C. ROY, A. J. SCHOCHER, AND R. W. WATSON

Mono- and di-dinitrophenyl (DNP) derivatives of the LL and meso isomers of diaminopimelic acid (Dap) have been prepared in pure crystalline form for the first time. Chromatographically pure mono- and di-DNP derivatives of DD-diaminopimelic acid have also been prepared, although the amounts were too small to crystallize. Isomeric DNP derivatives of diaminopimelic acid may be separated chromatographically (1) and the free isomers may be regenerated by catalytic hydrogenolysis of the dimethyl esters (2).

Infrared (IR) spectra of the crystalline mono- and di-DNP derivatives, automatically recorded from Nujol mulls using a Perkin–Elmer double-beam spectrophotometer (NaCl prism), have been deposited with Documentation of Molecular Spectroscopy, 4 and 5 Bell Yard, London, W.C.2, England. Differences between IR spectra of mono-LL and mono-meso derivatives include a shoulder at 3440, a small peak at 3400 and shoulders at 1675±20, 1492, 880–910, and 730 present in the meso and absent in the LL-form. Peaks at 3590, 3470, 1140, 1085, and 822 are present in the spectrum of mono-DNP-LL-diaminopimelic acid and absent in the related mono-meso compound. Differences in the IR spectra of di-DNP-LL-diaminopimelic and di-DNP-meso-diaminopimelic acid comprise (*a*) a small peak at 1672 present in the LL-derivative and absent in the meso form and (*b*) two small peaks at 996 and 777 present in the di-DNP-meso derivative and absent in di-DNP-LL-diaminopimelic acid. Besides these main differences a single peak at 3310 in the curve for di-DNP-LL-diaminopimelic acid is replaced by two small peaks at 3335 and 3290 in the spectrum of the di-DNP-meso derivative: two medium peaks at 1230 and

PREPARATION AND PROPERTIES OF ISOMERIC 2,4-DINITROPHENYL DERIVATIVES OF ALPHA–EPSILON DIAMINOPIMELIC ACID[1]

D. JUŠIĆ, C. ROY, A. J. SCHOCHER, AND R. W. WATSON

Mono- and di-dinitrophenyl (DNP) derivatives of the LL and meso isomers of diaminopimelic acid (Dap) have been prepared in pure crystalline form for the first time. Chromatographically pure mono- and di-DNP derivatives of DD-diaminopimelic acid have also been prepared, although the amounts were too small to crystallize. Isomeric DNP derivatives of diaminopimelic acid may be separated chromatographically (1) and the free isomers may be regenerated by catalytic hydrogenolysis of the dimethyl esters (2).

Infrared (IR) spectra of the crystalline mono- and di-DNP derivatives, automatically recorded from Nujol mulls using a Perkin–Elmer double-beam spectrophotometer (NaCl prism), have been deposited with Documentation of Molecular Spectroscopy, 4 and 5 Bell Yard, London, W.C.2, England. Differences between IR spectra of mono-LL and mono-meso derivatives include a shoulder at 3440, a small peak at 3400 and shoulders at 1675±20, 1492, 880–910, and 730 present in the meso and absent in the LL-form. Peaks at 3590, 3470, 1140, 1085, and 822 are present in the spectrum of mono-DNP-LL-diaminopimelic acid and absent in the related mono-meso compound. Differences in the IR spectra of di-DNP-LL-diaminopimelic and di-DNP-meso-diaminopimelic acid comprise (*a*) a small peak at 1672 present in the LL-derivative and absent in the meso form and (*b*) two small peaks at 996 and 777 present in the di-DNP-meso derivative and absent in di-DNP-LL-diaminopimelic acid. Besides these main differences a single peak at 3310 in the curve for di-DNP-LL-diaminopimelic acid is replaced by two small peaks at 3335 and 3290 in the spectrum of the di-DNP-meso derivative: two medium peaks at 1230 and

[1]*Issued as N.R.C. No. 7517.*

1202 in the di-meso derivative are replaced by a single medium peak with shoulders at 1230, 1205, and 1185 in the di-LL compound. Ultraviolet (UV) spectra of mono- and di-DNP derivatives of the LL and meso isomers are similar to those of DNP-L-valine and DNP-L-arginine (3) and closely resemble the recorded spectrum of di-DNP-diaminopimelic acid (4).

The electrophoretic behavior of the DNP derivatives of diaminopimelic acid is compared with that of DNP-alanine and DNP-glutamic acid in Table I. Mono-DNP-LL-diaminopimelic acid and the mono-DNP-meso derivative have equivalent electrophoretic mobilities. In 1 hour at pH 6.4 these compounds run about 2 cm behind the three di-DNP derivatives, whose net charges are sufficiently alike to prevent their separation from each other. Qualitatively similar differences were observed at pH 3.5.

EXPERIMENTAL

Di-DNP-LL-diaminopimelic Acid

Five grams of LL-enriched Calbiochem[2] diaminopimelic acid ($[\alpha]_D^{24-26} = +33.1°$, containing approximately 73% of the LL isomer), treated with 18.3 g of β-naphthalenesulphonic acid yielded 4.8 g of the crystalline LL-nasylate on cooling (5). From this material chromatographically pure LL-diaminopimelic acid was released by the addition of pyridine (6). LL-diaminopimelic acid (1 g) was dissolved in 80 ml of a 1% solution of trimethylamine in water, and 4 g of 1-fluoro-2,4-dinitrobenzene (FDNB) was added (7). After the aqueous solution was stirred for 3 hours in subdued light (8) at 40° C, with addition of 1% trimethylamine at intervals to maintain the pH close to 9, it was extracted: (*a*) with ether until the extracts were colorless (4×80 ml); (*b*) with benzene (3×; discard); and (*c*) again with ether (2×; discard). The water layer was then acidified to pH 1.2 with *N* HCl and extracted with ether until colorless (extract A). Evaporation of extract A to dryness, solution of the residue in a small amount of acetone, and addition of petroleum ether to first turbidity yielded crystals of di-DNP-LL-diaminopimelic acid on standing at 0° C. Recrystallization from (*a*) acetone – petroleum ether (2×) and (*b*) from acetone–water (2×) took place on cooling to 0° C in each solvent. Found: C, 43.70; H, 3.51; N, 15.87. Calculated for $C_{19}H_{18}N_6O_{12}$: C, 43.67; H, 3.45; N, 16.09. M.p. 87° C (decomp.).[3] $[\alpha]_D^{24-26} = -85 \pm 5°$ C.[4] $[M]_D^{24-26} = -444$ (9). Chromatographically pure di-DNP-DD-diaminopimelic acid was prepared in the same way from the pure DD isomer.

Di-DNP-meso-diaminopimelic Acid

This derivative was prepared from pure meso-diaminopimelic acid (1) by the procedure outlined for di-DNP-LL-diaminopimelic acid. Found: C, 43.63; H, 3.72; N, 16.22. Calculated for $C_{19}H_{18}N_6O_{12}$: C, 43.67; H, 3.45; N, 16.09. M.p. 220° C (decomp.)[3]. $[\alpha]_D^{24-26} = 0.0$.

Mono-DNP-LL-diaminopimelic Acid

In the preparation of mono-DNP-LL-diaminopimelic acid the yield was increased by adding one-half of the stoichiometric amount of FDNB to the reaction mixture. After extraction of the acidified aqueous layer with ether (extract A), further extraction of the water layer (pH 1.2) with ethyl acetate (10×) removed the mono-DNP-LL derivative (extract B). Evaporation of extract B to dryness and solution of the residue in a small amount of water gave the crystalline derivative on standing at 15° C. Occasionally the monoderivatives crystallized spontaneously from the aqueous layer after extraction with ether, but they were obtained more consistently after ethyl acetate extraction. Mono-DNP-LL-diaminopimelic acid was chromatographically pure after one recrystallization from water. Found: C, 43.92; H, 4.40; N, 15.51. Calculated for $C_{13}H_{16}N_4O_8$: C, 43.82; H, 4.49; N, 15.73. M.p. 164° C (decomp.).[3] $[\alpha]_D^{24-26} = -65 \pm 5°$ C.[4] $[M]_D^{24-26} = -231$. From the DD isomer a small amount of chromatographically pure mono-DNP-DD-diaminopimelic acid was prepared in the same way.

Mono-DNP-meso-diaminopimelic Acid

The mono-meso derivative is not internally compensated but is a racemic mixture of optically active enantiomorphs. It was prepared from pure meso-diaminopimelic acid by the procedure outlined for mono-DNP-LL-diaminopimelic acid. Both monoderivatives were chromatographically pure after one recrystallization from water. Found: C, 44.23; H, 4.33; N, 15.69. Calculated for $C_{13}H_{16}N_4O_8$: C, 43.82; H, 4.49; N, 15.73. M.p. 198° (decomp.).[3] $[\alpha]_D^{24-26} = 0.0$.

ACKNOWLEDGMENTS

The authors wish to thank Dr. E. Work for kindly providing a sample of the pure DD isomer and to acknowledge the expert assistance of Mr. A. Castagne with the elemental analyses and of Mr. F. Rollin and Mr. R. W. Rowsome in the preparation of infrared spectra.

PYROLYSIS OF 3-HEXENEDIOIC ACID

GARSON P. SHULMAN AND JEAN OSTERAAS

A recent publication (1) describes the formation of 4-pentenoic acid during attempted preparation of 3-cyclopentenone by pyrolysis of *cis*- or *trans*-3-hexenedioic acid and their barium salts. We required a reference sample of 4-pentenoic acid in this laboratory and chose this method for convenience. Analysis of the crude pyrolyzate by gas chromatographic and infrared techniques showed the presence of three other products, 4-valerolactone (29%), 3-cyclopentenone (3%), and an unidentified minor (<.01%) component. The 68% yield of 4-pentenoic acid is in good agreement with the 66–72% reported by Benington and Morin.

The valerolactone must result from addition of the carboxyl group to the double bond of 4-pentenoic acid. Since the pyrolysis of 3-hexenedioic acid would be expected to produce 3-cyclopentenone, failure to demonstrate the presence of even a trace leads to the erroneous conclusion that the cyclization does not occur in competition with the decarboxylation. Obviously, this is not true; rather, the rate of decarboxylation accompanying double bond migration must be several times that leading to ring closure (97% 4-pentenoic acid – 4-valerolactone to 3% cyclopentenone or 32:1).

Identification of products was by infrared analysis of fractions separated by gas chromatography. The 3-cyclopentenone showed a carbonyl absorption at 1710 cm^{-1}, C—H bands at 2900 cm^{-1} (aldehyde), 1660 cm^{-1} (olefinic), and 1440 cm^{-1} (methylene), with absence of the methyl C—H band at 1375 cm^{-1}. The 4-valerolactone was identified by comparison of the spectrum with that of commercially available material. The 4-pentenoic acid showed typical carboxyl OH bands at 2300–2700 cm^{-1}, a carbonyl band at 1720 cm^{-1}, and terminal olefin bands at 1655, 998, and 912 cm^{-1}. To confirm the presence of 3-cyclopentenone, the 2,4-dinitrophenylhydrazone precipitate was ozonized. Comparison by mixed melting point with the 2,4-dinitrophenylhydrazone of β-ketoglutaric acid showed them to be identical.

EXPERIMENTAL

Pyrolysis of 3-Hexenedioic Acid

A sample of 3-hexenedioic acid* was placed in a micro distillation apparatus and heated until decomposition was complete (flask temperature 280–295°). The distillate gave a positive 2,4-dinitrophenylhydrazone test (m.p. 148°) and a neutralization equivalent of 132 (calculated, 100).

Analysis of Distillate

A Perkin–Elmer Model 154 Vapor Fractometer with a 6 ft silicone column was employed for the analysis. Analytical scale (10 μl) chromatography showed four peaks (<.01%, 3%, 29%, and 68%). Fractions from

THE DETERMINATION OF SELF-ASSOCIATION EQUILIBRIUM CONSTANTS BY INFRARED ABSORPTION SPECTROSCOPY

SERGE N. VINOGRADOV*

Infrared absorption spectroscopy is one of the most widely used methods in the investigation of hydrogen-bonded equilibria in solution (1). The increase in intensity of the absorption band assigned to a X—H (X = N, O, S, etc.) stretching vibration of the "free" or "monomeric" molecule with decrease in concentration in an inert solvent is an important criterion for the existence of self-association through hydrogen bonding. Detailed quantitative data on the variation of the X—H band intensity with concentration can be used to deduce the mode of self-association and hence to calculate the pertinent equilibrium constants; from the latter it becomes possible to evaluate the thermodynamic parameters of the specific hydrogen bond formations.

Milestones in the development of such treatments of infrared absorption intensity data are the Mecke–Kempter relationship, first proposed to describe early data on the self-association of alcohols (2) and since then used in the determination of parameters governing the self-association of α-keto pyrroles (3), 4(5)-methylimidazole (4), and of several oximes (5); the Coggeshall–Saier scheme for the self-association of phenols (6) which has been used by Bono in the study of xylenols and cresols (7); and the recent, very elegant treatments by Rossotti *et al.* of the self-associations of imidazole (8), pyrazole (9), and several pyrazole derivatives (10) based on general methods for the determination of stability constants (11). The systematization by Rossotti and Rossotti of the methods of determination of self-association equilibrium constants (12) relies heavily on graphical procedures.

In the specific case where the absorption band, whose intensity is measured as a function of the concentration, is due only to the "free" molecules and does not include contributions from free "end" X—H groups, it becomes possible to calculate the stepwise self-association equilibrium constants β_{q0}, in the terminology of Rossotti and Rossotti (11), in a slightly more rigorous manner as follows. Assuming the validity of Beer's law, the concentration of the "free" molecules b_1 is given by $b_1 = \epsilon B/\epsilon_1$, where ϵ_1 is the absorptivity of the

*Present address: Biochemistry Department, Yale University, New Haven, Connecticut, U.S.A.

chromatography of 100 μl samples were collected in a dry ice trap and the infrared spectra of the second, third, and fourth peaks determined. Details of the spectra are given in the discussion.

Identification of 3-Cyclopentenone

Ten drops of the reaction product was added to 20 ml of 0.5% aqueous 2,4-dinitrophenylhydrazine hydrochloride, giving a precipitate, m.p. 153–156° decomp.

Ozonolysis of the precipitate in ethyl acetate solution gave an oily solid which crystallized from water, m.p. 112–118°. The 2,4-dinitrophenylhydrazone of β-ketoglutaric acid, previously unreported, was prepared from the acid, m.p. 118–120°. A mixture melted at 113–118°.

THE DETERMINATION OF SELF-ASSOCIATION EQUILIBRIUM CONSTANTS BY INFRARED ABSORPTION SPECTROSCOPY

SERGE N. VINOGRADOV*

Infrared absorption spectroscopy is one of the most widely used methods in the investigation of hydrogen-bonded equilibria in solution (1). The increase in intensity of the absorption band assigned to a X—H (X = N, O, S, etc.) stretching vibration of the "free" or "monomeric" molecule with decrease in concentration in an inert solvent is an important criterion for the existence of self-association through hydrogen bonding. Detailed quantitative data on the variation of the X—H band intensity with concentration can be used to deduce the mode of self-association and hence to calculate the pertinent equilibrium constants; from the latter it becomes possible to evaluate the thermodynamic parameters of the specific hydrogen bond formations.

Milestones in the development of such treatments of infrared absorption intensity data are the Mecke–Kempter relationship, first proposed to describe early data on the self-association of alcohols (2) and since then used in the determination of parameters governing the self-association of α-keto pyrroles (3), 4(5)-methylimidazole (4), and of several oximes (5); the Coggeshall–Saier scheme for the self-association of phenols (6) which has been used by Bono in the study of xylenols and cresols (7); and the recent, very elegant treatments by Rossotti *et al.* of the self-associations of imidazole (8), pyrazole (9), and several pyrazole derivatives (10) based on general methods for the determination of stability constants (11). The systematization by Rossotti and Rossotti of the methods of determination of self-association equilibrium constants (12) relies heavily on graphical procedures.

In the specific case where the absorption band, whose intensity is measured as a function of the concentration, is due only to the "free" molecules and does not include contributions from free "end" X—H groups, it becomes possible to calculate the stepwise self-association equilibrium constants β_{q0}, in the terminology of Rossotti and Rossotti (11), in a slightly more rigorous manner as follows. Assuming the validity of Beer's law, the concentration of the "free" molecules b_1 is given by $b_1 = \epsilon B/\epsilon_1$, where ϵ_1 is the absorptivity of the

*Present address: Biochemistry Department, Yale University, New Haven, Connecticut, U.S.A.

"free" molecules and ϵ is the absorptivity measured at a stoichiometric concentration B. The latter can then be expressed as

$$B = \sum_1^q qb_q = \sum_1^q q\beta_{q0}b_1{}^q = \epsilon B/\epsilon_1 + 2(\epsilon B/\epsilon_1)^2\beta_{20} + \ldots + q(\epsilon B/\epsilon_1)^q\beta_{q0}.$$

Dividing through by ϵB we obtain

$$1/\epsilon = 1/\epsilon_1 + (2\beta_{20}/\epsilon_1{}^2)(\epsilon B) + \ldots + (q\beta_{q0}/\epsilon_1{}^q)(\epsilon B)^{q-1}.$$

It is evident that a least-squares fit of the experimental data in terms of $1/\epsilon$ versus ϵB to the polynomial $f(x) = \sum_{k=0}^{k=n} a_{nk}x^k$ for different n starting with $n = 1$ will give several analytical functions from which the most valid polynomial can be selected on the basis of the two criteria all $a_{nk} > 0$ and best fit to the experimental data. If ϵ_1 is known experimentally the foregoing equation can be transposed to

$$\frac{1}{\epsilon B}\left(\frac{1}{\epsilon} - \frac{1}{\epsilon_1}\right) = 2\beta_{20}/\epsilon_1{}^2 + (3\beta_{30}/\epsilon_1{}^3)(\epsilon B) + \ldots + (q\beta_{q0}/\epsilon_1{}^q)(\epsilon B)^{q-2}.$$

In this case the experimental data in terms of $(1/\epsilon B)(1/\epsilon - 1/\epsilon_1)$ versus ϵB can be fitted by the method of least-squares to the foregoing general polynomial. In either case it becomes possible to calculate the β_{q0} from the a_{nk} of the selected polynomial. The latter thus defines a physically plausible self-association model.

Only recently has data of sufficient accuracy been published to warrant a calculation on the basis outlined above. Rossotti and his collaborators have investigated the self-association of pyrazole and some of its derivatives in CCl_4 over the concentration range 1×10^{-4} to 1×10^{-2} M at about 20° C and found them to self-associate to "closed" dimers and trimers (9, 10). Their published results were: pyrazole: $\epsilon_1 = 220\pm3$ mole^{-1} liter cm^{-1}, $\beta_{20} = 47.4\pm1.0$ mole^{-1} liter, $\beta_{30} = 7540\pm240$ mole^{-2} liter; 3,5-dimethylpyrazole: $\epsilon_1 = 295\pm2$, $\beta_{20} = 285\pm4$, $\beta_{30} = 45900\pm280$; 3,5-diethylpyrazole: $\epsilon_1 = 225\pm1$, $\beta_{20} = 110\pm1$, $\beta_{30} = 5940\pm360$.

The data of Rossotti *et al.* (9, 10) as plots of $1/\epsilon$ and $(1/\epsilon B)(1/\epsilon - 1/\epsilon_1)$ versus ϵB were fitted to the polynomial $f(x) = \sum_{k=0}^{k=n} a_{nk}x^k$, $n = 1, 2, 3, 4$, by the method of least-squares, using an IBM 1620 computer.* Some of the results are shown in Tables I and II. The standard deviation for each fit is given by $S = (\sum_{i=1}^{i=N} (y_i - \bar{y}_i)^2/(N-n-1))^{\frac{1}{2}}$, where N is the number of points and n is the order of the polynomial. This type of standard deviation gives a better comparison between polynomials of different orders (13).

Generally polynomials of order higher than second or third had at least one negative coefficient. The results of $1/\epsilon$ versus ϵB plots agreed fairly well with the results of Rossotti *et al.*, except in the case of 3,5-dimethylpyrazole, which is still appreciably self-associated even at 1×10^{-4} M (10) and where a procedure which gives ϵ_1 by extrapolation would be expected to give incorrect answers. The results of fitting the $(1/\epsilon B)(1/\epsilon - 1/\epsilon_1)$ versus ϵB plots agreed very well with those of Rossotti *et al.*; for some sets of data two or three equilibrium constants gave almost equally good fits. Hence in these systems there is no experimental evidence for or against the existence of cyclic tetramers.

The equilibrium constants higher than β_{20} varied appreciably with the number of points, i.e. with the concentration range used in the calculations. Although, admittedly, at the lowest concentrations, where the percentage of trimers and (or) higher polymers is small, the appropriate equilibrium association constants can not be too reliable, this

fact raises some suspicion concerning the physical validity of the higher self-association equilibrium constants. It is possible that the assumption concerning the ideality of dilute solutions of self-associating substances in inert solvents, which underlies the calculation of the equilibrium constants, may be invalid oftener than thought. This seems unlikely in the present case where concentrations are under 0.01 M; moreover 3,5-dimethylpyrazole, for example, begins to approach the limit of its solubility in CCl_4 at 20° C only above 0.1 M (14). The final possibility may be that some "open" polymers are present in some concentration ranges as intimated by Mirone and Lorenzelli in the case of 3,5-dimethylpyrazole (3), although the results of two other independent investigations (9, 10, 14) do not support it. Coexistence of "open" and "closed" dimers and (or) trimers as in the case of the dimers of caprolactam (15) is at present outside the scope of the proposed treatment.

THE FLASH PHOTOLYTIC REDUCTION OF 2-ACETONAPHTHONE IN SOLUTION

W. A. Bryce and C. H. J. Wells

INTRODUCTION

The excited intermediate responsible for the photolytic reduction of aromatic ketones is believed to be the triplet state (1, 2). The initial stages of the mechanism can be represented by the following sequence of reactions:

$$R_2CO + h\gamma \rightarrow R_2CO_S^* \quad [1]$$

$$R_2CO_S^* \rightarrow R_2CO \quad [2]$$

$$R_2CO_S^* \rightarrow R_2CO_T^* \quad [3]$$

$$R_2CO_T^* \rightarrow R_2CO \quad [4]$$

$$R_2CO_T^* + DH \rightarrow R_2COH + D^\cdot \quad [5]$$

fact raises some suspicion concerning the physical validity of the higher self-association equilibrium constants. It is possible that the assumption concerning the ideality of dilute solutions of self-associating substances in inert solvents, which underlies the calculation of the equilibrium constants, may be invalid oftener than thought. This seems unlikely in the present case where concentrations are under 0.01 M; moreover 3,5-dimethylpyrazole, for example, begins to approach the limit of its solubility in CCl_4 at 20° C only above 0.1 M (14). THE FLASH PHOTOLYTIC REDUCTION OF 2-ACETONAPHTHONE IN SOLUTION

W. A. Bryce and C. H. J. Wells

INTRODUCTION

The excited intermediate responsible for the photolytic reduction of aromatic ketones is believed to be the triplet state (1, 2). The initial stages of the mechanism can be represented by the following sequence of reactions:

$$R_2CO + h\gamma \rightarrow R_2CO_S^* \quad [1]$$

$$R_2CO_S^* \rightarrow R_2CO \quad [2]$$

$$R_2CO_S^* \rightarrow R_2CO_T^* \quad [3]$$

$$R_2CO_T^* \rightarrow R_2CO \quad [4]$$

$$R_2CO_T^* + DH \rightarrow R_2COH + D^\cdot \quad [5]$$

The ketone molecule is excited initially to an upper singlet state which will decay back to the ground state or form a triplet state by internal conversion. The triplet state will either decay to the ground state or abstract a hydrogen atom from the solvent DH to form a ketyl radical, $R_2\dot{C}OH$. The ketyl radical forms the final products by reacting with the solvent, DH, with the radical, $\dot{D}$, or by dimerization.

Since the photolysis of an aromatic ketone can result in the formation of both the triplet state of the ketone and the ketyl radical as intermediates care must be exercised in the assignment of transient absorption spectra. McClure and Hanst (3) observed the triplet absorption in the flash photolysis of benzophenone in a rigid medium. The close similarity between this absorption and the transient absorption in solution originally led Porter and Windsor (4) to believe that the transient observed in solution was also the triplet state. The absorption was subsequently assigned (5) to the relatively long-lived ketyl radical $C_6H_5\dot{C}OHC_6H_5$. The triplet absorption was not observed in solution, presumably because of the rapidity of the hydrogen transfer occurring in reaction [5].

It has been reported (6) that certain naphthoyl ketones, including 2-acetonaphthone, are not photoreduced in the presence of a weak hydrogen donor such as a secondary alcohol. The reduction of 2-acetonaphthone does occur, however, if a more active hydrogen donor, such as tributylstannane, is added to the system (7). This suggests that the corresponding ketyl radical for 2-acetonaphthone can only be formed in the presence of active hydrogen donors, and that any transient absorption observed when 2-acetonaphthone is photolyzed in the presence of a weak donor must be that of the triplet state. The present work was undertaken to study the decay of the triplet absorption of 2-acetonaphthone in an 'inert' solvent and to characterize any transient absorption that may be observed when 2-acetonaphthone is photolyzed in the presence of tributylstannane. The effect of the addition of 1-naphthol and triphenylene as quenching or energy-transfer agents in the system was also studied.

EXPERIMENTAL

2-Acetonaphthone (Eastman Kodak White label) was recrystallized three times from petroleum ether (60–80°). 1-Naphthol (Eastman Kodak White label) was vacuum sublimed, recrystallized three times from spectroscopic grade benzene, and resublimed. Triphenylene (Aldrich Chemical Corp.) was zone refined. Tributylstannane was prepared from tributyltin chloride (Metal and Thermit Corp.) by the method of Van der Kerk and Luitjen (8). The solutions were all made up in spectroscopic grade benzene (Eastman Kodak) and were thoroughly degassed before flashing. This was done by a freeze–pump–melt–freeze–pump procedure combined with trap-to-trap distillation under high vacuum.

The flash apparatus was of conventional design, the photolysis lamp consisting of a quartz tube of 42-cm length and 3.8-cm O.D., araldited into cylindrical stainless steel electrodes of a design developed by Claesson and Lindqvist (9). Discharge occurred between 1/4-in. tungsten rods mounted in the centers of the electrodes. The lamp was mounted coaxially in a cylindrical brass can coated on the inside with magnesium oxide, and was generally filled with nitrogen to a pressure of 5 cm. The duration of the flash on discharging a 66 μf condenser bank through the lamp at 10 kv was approximately 12 microseconds. The spectroscopic lamp was similar in design to the photolysis lamp but with a quartz capillary of 3-cm length and 2-mm bore. It was filled with nitrogen to a pressure of 4 mm and had a flash-time of 5 microseconds for a 50 joule flash. The timing of the spectroscopic flash was controlled by an electronic delay unit and checked by means of an oscilloscope. The discharge was focused through the reaction vessel onto the slit of a Hilger-Watts E 742 Automatic quartz spectrograph.

The reaction vessel was a quartz tube 21 cm long and 15 mm in diameter located beside the photolysis lamp. It was surrounded by a double quartz cylindrical vessel with an annular space 6 mm wide which could be filled with filter solutions. The absorption spectra were photographed on either Kodak 103-F or Ilford HP3 plates. The plates were scanned with a Hilger-Watts recording microdensitometer and the deflection readings at each wavelength converted to optical density of transient from a previously constructed calibration graph. Each plate was calibrated by inserting alumina-on-quartz neutral density filters between the reaction vessel and the spectrograph, firing the photolamp and the spectroscopic lamp with the delay set at 14 microseconds, and measuring the corresponding plate density.

RESULTS AND DISCUSSION

The transient absorption observed when a 1.01×10^{-3} M solution of 2-acetonaphthone in benzene was flashed is given by curve A in Fig. 1. The concentration of 2-aceto-

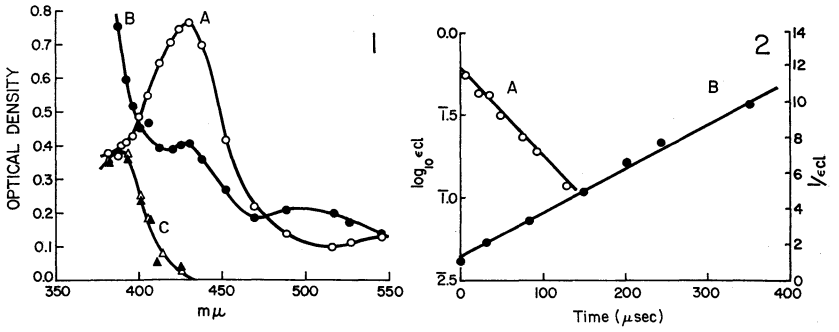

FIG. 1. Transient absorption spectra following photolysis in benzene solution of (A) 1.01×10^{-3} M 2-acetonaphthone; (B) 1.01×10^{-3} M 2-acetonaphthone + 0.17 M tributylstannane; (C) ▲, 0.90×10^{-4} M 1-naphthol, no filter present; △, 1.01×10^{-3} M 2-acetonaphthone + 0.90×10^{-4} M 1-naphthol; filter solution, 0.5 M 1-naphthol. Flash energy, 2220 joules; delay, 11 microseconds.

FIG. 2. (A) Logarithm of the optical density of the triplet state of a 1.01×10^{-4} M solution of 2-acetonaphthone in benzene, against time. (B) Reciprocal of the optical density of the triplet state of a 0.90×10^{-2} M solution of 2-acetonaphthone in benzene, against time. Flash energy, 2220 joules.

naphthone and the absorption spectrum of the solution were unchanged after 30 flashes at 2220 joules per flash, showing that the transient absorption was that of the triplet state. When a solution 1.01×10^{-3} M in 2-acetonaphthone and 0.17 M in tributylstannane was flashed under the same conditions a transient absorption was obtained (curve B, Fig. 1) which differed from that of the triplet state. The peak maximum of this absorption band lies below 385 mμ, and is hidden by the singlet–singlet absorption band of 2-acetonapthone. The new absorption band had a relatively long lifetime as compared to the triplet absorption band and could be detected some 10 milliseconds after flashing. This long lifetime, plus the observation that 20% of the 2-acetonaphthone had been decomposed after 20 flashes, indicates that the transient absorption spectrum was that of the ketyl radical $C_{10}H_7\dot{C}OHCH_3$. The maximum in the absorption in curve B at 430 mμ may be caused by simultaneous triplet–triplet absorption of 2-acetonaphthone, and hence it was not possible to decide whether the spectrum in this region is due to the ketyl radical only, or to a combination of triplet and ketyl radical absorption.

The kinetics of the decay of the triplet state was investigated for different initial concentrations of 2-acetonaphthone. For a 1.01×10^{-4} M solution a plot of the logarithm of the optical density against time was linear within the limitations of plate photometry (Fig. 2, curve A). The first-order rate constant, k_1, had a value of $1.27\pm0.25\times10^{4}$ sec^{-1}, and thus the triplet-state lifetime was $0.75\pm0.25\times10^{-4}$ sec. When the concentration of 2-acetonaphthone was increased to 0.90×10^{-2} M, the decay was second order (Fig. 2, curve B) with a rate constant k_2 of $5.5\pm0.9\times10^{5}$ $(\epsilon C)^{-1}$ sec^{-1}, where ϵ is the molar extinction coefficient and C is the molar concentration. The transition from primarily first-order kinetics at low concentrations to second-order kinetics at the higher concentrations suggests that at the lower concentrations there will be some contribution to the decay from second-order quenching, and hence the value obtained for the rate constant, k_1, is a maximum.

It has been shown (10, 11) that selective excitation of the triplet level of one molecule in the presence of another molecule with a lower-lying triplet level can lead to energy transfer from the upper triplet to the lower triplet. It was therefore of interest to see if the triplet state of 2-acetonaphthone could be quenched by the addition to the solution of a molecule with a lower-lying triplet level, and to examine the consequent effect on the extent of photoreduction. As illustrated schematically in Fig. 3, the energy levels of 1-naphthol relative to those of 2-acetonaphthone made it suitable for use as a quencher.

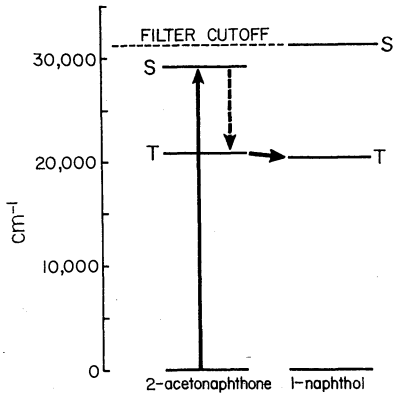

FIG. 3. Energy level diagram of the first excited states of 2-acetonaphthone and 1-naphthol.

Selective excitation of the 2-acetonaphthone in the presence of 1-naphthol was achieved by surrounding the solution to be flashed with a concentrated solution of 1-naphthol. The transfer of energy between the 2-acetonaphthone triplet and the 1-naphthol triplet is shown by the results presented in Fig. 1. Curve A illustrates the triplet-state absorption for a 1.01×10^{-3} M 2-acetonaphthone solution. Curve C shows the triplet absorption of a 0.90×10^{-4} M 1-naphthol solution with no filter in the system, and also shows the transient absorption of a solution which is 0.90×10^{-4} M in 1-naphthol and 1.01×10^{-3} M in 2-acetonaphthone with the 1-naphthol filter present. When a 0.90×10^{-4} M solution of 1-naphthol was flashed with the filter solution present no transient absorption could be detected.

Transfer of energy from the first excited singlet of 2-acetonaphthone to the corresponding state in 1-naphthol is unlikely since this state is higher in 1-naphthol than in 2-acetonaphthone. Direct transfer from the first excited singlet state of 2-acetonaphthone to the triplet of 1-naphthol is also unlikely as this is a spin-forbidden process and, for many donor–acceptor pairs, has been shown to be unimportant compared with triplet–triplet energy transfer (10–12).

The quenching effect of 1-naphthol on the photoreduction of 2-acetonaphthone is shown by the results given in Fig. 4(*a*). Solutions which were 1.01×10^{-3} M in 2-acetonaphthone and 0.42 M in tributylstannane were flashed in the presence of various amounts of 1-naphthol. The results show that the decomposition of the 2-acetonaphthone decreased as the concentration of 1-naphthol increased. The observation that 1-naphthol removes triplet excitation energy from 2-acetonaphthone and also quenches the photoreduction provides convincing evidence that the triplet state is the active intermediate in the photoreduction.

The possibility that 1-naphthol reacted with the tributylstannane on flashing, or that a complex was formed between the 1-naphthol and 2-acetonaphthone was ruled out by the

For personal use only.

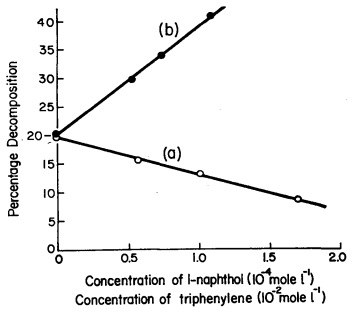

FIG. 4. Percentage decomposition of 2-acetonaphthone against concentration of 1-naphthol and triphenylene in benzene solution: (*a*) 1.01×10^{-3} *M* 2-acetonaphthone + 0.42 *M* tributylstannane + 1-naphthol; filter solution, 0.5 *M* 1-naphthol. (*b*) 5.2×10^{-4} *M* 2-acetonaphthone + 0.21 *M* tributylstannane + triphenylene; no filter present. Flash energy, 2220 joules; number of flashes, 20.

observation that the absorption spectrum of a solution containing 1-naphthol and tributylstannane was the same before and after being flashed, and by the fact that the absorption spectrum of a solution of 2-acetonaphthone and 1-naphthol after flashing was identical with the combined spectra of the two solutes in separate solutions.

Since the action of 1-naphthol as a quencher was to remove triplet-state energy it follows that a molecule which could transfer energy to the 2-acetonaphthone triplet should sensitize the photoreduction. The requirements for an ideal sensitizer are: (1) a first triplet level lying above that of 2-acetonaphthone; (2) a first excited singlet lying below that of 2-acetonaphthone; and (3) a triplet–triplet absorption band lying in a region of the spectrum different from that for 2-acetonaphthone to enable the energy transfer between triplets to be followed by plate photometry. Unfortunately it was not possible to obtain a molecule with all three requirements. Triphenylene, however, does meet the first requirement and was used as a sensitizer. The results presented in Fig. 4(*b*) show that the addition of triphenylene to a solution of 2-acetonaphthone and tributylstannane greatly increases the rate of removal of 2-acetonaphthone from the system. The absorption spectra of triphenylene and 2-acetonaphthone are so similar that it was not possible selectively to excite the triphenylene. However the concentration of 2-acetonaphthone was 5.2×10^{-4} *M* while the lowest concentration of triphenylene used was 5.0×10^{-3} *M* so that it is safe to assume that most of the light was absorbed by the triphenylene. Owing to the closeness of the energies of the first excited singlet states of 2-acetonaphthone and triphenylene it was not possible to decide whether the 2-acetonaphthone was excited to its triplet state by direct energy transfer from the triphenylene triplet or by singlet–singlet energy transfer between the two molecules followed by internal conversion of the singlet of 2-acetonaphthone to the triplet state.

Experiments similar to those carried out with 1-naphthol gave no indication that triphenylene and 2-acetonaphthone formed a complex in solution, or that triphenylene reacted with tributylstannane on flashing.

ACKNOWLEDGMENTS

We are greatly indebted to the National Research Council for financial support for this investigation, and to Dr. D. A. Ramsay for a blueprint of the design of the flash-lamp electrodes.

THE OXIDATION OF SODIUM FORMATE BY SODIUM HYPOCHLORITE

M. W. LISTER AND P. ROSENBLUM

The present note describes the measurements of the oxidation of formate ions by sodium hypochlorite solutions, a reaction that in fact turns out to be a reaction of hypochlorous acid.

RESULTS AND DISCUSSION

Table I shows that in a typical experiment the sodium hypochlorite and formate reacted in a precisely 1:1 ratio without any side reaction.

TABLE I

Time (min)	[NaOCl]$\times 10^2$ (M)	[HCOONa]$\times 10^2$ (M)	Difference$\times 10^2$ (M)
0	4.71	12.11	7.40
60.0	4.67	12.07	7.40
121.2	4.60	12.03	7.43
181.1	4.54	11.97	7.43
241.3	4.45	11.89	7.44
300.0	4.37	11.81	7.44
361.3	4.27	11.68	7.41
421.1	4.10	11.52	7.42

NOTE: Initial [NaOH) = 0.00782 M; 60° C; ionic strength 0.653.

Preliminary runs showed that the rate of reaction increased with time. This was attributed to the fact that sodium hydroxide was used by the reaction

$$OCl^- + HCOO^- + OH^- \rightarrow Cl^- + CO_3^{=} + H_2O,$$

and that the rate was faster in less alkaline solutions. In fact the reaction was found to obey the rate equation

$$\text{rate} = k[OCl^-][HCOO^-]/[OH^-].$$

THE OXIDATION OF SODIUM FORMATE BY SODIUM HYPOCHLORITE

M. W. LISTER AND P. ROSENBLUM

The present note describes the measurements of the oxidation of formate ions by sodium hypochlorite solutions, a reaction that in fact turns out to be a reaction of hypochlorous acid.

RESULTS AND DISCUSSION

Table I shows that in a typical experiment the sodium hypochlorite and formate reacted in a precisely 1:1 ratio without any side reaction.

TABLE I

Time (min)	[NaOCl]$\times 10^2$ (M)	[HCOONa]$\times 10^2$ (M)	Difference$\times 10^2$ (M)
0	4.71	12.11	7.40
60.0	4.67	12.07	7.40
121.2	4.60	12.03	7.43
181.1	4.54	11.97	7.43
241.3	4.45	11.89	7.44
300.0	4.37	11.81	7.44
361.3	4.27	11.68	7.41
421.1	4.10	11.52	7.42

NOTE: Initial [NaOH) = 0.00782 M; 60° C; ionic strength 0.653.

Preliminary runs showed that the rate of reaction increased with time. This was attributed to the fact that sodium hydroxide was used by the reaction

$$OCl^- + HCOO^- + OH^- \rightarrow Cl^- + CO_3^{=} + H_2O,$$

and that the rate was faster in less alkaline solutions. In fact the reaction was found to obey the rate equation

$$\text{rate} = k[OCl^-][HCOO^-]/[OH^-].$$

This gives the integrated equation

$$(x_0-z_0)\ln(x/x_0) + (z_0-y_0)\ln(x-x_0+y_0)/y_0 = -k(x_0-y_0)t,$$

and k was calculated from this equation and found to remain constant. Here $[OCl^-] = x$, $[HCOO^-] = y$, and $[OH^-] = z$, and x_0, y_0, and z_0 are the initial concentrations. Since there is a small spontaneous decomposition of sodium hypochlorite, a small correction for this was applied to the observed rate (and hence to the rate constant) using values of the rate constant for this decomposition obtained by Lister (1, 2). The average correction was 2.2%. The rate constants, which are given in Table II, have been corrected in this way.

TABLE II

Run	Temp. (°C)	Initial ionic strength	Initial [NaOCl]	Initial [$NaHCO_2$]	Initial [NaOH]	$k\times10^5$ (min^{-1})
1	60.0	0.653	0.0472	0.1215	0.00782	1.49
2	"	0.653	0.0473	0.1215	0.00782	1.41
3	"	1.05	0.0496	0.1215	0.00782	1.55
4	"	1.05	0.0497	0.1215	0.00782	1.62
5	"	1.10	0.0460	0.1620	0.01534	1.60
6	"	1.10	0.0460	0.1620	0.01534	1.57
7	"	1.17	0.1219	0.0405	0.00826	1.59
8	"	1.17	0.1221	0.0405	0.00826	1.57
9	"	1.84	0.0481	0.1215	0.00782	1.70
10	"	1.84	0.0482	0.1215	0.00782	1.70
11	"	1.85	0.0468	0.1215	0.01534	1.72
12	"	1.85	0.0468	0.1215	0.01534	1.73
13	50.0	1.04	0.0907	0.1221	0.00816	0.77
14	"	1.04	0.0908	0.1221	0.00816	0.77
15	70.0	1.05	0.0449	0.1209	0.01526	3.81
16	"	1.05	0.0449	0.1209	0.01526	3.82

The inverse dependence of the rate on concentration presumably shows that this is really a reaction of hypochlorous acid:

$$OCl^- + H_2O \rightarrow HOCl + OH^- \quad \text{(fast)}$$
$$HOCl + HCOO^- \rightarrow Cl^- + H_2CO_3 \quad \text{(slow)}$$
$$H_2CO_3 + 2OH^- \rightarrow CO_3^{=} + 2H_2O \quad \text{(fast).}$$

The extra proton is presumed to be attached to the hypochlorite rather than the formate ions, since formic acid is over 4000 times stronger than hypochlorous acid.

For the above mechanism the true rate constant of the slow step (k_T), defined by

$$\text{rate} = k_T[HOCl][HCO_2^-],$$

is related to the apparent rate constant, k, by

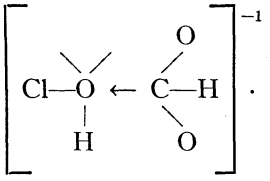
$$k_T = kK_a/K_W,$$

where K_a is the ionization constant of hypochlorous acid and K_W the ionic product of water. Using the known values of K_a and K_W at 60° C ($K_a/K_W = 1.93\times10^{-6}$ at 60° C), we get $k_T = 8.2$ (g-mol/l.)$^{-1}$ min^{-1} at 60° C, and an ionic strength of 1.05.

The apparent activation energy obtained from k is 17.7 kcal/g-mol. As ΔH for the hydrolysis of hypochlorite ions is about 11.0 kcal, this means that the true activation energy of the slow stage is only 6.7 kcal/mole. If k_T is given by the usual relation, $k_T = Ae^{-E\ddagger/RT}$, then $\log A = 3.53$ (time in seconds). This is unusually small, but similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

low values have been found for the reaction of hypochlorous acid with bromide ions (3) or nitrite ions (4). Also somewhat analogous oxidations by hydrogen peroxide have low values of log A, which are explained by Edwards (5) in terms of a transition complex requiring rather special orientation. If the same idea is applied to the present case the transition complex would be



The effect of ionic strength is to give a rather small increase in the rate of reaction with increasing ionic strength, as is to be expected for a reaction between an ion and a neutral molecule. Finally it may be noted that in acid solution the rather similar oxidations of formate ions by halogens have been shown (6, 7, 8) to be reactions of free halogen molecules, $HCOO^- + X_2 + H_2O \rightarrow CO_2 + H_3O^+ + 2X^-$, and are not due to hypohalous acid.

EXPERIMENTAL

Mixtures of aqueous solutions of sodium hypochlorite, sodium hydroxide, and sodium formate of known concentration were made up. Sodium chloride was added to control the ionic strength. The solutions were kept in a thermostat; samples were taken at frequent intervals, quenched in an ice bath, and analyzed as described below.

Sodium hypochlorite was estimated by measuring the absorbance of the solution on a Beckmann DU spectrophotometer. The extinction coefficient of OCl^- at 292 mμ is 350, while sodium formate, and other constituents of the solution, absorb negligibly at this wavelength. For the estimation of formate, a 5-ml aliquot was mixed with 25 ml of water containing 2 g, of sodium carbonate. Hydrogen peroxide (10 ml; 3%) was added to destroy the hypochlorite. Potassium permanganate (0.1 ml; 0.1 N) was added, and the mixture was boiled for 5 minutes to decompose excess peroxide. The solution was cooled, 25 ml of standard potassium permanganate (0.1 N) was added, and the solution was heated on a steam bath for 10 minutes. The sodium formate is quantitatively oxidized by the permanganate under these conditions. The excess potassium permanganate was estimated by acidifying the solution, adding 3 g of potassium iodide, and titrating the iodine with sodium thiosulphate.

LYCOPODIUM ALKALOIDS

XIV. FLABELLINE

J. C. F. YOUNG[1] AND D. B. MACLEAN

Department of Chemistry, McMaster University, Hamilton, Ontario

Received May 27, 1963

ABSTRACT

A new alkaloid, $C_{18}H_{28}ON_2$, designated flabelline, has been isolated by countercurrent distribution from the extract of *Lycopodium flabelliforme*. The structure and stereochemistry of flabelline have been established by its conversion to and preparation from lycopodine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The investigation of the alkaloids of *Lycopodium flabelliforme* was undertaken by Manske and Marion in 1942 (1). They reported the isolation of lycopodine, the bases L1 to L6, and nicotine. Base L1 has since been shown to be dihydrolycopodine (2), L2 to be acetyldihydrolycopodine (3), and L6 to be a mixture of two compounds, α- and β-obscurine (4). The structures of lycopodine and its derivatives (2) and the obscurines (5) are now known.

Flabelliformine, a hydroxy derivative of lycopodine, was recently isolated from this plant, and its structure elucidated (6).

In this communication we wish to report the isolation and structural elucidation of flabelline, another minor alkaloid of *L. flabelliforme*. The separation procedure used in working up the alkaloids is given in some detail since some fractions are still being investigated and will be reported upon in a subsequent paper.

The alkaloid was extracted according to the procedure of Manske and Marion (1) and the bulk of the lycopodine separated by the method of Barclay and MacLean (7). The residual alkaloids from a number of extractions collected over a period of several years were combined and subjected to a preliminary purification as described in the experimental section. The bases were then subjected, on a large scale, to column chromatography on alumina and divided into three fractions—those eluted with chloroform, those eluted with 2% methanol in chloroform, and a residue eluted with 5% methanol in chloroform. From the chloroform fraction, flabelliformine containing some dihydrolycopodine separated upon treatment with ether. The mother liquor from the separation of flabelliformine was concentrated and the residual bases distributed between chloroform and pH 6.0 citrate–phosphate buffer in a 12-funnel distribution. The distribution was carried out on a large scale and served merely to separate the weak from the strong bases. Many more transfers with a much smaller amount of base would have been necessary to achieve discrete separation of individual bases.

Fractions 1 and 2 from the distribution were almost pure dihydrolycopodine; fractions 3 and 4, a mixture of dihydrolycopodine and flabelline; and fraction 5, a mixture of

[1]*Holder of a National Research Council Bursary 1960–1961 and a Studentship 1961–1962.*

flabelline, flabelliformine, and α-obscurine. The dihydrolycopodine–flabelline mixture was separated by subjecting it to a 49-tube countercurrent distribution. The flabelline after recrystallization from ether–acetone melted at 185–187.5°, and its analysis was in agreement with the formula $C_{18}H_{28-30}ON_2$. The perchlorate of flabelline melted at 280–282° with decomposition. This is the same melting point as that reported by Manske and Marion for L5 perchlorate (1). A comparison of the two substances revealed that they were not identical. The investigation of fractions 6 to 12 has not been completed.

The presence of a secondary amide function in flabelline may be inferred from its infrared spectrum. In Nujol mull the presence of an >NH group is indicated by the split peak at 3180–3250 cm^{-1}. In dilute solution in chloroform the >NH absorption appears at 3415 cm^{-1}. As the concentration of the solution increases, a band shifting from 3315 cm^{-1} to 3270 cm^{-1} appears. This band has been assigned to trans intermolecular hydrogen bonding (8). The Nujol spectrum shows bands at 1645, 1550, and 1300 cm^{-1} which appear at 1656, 1475, and 1308 cm^{-1} in the chloroform spectrum. These peaks are the amide I, II, and III bands, respectively (9).

The ultraviolet spectrum of flabelline does not exhibit any strong absorption above 220 mμ but has strong end absorption.

The n.m.r. spectrum (60 Mc/sec) of flabelline in deuterochloroform shows a broad singlet of intensity corresponding to one proton shifting continuously from $\tau = 2.72$ at high concentration to $\tau = 3.39$ at lower concentration. This has been assigned to the amide >NH, and the chemical shift is assumed to be associated with the change in degree of intermolecular hydrogen bonding with the change in concentration. A singlet at $\tau = 7.98$ with intensity corresponding to three protons has been assigned to the methyl of an acetamide group. A doublet centered at $\tau = 9.11$ ($J = 6$ cycles/sec) indicates a >CH—CH_3 group. Because of underlying absorption, the integrated area of this peak is somewhat greater than three protons. Other peaks in the spectrum have not been assigned to specific groups in the molecule. The absence of absorption (other than that of the >NH group) below $\tau = 6$ precludes the presence of ethylenic protons.

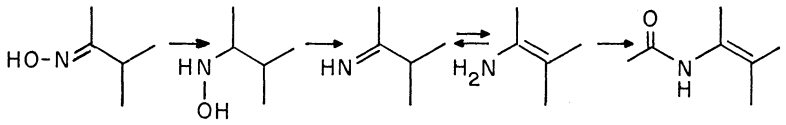
The spectroscopic data are compatible with the presence of an acetamide group in flabelline. The formation of a methiodide by interaction with 1 mole of methyl iodide implies that the basic nitrogen is tertiary. Since the n.m.r. spectrum does not have a peak corresponding to an >N—CH_3 group, one must conclude that the basic nitrogen is part of two rings. It seemed, therefore, that structure I, embodying those features and based upon the structure of lycopodine, II, was a reasonable representation for flabelline. Apparent confirmation of structure I for flabelline was obtained through the following series of reactions. Lycopodine was converted to its oxime, dissolved in acetic anhydride, and treated with hydrogen at 75 atm pressure and at 100°. The product of this reaction proved to be identical with flabelline. The melting points of synthetic and natural flabelline and a mixture of the two were identical. The infrared spectra of synthetic and natural flabelline, as well as those of their perchlorates, were superimposable. Thus structure I was apparently established as the structure of flabelline.

The mass spectrum of flabelline shows that the alkaloid has a mass of 288 and not 290, as required of structure I, and thus flabelline must contain one additional center of unsaturation. By placing a double bond at the 7,8-position of ring C, a structure, III, of the proper mass is obtained which is still compatible with the spectroscopic and chemical data cited above. Confirmation of structure III was obtained by treating flabelline with aqueous hydrochloric acid. Lycopodine was the sole hydrolysis product and was isolated in quantitative yield. It should be pointed out that the 6,7-position for the double bond,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

although compatible with the hydrolysis reaction, is not compatible with the n.m.r. data.

An explanation for the formation of the enamine III rather than the saturated amine I in the reduction reaction is offered below. Reduction of the oxime to the hydroxylamine, followed by dehydration and rearrangement to the enamine and acetylation of the latter would yield the desired product:

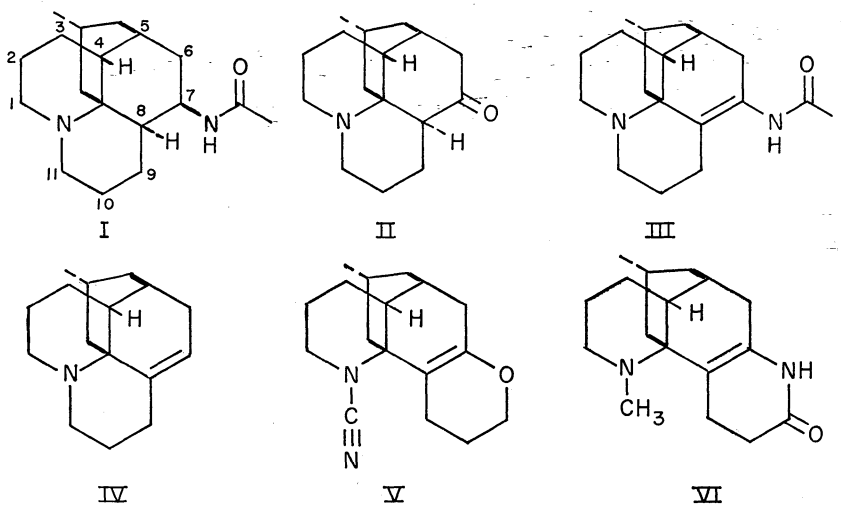


The fact that the reduction does not proceed further is not unexpected, for a double bond in the 7,8-position in the lycopodine skeleton is known to resist the addition of hydrogen. Thus it has been reported that anhydrodihydrolycopodine IV and the enol ether V are not affected at this site under conditions as stringent as those used here (2).

The ultraviolet spectrum of flabelline is worthy of comment. It does not exhibit an absorption band above 220 mμ, although its cyclic analogue, α-obscurine, VI, has an intense peak at 255 mμ. The intense absorption in α-obscurine at higher wavelength may be a consequence of the rigidity imposed upon the chromophore in the cyclic system. Although the preparation of acetylated enamines has recently been reported (10), their ultraviolet spectra were not recorded and thus no analogous cases were available for comparison.

The stereochemistry of flabelline depicted in III follows from its conversion to and preparation from lycopodine, the configuration of which is known (11, 12).

The biogenesis of flabelline can be accommodated by the proposal of Conroy (13). This is the first example of an alkaloid with the lycopodine skeleton carrying a second nitrogen atom, and in this respect its formation is an interesting variation in the usual biogenetic pathway.



EXPERIMENTAL

Apparatus, Methods, and Materials

All melting points were taken on a Kofler Micro Hot Stage. Infrared spectra were measured in Nujol mull unless otherwise specified and were determined on a Beckman Model IR-5 recording spectrophotometer with a sodium chloride prism. Ultraviolet spectra were measured in methanol on a Perkin–Elmer Model

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

4000 Spectrocord. The nuclear magnetic resonance spectra were measured on a Varian V-4300 B high-resolution spectrometer at a frequency of 60 Mc/sec. The n.m.r. spectra were measured in concentrated deuterochloroform solutions with tetramethylsilane as an internal standard. Chemical shifts are given on the τ scale of Tiers. The mass spectrum was run on a CEC 21–103C mass spectrometer equipped with a heated inlet system at an ionizing voltage of 70 ev and an ionizing current of 50 μa.

The crude extract used in these experiments was isolated in these laboratories over a period of several years from *L. flabelliforme* collected in the Wentworth Valley of Nova Scotia. The dry, ground plant material was extracted by the procedure of Manske and Marion (1). Lycopodine was isolated by column chromatography as described by Barclay and MacLean (7). The other more strongly adsorbed alkaloids were eluted and combined to give the mixture of crude alkaloids used in these experiments.

Preliminary Purification of Crude Alkaloids

To a collection of the crude alkaloids obtained after removal of lycopodine were added several liters of water and several hundred grams of tartaric acid. The resultant solution was steam-distilled to remove organic solvents used in the original extractions. Several more liters of water were added to the distillation residue, and the aqueous solution was shaken with about 60 g of powdered celite. Suction filtration through a pad of celite yielded a dark red filtrate which was then extracted twice with ether to remove fatty, non-basic material. The aqueous solution was basified with ammonia and extracted with chloroform. The chloroform extract was washed with water, and evaporated to dryness, yielding about 200 g of a black, tar-like residue.

First Chromatography of Crude Alkaloids

About 75 g of the crude alkaloid extract was taken up in a minimum of warm chloroform and adsorbed on a 5×45 cm column of alumina. The column was eluted with chloroform until the eluate was almost colorless. The eluates were combined and evaporated to dryness, yielding 50 g of dark resinous material. The column was then eluted with 2% methanol in chloroform and 5% methanol in chloroform, yielding dark resinous fractions weighing 14 g and 3 g, respectively.

Isolation of Flabelliformine

The mixture of crude bases obtained by elution with chloroform partially crystallized and the semisolid mas was shaken with cold ether. The insoluble crystalline material (13.0 g) which separated was worked up as described by Curcumelli-Rodostamo and MacLean (6) to yield flabelliformine as the major and dihydrolycopodine as the minor component.

First Separatory Funnel Distribution of Crude Bases

The mother liquor obtained from the separation of crude flabelliformine was evaporated to dryness and the resultant residue was dissolved in 350 ml of chloroform. The chloroform solution was then shaken with 350 ml of a pH 6.00 citrate–phosphate buffer solution for 15 minutes in a 1-liter separatory funnel. The chloroform phase, after separation was complete, was transferred to a second separatory funnel containing 350 ml of fresh buffer solution, and 350 ml of fresh chloroform was added to the first separatory funnel. Both funnels were then shaken for 15 minutes each. This procedure was continued until 12 transfers had been completed.

The resulting extracts were worked up as outlined below. The chloroform fractions were separated from their respective buffer fractions and each washed with ammonia to basify any salts which may have formed. The chloroform extracts were then dried over anhydrous sodium sulphate and evaporated to dryness in tared flasks. The buffer fractions were basified with ammonia and extracted with chloroform. The chloroform extracts were then dried over anhydrous sodium sulphate and evaporated to dryness in tared flasks. Each flask was weighed, the weights of the bases in each flask being recorded (see Table I).

TABLE I

Distribution of alkaloids

Flask No.	Buffer fraction (wt. in g)	Chloroform fraction (wt. in g)	Flask No.	Buffer fraction (wt. in g)	Chloroform fraction (wt. in g)

Resolution of Fraction 1

Crystalline material formed on treatment with acetone. Recrystallization from acetone yielded 3.0 g of dihydrolycopodine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Resolution of Fraction 2

This fraction was worked up in the same manner as fraction 1, yielding 4.0 g of dihydrolycopodine.

Resolution of Fraction 3

Crystalline material formed on treatment with acetone. Recrystallization from acetone yielded two crops of dihydrolycopodine weighing 2.0 and 0.5 g. The filtrate was evaporated to dryness, dissolved in a minimum of chloroform, and adsorbed on a column of alumina. Elution with 0.5% methanol in chloroform effected removal of a yellow band, giving 1.26 g of a yellow oil which resisted all attempts at crystallization. The oil was taken up in acetone, made slightly acid with perchloric acid, and treated with water until the solution was turbid. The crystals which separated were recrystallized from acetone–methanol to give small white crystals melting above 258° (with decomposition and effervescence). The infrared spectrum showed bands at 3480 cm^{-1}, 3300 cm^{-1}, a shoulder at 3150 cm^{-1}, and bands at 1650 cm^{-1} and 1515 cm^{-1}. The mixture of salts was taken up in water, basified with ammonia, and extracted with chloroform. The combined extract was dried over anhydrous sodium sulphate and evaporated to dryness. The residue was combined with fraction 4 and distributed between chloroform and buffer solution (*vide infra*).

Resolution of Fraction 4

This fraction was taken up in a minimum of chloroform, adsorbed on a column of alumina, and eluted with 0.5% methanol in chloroform. A yellow band passed through the column from which a yellow oil was obtained. Treatment with acetone–methanol gave yellow crystals which melted at 150–163°. The infrared spectrum showed bands in the NH region at 3250 cm^{-1}, and in the amide carbonyl region at 1650 cm^{-1} and 1515 cm^{-1}. The crystalline material and filtrates were combined with the residue from fraction 3 and distributed as described in the next section.

Countercurrent Distribution of Fraction 3 and Fraction 4

The residues remaining after removal of dihydrolycopodine from fraction 3 and fraction 4 were combined and dissolved in 50 ml of chloroform. The chloroform solution was divided and placed in the first two tubes of a 49-tube Craig countercurrent extractor. The alkaloid mixture was then distributed between chloroform and pH 6.0 citrate–phosphate buffer solution. The machine was agitated for 15 minutes for each transfer, the buffer layer being the moving phase. When the 49 transfers had been completed, the contents of each tube were made alkaline with ammonia, shaken, and the chloroform layer removed. The remaining aqueous layers were then extracted with fresh chloroform. The chloroform extract for each tube was dried over anhydrous sodium sulphate and evaporated to dryness in tared flasks.

Fractions 35–38 were taken up in acetone and combined. After initial concentration of the solution, ether was added and the solution further concentrated. Yellow rhombic crystals formed on cooling. These crystals (250 mg), after filtering and washing with 2:1 ether–acetone, melted at 185–187.5°. Calc. for $C_{18}H_{28}ON_2$: C, 75.00; H, 9.72; N, 9.72. Found: C, 75.11; H, 9.89; N, 9.45.

The infrared spectrum of flabelline showed a split band at 3250 cm^{-1} and 3180 cm^{-1} in the NH region, and absorption at 1645 cm^{-1}, 1550 cm^{-1}, and 1300 cm^{-1} attributed to the amide I, II, and III bands. The infrared spectra of fractions 39–43 showed the presence of flabelline, and they were combined, adsorbed on a column of alumina, and eluted with 1:1 benzene–chloroform. A wide yellow band passed through the column from which was obtained a yellow oil which crystallized on treatment with 2:1 ether–acetone. Recrystallization from 2:1 ether–acetone yielded about 400 mg of flabelline.

Fractions 44–48 had similar infrared spectra and were combined, adsorbed on a column of alumina, and eluted with 1.5% methanol in benzene. A fluorescent band quickly passed through the column from which light yellow crystals were obtained. Recrystallization from ether – petroleum ether gave about 250 mg of dihydrolycopodine.

Resolution of Fraction 5

This fraction was taken up in benzene, adsorbed on a column of alumina, and successively eluted with 1:1, 1:2, and 1:3 benzene–chloroform. The resultant 15 fractions were collected into three groups on the basis of their infrared spectra. Treatment of the first group with ether gave an amorphous precipitate which was then crystallized from 2:1 ether–acetone, yielding flabelline. The filtrate was taken up in 10% aqueous acetic acid and treated with excess perchloric acid. A dark solid and a crystalline material came down on standing in a refrigerator. Filtration yielded 125 mg of dark solid and 108 mg of crystals, both showing infrared spectra similar to that of flabelline perchlorate. After the filtrate was concentrated and allowed to stand, flabelliformine perchlorate (59 mg) separated. The second group resisted all attempts to obtain a crystalline compound. The third group was taken up in a 2:1 ether–acetone and yielded long needles on standing in a refrigerator. Several recrystallizations from 2:1 ether–acetone gave needle-like crystals of α-obscurine.

Preparation of Flabelline Methiodide

A solution of flabelline (79 mg) in 4 ml of acetone and an excess of methyl iodide was heated under reflux for 3 hours. Crystallization was induced by concentration and scratching. After filtration and recrystallization from acetone–methanol, flabelline methiodide melted sharply at 281–282°. Calc. for $C_{18}H_{28}ON_2 \cdot CH_3I$: C, 53.02; H, 7.20; N, 6.51%. Found: C, 53.15; H, 7.34; N, 6.14%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The infrared spectrum had N—H absorption at 3200 cm^{-1} and carbonyl absorption at 1653 cm^{-1}.

Preparation of Flabelline Perchlorate

Several drops of perchloric acid were added to a solution of flabelline (40 mg) in a minimum of warm 10% acetic acid. The resultant 37 mg of short white needles was removed by filtration and melted at 280–282° (with decomposition). Calc. for $C_{18}H_{23}ON_2 \cdot HClO_4$: C, 55.60; H, 7.46; N, 7.20%. Found: C, 55.44; H, 7.30; N, 7.00%.

Preparation of Lycopodine Oxime

To lycopodine (600 mg) dissolved in 10 ml of 95% aqueous ethanol was added a solution of hydroxylamine hydrochloride (600 mg) in 10 ml of 95% aqueous ethanol. Addition of potassium hydroxide pellets (3.0 g) and more ethanol (20 ml) resulted in formation of a white precipitate. The reaction mixture was heated under reflux for 3 hours and then cooled. After the ethanol had been removed, the residue was taken up in water and treated with dilute hydrochloric acid until the solution was only slightly basic. The resultant precipitate was filtered to give 440 mg of lycopodine oxime. Recrystallization from ethanol gave crystals melting at 275–277°. Douglas, Lewis, and Marion (3) report a melting point of 262–264°. Calc. for $C_{16}H_{26}ON_2$: C, 73.24; H, 9.99; N, 10.68. Found: C, 73.01; H, 9.79; N, 10.76.

Hydrolysis of Flabelline

Flabelline (50 mg) was dissolved in 10 ml of concentrated hydrochloric acid and the solution heated under reflux for 12 hours. The solution was made basic and extracted with ether. The dried ether extract upon evaporation yielded lycopodine, identified by comparison of its melting point and infrared spectrum with an authentic sample. The yield was quantitative.

High-pressure Reduction and Acetylation of Lycopodine Oxime with Raney Nickel and Acetic Anhydride

Lycopodine oxime (248 mg), dissolved in 40 ml of redistilled acetic anhydride, was treated with hydrogen (1160 p.s.i.g.) and Raney nickel (several hundred milligrams) at 100° for 24 hours. Excess acetic anhydride was destroyed with ice, and the catalyst removed by filtration. The filtrate was made alkaline with ammonia and extracted with chloroform. The extract was dried over anhydrous sodium sulphate and evaporated to dryness under reduced pressure, leaving a yellow oil which showed an infrared spectrum almost identical with that of flabelline. The residue was adsorbed on a column of alumina and eluted with 1:1 benzene–chloroform. A small amount of lycopodine quickly passed through the column, whereas the major product passed very slowly through the column. The eluates containing the bulk of the product were evaporated to dryness under reduced pressure to give about 100 mg of crystalline material showing an infrared spectrum identical with that of flabelline. Recrystallization from acetone–ether gave rectangular plates which showed no depression of the melting point on admixture with naturally occurring flabelline. The infrared spectrum of the crystalline product was identical with that of natural flabelline.

ACKNOWLEDGMENTS

One of us (D. B. M.) spent the academic year 1962–1963 as a guest of the Department of Chemistry, Massachusetts Institute of Technology, in the laboratories of Professor K. Biemann, where a part of this work was carried out, and wishes to thank Professor Biemann for his hospitality during the year.

We are indebted to the National Research Council and the Ontario Research Foundation for financial support of this work. We wish to thank Dr. L. Marion for a sample of L5 perchlorate.

THE EFFECT OF PHENOLS AND AROMATIC THIOLS ON THE POLYMERIZATION OF METHYL METHACRYLATE[1]

S. C. BARTON, R. A. BIRD, AND K. E. RUSSELL
Department of Chemistry, Queen's University, Kingston, Ontario
Received June 11, 1963

ABSTRACT

Chain transfer constants of a number of phenols in the polymerization of methyl methacrylate have been determined. They are small compared with the corresponding transfer constants with styrene, a maximum value of 0.0026 being observed with pyrogallol. Three deuterated phenols do not have a measurable effect on the rate and degree of polymerization, showing that attack takes place mainly at the O—H group.

The aromatic thiols investigated have transfer constants in the range 2.6 to 7.4. They cause only slight retardation of polymerization, and efficiencies of reinitiation by aromatic thiol radicals are estimated to be at least 95%. The transfer constants of meta-substituted thiols do not differ greatly from that of benzenethiol showing that inductive effects are small. A wider range of reactivities is observed with the para-substituted thiols, indicating the existence of small but significant resonance effects.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A study of the effect of phenols on the polymerization of styrene (1) has shown that most simple phenols do not retard the polymerization significantly and that their transfer constants are less than 0.008. Some phenols, such as 1-naphthol and 4-methoxyphenol, decrease the rate and degree of polymerization to an intermediate extent while catechol, *t*-butylcatechol, and pyrogallol act as fairly strong retarders with transfer constants approaching 1. The present work gives results of a comparable study using polymethyl methacrylate radicals as the hydrogen acceptors. These radicals differ in reactivity and polarity from polystyryl radicals and it is of interest to compare their rates of reaction with phenols of varying structure. Caldwell and Ihrig (2) have suggested that an addition complex is formed between a polymethyl methacrylate radical and hydroquinone prior to hydrogen abstraction. Information on this point has been obtained by comparison of the transfer activities of phenols and deuterated phenols.

The investigation was extended to the aromatic thiols because simple phenols are too unreactive to show detailed effects of meta and para substitution. An estimate of the influence of electron withdrawal on the transfer process was made from the results for certain meta-substituted thiols. Transfer constants were also determined for deuterated 4-chlorobenzenethiol and 2-naphthalenethiol.

EXPERIMENTAL

Materials

Methyl methacrylate was washed several times with sodium hydroxide solution and water and dried over calcium chloride at 0°. It was distilled at reduced pressure in an atmosphere of nitrogen and degassed on the high-vacuum line. After being stirred with calcium chloride for 1 hour it was subjected to two vacuum distillations and was stored at −78.5°. The phenols were either recrystallized and dried in a vacuum desiccator or sublimed at reduced pressure. Hydroquinone (Matheson, Coleman and Bell) was used without further purification since recrystallization from benzene–acetone mixtures in an atmosphere of nitrogen led to a more strongly retarding product. The deuterated phenols were prepared by dissolving them in a mixture of heavy water and deuterated methanol, followed by removal of the water and methanol at reduced pressure. Infrared analysis showed that conversion to deuterated phenol was greater than 85%.

Benzenethiol, 3- and 4-methylbenzenethiol, 4-chlorobenzenethiol, and 2-naphthalenethiol were commercial products which were purified by distillation or recrystallization. The remaining thiophenols were prepared

[1]*Presented in part at the Eleventh Canadian High Polymer Forum, Assumption University of Windsor, Windsor, Ontario, September 1962.*

by the xanthate method (3): 3-chlorothiophenol, b.p. 203–205° and n_D^{20} 1.6028; 3-bromothiophenol, b.p. 130–132° at 40 mm and n_D^{20} 1.6322; 3-acetylthiophenol, b.p. 143–144° at 12 mm and n_D^{20} 1.6012; 4-bromothiophenol, m.p. 74.5–75.2°; 4-acetylthiophenol, m.p. 27–28.5°.

Azobisisobutyronitrile was recrystallized from ether and stored at 0°.

Procedure

Azobisisobutyronitrile (0.02 g) was weighed into the reaction tube, a known amount of phenol or deuterated phenol up to a maximum of 0.25 g was added and the tube was evacuated. About 5 ml methyl methacrylate was distilled into the tube and, after sealing off, the reaction tube and contents were quickly weighed and placed in a bath at 45.00±0.04°. After approximately 3% of the monomer had been converted to polymer the tube was cooled and the polymer precipitated in methanol and dried *in vacuo* at 60°.

The thiols were added in small glass vials in quantities of the order of 0.001 g to about 15 ml monomer. Significant exchange occurred when deuterated thiols were used and 0.05 g heavy water was added to the reaction mixture to maintain the thiol almost entirely in the deuterated form. This procedure was suggested by Howard and Ingold after its successful use in their autoxidation studies (4). The heavy water has no significant effect on the polymerization in the absence of phenol.

Intrinsic viscosities of the polymethyl methacrylate samples were determined at 20° with chloroform as solvent, and degrees of polymerization were calculated using the relationship (5)

$$\log \bar{P}_n = 3.261 + 1.256 \log [\eta].$$

This relationship between $\bar{P}_n$, the number-average degree of polymerization and $[\eta]$, the intrinsic viscosity, was determined for unfractionated samples and it is probable that the polymer produced in these experiments with phenols and thiols has a similar molecular weight distribution. O'Brien and Gornick (6) state that their equation relating degree of polymerization and intrinsic viscosity in benzene solution applies to polymer samples produced with and without transfer agent; in general, however, it gives somewhat lower values of the number-average degree of polymerization than the above relationship.

Densities of solutions of phenols in methyl methacrylate were determined at 45°.

RESULTS AND DISCUSSION

Transfer Reaction with Phenols

The phenols investigated caused little or no retardation of the polymerization of methyl methacrylate at 45° and there was no evidence for induction periods. The maximum retardation observed was only 8% and this occurred with 0.28 *M* pyrogallol. In some solutions, e.g. of 4-methoxyphenol, the rate of polymerization was slightly greater than that predicted from the rate of polymerization of pure methyl methacrylate. Azobisisobutyronitrile decomposes more rapidly in solutions of phenols in benzene (1) and the increased rate of polymerization may be in part due to a more rapid breakdown of the initiator. It is probable that all phenols are potential retarders but in some cases the retarding influence is so weak that it is masked by another effect of the phenol, e.g. on the initiation process.

The measured retardation by hydroquinone at concentrations up to 0.2 *M* was less than 1%. Caldwell and Ihrig (2) observed a retardation of 13.7% with a 0.169 *M* solution of hydroquinone in methyl methacrylate. They show that the polymerization is extremely sensitive to traces of benzoquinone and it is probable that the retardation was due to the presence in their system of benzoquinone at a concentration of approximately 2×10^{-5} *M*.

The degree of polymerization of the polymethyl methacrylate was decreased only to a slight extent by the addition of phenols. Since the rate of polymerization is largely unaffected by phenols, transfer constants have been calculated using the simple transfer equation

$$\frac{1}{\overline{P}_n} = \frac{k}{k_p^2}\frac{R_p}{[M]^2} + C_X\frac{[X]}{[M]} + C_M,$$

where k is a function of the rate constants for termination by disproportionation and combination, k_p is the propagation rate constant, R_p is the rate of polymerization, X and M

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

represent phenol and monomer, and C_X and C_M are the transfer constants for phenol and monomer respectively. The constant k/k_p^2 was determined experimentally using solutions containing initiator and monomer only. C_M was determined from the variation of $\overline{P_n}$ with initiator concentration and was found to be approximately 5×10^{-6} at 45°; this compares with a value of 7×10^{-6} at 60° determined by O'Brien and Gornick (6). Transfer constants for a number of phenols are given in Table I. The reproducibility of the results suggests

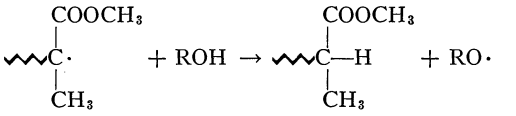
TABLE I

Transfer constants of phenols in the polymerization of methyl methacrylate and styrene

Phenol	Transfer constant with methyl methacrylate (45°)	Transfer constant with styrene (60°)
4-Methoxyphenol	<0.0005	0.026
1-Naphthol	<0.0005	0.048
Catechol	<0.0005	0.134
4-*t*-Butylcatechol	0.0009	0.36
2,3,4,6-Tetramethylphenol	0.0011	0.058
Pyrogallol	0.0026	1.04
Hydroquinone	0.0007	—

a maximum error of 0.0005 in C_X but since the experimental values of C_X for deuterated phenols were in the range 0 to −0.0008, results calculated from the above equation may be lower than the true values. It is possible that all the transfer constants quoted should be increased by as much as 0.001; a similar conclusion was reached in the investigation of the effect of phenols on the polymerization of styrene (1).

The reactivities of phenols towards polymethyl methacrylate radicals are relatively low but the significant retardation of polymerization and decrease in degree of polymerization caused by 2,3,4,6-tetramethylphenol, 4-*t*-butylcatechol, and pyrogallol indicate that a transfer reaction between polymer radical and phenol can occur. The corresponding deuterated phenols do not retard the polymerization and their transfer constants are smaller than those of undeuterated phenols. The main transfer reaction must therefore involve the attack of a polymethyl methacrylate radical on a phenol molecule at the O—H group:



[1]

Caldwell and Ihrig (2) have interpreted their results on the polymerization of methyl methacrylate in the presence of hydroquinone in terms of a preliminary complex formation between the polymer radical and the phenol. If complex formation occurs with 2,3,4,6-tetramethylphenol, 4-*t*-butylcatechol, or pyrogallol, it does not prevent the observation of a significant isotope effect.

The phenoxy radicals formed in reaction [1] can either reinitiate polymerization or be lost by reaction with a polymethyl methacrylate or phenoxy radical. Analysis of the rate measurements by the method of Allen, Merrett, and Scanlan (7) indicates that with pyrogallol, for example, over half the phenoxy radicals reinitiate polymerization by reaction with monomer molecules. If however the pyrogallol causes a significant increase in rate of decomposition of the initiator, the efficiency of reinitiation may well be considerably less than 50%.

Table I shows a comparison of transfer constants of phenols in the polymerization of methyl methacrylate and styrene. The transfer constants with styrene were obtained at 60° while those for methyl methacrylate were obtained at 45°, but preliminary results indicate that transfer constants of phenols vary only slightly with temperature. The observation of a great difference in transfer activity is not confined to phenols as hydrogen donors. Walling has noted that whereas polymethyl methacrylate radicals have a higher reactivity than polystyryl radicals towards toluene, the reverse is true for the substrate 1-butanethiol (8). Both he and Bamford (9) conclude that the difference in relative reactivity has its origin in a polar effect. Bamford has shown that rate constants for abstraction reactions can be correlated by the equation

$$\log k_s - \log k_{3,T} = \alpha\sigma + \beta,$$

where k_s and $k_{3,T}$ are the rate constants for the reactions of a polymer radical with substrate and toluene respectively, σ is an estimated Hammett σ constant for the radical and α and β are constants for a given substrate. Approximate α values of -9.5 for pyrogallol and 4-*t*-butylcatechol and -6.5 for 2,3,4,6-tetramethylphenol are obtained if it is assumed that the transfer constants for phenols in methyl methacrylate are the same at 45° and 60°. These α values are unusually large and they indicate that the rate constants for hydrogen abstraction from phenols are strongly influenced by polar substituents in the radical. Phenols appear to belong to the same class of substrates as 1-butanethiol and ferric chloride, and Walling and Bamford suggest that the high reactivity of polystyryl radicals towards these substrates is due to contributions to the transition state of polar structures involving donation of an electron from the radical to the substrate. Electron-attracting groups in the radical impede electron donation, and the relatively low reactivity of polymethyl methacrylate radicals towards phenols can therefore be ascribed to smaller contributions of polar structures to the transition state.

Transfer Reaction with Thiols

Transfer constants for a number of aromatic thiols in the polymerization of methyl methacrylate at 45° are given in Table II. The main attack of the polymer radical occurs

TABLE II

Transfer constants of thiols in the polymerization of methyl methacrylate

Thiol	Transfer constant (45°)	Thiol	Transfer constant (45°)
Benzenethiol	4.7	4-Methylbenzenethiol	7.4
3-Methylbenzenethiol	4.7	4-Chlorobenzenethiol	4.6
3-Chlorobenzenethiol	3.5	4-Bromobenzenethiol	5.6
3-Bromobenzenethiol	3.8	4-Acetylbenzenethiol	2.6
3-Acetylbenzenethiol	4.2	2-Naphthalenethiol	6.3

at the S—H group as is shown by the considerable decrease in transfer constant when deuterated thiols are used as substrates. Ratios of the transfer constants for deuterated and undeuterated 4-chlorobenzenethiol and 2-naphthalenethiol are 0.41 ± 0.1 and 0.33 ± 0.1 respectively. Wall and Brown (10) obtained a value of 0.25 for the ratio of transfer constants in the reaction of polystyryl radicals with 1-butanethiol at 60°. The observed isotope effects are smaller than those predicted by simple theory (11) but such a result is often observed when processes with low activation energies are involved.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The polymerization is only slightly retarded by the thiols, the maximum observed retardation being 15% with 2-naphthalenethiol and 4-methylbenzenethiol at a concentration of 0.001 *M*. The simple transfer equation has been used in the calculation of transfer constants because the correction for retardation is small and requires a knowledge of the fate of the thiol radicals in the termination reaction (1). A correction in the opposite direction of approximately equal magnitude due to loss of thiol during the first 3% polymerization has also been omitted. The overall error in the transfer constants from these causes is less than 5%. The extent of retardation can be used to estimate the efficiency of reinitiation of polymerization by the thiol radicals (7) assuming that the thiols have no effect on the rate of decomposition of the initiator. Approximately 95% of the 2-naphthalenethiol radicals reinitiate polymerization at a thiol concentration of 0.001 *M*, and the efficiencies with other thiol radicals are greater.

The transfer constants for the meta-substituted thiols yield a Hammett ρ value of -0.23 ± 0.1. This is a measure of the extent to which the inductive contribution of a substituent affects the reactivity of a thiol with polymethyl methacrylate radicals (12). The value is only about 10% of that for the ionic dissociation of the corresponding thiols in 48.9% ethanol (13) and is of opposite sign, and it is clear that inductive effects are of only minor importance. The negative Hammett ρ value suggests that there is a weak contribution to the transition state by polar structures in which the thiol is now the electron donor and the polymethyl methacrylate radical is the acceptor. Substituents such as methyl and bromo, which release charge by resonance interaction, favor polar contributions to the transition state when in the para position; 4-methyl and 4-bromobenzenethiol are thus slightly more reactive than the corresponding meta-substituted thiols. The reverse is true for the acetyl substituent which withdraws charge by resonance interaction, and 4-acetylbenzenethiol has a lower transfer constant than 3-acetylbenzenethiol.

A rough estimate of the difference between the activation energies of the transfer and propagation steps can be obtained by comparing the result of O'Brien and Gornick for the transfer constant of benzenethiol at 60° (6) with the present result of 45°. The result at 60° may be low because of the relatively high conversions used but it is probable that the activation energy for the transfer reaction is at least 2 kcal/mole smaller than that for the propagation reaction. Assuming an activation energy of 6.3 kcal/mole for the propagation reaction (14) the activation energy for the abstraction of a hydrogen atom by a polymethyl methacrylate radical from benzenethiol is estimated to be less than 4.3 kcal/mole.

GLYCOSIDATION OF SUGARS

II. METHANOLYSIS OF D-XYLOSE, D-ARABINOSE, D-LYXOSE, AND D-RIBOSE[1]

C. T. BISHOP AND F. P. COOPER

Division of Applied Biology, National Research Council of Canada, Ottawa

Received April 30, 1963

ABSTRACT

Rates of methanolysis reactions of D-xylose, D-arabinose, D-lyxose, and D-ribose have been determined. It was found that methanolysis of a pentose proceeds to equilibrium through four distinguishable, competing reactions: (1) pentose → furanosides; (2) anomerization of furanosides; (3) furanosides → pyranosides; (4) anomerization of pyranosides. The glycoside compositions at equilibrium are interpreted in terms of stabilities of each of the four glycosides from each sugar as influenced by steric and ionic effects; a system of conformational analysis of furanoside rings is presented. The free energies of reaction in anomerization of pyranosides were in excellent agreement with values calculated from previously reported interaction energies in the pyranoid ring. The relative rates of the reactions were consistent with the view that non-bonded interactions in the methyl glycosides are relieved in the transition states for their interconversions.

The first paper (1) in this series described a study of the reactions of D-xylose in methanolic hydrogen chloride; the four methyl D-xylosides, products of the reaction, were analyzed at different times by gas–liquid chromatography of their fully methylated derivatives. The resulting rate data showed that four reactions could be distinguished: (1) xylose → methyl furanosides, (2) anomerization of furanosides, (3) furanosides → pyranosides, (4) anomerization of pyranosides; a tentative mechanism was proposed.

The present paper describes an extension of this work to the other pentoses, D-arabinose, D-lyxose, and D-ribose; some of the reactions in the D-xylose series were repeated to obtain comparable data. It is shown that the methanolysis of each pentose proceeds via the reactions given above. The equilibrium compositions can be interpreted in terms of relative stabilities of each of the four glycosides from each sugar and the relative reaction rates indicated that non-bonded interactions in the methyl glycosides are relieved in the transition states for their interconversions.

The conditions cited for the reactions were carefully controlled and products in the D-xylose and D-arabinose series were analyzed by gas–liquid chromatography of their fully methylated derivatives as described previously (1). Reaction products in the D-lyxose and D-ribose series were analyzed by gas–liquid chromatography of their fully acetylated derivatives because of the better separations obtained. The rate at which reducing sugar disappeared was measured by gas–liquid chromatography of the acetylated reaction mixture; the pentopyranose tetraacetates, arising from the reducing sugars, were widely separated from the methyl tri-*O*-acetyl pentosides. Separation of individual methyl tri-*O*-acetyl pentosides in this procedure, although not always complete, was sufficient to provide information about the early products of reaction. The use of acetylation avoided the correction required (1) when the methylation procedure was used on reaction mixtures in which reducing sugars were present. The retention volumes (R_v) in Tables I and II illustrate the separations pertinent to this work. The R_v values of derivatives from a single pentose are made relative to the fastest moving component ($R_v = 1.00$) in that series and are not related to the values in another pentose series. For example, the R_v values for the methyl tri-*O*-methyl-D-xylosides are related only to each other.

TABLE I

Retention volumes of methyl tri-*O*-methyl-D-pentosides[a]

	D-Xylose	D-Arabinose		D-Xylose	D-Arabinose
α-Furanoside	1.95	1.00	α-Pyranoside	1.40	2.26
β-Furanoside	1.60	1.31	β-Pyranoside	1.00	2.10

[a]Gas–liquid chromatography on column (4 ft×4 mm) of 10% Carbowax 6000 on Gas-Chrom A, 100–120 mesh; 125° C; 100 ml argon/min. Methyl tri-*O*-methyl-D-ribosides not resolved completely.

TABLE II

Retention volumes of methyl tri-*O*-acetyl-D-pentosides and pentopyranose tetraacetates

	D-Xylose[a]	D-Ribose[a]	D-Lyxose[b]
α-Furanoside	1.24	1.00	1.57
β-Furanoside	1.00	1.32	1.28[c]
α-Pyranoside	1.33	1.08	1.00
β-Pyranoside	1.33	1.48	1.13
Tetraacetates (α, β)	2.67, 2.89	3.35, 3.73	2.47, 3.19

[a]Gas–liquid chromatography on column (8 ft×4 mm) of 13% OF-1-0065 on Chromosorb W, 100–120 mesh (packing prepared by Applied Science Laboratories, State College, Pennsylvania, U.S.A.); 200° C; 80 ml helium/min. Separation of D-arabinose derivatives not attempted.
[b]Column (4 ft×4 mm) of 10% ethylene glycol isophthalate polyester on Gas-Chrom Z, 100–120 mesh; 195° C; 60 ml argon/min.
[c]Identified by inference as the only peak not corresponding to one from an authentic sample.

Methanolysis of a sugar proceeds to equilibrium through four distinguishable, competing reactions and a unified kinetic treatment of the complete process is therefore very complicated. However, it has been possible to establish conditions under which a single reaction predominated. Since the observations were made at constant hydrogen ion concentrations the bimolecular reaction could be expressed in terms of first-order rate kinetics. Compositions of reaction products at different times under specific conditions are given in Tables VIII–XI (see Experimental). Inspection of these results shows that a single reaction was predominant during the early periods and was characterized reasonably well by a first-order rate constant. Minor variations in these rate constants for the initial reactions were probably within experimental error. At later stages deviations from first-order kinetics became noticeable and analysis of the products showed that other reactions were occurring to a significant extent. The rate constants indicated in Table VIII–XI were averaged to give the k_1 values in Table III. To give measurable rates reactions 3 and 4 required 10 and 100 times respectively the concentration of hydrogen chloride used for reactions 1 and 2. No Hammett acidity functions have been reported for the methanol – hydrogen chloride system but it had been found (1) that the rates of all methanolysis reactions of D-xylose were approximately proportional to the acid concentrations. The average first-order rates for reactions 3 (Table X) and 4 (Table XI) were therefore reduced to 1/10 and 1/100 respectively to provide comparable k_1 values (Table III) all relative to 0.01% of hydrogen chloride in methanol. This undoubtedly introduced inaccuracies as far as absolute values were concerned; however, the relative orders of reactivity, of major interest in this work, were probably not disturbed. The equilibrium constants (K) in Table III were obtained from glycoside compositions after prolonged reaction periods (Table V) and the k_2 values were calculated from k_1 and K.

Non-bonded interactions impose certain conformations upon molecules and the principles of conformational analysis have been of considerable assistance in interpreting the physical and chemical properties of the pyranoid sugars (2–5). Although Kilpatrick *et al.*

4. Pyranoside: $\beta \underset{k_2}{\overset{k_1}{\rightleftarrows}} \alpha$	0.031	0.014	0.04	2.2	0.093	0.18	0.27	0.52	0.62	0.072	0.64	8.6	0.02	0.11	0.13	0.176

[a]Reaction 2: $K = [\beta]/[\alpha]$; reaction 3: $K = [\alpha\text{-pyr}][\beta\text{-pyr}]/[\alpha\text{-fur}][\beta\text{-fur}]$; reaction 4: $K = [\alpha]/[\beta]$. Concentrations of products for these calculations were taken from the equilibrium values given in Table V.

(6) showed in 1947 that the cyclopentane ring is puckered, the furanoid sugars have been regarded as essentially planar molecules. However, the fructofuranosyl portion of crystalline sucrose (7) and the ribofuranosyl moiety of crystalline cytidine (8) were both found to have non-planar ring structures. More recently specific conformations, based upon nuclear magnetic resonance spectroscopy, have been proposed for D-ribofuranose in purine and pyrimidine nucleosides (9), in thymidine (10), in certain deoxyribonucleosides (11) and nucleotides (12), and in 1,3,5-tri-*O*-benzoyl-α-D-ribofuranose, methyl 2,3-anhydro-α-D-ribofuranoside, and its β-anomer (13). A specific conformation has also been proposed for a furanose ring having a cis-fused *O*-isopropylidene ring (14). However, no system of conformational analysis has been proposed for furanose sugars that permits the prediction of a preferred conformation and accounts for the chemical properties of the compounds concerned. The system shown in Fig. 1 was derived from a consideration of the non-bonded interactions which should be operative in these molecules.

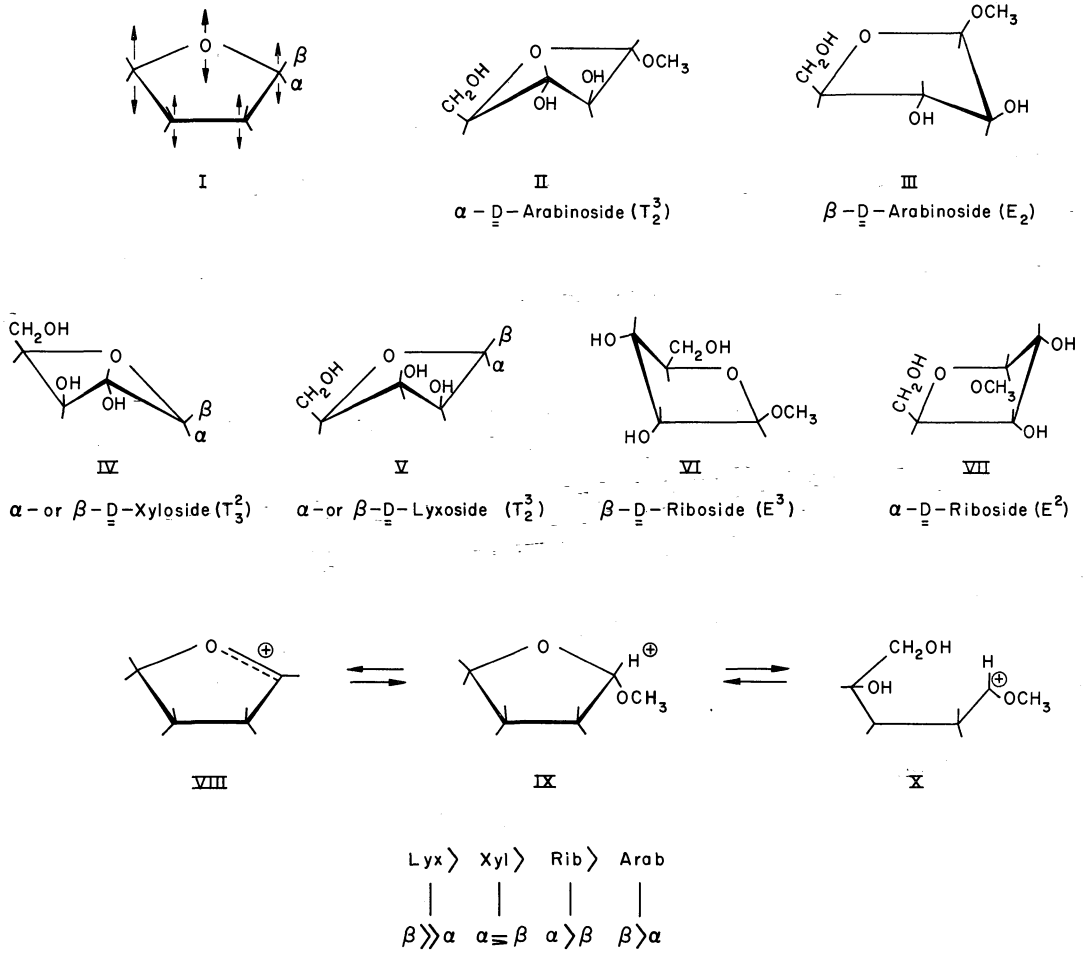

FIG. 1.

The strain inherent in a five-membered ring, cyclopentane or furanoid (I), can be relieved by a slight puckering brought about by movement of one or two atoms out of the plane of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the ring. For cyclopentane, in which all atoms are equivalent, this results in two possible conformations (6): (*a*) the C_s conformation in which a single atom is displaced from the plane of the other four, (*b*) the C_2 conformation in which two atoms are displaced, one above and the other below the plane of the remaining three adjacent atoms. In the furanoid sugars a more definitive designation of conformation is required because of the specific stereochemistry of the carbon atoms in the ring. Jardetzky (12) used a system for the ribofuranose ring in which the carbon atoms displaced from the plane were designated by number and the direction of displacement was related to the orientation of the C_4—C_5 bond by the terms *endo-* or *exo-*. Hall (13) has proposed a system in which the conformation with four atoms coplanar is designated by E (envelope), that with three atoms coplanar by T (twist). The atoms out of plane can then be indicated as subscripts or superscripts to show respectively displacement below or above the plane of reference; carbon atoms are given as numbers, the ring oxygen by "o". This system is simple, fully descriptive, adaptable to general use, and will be used in the present publication.

In the furanoside ring the effective interactions are those between eclipsed groups on adjacent carbon atoms and the most favored conformations will allow maximum staggering. Conformations with C_1, C_4, or O displaced have a fully or nearly fully eclipsed pair of carbon atoms and should be less stable than those in which C_2 or C_3 or both are displaced from the plane. Methyl α-D-arabinofuranoside (II) has all of its large substituents in trans orientation and the strain in the ring can therefore be relieved by the maximum staggering afforded by a T_2^3 or T_3^2 conformation. In methyl β-D-arabinofuranoside (III) there is an eclipsed interaction between the C_1- and C_2-substituents which should force them away from each other, giving an E_2 conformation. The methyl-D-xylofuranosides have large eclipsed groups at C_3 and C_4 with the bulky hydroxymethyl group at C_4 contributing to a greater repulsive force. The net result of the deformation in which the hydroxymethyl group forces the C_3-hydroxyl down and away will be that C_2 is pushed up, giving the conformation T_3^2 (IV). An important consequence of this conformation is that the C_2-hydroxyl is oriented in an almost ideal skew position with respect to the anomeric substituents and is only slightly closer to the C_1-α than the C_1-β bond angle in a projection along the C_2—C_1 bond. A possible alternate conformation for the methyl β-D-xylofuranoside is E_3. The methyl-D-lyxofuranosides have eclipsed interactions between C_2–C_3 and C_3–C_4 substituents. The molecule should therefore adopt a T_2^3 conformation V which provides for the maximum distance between the *O*-substituents within an ideally staggered form. An alternative for the methyl α-D-lyxofuranoside could be E_3. The interaction between the C_2- and C_3-hydroxyls in the methyl-D-ribofuranosides should result in an E^3 conformation (VI) or its equivalent E^2. The latter should be preferred for the methyl α-D-ribofuranoside (VII) because it would also relieve the interaction between the C_2-hydroxyl and the anomeric substituent. Table IV contains the preferred conformations for the methyl pentofuranosides and the hydroxyl interactions in each compound. On present evidence it is impossible to decide between alternative conformations for a single furanoside.

Analyses of products showed that furanosides were the first compounds formed in the methanolysis of a pentose (Table VIII). This reaction must be regarded as essentially irreversible because of the large excess of methanol present. The quantitative data obtained for three of the sugars showed that higher k_1 values for this reaction were associated with higher furanoside concentrations at equilibrium (Table V). The k_1 for D-arabinose in reaction 1 could not be measured because of the low solubility of that sugar in methanol. However, D-arabinose showed the largest amount of furanoside at equilibrium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

TABLE IV
Preferred conformations of methyl pentofuranosides

Methyl-D-pentofuranoside		Conformation	Hydroxyl interactions (total)	
Arabinoside	α	T_2^3 T_3^2	—	0
	β	E_2	C_1–C_2	(1)
Riboside	β	E^3	C_2–C_3	(1)
	α	E^2	C_1–C_2, C_2–C_3	(2)
Xyloside	α	T_3^2	C_3–C_4	(1)
	β	T_3^2 (E_3)	C_3–C_4	(1)
Lyxoside	α	T_2^3 (E_3)	C_2–C_3, C_3–C_4	(2)
	β	T_2^3	C_1–C_2, C_2–C_3, C_3–C_4	(3)

and should have the largest k_1 based on the correlation observed for the other three sugars. The relative rates in reaction 1 therefore reflected the relative stabilities of the pentofuranosides. In reactions 2, 3, and 4 the rate-controlling steps may be assumed to be the formation of ionic intermediates; since the anomerization of furanosides (reaction 2) and the furanoside to pyranoside conversion (reaction 3) proceed from the same initial products at different rates it is likely, although not proved, that the reaction routes are different. Possible intermediates for the furanoside anomerization (VIII) and for the furanoside to pyranoside conversion (X), both arising from the protonated furanoside (IX), are shown in Fig. 1. The non-bonded interactions between large eclipsed groups in the furanosides (II–VII) will be relieved in X by the opening of the ring. These same interactions will be relieved in VIII if it has a puckered form with C_3 being above or below the plane of the other four atoms. Thus, in VIII, dissociation at C_1 removes any interaction between C_1- and C_2-substituents and displacement of C_3 in an E_3 or E^3 conformation relieves interactions between substituents on that carbon atom and those on C_2 and C_4. The relative orders of reactivity for the four pentoses should therefore be the same for reactions 2 and 3 and should depend on the strength and number of eclipsed interactions in the furanosides. The same argument holds if reactions 2 and 3 proceed through a common intermediate which decomposes at different rates into furanoside and pyranoside. The order predicted from the proposed furanoside conformations is given in Fig. 1. The experimental values confirm this prediction. Thus, the lyxofuranosides, with two adjacent eclipsed interactions, should be the most reactive furanosides (see k_1 values, reaction 3). The xylofuranosides, also with only one eclipsed interaction, should be less reactive than the lyxofuranosides but more reactive than the ribofuranosides because the C_3–C_4 eclipsed interaction involving the hydroxymethyl group is stronger than the C_2–C_3 eclipsed interaction. The arabinofuranosides are free of eclipsed interactions, except at the anomeric position in the β-glycoside, and therefore should be the least strained and slowest reacting of the pentofuranosides.

A similar prediction of the reactivities of the anomeric forms in reaction 2 is shown in Fig. 1 and this was also in complete agreement with the experimentally determined rates (see k_1 and k_2, reaction 2). Starting with the most reactive pentose, the methyl β-D-lyxofuranoside should anomerize at a much faster rate than the α-anomer because of the extra interaction at C_1–C_2. In fact, no methyl β-D-lyxofuranoside could be detected in any of the reactions and the rate of reaction 2 for lyxose could not be determined experimentally. It is apparent, then, that k_1 for this reaction must be smaller and k_2 larger than any of the other rate constants in Table III. In the methyl-D-xylofuranosides (IV) the C_2-hydroxyl bond very nearly bisects the angle made by the bonds of the anomeric substituents being

For personal use only.

oriented slightly more toward the α- than the β-position. This accounts for the slightly greater (1.69 times) rate of anomerization of the α-form. In the D-ribofuranosides the α-glycoside has one more eclipsed interaction than the β- and should therefore be more reactive; for the same reason methyl β-D-arabinofuranoside should anomerize at a faster rate than its α-anomer. It is noteworthy that the one additional eclipsed interaction causes a 3-fold increase in the rate of anomerization in both the ribofuranosides and the arabinofuranosides. Another comparison which substantiates the predicted behavior of these compounds is the approximately equal rates of anomerization of methyl β-D-arabinofuranoside and methyl β-D-ribofuranoside, each having one eclipsed interaction in an envelope (E) conformation. This indicates that the eclipsed interactions at C_1–C_2 and at C_2–C_3 are of nearly the same strength. The rates for reaction 2 are greater than those for reaction 3 for each pentose. It should be emphasized that VIII and X are given only as possible intermediates for reactions 2 and 3 respectively. They are offered primarily to illustrate that any intermediate considered must be of a form that permits relief of the non-bonded interactions in the methyl pentofuranosides.

The differences in rates of pyranoside anomerization (reaction 4) can be explained by principles that are already familiar (2–5). If the pyranoside anomerization proceeds through a cyclic, half-chair carbonium ion, as postulated earlier for the xylopyranosides (1), the conformational changes shown in Fig. 2 must be involved (15). Formation of the

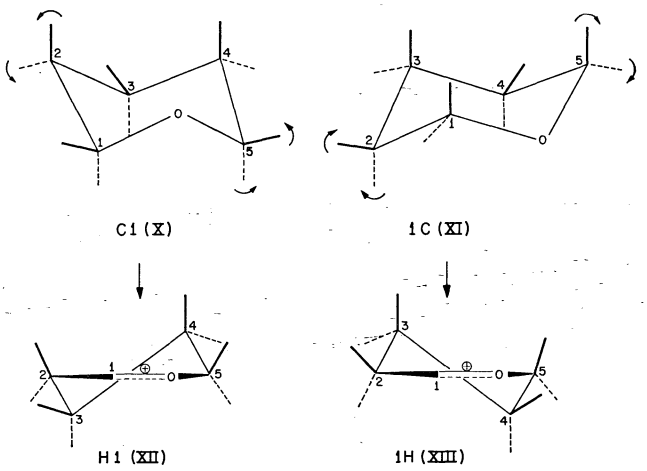

FIG. 2.

H1 (XII) or 1H (XIII) (4) carbonium ions from the C1 (X) or 1C (XI) chair forms (2) respectively requires rotation about the C_2—C_3 and C_4—C_5 bonds as shown. This will be hindered by increased opposition of C_2–C_3 substituents and of C_4—C_5 substituents but these will be of the same magnitude for all pentosides. However, the change will be helped by recession of an axial group on C_2 away from one on C_4 and by the recession of the C_5-axial group from that on C_3. The preferred conformations of the pentopyranosides (2) are shown in Fig. 3 together with the predicted order of reactivity. The xylosides, with no axial substituents, should anomerize at the slowest rate; the ribosides and arabinosides, each with one axial hydroxyl, should anomerize more rapidly than the xylosides but more slowly than the lyxosides, which have either two axial hydroxyls (1C conformation) or one axial hydroxyl and Reeves' $\Delta 2$ effect (2) (axial hydroxyl at C_2 bisects the

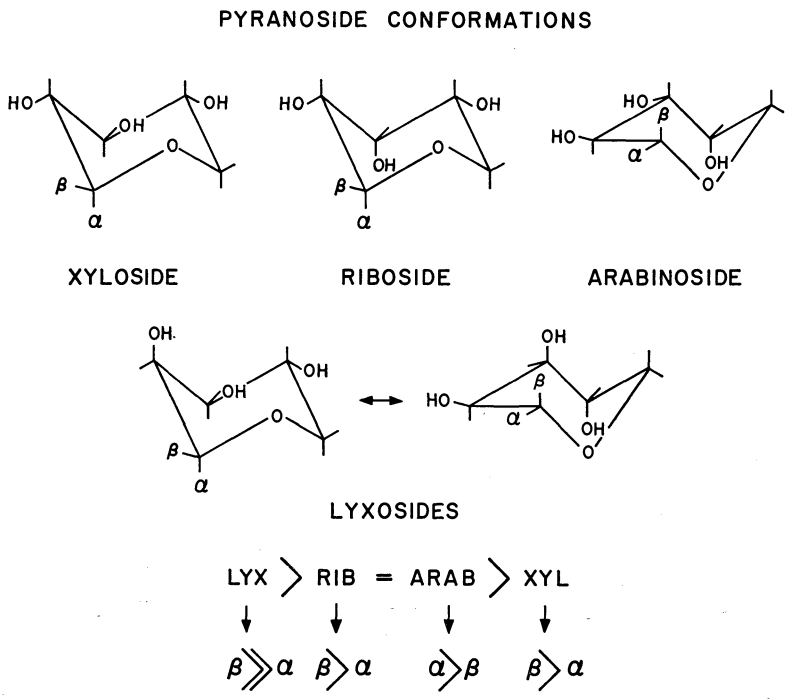

FIG. 3.

angle of the two C—O bonds at C_1). The rates in Table III (k_1+k_2, reaction 4) agree with this interpretation. The ribosides anomerize more slowly than the arabinosides because formation of the H_1 carbonium ion from the former causes increased eclipsing of the hydroxyls on C_2 and C_3.

The relative rates of anomerization of the anomeric pairs can be explained by principles enunciated by Edward (15). The unshared pair of electrons on the ring oxygen of the pyranosides impart a polar character to the C_5-ring oxygen bond and the negative end of this dipole is oriented so that the electrostatic repulsive forces with the C_1-*O*-substituent are stronger when that substituent is equatorially oriented. Those anomers should therefore be less stable and should display a faster rate of reaction; the predicted order of reactivity of anomeric pairs is given in Fig. 3. The k_1 and k_2 values for each pentopyranoside in reaction 4, Table III, confirm the prediction for the anomeric lyxopyranosides, arabinopyranosides, and xylopyranosides. The difference in rate between anomers is greater for the lyxopyranosides because of the additional repulsive force applied to the β-anomer by the axial hydroxyl at C_2. The anomeric ribopyranosides showed reactivities which were the reverse of those predicted on the basis of dipole interaction. Probably the axial–axial interaction between the C_3-hydroxyl and the C_1-α-substituent of anomeric ribopyranosides is stronger than the dipole interaction at the β-position and results in greater reactivity of the α-anomer.

Table V shows the glycoside compositions at equilibrium of the four pentoses and of some *O*-methyl derivatives of D-xylose and D-arabinose. Substitution of the C_2- and C_3-hydroxyl groups in D-xylose or D-arabinose by *O*-methyl groups greatly increased the concentrations of furanoside forms at equilibrium. This can be explained by considering the projections (Fig. 4) of the C_2—C_3 bond with trans *O*-substituents for pyranoside and

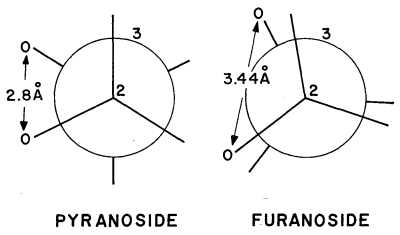

FIG. 4.

furanoside ring forms. Equatorial–equatorial *O*-substituents at C_2 and C_3 in the pyranoside ring are 2.8 Å apart while trans *O*-substituents on a furanoside ring are 3.44 Å apart. An increase in the size of the *O*-substituents will therefore result in a stronger repulsive interaction in the pyranoside than in the furanoside form and the equilibrium will be shifted toward the latter.

The free energies (Table VI) calculated from the equilibrium constants reflect the relative stabilities of the compounds concerned. In the conformation T_3^2 proposed for the

xylofuranosides anomerization involves the substitution of one skew orientation for another and no strong interactions. The small Δ*F* for this reaction is consistent with this proposal. Anomerization of arabinofuranosides and of ribofuranosides introduces or removes an eclipsed interaction between the C_1- and C_2-*O*-substituents which can be relieved somewhat because the ring is free to adopt a less strained conformation. The Δ*F* of reaction for these two anomerizations should therefore be nearly the same, greater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

For personal use only.

than for the xylofuranoside anomerization, but less than that of the lyxofuranosides where the C_1–C_2 interaction in the β-anomer cannot be relieved because of the fixed conformation imposed by the other interactions in the ring.

The ΔF of reactions for the furanoside to pyranoside conversions reflect the relative stabilities of the two ring forms in these sugars. In arabinose and ribose the furanoside forms have only one or two easily relieved cis interactions while the pyranoside forms each have an axial hydroxyl group. The ΔF for the ring conversions is therefore less for these two pentoses than for xylose or lyxose because the former has the best possible conformation in the pyranoside form and the latter has the worst possible furanoside conformation.

Similarly, the energy differences between the anomeric pyranosides of xylose and arabinose are very nearly the same; this indicates that the axial C_4-hydroxyl of arabinose has little effect on the relative stabilities of the two anomers. In lyxose and ribose the differences between the anomeric pyranosides are larger than for xylose or arabinose. These larger differences were undoubtedly caused by increased repulsions at the β-anomeric position in lyxose by the axial C_2-hydroxyl and at the α-anomeric position in ribose by the axial C_3-hydroxyl.

Angyal (16) has proposed a system of quantitative conformational analysis for the pyranoid sugars based on interaction energies derived from the equilibrium reactions of cyclitols (17, 18) and the anomeric equilibria of glucopyranose and mannopyranose (19). A similar system was given for acetylated sugars by Lemieux and Chu (20). Total interaction energies for the pyranoid pentoses in the two chair forms are shown in Table VII and were calculated from the following values in kcal/mole: O_1:O_2 = 0.50 (skew

TABLE VII

Interaction energies (kcal/mole) in pyranoid pentoses

interaction between *O*-substituents on adjacent carbon atoms): O_a:H_a = 0.40 (axial–axial interaction between a hydrogen and an *O*-substituent); O_a:O_a = 2.1 (interaction between two axial *O*-substituents); $\Delta 2$ effect (2) = 0.40 (interaction of axial *O*-substituent at C_2 on equatorial anomer); anomeric effect (15, 21) = 1.20 (interaction of C_5-ring oxygen dipole on equatorial anomer). These values have been reported by Angyal *et al.* (17–19) for aqueous systems and agree substantially with those given by Lemieux and Chu (20) for acetates in an acetic acid – acetic anhydride system. The value for the anomeric effect has been given as 1.45 kcal/mole for methyl glycosides (19) and as 1.3–1.5 kcal/mole for different aglycons in sugar acetates (21). We have found that a value of 1.20 kcal/mole for the anomeric effect gave calculated differences in free energy between anomers that were in excellent agreement (see Table VII) with those found from the glycoside compositions at equilibrium.

The results of the present work are in general support of the sequence of reactions and the mechanism proposed earlier for the methanolysis of D-xylose (1). Only for D-lyxose

was there any evidence for pyranosides being formed early in the reaction (Table VIII. C). It is possible that lyxopyranosides were formed directly from the free sugar as has been proposed by Mowery (22) for D-mannose and L-arabinose. The highly unfavorable conformations of the furanoside forms of lyxose and mannose would be expected to favor the direct formation of some pyranosides from the free sugars. The only example of the reverse reaction, furanoside → pentose, occurred in the D-lyxose series with methyl α-D-lyxofuranoside as the initial compound (see Table X.C), a further indication of the instability of the furanoside forms of this pentose. Although rate data could not be obtained for the reaction of D-arabinose, qualitative examination of the early products of reaction showed that only arabinofuranosides were present.

The present results are also consistent with the proposed mechanisms for the anomerizations of furanosides and pyranosides for which two different cyclic carbonium ion intermediates were postulated. However, the mechanism tentatively proposed earlier for the furanoside → pyranoside ring expansion in D-xylose, which has been criticized (23), must still be regarded as an open question. Further work on this aspect of glycosidation is in progress.

EXPERIMENTAL

Reagents

Sugars were purified products obtained from commercial sources; no impurities were detected by paper chromatography. Methanol was reagent grade and was distilled from magnesium–iodine immediately before use. Hydrogen chloride was dried by passage through calcium chloride.

Apparatus

An F and M Model 500 Chromatograph or a Pye Argon Chromatograph were employed for gas–liquid partition chromatography. Conditions used are cited in Tables I and II.

Preparation of Methyl Pentosides

Methyl pentosides were prepared by methods described in the literature. The physical properties of these compounds and the reported values were as follows:

[a]For the L-enantiomorphs.
[b]Not isolated in amounts sufficient for characterization. The fully acetylated or methylated derivative of each glycoside gave only one peak on gas–liquid chromatography.

Reactions and Analysis of Products

Reaction vessels were screw-capped bottles fitted with silicone rubber septums and maintained at 35±0.01°. Samples (0.4–0.5 ml) were removed by a hypodermic syringe, neutralized by sodium methoxide, and evaporated to dryness. Fully methylated derivatives were prepared from these samples as described previously

For personal use only.

(1). When acetylated derivatives were required (lyxosides, ribosides, and all samples containing reducing sugar) the dry residues were dissolved in 0.3 ml of a mixture of pyridine – acetic anhydride (1:1) at room temperature; acetylation was complete after 1 hour. The solutions from methylation and acetylation were analyzed directly by gas–liquid chromatography, the components being identified by comparison with authentic samples prepared from the glycosides listed above. Amounts of individual components were determined by tracing the peaks from the chromatogram onto glassine paper from which they were then cut out and weighed.

Results

The following tables show the percentage compositions at various times from which the rate constants used in the discussion were obtained. The tables are grouped according to reaction, the conditions for which are specified at the beginning of each section. For each reaction the initial compound is cited as the title of the table. The k values are based on the rate of decrease of initial product except for reaction 3, where they are based on decrease of total ($\alpha+\beta$) furanoside. The rate constants marked with an asterisk (*) were used to give the average values cited in the discussion (Table III).

Reaction 1.—Pentose → furanosides (Table VIII). Conditions: 2% of initial compound in 0.01% methanolic hydrogen chloride at 35±0.01° C.

INDUCTIVE AND MESOMERIC EFFECTS IN SUBSTITUTED FULVENE AND PYRIDINE DERIVATIVES

J. P. CARTIER AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Que.
Received May 21, 1963

ABSTRACT

The electronic charge distribution in substituted fulvene and pyridine derivatives is examined using the simple Hückel molecular orbital method. Parameters characterizing the electronegativity of the substituent and the carbon to which it is linked are varied in order to cover actually existing substituents.

It is found that the nature of the inductive and mesomeric effects is not basically different from that in the case of benzene. The most negative sites in fulvene show a certain variation with the place of substitution. In pyridine they are the ortho and para carbons for meta substitution and the meta carbons for ortho and para substitution.

INTRODUCTION

The inductive and mesomeric effect of substituents on the electronic charge distribution in benzene has been the subject of many theoretical treatments. In the simple Hückel approximation the extent of the mesomeric effect due to the addition of two more π-electrons to the system, as it occurs in phenol or aniline for example, depends on the difference between the Coulomb integral α_R associated with the substituent, R, and the Coulomb integral α_C of a carbon atom. This difference can be taken to be proportional to the corresponding difference in electronegativities (1, 2). The smaller it is the easier the penetration of the electrons of the substituent into the benzene π-orbitals.

The inductive effect is due to the alteration of the potential field in the benzene ring because of the presence of the substituent. The main consequence of this is an increase in the electronegativity of the carbon linked to the substituent (or decrease if the electronegativity of the substituent is lower than that of carbon) which may be represented by a supplement α_{C_R} to its Coulomb integral, generally taken as a fraction of α_R.

One of the present authors published a series of diagrams of electronic charge distributions in monosubstituted benzene derivatives of the phenol or aniline type (3). The quantity $(\alpha_R-\alpha_C)$ was given values of -2, -1, 0, 1, 2, and 3 in units of the carbon–carbon resonance integral, β. The value of α_{C_R} was taken to be 1/10 of that of the respective value of $(\alpha_R-\alpha_C)$. When α_{C_R} is taken as zero we obtain a series of diagrams representing the purely mesomeric effect. The purely inductive effect was obtained by cutting off the substituent from the ring by setting β_{C-R} equal to zero but giving α_{C_R} values equal to $\alpha_R/10$. The combined effect of the two was then computed with the appropriate values of α_R and α_{C_R} and with $\beta_{C-R} = \beta$. The substituents —NH_2, —OH, —F are examples for the positive values of α_R; —PH_2, —AsH_2 for the negative ones.

Recent developments in quantum chemistry (4–6) have given new justification to the simple Hückel method through its resemblance to the Pariser and Parr method (7). This fact encouraged us to undertake similar work on substituted fulvene and pyridine molecules. The former is an isomer of benzene although it contains a five-membered ring while the latter results from the substitution of one of the benzene carbon atoms by the more electronegative nitrogen atom. Comparisons with benzene derivatives were expected to be interesting.

The computational work for both molecules is more considerable than for benzene since for each of them there are three non-equivalent places for substitution. The simple Hückel approximation was used throughout with all resonance integrals taken as equal and all overlap integrals neglected. In the case of pyridine the supplemental Coulomb integral for the nitrogen atom, $\alpha_N - \alpha_C$, was taken equal to β and for the two ortho carbon atoms, $\alpha_{C_N} - \alpha_C = 0.1\beta$. These values are not indicated in the tables, which only show the variable parameters due to substitution on the pyridine molecule.

RESULTS AND DISCUSSION

Fulvene

Tables I, II, and III contain the electronic charge densities (q) and bond orders (p) for fulvene as used by Coulson and Longuet-Higgins (8). (See also earlier papers by Wheland and Pauling (9) and by Coulson (10).) In the first columns of these tables R, 1, 2, 3, and 4 correspond to the charges, R–1, 1–2, 2–3, 3–4, and 4–5 to bond orders.

The tables refer to substitution in 1, 3, and 4 respectively.

In drawing conclusions from these tables we must remember that in fulvene itself the electronic charge densities are different from unity, all the ring carbons having negative charges and the extracyclic carbon a large positive charge. The numerical values of these charges were shown to be much too high and lead to a dipole moment by far exceeding the experimental value (11–14). It is assumed, however, that this does not affect our comparative conclusions. The charges and bond orders of fulvene itself are in the column corresponding to $\alpha_{C_R} = 0$ among the columns related to the purely inductive effect. The + and − signs after the numbers indicate that the charge density was decreased or increased respectively with respect to fulvene. When the variation is less than 0.005 no signs were given. All the observations follow directly from the tables and therefore only some general features will be outlined.

The largest variations of q occur on the substituent (R) itself. For $\alpha_R = -2$, from the two electronic charges originally on R there only remains 0.15 to 0.30 according to the place of substitution. This great positive charge decreases rapidly with increasing α_R and for $\alpha_R = +3$ we have about 1.90 or 1.95 remaining from 2.00. This behavior is very similar to that obtained for benzene.

The corresponding variations for the carbon linked to the substituent also follow a pattern as in the case of benzene. The inductive effect moderately diminishes q for negative parameters and increases it for positive parameters. The mesomeric effect increases q very substantially for negative parameters, then it decreases it slightly for positive parameters so that the two effects always act in opposite directions. The combined effect is not obtained by addition of the two but it still is intermediate between them. This is so whether the substitution takes place in 1, 3, or 4.

The quaternary carbon 2 is significantly affected by substitution in 1 but the effect of substitution in 3 or 4 on carbon 2 is negligible.

Substitution in 1 increases the negative charge in both 3 and 4 for all values of the parameters. The combined effect is close to the mesomeric effect except for large positive parameters when it is about half way between the inductive and the mesomeric effects.

Substitution in 3 or 4 has an interesting effect on the charge density on carbon 1, which is the extracyclic carbon atom. The inductive effect is very slight for all parameters but the mesomeric effect, which is almost identical with the combined effect, sends large negative charges to 1 for negative values of α_R and slight negative charges for positive values of α_R.

Substitution in 3 sends additional negative charges into 4 and 6, the combined effect being only roughly additive. Carbon 5 is only slightly affected.

Substitution in 4 sends additional negative charges into 3. Except for negative values of the parameters, 5 and 6 are less affected.

Other regularities may be found on examination of the tables.

The "meta" positions (the next-nearest carbons to the place of substitution) are less affected than the others for substitution in 1 and 3. For substitution in 4, 5 and 6 are

comparable from this point of view. As in the case of benzene, for negative parameters the charge distribution undergoes more profound changes than for positive ones.

In conclusion we can say that the influence of inductive and mesomeric effects on the electronic charge distribution in the case of fulvene is not substantially different from what is found for benzene.

Looking at the absolute values of the charges in Tables I, II, and III, it is seen that in fulvene itself the most negative sites are the fields of carbons 3 and 6, 4 and 5 being somewhat less negative. This is still so after substitution in 1 with the apparent exception of $\alpha_R = 1\beta$. For substitution in 3 the most negative sites are 4 and 6 for $\alpha_R = 0$, 1, and 2, which would correspond to the cases of substituents occurring in practice.

For other values of α_R we refer to Table II. Substitution in 4 shows an even greater variety and only 3 is always negatively charged (Table III).

In general the negative charges in the ring become larger as a consequence of substitution. For negative parameters the extracyclic carbon is the most negative site.

Pyridine

Our work on pyridine was less extensive. Only $\alpha_R = 0$, 1, and 2 were used with the corresponding inductive parameters. The respective charge distributions have to be compared with that of pyridine itself, which is found in the third line of Tables IVA, B, and C.

Substitution in 2 (ortho to the nitrogen atom) increases the negative charge on the nitrogen appreciably and sends more negative charges to all the carbons. Carbon 5 will be the most negative, then carbon 3. The meta positions are the least positive in pyridine itself but now we have net negative charges there. The inductive effect diminishes q on N, 3, 5, and 6, increases it on 2, and leaves it unchanged on 4. The mesomeric effect increases it on N, 3, 4, 5, and 6 and decreases it on 2. The combined effect is seen to be intermediate between the two.

Substitution in 3 (meta) only affects q_N slightly, increases charges, rendering them negative in 2, 4, and 6 whereas in 3 and 5 it causes only a slight increase. This is a complete reversal in the charge distribution of the ring, the most negative sites being now the ortho and para carbons, not the meta. The inductive effect increases q on 3, decreases it on 2, 4, and 6, and leaves it practically unchanged on N and 5. The mesomeric effect increases charges in 2, 4, and 6, decreases them in 3, and leaves them unchanged on N and 5. The combined effect is again intermediate.

Substitution in 4 (para) increases q_N appreciably and also increases q in 2, 3, 4, 5, and 6; 3 and 5 become the most negative sites. This is a situation similar to that of the substitution in 2. The inductive effect slightly decreases q_N, increases q on 4, decreases it on 3 and 5, and leaves it unchanged on 2 and 6. The mesomeric effect increases q_N slightly, also increases q in 3 and 5, decreases it in 4, and leaves it unchanged in 2 and 6. Again the combined effect is intermediate.

We may summarize our observations by pointing out that the inductive and mesomeric effects are opposed for positive values of the parameters whatever the place of the substitution. Furthermore, whereas in pyridine itself the charge is positive on all carbons, in the substituted derivatives there are negative sites, namely the meta carbons for ortho or para substitution and the ortho and para carbons for meta substitution. This is likely to lead to acceleration of electrophilic reactions with respect to pyridine itself for all three types of substitution.

No attempt is made in this paper to make comparisons with experimental data. We only refer to reviews by Day (15) and by Bergmann (16) and to the work of Thiec and

Wiemann (17) on fulvene derivatives and to the review found in Streitwieser's book (18) on pyridine derivatives.

It is hoped that the results presented in this paper will prove useful in establishing correlations between the electronic charge distribution in fulvene and pyridine derivatives and kinetic data related to these molecules.

The spectra of fulvene and pyridine derivatives were extensively studied (19–24) as were the dielectric properties of the latter (25, 26).

ACKNOWLEDGMENTS

The eigenvalues and eigenvectors of the molecules treated in this paper were computed with the help of the Computation Centre, McLennan Laboratory of the University of Toronto. Our sincere thanks are due to Dr. C. C. Gotlieb and Mr. I. Farkas for their valuable assistance.

One of us (J. P. C.) was a holder of a scholarship from the Province of Quebec for which he expresses his gratitude.

TOSYLATED PEPTIDES AND *p*-NITROPHENYL ESTERS[1]

CASIMIR BERSE, THOMAS MASSIAH,[2] AND LUCIEN PICHÉ
Department of Chemistry, University of Montreal, Montreal, Que.

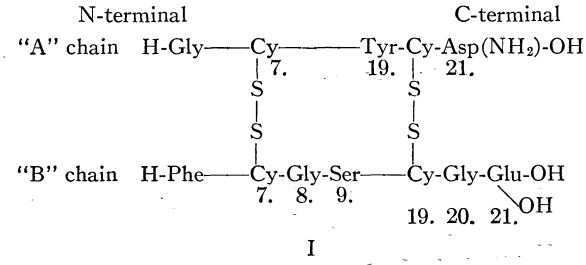
Received February 11, 1963

ABSTRACT

The tosyl group causes interference with mixed carbonic anhydride and *p*-nitrophenyl ester formation in certain instances. Several protected peptide sequences, occurring in the insulin molecule, and some tosylated *p*-nitrophenyl esters, have been prepared in the course of investigating this interference.

INTRODUCTION

At the inception of this work, we were interested in preparing certain peptide sequences which occur in the insulin molecule (1). Specifically, we were interested in preparing three peptides which occur in the vicinity of the interchain disulphide bridge of insulin, namely tyrosyl-cysteinyl-asparagine, cysteinyl-glycyl-glutamic acid, and cysteinyl-glycyl-serine, hereinafter abbreviated respectively as H-Tyr-Cy(SH)-Asp(NH_2)-OH, H-Cy(SH)-Gly-Glu-OH, H-Cy(SH)-Gly-Ser-OH, according to the system of Brand (2). A portion of the insulin molecule is reproduced in I. We were particularly interested in



I

these peptides, because we believed, for reasons which will not be delineated here, that the site of the hypoglycemic activity of insulin might be those peptides sequences in the vicinity of the interchain disulphide bridge (3).

In our search for a suitable method of "blocking" the amino group of the various amino acids, we were attracted to the tosyl blocking group, because of the general ease of preparation of tosylamino acids, and the ready crystallinity of such derivatives (4), particularly N-tosylated glutamic acid (5). Furthermore, it seemed desirable to attempt to limit ourselves to one amino blocking group and one method of forming the peptide bond. Indeed such an objective has been achieved in at least two syntheses of oxytocin (6, 7). For our purpose, we chose to use the tosyl blocking group, and to form the peptide bond by the mixed carbonic anhydride method (8). Later, we were forced to modify our original plan, such that we had to use other blocking groups, such as the well known "carbobenzoxy" (9) group, and other methods of forming peptide bonds, such as the N,N′-dicyclohexylcarbodiimide (10) method, because of the failure of the mixed anhydride method with N^{α}-tosylamino acids in certain instances, reported previously (11).

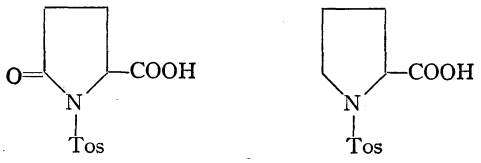
Ultimately, therefore, our main interest became the investigation of the factors influencing peptide bond formation, by various methods, with N^{α}-tosylamino acids.

In this paper, we report on the formation of peptide bonds and *p*-nitrophenyl esters of N-tosylamino acids and peptides, and propose a general basis for predicting when either of the foregoing reactions will occur.

DISCUSSION

In Table I, we have tabulated the results of our own work and those of other workers, in the formation of certain peptide sequences and derivatives, using various amino blocking groups. It can be seen that in the case of the tosyl blocking group, as contrasted with the carbobenzoxy and phthaloyl groups, peptide bond or *p*-nitrophenyl ester formation fails in every instance where the tosyl group is alpha to the carboxyl group being reacted with, except in the case of N-tosyl-L-pyroglutamic acid, II, and N-tosyl-L-proline, III. The significance of the structure of these two tosylamino acids

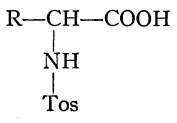


II III

(Tos = tosyl = CH_3—C$_6$H$_4$—SO_2—)

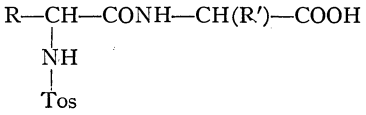
will be discussed later. In order to rule out the possibility of steric hindrance being a factor in the failure of the mixed anhydride method with the N^{α}-tosylamino acids, we prepared (or report numerous instances from the literature) sequences in which the amino acid residues are C-terminal in one instance and N-terminal in another. It is clear, from a study of Table I, that the failure of the desired reactions, in the case of tosylamino acids is ascribable to the tosyl group.

If one examines the structure of the tosylamino derivatives in which mixed anhydride or *p*-nitrophenyl ester formation *fails*, one will see that, in general, the derivatives have the structure IV. On the other hand, those instances where these reactions are successful,



IV

have the structure II, III, or V. It is evident, therefore, *that if the tosyl group is alpha*



V

to the carboxyl group undergoing activation, and if there is a hydrogen atom on the nitrogen atom to which the tosyl group is attached, there will be interference with *both* of the aforementioned reactions; otherwise the tosyl group does *not* cause interference with *either* of the reactions. This represents, in our view, an important extension of the conclusion

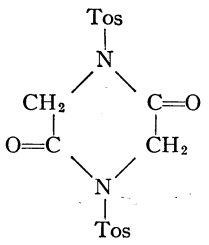
which Zaoral and Rudinger (12) had made regarding the *mixed carbonic anhydride method*. Furthermore, to the best of our awareness, the case of tosylated *p*-nitrophenyl ester formation does not seem to have been dealt with in the published literature.

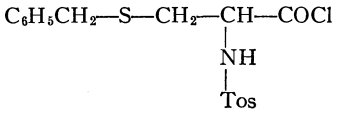
From the present work, and that of others (12, 13), we know, now, that we can form mixed carbonic anhydrides, and thence peptides, of N-tosylamino acids and peptides such as II, III, or V in the conventional manner (8), while mixed anhydrides of tosylamino acids such as IV may be prepared using pivaloyl chloride (13).

Each of the N^{α}-tosylamino acids investigated reacted with an ester of another amino acid to form dipeptides, in the presence of N,N′-dicyclohexylcarbodiimide (10). In contrast to this, only *certain* N^{α}-tosylamino acids formed *p*-nitrophenyl esters, even though the expected coproduct, N,N′-dicyclohexylurea (10), was observed to have formed in *every* case. The reaction of N-tosylglycine, IV (R = H), and N,N′-dicyclohexylcarbodiimide, alone and in the presence of an equimolar amount of each of these ingredients and *p*-nitrophenol, was investigated. In the former instance, N,N′-dicyclohexylurea and the diketopiperazine, VI, arising from N-tosylglycine, IV (R = H), were isolated in essentially quantitative yield. In the latter instance, the same two products were isolated, and 90% of the initial amount of *p*-nitrophenyl was recovered, unreacted. Since diketopiperazines were never detected among the reaction products, in the case of dipeptide formation, it would seem that they are *not* precursors of the dipeptides. Diketopiperazine formation appears to compete successfully with tosylated *p*-nitrophenyl ester formation, however, in those cases where one would predict interference with the desired reaction on the basis of the hypothesis enunciated previously.

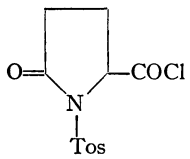


VI

The divergent behavior of N-tosyl-S-benzyl-L-cysteinyl chloride, VII, and N-tosyl-L-pyroglutamyl chloride, VIII (see Table I), towards the magnesium salt of L-asparagine



VII



VIII

is unexplained, but it may represent another aspect of the peculiar role of the amino hydrogen atom (12) under the influence of the tosyl group. Since the mechanism of Beecham (14) does not appear to be applicable to the foregoing case, it seems likely that the probable product from VII was the diketopiperazine analogous to VI. No attempt was made to identify the reaction product, however, once it was shown to be a product other than the one expected.

EXPERIMENTAL[3, 4]

N-Carbobenzoxy-S-benzyl-L-cysteinyl-L-asparagine, IX

This compound was prepared from N-carbobenzoxy-S-benzyl-L-cysteine (26) (10.35 g; 0.03 mole) and L-asparagine (3.96 g; 0.03 mole) by the mixed carbonic anhydride method, as reported by Leach and Lindley (15). The yield of the product was 6.5 g (47%), after recrystallization from boiling methanol (150 ml); m.p. 157–158° C (lit. (15): 180° C), $[\alpha]_D^{22}$ −32.7 (*c*, 2.43; *N,N*-dimethylformamide). Anal. Calc. for $C_{22}H_{25}O_6N_3S$ (459.5): C, 57.50; H, 5.48; N, 9.15%. Found: C, 57.87; H, 5.47; N, 9.21%.

N-Tosyl-S-benzyl-L-cysteinyl-glycine p-Nitrobenzyl Ester, XII

Glycine *p*-nitrobenzyl ester hydrobromide (27) (5.39 g; 18.5 mmoles) was dissolved in chloroform (75 ml) containing triethylamine (2.59 ml; 18.5 mmoles), and the solution was stirred for 10 minutes. N-Tosyl-S-benzyl-L-cysteine (17) (6.76 g; 18.5 mmoles) was added, the reaction mixture was cooled to 0° C, treated with a solution of *N,N*-'dicyclohexylcarbodiimide (3.82 g; 18.5 mmoles) in dry tetrahydrofuran (25 ml) and stirred for 30 minutes in the cooling bath. The viscous suspension was then transferred to a Burrell wrist action shaker, and agitated for 16 hours at room temperature. The precipitated N,N'-dicyclohexylurea (2.24 g; 57% of the theoretical) was filtered, and the filtrate was concentrated to a semisolid oil *in vacuo*. This oil was dissolved in chloroform (75 ml), and the resulting solution was washed successively with water, 1 *N* sodium bicarbonate, 1 *N* hydrochloric acid, water, and then it was dried over sodium sulphate. Petroleum ether (b.p. 65–110° C) was added to opalescence, and the product was allowed to crystallize at room temperature. The product, thus obtained, weighed 5.57 g (54%), m.p. 116–117° C. Further recrystallizations raised the melting point to a constant value of 118–119° C. $[\alpha]_D^{25}$ −3.12 (*c*, 1.41 in chloroform). Anal. Calc. for $C_{26}H_{27}O_7N_3S_2$ (557.6): C, 56.00; H, 4.88; N, 7.54%. Found: C, 55.62; H, 4.64; N, 7.16%.

N-Tosyl-L-pyroglutamyl-glycine Ethyl Ester, XV

To a stirred solution of N-tosyl-L-pyroglutamic acid (28) (2.83 g; 0.01 mole) in chloroform (30 ml), cooled to 0° C, was added triethylamine (1.4 ml; 0.01 mole) and ethyl chloroformate (0.95 ml; 0.01 mole). After 10 minutes a precooled solution of glycine ethyl ester (prepared from 1.39 g, 0.01 mole, of the hydrochloride and 1.4 ml; 0.01 mole, of triethylamine) in methylene chloride (40 ml) – chloroform (10 ml) was added. The solution was stirred for 30 minutes at 0° C, and 1.5 hours at room temperature, then it was washed to neutrality in the usual way, and dried over magnesium sulphate. The washed and dried solution was evaporated to an oil *in vacuo*, and the oily residue was taken up in 95% ethanol (5 ml) with slight warming. The yield of recrystallized product was 2 g (54%), m.p. 131–132° C (lit. (5): 132–133° C); $[\alpha]_D^{28}$ −21.8 (*c*, 1.19 in dioxane).

N-Tosyl-L-pyroglutamyl-S-benzyl-L-cysteine Ethyl Ester, XVI

This compound was prepared exactly as in the preceding case, from N-tosyl-L-pyroglutamic acid (28) (2.83 g; 0.01 mole) and S-benzyl-L-cysteine ethyl ester (20) (from 2.77 g; 0.01 mole of the hydrochloride).

The crude product was recrystallized from boiling absolute ethanol (2.0 ml) to give 2.21 g (43.8%) of the pure product, m.p. 145–146° C (lit. (19): 142–145° C), $[\alpha]_D^{28}$ −16.7 (*c*, 1.19; dioxane) (lit. (19): $[\alpha]_D^{21.5}$ −17 (*c*, 1.8; dioxane)).

N-Tosyl-S-benzyl-L-cysteinyl-glycyl-L-serine Ethyl Ester, XVIII

A solution of the mixed anhydride of N-tosyl-S-benzyl-L-cysteinyl-glycine (11) (2.12 g; 5 mmoles) in dry tetrahydrofuran (20 ml) was prepared as in XV. To this solution was added a precooled suspension of L-serine ethyl ester (prepared from 0.857 g; 5 mmoles of the hydrochloride (29), on treatment with triethylamine). After being stirred for 30 minutes in the cooling bath and overnight at room temperature, the reaction mixture was evaporated to dryness in a rotary evaporator. The residue was dissolved in boiling ethyl acetate, the resulting solution was filtered, and the filtrate was evaporated to dryness. The semicrystalline oil was dissolved in 10 ml each of warm absolute ethanol and ether. Petroleum ether (b.p. 30–52° C) was added to the solution until it became opalescent. Crystallization of the product was induced by scratching. The yield of crude product was 1.76 g (65%).

For analysis, the product was recrystallized from ethanol–water; m.p. 147.5–148.5° C, $[\alpha]_D^{23.5}$ −30.6 (*c*, 1.37 in ethanol). Anal. Calc. for $C_{24}H_{31}O_7N_3S_2$ (537.6): C, 53.61; H, 5.81; N, 7.82%. Found: C, 53.12; H, 5.78; N, 7.97%.

Products from the Attempted Preparation of p-Nitrophenyl-N-tosylglycinate, XIX

N-Tosylglycine (30) (2.29 g; 0.01 mole) and *p*-nitrophenol (1.39 g; 0.01 mole) were dissolved in a mixture of methylene chloride (100 ml) – dimethylformamide (10 ml), and the solution was cooled to 0° C. N,N'-Dicyclohexylcarbodiimide (2.06 g; 0.01 mole) was then added. The reaction mixture was stirred for 30 minutes at 0° C, and overnight at room temperature, prior to being filtered. The residue (3.6 g) "r_1" was

[3] *Melting points were determined in capillary tubes and are uncorrected.*

[4] *Microanalyses were performed by Dr. C. Daesslé, Organic Microanalyses, 5757 Decelles St., Montreal, Que.*

[5] *We were unable to obtain the melting point reported in reference 15, despite repeated recrystallization of the product or repetition of the preparation.*

retained. On concentrating the filtrate, *in vacuo*, there was obtained a semicrystalline residue "r_2", which was treated with anhydrous ether (50 ml) and filtered. The ether-insoluble residue "r_3" was combined with "r_1". These combined residues ("r_1"+"r_3") were treated with hot absolute ethanol (50 ml), filtered, and the alcohol-insoluble portion "r_4" was weighed (1.7 g; 80%), m.p. 260° C. For analysis, "r_4" was recrystallized from either pyridine or dimethylformamide–ether, m.p. 262° C (lit. (12, 31): 295–296, 275° C), then dried *in vacuo* at 100° C for at least 4 hours. The analysis of the fraction "r_4" corresponded to that for 1,4-ditosylpiperazine-2,5-dione, VI. Anal. Calc. for $C_{18}H_{18}N_2O_6S_2$: N, 6.63%. Found: N, 6.83%.

From the hot alcoholic solution, there separated in an essentially quantitative yield (2.1 g), a product, m.p. 213–215° C, raised to 230–232° C (undepressed by admixture with authentic N,N-'dicyclohexylurea), on recrystallization from hot dimethylformamide. The product gave the correct analysis for N,N'-dicyclohexylurea. Anal. Calc. for $C_{13}H_{24}ON_2$: N, 12.49%. Found: N, 12.61%.

p-Nitrophenol was recovered on evaporation of the ether solution, followed by recrystallization of the residue from toluene. Alternatively, the isolation was achieved by extracting the *initial* filtrate with three portions of 1 *N* sodium hydroxide, acidifying the aqueous alkaline extract with 1 *N* hydrochloric acid, and extracting the acidified solution with ether. Evaporation of the ether, followed by recrystallization of the residue from toluene, gave 1.2 g (86%) of *p*-nitrophenol, m.p. and mixed m.p. 114° C.

N-Tosyl-L-pyroglutamic Acid p-Nitrophenyl Ester, XXI

N-Tosyl-L-pyroglutamic acid (28) (2.83 g; 0.01 mole) and *p*-nitrophenol (1.39 g; 0.01 mole) were dissolved in dry tetrahydrofuran (50 ml). The solution was cooled to 0° C. N,N'-Dicyclohexylcarbodiimide (2.06 g; 0.01 mole) was added, and the reaction mixture was stirred for 30 minutes at 0° C, and for 16 hours at room temperature. The precipitated N,N'-dicyclohexylurea was filtered, and the filtrate was concentrated to a semicrystalline oily residue, *in vacuo*, at about 40° C. The residue was dissolved in a minimum of absolute ethanol, and the resulting solution was filtered. Crystallization of the product was allowed to proceed at room temperature. The yield of recrystallized product was 1.82 g (45%), m.p. 126–128° C (colorless needles), $[\alpha]_D^{24}$ −19.8 (*c*, 1.21 in dimethylformamide). Anal. Calc. for $C_{18}H_{16}O_7N_2S$ (404.4): N, 6.93%. Found: N, 7.16%.

N-Tosyl-L-proline p-Nitrophenyl Ester, XXII

This compound was prepared exactly as in the above case, from N-tosyl-L-proline hemibenzenate (32) (3.06 g; 0.01 mole) and *p*-nitrophenol (1.39 g; 0.01 mole). The yield of the product was 2.90 g (74.8%), m.p. 105–106° C (from ethanol), $[\alpha]_D^{27}$ −106 (*c*, 1.43 in dioxane). Anal. Calc. for $C_{18}H_{18}O_6N_2S$ (390.4): N, 7.18%. Found: N, 7.24%.

N-Tosyl-S-benzyl-L-cysteinyl-glycine p-Nitrophenyl Ester, XXIII

To a stirred, ice-cooled solution of N-tosyl-S-benzyl-L-cysteinyl-glycine (11) (2.12 g; 5 mmoles) and *p*-nitrophenol (0.84 g; 6 mmoles) in dry tetrahydrofuran (20 ml) was added N,N'-dicyclohexylurea (1.24 g; 6 mmoles). The reaction mixture was stirred for 30 minutes in the cooling bath, and 3.5 hours at room temperature. The precipitated dicyclohexylurea was filtered, and the filtrate was evaporated to dryness *in vacuo*. The residue was triturated under ether, then it was dissolved in a minimum of boiling absolute alcohol (5 ml). Almost immediately, the product crystallized out. It was washed with ether then dried at the water pump. The yield of the product was 1.40 g (52%), m.p. 144–145° C, $[\alpha]_D^{26}$ +17.5 (*c*, 1.66; dimethylformamide). Anal. Calc. for $C_{25}H_{25}O_7N_3S_2$ (543.6): C, 55.23; H, 4.64; N, 7.73%. Found: C, 54.91; H, 4.86; N, 8.00%.

THE PROTON MAGNETIC RESONANCE SPECTRUM OF CYCLOPROPYLAMINE

THE $A_2A_2'X$ CASE WITH STRONG CROSS-COUPLING: A PSEUDO FIRST-ORDER SPECTRUM WITH COMBINATION LINES

H. M. HUTTON[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received July 2, 1963

ABSTRACT

By means of the anisotropic solvent effect of benzene on the ring protons of cyclopropylamine the proton spectrum is converted to $A_2A_2'X$. Since the cross-coupling from the A_2 to the A_2' protons is large the spectrum does not approximate to a *pseudo* first-order AX_4 spectrum. Instead, it is one which may be described as *pseudo* first-order with combination lines. The presence of the latter allows a fairly complete set of coupling constants to be derived in a simpler way than by a computer attack on the general A_2B_2X spectrum. Conversely, the approach developed here, when applicable, allows the derivation of reliable input parameters for a computer program. From the temperature dependence of the $A_2A_2'X$ case the A_2 and A_2' protons can be distinguished and it is found that the protons trans to the amino group are preferentially shifted to high field by the benzene molecules.

INTRODUCTION

Sometimes many of the theoretical transitions in high-resolution n.m.r. spectra effectively coalesce or may be too weak to be observed. Since the analysis of the spectra usually reduces to the problem of assigning the observed peaks, there may then be more than one assignment and, therefore, more than one set of coupling constants which fits the observed spectrum. Abraham and Bernstein have discussed this situation for the ABX, A_2X_2, and ABXY spectra in some detail (1). In practice it is usually found that only sums or differences of coupling constants can be obtained from the observed *pseudo* first-order spectra. In general, such deceptively simple spectra are expected for the ABC...XYZ... systems when quantities of the type $J_{AB'}$ J_{XY} are large compared to the chemical shift differences $\delta_{AB'}$ δ_{XY} plus quantities of the type $J_{AX}-J_{AY}$. Separations between the lines in each group are then given by the average of constants of the type $J_{AX'}$ J_{AY}. When the system has some symmetry the general statements have to be modified slightly (1).

Examples of deceptively simple spectra are discussed in reference 1 and misinterpretations in the literature are also discussed. A similar discussion for the ABX case was given by Schaefer (2), by Grant and Gutowsky for the A_2B_2 case (3), and by Musher and Corey for the three-spin system (4).

We discuss here the ring-proton spectrum of cyclopropylamine. The proton on the substituted carbon atom is shifted far enough to low field by the inductive effect of the amino group that, in general, an A_2B_2X system is obtained at 60 Mc/s. This case was first discussed by Richards and Schaefer (5). By means of solvent effects we bring about a zero shift between the A and B protons and hence obtain an $A_2A_2'X$ system. A *pseudo* first-order spectrum is not found, however, but rather what may be described as a *pseudo* first-order spectrum with combination lines. As we shall show, this is due to a strong cross-coupling between A and A′ protons. Such a situation could have been qualitatively

[1]*Holder of a C.I.L. Fellowship, 1962–1963.*

predicted from the discussion in reference 1. It appears that our example is the first of this type. It will also appear that the existence of the few extra lines in the $A_2A_2'X$ spectrum allows one to place quite stringent limits on the values of the coupling constants. This is important in obtaining good starting values for the parameters in the computer solutions for systems as complex as a strongly coupled A_2B_2X.

EXPERIMENTAL

Proton spectra were taken on a Varian DP60 n.m.r. Spectrometer and calibrations were carried out by the side-band technique relative to internal tetramethylsilane (TMS). Spectra were taken in a number of solvents but in none of them except benzene were they strikingly different from the standard spectrum in $CDCl_3$ recorded by Bhacca *et al.* (6). In benzene it was possible to obtain a spectrum of simple appearance at a concentration of about 1:4 by volume. This concentration was very critical and the collapsed peaks were found to separate rapidly with concentration on *either* side of the critical one.

Spectra of this critical solution in benzene were run at various temperatures up to 131° C. Dissociation of the very weak complex formed with benzene (7) allowed the separation of the collapsed peaks to be followed in a sensitive way. In this way the assignments of the peaks could be checked and it was also possible to obtain the relative order of the shifts of the two sets of equivalent protons in the uncollapsed region.

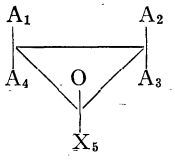
RESULTS AND DISCUSSION

The proton spectrum of the critical solution in benzene is shown together with calculated spectra in Fig. 1. In Fig. 2 the spectrum of the same solution at 64° C is shown.

1. *The Case $A_2A_2'X$*

The critical solution spectrum of the ring protons corresponds to the case $A_2A_2'X$.* The limiting case where the couplings from A_2 and A_2' to X are equal has already been discussed by one of us (8). None of the possible 46 combination lines were considered in that treatment. Because some of these play a major role in our discussion and for reasons of clarity we discuss here a rather general case, including the combination lines.

The ring-proton system for the critical solution can be characterized as in I:



$$H_A = H_{A'} = H_0(1-\sigma_A);$$
$$J_{12} \approx J_{34};\ J_{14} = J_{23};\ J_{15} = J_{25};$$
$$J_{35} = J_{45};\ J_{13} = J_{24}$$

I

We shall assume that $J_{12} = J_{34}$. This is the only approximation we make and from the analysis of cyclopropylcarboxylic acid (9, 10) this approximation is considered to be valid to at least 0.5 c.p.s. Thirty-six of the line positions are independent of J_{12} and J_{34} and from the analysis it is clear that the error in many other line positions will be about half that of the difference in J_{12} and J_{34} or about 0.25 c.p.s.

The matrix elements in the F_z representation are given in reference 8. In the $A_2A_2'X$ case the matrix is factored to eight 1×1, eight 2×2, and two 4×4 submatrices.

Positive quantities A, B, C, D and angles θ, ϕ, ψ, γ are defined by

[1]
$$4A\cos 2\theta = J_{35}-J_{15} \qquad 4B\cos 2\phi = J_{15}-J_{35}$$
$$2A\sin 2\theta = J_{23}+J_{13} \qquad 2B\sin 2\phi = J_{23}+J_{13}$$
$$4C\cos 2\psi = J_{35}-J_{15} \qquad 4D\cos 2\gamma = J_{15}-J_{35}$$
$$2C\sin 2\psi = J_{23}-J_{13} \qquad 2D\sin 2\gamma = J_{13}-J_{23}$$

**The amine protons gave a broad peak. Apart from a slight broadening of the neighboring proton there was no evidence of any coupling with the ring protons by either the amine protons or the nitrogen nucleus.*

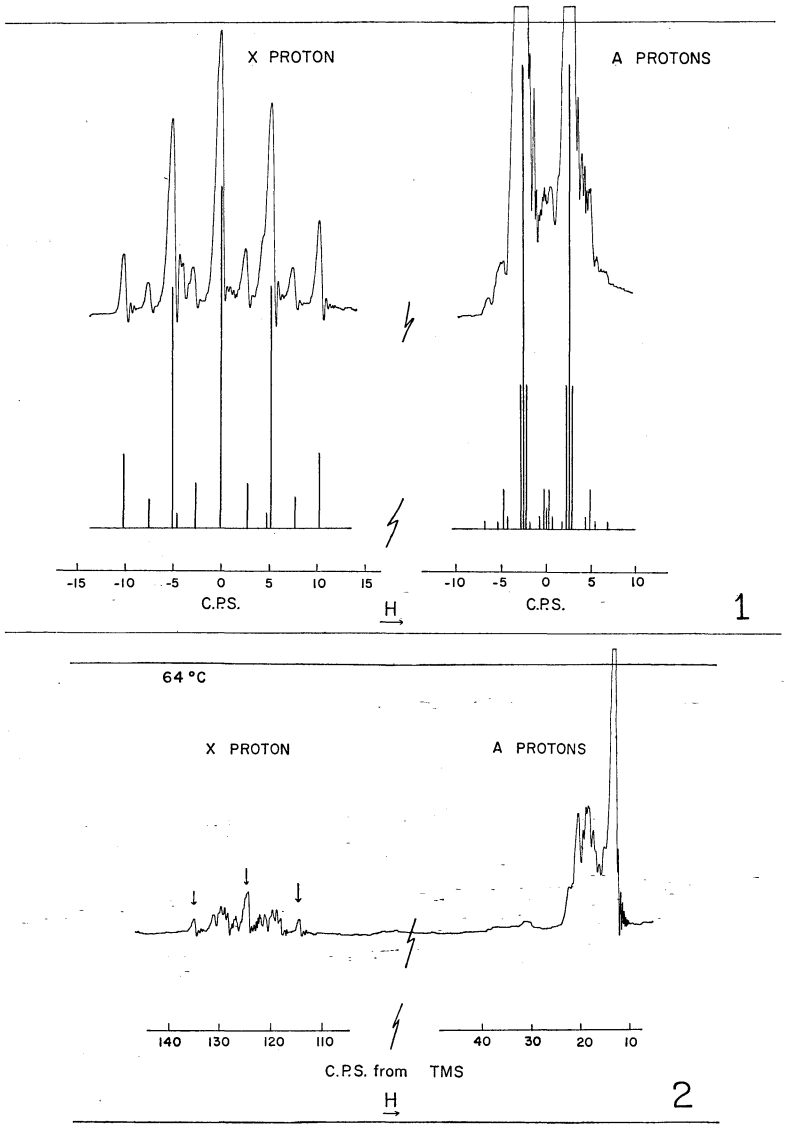

FIG. 1. Proton magnetic resonance spectrum at 60 Mc/s of cyclopropylamine in benzene at room temperature. Calibration is in c.p.s. with respect to $\nu_0(1-\sigma_A)$ and $\nu_0(1-\sigma_X)$, which are at 16.2 c.p.s. and 123.2 c.p.s. to low field of internal TMS, respectively. In the calculated spectrum, the two large *pseudo* triplets in the A region are drawn to one-third the intensity of the other transitions. The amino group resonance at 84.8 c.p.s. to low field of internal TMS is not shown.

FIG. 2. Proton magnetic resonance spectrum at 60 Mc/s of cyclopropylamine in benzene at 64° C; calibration is to low field of internal TMS. The amino group resonance at 90 c.p.s. is not shown. The transitions of the X proton which do not vary in position on introduction of a shift between A_2 and A_2' are indicated by the arrows.

The indicated orthogonal transformations were carried out on the eight 2×2 matrices and the stationary spin functions and energies are given in Tables III and IV of reference 8.*

**Reprint requests for this paper will also receive a reprint of reference 8.*

Selection rules allow a maximum of 110 transitions for the five nuclei. Of these, 46 are combination lines which were not considered in reference 8 but which will be taken into account here. Of the 46 combination lines, 18 are zero under all circumstances. This leaves 92 transitions for the general case. At this point we cease to distinguish between combination and other lines since for strong cross-coupling there is no longer a real distinction in the $A_2A_2'X$ limit.

The X protons give rise to a maximum of 36 lines of which 16 involve the two 4×4 submatrices. For the other 20, explicit energies and intensities are given in Table I. The A_2 and A_2' protons give rise to 56 lines of which 32 involve the 4×4 submatrices. Explicit energies and intensities for the other 24 are given in Table II.

TABLE I

Transitions and intensities of proton X

	Energy, relative to $\nu_0(1-\sigma_X)$	Relative intensity
1.	$J_{15}+J_{35}$	1
2.	$1/2(J_{15}+J_{35})-A+B$	$(\cos\theta\cos\phi+\sin\phi\sin\theta)^2$
3.	$1/2(J_{15}+J_{35})+A-B$	$(\cos\theta\cos\phi+\sin\phi\sin\theta)^2$

20.	$-1/2(J_{15}+J_{35})+C+D$	$(\sin\gamma\cos\psi+\sin\psi\cos\gamma)^2$

NOTE: Transitions 21–36 involve the 4×4 submatrices.

2. The Proton Spectrum of Fig. 1

(a) The X Region

If the six weakest lines in the region are disregarded there are left five equally spaced lines with a separation of 5.10 c.p.s.* Comparison with Table I indicates that we have $|J_{15}+J_{35}| = 10.2$ c.p.s. In a *pseudo* first-order spectrum these five lines would be expected to have intensities in the ratio of 1:4:6:4:1. It is obvious that this is not so and, clearly, the six weak lines derive their intensitis from the inner three of the main lines.

In Table I eight lines are listed (lines 13–20) which become combination lines in the limit of a large shift between the A_2 and A_2' protons. We assign lines 13–16 to the two pairs flanking the main peaks at ±5.10 c.p.s. From equation [1] it immediately follows that $A = B = 1.25$ c.p.s., and using the experimental intensities in Fig. 1 we can place the following limits on the parameters: $1/4(J_{35}-J_{15}) = 0.7 \rightarrow 0.8$ c.p.s., $1/2(J_{23}+J_{13}) = 1.0 \rightarrow 0.9$ c.p.s., $\phi-\theta = 41^\circ \rightarrow 44^\circ$.

**The intensities of these lines increase slightly towards high field, indicating that the X approximation is not quite valid. However, $\nu_0(\sigma_A-\sigma_X) = 107.0$ c.p.s. compared with the largest off-diagonal element, expected to be no larger than about 12 c.p.s. It is well known that the line positions are not nearly as sensitive to the spin functions as are the intensities and we can proceed with the analysis with some confidence.*

49.	$1/4(2J_{13}+2J_{23}+J_{15}+J_{35})+A$	$2(1-\sin 2\theta)$
50.	$1/4(2J_{13}+2J_{23}-J_{15}-J_{35})+B$	$2(1-\sin 2\phi)$
51.	$1/4(-2J_{13}-2J_{23}+J_{15}+J_{35})+A$	$2(1+\sin 2\theta)$
52.	$1/4(-2J_{13}-2J_{23}-J_{15}-J_{35})+B$	$2(1+\sin 2\phi)$
53.	$1/4(-2J_{13}+2J_{23}+J_{15}+J_{35})+C$	$1-\sin 2\psi$
54.	$1/4(2J_{13}-2J_{23}+J_{15}+J_{35})+C$	$1+\sin 2\psi$
55.	$1/4(-2J_{13}+2J_{23}-J_{15}-J_{35})+D$	$1+\sin 2\gamma$
56.	$1/4(2J_{13}-2J_{23}-J_{15}-J_{35})+D$	$1-\sin 2\gamma$
57.	$1/4(2J_{13}-2J_{23}+J_{15}+J_{35})+C$	$1+\sin 2\psi$
58.	$1/4(-2J_{13}+2J_{23}+J_{15}+J_{35})+C$	$1-\sin 2\psi$
59.	$1/4(-2J_{13}+2J_{23}-J_{15}-J_{35})+D$	$1+\sin 2\gamma$
60.	$1/4(2J_{13}-2J_{23}-J_{15}-J_{35})+D$	$1-\sin 2\gamma$

NOTE: Transitions 61–92 involve the 4×4 submatrices.

We have assumed here that J_{23} is smaller than and of opposite sign to J_{13} and that J_{15} and J_{35} are of the same sign with $J_{35} > J_{15}$. This agrees with a considerable set of data (10–13). The same sign of J_{23} and J_{13} would simply interchange the constants A, B with C, D so that the relative signs of J_{23} and J_{13} cannot be obtained from the spectrum at this point. Opposite signs of J_{15} and J_{35} can, however, be ruled out at this point. If they did have opposite signs then the spectrum would not be simple unless $1/4(|J_{35}|+|J_{15}|) \ll 1/2|J_{23}+J_{13}|$, which is hardly likely. On the other hand, if J_{13} were very small (cross-coupling small) and $1/4|J_{35}-J_{15}| \ll 1/2|J_{23}|$ then the spectrum would be completely *pseudo* first-order as has been shown, in effect, in reference 8.

From the additional demand that C and D be large enough to have $\sin^2(\psi+\gamma) \lesssim 0.01$ (lines 17–20 in Table I are then unobservable), it follows that $C = D = 6.5 \rightarrow 6.6$ c.p.s. with $1/2|J_{13}-J_{23}| = 6.5-6.6$ c.p.s. Hence we obtain $J_{23} = -5.5\pm0.1$ c.p.s. and $J_{13} = 7.5\pm0.1$ c.p.s.

With this set of data the intensities and positions of all the lines in Table I can be calculated. The positions of the two weak lines overlapping the main lines at ±5.10 c.p.s. are still to be accounted for. We note that the pairs of lines at ±10.2 c.p.s. are of unit intensity and should not vary in position on introduction of a shift between A_2 and A_2'. The same holds for the position of the six lines falling at 0 c.p.s. In Fig. 2 the spectrum verifies these statements. The separation of the three peaks in the X region is temperature independent.

(b) The A Region

The partial set of parameters derived from the X region allows the calculation of intensities and positions of the 24 lines in Table II. None of the intense lines deviate by more than 0.2 c.p.s. from the expected positions at $\nu_0(1-\sigma_A)\pm2.55$ c.p.s.

(c) The 4×4 Submatrices and J_{12}

We must now solve the two 4×4 submatrices. The energy levels of the one will differ from the energy levels of the others only by $\nu_0(1-\sigma_X)$. Hence four transitions between the two sets will fall at $\nu_0(1-\sigma_X)$, no matter what parameters are used for the solution, but the other transitions involving these eight energy levels will depend on the input parameters. J_{15} and J_{35} enter in the same way as in equation [1]. J_{23} and J_{13} enter separately and we take the values obtained above. J_{12} enters also, for the first time, and we chose it as an adjustable parameter. The 4×4 submatrices were solved for the values of J_{12} = 8.0, 9.0, 10.0, 11.0, and 12.0 c.p.s. The positions of the weak lines at ±4.6 c.p.s. in the X region were smooth and fairly sensitive functions of J_{12}, although their intensities were not very sensitive to J_{12}. In this way we found $J_{12} = 12.5\pm0.5$ c.p.s., a reasonable value (10).

The complete calculated spectrum of 92 lines is shown in Fig. 1. Note that additional intensity accrues to the lines at $\nu_0(1-\sigma_X)\pm2.7$ c.p.s. from transitions involving the 4×4 submatrices. Note also that all lines separated by 0.25 c.p.s. or less have been collapsed in order to take the finite resolution of the observed spectrum into account. The agreement found is thought to be satisfactory. It indicates also that J_{23} is indeed negative since it enters diagonally and off-diagonally into the 4×4 submatrices. In Fig. 1 it is seen that the lines in the A region which fall off the ±2.55 c.p.s. doublet calculated in *pseudo* first-order are relatively weak compared to the analogous lines in the X region. If the A region is run at an instrument gain such that the doublet just fills the paper no evidence of any other lines is noticeable.

(d) Summary of Results

We feel that the following sets of parameters in c.p.s. are reliable within the limits stated:

$$\begin{aligned}
\nu_0(\sigma_A-\sigma_X) &= 107.0,\\
J_{34} \approx J_{12} &= J_{cis} = 12.5\pm0.5,\\
J_{14} = J_{23} &= J_{gem} = -5.5\pm0.3,\\
J_{24} = J_{13} &= J_{trans} = 7.5\pm0.3,\\
(J_{15}+J_{35}) &= 10.2\pm0.1,\\
J_{25} = J_{15} &= J_{trans} = 3.6\pm0.5,\\
J_{45} = J_{35} &= J_{cis} = 6.6\pm0.5.
\end{aligned}$$

The last two values have been derived by considering the data in references 10–13, which suggest that the ratio of J_{cis} to J_{trans} falls between 1.5 and 1.8, increasing as the electronegativity of the substituent increases. The geminal coupling constant is designated as negative with respect to the vicinal coupling constants.

3. The Solvent and Temperature Dependence of the Shift of the A and A′ Protons

The effect of the benzene is to shift one pair of protons to high field more effectively than the other. For steric reasons (7, 14) we would expect the protons trans to the NH_2 group to be shifted most rapidly to high field by the anisotropic benzene molecules. If this is actually an association effect, similar to the one we studied for bis(2,2-dichlorocyclopropyl) ether (7), then increasing temperature should cause the fastest low-field shift for these protons. In Fig. 2 the low-field line of the intense doublet in the A region has split up while the high-field line has not. In equation [1] each of the cosine expressions has added to it a shift term on the right-hand side for the A_2B_2X case. From the values of the coupling constants given above we can calculate the values of A, B, C and D as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

a function of the shift between the A and A′ protons. It follows easily that only A changes rapidly in the region of small shift. For instance, when the shift is 1 c.p.s., A has changed from 1.3 to 2.1 c.p.s. while the others have changed by about 0.2 c.p.s. We expect lines like 37 and 51 in Table II to change their positions most rapidly and these are both originally centered on the low-field line of the intense doublet.

Now it is clear that in the limit of large shift the splitting in the group of lines arising from the protons trans to the amino group, i.e., cis to the X proton, will be largest: $J_{cis} > J_{trans}$. Hence, as the shift decreases to zero this group of lines will collapse last. This set of lines appears at low field as shown above and moves to low field as the temperature increases. We have shown, therefore, that it is the protons trans to the amino group which are most solvent dependent and experience the largest high-field shift on dilution in benzene. This is consistent with a preferred interaction with benzene molecules at this position.

The low-field shift of the trans protons can be understood in terms of Buckingham's electric field calculations (15). The cis protons would also be shifted to low field by the dipole whose negative end points in the C—N direction but, due to the angular factor, would be expected to be less, as observed. A quantitative estimate demands a knowledge of the magnitude of this dipole and also, perhaps, whether the contribution of the lone pair on the nitrogen is important.

THE TRANSMISSION OF POLAR EFFECTS

KEITH BOWDEN
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received June 6, 1963

ABSTRACT

The transmission of polar effects by various groups is assessed by means of the reaction constants ρ or ρ''. The results are critically discussed in terms of the various polar, steric, and solvent effects. Conclusions are drawn as to the importance of the inductive and direct field effects.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

INTRODUCTION

The processes which have been postulated to account for the polar influences of substituents are the direct field, inductive, and resonance effects. The direct field effect is the coulombic action on a reaction center of a charged or dipolar substituent. The inductive effect is the effect due to the polarization of the bonds connecting the substituent to the reaction center. The bonds so affected may be either the strong σ-bonds, which determine the skeletal geometry of the system, or the weaker, fluid π-bonds. In systems involving π-bonds a resonance effect may occur. If the substituent has electrons in suitable atomic orbitals, these can participate in the molecular orbital of a conjugated system (interaction of the π-electron cloud with a lone pair of the substituent), to displace electrons within the system.

Ingold (1) considered the first two effects separable. Other workers have thought this view to be mistaken and have either considered the two effects to be inseparable or one effect to predominate. Kirkwood and Westheimer (2) attempted to calculate the transmission of polar effects by considering the direct field effect alone. Later workers (3, 4, 5) have used their methods to give fair correlations of observed and calculated effects in a number of systems. Dewar and Grisdale (6) in recent studies have attempted an empirical relation on this basis. Jaffé (7) has used a M.O. method to calculate the transmission by π-bonded systems by assuming that only the π-inductive effect is important (cf. ref. 8). Taft (9) regards polar effects as separable into inductive and resonance contributions, in a similar manner to the earlier contributions by Branch and Calvin (10).

The Hammett equation (i) and similar linear free energy relations (4, 5, 9, 11) can be used to correlate reaction rates and equilibria. The substituent constant σ was considered

$$\log (k/k_0) = \rho\sigma \qquad \text{(i)}$$

to be independent of the nature of the reaction, and is a measure of the polar effect of a meta or para substituent relative to the unsubstituted compound. The reaction constant ρ for a reaction series is thus a measure of the susceptibility of the reaction to polar effects.

The relay of polar effects by 23 aryl and alkyl systems has been studied in an attempt to determine the relative importance of the various mechanisms of transmission. Linear free energy relations have been used to assess the efficiency of transmission without confusion caused by exalted resonance effects. Also a model system has been constructed to estimate the direct field effect and the apparent inductive transmission factors have been calculated. The transmission was then interpreted in terms of the direct field and

inductive effects. The steric effects of ortho substitution on the solvation and the transmission of polar effects are discussed. Substituent effects in benzene are related to these results and an analysis of the proposed model systems of benzene is given.

CALCULATIONS AND RESULTS

The correlations were made using the statistical methods of Jaffé (12). The ideals of Wepster and his co-workers (13) were observed, as closely as possible, in choosing the substituents to be studied, which were those in which extra-resonance interactions could be considered negligible, and the substituent constants σ were used (see ref. 13 and p. 000). In a limited number of reactions (Table I, reaction series 8; Table II, reaction series 6 and 8) it was necessary to use substituents (*p*-methyl, *p*-chloro, or *p*-bromo) which might exhibit exalted resonance effects. However, these substituents show only small variations in resonance effect and the σ^n values used should have general applicability.

Three reactions were chosen: ionization of carboxylic acids, esterification of carboxylic acids with diazodiphenylmethane, and alkaline hydrolysis of carboxylic esters, for which sufficient data are available. In Table I the Hammett reaction constants ρ are given for systems where a group Y separates the aromatic phenyl group from the reactive function. Table II shows the Hammett reaction constants for systems in which the ortho substituents of the aryl group are varied. The reaction constants ρ'' in Table III are based on the ionization of *trans* 4-substituted cyclohexanecarboxylic acids (5). The substituent constants σ'' for the hydrogen, chloro, hydroxy, cyano, carbomethoxy, and methoxy groups (5) are used.

Correlation coefficients are in all cases greater than 0.95 and are usually (70% of them) between 0.98 and 1.00. The number of substituents studied, n, is shown and the reference given. Where Wepster's work (13) is indicated, his value of ρ has been used.

Polar Effects

Kirkwood and Westheimer have proposed the equation (ii) to calculate the direct field effect of a substituent group on ionization constants and the relative rates of alkaline

$$[ii] \qquad \log K/K_0 = \frac{e\mu \cos\theta}{2.303kTD'r^2}$$

hydrolysis of esters (2), where μ is the dipole moment, e the electronic charge, k the Boltzmann constant, T the absolute temperature, r the distance between the center of the dipole and the reaction center, and D' the effective dielectric constant. θ is the angle between the line joining the reaction center and the center of the dipole and the axis of the dipole. The effective dielectric constant is difficult to calculate. Molecules are considered to be cavities of low dielectric ($D = 2.0$) embedded in the solvent, which has commonly a very high dielectric constant.

The transmission of the substituent effect is determined by the factor $\cos\theta/r^2D'$. A simple model of the systems studied was used to calculate the readily computable angle and distance. The center of the dipole was considered to be situated at the "para" carbon atom of the phenyl group for the systems involving aromatic and arylaliphatic groups. The direction of the dipole vector was then taken as the line generated by joining the "para" carbon atom to the carbon atom linked to the functional group. The chloro-substituted molecules were used as models for the systems shown in Table III (i.e. aliphatic and alkylaromatic). The reactive center was sited 0.89 Å beyond the carbon of the carboxyl group on the extension of the bond joining the carboxyl carbon to the rings.

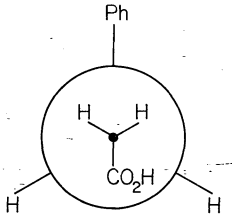
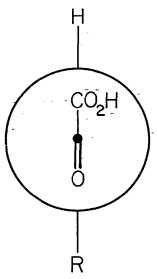
[b]ϕ is equal to $\cos\theta/r^2$ divided by the same factor for reference system.

Table IV shows the distance r, the angle θ, and $\cos\theta/r^2$. Only for systems 3, 4, 11 (Table I), and 4 (Table III) do conformational considerations affect the calculation. The calculation for both the "anti" and "eclipsed" conformational models (see ref. 40) is shown for the β-phenylpropionic system. However, the "anti" conformer (I) is sterically preferred and can be assumed to be that existing in solution. The benzylidenepyruvic acid system



I



II

(Table I, series 11) is also assumed to occur as the sterically preferred conformer. This molecule can be assumed to be nearly planar (fully conjugated) and have the conformation II where R is *trans*-PhCH.

The inductive effect can be transmitted by the successive polarization of the σ-bonds and the π-bonds. The σ-inductive effect will decrease progressively by transmission through the bonds. The magnitude of the π-inductive effect will depend on the position of the substituent in the same way as does a resonance effect (para substituents having a very much greater effect than meta substituents) and will also be progressively reduced by transmission (6). Inductive transmission of the polar effect can be represented by the relation (iii), where A is a constant, σ the substituent constant, and ϵ the transmission

(iii) $$\log K/K_0 = A\sigma \text{ II } \epsilon_t$$

For personal use only.

factor of the ith atom (see ref. 34). Each type of atom transmitting the effect will have a unique transmission factor. Different estimates of the transmission factors have been given by several workers, mainly on empirical grounds. The factors vary quite widely, with ϵ estimated in the range 0.1 to 0.6 (9, 34, 41).

The ratio ρ/ρ_0 has been used to evaluate the transmission of polar effects by groups (7, 39), where ρ_0 is the reaction constant of the reference system at the same temperature and in the same solvent. These ratios are given in Table V. The apparent transmissive factors, ϵ, for several transmission centers have been calculated from the reaction constants and are given in Table VI.

DISCUSSION

The effects of resonance and medium must be considered before an assessment of the relative importance of the various polar effects can be made.

Resonance Effects

The work of Wepster and Taft has demonstrated the variable resonance effects of substituents (13, 36). Three resonance effects must be considered:

(*a*) conjugation of the substituent and the reaction site through a π-electron system;

(*b*) Resonance interaction of the substituent and the aromatic π-electron system;

(*c*) Resonance interaction of the π-electron system and the functional group.

Reaction systems which allow exalted interactions of the first type to occur should be excluded as they will give rise to anomalous ρ values. Apart from the exceptions noted previously (see p. 000), the reaction constants obtained in this study are free from these effects.

Medium Effects

Reaction constants depend on the reaction medium. The reaction constant, ρ, has been considered to vary with the dielectric constant (D) of the medium according to the

$$\rho = (A+B/D)/RT \qquad \text{(iv)}$$

relation (iv), where the constants A and B respectively describe the susceptibility of the reaction to polar effects independent of and dependent on the medium (37). The polar effect appears to be transmitted through the molecule (term A) and the solvent medium (term B). However it is very likely that ρ is also determined by the solvating power of the medium (33, 38).

The ratio ρ/ρ_0 has been used to evaluate the transmission of polar effects. This ratio will be solvent dependent. The medium in the reactions studied varies from water ($D = 81.1$) to ethanol ($D = 24.3$). Any evidence from this ratio of the ability of a system to transmit polar effects must be considered carefully. As a first approximation, the mean value of the reaction constant ratio can be evaluated and discussed, but the variation of the ratio with both reaction and medium must be considered.

Substituent constants may also depend on the medium (12). This appears to be important only for systems where solvation either enhances the contribution of resonance of the exalted type, or when the substituent is very prone to protonic solvation (e.g. hydroxyl and amino substituents) (48). Such resonance systems have been excluded and the solvation character of the media in this study does not greatly vary.

The Reaction Constants

The results presented in Table I, II, and III lead immediately to certain conclusions. The existence of linear free energy relations of high precision between different series implies that the variable conformational factors present for certain series (e.g. Table I, series 2, 3, 4, and 11; Table III, series 3 and 4) must be unimportant in the change from reactant to transition or product state (9). Likewise these relations indicate that, for a significant direct field effect to operate, the effective dielectric constant must be constant for a series of substituted molecules. Several workers (5, 42) have suggested that a single value of the effective dielectric constant should be used in calculations on such series.

Aliphatic and Alkylaromatic Systems

The systems presented in Table III have the substituent bonded to an sp^3 hybridized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

carbon atom and usually the functional group bonded to a similarly hybridized carbon atom.

A choice of a reference system was necessary for the analysis of the data. The 4-substituted *trans*-cyclohexanecarboxylic acids have the advantage of data being available for several reactions and substituents, without the possibility of variable proximity effects. As reaction series 3 and 4 (α-substituted acetic and β-substituted propionic acids) give good linear relations, no significant primary steric effects of the type associated with alkaline hydrolysis (9) can occur for the ionization and esterification reaction.

Although the results are limited in scope, the significant medium dependence of ρ'' where the substituent is distant from the reaction center (Table III, reaction series 1: the ionization of substituted cyclohexanecarboxylic acids) contrasts sharply with the relative insensitivity to medium when the substituent is proximate to the reaction site (Table III, reaction series 3: the ionization of substituted acetic acids). Any explanation which neglects the transmission of polar effect through the medium must be unsatisfactory. As a solvent-induced change in the polarizability of the system appears very unlikely, the importance of the direct field effect seems confirmed.

The reaction constant ratios presented in Table V summarize the available evidence. If a dominant inductive effect occurs, a ratio of 1.50 must be ascribed to the bicyclo-(2.2.2)octane system, which has three dimethylene links compared to the two of cyclohexane. A mean value of 1.57 ($\pm$0.21) is observed. The mean ratio of 5.68 ($\pm$1.15) for the methylene group would require a transmissive relay ($\epsilon(C_{sp^3})$) equal to 0.45 ($\pm$0.03). Fair correlations have previously been made by direct field calculations (4, 5). The increasing size of the low-dielectric cavity, and the proximity of the dipole to the reactive site increases transmission. This can be seen in Table IV.

An interesting system, α-substituted *p*-toluic acids, has been studied recently by Exner and Jonáš (34). The efficient transmission of polar effects ($\rho''/\rho_0'' = 0.83$) by this system cannot be easily explained by a direct field calculation (using the results in Table IV and an effective dielectric constant which cannot be very much greater than that for the reference system). It is significant that the transmission coefficient for the *p*-phenylene link in Table III (0.21; from ρ'' for α-substituted *p*-toluic and acetic acids) approximates to that of the *p*-phenylene link in Table I (0.26; from ρ for *p*-phenylbenzoic and benzoic acids).

Aromatic and Arylaliphatic Systems

Table I presents the systems where the substituent is bonded to an sp^2 hybridized aromatic carbon atom and the functional group is bonded to a carbon atom which is either sp^1, sp^2, or sp^3 hybridized.

The interpolation of a single methylene group results in a reduction in the transmission, and a second methylene group reduces this further. This can be understood in terms of an inductive effect ($\epsilon(C_{sp^3}) = 0.48$) or a direct field effect (reduction caused by the change in dipole orientation and the higher effective dielectric constant). The increase in ρ observed for transmission by the oxygen atom, compared to the methylene group, can similarly be understood in terms of an inductive effect ($\epsilon(O) = 0.63$) or a direct field effect (see Table IV; for similar conformers $\cos\theta/r^2$ slightly increases, and D' is very similar).

The transmission of a polar effect by the *trans*-ethylenic link ($\rho/\rho_0 = 0.449$) is much greater than that of the dimethylene group ($\rho/\rho_0 = 0.246$). The β-phenylpropionic acids probably exist in the sterically preferred conformation (see p. 000). The direct field effect for this system would be very similar to that for the *trans*-cinnamic acids (see Table IV).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

As the σ-inductive effect will be similar, it is probable that a π-inductive effect causes the observed increase in transmission. The lower value of ρ observed for the *cis*-cinnamic acids compared to the *trans*-cinnamic acids could not be due to a change in a σ-inductive effect. The π-inductive effect is damped in the cis isomer, where steric interaction of the phenyl and carboxyl group is relieved by twisting. This results in a loss of conjugation. Cos θ/r^2 is much greater for the cis than for the trans isomer (ϕ = 0.71, 0.48 respectively; see Table IV). However, the effective dielectric constant will also be greater because of the change in spatial configuration. The field effect may well be greater for the proximate cis isomer (see below for cyclopropane). The decrease in ρ shown for the *cis*- compared with the *trans*-cinnamic acid system would then be due to a reduction in the π-inductive effect.

The markedly reduced transmission observed for the acetylenic link (ρ/ρ_0 = 0.330), compared to the ethylenic link, is very probably due to a reduction in the π-inductive effect, the triple bond being less polarizable (40). The σ-inductive effect should be similar in both cases. The electrostatic field effect would be expected to be greater for this system where the low-dielectric cavity is directly between the substituent and the functional group, and where cos θ/r^2 is comparable to that for the *trans*-cinnamic isomer.

Transmission by the *p*-phenylene system appears very efficient (ρ/ρ_0 = 0.259), considering the length of the carbon chain connecting the substituted phenyl group to the reactive site. If an inductive effect operates, a high transmissive factor ($\epsilon(C_{sp^2}$ aromatic) = 0.60) can be calculated. This system must have an effective dielectric comparable with and possibly slightly less than that of the phenyl group itself. The direct field effect calculations appear to show that a very reasonable estimate (0.30) of the reaction constant ratio (0.26) can be made.

The cyclopropane system seems to be very complex, but permits a number of observations. The magnitude of ρ/ρ_0 (0.338) for the trans isomers makes the occurrence of a π-inductive effect extremely unlikely (see ref. 21); e.g., the ratio can be calculated as 0.34 for an inductive transmission using $\epsilon(C_{sp^3})$ equal to 0.48 (Table VI). The results for the cis isomer ionization equilibria may be anomalous due to a steric effect on solvation (see below). The increase in ρ shown by the ester hydrolysis reaction for the *cis*- compared to the *trans*-phenylcyclopropane system (ρ = 1.098, 0.846 respectively) appears to be due to the direct field effect being much greater for the cis isomer (see Table IV).

Effect of Ortho or "Ortho" Fused Ring Substituents

The possible effects of ortho substituents and "ortho" fused ring substituents on the reaction constants are shown in Table VII.

TABLE VII

Effect of ortho groups on the reaction constants

	Effect on ρ
Polar facilitation of steric inhibited solvation	Increase
Steric inhibition of resonance of functional group (π-inductive effect)	Decrease
Increase in size of low dielectric cavity (field effect)	Increase
Increase in transmissive relay routes (σ- or π-inductive effect)	Increase

The importance of steric inhibition of solvation in the ionization equilibria has been demonstrated (43, 44). The reduced solvation will preferentially decrease the stability of the anion with respect to the acid. Polar facilitation of solvation will then become

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

important and will increase the susceptibility of the system to polar effects. The increase in the reaction constant (ρ = 1.15 to 1.25, see Table II) for the ionization reaction in water is very probably due to this effect (see ref. 30). The reaction constant for the ionization in water of the system having an ortho nitro group (ρ = 0.905) alone does not show this increase. This must be due to an effect operating in the opposite direction, to decrease the reaction constant. This decrease is probably due to the steric inhibition of the resonance interaction between the functional group and the aromatic system. The carboxylate group is twisted out of the plane of the aromatic ring by the bulky ortho group. The π-inductive effect will be greatly reduced in these circumstances and ρ will fall. The intense dipole–dipole interaction present in the anion of the *o*-nitrobenzoic acids will intensify this reduction.

Steric effects on solvation appear to be unimportant in the esterification of the acids with diazodiphenylmethane in ethanol (17, 45). The importance of the reduction in the π-inductive effect is then apparent. All other effects would be expected to increase ρ by increasing the transmitting power of the relaying molecule compared to the benzene molecule itself. Changes in the π-electron distribution, especially for the naphthalene or anthracene molecules, may affect these considerations. However, this would only emphasize the importance of the relay of the polar effect by the π-electron system. The results for the alkaline hydrolysis, though less certain and comprehensive, appear to confirm the conclusions for the esterification reaction. The ionization reaction in mixed solvents is more complex. The situation will be complicated by solvent-sorting which occurs in mixed-solvent media (46). However, the results can be understood in terms of a competition between the two effects, the polar facilitation of solvation and the steric inhibition of resonance.

Substituent Effects in Benzene

The polar effect of the substituent group $-NMe_3^+$ is greater at the meta than at the para position (47). It is accepted that this substituent has no resonance interaction with the aromatic ring. The observed ratio of the effects, σ_m/σ_p (1.14±0.02), can be accounted for either by an inductive effect or a direct field effect. The ratio is given as 1.17, using an inductive transmission factor, $\epsilon(C_{sp^2}$ aromatic), of 0.60 (see Table VI), while a direct field effect calculation gives 1.15 as the ratio, assuming the effective dielectric of the isomers to be the same. The ratio σ_m/σ_p^n for dipolar substituents having a negligible exalted resonance effect is 0.89±0.06 (see ref. 13). This ratio, calculated as above, is 1.17 for transmission by an inductive effect and approximately 1.09 for a direct field effect. The decrease in the ratio apparently results from the π-inductive effect, which is much greater from the para than from the meta position. These dipolar substituents have a polar effect from the para position which includes a π-inductive effect amounting to about 20% of the total.

Models of the Benzene System

Roberts and Moreland (4) have attempted to construct a model of the benzene system without the π-electron system. A number of criteria must be satisfied for such a model to be perfect:

(1) The model must be geometrically sound, having a reasonably correct dipole-reactive site distance (r) and angle (θ).

(2) The factors involved in relaying polar effects must remain constant, i.e. the number of chains connecting substituent and reactive site, and the size of low-dielectric cavity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(3) The steric environment of reactive center must be similar to that in the benzene system.

Two further factors can be cited which appear impossible to include in a model system:

(4) The substituent group should be bonded to a similar carbon atom (C_{sp^2}).

(5) The functional group should be the same, being a carboxyl group in resonance with an aryl group as in benzoic acid.

The model chosen by Roberts and Moreland, the bicyclo(2.2.2)octane system, fully satisfies only the first of the criteria. The similarity in the effects of substituent groups in both systems does not justify the conclusion that a π-inductive effect does not occur, because the transmissive relay factors (see 2 above) change as between the bicyclo-(2.2.2)octane-1-carboxylic and benzoic acids. The *trans*-cyclohexane system studied by Siegel and Komarmy (5) appears to be a more satisfactory model in terms of the first three criteria. The variation of reaction constants ρ'' with reaction type for the bicyclooctane or *trans*-cyclohexane systems does not parallel that for the benzene system. This throws serious doubt on the applicability of either system as a means of estimating the various transmissive effects in the benzene system.

CONCLUSIONS

The transmission of the polar effect of a substituent is at present best understood in terms of both the inductive and direct field effects. The polar effect is mainly conveyed through the molecular cavity. The direct field effect is an important feature of the polar effect. The σ-inductive effect, in comparison, seems to be less important. For aromatic and conjugated systems, the π-inductive effect is significant.

It is unlikely that an absolute separation of these two effects can be made, though model systems can be devised to attempt this.

PROTONATED CARBONYL GROUPS

III. ANTIPYRINE SALTS[1]

DENYS COOK

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received July 17, 1963

ABSTRACT

Salts of antipyrine (2,3-dimethyl-1-phenyl-5-pyrazolone) with halogen acids have been prepared and their infrared spectra from 4000 to 650 cm^{-1} recorded. Stoichiometrically they are normal 1:1 salts. Identification of bands due to vibrations of the protonating hydrogen atom has been aided by replacement with deuterium atoms. It is concluded that protonation occurs at the carbonyl group from the presence of a doublet (due to correlation field splitting) at 1320 and 1220 cm^{-1}, attributed to the in-plane hydrogen-bending mode. The OH stretching vibration gives rise to bands between 2278 and 2720 cm^{-1} in the different salts. Out-of-plane hydrogen-bending mode absorptions are observed between 840 and 770 cm^{-1}.

More complex acids ($HAsF_6$ etc.) give the anomalous 2 base:1 acid salts, characterized by strong absorption below 1400 cm^{-1}, which probably contain strong, possibly symmetrical, hydrogen bonds.

INTRODUCTION

Infrared spectroscopic methods have been used recently to ascertain the protonation site in compounds containing carbonyl groups. 4-Pyrones (1) and 4-pyridones (2) were shown to protonate at the carbonyl group oxygen atom, and not at the heterocylic atom. The bending mode of the O^+—H group gives rise to absorption bands near 1260 cm^{-1} (mean value of two components ascribed to correlation field splitting). Thus, while the OH stretching vibration absorption, which can be observed between about 2400 and 3400 cm^{-1} depending on the anion, is diagnostically of little use, except to indicate that protonation has taken place, the bending mode, δ_{OH}, shows increasing dependable utility as an indication of the site of protonation.

A recent study of the infrared spectra of N,N-dicyclohexylacetamide salts (3) showed the bending mode to absorb near 1287 cm^{-1}, a rather higher value than in γ-pyrones (1) and γ-pyridones (2), and with a smaller shift on deuteration. The mesomeric system in amides which is responsible for much vibrational coupling (4) may also give rise to the same effects in the salts. It is of interest therefore to investigate further systems containing the —NRCO— grouping. The salts of antipyrine (2,3-dimethyl-1-phenyl-5-pyrazolone) are described at this time.

RESULTS

The infrared spectrum of the HCl salt of antipyrine is shown in Fig. 1, the broken line being the DCl salt. The bands in the spectra are collected in Table I, and the bands associated with vibrations of the protonating hydrogen atom are summarized in Table II.

DISCUSSION

The broad strong band in the spectra near 2300 cm^{-1} is associated with the OH stretching vibration of the protonated carbonyl group as in I. As Y^- gets larger and the effect of its force field diminishes ν_{OH} gets larger, indicative of a decreasing interaction in the hydrogen bond O^+—H$\cdots Y^-$. In the deuterium substituted salts (I, H = D) the isotopic

shifts are as expected, with the ratios ν_{OH}/ν_{OD} varying from 1.25 to 1.29. These are normal values for salts of hydrogen halides.

It could perhaps be emphasized at this point that there is nothing in the shape or contour of the absorption band due to the OH stretching vibration to differentiate it from similar bands in other protonated bases. γ-Pyrones (1), γ-pyridones (2), amides (3),

I

pyridine (5), amine oxides (6), etc. all show a similar band with minor variations in contour. They vary in position for the same anion, naturally, due to the different degree of interaction in the hydrogen bond $X^+—H\cdots Y^-$. Consequently such an absorption band is of little diagnostic use in deciding what type of donor atom has been protonated.

An investigation of the in-plane hydrogen-bending mode has shown, by contrast, that it can be diagnostically very useful in determining the type of atom protonated. In the present series of carbonyl donors, γ-pyrones (1) and γ-pyridones (2) were both found to have δ_{OH} near 1260 cm^{-1} (mean value of split components). The known values of δ_{OH} and the splittings, $\Delta\delta_{OH}$, are summarized in Table III. The antipyrine salts reported here

TABLE III

Average OH and OD bending frequency, splitting, and carbonyl stretching frequency in protonated carbonyl compounds

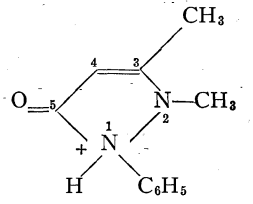
are no exception and their spectra reveal two bands near 1312 and 1218 cm^{-1} (average 1265 cm^{-1}) which shift on deuteration to near 1065 and 975 cm^{-1} (average 1020 cm^{-1}). These values for δ_{OH} are so typical of protonated carbonyl groups that 1265±20 cm^{-1} could be considered a useful group frequency. The values at the higher end of the scale are for salts containing the stronger hydrogen bonds. The ratio δ_{OH}/δ_{OD} (average values) varies from 1.18 to 1.33, but most are close to the higher figure. It seems that the low ratios are found in salts with high δ_{OD}, suggesting that if mechanical effects are concerned in these ratios, they will be more active in the deuterium salts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

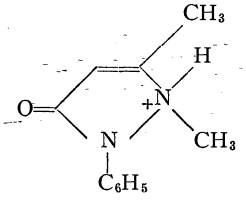
Splitting of the bending mode into two components is usually, but not universally, observed. In N,N-dicyclohexylacetamide salts (3) there was only one component near 1280 cm^{-1}; and in some unpublished data on 1,3-dimethyluracil salts only one component at 1278 cm^{-1} is observed. These values may seem a little high when compared with the average δ_{OH} in Table III. This is because only the hydrohalides have been studied for these two compounds which have stronger hydrogen bonds and therefore slightly higher δ_{OH}.

The doubling in the bending mode has been attributed (1, 2, 6) to correlation field splitting in the solid phase (7, 8). This occurs when two identical molecules having different orientations in the crystal are permitted, by coupling, to split certain vibrational modes. In the general case, the number of components is determined by the various symmetry groups involved, namely, the point group of the molecule, the site group, and the space group of the lattice, subject to a maximum equal to the number of molecules in the unit cell. Some of the components may be active under Raman selection rules, others may have infrared activity. The size of the splittings seems to vary, the larger values being associated with systems in which hydrogen bonding is important (see, for example ref. 9). The fact that in most of the carbonyl salts studied a doublet is common is not unexpected. Two or four is quite a common number of molecules per unit cell. This, in conjunction with a low symmetry for the protonated base and a site group of low symmetry, requires only a slightly higher space group symmetry to permit doubling. The higher the symmetry of the space group the more components will be possible. Naturally these higher symmetry space groups are rarer and therefore structures with more than two components will be more infrequently observed.

Two other atoms in antipyrine which can be considered to have basic character in certain circumstances are the two nitrogen atoms. Protonation of N_1 would give II and of N_2 would give III. Both of these structures have a protonated tertiary sp^3 amine group



II



III

which is well known to have a deformation mode near 1420 cm^{-1} (see refs. 1–3 for details). Such a band is not observed in the spectra of antipyrine salts. A further count for rejection of II arises from a consideration of carbonyl frequencies. Antipyrine itself has a strong band at 1670 cm^{-1} associated with the carbonyl stretching mode. A carbonyl group adjacent to a protonated sp^3 nitrogen atom (10) or a quaternized nitrogen atom carrying a positive charge (3, 11) has a much higher carbonyl frequency, close to 1800 cm^{-1}. Protonation at N_1 is therefore discounted from this evidence. This band at 1670 cm^{-1} in the neutral antipyrine, the strongest in the whole spectrum, is replaced by one near 1560 cm^{-1} in the salts, though another strong band is seen near 1496 cm^{-1}. While it has not been conclusively shown that the high-frequency band in amide salts is due exclusively to a C=N vibration, this mode probably makes the largest contribution. In the antipyrine salts there is probably even more coupling of these vibrational modes, so that four bands near 1590, 1560, 1552, and 1516 cm^{-1} are associated chiefly with CC and CN vibrations of the ring, and the 1496 cm^{-1} band predominantly with CO stretching. These

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

assignments, though almost certainly oversimplifications, nevertheless help to interpret vibrational modes in different salts. Thus the 1496 cm^{-1} band is close in frequency to other bands due to a protonated carbonyl stretching vibration (1, 2). These are listed under the heading $\nu_{C=O^+H}$ in Table III. With the exception of the two non-cyclic amides they are all close to 1500 cm^{-1}.

Salts Containing 2 Base:1 Acid

The salts of antipyrine and the more complex protonating acids such as $HAsF_6$ and $HSbF_6$ are not of the same stoichiometry as those of the hydrogen halides. The new salts contain two base units to one acid and examples are being more frequently discovered. The infrared spectrum of this type of salt, first observed by White (12), but interpreted correctly for acetamide hemihydrochloride by Albert and Badger (13), does not have an absorption band around 2400 cm^{-1} typical of HCl salts of organic bases, but instead shows very broad absorption below 1500 cm^{-1}; in the case of the antipyrine salts this absorption is centered near 900 cm^{-1}. Furthermore, the split bending mode at 1320 and 1220 cm^{-1} is not observed in the 2:1 salts, nor is there a band near 1270 cm^{-1} where the uncoupled bending mode should absorb. The structure of these salts must be quite different from that of the 1:1 salts. The structure derived from X-ray diffraction studies of acetamide hemihydrochloride (14), $(base\cdots H\cdots base)^+MX_{n+1}^-$, is also suggested for these salts, as it has been for other 2:1 salts (15, 16). (See ref. 15 also for details and further references to similar phenomena in certain acid salts of the type $(anion\cdots H\cdots anion)^-M^+$.)

EXPERIMENTAL

Antipyrine was obtained from Matheson, Coleman and Bell and was used without further purification. The HCl salt was made by passing anhydrous HCl into a solution of antipyrine in a little $CHCl_3$ and excess ether, m.p. 158–159° C. Found: C, 58.99%; H, 5.85%; N, 12.49%; HCl, 15.8%. Calc. for $C_{11}H_{12}N_2O.HCl$: C, 58.79%; H, 5.83%; N, 12.47%; HCl, 16.2%.

The HBr salt was made in the same way, m.p. 184–185°. Found: C, 49.20%; H, 4.78%; N, 10.37%; HBr, 29.6%. Calc. for $C_{11}H_{12}N_2O.HBr$: C, 49.09%; H, 4.87%; N, 10.41%; HBr, 30.0%.

The hydrated HI salt was made from aqueous solutions of each component, m.p. 94–96°. Found: C, 39.76%; H, 4.45%; N, 8.53%; HI, 37.8%. Calc. for $C_{11}H_{12}N_2O.HI.H_2O$: C, 39.53%; H, 4.52%; N, 8.38%; HI, 38.2%. The anhydrous salt was obtained from the hydrate by gentle heating *in vacuo*, m.p. 160–162°. The deuterated salts were prepared by exchange with an excess of D_2O followed by removal of the excess D_2O *in vacuo*. The $HSbF_6$ salt crystallized when 2.35 g antipyrine in 5 ml H_2O was mixed with 4.57 g aqueous (60%) $HSbF_6$, m.p. 271°, decomp. Found: C, 41.96%; H, 3.99%; N, 8.92%. Calc. for $(C_{11}H_{12}N_2O)_2.HSbF_6$: C, 43.09%; H, 4.11%; N, 9.14%.

THE INHIBITED AUTOXIDATION OF STYRENE

PART III. THE RELATIVE INHIBITING EFFICIENCIES OF ORTHO-ALKYL PHENOLS[1]

J. A. HOWARD[2] AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received May 31, 1963

ABSTRACT

The relative rates of reaction of a large number of ortho-alkyl phenols with styrylperoxy radicals have been measured at 65° C. These groups have both an accelerating effect owing to their electron-donating character and a retarding effect which arises from steric factors. With two ortho-alkyl groups both the reaction rate and the overall polar contribution to the transition state decrease as the size of the alkyl groups is increased. A single *o-t*-butyl group produces a small enhancement of the reaction rate over and above its polar effect but this is not observed with any other alkyl groups.

INTRODUCTION

In Part II of this series (1), it was shown that the relative rates of hydrogen abstraction by styrylperoxy radicals from meta- and para-substituted phenols at 65° C could be correlated with Brown's electrophilic substituent constants (2). That is, the relative rates of the reaction

$$RO_2\bullet + XC_6H_4OH \rightarrow ROOH + XC_6H_4O\bullet \qquad [6]$$

can be correlated by the relation

$$\log_{10}\frac{k_6}{(k_6)_0} = a+\rho\sigma^+ = -0.010-1.49\sigma^+. \qquad [1]$$

The influence of ortho-alkyl substituents on k_6 at 65° C is described in the present paper. It is shown that these substituents exert two opposing effects on the rate, i.e., an accelerating effect due to electron release from the substituents and a retarding effect due to steric factors. The relative reactivities and ρ factors for 2,6-dialkyl phenols can be correlated with the degree of hindering of the phenolic hydroxyl group as determined by infrared spectroscopy (3, 4).

EXPERIMENTAL

The experimental techniques and the kinetic treatment of the results have been described previously in Parts I (5) and II (1). Many of the phenols used in this work were carefully purified commercial products. With one exception, the preparation of the remaining phenols is described in the literature. The exception, 2-*t*-butyl-4-cyanophenol (white needles from *n*-hexane, m.p. 163–164° C), was prepared from 2-*t*-butyl-4-bromophenol by the Rosenmund – von Braun nitrile synthesis (6). All the phenols were checked for purity by gas chromatography before use. None contained more than 0.5% impurities.

RESULTS

Under conditions where the self-termination reaction between two peroxy radicals is unimportant, theory predicts (1, 5) that

$$P = \rho-(2e-1)k_1[I_2] = \frac{ek_1k_3[RH][I_2]}{k_6[AH]},$$

where ρ is the measured inhibited rate, e is the efficiency of radical production from the initiator I_2, k_1 is its rate constant for decomposition, k_3 is the propagation rate constant, RH represents the styrene, and AH the phenol. Although this equation fits the data for inhibition by 2,6-di-*t*-butyl-4-methylphenol (BMP) fairly well (5) it does not fit the data for simple meta- and para-substituted phenols (1). Instead, with these phenols, k_6 appears to decrease as the phenol concentration is increased. It was suggested (1) that this was due either to intermolecular hydrogen bonding of the phenols (which would decrease the availability of free phenol for the inhibition reaction) or to a chain transfer reaction between the initially formed phenoxy radical and the styrene. Although the kinetics applicable to inhibited autoxidations with chain transfer depend on the initial assumptions, a very complete analysis by Waters and Wickham-Jones (7) reveals that $P \propto [I_2]^{1/2}$ under almost all conditions.* It was shown previously (1) that P is approximately proportional to $[I_2]^{1.0}$ for the simple phenols and, therefore, the dependence of k_6 on [AH] would appear to be due to intermolecular hydrogen bonding rather than to chain transfer. It was surprising, therefore, to find that at high concentrations there was a similar variation in k_6 with the ortho-alkyl phenols (including 2,6-di-*t*-alkyl phenols), since it is known from infrared evidence that these phenols do not hydrogen bond very readily. Figure 1 shows a plot of $\log_{10}(P/[I_2])$ against $\log_{10}[AH]^{-1}$ for phenol and Fig. 2 shows a similar plot for 2,6-di-*t*-butylphenol and its 4-methyl derivative.† It can be seen that, at sufficiently low concentrations, the order in [AH] is 1.0 for all three phenols, i.e., k_6 is independent of the phenol concentration. However, as the concentration increases the order decreases and hence k_6 will appear to decrease, this effect being more marked for phenol than for the hindered phenols. The experimental points at high phenol concentrations show considerable scatter because the reaction is no longer exactly first order in $[I_2]$, e.g., with 1.0 mole/l. phenol, $P \propto [I_2]^{0.90}$. However, the order increases towards unity as the phenol concentration is reduced. This suggests that at high concentrations there may be some chain transfer with phenol and therefore, possibly, with some of the other simple phenols. For the hindered phenols, $P \propto [I_2]^{1.0}$ over the entire concentration range and chain transfer is therefore unlikely. Since hydrogen bonding is also of little importance with these phenols the reason for their curvature in Fig. 2 is not clear at present.

The lower the reactivity of a phenol the more difficult it is to obtain k_6. This is because an unreactive phenol will tend to be used at fairly high concentrations in order to obtain easily measurable effects and it is then that intermolecular hydrogen bonding and chain transfer are of importance. On the whole, this difficulty was greater for the simple meta- and para-substituted phenols studied previously (1) than in the present work since the simple phenols are generally less reactive than the ortho-alkyl phenols. Values of k_6 for the simple phenols were obtained by extrapolation of the measured values to zero phenol concentration. It is now clear that this extrapolation is not linear. However, additional experiments have shown that any corrections to the previous results are within the limits of the experimental error which is introduced by the extrapolation (approx. $\pm 25\%$).‡ Most of the present work was done in the range where k_6 was independent of the phenol concentration, extrapolation being necessary only for the least reactive ortho-alkyl

*The most likely assumptions lead to $P \propto [RH]^{3/2}[I_2]^{1/2}/[AH]^{1/2}$ (7, 8).

†All the data in these figures were obtained under conditions where the self-termination reaction could be neglected. Some of the data in Fig. 1 have been given previously (Fig. 1 of ref. 1). With the additional data obtained at very high and very low phenol concentrations the original linear plot of $1/k_6$ against [AH] is found to be a curve. The data at low concentrations of BMP have also been given previously (5).

‡For example, the new data for phenol at low concentrations where $P \propto [AH]^{-1}$ give $k_6 = 2.3 \times 10^3$ l./mole sec compared with a value of 2.9×10^3 l./mole sec reported previously (1).

phenols. The collected rate constants (referred to k_6 for 2,6-di-*t*-butyl-4-methylphenol (1)) are given in Table I together with the sum of the σ^+ constants for all the substituents on the phenol ($\sum\sigma^+$). In calculating ($\sum\sigma^+$) it has been assumed that $\sigma^+_{ortho} = \sigma^+_{para}$. The relative rate constants obtained in this work are in fairly good agreement with the relative rate constants for the reaction of tetralyl peroxy radicals with ortho-alkyl phenols (9).

The values of k_6 for substituted 2,6-dimethyl-, 2-*t*-butyl- and 2,6-di-*t*-butyl-phenols*

**2,6-Di-t-butyl-4-formylphenol has not been included in Fig. 3 owing to the possibility of side reactions between the radicals and the* CHO *group (cf. ref. 10).*

have been plotted against $\sum \sigma^+$ in Fig. 3. The slopes of the best straight lines through the three sets of points, i.e., the ρ factors, are -1.36 (std. dev. 0.059), -1.46 (std. dev. 0.012), and -1.11_5 (std. dev. 0.026), respectively. The best straight line which was obtained previously for simple meta- and para-substituted phenols ($\rho = -1.49$ (1)) is also shown for comparison as the heavy line in Fig. 3.

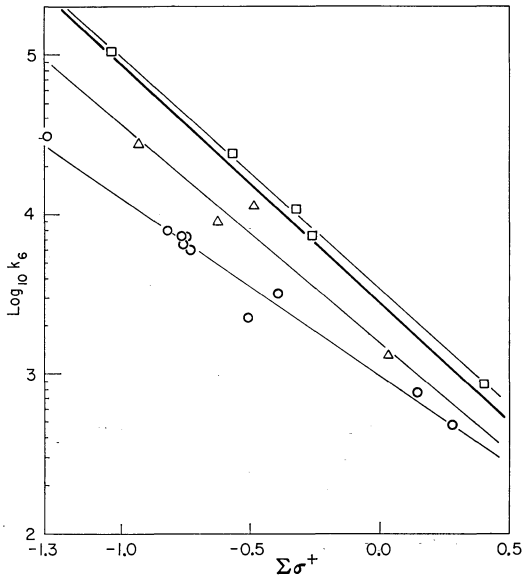

FIG. 3. $\log_{10} k_6$ plotted against $\sum \sigma^+$. Key: Heavy line, simple 3- and 4-substituted phenols (1); △ 2,6-dimethyl phenols; □ 2-*t*-butyl phenols; ○ 2,6-di-*t*-butyl phenols.

The deuterium isotope effect, $(k_6)_H/(k_6)_D$, for 2,6-di-*t*-butylphenol was measured by the technique described previously (5). It was found to be 10.5, which is in good agreement with the value obtained for its 4-methyl derivative (5).

The 2,6-di-*t*-butyl-4-substituted phenols all reacted with two peroxy radicals per molecule of phenol (5). 4,4′-Bis-2,6-di-*t*-butylphenol also reacted with two radicals per molecule but the other two bis-phenols both reacted with four radicals per molecule. The k_6 values of all three bis-phenols are about twice the values obtained for comparable 2,6-di-*t*-butylphenols presumably because they contain two OH groups per molecule.

DISCUSSION

In the two following papers we report on the reaction of *t*-butoxy radicals with hindered and non-hindered phenols (10). To a large extent, the present results can be interpreted along the same general lines and the following discussion has, therefore, been reduced to a minimum. Several points to which only brief reference is made in this paper are discussed in greater detail in the two following papers (10).

Following the suggestion of Russell (11) the transition state for reaction 6 can be considered to consist of three resonance forms:

$$[XC_6H_4O{:}H\bullet OOR \leftrightarrow XC_6H_4O^{+}\bullet H{:}\bar{O}OR \leftrightarrow XC_6H_4O\bullet H{:}OOR]$$
$$\text{I} \qquad\qquad \text{II} \qquad\qquad \text{III}$$

For personal use only.

Structure I resembles the reactants and structure III resembles the products. The importance of polar effects will increase in the order III < I < II. The correlation of the present results with σ^+ constants indicates that structure II contributes to the transition state but the magnitude of the ρ factors suggests that there is only a moderate degree of charge separation in the transition state.

For a given $\sum \sigma^+$, the decrease in k_6 produced by two ortho-alkyl groups is probably due largely to steric factors. That is, the alkyl groups prevent the peroxy radical from approaching the phenolic hydrogen quite as closely as it approaches the hydrogen in a non-hindered phenol. The two groups therefore tend to make the transition state resemble the products to an increasing extent as their size increases. This means that structure III will become of increasing importance and therefore ρ should decrease, as is, in fact, observed.*

The decrease in k_6 and in ρ factors produced by two ortho-alkyl substituents should be related to the degree of steric protection they afford the phenolic hydrogen. A rough measure of this protection is possibly given by the difference in free energy (ΔG) between the cis and trans isomers of ortho-alkyl phenols as determined by infrared spectroscopy in CCl_4 (3). In the reaction of *t*-butoxy radicals with phenols it was shown that the log of the relative reactivities could be correlated with ΔG (10). A similar correlation is shown in Fig. 4 for the reaction of styrylperoxy radicals with 2,6-dialkyl-4-methyl phenols. The circles represent the experimental points and the crosses the values calculated for $\sum \sigma^+ = -0.811$ (i.e., $\sum \sigma^+$ for a 4-CH_3 group ($\sigma^+ = -0.311$) and two *t*-alkyl groups ($\sigma^+ \approx -2\times0.250$).† The results can be represented by,

$$\log_{10} \frac{k_6}{(k_6)_0} = \alpha \Delta G, \qquad [2]$$

where $(k_6)_0 = 46\times10^3$ l./mole sec and $\alpha = -0.5$ mole/kcal. This value of α is significantly smaller than the value obtained with the *t*-butoxy radicals (i.e., -1.23 mole/kcal) presumably because the secondary styrylperoxy radicals are much less subject to steric factors than are the *t*-butoxy radicals. Incidentally, two *o*-ethyl or isopropyl groups appear to have about the same steric effect as two *o*-methyl groups. Moreover, both 2-*t*-butyl-6-methylphenol and 2-*t*-*t*-octyl-6-*t*-butyl-4-methylphenol appear to fit roughly on the line in Fig. 4 at the average ΔG for the two ortho substituents. However, 2-*t*-butyl-5,6-dimethylphenol is rather more reactive than would be expected.

In view of the similarity between equation [2] and the Hammett equation, the direct correlation between ρ and ΔG shown in Fig. 5 is not entirely unexpected.

The excellent agreement between the 4-*t*-alkyl-2,6-di-*t*-butyl phenols and the other phenols in this series indicates that there is little or no hindrance by the 4-substituent towards the attack of a styrylperoxy radical at the 4-position of the initially formed phenoxy radical (1, 12).

It is known from infrared studies of 2-alkyl phenols that these compounds exist as cis and trans isomers in which the phenolic hydrogen points towards the alkyl group and away from it, respectively (3, 4). Provided the alkyl substituent only exerts its normal

**The negative deviations of 2,6-dimethylphenol and 2,6-di-t-butylphenol and the positive deviations of their 4-chloro derivatives from the best straight lines are probably due to differences in the stabilities of the resulting phenoxy radicals which affect k_6 to an increasing extent as structure III becomes of progressively greater importance in the transition state (10).*

†The phenol point ($\Delta G = 0$) was calculated from equation [1]. 2,4,6-Trimethylphenol was corrected for the decreased polar effect of two t-alkyl groups compared with two methyl groups and pentamethylphenol was also corrected for the polar effect of two meta-methyl groups. In the last case ρ was taken to be -1.3 from Fig. 5.

polar effect on the *trans*-hydroxyl group we might expect to be able to calculate k_6 for a 2-alkyl phenol from equation [1] and the equation for the corresponding dialkyl phenol together with the proportions of the trans and cis isomer present, respectively, under the experimental conditions. Unfortunately, the calculation must be restricted to 2-methyl and 2,3-dimethyl phenols since the infrared evidence indicates that a 2-*t*-alkyl group has effects other than its polar effect on the *trans*-hydroxyl group (see below). A second difficulty is that the [trans]/[cis] ratio depends on the solvent and temperature as well as on the size of the alkyl group. However, the solvent effect is small for a non-polar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solvent (4) and the ratio can probably be taken to be the same in styrene as in CCl_4. The percentage of the trans isomer of 2,4-dimethylphenol at 65° C should therefore be about 67%. From equation [1], $(k_6)_{trans} = 0.67 \times 24 \times 10^3 = 16 \times 10^3$ l./mole sec. From k_6 for 2,4,6-trimethylphenol, $(k_6)_{cis} = 0.33 \times 10.57 \times 10^3 = 3.5 \times 10^3$ l./mole sec. The calculated k_6 for 2,4-dimethylphenol is, therefore, $= 19.5 \times 10^3$ l./mole sec, which is in excellent agreement with the measured value of 18.5×10^3 l./mole sec. Similarly, the percentage of the trans isomer of 2,3-dimethylphenol should be about 76% at 65° C, leading to a calculated k_6 of 8.9×10^3 l./mole sec in excellent agreement with the measured value of 9.3×10^3 l./mole sec.

The ρ factor for 2-*t*-butyl phenols is only slightly smaller than the ρ factor for the simple phenols, which suggests that a single ortho-alkyl group does not significantly increase the importance of structure III in the transition state. Of particular interest is the fact that the 2-*t*-butyl group causes a slight enhancement of k_6 over that for a simple phenol at the same $\sum \sigma^+$, whereas a slight depression of k_6 is observed with all the other 2-alkyl phenols. Therefore, even if σ^+_{ortho} is greater than σ^+_{para}, a single *o*-*t*-butyl group must exert a specific accelerating effect on the reaction relative to the other alkyl groups. This enhanced reactivity suggests the occurrence of an interaction between the *t*-butyl group and the *trans*-hydroxyl group. A similar conclusion was also derived from the infrared spectra of 2-*t*-alkyl phenols (3, 4).

In conclusion, the maximum rate of hydrogen abstraction from mononuclear phenols by peroxy radicals, i.e., the maximum inhibiting efficiency, will be achieved when the phenolic substituents have the largest possible negative $\sum \sigma^+$ consistent with a minimum of steric protection afforded to the hydroxyl group. In particular, the phenol should contain a *t*-butyl group in the 2-position, groups with large negative σ^+ constants in the 3,4- and 5-positions, and a vacant 6-position. Among mononuclear phenolic autoxidation inhibitors, the well-known commercial antioxidants 2-*t*-butyl-4-methoxyphenol, 2,5-di-*t*-butyl-4-methoxyphenol, and 2,5-di-*t*-butylhydroquinone are of almost optimum efficiency.

THE REACTION OF *tert*-BUTOXY RADICALS WITH 2,6-Di-*tert*-BUTYL-4-METHYLPHENOL AND 2,6-Di-*tert*-BUTYLPHENOL[1]

K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received May 25, 1963

ABSTRACT

The products of the reaction of *t*-butoxy radicals with 2,6-di-*t*-butyl-4-methylphenol and 2,6-di-*t*-butylphenol in carbon tetrachloride have been analyzed quantitatively. There is a satisfactory agreement between the measured and calculated yields of *t*-butanol with both phenols. The deuterium isotope effect (k_H/k_D) for abstraction of the phenolic hydrogen from 2,6-di-*t*-butyl-4-methylphenol is about 6.4.

INTRODUCTION

The abstraction of hydrogen atoms by alkoxy radicals from substrates in the liquid phase is of particular interest in relation to autoxidation phenomena (1). These radicals are produced in the chain branching decomposition of the initially formed hydroperoxides and are therefore responsible for the autocatalytic nature of most autoxidations.

$$ROOH \rightarrow RO\bullet + \bullet OH \qquad [1a]$$

$$2ROOH \rightarrow RO\bullet + H_2O + RO_2\bullet \qquad [1b]$$

$$RO\bullet + RH \rightarrow ROH + R\bullet. \qquad [2]$$

The *t*-butoxy radical is particularly suitable for studying the relative rates of reaction [2] with different substrates since it may either abstract a hydrogen to give *t*-butanol or decompose to give acetone and a methyl radical. The ratio, [*t*-butanol]/[acetone], produced in different substrates therefore gives a measure of the relative rates of hydrogen abstraction from the substrates. These radicals are readily prepared by the decomposition of di-*t*-butyl peroxide and the reactions can be represented by,

$$(CH_3)_3COOC(CH_3)_3 \rightarrow 2(CH_3)_3CO\bullet \qquad [3]$$

$$(CH_3)_3CO\bullet + RH \rightarrow (CH_3)_3COH + R\bullet \qquad [2a]$$

$$(CH_3)_3CO\bullet \rightarrow CH_3COCH_3 + CH_3\bullet. \qquad [4]$$

This technique has been employed by a number of workers in recent years to measure the relative rates of hydrogen abstraction by *t*-butoxy radicals from a variety of substrates such as hydrocarbons (2–9), ethers, (10, 11), alcohols (12), and amines (13, 14). As a part of our general program for studying the inhibition of autoxidation by phenols (15–17) we considered that an examination of the reaction of *t*-butoxy radicals with phenols might throw considerable light on the overall mechanism of inhibition. In particular, we were interested to see whether the phenolic hydrogen was abstracted by the *t*-butoxy radical in the rate-determining step.

In view of the comparative ease with which an isotope effect was detected in the reaction of peroxy radicals with 2,6-di-*t*-butyl-4-methylphenol (BMP) (15, 16) this compound was chosen for the present investigation. There have also been numerous studies in recent years of the products of oxidation of this phenol by a variety of oxidizing agents (18–25). Some results on the reaction of *t*-butoxy radicals with 2,6-di-*t*-butylphenol (BP) are also reported.

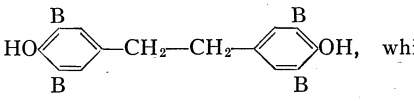
EXPERIMENTAL

Reagent grade carbon tetrachloride was chosen as the solvent to eliminate all possibility of the formation of *t*-butyl alcohol by abstraction from the solvent. In general, 14 ml solutions of the peroxide or peroxide + phenol (25 to 200 m*M**) were placed in glass bombs of 16–17 ml capacity. The dissolved air was carefully removed by freezing in liquid nitrogen and evacuating and repeating this procedure at least four times before the bombs were sealed off under vacuum. The peroxide was thermally decomposed at 122° C, at which temperature the half-life was about 16 hrs. and the dead space over the solution was between 1 and 2 ml. For some runs, from which the products were to be isolated, bombs of 40 ml capacity were used. All results represent the average of at least two experiments.

Methane yields were obtained by breaking the bombs in a vacuum system and measuring the volume of gas which could be pumped off at liquid nitrogen temperatures. Mass spectrometric analysis showed that this gas was entirely methane. All the other volatile products were analyzed by gas chromatography. The low-boiling compounds (mainly methyl chloride, *t*-butyl chloride, unreacted peroxide, *t*-butyl alcohol, chloroform, and acetone) were analyzed on a β,β'-thiodipropionitrile column at 70° C. The high-boiling compounds were analyzed on a polyester succinate column (chlorinated products such as hexachlorethane at 125°, and the phenols at 185° C). The identification of all volatile products was confirmed by mass spectrometry and, or, infrared spectroscopy. Since methyl chloride is a gas at room temperature chromatographic analyses were made on samples separate from those in which the methane was analyzed. The samples were injected into the low-temperature column immediately after the bombs were opened.

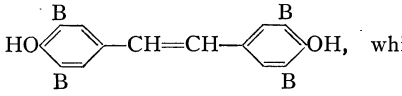
The three major products resulting from the oxidation of BMP by *t*-butoxy radicals are the following non-volatile dimers;

I. 3,5,3′,5′-tetra-*t*-butyl-4,4′-dihydroxy-1,2-diphenylethane



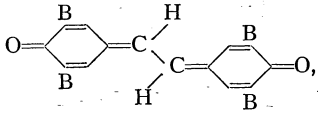
white needles from ethanol, m.p. 174–175°

II. 3,5,3′,5′-tetra-*t*-butyl-4,4′-dihydroxy-1,2-diphenylethylene



white crystals from ligroin, m.p. 241–242°

III. 3,5,3′,5′-tetra-*t*-butylstilbene-4,4′-quinone†



reddish needles from ethanol, m.p. 316–317° (decomp.)

Since these products could not be analyzed by gas chromatography, pure samples were prepared by the oxidation of BMP with benzoyl peroxide in refluxing chloroform (18, 22) to assist in analyses by other techniques. Compounds I (22) and III (18, 22) have been identified previously in this reaction. The present work showed that II is also formed in very small amounts. However, since III is most readily separated and purified it is much simpler to prepare I and II in pure form from III than to isolate them from the reaction mixture. Reduction of III with hydrogen over platinum in dimethoxyethane yields pure I after 1 hour at room temperature. Reduction of III with zinc and acetic acid in benzene yields II (18, 20, 21). Both I and II tend to go slightly yellow on standing in air and, in solution, II is fairly rapidly oxidized by air to III, and a quinhydrone of II and III is precipitated (21).

The n.m.r. spectra of compounds I, II, and III have been described in an earlier publication from this laboratory (26). The ultraviolet spectra showed band maxima (in order of decreasing intensity) at 283 and 277 mμ for compound I; 307, 325, and 295 mμ for II; 448, 420, and 395 mμ for III; 283 and 277 mμ for BMP; and 456, 439, and 307 mμ for 2,6-di-*t*-butylbenzoquinone. Compound I was analyzed by n.m.r. spectroscopy in CCl_4 and compounds II and III by ultraviolet spectroscopy in cyclohexane. At the end of a run, the volatiles were removed under vacuum at room temperature and the residue was dissolved in a known volume of deaerated CCl_4 or cyclohexane. The quantitative analysis of II is much less accurate than that of I and III but it appears to be only a minor product. In some cases unreacted BMP was removed by sublimation under vacuum at 40–50° before analysis. Compound III could be isolated almost quantitatively by washing the evaporated residues with a small quantity of ligroin, CCl_4, or ethanol.

**All concentrations are given in millimoles/liter (m*M*).*

†*The corresponding tetra-t-amyl compound was also prepared from 2,6-di-t-amyl-4-methylphenol. Red plates from ethanol, m.p. 219–220°, with a change to red needles above 200° and some decomposition.*

The oxidation of 2,6 di-*t*-butylphenol by *t*-butoxy radicals yields two dimeric products: IV, 3,3′,5,5′-tetra-*t*-butyl-4,4′-dihydroxydiphenyl, white needles from ethanol, m.p. 185°, and V, 3,3′,5,5′-tetra-*t*-butyldiphenoquinone, reddish plates from ethanol, m.p. 245–246°. Authentic V was prepared by oxidizing BP with nitric acid (23, 27, 28) and its reduction with hydrogen over platinum gave IV. The keto tautomer of IV (28) was not identified among the products, possibly because it rapidly isomerizes to the enol form (i.e., IV) under the reaction conditions. Compound IV was analyzed by infrared spectroscopy in the O—H fundamental stretching region (calibrated with known mixtures of IV and V) after removal of unreacted BP by sublimation or by extraction with a small quantity of ethanol. Compound V was analyzed by ultraviolet spectroscopy (band maxima at 423 mμ).

RESULTS AND DISCUSSION

The decomposition of di-*t*-butyl peroxide in CCl_4 at 122° C is first order within the limits of experimental accuracy over an initial concentration range from 25 to 200 m*M*. This suggests that the free radical induced decomposition of the peroxide is relatively unimportant compared with reaction [3]. The composition of the main products varies slightly with the initial peroxide concentration and with the extent of its decomposition (see Table I). In addition to the products listed in this table traces of isobutylene oxide, isobutyraldehyde, and chloro-*t*-butanol were also identified.

TABLE I

Reaction products in m*M* from the decomposition of di-*t*-butyl peroxide in CCl_4 at 122° C

[DTBP]	100	100	100	100	100	25	50	200

Methyl chloride	29	54	91	110	174	23	46	182
Chloroform	1	2	4	7	22	1	2	10
Hexachloroethane	15	25	44	57	86	11	22	82

Excellent product balances were obtained under all conditions. That is, the sum of the products from acetone to $(CH_3)_2CClCH_2CCl_3$ in Table I is roughly equal to twice the amount of peroxide decomposed. Furthermore,

$$[CH_4]+[CH_3Cl] = [CH_3COCH_3]+[CH_2ClCOCH_3]$$

and

$$[CHCl_3]+2[C_2Cl_6]+[(CH_3)_3COCCl_3] = [CH_3Cl]+[CH_2ClCOCH_3].$$

The major products obviously arise from reaction [5] and subsequent reactions of the methyl radical. These radicals are mainly converted to methyl chloride by reaction with the solvent and the resulting trichloromethyl radicals are mainly destroyed by dimerization. A small fraction of the $CH_3\bullet$, $CCl_3\bullet$, and *t*-butoxy radicals abstract hydrogen from

$$CH_3\bullet + CCl_4 \rightarrow CH_3Cl + CCl_3\bullet \quad [5]$$

$$2CCl_3\bullet \rightarrow C_2Cl_6 \quad [6]$$

the products. Some abstraction from the unreacted peroxide may also occur since it could account for the production of isobutylene oxide and isobutyraldehyde, i.e.,

$$X\bullet + (CH_3)_3COOC(CH_3)_3 \rightarrow XH + (CH_3)_3COOC(CH_3)_2CH_2\bullet \quad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$(CH_3)_3COOC(CH_3)_2CH_2\bullet \rightarrow (CH_3)_3CO\bullet + \begin{cases} (CH_3)_2C\overset{O}{\triangle}CH_2 \\ (CH_3)_2CHCHO \end{cases} \quad [8]$$

However, the hydrogen balance is not quite as good as the carbon balance since the yield of CH_4, $CHCl_3$, and *t*-butanol is larger than can be accounted for by the products which have obviously lost hydrogen (i.e., chloroacetone, chloro-*t*-butanol, isobutylene oxide, and isobutyraldehyde). This difference may be due to hydrogen loss by several other chlorinated compounds which were present in such small quantities that they could not be identified. The presence of *t*-butyl chloride suggests that some *t*-butyl radicals are formed. They might be produced either by the deoxygenation of *t*-butoxy radicals or by an assymetric decomposition of the peroxide.

The addition of BMP or BP at a comparable concentration to the peroxide greatly simplifies the products since reaction [2] now predominates over reaction [4] and the yield of methyl radicals is thereby greatly reduced. The decomposition of the peroxide is still a first-order reaction but the rate of decomposition is slightly increased by an excess of the phenol (see Fig. 1). This may be due to a direct reaction between the phenol and the peroxide (29) or to some indirect solvation phenomena. However, it is also possible that the increased rate is due to a reduction in the rate of recombination of *t*-butoxy radicals to re-form the peroxide (i.e., the reverse of reaction [3]) since the phenol will reduce the steady-state concentration of these radicals. The major products under varying conditions are given in Fig. 1 and in Tables II and III. Small traces of the following compounds were

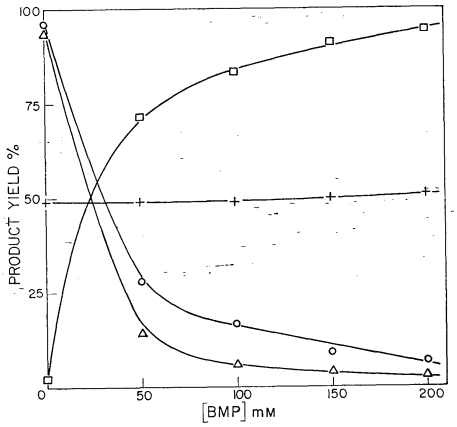

FIG. 1. Percentage composition of the products arising from the 16 hour decomposition of 100 m*M* di-*t*-butyl peroxide as a function of the 2,6-di-*t*-butyl-4-methylphenol concentration. Key: △ methyl chloride; ○ acetone; □ *t*-butanol; + percentage decomposition of the peroxide.

also identified: formaldehyde, trimethylacetic acid, $(CH_3)_2CClCH_2CCl_3$,* $(CH_3)_3COCCl_3$* and, in the presence of BP, traces of water, isobutylene oxide, isobutyraldehyde, and chloro-*t*-butanol were also present. Chloroform and hexachloroethane were not formed. The color of the 100 m*M* peroxide – 100 m*M* phenol mixtures after 16 hours was yellow for BMP and a deep red for BP.

With both BMP and BP the sum of [acetone]+[*t*-butanol]+[*t*-butyl chloride] is roughly equal to twice the amount of peroxide decomposed, but the $[CH_4]+[CH_3Cl]$ is significantly smaller than the amount of acetone produced. Since the yields of methane and chloroform

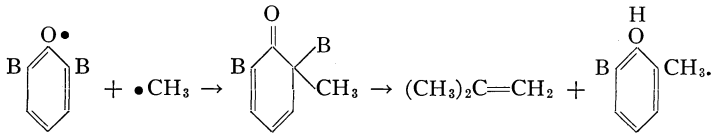
are extremely small neither the methyl radical nor the trichloromethyl radical abstracts a significant amount of hydrogen from the phenols, probably for steric reasons. However, the absence of C_2Cl_6 and the unexpectedly small yield of methyl chloride indicates that both radicals must react very rapidly with the phenols or, more probably, with the phenoxy radicals by some mechanism not involving abstraction. The formation of isobutylene (which is not formed in the absence of the phenols) and the identification among the phenolic products of BMP and 2-*t*-butyl-6-methylphenol from BP and 2,6-di-*t*-butyl-4-trichloromethylphenol from both BMP and BP suggest that radical replacement reactions occur rather readily at both the ortho and para positions, for example,



[9]

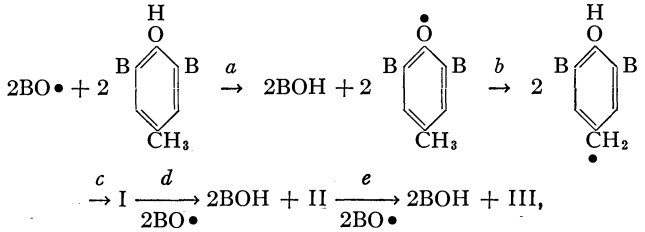
The radicals may also add to the quinone products III and V (30). The presence of traces of trimethylacetic acid among the products indicates that some rupture of the aromatic ring also occurs during the reaction.

For an equimolar peroxide–phenol mixture the [*t*-butanol]/[acetone] ratio increases approximately linearly with the increase in concentration and, at a given concentration,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

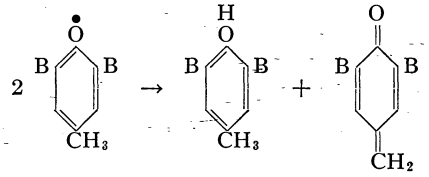
the ratio remains roughly constant until about half of the peroxide has been decomposed (see Tables II and III). At a constant peroxide concentration the ratio increases with increasing phenol concentration (see Fig. 1). Incidentally, no significant fraction of the acetone is produced by decomposition of the peroxide in the vapor above the liquid since increasing the dead space from 1 ml to 10 ml in bombs of 16 ml capacity had no effect on the product composition. Moreover, in the absence of peroxide, BMP is completely stable for 1 week under the reaction conditions and BP produces only minute traces of isobutene.

The ratio [*t*-butanol]/[BMP] reacted varies between a lower limit of 1.0 when there is a large excess of BMP and an upper limit which approaches 3.0 when there is insufficient BMP to react with all the *t*-butoxy radicals produced. The variation in this ratio is due to the formation of the three dimeric phenolic products in which 1, 2, and 3 atoms of hydrogen have been lost per component molecule of BMP. The reaction sequence can be represented as:

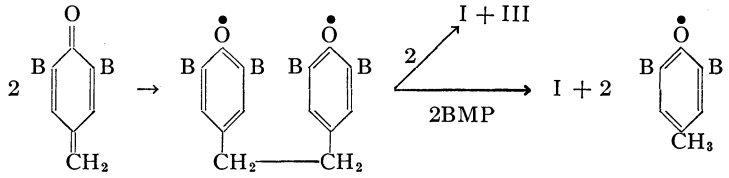


[10]

where B represents the *t*-butyl group. Reaction [10*a*] must involve abstraction of the phenolic hydrogen because of the large deuterium isotope effect found in this work (see below). The formation of I from two phenoxy radicals probably involves hydrogen migration from the 4-methyl group and dimerization of the resulting benzyl radicals. The alternative mechanism via the quinone methide seems less likely but cannot be completely ruled out (31). Reactions [10*d*] and [10*e*] probably also involve abstraction of the



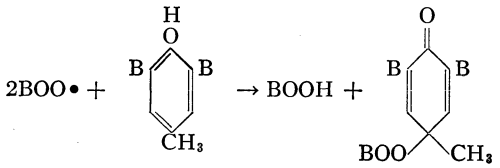
[11]



[12]

phenolic hydrogen followed by hydrogen migration since the intermediate radicals have been identified by e.s.r. during the oxidation of BMP with lead dioxide (32, 33).

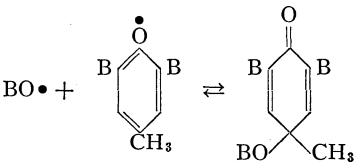
The reaction of BMP with *t*-butyl peroxy radicals results in the formation of 1-methyl-1-*t*-butylperoxy-3,5-di-*t*-butyl-2,5-cyclohexadienone-4 (24):



[13]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and a similar compound is obtained with 2-cyano-2-peroxy propyl radicals (34). The absence of this type of product under the present experimental conditions is probably due both to a reduced probability of addition of the *t*-butoxy radical at the 4-position (because of increased steric effects) and to the instability of the resulting product. That is, at 122° C equilibrium



[14]

probably lies largely towards the left and favors the dissociated radicals. This difference in the behavior of alkoxy and peroxy radicals probably accounts for the observation of Moore and Waters (19) that the oxidation of cumene containing BMP at 80–100° C initiated by α,α'-azodiisobutyronitrile yields only traces of I, whereas initiation by 0.1% ferric stearate (which catalyzes the decomposition of cumene hydroperoxide to cumyloxy radicals) yields about 10 times as much I. Both I and III have also been identified as products from the oxidation of oil containing BMP at 120° C catalyzed by iron and copper (20).

As complete product analyses as possible were made on 200 m*M* peroxide – 200 m*M* phenol mixtures at three different extents of peroxide decomposition. The results are given in Table III. With both BMP and BP the products from approximately 90% of the phenol which reacted were identified. 2,6-Di-*t*-butyl-4-formyl- and 4-trichloromethyl-phenol were estimated by gas chromatography. Traces of 2,4,6-tri-*t*-butylphenol, 2,6-di-*t*-butyl-4-*t*-butoxyphenol, and 2,6-di-*t*-butylbenzoquinone were also identified on the chromatograph as products from both BMP and BP. In addition, traces of BMP and 2-*t*-butyl-6-methyl-phenol were formed from BP. Extraction of the products with aqueous sodium carbonate and acidification yielded a very small amount of a white precipitate from BMP but not from BP. This was identified by its melting point (134–135°) as DL-*trans*-1,4-dioxo-5,6-di-*t*-butyl-2-hydroxy-2-cyclohexene (23). The ultraviolet spectra of the 168 hour BMP sample showed a small unknown band at 474 mμ. The e.s.r. spectra of unopened bombs indicated that the phenoxy radicals from BMP and BP were present in only very small amounts.

The concentrations of *t*-butanol which should be expected on the basis of the identified phenolic products, i.e., 2I + 4II + 6III + 2(2,6-Bu_2^t-4-CHO phenol) with BMP and 2IV + 4V + 2(2,6-Bu_2^t-4-CHO phenol) with BP, are also given in Table III. With BMP the calculated [*t*-butanol] is about 70% of the measured concentration, which is not unsatisfactory considering the difficulties involved in obtaining quantitative analyses of the phenolic products (particularly II). The remaining 30% of the *t*-butanol may arise from the unidentified phenolic products if their precursors donate hydrogen atoms very readily to *t*-butoxy radicals. With BP the agreement between the calculated and measured [*t*-butanol] is rather better. However, the large yields of *t*-butyl chloride and the fact that the calculated *t*-butanol is larger than the measured amount after 168 hours both suggest that the *t*-butoxy radical can be deoxygenated to give the *t*-butyl radical which then abstracts a chlorine atom from the solvent. The rapid increase in the yield of *t*-butyl chloride with increasing decomposition of the peroxide suggests that this reaction may involve an oxidation product of BP such as, for example, the keto tautomer of IV.

The occurrence of a large deuterium isotope effect in the reaction of *t*-butoxy radicals

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with BMP was readily demonstrated by adding 1 ml of H_2O and D_2O to bombs containing 14 ml of a 50 mM peroxide – 50 mM BMP mixture. After 16 hours at 122° C the former bomb showed the deep yellow color of compound III while the latter was nearly colorless. The yields of *t*-butanol and acetone in the CCl_4 layer were, respectively, 18 and 11 mM with BMP-H and 0.6 and 26 mM with BMP-D. With 500 mM of BMP-D and 50 mM of peroxide the yields were 28 and 6 mM, respectively. Obviously a significant fraction of the products had dissolved in the aqueous layer and these results are, therefore, not suitable for the calculation of the magnitude of the isotope effect.

Ideally, in order to obtain the true isotope effect without the complication introduced by the addition of D_2O or H_2O, a large excess of the deuterated BMP should be used relative to the amount of peroxide decomposed in order to reduce to negligible importance the loss of deuterium by hydrogen transfer from the 4-methyl group. That is, the initially formed phenoxy radicals will dimerize to give compound I (and then II) containing two OH groups. Since there is obviously a large isotope effect an increasing proportion of the *t*-butoxy radicals will abstract H from these products rather than D from the unreacted BMP as the reaction progresses. However, it can readily be calculated that the BMP-D concentration cannot be raised sufficiently nor the peroxide concentration reduced sufficiently to eliminate this hydrogen-transfer process and still obtain accurately measurable quantities of *t*-butanol and acetone. It is, therefore, necessary to add D_2O to the bombs containing BMP-D and H_2O to the bombs containing BMP-H and measure the products in both the CCl_4 and the aqueous phases.

The following procedure was employed. Solutions of BMP in CCl_4 at various concentrations were shaken with H_2O or D_2O for 24 hours at room temperature (16). 50 mM of peroxide was added to these solutions and the mixtures were shaken for an additional hour to saturate all the CCl_4 with water. The bombs were washed with H_2O or D_2O and dried under vacuum. Fourteen milliliters of the CCl_4 layer of the mixtures was sealed in the bombs by themselves and with the addition of 0.1 and 1.0 ml of water. The yields of *t*-butanol and acetone were measured after 16 hours at 122° C in the CCl_4 layer and also in the water layer for the bombs containing 1.0 ml water. A correction based on the latter figure was used for the bombs containing 0.1 ml water. In every case, the total yields of the two products were the same with both 0.1 and 1.0 ml water. The [*t*-butanol]/[acetone] ratios obtained in this way are shown plotted against the BMP concentration in Fig. 2.

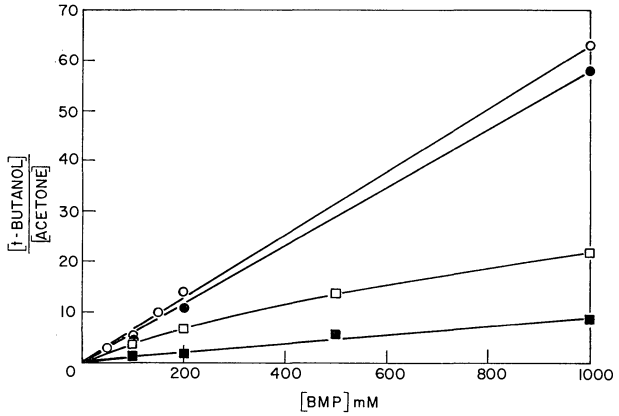


FIG. 2. [*t*-Butanol]/[acetone] ratio resulting from the decomposition of 50 mM of di-*t*-butyl peroxide for 16 hours at 122° C as a function of BMP concentration. Key: ○ saturated with H_2O; ● 14 ml H_2O saturated solution + 0.1 and 1.0 ml H_2O; □ saturated with D_2O; ■ 14 ml D_2O saturated solution + 0.1 and 1.0 ml D_2O.

For personal use only.

The results with H_2O suggest that saturating the CCl_4 with water may reduce the [*t*-butanol]/[acetone] ratio slightly compared with the values obtained in dry CCl_4 and a further slight reduction is produced by excess water. These small effects are quite possibly due to hydrogen bonding between the *t*-butoxy radicals and the water. This would produce a less reactive radical which would show an increased tendency to decompose rather than to abstract hydrogen.

The results with D_2O show that H migration is fairly important in determining the [*t*-butanol]/[acetone] ratio even with a large excess of BMP-D, but that its importance does tend to decrease as the phenol concentration is increased.* The true isotope effect should be roughly proportional to the slopes of the lines through the points obtained with excess H_2O and D_2O provided it is assumed that there is no significant difference in the ability of H_2O and D_2O to stabilize *t*-butoxy radicals. With this assumption, the isotope effect is:

$$k_H/k_D = 6.4.$$

This value can be compared with values of 3.3 at 135° C (3) and 3.8 to 5.3 at 107–116° C (8) for hydrogen abstraction from toluene by *t*-butoxy radicals. The larger isotope effect for hydrogen abstraction from BMP is to be expected because the hydrogen atom is transferred between two identical atoms and, its zero-point energy will probably, therefore, be lost in the transition state (35). In addition, the hindering effect of the *t*-butyl groups will also tend to increase the isotope effect (36) (see also following paper).

THE EFFECT OF SUBSTITUENTS ON THE RELATIVE RATES OF REACTION OF *tert*-BUTOXY RADICALS WITH PHENOLS IN CARBON TETRACHLORIDE AND IN CHLOROBENZENE[1]

K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received May 25, 1963

ABSTRACT

The relative rates of hydrogen abstraction from substituted phenols by *t*-butoxy radicals can be correlated with the σ^+ constants of the substituents. The effects of an aromatic solvent (chlorobenzene) and of ortho-alkyl substituents on the reactivities of the phenols and on the transition state of the reaction are discussed.

INTRODUCTION

In the previous paper (1) it was shown that *t*-butoxy radicals abstract the phenolic hydrogen from 2,6-di-*t*-butyl-4-methylphenol (BMP). As a continuing part of our investigation into the inhibition of autoxidation by phenols, the influence of substituents on the relative rates of hydrogen abstraction by *t*-butoxy radicals from a number of substituted phenols has been examined both in CCl_4 and in chlorobenzene.

RESULTS

The experimental and analytical procedures were described in the previous paper (1). The present work involved decomposition of equimolar peroxide–phenol mixtures (generally 50 m*M*) in CCl_4 and in chlorobenzene for 16 hours at 122° C (i.e., decomposition of approximately 50% of the peroxide). Only volatile products were analyzed and the consumption of the phenols in chlorobenzene was not measured.

Many of the phenols used in this work were commercial products. The preparation of the remainder is described in the literature. They were all checked for purity by gas chromatography before use and none contained more than 0.5% impurities.

The main investigation centered on the ratio [*t*-butanol]/[acetone] since this gives a measure of the relative rates of hydrogen abstraction from different phenols by *t*-butoxy radicals. This ratio was measured for 3- and 4-substituted phenols and for 4-substituted 2,6-di-*t*-butylphenols. The effect of 2,6-dialkyl substituents on this ratio in CCl_4 was also examined. The main results of this work are given in Table I.

With the notable exception of 4-hydroxybenzaldehyde and 2,6-di-*t*-butyl-4-formylphenol the sum of the [*t*-butanol] plus [acetone] is approximately equal to twice the amount of peroxide decomposed. Moreover, this product balance generally tends to be rather better for phenols containing electron-donating substituents than for those containing electron-attracting substituents, i.e., this balance is better for the more reactive phenols. It should be noted that in chlorobenzene the [*t*-butanol]/[acetone] ratios given in Table I have been corrected to allow for the fact that the decomposition of 50 m*M* of peroxide by itself for 16 hours yields 7 m*M* [*t*-butanol] in this solvent, (2×[DTBP] decomposed = 60 m*M*, [acetone] = 53 m*M*). The corrected [*t*-butanol] has therefore been taken to be the measured value minus (7/53)[acetone.] The reaction is still approximately first order in chlorobenzene but its rate is slightly greater than that in CCl_4, possibly because the

transition state for decomposition is stabilized by the aromatic solvent. In CCl_4 the ratio of [*t*-butanol]/[phenol] consumed varies from slightly under 1.0 for 3,4,5 trimethylphenol, pentamethylphenol, 2,6-di-*t*-butyl-4-chlorophenol, and 2,6-di-*t*-butyl-4-cyanophenol to slightly more than 2.0 for phenol.

The most complete product analyses were made with the 4-substituted 2,6-di-*t*-butylphenols in CCl_4 since these phenols give greater yields of secondary products than the much more reactive unhindered phenols. The products, other than acetone and *t*-butanol, resulting from 16 hours' reaction between 50 m*M* peroxide and 50 m*M* of the phenols are given in Table II. These products can be compared with those given previously (1) for 2,6-di-*t*-butylphenol and its 4-methyl derivative.

As was pointed out in the previous paper, the production of isobutene and 4-methyl-, 4-trichloromethyl- and 4-*t*-butoxy-2,6-di-*t*-butyl-phenols indicates that ring substituents can be displaced by the various free radicals present in solution. Further confirmation for such reactions was provided by the identification of 3 m*M* of α-methylstyrene among the products from 2,6-di-*t*-butyl-4-cumylphenol. These displacement reactions appear to become of greatly increased importance with the tri-*t*-alkyl phenols as the concentration of the peroxide and phenol is increased. For example, the yields of most secondary products are slightly more than doubled in the same reaction time with 100 m*M* mixtures but the yields of isobutene rise to 20 m*M* for 2,4,6-tri-*t*-butylphenol and to 30 m*M* for 2,6-di-*t*-butyl-4-cumylphenol. Since these two phenols give the most stable phenoxy radicals (see below) these results suggest that the displacement reactions occur more readily on phenoxy radical than on the free phenol (1).

The reaction of 50 m*M* of 2,6-di-*t*-butyl-4-formylphenol with 50 m*M* of peroxide for 16 hours gives 10 m*M* CH_4, 7.2 m*M* CO, and 2.1 m*M* CO_2 as well as traces of isobutylene oxide. Small amounts of C_2Cl_6 were detected among the products from 2,6-di-*t*-butyl-4-cyanophenol only.

The color of the solutions after reaction is a pale yellow in all cases except for 2,6-di-*t*-butyl-4-chlorophenol where it is orange and 2,4,6-tri-*t*-butylphenol where it is a light greenish blue which changes to a pale yellow after 30 minutes' exposure to the air. The e.s.r. spectra of unopened bombs were measured shortly after the reaction was stopped by cooling the bombs to room temperature. Tri-*t*-butylphenol contained at least 10 m*M* of the free phenoxy radical, the 4-cumylphenol contained a very much lower concentration, and only traces of free radicals were detected with the other phenols.

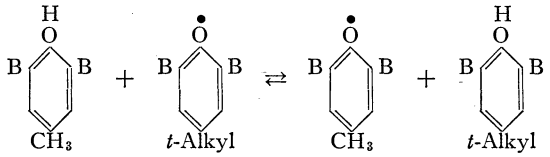
In principal, there is a second method of measuring the relative rates with which phenols react with *t*-butoxy radicals. It consists of decomposing the peroxide in the presence of two phenols and then measuring the amount of each that is consumed. In order to compare the rates of the primary hydrogen abstraction process without the interference of hydrogen abstraction processes from secondary phenolic products the concentrations of both phenols should be as large as possible relative to the peroxide concentration. However, the phenol concentrations must not be so large that the amounts reacted cannot be measured accurately. The results of some experiments in which 25 m*M* of peroxide was decomposed for 16 hours in CCl_4 in the presence of 25 m*M* of a 4-substituted 2,6-di-*t*-butylphenol plus 25 m*M* of the 4-methyl compound as the reference phenol are given in Table III.

In practice, it is obvious that this method of obtaining relative rates is complicated by a hydrogen-transfer reaction between one phenol and the phenoxy radical of the other. This type of reaction has been frequently observed in the past (2–4) and is known to be rapid* and to have a low activation energy (6). This process is very obvious with the 4-*t*-butyl and 4-cumyl phenols, both of which have about the same reactivity towards *t*-butoxy radicals as the 4-methyl phenol, and yet neither is consumed to any measurable extent. The reaction can be represented as the equilibrium



which lies strongly towards the right because the 4-methyl phenoxy radicals dimerize readily (1) whereas the 4-*t*-alkyl phenoxy radicals are rather unreactive towards one another and towards *t*-butoxy radicals. The importance of this equilibrium with the other 4-substituted phenols, which presumably give more reactive phenoxy radicals, cannot be estimated from the present data. However, both the amount of the second phenol consumed and the [*t*-butanol]/[acetone] ratio decrease as the 4-substituent becomes more strongly electron attracting, as is expected. This suggests that this equilibria is not of overriding importance with these other phenols. A comparison of the reactivities of 2,6-di-*t*-butyl-4-methylphenol and its two dimeric phenolic products (i.e., the ethane and ethylene dimers (1)) was also made by the same procedure but by following the consumption of the 4-methyl phenol only. The results indicate that the ethane dimer is slightly more reactive, and the ethylene dimer much more reactive, than the parent phenol.

DISCUSSION

Like many other similar hydrogen-abstraction reactions (7), the relative reactivities of both the simple phenols and the 2,6-di-*t*-butyl 4-substituted phenols towards *t*-butoxy radicals (i.e. [*t*-butanol]/[acetone] ratios) can be correlated with Brown's σ^+ substituent constants (8). That is,

$$\log\left(\frac{[t\text{-butanol}]}{[\text{acetone}]}\cdot\frac{[\text{acetone}]_0}{[t\text{-butanol}]_0}\right) = \rho\sigma^+.$$

With the exception of the 4-formyl phenols, the data given in Table I have been plotted against the σ^+ constants of the 3- and 4-substituents in Fig. 1. For the simple phenols the slopes of the best straight lines, i.e. the ρ values, are -1.19 and -0.74 in CCl_4 and

**The tri-t-butyl phenoxy radical can, in fact, abstract hydrogen from n-decane at 90° C (5).*

in chlorobenzene respectively, and for the 2,6 di-*t*-butyl-4 substituted phenols the slopes are −0.86 and −0.78. It should be added that there is, of course, considerable experimental uncertainty in the [*t*-butanol]/[acetone] ratios which are greater than about 20. The correlation of the simple phenols in CCl_4 with their σ^+ substituent constants is therefore surprisingly good. As was mentioned in the previous paper (1), for an equimolar peroxide–phenol mixture the [*t*-butanol]/[acetone] ratio increases with increasing concentration of the reactants. The results obtained with 100 m*M* peroxide – 100 m*M* 2,6-di-*t*-butylphenol mixtures in CCl_4 (16 hours) are also shown in Fig. 1. The ρ value in this case is −0.79, which is, within experimental error, the same as the value found with 50 m*M* mixtures. Accurate ρ factors cannot be obtained from the data in Table III on phenol consumption and on the [*t*-butanol]/[acetone] ratios because the experimental points show too much scatter, presumably because of the phenoxy radical – phenol equilibria.

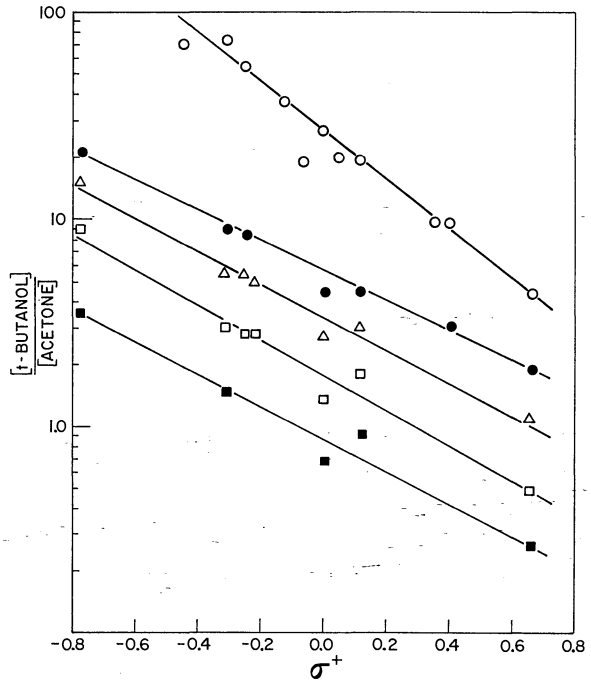

FIG. 1. The [*t*-butanol]/[acetone] ratio after 16 hours at 122° C for equimolar peroxide–phenol mixtures plotted against σ^+ for the 3- and 4-substituents. Key: ○, 50 m*M* of 3- and 4-substituted phenols in CCl_4; ●, 50 m*M* of 3- and 4-substituted phenols in C_6H_5Cl; □, 50 m*M* of 2,6-di-*t*-butyl-4-substituted phenols in CCl_4; ■, 50 m*M* of 2,6-di-*t*-butyl-4-substituted phenols in C_6H_5Cl; △, 100 m*M* of 2,6-di-*t*-butyl-4-substituted phenols in CCl_4.

Following the suggestions of Russell (9), the transition state for the attack of a *t*-butoxy radical on the phenolic hydrogen can be considered to consist of three resonance forms.

$$XC_6H_4OH + \bullet OB \rightarrow$$
$$[XC_6H_4O{:}H\bullet OB \leftrightarrow XC_6H_4O^{+}\bullet H{:}^{-}OB \leftrightarrow XC_6H_4O\bullet H{:}OB]$$
$$\text{I} \qquad\qquad \text{II} \qquad\qquad \text{III}$$
$$\rightarrow XC_6H_4O\bullet + HOB$$

The importance of polar effects will increase in the order III < I < II. In general, the greater the electronegativity of the attacking radical the more will structure II be favored

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and the more important will be the polar effect. Structure I should be important when the attacking radical is very reactive and there is little bond breaking in the transition state so that it resembles the reactants. Structure III should be important when the attacking radical is comparatively unreactive and there is considerable bond breaking in the transition state with the formation of a resonance-stabilized free radical. In this case, the transition state resembles the products. Therefore, if the electron density of the bond being broken determines reactivity, then substituent effects should be correlated by σ constants and the transition state will resemble I, but if polar effects predominate, substituent effects will be correlated by σ^+ constants and the transition state will resemble II.

The correlation of the present results with σ^+ constants indicates that structure II contributes strongly to the transition state. However, the difference in the ρ values between the simple phenols and the dibutyl phenol in CCl_4, the solvent effect, and the deviations of some of the phenols from the best straight lines in Fig. 1 can, tentatively, be accounted for by also taking account of structures I and III.

The sign and magnitude of the ρ factor of a reaction is generally considered to be a measure of the charge separation in the transition state (10). The values of ρ found in the present work (-1.19 and smaller) therefore indicate that there is only a moderate degree of charge separation in the transition state. The excellent correlation of the present results with σ^+ constants is somewhat fortuitous since an exact correlation need not exist for reactions in which a positive center is stabilized by resonance from an aromatic ring. Applying Yukawa and Tsuno's equation (11), i.e.,

$$\log k/k_0 = \rho(\sigma + r(\sigma^+ - \sigma)),$$

to our results we find that the resonance contribution to the reaction (r) is about 1.0. Therefore, the amount of resonance stabilization of the transition state is about the same as that in the solvolysis of cumyl chlorides (where $\rho = -4.62$ (8)). The reason for the absence of a quantitative correlation between r and ρ is at present unclear but it may possibly be connected with the differing effects of solvents upon different reactions (10, 11).

We have recently shown that the majority of radical hydrogen abstraction reactions of the same general type as the present reaction can be correlated with σ^+ substituent constants (7). In particular, it is interesting to compare the present ρ factors with those we have obtained in styrene at 65° C for hydrogen abstraction by polystyryl peroxy radicals from simple phenols ($\rho = -1.49$ (7)) and from 2,6-di-*t*-butyl phenols ($\rho = 1.11_5$ (12)). Although the data are not directly comparable owing to the different solvents and temperatures employed, the smaller ρ factors for the di-*t*-butyl phenols compared with the simple phenols and their decreased reactivity towards both peroxy and alkoxy radicals is of particular significance. The results suggest that two *o*-*t*-butyl groups prevent both radicals from approaching the phenolic hydrogen quite as closely as they approach the phenolic hydrogen of a simple phenol. The activation energy is thereby increased and the probability of reaction will be decreased. Compared with the simple phenols, the transition state for the di-*t*-butyl phenols will tend to resemble the products to a greater extent than it resembles the reactants, i.e., the contribution of structure III to the transition state will become of increasing importance as the phenolic hydrogen becomes sterically better protected.* Further support for this view comes from the fact that 2,6-di-*t*-butylphenol shows a negative deviation from the best line and 2,6-di-*t*-butyl-4-chlorophenol shows a positive deviation† although, in CCl_4, both phenol and 4-chlorophenol fall very close to

**The rather large deuterium isotope effect for the reaction of t-butoxy radicals with 2,6-di-t-butyl-4-methylphenol (1) may also be partly due to the importance of structure III in the transition state of this phenol. That is, the isotope effect will tend to be larger the greater the extent of bond breaking in the transition state.*

†Similar deviations also occur with the peroxy radicals (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the best straight line through the other simple phenols. The deviations of the di-*t*-butyl phenols can, perhaps, be explained if the increased importance of structure III is such that the stability of the resulting phenoxy radical has a significant effect on the reaction rate. That is, both electron-attracting and, to a lesser extent, electron-repelling substituents are known to increase the stability of radicals of the general type $XC_6H_4Y\bullet$ relative to the stability of $C_6H_5Y\bullet$ (13, 14). In particular, the 4-chloro atom has about the same stabilizing influence as a 4-methyl group (14). A positive deviation of the 4-chloro compound in a hydrogen-abstraction reaction therefore suggests that radical stabilization to some extent overcomes the opposing polar effect. Positive deviations with the 4-chloro derivative have been observed in the reaction of *t*-butoxy radicals with dibenzyl ethers (15, 16) and with toluenes at 110° (17) but not at 40° (18). The excellent correlation of phenol and 4-chlorophenol with the other simple phenols in CCl_4 suggests that when steric effects are absent structure III does not contribute significantly to the transition state.

Provided the decreases in reactivity and, in CCl_4, the ρ factor, for the di-*t*-butyl phenols compared to the simple phenols are due to steric effects we might expect a steady change in both quantities as the degree of steric protection afforded the phenolic hydrogen is increased. Although the ρ factors have not been measured, the reactivity data in Table I for 4-methyl-2,6-dialkylphenols certainly suggest such a trend. We have recently determined the difference in free energy (ΔG) between the cis and trans isomers of some ortho-alkyl phenols in CCl_4 by means of infrared spectroscopy (19). This quantity gives a measure of the steric repulsion of the phenolic hydroxyl group by an ortho-alkyl group and should therefore give a rough measure of the steric protection afforded the hydroxyl group by two ortho-alkyl substituents. In Fig. 2 the $\log_{10}$ of the measured and calculated ratios of [*t*-butanol]/[acetone] at a $\sum \sigma^+ = -0.811$* have been plotted against ΔG for the 2,6-dialkyl-4-methyl phenols in CCl_4. The phenol point ($\Delta G = 0$) was calculated from the best line through the simple phenols in Fig. 1. In calculating the points for the methyl phenols it was assumed that there is a linear relation between ρ and ΔG (12). The ρ factor was therefore taken to be -1.08 for 2,4,6-trimethylphenol and -1.03 for both 2,3,5,6-tetramethylphenol and pentamethylphenol.† The results can be represented by

$$\log_{10}\left(\frac{[t\text{-butanol}]}{[\text{acetone}]}\cdot\frac{[\text{acetone}]_0}{[t\text{-butanol}]_0}\right) = \alpha\Delta G,$$

where $[t\text{-butanol}]_0/[\text{acetone}]_0 = 249$ and $\alpha = -1.23$ mole/kcal.

The [*t*-butanol]/[acetone] ratio for 2,6-di-isopropyl-4-methylphenol suggests that the hydroxyl group in this compound is slightly less hindered than the one in pentamethylphenol, a conclusion which has also been reached from studies of the autoxidation of these phenols in alkaline media (20). On the other hand, two *o-s*-butyl groups apparently exert a greater hindering effect than five methyl groups.

In general, there is a small decrease in the reactivity of *t*-butoxy radicals towards hydrogen atom abstraction from hydrocarbons on changing from an aliphatic solvent (including CCl_4) to an aromatic or olefinic solvent (18, 21–24). By analogy to a similar, but much larger,‡ effect which has been observed with chlorine atoms (25, 26) it has been

That is, it has been assumed that $\sigma^+_{\text{ortho}} = \sigma^+_{\text{para}}$ and therefore $\sum \sigma^+ = -0.311$ (4-CH_3) $- 2\times 0.250$ (two o-t-alkyl groups) $= -0.811$.

†*The tetra- and penta-methyl phenols have been plotted at the ΔG value for the 2,3-dimethyl grouping. In actual fact, ΔG will be slightly greater for the latter phenol because of the additional buttressing effect of the 4-methyl group on the 2,3- and 5,6-dimethyl groups.*

‡*It has been suggested (21) that the smaller solvent effect observed with t-butoxy radicals may be due to a lower stability of the π complex owing both to the lower electron affinity of the t-butoxy radical compared with the chlorine atom and the higher temperatures employed in studying the reactions of the t-butoxy radicals. In addition, there may be some steric hindrance to complex formation from the bulky methyl groups (18).*

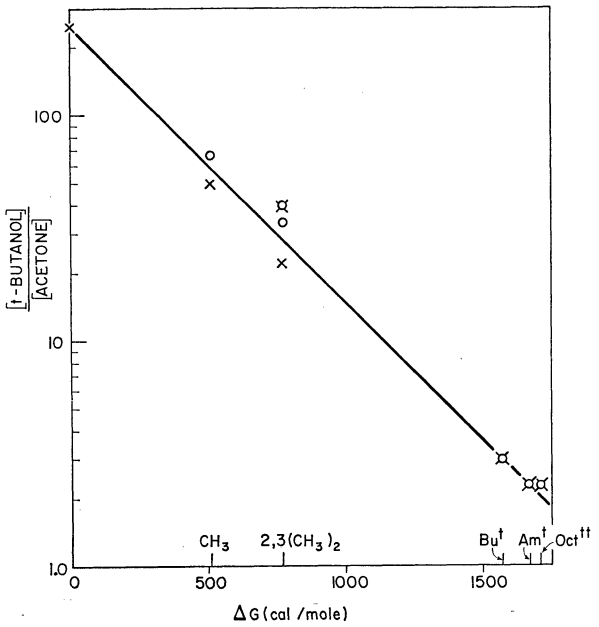

FIG. 2. The [*t*-butanol]/[acetone] ratio for 2,4,6-trialkyl phenols plotted against ΔG. The circles represent the experimental points and the crosses the points calculated for a $\sum \sigma^+ = -0.811$.

concluded that a π complex is formed between the *t*-butoxy radical and the aromatic π electrons. The complexed radical is apparently less reactive and it therefore tends to decompose rather than to abstract hydrogen. It is possible that the same explanation applies to the present results although the observed effects are so large as to suggest that other factors may also be involved. For example, it has been suggested (21) that the solvent may affect the rate of decomposition of the radical as well as its rate of hydrogen abstraction. That is, the large solvent effects observed in this work on changing from CCl_4 to chlorobenzene might be mainly due to an increase in the rate of decomposition of the radical rather than to a decrease in its rate of hydrogen abstraction.

The decrease in the ρ factors for both the simple phenols and the di-*t*-butyl phenols on changing from CCl_4 to chlorobenzene can be attributed to an increase in the relative contribution of structure III to the transition state.* The essentially identical ρ factors in chlorobenzene imply that there is about the same degree of charge separation in the transition state in this solvent for both types of phenols. However, the lower reactivities of the di-*t*-butyl phenols shows that the steric effects of the two *t*-butyl groups are still important. Incidentally, the similarity of the ρ factors suggests that the partially aliphatic character of the local environment surrounding the phenolic hydroxyl group in the 2,6-di-*t*-butyl phenols does not destabilize the charge separation relative to the charge separation in the simple phenols where the local environment is entirely aromatic (7). These decreases in ρ are much greater than have been observed for the reactions of *t*-butoxy radicals with substituted cyclohexanes (22) and of chlorine atoms with substituted toluenes (27).

It has recently been pointed out (25) that for hydrogen abstraction by chlorine atoms

**In this connection, it is interesting that in chlorobenzene the point for phenol falls below the best line through the other simple phenols.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

there is no consistency in the direction of small solvent effects on relative reactivities determined chiefly by polar factors. This is presumably because a complexed chlorine atom may have either a higher electron affinity (owing to the increased electron affinity of structures such as $Ar^{-}ClH^{+}R$) or a lower electron affinity (since polarization is in the same direction in the complex as in the transition state) than a free chlorine atom (26). In the case of the bulky *t*-butoxy radical a decrease in the electron affinity for the complexed radical seems most likely and this may therefore be the cause of the decreased ρ factors observed in chlorobenzene.

The large amounts of *t*-butyl chloride, chloroform, and carbon monoxide produced from 4-hydroxybenzaldehyde and 2,6-di-*t*-butyl-4-formylphenol might be due to the occurrence of a modified Dakin reaction (28). However, the reaction must involve free *t*-butoxy radicals rather than the peroxide since the consumption of peroxide is not much greater than that in reactions with the other phenols. We are indebted to the referee for suggesting the following radical mechanism to account for the products:

$$Bu^tO\bullet + RCHO \rightarrow Bu^tOH + R\dot{C}O$$
$$R\dot{C}O \rightarrow R\bullet + CO$$
$$R\dot{C}O + CCl_4 \rightarrow RCOCl + CCl_3\bullet \ (\rightarrow CHCl_3)$$
$$RCOCl + Bu^tOH \rightarrow RCO_2H + Bu^tCl.$$

THE STRUCTURE OF THE EXTRACELLULAR POLYSACCHARIDE OF AZOTOBACTER INDICUM

V. M. PARIKH AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received June 10, 1963

ABSTRACT

The extracellular polysaccharide of the *Azotobacter indicum* has been shown to be a mixture of two polymers of which the acidic polymer was a major fraction. The acidic polymer contained D-*glycero*-D-*manno*heptose in the molar ratio of 1:1:1 plus traces of mannose. It consumed 1 mole of sodium metaperiodate per mole of an average anhydroaldose unit and released 0.95 moles of formaldehyde per anhydroheptose unit. Reduction of the oxidized polymer followed by hydrolysis yielded D-glucose, glycerose, glycolaldehyde, and glycerol. Complete fission of the methylated polymer yielded 2,3-di-*O*-methyl-D-glucuronic acid, 2,4,6,-tri-*O*-methyl α-D-glucose and 3,4,6,7-tetra-*O*-methyl D-*glycero*-D-*manno*heptose. Partial hydrolysis of the methylated polymer produced a methylated aldotriouronic acid composed of 1 mole each of 2,3-di-*O*-methyl-D-glucuronic acid, 2,4,6-tri-*O*-methyl-D-glucose and 3,4,6,7-tetra-*O*-methyl D-*glycero*-D-*manno*heptose. A methylated aldobiouronic acid was also produced and was shown to be composed of 2,3-di-*O*-methyl-D-glucuronic acid and 2,4,6-tri-*O*-methyl D-glucose.

On the basis of these results it is proposed that the polysaccharide is a linear molecule composed of repeating units of D-glucuronic acid, D-glucose, and D-*glycero*-D-*manno*heptose.

DISCUSSIONS

The presence of aldoheptoses in the lipopolysaccharides of a number of microorganisms has been reported in the literature (1) in the past decade; however, very little appears to be known about the mode of their linkages with other units in the polysaccharides. Heptose residues in the polysaccharides of some microorganisms such as *Pasteurella pestis* and *Chromobacterium violaceum* 7917 (1*a*) have been shown to contain free hydroxyl groups at C_6 and C_7 by the action of sodium metaperiodate on the polysaccharides and the detection of formaldehyde thus produced. The microorganism *Azotobacter indicum* produces a polysaccharide rich in aldoheptose and the structural investigations of this polysaccharide form the basis for the present communication.

The presence of a heptose in the extracellular polysaccharide of *A. indicum* was first reported by Quinell and coworkers (2). The identity of the heptose was established by Sowa (3) as D-*glycero*-D-*manno*heptose. Stoodley and coworkers (4) made a detailed study of the factors affecting the production of the polysaccharide by *A. indicum*-446* and reported that the rate of production, the yield, and the composition of the polysaccharide varied largely with the variations in the conditions of growth of these organisms. The yield of the polysaccharide in the present work was 25% (based on D-glucose). The extracellular material was shown (3) to be a mixture of two polymers, the acidic fraction of which was a major constituent (85–90%) and contained D-glucose (33%), D-mannose (26%), D-*glycero*-D-*manno*heptose (16%), uronic acids (19%), and traces of arabinose, rhamnose, and unidentified sugars.

The crude polysaccharide isolated in the present work was a mixture of at least two polysaccharides. The major constituent was an acidic polymer (88%) which could be precipitated with "cetavlon". The acidic polymer contained D-glucuronic acid, D-*glycero*-D-*manno*heptose, and D-glucose, in the approximate molar ratio 1:1:1 (with traces of D-mannose), whereas the non-complexing fraction was a neutral polymer containing

D-glucose, D-mannose, L-arabinose, and L-rhamnose. The acidic polysaccharide, which contained less mannose than the one isolated by Sowa (3) was obtained in higher yield possibly because the organism was grown in an unbuffered medium.

Experiments such as (*i*) acetolysis, (*ii*) partial degradation of the polymer by dilute acids, and (*iii*) degradation by Fenton's reagent (5) failed to yield oligosaccharides from the acidic polymer. However, isolation of methylated oligosaccharides by the partial degradation of the methylated polymer helped to establish the order of the sugar residues (see below). On oxidation with sodium metaperiodate, the acidic polysaccharide consumed exactly 1 mole of the oxidant per an average anhydroaldose unit, but no significant production of formic acid was observed. The amount of formaldehyde released during the oxidation was found to be 0.95 moles of formaldehyde per anhydroheptose unit, indicating that at least 95% of the anhydroheptose units in the polymer had free hydroxyl groups at C_6 and C_7 and hence were responsible for the consumption of at least 1 mole of the oxidant per an anhydroheptose unit. Hydrolysis of the oxidized polymer gave D-glucose and the Smith-type degradation (6, 7) of the polymer gave glycolaldehyde, D-glucose, glycerol, and glycerose and a trace of arabinose. The proposed structure (see Fig. 1) of the polymer demands liberation of tetronic acid in addition to the compounds mentioned above. This would be absorbed on an ion-exchange resin during the deionization of the hydrolyzate and thus be lost. The presence of a trace of arabinose, however, cannot be explained.

A crude mixture of the acidic and neutral polysaccharides was used for the methylation studies. Isolation of the acidic fraction from the mixture was achieved by extracting an aqueous solution of the partially methylated mixture with chloroform at pH 8.5. This treatment left the sodium salt of the acidic polymer in the aqueous solution. The aqueous solution was acidified and the acidic polymer was isolated. Further methylation of the product was carried out by Kuhn's method (8). The methylated polymer, after fractionation with chloroform–petrol, was subjected to methanolysis followed by hydrolysis. Hydrolysis was later found to be incomplete, and some methyl glycosides were recovered. Considerable decomposition of the methylated sugar units, as evidenced by the dark brown color and the poor yield (approximately 70%) of the hydrolyzate, had taken place. The chromatographic examination of the hydrolyzate showed it to be a mixture of three major and four minor components. Five of the seven fractions were isolated; the remaining two very minor components of the mixture were lost during chromatography. These two minor components were tentatively identified as 3,4-di-*O*-methyl mannose and 4-*O*-monomethyl mannose respectively, on the basis of chromatographic evidence only.

Two (fractions III and IV) of the five fractions isolated after chromatography were found to be methylated oligosaccharides, whereas the remaining three fractions (I, II, and V), which were obtained in relatively low proportions, were found to be methylated derivatives of the monosaccharide units of the polymer (see Table I).

Fraction III proved to be a trisaccharide comprising 1 mole each of 2,3-di-*O*-methyl D-glucuronic acid, 2,4,6-tri-*O*-methyl D-glucose and 3,4,6,7-tetra-*O*-methyl D-*glycero*-D-*manno*heptose. The methylated uronic acid and methylated hexose were identified by the preparation of specific derivatives. The crystalline methylated heptose, a compound which is not reported in the literature, was identified as follows:

(i) The analysis of the sugar indicated that it was a tetramethyl heptose.

(ii) Hydrolysis of the unmethylated polysaccharide with dilute acid was very slow. This suggested that all the heptose was in the pyranose form in the polymer and that it possessed a potential hydroxyl group on C_5.

(iii) Liberation of 0.95 moles of formaldehyde per 1 mole of anhydroheptose unit during

the sodium metaperiodate oxidation of the polymer suggested that at least 95% of the heptose residues in the polymer had free hydroxyl groups at positions C_6 and C_7, and thus the tetramethyl heptose isolated from the methylated polymer had methyoxyl groups on C_6 and C_7, leaving C_2, C_3, and C_4 as possible points of attachment.

(iv) When treated with sodium metaperiodate, the tetra-*O*-methyl heptose (II) rapidly consumed 1.0 mole of the oxidant per mole of methylated heptose, and did not liberate either formic acid or formaldehyde, indicating thereby the presence of two adjacent groups in the methylated heptose, possibly at C_1 and C_2.

(v) The methylated heptose was reduced to the corresponding heptitol by reduction with sodium borohydride. The methylated heptitol thus obtained consumed 1 mole of periodate per mole of heptitol and liberated formaldehyde, proving the presence of free hydroxyl groups at C_1 and C_2 in the sugar. The identity of the tetra-*O*-methyl heptose was thus established as 3,4,6,7 tetra-*O*-methyl-D-*glycero*-D-*manno*heptose.

(vi) This identity was further confirmed by the demonstration of a free hydroxyl group at C_2 in the methylated heptose by a positive test with a specific tetrazolium red spray (9).

Fraction IV was proved to be 3-*O*-α-D-2,3-di-*O*-methyl glucuronosyl-2,4,6-tri-*O*-methyl D-glucose on the basis of its equivalent weight, optical rotation, and the identification of its hydrolysis products.

In view of the facts (*a*) that a large quantity (30%) of the material decomposed during the hydrolysis of the methylated polymer, (*b*) that an infrared spectrum of the partially methylated polymer gave a doublet peak in the carboxylic region of the spectrum, and (*c*) that Sowa (3) reported the possible presence of three uronic acids in the polymer, further investigations were undertaken. The methylated polysaccharide was treated with lithium aluminum hydride to reduce the carbomethoxy groups of the uronic acid residues in the polymer. The reduced product showed very little decomposition during methanolysis and hydrolysis. Again hydrolysis was incomplete and some glycosides were detected. Examination of the hydrolyzate indicated the presence of 2,3-di-*O*-methyl D-glucose, 2,4,6-tri-*O*-methyl D-glucose and its methyl glycoside, and 3,4,6,7-tetra-*O*-methyl D-*glycero*-D-*manno*heptose, together with traces of 3,4-di-*O*-methyl mannose (?) and 4-*O*-monomethyl mannose (?). The dimethyl derivatives of glucose and mannose could not be separated chromatographically from one another because of their close R_f values in a number of developing mixtures, but on demethylation of the mixture with boron trichloride (10) a mixture of glucose and mannose in the approximate proportion of 6:1 was obtained. The fact that no methylated sugar other than the three mentioned above was present in the hydrolyzate of the reduced methylated polymer, and that the ratio of glucose to mannose (6:1) in the mixture of dimethyl sugars was approximately the same as that of glucuronic acid (31%) to mannose (4.5%) in the unmethylated acidic polymer, proved that D-glucuronic acid was the only acidic component of the polysaccharide.

Thus, on the basis of these observations, it can be proposed that the acidic polysaccharide isolated from the extracellular material of *Azotobacter indicum*, grown in an unbuffered medium, is a linear, large molecular weight molecule containing several repeating units of the trimer as shown in Fig. 1. The observed optical rotation of the polymer, and of the methylated aldotriouronic acid, together with the fact that it gave a negative precipitin reaction with *Pneumococcus* type III antiserum, as reported by Sowa (3), suggested that the monosaccharide units in the polymer were all α-linked.

EXPERIMENTAL

Methods

Paper chromatography was carried out on Whatman No. 1 filter paper using the following solvent systems (v/v):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(a) butan-1-ol, ethanol, water (3:1:1);
(b) butan-1-ol, ethanol, water (5:1:4), (top layer clarified with a little ethanol);
(c) ethyl acetate, acetic acid, formic acid, water (18:3:1:4);
(d) butan-1-ol, pyridine, water, benzene (10:6:6:2);
(e) benzene, ethanol, water (169:47:15), (top layer clarified with a little ethanol).

Whatman 3MM paper and columns packed with Whatman cellulose powder by the wet method were used for separations of sugar mixtures. All solutions were concentrated under reduced pressure at 40–45°. Demethylation of methylated sugars was carried out by the procedure of Allen *et al.* (10). All infrared spectra were made in chloroform solutions (6%) using a Perkin–Elmer model 21 infrared spectrophotometer.

Growth of Azotobacter indicum and Isolation of the Polysaccharide

The following ingredients in the quantities given were used to prepare the growth medium: calcium sulphate (0.22 g), magnesium sulphate heptahydrate (0.44 g), dipotassium hydrogen phosphate (1.10 g), peptone (8.80 g), glucose (88.00 g), and distilled water (2200 ml). The medium was equally distributed between each of 11 conical flasks (1 liter), and the flasks were steam-sterilized for 15 minutes at a pressure of 15 p.s.i. They were cooled and innoculated with large doses (4.5 ml) of a highly viscous and fresh growth of *A. indicum*. The flasks were swirled on a mechanical shaker at 23±2° for 19 days, after which the culture medium had become extremely viscous.

The combined solution from 10 of the above flasks (equivalent to 80 g glucose) was diluted with water (2 vol) and centrifuged (12,000 r.p.m. for 90 minutes) to remove suspended cells. The supernatant was filtered through a bed of Celite and the filtrate was concentrated (800 ml). The solution was then poured into ice-cold ethanol (2 vol) containing 0.5% hydrogen chloride, with vigorous stirring. The polysaccharide precipitated in the form of a long continuous thread which was separated by centrifugation and washed repeatedly with ethanol until free from chloride ions, then with acetone (200 ml), and ether (200 ml). The material, on drying *in vacuo* over silica gel for several days, contained moisture (9.6%), ash (0.64%), and had $[\alpha]_D^{23}$ +35±2° (yield 20 g, 25% based on D-glucose). The dried material could not be redissolved completely in water.

Free Boundary Electrophoresis of the Polysaccharide

Electrophoresis of the polysaccharide in veronal or in borate buffer was not possible because the polysaccharide was insoluble in these buffers. A solution of the polysaccharide at a concentration of 1.0% could, however, be prepared in phosphate buffer (pH 7.4), which was then dialyzed twice against the phosphate buffer, 24 hours each time, to gain full equilibration of the ionic concentrations prior to electrophoresis. It was then subjected to moving boundary electrophoresis, and the polysaccharide was found to be a mixture of a major mobile component and a minor stationary component.

Fractionation of the Polysaccharide with "Cetavlon"

Since the dried polysaccharide could not be redissolved completely in water, the fractionation was carried out using an aqueous cell free extract of the *A. indicum*.

A growth from one of the conical flasks was diluted with water (2 volumes), centrifuged, and filtered, and to the filtrate (200 ml) was then added a 10% solution of "cetavlon" with stirring, until no further precipitate formed (11). The acidic polysaccharide complex thus precipitated was collected by centrifugation, and the polysaccharide (800 mg) was recovered from it in the usual way. The non-complexing neutral fraction was recovered from the filtrate by precipitation with alcohol (yield 76 mg). Chromatographic examination of the hydrolyzate of the acidic polymer indicated the presence of uronic acid, D-*glycero*-D-*manno*heptose, and D-glucose in the approximate molar ratio 1:1:1 (with a trace of D-mannose), whereas that of the neutral polysaccharide indicated the presence of glucose, mannose, arabinose, rhamnose, and a trace of heptose or galactose, and possibly a trace of ribose. The equivalent weight of the acidic polymer was found to be 591. This corresponds to the presence of 31.1% hexuronic acid.

Quantitative Analysis of the Component Sugars of the Acidic Polysaccharide

The acidic polysaccharide (138 mg dry wt.) was hydrolyzed by sulphuric acid (*N*, 10 ml) for 10 hours and the hydrolyzate was neutralized ($BaCO_3$), deionized (IR-120 ion exchange resin), and concentrated to a yellow syrup (127.2 mg). The syrup was examined by paper chromatography in solvents (*a*), (*c*), and (*d*) and the chromatograms were sprayed with *p*-anisidine hydrochloride or with silver nitrate/sodium hydroxide. The areas of various spots obtained on heating the chromatograms at 110° for 90 seconds were carefully measured using a compensating polar planimeter, model 4236 (Keuffer and Essex, Germany). The optical densities of these spots were then measured with the help of an optical densichron (Welch Manufacturing Company, Chicago, U.S.A.), and the percentages of the four constituent sugars were calculated to be, uronic acid (31±2), D-glycero-D-*manno*heptose (33±2), D-glucose (32±2), and mannose (4.5±2). A synthetic mixture containing the three sugars in the proportions indicated was prepared and analyzed by this procedure. The results obtained were within the ranges indicated.

Sodium Metaperiodate Oxidations of the Acidic Polysaccharide

Accurately weighed samples of the acidic polysaccharide (51.2 mg dry weight of each) were dissolved in carbon dioxide free distilled water and the solutions were adjusted to pH 7 with sodium hydroxide solution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(0.01 *N*). Sodium metaperiodate solution (0.03 *M*, 25 ml) was added to each sample and the solutions were made up to volume (100 ml) and kept in the dark. The periodate uptake was determined by the thiosulphate method (12), and the formic acid by the usual procedure (see Table II). Extrapolation of the overoxidation part of the periodate uptake curve gave an uptake of exactly 1.0 mole of the oxidant per mole of anhydrohexose unit. No significant production of formic acid was observed.

TABLE II

Periodate oxidation of the acidic polysaccharide of *A. indicum* moles uptake per $C_6H_{10}O_5$

Time (hours)	0.25	4	8	12	24	30	48	72
Periodate uptake								
Sample I	0.55	0.92	1.03	1.06	1.14	1.20	1.31	1.38
Sample II	0.55	0.91	1.02	1.05	1.13	1.19	1.25	1.37

Formaldehyde released during oxidations of the polysaccharide was estimated by the method of O'Dea and Gibbons (13). The experiment was carried out on three samples (5 mg each, dry weight) of the polysaccharide; each was dissolved in 25 ml of distilled water containing 1 ml of 0.6 *M* sodium metaperiodate solution. Curves were plotted with the optical densities obtained from the polysaccharide solutions as ordinates and duration of oxidation as abscissae. The portions of the curves along the abscissae were extrapolated to zero time to obtain the optical densities corrected for overoxidation of the polysaccharide. The numbers of moles of formaldehyde released per anhydroheptose unit were calculated from these figures. The heptose was considered to be 33.2% of the polysaccharide on the basis of previous chromatographic estimations. The results for the three samples were 0.96, 0.95, and 0.95 moles of formaldehyde per anhydroheptose unit.

Smith-type Degradation of Acidic Polysaccharide (6, 7)

The acidic polysaccharide (250 mg) in water (375 ml) was oxidized with sodium metaperiodate solution (0.03 *M*, 125 ml) for 24 hours. Ethylene glycol (25 ml) was added to destroy excess periodate. After dialysis to remove formaldehyde, ethylene glycol, and salts, a small quantity (ca. 10 mg) of the polyaldehyde was hydrolyzed with *N* sulphuric acid on a boiling water bath for 12 hours, and the hydrolyzate, after neutralization and chromatographic examination, was found to contain D-glucose as a major component together with a trace of arabinose. No uronic acid, heptose, or mannose was found to be present.

The remaining portion of the polyaldehyde (ca. 230 mg) was reduced with sodium borohydride solution (1%, 25 ml) for 18 hours. The excess borohydride was destroyed with dilute acetic acid and the solution was dialyzed three times against distilled water, each time for a period of 12 hours. The solution of polyalcohol thus obtained was concentrated under reduced pressure to yield a white, brittle solid (212 mg) which was hydrolyzed with sulphuric acid (*N*, 20 ml) for 10 hours. The solution was neutralized ($BaCO_3$), filtered, deionized [Amberlite IR-120 (H) and Duolite A-4 (OH) resins], and concentrated to a small volume (5 ml). Chromatographic examination of the hydrolyzate in solvents (*a*), (*b*), (*c*), and (*d*), and spraying with silver nitrate or with *p*-anisidine hydrochloride spray reagents, showed five components which were indistinguishable from D-glucose (major constituent), arabinose, glycerose, glycerol, and glycolaldehyde.

Methylation of the Polysaccharide

A crude mixture of acidic and neutral polysaccharides (18 g) was stirred overnight in water (360 ml) to obtain a highly viscous suspension of the polysaccharide in water. The polysaccharides were then methylated three times by the Haworth procedure. At the end of the third methylation, a separation of the acidic and neutral fractions of the mixed polysaccharides was achieved. The mixture was neutralized and concentrated to a suitable volume (800 ml). It was then rendered alkaline (pH 8.5) and extracted with chloroform (4×400 ml). This removed the neutral fraction of the methylated mixed polysaccharides leaving the sodium salt of the acidic polysaccharide in the aqueous solution. The chloroform solution was washed twice with a solution of sodium sulphate (20%), dried over anhydrous sodium sulphate, and concentrated to give a yellow solid (yield 2.15 g).

The residual aqueous layer (above) was cooled (0°) and acidified with ice-cold 2 *N* sulphuric acid to pH 2, when the acidic polysaccharide separated in the form of a viscous yellowish oily layer. It was isolated by extraction with chloroform (4×400 ml). The chloroform extracts were combined, washed four times with a solution of sodium sulphate (20%), and dried over anhydrous sodium sulphate. The extract was concentrated to a suitable volume (500 ml) and the residual polysaccharide was esterified with an ethereal solution of diazomethane (3%, 40 ml). The neutral solution was concentrated after it had been kept overnight to give a yellow solid (yield 13.2 g; OMe, 36.2%).

A comparative study of the chloroform solutions (6% w/v) of the neutral and acidic partially methylated polysaccharide fractions by infrared spectroscopy showed no absorption at 1755 cm^{-1} in the case of the neutral fraction, but the acidic fraction had a strong doublet peak at frequencies 1755 cm^{-1} and 1730 cm^{-1}. The neutral fraction showed a relatively greater absorption in the frequency range 3550–3500 cm^{-1} indicating thereby that it was more resistant to methylation than was the acidic fraction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The partially methylated acidic fraction (13 g) was treated twice with Purdie's reagents (14). However, little further methylation was achieved (yield 12.0 g, OMe, 36.5%) and no significant decrease was observed in the peak at 3500 cm^{-1} in the infrared spectrum of the material. The partially methylated acidic polymer was therefore methylated further by Kuhn's method (8). The methylated material thus obtained [yield, 10.4 g; OMe, 39.8%; $[\alpha]_D^{22}$ +42.3 (*c*, 6 in chloroform)] displayed a negligible hydroxyl peak in the infrared spectrum. A second treatment of the product by the Kuhn procedure did not increase the methoxyl content of the product.

Fractionation of the Methylated Acidic Polysaccharide

The methylated acidic polymer (9.5 g) was dissolved in chloroform (15 ml) and was fractionally precipitated by adding petrol (boiling range 40–60°). Four different fractions were collected (Table III).

TABLE III

Fractionation of the methylated acidic polysaccharide

Amount of petrol, ml	Fraction number	Yield, g	Methoxyl content, %	$[\alpha]_D^{22}$ *c*, 6 in $CHCl_3$
120 ml	A	0.20	Not studied	
130 ml	B	3.50	39.6	+42.5°
140 ml	C	5.40	39.7	+42.5°
Unprecipitated	D	0.36	42.5	+47.0°

Fractions B and C gave infrared spectra indistinguishable from one another and on hydrolysis they gave the same pattern of reducing sugars on paper chromatograms. Fractions B and C were therefore mixed and used for further investigations.

Partial Hydrolysis of the Methylated Polysaccharide

The methylated polymer (1.8 g) was heated with anhydrous methanolic hydrogen chloride (7%, 100 ml) in sealed tubes for 6 hours at 100°. The dark brown solution was diluted with water (50 ml) and the mixture was heated a further 3 hours. It was then neutralized with silver carbonate, filtered, and the filtrate was deionized by passage through Amberlite IR-120 ion exchange resin and concentrated to a dark brown gummy syrup (yield 1.28 g). Chromatographic examination of the syrup in solvents (*a*), (*b*), (*c*), and (*d*) showed the presence of seven components, three of which were major and four minor. The syrup was fractionated on a cellulose column (45×12 cm) using solvent (*c*) as the eluting mixture. Only five fractions could be isolated from the column. The two very minor fractions lost on the column had R_g values in solvent (*b*) of 0.58 and 0.32 respectively, which are the same as those of 3,4-di-*O*-methyl mannose and 4-*O*-methyl mannose.

Identification of the Methylated Fragments (see Table I)

Fraction I: Methyl α+β-2,4,6-Tri-O-methyl D-*glucoside*

This pale yellow syrup (34 mg) did not reduce Fehling's solution and gave only glucose on demethylation. It had R_g, 0.93 in solvent (*b*); OMe, 50.6%; $[\alpha]_D^{22}$ +106.5°, (*c*, 4.44 in methanol). Calculated for tetra-*O*-methyl hexose or methyl tri-*O*-methyl hexoside $C_{10}H_{20}O_6$; OMe, 52.5%. On hydrolysis with aqueous hydrochloric acid (*N*) it gave a crystalline material, indistinguishable from fraction $III_{(B)}$, which was identified as 2,4,6-tri-*O*-methyl D-glucose. It was concluded that fraction I was a mixture of α- and β-methyl glucosides of 2,4,6-tri-*O*-methyl D-glucose, the α-form predominating. The literature (15) value for the β-glucoside is $[\alpha]_D$ −27.4°. The α-glucoside is unknown but is certainly more than +106.5°.

Fraction II: 3,4,6,7-Tetra-O-methyl D-*glycero*-D-*mannoheptose*

This fraction (0.120 g) upon investigation was found to be indistinguishable from the component fraction $III_{(C)}$. A detailed investigation of this sugar is therefore reported at a later stage.

Fraction III: A Methylated Aldotriouronic Acid Containing Uronic Acid, Glucose, and Heptose

This pale yellow reducing syrup (0.475 g) was chromatographically pure and gave a brownish yellow spot on the chromatograms when sprayed with *p*-anisidine hydrochloride. It contained 40.8% methoxyl and had R_g, 0.74 in solvent (*b*). On demethylation, it produced a mixture of D-glucose, D-*glycero*-D-*manno*heptose and D-glucuronic acid. Hydrolysis of fraction III (0.450 g) with aqueous hydrochloric acid (2 *N*, 25 ml) for 17 hours on a boiling water bath gave rise to three fractions which were separated on sheets of Whatman 3MM paper. The three fractions were, fraction $III_{(A)}$ (76 mg); fraction $III_{(B)}$ (98 mg); and fraction $III_{(C)}$ (109 mg).

Fraction $III_{(A)}$: 2,3-Di-O-methyl D-*Glucuronic Acid*

This brown reducing syrup was chromatographically pure, gave a cherry red color on chromatograms sprayed with *p*-anisidine hydrochloride, and had $[\alpha]_D^{22}$ +39.0° (*c*, 2 in water); eq. wt. 221; OMe, 27.1%. Calculated for dimethyl glucuronic acid, $C_8H_{14}O_7$, eq. wt. 222; OMe, 27.9%. Hirst and Jones (16) gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the following figures for 2,3-di-*O*-methyl D-glucuronic acid; $[\alpha]_D^{22}$, +36° (*c*, 1.7 in water); eq. wt. 224; OMe, 32.6%. Identification of this fraction $III_{(A)}$ was further confirmed by preparing a crystalline methyl ester of 2,3-di-*O*-methyl D-glucosaccharo-1,4-lactone according to the procedure described by Smith (17). The crystalline methyl ester had melting point and mixed melting point with an authentic specimen, of 101°. Found: OMe, 39.2%; eq. wt. 118. Calculated for $C_9H_{14}O_7$; OMe, 39.75%; eq. wt. 117. Figures reported by Smith are m.p., 101°, OMe, 40.4%; eq. wt. 120.

Fraction $III_{(B)}$: 2,4,6-Tri-O-methyl-α-D-glucose

This fraction crystallized during the concentration of the eluate, in the form of colorless fine needles (yield, 98 mg). On recrystallization from a mixture of benzene–ethanol the crystals had m.p. 123–125°, which was not depressed when mixed with an authentic sample of 2,4,6-tri-*O*-methyl-α-D-glucose. The crystals reduced Fehling's solution, gave only D-glucose on demethylation, and had R_g, 0.76 in solvent (*b*), $[\alpha]_D^{22}$ +110°→ +69.4° (*c*, 3.6 in dry methanol) and OMe, 41.6%. Calculated for $C_9H_{18}O_6$: OMe, 41.9%. Barker, Hirst, and Jones (18) have reported the following figures for 2,4,6-tri-*O*-methyl-α-D-glucose, m.p. 123–126°; $[\alpha]_D^{22}$ +110°→ +70° (*c*, 1 in methanol). Identification of this fraction $III_{(B)}$ was further confirmed by preparing a crystalline amide of 2,4,6-tri-*O*-methyl-D-gluconolactone from it according to the procedure described by Barker, Hirst, and Jones (18). The crystals had m.p. 96–98°; $[\alpha]_D^{22}$ +54° (*c*, 2 in methanol); OMe, 39.1%. The figures reported by Barker *et al.* for the amide are m.p. 98°; $[\alpha]_D$ +54° (*c*, 1.1 in methanol); OMe, 39.2%.

Fraction $III_{(C)}$: 3,4,6,7-Tetra-O-methyl-D-glycero-D-mannoheptose

This fraction (109 mg), obtained by the chromatographic fractionation of the hydrolyzate of fraction III, crystallized. Recrystallization from ether, gave colorless large square plates, with m.p. 108–109°; $[\alpha]_D$ +49.7° (*c*, 2.5 in methanol, no mutarotation) and R_g, 0.855 in solvent (*b*). Found: C, 49.2; H, 8.1; OMe, 44.9%. Calculated for tetramethyl heptose, $C_{11}H_{22}O_7$: C, 49.6; H, 8.27; OMe, 46.6%. On demethylation of the crystals with boron trichloride, only D-*glycero*-D-*manno*heptose was obtained. Fraction $III_{(C)}$ gave a positive tetrazolium red test (9).

Periodate Oxidation of 3,4,6,7-Tetra-O-methyl-D-glycero-D-mannoheptose

Duplicate samples of fraction $III_{(C)}$ (15 mg each), accurately weighed, were dissolved in aqueous methanol (10 ml, 50% v/v). Sodium metaperiodate solution (0.03 *M*, 10 ml) was added to each flask and the solution was made up to 25 ml with distilled water. The oxidation of heptose and the estimation of periodate consumption were carried out according to the usual procedure. The molar periodate consumption per mole of tetramethyl heptose ($C_{11}H_{22}O_7$) was as shown in Table IV.

TABLE IV

Consumption of periodate during the oxidation of tetramethyl heptose

Time (hours)	0.25	1	2	3	6
Periodate uptake					
Sample I	0.26	0.83	1.01	1.02	1.05
Sample II	0.25	0.83	1.02	1.03	1.05

Extrapolation of the overoxidation part of the periodate uptake curve gave an uptake of exactly 1.0 mole of the oxidant per mole of tetramethyl heptose. Neither formic acid nor formaldehyde was found to be liberated during the oxidation.

Reduction of 3,4,6,7-Tetra-O-methyl-D-glycero-D-mannoheptose

Fraction $III_{(C)}$ (30 mg) was dissolved in aqueous methanol (7 ml, 50% v/v) and the solution was added dropwise to a vigorously stirred solution of sodium borohydride (0.1 g) in water (4 ml) at 0°. After 18 hours the excess borohydride was destroyed with dilute acetic acid. The solution was then neutralized and evaporated to dryness. The residue was extracted with dry ether (3×10 ml) and the ethereal extracts on evaporation left a white solid residue (18.5 mg) which was free from the original methylated heptose. The 3,4,6,7-tetra-*O*-methyl-D-*glycero*-D-*manno*heptitol thus obtained was oxidized by sodium metaperiodate in a manner exactly similar to that described for the oxidation of tetramethyl heptose. The molar periodate consumption per mole of tetramethyl heptitol, $C_{11}H_{24}O_7$ was as follows: 0.89 (15 minutes); 1.0 (1 hour), constant value, unchanged even after 9 hours. No formic acid was liberated, but when the mixture was tested qualitatively by the method of O'Dea and Gibbons (13) a deep violet color was formed indicating the liberation of formaldehyde.

Fraction IV: 3-O-α-D-2,3-Di-O-methyl glucuronosyl-2,4,6-tri-O-methyl-D-glucose

This brown colored syrup (0.325 g) reduced boiling Fehling's solution and gave a dark reddish brown spot on the chromatograms when sprayed with *p*-anisidine hydrochloride. It had an R_g value of 0.69 in solvent (*b*), was acidic to litmus, and showed a strong absorption at 1740 cm^{-1}, indicating the presence of uronic acid. Found: OMe, 41.6%; $[\alpha]_D^{22}$ +116.6° (*c*, 3.5 in methanol); eq. wt. 417. Calculated for a disaccharide containing a dimethyl hexuronic acid and a trimethyl hexose, $C_{17}H_{30}O_{12}$: OMe, 42.2%; eq. wt. 426. D-Glucose and D-glucuronic acid were produced on demethylating the disaccharide with boron trichloride. Hydrolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of fraction IV (250 mg) with aqueous hydrochloric acid (2 *N*, 15 ml) on a boiling water bath for 12 hours and subsequent neutralization, deionization, and concentration gave a syrup which on chromatographic examination gave two spots which were indistinguishable from 2,3-di-*O*-methyl D-glucuronic acid (fraction $III_{(A)}$) and 2,4,6-tri-*O*-methyl-α-D-glucose (fraction $III_{(B)}$). The two components of the syrup were separated on Whatman 3MM chromatographic paper using solvent (*a*). The strips of paper containing uronic acid were extracted in cold with dilute formic acid solution to give a syrup $IV_{(A)}$; the yield was 80 mg, after concentration and repeated distillation with methanol to remove all the formic acid. Strips containing neutral sugar were extracted with boiling ethanol and gave a pale yellow syrup $IV_{(B)}$ (103 mg), which crystallized on seeding with crystals of 2,4,6-tri-*O*-methyl-α-D-glucose. A detailed examination of fractions $IV_{(A)}$ and $IV_{(B)}$ showed that they were the same as fractions $III_{(A)}$ and $III_{(B)}$ described earlier.

Fraction V: 2,3-Di-O-methyl D-*glucuronic Acid*

A detailed investigation of fraction V (12 mg) could not be carried out because only a very small quantity of the sugar was isolated. However, this dark brown gummy syrup was believed to be 2,3-di-*O*-methyl D-glucuronic acid as it moved on the paper with the same speed as fractions $III_{(A)}$ and $IV_{(A)}$ in solvent (*c*) and gave a cherry red spot with *p*-anisidine hydrochloride. In view of the fact that some methylated monosaccharides (fractions I and II) were isolated from the column, along with tri- and di-saccharides containing 2,3-di-*O*-methyl D-glucuronic acid, isolation of some 2,3-di-*O*-methyl D-glucuronic acid was anticipated.

Reduction of the Methylated Polysaccharide

The methylated polysaccharide (3 g) was dissolved in dry ether (35 ml) and the solution was added dropwise to a vigorously stirred suspension of lithium aluminum hydride (0.7 g) in dry ether (100 ml), at room temperature. At the end of 24 hours, excess of hydride was destroyed with ethyl acetate (10 ml), the mixture was filtered, and the filtrate (A) was dried over anhydrous magnesium sulphate. The yellowish white residue on the filter paper was dissolved in ice-cold dilute sulphuric acid solution (20%, 50 ml) and the solution was extracted with ether. The ethereal extract was washed with sodium bicarbonate (5%, 50 ml) and then with water (2×20 ml). The extract was dried over anhydrous magnesium sulphate and then was mixed with filtrate (A). The combined filtrate and extracts gave on concentration a colorless amorphous solid (yield 2.4 g).

Examination of Reduced, Methylated Acidic Polysaccharide

Examination of the reduced, methylated acidic polysaccharide by infrared spectroscopy showed practically no absorption in the carboxyl region (1755 cm^{-1} to 1605 cm^{-1}) of the spectrum but showed a remarkable increase in the absorption at 3400 cm^{-1} in place of the very poor peak in that region which was shown by the unreduced polymer. Hydrolysis of the polymer (2 g) with anhydrous methanolic hydrogen chloride (7%, 100 ml) at 80° for 12 hours, and subsequent neutralization, deionization, and concentration of the hydrolyzate, gave a syrup (1.8 g) which, after hydrolysis with aqueous acid, showed the presence of five components on its chromatographic examination in solvents (*a*) and (*d*). One of these five components formed a very minor fraction of the mixture and travelled on chromatograms with a rate corresponding to that of 4-*O*-methyl mannose (R_g, 0.32 in solvent (*b*)). This fraction was lost on the cellulose column (45×12 cm) during the chromatographic fractionation of the mixture using solvent (*e*) as the eluant. The four fractions isolated from the column were examined as follows.

Fraction VI:

This pale yellow, non-reducing, chromatographically pure syrup (0.22 g) had R_g, 0.93 in solvent (*b*). Found: OMe, 50.5%; $[\alpha]_D$ +107° (*c*, 3 in methanol). It gave glucose on demethylation and on hydrolysis 2,4,6-tri-*O*-methyl-α-D-glucose (m.p. and mixed m.p. with $III_{(B)}$, or with $IV_{(B)}$ 124–125°) was obtained. It was thus the same as fraction I.

Fraction VII:

This fraction (0.505 g) was crystalline and was found to be the same as fraction $III_{(C)}$ on the basis of its melting point, mixed melting point with fraction $III_{(C)}$, R_g value, demethylation, and optical rotation. It was thus 3,4,6,7-tetra-*O*-methyl D-*glycero*-D-*manno*heptose.

Fraction VIII:

This fraction (0.350 g) crystallized immediately and was found to be the same as fraction $III_{(B)}$ on the basis of its melting point, mixed melting point with fraction $III_{(B)}$, R_g value, demethylation, and mutarotation. It was thus 2,4,6-tri-*O*-methyl-α-D-glucose.

Fraction IX:

This was a brown syrup (0.430 g) and gave only one brown spot on chromatographic examination in solvents (*a*), (*b*), (*c*), and (*d*). The R_g value of the spot in solvent (*b*) was 0.58. Found: OMe, 29.0%; $[\alpha]_D^{22}$ +66° → +33.2° (*c*, 2 in acetone). Calculated for dimethyl hexose, $C_8H_{16}O_6$: OMe, 29.8%. Irvine and Scott (19) reported the optical rotation of 2,3-di-*O*-methyl-α-D-glucose as $[\alpha]_D^{20}$ +81.9° → +48.3° (*c*, 1 in acetone). Demethylation of fraction IX produced a mixture of D-mannose and D-glucose which were estimated chromatographically to be in the approximate molar proportion of 1:6. Fraction IX was thus a mixture of a dimethyl glucose and dimethyl mannose. The glucose derivative was considered to be 2,3-di-*O*-methyl D-glucose as its formation by reduction, with lithium aluminum hydride, of the 2,3-di-*O*-methyl D-glucuronic acid unit of the polymer was expected.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The second dimethyl hexose derivative could not be firmly identified because of the difficulty in isolating it in the pure form. However, on the basis of its R_g value, 0.58 in solvent (*b*), and on the basis of the evidence obtained by the periodate oxidation of the polysaccharide, its identity could be tentatively established as 3,4-di-*O*-methyl mannose.

ACKNOWLEDGMENT

A NEW MUSTARD OIL GLUCOSIDE SYNTHESIS

THE SYNTHESIS OF GLUCOTROPAEOLIN

M. H. BENN

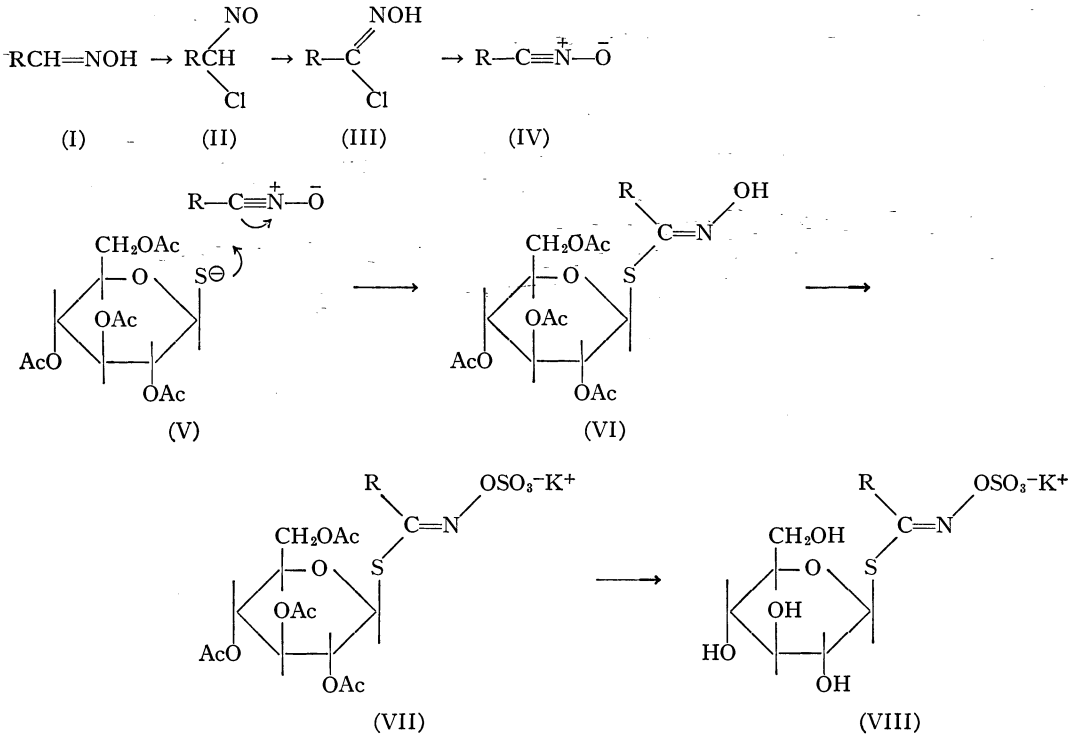
Chemistry Department, University of Alberta, Calgary, Alberta

Received July 2, 1963

ABSTRACT

A new synthesis of mustard oil glucosides is described, illustrated by the synthesis of glucotropaeolin. This synthesis, based on the reaction of thiols with nitrile oxides, leads to a conclusion concerning the stereochemistry about the carbon–nitrogen double bond in the mustard oil glucosides.

In connection with an investigation of their biogenesis and metabolism, it became necessary to synthesize some mustard oil glucosides (VIII). The addition of thiols to nitrile oxides, in the presence of base, has been demonstrated to yield thiohydroxamates (1, 2), and the reaction of 2,3,4,6-tetra-O-acetyl-β-D-glucopyranosylthiol* (V) with the appropriate nitrile oxide (IV) appeared to represent an attractively simple method of constructing the S-glucosyl thiohydroxamate skeleton which characterizes the mustard oil glucosides (3, 4). We wish to report here the successful application of this approach in the synthesis of glucotropaeolin (VIII, R = $PhCH_2$), so establishing a synthesis of the mustard oil glucosides alternative to that described by Ettlinger and Lundeen (5).



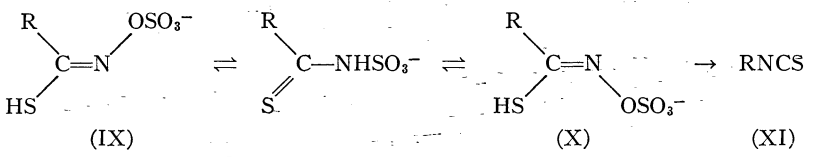
The acetylated sugar was used, in preference to the free thiose, since it afforded a product in which the hydroxyls of the sugar moiety were protected from sulphonation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Nitrile oxides are usually unstable compounds, best prepared *in situ* by treating a hydroxamic chloride (III) with base (6). The hydroxamic chloride is conveniently prepared by chlorination of the corresponding aldoxime (I), followed by the spontaneous rearrangement of the initially formed, blue chloronitroso compound (II) (6).

Phenylacetaldoxime (I, R = $PhCH_2$—) was chlorinated in chloroform solution and phenylmethylhydroxamic chloride (III, R = $PhCH_2$—) isolated as a crystalline solid. When excess triethylamine was added to an ethereal solution of tetra-O-acetyl-β-D-glucopyranosylthiol and this hydroxamic chloride, S-tetra-O-acetyl-β-D-glucopyranosyl phenylmethylthiohydroxamate (VI, R = $PhCH_2$—) was formed in excellent yield. Sulphonation of this material with sulphur trioxide – pyridine (5) afforded the tetra-O-acetylglucotropaeolate anion, isolated as the crystalline potassium salt (VII, R = $PhCH_2$—), identical in all respects with an authentic specimen of this salt. Deacetylation with ammoniacal methanol produced glucotropaeolin itself.

The compound (VI, R = $PhCH_2$—) was identical in all its physical properties with those recorded for this compound by Ettlinger and Lundeen (5). A stereochemical feature of the present synthesis is that the addition of the thiol to the nitrile oxide would be expected to produce by "trans" addition, a thiohydroxamate with the *syn-* configuration (of R and OH) about the oxime carbon–nitrogen double bond. This is the configuration opposite to that normally accepted and inferred from the enzyme-induced rearrangement of the mustard oil glucosides to isothiocyanates, a reaction analogous to the Lossen rearrangement (3, 4). It seems improbable that rearrangement about the oxime occurred during the isolation of (VI) and we therefore suggest that the natural mustard oil glucosides in fact have the *syn*-configuration. The enzyme present in the plant is known to be a thioglucosidase (4) and it presumably cleaves the glucoside to the *syn*-thiohydroxamic acid (IX) plus glucose. The *syn*-acid may isomerize to the *anti*-acid (X) as shown and this then undergoes the Lossen type rearrangement to produce the isothiocyanate (XI).



(IX) (X) (XI)

EXPERIMENTAL

Phenylmethylhydroxamic Chloride

Dry chlorine gas was bubbled slowly through an ice-cold solution of phenylacetaldoxime (3.0 g) in chloroform for 30 minutes. The initially blue, now green solution was concentrated under reduced pressure (bath ⩾ 40°) to a pale azure oil, which was crystallized and recrystallized from hexane–ether to give almost colorless prisms, m.p. 89–91°, (1.82 g). Found: C, 59.77; H, 6.52; N, 8.10; S, 17.99. Calc. for $C_9H_{11}NOS$: C, 59.61; H, 6.11; N, 7.73; S, 17.68%. The crude solid product is satisfactory for the subsequent reactions.

S-2′, 3′, 4′, 6′-Tetra-O-acetyl-β-D-glucopyranosyl Phenylthiohydroxamate

Anhydrous triethylamine (0.60 g) dissolved in ether (10 ml) was added in one portion to a gently stirred solution of 2,3,4,6-tetra-O-acetyl-β-D-glucopyranosylthiol (7) (1.19 g) and phenylmethylhydroxamic chloride (0.70 g) in dry ether (50 ml). A copious precipitate of triethylamine hydrochloride was immediately formed. After 30 minutes at room temperature, the reaction mixture was poured into ice-cold, dilute sulphuric acid (ca. 0.5 *N*, 25 ml), the ether layer separated, and the aqueous phase re-extracted with ether (20 ml). The combined ether extracts were dried ($MgSO_4$) and evaporated to a slurry of crystals, (1.32 g), m.p. 159–160°. Recrystallization from ethanol gave the pure compound as colorless needles (1.08 g), m.p. 163–164°, $[\alpha]_D^{26}$ −9.5° (*c*, 2.3 in $CHCl_3$). Lit. (5) records m.p. 163.8–164.1°, $[\alpha]_D^{32}$ −9.6° ($CHCl_3$).

Potassium 2,3,4,6-Tetra-O-acetylglucotropaeolate (5)

The thiohydroxamate (0.25 g) in dry pyridine (5 ml) was stirred with pyridine – sulphur trioxide (0.25 g) overnight, at room temperature. A solution of potassium bicarbonate (0.5 g) in water (15 ml) was then added and after effervescence had ceased, the reaction mixture was shaken with ether (2×20 ml), the ether

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

extracts combined and washed with water (2×20 ml), and the combined aqueous extracts freeze-dried. The residual salts were extracted with hot 95% ethanol (3×30 ml) and the combined extracts concentrated to small volume (ca. 10 ml) and filtered, hot. Crude potassium tetra-O-acetyl glucotropaeolate monohydrate crystallized on cooling, and recrystallization from 95% ethanol gave the pure salt (52 mg), m.p. 197–199° (decomp.), $[\alpha]_D^{25}$ $-19\pm1°$ (*c*, 0.5 in H_2O); infrared spectrum in KBr disk superimposable on that of an authentic specimen of the salt. The mixed melting point was undepressed. Lit. (4) m.p. 186–187°; 197–198°, $[\alpha]_D^{20}$ $-20°$ (*c*, 1.0 in H_2O). The melting point of these compounds is known to be dependent on the rate of heating (4).

Glucotropaeolin

The tetraacetate of glucotropaeolin (30 mg) was dissolved in anhydrous methanol, saturated with ammonia (1 ml), and kept at 0° overnight. The reaction mixture was taken to dryness under reduced pressure (bath temp. $\gtrsim$ 40°) and the residue extracted with ether (5 ml), taken up in water (2 ml), and freeze-dried to yield glucotropaeolin as a white amorphous powder (21 mg) chromatographically homogenous when examined on Whatman No. 1 paper in *n*-butanol – acetic acid – water (4:1:5) (8).

ACKNOWLEDGMENTS

We are grateful to Professor Anders Kjaer for the gift of an authentic specimen of potassium tetraacetylglucotropaeolate and to the National Research Council for financial support of this research.

THE BARIEAU–LI CONTROVERSY AND ITS SIGNIFICANCE FOR GENERAL THERMODYNAMICS

G. A. ELLIOTT[1]
Chemistry Department, University of Western Australia, Nedlands, Western Australia
Received January 2, 1963

ABSTRACT

The Barieau–Li controversy shows the need for a general method of discussing conditions of validity of thermodynamic equations. Such a method is here developed and illustrations of its usefulness are given. It is shown how Barieau's principle can be applied in all cases.

The papers by Barieau (1, 2) and by Li (3, 4) on the E.M.F.'s of cells having phases of varying concentrations have shown very clearly in at least one case (that of the Gibbs–Helmholtz equation) that exact knowledge of the conditions of validity of a thermodynamic relation is not readily available by reference to any established doctrine or method. To that serious extent thermodynamics must be regarded as not sufficiently understood, especially since it is not likely that the Gibbs–Helmholtz equation differs in this respect from other thermodynamic results. Barieau founded his first paper on the principle that the Gibbs–Helmholtz equation must be true for all (closed) systems. From this was derived Barieau's principle for calculating the correct cell reaction. Li (3) then intervened and submitted for consideration a cell which he claimed and Barieau incorrectly admitted could not be treated by Barieau's method. Later, Barieau was able to publish an *ab initio* proof of the Gibbs–Helmholtz equation and it became evident that it is true for all closed systems. Li's method, on the other hand, was based on the idea that the Gibbs–Helmholtz equation could only be proved for systems 'without a concentration variable'. Stout (5) then showed that the methods of Barieau and of Li are equivalent, though that of Barieau has advantages of convenience. Li (4) then pointed out that certain cells are essentially open systems and that Barieau's method would not hold for them.

As a result of this, the precise conditions of validity of the Gibbs–Helmholtz equation still remain a little doubtful, and the occurrence of this controversy and of these doubts confirms the initial statement that there exists no general method of discussing conditions of validity in thermodynamics. A very considerable time has elapsed, however, since the pioneer work of Gibbs (6), who by introducing the concept of molar or chemical potential (μ) first gave an analytical form to chemical thermodynamics, and it is the main object of the present paper to show that the method of Gibbs can easily be used for the solution of validity problems in thermodynamics.

The use of the Gibbs potential makes it possible to put the fundamental energy change equation of reversible thermodynamics in the now familiar form

$$[1] \qquad dE = TdS + \sum \mu \cdot dn - \sum X \cdot dx.$$

(E = energy; T = absolute temperature; S = entropy; μ = chemical potential; n = molar number; and $X \cdot dx$ is a generalized work term.) Gibbs, however, by his method of derivation, left the persisting impression among some scientists that the formulae of thermodynamics apply only to isolated systems. See, for example, the summary by

[1] *Visiting Lecturer to the School of Chemistry, University of Leeds, England, during 1961.*

Margenau and Murphy (7). However, most scientists will now agree that [1] is not restricted to isolated systems but is quite general, and any attempt to prove this generalization, although instructive, would now be considered too obvious for publication. We must therefore simply assume that (1) is universally valid for reversible changes.* Consequently, the conditions of validity of any thermodynamic relation that can be derived from (1), as most can, are simply the conditions imposed by the derivation. To use this idea, however, it is essential to define clearly the chemical potential and the work terms and to use more developed symbols adequate for a clear and unambiguous formulation of the problem which as far as possible will not allow any implicit assumption to pass unnoticed.

Essentially a work term represents work done by a definable generalized force which acts in definite directions normal or parallel to a macroscopically observable surface such as the wall of a vessel or the surface of a drop of liquid or else in the direction of a force field. The $\mu \cdot dn$ or chemical terms are, however, essentially without directional properties. It is clear that if any work term is not explicitly mentioned in the equation [1] it must be hidden in the chemical terms and we can learn nothing explicitly about it from [1] and its existence may even be overlooked. It is therefore strongly recommended that whenever possible the work terms should be mentioned explicitly. Since it is, strictly speaking, impossible to define a single electric potential difference between two phases there is therefore good reason in this one case to include the corresponding work term in the chemical term forming what Guggenheim (8) has termed an electrochemical potential. This is fully discussed by Guggenheim and those who follow him will find no alteration is necessary in the following general treatment since they will of necessity omit the, for them, undefinable single electric potentials and interpret μ as the electrochemical potential when that term is relevant. Alternatively one may use conventional values as explained in reference 10. Further this case emphasizes the point that the n's and the x's are not always independent variables and a definition of the process of differentiation which applies equally when the variables are dependent is needed. This has been given in a recent publication (9).

It is also necessary to distinguish those parts of the whole change dE which involve the surroundings from those which do not. It will be convenient to attach to a differential the suffix 'i' when it signifies an element of change which is internal and therefore possible for an isolated system; the suffix 'e', however, indicates that the change is external in the sense that it is not possible for an isolated system. For this purpose an isolated system is defined as one which satisfies $dE = 0$ for all changes together with $dS = 0$ for all reversible changes. The same suffixes will also be used when attached to the generalized forces to distinguish those which operate internally from those which operate on the surroundings. We assume T is uniform throughout and the term dS_i is omitted since its value is zero for reversible changes. It is also desirable to write the work of expansion ($P \cdot dV$) as a separate term; this we do by replacing $\sum X \cdot dx$ by $P \cdot dV + \sum' X \cdot dx$ and the meaning of the primed sum is obvious. Equation [1] now becomes

$$[2] \qquad dE = T \cdot dS - P \cdot dV + [\sum \mu \cdot dn_i - \sum X_i \cdot dx_i] + \sum \mu \cdot dn_e - \sum' X_e \cdot dx_e.$$

The quantities in brackets represent those parts of the change which are possible for an isolated system. They represent what is happening inside the 'black box', and the first

It is also applicable under certain conditions to irreversible processes but these will not be discussed in the present paper.

law of course requires that these terms shall sum to zero. Without any significant loss of generality we have transformed equation [1] into two equations [3] and [3*a*] of which the latter has been termed the general chemical condition of equilibrium (10).

$$[3] \qquad dE = T\cdot dS - P\cdot dV + \sum \mu\cdot dn_e - \sum' X_e dx_e$$

$$[3a] \qquad \sum \mu\cdot dn_1 = \sum X_1\cdot dx_1$$

On these two equations we base the new validity principle:

> The conditions of validity of any thermodynamic relation derivable from [3] or [3*a*] or from both are simply those conditions which are necessary for the derivation, plus the usual requirement of thermodynamic reversibility.

For example, since the Gibbs Free Energy is defined by $F = E - T\cdot S + P\cdot V$, we can at once obtain from [3] the result

$$[4] \qquad dF = -S\cdot dT + V\cdot dP + \sum \mu\cdot dn_e - \sum' X_e\cdot dx_e.$$

It follows that the equation

$$[5] \qquad \partial F/\partial T = -S$$

will be valid provided all terms on the right-hand side of [4], except the first one, sum to zero. In practice, this means we must have constant pressure, open circuit for a cell (since $\sum' X_e\cdot dx_e = 0$) during the temperature change, and we must also have $\sum \mu\cdot dn_e = 0$. This last requirement, except in certain rather contrived cases (v.i.), will be satisfied only by closed systems. Further, we may derive from [4] by cross-differentiation between the terms $S\cdot dT$ and any $X_e\cdot dx_e$ of that equation, the result

$$[6] \qquad \partial X_e/\partial T = \partial S/\partial x_e,$$

subject, as is usually stated, to the conditions that for each side of [6] all the variables of [4] except F and those actually involved in the differential coefficient concerned are to be constant. Each of the differential coefficients of [6] is in fact equal to the second partial differential $\partial^2 F/(\partial T\cdot \partial x_e)$ and the order of differentiation makes no difference. According to the true definition (9) of partial differentiation, however, individual constancy of the variables concerned is not required and it will be sufficient if the corresponding terms of [4] sum to zero. The molar conditions of validity of [5] and [6] are therefore identical, namely $\sum \mu\cdot dn_e = 0$. Since in the case of galvanic cells X_e must be identified with the E.M.F. of the cell on open circuit and dx_e with the number of equivalents of electricity transferred, equation [6] readily transforms to $\partial(-\Delta F)/\partial T = \Delta S$, the delta form of [5]. Equation [6], since it contains directly the temperature coefficient of the E.M.F., is in fact the basic form of the Gibbs–Helmholtz equation and [5] is closely related to it, being frequently quoted as such.

In either form, the Gibbs–Helmholtz equation is always valid when $\sum \mu dn_e = 0$. This includes closed systems and since almost any system can become closed simply by expanding the boundaries to include all changes, most cases are in this category. There remain, however, as Li (4) has pointed out, certain systems which are necessarily open; for example, those for which we insist, needlessly no doubt, that volume concentrations shall remain unchanged on heating despite thermal expansion. For such cases material must be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

added or removed during the heating process and the system is then unavoidably open. If during this process $\sum \mu \cdot dn_e = 0$, the material exchanges with the surroundings, as may be seen from [4], do not contribute to dF and the Gibbs–Helmholtz equation is still valid. If this condition is not satisfied, the Gibbs–Helmholtz equation no longer holds without correction. This correction is, however, easily made as we shall now show. Since, when the cell is heated at constant pressure on open circuit, we may omit from [4] $V \cdot dP$ and all the work terms, rearranging and dividing by dT we then obtain

$$[7] \qquad \partial F/\partial T - \sum \mu \cdot dn_e/dT = -S.$$

Hence the Gibbs–Helmholtz equation will effectively hold if we subtract from the $\partial(\Delta F)/\partial T$ calculated from the observed temperature coefficient of the E.M.F. of the cell the quantity $\Delta \sum \mu \cdot dn_e/dT$ by calculation or, more practically, by simply using the temperature coefficient of E.M.F. of the corresponding cell defined only at the lower temperature and heated without altering the material content.

After this correction has been made we can obtain a ΔS value for the correct cell reaction which can *always* be computed by Barieau's principle, since any departure from the Gibbs–Helmholtz equation has been allowed for. This cell reaction is, of course, the one which actually would occur on normal reversible discharge of the cell; that is if it were discharged as a closed system, isothermally and isopiestically, and in a sufficiently large system to prevent appreciable concentration changes during the reaction.

The 'conditions of equilibrium' do not differ in nature from other thermodynamic relations, and they also can usefully be discussed by the new method. Thus, we can see directly from [3] that $dE = T \cdot dS$ will be true for reversible changes provided the remaining terms of [3] vanish. Hence the condition of equilibrium favoured by Gibbs (essentially $dE = 0$ for a change at constant entropy) will be true when no external work is done and whenever $\sum \mu \cdot dn_e = 0$. Certainly, as Li (11) has recently ventured to point out (but without formal proof) it is not necessary for the system to be enclosed in a thermally insulating envelope. Similarly, equation [4], derived unconditionally from [3], reminds us that the much favored condition $dF_{T,P} = 0$ is only true if no net work ($\sum' X_e \cdot dx_e$) is done and if $\sum \mu \cdot dn_e = 0$. Strictly, it is not necessary in either case for the system to be closed. As a concluding example, we discuss the validity of the well-known and frequently misunderstood equation $\sum \mu \cdot dn = 0$. We note first that $\sum \mu \cdot dn = \sum \mu \cdot dn_i + \sum \mu \cdot dn_e$. A glance at [3*a*] now shows that $\sum \mu \cdot dn = 0$ is true provided no internal work is done which is not implicit in the $\sum \mu \cdot dn_i$ term, and provided $\sum \mu \cdot dn_e = 0$. If this latter condition is satisfied, which almost always means the system is closed, it is true for ordinary phase equilibria, but not for systems involving membrane potentials (Donnan equilibria) or in presence of, for example, a gravitational field whereby internal work can be done storing up potential energy within the system, unless the relevant work terms are implicit in the definitions of μ.

All these illustrations show that the usefulness of the Gibbsian method can be increased and precision gained by incorporating the new validity principle which this article describes. The full utilisation of this method requires the adoption of symbols which are clearly defined and adequate to express all relevant matters.

STRUCTURAL STUDIES ON AN ARABINOXYLAN FROM PEA SKIN (PISUM SATIVUM)

PART I. METHYLATION STUDIES

N. BANERJI AND C. V. N. RAO

Department of Macromolecules, Indian Association for the Cultivation of Science, Calcutta-32, India

Received April 4, 1963

ABSTRACT

The polysaccharide extracted by 4% sodium hydroxide solution from pea skin (*Pisum sativum*) was shown to be composed of D-xylose and L-arabinose in a ratio of 5:1. Hydrolysis of the fully methylated arabinoxylan yielded 2,3,5-tri-*O*-methyl-L-arabinose, 2,3-di-*O*-methyl-D-xylose, and 2-*O*-methyl-D-xylose in the molar ratio of 1:4.2:1.1 and traces of 2,3,4-tri-*O*-methyl-D-xylose and D-xylose. From these results and those of periodate oxidation studies, a structural formula for the arabinoxylan has been proposed.

Substantial work has been done in the identification of carbohydrate constituents of pea (1), but no polysaccharide has been isolated from pea skin. The present paper describes the isolation and structural chemistry of an arabinoxylan that is present in pea skins.

Powdered pea skins were extracted successively with a boiling mixture of benzene and alcohol, hot water, and 0.4% and 4% alkali solutions. The polysaccharide extracted by hot water gave a blue color with iodine and yielded only glucose on hydrolysis, indicating it to be a starch. The polysaccharides, extracted by 0.4% and 4% alkali solutions, gave on hydrolysis arabinose and xylose in the same ratio together with trace quantities of galactose. As the former one was obtained in very poor yield the later was selected for structural studies.

The polysaccharide extracted from pea skin by 4% sodium hydroxide solution, having specific rotation −86.9°, gave on hydrolysis D-xylose and L-arabinose in the ratio of 5:1 respectively.

The polysaccharide was purified (2) by repeated complex formation with Fehling's solution. After three treatments the material obtained had specific rotation −87.6° and gave arabinose and xylose in the ratio of 1:5. Galactose and uronic acid originally present in traces were removed during purifications. As there was no change in specific rotation or the ratio of arabinose to xylose after repeated purifications, the material was considered to be homogeneous.

The arabinoxylan was methylated to yield a fully methylated derivative, having a weight-average molecular weight 5.12×10^5.

Hydrolysis of the fully methylated arabinoxylan yielded three major components, viz., 2,3,5-tri-*O*-methyl-L-arabinose, 2,3-di-*O*-methyl-D-xylose, and 2-*O*-methyl-D-xylose, which were characterized by their crystalline derivatives. Trace amounts of 2,3,4-tri-*O*-methyl-D-xylose and D-xylose were also obtained. Column chromatographic analysis showed that tri-*O*-methyl-L-arabinose, di-*O*-methyl-D-xylose, and mono-*O*-methyl-D-xylose were present in the ratio of 1:3.81:1.

A small quantity of the mixture was resolved by quantitative paper chromatography and the sugars were estimated by alkaline hypoiodite method (3). The ratio of trimethylarabinose to dimethylxylose to monomethylxylose was 1:4.2:1.1, which is in close agreement with column chromatographic results.

The above results indicate that the main chain of the arabinoxylan from pea skin is

composed of D-xylopyranose molecules joined through $1 \rightarrow 4$ linkages, with branching mainly through position 3 of certain xylose units. The majority of non-reducing end positions are occupied by L-arabinofuranosyl residues. Trace amounts of 2,3,4-tri-*O*-methyl-D-xylose probably originated from a few end points of the macromolecules. The trace quantities of D-xylose present in the mixture are of uncertain structural significance.

The simplest structure of the repeating unit of the arabinoxylan which can accommodate the above facts is given below:

$$\rightarrow (X_p)1 \underset{4}{\rightarrow} 4(X_p) \rightarrow$$
$$\underset{3}{\uparrow}$$
$$A_f1$$

X_p—D-xylopyranose residues; A_f—L-arabinofuranose residues

From the negative rotation of the polysaccharide and its methylated derivative, it is concluded that the majority of the linkages are of β-type.

The above structure is supported by the fact that during periodate oxidation, 0.84 mole of periodate was consumed per anhydro pentose unit, the theoretical value being 0.83 assuming the above structure. As the non-reducing end groups were arabinofuranose residues, no formic acid was liberated but an equal number of xylose residues (16.2%) at the branch points should remain unoxidized. The periodate-oxidized polysaccharide on hydrolysis yielded 14.2% of xylose, a figure in agreement with that expected theoretically.

The fact that the arabinofuranose residues were present as single-unit side chains was further confirmed by subjecting the arabinoxylan and its methylated derivative to mild hydrolysis, taking advantage of the labile linkage of non-reducing arabinofuranose residues. Hydrolysis of the polysaccharide with dilute oxalic acid solution for 1.5 hours yielded a degraded polysaccharide and the supernatant liquid contained arabinose only. The degraded polysaccharide on hydrolysis afforded xylose (80.2%) and arabinose (5.4%) (these and subsequent values are expressed as percentages of the undegraded polysaccharide). The degraded polysaccharide was oxidized with sodium metaperiodate and the xylose residues unattacked by periodate were estimated to be 6.1%.

The fully methylated polysaccharide was heated with dilute aqueous methanolic hydrochloric acid under controlled conditions (4) and the degraded methylated polysaccharide was precipitated, remethylated, and subjected to methanolysis and hydrolysis. The hydrolyzate was found to contain 2,3,5-tri-*O*-methyl-L-arabinose, 2,3-di-*O*-methyl-D-xylose, 2-*O*-methyl-D-xylose, and traces of 2,3,4-tri-*O*-methyl-D-xylose and D-xylose. Quantitative estimation of tri-*O*-methylarabinose, di-*O*-methylxylose, and mono-*O*-methylxylose showed that the length of the repeating unit is about 16 pentose units and the ratio of 2,3,5-tri-*O*-methylarabinose to 2,3,4-tri-*O*-methylxylose is 12:1. Removal of arabinose residues from the methylated polysaccharide did not result in any substantial increase in the amount of trimethylxylose in the hydrolyzate of the degraded and remethylated product. These results together with those of periodate oxidation studies on the original and degraded polysaccharides show that arabinose is present as single-unit side chain in the arabinoxylan. The arabinoxylan obtained from pea skin is structurally similar to the arabinoxylan obtained from other sources, viz., from wheat (5, 6), rye flour (7), barley flour (4), but the length of the repeating unit varies from source to source.

EXPERIMENTAL

Methods

The following solvent systems (v/v) were used for partition chromatography: (A) ethyl acetate – pyridine – water (8:2:1); (B) *n*-butanol – acetic acid – water (4:1:5), upper layer; (C) *n*-butanol–benzene–pyridine–

water (5:1:3:3), upper layer; (D) benzene–ethanol–water (169:47:15), upper layer; (E) methyl ethyl ketone – water azeotrope; and (F) *n*-butanol–ethanol–water (4:1:5), upper layer. The spray reagents used were: (*a*) saturated solution of aniline oxalate in water (8); (*b*) aniline hydrogen phthalate; and (*c*) *p*-anisidine hydrochloride (3% solution in butanol).

All specific rotations are equilibrium values. Unless otherwise stated all evaporations were carried out *in vacuo* at 30–40°. Whatman No. 1 filter papers were used for paper partition chromatography. Large quantities of sugar mixture were separated by Whatman No. 3MM papers.

Isolation of the Polysaccharide

Peas were kept under water overnight and the skins were separated by hand. They were dried in an oven at 35–40° and powdered. The powder (200 g) in batches was extracted for 24 hours with a boiling mixture of benzene and ethanol (2:1, v/v), to remove fats and coloring matter.

The material (200 g), which was free from fats and coloring matter, was extracted with hot water (4 l.) and the polysaccharide, precipitated by alcohol, was triturated and dried. Yield 0.4%, moisture 9.2%, ash 0.05%, nitrogen 0.25%, $[\alpha]_D^{30}$ +98° (*c*, 0.5 in 4% sodium hydroxide solution). The polysaccharide developed a blue color with iodine solution and yielded only glucose when hydrolyzed. The remaining material was subjected to extraction twice with 0.4% sodium hydroxide solution (750 ml each time) at room temperature in an atmosphere of nitrogen for 16 hours. The polysaccharide was precipitated by addition of the acidified extract to twice its volume of acetone. Yield 0.6%. The polysaccharide on hydrolysis gave xylose and arabinose in the ratio of 5:1, with traces of galactose.

The material left after the above treatment was extracted four times with 4% sodium hydroxide solution (1500 ml) and the polysaccharide was isolated as described above. The product was dialyzed for 7 days, reprecipitated, and dried to yield an amorphous powder. Yield 2%, moisture 11.2%, ash 1.2%, $[\alpha]_D^{29}$ −86.9° (*c*, 0.5 in 4% sodium hydroxide solution), pentosan (9) 96.7%, methoxyl 0.34%, uronic acid (9) 0.84%. Intrinsic viscosity 0.89 dl/g (in 4% sodium hydroxide solution).

Hydrolysis, Identification, and Estimation of Xylose and Arabinose

The polysaccharide (1 g) on complete hydrolysis yielded xylose and arabinose together with a trace quantity of galactose. D-Xylose and L-arabinose were separated by paper chromatography.

The dry sirup containing D-xylose was crystallized from dry ethanol; m.p. and mixed m.p. 144–145°; $[\alpha]_D^{30}$ +19° (*c*, 1 in water), lit. +18° (11).

The dry sirup corresponding to L-arabinose was crystallized from dry ethanol; m.p. and mixed m.p. 155–157°; $[\alpha]_D^{30}$ +105° (*c*, 1 in water), lit. +103° (12).

The polysaccharide (0.1002 g) was hydrolyzed with 2 *N* sulphuric acid and the component sugars were estimated quantitatively by the periodate method (10), using D-ribose as reference sugar. Xylose and arabinose were found to be present in the ratio of 5:1.

Purification of the Polysaccharide

The crude polysaccharide was purified by complexing with Fehling's solution (2). The arabinoxylan (20 g) was dissolved in 4% sodium hydroxide solution (1.5 l.) in an atmosphere of nitrogen, and freshly prepared Fehling's solution (1.5 l.) was added whereupon the copper complex precipitated. The precipitate was washed with ice-cold water (1 l.), and cold hydrochloric acid (0.5 *N*) was added to a suspension of the precipitate in water with stirring, until the copper complex decomposed giving, a slightly opalescent solution. The polysaccharide was precipitated by the addition of an equal volume of acetone and was isolated in the usual way. Yield 15 g, $[\alpha]_D^{29}$ −87.6° (*c*, 1 in 4% sodium hydroxide solution). Intrinsic viscosity 1.02 dl/g in 4% sodium hydroxide solution. Xylose and arabinose, estimated in the above manner, were found to be present in the ratio of 5:1; galactose and uronic acid were absent.

Methylation of the Arabinoxylan

The arabinoxylan (5 g) was methylated by treatment first with dimethyl sulphate and alkali and then with methyl iodide and silver oxide according to the method of Falconer and Adams (15, 16) to yield a fully methylated derivative (3.2 g) showing no hydroxyl absorption band in the infrared spectrum. OMe 38.05%; intrinsic viscosity 0.35 dl/g in chloroform; $[\alpha]_D^{29}$ −58° (*c*, 1 in chloroform).

Molecular Weight Determination of the Methylated Arabinoxylan

All measurements of the intensity of scattered light for molecular weight determination of the methylated arabinoxylan were carried out with a Brice-Phoenix light-scattering photometer (Model OM 1000A) using a semioctagonal cell. The concentration used was over a range of $(1–4)\times10^{-3}$ g/ml. The molecular weight was found to be 5.12×10^5, calculated by the dissymmetry method (17).

Methanolysis and Hydrolysis of the Methylated Arabinoxylan and Separation of Methyl Sugars

The methylated arabinoxylan (1 g) was refluxed with 3% methanolic hydrogen chloride (80 ml) till the rotation reached a constant value (18 hours). The resulting mixture of methyl glycosides was hydrolyzed with *N* hydrochloric acid (80 ml) till the rotation reached a constant value (16 hours). After neutralization

and deionization by passing through Amberlite I.R. 120(H)* and Amberlite I.R. 45(OH)* the hydrolyzate was concentrated to a sirup.

The sirup (600 mg), containing the methyl sugars, was resolved on a cellulose column (13) (40×2 cm) using solvent E (14) as eluant to give five fractions.

Fraction I.—On evaporation, this fraction yielded a chromatographically homogeneous sirup (82 mg) having $[\alpha]_D^{29}$ −35.5° (*c*, 0.5 in water), lit. −35° (4). Calculated for $C_8H_{16}O_5$: OMe, 48.4%. Found: OMe, 48.2%. The sirup (5 mg), on demethylation (18), gave arabinose only along with some partially demethylated sugars. The identity of 2,3,5-tri-*O*-methylarabinose was confirmed by preparing the crystalline 2,3,5-tri-*O*-methyl-L-arabonamide through its lactone in the usual way, m.p. and mixed m.p. 129–131°, lit. 130–132° (19).

Fraction II.—The sirup (15 mg), on demethylation, gave arabinose and a trace of xylose. Paper partition chromatography using solvent D, showed the sirup to contain 2,3,5-tri-*O*-methyl-L-arabinose and 2,3,4-tri-*O*-methyl-D-xylose. A small portion of the mixture was separated by paper chromatography and the sugars were estimated by alkaline hypoiodite (3). The ratio of 2,3,5-tri-*O*-methyl-L-arabinose to 2,3,4-tri-*O*-methyl-D-xylose was approximately 2:1.

Fraction III.—On evaporation, this fraction gave a sirup (370 mg) which had $[\alpha]_D^{29}$ +24.2° (*c*, 0.45 in water), lit. +22.6° (19) and which was chromatographically homogeneous. Calculated for $C_7H_{14}O_5$: OMe, 35.0%. Found: OMe, 34.6%. On demethylation it gave xylose only. The 2,3-di-*O*-methyl-D-xylose was characterized through its crystalline N-phenyl-2,3-di-*O*-methyl-D-xylosylamine, m.p. and mixed m.p. 120–122°, lit. 123–124° (4).

Fraction IV.—This fraction yielded a sirup (96 mg) having $[\alpha]_D^{29}$ +34° (*c*, 0.5 in water) lit. +35° (19). Calculated for $C_6H_{12}O_5$: OMe, 18.8%. Found: OMe, 18.2%. It was chromatographically homogeneous and on demethylation gave only xylose. The 2-*O*-methyl-D-xylose was crystallized from methanol–water, m.p. and mixed m.p. 128–129°, lit. 130° (19).

Fraction V.—The sirup (about 7 mg) had the same mobility as that of an authentic D-xylose on a paper chromatogram and had $[\alpha]_D^{29}$ +19° (*c*, 0.25 in water).

From the column chromatographic results the molar ratio of 2,3,5-tri-*O*-methyl-L-arabinose, 2,3-di-*O*-methyl-D-xylose, and 2-*O*-methyl-D-xylose was 1:3.81:1.

Estimation of O-Methyl Sugars

A small quantity (10 mg) of the mixture of methyl sugars was separated quantitatively by paper chromatography using solvent E and the amounts of sugars were estimated by alkaline hypoiodite (3). The molar ratio of 2,3,5-tri-*O*-methyl-L-arabinose to 2,3-di-*O*-methyl-D-xylose to 2-*O*-methyl-D-xylose was 1:4.2:1.1. D-Xylose and 2,3,4-tri-*O*-methyl-D-xylose were present in negligible amounts.

Periodate Oxidation of the Arabinoxylan

The arabinoxylan (94.6 mg) was dispersed in water (50 ml) and oxidized by shaking with 0.1 *M* sodium metaperiodate (50 ml) in the dark at 15°. The amount of periodate consumed during the reaction was estimated by Fleury and Lange's method (20) and at regular intervals. The periodate uptake became constant after 95 hours, corresponding to 0.84 mole of the oxidant per anhydro pentose residue.

Estimation of Sugar Residues Unattacked by Periodate

The polysaccharide (350 mg) in water (25 ml) was oxidized for 4 days with sodium metaperiodate (792 mg) at room temperature in the dark. After removal of the iodate and periodate ions as insoluble barium salts the solution was dialyzed to remove the remaining ions and the periodate-oxidized polysaccharide was precipitated. Yield 180 mg. A portion (119.7 mg) of this precipitate on hydrolysis yielded xylose, which was estimated, in the usual way, to be 14.2%.

Preparation of Degraded Polysaccharide by Mild Acid Hydrolysis (19)

The polysaccharide (2.04 g) was heated with oxalic acid solution (100 ml of 0.02 *N*) on a boiling-water bath for 1.5 hours, cooled quickly, and an equal volume of acetone was added to precipitate the degraded polysaccharide. On paper chromatographic examination, the supernatant liquid was found to contain arabinose and a trace of xylose.

The degraded polysaccharide (166.6 mg) was hydrolyzed quantitatively and estimation of the component sugars of the hydrolyzate, using D-ribose as reference sugar, showed xylose and arabinose to be present in the percentages of 80.1 and 5.4 respectively (these and subsequent values are expressed as percentages of undegraded polysaccharide). The periodate-oxidized degraded polysaccharide (270 mg) was prepared as in the case of original polysaccharide and the amount of xylose unattacked by periodate was estimated, in the usual way, to be 6.1%.

Partial Hydrolysis of Fully Methylated Arabinoxylan

The fully methylated arabinoxylan (100 mg) was dispersed in methanol (25 ml), and 0.2 *N* hydrochloric acid (10 ml) was added and the mixture was refluxed on a boiling-water bath for 4 hours. The solution was cooled and poured into petroleum ether (100 ml) to precipitate the degraded methylated polysaccharide. After removal of the precipitate at the centrifuge, the supernatant liquid was neutralized (silver carbonate),

**A product of Rohm and Hass Company, Pennsylvania, U.S.A.*

filtered, and deionized. Chromatographic examination of the resulting solution showed the presence of 2,3,5-tri-*O*-methyl-L-arabinose and a trace of 2,3-di-*O*-methyl-D-xylose.

The degraded methylated product, obtained in the above treatment, was remethylated twice by Purdie's method (21) to yield a degraded and fully methylated arabinoxylan (52 mg). OMe 38.7%, $[\alpha]_D^{29}$ −52.4° (*c*, 0.5 in chloroform).

After methanolysis and hydrolysis of the methylated degraded polysaccharide followed by the usual treatments, the hydrolyzate afforded a sirup containing 2,3,5-tri-*O*-methyl-L-arabinose, 2,3-di-*O*-methyl-D-xylose, and 2-*O*-methyl-D-xylose with trace amounts of 2,3,4-tri-*O*-methyl-D-xylose and D-xylose as revealed by paper chromatography. The mixture was separated by quantitative paper chromatography and the amount of each sugar was estimated by alkaline hypoiodite. The ratio of trimethylarabinose, dimethylxylose, and monomethylxylose was 1.1:14.5:1.05. The tri-*O*-methyl pentose fraction was resolved chromatographically by solvent D into 2,3,5-tri-*O*-methyl-L-arabinose and 2,3,4-tri-*O*-methyl-D-xylose and quantitative estimation, by the alkaline hypoiodite method, showed them to be present in the ratio of 12:1.

ACKNOWLEDGMENT

The authors are thankful to Dr. P. Bagchi, Director of Research, East India Pharmaceutical Works Ltd., for suggesting the problem and his valuable advice and interest in the work reported in this paper.

THE REACTION OF *t*-BUTYL ALCOHOL VAPOR WITH Hg 6($^3P_1$) ATOMS[1]

ARTHUR R. KNIGHT AND HARRY E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 26, 1963

ABSTRACT

The nature of the decomposition of *t*-butyl alcohol vapor, photosensitized by Hg 6($^3P_1$) atoms in a static system at room temperature, has been examined under a variety of conditions of continuous and intermittent illumination. The inhibiting effect of nitric oxide has also been studied, as well as the influence of added inert gas.

In the decomposition of pure substrate, the reaction products, with the initial quantum yields, Φ^o, under continuous illumination in parenthesis, were: H_2 (0.045), Me_2CO (0.090), CO (0), CH_4 (0.015), C_2H_6 (0.030) together with lesser amounts of C_3H_8, Me_3CH, Me_3CMe, and Me_3COMe. On addition of nitric oxide, Me_3CONO, Me_2CO, N_2O, N_2, H_2O, and trace quantities of H_2 and CO were the only products observed.

The reaction

$$Me_3COH + Hg\ 6(^3P_1) \rightarrow Me_3CO + H + Hg\ 6(^1S_0)$$

is proposed as the primary process in the decomposition and kinetic evidence is presented that the initially formed *t*-butoxy radicals possess excess energy and that their principal subsequent reaction is unimolecular cleavage into acetone and methyl. The results furthermore indicate that the substrate itself is quite inert to abstractive attack by the primary radicals.

INTRODUCTION

Recent investigations of the vapor-phase reactions between Hg 6($^3P_1$) atoms and methanol (1, 2, 3), ethanol (4), and isopropanol (5, 6) have shown that scission of the O—H bond in each case is the dominant primary step in the reaction. What is more, the rate of abstraction of H-atoms from the substrate, by both primary fragments, rises with decreasing strength of the α(C—H) bond, the site of abstractive attack. Thus, $\Phi(H_2)$ increases in the series MeOH, EtOH, *i*-PrOH, with values of 0.45 (2), 0.53 (4), and 0.72 (5) respectively. In the systems inhibited by nitric oxide, a similar trend is shown in the nitrite yield Φ(RONO), in that as the rate of abstraction by RO increases with decreasing $D(C—H)_\alpha$ in the substrate, there is a concomitant drop in Φ(RONO). The foregoing predicts a marked change in the complexion of the reaction when no α(C—H) bonds are present in the alcohol, suggesting the present study of *t*-butyl alcohol.

The photochemical decomposition of *t*-butyl alcohol has not been investigated previously. However, the photolysis of di-*t*-butyl peroxide has been the subject of several studies (7, 8, 9). It has been unequivocally demonstrated that the *t*-butoxy radical decomposes via

$$Me_3C\dot{O} \rightarrow Me_2CO + CH_3, \qquad [2]$$

for which activation energies of 11.2±2 kcal/mole (9) and 13.2±2.4 kcal/mole (10) have been reported. McMillan and Wijnen re-investigated the photolysis (11), taking into account the reaction

$$Me_3C\dot{O} + (Me_3CO)_2 \rightarrow Me_3COH + \dot{R} \qquad [9']$$

and obtained an activation energy difference of 3 kcal/mole for E_2–$E_{9'}$.

Recently, however, McMillan (12) has found evidence for the formation of excited *t*-butoxy radicals in the photolytic system, thereby rendering uncertain the activation

energy calculations previously reported. This author has also reported (13) the presence of vibrationally excited $Me_3C\dot{O}$ radicals in the photolysis of *t*-butyl nitrite, and has shown that such species can be collisionally deactivated by the addition of inert gas. Finally, in a recent study of the Hg-photosensitized decomposition of isopropanol (6) carried out in this laboratory, evidence was obtained for excited isopropoxy radicals in the reaction. Thus the formation of vibrationally excited alkoxy radicals appears to be a common characteristic of RȮ-generating systems where the excitation energy exceeds the minimum required for primary bond-scission. For *t*-butyl alcohol, the exothermicity of the primary interaction with Hg $6(^3P_1)$ atoms is very close to the activation energy for the decomposition of the *t*-butoxy radical (*vide infra*) and the presence of excited species might be expected to have a profound effect on the system.

In the present investigation, the decomposition of *t*-butyl alcohol, photosensitized by Hg $6(^3P_1)$ atoms, has been studied to determine the mechanism and the role of energy-rich species in determining the course of the reaction.

EXPERIMENTAL

The essential details of apparatus, procedures, and purification techniques have been given in earlier papers in this series (2, 3, 6).

t-Butyl alcohol (British Drug Houses) was fractionally distilled, and a small, constant-boiling fraction was retained, prior to trap-to-trap distillation and degassing *in vacuo*. Analysis by gas liquid chromatography of the refined material proved the absence of impurities.

At the end of each experiment with pure substrate, products non-condensable at liquid nitrogen temperature were measured in a gas burette and analyzed by gas liquid chromatography, on a molecular sieves column, for CO and CH_4, with hydrogen being determined by difference. The remaining fraction was treated in one of two ways: (*a*) removal of the fraction non-condensable at −98° (methanol slush) for hydrocarbon product analysis on a silica gel column, or, (*b*) analysis of the complete fraction via didecyl phthalate, $\beta\beta'$-oxydipropionitrile, or Carbowax 20M columns, for acetone and methyl *t*-butyl ether. Duplicate runs were carried out at each exposure period (*t*) to allow both procedures to be used.

For the NO-inhibited reaction, products non-condensable at liquid nitrogen temperature, consisting largely of NO, were pumped off (except at $t = 30$ minutes where mass spectrometric analysis was performed). Subsequently, the fraction non-condensable at −130° (*n*-pentane slush) was removed and analyzed on the silica-gel column for N_2O. Finally, the remainder of the products was withdrawn and acetone and *t*-butyl nitrite yields determined with a didecyl phthalate or Carbowax 20M column.

In the intermittent illumination studies, the total yield of products non-condensable at −196° was determined, after which the sample was analyzed by mass spectrometry. In these runs the condensable products were not examined.

An attempt was made to determine the nature of any cell deposit formed in the reaction. In contrast to the alcohol systems previously studied (2, 4, 5), where the formation of a non-volatile product on the walls of the reaction cell could be readily discerned visually after approximately 2 to 4 hours of irradiation, none was apparent in the present system. Infrared spectra of chloroform washings of the cell were taken, but only after about 36 hours of reaction could a weak OH-bond absorption be detected. When the complicating effects of prolonged exposure are considered, however, these results must be regarded as inconclusive with respect to the formation of any glycol, although the results obtained in general indicate that the production of a small amount of glycol is likely.

Light intensities were determined with propane as actinometer (14), using the differential method of Back (15) to obtain a constant value for $d[H_2]/dt$. The values obtained, in μeinsteins/minute were: 1.08 (intermittent illumination) and 2.62 and 2.53 (steady illumination).

In experiments where both NO and CF_4 were added, special precautions were necessary to avoid the complicating effects of the dark reaction previously found in the isopropanol system under the same conditions (6). Blank runs showed that unless NO and CF_4 are stored together for at least 12 hours and subsequently distilled into the reaction cell containing the alcohol, at a temperature at which NO_2 has negligible vapor pressure, i.e. −130°, the NO_2 formed by reaction of NO with trace quantities of oxygen present in the CF_4, reacts with the alcohol to form *t*-butyl nitrite in appreciable quantities. Fairlie *et al.* (16) have studied the kinetics of this reaction in the liquid phase and these authors suggest that the overall reaction can be represented by

$$2NO_2 + ROH \rightarrow HNO_3 + RONO.$$

In the present study, as in the isopropanol work (6), it was found that the reaction could be eliminated by ensuring the absence of NO_2 in any gas admixed with pure *t*-butyl alcohol vapor.

RESULTS

As reaction products for the decomposition of *t*-butyl alcohol, at a pressure of 35 mm and at room temperature, H_2, CO, CH_4, Me_2CO, C_2H_6, C_3H_8, Me_3CH, Me_4C, and Me_3COMe were observed. A detectable yield of water was not observed. A specific search was made for isobutylene oxide and di-*t*-butyl peroxide but these products apparently do not form in this system. When the reaction was run in the presence of nitric oxide, the products, Me_3CONO, N_2O, H_2O, N_2, Me_2CO, as well as trace quantities of CO and H_2 were found, and at the same time the yields of hydrocarbon products and methyl *t*-butyl ether were completely suppressed. No search was made for products of the methyl radical-nitric oxide reaction.

The uninhibited reaction was first examined under continuous illumination and the results, as a function of duration of exposure, are summarized as follows: Fig. 1, $\Phi(H_2)$, $\Phi(CO)$, $\Phi(CH_4)$; Fig. 2, $\Phi(Me_2CO)$, $\Phi(C_2H_6)$; Fig. 3, $\Phi(Me_4C)$, $\Phi(Me_3CH)$, $\Phi(Me_3COMe)$, $\Phi(C_3H_8)$.

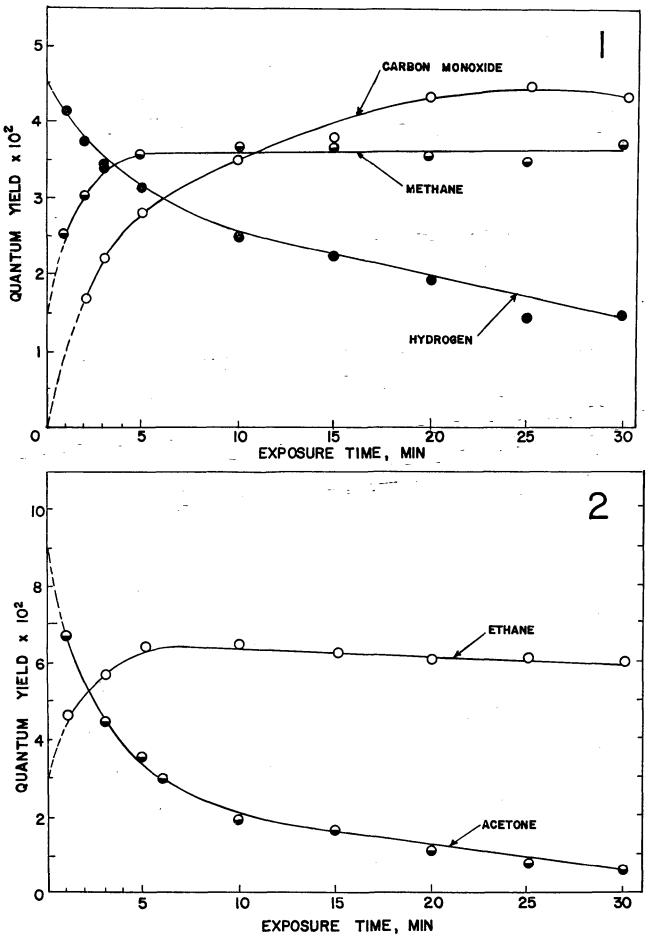

FIG. 1. Mean quantum yield of hydrogen, ●, carbon monoxide, ○, and methane, ◒, as a function of exposure time for 35 mm pure *t*-butyl alcohol.

FIG. 2. Mean quantum yield of acetone, ◒, and ethane, ○, as a function of exposure time for 35 mm pure *t*-butyl alcohol.

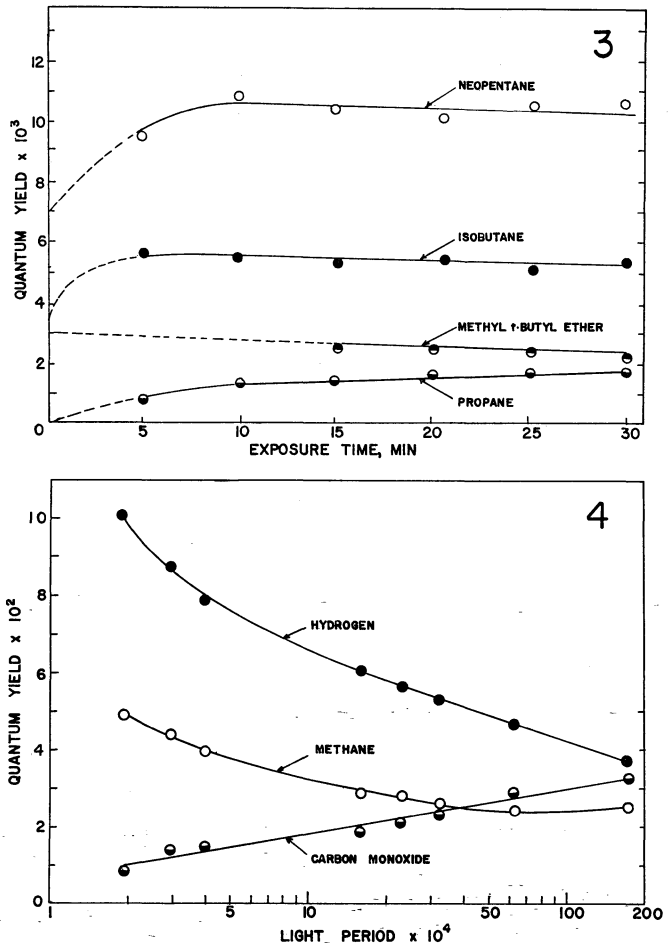

FIG. 3. Mean quantum yield of neopentane, ○, isobutane, ●, methyl *t*-butyl ether, ◓, and propane, ◒, as a function of exposure time for 35 mm pure *t*-butyl alcohol.

FIG. 4. Quantum yield of hydrogen, ●, methane, ○, and carbon monoxide, ◒, as a function of light period, t_L, for a constant dark period of 160 msec for 35 mm pure *t*-butyl alcohol under intermittent illumination.

Under intermittent illumination, the effect of varying the light period, t_L, at a constant dark period, t_D, of 160 msec, on the yields of hydrogen, carbon monoxide, and methane was determined and the results are presented in Fig. 4.

The results obtained in the NO-inhibited reaction are given in Fig. 5. The reported quantum yields have been corrected for competitive quenching by nitric oxide, which was present at a pressure of 10 mm, assuming a quenching cross section, $\sigma_{Q'}^2$ of 15 Å^2 for *t*-butyl alcohol. The resulting correction factor was 1.7. For 30 minutes of exposure, the other products, water excepted, were determined by mass spectrometry and the values found were: $\Phi(N_2) = 2.7\times10^{-2}$, $\Phi(CO) = 8.8\times10^{-3}$, and $\Phi(H_2) = 7.6\times10^{-4}$.

The effect of adding the inert gas, CF_4, on the uninhibited reaction is shown in Figs. 6 and 7. Figure 6 gives the results of a series of runs wherein the yield of acetone was determined as a function of $P(CF_4)$. Here, a short exposure time of 3.0 minutes was employed to minimize the complicating effects of secondary acetone decomposition. One additional

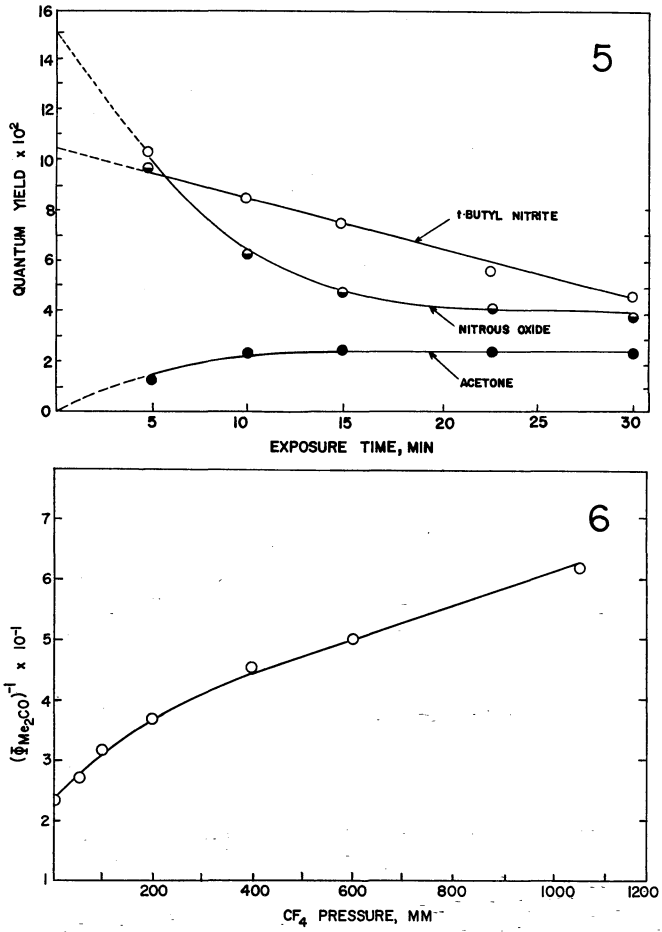

FIG. 5. Mean quantum yield, corrected for competitive quenching by NO, for *t*-butyl nitrite, ○, nitrous oxide, ◒, and acetone, ●, as a function of exposure time for 10 mm NO and 35 mm *t*-butyl alcohol.

FIG. 6. The reciprocal of the acetone quantum yield as a function of carbon tetrafluoride pressure for 35 mm *t*-butyl alcohol at an exposure time of 3 minutes.

run was performed with the *t*-butyl alcohol–CF_4 system, at an exposure time of 10 minutes, in which $\Phi(H_2)$ was determined by mass spectrometry to be 1.4×10^{-2}, for $P(CF_4) = 444$ mm. The addition of inert gas causes a marked decrease in the acetone yield, but the plot of $1/\Phi(Me_2CO)$ vs. $P(CF_4)$ does not give the expected straight line (Fig. 6). In a separate series of experiments, the influence of CF_4 pressure on the yields of isobutane and neopentane was determined. These results are given in Fig. 7. In this series an exposure time of 12 minutes was employed to allow product yields to attain levels consistent with accurate analysis. As shown in the figures, however, even under these conditions, the yields drop off to very small but finite values at $P(CF_4) > 150$ mm. The experimental error in the minute yields at high pressures is unfortunately too large to allow a meaningful plot of reciprocal quantum yields over the entire pressure range.

Finally, the yields of *t*-butyl nitrite and acetone, from the decomposition of a mixture of 35 mm *t*-butyl alcohol and 10 mm nitric oxide, were determined in a series of runs with exposure time = 5 minutes, as a function of CF_4 pressure up to $P(CF_4) = 900$ mm. The results are presented graphically in Fig. 8.

FIG. 8. The quantum yields of *t*-butyl nitrite, ○, and acetone, ◒, as a function of carbon tetrafluoride pressure, for 35 mm *t*-butyl alcohol and 10 mm nitric oxide at an exposure time of 5 minutes. The yields have been corrected for competitive quenching by nitric oxide.

DISCUSSION

The results obtained are consistent with the occurrence of O—H bond scission in the primary process. The appearance of *t*-butyl nitrite as the major heavy product in the NO-inhibited system, the formation of methyl *t*-butyl ether in the uninhibited decomposition, and the close correspondence of the products to those found in the photolysis of the peroxide, where the production of *t*-butoxy radicals has been unequivocally established, all indicate the formation of *t*-butoxy radicals in the decomposition of *t*-butyl alcohol. The fact that nitrous oxide, nitrogen, and water are formed when NO is added, is evidence for the presence of HNO (*vide infra*) and thus, for the formation of hydrogen atoms. The formation of an excited molecule in the primary step can be ruled out, since increasing inert gas pressure in the NO-inhibited reaction results in an increased nitrite yield, whereas an excited molecule would be collisionally deactivated and reduction of product yields would occur.

The following mechanism is proposed to account for the observed results.

$$Me_3COH + Hg\ 6(^3P_1) \rightarrow Me_3CO^* + H + Hg\ 6(^1S_0) \quad [1]$$

$$Me_3CO^* \rightarrow Me_2CO + CH_3 \quad [2]$$

$$Me_3CO^* + M \rightarrow Me_3CO + M \quad [3]$$

$$H + H + M \rightarrow H_2 + M \quad [4a]$$

$$H + H \xrightarrow{\text{wall}} H_2 \quad [4b]$$

$$CH_3 + H + M \rightarrow CH_4 + M \quad [5]$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \quad [6]$$

$$CH_3 + Me_3CO \rightarrow Me_3COCH_3 \quad [7]$$

$$R + Me_3COH \rightarrow RH + Me_2(\dot{C}H_2)COH \quad [8]$$

$$R + R'H \rightarrow RH + R' \quad [9]$$

$$Me_3CO + H \rightarrow Me_3COH^* \quad [10]$$

$$Me_3COH^* + M \rightarrow Me_3COH + M \quad [11]$$

$$Me_3COH^* \rightarrow Me_3C + OH \quad [12]$$

$$Me_3C + H \rightarrow Me_3CH \quad [13]$$

$$Me_3C + CH_3 \rightarrow Me_3CCH_3 \quad [14]$$

$$2Me_2(\dot{C}H_2)COH \rightarrow \text{glycol} \quad [15]$$

where, R = Me_3CO, CH_3, H, Me_3C, OH; and R'H = Me_2CO, C_2H_6.

Since acetone and methyl radicals are the known decomposition products of *t*-butoxy radicals, and since the presence of this radical has been confirmed, reaction [2] is proposed. The following stoichiometric considerations show [2] to be the sole source of CH_3. In the initial stages of the reaction, methyl radicals evidently give rise to methane, ethane, methyl *t*-butyl ether, and neopentane, and thus their initial quantum yield is given by

$$\Phi^o(CH_3) = \Phi^o(CH_4) + 2\Phi^o(C_2H_6) + \Phi^o(Me_3COCH_3) + \Phi^o(Me_3CCH_3). \quad [16]$$

Substitution of the appropriate values from Figs. 1, 2, and 3 gives a value of 8.5×10^{-2} for $\Phi^o(CH_3)$. On the basis of reaction [2] alone, $\Phi^o(Me_2CO)$ should have the same value. Figure 2 shows that the value is 9.0×10^{-2}, which is in agreement with the value for $\Phi^o(CH_3)$ from equation [16], within experimental error.

Although the results showed that abstraction reactions involving the substrate were apparently minor, this does not preclude abstraction from products or the formation of $Me_2(\dot{C}H_2)COH$ radicals, which give rise to other products or reform the substrate in a step analogous to reaction [10]. It is thus important to establish the contribution of abstraction reactions.

Considering first abstraction by CH_3 radicals, McMillan (11) found in the photolysis of di-*t*-butyl peroxide that only ca. 3% of the methyl radicals formed resulted in methane. Since no H-atoms were present in that system, it is only this fraction which arose by abstraction from substrate or products. In the present system, however, if equation [16] is applied at t = 30 minutes, the data show that 21% of CH_3 radicals give rise to methane. Thus, if the abstraction reaction proceeds, as may be expected, at the same rate here as in the peroxide case, only approximately 14% of the observed methane yield arises via the abstraction of an H-atom by CH_3 radicals. On this basis and evidence presented below for a high H-atom concentration, reaction [5] is the proposed principal mode of methane formation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

For *t*-butoxy radicals, McMillan and Wijnen (11) found that ca. 5% of this species resulted in *t*-butyl alcohol when the peroxide was photolyzed. However, in view of recent evidence (12) for excited radicals which decompose before abstraction can occur, the estimate of the fraction abstracting may be low when applied to Me_3CO radicals of normal energies. Nevertheless, such radicals react very slowly with primary C—H bonds. In the pyrolysis of di-*t*-butyl peroxide, the relative rates of the reactions

$$Me_3CO \rightarrow Me_2CO + CH_3, \qquad [2]$$

$$Me_3CO + RH \rightarrow Me_3COH + R \qquad [19]$$

have been determined for a large number of hydrogen donors. Relevant to the present argument, k_{19}/k_2 has a value of 0.47 l mole^{-1} for RH = isopropyl benzene (17) but is only 0.06 l mole^{-1} for RH = *t*-butyl benzene (18). An important point here is the possible effects of the residual energy possessed by Me_3CO^*, on the $(k_8+k_9)/k_2$ ratio (analogous to the k_{19}/k_2 ratio in the peroxide case). The energy of the Hg $6(^3P_1)$ atom is 112 kcal/mole, while D(O—H) for *t*-butyl alcohol is reported to be 104 (19) and 102 (20) kcal/mole. If D(O—H) is taken as 103±1 kcal/mole, the maximum excess energy which could be taken by Me_3CO^* is 9±1 kcal/mole. Activation energies of 11.2±2 kcal/mole (9) and 13.2±2.4 kcal/mole (10) have been reported for reaction [2]. Thus the energetic probability of unimolecular decomposition is marginal and no meaningful prediction of the decomposition/abstraction ratio can be made. The results, however, indicate that unimolecular decomposition predominates.

Abstraction by hydrogen atoms may also be important. The reduction of $\Phi(H_2)$ from a value of 1.5×10^{-2} at t = 30 minutes to 7.6×10^{-4} when 10 mm nitric oxide is added indicates that at least 95% of the molecular hydrogen produced arises from H-atoms. A material balance requires that one hydrogen atom be formed along with each acetone molecule and methyl radical, since the latter products are formed in equal quantities initially. $\Phi^0(Me_2CO)$ is 9.0×10^{-2} and this must also be the minimum value for the initial yield of H-atoms. The value is minimal, since any abstraction by Me_3CO radicals results in less acetone being formed than H-atoms. Since the initial yield of molecular hydrogen is 4.5×10^{-2} it first appears that most, if not all, of the hydrogen atoms produced recombine. We have seen, however, that ca. 86% of the methane is arising from CH_3—H combination in [5]. Similarly, reaction [13] accounts for 86% of the isobutane formed. One this basis, the total yield of hydrogen atoms is given by

$$\Phi^0_{\text{H-atoms}} = 2(\Phi^0_{H_2}-\alpha\Phi^0_{H_2})+\alpha\Phi^0_{H_2}+0.86\Phi^0_{CH_4}+0.86\Phi^0_{Me_3CH} \qquad [20]$$

where α is the fraction of molecular hydrogen arising through abstraction by H-atoms. Substitution of the appropriate values from Figs. 1 and 3 yields

$$\Phi^0_{\text{H-atoms}} = 0.107+\alpha 0.045. \qquad [21]$$

Considering the derivation of an analogous equation for Me_3CO radicals, if β is defined as the fraction of Me_3CO abstracting H-atoms, then $(1-\beta)$ will be the fraction yielding acetone. Thus,

$$(1-\beta)\Phi^0_{Me_3CO} = \Phi^0_{Me_2CO}, \qquad [22]$$

$$\Phi^0_{Me_3CO} = \Phi^0_{Me_2CO}/(1-\beta). \qquad [23]$$

Since the initial yields of *t*-butoxy radicals and hydrogen atoms must be the same, [23]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and [21] may be equated, and after substitution of the value for Φ_{Me_2CO} from Fig. 2, the resulting equation is:

$$0.107-\alpha 0.045 = 0.090/(1-\beta). \quad [24]$$

Now the values of α and β cannot be determined from this single equation, but maximum values can be established. A reasonable assumption is that the minimum fraction of Me_3CO radicals that are abstracting is that observed for the decomposition of the peroxide (see above), thus $\beta = 0.05$. This value corresponds to a maximum of 13% of all H-atoms abstracted. Similarly, it would be unlikely that the amount of H-atom abstraction would be less than that for CH_3 radicals, i.e. 3% (and thus $\alpha = 0.07$). Substitution of this value into equation [24] yields 14% for the extent of abstraction by Me_3CO. Thus limits can be set on the contribution of abstraction reaction by H and Me_3CO as follows: 3% <% H-atoms abstracting <13%; 5% <% Me_3CO radicals abstracting <14%. Thus an estimate of the initial quantum yield of *t*-butyl alcohol disappearance can be obtained. The initial quantum yield of H-atoms and *t*-butoxy radicals is 0.100 ± 0.005 (from limiting values calculated above) and if the quantum yield of decomposition giving isobutyl radicals, 0.010, is added, we have that:

$$\Phi^0_{-ROH} = 0.110\pm0.005.$$

The accumulated evidence points to a very high radical concentration in the system. Thus the reaction resulting in substrate reformation, observed with the other alcohols (2, 4, 5), should also be operative. Since the concentration of H-atoms is considerably higher here, reaction [10] should play an even more important role. Considering first the results of the sector experiments, as illustrated in Fig. 4, the observed increase in $\Phi(H_2)$ and $\Phi(CH_4)$ as the light period is made progressively shorter, is evident for the importance of reaction [10] in lowering the observed yields under steady illumination. As the mean concentration of H-atoms and *t*-butoxy radicals is decreased, the probability of reaction [2] will rise, and hence the concentration of H and CH_3, relative to that of Me_3CO, will be increased, leading to an increased rate for reactions [4] and [5]. The similarity of the $\Phi(H)$ and $\Phi(CH_4)$ curves in Fig. 4 also suggest similar modes of formation of these products.

Further evidence for the importance of the back reaction derives from the fact that when 444 mm CF_4 is added to the system (cf. Results) the hydrogen quantum yield for $t = 10$ minutes drops from a value of 2.49×10^{-2} (for $P(CF_4) = 0$) to 1.36×10^{-2}. As will be seen later, the main effect of added CF_4 is to quench excited *t*-butoxy radicals before decomposition occurs and thus raise their steady-state concentration. Under such conditions the rate of reaction [10] should increase and $\Phi(H_2)$ would be diminished.

The formation of isobutane and neopentane is also related to the occurrence of step [10]. In the decomposition of methanol (2), CH_3 radicals apparently resulted from the decomposition of energy-rich MeOH, in the reaction analogous to [12]. In that case, where the amount of back reaction was less than in the present system (because of the high rate of abstraction from the substrate) the atomic cracking reaction amounted to ca. 5% of the total decomposition at 50 mm methanol pressure (2) and 18% at 8 mm (1). With 35 mm *t*-butyl alcohol, the *t*-butyl radicals produced in reaction [12] account for ca. 10% of the total decomposition. The results of the series of runs with added CF_4, shown in Fig. 6, also indicate that isobutane and neopentane result from $(Me)_3\dot{C}$ radicals formed in step [12] in that, as the partial pressure of CF_4 is increased, there is evidently increased collisional deactivation of Me_3COH^*, thereby reducing the rates of [12], [13], and [14]. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

residual yield of Me_3CH and Me_4C may be due to a small fraction of the primary process yielding OH and $Me_3\dot{C}$ radicals. However, this fraction cannot exceed ca. 3%.

Figure 2 shows that acetone is undergoing very rapid secondary decomposition in the early stages of the reaction. As in the case of isopropanol (5), acetone may be decomposing by Hg-photosensitization or by photolysis, or both. The overall reaction can be expressed as

$$Me_2CO + Hg^* \text{ and (or) } h\nu \rightarrow 2CH_3 + CO. \qquad [25]$$

Using the mean quantum yield of acetone production for the first minute of exposure, $\Phi(Me_2CO) = 0.067$ (Fig. 2), there should be $0.067 \times 2.53 \times 30 = 5.09$ μmoles of this product after 30 minutes. Only 0.55 μmoles were actually found, indicating that 4.45 μmoles suffered secondary decomposition. Thus, in addition to the 5.09 μmoles CH_3 produced in reaction [2], there should be an additional yield of 2×4.54 μmoles from reaction [25], in all, a total of 14.2 μmoles of methyl radicals. Calculating from the observed yields, we found a value for the CH_3 yield at 30 minutes of 13.8 μmoles. The accountability in CO is not as satisfactory, in that, of the 4.54 μmoles predicted by the calculation, only 3.5 were found after 30 minutes of reaction. In view of the high H-atom concentration in the system, however, some of the missing CO may have disappeared in reactions with H-atoms, and this would likely be followed by dilution of the 1 μmole of HCO radicals among indetectable quantities of minor products.

Two factors may determine the decrease in $\Phi(H_2)$ with time, shown in Fig. 1. Secondary quenching by hydrogen itself, in addition to lowering the rate of reaction [1], will increase the concentration of hydrogen atoms, resulting in increasing importance of [10]. Secondary quenching by reaction products other than hydrogen will also diminish the rate of primary decomposition.

Methane and ethane, as shown in Figs. 1 and 2, increase in yield very rapidly with exposure time during the first ca. 5 minutes of reaction, and thereafter remain essentially constant. In the initial stages of the reaction, methyl radicals result solely from reaction [2], but as reaction [25] increases in importance, it will provide an additional source of methyl radicals. Thus the yields of CH_4 and C_2H_6 would be expected to rise rapidly as $\Phi(Me_2CO)$ falls off (cf. Fig. 2), but level off when acetone had attained a steady-state concentration. Although the rate of the overall reaction [25] decreases very rapidly with time, this condition does not obtain until ca. 15–20 minutes. The fact that $R(CH_4)$ and $R(C_2H_6)$ reach constant values earlier may arise from their rate of formation in reaction [2] being diminished through a general decrease in the rate of step [1] with time, as the concentration of products capable of quenching a detectable fraction of the incident energy increases.

The following mechanism is proposed to account for the observed results in the presence of 10 mm nitric oxide: reactions [1] through [3] will be followed by the following reactions.

$$Me_3CO^* + NO \rightarrow Me_3CO + NO \qquad [26]$$

$$Me_3CO + NO \rightarrow Me_3CONO \qquad [26']$$

$$CH_3 + NO \rightarrow \text{products} \qquad [27]$$

$$H + NO \xrightarrow{M} HNO \qquad [28]$$

$$2HNO \rightarrow N_2O + H_2O \qquad [29]$$

$$2NO + HNO \rightarrow N_2 + HNO_3? \qquad [30]$$

$$Me_3CO + HNO \rightarrow Me_3COH + NO \qquad [31]$$

The reaction of H-atoms with nitric oxide has been discussed previously (6). There is probably, however, an additional step giving rise to N_2O, since the yield of H-atoms calculated from the stoichiometry of reactions [28] to [30] is inordinately high, and the water yield, though not determined quantitatively, was clearly smaller than that of N_2O.

Since the yields have been corrected for competitive NO quenching, using an assumed value of the quenching cross section for *t*-butyl alcohol, $\sigma_Q^2 = 15$ Å^2, an attempt to obtain a quantitative correlation between yields in the inhibited and NO-free systems does not appear justified.

The marked decrease in $\Phi(Me_2CO)$ with increasing CF_4 pressure shown in Fig. 7 indicates that excited *t*-butoxy radicals are the precursors of acetone. The observed results cannot be interpreted in terms of an excited molecule mechanism, since increased collisional deactivation would decrease the yield of Me_3CO radicals, and when NO is present (cf. Fig. 8 and discussion below), the nitrite yield would drop. Now if there is a simple competition between reactions [2], unimolecular decomposition, and [3] deactivation of Me_3CO^*, the plot of $1/\Phi(Me_2CO)$ vs. $P(CF_4)$ should be linear, whereas the curve of Fig. 10 is not, particularly at low CF_4 pressures. This suggests (*a*) a second acetone-producing step only slightly affected by inert gas pressure, or (*b*) collisional deactivation of Me_3CO^* by a third body is not a simple function of the collison frequency. The latter is more attractive, since the results appear to exclude any acetone-producing reaction other than [2]. Hershenson and Benson (21) have recently suggested that the unimolecular decomposition of Me_3CO, produced in pyrolysis or photolysis, is pressure dependent. Thus the results here may be a combination of this effect and the "normal" removal of vibrational energy through collision.

The observed increase in nitrite yield as the pressure of CF_4 is increased, as shown in Fig. 8, can be ascribed to the dual effect of CF_4 in deactivating excited *t*-butoxy radicals and in removing excess energy from any nitrite formed by the combination of Me_3CO^* radicals and nitric oxide.

Since $\Phi(Me_2CO)$ is essentially invariant with increasing inert gas pressure, the *t*-butoxy radicals giving rise to the "additional" nitrite formed under these conditions, must participate in a reaction other than unimolecular decomposition in the absence of inert gas, where the reaction mixture consists of 35 mm *t*-butyl alcohol and 10 mm nitric oxide. The two alternatives are abstraction and substrate reformation. However, the contribution of the latter reaction would not be expected to *decrease* with rising inert gas pressure since we have seen that with pure *t*-butyl alcohol $\Phi(H_2)$ decreases with increasing CF_4 pressure under these conditions, indicating an *increasing* role for the back reaction. Furthermore, it has been shown that a maximum of 14% Me_3CO^* radicals take part in the abstraction reaction in the absence of both nitric oxide and carbon tetrafluoride. Thus it is apparent that the addition of just 10 mm nitric oxide, greatly facilitates H-atom abstraction by *t*-butoxy radicals. The nitric oxide must cause a partial deactivation of Me_3CO^* to an energy level below the minimum required for reaction [2], but sufficiently high to overcome part of the activation energy requirement for abstraction from the substrate. A similar behavior was found by McMillan (13) in the photolysis of *t*-butyl nitrite – nitric oxide mixtures, where it was found that nitric oxide had an unexpectedly high efficiency in quenching excited alkoxy radicals. From these results, it is apparent that the quenching of excited *t*-butoxy radicals is not a simple collisional deactivation, and further investigation is evidently required to uncover the exact nature of this process.

In summary, the reaction of *t*-butyl alcohol vapor with Hg $6(^3P_1)$ atoms produces excited *t*-butoxy radicals and hydrogen atoms in the primary interaction of substrate and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sensitizer. The principal mode of disappearance of *t*-butoxy radicals is unimolecular decomposition into acetone and methyl radicals. The alcohol is relatively inert to abstractive attack with the result that radical concentrations are high in the system and combination reactions are thus of considerable importance.

REARRANGEMENT STUDIES WITH C^{14}

XVII. A REINVESTIGATION OF THE REACTION OF 2-PHENYLETHYL-1-C^{14} BROMIDE WITH MAGNESIUM AND COBALTOUS BROMIDE IN REFLUXING ETHER

ABSTRACT

Treatment of 2-phenylethyl-1-C^{14} bromide with magnesium and cobaltous bromide in refluxing ether gave ethylbenzene and styrene with no isotope position rearrangement. The results are contrary to those reported by Smith and Anderson. It was also found that oxidation of styrene-β-C^{14} with concentrated nitric acid gave *p*-nitrobenzoic acid containing 3–4% of the original styrene activity. Nitric acid oxidation of "regenerated styrene" from labeled styrene dibromide under different conditions gave 5.7–37.8% rearrangement. The mechanistic implications of the experimental results are discussed.

INTRODUCTION

Studies in this laboratory on isotope position rearrangement induced by γ-irradiation of 2-arylethyl-1-C^{14} halides (1, 2) have led our attention to the possible extents of 1,2-phenyl shift in the 2-phenylethyl radical. Slaugh (3) has found that the peroxide-catalyzed decarbonylation of 3-phenylpropionaldehyde-2-C^{14} produced the 2-phenylethyl radical which showed 2–5% rearrangement of the C^{14} label in forming ethylbenzene. On the other hand, Smith and Anderson (4) have reported that the 2-phenylethyl radical from reaction of 2-phenylethyl-1-C^{14} bromide with magnesium and cobaltous bromide in refluxing ether gave ethylbenzene and styrene with about 20% isotope position rearrangement. The magnitude of rearrangement for the latter reaction appears to be extraordinarily high in comparison to the results of Slaugh (3). As Smith and Anderson (4) reported the data from apparently only a single experiment with 2-phenylethyl-1-C^{14} bromide, it was decided to repeat this work so as to obtain a confirmation, or otherwise, of their finding. Smith and Anderson (4) degraded their products, ethylbenzene and styrene, by oxidation with concentrated nitric acid. While Roberts, Ropp, and Neville (5) have shown that oxidation of C^{14}-labeled ethylbenzene by concentrated nitric acid does not cause any rearrangement, the applicability of this method for the degradation of C^{14}-labeled styrene has not been studied. The present paper also reports observations on the absence or occurrence of isotope position rearrangements in the oxidation, under various conditions, of styrene-β-C^{14} and *p*-nitrostyrene-β-C^{14}.

RESULTS AND DISCUSSION

2-Phenylethyl-1-C^{14} bromide (2) was treated with magnesium and cobaltous bromide in refluxing ether as described by Smith and Anderson (4). The monomeric products were obtained in 65% and 58% yields for duplicate runs which were found by v.p.c. analysis to consist of 65% ethylbenzene, 35% styrene and 62% ethylbenzene, 38% styrene, respectively. Part of each product mixture was hydrogenated to give pure ethylbenzene. The remainder was separated into ethylbenzene and styrene dibromide, and from the latter, styrene was regenerated by refluxing it with sodium iodide in acetone (4, 6). Each of these fractions was oxidized with alkaline permanganate to give benzoic

[1]*Holder of a Commonwealth Scholarship, 1961–63.*

acid. As shown in Table I, all samples of benzoic acid were inactive, indicating that, contrary to the report of Smith and Anderson (4), no isotope position rearrangement was involved in the formation of ethylbenzene and styrene.

Although certain details of the mechanism for the Kharasch reaction between an alkyl halide and a Grignard reagent in the presence of cobaltous halide are still in doubt (7–9), the free alkyl radical is generally believed to be involved as an intermediate. In the present studies with 2-phenylethyl bromide, the products, ethylbenzene and styrene, may well be derived from the 2-phenylethyl radical as suggested by Smith and Anderson (4). The excess of ethylbenzene over styrene could be due to a greater amount of hydrogen abstraction over disproportionation reactions. Another possibility is that unreacted 2-phenylethylmagnesium bromide might be present, which on hydrolysis would result in ethylbenzene (9). In an inactive trial, the reaction with 2-phenylethyl bromide and magnesium and cobaltous bromide in refluxing ether was effected as before and the resulting mixture was treated with Dry Ice before hydrolysis by dilute hydrochloric acid. The monomeric products, consisting of 59% ethylbenzene and 41% styrene, were obtained in 63% yield. This yield and product composition were not very different from those obtained in the active runs when no Dry Ice was used. Moreover, no 3-phenylpropionic acid could be isolated after the treatment with Dry Ice. These findings, therefore, suggest that unreacted 2-phenylethylmagnesium bromide was not present in significant amounts when the reaction mixtures were hydrolyzed.

The fact that there was no isotope position rearrangement in the ethylbenzene and styrene indicated that under the conditions used in the present studies, 1,2-phenyl shift in the 2-phenylethyl radical did not occur before the formation of stable products. Seubold (10) has noted that the extent of rearrangement in the neophyl radical increased with increasing dilution in a solvent which was stable towards radical attack. This finding indicated that the longer the lifetime of the radical the greater the opportunity for 1,2-phenyl shifts. In the present case, radical attack on the solvent, ether, is quite feasible, thus decreasing the chance of 1,2-phenyl shift in the 2-phenylethyl radical. Another factor, which may even be more important, is the fact that Slaugh (3) has shown a temperature dependency, which indicated an appreciable activation energy, for the 1,2-phenyl shift in the 2-phenylethyl radical derived from the decarbonylation of 3-phenylpropionaldehyde-2-C^{14}. The rearrangement of 2–5% resulted from decarbonylation carried out at temperatures ranging between 145 and 175° C. The present studies with 2-phenylethyl-1-C^{14} bromide were effected in refluxing ether, a temperature which may be too low to give any measurable extent of 1,2-phenyl shift before the formation of ethylbenzene and styrene.

In an attempt to find some probable explanation for the discrepancy between the present results and those reported earlier (4), degradations of C^{14}-labeled ethylbenzene and styrene by various methods of oxidation were investigated. 2-Phenylethyl-1-C^{14} bromide was converted to the Grignard reagent and then treated with water to give ethylbenzene-β-C^{14}, which was oxidized by concentrated nitric acid to practically inactive *p*-nitrobenzoic acid, thus confirming the finding of Roberts, Ropp, and Neville (5). The results from the oxidation of styrene-β-C^{14}* are given in Table II. It can be seen that oxidation with alkaline potassium permanganate or with potassium dichromate in 38% sulphuric acid produced inactive benzoic acid indicating no rearrangement. On the other hand, oxidation with concentrated nitric acid resulted in *p*-nitrobenzoic acid containing about 3–4% of the original styrene activity. These observations suggest that concentrated nitric acid is not the proper reagent for the degradation of C^{14}-labeled styrene.

Smith and Anderson also used concentrated nitric acid to oxidize the styrene regenerated from styrene dibromide. In order to ascertain whether the regeneration procedure will affect the extent of rearrangement, labeled styrene dibromide, prepared from styrene-β-C^{14} and bromine, was refluxed with sodium iodide in acetone for 0.5, 1.5, or 4.0 hours and the resulting material was oxidized. While the use of alkaline permanganate again gave inactive benzoic acid, oxidation of the regenerated material with concentrated nitric acid showed rearrangements varying between 5.7% and 37.8%. The results, also included in Table II, clearly indicate that the shorter the time of refluxing of the dibromide with sodium iodide in acetone, the greater will be the extent of rearrangement as measured by the activity of the *p*-nitrobenzoic acid. Apparently, nitric acid oxidation of incompletely regenerated styrene resulted in further rearrangements which probably directly involved styrene dibromide. An attempt to oxidize pure styrene dibromide with concentrated nitric acid gave a very impure product. Consequently, possible rearrangements in the oxidation of labeled styrene dibromide alone were not investigated.

The rearrangements observed in these nitric acid oxidations, which eventually led to radioactive *p*-nitrobenzoic acid, must involve an overall 1,2-shift of the phenyl group of styrene. A question that arises is whether the *p*-nitro group is introduced before or after the phenyl shift. Starting with 2-phenylethyl-1-C^{14} bromide, nitration (11) gave 2-*p*-nitrophenylethyl-1-C^{14} bromide which was treated with triethanolamine (12) to give *p*-nitrostyrene-β-C^{14}. Oxidation of this compound with alkaline permanganate or with concentrated nitric acid caused no rearrangement (Table II). Conversion of *p*-nitrostyrene-β-C^{14} to the corresponding dibromide followed by refluxing with sodium iodide in acetone for 0.5 hour gave regenerated materials which on nitric acid oxidation showed only very small amounts of rearrangement (Table II). These findings indicate that in the nitric acid oxidation of styrene-β-C^{14}, the fraction of the reaction that is accompanied by rearrangement likely involved nitration after the 1,2-phenyl shift. This is in accord with expectation as nucleophilic migration of the *p*-nitrophenyl group is much less favorable than phenyl migration (13).

While the mechanistic paths responsible for the rearrangements in the nitric acid oxidation of pure styrene or incompletely regenerated styrene are not clear, the observed results suggest that the rearrangement reported by Smith and Anderson (4) for the reaction of 2-phenylethyl-1-C^{14} bromide with magnesium and cobaltous bromide in refluxing ether could be related to their method of degradation of the products. By the nitric acid oxidation of regenerated styrene, with the reaction time in the regeneration process unspecified, Smith and Anderson reported a 20.6% rearrangement, which is well within

*Styrene-β-C^{14} or p-nitrostyrene-β-C^{14}.
†Benzoic acid or p-nitrobenzoic.
‡From mother liquor after fractional crystallization of p-nitrobenzoic acid, presumably containing a high proportion of o-nitrobenzoic acid.
§Assayed as styrene dibromide.
‖Not as pure as other p-nitrobenzoic acid samples because of difficulties in recrystallization (see experimental part).

the range of rearrangements presently observed for such an oxidation of incompletely regenerated styrene. It is, however, not possible to rationalize the claim of these workers (4) that after hydrogenation of the mixed products to ethylbenzene, nitric acid oxidation gave 18.9% rearrangement.

EXPERIMENTAL

Reaction of 2-Phenylethyl-1-C^{14} Bromide

To a stirred mixture of 1.7 g of magnesium and 20 ml of anhydrous ether under reflux, a few drops of a solution of 10.0 g of 2-phenylethyl-1-C^{14} bromide in 90 ml of anhydrous ether were added. After the start of the typical Grignard reaction, an additional 250 ml of anhydrous ether and 14.5 g of anhydrous cobaltous bromide were introduced into the reaction vessel. Dropwise addition of the 2-phenylethyl-1-C^{14} bromide solution was then continued while the mixture was maintained at a gentle reflux by heating. When the addition of the bromide solution was completed, the mixture was refluxed overnight and then hydrolyzed with dilute hydrochloric acid. The ether layer was separated, washed with water, and dried over anhydrous magnesium sulphate. Fractionation through a 20-inch Dufton column gave, for duplicate runs, 3.7 g (65%) and 3.3 g (58%) of monomeric products boiling between 45–55° C at 20 mm. Vapor phase chromatographic analysis (2) showed the product mixtures from the two runs to consist of 65% ethylbenzene, 35% styrene and 62% ethylbenzene, 38% styrene, respectively.

In another trial using inactive 2-phenylethyl bromide, the reaction was carried out in exactly the same way with the exception that at the end of the reaction, Dry Ice was introduced into the reaction mixture before the addition of dilute hydrochloric acid. The resulting ether layer was washed with diluted sodium hydroxide solution besides water, and then worked up as before. Monomeric products, b.p. 45–55° C at 20 mm, were obtained in 63% yield (3.6 g) which consisted of 59% ethylbenzene and 41% styrene according to v.p.c. analyses. No 3-phenylpropionic acid could be isolated from the sodium hydroxide washings.

Treatment of the Active Monomeric Products

A portion (0.7 g) of the monomeric product mixture from each of the two active runs above was hydrogenated in 50 ml of ethyl acetate using platinum oxide as catalyst. The hydrogen absorbed corresponded to 97% of theoretical and the resulting material was shown by v.p.c. to contain ethylbenzene, but no styrene. After removal of the catalyst and solvent, the residue was oxidized with alkaline permanganate.

To the remainder of each monomeric product mixture, a solution of bromine in chloroform was added dropwise, with stirring. When a slight bromine color persisted, the solvent was distilled off through a small helix-packed column and the residue distilled under reduced pressure. The distillate boiled at 45° C at 20 mm and was identified as ethylbenzene by v.p.c. This fraction was also oxidized with alkaline permanganate.

After the distillation of the ethylbenzene, the residual styrene dibromide solidified on cooling. Recrystallized from pentane, it melted at 73° C (lit. (4) m.p. 73–74° C). About 1.5 g of this dibromide and 50 ml of a saturated solution of sodium iodide in acetone were refluxed with stirring for 5 hours. The resulting material was worked up to give regenerated styrene as described by Smith and Anderson (4). This regenerated styrene was also oxidized by alkaline permanganate.

Permanganate Oxidation

Ethylbenzene was oxidized to benzoic acid with potassium permanganate in the presence of sodium hydroxide according to the procedure previously used for the oxidation of 2-phenylethylamine (14). For the oxidation of styrene-β-C^{14}, *p*-nitrostyrene-β-C^{14}, or regenerated styrene, sodium carbonate was used instead of sodium hydroxide. In a typical run, a mixture of 0.8 g of styrene-β-C^{14}, 4.5 g of potassium permanganate and 1.0 g of sodium carbonate in 50 ml of water was heated under reflux for 3 hours. The resulting material was worked up to give benzoic acid, m.p. 121° C, as previously described (14). Similarly, *p*-nitrobenzoic acid, m.p. 240° C, was obtained from *p*-nitrostyrene-β-C^{14}.

Dichromate Oxidation

To a cooled solution of 4.0 g of potassium dichromate in 25 ml of 38% sulphuric acid was added 0.5 g of styrene-β-C^{14}. The mixture was heated under reflux, and after the initial vigorous reaction had subsided, it was refluxed for 1 hour. On cooling, about 0.5 g of product crystallized. The product was collected by filtration, redissolved in sodium carbonate solution, washed with chloroform, reprecipitated by acidification, and then recrystallized and sublimed to give benzoic acid, m.p. 121° C.

Nitric Acid Oxidation

A mixture of 1.5 g of styrene-β-C^{14} and 9.0 ml of concentrated nitric acid was heated gradually under reflux in an oil bath. After an initial vigorous reaction accompanied by the evolution of copious amounts of fumes, the mixture was maintained at about 100° C for 30 hours. On cooling and with the addition of water, about 2.0 g of crude product was precipitated. This product was taken up in sodium carbonate solution, filtered, repeatedly washed with carbon tetrachloride, and then reprecipitated by acidification. The desired product was then recovered by fractional crystallization. After about 10 recrystallizations from aqueous

For personal use only.

ethanol, pure *p*-nitrobenzoic acid, m.p. 240–241° C (lit. (15) m.p. 241° C) was obtained. In one of the runs, all the filtrates from the recrystallizations were combined and evaporated giving a residue which, after sublimation under high vacuum, melted at 113–118° C. Presumably, this crude material contained a high proportion of *o*-nitrobenzoic acid (lit. (15) m.p. of *o*-nitrobenzoic, 146° C).

p-Nitrostyrene-β-C^{14} was oxidized by concentrated nitric acid in a similar manner. The *p*-nitrobenzoic acid, m.p. 240–241° C, was recrystallized from a mixture of ethyl acetate and pentane. It was not necessary to subject the product to extensive fractional crystallization.

Regeneration of Styrene or p-Nitrostyrene from the Dibromides

Styrene-β-C^{14} or *p*-nitrostyrene-β-C^{14} was treated with the calculated amount of bromine. Styrene dibromide, recrystallized from pentane, melted at 73° C, and *p*-nitrostyrene dibromide, recrystallized from ether-pentane, melted at 74° C (lit. (16) m.p. 72–73° C).

A mixture of 4.0 g of the labelled styrene dibromide and 100 ml of a saturated solution of sodium iodide in acetone, while stirred with a magnetic stirrer, was refluxed for 0.5, 1.5, or 4.0 hours. The resulting material was decolorized with sodium bisulphite solution and then extracted with ether. The extract was washed with water, dried over anhydrous magnesium sulphate, and then the ether was removed by distillation through a helix-packed column. The residual material was used for oxidation.

A similar reaction was carried out with *p*-nitrostyrene dibromide using a refluxing time of only 0.5 hour.

Oxidation of Regenerated Materials

The regenerated materials obtained above were oxidized in alkaline permanganate or in concentrated nitric acid in the same manner as described earlier. However, in the case of the nitric acid oxidation of regenerated styrene obtained after 0.5 hour of refluxing, purification of the *p*-nitrobenzoic acid proved to be more difficult and the product, after repeated recrystallizations, melted over the range of 210–220° C. In an inactive trial, oxidation of pure styrene dibromide with concentrated nitric acid gave a product melting over the range of 130–160° C.

Radioactivity Assays

Samples weighing 10–20 mg were dissolved in toluene containing the appropriate scintillators and counted in a liquid scintillation counter as previously described (17). In the case of *p*-nitrobenzoic acid, its low solubility in toluene necessitated the use of 20% ethanol–80% toluene as solvent. Absolute counting efficiencies were determined using standards containing known amounts of C^{14}. Considerable quenching was observed in the counting of *p*-nitrostyrene and *p*-nitrobenzoic acid. In these cases, corrections for quenching were made with the aid of known quantities of toluene-C^{14} as internal standard.

ADDENDUM

Having learned of our results, Dr. W. B. Smith has repeated the reaction of 2-phenylethyl-1-C^{14} bromide with magnesium and cobaltous bromide and obtained results which are in agreement with ours regarding the lack of rearrangement in this system.

ACKNOWLEDGMENT

THE EFFECT OF TIME AND TEMPERATURE ON THE HYDROGENATION OF ASPEN LIGNIN

J. M. Pepper and Warren Steck
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received July 15, 1963

ABSTRACT

A study has been made of the hydrogenation of preextracted aspen sapwood meal under conditions whereby the lignin is degraded to identifiable products. By gas liquid chromatography, guaiacol, 4-methylguaiacol, 4-ethylguaiacol, 4-*n*-propylguaiacol, dihydroconiferyl alcohol, syringol, 4-methylsyringol, 4-ethylsyringol, 4-*n*-propylsyringol, and dihydrosinapyl alcohol were separated and identified.

The relative abundance of these 10 compounds was determined in the chloroform-soluble product after hydrogenation using a dioxane–water (1:1) solvent medium, Raney nickel catalyst, an initial hydrogen pressure of 500 p.s.i. and temperatures of 150°, 165°, 185°, 195°, 210°, and 220° for a reaction time of 5 hours and a temperature of 195° for times of 0, 1.3, 5.0, and 24 hours. The best yield (52.2% of the Klason lignin) of such phenolic derivatives was obtained at a reaction temperature of 195° for 5 hours.

The significance of the observed variation in the yields of these compounds with time and temperature and the relationship of these yields to the structure of lignin is discussed. Evidence is presented in support of both γ-alkyl ether and β-aryl ether linkages in the lignin substance.

INTRODUCTION

In 1938, Harris, D'Ianni, and Adkins (1) reported a successful catalytic hydrogenolysis of an isolated aspen lignin and isolated and identified lignin derivatives of a cyclohexylpropyl nature. Since that time this technique has been applied to the study of various wood and straw meals and isolated lignins, under a variety of conditions involving different catalysts, solvents, times, temperatures, and initial pressures of hydrogen (2, 3). A significant contribution was made in 1948 by Brewer, Cooke, and Hibbert (4), who reported the degradation of maple wood lignin under much milder conditions of hydrogenation than those used by earlier workers and obtained phenylpropyl lignin derivatives, thus providing direct evidence for the aromatic nature of the lignin substance. Subsequently, other workers (5–9) have extended these studies to other lignified materials and various isolated lignins and have thereby added to the variety of aromatic compounds that have been isolated and identified. Of particular interest is the recent work of Coscia, Schubert, and Nord (10) and of Olcay (11), who obtained aromatic lignin derivatives by the hydrogenation of the milled wood lignins from birch, oak, pine, and spruce under conditions which, when applied earlier to other isolated lignins, had given rise to cyclohexyl derivatives. These workers introduced the use of gas–liquid chromatography for the separation and quantitative estimation of the lignin derivatives.

Earlier, in these laboratories, a study had been made of the conditions affecting the isolation, as a chloroform-soluble fraction, of the lignin derivatives resulting from the catalytic hydrogenation of aspen wood meal (8). It was thus found that at temperatures of 170°–180° for a reaction period of 3 hours, using a dioxane–water (1:1) medium, Raney nickel catalyst, and an initial hydrogen pressure of 500 p.s.i., essentially all the lignin was removed from the wood and recovered as a choloroform-soluble fraction. It was of interest, therefore, to apply the technique of gas–liquid chromatography to a detailed study of the products of such a hydrogenation of aspen wood meal and to compare the results with those reported by the earlier workers (10, 11), who used different lignins, copper chromite catalyst, and much higher temperatures of around 225°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

To this end extractive-free aspen wood meal was subjected to 5 hours contact with dioxane–water (1:1), Raney nickel, and hydrogen, at a temperature of 195±3°. The resulting bomb contents were separated as described in the Experimental section to yield a chloroform-soluble fraction containing the lignin degradation products. By gas–liquid chromatography the major part of this fraction was separated and the identity and relative abundance of the compound represented by each peak was determined. A 10% Apiezon N on Fluoropak column, of a type that had been shown of value for the separation of phenolic lignin oxidation products (12) was found to be equally useful for the separation of phenolic hydrogenation products. All compounds represented by peaks on the chromatogram were identified by comparison of their relative retention times with those obtained for pure reference samples. For the major components, the products were collected and the identity confirmed by infrared and refractive index measurements. Neither 2-(4-hydroxy-3-methoxyphenyl)ethanol nor 2-(4-hydroxy-3,5-dimethoxyphenyl)ethanol, which had been reported as lignin hydrogenation products (9), was found. The relative abundance data were obtained by the measurement of peak areas. The nature and yield of the products so obtained are given in Table I under the column headed 195°.

The significantly large percentage of original wood lignin that could thus be recovered as small molecular weight degradation products capable of being analyzed by gas–liquid chromatography, prompted a more detailed study of this reaction with a view to obtaining maximum yields of structurally important products. To approach this goal two of the important variables were studied, namely, temperature and time of reaction. In the first instance, similar hydrogenations to that described at 195° were effected at 150°, 165°, 185°, 210°, and 220°, and the respective chloroform-soluble fractions studied as before. These results are also found in Table I. From these data it would appear that the initially chosen temperature of 195° was optimum. No appreciable increase in total yield occurs above this temperature and, indeed, at 210°, the important arylpropanols are being further reduced and cracked and at 220° aliphatic ring-saturated compounds began to appear. For these reasons a temperature of 195° was chosen for a subsequent study of the effect of a variation in the time of reaction. A series of hydrogenations was made under conditions similar to those discussed earlier but for times of 0, 1.3, 3.0, and 24 hours. Reaction times are defined as the time at the stated temperature and are exclusive of heating and cooling times which were approximately 1.5 and 6 hours respectively. The resulting chloroform-soluble fractions were treated as before and the results are given in Table II.

DISCUSSION OF RESULTS

This study has again demonstrated the effectiveness of the hydrogenation technique as a prime method of lignin isolation and subsequent degradation to readily identifiable phenolic products. The application of gas–liquid chromatography has made it possible to characterize derivatives which heretofore have been unnoticed, and to do so in such a way that the relative abundance of each product had real meaning. If, as a criterion of value to the study of lignin structure, the maximum yield of oxygen-bearing, phenylpropanoid derivatives be chosen, then the conditions for such a study have been optimized for a reaction temperature of 195° for a period of 5 hours. Under these conditions, 52.2% of the original lignin in the wood (Klason lignin) has been recovered in the form of identifiable derivatives having either a 4-hydroxy-3-methoxyphenyl (type A) or a 4-hydroxy-3,5-dimethoxyphenyl (type B) nucleus. This represents a marked increase in the amount of such aromatic lignin derivatives over that obtained by earlier hydrogenation studies and is now comparable with the recovery of phenolic products obtained by means of oxidation.

*Aspen wood meal (50 g), dioxane–water (1:1) (400 ml), Raney nickel (10 g), initial hydrogen pressure (500 p.s.i.), reaction temperature (195°).
†No $CHCl_3$-soluble product

Of significance, too, is the fact that the major portion of the chloroform-soluble products is capable of being separated by gas–liquid chromatography and that no unidentified peaks appear in the chromatograms. It would thus appear that for that fraction of the protolignin which is released and degraded by this catalytic hydrogenolysis, the cleavage process is quite selective and that the lignin substance itself is joined together in a uniform manner.

From the separate study involving the effect of temperature, some interesting observations may be made. If the chloroform-soluble faction be accepted as a crude lignin fraction (carbohydrates being chloroform-insoluble), than a rapid release of lignin occurs with increasing lower temperatures but levels off to about an 80% recovery at the higher temperatures. Similar results have been reported as a result of a study of the liberation of lignin by an acid-catalyzed solvolysis (13) and the suggestion has been made that the more easily isolated fraction is that associated with the middle lamella whilst the lignin in the cell walls requires more drastic conditions for isolation and degradation to chloroform-soluble fragments. The extraction of the lignin was reflected in the recovery of the residual wood meal which was essentially complete at 150°, dropped steadily through 195°, at which temperature the residue was pulpy and gave a negative Maule reaction. At 210° only a fraction of the meal remained and at 220° the entire sample was solubilized.

The nature and relative abundance of the lignin degradation products have structural significance. No fragments were identified that had other than the type A or type B nucleus. Only at temperatures greater than 150° was there any significant degradation, and initially those compounds with a propanol side chain were in great excess. With increasing temperature, the decrease in the yield of the phenylpropanol derivatives, paralleled as it was for both types of nuclei, was accompanied by an increase in products of a higher state of reduction and even products resulting from a carbon–carbon fission. These secondary effects were checked by studying a similar hydrogenolysis of pure samples of each of dihydroconiferyl alcohol and of dihydrosinapyl alcohol. In each case there was unchanged starting material, but the former gave rise to all of 4-*n*-propylguaiacol, 4-ethylguaiacol, and guaiacol itself; whilst the latter yielded the analogous 4-*n*-propyl-, 4-ethyl-, and 4-methylsyringol and syringol as well as small amounts of the corresponding guaiacol derivatives. This observed conversion of syringol and guaiacol derivatives, by the loss of methoxyl, must not be overlooked in assigning any significance to the relative abundance of each of these types of lignin derivatives.

The molar abundance data of Table I may best be interpreted on the basis of two rather independent lignin substances, one a polymer of essentially type A units and the other of essentially type B units but in each case involving a similar mode of linkage which may be cleaved by catalytic hydrogenolysis. The greater abundance of the syringyl (type B) compounds over the guaiacyl (type A) analogues by a factor of at least two may actually be indicative of the amounts of each such nucleus in the lignin or it may reflect some more basic difference in the ease of liberation of such units. The results also indicate that the increasing molar ratio of type B to type A compounds with increasing temperature is really due to a relative decrease in the latter type since the molar abundance of the former remains more constant. This may result from some as yet unproved condensation reaction involving the free 5-position of type A compounds but for which a similar reaction is impossible for type B compounds.

From a consideration of the data given in Table II many similar conclusions may be drawn regarding the effect of increasing the reaction time on the nature of the products

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of hydrogenation of aspen lignin. The very rapid increase in the yield of chloroform-soluble material from the 1.3-hour to the 3-hour reaction time may be due to the autocatalytic effect of the released phenolic compounds. It is well known that the addition of even traces of mineral or organic acids aid markedly in any lignin isolation procedure (13) With increasing time of reaction there is a similar total increase in aromatic derivatives but less secondary reduction or cracking than in the case of those runs with temperatures over 195°. Again the increasing molar ratio of type B over type A compounds, with increasing time, is a result of a relative decrease in compounds of the latter type since there is no significant decrease in the yield of compounds of the former type.

It may also be of some significance that in none of the hydrogenations was any direct evidence found for the liberation of lignin fragments having molecular weights lying in the range between the monomers and the polymers. As earlier stated, the major part of the chloroform-soluble fraction was chromatographable and was shown to be composed of low molecular weight (monomeric) compounds. The chloroform-soluble portion of one run was, therefore, investigated to determine if dimeric or slightly higher molecular weight lignin fragments might be found in the non-chromatographable part. After removal of the chloroform and precipitation into water, a cream-colored solid was collected and dried over P_2O_5. This material analyzed for C, 63.23; H, 6.59; ash, 0.81; methoxyl, 21.8%, had an average molecular weight above 2480, and gave an infrared spectrum typical of that of an isolated dioxane aspen lignin (13). Similarly, the chloroform-insoluble lignins were examined for the presence of any medium molecular weight substances. From the 1.3-hour run, an ash-free sample analyzed for C, 66.5; H, 6.53; OCH_3, 22.0%, and two similarly isolated fractions had average molecular weights of 6230 and 6800. Rehydrogenation of this polymeric lignin for a further 5 hours at 195° degraded it, in part, to the same kind of monomeric products given in Table I and having no significant variation in their relative abundance as that obtained from other runs conducted for 5 hours.

Finally some comments may be made regarding the nature of aspen protolignin and its mode of isolation by means of the catalytic hydrogenation technique. For the isolation, four distinct phases may be involved: *primary hydrogenolysis*, by which the lignin polymers are freed from other plant constituents; *secondary hydrogenolysis*, by which partial degradation occurs to produce phenylpropanoid derivatives; *cracking*, by which carbon–carbon cleavage occurs with loss of hydroxyl and even methoxyl groups; and finally *ring saturation* to produce cyclohexyl derivatives. An attempt has been made in this investigation to find the conditions which minimize any major reaction beyond the secondary hydrogenolysis stage. During the early stages of the reaction there was some evidence for the simultaneous release of a carbohydrate fraction along with the lignin. From the chloroform-insoluble fraction of the runs conducted for 0, 1.3, and 3.0 hours, it was possible, by an extraction with acetic acid to remove soluble lignin, to isolate a substance which analyzed closely for $(C_6H_{10}O_5)_x$ and which had an average molecular weight of 3860 and 1350 for the 0- and 1.3-hour runs respectively. The parallel increase in the amount of this fraction with the increase in the amount of chloroform-soluble lignin derivatives supports the concept of a lignin-carbohydrate linked substance. Indeed under conditions of low temperatures or short reaction times, relatively stable emulsions were obtained during the chloroform extraction process, which may be the result of the presence of a lignin-carbohydrate substance acting as a surface active agent.

The ready release of arylpropanols, by a hydrogenolysis reaction and in yields representing over 40% of the original lignin, can only be interpreted to mean that a major portion of the lignin has a γ-oxygen function, most likely as either a free primary alcohol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

group or as an ether. However, since aryl alkyl ethers are known to be cleaved, under similar conditions, with aryl retention of the oxygen as a phenolic fragment (14), it would appear that if an ether linkage be present it is of the dialkyl type. The absence of any products bearing α- or β-oxygen functions does not exclude the possibility that such do occur in the lignin. Indeed, the β-aryl ether type of linkage, for which much evidence exists, would, as indicated above, cleave to release the phenolic portion and the β-methylenic group.

Mention has already been made of the absence of lignin derivatives with molecular weights between the isolated monomeric and polymeric substances. Two possible explanations are herein presented, but with no experimental support. It may be that the protolignin consists of a basic polymeric core structure attached to which are much smaller fragments which represent that part of the lignin substances which is separated from the core and degraded into identifiable products by processes of hydrogenolysis, oxidation, or acid-catalyzed hydrolysis. On the other hand, the release of the stabilized monomeric units may result by a process which is in competition with another in which reactive lignin precursors in the wood readily polymerize. The yields resulting from each competitive process would be dependent on the conditions of the reaction.

EXPERIMENTAL

Aspen sapwood (*Populus tremuloides* Michx.) was ground to 20 mesh in a Wiley mill, extracted 48 hours with ethanol–benzene (1:1), and air-dried. Anal: Klason lignin, 17.7%; moisture, 6.1%.

Raney nickel catalyst was prepared according to Pavlic and Adkins (14) with the exception that the washing under a hydrogen atmosphere was deleted. The catalyst was stored under cold dioxane. The dioxane was purified according to Fieser (15).

General Reaction Procedure

Preextracted, air-dried aspen wood meal (50 g), Raney nickel (10 g), and 50% aqueous dioxane (400 ml) were stirred together in a 1410-ml capacity Aminco hydrogenator. The sealed bomb was flushed twice with hydrogen and then filled with hydrogen to 500 p.s.i.g. The temperature was raised (about 120° per hour) and controlled automatically at the desired value for the required time. During this heating period the bomb was rocked continuously but allowed to cool overnight without rocking.

The bomb contents were suction-filtered. The residual wood meal and nickel were washed with 90% aqueous dioxane until the washings were colorless. These washings and the original filtrate were combined, gravity-filtered (if cloudy), concentrated under reduced pressure just beyond the point at which sludge began to form, then extracted with chloroform (3×80 ml or until colorless).

The chloroform solution was back-extracted with 100 ml water, dried over anhydrous sodium sulphate, filtered, and concentrated free of chloroform below 50° at reduced pressure. The resulting reddish oil was termed the chloroform extract; it contained residual dioxane besides lignin degradation products.

The residual nickel and wood meal from the initial filtration were finally soaked in warm water, refiltered, and dried overnight at 100°. The weight of cooled material was recorded and, if desired, a Maule test was performed.

Gas–Liquid Chromatographic Analysis of the Chloroform Extracts

An Aerograph chromatograph, Model A–90P, was used. All separations were made using a 6-foot, 1/4 in. O.D. copper column packed with 10% Apiezon N grease on Fluoropak at 205° (injector and detector at 232°), the helium flow rate being 36 ml/min at 50 p.s.i.g. with a filament current of 200 milliamperes.

Analytical Procedure

The general method consisted of the injection of the crude chloroform-soluble fraction with subsequent progressive calculated corrections for unidentified and for non-lignin material in that fraction.

In preliminary work a large forepeak was always encountered. The collection and determination of the boiling point (100°/730 mm), the refractive index (1.4180 at 25°) and the infrared spectrum indicated this peak to be dioxane (b.p. 101°/760 mm; n_D^{25} 1.4178).

The Aerograph was calibrated as follows for the subsequent determination of dioxane. Measured volumes, of between 0.5 and 7.0 microliters, of dioxane were injected into the column under the same conditions as were used for the analysis of the lignin products, and the height was recorded in each case. A curve of the peak height versus the volume of dioxane injected was drawn so that in the lignin hydrogenation runs the measurement of forepeak height, from a measured volume of chloroform extract, would permit direct reading of the volume of dioxane present in the extract. This volume of dioxane was then subtracted from the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

measured volume of the injected chloroform extract to give the actual volume of lignin products that had been injected. Only a certain portion of these products passed through the column. To discover what fraction of the injected lignin was represented by this portion, a second calibration was made.

This was done as for dioxane using a representative phenol (4-*n*-propylguaiacol) but for which peak area rather than peak height was plotted against the injected volume. This was a straight line plot, the slope of which represented the peak area to be expected from each microliter of chromatographable products. The total peak area from all degradation products in an analysis was measured. The fraction of the original solvent-free chloroform extract detected in the chromatogram was calculated as the found total peak area divided by the theoretical peak area as read from the 4-*n*-propylguaiacol calibration curve.

Finally, by knowing the volume and weight of the whole chloroform-soluble fraction it was possible to apply the gas–liquid chromatography results to find the amount of dioxane in the extract, the percentage of the Klason lignin isolated as chloroform-soluble material, and the percentage of the Klason lignin identified as monophenols.

Peak Identification

Initially samples of the four compounds represented by the major peaks were collected. The infrared spectra, refractive indices, and retention times were compared with those of authentic samples of probable hydrogenation monomers. In this way the presence was established of 4-*n*-propylguaiacol, 4-*n*-propylsyringol, dihydroconiferyl alcohol, and dihydrosinapyl alcohol. Other components were identified by matching retention times and relative retention times with those of authentic reference compounds.

The correctness of the assignments was demonstrated when a synthetic mixture and a hydrogenated lignin sample gave traces superposable with regard to peak positions when run using a 3% SE-30 on firebrick column at 190°.

Preparation of Reference Compounds

All melting points are uncorrected.

Guaiacol, creosol, and syringol (2,6-dimethoxyphenol) were obtained commercially. Prior to use, the former two were redistilled and the last recrystallized from dilute ethanol.

4-Ethylguaiacol.—Acetoguaiacone was reduced in methanol using 10% palladium on charcoal and a trace of hydrochloric acid. The product distilled at 62–64°/0.4 mm.

4-n-Propylguaiacol.—Eugenol was hydrogenated for 1 hour at 150° in ethanol using Raney nickel catalyst. The product distilled at 245–246°/730 mm; reported, b.p. 246°/760 mm (16).

Dihydroconiferyl Alcohol.—The synthesis reported by Coscia, Schubert, and Nord (10) was modified as follows. Ferulic acid was prepared according to Brewer, Cooke, and Hibbert (4) and then converted to ethyl dihydroferulate before reduction with lithium aluminum hydride. This final reduction was effected in 83% yield by using an 18-hour reaction period. The final product distilled at 154–158°/0.2 mm.

4-Methylsyringol.—Syringaldehyde was reduced by the method of Coscia *et al.* (10). The final product distilled at 80–83°/0.16 mm.

4-Ethylsyringol.—The procedure reported by Arlt, Gross, and Schuerch (9) was used. The final product distilled at 85–88°/0.2 mm.

4-n-Propylsyringol.—The synthesis reported by Coscia *et al.* (10) was used. The final product distilled at 118–121°/0.3 mm.

Dihydrosinapyl Alcohol.—Syringaldehyde was converted to sinapic acid in 81% yield by the method of Vorsatz (17). The remainder of the synthesis was similar to that used for the preparation of dihydroconiferyl alcohol. The final product was distilled at 158–162°/0.5 mm.

4-(β-Hydroxyethyl)guaiacol.—2-(4-Hydroxy-3-methoxyphenyl) acetic acid was reduced with lithium aluminum hydride in tetrahydrofuran. A 20% yield of the alcohol was obtained, m.p. 40–42°.

4-(β-Hydroxyethyl)syringol.—A sample that had been prepared by Pepper and Hibbert (5) was available.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council for financial assistance and for the award of scholarships to one of them (W. S.). Grateful acknowledgment is made of the kindness of Mr. M. Mazurek, who performed the analyses.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART IX. THE VOLATILE OIL OF THE LEAVES OF JUNIPERUS SABINA L.[1]

E. VON RUDLOFF

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received July 15, 1963

ABSTRACT

The chemical composition of the volatile oil of the leaves of local savin juniper and of commercial oil of savin was determined by an improved gas chromatographic technique. Both oils contain *d*-sabinyl acetate (38, 37.5%) and *d*-sabinene (30.5, 26%) as the major constituents. Smaller amounts of *d*-α-pinene, *d*-myrcene, *d*-limonene, γ-terpinene, *p*-cymene, *d*-isothujone, *d*-terpinen-4-ol, *d*-sabinol, *d*-citronellol, *d*-cadinene, and *l*-elemol were isolated. Trace amounts of α-thujene, camphene, α-terpinene, 1,8-cineole, terpinolene, thujone, geraniol, a cadinene isomer, and δ-cadinol were tentatively identified. A fraction having the typical pungent odor of juniper leaves was isolated, but it was found to consist mainly of the methyl ester of *d*-citronellic acid. Several unidentified oxygenated sesquiterpenes and a phenol ether were isolated in trace amounts.

Some phylogenetic relationships with other thujone-bearing oils analyzed in this series are discussed.

As part of a systematic study of phylogenetic relationships, the volatile oil of the leaves of *Juniperus sabina* L. and commercial oil of savin have been analyzed by means of the improved technique described in the previous paper of this series (1). Fromm (2) found the main constituent of this oil to be *d*-sabinyl acetate and Semmler (3) obtained *d*-sabinene from the hydrocarbon fraction. Other early reports (4) indicate that minor amounts of α-pinene, α-terpinene, *n*-decanal, dihydrocuminyl alcohol, citronellol, geraniol, and an aldehyde (cuminaldehyde ?) are present. More recently, the oil was examined by fractional distillation by Booth (5), who reported the presence of *d*-sabinene (20%), *d*-sabinyl acetate (40%), and minor constituents (40%), including α-pinene, myrcene, limonene, *p*-cymene, *cis*- and *trans*-thujones, sabinol, terpinen-4-ol, and carvacrol. Bruno (6) identified α-pinene, *d*-sabinene, limonene, and sabinyl acetate by gas–liquid chromatography (GLC).

In contrast, the improved technique used in this study revealed the presence of at least 37 components (see Fig. 1). The average composition, as determined on a variety of columns, is shown in Table I. Little qualitative and quantitative difference was found between the commercial oil and that obtained from local savin juniper plants, except that the sesquiterpene content of the latter was higher. The results obtained confirm that *d*-sabinyl acetate is the major constituent, although an almost equal amount of *d*-sabinene was recorded. Goryaev and Dzhalilov (7) found that the leaf oil of a central Asian savin juniper contained as much as 40% sabinene, which is considerably higher than found in European varieties. GLC analysis of the sabinene isolated in this study did not reveal the presence of any β-pinene, but trace amounts may be present. In the monoterpene hydrocarbon range (peaks 1 to 11) appreciable amounts (2 to 7%) of *d*-α-pinene, *d*-myrcene, *d*-limonene, and γ-terpinene (peaks 2, 5, 7, and 9) as well as smaller amounts (up to 1%) of α-thujene, camphene, α-terpinene, 1,8-cineole, terpinolene, and *p*-cymene (peaks 1, 3, 6, 8, 10, and 11) were recorded.

Amongst the oxygenated monoterpenes thujone, *d*-isothujone, *d*-methyl citronellate, *d*-terpinen-4-ol, *d*-sabinyl acetate, *d*-sabinol, and *d*-citronellol were isolated (peaks 13,

[1]*Issued as N.R.C. No. 7574.*

For personal use only.

14, 17, 18, 20, 21, and 23). Peak 25 was tentatively identified as geraniol by comparison of retention data. The trace components 15, 16, and 19 were not identified. The typical pungent juniper odor was associated with peak 17, but methyl citronellate prepared by mild oxidation of citronellal (8) had only the mild and pleasant odor expected for this type of ester. Comparison of the infrared and n.m.r. spectra of the isolated and synthetic materials showed no significant difference. However, the former did have a weak ultraviolet absorption (λ_{max}^{EtOH} approx. 280 and 240–230 mμ), indicating contamination with a small amount of an aromatic compound. No reference of which component is responsible for the typical juniper odor was found in the literature.

The oil of savin was found to contain many sesquiterpenes (peaks 22, 24, 27 to 37) and isolation of individual compounds proved difficult, not only because of the small amounts present (see Table I), but because some components decomposed readily. Also, there was some overlap between some of the sesquiterpene hydrocarbons and oxygenated monoterpenes when the more efficient polyester or polyethylene glycol columns were used. Prefractionation on a silicone polymer (SE-30) column did separate the oxygenated monoterpenes from sesquiterpenes (9), but some decomposition was encountered in this study. Similar results were obtained by column chromatography on silicic acid. By a combination of these techniques peaks 22, 24, 27, 33, and 37 were isolated fairly pure and peaks 35 and 36 were obtained as a mixture. Peak 22 was found to correspond to the cadinene isomer, which is obtained when δ-cadinol is dehydrated with pyridine-modified alumina (10). Since its infrared spectrum showed the presence of a terminal methylene group, this is not δ-cadinene (11). Peak 24 was found to be another *d*-cadinene isomer having a terminal methylene group. This may be identical with the major hydrocarbon found in the oil of cade and could be *d*-γ_1-cadinene. Wallach (12) identified cadinene in the oil of savin by formation of the crystalline dihydrochloride, but did not establish the position of the double bonds.

Amongst the oxygenated sesquiterpenes, *l*-elemol (peak 33) was isolated and δ-cadinol (peak 36) was tentatively identified. Juniperol and γ-eudesmol have the same relative retention times as peak 35, but their presence could not be confirmed. Peak 37 had the same retention time as eudesmol (mixture of α- and β-isomers) and the infrared spectrum showed some similarities with that of β-eudesmol, but did not agree in all respects. Sorm *et al.* (13) reported the presence of elemene, junipene, juniperol, juniper camphor, and α- and δ-cadinol in juniper berry oil. In this study a very small amount of β-elemene was obtained by chromatography on silicic acid, but this compound appeared to be derived rather by dehydration of elemol than from the oil itself. Juniper camphor was not found to be present. An attempt was made to classify some of the sesquiterpenes into cadinene or eudalene types by means of dehydrogenation with selenium or palladium-on-charcoal (14), but this technique failed to give positive results on a milligram scale. This aspect and other possible means of identifying or classifying such small amounts of sesquiterpenes are being studied further.

Comparison of retention times showed that aromatic compounds of the allyl benzene type may be present. Peak 26 has the retention time (on PEG 20M) of anethole and peak 27 has that of safrole. Peak 27 was isolated and appears to be a mixture containing mainly a phenol ether. The infrared spectrum differed from that of safrole and it is possible that the compound is estragole (methyl chavicol). Cuminaldehyde, carvacrol and its methyl ether, eugenol, and isoeugenol were not detected.

In previous papers of this series the analysis of the oils of the leaves of *Thuja occidentalis* L. (15), *Thuja plicata* D. Don (16), and *Tanacetum vulgare* L. (1) was described. These

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

three oils contain thujone or isothujone as the major constituent. A certain biogenetic relationship between these oils and the oil of savin juniper is discernible in that all contain the thujones and several other compounds having a cyclopropane ring. Common to all four oils are also most of the monoterpene hydrocarbons and terpinen-4-ol. However, little or no taxonomic value may be attached to the latter compounds since it is conceivable that they are formed by a non-specific rearrangement or hydroxylation of a common precursor, such as the carbonium-ion derived from geraniol (geranyl pyrophosphate) as proposed by Ruzicka (17). The oil of savin differs from the other three oils in that it contains sabinyl acetate and sabinene as major constituents and several minor components having a terminal methylene group. Also, certain of the oxygenated monoterpenes, including sabinol, methyl citronellate, citronellol, and perhaps geraniol, are specific constituents of the juniper leaves, whereas, for example, carvone and carvotanacetone (besides major amounts of the thujones) are characteristic of the oil of tansy. Thus, it appears that the formation of at least some of the oxygenated monoterpenes may be subject to genetic control and these constituents may therefore have considerable phylogenetic value. Several authors have attempted to find genetic relationships on the basis of the chemical composition of essential oils (18). However, most of the earlier analyses of volatile oils were incomplete and thus do not lend themselves to critical comparison. Other oils will be analyzed by the gas chromatographic technique to determine the scope of the above conclusions.

EXPERIMENTAL

The same gas chromatographic instruments and procedures as described previously (1) were used. Optical rotations of the oils were measured undiluted at 25±2° and those of individual fractions in chloroform solution (1 to 5%). Infrared spectra were recorded with a Perkin–Elmer model 21 double beam spectrophotometer as films between sodium chloride plates and n.m.r. spectra with a Varian 60 spectrograph, using tetramethyl silane as internal standard.

Materials

The commercial oil (Fritzsche Bros., Inc., New York) had n_D 1.4702, $[\alpha]_D$ +65.0°. Steam distillation of the leaves (240 g) of locally grown savin juniper gave a light yellow oil (11.0 g) having n_D 1.4714, $[\alpha]_D$ +47.7°. Reference compounds were either purified commercial samples or those obtained from other plant sources (1). Cadinene was kindly donated by Messrs. Fritzsche Bros., Inc. and elemol, δ-cadinol, juniperol, juniper camphor, and ledol were gifts from Prof. F. Sorm.

Analytical Chromatograms

Temperature-programmed chromatograms were obtained with 1–5 μl aliquots on 6 ft × 1/4 in. O.D. coiled stainless steel column using polyethylene glycol (Carbowax, PEG 20M) (see Fig. 1), Apiezon N, silicone polymer (SE-30) and adipate polyester (NGA) as liquid phases. *n*-Decane, limonene, camphor, terpinen-4-ol and (or) *n*-decanol were used as internal standards in the quantitative measurements. Area measurement (triangulation method) of the peaks accounted for 98±2% of the oils (1).

Isothermal runs were carried out on the same columns and those containing rapeseed oil and ethylene glycol bis-(propionitrile) (EGPN) as liquid phase. Fractions obtained from preparative runs were analyzed for purity on these columns and the identity of essentially pure fractions was confirmed by comparison of spectral properties and retention data. The average percentage composition, as well as some of the physical data of the isolated components, are shown in Table I. Relative retention times of monoterpene hydrocarbons were measured with respect to limonene, those of oxygenated monoterpenes and sesquiterpene hydrocarbons with respect to camphor, and those of oxygenated sesquiterpenes with respect to cedrol.

Prefractionation

The commercial oil (100 ml) was fractionally distilled *in vacuo* (42 mm Hg; takeoff ratio 1:90) through a Podbielniak spinning band column (100×0.8 cm) to give the following fractions:

I (b.p. 63–74° C, 10.5 ml) monoterpene hydrocarbons,
II (b.p. 74–81° C, 17.0 ml) mainly monoterpene hydrocarbons,
III (b.p. 81–123° C, 12.5 ml) mixture of monoterpenes,
IV (b.p. 123–128° C, 6.0 ml) mixture of oxygenated monoterpenes,
V (b.p. 128–132° C, 18.0 ml) mainly sabinyl acetate.

At this stage some decomposition appeared to take place, and the vacuum was reduced to 10 mm Hg. Distillation was continued rapidly (takeoff ratio 1:20) to give:

VI (b.p. 95–105° C, 20 ml) sabinyl acetate and higher boiling terpenes,

VII (b.p. 105–145° C, 8 ml) mainly sesquiterpenes.

The distillation residue (6–7 ml) was a black tar which was not further investigated.

The oil from the local plants was prefractionated by preparative GLC (3/8 in. O.D. SE-30 column (1)) and fractions of approximately the same composition were collected by operating the collector manually.

Monoterpene Hydrocarbons

Preparative GLC of fraction I on a 6 ft × 3/8 in. O.D. PEG 20M column (30–50 μl aliquots, repeated injection, 65–90° C in 12 minutes) gave two fractions. The first was impure *d*-α-pinene (peak 1), which contained α-thujene (peak 2). The second was essentially pure *d*-sabinene (peak 4). Analytical runs showed no signs of β-pinene, although up to 2% would not be detectable in the sabinene fraction because of the close retention times.

Similar fractionation of fraction II gave *d*-sabinene, *d*-myrcene (peak 5), impure α-terpinene (peak 6), impure limonene (peak 7), γ-terpinene (peak 9), and impure *p*-cymene. Peaks 3, 8, and 10 were tentatively identified by retention characteristics as camphene, 1,8-cineole, and terpinolene respectively.

Almost identical results were obtained with corresponding fractions from the oil obtained from local plants.

Oxygenated Monoterpenes

Fraction IV was fractionated on a 20 ft × 3/8 in. O.D. PEG 20M column (60 μl aliquots, 170° to 200° C in 25 minutes). Peaks 14, 17, 18, and 20 were isolated practically pure and found to be *d*-isothujone, an unknown ester, *d*-terpinen-4-ol, and *d*-sabinyl acetate (see below) respectively. Peak 13 was obtained only impure but GLC and infrared spectra confirmed that it contained mainly thujone.

Methyl Citronellate

The unknown ester (peak 17) had the typical pungent smell of juniper leaves. Strong infrared absorption bands were recorded at 2970–2860, 1735, 1440, 1380, 1362, 1195, and 1153 cm^{-1}, and medium intensity bands at 1010 and 827 cm^{-1}. Saponification confirmed it to be an ester. Found: C, 71.69; H, 10.97; COOH, 23.38%. Calculated for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94; COOH, 24.43%. The n.m.r. spectrum (trimethyl silane = 0.00) contained the following:

Band	Protons	δ	Assignment
Triplet	1	5.18	$\diagdown C{=}CH-$
Singlet	3	3.67	$-OCH_3$
Complex	3	2.20–2.00	—
Singlet	2	1.92	—
Doublet	6	1.65	$\diagdown C{=}C(CH_3)_2$
Complex	2	1.50–1.10	—
Doublet	3	0.95	$-C-CH_3$

The data were those expected for methyl citronellate, or a closely related compound. Citronellic acid was synthesized by shaking citronellal with a suspension of silver oxide in very dilute aqueous ammonium hydroxide for 5 hours (8). The synthetic acid was converted to the methyl ester with diazomethane and purified by GLC. The synthetic ester had identical infrared and n.m.r. spectra as well as retention characteristics as those of peak 17. However, the smell was only the faint pleasant odor of an unsaturated aliphatic ester. The ultraviolet spectrum of peak 17 showed only very weak, broad absorption bands near 280, 240, and 230 mμ, indicating that a very small amount of an aromatic aldehyde may be present. This impurity could not be detected by GLC.

Sabinyl Acetate

Fraction V contained better than 95% of peak 20. The infrared spectrum suggested this to be an acetate (1737, 1242 cm^{-1}). Saponification gave essentially pure *d*-sabinol, n_D 1.4868, $[\alpha]_D$ +11.2°, *p*-nitrobenzoate m.p. 75–76° C. The ester was obtained almost pure (cf. Table I) by preparative GLC from fractions IV, V, and VI.

From fraction V of the oil from the leaves of the local plants, pure sabinyl acetate, with n_D 1.4675, $[\alpha]_D$ +78.9°, was isolated.

Higher Oxygenated Monoterpenes

Fraction VI was found to be a mixture of *d*-sabinyl acetate, higher boiling monoterpene alcohols, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

sesquiterpene hydrocarbons. Preparative GLC gave peaks 21, 23, and 24 fairly pure and these were found to be *d*-sabinol, *d*-citronellol, and *d*-cadinene (see below) respectively. Peak 22 appeared to be a cadinene isomer but it was not obtained pure by this technique. The concentration of peaks 25 and 26 was still very low in either fraction VI or VII and could not be isolated in sufficient amounts to record satisfactory infrared spectra.

Sesquiterpenes

To obtain larger amounts of the two cadinene isomers (peaks 22 and 24, see above), aliquots (1.0 g) of fractions VI and VII were chromatographed on silicic acid (30 g). Elution with hexane gave a hydrocarbon fraction which was separated further into three components by preparative GLC. The first was found to have the same infrared spectrum as β-elemene (RRT 1.30). The latter was prepared in small amounts by dehydration of elemol with the pyridine-modified alumina reagent (10). The second component (peak 22) had a similar infrared spectrum and the same retention times as the major hydrocarbon obtained on dehydration of δ-cadinol with the alumina reagent. Typical absorption bands for terminal methylene groups (3070, 1645, and 880 cm^{-1}) were recorded. The third component (peak 24) was obtained in comparatively large amounts; n_D 1.5072, $[\alpha]_D$ +41.6°, infrared bands at 3080, 1645 cm^{-1} (weak), 883, 830, 798 cm^{-1} (medium intensity). It had the same retention times as the major hydrocarbon of the oil of cade.

Elution of the silicic acid chromatogram with chloroform gave a complex mixture of oxygenated mono- and sesqui-terpenes, which was not resolved by preparative GLC. Several decomposition peaks were recorded.

Preparative GLC (6 ft × 3/8 in. O.D. PEG 20M, 115 to 220° C in 30 minutes) of fraction VII gave fairly pure sabinyl acetate (peak 20), *d*-cadinene (peak 24), and peaks 27, 33, and 37; peaks 35 and 36 were collected as one fraction. Peak 27 had a strong ultraviolet absorption (λ_{max}^{EtOH} 276, 235–205 mμ) but no characteristic odor. The aromatic character was confirmed by a sharp, strong band at 1516 cm^{-1} in the infrared spectrum. In addition, the latter showed strong bands at 2930, 1465, 1260, 1235, 1153, 1140, and 1030 cm^{-1}, and medium bands at 3520, 3070, 1725, 1700, 1633, 1605, 1592, 907, and 800 cm^{-1}. Peak 33 had an infrared spectrum which was very similar to that of elemol. The viscous material crystallized on seeding with elemol; m.p. 44–50° C, $[\alpha]_D$ −9.7°. The mixture of peaks 35 and 36 had n_D 1.5054, $[\alpha]_D$ −23.4°, and strong infrared bands at 3440, 2940, 1460, 1375, 1130, 906, and 885 cm^{-1}, and weaker ones at 3090, 1640, 1592, 1505, 1260, 1240, and 800 cm^{-1}. Superimposition of the infrared spectrum of δ-cadinol showed that this compound could be present whereas that of juniperol differed extensively. The infrared spectrum of peak 37 had bands at 3500, 3090 (weak), 2930, 2860, 1710 (weak), 1642, 1592 (weak), 1470–1440, 1385–1370, 1260, 1120 (broad), 1030, 1010, 950 (weak), 932, 910, 885, 875 (weak), 812, and 798 cm^{-1}, and resembled that of β-eudesmol.

ACKNOWLEDGMENTS

The gift of sesquiterpenes by Prof. F. Sorm, Prague, and the technical help of Mr. M. Granat are gratefully acknowledged. The spectra were recorded by Mr. M. Mazurek and Mr. W. C. Haid.

REACTIONS OF ORGANOTIN COMPOUNDS

I. THE STABILITY OF DIMETHYLTIN DIHYDRIDE, AND ADDITIONS TO SOME FLUORO-OLEFINS[1]

H. C. CLARK, SHARON G. FURNIVAL, AND J. T. KWON

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received July 22, 1963

ABSTRACT

The effect of heat and ultraviolet irradiation on dimethyltin dihydride is reported. At 120°, the major decomposition products are $(CH_3)_3SnH$, Sn, and H_2, with a small amount of $(CH_3)_6Sn_2$. At 130° under ultraviolet light, decomposition is much more rapid giving $(CH_3)_3SnH$, Sn, and H_2, and an appreciable quantity of $(CH_3)_4Sn$. If the dihydride is maintained under these conditions for a longer period (40 hours), $(CH_3)_6Sn_2$ is formed in place of $(CH_3)_3SnH$, and other products are $(CH_3)_4Sn$, Sn, and H_2. Negligible decomposition occurs at 25° even under irradiation.

The ready addition of C_2F_4 to $(CH_3)_2SnH_2$ gives the first reported mono-addition product of an organotin dihydride, $(CH_3)_2SnH(C_2F_4H)$, as well as $(CH_3)_2Sn(C_2F_4H)_2$. Physical and chemical properties of these compounds are described. The additions of $(CH_3)_2SnH_2$ to CF_2CFH, CF_2CH_2, and CF_2CFBr are reported and the results interpreted in terms of the formation of unstable mono-addition products, $(CH_3)_2SnH(C_2F_nX_mH_p)$. Surprisingly, these species decompose through the exchange of halogen and hydrogen between $(CH_3)_2SnH_2$ and the olefin. Thus, usual products from the reaction of $(CH_3)_2SnH_2$ with CF_2CFBr are $(CH_3)_2SnBr_2$ and CF_2CFH, with some $(CH_3)_3SnBr$.

INTRODUCTION

Since the initial discovery in 1956 by van der Kerk and co-workers (1–3), many studies have been made of the non-catalyzed addition of the Sn–H group across an olefin or acetylene bond. These additions, which generally take place at 80–100° in the absence of solvent, give excellent yields, and have been applied to the preparation of functionally substituted organo-tin compounds (4), and of organometallic polymers (5). Most work has been related to the preparation and characterization of new derivatives, and no systematic studies have yet been made to elucidate the mechanism of these addition reactions. From the qualitative evidence so far available, it has been concluded (5) that (*i*) the mechanism is ionic, (*ii*) predominantly steric factors determine the course of the reaction, and (*iii*) polar effects only influence the rate of the addition.

A noticeable feature of previous studies is that the olefins and acetylenes employed all contain large substituent groups (e.g. phenyl-acetylene, styrene, methyl acrylate). There are no reports of additions to ethylene or acetylene, and in particular, Noltes and van der Kerk have stated (4, p. 39) that aliphatic organotin dihydrides do not react with simple olefins, so that dienes such as butadiene or hexadiene could not be used in polymer-forming reactions. Our own interest originated in a preliminary study of the addition of tetrafluoroethylene to hexamethylditin and to diphenyltin (6), in which the fluoro-olefin is added across the Sn—Sn bond. As a related investigation, we have now examined the addition of several fluoro-olefins to dimethyltin dihydride, $(CH_3)_2SnH_2$.

DISCUSSION

The organotin hydrides, particularly the aryl derivatives, possess only moderate stability towards heat and oxidizing agents. However, in reports of the addition of these hydrides to unsaturated compounds, no mention is usually made of decomposition products of the hydride, nor has any attempt been made to ascertain the importance of this

[1]*Presented at the Symposium on Current Trends in Organometallic Chemistry, Cincinnati, 12–15 June, 1963.*

decomposition to the general mechanism of the addition reaction. Initially, therefore, it seemed desirable to determine the extent of decomposition of dimethyltin dihydride, and to identify the products formed, under the influence of heat and radiation.

Although dimethyltin dihydride is stable indefinitely at 25° in the dark *in vacuo*, decomposition is moderately rapid at 120° in the dark. Some estimate of the rate of decomposition can be obtained from the fact that 6 hours at this temperature was required to give a visible deposit of metallic tin. After 45 hours, decomposition was complete, the products being trimethyltin hydride (50.7%), hexamethylditin (6.1%), metallic tin (39%), and hydrogen (~60%) containing a small quantity of methane. These results are consistent with decomposition according to the equation

$$3(CH_3)_2SnH_2 \rightarrow 2(CH_3)_3SnH + Sn + 2H_2 \quad [1]$$

followed, to a lesser extent, by the reaction

$$2(CH_3)_3SnH \rightarrow (CH_3)_6Sn_2 + H_2. \quad [2]$$

The influence of ultraviolet irradiation can be seen from a similar experiment at 130° when after only 6 hours, decomposition was virtually complete, the products being tetramethyltin (20%), trimethyltin hydride (40%), hydrogen (53%), and metallic tin (49.1%). Under similar conditions (110° and ultraviolet irradiation) but for a period of 40 hours, there was a marked difference in the products obtained. No trimethyltin hydride was isolated, although there was little change in the yields of tetramethyltin (21.9%), metallic tin (69%), and hydrogen (55%, containing a small amount of methane). Instead, hexamethylditin was formed. In the presence of ultraviolet radiation, it therefore appears that two reactions take place, reaction [1] and

$$2(CH_3)_2SnH_2 \rightarrow (CH_3)_4Sn + Sn + 2H_2. \quad [3]$$

Over long periods of time (40 hours) further decomposition occurs to form hexamethylditin, so that reactions [1], [2], and [3] are all involved. For appreciable decomposition of dimethyltin dihydride, a high temperature is necessary, since a sample exposed to ultraviolet light for 40 hours at 25° was very largely (92%) recovered unchanged.

The mechanism of decomposition is clearly complex. Presumably, the first step involves the loss of hydrogen to form $(CH_3)_2HSn\bullet$, which in turn must be responsible directly or indirectly for the cleavage of the CH_3—Sn bond, but detailed kinetic studies are very necessary. In the present investigation, to minimize decomposition effects of the dihydride, reactions were performed at 50° or lower, either with or without ultraviolet radiation.

When equimolar quantities of dimethyltin dihydride and tetrafluoroethylene were allowed to react at 25° in the dark, 63% of the dihydride was consumed giving a 52.3% total yield of *dimethyl(tetrafluoroethyl)tin hydride*, $(CH_3)_2SnH(C_2F_4H)$, and a 9.2% total yield of dimethylbis(tetrafluoroethyl)tin, $(CH_3)_2Sn(C_2F_4H)_2$. The small amount of involatile residue (10% of total mass) was composed of metallic tin and polymerized tetrafluoroethylene. This is only the second instance in which a simple olefin such as C_2F_4 has been found to add readily across the Sn—H bond, and it is the first time that the addition has been found to occur in a stepwise fashion. Previous attempts to isolate the mono-addition product from the reaction of an olefin with an organotin dihydride (e.g. dipropyltin dihydride and methyl acrylate (4, p. 38)) were unsuccessful, only the bis-addition compound being isolated. Similarly, in the only other reported addition of a fluoro-olefin to a tin hydride (7), $(C_4H_9)_2Sn(C_2F_4H)_2$ was the only product obtained from the reaction of dibutyltin dihydride with tetrafluoroethylene. It seems reasonable to suggest, therefore, that the overall reaction can be described in terms of the three equations [4], [5], and [5*a*]:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$(CH_3)_2SnH_2 + C_2F_4 \rightarrow (CH_3)_2SnH(C_2F_4H), \quad [4]$$

$$2(CH_3)_2SnH(C_2F_4H) \rightarrow (CH_3)_2SnH_2 + (CH_3)_2Sn(C_2F_4H)_2, \quad [5]$$

$$(CH_3)_2SnH(C_2F_4H) + C_2F_4 \rightarrow (CH_3)_2Sn(C_2F_4H)_2. \quad [5a]$$

There is no evidence at present which allows us to distinguish between [5] and [5*a*].

A series of experiments was performed under different experimental conditions to determine some of the factors influencing the rate of the reaction, and the yields. It is not suggested that these studies elucidate the reaction mechanism, for which considerably more detailed and more systematic studies would be required. Firstly, the effect of ultraviolet light was determined. As can be seen from the experimental results below, the rate of the reaction is increased markedly; for instance after only 20 hours at 25° with ultraviolet irradiation, the yield of dimethyl(tetrafluoroethyl)tin hydride was 23.2% and of $(CH_3)_2Sn(C_2F_4H)_2$, approximately 2%, so that the relative proportions of the two products was unchanged. If the time was increased to 50 hours under the same conditions, the yield of $(CH_3)_2SnH(C_2F_4H)$ was almost the same (22.4%), but the yield of $(CH_3)_2Sn(C_2F_4H)_2$ was raised considerably to 40%. For a 20 hour reaction period, the effect of increasing the temperature from 25° to 50° was to give an excellent yield (75%) of $(CH_3)_2SnH(C_2F_4H)$, and only 1 to 2% of $(CH_3)_2Sn(C_2F_4H)_2$. When the ratio olefin:tin dihydride was changed from 1:1 to 2:1 and the reaction performed at 50° with ultraviolet irradiation for 20 hours, a 77% total yield of $(CH_3)_2Sn(C_2F_4H)_2$, and a 13% total yield of $(CH_3)_2SnH(C_2F_4H)$ was obtained.

Dimethyl(tetrafluoroethyl)tin hydride is a colorless liquid, b.p. 124°, which when sealed *in vacuo*, is stable at 25° for at least 3 months. At higher temperatures, disproportionation is extensive; thus, 72.6% of a sample decomposed at 140° over a 26-hour period to give an almost quantitative yield of $(CH_3)_2Sn(C_2F_4H)_2$. For simple disproportionation to occur, according to equation [5], dimethyltin dihydride should also be formed, but as already described, extensive decomposition of the dihydride occurs at this temperature. As in other tin hydrides, the Sn—H group in $(CH_3)_2SnH(C_2F_4H)$ is reactive, so that chlorination gives a quantitative yield of hydrogen chloride and forms *dimethyl(tetrafluoroethyl)tin chloride* $(CH_3)_2SnCl(C_2F_4H)$, m.p. 18.7–19.1°, b.p. 220°.

$$(CH_3)_2SnH(C_2F_4H) + Cl_2 \rightarrow HCl + (CH_3)_2SnCl(C_2F_4H). \quad [6]$$

The infrared spectrum of $(CH_3)_2SnH(C_2F_4H)$ shows the expected strong absorption at 1877 cm^{-1} due to the Sn—H stretching vibration, and also shows strong bands at 1182, 1102, 1046, and 1028 cm^{-1} due to C—F vibrations. In the spectrum of $(CH_3)_2Sn(C_2F_4H)_2$, the Sn—H band is, of course, absent, and the C—F vibrations give very similar bands although at slightly different frequencies. A detailed study of the proton and F^{19} nuclear magnetic resonance spectra of $(CH_3)_2SnH_2$, $(CH_3)_2SnH(C_2F_4H)$, and $(CH_3)_2Sn(C_2F_4H)_2$ is reported elsewhere (8).

The problem of the mechanism of these additions is of considerable interest. Earlier workers (1) have shown that the reactions are unaffected by free radical inhibitors and have concluded that an ionic mechanism is probable. This would presumably involve hydride-ion attack of the olefin, but it is not possible to exclude a molecular, four-center type of mechanism. From the present results, ultraviolet radiation markedly affects the course of the reaction and more detailed kinetic studies are clearly necessary. Further qualitative information might well result from an investigation of the addition of unsymmetrical fluoro-olefins to dimethyltin dihydride, since any polar influence of the olefin, as well as any steric effect, might then become apparent. For this reason, reactions with trifluoroethylene, 1,1-difluoroethylene, and trifluorobromoethylene were examined.

Surprisingly, trifluoroethylene did not react readily with dimethyltin dihydride in a reaction at 25° in the dark for a period of 94 hours; using a 1:1 molar ratio, 95.5% of the dihydride was recovered, and 88% of the olefin; the remainder was apparently lost as polymer. Very similar results were obtained in an identical experiment performed at 50° for 44 hours. However, reaction was much more extensive when carried out in ultraviolet light. When the reaction was performed at 25° for 20 hours with ultraviolet irradiation, using a 1:1 molar ratio, approximately 90% of the dihydride was consumed, hydrogen and a mixture of CF_2=CFH and CHF=CHF were produced, leaving a large quantity of involatile residue which contained metallic tin and dimethyltin difluoride. Moreover, a small quantity of less volatile material, was condensed at −45° *in vacuo*. This was unstable and on standing changed from a liquid to an involatile solid. The infrared spectrum of a freshly prepared sample showed the presence of Sn—H and C—F groups, and the n.m.r. spectrum also indicated two different types of CH_3—Sn groupings. All the evidence indicated that this fraction contained tetramethyltin and $(CH_3)_2SnH(C_2F_3H_2)$. Similar results were obtained in a reaction carried out at 50° for 17 hours with ultraviolet irradiation. In this case it was possible to separate and identify some pure $(CH_3)_4Sn$ as one of the products, although pure $(CH_3)_2SnH(C_2F_3H_2)$ could not be isolated.

Hence, ultraviolet radiation appears necessary to cause reaction with trifluoroethylene. The observations can be interpreted in terms of the initial reaction of equation [7]

$$(CH_3)_2SnH_2 + C_2F_3H \rightarrow (CH_3)_2SnH(C_2F_3H). \qquad [7]$$

However, this product spontaneously decomposes, and

$$(CH_3)_2SnH(C_2F_3H) \rightarrow [(CH_3)_2SnHF] + CFH{=}CFH,$$

rearrangement, and decomposition of the dihydride follow;

$$2[(CH_3)_2SnHF] \rightarrow (CH_3)_2SnF_2 + (CH_3)_2SnH_2, \qquad [8]$$

$$2(CH_3)_2SnH_2 \rightarrow 2H_2 + Sn + (CH_3)_4Sn.$$

The reaction between dimethyltin dihydride and 1,1-difluoroethylene likewise occurred to a negligible extent in the dark, even at 50°. However, under ultraviolet radiation at 25° for 19 hours, consumption of the dihydride was virtually complete, only a small amount (9%) of hydrogen was evolved, and fluoroethylene was a major volatile product. The involatile residue did not appear to contain metallic tin and was composed essentially of dimethyltin difluoride, and fluorocarbon polymer. Again, in some experiments, there was evidence for the existence of $(CH_3)_2SnH(C_2F_2H_3)$ as an unstable −45° fraction which underwent immediate decomposition, and the results can again be interpreted in terms of its transient formation and decomposition,

$$(CH_3)_2SnH_2 + C_2F_2H_2 \rightarrow (CH_3)_2SnH(C_2F_2H_3), \qquad [9]$$

$$(CH_3)_2SnH(C_2F_2H_3) \rightarrow [(CH_3)_2SnHF] + CH_2{=}CHF, \qquad [10]$$

$$2[(CH_3)_2SnHF] \rightarrow (CH_3)_2SnF_2 + (CH_3)_2SnH_2. \qquad [11]$$

When 1,1-difluoroethylene and dimethyltin dihydride were allowed to react in a 2:1 molar ratio, under identical conditions, the products were the same and also included trimethyltin fluoride, as well as dimethyltin difluoride.

Trifluorobromoethylene reacted much more readily with $(CH_3)_2SnH_2$ than either C_2F_3H or CF_2CH_2; after 21 hours in the dark at 50°, at a 1:1 molar ratio, only approximately 2% and 4% of the dihydride and olefin respectively were recovered. Most of the olefin (77%) was converted to trifluoroethylene. A small −45° fraction was unstable and decomposed to a white solid. Approximately half of the total material from the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

was either involatile or was condensed at −10° and contained a small quantity of metallic tin but consisted chiefly of a mixture of dimethyltin dibromide and trimethyltin bromide. When a similar reaction, using a 1:1 molar ratio of reactants, was carried out at 25° for 20 hours under ultraviolet irradiation, the identity and distribution of products was unchanged, except that very little $(CH_3)_3SnBr$ was formed, the major tin-containing product being $(CH_3)_2SnBr_2$.

Again, therefore, the experimental results are consistent with the formation of a mono-addition compound, and indeed the evidence clearly indicates that this was the major component of the −45° fractions described above. The mono-addition compound is unstable and decomposes as shown:

$$(CH_3)_2SnH_2 + C_2F_3Br \rightarrow (CH_3)_2SnH(C_2F_3BrH), \quad [12]$$

$$(CH_3)_2SnH(C_2F_3BrH) \rightarrow [(CH_3)_2SnHBr] + C_2F_3H, \quad [13]$$

$$2[(CH_3)_2SnHBr] \rightarrow (CH_3)_2SnBr_2 + (CH_3)_2SnH_2.$$

Hydrogen, metallic tin, and trimethyltin bromide may result from decomposition of $(CH_3)_2SnH_2$,

$$2(CH_3)_2SnH_2 \rightarrow (CH_3)_4Sn + Sn + 2H_2, \quad [14]$$

$$(CH_3)_4Sn + (CH_3)_2SnBr_2 \rightarrow 2(CH_3)_3SnBr. \quad [15]$$

The results, therefore, indicate low stability of the $Sn(C_2F_3BrH)$ group, and this was confirmed by the reaction of dimethyltin dihydride with trifluorobromoethylene in a 1:2 molar ratio at 50° in the dark for 19 hours. The formation of metallic tin, hydrogen, C_2F_3H, dimethyltin dibromide, and trimethyltin bromide can be interpreted in terms of equations [12–15] (i.e. through the formation of an unstable mono-addition compound). In addition, however, there was a small quantity (13%) of *dimethylbis(2-bromotrifluoro)tin*, $(CH_3)_2Sn(C_2F_3BrH)_2$, identified by its infrared and n.m.r. spectra. This colorless liquid decomposed at approximately 100°, the only products being C_2F_3H and $(CH_3)_2SnBr_2$. A simple decomposition therefore occurs,

$$(CH_3)_2Sn(C_2F_3BrH)_2 \rightarrow 2C_2F_3H + (CH_3)_2SnBr_2, \quad [16]$$

again indicating the inherent instability of the $Sn(C_2F_3BrH)$ group.

The question of the direction of addition of C_2F_3Br to the Sn—H bond is also of considerable interest. That is, is the $Sn—CF_2—CFBrH$ group formed, or is it the $Sn—CFBr—CF_2H$ group? The proton magnetic resonance spectrum shows a pair of triplets for the single proton, as distinct from the methyl protons and this is consistent only with the $Sn—CF_2—CFBrH$ arrangement.

The importance of the present work lies in the fact that it establishes (*a*) that simple olefins can be added directly and easily across the Sn—H bond, and (*b*) that such addition occurs in a stepwise fashion, forming first the mono-addition compound, $R_2SnH(R'H)$. A number of puzzling questions remain. Firstly, the mechanism of addition is most uncertain. Our results indicate that in certain instances, appreciable reaction only occurs under ultraviolet irradiation. On the other hand, all previous evidence argues against a free radical mechanism, and, moreover, there is no evidence for the formation of products of the type $R_2SnH[(C_2F_4)_nH]$, similar to those observed in the free-radical addition of olefins to silanes (9).

Secondly, it is not at all clear why groups such as $>SnC_2F_3H_2$, $>SnC_2F_2H_3$, and $>SnCF_2CFBrH$ should be unstable; the isolation of stable compounds such as $(CH_3)_2Sn(C_2F_2H_3)_2$ would normally be predicted. The high stability and inertness of methyltin

fluorides (e.g. ref. 10) may well favor the formation of dimethyltin difluoride and trimethyltin fluoride, but this argument cannot apply to the formation of $(CH_3)_2SnBr_2$ and C_2F_3H from the $>Sn(CF_2CFBrH)$ group. Further investigation of these reactions and of additions with other olefins, which may throw some light on these questions, is now in progress.

EXPERIMENTAL

General

All reactions were carried out in sealed pyrex Carius tubes of approximately 80-ml capacity. The manipulation and separation of volatile compounds were performed using standard high-vacuum techniques. Volatile products were identified by molecular-weight determinations by the Regnault method, by elemental analysis, by vapor pressure measurements, by the determination of infrared spectra, and in some instances by nuclear magnetic resonance spectra.

Preparation of Dimethyltin Dihydride

The procedure described by Finholt *et al.* (11) was used; this required the reduction of dimethyltin dichloride with lithium aluminum hydride. The apparatus consisted of a three-necked flask fitted with a stirrer, a low temperature condenser (−78°), and dropping funnel, and the reaction was carried out in an atmosphere of dry nitrogen. When dioxane was used as the solvent, the maximum yield of the dihydride was 55% of the theoretical, and it was not possible to remove completely the dioxane from the product. Hence, *n*-butyl ether was used as solvent. In a typical reaction, dimethyltin dichloride (66.1 g, 0.30 mole) was reduced with lithium aluminum hydride (21.1 g, 0.56 mole) in 150 ml *n*-butyl ether to give dimethyltin dihydride (36.3 g) in 81% yield.

Dimethyltin dihydride [M.W. obs. 150, calc. 151; b.p. 35.9°, lit. value 35° (1)] was also characterized by its proton magnetic resonance spectrum (8, 12), and by its infrared spectrum. The principal absorption bands in the latter were: a strong doublet at 1858, 1871 (Sn—H stretch), an intense band at 700–780 cm^{-1} with subsidiary maxima at 776, 759, 748, 727, and 711 cm^{-1}, a broad peak at 670–680 cm^{-1}, and a triplet at 536, 526, 517 cm^{-1}. The active hydrogen of the dihydride was readily determined by reaction with aqueous nitric acid, to give a quantitative yield of hydrogen.

Decomposition of Dimethyltin Dihydride

(*a*) The dihydride (2.193 g, 14.5 mmole) was heated in a sealed tube at 120° in the dark for 45 hours. After 6 hours, metallic tin had formed, and appreciable amounts had been deposited after 20 hours. Vacuum fractionation of the volatile products gave approximately 9 mmole of permanent gas (mainly hydrogen), a white solid (0.287 g) melting at 25°, which was hexamethylditin, and trimethyltin hydride (1.213 g, M.W. obs. 165, calc. 164). This last product was further characterized by its proton magnetic resonance (12) and infrared spectra. Metallic tin (0.670 g) remained in the reaction tube.

(*b*) A sample (2.141 g, 14.2 mmole) was heated at 130° under ultraviolet irradiation (100-watt lamp) for 6 hours, to give hydrogen (approximately 7.5 mmole), a fraction (1.216 g) which condensed *in vacuo* at −45° and which had a molecular weight of 180 and vapor pressure at 25° of 90 mm, unreacted dimethyltin dihydride (0.132 g), and metallic tin (0.777 g). In accord with the observed molecular weight, the −45° fraction was shown spectroscopically to contain tetramethyltin and trimethyltin hydride in an approximately 1:2 ratio.

(*c*) Dimethyltin dihydride (2.550 g, 16.9 mmole) was heated at 110° under ultraviolet irradiation for 40 hours. Hydrogen (approximately 11 mmole) containing a small amount of methane, hexamethylditin (0.466 g; m.p. 25°), tetramethyltin (0.679 g; M.W. obs. 178, calc. 178), and trimethyltin hydride (0.008 g) were the volatile products. Pure metallic tin (1.375 g) in mirror form was the only involatile product. The hexamethylditin and tetramethyltin were shown to be pure from their infrared spectra, and in the latter case by its n.m.r. spectrum.

(*d*) When the dihydride (2.220 g, 14.7 mmole) was subjected to ultraviolet irradiation at 25° for 40 hours, 92% was recovered unchanged. Hydrogen (0.3 mmole), a fraction (0.103 g, M.W. obs. 73) which was condensed at −64°, and metallic tin (0.067 g) were the other products. The −64° fraction was not characterized unambiguously but its infrared spectrum and molecular weight, indicated that only hydrocarbons were present.

Reactions with Tetrafluoroethylene

Typical reactions were as follows.

(*a*) Dimethyltin dihydride (1.650 g, 11.0 mmole) and tetrafluoroethylene (1.100 g, 11.0 mmole) were allowed to react in a sealed tube at 25° in the dark for 160 hours. Vacuum fractionation gave hydrogen (0.04 mmole), unreacted tetrafluoroethylene (0.177 g, 1.77 mmole), unreacted dimethyltin dihydride (0.614 g, 4.06 mmole), and two volatile fractions which were condensed at −10° and −46°. The former was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

dimethylbis(tetrafluoroethyl)tin, $(CH_3)_2Sn(C_2F_4H)_2$, (0.176 g, 0.503 mmole) [calc. for $C_6F_8H_8Sn$: C, 20.6; H, 2.6%. obs: C, 20.3; H, 2.2%. M.W. obs. 349; calc. 351], which has a boiling point of 124.0° and $\Delta H_v = 8.3$ kcal mole^{-1}. The −46° fraction was *dimethyl(tetrafluoroethyl)tin hydride*, $(CH_3)_2(C_2F_4H)SnH$, (1.443 g, 5.75 mmole) [calc. for $C_4F_4H_8Sn$: C, 19.2; H, 3.2%. obs: C, 18.8; H, 2.7%. M.W. obs. 252; calc. 251], which boils at 77.9° and has $\Delta H_v = 9.20$ kcal mole^{-1}. Further characterizations of these compounds are given below. An involatile residue (0.340 g), composed partly of tin, remained in the reaction tube.

(*b*) A similar reaction of the dihydride (0.538 g, 3.60 mmole) and tetrafluoroethylene (0.361 g, 3.61 mmole) at 25° for 22 hours with ultraviolet irradiation, gave a trace of dimethylbis(tetrafluoroethyl)tin, dimethyltetrafluoroethyltin hydride (0.209 g, 0.83 mmole, 23.2%), unreacted dihydride (0.367 g), and unreacted olefin (0.303 g), as well as some involatile residue (0.021 g).

(*c*) With dihydride (1.205 g, 8.03 mmole) and C_2F_4 (0.803 g, 8.03 mmole) at 25° for 50 hours with ultraviolet irradiation, a 40.0% yield of dimethylbis(tetrafluoroethyl)tin (0.934 g, 2.65 mmole) and a 22.4% yield of dimethyl(tetrafluoroethyl)tin hydride (0.373 g, 1.49 mmole) was obtained. The only other products were unreacted starting materials, and an involatile residue (0.387 g) which, from its appearance and infrared spectrum, contained metallic tin and polymerized olefin.

(*d*) Dimethyltin dihydride (1.452 g, 9.62 mmole) and C_2F_4 (0.874 g, 8.74 mmole), after 20 hours at 50° with ultraviolet irradiation, gave dimethyl(tetrafluoroethyl)tin hydride (1.801 g, 7.17 mmole), unreacted dihydride (0.271 g, 1.73 mmole), unreacted olefin (0.052 g, 0.52 mmole), hydrogen (1.1 mmole), and an involatile residue (0.161 g) composed largely of tin and polymerized tetrafluoroethylene.

(*e*) Dimethyltin dihydride (1.145 g, 7.58 mmole) and C_2F_4 (2.200 g, 22.00 mmole), under the same conditions as (*d*), gave hydrogen (0.07 mmole), unreacted olefin (0.611 g, 6.11 mmole), unreacted dihydride (0.314 g), which also appeared to contain small amounts of fluorocarbon material other than C_2F_4, dimethyl(tetrafluoroethyl)tin hydride (0.144 g, 0.960 mmole), dimethylbis(tetrafluoroethyl)tin (2.038 g, 5.83 mmole), and the same involatile residue (0.179 g) as observed in all other reactions.

Pyrolysis of $(CH_3)_2SnH(C_2F_4H)$

A sample (0.260 g) was heated at 140° for 26 hours. The volatile products were hydrogen (0.22 mmole), a fraction (0.032 g) which condensed *in vacuo* at −196°, and which from its infrared spectrum was a mixture of fluorocarbons, unreacted dimethyl(tetrafluoroethyl)tin hydride (0.071 g, M.W. obs. 249, calc. 251), and dimethylbis(tetrafluoroethyl)tin (0.120 g, M.W. obs. 350, calc. 351). An involatile residue (0.037 g) of tin and polymeric material remained.

Chlorination of Dimethyl(tetrafluoroethyl)tin Hydride

The reaction of $(CH_3)_2SnH(C_2F_4H)$ (0.127 g, 0.508 mmole) with chlorine (0.040 g, 0.57 mmole) occurred readily at room temperature to give hydrogen chloride (0.0018 g, 0.51 mmole), and *dimethyl(tetrafluoroethyl)tin chloride* (0.144 g, 0.507 mmole, M.W. obs. 284, calc. 285.5), which has m.p. 18.7–19.1°, b.p. 220°, $\Delta H_v = 6.2$ kcal mole^{-1}.

The infrared spectrum of $(CH_3)_2SnH(C_2F_4H)$ in the vapor phase showed absorption (cm^{-1}) at 2980 (m), 2920 (m) (C—H stretch); 1877 (s) (Sn—H stretch); 1418 (w) (CH_3 asymmetric, deformation); 1368 (m), 1343 (w), 1210 (w) (CH_3 symmetric deformation); 1182 (m), 1102 (s), 1046 (s), 1028 (w, sh), (C—F stretch); 980 (w); 775 (s) (CH_3 rocking); 724 (m); 640 (m); 583 (m); 551 (m); and 521 (m). Infrared absorption bands of $(CH_3)_2Sn(C_2F_4H)_2$ (liquid film) were observed at 2970 (w), 2915 (w) (C—H stretch); 1402 (w, sh), 1384 (w, sh), 1362 (s), 1341 (w, sh); 1274 (w); 1205 (w, sh) (CH_3 symmetric deformation); 1177 (s), 1088 (s), 1042 (s) (C—F stretch); 974 (m); 785 (s) (CH_3 rocking); 736 (w, sh); 638 (m); 580 (m); 549 (m); and 520 (s). The infrared spectrum of $(CH_3)_2SnCl(C_2F_4H)$, as a liquid film, showed absorption at 2970 (w), 2915 (w) (C—H stretch); 1609 (w); 1402 (w) (CH_3 asymmetric deformation); 1382 (w, sh), 1366 (s), 1342 (w, sh); 1282 (w); 1205 (w, sh) (CH_3 symmetric deformation); 1178 (s), 1088 (s), 1046 (s) (C—F stretch); 971 (m); and 790 (s) (CH_3 rocking).

The proton and F^{19} magnetic resonance spectra of $(CH_3)_2SnH(C_2F_4H)$ and $(CH_3)_2Sn(C_2F_4H)_2$ are fully consistent with these formulations and are described in detail elsewhere (8).

Reactions with Trifluoroethylene

(*a*) Dimethyltin dihydride (0.810 g, 5.36 mmole) and trifluoroethylene (0.437 g, 5.33 mmole) were allowed to react at 25° in the dark for 94 hours. Nearly all the dihydride (0.773 g, 95.4%) was recovered, as well as much of the olefin (0.382 g, 87.5%). There remained a white, involatile solid (0.090 g).

(*b*) A similar reaction with equimolar quantities at 50° in the dark for 44 hours led to the recovery of 96% of the dihydride and 86% of the olefin. The infrared spectrum of the involatile residue (9% of total mass) showed the presence of CH_3—Sn groups (strong 780 cm^{-1} band) and C—F groups.

(*c*) Dihydride (1.715 g, 11.4 mmole) and C_2F_3H (0.934 g, 11.4 mmole) were allowed to react under ultraviolet irradiation for 20 hours at 25°. Hydrogen (1.92 mmole, 23.4%) was recovered and a fraction (0.038 g) of low volatility condensed at −45°. The remaining products, apart from an involatile residue (1.540 g), were very volatile and only partial separation into −125° (0.406 g, M.W. 84) and −196° (0.643 g, M.W. 75.5) fractions could be achieved. Infrared examination showed that only the former contained unreacted dimethyltin dihydride, the remaining components of this fraction and those of the latter being unreacted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

trifluoroethylene (M.W. 82), and 1,2 difluoroethylene [M.W. 64]. The infrared spectra of these two compounds allows unambiguous identification in terms of the triplets observed (13) for CHF=CHF at 1117, 1128, and 1138, and 762, 769, and 778 cm^{-1}, which are distinct from absorption bands of CF_2=CHF. The involatile residue contained some metallic tin, and dimethyltin difluororide identified by its infrared spectrum and an X-ray powder photograph.

The −45° fraction was identical with a similar fraction obtained in experiment (*d*) below. Both materials were originally separated as clear liquids, but on standing at 25° decomposed with gas evolution to leave a white involatile solid. Because of this decomposition, molecular weights could not be determined. However, the infrared spectra showed the presence of Sn—H and C—F bonds, although absorption attributable to the latter in the 1000–1200 cm^{-1} region was of much lower intensity in relation to absorption due to Sn—H at approximately 1850 cm^{-1} than would be expected for $(CH_3)_2SnH(C_2F_3H_2)$. Moreover, a proton magnetic resonance spectrum showed two types of CH_3 peaks, in accord with the distinct CH_3—Sn rocking absorptions at 780 and 730 cm^{-1} in the infrared, and these results can be interpreted in terms of a mixture of $(CH_3)_4Sn$ and $(CH_3)_2SnH(C_2F_3H_2)$.

(*d*) Dimethyltin dihydride (1.189 g, 7.98 mmole) and C_2F_3H (0.660 g, 8.03 mmole), after 17 hours at 50° under ultraviolet radiation, gave 4.58 mmole of hydrogen (57%), a −45° fraction (0.172 g) having the properties described above, a −64° fraction (0.339 g, M.W. 170), and fractions which condensed at −125° (0.134 g) and −196° (0.568 g). The involatile residue (0.648 g) was again composed largely of metallic tin with some $(CH_3)_2SnF_2$. The −64° fraction, from its molecular weight and infrared spectrum, was almost pure tetramethyltin (M.W. 178), while the −125° and −196° fractions again contained unreacted dihydride (−125° only), unreacted C_2F_3H, and CHF=CHF.

Reactions with 1,1-Difluoroethylene

(*a*) Dimethyltin dihydride (1.529 g, 10.1 mmole) and CF_2CH_2 (0.647 g, 10.1 mmole) were allowed to react at 25° for 19 hours under ultraviolet irradiation. A small amount of hydrogen was formed (0.95 mmole, 9%), and the only other volatile products were unreacted dihydride (0.085 g) and a fraction which condensed at −196°. The latter (0.420 g) had molecular weight 56, and its infrared spectrum showed the presence of unreacted CF_2=CH_2 (M.W. 64) and of $CHFCH_2$ (M.W. 46). The latter was clearly identified by characteristic triplets (14) at 1142, 1156, 1170, and 913, 929, 949 cm^{-1} and sharp peaks at 863 and 711 cm^{-1}, all of which are absent from the spectrum of CF_2CH_2. The remaining involatile residue (1.671 g) was a clear, white solid which gave an analysis corresponding to $C_{3.0}H_{7.5}SnF_{2.5}$, and whose infrared spectrum showed the presence of fluorocarbon groups. An X-ray diffraction powder photograph identified dimethyltin difluoride, so that this solid was composed of a fluorocarbon polymer, probably of $CHFCH_2$, and $(CH_3)_2SnF_2$, in an approximately 1:2 ratio.

(*b*) When equimolar quantities of $(CH_3)_2SnH_2$ and CF_2CH_2 were allowed to react at 50° in the dark for 21 hours, 90% of the dihydride was recovered unchanged. Most of the olefin (97%) was recovered, although its spectrum indicated the presence of a small amount of $CFHCH_2$. A small quantity of material condensed at −45° but rapidly changed from a clear liquid to a non-volatile white solid with gas evolution.

(*c*) The dihydride (0.931 g, 6.17 mmole) and CF_2CH_2 (0.788 g, 12.3 mmole) were subjected to ultraviolet irradiation for 17 hours at 25°. Hydrogen (0.17 mole, 3%) was obtained, and 12% of the dihydride (0.113 g) was recovered. The fraction (0.510 g) collected at −196° had a molecular weight of 59.6 and was shown spectroscopically to contain unreacted CF_2CH_2, and $CFHCH_2$. The only other product was the white involatile residue which contained a small amount of metallic tin. Elemental analysis, as well as infrared spectroscopic, and X-ray powder photographic examination showed the presence of some fluorocarbon polymer, and considerable amounts of dimethyltin difluoride and trimethyltin fluoride, these two being in an approximately 2:1 ratio.

Reactions with Trifluorobromoethylene

(*a*) Dimethyltin dihydride (1.831 g, 12.1 mmole) and C_2F_3Br (1.950 g, 12.1 mmole) were allowed to react at 50° in the dark for 21 hours. Hydrogen (5.10 mmole, 42%) was recovered, and the fraction (0.722 g) which condensed at −196° (M.W. 83) was shown by its infrared spectrum to be C_2F_3H (M.W. 82). Only 2% of the dihydride (0.030 g) was recovered. Other fractions condensed at −45° (0.024 g) and −10° (1.256 g) leaving a residue (1.693 g). The small −45° fraction showed infrared absorption expected for the presence of Sn—H, C—F, and CH_3—Sn groups, but decomposed on standing to form a white solid, identified as dimethyltin dibromide.

The −10° fraction, which melted at ca. 25°, was separated into trimethyltin bromide (1.192 g) and dimethyltin dibromide (0.060 g) which were readily identified by their spectra and by melting point determinations. Similarly, the remaining grey reaction residue was found to contain some metallic tin, but to consist chiefly of dimethyltin dibromide.

(*b*) When $(CH_3)_2SnH_2$ (1.585 g, 10.5 mmole) and C_2F_3Br (1.694 g, 10.5 mmole) were allowed to react at 25° for 20 hours under ultraviolet irradiation, the products were hydrogen (2.25 mmole, 22%), trifluoroethylene (0.550 g, M.W. 83), unreacted dimethyltin dihydride (0.05 g), and unreacted C_2F_3Br (0.05 g), a −45° fraction (0.037 g) which again decomposed on standing to give involatile, white dimethyltin dibromide, a −10° fraction (0.366 g) which was almost pure trimethyltin bromide, and a grey residue (2.217 g) composed of metallic tin, some trimethyltin bromide, and chiefly dimethyltin dibromide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*c*) Dimethyltin dihydride (3.597 g, 23.8 mmole) and C_2F_3Br (7.791 g, 47.8 mmole) were allowed to react in the dark at 50° for 19 hours. Hydrogen (1.58 mmole, 6.7%) was formed, together with CF_2CFH (1.812 g, 22.1 mmole, 46.5%), and unreacted C_2F_3Br (1.571 g, 20.4%) was recovered. A very small fraction was collected at −45° but again this decomposed on standing at 25° to form $(CH_3)_2SnBr_2$. A clear liquid was condensed in each of a series of traps cooled at +10°, 0°, and −10°; spectroscopic examination showed these fractions (total 1.531 g) to be identical. There remained in the reaction tube, a white solid, m.p. 75° whose infrared spectrum showed it to be $(CH_3)_2SnBr_2$ (m.p. 74°).

A sample of the clear liquid, left to stand *in vacuo* at 25° for 16 days, decomposed completely leaving a residue of dimethyltin dibromide. An attempt to measure the vapor pressure of the liquid showed that slow decomposition occurred above 80°, and above 105° decomposition was rapid and complete. Extrapolation from the vapor pressure readings below 80° gave an approximate b.p. 192°. From a sample decomposed above 105° the only products were C_2F_3H (M.W. 81 and infrared spectrum) and involatile $(CH_3)_2SnBr_2$.

The infrared spectrum of the original liquid showed absorption at 3000 (w), 2920 (w) (C—H stretch), 2335 (w), 1710 (w), 1645 (w), 1605 (w), 1455 (w), 1405 (w), 1375 (m), [1258 (m), 1245 (m), 1152 (s), 1108 (s), 1080 (sh), 1045 (s) (C—F vibrations)], 952 (m), 895 (s), 780 (s) (CH_3—Sn rock), 760 (w, sh). This spectrum, together with the proton magnetic resonance spectrum, and the above evidence, identified the compound as *dimethylbis(2-bromotrifluoroethyl)tin*, $(CH_3)_2Sn(CF_2CFBrH)_2$. The n.m.r. spectrum, which will be discussed more fully elsewhere, showed a single peak at −0.95 and a pair of triplets at −4.65 p.p.m. with respect to tetramethylsilane, the areas being in the ratio 3:1. Such a spectrum is consistent with a formula $(CH_3)_2Sn(CF_2CFBrH)_2$ and not with $(CH_3)_2Sn(CFBrCF_2H)_2$, dimethylbis(1-bromotrifluoroethyl)tin.

THE RELATIVE ACCEPTOR POWER OF BORON TRIHALIDES AND BORANE TOWARD TRIMETHYLAMINE[1]

J. M. MILLER[2] AND M. ONYSZCHUK
Inorganic Chemistry Laboratory, McGill University, Montreal, Quebec
Received July 15, 1963

ABSTRACT

Gas phase displacement reactions of boron trihalides from their trimethylamine adducts show that the order of acceptor power is: $BBr_3 > BCl_3 > BF_3 > 1/2(B_2H_6)$. This order agrees with recent theoretical calculations and dipole moment, calorimetric, and infrared measurements on boron trihalide complexes with other reference bases.

INTRODUCTION

On the basis of electronegativities and steric requirements of the halogens, the classically accepted order of acceptor power of the boron trihalides was $BF_3 > BCl_3 > BBr_3$ (1). Recent work, however, has indicated the reverse order to be correct. Calorimetric studies by Brown and Holmes (1) on the pyridine complexes of boron trihalides in nitrobenzene solution first revealed the new order. This order was confirmed by Bax, Katritzky, and Sutton (2), who measured dipole moments of boron trihalide and borane (BH_3) adducts of pyridine and trimethylamine. Lappert (3), using ethyl acetate as reference base and taking the shift of the carbonyl stretching frequency in the infrared as an indication of donor–acceptor bond strength, concluded that BBr_3 is a stronger acceptor than BCl_3. Similar studies by Cook (4) on boron trihalide–xanthone complexes also confirm the new order, as do the theoretical calculations of Cotton and Leto (5).

The same order, if correct, should be evident from a study of the displacements of boron trihalides from their molecular addition compounds. Displacement reactions, although complicated by lattice energy and volatility effects, are often used to determine qualitatively the relative stability of a series of closely related complexes in which lattice energies do not vary significantly (6). From such data the relative acceptor strengths of a series of related Lewis acids can be inferred. In all cases where this has been done, the conclusions have not had to be changed when quantitative data have subsequently been reported for gas phase dissociation of the same complexes (6).

Graham and Stone (7) using trimethylamine as reference base found no displacement of BF_3 from $(CH_3)_3N \cdot BF_3$ by B_2H_6 at 80° C. Dutton *et al.* (8) reported that BCl_3 almost quantitatively displaced BF_3 from $(CH_3)_3N \cdot BF_3$ at 205° C, and the reverse reaction was not detected. We have now extended this work by investigating gas phase displacements of BH_3, BF_3, BCl_3, and BBr_3 from their trimethylamine adducts.

RESULTS AND DISCUSSION

It is evident from the results summarized in Table I that BCl_3 almost quantitatively displaced BF_3 from $(CH_3)_3N \cdot BF_3$ while the reverse reaction was not detected. Similarly, BBr_3 displaced BCl_3 and BF_3 from their trimethylamine adducts, while the reverse reaction occurred to a negligible extent. All three boron trihalides displaced BH_3 from

TABLE I
Displacement data

Reaction	Time (hr)	Temp	Average displacement (%)
$(CH_3)_3N \cdot BF_3 + BCl_3$	3	205	96.4[a]
$(CH_3)_3N \cdot BCl_3 + BF_3$	3	205	0.0[a]
$(CH_3)_3N \cdot BH_3 + BCl_3$	12	130	77.5
$(CH_3)_3N \cdot BF_3 + BBr_3$	2/3	250–300	89.2
$(CH_3)_3N \cdot BBr_3 + BF_3$	3/4	250–300	0.0
$(CH_3)_3N \cdot BCl_3 + BBr_3$	1/2	250–300	72.6[b]
$(CH_3)_3N \cdot BCl_3 + BBr_3$	3/4	250–300	91.3[b]
$(CH_3)_3N \cdot BCl_3 + BBr_3$	3	263–265	95.6[b]
$(CH_3)_3N \cdot BBr_3 + BCl_3$	3/4	250–300	14.7[b]
$(CH_3)_3N \cdot BH_3 + BBr_3$	1	250–300	90.2
$(CH_3)_3N \cdot BH_3 + BF_3$	3/4	130–140	83.3
$(CH_3)_3N \cdot BF_3 + 1/2(B_2H_6)$	3/4	130–140	23.4

[b]Based on BCl_3.

$(CH_3)_3N \cdot BH_3$ with the evolution of diborane which decomposed at the temperatures used. The reverse reaction of B_2H_6 with $(CH_3)_3N \cdot BF_3$ occurred only to a small extent. These results lead us to conclude that the order of acceptor power of boron trihalides and diborane toward trimethylamine is: $BBr_3 > BCl_3 > BF_3 > 1/2(B_2H_6)$.

Brown and Holmes (1) suggested that the order of acceptor power of boron trihalides depends mainly on the extent of p_π—p_π back bonding between the vacant $2p$-orbital of boron and a doubly occupied p-orbital of the halogen.

During adduct formation the hybridization of boron changes from sp^2 to sp^3 with resultant breaking of the p_π—p_π bonds. Cotton and Leto (5) have shown that the strength of boron–halogen p_π—p_π bonding decreases in the order $BF_3 > BCl_3 > BBr_3$, and that the reorganization energy required for adduct formation is also in the same order (48.3, 30.3, and 26.2 kcal mole^{-1} respectively). These reorganization energies provide the most satisfactory explanation of the relative acceptor power of boron trihalides; the larger the reorganization energy, the weaker the acceptor power. The observation that BBr_3 displaced BF_3 to a greater extent than BCl_3 from their trimethylamine adducts may be due to the fact that the difference in reorganization energy between BBr_3 and BF_3 is much greater than that between BBr_3 and BCl_3. Similarly, the great difference between BF_3 and BCl_3 could account for the nearly quantitative displacement of BF_3 by BCl_3 and the absence of the reverse displacement. In the case of BCl_3 and BBr_3 where the difference in reorganization energy is small, the reverse reaction occurred to a significant extent (14.7%).

Since displacement reactions probably occur in the following two steps* (where X and X′ represent different halogen atoms)

$$(CH_3)_3N \cdot BX_{3(g)} \rightleftarrows (CH_3)_3N_{(g)} + BX_{3(g)}$$
$$(CH_3)_3N_{(g)} + BX'_{3(g)} \rightleftarrows (CH_3)_3N \cdot BX'_{3(g)}$$

it might be argued that the least volatile complex would always be formed. In general, volatility and stability of adducts are inversely related, and only if stabilities were equal

The mechanism of this type of reaction is being investigated by Coyle, who has reported, in a recent preliminary communication (Proc. Chem. Soc. 172 (1963)), that the heterogeneous reaction of BCl_3 with $(C_2H_5)_3N \cdot BF_3$ below 60° occurs by halogen exchange without appreciable boron–nitrogen bond cleavage. However, he finds that at 60° boron–nitrogen bonds are broken and reformed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

would the heavier and presumably less volatile complex be formed in preference. However, the volatility of an adduct is not always determined by its molecular weight. For example, in trimethylamine complexes of germanium and silicon tetrahalides, $(CH_3)_3N \cdot GeF_4$ is more stable and less volatile than $(CH_3)_3N \cdot GeCl_4$ despite the latter's higher molecular weight (9). Similarly, $(CH_3)_3N \cdot SiF_4$ is more stable and less volatile than the heavier $(CH_3)_3N \cdot SiCl_4$ (9). Also, ammonia displaces tetrahydrofuran from its BH_3 complex forming a less volatile adduct (10), even though ammonia is lighter and more volatile than tetrahydrofuran.

Dipole moment measurements on trimethylamine and pyridine adducts (2) indicate that BH_3 is a slightly stronger acceptor than BF_3 but weaker than BCl_3. Although there is no possibility of supplementary π-bonding in the BH_3 group, there is the reorganization energy of BH_3 from sp^2 to sp^3 hybridization and the dissociation energy of diborane to be considered in displacement reactions involving diborane. No calculations have yet been made of the reorganization energy, but the dissociation energy of diborane is known to be 28.4 ± 2 kcal mole^{-1} (11). Thus in displacement reactions involving the BH_3 group, additional energy (14.2 kcal mole^{-1} of BH_3) is produced by dimerization of BH_3 groups. It appears that this extra energy makes the displacement of BH_3 by BF_3 energetically favorable even though $(CH_3)_3N \cdot BH_3$ is thermodynamically more stable than $(CH_3)_3N \cdot BF_3$. Thermochemical data (11) show that although the heat of reaction for $BF_3 + (CH_3)_3N$ is 26.6 kcal mole^{-1} and 17.3 kcal mole^{-1} for $1/2(B_2H_6) + (CH_3)_3N$, the calculated heat of reaction for $BH_3 + (CH_3)_3N$ is 31.5 kcal mole^{-1}. These values indicate that if BH_3 existed as a stable monomer it would be a stronger acceptor than BF_3 toward $(CH_3)_3N$ by about 5 kcal mole^{-1} (11).

EXPERIMENTAL

Methods and Apparatus

Volatile substances were manipulated in a standard high vacuum apparatus made of Pyrex glass (12). Stopcocks and ground glass joints were lubricated with Kel-F 90 grease which is not appreciably attacked by boron trihalides. Molecular weights (M) were determined by vapor density. The purities of volatile components were checked by vapor pressure, molecular weight, and gas phase infrared spectra measurements. The purities of solid adducts were checked by melting point (m.p.) determinations.

The reaction vessel was a pyrex tube, 40 cm long and 4.1 cm diameter, which had at one end a capillary constriction and a magnetically operated break-seal. The other end of the reaction vessel was fused to 20 cm of 2.5 cm tubing through which the weighed solid was inserted in a fused solica boat. This end was then sealed off about 8 cm from the larger diameter tube. After the vessel and its contents were evacuated, a measured amount of the volatile component was condensed in, and the capillary constriction was sealed off. Reactions were carried out by heating the reaction vessel in a tube furnace so that one end of the reaction vessel projected slightly. When all the material had sublimed to this cool end, the reaction tube was pushed into the furnace so that the hot end emerged and cooled, and the sublimation process reversed. This procedure was repeated until the desired reaction time had elapsed. Several reactions were done by placing the entire reaction vessel in a closed oven, but there were no significant differences between these results and those obtained by the multiple pass procedure. On completion of a displacement reaction the vessel was cooled with liquid air and then opened to the vacuum system through the magnetic break seal. Volatile products were removed and analyzed in the vacuum apparatus. The reaction tube was then cut open and the solid material examined, usually by infrared spectroscopy.

Observations of the infrared spectra of solid complexes in KBr discs revealed that each complex had at least one unique peak; these were: 690 cm^{-1} for $(CH_3)_3N \cdot BF_3$; 790 cm^{-1} for $(CH_3)_3N \cdot BCl_3$; 730, 714, and 672 cm^{-1} for $(CH_3)_3N \cdot BBr_3$ and 2357 cm^{-1} for $(CH_3)_3N \cdot BH_3$.

Materials

Diborane was prepared by the reaction of sodium borohydride with sulphuric acid (13). Commercial samples of boron trifluoride (Matheson), boron trichloride (Matheson), boron tribromide (Anderson), and trimethylamine (Matheson) were purified by several vacuum distillations and their purities were checked by vapor pressure, molecular weight, and infrared spectra measurements. Borane-trimethylamine (Callery) was purified by several vacuum sublimations (found m.p. 93–95°; lit. (14) m.p. 94°). Boron trifluoride-trimethylamine was prepared by bubbling trimethylamine and boron trifluoride into a flask of cooled dry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

benzene. This method proved to be more satisfactory than that described in Inorganic Syntheses (15). The crude product was recrystallized from pure ethanol and dried under vacuum (found m.p. 141°; lit. (15) m.p. 138°). Boron trichloride-trimethylamine was prepared from boron trichloride and trimethylamine as described in Inorganic Syntheses (15) (found m.p. 238–240°; lit. (15) m.p. 242–243°). Boron tribromide-trimethylamine was prepared by bubbling trimethylamine into boron tribromide in cooled dry benzene. The white precipitate was recrystallized from hot ethanol (found m.p. 239°; lit. (16) m.p. 238°). The infrared spectra of the trimethylamine complexes were identical to those of Katritzky (17).

Reaction of BBr_3 with $(CH_3)_3N \cdot BF_3$

The reaction of $(CH_3)_3N \cdot BF_3$ (4.85 mmole) with BBr_3 (10.21 mmole) at 250–300° for 40 minutes produced, after distillation at −130°, BF_3 (4.32 mmole) and BBr_3 (5.87 mmole), corresponding to 89.2% displacement. The solid product was shown by its infrared spectrum to be mainly $(CH_3)_3N \cdot BBr_3$, with only a trace of $(CH_3)_3N \cdot BF_3$. After recrystallization once from hot ethanol the solid melted at 234–239° (lit. (15) m.p. for $(CH_3)_3N \cdot BBr_3$: 238°).

Reaction of BF_3 with $(CH_3)_3N \cdot BBr_3$

When $(CH_3)_3N \cdot BBr_3$ (3.69 mmole) and BF_3 (9.24 mmole) were brought together for 45 minutes at 250–300°, the volatile products, separated by distillation at −120°, consisted of BF_3 (9.35 mmole) and BBr_3 (0.25 mmole), indicating that no significant reaction had occurred. The observed BBr_3 probably resulted from slight thermal decomposition of $(CH_3)_3N \cdot BBr_3$. The infrared spectrum of the solid was that of $(CH_3)_3N \cdot BBr_3$ with no sign of $(CH_3)_3N \cdot BF_3$.

Reaction of BBr_3 with $(CH_3)_3N \cdot BCl_3$

After 30 minutes at 250–300°, $(CH_3)_3N \cdot BCl_3$ (4.16 mmole) and BBr_3 (6.79 mmole) yielded a volatile product the infrared spectrum of which contained bands characteristic of BBr_3 and BCl_3 in addition to bands at 878, 916, 918, and 954 cm^{-1}. The first two bands are characteristic of BCl_2Br and the last two of $BClBr_2$; both molecular species are present in a mixture of BCl_3 and BBr_3, and are impossible to isolate (18). Since it was not possible to separate the BCl_3–BBr_3 mixture quantitatively, its composition was estimated from the molecular weight of the gaseous mixture; the results were, BCl_3 (3.02 mmole) and BBr_3 (3.03 mmole). The BCl_3 value indicated 72.6% displacement, while the BBr_3 value indicated 90.0% displacement. The infrared spectrum of the solid showed $(CH_3)_3N \cdot BBr_3$ together with a small amount of $(CH_3)_3N \cdot BCl_3$. A mixed halide analysis of the solid indicated that 71.7% displacement had occurred, which is in excellent agreement with the value indicated by the BCl_3 recovery.

A second reaction of $(CH_3)_3N \cdot BCl_3$ (4.18 mmole) with BBr_3 (8.47 mmole) at 250–300° for 45 minutes produced BCl_3 (3.81 mmole), corresponding to 91.3% displacement.

The same reaction was repeated a third time with $(CH_3)_3N \cdot BCl_3$ (2.57 mmole) and BBr_3 (5.22 mmole) at 263–265° for 3 hours. In this case the reaction was carried out in an oven with more accurate temperature control. The amount of BCl_3 recovered (3.46 mole) indicated 95.6% displacement.

The three experiments show that displacement becomes almost quantitative as the reaction time is increased.

Reaction of BCl_3 with $(CH_3)_3N \cdot BBr_3$

The reaction of $(CH_3)_3N \cdot BBr_3$ (2.52 mmole) with BCl_3 (6.31 mmole) at 250–300° for 45 minutes produced BBr_3 (0.56 mmole) and unconsumed BCl_3 (5.94 mmole), corresponding to displacements of 22.2 and 14.7% based on BBr_3 produced and BCl_3 consumed, respectively.

The solid was mainly $(CH_3)_3N \cdot BBr_3$ as evident from its infrared spectrum which also indicated a small amount of $(CH_3)_3N \cdot BCl_3$.

Reaction of BF_3 with $(CH_3)_3N \cdot BH_3$

Boron trifluoride (6.18 mmole) and $(CH_3)_3N \cdot BH_3$ (3.32 mmole) reacted at 130–150° for 45 minutes to yield a yellow non-volatile oil which solidified on cooling. This solid was probably polymeric $(BH)_x$ produced by thermal decomposition of diborane formed from the displaced BH_3: $xB_2H_6 \rightarrow 2xH_2 + 2(BH)_x$. This decomposition, if quantitative, should yield 1 mole of hydrogen per mole of $(CH_3)_3N \cdot BH_3$ decomposed. The volatile products from the displacement and simultaneous decomposition were hydrogen (2.78 mmol) and BF_3 (3.58 mmole). On the basis of BF_3 consumed, displacement had occurred to 80.5%, while, on the basis of hydrogen produced, the displacement reaction was 86% complete. The infrared spectrum of the solid showed $(CH_3)_3N \cdot BF_3$ with a small amount of $(CH_3)_3N \cdot BH_3$.

Reaction of B_2H_6 with $(CH_3)_3N \cdot BF_3$

Diborane (3.90 mmole, i.e. 7.80 mmole BH_3) and $(CH_3)_3N \cdot BF_3$ (2.64 mmole) were kept at 130–140° for 45 minutes. Then, while all the solid material was at one end of the reaction vessel, the other end was heated to 200° for 1 hour to decompose excess B_2H_6. This procedure was adopted because B_2H_6 cannot be easily separated quantitatively from BF_3 by vacuum distillation. The volatile products consisted of hydrogen (6.84 mmole), boron trifluoride (0.84 mmole), and diborane (0.42 mmole). The displacement based on the amount of BF_3 recovered was 31.8%, and 14.9% based on hydrogen produced. The infrared spectrum of the solid showed it to be mainly $(CH_3)_3N \cdot BF_3$ with a small amount of $(CH_3)_3N \cdot BH_3$.

For personal use only.

Reaction of BCl_3 with $(CH_3)_3N \cdot BH_3$

The reaction of $(CH_3)_3N \cdot BH_3$ (5.82 mmole) with BCl_3 (6.38 mmole) in an oven at 130° for 12 hours produced hydrogen (4.46 mmole) and BCl_3 (1.84 mmole) as the only volatile products. The percentage displacement was 76.9 calculated on the amount of hydrogen produced, and 78.0 on the basis of BCl_3 produced. Infrared measurements revealed that the solid was $(CH_3)_3N \cdot BCl_3$ contaminated with some $(CH_3)_3N \cdot BH_3$.

Reaction of BBr_3 with $(CH_3)_3N \cdot BH_3$

Boron tribromide (6.12 mmole) reacted with $(CH_3)_3N \cdot BH_3$ (4.18 mmole) at 250–300° for 60 minutes to produce hydrogen (3.85 mmole) and BBr_3 (2.42 mmole). The BBr_3 consumed indicated 88.5% displacement while the hydrogen produced indicated 92%. The solid was almost entirely $(CH_3)_3N \cdot BBr_3$, as evident from its infrared spectrum.

Effect of Heat on the Trimethylamine Adducts

The pure complexes were heated separately under the same conditions used in the displacement reactions. In the case of $(CH_3)_3N \cdot BF_3$, $(CH_3)_3N \cdot BCl_3$, and $(CH_3)_3N \cdot BBr_3$ there was no detectable decomposition in 45 minutes at 250–300°, and the infrared spectra of each was unchanged. However, $(CH_3)_3N \cdot BH_3$ decomposed, with formation of hydrogen and $(CH_3)_3N$, to an extent of 30.0% based on the amount of hydrogen evolved.

NOTES

SYNTHESIS OF DIKETOPIPERAZINES[1]

L. C. VINING[2]

A number of diketopiperazines derived from amino acids have recently been found as metabolic products of microorganisms (1–5). Several (2–4) are reported to possess biological activity against plants or insects, and it has been suggested (5) that compounds of this type are intermediates in the biosynthesis of related microbial metabolites containing the 1:4-diazine ring.

Diketopiperazines have received attention in the past as intermediates in the synthesis of peptides as well as hydrolytic fragments from proteins. They have frequently been prepared by the self-condensation of two molecules of an amino acid ester (6). However, the rate of diketopiperazine formation decreases with increasing molecular size of both the amino acid and the ester substituent (7, 8) and for the less reactive compounds relatively high temperatures are required and yields are poor. Unsubstituted amino acids also afford the dimeric anhydride when heated in a high-boiling solvent (9), and similar conditions can be used to cyclize a dipeptide (10). Need for the more drastic conditions which may lead to racemization (e.g. ref. 5) can be avoided by preparing a dipeptide ester which cyclizes with extreme ease (11). Use of this intermediate also has the obvious advantage of permitting the synthesis of diketopiperazines derived from two different amino acids.

As part of a study in this laboratory of the biosynthesis of aspergillic acid and related compounds it became necessary to prepare certain C^{14}-labeled diketopiperazines. Since no satisfactory procedure was available in the literature a number of methods for the synthesis of dipeptide esters were examined for their convenience and adaptability to the preparation of diketopiperazines on a small scale in good yield. The route selected involved the coupling of an N-carbobenzoxyamino acid with an amino acid ester via the mixed carbonic acid anhydride (12). The protecting carbobenzoxy group was removed by hydrogenation and the resulting dipeptide ester hydrochloride cyclized by treatment with methanolic ammonia (13).

C^{14}-Labeling is most efficiently introduced into the diketopiperazine from the synthetic route outlined above by using the methyl ester hydrochloride derivative of the appropriate C^{14}-labeled amino acid. This derivative can be conveniently prepared in high yield on a small scale. Use of a 10% excess of the N-carbobenzoxy-substituted moiety in the coupling reaction is then advisable. Synthesis of the diketopiperazine has been carried out without isolation of intermediates with an overall yield of 62%.

EXPERIMENTAL

N-Carbobenzoxy-L-isoleucine was prepared in a yield of 92% by the procedure of Fox and co-workers (14). D- and L-Leucine were esterified with methanol using thionyl chloride as catalyst (15). The yields of methyl D- and L-leucinate hydrochlorides were 95 and 93% respectively.

[1]*Issued as N.R.C. No. 7540.*

[2]*Present address: Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia.*

Methyl N-Carbobenzoxy-L-isoleucyl-L-leucinate

N-Carbobenzoxy-L-isoleucine (0.26 g = 1 mmole) in dry acetone (2 ml) containing triethylamine (0.14 ml = 1 mmole) was cooled to −10° C in an ice–salt bath, and ethyl chloroformate (0.7 ml = 1 mmole) added slowly, with stirring. After 25 minutes a solution prepared by neutralizing methyl L-leucinate hydrochloride (0.18 g = 1 mmole) in chloroform (1 ml) at −10° C with triethylamine (1 mmole) was added and rinsed in with two 0.5 ml washes of cold chloroform. The temperature of the reaction mixture was allowed to rise to ambient, and after a further 4 hours the solution was evaporated to dryness *in vacuo*. The residue was redissolved in ethyl acetate (25 ml) and the solution extracted successively with 0.1 *N* HCl (2×5 ml) and 0.1 *N* $NaHCO_3$ (2×5 ml), washed with water (3×5 ml), then dried over anhydrous sodium sulphate. The solvent was removed to give methyl N-carbobenzoxy-L-isoleucyl-L-leucinate which, after one crystallization from an ethyl acetate – light petroleum mixture had m.p. 143.5–145° C, $[\alpha]_{D^{26}} = -37.4°$ ($c = 0.3$ in ethanol). Found: C, 64.44; H, 8.25; N, 7.21%. Calc. for $C_{21}H_{32}O_5N_2$: C, 64.26; H, 8.22; N, 7.14%. The yield was 86%.

Methyl N-carbobenzoxy-L-isoleucyl-D-leucinate, m.p. 113–115° C, $[\alpha]_{D^{26}} = -21.6°$ ($c = 0.3$ in ethanol) was prepared similarly in a yield of 79%. Found: C, 64.27; H, 8.10; N, 7.14%.

Methyl L-Isoleucyl-L-leucinate Hydrochloride

Methyl N-carbobenzoxy-L-isoleucyl-L-leucinate (274 mg) was dissolved in glacial acetic acid (20 ml) containing Adams catalyst (300 mg). A slow stream of dry hydrogen was passed through the stirred reaction mixture at room temperature. The effluent gas was led through a trap containing 0.2 *N* barium hydroxide. After 24 hours when no further carbon dioxide was being evolved the catalyst was removed. The product recovered by evaporation of the solvent was crystallized from an ether–methanol mixture as needles (175 mg, 78%), m.p. 163–164° C, $[\alpha]_{D^{26}} = -3.4°$ ($c = 0.5$ in ethanol). Found: C, 52.69; H, 9.07; N, 9.44; Cl, 11.80%. Calc. for $C_{13}H_{27}O_3N_2Cl$: C, 52.96; H, 9.23; N, 9.50; Cl, 12.03%.

Methyl L-isoleucyl-D-leucinate hydrochloride could be prepared in a similar manner, or alternatively by hydrogenation of a solution of methyl N-carbobenzoxy-L-isoleucyl-D-leucinate (0.27 g) in methanol (20 ml) containing *N* hydrochloric acid (1.0 ml) over 5% palladium on charcoal (100 mg) for 16 hours at room temperature and atmospheric pressure. The product after one crystallization from ether–methanol gave prisms, m.p. 204–205° C, $[\alpha]_{D^{26}} = +64.6°$ ($c = 0.5$ in ethanol), in 82% yield. Found: C, 52.78; H, 9.08; N, 9.32; Cl, 11.88%.

Attempts to prepare methyl L-isoleucyl-L-leucinate hydrochloride by the latter procedure gave a product which could not be crystallized.

L-Isoleucyl-L-leucyl Anhydride

A solution of methyl L-isoleucyl-L-leucinate hydrochloride (0.25 g) in dry methanol (50 ml) cooled to −10° C in an ice–salt bath was saturated with dry ammonia. After 30 minutes the reaction mixture was allowed to warm to room temperature and kept for 18 hours. The solvent was evaporated and the residue crystallized from aqueous ethanol to give fine needles (0.14 g = 74%), m.p. (sealed capillary) 283° C, $[\alpha]_{D^{26}} = -83.0°$ ($c = 0.1$ in chloroform). Found: C, 63.86; H, 9.86; N, 12.11%. Calc. for $C_{12}H_{22}O_2N_2$: C, 63.68; H, 9.80; N, 12.38%.

L-Isoleucyl-D-leucyl anhydride, prepared similarly in a yield of 72%, had m.p. (sealed capillary) 289.5–290.5° C $[\alpha]_{D^{26}} = +16.1°$ ($c = 0.1$ in chloroform). Found: C, 63.82; H, 9.70; N, 12.34%.

THE STRUCTURE OF CYCLOHEXYLIDENEMALONONITRILE DIMER

M. R. S. Weir and J. B. Hyne

The reaction between cyclohexanone and malononitrile in the presence of base was reported (1) to form cyclohexylidenemalononitrile, described as a crystalline solid of m.p. 173.5–174.5°. A second group of investigators (2) showed that cyclohexylidenemalononitrile is in fact a liquid of b.p. 137–138° at 10 mm, and they suggested that the crystalline solid previously reported was a dimer or polymer of this substance.

Reinvestigation of the solid product, prepared either by treatment of a mixture of cyclohexanone and malononitrile with base (Corson and Stoughton's method (1)) or by treatment of cyclohexylidenemalononitrile with base, has shown it to be a dimer of cyclohexylidenemalononitrile, and we suggest that it has structure I(*a*), I(*b*), existing as a tautomeric mixture. An analogous base-catalyzed dimerization of isopropylidenemalononitrile to give a cyclic product has recently been reported (3). The mechanism for the formation of cyclohexylidenemalononitrile dimer is outlined in Chart I.

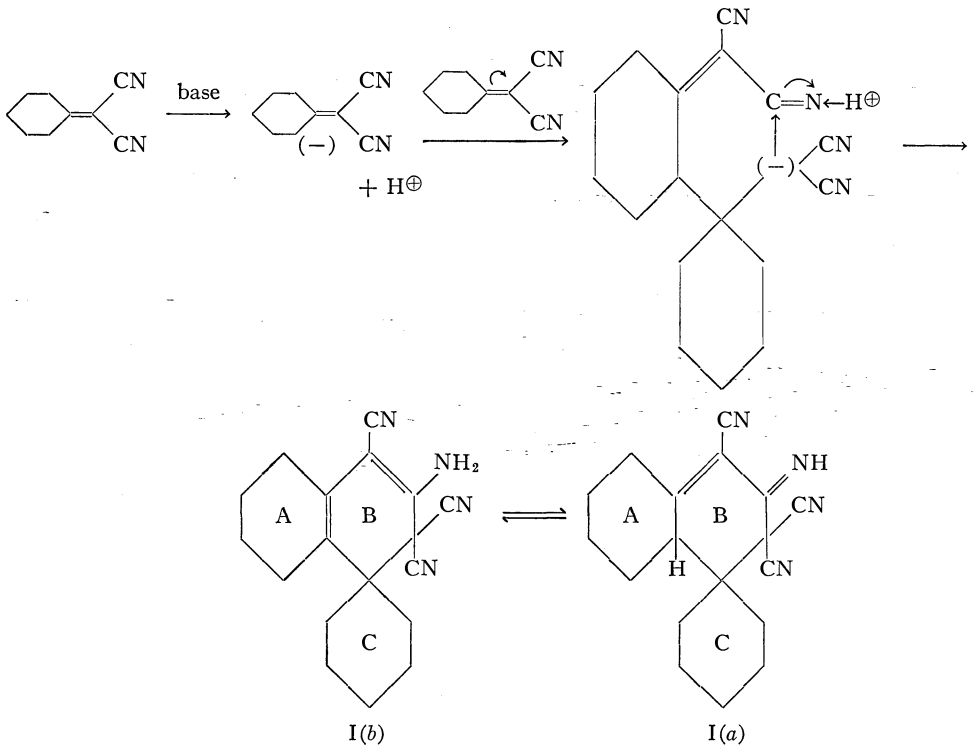

Chart I.

The dimer has the following infrared absorption pattern: 2.79, 2.85 μ (doublet, s, —NH_2); 3.00 μ (w, =NH); 3.30, 3.41 μ (doublet, s, C—H); 4.45 μ (s, conjugated CN); 6.08, 6.22 μ (doublet, s, C=N and C=C).

The positions and areas of the five peaks in the n.m.r. spectrum of the dimer can be assigned as shown in Table I, (I).

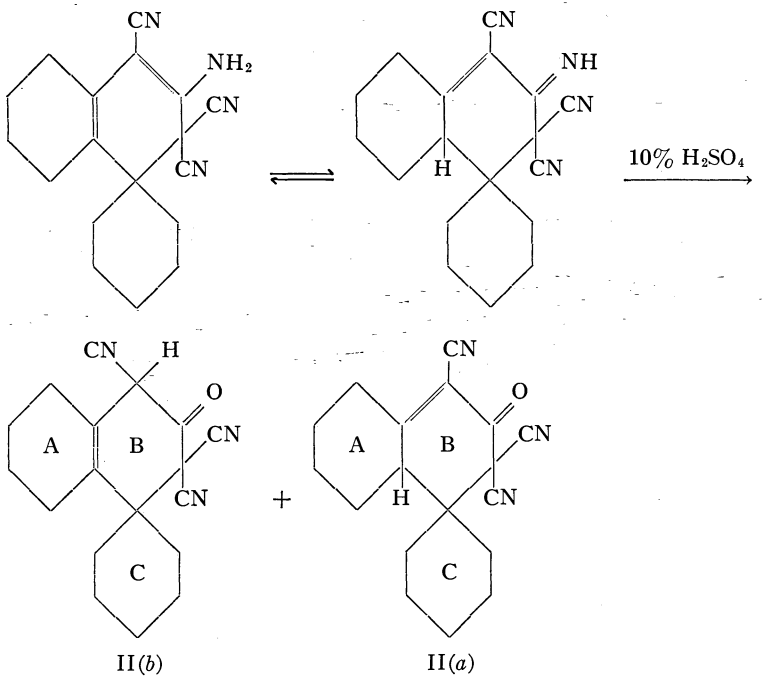
TABLE I

	τ, p.p.m. (T.M.S. = 10)	Rel. area (exptl.)	Theoret. area if tautomeric mixture were 50:50	Assignment
(I)	3.90	0.7	0.5	=N*H*
	4.95	1.3	1	—NH_2
	7.45	0.4	0.5	Bridgehead hydrogen between rings A & B in imino form
	8.00*	8	8	A ring hydrogens
	8.42*	9.5	10	C ring hydrogens
(II)	6.80	0.6	0.5	B ring hydrogen
	7.00	0.7	0.5	Bridgehead hydrogen between rings A & B in imino form
	8.00*	8	8	A ring hydrogens
	8.45*	9.5	10	C ring hydrogens

NOTE: Both spectra were run in $CDCl_3$ (~20% solutions).
*The bands at 8.00 and 8.42 τ are broad and overlap very considerably, making area estimation difficult. Consequently, it is also difficult to *accurately* relate these areas, which will be fixed and not upset by the tautomeric equilibrium, to the areas of the other peaks.

When the dimer is subjected to gentle acid hydrolysis the ketones II(*a*), II(*b*) are formed:



II(*b*) II(*a*)

The infrared spectrum of the hydrolysis product showed no absorption in the N—H stretching region; the characteristic bands were the following: 3.31, 3.42 μ (doublet, s, C—H); 4.50 μ (m, C≡N); 5.80, 5.85 μ* (doublet, s, C=O); 6.20 μ (s, C=C).

The n.m.r. spectrum of the hydrolysis product also showed complete absence of bands corresponding to =NH and —NH_2 groups. The bands are listed in Table I, (II).

**The carbonyl band showed distinct splitting into a doublet, when the spectrum was run in nujol: in a KBr pellet it appeared as one peak at 5.80 μ, with a shoulder at 5.85 μ.*

Dimerizations of alkylidenemalononitriles to give *acyclic* products has also been suggested by earlier workers (2, 4). Cyclohexylidenemalononitrile could conceivably dimerize to give the acyclic products shown in Chart II.

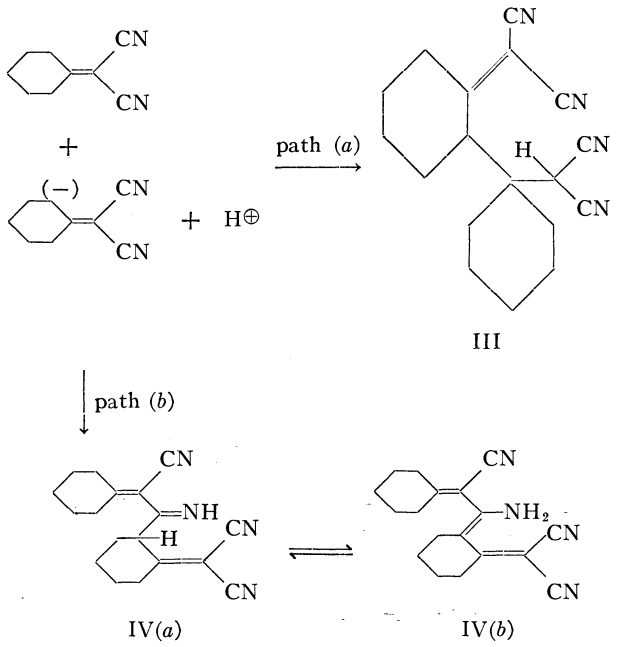

CHART II.

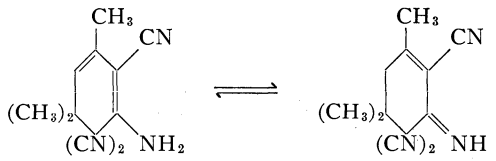
Structure III can be rejected since it does not contain an $—NH_2$ or an =NH group. Structures IV(*a*), IV(*b*) have been rejected in favor of I(*a*), I(*b*) after consideration of the following points. (*a*) If the dimer had this open-chain structure then the ratio of the intensity of the CN to CH absorption in the infrared would be expected to be greater than this ratio for the monomer. We find, in fact, that the ratio is significantly less for the dimer than for the monomer. (*b*) The ultraviolet absorption spectrum of the monomer has one intense band at 235 mμ ($\epsilon \simeq 59{,}000$), while that of the dimer has two bands, one at 300 mμ ($\epsilon = 12{,}400$) and one at 245 mμ ($\epsilon = 7{,}500$). An acyclic dimer with the triene structure IV(*b*) would be expected to absorb at longer wavelength and to have a significantly more intense absorption than the monomer. The reduction in the intensity of the absorption in the dimer relative to the monomer is consistent with the cross-conjugated systems I(*a*), I(*b*). (*c*) The n.m.r. spectra of both the dimer and its hydrolysis product show undisturbed cyclohexane hydrogen absorptions (τ for cyclohexane = 8.5 p.p.m.), consistent with the cyclic spiro structure, where the C ring hydrogens would be expected to be undisturbed. (*d*) The close analogy between this reaction and the dimerization of isopropylidenemalononitrile (3) to give a dimer of the structure



strongly suggests a cyclic product rather than an acyclic one.

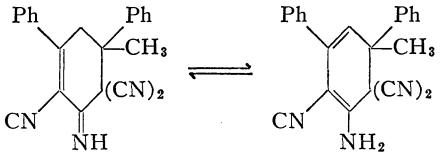
It is also noteworthy that Anderson, Bell, and Duncan (4) showed that the reaction of acetophenone with malononitrile in the presence of base gave two products: (*a*) 1,1-dicyano-2-methyl-2-phenylethylene, and (*b*) a high-melting yellow solid, described as an isomer of the above. The authors state that the infrared spectrum of this yellow compound did not agree with the expected 4-amino-1,1,5-tricyano-2,6-diphenylhepta-1,3,5-triene. It seems probable that this material was in fact the cyclic dimer



produced by a mechanism analogous to the one given above for the dimerization of cyclohexylidenemalononitrile.

EXPERIMENTAL

Preparation of Cyclohexylidenemalononitrile (2)

Malononitrile (20 g, 0.26 m) was dissolved in 30 g (0.3 m) of cyclohexanone, and 0.5 ml of piperidine was added. The mixture was allowed to stand for about 1 hour, then was dissolved in benzene, washed with 2% hydrochloric acid and then with water. The benzene solution was dried over anhydrous magnesium sulphate and the product distilled, b.p. 85–90° at 1–0.7 mm, n_D^{25} 1.5098. Lit. b.p. 137–138° at 10 mm, n_D^{25} 1.5110.

Preparation of Cyclohexylidenemalononitrile Dimer

When cyclohexylidenemalononitrile was treated with a few drops of piperidine and the mixture allowed to stand at room temperature overnight it solidified to a glass, which on treatment with solvent (95% ethanol) gave a pale yellow crystalline solid, m.p. 172–173°. Recrystallization from 95% ethanol gave pale yellow plates of m.p. 174°. Lit. (1) m.p. 173.5–174.5°. Anal.: Calc. for $C_{18}H_{20}N_4$: C, 74.00; H, 6.86; N, 19.27 mol. wt., 292. Found: C, 73.69; H, 7.00; N, 19.28; mol. wt., 304.

Identical material was obtained by leaving the mixture of malononitrile, cyclohexanone, and piperidine in contact overnight and recrystallizing the resultant glass from 95% ethanol.

Sulphuric Acid Hydrolysis of Cyclohexylidenemalononitrile Dimer

The dimer (100 mg) was stirred overnight with gentle warming in 10 ml of 10% aqueous sulphuric acid. The resulting white solid was washed with water and dried, m.p. 170–175°. Recrystallization from 70% aqueous ethanol gave needles, m.p. 170–173°. Anal.: Calc. for $C_{18}H_{19}N_3O$: C, 73.75; H, 6.49; N, 14.31. Found: C, 73.80; H, 6.52; N, 14.06.

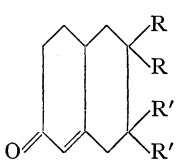
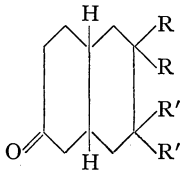
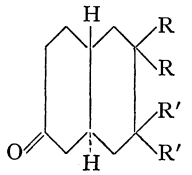
du fusion 69–71°, en mettant en œuvre la méthode de Stork (1): condensation de la méthyl-vinyl-cétone avec l'ène-pyrrolidine issue de la diméthyl-4,4 cyclohexanone, suivie de la cyclisation et de l'hydrolyse habituelles. Le spectre infrarouge montre la présence de quelques pourcents de la cétone correspondante β,γ-éthylénique; le spectre ultraviolet présente un maximum à 239 mμ, log ϵ = 4.20.



I: R = CH_3; R′ = H
II: R = H; R′ = CH_3



III: R = CH_3; R′ = H
IV: R = H; R′ = CH_3



V: R = CH_3; R′ = H
VI: R = H; R′ = CH_3

Nous avons réduit l'octalone I sur palladium/charbon en présence d'acide chlorhydrique et par le lithium dans l'ammoniac liquide et obtenu deux décalones différentes, auxquelles, par analogie avec la série diméthylée en -7,7 (2), nous attribuons les configurations *cis* (III) et *trans* (V) respectivement. Brutes, les décalones ne sont pas pures: la *trans* contient de l'alcool correspondant et la *cis* 9% d'isomère *trans*, décelé par chromatographie en phase gazeuse. La décalone *trans* pure fut obtenue par oxydation chromique de la décalone *trans* brute et la décalone *cis* par chromatographie en phase gazeuse à grande échelle qui permet d'éliminer l'isomère *trans*. Les dinitro-2,4 phénylhydrazones fondent à 193–194° (*trans*) et 170–172° (*cis*).

Augustine et Broom (2) ont réduit l'octalone II sur palladium/charbon en présence d'acide chlorhydrique en diméthyl-7,7 décalone-2 *cis* (IV) qu'ils décrivent comme liquide; dans nos mains, cette décalone est un solide, p.f. 43°, homogène en chromatographie en phase gazeuse. La réduction de l'octalone II par le lithium dans l'ammoniac liquide en décalone VI *trans*, conduit à une décalone *trans* brute qui contient de 10–20% de diméthyl-7,7 décalol-2 *trans* (la configuration du groupe —OH n'a pas été établie). Par oxydation chromique de la décalone brute nous avons obtenu la décalone *trans* VI pure, homogène en chromatographie en phase gazeuse. Les dinitro-2,4 phénylhydrazones que nous avons préparées à partir de nos échantillons de décalones *cis* et *trans* n'ont pas les points de fusion donnés par Augustine et Broom (2).

L'octalone II que nous avons préparée selon la méthode de Stork est en tout point semblable à celle que décrivent Augustine et Broom (2). L'ène-pyrrolidine issue de la diméthyl-3,3 cyclohexanone ne conduit, à la cyanoéthylation, qu'à la diméthyl-3,3 cyanoéthyl-5 cyclohexanone (3): nous pouvions ainsi prévoir la formation exclusive de l'octalone II.

PARTIE EXPÉRIMENTALE[3]

1. Diméthyl-6,6 $\Delta^{1(9)}$-octalone-2 (I)

L'ène-pyrrolidine correspondant à la diméthyl-4,4 cyclohexanone, p.é. 116–117° sous 13 mm, n_D^{22} = 1.5031, a été préparée avec un rendement de 91.1% selon (1). L'octalone I, p.f. 69–71° (cristallisation dans l'éther

[3]*Les points de fusion ont été déterminés en tubes capillaires, en utilisant un thermomètre étalonné avec des substances de points de fusion connus. Les spectres infrarouges ont été déterminés avec un spectromètre Perkin–Elmer, modèle 221, optique* NaCl, *les spectres ultraviolets avec un appareil Beckman DK1. La chromatographie en phase gazeuse fut effectuée avec un appareil Kromo-tog K-2 de Burrell Corporation, pour les déterminations analytiques, et un appareil Fisher Prep-Partitioner, pour les séparations à grande échelle. DNP: dinitro-2,4 phénylhydrazone. SEM: semicarbazone. CPG: chromatographie en phase gazeuse. Les analyses sont de W. Manser, Herrliberg (Suisse) et de C. Daesslé, Organic Microanalyses, Montréal.*

de pétrole) a été préparée selon la méthode II, 2 de Stork *et al.* (1), avec un rendement de 39.5% à partir de la cétone. Calc. pour $C_{12}H_{18}O$: C, 80.84; H, 10.18%. Trouvé: C, 80.82; H, 10.21%. SEM, p.f. 223–225° (EtOH–dioxanne). Calc. pour $C_{13}H_{21}ON_3$: C, 66.36; H, 8.99; N, 17.86%. Trouvé: C, 66.12; H, 8.94; N, 17.88%.

2. Diméthyl-6,6 décalone-2 cis (III) (cf. réf. 2)

Un mélange de 17.6 g d'octalone I, 1.76 g de palladium sur charbon 10%, 88 ml d'éthanol anhydre et 8 ml de HCl 3 *N* est agité en atmosphère d'hydrogène pendant 12 heures. Une mole d'hydrogène est absorbée. Le catalyseur est essoré et lavé avec un peu d'acétone. Le filtrat et les solvants de lavage sont réunis et évaporés à 11 mm. Le résidue est repris par de l'éther; on lave avec une solution aqueuse saturée de NaCl, sèche sur sulfate de sodium et évapore. Le résidu est distillé: 14.6 g de décalone, p.é. 142° sous 20 mm, n_D^{22} = 1.4858. Rendement: 82%. La CPG (2.5 m, 20% polyester succinique de Craig sur brique) révèle la présence de 9% d'isomère *trans* décrit en 3. L'ordre d'élution est *trans*, *cis*. L'isomère *cis* pur fut obtenu par CPG, à l'échelle du gramme (une colonne de 45×5 cm, suivie de trois colonnes en série de 45×3 cm, 20% huile de silicone No. 200, 1000 cs de Dow Corning sur brique). Calculé pour $C_{12}H_{20}O$: C, 79.94; H, 11.18%. Trouvé: 79.92; H, 11.07%. SEM, p.f. 207–208° (EtOH). Calculé pour $C_{13}H_{23}ON_3$: C, 65.77; H, 9.76; N, 17.70%. Trouvé C, 65.69; H, 9.80; N, 17.61%. DNP, p.f. 170–172° (EtOH). Calculé pour $C_{18}H_{24}O_4N_4$: C, 59.98; H, 6.71; N, 15.55%. Trouvé: C, 59.91; H, 6.66; N, 15.59%.

3. Diméthyl-6,6 décalone-2 trans (V)

A 100 ml d'ammoniac liquide on ajoute 3 g d'octalone I dans 23 ml d'éther anhydre, puis 0.136 g de lithium coupé en petits morceaux jusqu'a ce que la couleur bleue persiste; après 15 minutes, la coloration bleue disparaissant, on ajoute 30 mg de lithium. La solution est agitée pendant 3 heures. On ajoute alors 3.64 g de NH_4Cl et laisse l'ammoniac s'évaporer à température de la pièce. Le résidu est repris par de l'eau et extrait par de l'éther; la solution éthérée est lavée par HCl 3 *N*, puis par de l'eau saturée de NaCl, séchée et évaporée. Le résidu est distillé: 1.1 g, p. é. 74° sous 0.5 mm, n_D^{21} = 1.4880. Rendement: 37%. La décalone brute contient de l'alcool et de l'octalone de départ (décelés par spectroscopie infrarouge). La réduction par NH_3/Li est répétée. Puis 5.3 g de décalone brute sont mis en solution dans 50 ml de pyridine anhydre; cette solution est ajoutée, goutte à goutte, à température de la pièce, à 50 ml de pyridine contenant 5 g de CrO_3. Le tout est agité pendant 12 heures à température de la pièce. On extrait à la manière habituelle la décalone *trans* pure, n_D^{22} = 1.4892 (rendement 31%); un seul pic en CPG, dans les conditions décrites en 2.

Calculé pour $C_{12}H_{20}O$: C, 79.94; H, 11.18%. Trouvé: C, 80.06; H, 11.14%. SEM, p.f. 217–219° (EtOH–dioxanne). Calculé pour $C_{13}H_{23}ON_3$: C, 65.77; H, 9.76; N, 17.70%. Trouvé: C, 65.61; H, 9.69; N, 17.79%. Donne une dépression de p.f. en mélange avec la SEM de la décalone *cis* décrite en 2. DNP, p.f. 193–194° (EtOH–$CHCl_3$). Calculé pour $C_{18}H_{24}O_4N_4$: C, 59.98; H, 6.71; N, 15.55%. Trouvé: C, 59.93; H, 6.65; N, 15.34%. Donne une dépression de p.f. en mélange avec la DNP de l'isomère *cis* décrite en 2.

4. Diméthyl-7,7 $\Delta^{1(9)}$-octalone-2 (II)

Elle fut préparée selon la méthode décrite plus haut en 1, avec un rendement de 43% à partir de la diméthyl-3,3 cyclohexanone, en passant par l'ène-pyrrolidine décrite en réf. 3. P. é. 94° sous 0.15 mm, n_D^{25} = 1.5050. DNP, p.f. 196–197°. Augustine et Broom (2) donnent: DNP, p.f. 196–197°.

5. Diméthyl-7,7 décalone-2 cis (IV)

Elle fut préparée, avec un rendement de 95%, à partir de l'octalone décrite en 4, selon la méthode décrite en 2. Il n'est pas nécessaire de chromatographier en phase gazeuse, la décalone brute cristallisant d'elle-même. P.f. 43° (éther de pétrole). Calculé pour $C_{12}H_{20}O$: C, 79.94; H, 11.18%. Trouvé: C, 79.94; H, 11.18%. SEM, p.f. 186–187° (EtOH 95%). Calculé pour $C_{13}H_{23}ON_3$: C, 65.77; H, 9.76; N, 17.70%. Trouvé: C, 65.57; H, 9.82; N, 17.55%. DNP, p.f. 161.0–162.0° (MeOH). Calculé pour $C_{18}H_{24}N_4O_4$: C, 59.98; H, 6.71; N, 15.65%. Trouvé: C, 59.88; H, 6.63; N, 15.63%. Augustine et Broom (2) donnent: liquide; DNP, p.f. 129–130°.

6. Diméthyl-7,7 décalone-2 trans (VI)

Elle fut préparée avec un rendement de 52% à partir de l'octalone décrite en 4, selon la méthode détaillée en 3. P.é. 69–70° sous 0.45 mm, n_D^{20} = 1.4786. Calculé pour $C_{12}H_{20}O$: C, 79.94; H, 11.18%. Trouvé: C, 79.87; H, 11.15%. SEM, p.f. 195°. Calculé pour $C_{13}H_{23}ON_3$: C, 65.77; H, 9.76; N, 17.70%. Trouvé: C, 65.64; H, 9.85; N, 17.73%. DNP, p.f. 141.5°. Calculé pour $C_{18}H_{24}N_4O_4$: C, 59.98; H, 6.71; N, 15.55%. Trouvé: C, 59.75; H, 6.61; N, 15.63%. Augustine et Broom (2) donnent: liquide; DNP, p.f. 164–165°.

THE MOLECULAR STRUCTURE OF HETERATISINE HYDROBROMIDE MONOHYDRATE*

MARIA PRZYBYLSKA

The HBr salt of heteratisine, prepared by Dr. O. E. Edwards, was found to be unstable, but its monohydrate, $C_{22}H_{33}O_5N.HBr.H_2O$, which crystallized from water in the form of large colorless prisms, was satisfactory for the X-ray analysis. The space group is $P2_1$ with two molecules per unit cell of the following dimensions: $a = 8.96$, $b = 14.54$, $c = 8.55$ Å, $\beta = 90° 40'$.

Thirteen b axis levels were scanned with filtered Mo radiation and a scintillation counter using the Hilger and Watts' automatic linear diffractometer designed by U. W. Arndt and D. C. Phillips. Close to 1300 intensities were measured.

Two-dimensional Patterson projections along each of the three axes gave two possible locations for the bromine atom. An additional P(UVW) synthesis, however, carried out only for the section at $V = \frac{1}{2}$, led to the unambiguous positioning of bromine at $x = 0.236$ and $z = 0.080$. The y coordinate was taken as 0.250 and a Fourier summation was carried out for sections perpendicular to the b axis, using the phases calculated on the basis of the heavy atom alone. The interpretation of the perspex model of this three-dimensional synthesis gave the position of 13 light atoms of the molecule. These atoms, all treated as carbons, were used in the subsequent calculation of structure factors. The two Fourier syntheses, which followed, yielded the additional 13 and finally the last 3 light atoms. Once all the atoms were located, it became obvious that heteratisine has a similar carbon–nitrogen skeleton to lycoctonine (1) and other related highly oxygenated *Aconitum* and *Delphinium* alkaloids.

There was no difficulty in distinguishing the oxygen peaks from those of carbon, as they were considerably higher, whereas the nitrogen atom was identified on comparison with other structurally similar alkaloids.

The six-membered ring carrying the methoxy group is of appreciably distorted 'boat' form. The methoxyl has the same configuration as the corresponding hydroxyl in delcosine (2), in which the six-membered ring is also in the 'boat' form.

A photograph of the molecule together with its structural formula is given in Fig. 1.

The absolute configuration represented in Fig. 1 has not been determined in this study, but conforms to that of other known diterpenoid alkaloids with the same basic skeleton (3). Evidence from optical rotation† of heteratisine derivatives is also consistent with this absolute stereochemistry.

Issued as N.R.C. No. 7583.

N.M.R. SOLVENT STUDIES: HYDRAZINE AS A SOLVENT

H. AGAHIGIAN, H. GAUTHIER, H. HOBERECHT, AND L. RAPHAELIAN

The studies of hydrogen bonding (1, pp. 400–407; 2–4, 5 and references cited therein) with respect to proton chemical shifts have shown effects the order of magnitude of which was dependent on causes such as concentration, solvent–solute interactions, and the nature of the solvents, to mention a few. It is interesting to note that, for none of the solvent systems studied, has work been done with anhydrous hydrazine as a solvent. In most cases, the solvent systems used are polar to non-polar with varying concentrations of solute. No study concerning groups such as amino or hydroxyl groups in aromatic systems has been done and the hope is that some information might be obtained which will lead to a better understanding of hydrogen bonding.

Recently, the methyl resonances (6) in steroids were assigned by using pyridine as a solvent, and from the published spectra, a dramatic change was effected which made the assignment possible. In addition, a study of pyrrole and N-substituted pyrroles (7), as well as substituted quinolines (8), and a study of interactions in benzene (9) have shown that the solvent effects are not a function of the extent of hydrogen bonding but require an explanation which involves a preferred orientation of solvent–solute interaction. The scope of this study embodies the use of hydrazine as a solvent in nuclear magnetic resonance (n.m.r.) studies and its effects on the various aromatic protons in systems where the substituents are electron-donating, and will themselves be more susceptible to hydrogen bonding or association with the solvent. The spectra of the saturated heterocyclics, 2-pyrrolidone, and N-methyl 2-pyrrolidone were observed in anhydrous hydrazine using tetramethylsilane as an external standard, as well as in deuterochloroform with external tetramethylsilane, and the spectra were identical. A similar experiment with about 10% solution *dl*-2,3 diphenyl-2,3-butanediol yielded spectra which were essentially unchanged, indicating little or no effect on the aromatic protons in this type of system. The aromatic proton resonance of *dl*-2,3-diphenyl-2,3-butanediol in hydrazine was 456 c/s from external tetramethylsilane; in deuterochloroform the phenyl resonance was 457 c/s from external tetramethylsilane, i.e., essentially unchanged in the two solvents. Although hydrazine is a compound which has applicability in synthetic chemistry it appears to be of value as a solvent for some organic compounds.

The spectrum of *o*-phenylenediamine in deuterochloroform was a single peak; however, in anhydrous hydrazine the aromatic protons were a typical A_2B_2 case similar to *o*-dichlorobenzene (1).* The spectrum of 1,3-phenylenediamine was obtained in both deuterochloroform and hydrazine and marked low field displacement of the ortho protons (H_4 and H_6) in hydrazine compared to the deuterochloroform solution suggested a change in the amino functions possibly due to association.

The spectrum of 2,4-dichlorophenol was obtained in deuterochloroform, deuterochloroform and hydrazine mixtures, and anhydrous hydrazine (Table I). Since the use of an external standard was needed for the anhydrous hydrazine, more reliable data was obtained by viewing the 2,4-dichlorophenol in deuterochloroform while anhydrous hydrazine was added dropwise to effect the changes in line positions of the aromatic protons. While the protons at positions 5 and 6 shifted to high field, the proton at position

*In the terminology of D. R. Whitman, J. Mol. Spectry. **10**, 250 (1963), the aromatic protons should be designated as an AA'BB' type.*

TABLE I

Chemical shifts of aromatic protons
(c/s from internal TMS)

Compound		Solvent $CDCl_3$	Solvent N_2H_4	Δ
2,4-Dichlorophenol 	H_3	436±2	436	—
	H_5	430	418	+12
	H_6	413	395	+18
2,5-Dichloroaniline 	H_3	425	428	− 3
	H_4	399, 393	393	—
	H_6		408	—(11–13)
m-Nitrocresol 	H_3	470	457	+13
	H_5	443	420	+23
	H_6	420	395	+25

3 remained essentially unchanged. The possibility of hydrogen bonding with the halogens would not sufficiently explain this phenomenon and a more reasonable explanation is the contributing resonance forms, which might be drawn for ortho and para quinoid types. The high field shift of the other aromatic protons are most likely due to hydrazine salt formation yielding a phenoxide-type ion. In order to establish that no reaction had occurred, the 2,4-dichlorophenol was dissolved in anhydrous hydrazine and allowed to stand, at which time the hydrazine was removed by vacuum. The proton resonance spectrum of the isolated material indicated it was the starting compound.

The study of a 2,5-dichloroaniline yielded some interesting data concerning the chemical shifts of the three ring protons (Table I). The proton spectrum in deuterochloroform consisted of a doublet at 425 c/s (ortho coupled) from internal tetramethylsilane and two unresolved resonances at 399 and 393 c/s. Successive dropwise addition of hydrazine resulted in a spectrum which consisted of ortho-coupled, ortho- and meta-coupled, and meta-coupled protons (Fig. 1); the ortho coupled proton moving to low field by 3 c/s, the ortho and meta coupled remaining essentially unchanged, and the meta-coupled proton resonance appearing at low field by 11–13 c/s. This low-field shift is most likely due to association of the amino group on the aromatic ring with the hydrazine.

In *m*-nitrocresol, a limitation existed in that, upon addition of a drop of hydrazine to the deuterochloroform solution, a red–orange solid separated. As a result, the chemical shifts (Table I) were obtained by the addition of a drop of deuterochloroform, containing tetramethylsilane, to the anhydrous hydrazine solution. The high-field shifts imply association or interaction with the hydroxyl function and the nitro group.

This study not only applied to amino and phenolic functions on aromatic rings but

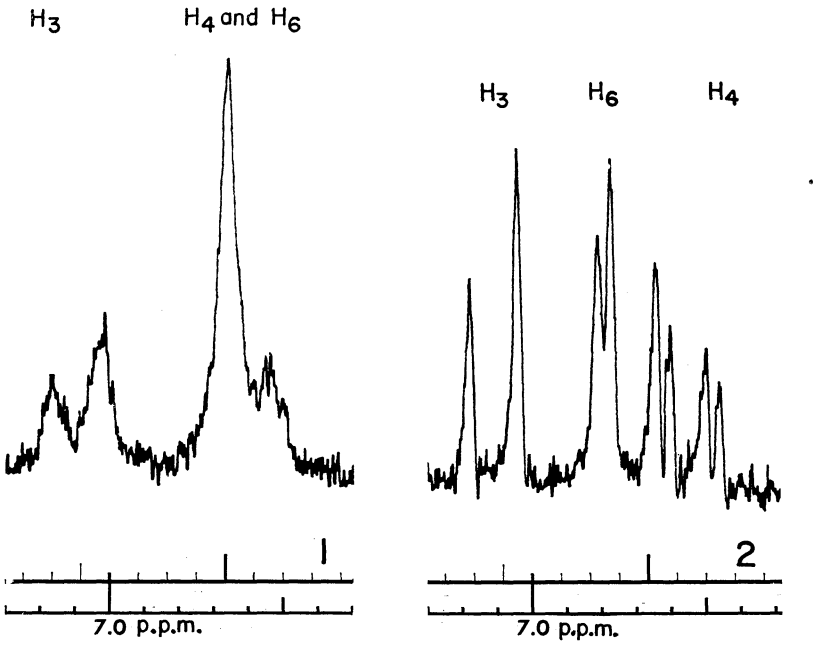

FIG. 1. The aromatic protons of 2,5-dichloroaniline in deuterochloroform using internal $(CH_3)_4Si$.
FIG. 2. The spectrum of 2,5-dichloroaniline in hydrazine demonstrates the effect of hydrazine on the ring protons.

also to systems such as indoles and substituted indoles with the only limitation being the solubility of the organic material in the anhydrous hydrazine. Some of the aromatic compounds studied were *p*-amino-N,N-dimethylaniline, 3-ethoxyaniline, 2-fluoroaniline, and aniline, as well as the various toluenediamine isomers.

EXPERIMENTAL

The n.m.r. spectra were obtained by means of the Varian Associates A-60 spectrometer. The chemical shifts were measured relative to internal tetramethylsilane and in the case of anhydrous hydrazine, a drop of chloroform containing tetramethylsilane was added. In addition, the spectra were obtained in anhydrous hydrazine and no changes were observed which might be due to the addition of a drop of tetramethylsilane in deuterochloroform.

ACKNOWLEDGMENT

The authors wish to thank Mr. G. D. Vickers for his part in this study and the determination of the purity of the anhydrous hydrazine and Dr. Allan P. Gray for his comments and observations.

HALOGEN MIGRATION AND ELIMINATION IN THE CLAISEN REARRANGEMENT OF ALLYL 2,6-DIHALOPHENYL ETHERS[1]

E. PIERS AND R. K. BROWN

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received June 17, 1963

ABSTRACT

A study has been made of some factors affecting the migration or elimination of halogen in the Claisen rearrangement of allyl 2,6-dihalophenyl ethers.

In the thermal rearrangement of allyl 2,6-dichlorophenyl ether, carried out in a number of solvents of different dielectric constant, halogen migration proceeds somewhat better in highly polar solvents. However, a competitive reduction to the monohalogenated allylphenol occurs in the presence of oxidizable solvents and/or products. The reaction is also complicated by the catalytic effects of certain solvents and the phenolic products, which give results similar to those obtained with Lewis acids. Stannous chloride acts as a Lewis acid and catalyzes the rearrangement of allyl 2,6-dichlorophenyl ether with simultaneous halogen rearrangement. As well, a competitive reductive removal of the halogen takes place. Results from the rearrangement of allyl 2,6-dibromophenyl ether with zinc chloride and of allyl 2,6-dichlorophenyl ether with zinc bromide, as well as those from the stannous chloride reactions indicate that the halogen *migration* takes place not only by an allylic shift but also via a competitive halogen *substitution* probably occurring by an S_N2' pathway possibly assisted by a zinc halide bridge mechanism and/or an ionic species such as $ZnX_2Y^{\ominus}$.

INTRODUCTION

In a recent publication (1) it was shown that the thermal Claisen rearrangement of allyl 2,6-dichlorophenyl ether gave not only the previously reported products, 4-allyl-2,6-dichlorophenol and 2-allyl-6-chlorophenol (2), but also a small yield (2%) of the halogen migration product, 2-allyl-4,6-dichlorophenol. The proportion of the halogen migration product increased to 7% and 11% respectively if the thermal rearrangement was conducted in nitrobenzene and in nitrobenzene containing lithium chloride. Addition of the Lewis acid, anhydrous zinc chloride, to a nitrobenzene solution of allyl 2,6-dichlorophenyl ether not only accelerated the rate of rearrangement but also increased the proportion of 2-allyl-4,6-dichlorophenol to as much as 91% of the product (1). It was suggested that the migration of the halogen occurred during the dienone intermediate stage partly by an allylic rearrangement assisted by increased polarity of solvent and/or the presence of the Lewis acid, and partly by a zinc halide bridge mechanism (Fig. 1, routes *a* and *b*). The work reported in the present paper was designed to give additional information concerning the mechanism of rearrangement of the halogen atom.

RESULTS AND DISCUSSION

Thermal Rearrangement of Allyl 2,6-Dichlorophenyl Ether in Various Solvents

To determine the effect of polarity of solvent on the extent of halogen migration, the

For personal use only.

thermal rearrangement of allyl 2,6-dichlorophenyl ether was carried out in a number of solvents* whose polarity, as indicated by their dielectric constant, differed widely. The results are shown in Table I. Although the dielectric constant of a substance generally decreases with increase in temperature, it is reasonable to assume that the *relative* dielectric constants, and hence relative polarity, of a number of solvents would be roughly the same at 170–190° (the temperature of our reaction) as they are at 20° (the temperature at which the dielectric constants are usually measured). Some support for this view is obtained by comparison of the dielectric constant values of several organic liquids at various temperatures (3).

A. Occurrence of Ether Cleavage

In phenol, 10% of the total product of the rearrangement was the ether cleavage material 2,6-dichlorophenol, and 5% of the product was a substance identified as 2-methyl-7-chlorocoumaran, obviously obtained by the cyclization of 2-allyl-6-chlorophenol. Both of these products are characteristic of the zinc chloride catalyzed rearrangement (1) and indicate that phenol not only catalyzes the Claisen rearrangement as has been shown by Goering and Jacobson (5) but also acts in a manner somewhat like that of a Lewis acid by causing ether cleavage as well as coumaran formation. In both N,N-diethylformamide and N-methylformamide the cleavage product also occurred (to the extent of 8% and 6% respectively) but unaccompanied by coumaran formation. A great deal of decomposition took place in these two solvents. The cause of the formation of the cleavage product is not known.

B. Occurrence of Reductive Removal of Halogen

The reduction product, 2-allyl-6-chlorophenol, was found in larger amount in those solvents most easily oxidized. Thus, in decalin, a non-polar solvent wherein considerable decomposition took place during the reaction, 64% of the product was 2-allyl-6-chlorophenol. It is possible that the phenolic products could act as reducing agents under the reaction conditions to yield the monochlorophenol, as is likely in the case of experiment No. 4 where no solvent was used, or in benzonitrile (experiment 6) or in nitrobenzene solutions (experiments 8 and 9). However, for the decalin solution, the fact that the reduction product, 2-allyl-6-chlorophenol, appeared even at a very early stage of the reaction when relatively little phenolic product was present, and that it was present in such a large proportion at the end of the reaction, indicates that the solvent decalin did participate as a reducing agent. Due to the extensive decomposition it was impossible to isolate oxidation products of decalin, such as tetralin etc. to support this view. In N-methylformamide and N,N-diethylformamide, much decomposition took place and the proportion of reduction product was 59% and 23% respectively, presumably also as result of facile oxidation of the solvent and/or its decomposition products.

C. Occurrence of Halogen Migration

In non-acidic solvents of low polarity (diphenyl ether, *o*-dichlorobenzene, allyl 2,6-dichlorophenyl ether) little or no halogen migration occurred (0–2%). The exception to this was decalin wherein 6% of the product was 2-allyl-4,6-dichlorophenol. Since very little of this compound appeared *before 50%* of the original ether had disappeared, it is likely that the phenolic products, associating minimally with the non-polar solvent decalin, and therefore to a greater extent with the remaining unreacted ether, aided the rearrangement of the halogen via a protonation or hydrogen bonding of the acidic proton in the

**The number of solvents was necessarily limited to those of suitable physical characteristics and chemical inertness.*

9	Nitrobenzene + LiCl, 180–185°, 3 hr	?	Nil	15	11	74	Moderate amount of decomposition
10	N-Methylformamide 180°, 2.7 hr	190	6	59	25	10	Very much decomposition

*In all cases the reaction time was extended until all of the original ether had disappeared.

†The solvents were arranged in order of increasing dielectric constant (at 20°). Those whose dielectric constants are unknown to us were placed in the order expected, e.g. N,N-diethylformamide is expected to have a dielectric constant not too much different from that of dimethylformamide (37.6). Values of the dielectric constants were obtained from A. A. Maryotte and E. R. Smith, Table of dielectric constants of pure liquids, Natl. Bur. Std., Circ. 514, 1951; reference 3; and reference 4, p. 43. Those for N-methylformamide and N,N-dimethylformamide were obtained from G. R. Leader and J. F. Gormley, J. Am. Chem. Soc., **73**, 5731 (1951).

‡Separate tests showed that in all cases the products were stable under the reaction conditions.

§Analysis of samples of the reaction mixture showed that 2-allyl-6-chlorophenol was formed very early in the reaction (10% after 0.5 hour) and that only very little (1%) of 2-allyl-4,6-dichlorophenol was formed before 50% of the original ether had disappeared.

‖Experiment 5 also gave 5% of a substance which was found to be 2-methyl-7-chlorocoumaran, no doubt derived from the cyclization of some of the 2-allyl-6-chlorophenol in the presence of the acidic phenol solvent. No coumaran was found in any of the other cases.

phenol with the allylic halogen in the intermediate dienone stage, thus promoting the ionization of the allylic halogen. Similarly, rearrangement of halogen in the solvent phenol no doubt is assisted not only by the polarity of the solvent but probably more so by the same effect mentioned above, resulting in the products characteristically produced in the presence of Lewis acids.

In the more highly polar but non-acidic solvents, those of dielectric constant greater than 30 (nitrobenzene, nitrobenzene + LiCl, N,N-diethylformamide, and N-methylformamide) there is a larger extent of halogen migration (7% to 38%). However, the amount of halogen migration does not parallel the polarity of the solvent as expressed by dielectric constant (D.C.) values since N-methylformamide (D.C. = 190) yields 25% of the product as 2-allyl-4,6-dichlorophenol while N,N-diethylformamide (D.C. = 38) yields 38% of the product as halogen-migrated material. However, this can be rationalized if one considers that at the dienone stage there are two competing reactions, one in which the halogen undergoes allylic rearrangement and the other in which the allyl group migrates to the C_4 position. At this stage the halogen migration from C_2 to C_4 is assisted by the greater polarity of solvent while allyl migration from C_2 to C_4 is influenced only minimally if at all by increased solvent polarity (5). Thus the ratio of chlorine migration to allyl rearrangement should give an indication of the effect of polarity of solvent on the extent of halogen migration. In N-methylformamide the ratio is 25/10 while in N,N-diethylformamide it is 38/31. The larger ratio in N-methylformamide parallels its larger dielectric constant. The reductive removal of halogen, greater in the case of N-methylformamide than for N,N-diethylformamide, also must occur at the dienone stage and thus competes with halogen migration. It is likely that if this reductive removal of halogen were not present, the difference in the ratios of halogen to allyl migration in the solvents N-methylformamide and N,N-diethylformamide would be even greater.

Benzonitrile (D.C. = 25.2) is considered to be a polar solvent, yet very little of either the halogen migration product, 2-allyl-4,6-dichlorophenol (3%), or the reduction product, 2-allyl-6-chlorophenol (2%), was formed.

D. Summary re Factors which Affect Halogen Migration and Reductive Removal of Halogen

From the experiments shown in Table I it is seen that a highly polar solvent (expt. 7–10) does assist in the halogen migration as well as in the reductive removal of one of the halogen atoms, with the latter reaction depending upon the presence of an oxidizable substance. However, acidic solvents of lower polarity (and this includes phenolic products of the reaction to some extent) can accomplish the same thing. From the results with benzonitrile it appears that a moderate polarity of the solvent does not promote rearrangement significantly, but requires some additional factor. There is thus no linear comparison between rearrangement of halogen and polarity of solvent due to the complicating effects of solvent and product acidity as well as the effects of the decomposition products.

The Rearrangement of Allyl 2,6-Dichlorophenyl Ether in the Presence of Stannous Chloride

Carlin *et al.* (6) had found that several 2,6-dichlorophenylhydrazones, heated to 260° with a large excess of anhydrous stannous chloride, gave only the corresponding 7-chloroindoles, and these only in small yield (3–17%). Apparently no 5,7-dichloroindole, the result of halogen migration, was obtained. In view of the observation that the presence of oxidizable substances did cause a competitive reductive removal of one halogen atom during the Claisen rearrangement, it was of interest to discover whether stannous chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

would yield only the monohalo product, 2-allyl-6-chlorophenol, analogous to the finding by Carlin concerning the Fischer indole synthesis (6). The results of the rearrangement of allyl 2,6-dichlorophenyl ether in the presence of stannous chloride are shown in Table II.

A. Stannous Chloride as a Lewis Acid

There is no doubt that the presence of stannous chloride accelerates the Claisen rearrangement since, for example, in 8 hours 30% of the original ether was left when stannous chloride was used, whereas without stannous chloride under otherwise identical conditions 60% of the ether remained after 8 hours' time (Table II columns 1 and 2, compare sections A and B). Furthermore, both the ether cleavage product, 2,6-dichlorophenol, and the coumaran were formed in the presence but not in the absence of stannous chloride. These products are characteristic of Lewis acid catalyzed rearrangements of the allyl phenyl ethers and do not appear in the purely thermal rearrangement. Thus stannous chloride does behave as a Lewis acid.*

B. Halogen Rearrangement and Reductive Removal

Both the reduction product, 2-allyl-6-chlorophenol, and the halogen migration product, 2-allyl-4,6-dichlorophenol, are formed, the former in somewhat larger amount in the first 6 hours of reaction but in a relatively lesser amount by the end of the reaction.†

The possibility that a large excess of stannous chloride might increase the amount of reduction product was examined. The solubility of stannous chloride in *o*-dichlorobenzene is quite limited, hence relatively dilute solutions of reagents were employed in this experiment. A mixture of 1.25 g (0.006 mole) of allyl 2,6-dichlorophenyl ether and 2.5 g (0.012 mole) of stannous chloride‡ in 125 ml of *o*-dichlorobenzene, when heated to 150–155° for 24 hours, gave only two products, the 2-allyl-6-chlorophenol (reduction product), 37%, and 2-allyl-4,6-dichlorophenol (rearrangement product), 63%. Thus, an increase in the proportion of stannous halide enhanced the proportion of halogen rearrangement. This is in contrast to the findings of Carlin, Wallace, and Fisher (6), who added their hydrazones to an excess of fused (260°) stannous chloride. Such vigorous conditions might account for their failure to find any dihalogenated indole.

The Rearrangement of Allyl 2,6-Dichlorophenyl Ether in the Presence of Anhydrous Zinc Bromide and of Allyl 2,6-Dibromophenyl Ether in the Presence of Anhydrous Zinc Chloride

It was suggested (1) that the halogen migration in the zinc chloride catalyzed Claisen rearrangement of allyl 2,6-dichlorophenyl ether might occur via a zinc chloride§ bridge as shown below (Fig. 1, route *a*). Alternatively, the Lewis acid could promote ionization and create an ion pair which could then rearrange more readily (route *b*) in a manner similar to that which takes place in the thermal rearrangement of the halogen. Route *b* might also be modified to give a species such as $ClZnX_2^{\ominus}$ which could then cause substitution at C_4 by $X^{\ominus}$ as well as enhance migration of $Cl^{\ominus}$. In addition to these routes,

**It is possible that the accumulating stannic chloride is responsible at least in part for the acceleration of reaction. However, it cannot be completely so, since if stannous chloride were not a Lewis acid, some 4-allyl-2,6-dichlorophenol (the product from thermal rearrangement) would have been formed at least in the early stages of the reaction. No 4-allyl-2,6-dichlorophenol was detected.*

†It is possible that the accumulating stannic chloride from the reduction process could be responsible for the increasing proportion of migration product as compared with the reduction product as the reaction progressed.

‡Nearly all of this quantity of stannous chloride went into solution.

§The state of the zinc halides under the conditions of our reactions is not certain. In an organic solvent which only partially dissolves the zinc halides, there might exist a mixture of monomeric, dimeric, and higher aggregate species possibly existing in part, for example, as $ZnX^{\oplus}ZnX_3^{\ominus}$. *Because of the lack of more precise information, the designation* ZnX_2 *is used for simplicity.*

*Separate tests showed that in all cases the products were stable under the reaction conditions, except that in the presence of stannous chloride the 2-allylphenols were converted partly to their respective 2-methylcoumarans.

†A considerable portion of the stannous chloride remained undissolved.

‡Nearly all the stannous chloride dissolved.

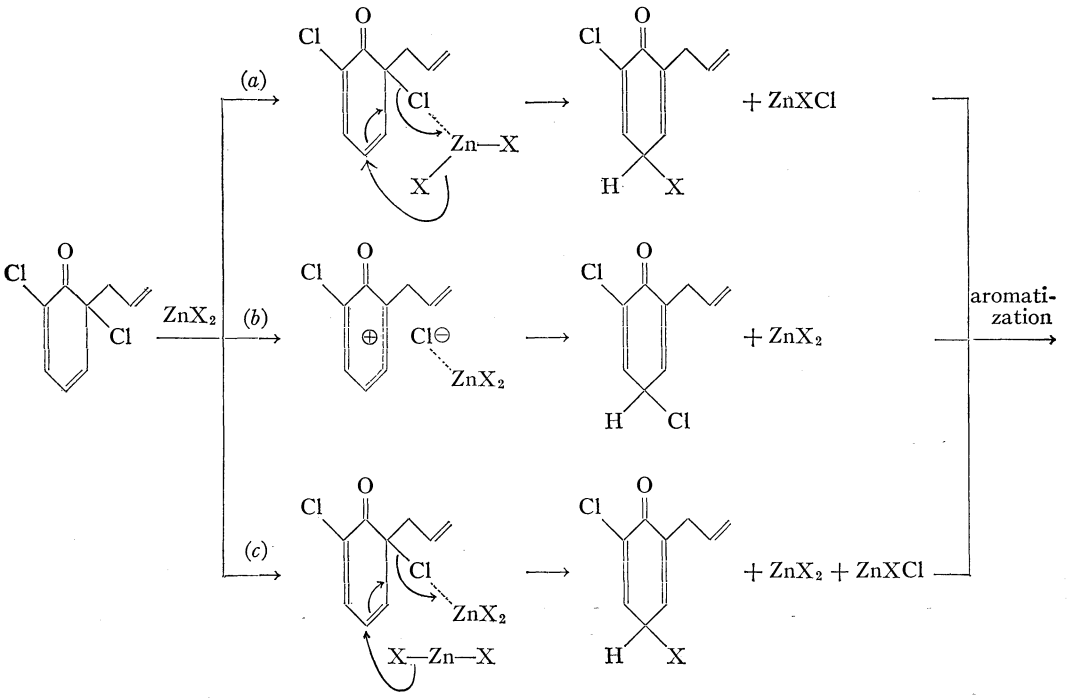

FIG. 1. Mechanistic routes for halogen migration.

halogen rearrangement might be accomplished by an S_N2' mechanism (reference 4, pp. 127–131) involving attack by the metal halide, with or without assistance of the Lewis acid, on the allylic system (route *c*).

In an effort to determine whether all or some of these schemes contribute in the rearrangement of the 2,6-dihalophenyl ethers in the presence of a Lewis acid, the rearrangement of allyl 2,6-dichlorophenyl ether was carried out in the presence of anhydrous zinc bromide. As well, allyl 2,6-dibromophenyl ether was rearranged in the presence of anhydrous zinc chloride. A high proportion of 2-allyl-4-bromo-6-chlorophenol in the first case and of 2-allyl-4-chloro-6-bromophenol in the second would favor the zinc halide bridge concept (Fig. 1, route *a*) and/or the S_N2' mechanism (Fig. 1, route *c*). The results of these experiments are shown in Tables III and IV.

A number of observations can be made from the information in Tables III and IV.

(i) No Rearrangement of the Allyl Group to the Para Position

In neither case was there any indication of the formation of 2,6-dihalo-*p*-allylphenol, the product found in large amount in the purely thermal rearrangement (Table I). Apparently the presence of the Lewis acid was sufficient to cause, at the dienone intermediate stage, reaction exclusively with the halogen atom.

(ii) Little or No Reductive Removal of Halogen

The zinc bromide catalyzed reaction of the dichloro ether (Table III) showed no evidence of reductive removal of a chlorine atom. On the other hand, approximately 3% of the product of the zinc chloride catalyzed reaction of the di*bromo* ether (Table IV, columns 3 and 4) was the monobromo reduction product. Thus, the carbon–bromine bond is more susceptible to the competitive reductive cleavage than is the carbon–chlorine bond.

§The ratios are obtained by comparing the sums of the 4,6-dihalophenol and 5,7-dihalocoumaran in each case, i.e. the sums of columns 5 and 6 vs. 7 and 8.

(iii) Ether Cleavage, Dependent upon Temperature and the Presence of Water

Cleavage of the ether to the 2,6-dihalophenol in both instances increased with increase in temperature of the reaction, but was more pronounced when zinc bromide was the catalyst. It is noteworthy that, in contrast to the results obtained with zinc chloride as catalyst, those for the zinc bromide catalyzed reactions were difficult to reproduce in duplicate reactions. Commercial anhydrous zinc bromide* itself was particularly bad in this regard, hence it was heated to its melting point (as was done for zinc chloride) to drive off traces of water. If one prepared zinc bromide in this way and then allowed it to cool in a desiccator containing P_2O_5 and dry nitrogen, and as well stored the desiccator in a dry box (P_2O_5) flushed with dry nitrogen and then carried out all weighings, transfers, and mixing manipulations in this dry box, considerable improvement in reproducibility was found, although the results even then were not entirely satisfactory. Traces of water could be the cause of this difficulty in variability of results. Zinc bromide from our observations was found to be considerably more hygroscopic than was zinc chloride. Furthermore, the addition of one drop of water to the reaction mixture containing zinc bromide catalyst (Table III, 26 hour run at 130–135°) increased the amount of ether cleavage. It is already known that addition of a small amount of water to anhydrous boron trifluoride does enhance the catalytic power of this Lewis acid, probably by production of a proton according to the reaction $BF_3 + H_2O \rightleftarrows BF_3(OH)^{\ominus} + H^{\oplus}$ (7–10).

The greater effectiveness of zinc bromide as compared with zinc chloride in causing cleavage of the ether and also in promoting cyclization of the *o*-allyl-4,6-dihalophenols to the coumarans (a distinctly acid-catalyzed reaction) might be due to a somewhat stronger Lewis acid character of zinc bromide. Analogously, aluminum bromide is considered to be a more effective catalyst in the Friedel and Crafts reaction than is aluminum chloride (11). Also, it has been shown that the electrophilicities of the boron halides towards pyridine or nitrobenzene are in the order $BF_3 < BCl_3 < BBr_3$ (12). To our knowledge no such comparison has yet been reported concerning the aluminum halides (or zinc halides) although such work has been under consideration (12). If one can extrapolate these results to the zinc halides, support is thus obtained for the view that zinc bromide is a stronger Lewis acid than is zinc chloride. The greater solubility of zinc bromide in nitrobenzene as observed in our work indicates greater coordinating power with the solvent. On the other hand, the greater solubility of the bromide in nitrobenzene, as well as that of aluminum bromide in benzene in the Friedel and Crafts reaction (11), could well explain the greater catalytic effect observed. The limited amount of information available precludes any definite conclusion as yet concerning the cause of the greater activity of the zinc bromide.

(iv) Allylic Halogen Migration in Competition with Halogen Substitution by Halide Ion

The ratio of halogen *substitution* to halogen *migration* increased with temperature for the zinc chloride catalyzed rearrangement of allyl 2,6-dibromophenyl ether but decreased slightly for the zinc bromide catalyzed rearrangement of allyl 2,6-dichlorophenyl ether. Under the same conditions, more bromine (from $ZnBr_2$) replaced chlorine than chlorine (from $ZnCl_2$) replaced bromine in the dihalo ethers, but the difference was nearly eliminated at the higher temperature (150–155°). It is clearly seen that predominant substitution, which must occur if the zinc halide bridge concept and/or S_N2' mechanism is 100% operative, does not take place. Hence halogen "migration" can occur only partially, if at all, by one or both of these processes. Alternatively, simple allylic rearrangement of the

**Reagent grade material obtained from Matheson, Coleman and Bell, Norwood, Ohio, U.S.A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

halogen atom at the dienone stage, with the assistance of the zinc halide, and involving a rather tight ion pair (route *b*) is also not completely operative since halogen substitution is quite substantial.

Conclusions as to Possible Mechanistic Routes in Halogen Migration and/or Substitution in the Zinc Halide Catalyzed Rearrangement of Allyl 2,6-Dihalophenyl Ethers

Unquestionably, the Lewis acids exert a marked control over these reactions. The absence of *para*-allyl rearrangement must mean that the zinc halide must first be associated with the allylic halogen of the dienone intermediate stage in every case. Subsequently, only halogen substitution and halogen migration, and in some cases reductive halogen elimination, take place.

The results shown in Tables III and IV might be interpreted in terms of the modified route *b* involving the species $ZnClBr_2^{\ominus}$ and $ZnBrCl_2^{\ominus}$ respectively. Thus, in the rearrangement of allyl 2,6-dichlorophenyl ether in the presence of $ZnBr_2$, the carbonium ion could abstract from $ZnClBr_2^{\ominus}$ either a chloride ion to form the dichloro "migration" product or a bromide ion to give the chlorobromo "substitution" product. One would expect that more bromide than chloride ion would be extracted on the basis of both the greater nucleophilicity and greater amount of bromine atoms in the species $ZnClBr_2^{\ominus}$, hence giving rise to a high ratio of bromine substitution to chlorine migration. The ratio actually found is only about 1.2 to 1.3 at 130–135°. On the other hand, for the $ZnCl_2$ catalyzed rearrangement of the di*bromo*ether, where the involvement of the species $ZnBrCl_2^{\ominus}$ is suggested, the ratio of bromine "migration" to chlorine "substitution" at C_4 is 1.8 (i.e. 1/0.56) at the same temperature. One would expect the reverse on the basis of relative amount and nucleophilicity of the halogen. Furthermore, the decrease of these ratios to nearly 1.0 in both cases as the temperature of reaction rose from 130° to 150–155° cannot readily be explained solely by this reaction path. Hence the modified route *b* can contribute only partly to the reaction.

The formation of a greater amount of the product, 2-allyl-4,6-dichlorophenol, as compared with the reduction product, 2-allyl-6-chlorophenol rather than the reverse when the proportion of stannous chloride to the dichloroether was increased (Table II) can be taken as support for the participation of a second molecule of stannous chloride in an S_N2' reaction (route *c*) in competition with reduction. However, from the results of the zinc bromide and zinc chloride catalyzed reactions (Tables III and IV) it is clear that substantial amounts of migration product occurred and therefore a scheme such as *c* can contribute only partly to the reaction.

The results of the zinc bromide catalyzed rearrangement of allyl 2,6-dichlorophenyl ether (Table III) in which the ratio of halogen substitution product to halogen migration product decreases from 1.5 at 100–110° to 1.1 at 150–155° can be rationalized as a competition between the slower allylic migration of chlorine and the reaction by an S_N2' pathway (route *c*) and/or zinc halide bridge (route *a*). Higher temperatures facilitate the breaking of the carbon–chlorine bond and hence route *b* becomes more important, decreasing the ratio of bromine to chlorine attachment at C_4.

The more readily ionizable carbon–bromine bond in the dibromoether (Table IV, catalysis by $ZnCl_2$) would permit greater contribution of allylic halogen migration (route *b*) even at the lower temperature of 130°. Higher temperatures could cause the formation of the species $ZnBrCl_2^{\ominus}$ and modified mechanism *b* could become predominant, thus decreasing the amount of bromine relative to chlorine attachment at C_4.

It is clear that the zinc halide catalyzed reactions of the allyl 2,6-dihalophenyl ethers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

are quite complex and that the results obtained so far cannot be explained solely on the basis of any one of the suggested routes. It is likely that contributions from several or all might be involved in the halogen migration and substitution reactions.

EXPERIMENTAL

Analyses by Gas Chromatography

A Burrell Model K-2 Kromo-Tog, equipped with an integrator and with helium as the carrier gas, was used for all analyses. A 2 m column, packed with 20% Apiezon L on Gas Chrom P (60–80 mesh), afforded good separation of components of the mixtures into clearly resolved peaks. Analyses of carefully weighed authentic mixtures of the reaction products showed that the paper areas of the peaks could be used as a direct measure of the molar compositions of the reaction mixtures. Products were identified by comparison of their retention times with those of authentic samples and/or by means of infrared spectroscopy as well as n.m.r. analyses (Varian H-60).

2,6-Dibromophenol

Decarboxylation of 3,5-dibromo-4-hydroxybenzoic acid (148 g, 0.5 mole) (13) according to the procedure used by Tarbell and co-workers for the corresponding dichloro compound (14) afforded 112 g (89%) of 2,6-dibromophenol, m.p. 55–56° (from hexane). Lit. m.p. 56–57° (15).

Preparation of Ring-Halogenated Allyl Phenyl Ethers

The method previously described (1) for the preparation of allyl 2,6-dichlorophenyl ether was employed to obtain a number of ethers necessary for the present work. The required phenols were all commercially available. A summary of the properties and yields of the ethers is given in Table V.

TABLE V

Allyl phenyl ethers

Ring substituents	Yield, %	Boiling point, °C (mm) Found	Reported	Ref.
2-Chloro	89	100–102 (11)	108–110 (15)	2

Preparation of Ring-Halogenated 2-Allylphenols

Several 2-allylphenols were obtained from the correspondingly substituted allyl phenyl ethers by rearrangement according to the following general procedure.

A solution of the allyl phenyl ether (0.2 mole) in 80 ml of diphenyl ether was heated with stirring, under an atmosphere of nitrogen, to 205–210° and kept at this temperature for 3 hours. When the solution had cooled, it was diluted with 400 ml of commercial pentane and extracted thrice with Claisen's alkali (19). The combined alkaline extracts were washed several times with pentane, thoroughly cooled in an ice-water bath, acidified with concentrated hydrochloric acid and then twice extracted with pentane. The combined extracts were washed with saturated salt solution and dried with anhydrous sodium sulphate. Removal of the solvent gave an oil which was distilled under vacuum through a short Vigreux column, thus giving the desired phenol. The results are tabulated in Table VI.

Preparation of Halogenated 2-Methylcoumarans

The general procedure reported in the literature (18) was employed to obtain the halogenated 2-methylcoumarans from the corresponding halogen-substituted 2-allylphenols. The results are shown in Table VII.

Thermal Rearrangement of Allyl 2,6-Dichlorophenyl Ether in Various Solvents. General Procedure

Dried and redistilled solvent (50 ml) was stirred and heated, under an atomsphere of purified dry nitrogen, to the desired temperature and then allyl 2,6-dichlorophenyl ether (10 g, 0.05 mole) slowly added over a period of approximately 30 minutes. The resulting solution was then heated for the required time, cooled,

and then analyzed directly for products by vapor phase chromatography (v.p.c.) by injecting aliquots of the reaction solution into the Kromo-Tog. The results are recorded in Table I.

Zinc Halide Catalyzed Rearrangement of Allyl 2,6-Dihalophenyl Ethers. General Procedure

A quantity (0.1 mole) of anhydrous zinc halide (prepared by heating the salt to the molten state, cooling it in a desiccator in a dry box flushed with nitrogen, and then grinding it under anhydrous conditions in the dry box) was stirred into 50 ml of dry ether. The mixture was then gently heated to permit evaporation of the ether while dried, redistilled nitrobenzene (41 g) was slowly added. The resulting mixture was heated to the desired rearrangement temperature. Much of the zinc halide remained undissolved as a suspension. After slow addition of the allyl 2,6-dihalophenyl ether (0.05 mole), the resulting mixture was stirred and heated under an atmosphere of purified, dry nitrogen for the specified time. The reaction mixture was then cooled and poured into a mixture of ether and water (1:1). When the resulting solution was filtered, the ether layer was separated, washed twice with saturated salt solution, and then dried (Na_2SO_4). Removal of the ether gave a mixture of reaction products which was analyzed directly by v.p.c. The results are recorded in Tables III and IV.

Rearrangement of Allyl 2,6-Dichlorophenyl Ether in the Presence of Stannous Chloride

(*a*) Anhydrous powdered stannous chloride (9.5 g, 0.05 mole) (21) was stirred into 50 ml of dried, redistilled *o*-dichlorobenzene. After the mixture had been heated to 150–155° under an atmosphere of purified, dry nitrogen, allyl 2,6-dichlorophenyl ether (10 g, 0.05 mole) was slowly added. The reactants were then heated at 150–155° for 24 hours. The cooled material was treated as described above for the zinc halide catalyzed rearrangements and product analysis carried out directly by v.p.c. The results are recorded in Table II.

(*b*) Procedure (*a*) was repeated, employing 1.25 g (0.006 mole) of allyl 2,6-dichlorophenyl ether and 2.5 g (0.012 mole) of stannous chloride in 125 ml of dried, redistilled *o*-dichlorobenzene. After treatment of the cooled reaction mixture as described above, 50 ml of *o*-dichlorobenzene was removed by careful fractional distillation under vacuum. The distillate was shown by v.p.c. to be pure solvent, containing no phenolic products. The residual solution was analyzed by v.p.c. and the results recorded in Table II, section C.

Stability Tests on Products under Reaction Conditions

In all cases synthetic mixtures of the products of the reactions were shown, by the use of an internal

For personal use only.

standard (*n*-tetradecane) in the v.p.c. analysis, to be stable within the limits of experimental error. However, in the case of the metal halide catalyzed reactions the 2-allylphenols were converted in part or completely to the corresponding stable 2-methylcoumarans and to no other product.

ACKNOWLEDGMENT

The authors gratefully acknowledge the generous financial assistance given by the National Research Council of Canada throughout the course of this work. One of us (E. P.) thanks the National Research Council for the award of a Studentship.

THE METHYL 3-NITRO-3-DEOXY- AND 3-AMINO-3-DEOXY-ARABINOPYRANOSIDES[1]

HANS HELMUT BAER AND ALAUDDIN AHAMMAD[2]
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received July 16, 1963

ABSTRACT

The nitromethane cyclization of L′-methoxy-diglycolic aldehyde was shown to furnish methyl 3-nitro-3-deoxy-α-L-arabinopyranoside and methyl 3-nitro-3-deoxy-β-D-arabinopyranoside as coproducts of the previously obtained β-D-*ribo* isomer. As expected, the enantiomorphic dialdehyde, D′-methoxy-diglycolic aldehyde, afforded the corresponding α-D- and β-L-*arabino* derivatives in addition to the β-L-*ribo* isomer. Catalytic hydrogenation of the four new nitroglycosides gave the corresponding aminoglycoside hydrochlorides. The 3-amino-3-deoxy-D- and L-arabinose hydrochlorides were obtained from their glycosides by hydrolysis and crystallized as mutarotating β-forms.

The spontaneous epimerization, in aqueous solution, of *aci*-nitropentoside sodium salts was investigated.

In the cyclization (1), with nitromethane and sodium methoxide, of L′-methoxy-diglycolic aldehyde (I) a methyl *aci*-nitrodeoxy pentoside sodium salt had been isolated in crystalline condition in a yield of about 40%. This salt had been shown to possess formula II and must therefore be denoted as methyl 3-*aci*-nitro-3-deoxy-β-D-*erythro*-pentopyranoside sodium.[3] Manifold experiences gathered subsequently in similar nitromethane condensations and recorded in papers of this series have borne out the hardly surprising fact that this type of reaction does not proceed in a stereospecific way, although a notable stereoselectivity is always observed. It was of interest, therefore, to investigate whether, and to which extent, stereoisomers of II were formed in the reaction which produced the latter as the apparent main product. The three possible stereoisomers of II which might arise from the dialdehyde I are the corresponding α-L-*threo* (III), β-D-*threo* (IV), and α-L-*erythro* (V) 3-deoxypentose derivatives. The present study was intended, furthermore, to uncover the cause of the previously observed mutarotation of II; i.e. to verify in the pentose series that glycoside nitronates in solution are liable to undergo spontaneous epimerizations, as has been found to be the case with nitronates derived from hexosides (2, 3).

We are now able to demonstrate that when dialdehyde I is cyclized with nitromethane, the α-L-*threo* and β-D-*threo* forms of methyl 3-*aci*-nitro-3-deoxypentopyranoside sodium (III and IV, respectively) indeed occur in the reaction mixture as minor components beside the chief product, β-D-*erythro* salt II. Although the salts III and IV could not be isolated as such, their presence was indicated by the isolation of two new, free nitroglycosides that arose upon deionization of the mixture. Thus, methyl 3-nitro-3-deoxy-α-L-arabinopyranoside (VI), originating from III, and methyl 3-nitro-3-deoxy-β-D-arabinopyranoside (VII), arising from IV, were obtained in yields of approximately 5% each. These crystalline nitroglycosides were hydrogenated to furnish the corresponding aminoglycosides, which crystallized as hydrochlorides: methyl 3-amino-3-deoxy-α-L-arabinopyranoside hydrochloride (VIII) and methyl 3-amino-3-deoxy-β-D-arabinopyranoside

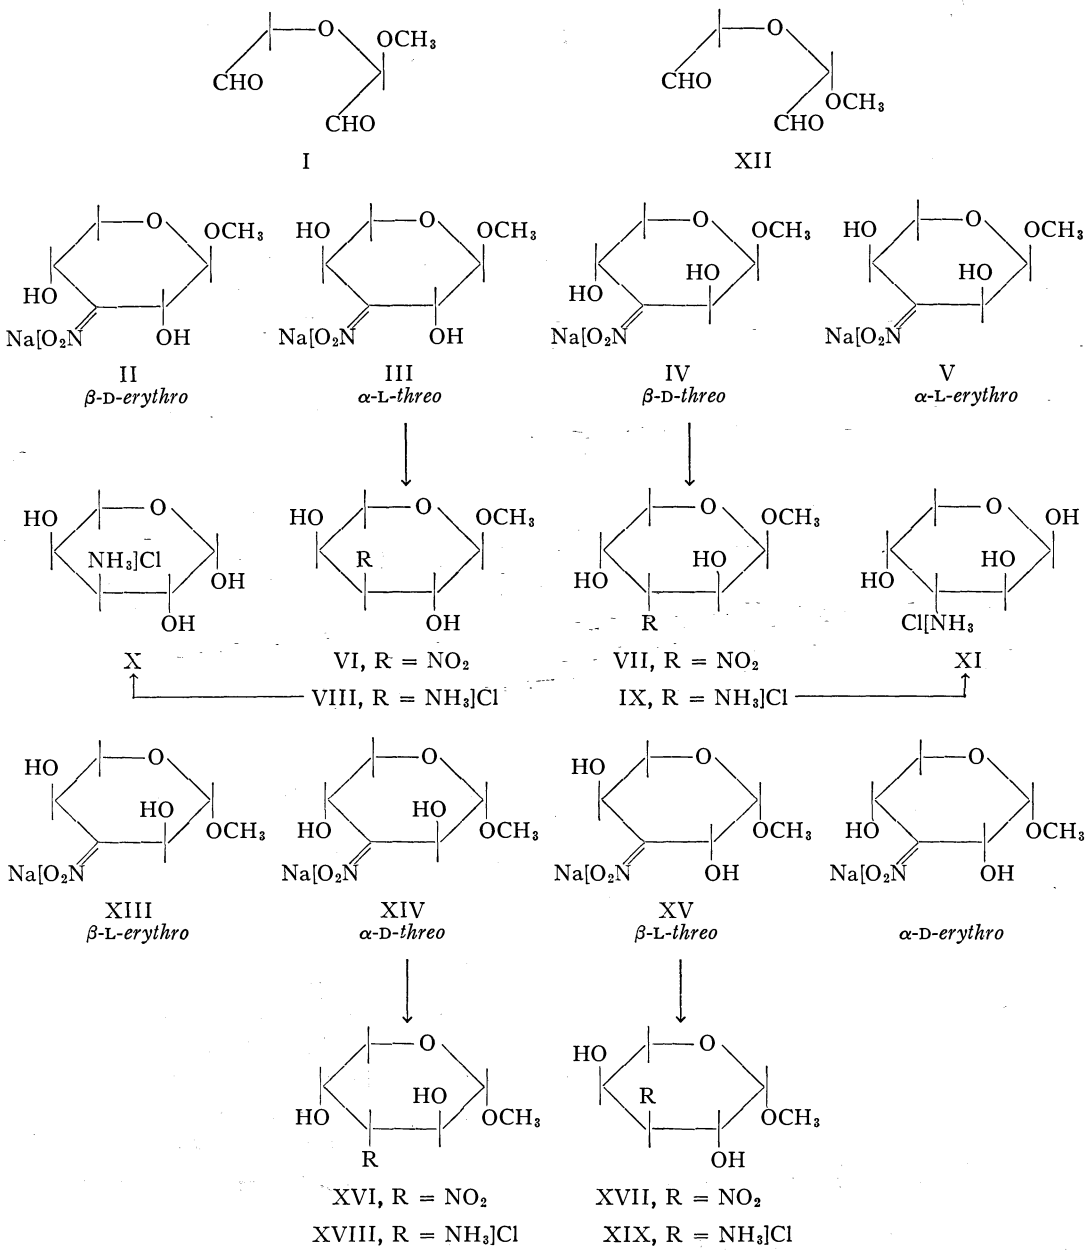
hydrochloride (IX). Proof of the structure and configurations of VIII and IX was afforded by acid hydrolysis yielding reducing amino sugars. Glycoside IX gave 3-amino-3-deoxy-D-arabinose hydrochloride (XI), which has been described by Baker, Schaub, and Williams, (4). We obtained an upward-mutarotating β-form ($[\alpha]_D$ $-147° \rightarrow -113°$). Glycoside VIII afforded the hitherto unknown enantiomorph of XI, namely 3-amino-3-deoxy-L-arabinose hydrochloride (X). Belonging to the L-series and exhibiting downward mutarotation ($[\alpha]_D +145° \rightarrow +110°$), the crystalline compound has to be designated as β-form.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

In the earlier paper (1) there has also been described a parallel nitromethane condensation using D′-methoxy-diglycolic aldehyde (XII; i.e. the enantiomorph of I) and, accordingly, furnishing methyl 3-*aci*-nitro-3-deoxy-β-L-*erythro*-pentopyranoside sodium (XIII; i.e. the enantiomorph of II). Obviously, then, the α-D-*threo* salt XIV and the β-L-*threo* salt XV, being the enantiomorphs of III and IV, respectively, had to be expected to arise as coproducts in this parallel case. This has, in fact, proved true as we have now isolated the corresponding free nitroglycosides, methyl 3-nitro-3-deoxy-α-D-arabinopyranoside (XVI) and methyl 3-nitro-3-deoxy-β-L-arabinopyranoside (XVII). Hydrogenation furnished methyl 3-amino-3-deoxy-α-D-arabinopyranoside hydrochloride (XVIII) and methyl 3-amino-3-deoxy-β-L-arabinopyranoside hydrochloride (XIX), respectively. The physical constants of the new glycosides are shown in Table I.

TABLE I

Physical data of the new glycosides

Compound	Configuration	m.p.	$[\alpha]_D$ in water
(Nitro)			
VI	α-L-*arabino*	180–182°	+85.5°
XVI	α-D-*arabino*	179–180°	−86°
XVII	β-L-*arabino*	179–180°	+278°
VII	β-D-*arabino*	178.5–179.5°	−278°
(Amino)		m.p. (decomp.)	
VIII	α-L-*arabino*	164–165°	+24.7°
XVIII	α-D-*arabino*	165°	(−24.7°)*
XIX	β-L-*arabino*	180–183°	+202°
IX	β-D-*arabino*	181–183°	−205°

*By reversal of the sign of rotation of the enantiomorph (VIII). The amount of substance available was insufficient for measurement of the rotation.

The compounds obey Hudson's rule of isorotation. Thus, the value A for the molecular rotational contribution of the glycosidic carbon atom in a pair of nitro anomers, e.g. VI and XVII, is 18,525; the value is 18,015 for the corresponding amino derivatives VIII and XIX, and 18,710 (5) for the nitrogen-free, parent methyl α- and β-L-arabinopyranosides. The values B for the cores of the molecules are +35,125 for the pair of nitroglycosides VI:XVII; +22,915 for the pair of amines VIII:XIX; and +21,550 for the anomeric methyl L-arabinopyranosides. The latter set of figures exemplifies anew that substitution of an amino group for a hydroxyl in glycosides has little influence upon the optical rotation (3, 6,[4] 7[5]). Introduction of a nitro group, on the other hand, can produce a considerable change in the molecular rotation, as is seen in the present case and in various earlier examples (3, 7).

The course of the cyclization with nitromethane of I in methanol was followed by paper chromatography. It was found that even at 0° the dialdehyde disappeared within about 10 minutes. Already, after 3 minutes, the three nitronates II, III, and IV were present, as was revealed by chromatographic detection of the corresponding free nitroglycosides following deionization. There appeared to be a preponderance of IV during the first few minutes of the reaction, but the final pattern, with II as the chief product, was largely established after 15 minutes; and small changes, if any, in the proportions of II, III, and IV in solution occurred thereafter over a period of 48 hours. The salt II began to crystallize

[4]*Further literature in support of this rule is cited there.*

[5]*In reference 7, tentative configurational assignments for two new amino sugars were based on this rule. They have now been confirmed by nuclear magnetic resonance studies (8).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

out after an induction period of 10 to 15 minutes, a circumstance which evidently furthered its formation as main product.

The β-D-*erythro* nitronate II had been found (1) to exhibit, in aqueous solution, an unexpected mutarotation (Fig. 1). We have now converted the isolated nitroarabinosides

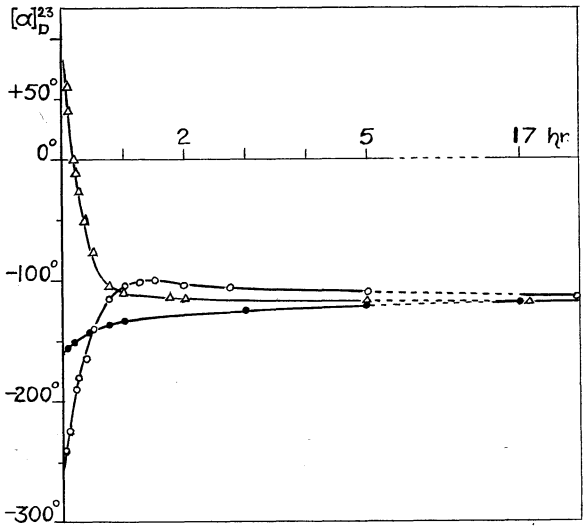


FIG. 1. The mutarotations of the nitronates II (●), III (△), and IV (○) in water.

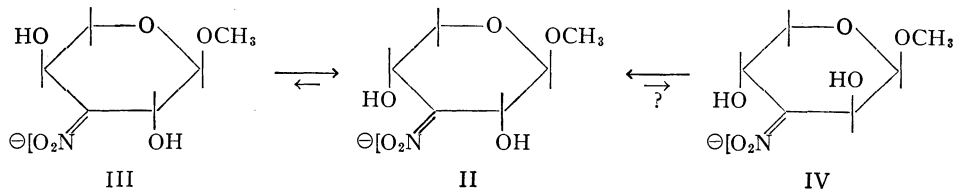
VI and VII into their respective sodium nitronates, III and IV, by the addition of equivalent amounts of sodium hydroxide in water. Immediately there commenced mutarotations leading to the same final $[\alpha]_D$ value. When, after attainment of the end value, the solutions were deionized, they all showed identical chromatographic patterns, indicating that an equilibration had taken place. In the equilibrium the levorotatory β-D-*erythro* salt II greatly predominated. On account of the rotation value of the equilibrated solution the remainder was judged to consist largely of the dextrorotatory α-L-*threo* salt III. It was in fact possible to isolate the crystalline product of deionization of III, methyl 3-nitro-3-deoxy-α-L-arabinopyranoside (VI), in a yield of 6% from an equilibrated solution of II. An estimate based on the initial rotations of II and III and on the final rotation would indicate a ratio of 85:15 of the two salts, which was consistent with the chromatographic picture. This calculation neglects a possible participation in the equilibrium of the strongly levorotatory β-D-*threo* salt IV; however, since no evidence for its presence was found, it could have been present in negligible amount only. The apparent failure of IV to play a significant part in the composition of the epimerization equilibrium in water is not necessarily inconsistent with the fact that in a kinetically controlled condensation reaction in methanolic medium it does arise to an appreciable extent. The spontaneous epimerization is represented by the following scheme:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

As for the fourth possible isomer, the α-L-*erythro* salt V, no sign of its formation has thus far been observed either in cyclization or in epimerization experiments. The present results, then, lead to the conclusion that the thermodynamic stabilities of the *aci* nitro salts decrease in the order II > III > IV > V, and hence confirm the conformational considerations which were discussed previously (1).

EXPERIMENTAL

The melting points were taken in an aluminum block. All evaporations were done *in vacuo* at 35–40° (bath temperature). Paper chromatography was performed as described previously (3).

Methyl 3-Nitro-3-deoxy-α-L-arabinopyranoside (VI) and Methyl 3-Nitro-3-deoxy-β-D-arabinopyranoside (VII)

L′-Methoxy-diglycolic aldehyde (I) was prepared (1) from 8.2 g (0.05 mole) of methyl β-D-xylopyranoside, and was dissolved in 75 ml of methanol. Nitromethane (2.8 ml, 1 molar equivalent) was added and the solution was chilled in an ice bath. With swirling, 38.5 ml of a chilled, methanolic sodium methoxide solution (containing 3 g of sodium per 100 ml) was dropped in at a moderately rapid rate. After 15 minutes the reaction mixture was deionized, with efficient magnetic stirring at 0°, by addition of 75 ml of Amberlite IR–120 (H^+) which had been prewashed with methanol. The solution was decanted from the resin and, to ensure complete deionization, slowly passed over a column which contained another 25 ml of fresh Amberlite. The first batch of resin was washed repeatedly with methanol and the washings were also passed over the column. The colorless effluent was evaporated to a sirup that was further evaporated with two successive additions of ethanol. The residue was then taken up in about 10 ml of dichloromethane. Upon inoculation[6] with VI and scratching with a glass rod, crystallization occurred and was allowed to proceed at room temperature for 1 hour. The crystals were collected and washed with ice-cold dichloromethane; yield, 391 mg; $[\alpha]_D^{23}$ +83.7° (*c*, 1.05 in water). Recrystallization from ethyl acetate afforded rectangular platelets of m.p. 180–182° and $[\alpha]_D^{23}$ +85.5° (*c*, 1.1 in water). The product was chromatographically uniform (R_f 0.64) methyl 3-nitro-3-deoxy-α-L-arabinopyranoside (VI). Anal. Calc. for $C_6H_{11}O_6N$ (193.2): C, 37.31; H, 5.74; N, 7.25. Found: C, 37.25; H, 5.63; N, 7.27.

From the above dichloromethane mother liquor a second crop of crystals separated in the course of 24 hours at 0°. This material (379 mg; $[\alpha]_D^{23}$ −149°) was revealed by paper chromatography to be a mixture giving a double spot (R_f 0.64–0.68) corresponding to the two nitroarabinosides VI and VII, and a spot (R_f 0.80) corresponding to methyl 3-nitro-3-deoxy-β-D-ribopyranoside (1).

Now petroleum ether (b.p. 30–60°) was added dropwise to the mother liquor to incipient cloudiness. Upon standing overnight in a refrigerator the solution deposited crystals, the amount of which could be augmented by careful addition of carbon tetrachloride and by keeping the flask first at room temperature, then at 4° for 24 hours. The crystals were isolated and washed with ice-cold dichloromethane; yield, 325 mg, m.p. 160–167°, $[\alpha]_D^{23}$ −218° (*c*, 1.1 in water). After one recrystallization from ethyl acetate the product was not yet chromatographically uniform but showed two spots of R_f 0.68 and R_f 0.80. A pure product, methyl 3-nitro-3-deoxy-β-D-arabinopyranoside (VII), was obtained after three recrystallizations from 1-propanol. It had m.p. 178.5–179.5°, R_f 0.69, and $[\alpha]_D^{23}$ −278° (*c*, 0.5 in water). Anal. Calc. for $C_6H_{11}O_6N$ (193.2): C, 37.31; H, 5.74; N, 7.25. Found: C, 37.58; H, 5.89; N, 7.16.

With a theoretical yield of 9.66 g, the combined nitroglycosides isolated up to this stage amounted to 11.3%. Clearly, the bulk of reaction products was still contained in the main mother liquor. Chromatography showed the presence of both VI and VII, with the latter being in preponderance. The chief component, however, was the β-D-*ribo* isomer (R_f 0.80). An additional weak spot (R_f 0.83) was judged, on the basis of previous experience (1), to be due to the β-D-*xylo* isomer.[7]

An experiment conducted in the same way as described above, except for a reaction time of 50 rather than 15 minutes, gave essentially the same results. When in a further experiment the reaction was interrupted by deionization after 3 minutes, no VI could be isolated but only a levorotatory mixture ($[\alpha]_D$ −222°) of VII and the β-D-*ribo* isomer.

Methyl 3-Nitro-3-deoxy-α-D-arabinopyranoside (XVI) and Methyl 3-Nitro-3-deoxy-β-L-arabinopyranoside (XVII)

D′-Methoxy-diglycolic aldehyde (XII) was prepared (1) from 2.46 g of methyl α-D-xylopyranoside. It was cyclized with nitromethane exactly as described above for I. The yield of crude XVI was 140 mg. It showed m.p. 178–179° and $[\alpha]_D^{23}$ −78° (*c*, 1 in water) after one, and m.p. 179–180° and $[\alpha]_D^{23}$ −86° (*c*, 1 in water) after a second recrystallization from ethyl acetate. Anal. Calc. for $C_6H_{11}O_6N$ (193.2): C, 37.31; H, 5.74; N, 7.25. Found: C, 37.11; H, 5.64; N, 7.09.

The mother liquor furnished 268 mg of a crystalline product of $[\alpha]_D^{23}$ +228.5°. It was XVII accompanied

[6]*Seed crystals were obtained when in a preliminary experiment the sirup was treated with ether and left for several days in an unevacuated desiccator over concentrated sulphuric acid.*

[7]*A pair of poorly resolved spots with R_f 0.80 (strong) and R_f 0.83 (weak) was seen when the crystalline β-D-erythro nitronate II was chromatographed following acidification.*

For personal use only.

by the β-L-*ribo* isomer. Several recrystallizations, first from ethyl acetate, then from 1-propanol, afforded pure XVII with m.p. 179–180° and $[\alpha]_D^{23}$ +278° (*c*, 0.5 in water). Anal. Calc. for $C_6H_{11}O_6N$ (193.2): C, 37.31; H, 5.74; N, 7.25. Found: C, 37.07; H, 5.68; N, 7.17.

The infrared spectra of the two anomeric glycosides XVI and XVII showed marked differences, but they were, as expected, identical with those of the enantiomorphs, VI and VII.

Methyl 3-Amino-3-deoxy-α-L-arabinopyranoside Hydrochloride (VIII)

A sample of 200 mg of the nitroarabinoside VI in 5 ml of water was hydrogenated with a platinum catalyst (200 mg of PtO_2, prehydrogenated) in the presence of 11 ml of *N*/10 hydrochloric acid. The hydrogen uptake was 77 ml at 23° and 757 mm Hg. After filtration and removal of excess acid with Amberlite IR-45(OH^-) to pH 6, the solution was evaporated leaving a colorless sirup which was crystallized from ethanol – ethyl acetate. The yield of colorless needles of VIII showing $[\alpha]_D^{23}$ +21.5° (*c*, 0.5) and m.p. 167–169° was 160 mg (77.5%). For analysis, the product was recrystallized from the same solvents and then exhibited m.p. 164–165° decomp. and $[\alpha]_D^{23}$ +24.7° (*c*, 1 in water). Anal. Calc. for $C_6H_{14}O_4NCl$ (199.6): C, 36.09; H, 7.07; N, 7.02. Found: C, 36.51; H, 7.37; N, 6.80.

Methyl 3-Amino-3-deoxy-β-D-arabinopyranoside Hydrochloride (IX)

A sample of 300 mg of the nitroarabinoside VII in 10 ml of water was hydrogenated with addition of 16.5 ml of *N*/10 hydrochloric acid as described in the preceding section. There was obtained 150 mg of recrystallized, pure IX as colorless needles of m.p. 181–183° decomp. and $[\alpha]_D^{23}$ −205° (*c*, 0.5 in water). Anal. Calc. for $C_6H_{14}O_4NCl$ (199.6): C, 36.09; H, 7.07; N, 7.02. Found: C, 35.65; H, 7.09; N, 6.86.

Methyl 3-Amino-3-deoxy-α-D-arabinopyranoside Hydrochloride (XVIII)

A sample of 14 mg of the nitroarabinoside XVI in 3 ml of water was hydrogenated with the use of 20 mg of platinum dioxide in the presence of 0.72 ml of *N*/10 hydrochloric acid. The hydrogenation product was isolated analogously to VIII. The yield was 7 mg of colorless needles of XVIII. The product was confirmed, by its melting point of 165° (decomp.) and by its infrared spectrum, to be the enantiomorph of VIII.

Methyl 3-Amino-3-deoxy-β-L-arabinopyranoside Hydrochloride (XIX)

Nitroarabinoside XVII (75 mg) in water (5 ml) was hydrogenated with 80 mg of platinum dioxide in the presence of 3.9 ml of *N*/10 hydrochloric acid. The hydrogen uptake was 28 ml (23°, 763 mm Hg) after 1 hour. Work-up of the reaction mixture (as described above for VIII and IX) afforded 46 mg of crystals of XIX, which showed $[\alpha]_D^{25}$ +202° (*c*, 0.5 in water). Although this was in good agreement with the expected value, the melting point of 150–151° did not match that of the enantiomorph IX and could not be raised by simple recrystallization. There were noticeable, if slight, differences in the infrared spectra in nujol of IX and XIX, too. These discrepancies were resolved, however, when XIX was recrystallized, from ethanol – ethyl acetate, with inoculation of the supersaturated solution with a trace of the antipode (IX). The crystals so obtained melted at 180–183° (decomp.) and gave an infrared spectrum identical with that of IX. It appears, therefore, that these aminoglycosides are capable of existing in different crystal modifications.

3-Amino-3-deoxy-β-L-arabinose Hydrochloride (X)

A sample of 104.3 mg of methyl 3-amino-3-deoxy-α-L-arabinopyranoside hydrochloride (VIII) in 10 ml of 2*N* hydrochloric acid was heated in a sealed container for 19 hours at 95–98°. After cooling, the rotation of the yellowish solution was α_D +2.06° in a 2-dm tube, corresponding to a specific rotation for the free sugar of +106.5°. The solution was decolorized with activated carbon and evaporated repeatedly with water to remove excess acid, and the remaining sirup was crystallized by trituration with 1 ml of glacial acetic acid. There could be isolated 80 mg (83%) of X whose infrared spectrum was identical with that of the known enantiomorph (see next section). The product decomposed on being heated at about 150°. On the grounds of a downward mutarotation, the β-configuration was assigned to the crystalline sugar. $[\alpha]_D^{23}$ +145° (2 1/2 minutes) → +110° (20 minutes, final; *c*, 0.5 in water).

3-Amino-3-deoxy-β-D-arabinose Hydrochloride (XI)

A sample of 146 mg of methyl 3-amino-3-deoxy-β-D-arabinopyranoside hydrochloride (IX) was hydrolyzed as described in the preceding section. The hydrolyzate showed α_D −2.77° in a 2-dm tube, which corresponded to $[\alpha]_D^{23}$ −101.8° for the free sugar (XI). Of the latter, an amount of 83 mg could be isolated as crystals showing decomposition at about 150°. The upward mutarotation, $[\alpha]_D^{23}$ −147.4° (2 minutes), → −113° (20 minutes, final; *c*, 0.5 in water) alllowed the assignment to XI of β-configuration. The equilibrium rotation value of XI agreed well with that given in the literature ($[\alpha]_D$ −112°, in water), although a mutarotation had not been recorded previously (4).

The Partial Epimerization of Methyl 3-aci-Nitro-3-deoxy pentopyranoside Sodium Salts

β-D-erythro Salt II

A sample of 1.231 g of II (1) was dissolved in 100 ml of carbon-dioxide-free water at 22°. After 17 hours the mutarotation had reached a final value of $[\alpha]_D^{23}$ −117.9° (Fig. 1). The solution was then deionized with 25 ml of Amberlite IR-120(H^+) and evaporated. The colorless, sirupy residue was evaporated twice with dichloromethane, and finally taken up in a small amount of the latter solvent. Upon scratching with a glass

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rod, crystallization of the nitroarabinoside VI occurred and was allowed to proceed in a refrigerator for 1 hour. The isolated material was washed with ice-cold dichloromethane and amounted to 59 mg; $[\alpha]_D^{22}$ +70.8° (*c*, 0.5 in water). In a parallel experiment the yield was 66 mg; $[\alpha]_D^{23}$ +73.4°. Upon recrystallization from ethyl acetate the product showed m.p. 180° and $[\alpha]_D^{23}$ +85.5° (*c*, 0.5 in water). Identity with VI described in a preceding paragraph was confirmed by the infrared spectra as well as by a mixed melting point that was undepressed.

Paper chromatography of the mother liquor revealed the presence of some residual nitroarabinoside VI (R_f 0.64) besides a large amount of methyl 3-nitro-3-deoxy-β-D-ribopyranoside (R_f 0.80). There was also a little of the slightly faster-moving *xylo* isomer (R_f 0.83). This pattern of composition was confirmed when the corresponding amino glycosides appeared on a chromatogram after hydrogenation of the mother liquor. In addition to these there were detected traces of several slow-moving as well as fast-moving, ninhydrin-positive by-products. The chief component of the hydrogenated mother liquor was isolated in crystalline form and identified as methyl 3-amino-3-deoxy-β-D-ribopyranoside hydrochloride (1); it had m.p. 167–168° decomp. and $[\alpha]_D^{23}$ −119° (*c*, 0.5 in water) after one recrystallization from 95% ethanol.

α-L-threo Salt III

To a sample of 38.75 mg of methyl 3-nitro-3-deoxy-α-L-arabinopyranoside (VI) there was added 2 ml of *N*/10 sodium hydroxide, and the volume of the solution was made up to 5 ml by the addition of carbon dioxide free water. Thus 43.16 mg of the sodium salt III was present. The mutarotation was measured in a 2-dm tube and was found to be $[\alpha]_D^{23}$ +57.9° (3 minutes) → −116.4° (5 hours, constant) (Fig. 1). After deionization, the same chromatographic pattern of nitro compounds, and after hydrogenation, the same pattern of amino compounds were observed as in the partial epimerization of the salt II.

β-D-threo Salt IV

To a sample of 14.78 mg of methyl 3-nitro-3-deoxy-β-D-arabinopyranoside (VII) there was added 0.77 ml of *N*/10 sodium hydroxide and water to make up a volume of 3 ml. Thus 16.45 mg of the salt IV was present. Mutarotation readings were taken with a 2-dm tube and are recorded in Fig. 1. $[\alpha]_D^{23}$ −239° (3 minutes) → −100.3° (90 minutes) → −115.1° (18 hours, final). The chromatograms obtained after deionization as well as after hydrogenation of the equilibrated solution showed the same patterns as those obtained above from III and IV.

OXIDATION OF N,N-DIMETHYLANILINE

I. THE REACTION WITH BENZOYL PEROXIDE[1]

DONALD M. GRAHAM[2] AND ROBERT B. MESROBIAN[3]

The Polymer Research Institute, Polytechnic Institute of Brooklyn, Brooklyn, New York

Received June 25, 1963

ABSTRACT

The reaction of *N,N*-dimethylaniline (A) with benzoyl peroxide (P) has been shown to exhibit complex kinetics. The observed rates of peroxide decomposition between 0° and 25° C could be described by the relation $-d[P]/dt = k_a[A][P]+k_b[A]^{1/2}[P]^{3/2}$. An unstable Würster salt of tetramethylbenzidine was shown to be one of the main products of the reaction, and a mechanism has been postulated which is consistent with the observed kinetics, involving tetramethylbenzidine as a reaction intermediate.

INTRODUCTION

The oxidation of *N,N*-dimethylaniline by benzoyl peroxide has been extensively studied (1–13), and much of the work has been reviewed by Walling (14). This system is of particular interest since it produces free radicals which can initiate polymerization. According to Horner and his students (2, 5), when the reaction is carried out at 0° C under nitrogen, in chloroform as a solvent, the main products which can be isolated are an almost quantitative yield of benzoic acid, and from the amine, formaldehyde and methylaniline. In addition, small amounts of *p*-benzoyloxydimethylaniline, and *p,p*-methylene-bis-*N,N*-dimethylaniline were isolated. The mechanism suggested for the reaction involves the initial polar formation of a quaternary hydroxylamine derivative which subsequently decomposes to give radical products. In order to explain the existence of formaldehyde and methylaniline, it is supposed that dealkylation of the tertiary amine plays an important role in the oxidation sequence, although the exact way in which this occurs has not been substantiated.

There still exists a good deal of confusion about the kinetics of the reaction. Horner and Scherf (3, 4) have attempted to make comparative studies of the effect of a large number of substituted dimethylaniline derivatives on the rate of decomposition of benzoyl peroxide. However, it becomes apparent that the rate measurements are quite difficult and unreliable, since the reported rates may vary from paper to paper for a particular amine. Also, although it has been reported that the reaction is second order, the published data are not consistent with this generalization. The results obtained by following the initiation of polymerization by this system also exhibit complex kinetics (9, 13), and the low initiation efficiencies obtained (2–25% (13–16)) indicate side reactions.

EXPERIMENTAL

Reagents

Dimethylaniline (Mallinckrodt reagent grade) was refluxed with acetic anhydride for 12 hours, and then fractionated under 7 mm of nitrogen at least three times, middle cuts being taken each time. The amine was immediately degassed by successive freezing and evacuating, and stored under its own vapor at dry ice temperature. The amine was vacuum-distilled from the storage flask into a transfer pipette when the reaction tubes were charged. *Benzoyl peroxide* (Fisher C.P. grade) was recrystallized twice from chloroform and stored

[1]*Taken from a thesis submitted by D. M. Graham in partial fulfillment of the requirements for a Ph.D. degree, June 1958.*

at 0° C. *Toluene* (Fisher reagent grade) was distilled over sodium. *Acetonitrile* (Fisher reagent grade) was purified according to the method of Mann and Saunders (17) and fractionally distilled.

Procedure

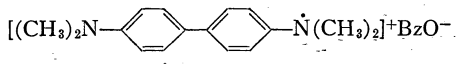
The reactions were carried out in a container consisting of two test tubes sealed at the top to a common ground joint which could be attached to a vacuum manifold. Dimethylaniline and solvent were placed in one arm, and a solution of benzoyl peroxide in the other. The contents were degassed by successive freezing, pumping, and melting until no gas was evolved in the last step; this usually required three to four repetitions. The double-tubes were then sealed under vacuum, above the common juncture, and placed in a brine bath regulated to ±0.05° C.

When sufficient time had elapsed for the contents to reach bath temperature, all of the tubes were quickly inverted and shaken, mixing the contents, and reimmersed in the thermostat. After successive time intervals, the tubes were removed, and were quickly immersed in liquid nitrogen to stop the reaction. Each tube was then opened, and, while the contents were still frozen, flushed with a stream of prepurified nitrogen. It was then inverted over a flask containing glacial acetic acid, a few crystals of potassium iodide, and several pieces of dry ice. After all the contents had melted and passed into the flask, the tube was rinsed with cold glacial acetic acid, and the liberated iodine was titrated with sodium thiosulphate.

Although this may appear to be a rather unnecessarily laborious procedure, it was found that all of the steps indicated were required in order to obtain reproducible results. The amine–peroxide system is so susceptible to reaction with oxygen that complete exclusion of the latter during titration is imperative. It was found to be quite impossible to obtain any order of reproducibility when the method reported by Horner and co-workers (1–7) was used.

Reaction Products

Dimethylaniline (79.0 mmole) and benzoyl peroxide (0.94 mmole) in 20 ml toluene were mixed at about −25° C in the absence of oxygen by the procedure described above. When they were mixed, a yellow color was instantaneously formed. This changed slowly to a fluorescent blue-green color and then a bright green precipitate separated, leaving a yellow-orange solution. After filtering and washing the precipitate with cold toluene and drying it *in vacuo*, the yield of green solid was 0.13 g. This compound decomposed rapidly at 60° C and more slowly at room temperature to a yellow-brown solid. Addition of 50% potassium hydroxide to a methanol solution of the green solid deposited a yellow precipitate which, when recrystallized from petroleum ether – toluene, was identified as *N,N,N′,N′*-tetra-methylbenzidine by mixed melting point and elemental analysis. Acidification of the filtrate precipitated white crystals identified as benzoic acid by mixed melting point analysis. Elemental analysis on a fresh sample of the green solid gave: C, 74.9%; H, 6.2%; N, 7.1%. The solid can therefore be tentatively identified as the Würster salt:



Calc.: C, 76.5%; H, 6.9%; N, 7.7%. On this basis, the observed yield would be 0.36 mmole or 38% based on benzoyl peroxide.

In order to estimate the relative yield of formaldehyde, dimethylaniline (79 mmole) and benzoyl peroxide (2.6 mmole) in 20 ml toluene were allowed to react for 5 hours at 0° C in the absence of oxygen. The reaction mixture was extracted several times with water, and from the extracts 0.36 mmole of the 2,4-dinitrophenylhydrazone of formaldehyde was obtained. The yield of formaldehyde is therefore 14% based on peroxide.

Reaction of tetramethylbenzidine (2.5 mmole) and benzoyl peroxide (0.94 mmole) in toluene at 0° C in the absence of oxygen yielded 0.19 g of green solid. The reaction was much faster than for dimethylaniline and precipitation appeared to be complete after about 30 seconds. The solid exhibited the same properties as those obtained from dimethylaniline and analyzed as: C, 74.3%; H, 6.0%; N, 7.8%. The two green compounds may therefore be assumed to be identical. The corresponding bromide salt having similar properties has been isolated from the bromine oxidation of tetramethylbenzidine (18).

When the green compound was stored, its oxygen content was found to increase (from the results of several attempts at elemental analysis); this may account for the lack of agreement in the above analyses. When tetramethylbenzidine was reacted with benzoyl peroxide in the presence of air, the toluene-washed green solid formed was found capable of oxidizing iodide ion, while the product formed in the absence of oxygen did not, indicating the possible presence of peroxide bonds in the former.

An attempt to polymerize styrene (4.3 mole/l.) in toluene at 0° C with tetramethylbenzidine (6.24×10^{-2} mole/l.) and benzoyl peroxide (2.28×10^{-2} mole/l.) in the absence of oxygen produced only a very small amount of apparently low molecular weight polymer soluble in methylethylketone.

It was also established that no carbon dioxide was evolved in the reaction between benzoyl peroxide and dimethylaniline. Degassed solutions of these compounds were allowed to react at 0° C under prepurified nitrogen in a closed system containing an oil manometer. No pressure change was detected during a period in which 85% of the peroxide should have decomposed. Conditions of the experiment were such that as little as 0.5 mole% yield of carbon dioxide evolved would be detectable.

RESULTS AND DISCUSSION

Kinetics

Benzoyl peroxide was found to react with dimethylaniline extremely rapidly. Although several authors have reported that the reaction is second order (1–12), this was found not to be strictly true over the concentration range studied here (Fig. 1). In fact, the initial

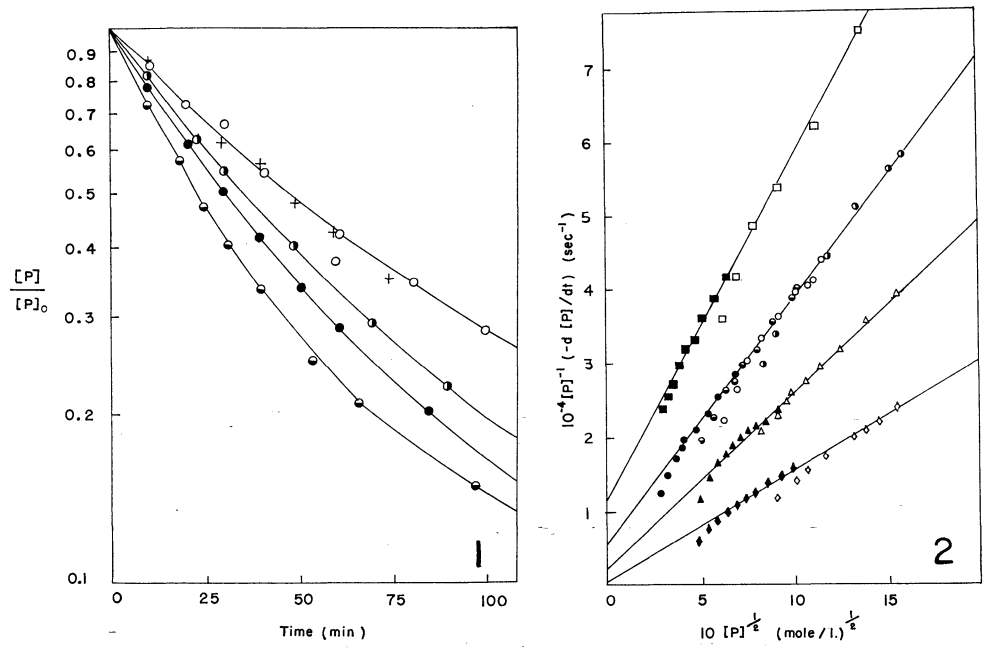

FIG. 1. Decomposition of benzoyl peroxide catalyzed by dimethylaniline at 0° C; initial amine concentration 0.395 mole/l.; initial peroxide concentrations (mmole/l.) in toluene ○ 4.11, ◑ 9.75, ● 13.7, ◒ 25.1, in acetonitrile, + 4.09.

FIG. 2. Differential plots for the catalyzed decomposition of benzoyl peroxide at 0° C; initial amine concentrations (mole/l.) ■ □ 0.790, ● ◒ ○ ◑ 0.395, ▲ △ 0.197, ◆ ◇ 0.079.

slopes of the first order decomposition plots are dependent upon the initial peroxide concentrations; the initial rates were about 4/3 order with respect to peroxide, and about 2/3 order with respect to amine. This probably indicates the presence of an additional decomposition reaction with an order dependence on peroxide greater than unity and, on amine, less than unity.

It was found that plotting $[P]^{-1}(d[P]/dt)$ against $[P]^{1/2}$, where [P] is the peroxide concentration, gave linear plots up to at least 65% decomposition. Some of the plots are shown in Fig. 2, for different peroxide and amine concentrations. In addition, the intercept and the slope are proportional to the initial amine concentration and to its root, respectively; this is evident from the summary of the peroxide decomposition results given in Table I. All measurements were made in toluene solution, but, on the basis of the one run carried out in acetonitrile, it may be tentatively concluded that the nature of the solvent has no great effect on the rate of the reaction, in agreement with the polymerization studies (13).

The rate of peroxide decomposition in the presence of dimethylaniline can therefore be described by the equation

$$-d[P]/dt = k_a[A][P]+k_b[A]^{1/2}[P]^{3/2} \qquad [1]$$

NOTE: $[A]_0$ and $[P]_0$ are, respectively, the initial amine and peroxide concentrations.

and the constants k_a and k_b can be determined from the results. The temperature dependence of the rate constants are given in Table II from which is obtained:

$$k_a = 1.1 \times 10^8 \exp(-14800/RT)$$

and

$$E_b = 2.3 \text{ kcal.}$$

The low activation energy of the induced decomposition term compared to E_a is undoubtedly responsible for the reported first order (with respect to peroxide) behavior of the initial rate at high temperatures and low amine concentrations (12).

Mechanism

The following free radical scheme is not intended to be definitive. The evidence available indicates that the overall reaction is complex and that ionic mechanisms likely play a competitive role, at least in the more advanced stages. This sequence, however, does explain the behavior of the system in what must be essentially free radical reactions such as vinyl polymerization and oxidation.

[0] $A + Bz_2O_2 \rightarrow \dot{A}^+ + BzO^- + Bz\dot{O}$

[1*a*] $Bz\dot{O} + A \rightarrow \dot{A}^+ + BzO^-$

For personal use only.

A, T, $\dot{T}^{+}$, T^{++} represent dimethylaniline, tetramethylbenzidine, and its semiquinone and quinone, respectively. The reasons for deciding on this particular reaction sequence will become more apparent if the reactions are discussed individually.

Reaction [0].—Spectrophotometric evidence indicates that the primary step occurs through the reversible formation of a molecular complex between the amine and benzoyl peroxide (16). In order to explain the presence of free radicals which do not contain nitrogen and which can initiate vinyl polymerization (2), it is necessary to suppose that benzoyl radicals are produced by decomposition of this complex or perhaps of the hydroxylamine derivative $[(BzO)(CH_3)_2NC_6H_5]^{+}BzO^{-}$, which has been suggested as a further intermediate (13). The overall process has been represented by a single reaction which is kinetically indistinguishable from the detailed sequence.

Reaction [1a].—The benzyol radicals once formed must react rapidly with amine in order that no carbon dioxide be evolved. A reaction similar to [1*a*] has been suggested for hydroxyl radicals formed from hydrogen peroxide and peroxidase in the presence of dimethylaniline (18). The extreme ease of this reaction is very likely responsible for the inhibitory ability of dimethylaniline in certain free radical reactions (19).

Reaction [1b].—The isolation of a tetramethylbenzidine derivative as a major product indicates a para coupling reaction. Such reactions are well known for phenols and aromatic amines under oxidizing conditions, and in this case likely occurs through the intermediate $[(CH_3)_2\dot{N}C_6H_5]^{+}BzO^{-}$ in either a one- or a two-step process (although the absence of *p*-benzoyldimethylaniline in the products would indicate the former). In the mechanism suggested by Horner *et al.* it was postulated that the proton was lost exclusively from one of the *N*-methyl groups on the basis of isolation of formaldehyde and methylaniline from the reaction products. However from the results reported here and by Goode and Gratch (10), it would appear that, in the absence of oxygen and at low temperatures, formaldehyde is formed only in small quantities. It is suggested therefore that methylaniline and formaldehyde are produced primarily during the isolation procedure or in the advanced stages of the oxidation reaction (27).

Reaction [1c].—In order to explain the observed kinetics, it is necessary to postulate an additional reaction involving peroxide and some reactive intermediate. Induced decomposition has usually been explained in terms of attack on peroxide by secondary radicals formed by reaction of the primary radicals (BzO or $\dot{\emptyset}$) with the solvent. In this case, however, this type of mechanism is incompatible with the product analysis. As mentioned previously, the reaction of tetramethylbenzidine with benzoyl peroxide is extremely rapid; this reaction then, along with [5], is very likely responsible for the 4/3 order dependence of the rate on peroxide.

Reaction [4].—According to Michaelis and Granick (20), the semiquinones of tetramethylated diamines do not dimerize, but exist as free radicals even in the solid state. Later work (21, 22), however, indicates that polymerization can indeed occur under certain conditions. It was found that in precipitating semiquinone salts, a solid with a low magnetic susceptibility was associated with a low dielectric constant of the precipitating medium. In the case of tetramethylbenzidine a diamagnetic solid was obtained in all cases. It is very probable therefore, that the green tetramethylbenzidine derivative isolated is the semiquinone dimer, and that the equilibrium favors reaction [4] and not the reverse reaction.

Reaction [5].—According to the theory of hydroquinone oxidation (23), the semiquinone is much more readily oxidizable than the corresponding hydroquinone; hence, reaction [5] might be expected to be a great deal faster than reaction [1*c*].

Therefore, from these equations, and assuming that the steady-state approximation is applicable, the rate of peroxide decomposition is given by

$$-d[\mathrm{P}]/dt = 3k_0[\mathrm{A}][\mathrm{P}] + 2k_5(k_0/k_4)^{1/2}[\mathrm{A}]^{1/2}[\mathrm{P}]^{3/2}. \qquad [2]$$

If semiquinone dismutation (quinone catalysis (23)), i.e.,

$$\mathrm{T} + \mathrm{T}^{++} \xrightarrow{k_s} 2\dot{\mathrm{T}}^{+} \text{ (or dimer)},$$

is included, and if k_s, the rate constant, is sufficiently large so that the concentration of T^{++} has a steady-state value, the rate of peroxide decomposition will be given by the first term of equation [2]. However, if k_s is small, as appears to be the case for tetramethylbenzidine (18), so that the concentration of T^{++} increases during the reaction, the reaction will be autoinhibited in the late stages, i.e., as the rate $k_s[T][T^{++}]$ approaches $k_4[T][P]$. Such inhibition was observed after about 65% decomposition.

Comparing equations [1] and [2] it is seen that $k_a = 3k_0$ and $k_b = 2k_5(k_0/k_4)^{1/2}$. The calculated rate constants are given in Table II; and from their temperature dependence is obtained:

$$k_0 = 3.7\times10^7 \exp(-14{,}800/RT), \text{ and, } \tfrac{1}{2}E_4 - E_5 = 5.1 \text{ kcal.}$$

TABLE II

Rate constants

Temp., °C	10^4k_a, l./mole sec	10^3k_b, l./mole sec	10^5k_0, l./mole sec	$k_5k_4^{-1/2}$ (l./mole sec)$^{\frac{1}{2}}$
0	1.5	5.2	5.0	0.37
10	3.6	6.0	12	0.27
20	8.2	7.1	27	0.22
25	16	7.4	53	0.17

It is difficult to compare the rate constants evaluated in this work with the results obtained from measurements of the rate of initiation of styrene polymerization. It would appear that the kinetic behavior reported here to a certain extent invalidates the method by which the "apparent second order rate constants" and initiation efficiencies were obtained in the polymerization work. The values of the "apparent rate constants" reported are, however, of the same order of magnitude as k_a and their variation with initial peroxide concentration is consistent with the kinetic analysis presented here. The low efficiency of this system in initiating polymerization is likely due to reaction [1*a*] being able to compete for BzȮ radicals even in the presence of a much higher concentration of styrene than amine. With the tetramethylbenzidine benzoyl peroxide system, the reaction corresponding to [1*a*] would be extremely fast, and as observed, very little initiation of polymerization can occur.

The activation energy, E_0, is of the same order as the activation energies for metal-catalyzed peroxide decomposition (24) but is higher than that observed in the polymerization work. The low temperature independent factor indicates a negative entropy of activation, which might be expected in this case. E_5 is the activation energy for electron transfer between a semiquinone radical and peroxide, and may well be close to zero; this would set a lower limit of about 10 kcal for E_4. The magnitude of E_4 seems perhaps rather high for a radical–radical reaction, and it likely reflects the fact that it was obtained from the difference in temperature dependence of two terms, one of which was relatively

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

insensitive to temperature. This high activation energy may also only be apparent, since results from the autoxidation of dimethylaniline indicate that the intermediates involved in the induced decomposition reactions are likely unstable at higher temperatures.

OXIDATION OF N,N-DIMETHYLANILINE

II. THE REACTION WITH OXYGEN CATALYZED BY BENZOYL PEROXIDE[1]

DONALD M. GRAHAM[2] AND ROBERT B. MESROBIAN[3]

ABSTRACT

When benzoyl peroxide was used to initiate the reaction of oxygen with *N,N*-dimethylaniline, a chain reaction was shown to occur, resulting in an almost quantitative yield of hydrogen peroxide. The reaction was inhibited by mercaptan and benzoquinone, but not by hydroquinone, and was shown to be autoinhibited as well. The rate of oxidation was observed to be much greater in polar solvents, such as acetonitrile or methanol, than in non-polar solvents such as toluene and benzene. Diethyl- and dipropyl-aniline exhibited no chain characteristics under similar conditions, whereas dimethylbenzylamine and dimethyldodecylamine did not react at all.

A mechanism has been postulated involving both semiquinone and peroxide chain carriers which is consistent with all of these observations. From an analysis of the oxidation rates in the presence and absence of mercaptan inhibition, the appropriate rate constants have been determined.

INTRODUCTION

The research described in this series of papers was originally undertaken in an attempt to clear up some of the confusion concerning the mechanism by which tertiary aromatic amines act as inhibitors in hydrocarbon oxidation. In studying the inhibition of cumene autoxidation by dimethylaniline, it became apparent that the amine was being rapidly and preferentially oxidized in the initial stages of the reaction. As the reaction progressed, the amount of retardation increased, indicating that the autoxidation products of the amine are very effective antioxidants. Accordingly, it was realized that in order to understand the antioxidant action of tertiary amines, it was first necessary to investigate the mechanism of their autoxidation.

It was found that highly purified dimethylaniline autoxidized extremely rapidly at 60° C. The highest maximum rate observed for freshly purified dimethylaniline was 2×10^{-4} mole/l. per sec; the corresponding rate measured for pure tetralin was 5×10^{-6} mole/l. per sec. The reaction was initially autocatalytic, and appeared to be also autoinhibited. The maximum degree of oxidation that could be obtained before the rate began to approach zero was about 2 mole%.

Unfortunately, in all cases the measured rates were irreproducible within an order of magnitude and there appeared little prospect of obtaining useful information under such conditions. It therefore appeared desirable to work at lower temperatures using benzoyl peroxide as an initiator in the hope of minimizing side reactions. Some time after the inception of this work, Horner and Junkermann (2) published some semiquantitative results on this system; however, their postulated mechanism was based primarily on the products isolated in the presence of oxygen and of nitric oxide, and differs in detail from that indicated by the results presented in this paper.

EXPERIMENTAL

Reagents

Dimethylaniline, *benzoyl peroxide*, *toluene*, *acetonitrile*, and *tetramethylbenzidine* were purified as in Part I (1). *Hydroquinone* (Eastman) was recrystallized from benzene under nitrogen. *Benzoquinone* (Eastman) was recrystallized from methanol. *1-Dodecanethiol* (Humphrey-Wilkinson) was fractionally distilled; a middle cut boiling at 126° C and 6 mm (of nitrogen) was used. *Diethyl-*, *Dipropyl-*, *methylethyl-*, and *methylaniline* were Eastman White Label grade, and were purified by fractional distillation under vacuum, in a nitrogen atmosphere.

Oxygen Absorption Measurements

Oxygen absorption was measured with an apparatus of the constant pressure type, slightly modified from that described by Cooper and Melville (3). The reaction flask was first cleaned with alcoholic sodium hydroxide, concentrated nitric acid, rinsed five times with distilled water, and flamed while under a pressure of less than 10^{-5} mm. The amine to be studied was transferred to the reaction flask using an all-glass apparatus in the absence of oxygen. Benzoyl peroxide and the inhibitors were added to the flask immersed in liquid nitrogen as solutions in the solvent to be used. The flask was then evacuated and filled with oxygen. It was then placed in a thermostat and shaken at a rate of 200 strokes per minute; zero time was taken as the time at which the pressure stopped increasing (usually 2–3 minutes).

Measurements at different oxygen pressures indicated that the initial rate was independent of the oxygen pressure above about 150 mm; accordingly, most of the results reported were made at an oxygen pressure of 750 mm in order to minimize the possibility of oxygen diffusion controlled kinetics.

RESULTS

Rate Measurements

Highly purified dimethylaniline exhibited no measurable autoxidation at 0° C; however, the addition of a small amount of benzoyl peroxide caused an extremely rapid uptake of oxygen. On oxidation, the solution changed from light yellow to deep red; at very high concentrations of peroxide and amine, a green solid was observed to precipitate. The catalyzed reaction was much less sensitive to the purity of the dimethylaniline than was the high temperature autoxidation reaction. For example, the catalyzed rate of oxidation of a sample taken from a freshly opened bottle was 5.02×10^{-5} mole/l. per sec, while for the highly purified material, the rate was 6.15×10^{-5} mole/l. per sec; the corresponding autoxidation rates were 0 and 2×10^{-4} mole/l. per sec respectively, at 60° C.

The data are summarized in Table I, and some representative oxygen absorption curves are shown in Fig. 1. No induction period was detected; although if it were less than 2–3 minutes, the time required for the reaction mixture to warm to 0° C, it would not have been observable.

The order dependence of the initial rate on peroxide concentration was between 0.5 and 1.0, and increased with increasing amine concentration. With respect to amine concentration, it was between 1.0 and 1.5, and decreased with increasing peroxide concentration. It was found by plotting $(-d[O_2]/dt)_0/[A]_0[P]_0$ vs. $([A]_0/[P]_0)^{1/2}$, where $(-d[O_2]/dt)_0$ is the initial rate of oxygen uptake, and $[A]_0$ and $[P]_0$ are the initial concentrations of amine and peroxide respectively, that the data are closely fitted by an equation of the form:

$$(-d[O_2]/dt)_0 = k_c[A]_0[P]_0+k_d[A]_0^{3/2}[P]^{1/2}. \qquad [1]$$

The values obtained for k_c and k_d at 0° C and 25° C from least square plots are given in the second and fifth columns of Table VI.

It was also observed that when acetonitrile is used as a solvent, the rate is increased about sevenfold with no apparent change in the order dependence of the rate on peroxide. This is further substantiated by the fact that, for solvent mixtures of acetonitrile and toluene, the ratios of the rates in the mixed solvents to that in the pure toluene (plus amine), when plotted against solvent composition, all fell on a smooth curve, irrespective of the initial concentrations of reactants (Fig. 2). No difference was noted between the

rate in benzene and that in toluene at 25° C, but an increase in rate was observed in a mixture of methanol (55 mole%) and toluene at 0° C, and this increase is almost exactly equivalent to that which would be observed in the corresponding acetonitrile–toluene mixture.

The rate of oxidation was shown to be autoinhibited by an inhibitor formed in the reaction with oxygen; whereas the reaction of benzoyl peroxide in the absence of oxygen appeared to produce a compound which accelerates the rate. This is apparent from the following two sets of experiments. Solutions of amine (1–2 mole/l.) and peroxide (24 mmole/l.) were allowed to react to completion in the presence of oxygen; a known concentration of peroxide was then added and the rate of oxygen uptake measured. The

observed rate was in all cases about one-half that estimated from equation [1] after allowing for the decrease in amine concentration by the initial reaction. These experiments were repeated; however, in this case the solutions were degassed before mixing and the preliminary reaction was carried out in the absence of oxygen. The reacted mixture was then placed in an oxygen atmosphere. No oxygen uptake was observed until more peroxide was added; and then the rate of oxidation was about 1.5 times that estimated from equation [1].

Stoichiometry

The total amount of oxygen that reacted, $[O_2]_T$, in any given run appeared to approach a maximum which was dependent on the initial concentrations of reactants. In fact when $[O_2]_T/[P]_0$ was plotted against $([A]_0/[P]_0)^{1/2}$ linear relations were obtained.

It would be particularly desirable to supplement the oxidation uptake measurements with simultaneous measurements of the total peroxide content of the reacting mixture. Unfortunately, due to the extreme lability of the system, the results obtained varied so widely as to be meaningless. It was possible though, to determine the peroxide present at the end of the reaction, $[P]_T$, and to obtain reproducible results; these are given in Table II. Thus, most of the oxygen which is absorbed is in the form of peroxide at the completion of the reaction.

Inhibition

In contrast to its ability to inhibit completely the rate of autoxidation of dimethylaniline, hydroquinone was found to have no effect on the peroxide-catalyzed reaction. Also, although it has been stated (2) that benzoic acid, "by virtue of its acidic function",

retards the decomposition of benzoyl peroxide in dimethylaniline, its presence produced no diminution in rate, nor did the presence of a much stronger acid, toluenesulphonic acid.

Dodecanethiol-1 (RSH) and benzoquinone (Q) were found to retard the reaction considerably, and both proved quite useful in elucidating the reaction mechanism. With both inhibitors the rate was retarded, but no induction period was observed; in addition, the total oxygen absorbed appeared to be decreased.

The results obtained in the presence of benzoquinone are given in Table III. It is

2.80	98.8	9.11	134	1.81		

apparent from the last column that the initial inhibited rate is proportional to the product of the initial concentrations of amine and peroxide, and is inversely proportional to the initial quinone concentration. This rate is also a function of the oxygen pressure; however, the direct proportionality suggested by the results cannot be assumed, since no correction has been made for the vapor pressure of the solution, and the rate might well be diffusion-controlled at low pressures. The initial rate of oxidation, in the presence of quinone, is therefore given by the relation: $(-d[O_2]/dt)_0 = 4.01\times 10^{-7}[A]_0[P]_0/[Q]_0$, at 726 mm, 0° C, in toluene.

In contrast to inhibition by benzoquinone where the rate approaches zero as the inhibitor concentration is increased, in the presence of mercaptan the rate appears to approach a limiting minimum value as the concentration of inhibitor is increased. This minimum rate is proportional to both the initial amine and peroxide concentrations. These results are given in Table IV. Another striking thing about the values obtained for the inhibited rate is that, when they are divided by the product $[A]_0[P]_0$ the result

is almost exactly equal to twice the rate constant k_c. As will be seen later, k_c is the initiation rate constant, k_0, and this equality can be predicted from the postulated mechanism. The values of k_0 in the third column of Table VI are $(-d[O_2]/dt)_0/2[A]_0[P]_0$ and are equal to the corresponding values in the second column, within experimental error. This makes it possible to determine the rate constants k_c and k_d from two initial rate measurements, one in the presence of mercaptan and one in its absence. The rate constants for the four other temperatures given in Table VI were obtained in this way from the data in Table V.

DISCUSSION

Mechanism

In determining a mechanism for this reaction, it is necessary to account for the chain character of the oxidation (which is evident from the kinetics and from the stoichiometry), and for the products formed. The former is readily explained in terms of the mechanism used to describe hydrocarbon oxidation (4); this mechanism is, however, not compatible with the products isolated, nor can it easily explain quinone inhibition. Hence, a reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

sequence has been suggested which is superficially similar to the hydrocarbon mechanism, but which can account for these other observations. The following mechanism is necessarily an oversimplification of the entire process, but is, at least, consistent with the information presently available concerning the initial stages of the reaction. The separate steps have been numbered in such a fashion so as to emphasize the similarities between this chain mechanism and that postulated for hydrocarbon oxidation.

[0] $A + Bz_2O_2 \rightarrow \dot{A}^+ + BzO^- + Bz\dot{O}$

[1a] $Bz\dot{O} + A \rightarrow \dot{A}^+ + BzO^-$

[1b] $2\dot{A}^+ \rightarrow T + 2H^+$

[1c] $T + Bz_2O_2 \rightarrow \dot{T}^+ + BzO^- + Bz\dot{O}$

[2] $\dot{T}^+ + O_2 \rightarrow T^{++} + \dot{O}_2^-$

[3] $\dot{O}_2^- + A \rightarrow \dot{A}^+ + O_2^{=}$

[6] $2\dot{O}_2^- \rightarrow O_2 + O_2^{=}$

The symbols used have been defined in Part I (1).

Reactions [0] and [1_{a-c}] have been discussed in Part I. The following considerations are important in the choice of the remaining three reactions.

Reaction [2]

There is no direct evidence available concerning the step involving the reaction of molecular oxygen. Isolation of formaldehyde, hydrogen peroxide, and methylaniline led Horner and Junkermann (2) to postulate the formation of a peroxide which hydrolyzed to these products on contact with water. All attempts to synthesize this peroxide failed, although a peroxidic solid was obtained from dimethylmesidine with performic acid as an oxidizing agent. The existence of this peroxide is therefore questionable, and an alternative mechanism would seem desirable.

One of the distinguishing features of hydroquinone oxidation, as contrasted with the oxidation of hydrocarbons, is the nature of the peroxides formed; in the former case, hydrogen peroxide is exclusively produced, while, in the latter, hydroperoxides and diperoxides are the main products. This difference undoubtedly arises because of the ability of non-hydrocarbon compounds to enter into electron transfer reactions. Hence, as the results reported here seem to indicate, it is likely that the peroxide formed in this reaction is hydrogen peroxide, probably existing in equilibrium with $[C_6H_5N(CH_3)_2OH^+]OH^-$.

Since it was observed that highly purified *N*-methylaniline is a very effective retarder for both the benzoyl peroxide catalyzed oxidation and the high temperature autoxidation reactions, it appears likely that this compound is responsible, at least in part, for the observed autoinhibition. The results indicate that it is formed only in the reaction sequence involving oxygen and not in the reactions with benzoyl peroxide. Thus, methylaniline and formaldehyde are likely produced mainly in the later stages of the reaction, possibly by rearrangement of dimethylaniline oxide (5–7) or its hydrate, or, by a similar mechanism, from hydrolysis of the unstable diimine of tetramethylbenzidine* (8).

The kinetics of benzoquinone inhibition also favors a semiquinone oxidation mechanism. Benzoquinone is a very poor inhibitor of hydrocarbon oxidation (10), where its action is presumably due to free radical addition. Here, though, it was found to be an extremely efficient inhibitor, and the inhibited rate of oxidation is dependent on the oxygen as well

**It is probably due to this instability that quinone catalysis (9) does not play an important part in the reaction mechanism.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

as on the inhibitor concentration. This immediately suggests that the inhibitor is competing with oxygen for some reactive intermediate. The fact that hydroquinone is formed quantitatively from the quinone that reacts (11) is analogous to the formation of hydrogen peroxide from oxygen, and further suggests the similarity of action of these two oxidizing agents here.

It seems probable, therefore, that benzoquinone, and hence oxygen, are acting, in a sense, as electron acceptors. Also, since no low temperature oxidation of dimethylaniline in the absence of benzoyl peroxide was detected, and because of the known susceptibility of the semiquinones of diamines to reaction with oxygen, reaction [2] has been postulated to explain the absorption of oxygen.

Reaction [3]

This reaction is analogous to reaction [1*a*] and involves electron transfer between the peroxide radical $\dot{O}_2^-$ and dimethylaniline.

Reaction [6]

Chain termination occurs by electron transfer between two peroxide radicals to a diperoxide and oxygen. This reaction follows from the independence of the rate with respect to oxygen pressure, and it is equivalent to disproportionation of two $R\dot{O}_2$ radicals, which appears to be the main mode of termination in the oxidation of many hydrocarbons at high oxygen pressures (12).

Assuming the applicability of the steady state approximation, this mechanism leads to the following expression for the rate of oxidation at high pressures:

$$-d[O_2]/dt = nk_0[A][P]+k_3(k_0/k_6)^{1/2}[A]^{3/2}[P]^{1/2} \qquad [2]$$

If, as written in reaction [6], oxygen is produced in the termination reaction, then $n = 1$, otherwise $n = 2$, assuming 100% initiation efficiency.

There are three main ways in which reaction with inhibitor might occur:

[7] $$\dot{O}_2^- + I \rightarrow \text{products}$$

$$-d[O_2]/dt = 2k_0[A][P]+2k_0k_3[A]^2[P]/k_7[I] \qquad [3]$$

At high inhibitor concentrations,

$$-d[O_2]/dt = 2k_0[A][P] \qquad [4]$$

If $Bz\dot{O}$ reacts with inhibitor as well, the inhibited rate will be 1/2 this.

[8] $$\dot{T}^+ + I \rightarrow \text{products}$$

$$-d[O_2]/dt = 2k_0[A][P]k_2[O_2]/k_8[I] \qquad [5]$$

[9] $$T + I \rightarrow \text{products}$$

$$-d[O_2]/dt = k_0[A][P]k_{1c}[P]/k_9[I] \qquad [6]$$

In deriving the expression for the rate, in each case the assumption has been that termination occurs predominantly by reaction with inhibitor, that oxygen is not one of the products of the inhibition reaction, and that the primary radical, $Bz\dot{O}$, does not react with inhibitor as rapidly as with amine.

It is apparent from the data given in Table IV that mercaptan inhibition occurs, in this case, by reaction [7]. The initial rate is proportional to the initial peroxide and amine concentrations. In addition, the ratio $-d[O_2]/dt[A]_0[P]_0$ is, within experimental error, equal to twice the rate constant obtained from the intercept of the rate plot. Therefore, oxygen is released in the termination step (i.e., $n = 1$), and the rate constants can be evaluated from equations [2] and [4], and are reported in Table VI.

*l./mole sec.
†(l./mole sec.)$^{1/2}$.
‡$E_3-\frac{1}{2}E_6$.
NOTE: All precision indices are 90% confidence limits (t test).

The k_0 values are surprisingly close to those obtained from peroxide decomposition in the absence of oxygen, with the exception of the 25° C value. The difference in the E_0 results are due to this discrepancy. This may reflect either the poorer precision that is obtainable from the peroxide decomposition results, or a real decrease in initiation efficiency with increasing temperature. The latter could be due to the instability of one of the intermediates involved in reactions [1] to [4].

There is very little useful information that can be inferred from the ratio $k_3/k_6^{1/2}$ without knowing the magnitude of one of the constants. Since the activation energy, E_6, is usually close to zero, the value obtained for the energy difference, $E_3-\frac{1}{2}E_6$, places dimethylaniline between the highly susceptible aldehydes and the less readily oxidizable hydrocarbons with respect to "dehydrogenation".

On comparing equation [5] and the relation obtained for the rate of oxidation in the presence of benzoquinone, it appears likely that quinone inhibition occurs by reaction [8]. This reaction is readily understood either in terms of a semiquinone–quinone complex, or in terms of electron transfer. Both would lead to the formation of hydroquinone from the inhibitor. Unfortunately, since the solubility of oxygen in mixtures of dimethylaniline and toluene is not known, the rate constants involved in inhibition can not be determined.

The observed stoichiometry can also be explained by this mechanism. If equation [2] describes the entire reaction, the ratio of total oxygen absorbed to peroxide initially present will be given by the relation:

$$\frac{[O_2]_T}{[P]_0} = \frac{n}{3} + \frac{6-2n}{9}\frac{k_3^2}{k_0k_6}\frac{[A]_0}{[P]_0}. \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Values of $[O_2]_T$ calculated from this relation and the measured rate constants are given in Table I and agree quite well with the observed results. This agreement does not necessarily conflict with the observation that the reaction is autoretarded, since it might be expected that the stoichiometry would be much less sensitive than the rate to this type of inhibition.

The increase in rate observed in going from toluene to acetonitrile (or methanol) is likely a result of the increase in dielectric constant. Such an effect should be very small in purely free radical reactions, and it was for this reason that a mechanism involving charged species seems most likely, particularly since the increase appears to occur mainly in the second term of the rate equation, i.e. in k_3 or k_6. This may mean that the sensitive reaction is the termination reaction, since reactions [0] and [3] are similar, and reaction [6] involves the reaction of two anions, or, at least, two strongly polarized radicals. The order of magnitude of the effect is only explainable in terms of the reaction of two like-charged species. The fact that there are probably other reactions involved in polar solvents than those considered in deriving equation [7] is apparent from the $[O_2]_T$ values obtained in acetonitrile. These are much larger than the corresponding values observed in toluene, but much less than would be predicted on the basis of equation [7]. It may be that the apparent continuity of mechanism is fortuitous.

Oxidation of Related Compounds

Tetramethylbenzidine is of particular interest since it is apparently an intermediate in the oxidation of dimethylaniline. It proved impossible to obtain any accurate kinetic data, since at 0° C the reaction is much too fast to follow, and only a rough estimate of its relative overall reactivity could be made. It was found that, for a toluene solution of tetramethylbenzidine (53.2 mmole/l.) and benzoyl peroxide (99.6 mmole/l.), the initial rate was at least 7×10^{-5} mole/l. per sec; the corresponding rate for dimethylaniline would be 4.0×10^{-7} mole/l. per sec. Hence, tetramethylbenzidine oxidizes at least 200 times as fast as dimethylaniline. The reaction may be retarded by mercaptan, but not sufficiently to allow accurate rate measurements.

Results obtained for several other compounds are given in Table VII. *Methylethylaniline*

appears to oxidize by the same mechanism as dimethylaniline; the estimated rate constants are given in Table VI. *Diethylaniline* and *dipropylaniline*, however, do not exhibit a corresponding similarity. Their oxidation rates are much less than for dimethylaniline, and the reaction is not inhibited by mercaptan; if anything, it is slightly accelerated. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

addition, although it was difficult to estimate accurately the total oxygen absorbed, because of the low rates, it appeared to be equal to about 0.3 to 0.5 times the initial peroxide concentration.

These results would seem to indicate the almost complete absence of a chain reaction, with the initial rate of oxidation being approximately equal to $2k_0[A]_0[P]_0$. The values of k_0 reported in Table VI are based on this assumption.

If oxidation occurred by the *N*-alkyl dehydrogenation mechanism of Horner and Junkermann (2), a diminution in rate might be expected as the size of the alkyl group is increased, although, perhaps not as great as observed here. On the other hand, increasing the size of the alkyl group will undoubtedly sterically hinder the formation of the complex which precedes electron transfer in reaction [3]. In addition, there might be expected to be a limit, beyond which, increasing the size of the alkyl group would not further influence the reaction, as was observed with diethyl- and dipropyl-aniline. If this is the case, the rate of reaction [3] should be greater in solvents of high dielectric constant, where the separation of the cationic quinone and anionic oxygen should be greater.

The other two amines listed in Table VII showed no tendency to react, and the rate limits are those imposed by the experimental conditions.

THE KINETICS OF THE THERMAL REACTIONS OF ETHYLENE OXIDE[1,2]

M. Lynne Neufeld and Arthur T. Blades
Research Council of Alberta, Edmonton, Alberta
Received July 19, 1963

ABSTRACT

The thermal reactions of ethylene oxide in the presence of an excess of propylene have been studied as a function of pressure and it has been found that there are two sets of products, acetaldehyde and free radicals, presumably methyl and formyl. These products are believed to arise from an excited acetaldehyde intermediate. Some evidence has been obtained for the occurrence of a surface-catalyzed rearrangement to acetaldehyde but the free radical products are uninfluenced by surface.

INTRODUCTION

Ethylene oxide decomposes homogeneously in the gas phase at 400° C to give hydrogen, carbon monoxide, methane, ethane, ethylene, formaldehyde, ketene, and acetaldehyde; it has been suggested that the latter product arises by rearrangement while the others result from a free radical chain reaction (1). Mueller and Walters (2) have shown that the addition of sufficient propylene reduces the rate of ethylene oxide disappearance to a constant value and reduces the pressure increase to zero, and it may be inferred that the free radical reaction is a minor primary mode of decomposition. They do, however, suggest that the primary radicals which initiate the chain reaction in the absence of propylene are methyl and formyl (3).

Lossing, Ingold, and Tickner (4), using a high temperature, low pressure flow system coupled to a mass spectrometer, confirmed the production of methyl radicals but were unable to observe acetaldehyde although this compound was stable under their experimental conditions. They proposed only two primary reactions

$$\begin{array}{ll} CH_2\text{—}CH_2 & \rightarrow CH_4 + CO \\ \quad\diagdown\ \diagup & \\ \quad\ O & \rightarrow CH_3 + CHO. \end{array}$$

It has recently been suggested that acetaldehyde may also arise from a free radical chain reaction (5):

$$R\cdot + C_2H_4O \rightarrow C_2H_3O\cdot + RH$$
$$C_2H_3O\cdot \rightarrow \cdot CH_2\text{—}CHO$$
$$\cdot CH_2CHO + C_2H_4O \rightarrow CH_3CHO + C_2H_3O\cdot.$$

The present study was designed to re-examine the pyrolysis of ethylene oxide under conditions such that the origin and contribution of the primary free radical reaction might be assessed and the mechanism and energetics of the rearrangement further elucidated.

EXPERIMENTAL

Ethylene oxide was obtained from Eastman Organic Chemicals and was distilled on a four-foot pyrex helices-packed column with a vapor take-off. Deuterated ethylene oxide was supplied by Merck, Sharp and Dohme, Montreal, and was used without further purification. The propylene was Phillips Research Grade (99.4+ %). Mixtures of these gases were shown to be free of the compounds which were later found to be products of the reaction.

Quantitative analyses were carried out for only three of the reaction products, carbon monoxide, methane, and acetaldehyde. The non-condensible products were separated on a 2 ft charcoal gas chromatographic column at 0° and the carbon monoxide and methane estimated from the response of a thermal conductivity detector. The acetaldehyde was determined by the *p*-hydroxybiphenyl colorimetric method (6). Qualitative analysis of the condensible reaction products was carried out on a 20 ft polypropylene glycol gas chromatographic column at 60° and on a 2 ft silica gel column at 25°.

A conventional static pyrolysis system was used for all experiments, two reactors of 75 and 875 cc volume being used for the high and low pressure experiments respectively. The reactors were enclosed in large aluminum block furnaces and the temperatures monitored by a Pt, Pt-Rh thermocouple.

In order to limit the importance of chain reactions, all pryolyses herein reported were carried out in a 4- to 10-fold excess of propylene.

RESULTS

Qualitative analyses revealed carbon monoxide, methane, ethane, ethylene, propane, 1-butene, *cis*- and *trans*-2-butene, acetaldehyde, and diallyl as the major products of the reaction. Since only two oxygen-containing products were observed, the rates of production of these were assumed to be indicative of the rates of two reactions. At conversions up to 10%, these two products were found to increase linearly with time (Fig. 1),

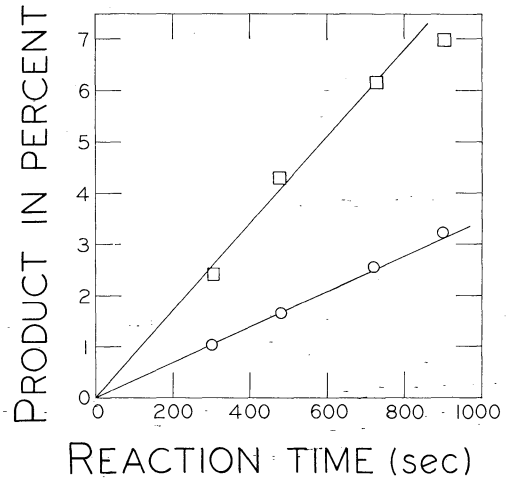

FIG. 1. Percentage yield of the products acetaldehyde □ and carbon monoxide ○ vs. reaction time at 690° K and 31 cm Hg. pressure, 22.6% oxide.

but above this conversion, the ratio of the acetaldehyde to carbon monoxide began to fall rapidly, indicating the onset of a chain decomposition of the acetaldehyde to carbon monoxide. A series of experiments was then carried out at 30 cm Hg pressure in the temperature range 643.5 to 702.3° K, with the conversion limited to 10%, to determine the initial rates of disappearance of ethylene oxide as a function of temperature. These gave a rate expression:

$$k = 10^{14.13} \exp(-56{,}900/RT) \text{ sec}^{-1}$$

which agrees favorably with the expression of Mueller and Walters (2)

$$k = 10^{14.34} \exp(-57{,}400/RT) \text{ sec}^{-1}.$$

Changing the concentration of the oxide in the propylene had no effect on the rates.

Maintaining the total conversion at less than 6%, the rates of production of carbon monoxide and acetaldehyde were measured at constant temperature in the pressure

range 0.6 – 80 cm Hg. These data are displayed as total and individual rates in percent per minute in Fig. 2, and in Fig. 3 as the ratio of rates as a function of the total pressure. In these experiments, two standard mixtures of the oxide and propylene were used (22.6% and 12.0% oxide).

A number of pyrolyses were carried out in variously treated glass reactors and a wide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

range of total rates were obtained. Conditioning by repeated reaction tended to decrease rates only to a limited extent and the lowest rates were obtained with reactors which had been conditioned only by prolonged evacuation at 500° C. It was also observed that despite the conditioning procedure, the rates of production of carbon monoxide remained constant and only the rate of acetaldehyde production was variable.

The hydrogen isotope effects in the production of acetaldehyde and carbon monoxide were measured at 664° K and 30 cm Hg total pressure and were found to be 3.1 ± 0.1 for each product.

DISCUSSION

The production of acetaldehyde, carbon monoxide, diallyl, and a number of other hydrocarbon products in the pyrolysis of ethylene oxide – propylene mixtures confirms the previous observations of a rearrangement reaction and a free radical decomposition of ethylene oxide. The variety of hydrocarbon products gives no reliable clue to the identity of the primary free radical fragments. They do show, however, that even with "totally inhibiting" concentrations of propylene, chain reactions are occurring and that useful information on the free radical reaction must be obtained at low concentrations of the product acetaldehyde. These points are particularly accented by the observation of both butene-1 and butene-2 in the products at high conversions. Butene-1 is believed to arise from allyl and methyl radicals; the butene-2 then arises from the sequence

$$C_3H_5^{\cdot} + 1\text{-}C_4H_8 \rightarrow C_3H_6 + C_4H_7^{\cdot}$$
$$C_4H_7^{\cdot} + C_3H_6 \rightarrow 2\text{-}C_4H_8 + C_3H_5^{\cdot}.$$

Under the conditions of low conversion used for rate measurements, the unimportance of the chain decomposition of acetaldehyde was demonstrated by the linear increase in product yields with time. This was further shown in experiments where acetaldehyde yields were abnormally high because of heterogeneous reaction without any corresponding increase in the carbon monoxide yield. At higher conversions, this situation was not maintained as evidenced by the decrease of the acetaldehyde – carbon monoxide ratio.

The unusual variation in the rate of production of carbon monoxide with pressure and the interrelation of the two products demonstrated by Fig. 3 suggest a mechanism for this pyrolysis involving an excited acetaldehyde intermediate which either collides to become stable acetaldehyde or unimolecularly decomposes to carbon monoxide and free radical fragments, presumably hydrogen atoms and methyl radicals. The possibility of such a mechanism has been discussed before (7) but no evidence has been obtained to support it. The exothermicity (27.6 kcal/mole) (8) and the activation energy (57.4 kcal/mole) (2) provide just about the energy required to break the carbon–carbon bond in acetaldehyde (9). In terms of the Rice, Ramsperger, and Kassel theory (9), this 85 kcal/mole of excess energy in the acetaldehyde is the minimum energy of the product molecules, and the total energy of excitation is greater by an amount determined by the Maxwell-Boltzmann distribution of energy of the reactant molecules and the variation of the specific rate constant with energy. According to this theory, the energy distribution of the product acetaldehyde has a maximum at $(85+(s-1)RT)$ kcal/mole and a substantial fraction have energies in excess of $(85+2(s-1)RT)$ kcal/mole. The value of s is determined from the quasi-unimolecular decrease of the first order rate constant with pressure, and from Fig. 2 s can be estimated to have a value of 11–12 by comparison with the similar effect in cyclopropane (10). This results in an energy of excitation of from 85 to something in excess of 115 kcal/mole (with the most abundant species at 100 kcal/mole)

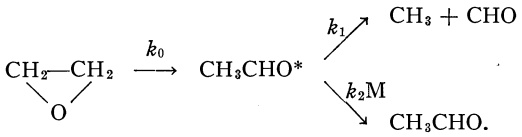
for the product acetaldehyde. That such highly excited molecules of acetaldehyde should unimolecularly decompose at about 1 atm pressure seems entirely reasonable, and the following mechanism is proposed for the thermal reactions of ethylene oxide:



On the basis of this mechanism, the percentage yield curves in Fig. 2 can be explained as follows. At high pressure, a reduction in pressure tends to increase the CO yield at the expense of the acetaldehyde yield; as the pressure is further reduced, the total rate begins to fall because of the onset of quasi-unimolecular behavior, and the individual rates are affected in that the acetaldehyde decreases more rapidly than previously while the CO increases more slowly, and then it too, gradually decreases with decreasing pressure, having become in the process the major product.

The curvature in the product ratio vs. pressure plot is to be expected in this system because of the wide variation in the excess energy of the excited intermediate, the exact curvature being determined by both the energy of excitation distribution curve and the variation of the specific rate constant k_1 with energy. Unfortunately, in the present system this is further complicated by a tendency of the energy distribution curve to shift somewhat to lower energies at very low pressures.

The mechanism proposed above for the production of free radicals in this system explains the failure of Lossing, Ingold, and Tickner (4) to observe the product acetaldehyde. At a pressure of 15 mm Hg of helium, whose collision efficiency of 0.06 compared with cyclopropane (10) would imply an effective pressure of 1 mm Hg, according to Fig. 3, the free radical products would be expected to predominate tenfold over the acetaldehyde; the combination of the high radical concentration and relatively poor discrimination of the two isomers in the mass spectrometer suggest that this minor product would be difficult to detect.

The one unsatisfactory aspect of the mechanism proposed above is the possibility of a considerable contribution from heterogeneous rearrangement reactions. The pressure effects certainly imply that a major portion of the reaction is homogeneous, and this view is supported by the large hydrogen isotope effects observed. All of the data herein recorded were obtained with reaction vessels which had been maintained free from air or water for considerable periods and no lower rate values were obtained. The fact that the free radical reaction was completely uninfluenced by the activity of the surface as indicated by the acetaldehyde production implies that this reaction is not heterogeneous. Unfortunately, no method presently exists for unequivocably determining the extent of the residual contribution of heterogeneous reaction to the acetaldehyde products.

The thermal reactions of ethylene oxide appear to represent a limited class of unimolecular gas phase rearrangements wherein an excited product species is formed of sufficient energy to decompose unimolecularly. It is regrettable that the complications of chain and surface reactions impede the acquisition of more reliable data on this unusual reaction.

ANTINEOPLASTIC AGENTS

IX. N-BENZYL-N-BIS(2-HALOETHYL)AMINES[1,2]

GEORGE R. PETTIT, DAVID S. BLONDA, AND ERNEST C. HARRINGTON
Department of Chemistry, University of Maine, Orono, Maine, U.S.A.

Received June 28, 1963

ABSTRACT

A number of N-bis(2-chloroethyl)amines and three N-bis(2-iodoethyl)benzylamines have been prepared for cancer chemotherapy studies. The chloro-nitrogen mustards were readily obtained by aluminum chloride – lithium aluminum hydride reduction of the corresponding N-bis(2-chloroethyl)amides. A convenient procedure for converting N-bis(2-chloroethyl)-benzylamine hydrochlorides to N-bis(2-iodoethyl)benzylamine hydroiodides, employing sodium iodide, was also developed.

For personal use only.

A substantial increase in the survival time of Fischer F-344 rats with Dunning leukemia following treatment with N-bis(2-chloroethyl)-3,4,5-trimethoxybenzylamine hydrochloride or N-bis(2-chloroethyl)-3,4-methylenedioxybenzylamine hydrochloride was reported in a prior study (1). The encouraging chemotherapeutic properties of these benzylamines (see also ref. 2) led us to consider a number of related benzyl groups (Table I) as nitrogen mustard carriers (1, 3, 4).

The amines summarized in Table I were prepared by aluminum chloride – lithium aluminum hydride reduction of the corresponding nitrogen mustard amides. Conversion of 3,5-dimethoxybenzoyl chloride to N-bis(2-chloroethyl)-3,5-dimethoxybenzamide and subsequent reduction (I*a* → II*a*) illustrates the general synthetic route. Although several of the water-sensitive (1) amide intermediates (e.g., I*a* and I*b*) were carefully isolated and purified before reduction, it generally proved more efficient to employ the crude products. The amides were very sensitive to trace amounts of water and readily rearranged to 2-(2′-chloroethylamino)ethyl esters. A number of the N-bis(2-chloroethyl)amides were further characterized by quantitative conversion (5–30 minutes in 95% ethanol) to ester (III*a–d* and IV) hydrochlorides.[3] Interestingly, Popp and colleagues (5) have reported that a related series of N-bis(2-chloroethyl)amides were "very hygroscopic" and gave analytical results consistent with 1–3 moles of water in each case. While "no evidence for rearrangement of the mustard amides was noted" we suggest that these observations are in better accord with an amide → ester rearrangement reaction (1, 6). The latter transformation may generally provide a useful route to stable derivatives of nitrogen mustard amides.

Synthesis of the methyl- and dimethyl-benzylamines noted in Table I was suggested by the favorable action of embitol[4] upon certain human lymphomas (7). Recently, embitol and N-bis(2-chloroethyl)-4-fluorobenzylamine (cf. Table I) were reported (8) to markedly inhibit growth of both sarcoma 45 in rats and Guerin carcinoma in rabbits.

An initial attempt to evaluate the utility of N-bis(2-chloroethyl)amines related to substances with central nervous system activity led to preparation of N-bis(2-chloroethyl)-3,4,5-trimethoxyphenethylamine (V) hydrochloride: a mescaline derivative.

Melting point reported by K. V. Levshina and S. I. Sergenshaza, Zh. Obsch. Khim. **24**, 902 (1954); Chem. Abstr. **49**, 8160 (1954).

Nitrogen mustards of this type, capable of penetrating the brain (9) without producing bizarre mental effects, might prove useful in treating brain tumors. Two other N-alkyl-N-bis(2-chloroethyl)amines, N-bis(2-chloroethyl)-4-fluorophenethylamine (Table I), and hexadecylamine VI, were prepared for comparison purposes. The amide (VII) precursor of amine VI was of particular interest since N-(2-hydroxyethyl)hexadecanamide is the antiallergic factor of egg yolk (10).

Another phase of the present study was devoted to preparing the diiodo-derivative[5] of N-bis(2-chloroethyl)-3,4-methylenedioxy- and 3,4,5-trimethoxybenzylamine (1). For this purpose, a procedure employing sodium iodide in acetone (compare refs. 13 and 14) was developed for directly converting the nitrogen mustard hydrochlorides to N-bis(2-iodoethyl)amine hydroiodides. Model experiments were conducted with N-bis(2-chloroethyl)amine II*b* hydrochloride, and eventually N-bis(2-iodoethyl)-3,4,5-triethoxybenzylamine (II*c*) hydroiodide was prepared in 87% yield. Subsequently the required N-bis(2-iodoethyl)amines, II*d* and VIII, were also obtained by this method.

Each of the N-bis(2-haloethyl)amine derivatives arising from this investigation has been submitted to the Cancer Chemotherapy National Service Center (National Institutes of Health, U.S. Public Health Service) for biological studies.

EXPERIMENTAL[6]

Acyl Chlorides

The following acid chlorides were prepared with appropriately adjusted quantities of the corresponding carboxylic acids and phosphorus pentachloride as illustrated (*vide infra*) for 3,5-dimethoxybenzoic acid: 2-methylbenzoyl chloride (15), b.p. 48–49° (2 mm); 3-methylbenzoyl chloride (16), b.p. 52–53° (2 mm); 4-methylbenzoyl chloride (17), b.p. 54–55° (2 mm); 2,4-dimethylbenzoyl chloride (18), b.p. 86–88° (2–3 mm); 2,5-dimethylbenzoyl chloride (19), b.p. 89–90° (2 mm); 3,4-dimethylbenzoyl chloride (19), b.p. 66–70° (2 mm); 3,5-dimethylbenzoyl chloride (20), b.p. 70–72° (2.5 mm); 4-methoxybenzoyl chloride (21), b.p. 96–97° (3 mm); 3,4-dimethoxybenzoyl chloride (21), m.p. 69–71°, b.p. 95–98° (1 mm); 4-fluorobenzoyl chloride (22); b.p. 27–32° (1 mm); and 4-fluorophenylacetyl chloride (23), b.p. 54–58° (1.5 mm).

N-bis(2-Chloroethyl) Amides

Amide precursors of the N-bis(2-chloroethyl)amine hydrochlorides summarized in Table I were prepared according to the method described below for N-bis(2-chloroethyl)-3,5-dimethoxybenzamide (I*a*). Isolation of the amides was most favorable during periods of low laboratory humidity. Solvents used to purify the nitrogen mustard amides were redistilled and stored over sodium. Although several of these *water-sensitive* amides were carefully purified, as noted in the sequel, the crude oily amides were generally employed in the reduction sequence. All glass apparatus used for preparation and subsequent reduction of the amides was dried at 120° for ca. 24 hours.

N-bis(2-chloroethyl)amine Hydrochlorides (Table I)

With one exception, (II*e*), the nitrogen mustard hydrochlorides noted in Table I were obtained by the general experimental methods described (below) for conversion of 3,5-dimethoxybenzoic and 3,4,5-trimethoxyphenylacetic acids to, respectively, benzylamine II*a* and phenethylamine V hydrochlorides. Preparation of N-bis(2-chloroethyl)-3,4,5-triiodobenzylamine (II*e*) was accomplished by employing an amide to lithium aluminum hydride ratio of 1:0.5. Reduction of amide I*c* by an approximately 1:1 molar ratio led to amines containing ca. 6% less iodine than calculated for triiodo-derivative II*e*. Tetrahydrofuran used in the reduction step was first heated at reflux over sodium for 2 hours, then distilled, and stored over sodium wire.

The infrared spectrum of each pure hydrochloride (in potassium bromide) was consistent with the assigned structure.

3,5-Dimethoxybenzoyl Chloride

A mixture of 3,5-dimethoxybenzoic acid (55 g, 0.30 mole) and phosphorus pentachloride (63.5 g, 0.30 mole) was cautiously warmed. After the initial exothermic reaction subsided, heating (steam bath) was

[5]*Decreased toxicity and increased antineoplastic activity with iodo- as compared to chloro-nitrogen mustards has been observed: see refs. 11 and 12.*

[6]*Melting points were observed with open Kimble glass capillaries (silicone oil bath) unless otherwise noted, and are uncorrected. Dr. R. A. Hill of this laboratory recorded the infrared data. Elemental analyses were provided by the microanalytical laboratories of: Dr. A. Bernhardt, Max-Planck Institute, Mülheim (Ruhr), Germany; Dr. C. Janssen, Beerse, Belgium; and Drs. Weiler and Strauss, Oxford, England.*

continued 1 hour. The phosphorus oxychloride was then removed *in vacuo*. Rapid distillation of the reddish brown residue yielded 52 g (86%) of colorless liquid boiling at 91–100° (0.7 mm). An analytical specimen (b.p. 90° at 0.7 mm, ν_{max}^{pure} 1770 cm^{-1}) was prepared by distillation through a 15-cm Vigreux column. Calc. for $C_9H_9ClO_3$: C, 53.90; H, 4.52; Cl, 17.68. Found: C, 53.70; H, 4.82; Cl, 17.81.

Conversion of 3,5-dimethoxybenzoic acid to the acid chloride derivative (b.p. 163–165° at 19–20 mm) with thionyl chloride has been reported (24).

N-bis(2-chloroethyl)-3,5-dimethoxybenzamide (Ia)

A solution of 3,5-dimethoxybenzoyl chloride (21.7 g, 0.108 mole) in *dry* benzene (200 ml) was slowly added (1 hour) to a *dry* benzene (150 ml) solution (ice-bath cooling) of the free amine from 44.4 g (0.248 mole) of N-bis(2-chloroethyl)amine hydrochloride (see ref. 1, footnote 23). The mixture was heated at reflux for 2 hours before collecting N-bis(2-chloroethyl)amine hydrochloride (19.5 g). Removal of solvent from the filtrate led to 31.2 g (98%) of colorless viscous oil. Crystallization from benzene – petroleum ether gave 24.8 g of amide I*a* melting at 58–60°. Three recrystallizations from the same solvent yielded an analytical sample; colorless prisms, m.p. 59–60°, ν_{max}^{KBr} 1650–1600 (broad) cm^{-1}. Calc. for $C_{13}H_{17}Cl_2NO_3$: C, 50.98; H, 5.60; Cl, 23.16; N, 4.58. Found: C, 51.25; H, 5.54; Cl, 23.47; N, 4.49.

2-(2'-Chloroethylamino)ethyl-3,5-dimethoxybenzoate Hydrochloride (IIIa)

A solution of N-bis(2-chloroethyl)-3,5-dimethoxybenzamide (I*a*, 1.0 g) in 95% ethanol (25 ml) was heated at reflux for 5 minutes. Concentrating (*in vacuo*) the solution to dryness afforded a quantitative yield of ester III*a* melting at 123–126°. Five recrystallizations from acetone gave a pure specimen as colorless

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

crystals; m.p. 125–126°, ν_{max}^{KBr} 2900–2450 (broad) and 1715 cm^{-1}. Calc. for $C_{13}H_{19}Cl_2NO_4$: C, 48.16; H, 5.91; Cl, 21.87; N, 4.32. Found: C, 48.02; H, 6.00; Cl, 21.40; N, 4.21.

Saponification of 2-(2'-Chloroethylamino)ethyl-3,5-dimethoxybenzoate Hydrochloride (IIIa)

A 0.75-g sample of ester III*a* was saponified in refluxing (3 hours) methanol (20 ml) – aqueous potassium hydroxide (10 ml of 10%) solution. Following removal of solvent and dilution with water (20 ml), the mixture was filtered and neutralized with 5% hydrochloric acid. The 3,5-dimethoxybenzoic acid which separated weighed 0.35 g (100%) and melted at 180–185°. The structural assignment was confirmed by mixture melting point determination and infrared spectral comparison (in potassium bromide) with an authentic sample (m.p. 182–183.5°) of 3,5-dimethoxybenzoic acid.

N-bis(2-chloroethyl)-3,5-dimethoxybenzylamine (IIa) Hydrochloride

To a cold (ice-bath) mixture of aluminum chloride (14.0 g, 0.105 mole), lithium aluminum hydride (4.0 g, 0.105 mole), and tetrahydrofuran (300 ml), under nitrogen, was slowly added (1 hour) a solution of crude amide I*a* (31.2 g, 0.101 mole) in tetrahydrofuran (200 ml).[7] Stirring and cooling were continued 2 hours (total reaction time) before cautiously adding 30-ml portions of acetone, moist ether, and water. After removing the solvent *in vacuo* at 35–40° the residue was diluted with 40% sodium hydroxide solution (250 ml) and extracted with benzene (3 × 100 ml). The combined solvent was dried (magnesium sulphate) and treated with a saturated solution of hydrogen chloride in ethyl ether. The hydrochloride which separated weighed 25.3 g and melted at 135–137°. Four recrystallizations from methanol – ethyl ether afforded an analytical specimen as colorless crystals (see Table I); ν_{max}^{KBr} 2900–2300 (major absorption at 2900 and 2650) cm^{-1}.

2-(2'-Chloroethylamino)ethyl-3,4-dimethoxybenzoate Hydrochloride (IIIb)

The crude amide derived (cf. I*a*) from 3,4-dimethoxybenzoyl chloride (9.0 g) and the amine corresponding to 19.3 g of bis(2-chloroethyl)amine hydrochloride was obtained as a viscous oil. Crystallization from benzene – petroleum ether yielded 9.1 g (81%), m.p. 79–80°, of N-bis(2-chloroethyl)-3,4-dimethoxybenzamide. The corresponding benzylamine derivative has been described by Kravchenko (2).

Conversion of the amide to ethyl ester III*b* was easily accomplished (see III*a*). Three recrystallizations from ethanol – ethyl ether gave pure colorless crystals melting at 144–146°. Calc. for $C_{13}H_{19}Cl_2NO_4$: C, 48.16; H, 5.91; Cl, 21.88; N, 4.32. Found: C, 48.01; H, 5.95; Cl, 21.43; N, 4.28.

3,4,5-Triethoxybenzoyl Chloride

Conversion of 3,4,5-triethoxybenzoic acid (50 g) to the corresponding acid chloride was accomplished essentially as described for preparation of 3,5-dimethoxybenzoyl chloride. In this example, excess phosphorus pentachloride (45 g) and a 1.5 hour reaction period were employed. The fraction (48.5 g, 90%), boiling at 120–124° (1.1 mm), was collected and allowed to crystallize, m.p. 64–67°. Five recrystallizations from benzene – petroleum ether gave pure colorless crystals melting at 70–71° (Feist *et al.*, ref. 25, report a m.p. of 68°), ν_{max}^{KBr} 1745 cm^{-1}. Calc. for $C_{13}H_{17}ClO_4$: C, 57.24; H, 6.28; Cl, 13.00. Found: C, 57.13; H, 6.25; Cl, 12.72.

2-(2'-Chloroethylamino)ethyl-3,4,5-triethoxybenzoate Hydrochloride (IIIc)

A crude oily sample (1.0 g) of N-bis(2-chloroethyl)-3,4,5-triethoxybenzamide prepared as reported for benzamide I*a* was readily rearranged to ester III*c* (1.0 g, m.p. 154–157°) as described using amide I*a*. Five recrystallizations from acetone yielded pure colorless crystals melting at 157–158°, ν_{max}^{KBr} 2900–2450 (broad) and 1715 cm^{-1}. Calc. for $C_{17}H_{27}Cl_2NO_5$: C, 51.52; H, 6.87; Cl, 17.89; N, 3.54. Found: C, 51.64; H, 6.99; Cl, 18.08; N, 3.61.

N-bis(2-chloroethyl)-4-fluorobenzamide (Ib)

The crude product prepared (refer to I*a*) from *p*-fluorobenzoyl chloride (5.0 g) and 11.6 g of bis(2-chloroethyl)amine hydrochloride crystallized from benzene – petroleum ether as colorless needles; yield, 7.1 g (81%); m.p. 69–70°. Recrystallization from the same solvent afforded an analytical specimen melting at 69.5–70.5°, ν_{max}^{KBr} 1640–1620 cm^{-1}. Calc. for $C_{11}H_{12}Cl_2FNO$: C, 50.01; H, 4.58; Cl, 26.85; N, 5.30. Found: C, 50.21; H, 4.81; Cl, 26.78; N, 5.34.

N-bis(2-chloroethyl)-3,4,5-triiodobenzamide (Ic)

Conversion of 3,4,5-triiodobenzoyl chloride (9.0 g, ref. 26) to oily amide I*c* (10.9 g) was readily accomplished (cf. I*a*). The crude amide eventually crystallized (m.p. 113–115°) from benzene – petroleum ether. Three recrystallizations from the same solvent led to an analytical sample in the form of pale yellow plates; m.p. 115–116°,[8] ν_{max}^{KBr} 1630 cm^{-1}. Calc. for $C_{11}H_{10}Cl_2I_3NO$: C, 21.18; H, 1.62; N, 2.25. Found: C, 21.46; H, 1.77; N, 2.08.

A crystalline sample of amide I*c* (0.5 g) was converted to *2-(2'-chloroethylamino)ethyl-3,4,5-triiodobenzoate* (0.5 g) as described for preparation of ester III*a*. A pure specimen recrystallized from methanol – ethyl ether as pale yellow crystals; m.p. 203–204°, ν_{max}^{KBr} 2300–3000 (broad) and 1720 cm^{-1}.

[7]*The aluminum chloride and lithium aluminum hydride were separately dispersed in 150-ml portions of tetrahydrofuran and mixed just before adding the amide solution.*

[8]*Kofler melting point apparatus.*

N-bis(2-chloroethyl)-3,4,5-trimethoxyphenethylamine (V) Hydrochloride

The acyl chloride (13.4 g, ref. 27) from 3,4,5-trimethoxyphenylacetic acid was converted to N-bis(2-chloroethyl)-3,4,5-trimethoxyphenylacetamide (18.5 g) by using the general procedure described above (see I*a*). Several attempts to crystallize this moisture-sensitive amide were unsuccessful. The crude amide exhibited infrared absorption at ν_{max}^{pure} 1740 (weak) and 1660–1640 (broad) cm^{-1}. Weak absorption at 1740 cm^{-1} was attributed to a small amount (10%) of the corresponding 2-(2′-chloroethylamino)ethyl ester.

Reduction of the amide (11.0 g) to amine V was accomplished as described for preparation of benzylamine II*a* with proportionally adjusted reagent quantities. The crude hydrochloride weighed 6.84 g and melted at 143–146° following recrystallization from methanol – ethyl ether. Four recrystallizations from the same solvent mixture gave pure colorless plates (see Table I); ν_{max}^{KBr} 2700 and 2600 cm^{-1}.

Hexadecanoyl Chloride

Technical grade palmitic acid (30.0 g) was treated with excess phosphorus pentachloride (37 g) as described using 3,5-dimethoxybenzoic acid. The acid chloride boiling at 132–138° (4 mm) was collected: yield, 28.7 g (89%). Ralston (28) has reported a boiling point of 194° at 15 mm. An analytical specimen, distilled through a 15-cm Vigreux column, boiled at 127° (0.8 mm). Calc. for $C_{16}H_{31}ClO$: C, 69.90; H, 11.37; Cl, 12.90. Found: C, 69.97; H, 11.18; Cl, 12.90.

N-bis(2-chloroethyl)hexadecanamide (VII)

The crude amide prepared (see I*a*) from palmitoyl chloride (17.2 g) and N-bis(2-chlorethyl)amine hydrochloride (25.6 g) crystallized following removal of solvent *in vacuo*: yield, 19 g (80%). A small aliquot (ca. 0.5 g) recrystallized from benzene (5 ml) – petroleum ether (20 ml) as colorless microcrystals, m.p. 48–51°. Three recrystallizations from the same solvent led to a pure specimen melting at 55–57°, ν_{max}^{KBr} 1660 cm^{-1}. Calc. for $C_{20}H_{41}Cl_2NO$: C, 63.14; H, 10.33; Cl, 18.64; N, 3.68. Found: C, 63.24; H, 10.11; Cl, 18.38; N, 3.86.

2-(2′-Chloroethylamino)ethyl-hexadecanoate Hydrochloride (IV)

A solution of N-bis(2-chloroethyl)hexadecanamide (VII, 1.0 g) in 95% ethanol (30 ml) was heated at reflux for 30 minutes. After cooling, the colorless crystals (1.0 g) were collected. Three recrystallizations from methanol provided an analytical sample as colorless needles melting[8] at 135–136°, ν_{max}^{KBr} 2700, 2400, and 1715 cm^{-1}. Calc. for $C_{20}H_{41}Cl_2NO_2$: C, 60.28; H, 10.37; Cl, 17.80; N, 3.52. Found: C, 60.48; H, 10.58; Cl, 18.15; N, 3.89.

N-bis(2-chloroethyl)hexadecylamine (VI) Hydrochloride

The crude amide (VII, 16.9 g, 0.044 mole) was reduced using a mixture of aluminum chloride (6.54 g, 0.049 mole) and lithium aluminum hydride (1.85 g, 0.049 mole) as described for preparation of nitrogen mustard II*a*. After cooling[9] the ethereal solution to ca. −10°, the hexadecylamine (VI) hydrochloride (13.9 g, 78%) was collected. Three recrystallizations from methanol – ethyl ether yielded a pure sample as long colorless needles; m.p. 80–81°, ν_{max}^{KBr} 2800–2300 (broad) cm^{-1}. Calc. for $C_{20}H_{42}Cl_3N$: C, 59.63; H, 10.50; Cl, 26.40; N, 3.48. Found: C, 59.95; H, 10.55; Cl, 26.57; N, 3.43.

Wilson and Tishler have reported (29) an alternate route to amine IV hydrochloride (m.p. 76.4–77.2°).

N-bis(2-iodoethyl)-3,4,5-triethoxybenzylamine (IIc) Hydroiodide

A solution of N-bis(2-chloroethyl)-3,4,5-triethoxybenzylamine hydrochloride (1.2 g, 0.003 mole, Table I) in reagent grade acetone (30 ml) was added to 1.35 g of sodium iodide (0.009 mole) in the same solvent (30 ml). The reaction mixture was sealed and stored (with occasional shaking) in the dark at room temperature for 4 days. After removing sodium chloride by filtration, the red filtrate was diluted with ethyl ether. The light-sensitive iodide (1.77 g, 87.5%), m.p. 153–154°, was collected and recrystallized three times from methanol – ethyl ether. Two additional recrystallizations from methanol afforded an analytical sample as pale yellow plates, m.p. 158–159°. Calc. for $C_{17}H_{28}I_3NO_3$: C, 30.24; H, 4.18; I, 56.40; N, 2.08. Found: C, 30.31; H, 3.99; I, 56.40; N, 2.13.

The hydroiodide salt of II*c* exhibited a series of infrared absorption bands (ν_{max}^{KBr} 1290, 1220, 1090, 975, 920, and 955 cm^{-1}) not shown by the hydrochloride derivative of its precursor (II*b*).

N-bis(2-iodoethyl)-3,4,5-trimethoxybenzylamine (IId) Hydroiodide[10]

Conversion of N-bis(2-chloroethyl)-3,4,5-trimethoxybenzylamine hydrochloride (3.6 g, ref. 1) to the hydroiodide salt of nitrogen mustard II*d* was accomplished essentially as outlined in the preceding experiment (cf. II*c*). The iodide crystallized from methanol – ethyl ether as colorless crystals; yield, 4.2 g (66%), m.p. 131–135°. Four recrystallizations from the same solvent gave an analytical sample melting at 151–152° (with decomposition).[8] Calc. for $C_{14}H_{22}I_3NO_3$: C, 26.57; H, 3.50; N, 2.21. Found: C, 26.74; H, 3.77; N, 2.32.

N-bis(2-iodoethyl)-3,4-methylenedioxybenzylamine (VIII) Hydroiodide

A 2.5-g sample of N-bis(2-chloroethyl)-3,4-methylenedioxybenzylamine hydrochloride (1) was treated with sodium iodide as described for preparation of N-bis(2-iodoethyl)-3,4,5-triethoxybenzylamine (II*c*)

[9]*The hydrochloride was relatively soluble in ethyl ether.*
[10]*R. L. Smith performed this experiment.*

hydroiodide. The pale yellow iodo mustard (VIII) hydroiodide weighed 3.7 g (78%), m.p. 162–164°. Following four recrystallizations from methanol, a colorless analytical specimen (needles) melted at 166–167° (darkening from 162°). Calc. for $C_{12}H_{16}I_3NO_2$: C, 24.55; H, 2.75; I, 64.87; N, 2.39. Found: C, 24.91; H, 3.10; I, 65.33; N, 2.15.

POSSIBLE INTRAMOLECULAR VAN DER WAALS CONTRIBUTIONS TO PROTON AND CARBON-13 SHIFTS IN ALIPHATIC AND AROMATIC HALOGEN COMPOUNDS

T. SCHAEFER, W. F. REYNOLDS,[1] AND T. YONEMOTO[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received June 9, 1963

ABSTRACT

The chemical shifts of protons and carbon-13 nuclei in aliphatic and aromatic halogen compounds are considered on the basis of inductive, magnetic anisotropy, and intramolecular dispersion effects. It is suggested that a model based on all three effects is more consistent with experiment than a model based on the first two effects only. The dispersion effects in general cause a low-field shift and seem to outweigh magnetic anisotropy effects in some cases.

I. INTRODUCTION

Chemical shifts of protons and carbon-13 nuclei in compounds of the type CH_3X and CH_3CH_2X have been interpreted in terms of the electronegativity of X (a charge density effect), together with contributions due to magnetic anisotropy of the C—X bond and of the group X itself and (or) anisotropy of the C—C bond (1, 2). As noted by Spiesecke and Schneider contributions from other origins also are indicated (1). Similarly, the neighboring proton and carbon-13 shifts of the phenylhalides have also been attributed to anisotropy effects (3).

Now it is undoubtedly true that anisotropy does play an important role in determining chemical shifts in many instances. The most famous cases are perhaps the low-field shifts of the ring protons in aromatic systems and the high-field shift of the acetylenic protons. The former is the "ring-current" effect (4) and the latter can be thought of as due to the large magnetic susceptibility of the cylindrically symmetrical triple bond in the direction of the bond axis.

A classical formula based on the point-dipole approximation has been given by McConnell (5) and has been widely invoked (1, 2, 3). It is $\Delta\sigma = \Delta\chi/3\mathbf{R}^3 (1 - 3\cos^2\theta)$ where θ is the angle between the vector $\mathbf{R}$ to the point of interest and the bond axis on which the dipole lies; the bond having a magnetic anisotropy of $\Delta\chi$. $\Delta\chi$ is presumably large and negative for bonds C—X where X is a halogen (1). $\Delta\sigma$ is the change in the screening constant σ. When $\mathbf{R}$ is of the order of the radius r of the charge distribution giving rise to the anisotropy, the point-dipole approximation breaks down. However, from considerations of the potential due to a non-ideal dipole it can be said that when $\mathbf{R} \approx r$ the error in the formula will be much less than 100% (6). As long as we accept McConnell's formula and do *not* go over to a quantum-mechanical formulation, we must demand of it a consistent interpretation of low- or high-field shifts. It appears, however, that this is not so for the alkyl and aromatic halogen compounds. An indication of discrepancies is the work of Dailey and Cavanaugh (2) who were led to attribute the shielding in the alkyl halides to a "varying C—C bond anisotropy" because the assumption of a C—X bond anisotropy led to contradictions. Measurements of Diehl (7) on the *ortho* methyl protons of the mesitylene halides showed that these shifts are proportional to and less than those of the *ortho* ring protons of the aromatic halides. This is difficult to explain on an anisotropy

basis. We suggest that intramolecular van der Waals or dispersion forces may also be important in causing anomalous low-field shifts.

II. VAN DER WAALS SHIFTS

Shifts due to dispersion forces are certainly important in intermolecular solvent effects (8). First, interaction in the equilibrium configuration causes a distortion of the electronic environment of the nucleus. This distortion is probably an expansion and leads to a low-field shift. Second, the motion of the molecules at moderate temperatures leads to a time-dependent distortion of the symmetry of the C—H bonds and hence to a negative shift. For molecules whose C—H bonds are exposed to a "sideways" attack this second effect could be important. Now both of these effects could presumably also operate on an intramolecular basis. Certainly the first is possible and the second may arise from internal rotations and vibrations of the molecule. These effects should increase as the number of electrons in the perturbing atom increases (8).

For instance, a plot of the β-methyl proton shifts found by Spiesecke and Schneider (1) for the ethyl halides versus the cube of the van der Waals radius of the halogen atom is a straight line. There is a slight deviation for the chloride but it is much less than 10% of the shift range. The total range is over 30 c.p.s. and the other three shifts lie right on the line. The greatest shift to low field is found for the iodide, as expected. It is true that anisotropy effects might also cause a low-field shift, increasing in that order.

In order to estimate the approximate magnitude of such intramolecular dispersion shifts we assume that they are comparable in magnitude to the known intermolecular dispersion shifts in liquids. Linder and co-workers (9) have given a continuum model treatment of the latter and have considered, in particular, the experimental gas-to-solvent shifts of methane (8). They found that no type of interaction other than dispersion need be invoked to explain the solvent shifts of nonpolar solutes (like methane) in reasonably isotropic solvents. Thus the gas-to-solvent shift for methane in *n*-hexane was about -0.2 p.p.m. and increased rapidly with the number of electrons in the solvent molecule, becoming as large as -0.7 p.p.m. for methylene iodide. On this basis it would be possible to expect intramolecular proton dispersion effects as large as -1 p.p.m.

Another estimate may be obtained as follows. On the basis of London's calculations, Stuart has estimated the dispersion interaction energy of two molecules in a vacuum at various separations (10). He uses average values for the molecular parameters and finds about 2 kcal/mole at a distance of 3 Å. This is very nearly the same as the dipole–dipole interaction energy of two molecules having a dipole moment of 1.6 D. Cresswell and Allred (11) have measured a hydrogen-bond shift with tetrahydrofuran of from -0.5 to -0.8 p.p.m. for the haloforms. The enthalpies of formation were of the order of 2.5 kcal/mole. If we make the assumption that weak hydrogen bond shifts are due to fluctuating electric fields in the immediate vicinity of the acceptor atom and that a somewhat similar effect causes intramolecular low-field dispersion shifts, we again arrive at an expected magnitude of the latter of 0 to -1 p.p.m. depending on the properties of the bonded atom perturbing the C—H bond in the same molecule.

We examine below the shifts of a series of halogen compounds, especially the extensive and accurate data of Spiesecke and Schneider, with a view to establishing the importance of dispersion shifts. We choose the halides because of the large atomic number and radius range, important in dispersion interactions, and also because the anisotropy will be expected to be centered somewhere along the C—X bond in a regular fashion. Groups like the nitro and carboxyl groups would not serve our purpose nearly as well.

*Positive numbers indicate greater screening than for the reference nucleus. Data are from references 1, 3, 7.
†The shifts are for the *ortho* methyl protons and are given on the τ-scale.

(a) Methyl Halides

Spiesecke and Schneider plotted the carbon-13 and proton shifts of a whole series of CH_3X compounds against the electronegativity of X and found deviations to low field for the proton shifts of the chloride, bromide, and iodide. Deviations to high field were found for the carbon-13 shifts for all four halides. These deviations were put down to anisotropy effects of the halide. In Fig. 1(*a*) a scale model for the ethyl halides is shown. Tetrahedral angles have been assumed and internuclear distances were taken from the compilation by Sutton *et al.* (12). Before we can apply the point-dipole formula we must decide where to put the dipole. The proper place is at the electrical center of gravity of the C—X bond. At any rate it would be somewhere between the mid-point of the C—X bond and the X nucleus. In Fig. 1(*a*) lines are drawn connecting these extreme points with the relevant nuclei.

Consider the α-carbon nuclei. The angle θ is zero and the formula predicts a relatively large high-field anisotropic shift after electronegativity (charge density) effects are allowed for. This Spiesecke and Schneider found with the largest high-field shift for the iodide, as expected from a consideration of Pascal's constants and ionic susceptibilities (13).

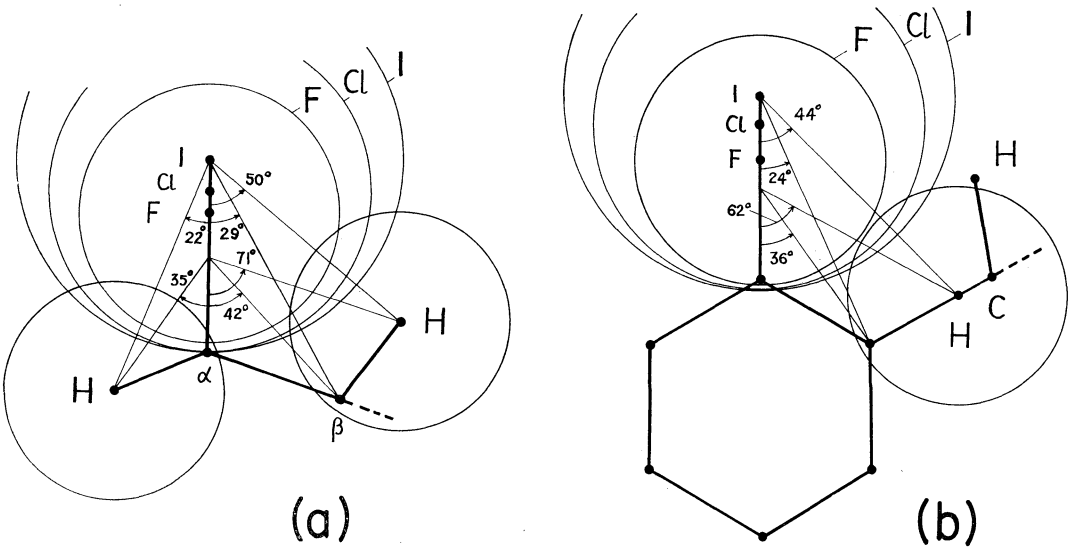

FIG. 1. The figure represents scale models of an ethyl halide molecule (*a*) and of a phenyl halide (or halo-mesitylene) (*b*). Bonds are indicated by heavier lines. The circles represent the van der Waals radii approximately. In (*a*) note that the model should be looked at as representing the halogen-α-carbon-α-hydrogen spatial relationships and, independently, the halogen-α-carbon-β-carbon relationships.

Consider now the α-proton, corresponding to the methyl protons in CH_3X. The angle θ lies between 35° and 22° and remains constant over the rotation of the methyl (or methylene) group. According to McConnell's formula a *high-field* shift should result after allowance for inductive effects. This was not found by Spiesecke and Schneider (1). They found a *low-field* shift and attributed this to inaccuracies of the point-dipole approximation (the finite volume of the electron cloud is ignored). However, the excess low-field shift is quite large (over 1 p.p.m. for CH_3I) and we would expect at least qualitative agreement with the formula.

Whether this is so or not we suggest that dispersion interactions arising from bond vibrations and (or) rotations will cause a low-field shift also and that this explanation is consistent with other data to be considered below. In Fig. 1 circles representing the van der Waals radii of the halogens and the hydrogen atom have been drawn. The values are from Pauling (14). These circles represent a crude attempt to show that electrical interactions between the relevant charge clouds could be large enough to affect bond symmetries and hence cause a low-field shift. For a better approximation the circles should be replaced by "pear-shaped" or other types of contours. However, the overlap of the circles is large enough to indicate that vibrations (perhaps especially bending motions) would be large enough to give rise to dispersion effects.

At this point we may well ask why the proton shift in dimethyl sulphide is displaced to low field by an amount comparable to that of methyl iodide (Fig. 4 of ref. 1). A similar situation is found in the corresponding ethyl compounds. Part of the explanation may go as follows. It has been argued by Linnet and co-workers (15) and very recently by Clementi (16) that there is, at least instantaneously, a pronounced directional character in the pair distribution of atoms. If the pairs in methane can be considered to be strongly localized and directional, the pairs in the neon atom have as much localization and direction (16). While in methane the protons stabilize the directional and localized character of the pairs, in neon there is a large directionality instantaneously. The lone pairs in bonded atoms should have a similar directionality and the spatial extension of these lone pairs would,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of course, become larger as the screening by the inner shells increases, that is, as the atomic number increases. The electric fields from these lone pairs could presumably lead to a dispersion shift, which would increase in importance as the lone pairs increase in number and spatial extension. Even in the absence of intramolecular vibrations and rotations, then, the electric fields from the lone pairs could cause a low-field shift. This effect would be augmented and perhaps outweighed by favorable vibrational and rotational configurations.

Since the points for dimethylether and trimethylamine lie on the electronegativity correlation line in Fig. 4 of ref. 1, on this basis it would then follow that for these compounds, both in row 2, the spatial extension of the lone pairs is not large enough to result in appreciable "lone pair dispersion" effects. In this connection we note that the point for methyl fluoride also lies on the correlation line. In third row compounds this is no longer so and the two lone pairs of sulphur then give rise to an appreciable low-field shift; augmented, perhaps, by intermethyl dispersion effects. In tetramethylsilane there are no lone pairs and its point lies almost on the line: perhaps intermethyl group effects account partly for the small deviation to low field. On this basis dimethyl selenide should exhibit a greater low-field shift for the protons than dimethylsulphide, *given* that bond pair – lone pair angles do not change. This is a further complication which would have to be considered in a quantitative theory.

(b) Ethyl Halides

The argument presented above for the methyl halides holds also for the carbon and proton shifts of the methylene group in the ethyl halides.

We assume that the inductive effect of the substituent is largely absent at the methyl group (1). Consider the β-carbon. The angle θ varies between 42° and 29° for the extreme positions of the magnetic dipole for the iodide. The anisotropy effect should be a high-field shift, although smaller than for the α-carbon because of the larger separation. A low-field shift is found and can again be attributed to dispersion interactions, the low-field shift being largest for the iodide. In the case of the β-proton a low-field shift was found (Table I). For the position shown in Fig. 1 both anisotropy and dispersion forces would cause a shift to low field. For an average position indicated by the dotted line* the anisotropy contribution would now be to high field. The dispersion interaction would be at a maximum for the position shown in Fig. 1 and would presumably drop off rapidly with distance becoming small in other rotational configurations.

After correction for inductive effects the α-carbon shifts in methyl and ethyl halides can be attributed to magnetic anisotropy effects of the C—X bond. We suggest that the α-proton, β-proton, and β-carbon shifts can also be qualitatively described as due to dispersion interactions which result in an asymmetry of the chemical bond. On this model the dispersion interactions outweigh the anisotropic shifts for the α-protons and β-carbons. The dispersion effects should in general fall off more rapidly with distance than the magnetic effects but it is hard to put this on a quantitative basis, especially since internal motions of the molecule would have to be considered.

IV. PROTON AND CARBON-13 SHIFTS IN AROMATIC HALIDES

The ring proton chemical shifts of substituted benzenes have been a subject of considerable study (17, and references therein; 18–20). Additivity relationships of substituent

**This is a very rough way of estimating the effect but should indicate the approximate extent of the rotational averaging. An accurate averaging process would involve some intransigent integrals hardly necessary in a qualitative discussion of this type.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

effects in polysubstituted benzenes have been established (17, and references therein; 18, 19). The *para* proton shifts are understood insofar as they correlate with Hammett sigma constants, as do the *para* carbon-13 shifts (3, 17, and references therein). At this position anisotropy, inductive, and, we suggest, dispersion contributions to the shifts will be very small; and, as suggested by Spiesecke and Schneider, the shifts will mirror the π-electron density at the *para*-carbon (3). For strongly electron-withdrawing or electron-releasing substituents the *ortho* shifts should also reflect this effect. This is found for the nitro and amino group, for instance (3). At the *ortho* positions of the halides magnetic and dispersion effects may be large enough, compared to resonance effects, to affect the shifts considerably. In Table I the carbon-13 and proton shifts relative to benzene are given for the phenyl halides. They are taken from reference 3.

(a) Carbon-13 Shifts

In Fig. 1(*b*) a scale model is shown for the aromatic halides. The construction is analagous to that in Fig. 1(*a*) as described above. Consider the C—X carbon-13 shifts. After correction for anisotropy effects as estimated from the α-carbon shifts in the alkyl halides, a rough correlation with electronegativity was found by Spiesecke and Schneider (3). This is very reasonable.

Consider now the *ortho* carbon-13 shifts. The high-field shift for the fluoride is reasonably explained as indicating the predominant effect of the $=F^+$ resonance structures. In this connection it is important to remember that, of all the halogens, fluorine will most easily form a double bond with the ring carbon. Also, the dispersion and anisotropy effects should be smallest for fluorine. The *ortho* carbon-13 shifts for the other halogens progressively decrease as the halogen atom increases in size. From the angles in Fig. 1(*b*), it appears that the anisotropy should cause a high-field shift. An increasing dispersion interaction would cause an increasing low field shift, as observed.*

(b) Ortho Proton Shifts

For the *ortho* proton in fluorobenzene we can again invoke the predominance of the resonance effect. The resonance structure above predicts a high-field shift for this proton as indicated by a large series of measurements (21, and references therein). Anisotropy and dispersion effects are again presumably too small to offset the resonance effect.

For the other compounds there is once more an increasing shift to low field as the size of the halogen increases. If the point dipole is placed at the halogen nucleus a high-field shift is predicted while a small low-field shift is predicted if the dipole is placed at the mid-point of the bond. The dispersion interaction predicts an increasing shift to low field with increase in size of halogen atom, as observed.

(c) Estimation of the Magnitudes of the Dispersion Shifts

In the absence of quantitative information on the magnitude of the anisotropy shifts, only a very crude estimate of the dispersion shifts can be made. If we accept the correlation plots of shift versus electronegativity of Spiesecke and Schneider (1) the deviations to low field may be taken as rough estimates of the dispersion shifts. If the anisotropy formula above is taken as exact these must be regarded as minimum values. These range from about -1.0 to -1.5 p.p.m. for α-protons in the iodide to -0.7 to -1.0 p.p.m. for the chloride. For β-protons the values are correspondingly less by about 0.5 p.p.m. For *ortho* protons in the phenyl halides these shifts seem to be still less but in view of the

**A very small low-field shift is also observed for the meta carbon-13 nuclei but if this is attributed to anisotropy then the high-field shift for the meta protons remains unexplained. Resonance effects are expected to be small at the meta position.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

added complications due to possible mesomeric effects it is hard to say how much. Presumably dispersion effects are almost negligible for the fluorides. For β-carbons the dispersion shift may be as much as -20 p.p.m. in the iodide and as large as -10 p.p.m. for the *ortho* carbon in the phenyl iodide. Again, estimates of the anisotropy and mesomeric shifts are needed.

V. *ORTHO* METHYL PROTON SHIFTS IN MESITYLENE

Diehl has measured the *ortho* methyl proton shifts in the mesitylene halides (7). He finds the shifts are proportional to those of the *ortho* proton in the phenyl halides. They are smaller by a factor of 0.35. The τ-values are given in Table I. In Fig. 1(*b*) the methyl group is indicated with the proton in the configuration nearest the halogen. The dotted line running through the methyl carbon represents an average position of the proton. With the methyl proton near the halogen it is seen that **R** is virtually the same as for an *ortho* proton in the phenyl halide. The angle is very nearly 90° resulting in a predicted low-field shift for the methyl proton of about 3 times that of the ring proton if the dipole is put at the bond center. Otherwise the difference would be even greater. On the other hand, in the averaged position the increase in **R** is roughly offset by the decrease in θ. At any rate, it is hard to reconcile the greatly reduced effect on the methyl protons with an anisotropy contribution only, as noted by Diehl (7).

In the situation shown in Fig. 1(*b*) there is very strong overlap and therefore, perturbation of the methyl hydrogen electron cloud by the electron cloud of the larger halogen atoms. But in the rotational configuration related to this one by 180° there will be no appreciable overlap. In this case the low-field dispersion shift would therefore be much smaller than for the *ortho* proton in the phenyl halide. After rotational averaging it may be that the smaller low-field methyl proton shift becomes understandable.

On this assumption the high-field shift of 0.04 p.p.m. for the *ortho* methyl group in fluoromesitylene as compared to mesitylene is to be explained as in the corresponding *ortho* proton case. The effect is reduced as would be expected. Whether this argues for hyperconjugation of the methyl group with the ring is questionable.

VI. CONCLUSIONS

As mentioned above, it is hard to put intramolecular dispersion shifts on a quantitative basis. However, we consider that they are present, that they lead in general to low-field shifts of nuclear resonances, and that they may in certain situations be at least as important as anisotropy effects. Various experiments suggest themselves as a check on these considerations. At any rate, we feel that the possibility of the importance of intramolecular dispersion shifts cannot be rejected out of hand.

SYNTHESES AND POLYMERIZATION OF α-TRIMETHYLSILYL ACRYLIC MONOMERS

ARIEL OTTOLENGHI, MATI FRIDKIN, AND A. ZILKHA
Department of Organic Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel
Received July 24, 1963

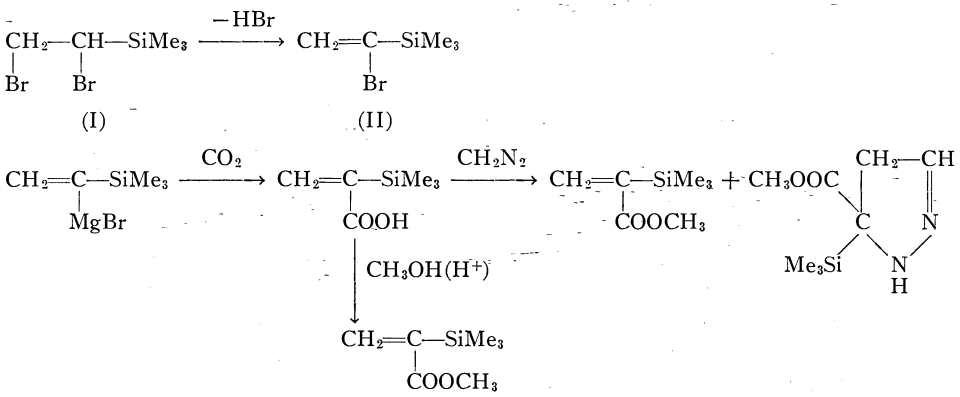
ABSTRACT

α-Trimethylsilyl acrylic acid and its methyl ester were prepared in good yield starting from 1,2-dibromoethyltrimethylsilane. These monomers were polymerized with difficulty by free radicals to viscous polymers, but gave solid copolymers with styrene. The methyl ester was also a weak monomer in anionic polymerization. This non-reactivity is due to the steric effect of the α-trimethylsilyl group adjacent to the double bond.

In the present work the preparation and polymerization of α-trimethylsilyl acrylic acid and its methyl ester were investigated. Apart from their intrinsic interest as new monomers, they permit the study of the steric and electric effects of bulky groups attached directly to reactive double bonds, on free radical and anionic polymerization.

Petrov, Mironov *et al.* (1, 2) prepared α-trimethylsilyl acrylic acid by carbonation of the Grignard reagent prepared from α-bromovinyltrimethylsilane (II), and also mentioned its polymerization without giving any details.

We prepared the α-trimethylsilyl acrylic derivatives according to the following scheme:



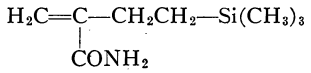
Agre and Hilling (3) have prepared α-bromotrichlorovinylsilane by bromination of vinyl trichlorosilane and subsequent dehydrobromination with quinoline. This last step was realized in 40% yield only due to decomposition of the dibromoderivative with the formation of silicon tetrachloride. This same procedure was later reported (2) to give the α-bromo derivative in 65% yield. α-Bromovinyltrimethylsilane (II) was prepared in 74% yield from this derivative by reaction with methyl magnesium bromide.

We tried to obtain α-bromovinyltrimethylsilane (II) in higher yield starting from 1,2-dibromoethyltrimethylsilane (I) which is obtained in 90% yield from vinyltrimethylsilane (4). Dehydrobromination of this derivative by quinoline gave 10% yield of (II). Since the lower yield of the dehydrobromination in this case may be due to the lower activating effect of the adjacent trimethylsilyl group as compared to the trichlorosilyl group, stronger bases were tried to determine the effect on the yield. Reaction of the dibromo derivative

with sodium methoxide, both solid and in methanol solution, caused an immediate β-elimination reaction, similar to that found by Sommer *et al.* (4), leading to the formation of trimethylsilyl methoxide. Use of sodium butoxide in butanol led to a similar elimination reaction with formation of trimethylsilyl butoxide. Diethylamine in ether, which is a stronger base than quinoline, gave a 70% yield of (II). The reaction was slow and required several days. However, it was found that with diethylamine alone yields of more than 90% were obtained in a relatively short reaction time.

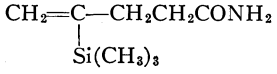
From α-trimethylsilyl acrylic acid (1, 2) the methyl ester was prepared either by direct esterification with absolute methanol in the presence of mineral acid, or by reaction with diazomethane. The latter reaction carried out at 0° in ether, led to the formation of appreciable amounts of probably 5-trimethylsilyl 5-carbomethoxypyrazoline, formed by addition of diazomethane to the double bond, together with a 50% yield of the methyl ester. However, on carrying out the reaction at −70°, a 75% yield of ester was realized and only traces of the pyrazoline derivative were formed.

Reaction of α-trimethylsilyl acrylic acid with thionyl chloride at room temperature, followed by heating the reaction mixture under reflux, resulted in the formation of an acid chloride which had a lower chlorine content than that required by α-trimethylsilyl acrylyl chloride. This acid chloride was converted to the amide derivative by reaction with gaseous ammonia in ether solution. The amide did not analyze for α-trimethylsilyl acrylamide. The infrared spectrum showed absorptions for a carbon–carbon double bond, as well as for the trimethylsilyl group and for the amide group. Its n.m.r. spectrum indicated nine protons of the trimethylsilyl group at 10 τ, four aliphatic protons at 7.5–7.8 τ, two vinyl protons at 4.7–4.8 τ and 4.5 τ (doublet), and two amino protons at 3.8–4.8 τ. The n.m.r. spectrum and the analytical results are in accordance with the following formula:



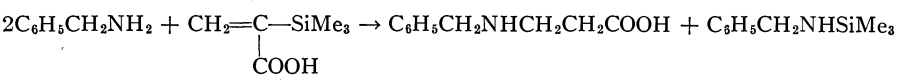
It is difficult to establish the mechanism by which the acid chloride (starting material for the amide derivative) was obtained, but it may be formed by joining two molecules of α-trimethylsilyl acrylic acid, one which has undergone decarboxylation, and the other which has undergone cleavage of the trimethylsilyl group, due to the strongly acidic medium and the heating. Such cleavages of α-trimethylsilylvinyl derivatives by strong acids have been found to occur easily (5, p. 140).

From the analytical and physical data, the following formula is also possible for the amide derivative.



However, this structure contains a trimethylsilyl group adjacent to a vinyl double bond, which is difficult to obtain because of acid cleavage.

In an attempt to prepare β-amino acids substituted in the α position by trimethylsilyl groups, α-trimethylsilyl acrylic acid was heated with benzylamine in pyridine. No addition of benzylamine to the double bond occurred, but β elimination did, resulting in splitting off of the silicon residue and formation of acrylic acid, which on reaction with benzylamine led to the formation of *N*-benzyl-β-alanine (6) as follows:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In an attempt to prepare other vinylsilicon monomers, we tried the reaction of α-trimethylsilylvinyl magnesium bromide in tetrahydrofuran with benzophenone. The reaction did not lead to the addition of the Grignard reagent to the carbonyl double bond but to the formation of benzopinacol, as seen from analyses, melting point, and mixed melting points with an authentic sample. Such a reaction can occur if the Grignard reagent acted as an electron transfer agent leading to the formation of intermediate ketyl derivatives. This seems to have been the case as a blue color, similar to that shown by benzophenone sodium, developed in the reaction mixture during the addition of benzophenone.

Polymerization Experiments

The free radical polymerizations of α-trimethylsilyl acrylic acid and its methyl ester were investigated. These monomers polymerized only with great difficulty even in the presence of relatively high concentrations of benzoyl peroxide and required long reaction times. Irradiation with ultraviolet light in the presence of azo-bis-isobutyronitrile did not cause significant polymerization. The polymers obtained, were highly viscous.

On the other hand, free radical copolymerization of these monomers with styrene was much easier, and solid copolymers were obtained.

The anionic polymerization of the methyl ester was also investigated with phenyl and butyl lithium as catalysts in tetrahydrofuran and petroleum ether. Only partial polymerization occurred even when high catalyst concentrations were used. In all cases, side reactions occurred leading to the formation of liquid products, having relatively low boiling point, which might be formed on addition of the alkyl lithium to the double bond (7), or to the ester group as found in the case of methylmethacrylate (8).

In contrast, it was found that trimethylsilylmethylvinylketone in which the trimethylsilyl group is in a β-position to the active double bond polymerized easily on heating. This is illustrated by the direct preparation of solid polymer in the synthesis of the ketone by reaction of trimethylsilyl methyl magnesium bromide and acrylyl chloride.

The unreactivity of the α-trimethylsilyl acrylic derivatives both in free radical and anionic polymerizations is due to the presence of the trimethylsilyl group in the α position to the vinyl double bond. The silicon atom is more electropositive than carbon. It has vacant *d* orbitals that can hybridize with the π electrons of the adjacent vinyl double bond ($d\pi$—$p\pi$ interaction) (5, p. 100), and thus cause an electron withdrawing effect ($-T$) which is contrary to the $+I$ effect of the methyl groups attached to the silicon atom. There is evidence that the $-T$ effect is stronger than the $+I$ effect, as is seen, for example, from the anti-Markownikoff addition of hydrogen halides to vinyl trimethyl silane (9). From this electric consideration, it would be expected that the trimethylsilyl group should favor the anionic polymerization of the methyl ester by contributing to the reactivity of the double bond by making it more acidic. Since the monomers were not sufficiently reactive it must be that the steric hindrance of the bulky trimethylsilyl group is the governing factor in determining the reactivity of the monomers.

EXPERIMENTAL

*Vinyltrimethylsilane**

Into a three-necked flask fitted with a high speed stirrer, a dropping funnel, and a reflux condenser magnesium metal filings (26.4 g, 1.1 mole), tetrahydrofuran (800 ml), and an iodine crystal were added. Vinyl bromide (107 g, 1 mole) dissolved in tetrahydrofuran (200 ml) was added dropwise so that there was a

**This compound was previously prepared in about 60% yield starting from methyl magnesium halide and vinyltrichlorosilane, or by the Wurtz reaction between vinyl chloride and trimethylchlorosilane (10). The following method starting from vinyl magnesium bromide and trimethylchlorosilane gives higher yields.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

gentle reflux. The addition required about 3 hours, and the reaction mixture was refluxed for another hour. Trimethylchlorosilane (108 g, 1 mole) dissolved in tetrahydrofuran (100 ml) was added dropwise during 2 hours, and the reaction mixture refluxed for 1 hour more. The reaction mixture was fractionally distilled with an efficient column, and the material boiling up to 60° was collected. This distillate contained tetrahydrofuran together with vinyltrimethylsilane. The tetrahydrofuran was separated by successive washings with water, in which the vinyltrimethylsilane is insoluble. The substance was dried over anhydrous calcium chloride and fractionally distilled. The vinyltrimethylsilane was collected at 55–56°; yield 90 g (90%); n_D = 1.390 (11).

Reaction of 1,2-Dibromoethyltrimethylsilane with Potassium Methoxide

To 1,2-dibromoethyltrimethylsilane (10.4 g, 0.04 mole), prepared by bromination of vinyltrimethylsilane (4), was added with stirring and exterior cooling potassium methoxide solution in methanol (0.78 N, 51 ml) (0.04 mole). Potassium bromide precipitated immediately. It was filtered, and the filtrate was washed with water to remove methanol, dried, and distilled. The compound distilled at 55° and 690 mm, n_D = 1.367, the infrared spectrum showed a (Si—O—C) bond at 9.2 μ, and the compound is therefore trimethylsilylmethoxide (11).

Similar results were obtained on reaction of 1,2-dibromoethyltrimethylsilane with solid sodium methoxide.

Reaction of 1,2-Dibromoethyltrimethylsilane with Potassium Butoxide

This was carried out as before using potassium butoxide in butanol. Trimethylsilyl butoxide (11) was obtained, b.p. 118° at 690 mm, n_D = 1.392.

α-Bromovinyltrimethylsilane

1,2-Dibromoethyltrimethylsilane (217 g, 0.83 mole) and diethylamine (121 g, 1.66 mole), dried over sodium hydroxide, were shaken in a flask for 5 hours at room temperature. The precipitate of diethylamine hydrobromide was filtered and washed with ether. The filtrate was washed several times with cold 5% hydrochloric acid to remove diethylamine, followed by water and dried over magnesium sulphate. α-Bromovinyltrimethylsilane (2) was collected at 26–27° and 15 mm, n_D = 1.458; yield 137 g (92%).

The same reaction carried out in ether (200 ml), with 1,2-dibromoethyltrimethylsilane (200 g) and diethylamine (2 equiv.), with stirring under reflux gave only 70% yield of the α-bromovinyltrimethylsilane after 30 hours, the unreacted dibromo derivative being recovered unchanged.

Methyl α-Trimethylsilyl Acrylate

α-Trimethylsilyl acrylic acid (16 g), prepared by carbonation of the Grignard reagent obtained from α-bromovinyl trimethylsilane (1, 2), was dissolved in absolute methanol (35 ml), concentrated sulphuric acid (0.9 ml) added, and the reaction mixture refluxed for 15 hours. Excess methanol was removed at room temperature *in vacuo*, the residue was taken up in ether (30 ml) and washed with bicarbonate. The ether extract was dried and distilled. The ester was collected at 75° and 50 mm or at 152° and 690 mm, n_D = 1.436, yield 12 g (68%). The infrared spectrum showed absorptions at 5.8 μ (ester group), at 6.2 μ (C=C), and at 8.0 μ and 11.9 μ (trimethylsilyl).

Anal. Calc. for $C_7H_{14}SiO_2$: C, 53.2; H, 8.9; Si, 17.7. Found: C, 54.0; H, 9.0; Si, 17.6.

Methyl α-Trimethylsilyl Acrylate and 5-Trimethylsilyl-5-Carbomethoxy Pyrazoline

Into a three-necked flask fitted with a mechanical stirrer, a dropping funnel and a reflux condenser, α-trimethylsilyl acrylic acid (31.7 g, 0.22 mole) and dry ether (50 ml) were added. An ethereal solution of diazomethane (0.25 mole) was added dropwise at 0°. Nitrogen gas was evolved and a precipitate formed. After addition of the diazomethane the reaction mixture was stirred for another hour. The precipitate (7 g) was filtered, and the ethereal solution fractionally distilled. The methyl ester was collected at 75° and 50 mm, n = 1.436; yield 18.5 g (53%).

The yellowish precipitate, consisting of 5-trimethylsilyl-5-carbomethoxy pyrazoline, was recrystallized from ether – petroleum ether, m.p. 65°. The pyrazoline was soluble in water, acetone, and alcohol. It darkened on exposure to light.

Anal. Calc. for $C_8H_{16}N_2O_2Si$: C, 48.0; H, 8.0. Found: C, 47.4; H, 7.9.

Reaction of α-Trimethylsilyl Acrylic Acid with Thionyl Chloride

Redistilled purified thionyl chloride (50 g, 0.44 mole) was added dropwise at 0° to α-trimethylsilyl acrylic acid (22 g, 0.15 mole). The reaction mixture was left at 0° for 30 minutes and then for several hours at room temperature. The reaction mixture darkened considerably and was refluxed for 2 hours. Excess thionyl chloride was distilled at atmospheric pressure, and the acid chloride was collected at 45–50° and 1 mm; n_D = 1.48; yield 6 g. It contained 19.1% chlorine as compared to 21.8% required by α-trimethylsilyl acrylyl chloride and 18.7% required by 2-methylene-4-trimethylsilyl butyryl chloride. The acid chloride was dissolved in dry ether (50 ml) and cooled to 0° while dry ammonia gas was passed in for 15 minutes. The ethereal solution was washed with water followed by dilute hydrochloric acid, water, and dried over sodium sulphate. The ether was stripped off and the amide derivative recrystallized from dilute ethanol, m.p. 67°. The substance analyzed for 2-methylene-4-trimethylsilyl butyramide.

Anal. Calc. for $C_8H_{17}NOSi$: C, 56.1; H, 9.9; N, 8.2; Si, 16.4. Found: C, 56.1; H, 9.9; N, 8.3; Si, 16.2.

Reaction of α-Trimethylsilyl Acrylic Acid with Benzylamine

α-Trimethylsilyl acrylic acid (0.8 g) was dissolved in pyridine (2 ml) and benzylamine (1 g) added. The solution was heated at 100° for 3 hours. The reaction mixture was cooled, acetone added, and the resulting precipitate was filtered and recrystallized from water–acetone, m.p. 196°. It did not contain silicon. From analysis, infrared spectrum, and mixed melting point with an authentic sample, the substance was found to be *N*-benzyl-β-alanine (6).

Reaction of α-Trimethylsilylvinyl Magnesium Bromide with Benzophenone

α-Bromovinyltrimethylsilane (10 g, 0.055 mole) was added dropwise with stirring to magnesium filings (1.32 g, 0.055 mole) and dry tetrahydrofuran (50 ml), so as to keep a gentle reflux. (If necessary, a few drops of ethylene dibromide were added to start the reaction.) Refluxing was continued for 1 hour after addition. Benzophenone (10 g) in ether (30 ml) was dropped in during 30 minutes with exterior cooling, and the reaction mixture was heated for 1 hour. During addition, a deep blue color appeared in the solution. The reaction mixture was cooled, ice-cold dilute sulphuric acid was added, and the organic layer separated. The aqueous layer was further extracted with ether. The tetrahydrofuran and ether were driven off from a water bath and the residue recrystallized from alcohol–water. The compound melted at 185°; yield, 3 g. From analyses, infrared spectrum, and mixed melting points it was found to be benzopinacol.

Free Radical Polymerization of α-Trimethylsilyl Acrylic Acid and its Methyl Ester

Monomer (1 g) was placed in an ampoule together with 5% benzoyl peroxide, purified oxygen-free nitrogen was passed in for 10 minutes, and the ampoule was closed and heated at 80°. The acid polymerized to a very viscous mass after 3 days while the ester polymerized only partially after 2 weeks.

Copolymerization experiments with styrene were carried out under the same general conditions at 90°. The copolymers were ground and purified by extraction with methanol. Generally the yields were quantitative. The results are summarized in Table I.

TABLE I

Copolymerization of α-trimethylsilyl acrylic acid and its methyl ester with styrene

Acid (mmole)	Ester (mmole)	Styrene (mmole)	Benzoyl peroxide (mmole)	% Si in copolymer	Time of solidification (days)

[a]Copolymer is insoluble in methanol; m.p. 110–115°.
[b]Melting point of copolymer 100–110°.
[c]Melting point of copolymer 95–100°; a small part of the polymer is soluble in methanol.
[d]Melting point of copolymer 115–120°; copolymer is insoluble in methanol.
[e]Copolymer is partially soluble in methanol.
[f]Copolymer is partially soluble in methanol.
[g]The polymer is partially soluble in methanol. The soluble fraction melted about 120° and contained 7.9% Si (acid in copolymer 40.5%), while the insoluble fraction melted at 185–195° and contained 12.5% Si (acid in copolymer 64%).

Polymerization of Methyl α-Trimethylsilyl Acrylate with Butyl Lithium

(*a*) Methyl α-trimethylsilyl acrylate (4 g) was dissolved in dry ether (10 ml) and butyl lithium in toluene (6×10^{-3} mole) was added at 0° under nitrogen. The reaction mixture was left overnight and was washed with dilute hydrochloric acid. The organic layer was dried over magnesium sulphate, and fractionally distilled. A fraction (0.5 g) was collected at 100° and 5 mm, $n_D = 1.455$. In the infrared it showed absorptions for the trimethylsilyl group and it may be a product of addition of butyl lithium to the ester. A viscous polymer residue (2 g) remained which did not distill up to 200° at 1 mm. In the infrared it showed absorptions for ester groups for trimethylsilyl groups but essentially no carbon–carbon double bond.

(*b*) The reaction between butyl lithium and the ester was carried out under the same conditions as above except that the polymerization temperature was 20°. Fractional distillation gave 1 g unreacted ester and 1.5 g of the product boiling at 100° and 5 mm, $n_D = 1.455$. A polymeric viscous residue (1 g) remained which behaved similarly as before.

Polymerization of Methyl α-Trimethylsilyl Acrylate with Sodium Naphthalene

To freshly distilled methyl α-trimethylsilyl acrylate (4 g) dissolved in dry ether (10 ml), sodium naphthalene in tetrahydrofuran (6×10^{-3} mole) was added at 0° under nitrogen. The reaction mixture was left overnight, and was worked up as before. Fractional distillation gave a fraction boiling at 190–200° and 5 mm, $n_D = 1.490$, and a polymeric viscous residue (1 g) which was similar to the above polymers.

Attempted Preparation of Vinyltrimethylsilylmethylketone

Trimethylsilylmethyl iodide (7 g, 0.033 mole) dissolved in dry ether (20 ml) was added dropwise with stirring during 30 minutes to magnesium filings (0.8 g, 0.033 mole) and 30 ml ether. The reaction mixture was refluxed gently for 30 minutes, cooled, and added dropwise during 1 hour to acrylyl chloride (3 g, 0.033 mole) in ether (30 ml). The reaction mixture was refluxed for 1 hour and the ether was driven off from a water bath. The residue was heated *in vacuo* to continue the distillation, but nothing distilled and the residue became very viscous. It was purified by trituration with methanol. The polymer was insoluble in acetone but soluble in tetrahydrofuran. It softened around 120° and melted at about 150°. Its infrared spectrum showed absorptions at 5.8 μ (carbonyl) and 8.9 μ and 11.9 μ (trimethylsilyl). It gave a dinitrophenylhydrazone showing the presence of the carbonyl group. The material obtained is, as indicated by analysis, polymeric trimethylsilylmethyl vinyl ketone contaminated with polyacrylic acid.

STEREOCHEMISTRY OF ARSENIC

PART XII.[1] BIS(DIPHENYLARSENIC) OXIDE

W. R. CULLEN AND J. TROTTER

Department of Chemistry, The University of British Columbia, Vancouver, British Columbia

Received July 26, 1963

ABSTRACT

Crystals of bis(diphenylarsenic) oxide are monoclinic, with four molecules in a unit cell of dimensions $a = 11.48$, $b = 30.2$, $c = 5.97$ Å, $\beta = 93.8°$, space group $P2_1/n$. The structure has been determined from projections along the a and c axes, using Fourier and difference syntheses. The As—O—As angle is 137°, the increase from the normal oxygen valency angle probably being a result of $p\pi$—$d\pi$ bonding involving arsenic $4d$ orbitals. The As—O distance is 1.67 Å, and all the other bond lengths and angles are normal. The orientations of the substituent phenyl groups have been determined.

INTRODUCTION

The crystal and molecular structure of bis(diphenylarsenic) oxide, $(C_6H_5)_2As.O.As(C_6H_5)_2$, has been determined as part of a series of investigations of arsenic compounds (1).

EXPERIMENTAL

Crystals of bis(diphenylarsenic) oxide are colorless prisms elongated along c. The density was measured by flotation in aqueous silver nitrate, and the unit cell dimensions and space group were determined from various rotation, oscillation, and Weissenberg films (Cu$K\alpha$ radiation, $\lambda = 1.5418$ Å).

Crystal Data

Bis(diphenylarsenic) oxide, $C_{24}H_{20}OAs_2$; $M = 474.2$; m.p. = 95° C.

Monoclinic, $a = 11.48 \pm 0.03$, $b = 30.2 \pm 0.1$, $c = 5.97 \pm 0.02$ Å, $\beta = 93.8° \pm 0.5°$.

Volume of the unit cell = 2065 Å^3.

$D_m = 1.514$, $Z = 4$, $D_x = 1.516$ g cm^{-3}.

Absorption coefficient for X-rays, $\lambda = 1.5418$ Å, $\mu = 45$ cm^{-1}. $F(000) = 952$.

The intensities of the $hk0$ reflections were recorded on Weissenberg films and estimated visually. The $0kl$ intensities were measured with a G.E. Spectrogoniometer, using a scintillation counter, Cu$K\alpha$ radiation (nickel filter and pulse height analyzer), and the moving crystal–moving counter technique (2). The crystals used had fairly uniform cross-sections and no absorption corrections were applied. The relative structure amplitudes were derived as usual, the absolute scale being established later by correlation with the calculated structure factors. 253 $hk0$ and 114 $0kl$ reflections were observed.

Structure Analysis

The projection along the short c-axis was examined first, and the coordinates of the arsenic atoms were determined from a Patterson synthesis. Structure factors were calculated for the $hk0$ reflections with the arsenic contributions only, using the scattering factor of the International Tables (3), corrected for thermal vibration as usual with $B = 4.5$ Å^2. R for the observed reflections was 0.42. A Fourier series was summed by using as coefficients measured structure amplitudes and calculated signs, but the resulting electron-density map was difficult to interpret. The arsenic atoms and the oxygen atom were well resolved, and one six-membered ring was reasonably well defined and a second rather poorly resolved, but the other two rings could not be located. Inclusion of the contributions of the oxygen and 12 carbon atoms, again with the International Tables' scattering curves (3) with $B = 4.5$ Å^2, reduced R, but only to 0.37. Two more successive Fourier syntheses revealed the third and then the fourth rings, R being reduced to 0.36 and then 0.28. A fourth electron-density distribution, with signs based on all the atoms, gave improved resolution and better positional parameters ($R = 0.21$). The positional and isotropic thermal parameters were then further refined by $(F_o - F_c)$ syntheses. The first difference map suggested small shifts in positional parameters, changes in the isotropic thermal parameters, and the need for anisotropic temperature factors for the arsenic atoms, the directions of maximum thermal vibration being parallel to b. The thermal anisotropy was treated by splitting each arsenic into two half-atoms (4), and application of the various changes reduced R to 0.18.

For personal use only.

A second (F_o–F_c) synthesis suggested smaller changes, giving $R = 0.16$, and a third (F_o–F_c) synthesis showed no further significant changes in parameters.

The arsenic positions in the *a*-axis projection were determined by Patterson methods, and location of the other atoms and refinement of the parameters proceeded as for the *c*-axis projection. Since the resolution was poorer, no account was taken of thermal anisotropy, and the final R value was 0.18.

The measured and calculated structure factors for both zones are not listed here to save space but are available from the authors. Electron-density projections are shown in Figs. 1 and 2.

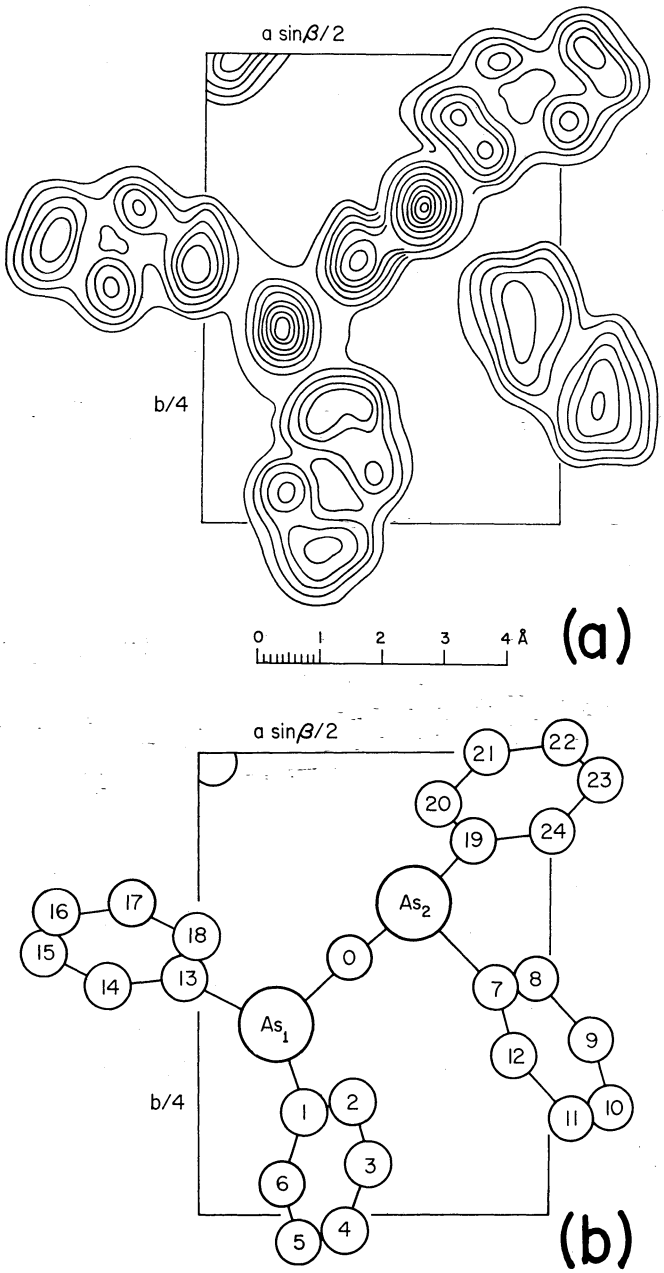

FIG. 1. (*a*) Electron-density projection along *c*. Contours start at 2 eÅ^{-2} and are at intervals of 1 eÅ^{-2}, except at the As atoms, where they start at 5 eÅ^{-2} and are at intervals of 5 eÅ^{-2}. (*b*) Projection of the molecule along ***c***.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

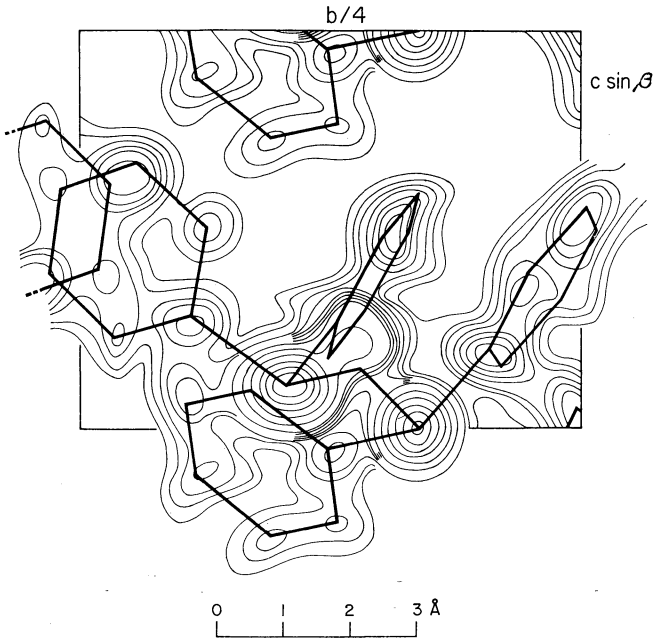

FIG. 2. Electron-density projection along *a*. Contours start at 2 eÅ^{-2} and are at intervals of 1 eÅ^{-2}, except above 10 eÅ^{-2}, where the interval is 5 eÅ^{-2}.

Coordinates and Molecular Dimensions

The final positional parameters are listed, as fractions of the unit cell edges, in Table I; the final temperature factor is $B = 6.0$ Å^2 for all the atoms. The coordinates of the half-atoms used to allow for anisotropic thermal motion of the arsenic atoms in the *c*-axis projection are included in the table. The standard deviations (5) are given in Table II.

The best planes through the four separate phenyl groups have equations:

I. C_1–C_6: $-0.8886\,X' + 0.1759\,Y + 0.4236\,Z' + 0.4598 = 0$,

II. C_7–C_{12}: $-0.6659\,X' - 0.5401\,Y - 0.5147\,Z' + 5.1276 = 0$,

III. C_{13}–C_{18}: $-0.1211\,X' - 0.8669\,Y + 0.4836\,Z' + 2.5522 = 0$,

IV. C_{19}–C_{24}: $+0.2170\,X' - 0.8098\,Y + 0.5451\,Z' + 3.3592 = 0$,

where X', Y, and Z' are coordinates in Å referred to orthogonal axes *a*, *b*, and *c**. None of the carbon atoms deviates significantly from the appropriate plane (maximum displacement 0.03 Å), and each arsenic atom also lies close to the planes of the groups to which it is bonded.

The bond lengths and valency angles in the molecule are given in Table III.

All the intermolecular contacts correspond to van der Waals interactions.

DISCUSSION

The standard deviations (Table II) indicate that the atomic positions (particularly for the carbon atoms) have not been determined very precisely, and only mean values of bond lengths and valency angles are quoted in Table III. Apart from the As—O distances and As—O—As angle, none of the dimensions require special comment: the means are 1.9 Å for As—C, 1.4 Å for C—C, 100° for C—As—C, 104° for C—As—O, and 120° for As—C—C and C—C—C. The mean As—O length is 1.67±0.03 Å, close to the distance in *o*-phenylenediarsine oxychloride (1.69 Å) (6). The As—O—As angle (137°±2°) is considerably larger than the usual valency angle at oxygen (e.g. 105° in H_2O (7)), but is rather similar to corresponding angles in other arsenic compounds, for example about 130° in As_4O_6 (7) and 151° in *o*-phenylenediarsine oxychloride (6) (the last angle is probably influenced by the fact that the As—O—As unit is part of a five-membered ring). The large

angle in the present case is probably again a result of a change in the usual hybridization of the oxygen orbitals to form $p\pi$—$d\pi$ bonds involving donation of oxygen lone-pair electrons to vacant $4d$ orbitals on the arsenic atoms (6).

The orientations of the substituent phenyl groups, which depend on the equations of the mean planes, have been established more reliably than the individual bond lengths and angles. The shape of the molecule is illustrated in Fig. 3. It is seen that the two

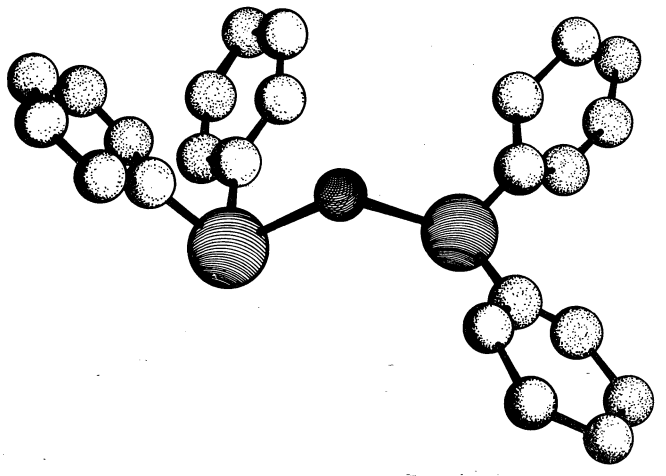

FIG. 3. Perspective drawing of the molecule.

Ph_2As units are not identical and are not related by any symmetry. The orientations of the separate phenyl groups are probably influenced to some extent by intermolecular interactions, and for this reason it is not considered useful to make comparisons with an ideal model as in the diphenylhalogenoarsines (8) and triarylarsines (9). Comparisons with various models can readily be made from the data in Table I.

We are indebted to the National Research Council of Canada and to the President's Research Fund, University of British Columbia, for financial support. We thank Dr. F. R. Ahmed for making available his IBM 1620 programs, and the staff of the UBC Computing Centre for assistance.

A LINEAR RELATIONSHIP BETWEEN BOND ORDERS AND STRETCHING FORCE CONSTANTS

E. A. ROBINSON AND M. W. LISTER
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 22, 1963

ABSTRACT

A linear correlation between the bond orders and stretching force constants of bonds, which appears to have general application, is derived on the basis of a potential energy function previously used by Pauling in a correlation of C—C bond length with bond order. The relationship is shown to be consistent with predicted bond orders and experimentally determined force constants of C—C, C—O, N—N, and N—O bonds.

The possible effects of anharmonicity and resonance energy on the force constant and equilibrium C—C bond distance are considered for the case of the benzene molecule, and it is concluded that the best agreement with experiment is obtained if we postulate a low degree of anharmonicity and allow for the change of resonance energy with bond distance.

INTRODUCTION

In a recent paper (1) one of us established a linear correlation between S—O stretching force constants and S—O bond orders; and a linear relationship between carbon single, double, and triple bond stretching constants and bond order has been suggested previously by Siebert (2) and by Somayajula (3). A similar relationship has been derived and discussed by Warhurst (4), who applied it to bonds in hydrogen halides. The object of the present paper is to examine the validity of this correlation, namely that the force constant of a bond between any two atoms is a linear function of the order of the bond, and to suggest a reason for it.

Pauling (5) examined the lengths of bonds with fractional bond orders in molecules such as benzene. He noted that the observed bond lengths were close to what one would calculate on the assumption that the observed structure was formed by distorting a conventional, nonresonating molecule (e.g. a Kekulé structure for benzene) to a shape with the symmetry of a resonance hybrid (a regular hexagon for benzene), and that the observed bond lengths were those corresponding to the minimum distortion energy. If the bonds are harmonic oscillators, the distortion energy per bond will be given by

$$V = \tfrac{1}{2}(2 - n)k_1(r - r_1)^2 + \tfrac{1}{2}(n - 1)k_2(r - r_2)^2, \qquad [1]$$

where V is the distortion energy, n is the total bond order, k_1 and r_1 are the force constant and length of a single bond, and k_2 and r_2 are the force constant and length of a double bond.

This assumes that the bond is between a single and double bond; a similar equation could be written for a bond between a double and triple bond. If we put $dv/dr = 0$, equation [1] leads to

$$r = \frac{(2 - n)k_1r_1 + (n - 1)k_2r_2}{(2 - n)k_1 + (n - 1)k_2}, \qquad [2]$$

which is the correlation between bond length and bond order obtained by Pauling; *or*

$$r = r_1 - \frac{r_1 - r_2}{1 + \dfrac{(2 - n)k_1}{(n - 1)k_2}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

as obtained by Coulson (6). Observed distances for C—C bonds agree moderately well with this equation. However, the precise degree of agreement depends on the value used for k_1/k_2, and for the bond order, n. As regards the latter, this can be most simply defined as the average number of electron pairs available per bond, which would make $n = 1.5$ in benzene if only the Kekulé structures are considered; or n may be derived from the coefficients of the atomic orbitals in the molecular orbital treatment of benzene. The latter treatment gives n (defined by $n = 1+\sum c_i c_j$) equal to 1.67 for benzene; Coulson (6, 7) has applied the molecular orbital method to carbon–carbon bonds in a variety of compounds; however, he gets agreement with equation [2] if $k_1/k_2 = 0.765$, which seems to be rather high for this ratio. Experimentally k_1/k_2 is about 0.46; and in fact if we take this value, and $n = 1.5$ for benzene, the calculated bond length is 1.403 Å, as compared with an observed 1.397 Å. Since the present paper is concerned primarily with the force constants, the question of bond lengths will not be pursued further, except in so far as they throw light on treatments of force constants.

The equation given above for V immediately leads to a linear relation between bond order and force constant, since if k is the force constant for the bond of intermediate order n, then

$$k = \frac{d^2V}{dr^2} = (2 - n)k_1 + (n - 1)k_2, \qquad [3]$$

which is the required relation. It is evident that similar considerations applied to a bond with n between 2 and 3 give

$$V = \tfrac{1}{2}(3 - n)k_2(r - r_2)^2 + \tfrac{1}{2}(n - 2)k_3(r - r_3)^2, \qquad [4]$$

whence

$$k = (3 - n)k_2 + (n - 2)k_3. \qquad [5]$$

It should be noted that these equations do not justify writing

$$k_2 = \tfrac{1}{2}(k_1 + k_3); \qquad [6]$$

which is the requirement that equations [3] and [5] represent the same straight line; however, there seems to be experimental evidence for equation [6], and we will therefore now consider this evidence. The question of the approximations made in assuming the above simple function for V will be left until later.

VALUES OF FORCE CONSTANTS

Values of stretching force constants are available in the literature for a fair number of molecules containing C—C, C—O, C—N, N—N, and N—O bonds. Since a variety of bond orders is exhibited by bonds between each pair of atoms these form the most suitable group for testing the proposed linear relation between force constant and bond order.

Only for diatomic molecules are values for the force constants easily and unequivocally calculated from the observed spectral frequencies, and even in these cases anharmonicity should be allowed for. For polyatomic molecules the values of the force constants, quite apart from errors due to neglect of anharmonicity, depend on the force field assumed. Generally, calculations in the past have been based on a simple valency force field (S.V.F.F.), or a S.V.F.F. plus one or more interaction terms. More recently the calculation of force constants has been based by some workers on a more general force field suggested by Urey and Bradley (8). This assumes in addition to a S.V.F.F. that there is a repulsive potential between all non-bonded atoms. Although this is probably a realistic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

force field, it is difficult to apply in practice. For most of the fairly simple molecules considered in this paper, the S.V.F.F. plus some interaction terms is probably the most useful approach. More approximate and simpler methods have also been used quite successfully in cases when group frequencies can be assigned to a diatomic or triatomic group in a more complex molecule (1). At least it is to be hoped that the S.V.F.F. approach will remain useful in aiding our understanding of molecular structure. In the present paper we show that force constants obtained by the S.V.F.F. method can be correlated with bond orders.

Values of the force constants for C—C, C—N, C—O, N—N, and N—O bonds in a variety of molecules have been collected in Table I. Force constants for polyatomic groups are probably not accurate to better than 5–10%, since the values obtained are dependent

on the number of interaction constants in the potential function used in the calculation. Most of the bond orders in this table are those obtained by simple considerations of resonance structures. In the case of CO, NO^+, and CN^-, which are isoelectronic with the N_2 molecule, bond orders of 3 have been assumed.

Some of the numbers in Table I deserve special comment. The force constant for the C—N double bond in compounds of the type RHC=NR′ is taken as 10.7×10^5 dynes cm^{-1} calculated from the carbon–nitrogen stretching frequency in acetoxime CH_3CH=NOH. The guanidinium ion $C(NH_2)_3^+$ is assigned a bond order of 4/3 on the assumption that there are eight electrons round the carbon atom. The azide ion is predominantly $\overset{-}{N}=\overset{+}{N}=\overset{-}{N}$, and although structures such as $N\equiv\overset{+}{N}-\overset{2-}{N}$ must contribute somewhat, these still leave the average bond order as 2.0. The nitrate ion is presumably a resonance hybrid of structures of type $O=\overset{+}{N}\begin{matrix}\diagup O^-\\ \diagdown O^-\end{matrix}$, making the bond order 1.33.

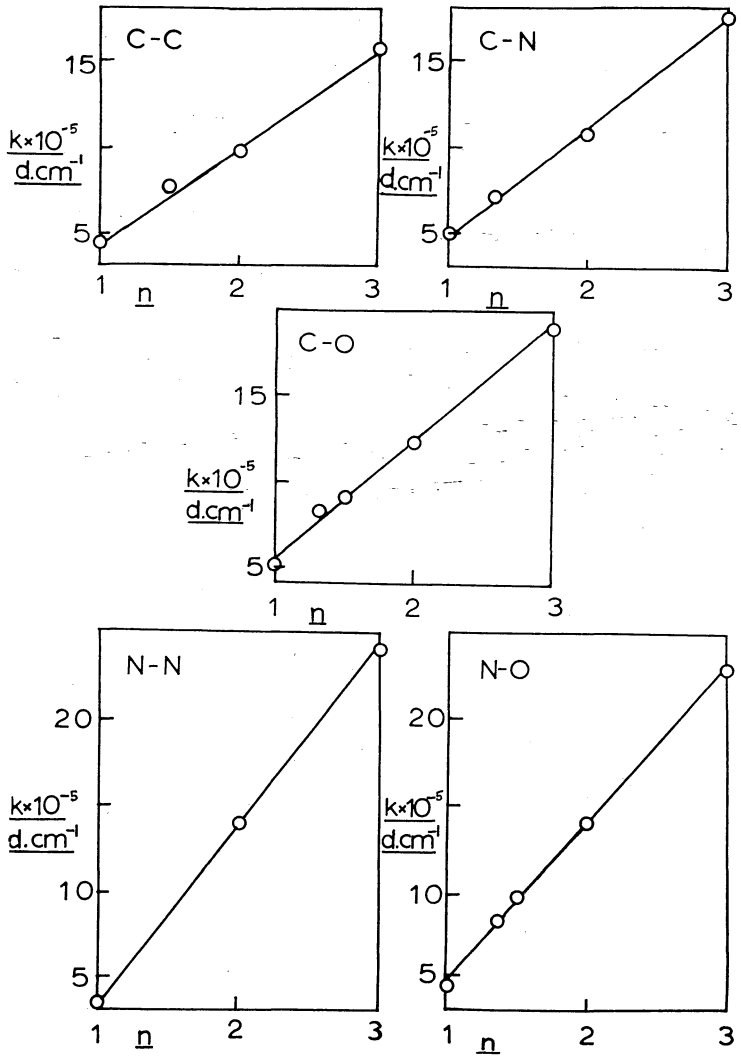

FIG. 1. Bond order – force constant relationships for C—C, C—N, C—O, N—N, and N—O bonds.

Figure 1 shows the force constants plotted against bond order and in every case a fairly good straight line is obtained. Hence there is experimental justification for the proposed linear relation of force constant and bond order.

DISCUSSION

Two aspects of this correlation deserve further comment. Firstly, as mentioned above neither equation [3] nor [5] requires that $2k_2 = k_1+k_3$, and in fact at present this can be only justified experimentally, as is shown in Table II. It might be suggested that any bond

TABLE II

Constants of single and multiple C—C, C—N, C—O, N—N, and N—O bonds $k\times10^{-5}$ (dynes cm^{-1})

	k_1	k_2	k_3	k_1+k_3	$2k_2$
C—C	4.5	9.7	15.6	20.1	19.4
C—N	5.0	10.7	17.5	22.5	21.4
C—O	5.0	12.1	18.7	23.7	24.2
N—N	3.6	13.7	22.9	26.5	27.4
N—O	4.5	14.0	23.0	27.5	28.0

intermediate between a single and a triple bond should be considered in terms of them, in which case the corresponding potential would be

$$V = \frac{1}{2}\frac{(3-n)}{(2)}k_1(r-r_1)^2+\frac{1}{2}\frac{(n-1)}{(2)}k_3(r-r_3)^2,$$

which gives $k = \frac{1}{2}(3-n)k_1+\frac{1}{2}(n-1)k_3$, and if $n = 2$ then $k_2 = \frac{1}{2}(k_1+k_3)$, as is observed. The distance calculated for intermediate bonds will be

$$r = \frac{(3-n)k_1r_1+(n-1)k_3r_3}{(3-n)k_1+(n-1)k_3}$$

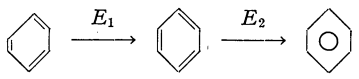
and if $n = 2$

$$r_2 = \frac{k_1r_1+k_3r_3}{k_1+k_3}.$$

Putting in the appropriate values for C—C bonds unfortunately makes $r_2 = 1.28$, which is much too short. Hence the relation $2k_2 = k_1+k_3$ cannot be justified in this way.

Secondly, when we consider compounds containing non-integral double bonds, and benzene in particular, it is evident that a simple potential function like [1] above ignores the effect of certain factors, particularly resonance energy and anharmonicity. Somewhat more detailed considerations were attempted, as follows, using the benzene molecule as a test case.

Suppose we rather artificially consider converting a Kekulé structure for benzene into a resonance hybrid by the steps



I II III

Here I is a Kekulé structure; in II it is deformed to a regular hexagon, and in III delocalization of the π bonds is included. If the energy change for the transition from I to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

III can be calculated for different ring sizes, then the equilibrium distance, r_e, will correspond to the minimum (i.e. most negative) value for this energy; and from the variation of energy with distance, we can calculate the force constant.

If the bonds are harmonic oscillators, E_1 is given by

$$E_1 = \frac{3}{2}k_1(r - r_1)^2 + \frac{3}{2}k_2(r - r_2)^2.$$

If this is the sole energy term $6k = d^2E_1/dr^2 = 3k_1 + 3k_2$. This gives $k = 7.1 \times 10^{-5}$ dynes cm^{-1} and $r_e = 1.403$ Å for the equilibrium distance. However, the bonds are presumably anharmonic oscillators. No reliable data seem to be available for the anharmonicity of a carbon–carbon bond in a state that is directly applicable to benzene. Spectral data on the C_2 molecule (10) make its potential energy

$$V = 1179.4\frac{(\delta r)^2}{(r_e)} - 2176.8\frac{(\delta r)^3}{(r_e)}$$

where $\delta r = r - r_e$, and r_e is the equilibrium distance. V is in kcal/g-mole. Data of this sort were examined for a variety of diatomic molecules (9); in general we can write

$$V = c_1\frac{\delta r^2}{r_e} - c_2\frac{\delta r^3}{r_e}$$

and it was found that the ratio c_2/c_1 varied only over a small range. Some typical values of c_2/c_1 are given below:

Molecule	Br_2	BrF	I_2	ICl	Cl_2	HF	HCl	HBr	HI	Na_2	
c_2/c_1	2.51	2.00	2.80	2.47	2.80	1.43	1.52	1.59	1.69	1.22	
Molecule	OH	O_2	S_2	Se_2	SO	N_2	P_2	As_2	CN	CO	NO
c_2/c_1	1.44	2.17	2.15	2.36	2.03	1.85	2.10	2.06	1.81	1.82	1.87

There is no particular drift of c_2/c_1 with bond order, or with the position of the atoms in the Periodic Table, though the halogens seem to give rather higher values than other diatomics. Probably a value for carbon between 1.5 and 2 would be correct, and the equilibrium distance and force constant of benzene were calculated with these two values of c_2/c_1. Again this is at present considering only the step I to II. The results were

c_2/c_1	1.5	2.0	Benzene
r_e	1.417	1.423 Å	
k	6.67	6.67×10^5 dynes cm^{-1}	

The effect of including anharmonicity is to make both r_e and k agree less well with experiment.

Another factor that should be considered is that the resonance energy will vary with distance. An estimate of this can be made as follows. If we use the Hückel molecular orbital treatment (10), but do not assume that S, the overlap integral between nearest neighbors is zero, the roots of the secular determinant give for the energy of various molecular orbitals

$$\epsilon = \frac{\alpha - n_i\beta}{1 - n_iS}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where α is the coulomb integral, β the exchange integral, and n_i can have the values -2, -1, -1, 1, 1, and 2. For six electrons in benzene this makes the resonance energy,

$$\Delta\epsilon = \frac{2(\beta - \alpha S)}{(1+S)(1+2S)}.$$

β will vary with distance, and as a first approximation we may take $\beta = \beta_0 S$, as is often done (11). Here β_0 is a constant. This makes the resonance energy

$$\Delta\epsilon = \frac{2S}{1+3S+2S^2} \cdot (\beta_0 - \alpha).$$

The S integrals have been evaluated by Mulliken, Rieke, Orloff, and Orloff (12) for a variety of wave functions and distances, and S can be obtained from their tables. The quantity $(\beta_0 - \alpha)$ can be selected to give the observed effective resonance stabilization of benzene (36 kcal) at the equilibrium distance.

The results of this calculation, on the assumption of harmonic potentials for the bond distortions, are $r_e = 1.395$ Å, $k = 7.22\times10^5$ dynes cm^{-1}. Inclusion of anharmonicity, with $c_2/c_1 = 1.5$, gives $r_e = 1.408$ Å and $k = 6.84\times10^5$ dynes cm^{-1}. If a Morse curve

$$V = D_e(1 - e^{-a(r-r_e)})^2,$$

where D_e is the dissociation energy of the bond, and a is a constant, is used for the distortion of the single and double bonds, the results are $r_e = 1.423$ Å, and $k = 7.22\times10^5$ dynes cm^{-1}. These are to be compared with the experimental $r_e = 1.397$ Å and $k = 7.6\times10^5$ dynes cm^{-1}. The results are summarized in Table III.

TABLE III

Calculated r_e and k for benzene

$k_1 = 4.5\times10^5$ $k_2 = 9.7\times10^5$ $r_1 = 1.54$ Å $r_2 = 1.34$ Å

Vibrational terms	Resonance	r_e(Å)	$k\times10^{-5}$ (dynes cm^{-1})
Harmonic	No	1.403	7.10
"	Yes	1.395	7.22
Morse function	Yes	1.423	7.22
Anharmonic $c_2/c_1 = 1.5$	No	1.417	6.67
" $c_2/c_1 = 1.5$	Yes	1.408	6.84
" $c_2/c_1 = 2.0$	No	1.423	6.67
" $c_2/c_1 = 2.0$	Yes	1.413	6.65

Hence the best agreement comes if we postulate a very low anharmonicity in the bonds, and allow for the resonance energy varying with distance. This explains qualitatively the fact that k for benzene is somewhat above $1/2(k_1+k_2)$, but does not make it enough above this average value. It gives fairly good agreement with the observed distance.

In the above calculations the distance for the single bond was taken to be 1.54 Å as in diamond or ethane. However, these contain σ-bonds with sp^3 hybridization, while in benzene the σ-bonds are sp^2 hybrids. The distance between two carbon atoms with sp^2 hybridization, but joined by a single bond has been derived and found to be 1.504 Å (ref. 5, p. 236), 1.50 Å (13), and 1.503 Å (14). If a mean value of 1.503 Å is used in the calculations, the slightly modified results given in Table IV are obtained. There is now good agreement with the observed distance on the assumption of a moderate degree of anharmonicity ($c_2/c_1 = 2.0$), with due allowance for the effect of resonance. However, the calculated force constants are in general below the observed value, and usually below

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

TABLE IV

Calculated r_e and k for benzene

$k_1 = 4.5\times10^5$ $k_2 = 9.7\times10^5$ $r_1 = 1.503$ Å $r_2 = 1.34$ Å

Vibrational terms		Resonance	r_e(Å)	$k\times10^{-5}$ (dynes cm^{-1})
Harmonic		No	1.392	7.10
"		Yes	1.385	7.21
Morse function		Yes	1.404	7.01
Anharmonic	$c_2/c_1 = 1.5$	No	1.401	6.83
"	$c_2/c_1 = 1.5$	Yes	1.394	7.08

$\frac{1}{2}(k_1+k_2)$. Only for a harmonic bond is k for benzene above $\frac{1}{2}(k_1+k_2)$, and then the bond length is a little too short.

In every other case noted in Table I for fractional bond orders the observed k is a little higher than that calculated from the simple linear relation. These deviations can be at least partially explained by allowing for variation of resonance energy with distance, though, as with benzene, it is necessary to assume very little anharmonicity. In contrast to the behavior of fractional bonds, it is found that when only single, double, and triple bonds are considered, the deviations from $k_2 = \frac{1}{2}(k_1+k_3)$ are small, and occur in both directions.

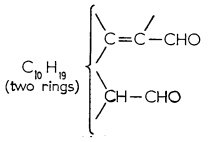
Received June 28, 1963

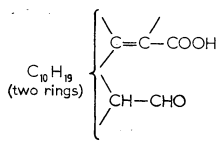
ABSTRACT

Helminthosporal has been converted into the anhydride (X), which has been dehydrogenated to give (VI): this compound has been synthesized. Spectroscopic study of a number of derivatives of helminthosporal has enabled a decision to be made in favor of (XXVI; R = CHO) as a representation of the structure and stereochemistry of the dialdehyde.

In an earlier publication (3) the isolation and characterization of helminthosporal, the toxin from *Helminthosporium sativum* responsible for widespread cereal crop damage, was reported. It was established that this substance contained, as functional groups, a saturated aldehyde and a fully substituted $\alpha\beta$-unsaturated aldehyde, as summarized in the part formulae (I), and that, furthermore, it contained two carbocyclic rings with no



(I)



(II)

other centers of unsaturation. The presence of a methyl group as one of the substituents on the ethylenic linkage was shown by the presence of a singlet (3H) at τ 7.91 in the dialdehyde and 8.0 in the corresponding unsaturated acid (II) (3): in the oxime from this acid (3) the band appeared at τ 8.3. The next objective was to ascertain the size and mode of fusion of the two carbocyclic rings.

Reduction of (II) with sodium borohydride has been shown to give a γ-lactone (3). This lactone is not formed, however, by simple closure between the carboxyl and the newly formed alcoholic function. No indication was found, in the appropriate region of the n.m.r. spectrum, of the presence of the methylene protons in a —C$\underline{H_2}$—O—CO— grouping. On the other hand the peak at τ 8.0, already attributed to the vinyl methyl group, moved in the reduction and lactonization to τ 8.6. The infrared spectrum (bands at 3080, 1615, and 905 cm^{-1}) and n.m.r. spectrum (doublets at τ 4.74, 5.03; $J \sim 2$ c.p.s.) gave indication of the presence of an exocyclic methylene group, and this was confirmed by the obtention of formaldehyde (3) on ozonolysis. These observations led to the conclusion that the formation of the lactone involved an allylic rearrangement, as indicated

[1]*Part of the following constituted a preliminary communication (1). Reference 2 is considered part III in this series.*

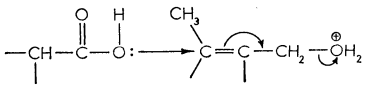
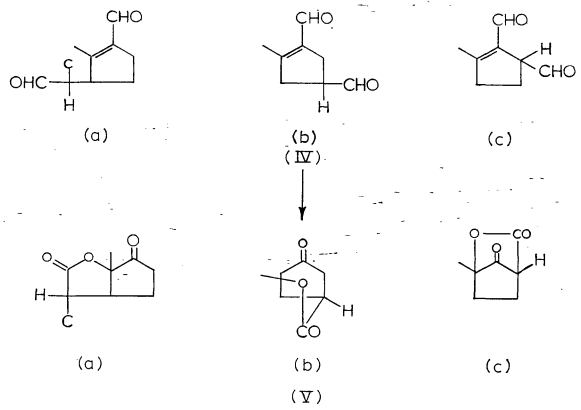
in (III), and this conclusion was substantiated when it was found that, by reduction with lithium aluminum hydride, a crystalline diol, characterized as the acetate, was obtained which was different from that obtained by lithium aluminum hydride reduction of helminthosporal itself.



(III)

This lactone gave the expected diol with osmium tetroxide (3), which has been further characterized as the monoacetate. On cleavage with periodic acid a ketone was obtained with the concomitant loss of one carbon atom as formaldehyde. This ketone showed maxima in the infrared at 1802 and 1767 cm^{-1}, one of which was to be attributed to the γ-lactone carbonyl and the other to that of the new cyclanone. It was presumed that these high values were associated with α-oxygen substitution of the cyclic ketone, and this view was confirmed when it was found that zinc and acetic acid reduction gave a keto acid with maxima at 1745 and 1703 cm^{-1}. Since the band at 1703 is to be attributed to the carboxyl carbonyl the new carbonyl was revealed as being present in a five-membered ring. These results may be expressed in terms of the part formulae (V), *a*, *b*, or *c* for the keto lactone and the corresponding (IV), *a*, *b*, or *c* for helminthosporal.



(IV)

(V)

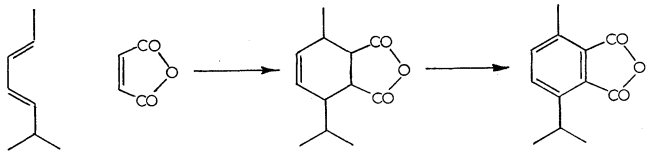
The nature of the second carbocyclic ring was elucidated directly. Ozonolysis of helminthosporal, of (II), or of the borohydride reduction product of (II), gave, after heating, a substance to which the empirical formula $C_{14}H_{20}O_4$ is attributed. The nature of this substance will be discussed below; however, at this point, it may be noted that the loss of only one carbon atom in the ozonolysis excludes (IV*c*), since by the oxidative cleavage a β-dicarbonyl compound would be produced which should suffer a further loss of carbon dioxide or equivalent.

Dehydrogenation of the substance, $C_{14}H_{20}O_4$, gave a crystalline anhydride, $C_{12}H_{12}O_3$, the infrared spectrum of which was similar to that of phthalic anhydride. Its ultraviolet absorption (λ_{max} 253, 307, 318, ϵ_{max} 3000, 3100, 3100 respectively) was also similar to that of phthalic anhydride, but displaced to somewhat longer wavelengths. The n.m.r. spectrum contained a doublet (6H) at τ 8.67 ($J \sim 9.6$ c.p.s.), which bespoke the presence of an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

isopropyl group, whilst a band (singlet, 3H) at τ 7.32 indicated the attachment of a methyl group to the aromatic ring. Two barely resolved singlets at τ 2.4 were to be attributed to two aromatic hydrogen atoms in a nearly identical physical environment. These facts were accommodated by the structure (VI) which also enjoyed inherent biogenetic plausibility. The substance represented by this formula was therefore synthesized.

Isobutyl bromide was converted to the Wittig reagent and condensed with crotonaldehyde. The resultant mixture of dienes was heated with maleic anhydride under the conditions of the Diels-Alder reaction; from the products the crystalline anhydride (VII) was readily isolated. Dehydrogenation then gave (VI), identical in every respect with the product obtained from helminthosporal.



(VII) (VI)

The anhydride (VI) contains 12 of the original carbon atoms present in helminthosporal. Of the two potential carboxyl groups constituting the anhydride, one must be derived, eventually, from the saturated aldehyde in helminthosporal whilst the other must be derived from the α-keto aldehyde formed by cleavage of the ethylenic linkage. Since the two carboxyl functions are vicinal a decision can now be made between (IV*b*), which would permit this feature, and (IV*a*), which would not.

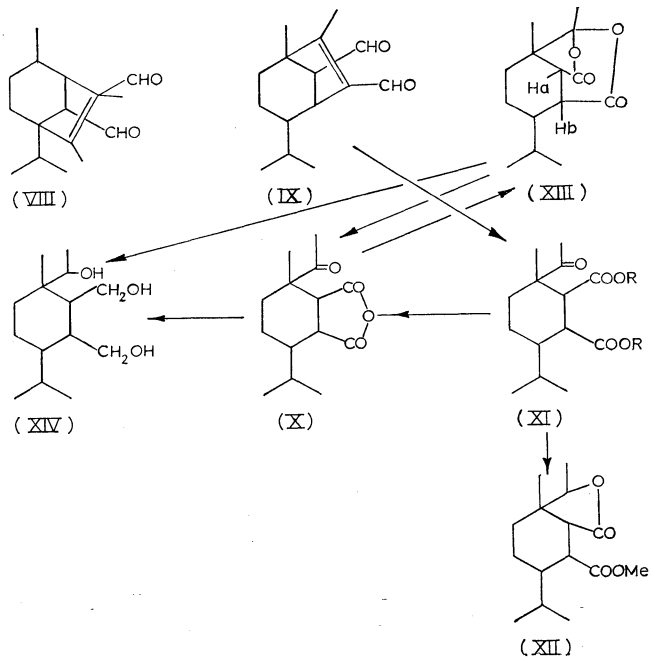
The complete structure of helminthosporal may be arrived at by the combination of the skeleton represented by (VI) and that represented by (IV*b*). This may be accomplished in two ways only leading to (VIII) and (IX) as possible representations of helminthosporal. A decision between these alternatives was possible from a study of the compound $C_{14}H_{20}O_4$ already mentioned, and, for simplicity, further discussion will be in terms of (IX), the formulation finally arrived at.

This substance, $C_{14}H_{20}O_4$, had maxima in the infrared spectrum at 1790 and 1820 cm^{-1}, both absorption bands being strong and broad: it was not, therefore, the expected keto anhydride (X). On mild hydrolysis, however, a dibasic acid, $C_{14}H_{22}O_5$, was formed (XI, R = H) which gave an oily dimethyl ester (XI, R = Me). In this substance, in addition to the ester carbonyl absorption at 1740 cm^{-1}, there could be observed the required acetyl carbonyl at 1715 cm^{-1}. In agreement, reduction with sodium borohydride gave rise to the γ-lactone (XII).

From these results it was concluded that a dilactonic structure (XIII) must be ascribed to the compound $C_{14}H_{20}O_4$. This interpretation was supported by the n.m.r. spectrum which exhibited, in addition to the required two singlet methyl bands (at τ 8.4 and 8.85), a doublet (1H) at τ 7.6 ($J \sim 3.6$ c.p.s.) and a multiplet (1H) at τ 6.89; this and the spectra of other derivatives (4) (see below) exclude formulations based on (VIII) for these substances. In addition, the presence of two doublets (6H) in the methyl region (see also Fig. 1) reveals the presence of the isopropyl group in (XIII), and, therefore, in helminthosporal itself, and excludes the possibility that ring contraction or rearrangement had taken place on dehydrogenation.

The dilactonic structure (XIII) has ample analogy: such a formulation has been established, for instance, for a derivative of δ-ketopimelic acid. For the latter we have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



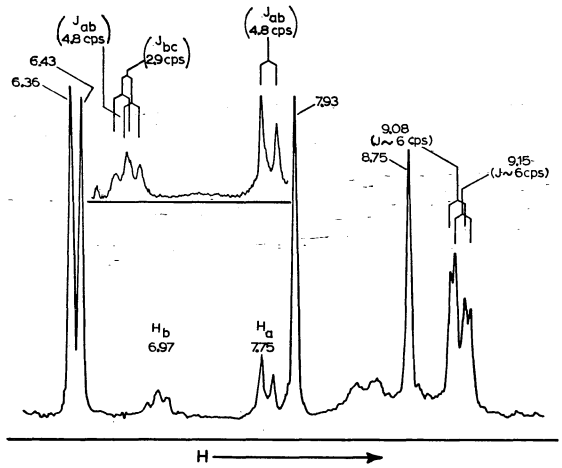


FIG. 1. Nuclear magnetic resonance spectrum of the dicarboxylic ester (XI, R = Me).

observed a broad maximum in the infrared spectrum at 1790 cm^{-1}. However, to complete the structural proof it was desirable to obtain the keto anhydride (X) itself. This was achieved by heating (XI, R = H) with acetic anhydride. At a higher temperature (X) was converted into (XIII). Both compounds gave the same triol (XIV) on reduction with lithium aluminum hydride precluding the possibility of thermal rearrangement of the carbon skeleton at the higher temperature.

With the gross structure of helminthosporal established as (IX) it remains to consider how the dilactone (XIII) is formed, together with the keto lactone [now to be formulated

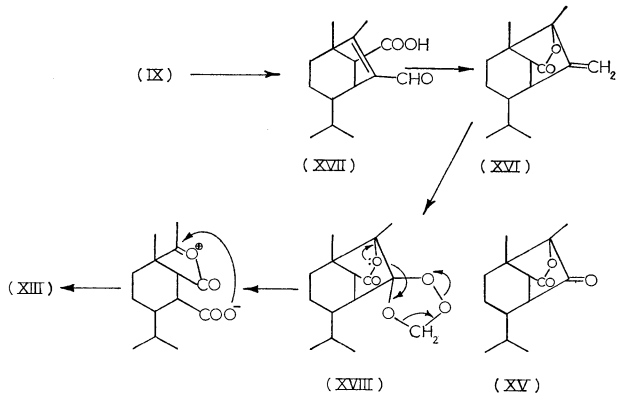
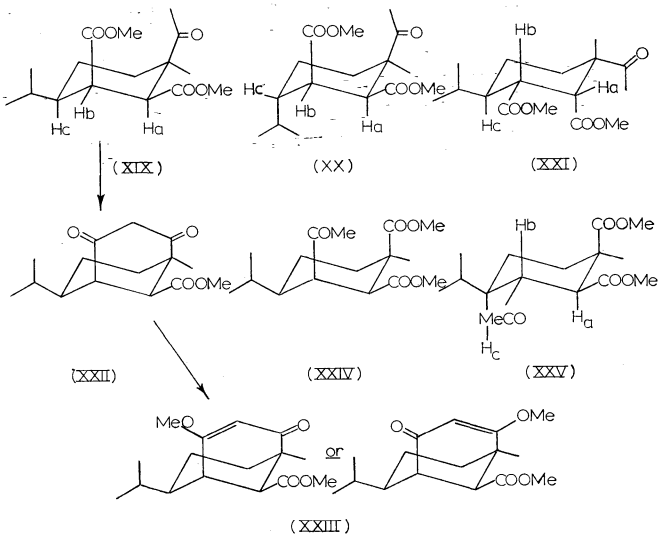
as (XV)], by ozonolysis of the borohydride reduction product (XVI) of the aldehyde acid (XVII). This may most simply be explained by postulating the intermediate formation of the ozonide followed by decomposition in the manner indicated in (XVIII).



The bridged system in helminthosporal defines the stereochemistry in all but two points: the configuration of the isopropyl group with respect to the carbon bridge, and the configuration of the saturated aldehyde. In the derived aldehyde–acid (XVII) the configuration of the corresponding carboxyl group is defined by the formation of the lactone (XVI). The stereochemistry of the diester (XI, R = Me) may therefore be represented by the alternatives (XIX) and (XX). In the former case the most probable conformation is that depicted, but in the epimer (XX) conformational inversion to (XXI) (mirror image represented) must be expected.



In (XIX) both H_a and H_b would be expected to be weakly coupled since interactions are between axial and equatorial hydrogen atoms. In (XXI) H_b undergoes both a diaxial and an axial–equatorial coupling. Inspection of the n.m.r. spectrum of (XI, R = Me) [see Fig. 1] shows that J_{ab} is ~4.8 c.p.s. and that J_{bc} is smaller, probably about 3 c.p.s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

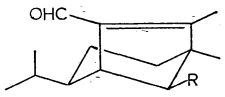
The spectrum also shows the isopropyl group at τ 9.15 and 9.08 ($J \sim 6$ c.p.s.) and the singlet methyl (at τ 8.75). This evidence therefore supports the assignment of (XIX) as the steric representation of (XI, R = Me).

In (XIX) one carbomethoxyl group and the acetyl group are situated 1:3 and diaxial. In consequence the ketone may be expected to be hindered (even for a *t*-butyl ketone) and bridging reactions may be expected to be facile. Indeed no derivative of the ketone could be made even under forcing conditions, but treatment with potassium *t*-butoxide readily induced cyclization with the formation of a β-diketone (XXII) characterized as the crystalline enol ether (XXIII).

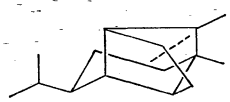
Using sodium methoxide, followed by hydrolysis, (XIX) was converted into a dicarboxylic acid monomethyl ester which resisted attempts at further hydrolysis. This substance gave, with diazomethane, a diester different from (XIX). Since the monoester could not be hydrolyzed it must be presumed that the intermediate (XXII) has opened in the opposite sense from its formation to give a tertiary carbomethoxyl group as in (XXIV). But under the conditions of formation the acetyl group would now be expected to invert from its axial configuration to the more stable equatorial arrangement. The final diester may thus be formulated as (XXV).

In this keto diester, from which a 2,4-dinitrophenylhydrazone could now be derived, the couplings between H_a, H_b, and H_c are all those of diaxial protons. They should be considerably larger than those in (XIX) (5); in fact J_{ab} was about 11 c.p.s. and J_{bc} was also large though the pattern did not permit the assignment of an exact figure.

It is concluded that (XI, R = Me) is correctly designated by (XIX) and thus that (XXVI, R = COOH) is a steric representation of (XVII). Provided no inversion of the aldehyde has taken place in the formation of (XVII) from (IX), helminthosporal may be represented by (XXVI, R = CHO). That this condition has been fulfilled has been shown by the reduction of (XVII) with lithium aluminum hydride to give the same diol, characterized as the 3,5-dinitrobenzoate, as was obtained from helminthosporal (3).[3]



(XXVI)



(XXVII)

Inspection of the helminthosporal skeleton reveals that, although constructed from three isoprene units, it is not to be formed by simple cyclization of a farnesyl precursor. We have shown elsewhere (2) that it is most probably derived from a tricyclic precursor with a carbon skeleton such as (XXVII) by oxidative cleavage at the bond indicated.

EXPERIMENTAL

Infrared spectra and n.m.r. spectra were determined in carbon tetrachloride solution, ultraviolet spectra in ethanol, and rotations in chloroform. Light petroleum refers to the fraction of b.p. 35–60°. Melting points were determined on the Köfler hot stage.

The n.m.r. spectra were determined using 1% tetramethylsilane as internal standard using a Varian D.P. 60 spectrometer. The peak positions were determined using an audio oscillator calibrated with a Hewlett Packard 522-B frequency counter.

[3]*The remaining possibility, that epimerization may occur during hydride reduction, whilst not an unknown phenomenon (6), is exceedingly improbable since, in such a delicately balanced situation the aldehyde would certainly have epimerized during isolation.*

Preparation of the Keto Lactone (XV)

To the diol from the unsaturated lactone (3) (69 mg) in ethanol (4 ml) was added aqueous periodic acid solution (0.01 *N*; 5 ml). After 24 hours, titration of an aliquot indicated an uptake of 0.95 atoms of oxygen. Dilution of the mixture with water, filtration, and crystallization from light petroleum ether gave the keto lactone (XV), m.p. 123–124°, $[\alpha]_D$ +40° (*c*, 1.14), ν_{max} 1802, 1767 cm^{-1}. Calc. for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53. Found: 71.16; 8.49%. The ketone was not brominated in bromine/acetic acid.

Lithium Aluminum Hydride Reduction of the Lactone (XVI)

The lactone (50 mg) was refluxed in ethereal solution containing an excess of lithium aluminum hydride. The diol, isolated in the usual way, was crystallized from light petroleum, m.p. 113.5–114°, $[\alpha]_D$ +38° (*c*, 1.02). Calc. for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00. Found: C, 75.38; H, 10.63%. The monoacetate (acetic anhydride – pyridine at room temperature overnight) had m.p. 80.5–82° (crystallized from light petroleum). Calc. for $C_{17}H_{28}O_3$: C, 72.82; H, 10.06. Found: C, 72.77; H, 9.73%.

Reduction of the Keto Lactone (XV)

The keto lactone (720 mg) was dissolved in glacial acetic acid (100 ml) and activated zinc (30 g) added. The mixture was refluxed for 96 hours, the acetic acid removed by evaporation and the acidic material isolated with aqueous sodium bicarbonate. After crystallization from ether – light petroleum the keto acid was obtained, m.p. 140–142°, $[\alpha]_D$ −66° (*c*, 1.02) ν_{max} 1746, 1703 cm^{-1}. Calc. for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31. Found: C, 70.88; 9.28%.

The Nordilactone (XIII)

(*a*) The aldehyde–acid (XXVI, R = COOH) (100 mg) in ethyl acetate (15 ml) was cooled to −70° and ozone passed until disappearance of the peak at 265 mμ. After evaporation of the solvent, aqueous sodium hydroxide (5%: 10 ml) and hydrogen peroxide (30%: 1 ml) were added and the mixture heated on the steam bath for 1 hour. Isolation of the acidic product in the usual way gave a glass which was heated for 15 hours at 130° under nitrogen. Chromatography of this product on silica gel gave, on elution with benzene, the nordilactone (XIII). Crystallization from light petroleum (b.p. 60–80°) afforded material of m.p. 76.5–77° (56 mg), $[\alpha]_D$ +70° (*c*, 1.01) ν_{max} 1820, 1790 cm^{-1}. Calc. for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99; M.W. 252. Found: C, 66.66; H, 8.06%, M.W. (mass spectrum) 252.

(*b*) Similar ozonolysis of the lactone (XVI) gave formaldehyde, the keto lactone (XV) (identical in every way with the material obtained from periodic acid cleavage), and the nordilactone, the latter two substances in poor yield.

Hydrolysis of the Nordilactone (XIII)

The nordilactone (50 mg) was dissolved in alcoholic alkali (50% aqueous: 5% sodium hydroxide) and refluxed for 1 hour. Isolation of the acidic material gave, on crystallization from light petroleum, the nordiacid (XI, R = H) m.p. 143.5–145°, $[\alpha]_D$ −70° (*c*, 1.01). Calc. for $C_{14}H_{22}O_5$: C, 62.20; H, 8.20. Found: C, 62.10; H, 8.17%.

Treatment with ethereal diazomethane gave the corresponding dimethyl ester (XI, R = Me), n_D^{25} 1.4785. Calc. for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78; OMe (2), 20.80. Found: C, 64.70; H, 8.41; OMe, 19.90%.

Reduction of the Nordilactone (XIII)

The dilactone (25 mg) was added to a solution of lithium aluminum hydride (100 mg) in ether and the mixture allowed to stand overnight. After decomposition of the excess reagent with ethyl acetate and sodium potassium tartrate the product was isolated with ether and crystallized from ether – light petroleum (b.p. 60–80°) to give the triol (XIV), m.p. 158.5–159.5°, $[\alpha]_D$ ±0° (*c*, 0.55). Calc. for $C_{14}H_{28}O_3$: C, 68.81; H, 11.55. Found: C, 68.47; 11.62%.

The Norketo Anhydride (X)

The nordiacid (from 100 mg nordilactone) was heated with acetic anhydride for 5 hours at 150° (bath temperature). The acetic anhydride was then removed *in vacuo* and the residue crystallized from chloroform – light petroleum (60–80°) to give the anhydride (70 mg) m.p. ca. 140° and 156–158°, $[\alpha]_D$ −31° (*c*, 0.93), ν_{max} 1850, 1780, 1720 cm^{-1}. Calc. for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99. Found: C, 67.14; H, 8.05%.

Reduction of the anhydride as described for the dilactone gave the same triol, m.p. and mixed m.p. 158.5–159.5°.

Reduction of the Nordimethyl Ester (XI, R = Me) with Sodium Borohydride

To the ester (200 mg) in 50% aqueous ethanol (40 ml) was added sodium borohydride (1 g). After 3 hours at room temperature the product was isolated in the usual way. Chromatography on silica gel (10 g) afforded a partial separation of the mixture so obtained, elution with benzene giving an oil which gradually solidified. Crystallization from light petroleum (b.p. 60–80°) gave the lactone ester (XII) m.p. 72.5–73.5°, $[\alpha]_D$ −71° (*c*, 0.96), ν_{max} 1770, 1725 cm^{-1}. Calc. for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02. Found: C, 67.67; H, 8.79%.

Dehydrogenation of the Nordilactone

The lactone (300 mg) and powdered selenium (600 mg) were intimately mixed and heated in a sealed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tube at 325° for 24 hours. After cooling the contents of the tube were extracted with light petroleum. This solution was applied to a column of silica gel and elution continued with the same solvent. After evaporation of the petroleum eluates the product was crystallized from the same solvent to give 3-isopropyl-6-methylphthalic anhydride (26 mg) (VI) m.p. 100.5–101°. Calc. for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92. Found: C, 70.64; H, 5.69%. The material was identical in every respect with the material obtained by synthesis.

Synthesis of 3-Isopropyl-6-methylphthalic Anhydride

(a) Isobutyl Triphenyl Phosphonium Bromide

Triphenylphosphine (25 g) and isobutyl bromide (14.3 g) were heated in a sealed tube at 125° for 15 hours. The resultant white solid was boiled in benzene, filtered, and dried. It had m.p. 210–220°.

(b) 6-Methylhepta-2,4-diene

n-Butyl lithium in pentane was prepared from *n*-butyl chloride. Titration with standard hydrochloric acid indicated 1.19 mmole butyl lithium per ml.

To 10 ml of this solution, under nitrogen, was added pentane (50 ml) and, over 30 minutes, the phosphonium bromide (3.99 g). The solution turned orange, darkened, and a precipitate formed. Anhydrous ether (100 ml) was added and the mixture stirred at room temperature for 3 hours. Crotonaldehyde (0.7 g) was then added and the mixture stirred and refluxed for 7 hours. After removal of the phosphine oxide by filtration the hydrocarbon fraction was isolated in the usual way. This material (1.02 g), λ_{max} 227, $\epsilon \sim 12{,}000$, was used directly in the following experiment.

(c) 3-Isopropyl-6-methylcyclohex-4-ene-1,2-dicarboxylic Acid (VII)

The diene (1.0 g), maleic anhydride (1.2 g), a few crystals of hydroquinone, and benzene (2 ml) were sealed in a tube which was then heated at 150° for 17 hours. The acidic products were extracted with 5% sodium carbonate solution (charcoal) and after acidification the diacid was crystallized from ethyl acetate when it had m.p. 194.5–195° (119 mg). Calc. for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02. Found: C, 63.99; H, 7.96%.

(d) 3-Isopropyl-6-methylphthalic Anhydride (VI)

The diacid (100 mg) was heated at 210° for 45 minutes and then sulphur (50 mg) was added and the temperature increased to 240–260°. After 1 hour the mixture was cooled and extracted with light petroleum. This was filtered through a column of silica gel and the column eluted with the same solvent. Repeated crystallization from light petroleum gave a product identical in every way with the selenium dehydrogenation product of the nordilactone.

Alkali Treatment of the Nordimethyl Ester

A solution of the ester (100 mg) in methanol (1 ml) was added to a solution of sodium methoxide (*N*; 30 ml) and the mixture refluxed for 15 hours. Water (20 ml) was then added and heating continued for a further 3 hours.

The acidic material was isolated and filtered through silica gel in ether–benzene (1:3) solution. After evaporation of the solvent the product was crystallized from light petroleum (b.p. 60–80°) to give the allonordiacid monomethyl ester m.p. 122–123.5°, $[\alpha]_D$ +15° (*c*, 1.25), ν_{max} 3300, 1715, 1730, 1710 cm^{-1}. Calc. for $C_{15}H_{24}O_5$: C, 63.36; H, 8.51; OMe (1), 10.91. Found: C, 63.42; H, 8.75; OMe, 10.77%.

Treatment of the monoacid with ethereal diazomethane, followed by crystallization from light petroleum, gave the dimethyl ester (XXV), m.p. 60–62.5°, $[\alpha]_D$ +32° (*c*, 0.87). Calc. for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78, OMe (2) 20.80. Found: C, 65.18; H, 8.80; OMe, 20.57%. A 2,4-dinitrophenylhydrazone was obtained (steam bath for 1 hour) which crystallized from light petroleum (b.p. 60–80°), m.p. 150.5–152.5°. Calc. for $C_{22}H_{30}N_4O_8$: C, 55.22; H, 6.32; N, 11.70. Found: C, 55.44; H, 6.30; N, 11.51%.

Cyclization of the Nordiester (XIX)

The ester (50 mg) was dissolved in *t*-butanol (10 ml) containing 4% potassium *t*-butoxide, and left at room temperature for 15 hours. The mixture was then diluted with water and acidified and the products isolated with ether. After application to a column of silica gel elution with ether–benzene (1:3) gave the mono ester described above (10 mg). Further elution then afforded an oil which had ν_{max} 1740, 1700, and 1603 cm^{-1}, λ_{max} (neutral) 257 mμ ($\epsilon \sim 11{,}000$), λ_{max} (alkaline) 285 mμ ($\epsilon \sim 10{,}000$).

The oil was treated with an excess of ethereal diazomethane and the residue after evaporation applied to a column of silica gel. Elution with ether–benzene (1:19) yielded the enol ether (XXIII), which, after crystallization from light petroleum (b.p. 60–80°) had m.p. 170–172°, λ_{max} 255 mμ (ϵ, 12,000), λ_{max} 1740, 1660, 1600 cm^{-1}. Calc. for $C_{16}H_{24}O_4$: C, 68.54; H, 8.63. Found: C, 68.20; H, 8.93%.

Reduction of the Monoacid (XXVI, R = COOH)

To lithium aluminum hydride (400 mg) in dioxan (50 ml) was added a solution of the monoacid (400 mg) in dioxan (50 ml). The mixture was refluxed for 12 hours, the excess hydride decomposed with ethyl acetate, and the diol isolated in the usual way. An acidic fraction was obtained which gave 114 mg of starting acid. The glycol (200 mg) was converted directly to the bis-3,5-dinitrobenzoate, m.p. and mixed m.p. 149–151° identical in every respect with material obtained by reduction of the aldehyde (XXVI, R = CHO).

ABSTRACT

The H^1 and F^{19} magnetic resonance spectra of three tin compounds have been examined. Taking advantage of C^{13}, Sn^{117}, and Sn^{119} being magnetic nuclei in small natural abundance, it has been possible to obtain 31 coupling constants from the spectra.

INTRODUCTION

Some considerable work has now been devoted to nuclear magnetic resonance spectra (n.m.r.) of organometallic derivatives of group IV elements. First reported values of chemical shifts in methyl and perfluoromethyl tin derivatives showed relatively small variation of methyl and perfluoromethyl chemical shifts (1). Tetravinyltin shows a collapsed ABC proton resonance spectrum which was analyzed by use of the Sn^{119} side bands. These side bands appear due to Sn^{119} indirect spin coupling with protons (2). Parameters obtained from the side bands make possible an exact fit of the main resonance lines. Large differences between the F^{19} chemical shifts of perfluoro transition metal compounds and those of non-transition metals such as tin have been reported (3). Sn^{119} spectra have been studied by Lauterbur and Burke (4) and chemical shifts of a variety of tin compounds obtained. The F^{19} magnetic resonance spectra of triethylfluoroethyl and triethylperfluorovinyl derivatives, of Si, Ge, and Sn (5) reveal smaller metal–fluorine coupling constants in the perfluorovinyl compounds than obtained earlier for metal–H^1 coupling in tetravinyltin (3).

H^1–H^1, H^1–Si^{29}, H^1–F^{19}, and Si^{29}–F^{19} coupling constants have been evaluated from spectra of deuterated silicon derivatives (6). Metal–proton coupling in the methyltin compounds reported earlier (1) has been studied by Kaesz (7, 9). Chemical shifts and some coupling constants have now been reported for mixed hydrides of silicon, phosphorus, germanium, and arsenic (8).

EXPERIMENTAL

Proton magnetic resonance spectra were recorded at 28° C on both Varian A60 and H.R. 60 spectrometers. Peak positions were determined in both cases by bracketing peaks to be measured with audio side bands generated by a Hewlett Packard wide band audio oscillator and calibrated by a Hewlett Packard 522 B electronic counter. Proton resonance peaks were compared to an internal tetramethyl silane reference and fluorine chemical shifts obtained with respect to an external trifluoroacetic acid sample. Fluorine magnetic resonance spectra were recorded at 40 Mc/sec with a Varian V4300 spectrometer.

The preparation and purification of these compounds will be described elsewhere (10).

RESULTS

The magnetic nuclei in the compounds studied are H^1, F^{19}, Sn^{119}, Sn^{117}, and C^{13}; of these H^1 and F^{19} have been observed directly. All the nuclei studied have spin 1/2, and the isotopic abundances are Sn^{117}, 8.68; Sn^{119}, 7.67; and C^{13}, 1.108%. Deuterium, present to a small extent in hydrogen, together with 0.35% abundant Sn^{115} with a moment of

−0.9132 and spin 1/2, do not contribute observable effects in the n.m.r. spectra obtained here.

Spectra of Dimethyltin Dihydride

The proton resonance spectrum of this compound is shown in Fig. 1. The main features are a simple septet for the two hydrogens directly bonded to tin, chemically shifted −4.39 p.p.m. from the internal TMS reference, and a triplet for the hydrogens of the two methyl groups at −0.2 p.p.m. The coupling constants and chemical shifts for this

[a]Summary of coupling constants obtained from the first order analysis of the spectra of compounds listed.
[b]Summary of chemical shifts obtained for protons. 'δ' is expressed in p.p.m., with respect to an internal TMS reference. For fluorine resonance positions the standard is an external trifluoroacetic acid sample.

compound are listed in Table I. In addition to the main peaks, subsidiary peaks appear because of the detectable amounts of the following:

I H_3C^{13}, H_3C, H, H on Sn

II CH_3, CH_3, Sn^{117}, H, H

III CH_3, CH_3, Sn^{119}, H, H

In I the Sn nucleus is magnetically inactive, but side bands, $\frac{1}{2}\%$ of the height of the methyl peaks, appear on each side of the methyl triplet with a separation $J_{C^{13}-H}$. The relatively low intensity side bands are shown in Fig. 2; $J_{C^{13}-CH_3}$ was measured as 129.9 c.p.s. In addition the molecules II and III contribute to side bands shown in Fig. 2 as

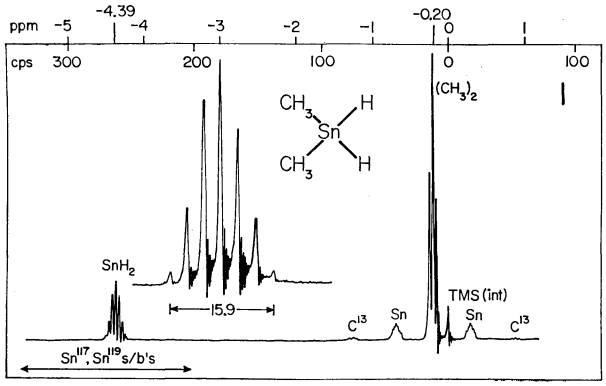
$J_{Sn^{119}-CH_3}$ and $J_{Sn^{117}-CH_3}$. The *I.I* coupling of nuclear spins in high resolution spectra generally decreases markedly as the number of bonds between the two magnetically active nuclei increases, thus $J_{C^{13}H_3-SnH_2}$ is expected to be much smaller than $J_{C^{13}-CH_3}$ but



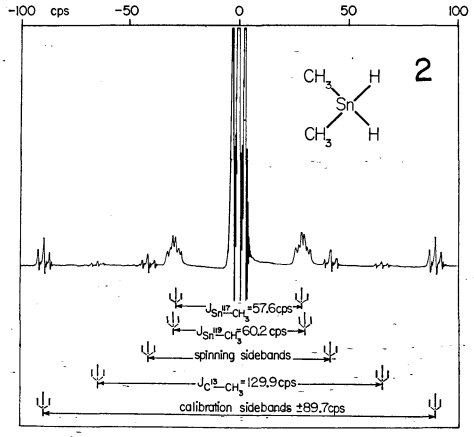


FIG. 1. 60 Mc/s proton spectrum of dimethyltin dihydride, showing main features of the spectrum. Chemical shifts are given with respect to the internal TMS standard. The Sn^{117} and Sn^{119} side bands are located at ±900 from the SnH_2 septet. (See Fig. 3.)

FIG. 2. Expanded 60 Mc/s proton spectrum of dimethyltin dihydride near the methyl resonance region, showing Sn^{117}, Sn^{119}, and C^{13} side bands.

because of the much lower intensity of the main resonance it could not be observed. The coupling of the SnH_2 protons to the magnetically active Sn^{117} and Sn^{119} in molecules II and III produces a very large splitting, the high field component of which exceeds the range of the A60 spectrometer. Figure 3 shows the spectra for determination of $J_{Sn^{117}-H}$ and $J_{Sn^{119}-H}$, with calibrating side bands from the main peak. The low field component of the tin doublets was bracketed repeatedly between calibrated side bands from the main SnH_2 peak on the A60 spectrometer. The precise position of the high field component was obtained by using the same oscillator and electronic counter for the calibrating side bands, on an HR 60 spectrometer. As far as could be determined there was no difference in chemical shift of $>SnH_2$ protons in molecules II and III, that is to say we could detect no isotope shift.

The $I \cdot I$ coupling between magnetically active Sn nuclei in molecules II and III and

the methyl protons is shown in Fig. 2. Two overlapping triplets due to two tin isotopes are shown. The coupling constant between two nuclei is proportional to the product of the gyro-magnetic ratio of the two nuclei (11) and thus the splitting $J_{Sn^{119}-H^1}$ and $J_{Sn^{117}-H^1}$ are in the ratio of the gyromagnetic ratios of the two tin isotopes. This factor is 1.046, so

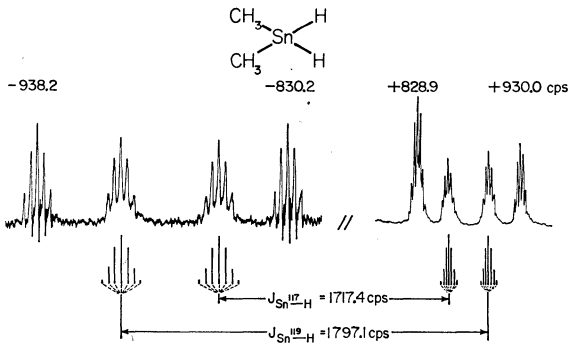

FIG. 3. Side bands from the two magnetic tin isotopes Sn^{117} and Sn^{119} of the SnH_2 group in the 60 Mc/s proton spectrum of dimethyltin dihydride.

that the larger splitting results from 8.68% of Sn^{119} and the smaller splitting from 7.67% of Sn^{117}. Intensities of appropriate side bands were found to be proportional to isotopic abundances, and coupling constants to gyromagnetic ratios within experimental error.

Dimethyl-1,1,2,2-tetrafluoroethyltin Hydride—Proton Magnetic Resonance

The compound contained a small amount of $(CH_3)_2Sn(C_2F_4H)_2$ the peaks of which are assigned in Fig. 4, together with the proton resonance spectrum of the desired compound. The main methyl proton resonance is a doublet and the C^{13}, Sn^{117}, and Sn^{119} side bands are shown with values of the appropriate coupling constants. Proton *a* attached to the tin and proton *b* geminal to the CF_2 group produce overlapping signals. The spectra are all first order and are complete with Sn^{117} and Sn^{119} side bands. The main splitting of the hydrogen H^b signal is the triplet due to coupling with geminal fluorine nuclei, and there is further splitting due to coupling with vicinal fluorine nuclei and interproton coupling H^a—H^b. The central component of the main triplet is overlapped by the signals of H^a. This region in expanded form is the subject of Fig. 5.

The spectrum of H^a is very complex because of a large number of first order splittings. The contributing coupling constants are $J_{H^a-CH_3}$, (seven lines), $J_{H^a-CF_2{}^a}$ (three lines), $J_{H^a-CF_2{}^b}$ (three lines); $J_{H^a-H^b}$ (two lines) and since these are multiplied together to give the total number of lines, we expect 126 components. These are constructed below the spectrum on the same scale. Although all lines are not completely resolved, it is evident that computed spectrum and measured spectrum are in good agreement.

The center component of the triplet for proton H^b is indicated above the spectrum in Fig. 5. This comprises lines due to $J_{H^b-F_2{}^a}$ and $J_{H^b-H^a}$ with corresponding Sn^{117} and Sn^{119} side bands. The agreement of the measured and computed spectrum in the region of overlap is also apparent.

The main peaks for H^a overlap those for H^b but the tin side bands are well separated because J_{Sn-H^a} is such a large coupling constant. The tin side bands of H^a are shown in Fig. 6 between calibrating side bands of the main peak. The center component of the main triplet for H^b was used for calibration purposes and the low field component of this tripleted

Dimethylbis(1,1,2,2-tetrafluoroethyl)tin—Proton Magnetic Resonance

The proton magnetic resonance spectrum of the above compound is shown in Fig. 7. A very small impurity of the compound whose spectrum is illustrated in Fig. 4 is present and identified in the diagram. The methyl peak of the dimethylbis(tetrafluoroethyl)tin appears to be a single peak but displays some evidence of unresolved couplings since the

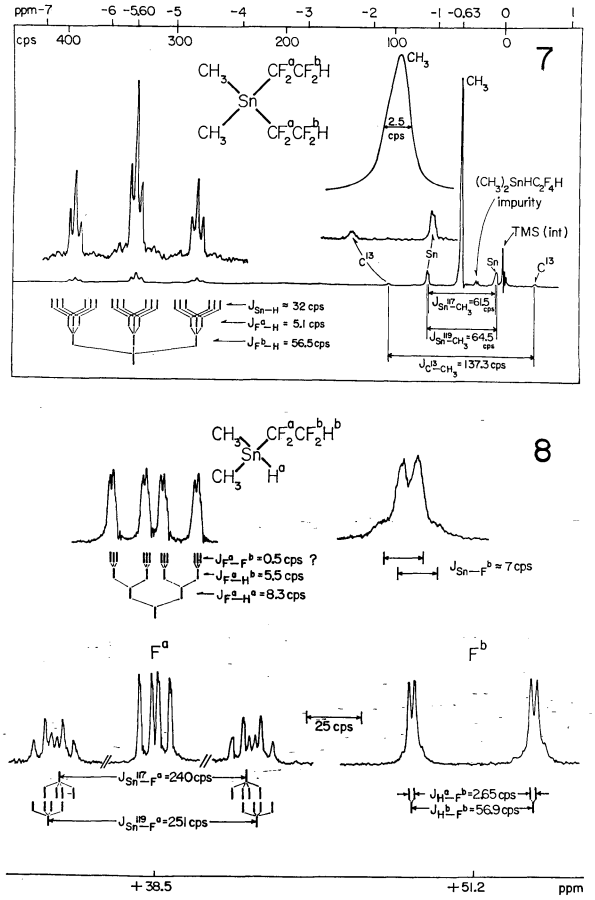

FIG. 7. 60 Mc/s proton resonance spectrum of $(CH_3)_2Sn(CF_2CF_2H)_2$. Chemical shifts are given relative to internal tetramethyl silane.

FIG. 8. 40 Mc/s F^{19} magnetic resonance spectrum of $(CH_3)_2SnH(CF_2{}^aCF_2{}^bH)$. The F^a quartet, with tin side bands, and the two F^b doublets are drawn to the same (broken) frequency scale, though not to the same intensity scale. The chemical shifts are quoted in p.p.m. from an external CF_3COOH standard (not shown). The assignment of each of the F^a quartets as a hyperfine triplet is uncertain (see text).

half width was unusually high, 2.5 c.p.s. C^{13}, Sn^{117}, and Sn^{119} side bands are clearly observed and couplings have been noted. The proton geminal to two fluorine atoms in this compound is a tripleted triplet due to coupling with $F_2{}^b$ and $F_2{}^a$. A remote coupling to the active tin nuclei was observed but the difference in coupling constant H—Sn^{117} and H—Sn^{119} is too small to resolve. The value quoted is a good average of the two values.

Fluorine Magnetic Resonance Spectra

The F^{19} spectrum of the compound with one tin hydrogen is shown in Fig. 8. The peaks due to $F_2{}^a$ are doubleted due to coupling with H^a, doubleted again due to coupling with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

H^b, and then further split. The assignment of splittings to numerical coupling constants is ambiguous here but knowledge of the proton spectrum allows a unique assignment. The smaller splittings assigned as a triplet of 0.5 c.p.s. separation is somewhat doubtful. An alternative assignment might be an incompletely resolved septet, a little distorted due to lack of resolution. However, no hyperfine structure could be detected in the relatively sharp doublet in the proton spectrum of the methyl group. Below the expanded spectrum of $F_2{}^a$ is shown the Sn^{117} and Sn^{119} side bands.

The spectrum of $F_2{}^b$ is a doublet due to coupling $F_2{}^b$—H^b and a smaller doublet structure due to $F_2{}^b$—H^a interaction. Above this on Fig. 8 the tin side bands are resolved for each doubleted component.

Figure 9 illustrates the fluorine magnetic resonance spectrum of dimethylbis(tetrafluoroethyl)tin. The peaks of $F_2{}^b$ are very similar to those in Fig. 8 but lack the splitting

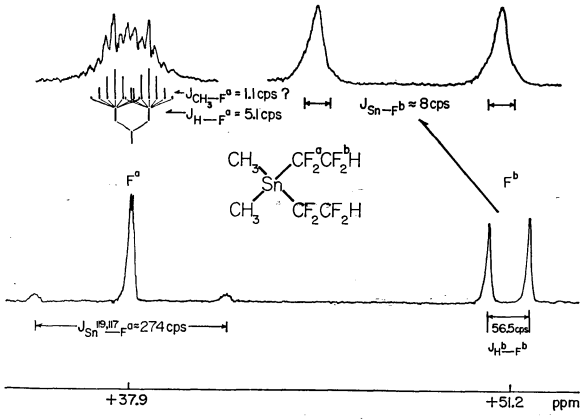

FIG. 9. 40 Mc/s F^{19} spectrum of $(CH_3)_2Sn(CF_2CF_2H)_2$. The relationship of the F^a and F^b resonance on a linear frequency scale is shown below, and the F^a fine structure above. Chemical shifts of the mean frequencies are quoted relative to an external standard of CF_3COOH.

due to the proton on the tin. The peaks due to the fluorine nuclei $F_2{}^a$ do not fit the doubleted septet pattern indicated very well, since the intensities of peaks seem distorted. The double tin side bands are not resolved but an average $J_{Sn^{117,119}-F^a}$ can be evaluated.

We note here that the arrangement of fluorine atoms in this molecule is analogous to that in the compounds studied by Petrakis and Sederholm (12). A good example for comparison would be the molecule

IV  with V 
Musher (13) has noted that coupling interpreted by previous authors (12) as being equal, i.e. *ba* and *ba*^{1}, was, in fact, not equal and the mechanism of the simple multiplet spectra observed has been labelled 'virtual coupling'. In the extreme case of two strongly coupled inequivalent sets of spins B_n and C_m (all $I = 1/2$) coupling to a third group of spins, A appears as a simple multiplet of $(n+m+1)$ lines. Petrakis and Sederholm (14) concur with this explanation and some further work has been published by Musher and Corey (15). The multiplet for our fluorines $F_2{}^a$ may well be an intermediate case of virtual coupling (15) where simple multiplets are not observed.

A summary of all coupling constants and chemical shifts is given in Table I.

DISCUSSION

A consideration of the $I \cdot I$ coupling constants, for compounds containing group IV elements with favorable nuclear spin, is made in a recent note by two of the authors (16). A qualitative extension of factors which influence the coupling in C^{13}—H and Si^{29}—H bonds (17, 18) can be applied to the values $J_{Sn^{119}-H}$ in the compounds studied here. In all three compounds studied, we expect approximately sp^3 hybridization on the tin and no back donation of charge into the empty d orbitals of tin. Recent theoretical work (17) suggests that the sharing of s character amongst the four bonds is uneven and electropositive groups have more s character in the bonding electrons than electronegative groups; thus the Fermi contact term at the group IV nucleus is enhanced. This is illustrated well by the Sn^{119}—H coupling in $(CH_3)_2SnH_2$ and in $(CH_3)_2SnH(C_2F_4H)$. The more electronegative —C_2F_4H group replaces hydrogen in dimethyl tin dihydride with a consequent increase in $J_{Sn^{119}-H}$ from 1797 to 1976 c.p.s. This effect is also seen (Table I) in the $J_{C^{13}-H}$ coupling in the methyl groups, which increases progressively in the series $(CH_3)_2SnH_2$, $(CH_3)_2SnH(C_2F_4H)$, $(CH_3)_2Sn(C_2F_4H)_2$. The group attached to the carbon 13 becomes more and more electronegative with the more distant addition of —C_2F_4H groups. The increase of $J_{Sn^{119}-CH_3}$ follows a similar trend. Hydrogen to fluorine coupling constants via geminal atoms $J_{H^b-F^b}$ are unaffected by changes in the molecules.

ABSTRACT

The rates of reaction of sodium hypochlorite with sodium iodide and sodium sulphite have been measured by means of a rapid-flow technique. The measurements were made over a range of temperature and hydroxide concentrations, and show that the actual slow steps of the reactions are

(i) $OCl^- + SO_3^{-2} \rightarrow Cl^- + SO_4^{-2}$

with $K = 2.7\times10^9 \exp(-7.5 \text{ kcal}/RT)$,

and

(ii) $HOCl + I^- \rightarrow HOI + Cl^-$

with $K = 1.6\times10^{-9} \exp(-0.9 \text{ kcal}/RT)$,

with time in seconds.

The decomposition of hypoiodite ions was also measured.

These results, and those for other reactions of hypochlorite ions, or hypochlorous acid, form a series similar to the reactions of peroxides. It is found that the regularities observed for peroxides apply to some extent to the present reactions, and other possible regularities are also examined.

INTRODUCTION

The present work is part of a study on the oxidations effected by hypochlorite ions or hypochlorous acid. The oxidations of sulphite and iodide ions were measured by means of a rapid-flow technique. These reactions, together with those previously reported, form a moderately extensive series, and it is of interest to discover whether the rates of these reactions can be correlated with other properties of the reducing agent. A similar sequence of reactions consists of the oxidations by hydrogen peroxide, which have been particularly studied by Edwards (1, 2, 3), who was able to observe regularities in their rate constants. These reactions of hydrogen peroxide have been used as a basis for comparison in the present work.

EXPERIMENTAL

The rapid-flow technique used in the present work is based on that developed by Hartridge, Roughton, and Millikan (4–7). Briefly, the two reagents are driven by syringe into a Plexiglas mixing chamber. From here the reacting solution passes into a quartz observation tube. The absorbance of the solution is measured at various points along the tube by means of a Beckmann DU spectrophotometer. If d is the distance in cm between the mixing chamber and the point of measurement, and v is the linear rate of flow in cm/sec, then the time for which the reaction has proceeded in the fluid is d/v seconds.

In greater detail, the apparatus is as follows. The reactants are brought to correct temperature in 100 ml syringes held in a thermostat box. A continuously variable speed motor drives a trolley carrying both syringes and observation tube while a second motor drives a block which pushes forward the plungers of the syringes. The mixing chamber and jets are constructed from a drilled-out block of Plexiglas, each jet being 2.5 cm long and 1 mm in diameter, while the mixing chamber is 2 mm long and 1 mm in diameter. A 16-inch long piece of Corning, Vycor 96% silica glass No. 7910 serves as the observation tube; the inside diameter of the capillary is 2 mm while the outer diameter is 7 mm. Both mixing chamber and observation tube are mounted inside a cover similar to that used by Dalziel (8) in his rapid-flow apparatus, but refined to include copper tubing for heating or cooling purposes. A jacket mounted between the Beckmann body and photocell allows the tube to slide smoothly through the light path of the spectrophotometer. The voltage from the photocell is amplified by a Beckmann 5800 Energy Recording Adapter and the amplified voltage is then applied to a Sargent model SR chart recorder. To ensure that a deflection of 100 units on the chart

corresponds to a transmission of 100%, the recorder pen is adjusted to read 100% with the blank solution in the capillary and to indicate zero with the shutter closed. Narrow strips of black tape on the observation tube permit a correlation between distances on the chart paper and the actual distance on the observation tube.

REACTION OF HYPOCHLORITE AND SULPHITE IONS

A study of the kinetics of the oxidation of sulphite ions by hypochlorite ions has not previously been reported; all that was known about the rate was that the reaction is a rapid one.

Experimental Method

The hypochlorite solutions were made up by mixing known volumes of stock hypochlorite (analyzed as in a previous paper) (9), sodium hydroxide, and sodium chloride solutions. Sodium sulphite solutions were analyzed immediately before the run in the following way. A 50 ml aliquot was added to a solution containing a 10 ml aliquot of standard iodine solution and 10 g of sodium bicarbonate. Then the unreacted iodine was titrated with standard arsenious oxide solution, 5 ml of 0.2% starch solution being added just before the end-point.

Since the only absorbing species at 292 mμ in the reaction mixture is the hypochlorite ion (extinction coefficient = 350), this wavelength was used for following the course of the reaction.

For a run the sodium hypochlorite solution was first drawn into one syringe, after the syringe had first been carefully rinsed with the same solution. Next, the sodium sulphite solution was drawn into the other syringe and some ejected in order to displace any hypochlorite in the capillary tube. After allowing the solutions to come to temperature equilibrium, the recorder was adjusted to read 100% as previously described, and the whole length of the observation tube was scanned. This blank served to correct for the effect of fluctuations in the transmission of the glass. A reaction graph was next made with both trolley and syringes moving, then the capillary, filled only with hypochlorite, was scanned in order to determine the extinction coefficient of hypochlorite in the capillary. A fourth scan was made, using the sulphite solution only, to check for drift of the zero setting.

The rate of flow was determined by measuring the volume of water delivered in a certain time interval; this flow rate was found constant to within 1% over the time of the experiment. From the volume rate of flow the linear flow rate was calculated. The diameter of the capillary was determined by measuring the exact length of a weighed 1 cm plug of mercury at various positions along the capillary.

For the constant flow method to give valid results, all parts of the reacting solution should reach the place of observation at the same time. This occurs only in the case of ideal or mass flow. In practice, the central parts of the fluid always move faster than the edges. Such deviations from mass flow are much greater in the case of streamline flow than with turbulent flow (8). Consequently the flow rates used in the present work were always well in excess of the streamline flow region (3 ml/sec). The flow velocity used in most of the present work was approximately 210 cm/sec (6 ml/sec).

A physical test for the efficiency of mixing, i.e., the approach to optical homogeneity of a solution of ammonium sulphate (10), was applied and showed that mixing was complete before the first reading on any run. As an added check to ensure that deviations from mass flow and mixing errors were negligible, some runs were performed at a slower flow rate. These gave the same rate constant as the other runs.

The liquid flowing from the end of the observation tube was a little closer to room temperature than the liquid in the syringes. Measurements performed on water by means of an iron–constantan thermocouple placed in the capillary showed that there was no temperature gradient along the capillary. This meant that the main source of heat loss or gain came from the connecting tubing. The temperature of the reacting fluid was therefore taken to be the same as that of the emerging fluid.

Preliminary tests showed that there are no side reactions in the conversion of sulphite to sulphate by hypochlorite. Consequently the reaction is simply

$$OCl^- + SO_3^{--} \rightarrow Cl^- + SO_4^{--}$$

and the rate constant was found as follows. If the reaction is second order, and if we write $[OCl^-] = x$, and $[SO_3^{--}] = y$, then $dx/dt = -kxy$. Integration gives: $\ln (xy_0/yx_0) = kt(x_0-y_0)$. If A is the absorbance (at 292 mμ) and ϵ the extinction coefficient of OCl^-, then $A/\epsilon = x$, and

$$\ln(A/[A + \epsilon(y_0-x_0)]) = \ln(x_0/y_0) + k(x_0-y_0)t.$$

It was found that a plot of $\ln (A/[A + \epsilon(y_0-x_0)])$ against time was a straight line as required. The rate constant was calculated from the slope of this line. Results from a typical run are given in Table I. The last column gives $\log (A/[\epsilon(y_0-x_0) + A])$. The values of the rate constant, k, are given in Table II.

Inspection of Table II shows that there is no significant change of rate constant with hydroxide concentration.

The temperature dependence of rate constant gives an activation energy of 7.5 kcal mole^{-1}, log A is 9.43 (time in seconds).

REACTION OF HYPOCHLORITE AND IODIDE IONS

Chia and Connick (11, 12) have studied the oxidation of iodide ion by hypochlorite ions in alkaline solution. They found the rate law to be $d[IO^-]/dt = k[I^-][ClO^-]/[OH^-]$ and the rate constant at 25° C and an ionic strength of 1.00 to be 61 sec^{-1}. Since this rate constant has been measured at one temperature only, the present work was undertaken in order to determine the variation of rate constant with temperature and thereby obtain the activation energy.

Experimental Method

The sodium hypochlorite solutions were made up as in the study of the oxidation of sulphite. Sodium iodide solutions were analyzed as follows. A 25 ml aliquot of the stock iodide solution was transferred to a 250 ml glass-stoppered flask. One gram of urea (to destroy excess nitrous acid), 8 ml of 0.5 *M* sodium nitrite solution, and 5 ml of 4 *N* sulphuric acid were added. The flask was immediately stoppered to prevent the escape of iodine vapor and allowed to stand for about 10 minutes with frequent shaking. It was then cooled in an ice bath, 2 g of potassium iodide were added, and the solution was shaken well to dissolve all the iodine. The iodine was titrated with standard sodium thiosulphate solution, starch solution being added just before the end-point.

At 400 mμ the extinction coefficient for IO^- is 38.5 (12), while that for OCl^- is only 0.52. Therefore, this wavelength was chosen as the one for following the course of the reaction.

The method of carrying out the run was the same as in the oxidation of sulphite ions. A blank was run on the sodium iodide, a reaction graph on the recorder was made, and then another blank was run on the iodide to check for drift. A determination of the extinction coefficient of IO^- was carried out as follows. The chart recorder was started and the syringes were given a short push with the pusher block. Immediately the stopcocks were closed. A graph, made in this way, showed a sharp rise to a maximum, which corresponded to the maximum amount of hypoiodite formed, and then a slow decay, due to formation of iodate.

Chia showed that the rate expression is:

$$-d[OCl^-]/dt = k[OCl^-][I^-]/[OH^-]$$

or

$$dx/dt = -kxy/[OH^-]$$

which on integration leads to

$$\ln xy_0/yx_0 = (kt/[OH^-])(x_0-y_0).$$

If IO^- is the only absorbing species at 400 mμ, $x = A\epsilon$, where A is the absorbance (actually corrected), and

$$\ln x/y = \ln (x_0\epsilon-A)/(y_0\epsilon-A).$$

A plot of log $[(x_0\epsilon-A)/(y_0\epsilon-A)]$ against time gives a straight line of slope equal to $k(x_0-y_0)/[OH^-]$ 2.303, from which the rate constant can be calculated. Results from a typical run are given below.

TABLE III

(Run 43; at 17.7° C; $[NaOCl]_0$ = 0.04084 *M*; $[NaI]_0$ = 0.05103 *M*; [NaOH] = 0.2955 *M*; ionic strength = 1.00)

Column 2 indicates the absorbance corrected for drift in the chart recorder. According to Chia and Sigalla (13), I_2OH^- is formed in the reaction mixture as

$$IO^- + I^- + H_2O \rightleftarrows I_2OH^- + OH^-,$$

although they differ as to the size of the equilibrium constant. Chia quotes a value of 0.13 at 25° C for $K = [I_2OH^-][OH^-]/[IO^-][I^-]$ while Sigalla's value is 0.03 for the same constant. Column 3 gives the absorbance corrected for the presence of I_2OH^-, the correction being applied in the following manner. Using Chia's value for K of 0.13, the $[I_2OH^-]$ was calculated. From this the contribution to A'' of the I_2OH^- was calculated at each point by using an extinction coefficient of 100 found for I_2OH^- by Chia. The contribution of I_2OH^-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was then subtracted from A'' to obtain A'. Column 4 gives the absorbance corrected for the presence of unreacted OCl^-, which absorbs only slightly at 400 mμ. The last column shows the values of log $[(x_0\epsilon - A)/(y_0\epsilon - A)]$. This varies linearly with time, as required by the proposed rate equations.

Table IV contains all the values of the rate constant determined for the hypochlorite–iodide reaction.

As in the case of the oxidation of nitrite (9) and formate ions (14) by sodium hypochlorite, the rate of the oxidation of iodide is also inversely proportional to the hydroxide concentration as shown by the relative constancy of k in Table IV over a wide range of NaOH concentration. Similarly, this reaction is probably one of the undissociated hypochlorous acid and the rate is given by

$$\text{rate} = k_T[HOCl][I^-],$$

where k_T is the rate constant of the slow step. If the mechanism is given by

$$OCl^- + H_2O \overset{K_h}{\rightleftharpoons} HOCl + OH^-$$

$$HOCl + I^- \overset{k_T}{\rightarrow} HOI + Cl^- \text{ (slow step)}$$

$$HOI + OH^- \rightleftharpoons IO^- + H_2O$$

where steps 1 and 3 are rapid equilibria and step 2 is rate-determining, then

$$-d[OCl^-]/dt = k_T K_h([OCl^-][I^-]/[OH^-])$$

and

$$k_T = k/K_h.$$

K_h, calculated from the known values of K_w and K_A for the dissociation of HOCl, is 2.8×10^{-7} at 25° C, and therefore k_T is 3.3×10^8 liters $mole^{-1}$ sec^{-1} at an ionic strength of 1.00 at 25° C. The apparent activation energy, E_a, calculated from the variation of k with temperature, is 11.9 kcal $mole^{-1}$. Data on the heats of formation of the compounds (in aqueous solution) in the reaction

$$NaOCl + H_2O \rightarrow HOCl + NaOH$$

make the heat of hydrolysis of the hypochlorite ion to be 11.0 kcal $mole^{-1}$. Hence, the energy of activation for the reaction of iodide ions and hypochlorous acid is only 0.9 kcal $mole^{-1}$.

Hypoiodite decomposes at a much faster rate than does hypobromite or hypochlorite. However, the decomposition of hypoiodite could be disregarded in the calculation of rate constant, since the oxidation of iodide is much faster than the decomposition of hypoiodite. Li and White (15) have studied the decomposition, the overall reaction being

$$3OI^- \rightarrow IO_3^- + 2I^-,$$

and have found that the decomposition can proceed along two paths.

$$-d[OI^-]/dt = k'[OI^-]^2 + (k''[OI^-]^2[I^-]/[OH^-])$$

At 25° C they have determined a k'' of 104 (time in minutes) and a k' of 2.9 (time in minutes).

In the present work it was an easy matter to check the rate constants by a simple stopped-flow method. A k'' of 180 (time in minutes) was obtained at 25° C.

In applying the correction for I_2OH^-, Chia's value for the equilibrium constant was used, as well as his value for the extinction coefficient of I_2OH^-. Chia states that this is a rapidly established equilibrium, though there is no evidence, at present, to show whether it is really fast relative to the times involved in the present measurements. If further work shows that the formation of I_2OH^- is in fact slow, the rate constant would be about 6% too high.

The mean value of k at 25° C and an ionic strength of 1.0 is 91.3. This is appreciably higher than Chia's value of 61, and at present the cause of the discrepancy is unknown.

DISCUSSION OF RESULTS

The present results, together with others from earlier work, cover a series of oxidations by hypochlorite ions, or hypochlorous acid. These results are summarized in Table V. The rate constants in this table are all second order constants, with time measured in seconds. E_a is the activation energy, and A in column 5 is the pre-exponential factor in the usual equation, $k = A \exp(-E_a/RT)$.

It will be noted that the reactions in Table V are either due to OCl^- or HOCl. In the mildly alkaline solutions on which these measurements were made, the pH dependence of the reactions showed that one or the other species (but not both) was responsible for the reaction. It does not at present seem possible to explain why certain reducing agents favor one path rather than the other. Reactions of hydrogen peroxide, on the other hand, often follow a rate equation, which is interpreted by Edwards (16) as showing that both H_2O_2 and $H_3O_2^+$ contribute appreciably to the total reaction.

It was mentioned at the beginning of this paper that peroxides give a series of reactions whose rates can be correlated with other properties of the reagents. In particular, Edwards (16) has observed that if different peroxides, of formula ROOH ,where R is any group of atoms (or hydrogen) react with the same reducing agent (e.g. Br^-), then the rates are related to the stability of the ion RO^-. This is explained by the mechanism:

$$R\text{—}O\text{—}O\text{—}H + Br^- \rightarrow R\text{—}O\text{—}O(Br)\text{—}H \xrightarrow{\text{slow}} RO^- + HOBr,$$

$$HOBr + H_3O^+ + Br^- \rightarrow Br_2 + 2H_2O \text{ (fast)},$$

$$RO^- + H_3O^+ \rightarrow ROH + H_2O \text{ (fast)},$$

the suggestion being that if RO^- is stable, the products are formed more rapidly. The relevant stability of RO^- is assumed to be its stability compared with ROH; that is, if pK_a of ROH is low, RO^- is relatively stable. In fact if log k (where k is the rate constant) is plotted against pK_a of ROH a straight line is obtained, with slope, $d \log(k/dpK_a)$, of about −0.4. The reactions of HOCl with Br^- or I^- fall on nearly the same line as do the peroxide reactions, if we take RO^- to be Cl^-, and pK_a for HCl as −7 (17). The data are shown in Fig. 1. This agreement may be partly coincidental, since we are comparing breaking O—O and O—Cl bonds, but these are similar in strength.

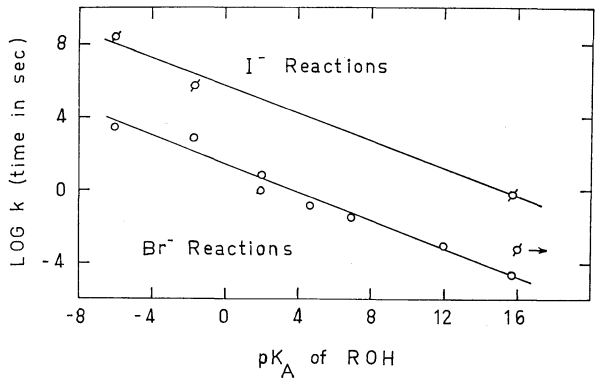

FIG. 1.

Many reactions of peroxides have a relatively low value of log A (16, p. 71); or, in other words, a negative entropy of activation, the values falling between -15 and -35 cal/degree. This is explained on the supposition that the activated complex requires rather careful orientation of the incoming reducing agent. This should also apply to reactions of hypochlorite ions (or HOCl) when the mechanism would be

$$\text{Cl—O(H)} + X^- \rightarrow \text{Cl—O(H)—}X^- \rightarrow Cl^- + XOH.$$

The atoms ClOX are roughly linear in the activated complex. The values of $\Delta S^{\ddagger}$ given in Table V mostly fall in the same range of -15 to -35 cal/degree. The relatively high values with iodate and oxalate ions cannot be explained at present.

A correlation between the activation energy and the heat of reaction ($\Delta H°$) seems to exist. This might reasonably be expected, since if a strong bond is being formed the maximum of energy in the transition state will probably be reached earlier. Other factors, such as the energy of hydration of the various ions, will, of course, modify the results, but the heat of reaction is bound to be an important factor. Figure 2 shows a plot of $\Delta H°$ against activation energy for reactions of OCl^- and HOCl. In both cases the graph is roughly linear with a slope, $dE_a/d\Delta H°$ of 0.22 for OCl^-, and roughly the same for HOCl.

CHARACTERISTIC VIBRATIONAL FREQUENCIES OF OXYGEN COMPOUNDS OF SILICON, PHOSPHORUS, AND CHLORINE: CORRELATION OF STRETCHING FREQUENCIES AND FORCE CONSTANTS WITH BOND LENGTHS AND BOND ORDERS

E. A. ROBINSON
Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 25, 1963

ABSTRACT

For oxygen compounds of chlorine, phosphorus, and silicon, respectively, correlations are established between stretching frequencies and force constants of Cl—O, P—O, and Si—O bonds, and their bond lengths.

By deducing bond orders on the assumption that only $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals on the central chlorine, phosphorus, or silicon atom are utilized in the formation of double bonds with lone pairs of electrons on oxygen, linear correlations between bond orders and force constants are established.

The present treatment leads to the conclusion that the presence of a maximum of 12 electrons in the valency shells of chlorine, phosphorus, and silicon is required to best explain the bond length and force constant data, when highly electronegative ligands such as oxygen or fluorine are attached to the central silicon, phosphorus, or chlorine atom.

INTRODUCTION

In a previous paper (1) we have obtained a correlation between the lengths and stretching frequencies, or force constants, of S—O bonds, and the problem of defining and measuring the bond orders of S—O bonds was also discussed. It was shown that there is a linear correlation between bond order, simply defined as the number of electron pairs in the bond, and the stretching force constant. The general validity of a linear relationship between bond order and stretching force constant was discussed in a recent paper (2).

The assignment of spectral frequencies to the symmetric and asymmetric stretching modes of PO_2 and ClO_2 groups was discussed recently (3). It was shown that there are straight line correlations between the symmetric and asymmetric frequencies and these correlations are useful in assigning the frequencies of P—O and Cl—O stretching vibrations in species of the type $X_2PO_2^-$, XPO_3^{2-}, PO_4^{3-}, and $XClO_3$, ClO_3^-, ClO_2, ClO_2^-, and ClO_4^-, respectively. The frequencies assigned previously (3) are used as the basis of this paper.

It was shown previously (1) that Lehmann's approximate method of reducing the symmetric and asymmetric A—B stretching frequencies of AB_2, AB_3, and AB_4 groups to the vibrational frequency of an 'equivalent' AB group (4) can be successfully used to calculate the force constants of S—O bonds in SO_2, SO_3, and SO_4 groups. In this paper the same method is applied to PO_2, PO_3, and PO_4, and ClO_2, ClO_3, and ClO_4 groups. The force constants so obtained are compared with those obtained by more rigorous methods, where such data are available.

CHLORINE–OXYGEN BONDS

The Cl—O stretching frequencies and observed bond lengths for various species containing this bond are shown in Table I, which also shows the Cl—O stretching frequency of an equivalent Cl—O group calculated by the method of Lehmann (4), and the force constant calculated from it by treating the Cl—O group as a simple diatomic molecule.

TABLE I

These force constants are compared with those obtained by other workers using more sophisticated methods. Figure 1 shows the plot of ν_{Cl-O} against bond length, and the

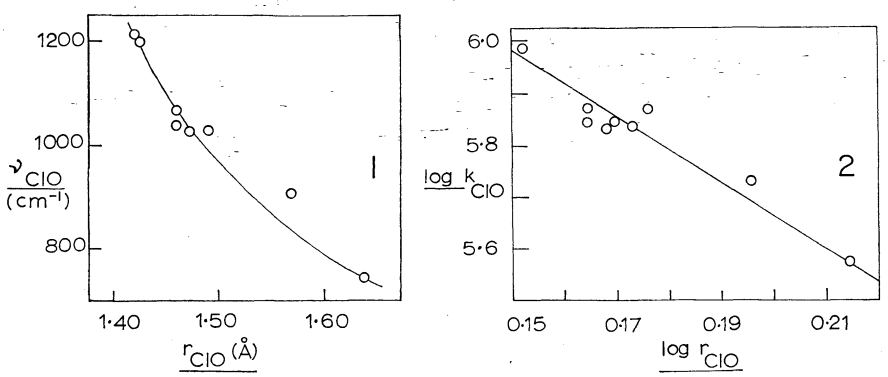

FIG. 1. r_{Cl-O} plotted against bond length.
FIG. 2. log r_{Cl-O} plotted against log k_{Cl-O}.

logarithm of bond length is plotted against the logarithm of force constant in Fig. 2. The latter plot is a straight line which is given by the equation

$$\log k_{Cl-O} = -6.45 \log r_{Cl-O} + 7.0$$

or

$$k_{Cl-O}\, r_{Cl-O}^{6.45} = 1.00\times10^{7} \qquad [1]$$

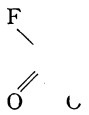
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which is the form of the relationship suggested by Linnett (5) on the basis Clark's relationship between bond length and force constant (6).

Force Constant – Bond Order Relationship

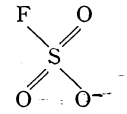
The longest Cl—O bonds reported in the literature are 1.64 Å for in perchloric acid (7), 1.70 Å in Cl_2O (8), and 1.725±0.03 Å for th in Cl_2O_7 (9). It therefore seems likely that the Cl—O single-b 1.70 Å. Equation [1] enables the value of the stretching force c of length 1.70 Å to be calculated. The value obtained is 3. is very close to the force constant calculated for the Cl—C (10).

We assume, as we did previously in the case of S—C $3d_{z^2}$ orbitals on chlorine are used in π-bonding with and then predicted bond orders are easily calculate electrons in the valency shell of chlorine. For ex as perchloryl fluoride the maximum Cl—O bor to resonance structures such as I.



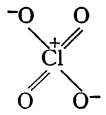
I

The Cl—O stretching force constant in this compound ues cm^{-1} which is the highest Cl—O force constant observed for the Cl—O compound. This is consistent with the fact that there are four highly electroneg groups attached to the central chlorine atom. The force constant is to be compared with that of the S—O bonds in the fluorosulphate ion (structure II), which has the value 8.8×10^5 dynes cm^{-1}



II

(1). Similarly we might expect the Cl—O bond order in the perchlorate ion to be 1.50 (structure III), and the most reliable value for the Cl—O force constant is probably 8.2×10^5 dynes cm^{-1} (11) (cf. $k = 7.1\times10^5$ dynes cm^{-1} for the sulphate ion (1)).



III

On the basis of the force constants 3.3×10^5, 8.2×10^5, and 9.8×10^5 dynes cm^{-1} for bond orders 1.00, 1.50, and 1.67, respectively, a linear force constant – bond order relationship is suggested as is shown in Fig. 3. This is theoretically justifiable (2) and consistent with the similar relationship obtained for S—O bonds (1). It is interesting to note that the linear force constant – bond order curve for Cl—O bonds is almost

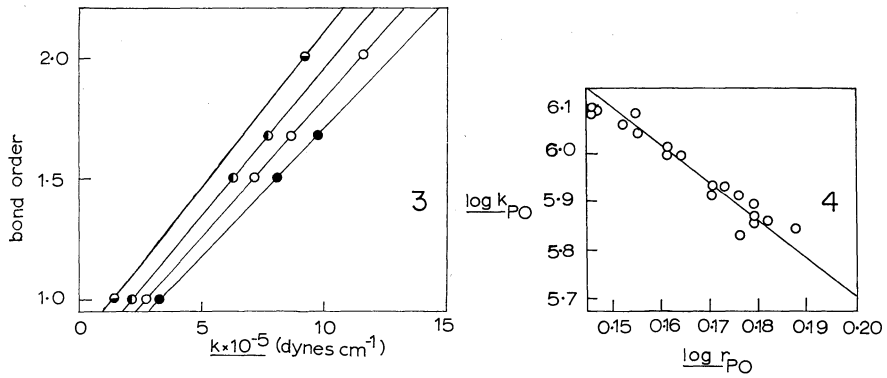

FIG. 3. Bond order – force constant relationships. Key: Cl—O, ●; S—O, ○; P—O, ◐; Si—O, ◒.
FIG. 4. log r_{P-O} plotted against log k_{P-O}.

parallel to that obtained for S—O bonds (Fig. 3). The bond order – force constant relationship fits the equation

$$n_{Cl-O} = 1.02\times10^{-6}\, k_{Cl-O} + 0.66, \qquad [2]$$

where n_{Cl-O} is the bond order.

Bond Order – Bond Length Relationship

Combination of equations [1] and [2] gives a relationship between bond order and bond length.

$$n_{Cl-O} = 10.2/r_{Cl-O}^{6.45} + 0.66 \qquad [3]$$

Bond lengths calculated from this equation for various values of the bond order, n_{Cl-O}, are shown in Table III.

TABLE II

Bond orders and calculated P—O and Cl—O bond lengths

the same relationship to Cl—O bonds. On the basis of the Cl—O single-bond length of 1.70 Å and the lengths of bonds of order 1.67 and 2.00, which can be calculated from equation [3] as 1.43 Å and 1.37 Å, respectively, the constants in the Pauling equation may be calculated. The equation takes the form

$$r_{Cl-O} = 1.70 - \frac{0.33}{1+0.44\left[\frac{2-n}{n-1}\right]}. \qquad [4]$$

Bond lengths calculated from this equation for given bond orders are compared with those obtained from equation [3] in Table II. Both equations give very similar values.

Table III shows the bond orders obtained from the stretching force constants, the observed bond lengths, and the bond lengths calculated from the bond orders by means of equation [3].

PHOSPHORUS–OXYGEN BONDS

Phosphorus–oxygen stretching frequencies, bond lengths, and stretching force constants are collected in Table IV. Figure 4 shows the plot of the logarithm of force constant against the logarithm of the bond length. As was found to be the case for S—O bonds (1) and for Cl—O bonds, this plot is a straight line given by the equation

$$\log k_{P-O} = -8.0 \log r_{P-O} + 7.30$$

or

$$k_{P-O} r^{8.0} = 2.0\times10^7 \qquad [5]$$

Extrapolation to the sum of the Pauling covalent radii of phosphorus and oxygen (r_{P-O} = 1.76 Å) gives the value $k_{P-O} = 2.2\times10^5$ dynes cm^{-1} for the force constant of a single bond.

Force Constant – Bond Order Relationship

On the basis of the assumption that only the $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals of phosphorus

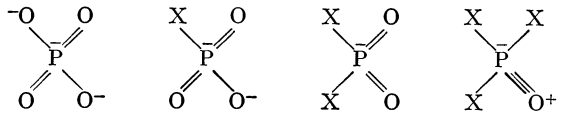
are available for π-bonding, the maximum bond orders expected are 1.50 in the phosphate ion (structure IV), 1.67 in ions of the type XPO_3^{2-} (structure V), 2.00 in ions of the type $X_2PO_2^-$ (structure VI), and 3.00 in compounds of the type X_3PO (structure VII).



IV V VI VII

The maximum possible bond orders are expected to be approached when the substituents X are highly electronegative ligands such as oxygen or fluorine.

The P—O stretching frequencies are 6.3×10^5 dynes cm^{-1} (12), for the bonds in the phosphate ion ($n_{P-O} = 1.50$), and 7.8×10^5 dynes cm^{-1} for the monofluorophosphate ion ($n_{P-O} = 1.67$), where the maximum possible bond orders might be expected to be achieved. These force constants and bond orders, together with the force constant for a single bond ($n_{P-O} = 1.00$; $k_{P-O} = 2.2\times10^5$ dunes cm^{-1}), fit a straight line correlation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

between P—O bond order and stretching force constant, as is shown in Fig. 3. The straight line is given by

$$n_{P-O} = 1.19\times10^{-6}\, k_{P-O} + 0.74 \quad [6]$$

and is nearly parallel to the linear bond order – force constant plots obtained for Cl—O and S—O bonds.

Bond Order – Bond Length Relationship

Combination of equations [5] and [6] gives a correlation between bond order and bond length,

$$n_{P-O} = 23.8/r^8_{P-O} + 0.74. \quad [7]$$

Equation [7] gives bond lengths of 1.54 Å and 1.44 Å for P—O bonds of order 1.5 and 2.0, respectively, and the single bond length is 1.76 Å. These distances allow the parameters in the Pauling equation (12) to be evaluated, giving

$$r_{P-O} = 1.76 - \frac{0.32}{1+0.45\left[\frac{2-n}{n-1}\right]}. \quad [8]$$

Calculated bond lengths obtained from equations [7] and [8] are shown in Table II. Both equations give comparable values.

Bond orders calculated from the stretching force constants of P—O bonds in various

For personal use only.

species are shown in Table V, which also gives P—O bond lengths calculated from these bond orders by means of equation [7].

The bond lengths reported for the P—O bonds in the phosphoryl halides (8) require some comment. The bond length reported for the P—O bond in POF_3 is 1.45±0.02 Å, which is the same as the length of the P—O bond in $POCl_3$ (1.45±0.03 Å), while that in POF_2Cl is 1.55±0.02 Å and the length of the P—O bond in $POBr_3$ is given as 1.41 ±0.07 Å. These bond lengths are clearly inconsistent with, e.g., the P—O stretching frequencies which increase from $POBr_3$, to $POCl_3$, to POF_2Cl, to POF_3, and show a definite correlation with the electronegativities of the ligands attached to phosphorus. It is thus clear that there is inconsistency in the observed values whereas the calculated values of both bond length and bond order show the expected trend with the sum of the electronegativities of the attached ligands.

SILICON–OXYGEN BONDS

Unfortunately very little data is available for the bond lengths and force constants of Si—O bonds but it seems justifiable to assume that the relationship between bond order and stretching force constant is linear as it is for S—O, P—O, and Cl—O bonds, so that just two pairs of bond orders and force constants are required to define the correlation.

We have seen previously that there are linear correlations between logarithms of bond lengths and logarithms of stretching force constants for P—O, Cl—O, and S—O (1) bonds, respectively. The available data for Si—O bonds are given in Table VI and plotted

in Fig. 5, assuming a linear correlation between $\log r_{Si-O}$ and $\log k_{Si-O}$. If the length of a single Si—O bond is taken as 1.83 Å (the sum of the Pauling covalent radii of Si and O), extrapolation of the straight line in Fig. 5 gives a value of 1.5×10^5 dynes cm^{-1} for the force constant of a single Si—O bond. This value seems reasonable in comparison with the values 2.2, 2.7, 3.3×10^5 dynes cm^{-1} for the force constants of single P—O, S—O (1), and Cl—O bonds, respectively.

We could assume that the bond order of the Si—O bonds in the silicate ion are 1.50; however, unfortunately, no reliable values seem to be available for the vibrational frequencies of this species. For example, the values given by Siebert (13) for SiO_4^{4-} are the same as those attributed to the $(HO)_2SiO_2^{2-}$ ion by Fortnum and Edwards (14).

Analysis of the spectrum of the diatomic species SiO leads to a value of 1.51 Å for the bond length and 9.25×10^5 dynes cm^{-1} for the force constant (15). The bond length of 1.51 Å suggests that the bond in SiO may be a double bond (cf. the double bond lengths Cl=O, 1.37; S=O, 1.40; and P=O, 1.45 Å). On the basis of the assumed double

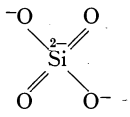
bond in SiO, and the single bond force constant of 1.5×10^5 dynes cm^{-1}, the bond order – force constant linear relationship may be deduced and is plotted in Fig. 3. It is almost parallel to the corresponding curves for P—O, S—O, and Cl—O bonds and fits in with their relative trends.

The bond order – force constant correlation fits the relationship

$$n_{Si-O} = 1.29\times10^{-6}\, k_{Si-O} + 0.81. \qquad [9]$$

Bond Order – Bond Length Relationship

The bond order in the silicate ion is 1.5 (structure VIII), if it is assumed that there are 12 electrons in the valency shell of silicon. The bond length is 1.63 Å (16) and the corresponding bond lengths for P—O, S—O, and Cl—O bonds of order 1.50 in the PO_4^{3-}, SO_4^{2-}, and ClO_4^- ions are 1.54, 1.49, and 1.47 Å, respectively. On the basis of



VIII

the single bond length of 1.83 Å, the double bond length of 1.51 Å, and the length of 1.63 Å for a bond of order 1.50 the Pauling formula (12) gives

$$r_{Si-O} = 1.83 - \frac{0.32}{1+0.60\left[\frac{2-n}{n-1}\right]} \qquad [10]$$

Bond lengths calculated from the bond orders obtained from stretching force constants are compared with observed bond lengths in Table VI. Single and double bond lengths and force constants for Si—O, P—O, S—O, and Cl—O bonds are summarized in Table VIII.

DISCUSSION

The formation of double bonds in compounds containing Si—O, P—O, S—O, and Cl—O bonds has recently been discussed by Cruickshank (9) on the basis of evidence obtained from a study of bond lengths, and Wagner (17, 18) has carried out l.c.a.o. – m.o. calculations for species containing Cl—O and P—O bonds, on the basis of a similar approach

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

to that used by Moffitt (19) in the case of, e.g., S—O bonds. Both Cruickshank and Wagner concluded that $3d$ orbitals participate significantly in π-bonding between lone pairs of electrons on oxygen and phosphorus or chlorine. Cruickshank's paper (9) has been discussed previously (1). He concluded that for tetrahedrally coordinated silicon, phosphorus, sulphur, and chlorine atoms significant delocalization of lone pairs on atoms

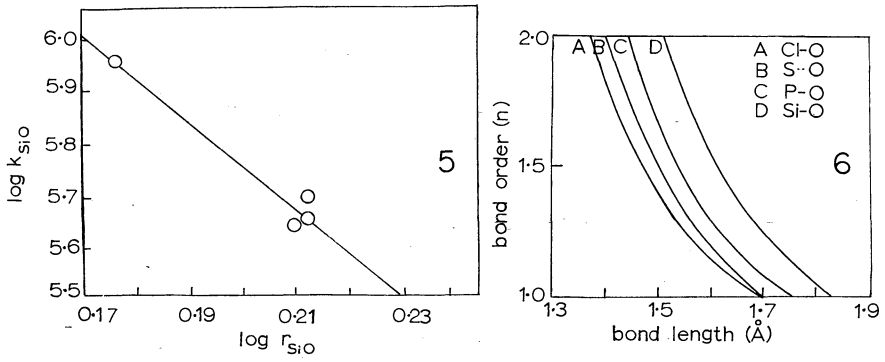

FIG. 5. log r_{Si-O} plotted against log k_{Si-O}.
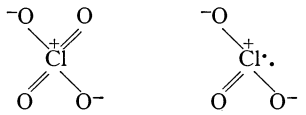
FIG. 6. Relationships between Cl—O, P—O, and Si—O bond lengths and bond orders.

such as nitrogen or oxygen into the $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals of the second row element can occur. He assumed a linear correlation between bond length and bond order but the bond length – bond order relationships obtained in this work for Si—O, P—O, and Cl—O bonds are not linear (Fig. 6), but show the same kind of trend that is shown by, for example, C—C bonds.

Wagner (17) concluded that there is no double bond character in the Cl—O bonds in Cl—O$^-$ or ClO_2, and that the π-bond order in ClO_2 is about 0.74, and that 52% of this is of d character. His calculations showed that the extent of participation of $3d$ orbitals in π-bonding increases in the series Cl—O$^-$, ClO_2^-, ClO_3^-, and ClO_4^-, which is in qualitative agreement with the present results. The actual bond orders calculated by Wagner do not agree with those obtained in the present paper. In particular, he obtained very high values for the π-bond orders of ClO_3^- and ClO_4^- of 0.61 and 0.91, respectively. Because of the difficulties encountered in m.o. calculations of this kind the disagreement with the present results is not surprising or unexpected. Also the definition of bond order appropriate for the molecular orbital approach is different from that of the valence bond approach used in the present paper which, at least in part, explains the discrepancies between these results and those of Wagner.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

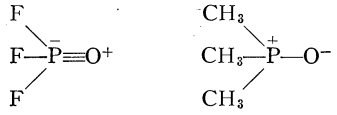
Chantry and Plane (20) have concluded from Raman intensity studies that the important resonance structures for ClO_3^- and ClO_4^- are IX and X, respectively,



IX X

corresponding to bond orders of 1.50 and 1.33. The conclusions of Chantry and Plane are in excellent agreement with those obtained from the linear force constant – bond order relationship.

In the case of compounds containing P—O bonds Wagner (18) has considered only the bonding in phosphoryl compounds (XYZ)PO. He concludes from his m.o. calculations that the π-bond character of the P—O bonds decreases as the sum of the electronegativities of the attached groups X, Y, and Z decrease; a trend which is consistent with the change in the values of the P—O stretching frequencies and force constants (21). However, his calculated bond orders decrease from 2.98 in F_3PO (essentially a triple bond) to 1.00 in $(CH_3)_3PO$ (a single bond), suggesting valence bond structures such as XI and XII.



XI XII

The P—O stretching frequencies or force constants in oxyphosphorus ions, for example, suggest longer P—O bond lengths than in $(CH_3)_3PO$, which is inconsistent with the conclusion that the latter contains a single P—O bond. The present correlations between the character of P—O bonds and their force constants and bond lengths are clearly more satisfactory than those of Wagner.

Very few previous estimates of the double bond character of Si—O bonds appear to be available (9). The present results lead to the conclusion that Si—O bonds in all oxysilicon compounds have a large amount of double bond character.

It is thus apparent that the bond lengths and stretching force constants of compounds containing Si—O, P—O, and Cl—O bonds can be very satisfactorily accounted for by assuming that there is a tendency for the valency shell of the central atom to contain 12 electrons, rather than 8, as the Lewis Octet Rule assumed. The $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals are fully utilized in forming π-bonds in all cases where there are no lone pairs of electrons on the central atom and the attached ligands have high electronegativities. The presence of lone pairs of electrons on the central atom tends to prevent maximum delocalization into the *d* orbitals presumably because they reduce the electronegativity of the central atom. In the case of, e.g., POF_3 and $F_2PO_2^-$, even the presence of highly electronegative fluorine atoms is insufficient to achieve maximum multiple bonding to oxygen, but the calculated bond orders of 2.22 and 1.84, respectively, indicate important contributions from the resonance structures $F_3\bar{P}\equiv\overset{+}{O}$ and $F_2\bar{P}\!\!<\!\!\begin{matrix}O\\O\end{matrix}$, respectively. In this paper no consideration will be given to the likely possibility of double bonding between lone pairs of electrons on fluorine atoms and *d* orbitals on phosphorus or chlorine.

It should be noted that, although the discussion of double bonding has been couched in the familiar language of atomic orbitals and valence bond resonance structures, so as to conform to current conventions, the fundamental idea involved is that there is space for six pairs of electrons in the valency shells of silicon, phosphorus, sulphur, and chlorine, if these electron pairs are used to bond to highly electronegative ligands. This is most clearly shown in molecules such as SiF_6^{2-}, PF_6^-, and SF_6, where there are six pairs of electrons in single bonds, but 12 electrons in the valency shell is also clearly possible in species such as SiO_4^{4-}, PO_4^{3-}, SO_4^{2-}, and ClO_4^-, and SO_2F_2 and $FClO_3$, etc., where some of the electrons are in multiple bonds. The same idea can also be used to account for the approximately 90° bond angles in molecules such as PH_3 and H_2S (22). The fundamental concept is that the number of localized orbitals that can be fitted around a central atom is a function of their shape and of the space available. In the case of Si, P, S, and Cl there appears to be sufficient space for six pairs of electrons in single bonds if they bond highly electronegative ligands, or the equivalent of six pairs, if some of them are in multiple bonds, in the case of ligands of somewhat smaller electronegativity. It is reasonable to regard the electron pairs in single bond orbitals as occupying less space, or a smaller solid angle, than a pair of electrons in a lone pair orbital (22, 23), since the bond pair is under the influence of two nuclei whereas the lone pair is influenced largely by only one nucleus. Presumably, also, two electron pairs in a double bond orbital occupy more space than a single bond orbital. In the case of oxygen compounds of phosphorus and sulphur it appears that a double bond orbital occupies about the same amount of space as a lone pair orbital, as can be seen by comparing the very similar bond angles in species such as PCl_3 and $POCl_3$, SO_2F_2 and SOF_2, and SO_2 and SO_3 (Table VII). Thus it is very reasonable from this point of view that various combinations of single bond, double bond, and lone pair orbitals around a second row element will occupy *all* the space available.

SOLVENT EFFECTS ON THE PROTON RESONANCE SPECTRA OF THE DICHLORO- AND DIBROMO-ETHYLENES

REACTION FIELD EFFECTS IN ALIPHATIC SOLVENTS AND SPECIFIC INTERACTIONS IN AROMATIC SOLVENTS[1]

F. HRUSKA,[2] E. BOCK, AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received July 12, 1963

ABSTRACT

The proton resonance shifts relative to internal cyclohexane and tetramethylsilane of *cis* and *trans* dichloro- and dibromo-ethylenes were measured in dioxane–water solutions, aliphatic solvents, and aromatic solvents. The dielectric constants of the dioxane–water solutions could be smoothly varied between 2 and 10 and, by taking Δ = *cis*−*trans* shifts as containing only the dipolar reaction field effect, the data for these solutions were treated as a test of the Buckingham reaction field equation. Linear plots were obtained and reasonable values of the coefficients of the E term confirmed the usefulness of this equation. An equation based on a nonspherical cavity was also used. It was also shown that quadrupolar reaction fields affected the proton shifts. Sizeable deviations from the dioxane–water standards were found for halogenated aliphatic solvents and those containing double or triple bonds. These deviations are interpreted in terms of the shape of the solute molecules and dispersion and anisotropic interactions. The much larger deviations found for aromatic solvents are harder to rationalize but specific interactions were found for both *cis* and *trans* forms, indicating an inadequacy in a simple dipole-induced dipole model.

INTRODUCTION

The effect of the medium on the proton shift may involve magnetic and electrical interactions. The former include bulk susceptibility effects which will not be considered further because in this study we use internal references. Magnetic anisotropy effects are well known, especially for disc-like and rod-like molecules (1). The former usually cause a shift to high field of the solute molecule while the latter give rise to a low-field shift (1).

Electrical interactions are often attributed to orientation effects between permanent dipoles or between permanent and induced dipoles and to interactions arising from dispersion effects (2). These effects tend to expand the electron cloud about a resonating nucleus, thereby decreasing the diamagnetic shielding; they also reduce the symmetry of the electronic environment of the nucleus which reduces the shielding too (1). Shifts due to dispersion interactions are often smaller than those produced by dipolar interactions.

1. Dipolar Effects

The electric dipole of a solute molecule polarizes the surrounding medium. This polarization results in a secondary electric field, the reaction field, at the dipole. It, in turn, polarizes the solute dipole to an extent depending on the polarizability of the solute molecule. In the Onsager treatment (3) the solute molecule is represented by a point dipole at the center of a spherical cavity of radius r in a continuous medium with uniform dielectric constant. The reaction field R is then (3)

$$R = \frac{2(\epsilon-1)(n^2-1)}{3(2\epsilon+n^2)}\frac{\mu}{\alpha} \qquad [1]$$

where n is the refractive index of the solute for sodium D light, μ is the permanent dipole moment of the solute molecule and α is its polarizability, taken as $(n^2-1)r^3/(n^2+2)$.

[1]*Presented in part at the C.I.C. Symposium on Solvation Phenomena at Calgary, Alberta, in August, 1963.*
[2]*Holder of an N.R.C. bursary 1962–63.*

In the treatment of Marshall and Pople (4) the reduction in shielding of a proton in a hydrogen atom is proportional to the square of the applied electric field E. The dependence on E^2 is reasonable for symmetry reasons. A field along an X—H bond will either increase or decrease the electron density at the proton depending on the direction of E. Shifts proportional to E are then expected. A field perpendicular to the X—H bond destroys the axial symmetry of the bond and results in low-field shifts proportional to E^2.

Buckingham's treatment (3) gives a calculated contribution to the shielding of a proton in an X—H bond of

$$\sigma_E = -\chi\times10^{-12}E\cos\theta-10^{-18}E^2, \qquad [2]$$

where θ is the angle between the X—H axis and E and χ are a constant. He suggests a value of $\chi = 2$ while Musher (5) lists values of $\chi = 2$ to 3.4 obtained by several methods. Equations [1] and [2] yield a contribution to the shielding of the X—H proton due to the reaction field R of

$$\sigma_R = -\chi\times10^{-12}\frac{2}{3}\frac{(\epsilon-1)(n^2-1)}{2\epsilon+n^2}\frac{\mu}{\alpha}\cos\theta. \qquad [3]$$

The E^2 term has been neglected since even for the nitrobenzene molecule, as an extreme example, the reaction field in the pure liquid is 0.14×10^6 e.s.u./cm and the E^2 term is then only 8% of the linear term.

Equation [3] predicts a linear variation of the proton shielding as a function of $(\epsilon-1)/(2\epsilon+n^2)$ with a slope of $-2/3\ \chi(n^2-1)\mu\cos\theta\times10^{-12}/\alpha$. Buckingham *et al.* (1) measured the proton shift of CH_3CN in a variety of solvents. The experimental points lay on or near the line of theoretical slope. The scatter was attributed to inaccuracies in bulk susceptibility corrections and to dispersion effects.

Diehl and Freeman (6) utilized a model based on an ellipsoidal cavity and wrote

$$\sigma_R = -\chi\times10^{-12}\frac{3\mu}{abc}\cos\theta\xi_a[1+(n^2-1)\xi_a]\frac{\epsilon-1}{\epsilon+\beta} \qquad [4]$$

where $\beta = n^2\xi_a/(1-\xi_a)$, a, b, c, are the axes of the ellipsoid, and ξ_a is a shape factor. Ross and Sack (7) have evaluated ξ_a for cavities of various shapes. The observed shifts of CH_3CN and paraldehyde yielded values for χ of 3.4 and 3.0, respectively. The spherical cavity model required 1.9 and 7.1, respectively. These results appear encouraging but it is difficult to see why the simple Onsager model could be improved in this way.

2. Quadrupolar Effects

In the presence of two equal and opposed bond dipoles a quadrupolar reaction field may arise. The reaction field gradient of a quadrupolar moment, R^1, is given by (8)

$$R^1 = [6(\epsilon-1)/(3\epsilon+2)]r^{-5}\Phi \qquad [5]$$

where the symbols have been defined above except for Φ, which is the molecular quadrupole moment. For a molecule with two opposed dipoles of moment μ separated by a distance d we have $\Phi = 2\mu d$. The magnitude of r^{-5} is readily obtained if the assumption is made that the molecule is spherical and completely fills the cavity.

3. The Present Measurements

The difficulty in obtaining the reaction field shift lies in the correction necessary for the other factors contributing to the total shift. For our study of polar interactions *cis* and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

trans dichloro- and dibromoethylene* were chosen. All four have single peak proton spectra. The two *cis* forms are dipolar and experience a reaction field. The *trans* forms are nonpolar and a change in ϵ of the medium is not expected to alter the proton shift in the first instance (higher order polar interactions may, however, be present). The shapes of the corresponding *cis* and *trans* forms are very similar and we anticipate the magnetic and dispersion interactions with any one medium to be nearly the same. Then subtraction of the chemical shift of the *trans* from *cis* form isolates the contribution of the reaction field to the total proton shift of the *cis* form. On the other hand, intermolecular dispersion shifts and nonspecific interactions with magnetically anisotropic solvent molecules may well be accounted for by using, as we did, a nonpolar internal reference.

EXPERIMENTAL

Chemical shift measurements were made on 5% solutions in a series of dioxane–water solutions with dielectric constants ranging from about 2 to 10 (see Table III), and also in a variety of aliphatic and aromatic solvents. A Varian DP-60 spectrometer was employed using cyclohexane and tetramethylsilane as internal references. The shift values are estimated to be accurate to at least 0.2 c.p.s. and normally to 0.1 c.p.s.

RESULTS AND DISCUSSION

In Table I the measured shifts of the four compounds in about 40 solvents are given. Also included are the differences Δ = *cis*−*trans* for each pair. In Table II the relevant physical constants are given. In Table III the dielectric functions for the various 5% solutions are presented. Note that these functions were calculated taking the *amount and dielectric constant of the solute and reference into consideration*, assuming an additivity law. In Fig. 1 the Δ values from Table I are plotted against the dielectric functions A and B from Table III.

1. Dioxane–Water Solutions

Since the dielectric constants of these solutions could be varied smoothly between about 2 and 10, and since the weight per cent of water only changed from 0 to 15 in this range, we propose to treat their Δ values as a test of the reaction field model. A least squares treatment of the points 6 and 32 to 38 in Fig. 1 yielded values of χ = 1.3 and 1.6 for Cl and Br, respectively, on substitution of appropriate values from Table II into Equation [3]. We take this as a confirmation of Buckingham's model, although an ideal model would have the same value of χ for Cl and Br. In view of the many unavoidable approximations in the molecular parameters the agreement is perhaps satisfactory.

The shifts from internal cyclohexane for the two *cis* forms were also plotted vs. the dielectric functions A and B. The graphs were accurately linear and yielded χ = 1.9 and 3.0 for *cis* Cl and *cis* Br, respectively. From the smaller slopes for the Δ plots above it follows that the *trans* forms also show a negative slope. Such plots were constructed and on the basis of a quadrupolar effect using Equation 5, trigonometric evaluation of the C—Cl and C—Br bond dipole moments and estimation of the r^{-5} factor from the molecular volume yielded χ = 1.3 for *trans* Cl and χ = 2.2 for *trans* Br. It appears that quadrupole effects are indeed present and can be estimated in this way.

We assume that subtraction of the *trans* from the *cis* shifts corrects for most of the quadrupolar reaction field shifts of the *cis* forms. The quadrupole moments of the *cis* forms are hard to evaluate but are estimated to be slightly smaller than those of the *trans* forms. We are, of course, also assuming that any small changes in dispersion shifts, as the composition of dioxane–water solutions varies, will be the same for the solute and internal reference.

**Hereafter to be called cis* Cl, *trans* Br *etc.*

An attempt at an improvement in the consistency of the experimental χ values can be based on Equation [4] using an ellipsoidal cavity. Plots of Δ vs. the dielectric functions C and D of Table III are straight lines with slopes of −6.3 c.p.s. for Cl and −4.2 c.p.s. for Br. These shape-corrected slopes yield $\chi = 0.6$ and 0.7, respectively. Whether this consistency indeed argues for small values of χ for the C—H bond is questionable, however.

2. Aliphatic Solvents

(a) The Chloroethylenes

From Fig. 1*a* it is clear that the line through the dioxane–water points also passes through the points for the hydrocarbons (points 1 to 4). Sizeable deviations of up to 2.5 c.p.s. do occur for some of the halogenated solvents and those containing double or triple bonds, e.g., points 5, 8, 12, 14, 15, 16, and 18. Most of these deviations are to negative values of Δ, indicating an excess low-field shift for *cis* Cl. This might be expected on the basis of a stronger van der Waals or anisotropy interaction at the C—H bond for *cis* Cl and this appears reasonable on the basis of the structures of the two forms.

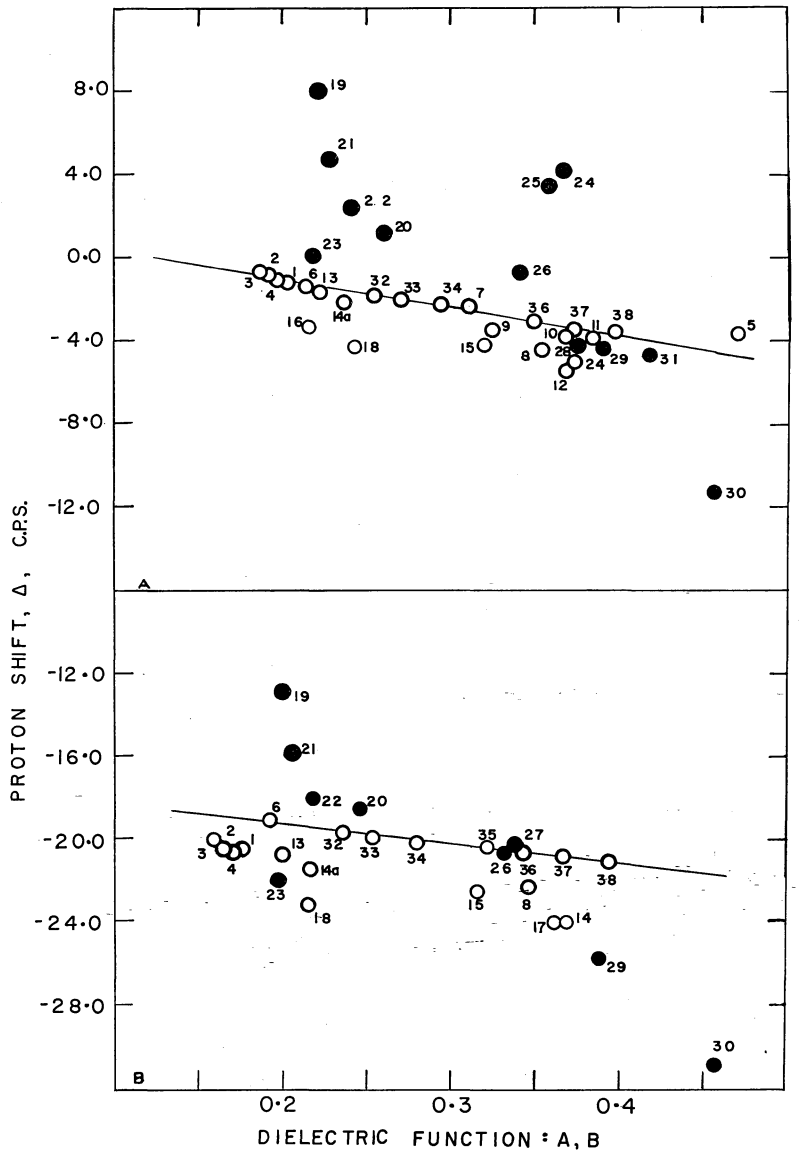

FIG. 1. Δ values from Table I are plotted against the dielectric functions *A* and *B* from Table III for dichloroethylene in *a* and for dibromoethylene in *b*. Open circles indicate dioxane–water solutions (points 6, 32–38) and aliphatic solvents. Solid circles indicate aromatic solvents.

(b) The Bromoethylenes

Here, in Fig. 1*b* the points for the hydrocarbons fall below the Δ line, which is disturbing, and the excess shifts to low field for the *cis* form are also larger for the halogenated solvents and those containing double bonds. These larger excess shifts are understandable on the basis of the somewhat larger size of the bromine atoms. This leads to increased hindrance to approach of the solvent molecule to the *trans* form. We have, however, no explanation for the 1 c.p.s. deviations to low field for the hydrocarbon solvents points 1 to 4.

For personal use only.

3. Aromatic Solvents

It is immediately clear from the solid points in Fig. 1*a* that the Δ values for the aromatic solvents contain large effects other than the reaction field effects. Thus Δ is positive for benzene (point 19) while a reaction field would, of course, shift *cis* Cl to low field of *trans* Cl. The points for *o*-dibromobenzene, phenyl isocyanate, and pyridine, however, appear almost normal for Cl. Only for benzonitrile is Δ large and negative (point 30) for both Cl and Br.

(a) Benzene Solutions

In Table IV the shifts of the four compounds are given relative to their shifts in

TABLE IV

The proton shifts in c.p.s. at 60 Mc.p.s. of the haloethylenes in aromatic solvents relative to their shifts in cyclohexane. Positive values indicate shifts to high field

Solvent	*cis* Cl	*trans* Cl	*cis* Br	*trans* Br
Benzene	38.4	29.3	38.5	30.8
Toluene	37.2	31.5	38.0	33.4
o-Xylene	36.5	32.9	39.5	37.0

Pyridine	−31.5	−27.9		
Benzonitrile	−20.2	−10.1	−17.3	−8.0

cyclohexane. The excess shifts are 0.5–0.6 p.p.m. to high field in benzene. They are less for the *trans* than for the *cis* compounds but about the same for Br and Cl.

The work of Schneider (9) is of particular interest in this regard. His measurements indicate a specific interaction of vinyl-X compounds with benzene. The two molecular planes are thought to assume a parallel orientation, with the polar group off the ring. The proton *trans* to the group X is then expected to have the largest shift to high field, as is the case (9). If we think of this as indicating that the benzene avoids electron-rich or bulky groups (10) the smallest high-field shift would be expected for the bromide. This is roughly borne out by the results (9).

Specific interactions are no doubt also present in our aromatic solutions. However, the unmodified dipole – induced dipole model used by Schneider for the alkyl-X and vinyl-X shifts in benzene is not quite compatible with our measurements for the *trans* forms. Also since μ/v, where v is the molecular volume, is less for *cis* Br than for *cis* Cl this should result in a lower excess shift for the former, contrary to the data in Table IV.

A quadrupole – induced quadrupole model will cause excess high-field shifts for the *trans* forms but it is then difficult to see why *trans* Br should have a higher shift than *trans* Cl and, indeed, why the *trans* shifts are almost as large (in one case larger) as the *cis* shifts.

As mentioned by Schneider, experiments with aromatic solutes and aromatic solvents indicate extensive polarizations of the interacting molecules. If we extend this idea to our solutes we note that the polarizability of the bromo compounds is considerably larger (by about 50%) than that of the chloro compounds. We therefore postulate extensive mutual polarization by dispersion interactions of the haloethylene and benzene. A simple

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

van der Waals interaction leads to low-field shifts (1) but in this case it is also assumed to lead to a parallel orientation of the solute and solvent molecules. It appears that the large anisotropy of the benzene thus leads to a net high-field shift. Since the van der Waals radii of the Cl and Br are not very different (1.81 and 1.95 Å) the larger polarizability of Br appears to compensate for its larger size and we find comparable excess shifts for the Cl and Br in benzene.

On the other hand, a simpler but related picture in which the larger bromine atoms force the benzene molecules to sit closer to the protons, on an average, might also appear reasonable. Whether, in that case the shift of *trans* Cl may be expected to be larger than the *trans* Br shift in the bulkier solvent molecule, mesitylene, is not clear.

(b) Ethynylbenzene and Benzonitrile Solutions

For ethynylbenzene a similar excess shift is expected since its dielectric constant is only a little larger than that of benzene and its methyl homologues. There is a decrease of from 20–30 c.p.s., however, in the excess shift for both *cis* and *trans* forms. A rationalization assumes a model in which the triple bond is close to the protons, causing a low-field shift by virtue of its cylindrical magnetic anisotropy. The proper orientation may be brought about in an admittedly obscure way by dispersion interactions or, perhaps, by hydrogen bonding of the polar C—H bonds to the triple bond (11, 12).

A somewhat similar effect is then predicted for benzonitrile solutions and, after correction for the triple bond shift using the ethynylbenzene shifts as a reference, we obtain $\Delta = -4.4$ c.p.s. for Cl and $\Delta = -24.1$ c.p.s. for Br. The points 30 are then brought into much closer agreement with the reaction field lines in Fig. 1, the discrepancy being about zero for Cl and about 4 c.p.s. for Br.

(c) Other Aromatic Solvents

The Δ values of Cl for aniline and toluidine also show positive deviations comparable in size to those for the benzenes. Presumably a similar interaction is present. The chloro- and bromo-benzene points fall much closer to the reaction field lines in Fig. 1, as does the point for pyridine. Why this should be so we hesitate to speculate further. From the discussion in this section it is clear, however, that while reaction fields no doubt play their part, there are equally important specific interactions whose magnitude is not predictable a priori. It may well be that each case will have to be individually studied using temperature and concentration techniques.

EFFECT OF NON-ZERO EXTINCTION COEFFICIENT ON ABSTRACTION–RECOMBINATION RATE RATIOS IN PHOTOCHEMICAL SYSTEMS[1]

Received April 22, 1963

ABSTRACT

The data of Marjury and Steacie on the photolysis of acetone and acetone-d_6 in the presence of H_2 and D_2 respectively have been re-analyzed in terms of the integrated rate equations. It is concluded that only part of the discrepancy between the results for the methyl and hydrogen reaction can be accounted for in this way.

In an appendix, it is shown that for high extinction coefficients, the integrated rate expression reaches a limit which may sometimes be attainable experimentally without undue complication from diffusion effects.

The results of Marjury and Steacie (1) for the reaction of CH_3 and CD_3 with H_2 and D_2, and of Whittle and Steacie (2) for the reaction of CH_3 and CD_3 with HD are shown in Table I. There is a pattern about these results in that activation energies obtained by what Steacie and co-workers call "method I" are consistently about 0.7 kcal below those obtained by "method II". In "method I" the methane formed in the reaction under consideration is deduced from the difference between the total methane obtained and an

TABLE I

$H\underline{\underline{D}}$	CH_3		11.3	II	11.3

estimate of the methane produced by abstraction from the radical source. In "method II" the methane formed in the particular reaction has an isotopic constitution different to any of the other methanes produced, and is determined directly mass-spectrometrically.

In the final column in Table I, we have added 0.7 kcal to all the "method I" results. Assuming no isotope effect in the attacking radical, this suggests that there may be some

[1]*Paper presented at the International Symposium on Photochemistry held at the University of Rochester, March 27–29, 1963.*

flaw in the method of correcting for the methane produced by radical attack on the photolytic source.[2]

A similar pattern can be found amongst the abstraction reactions of methyl radicals with other substrates. The data are collected in Table II, and again indicate that a

[a]The figures quoted for these reactions are based on the data compiled in ref. 4, but recalculated on the basis of an activation energy of 11.3 kcal for $CD_3 + CD_3COCD_3 \rightarrow CD_4 + CD_2COCD_3$ used by Gordon and Smith (6).

systematic error of about 1 kcal low occurs whenever correction has to be made to the CH_4 formed due to abstraction from the radical source. (Di-*t*-butyl-peroxide (D.T.B.P.) is regarded as a "method II" source since it is very resistant to methyl radical attack.) It is also significant that no such variation occurs in the values of activation energies for abstraction by CF_3 radicals using different sources (3). In this paper, we confine our attention to the results of Marjury and Steacie since they appear to be a good example of this discrepancy.

An obvious source of possible error is that the experimental data are always reduced according to the local rate equations instead of the correct integrated form of these equations. In the case of the abstraction–recombination system, the integration can be performed analytically for the steady state in the absence of diffusion, as was shown by

[2]*Marjury and Steacie also observed, in agreement with this postulate, that their results obtained by "method II", when calculated by "method I", tended to yield lower values for the activation energy. Whittle and Steacie observed the same behavior for the* $CH_3 + D_2$ *and* $CD_3 + H_2$ *reactions; these results are not included in Table I. The value obtained for* $CH_3 + D_2$ *by Marjury and by Whittle are in exact agreement; however, Whittle obtained a value of 11.1 kcal for* $CD_3 + H_2$, *calculated by "method II".*

Cvetanović and Whittle (7). Using the photolysis of a ketone as an example, we have

$$X_2CO + h\nu \rightarrow 2X + CO$$

$$X + X_2CO \xrightarrow{k_3} XH + \text{etc.}$$

$$X + X \xrightarrow{k_2} X_2$$

$$X + RH \xrightarrow{k_1} XH + R \text{ etc.},$$

where locally,

$$R_{XH}/R_{X_2}^{\frac{1}{2}} = (k_3[X_2CO]+k_1[RH])/k_2^{\frac{1}{2}}. \qquad [1]$$

If we put $u = (k_3[X_2CO]+k_1[RH])^2$, $v = 8k_2m\phi I_0$, and $w = 2.3\epsilon c$ ($c \equiv [X_2CO]$) we have, per unit volume, etc.,

$$R_{XH} = \frac{B\sqrt{u}}{4k_2wL} \quad \text{and} \quad R_{X_2} = \frac{vw(1-e^{-wL})-2B\sqrt{u}}{16k_2wL}$$

where

$$B = 2\sqrt{u+vw} - 2\sqrt{u+vwe^{-wL}} - 2\sqrt{u}\ln\frac{(\sqrt{u+vw}+\sqrt{u})}{(\sqrt{u+vwe^{-wL}}+\sqrt{u})}$$

and m, ϕ, ϵ, and I_0 have their usual meanings. Equation [1] therefore becomes

$$\delta\cdot\frac{R_{XH}}{R_{X_2}^{\frac{1}{2}}} = (k_3[X_2CO]+k_1[RH])/k_2^{\frac{1}{2}}, \qquad [2]$$

where $\delta = L^{\frac{1}{2}}\left(\int_0^L [X]_l^2 dl\right)^{\frac{1}{2}} \Big/ \int_0^L [X]_l dl = L^{\frac{1}{2}}w^{\frac{1}{2}}[vw(1-e^{-wL})-2B\sqrt{u}]^{\frac{1}{2}}/B$;

putting $\beta = wL$ and $s = vw/u$ gives the expression quoted in reference 7.

If we photolyze acetone (Ac) on its own, the correct form of equation [1] is

$$\frac{k_3}{k_2^{\frac{1}{2}}} = \frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[Ac]}\cdot\frac{L^{\frac{1}{2}}w^{\frac{1}{2}}[vw(1-e^{-wL})-2B\sqrt{u}]^{\frac{1}{2}}}{B} \qquad [3]$$

where $u = (k_3[Ac])^2$. We can find k_3 by trial and error. In the presence of RH we have

$$\frac{k_1}{k_2^{\frac{1}{2}}} = \frac{R_{CH_4}}{R_{C_2H_6}^{\frac{1}{2}}[RH]}\cdot\frac{L^{\frac{1}{2}}w^{\frac{1}{2}}[vw(1-e^{-wL})-2B'\sqrt{u'}]^{\frac{1}{2}}}{B'} - \frac{k_3[Ac]}{k_2^{\frac{1}{2}}[RH]}, \qquad [3']$$

where $u' = (k_3[Ac]+k_1[RH])^2$, and if k_3 is already known, k_1 can now be found by trial and error. Note that the dependence of k_1 on ϵ is slightly different from the dependence of k_3 on ϵ.

In applying these equations to the data of Marjury and Steacie, some assumptions have to be made since the intensity distribution of the mercury lamp used is not known. Also, the extinction coefficient of acetone increases with temperature and decreases with pressure between room temperature and 150° C (see Table III and ref. 8). It was therefore necessary to assume a reasonable value for the average light intensity ($\bar{I}_0$), and derive the mean extinction coefficient ($\bar{\epsilon}$) of acetone for each run from the yield of CO, on the assumption of unit quantum yield for all temperatures. It was also necessary to assume that this light intensity remained constant throughout the series of experiments, and that raising the furnace temperature did not indirectly increase $\bar{I}_0$ by causing the lamp to

NOTE: $\bar{\epsilon}$ is in liter mole^{-1}cm^{-1} units, $\bar{I}_0$ in quanta/cm^2 sec. $A_3/A_2^{\frac{1}{2}}$ and $k_3/k_2^{\frac{1}{2}}$ in cc$^{\frac{1}{2}}$ molecule$^{-\frac{1}{2}}$ sec$^{-\frac{1}{2}}$ except that all k values are multiplied by 10^{13}.

The two runs marked * were carried out with a filter which transmitted 27% of the incident light at 2537 Å. If this value for $\bar{I}_0$ is used, the mean extinction coefficients are considerably out of line, and can only be reconciled with the other values by choosing a mean transmission of 18.5%; this indicates that much of the photolysis is brought about by radiation, other than at 2537 Å, as was assumed by Marjury and Steacie.

Some of the uncorrected values for the rate constants are not the same as those given by Marjury and Steacie; this is because their rate constants do not always agree with the rates of formation of methane and ethane which they quote.

increase the rate constants slightly, particularly in those runs with high acetone concentration. It is seen that the mean extinction coefficient calculated from the CO yield rises with temperature, and this tends to make the correction factor δ larger at higher temperatures. Thus, the overall effect is to raise both the activation energy and frequency factor somewhat over the uncorrected values. It is this variation of ϵ with T that is more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

important than just the simple correction of the rate constants[3] for light absorption since, as shown in the Appendix, δ is fairly insensitive to everything except ϵ and the acetone concentration.

With these rate constants k_3 for acetone and acetone-d_6, it is now possible to apply equation [3′] to the reactions of CH_3 with H_2 and CD_3 with D_2, as is done in Table V. It is

NOTE: Units as in Table IV.

seen that the δ-correction leads to an activation energy which, at most, is only 0.2 kcal greater than the uncorrected value. It is worth noting, however, that when $k_1 \approx k_3$, as is the case here, a rise of 0.1 kcal in E_3 causes a fall of ~0.4 kcal in E_1, and it seems likely that the discrepancies in Table I can largely be accounted for by the δ-correction *and* the sharp dependence of E_1 on small errors in E_3; it is indicative that Whittle's results (2) did not always agree with those of Marjury (1) in those cases where the investigations overlapped. Similar considerations must apply to Table II.

APPENDIX

The behavior of the function δ was investigated for a series of typical reaction mixtures. A basic reaction was considered in which

$$L = 10 \text{ cm}; I_0 = 10^{15} \text{ quanta/cm}^2 \text{ sec}; m\phi = 2;$$

$$k_3[X_2CO]/k_2^{\frac{1}{2}} = k_1[RH]/k_2^{\frac{1}{2}} = 10^6 \text{ molecules}^{\frac{1}{2}} \text{ cc}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}$$

(i.e. equivalent to $k_3/k_2^{\frac{1}{2}} = k_1/k_2^{\frac{1}{2}} = 10^{-12} \text{ cc}^{\frac{1}{2}} \text{ molecule}^{-\frac{1}{2}} \text{ sec}^{-\frac{1}{2}}$ and

$$[X_2CO] = [RH] = 10^{18} \text{ molecules/cc});$$

$$k_2 = 3.63\times10^{-11} \text{ cc molecule}^{-1} \text{ sec}^{-1}$$

and the correction factor δ was calculated as a function of extinction coefficient.

[3]*J. Caldwell and D. E. Hoare, J. Am. Chem. Soc.* **84**, *3987 (1962), have suggested that the rise in* CO *yield with temperature is not solely due to a rise in* $\bar{\epsilon}$*; in this case, our calculations will exaggerate the error involved in ignoring the* δ*-correction. (The same comment applies to our assumption that* $\bar{I}_0$ *does not increase with* T.)

For personal use only.

The following variations were also tested:

L and I_0 by a factor of 10 each way;

k_2 reduced by a factor of 10^4, keeping $k_3/k_2^{\frac{1}{2}}$ and $k_1/k_2^{\frac{1}{2}}$ fixed, also keeping k_1 and k_3 fixed;

$k_3[X_2CO]/k_1[RH]$ from 0 to ∞, the two extremes corresponding to zero attack on the source [e.g. with CF_3COCF_3] and the absence of RH respectively.

With the exception of the length L of the reaction vessel, the correction δ was virtually independent of all these variations, and the results are shown in Fig. 1 (cf. also Fig. 3 of reference 7, which shows the bottom 2% of these curves on a highly magnified scale). ϵ and c are complementary quantities; ϵ and L are complementary to an acceptable degree of accuracy.

Placing a mirror at the end of the reaction vessel to reflect the light has little effect and, for all practical purposes, the curves with and without the mirror are indistinguishable. The dotted curves in Fig. 1 represent the improvement gained by having two light sources of equal intensity, one at either end of the reaction vessel. The integration of the steady state equations for these two cases was performed numerically.

It would be logical experimentally to make use of the fact that δ tends to a limit of 10.95 (7.75 for two light sources) at very high ϵcL values. Two examples may be cited: (i) the use of a very long vessel would keep δ constant even though the source was being consumed; (ii) in the photolysis of mercury diphenyl (9), one of the products is diphenyl, whose extinction coefficient is even higher by a factor of 10; if L were such that δ already had its limiting value, the accumulation of this strongly absorbing product could not affect the results, provided that its concentration was not allowed to become so large as to cause diffusion problems.

There are two diffusion effects. One is diffusion to the walls, which has been discussed by Hill (10), and the other is diffusion along the concentration gradient. To include these effects one would need to solve an equation of the kind

$$\mathscr{D}(\partial^2[X]_l/(\partial l^2) + m\phi I_0(2.3\,\epsilon c)e^{-2.3\epsilon c l} - (k_3[X_2CO] + k_1[RH])[X]_l - k_2[X]_l^2 = 0,$$

where $\mathscr{D}$ is the diffusion coefficient for the radicals in the reaction mixture; Hill has considered the solution of this equation in the absence of the exponential factor.

It is not likely that the diffusion coefficient $\mathscr{D}$ for any radical will exceed 5 cm^2/sec for any normal reaction mixture: this can be seen by assuming reasonable values for the Lennard-Jones potential between a methyl radical (taken to be like methane) and acetone, and evaluating equation 8.2–44 of Hirschfelder, Curtiss, and Bird (11). The term $\partial^2[X]_l/\partial l^2$ was obtained for our series of model reactions by calculating the radical concentration distributions, as shown in Fig. 2, and differentiating numerically (for simplicity, k_3 was assumed to be zero). Table VI compares, for representative positions in the vessel, the rate of photochemical production of radicals with the net increase in concentration due to diffusion, both in units of molecules/cc sec in the vicinity of the representative point. Clearly longitudinal diffusion has quite an unimportant effect on δ in normal reaction mixtures until ϵ exceeds 1000 liter $mole^{-1}$ cm^{-1} (note that ϵ and c are no longer complementary quantities since $\mathscr{D}$ is concentration-dependent). At the same time, Hill's data show that for $\epsilon > 1000$ liter $mole^{-1}$ cm^{-1}, the diffusion path of the radicals is of the order of 0.1 cm, and Fig. 2 shows that further complications must arise if there is significant removal at the wall.

THE PREPARATION OF SOME THIOSEMICARBAZONES CONTAINING THE *s*-TRIAZINE RING[1]

B. A. GINGRAS, T. SUPRUNCHUK, AND C. H. BAYLEY
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received July 23, 1963

ABSTRACT

The reaction between cyanuric chloride and aliphatic thiosemicarbazones results in the formation of 1:1 adducts containing a dichloro-*s*-triazine ring. Chemical evidence, infrared spectroscopy, and microbiological studies indicate that the addition of the triazine ring takes place at the N^2 atom of thiosemicarbazones. Since cyanuric chloride failed to react similarly with aromatic thiosemicarbazones, a different type of condensation product was obtained by another method, in which cyanuric chloride was first condensed with *o*-, or *p*-hydroxybenzaldehyde to give 1:3 adducts containing free carbonyl groups. Reaction of these compounds with thiosemicarbazide gave the corresponding tri-thiosemicarbazones.

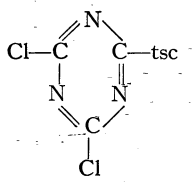
Continuing our work on thiosemicarbazones (tscs) as possible fungistatic agents (1), it became interesting to study the reaction of these compounds with cyanuric chloride for the following reasons: firstly, a number of cyanuric chloride derivatives have been described in which addition of the cyanuric chloride molecule enhances the antifungal activity of the original compounds (2–5); secondly, the *s*-triazines thus formed usually contain one or two chlorine atoms which can be used for further condensation reactions. Since it has been reported earlier (1) that aliphatic tscs with chain lengths ranging from C_7 to C_{12} were the most active fungistatic agents in this class, this particular series was used in the present study. Under the various experimental conditions used, it was found that only one chlorine atom was replaced so that the products, in all cases, were substituted 4,6-dichloro-1,3,5-triazines of the general formula (I).



(I)

The products are listed in Table I together with their melting points and analyses.

Thiosemicarbazones (II) are bifunctional compounds containing a thioamide and a thiocarbohydrazide residue, and it was of interest to find out the site of reaction with cyanuric chloride, hence which hydrogen atom was being replaced.

$$RR^1C{=}N^1{-}N^2H{-}C^3S{-}N^4H_2$$

(II)

Since the $-NH_2$ group is known to react easily with cyanuric chloride (6), the possibility of this group being the reactive site in tscs was the first one to be considered. It was found, however, that this was not the case and that tscs reacted with cyanuric chloride even when the terminal $-NH_2$ was replaced by $-NMe_2$; thus, *n*-undecanal-4,4-dimethyl tsc reacted normally with cyanuric chloride to give the 1:1 condensation product. The

infrared spectrum of this product had no —N—H band indicating that the N^2 hydrogen atom had been substituted. It was also found that, with the terminal $—NH_2$ present but replacing the N^2 hydrogen atom by Me, the resulting 2-methyl tscs failed to react with cyanuric chloride. This shows the importance of the N^2 hydrogen atom and this is in complete agreement with earlier findings that 2-methyl tscs are quite stable, do not dissolve in alkali, and do not form complexes with copper (7, 8). There remains the possibility of reaction at the sulphur atom since tscs may undergo the following tautomeric change:

$$=N—NH—CS—NH_2 \rightleftharpoons =N—N=CSH—NH_2.$$

It is difficult to discriminate between addition of the triazine ring at the N^2 or at the sulphur atoms, since in both cases the hydrogen atom at the N^2 position would be involved. Of course, replacement of this hydrogen atom by a methyl group prevents the tautomerism and the possibility of reaction at either N^2 or S. Two reactions were carried out using the S-sodium salt of acetone tsc and the corresponding S-benzyl derivative with cyanuric chloride, but no condensation products were formed. It should be pointed out that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

S-substituted derivatives also lacked the N^2 hydrogen atom. In spite of this difficulty, however, it is felt that the addition probably takes place at the N^2 atom, since the tautomerism discussed above is not likely to take place in acetone or dioxane solution in which these reactions were carried out. It was shown that the thione form was the only existing species in the solid state (9) and that the thiol form would be predominant in alkaline solution. Furthermore, infrared spectroscopy provides evidence in favor of the reaction at N^2. The C=S vibration in tscs has been shown to be in the 1080–1130 cm^{-1} region (7) and the spectra of tsc – cyanuric chloride adducts show this band, although it is shifted to higher frequencies by 4 to 20 cm^{-1}. Table II shows this particular region of the spectrum for some compounds.

TABLE II

C=S absorption bands (cm^{-1}) for tscs and their corresponding *s*-triazine derivatives

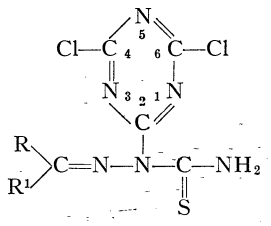
The probable structure for the condensation products is thus as follows:



(III)

A second chlorine atom can be substituted on heating (III) with methanol in the presence of sodium bicarbonate. Thus, 2-(*n*-decanal-tsc)-4,6-dichloro-1,3,5-triazine gave the corresponding monomethoxy derivative. The third chlorine atom was not replaced.

We failed to obtain 1:1 adducts between cyanuric chloride and benzaldehyde or the chlorobenzaldehyde tscs. However, aromatic tscs with a primary amino group on the ring gave compounds in which the triazine group is added onto the amino group. Thus, *m*-aminoacetophenone tsc afforded the corresponding substituted 2-amino-4,6-dichloro-1,3,5-triazine (IV). Similar reactions were carried out with the three isomeric hydroxybenzaldehyde tscs but without success. However, an indirect route led to triazine derivatives containing the hydroxybenzaldehydes which gave the corresponding tscs upon further reaction with thiosemicarbazide. The trisubstituted triazines (V*a*, V*b*, V*c*) were described by Allan (10) who obtained them from cyanuric chloride and *o*-, *m*-, and *p*-hydroxybenzaldehyde. The corresponding tri-tscs (V*f*, V*g*) were obtained by the usual method in fair yields (11). The reaction with the *m*-isomer (V*b*) gave a product which could not be purified satisfactorily.

5-Bromo- and 5-chlorosalicylaldehyde were found to be somewhat less reactive and 2:1 adducts containing one chlorine atom were obtained (V*d* and V*e*). Thiosemicarbazones have not as yet been obtained from these last two derivatives.

The fungistatic activities of all compounds described in this work were examined against two organisms and by two methods previously described (1). It was found that the triazines were generally less active than the original tscs so that addition of the cyanuric chloride ring did not enhance the fungistatic activities in this case. This is an interesting finding in itself since it supports the theory that the reaction between cyanuric chloride and tscs takes place at the N^2 atom of the latter. Indeed, it has been shown in this laboratory (12) that the N^2 hydrogen atom must be present for the tscs to have any fungistatic activity. This is related to the fact that N^2-substituted tscs do not form complexes with metals. This phase of the work is being examined further and will form the subject of a separate publication.

EXPERIMENTAL

Thiosemicarbazones and their derivatives not described in the following preparations were reported earlier (7, 11). Reactions between five 2-methyl tscs (from octanal to undecanal), and two *s*-substituted acetone tscs with cyanuric chloride were attempted but are not reported since no tractable products could be obtained. Cyanuric chloride was from commercial sources and was used without further purification. Melting points were taken on a Fisher-John apparatus and are corrected. Infrared spectra are from KBr pellets.

General Procedure for the Preparation of 2-(n-Alkyl tsc)-4,6-dichloro-1,3,5-triazines (III)

A solution of tsc (0.02 mole) in acetone (40 ml) was added slowly to a solution of cyanuric chloride (0.02 mole) in acetone (300 ml). After stirring for 15 minutes, a saturated aqueous solution of sodium bicarbonate was added to bring the pH to 7. The precipitated material was separated by filtration, freed from inorganic salts by washing with water, and after drying, was crystallized from benzene – *n*-hexane. The product was recrystallized from cyclohexane. The various compounds obtained are listed in Table I.

2-(n-Decanal tsc)-4-methoxy-6-chloro-1,3,5-triazine

A mixture of 2-*n*-decanal tsc-4,6-dichloro-1,3,5-triazine (3.56 g, 0.01 mole), methyl alcohol (35 ml), and sodium bicarbonate (1.68 g, 0.02 mole) was stirred for 15 minutes at room temperature, followed by heating under reflux for 30 minutes. After cooling, water was added until the mixture turned cloudy, and the methoxy derivative crystallized out overnight. It was collected and recrystallized twice from ethyl alcohol and finally from *n*-hexane. Yield, 3.2 g, 86.5%; m.p. 114° C. Required for $C_{15}H_{25}ClN_6OS$: C, 48.32; H, 6.71; Cl, 9.68; N, 22.55; S, 8.59%. Found: C, 48.21; H, 7.12; Cl, 9.53; N, 22.90; S, 8.46%.

n-Undecanal-4,4-dimethyl tsc

A solution of *n*-undecanal (6.12 g, 0.036 mole) in ethyl alcohol (150 ml) was added to a warm solution of 4,4-dimethyl thiosemicarbazide (13) (4.32 g, 0.036 mole) in water (100 ml). After addition of glacial acetic acid (5 ml) the resulting mixture was heated on a steam bath for 15 minutes. The mixture was then cooled in ice and enough sodium hydroxide solution to neutralize the acid was added. The 4,4-dimethyl tsc precipitated out, was collected, dried, and recrystallized twice from *n*-hexane. Yield, 8.75 g, 90%; m.p. 49° C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Required for $C_{14}H_{28}N_3S$: C, 62.8; H, 10.22; N, 15.33; S, 11.67%. Found: C, 61.50; H, 10.65; N, 15.75; S, 12.15%.

The infrared spectrum of this compound is of requisite character and shows only one —NH band at 3200 cm^{-1}. This band disappears in the 1:1 adduct with cyanuric chloride described below.

2-(n-Undecanal-4',4'-dimethyl tsc)-4,6-dichloro-1,3,5-triazine

To a solution of cyanuric chloride (3 g, 0.016 mole) and *n*-undecanal-4,4-dimethyl tsc (4.5 g, 0.016 mole) in acetone (150 ml) was added slowly, with stirring, a saturated aqueous solution of sodium bicarbonate in order to keep the pH of the mixture at 7. After 30 minutes, the acetone was distilled off and the product was extracted from the aqueous solution with chloroform. The chloroform extract was dried, the solvent evaporated, and the residue was dissolved in benzene and passed through a chromatographic column containing silica. A mixture of benzene–ether (4:1) eluted the required material which was further recrystallized from *n*-hexane. Yield, 3.2 g, 47%; m.p. 73° C. Required for $C_{17}H_{28}Cl_2N_6S$: C, 48.68; H, 6.68; Cl, 16.94; N, 20.05; S, 7.64%. Found: C, 48.23; H, 6.72; Cl, 17.45; N, 20.55; S, 7.65%.

2-(m-Aminoacetophenone tsc)-4,6-dichloro-1,3,5-triazine (IV)

A solution of cyanuric chloride (5.35 g, 0.03 mole) in acetone (150 ml) was poured onto crushed ice (ca. 600 ml). To this mixture were added slowly a solution of *m*-aminoacetophenone tsc in acetone (100 ml) and sufficient aqueous sodium hydroxide to keep the mixture neutral, the temperature being maintained between 0 and 5° C. A precipitate was formed and the mixture was stirred until the temperature reached 20° C. The precipitate was collected and recrystallized successively from acetone–water, dimethyl formamide – water, and finally twice from methyl alcohol. Yield, 97%; m.p. > 300° C. Required for $C_{12}H_{11}Cl_2N_7S$: C, 40.45; H, 3.09; Cl, 19.94; N, 27.53; S, 8.99%. Found: C, 39.43; H, 3.17; Cl, 20.20; N, 27.40; S, 9.29%.

Reactions between the three 2,4,6-Tri(formylphenoxy)-1,3,5-triazines (Va, Vb, Vc) and Thiosemicarbazide

Compounds (V*a*), (V*b*), and (V*c*) were prepared by the method of Allan and Allan (10). The reaction of (V*a*) and (V*c*) with thiosemicarbazide gave the corresponding tri-thiosemicarbazones (V*f*) and (V*g*). The procedure described below was used.

A solution of the triazine (8.8 g, 0.02 mole) in dioxane (180 ml) was added to thiosemicarbazide (5.82 g, 0.06 mole) dissolved in hot water (180 ml) containing acetic acid (12 ml). The resulting mixture was heated on the steam bath for 15 minutes and finally allowed to cool. The tri-tsc crystallized out and, after being collected, was recrystallized twice from dimethyl formamide – acetone. (V*f*): Yield, 8.5 g, 64%, m.p. 231° C. Required for $C_{27}H_{24}N_{12}O_3S_3$: C, 49.09; H, 3.64; N, 25.45; S, 14.55%. Found: C, 48.82: H, 3.84; N, 25.45; S, 14.20%. (V*g*): This was best recrystallized from dimethyl formamide – ethyl alcohol. Yield, 8.1 g, 60%; m.p. 243° C. Found: C, 48.20; H, 4.07; N, 25.35; S, 14.80%.

2,4-Di(2-formyl-5-bromophenoxy)-6-chloro-1,3,5-triazine (Vd)

A solution of cyanuric chloride (4.61 g, 0.025 mole) in dioxane (75 ml) was added dropwise to a mixture of 5-bromosalicylaldehyde (15.2 g, 0.075 mole) and sodium hydroxide (3 g, 0.075 mole) in dioxane (100 ml) and water (150 ml). After stirring the mixture for 1.5 hours, a precipitate formed. It was collected and treated with ethyl alcohol from which the unreacted 5-bromosalicylaldehyde (12.1 g) was recovered. The alcohol left a residue which, after recrystallization from dimethyl formamide – water, was shown to be the disubstituted triazine V*d*. Yield, 1 g, 7.8%; m.p. 225° C. Required for $C_{17}H_8Br_2Cl\,N_3O_4$: C, 39.73; H, 1.56; Br, 31.16; Cl, 6.91; N, 8.18%. Found: C, 39.66; H, 1.70; Br, 31.80; Cl, 7.33; N, 8.39%.

2,4-Di(2-formyl-5-chlorophenoxy)-6-chloro-1,3,5-triazine (Ve)

This was prepared as above and the disubstituted triazine V*e* was obtained in a 20% yield; m.p. 212° C. Required for $C_{17}H_8Cl_3N_3O_4$: C, 48.05; H, 1.88; Cl, 25.09; N, 9.89%. Found: C, 47.66; H, 1.82; Cl, 25.20; N, 10.50%.

THE STRUCTURE OF BIKHACONITINE[1]

Y. TSUDA[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 19, 1963

ABSTRACT

Aconitum spicatum Stapf has been found to contain two major alkaloids, pseudaconitine and bikhaconitine. The latter ($C_{36}H_{51}O_{11}N$) contains one free hydroxyl, four aliphatic methoxyl groups, one acetic and one veratric ester group, while the former ($C_{36}H_{51}O_{12}N$) contains the same substituents plus a second free hydroxyl. Like pseudaconitine, which forms a pyro-derivative hydrolyzable to pyropseudaconine, which can be isomerized to isopyropseudaconine, bikhaconitine gives rise to pyrobikhaconitine, pyrobikhaconine, and isopyrobikhaconine. Bikhaconitine was assumed to differ from pseudaconitine in lacking one secondary hydroxyl. The correctness of this assumption was proved by the conversion of pseudaconitine into bikhaconitine and further to triacetylbikhaconine. This correlation establishes the structure of bikhaconitine and also, since pseudaconitine had previously been correlated with aconitine, establishes its absolute configuration.

In 1905 Dunstan and Andrews (1) isolated from *Aconitum spicatum* Stapf an alkaloid, $C_{36}H_{51}O_{11}N.H_2O$, $[\alpha]_D$ +12.21 (EtOH) which they named bikhaconitine from the Indian trivial name of the plant, i.e., bikh. They described the base as a solid with a variable melting point (113–116° from dilute ethanol, 118–123° from ether) because of solvation, but they obtained a hydrobromide of constant m.p. 173–175°, $[\alpha]_D$ −12.4 (H_2O). The base which contained six methoxyl groups was saponifiable into acetic acid, veratric acid, and the amorphous bikhaconine $[\alpha]_D$ +33.9 (EtOH). Furthermore, on heating to 180° bikhaconitine lost the elements of acetic acid and formed pyrobikhaconitine, $C_{34}H_{47}O_9N$.

In order to study this base further, a quantity of the root of *A. spicatum* Stapf[3] was procured and the crude alkaloids isolated. There were present two major and several minor alkaloids. The two major alkaloids were separated by chromatography on alumina. The first was eluted from the chromatogram with benzene while the second was eluted afterwards with benzene–chloroform. The latter crystallized readily from methanol. It proved to be identical with pseudaconitine, $C_{36}H_{51}O_{12}N$ (I, R = Et, R_1 = OH, R_2 = $C_6H_3(OCH_3)_2$) (2). The amorphous base obtained from the benzene eluate was characterized as the crystalline perchlorate, m.p. 240–242°. The free base, recovered from the

[3]*We express our gratitude to S. B. Penick and Company, who kindly obtained the plant material, and to Dr. H. R. Schmidt, of that firm, who identified it.*

purified perchlorate, crystallized readily from ethanol–water or from ether with one mole of water of crystallization, $C_{36}H_{51}O_{11}N.H_2O$, $[\alpha]_D$ +16° (EtOH). It did not have a sharp melting point (105–115°) and even after 10 hours at 100° at 10^{-2} mm still retained its water of crystallization (see footnote 4). The base formed a crystalline hydrobromide which after drying melted at 174–176°, $[\alpha]_D$ −8.5° (H_2O).

Although they could be separated readily by chromatography and their mobilities in thin layer chromatography were quite different, yet the IR spectrum of the benzene-eluted base was hardly different from that of pseudaconitine and the n.m.r. spectra of both bases were also very similar.

The infrared spectrum of the perchlorate of the benzene-eluted alkaloid revealed the presence of a hydroxyl (3500 cm^{-1}), two ester carbonyls (1727, 1713 cm^{-1}), and a substituted benzene ring (1600, 1518 cm^{-1}). The n.m.r. spectrum of the free base contained signals indicating the presence of an N-ethyl group (triplet centered at δ 1.08); four aliphatic methoxyls (δ 3.13, 3.24, 3.27, 3.51); a veratroyl group (two aromatic methoxyls δ 3.90, 3.93; three aromatic protons δ 6.8 ∼ 7.8); an acetoxy group (δ 1.30) (3); and a signal at δ 4.87, $J \sim 4.5$ c/s, which will be referred to later.

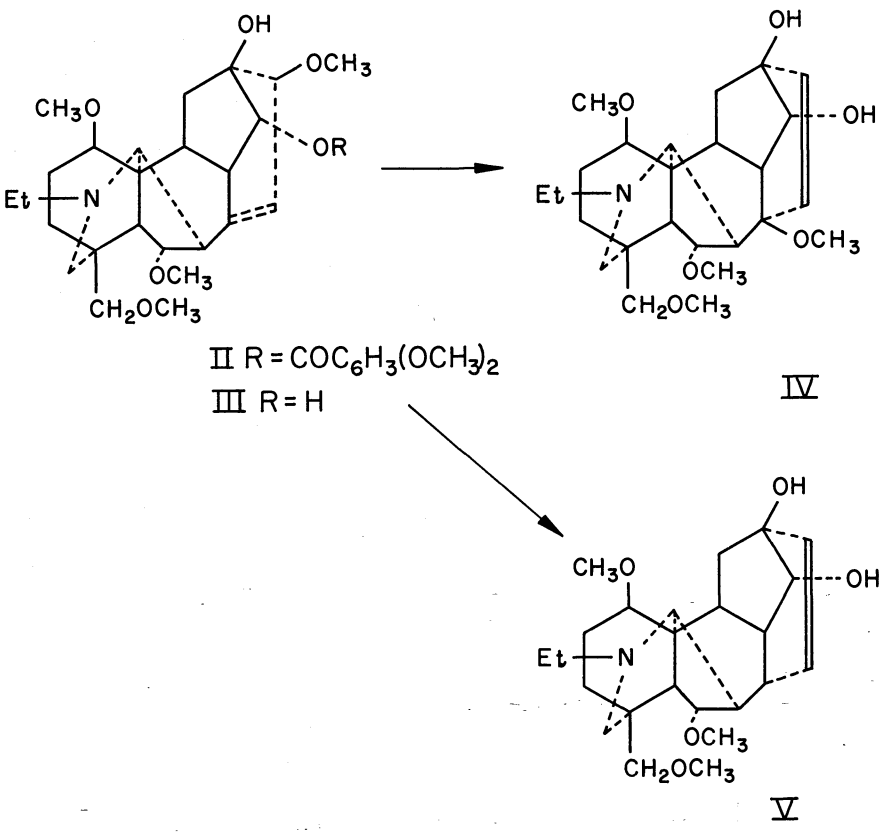
When treated with alkali the alkaloid was hydrolyzed to veratric acid, acetic acid, and an amorphous alkamine, $[\alpha]_D$ +33.4° (EtOH), the n.m.r. spectrum of which showed the presence of an N-ethyl and four aliphatic methoxyl groups, but no longer contained the signals corresponding to the veratroyl and the acetoxy groups.

The agreement between the properties already described of the benzene-eluted alkaloid and those of bikhaconitine is such as to establish the identity of the two.

The bikhaconitine isolated from *A. spicatum* when acetylated with acetic anhydride and *p*-toluenesulphonic acid gave a quantitative yield of a monoacetate, m.p. 197–199°, while the complete acetylation of the hydrolytic bikhaconine produced the dimorphous triacetylbikhaconine, m.p. 149–151° or 159–162° depending on the rate of crystallization. Under the same conditions pseudaconitine and pseudaconine gave rise to diacetylpseudaconitine and tetraacetylpseudaconine respectively (2). Hence bikhaconitine contains one free hydroxyl only, and as a working hypothesis, it will be assumed to have structure I (R = Et, R_1 = H, $R_2 = C_6H_3(OCH_3)_2$) which lacks the ring A hydroxyl of pseudaconitine.

Dunstan and Andrews (1) had described the pyrolysis of bikhaconitine in which the base lost the elements of acetic acid and formed an amorphous pyro-derivative. In repeating this work it has now been found that bikhaconitine when heated *in vacuo* at 190–195° lost acetic acid very readily and produced pyrobikhaconitine $C_{34}H_{47}O_9N$ (II, R = $COCH_3(OCH_3)_2$) which crystallized from ether, m.p. 155–157°. The n.m.r. spectrum of this product contained a doublet (δ 5.56, $J \sim 6$ c/s) corresponding to one olefinic proton. Alkaline hydrolysis of pyrobikhaconitine gave rise to the amorphous pyrobikhaconine (III, R = H) which also showed in its n.m.r. spectrum a doublet (δ 5.54, $J \sim 8$ c/s) corresponding to one olefinic proton. Pyrobikhaconine when warmed in methanol in the presence of a trace of acid, like pyrodelphonine (4), underwent an allylic rearrangement and gave crystalline isopyrobikhaconine, $C_{25}H_{39}O_6N$, m.p. 189–192°, IV, the n.m.r. spectrum of which showed the presence of four methoxyl groups and contained a broad peak (δ 5.90) corresponding to two olefinic protons. It can be concluded, therefore, that bikhaconitine contains the sequence $\diagdown$C(OAC)—CH_2—CH(OMe)—, just like pseudaconitine (2) and delphinine (4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



Pyrobikhaconitine on treatment with lithium aluminum hydride, just like pyropseudaconitine (2), underwent reductive cleavage and a rearrangement with accompanying loss of a methoxyl. Under these conditions the product was demethoxyisopyrobikhaconine V, $C_{24}H_{37}O_5N$, m.p. 147–150°, which had an n.m.r. spectrum containing signals indicative of three methoxyl groups, and a poorly resolved signal centered at δ 5.68 attributable to two olefinic protons. Demethoxyisopyrobikhaconine V formed a diacetyl derivative, m.p. 161–163°, indicating the presence of two free hydroxyls. A monoacetyl derivative was also obtained as a by-product which could be converted into the diacetyl compound by further acetylation. The double bond present in V according to the n.m.r. spectrum was confirmed by hydrogenation of the diacetyl derivative which gave rise to dihydrodiacetyldemethoxyisopyrobikhaconine, $C_{28}H_{43}O_7N$, m.p. 172–174°.

Just like the n.m.r. spectra of pseudaconitine and of delphinine, the spectrum of bikhaconitine contains a doublet at δ 4.87 (J = 4.5 c/s) and a signal at δ 1.30 indicating a single proton split by a single neighboring proton, and a shielded acetoxy group respectively. These signals indicate (cf. ref. 3) that the two ester groups of bikhaconitine must be located as in pseudaconitine and be similarly oriented. The fact that the C_{10} proton has one neighboring proton only is evidence that the C_{11} position must be substituted by an oxygenated function. Consequently rings D and E of bikhaconitine must be substituted exactly as rings D and E of pseudaconitine.

Since bikhaconitine contains one free hydroxyl only while pseudaconitine contains two

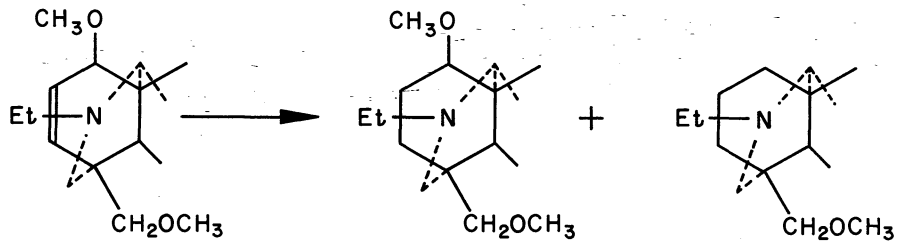
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and since position 11 is known to be substituted, it is apparent that the C_3 hydroxyl of pseudaconitine must be absent in bikhaconitine as required by structure I (R = Et, R_1 = H, R_2 = $C_6H_3(OCH_3)_2$). This structure accounts well for the formation of monoacetylbikhaconitine and triacetylbikhaconine. It is also in agreement with the formation of an olefinic pyrobikhaconine (II).

If this assumed structure of bikhaconitine is valid, then it should be possible to convert pseudaconitine into bikhaconitine by substitution of hydrogen for the C_3 hydroxyl and thereby prove the structure.

Pseudaconitine was dehydrated with thionyl chloride by a procedure already described (5) and converted into anhydropseudaconitine (perchlorate, m.p. 235–236°). The presence of complex peaks at δ 5.9 corresponding to two olefinic protons in the n.m.r. spectra of both anhydropseudaconitine and its hydrolytic product anhydropseudaconine confirmed that loss of water had occurred at C_2–C_3. A similar pattern has been observed in the n.m.r. spectrum of anhydroindaconitine (5).

Hydrogenation of anhydropseudaconitine (VI) over Adams' catalyst gave a saturated compound which failed to crystallize but had the same mobility as bikhaconitine in thin layer chromatography. It was isolated as its crystalline perchlorate, m.p. 227–233°. Although the melting point was lower than that of bikhaconitine perchlorate, it was not depressed on admixture. The infrared spectra of the two were only very slightly different in the fingerprint region. The base proved to be a mixture of bikhaconitine and the corresponding demethoxy-base, e.g. bikhaconitine, in which one methoxyl had been eliminated. A small quantity of the latter was isolated in pure condition and its n.m.r. spectrum showed the presence of three aliphatic methoxyl groups only (δ 3.16, 3.28, 3.52) together with two aromatic methoxyls (δ 3.10, 3.92). Since many examples of the hydrogenolysis of an allylic-methoxyl have been reported (cf. ref. 6) it is reasonable to assume that it is the methoxyl of ring A which has been removed during hydrogenation and that the base can therefore be represented by partial formula VII.



VI VII

Deoxypseudaconitine (bikhaconitine), however, was not obtained in pure form from the mixture although it was the major component. Hence, some of the crude product was hydrolyzed by alkali into the alkamine which in thin layer chromatography showed a strong spot which had the same mobility as bikhaconine, accompanied by a close but weak spot. The crude hydrolytic product was acetylated with acetic anhydride and *p*-toluenesulphonic acid. The product of this last reaction was chromatographed on alumina. A fraction was obtained from the chromatogram which crystallized from hexane, m.p. 147–150°, $[\alpha]_D$ −8.0°, which was identical in melting point with that of the mixture, optical rotation, infrared spectrum, and mobility in thin layer chromatography with triacetylbikhaconine.

This correlation of bikhaconitine with pseudaconitine proves the correctness of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

assumed structure I (R = Et, R_1 = H, R_2 = $C_6H_3(OCH_3)_2$) and at the same time establishes its absolute configuration, since pseudaconitine has been correlated previously with aconitine (2).

EXPERIMENTAL

All n.m.r. spectra were measured in $CDCl_3$ solution with tetramethylsilane as an internal reference. In each column chromatography Woelm grade IV neutral alumina was used. The melting points were taken on a Kofler hot stage, and are uncorrected. For thin layer chromatography, silica gel G was used as an adsorbent, cyclohexane–chloroform–diethylamine as the solvent system.

Separation of the Alkaloids

The powdered root of *A. spicatum* Stapf (36 kg) was percolated with 95% ethanol. The concentrated extract was diluted with water, acidified with hydrochloric acid, and extracted repeatedly with methylene chloride. The liquor was alkalized with sodium carbonate to liberate the weak bases and extracted with chloroform (Extract A). Sodium hydroxide was then added to liberate the strong bases and the liquor again extracted with chloroform (Extract B).

The methylene chloride extract was evaporated and the residue taken up in dilute hydrochloric acid. Filtercel was added to the acid solution which was filtered and the filtrate extracted with ether. The liquor was then made basic with sodium hydroxide and extracted exhaustively with chloroform. This chloroform extract when evaporated to dryness left a residue of crude bases (340 g). The crude residue consisted of bases forming methylene-chloride-soluble hydrochlorides. A thin layer chromatography test showed two strong spots accompanied by several weak spots indicating the presence of two major alkaloids and several minor ones.

A quantity (130 g) of the crude basic residue was dissolved in benzene containing some chloroform and the solution filtered. The filtrate was poured through a column (6 × 33 cm) of alumina (800 g) which was eluted first with benzene and then with benzene–chloroform. The first two fractions (benzene, 1 l.) yielded a pale yellow gum (84 g). Fractions 3–8 (benzene, 1.5 l., and benzene–chloroform 1.7 l.) gave pseudaconitine (14 g), m.p. 203–205°, after crystallization from methanol (cf. ref. 2).

The yellow gum (84 g) obtained from the first two fractions of the eluate was rechromatographed over alumina (1 kg) in a column (6 × 42 cm) and eluted as follows. Fraction 1 (benzene, 500 ml) was discarded. Fractions 2–15 (benzene, 3.2 l.; benzene–chloroform, 8:2, 1.1 l.; benzene–chloroform, 1:1, 1.1 l.) yielded a gummy base which was dissolved in ethanol. The solution was made just acid to Congo red by the careful addition of 70% perchloric acid, and after it had stood some time at room temperature it deposited the salt as colorless needles (30 g). Fractions 16–18 (benzene–chloroform, 1:1, 250 ml; chloroform, 500 ml) gave a mixture of the base already obtained as its perchlorate and pseudaconitine. Fractions 19–21 (chloroform, 1.4 l.) left on evaporation a residue (28 g) which when crystallized in methanol produced pseudaconitine (13 g). Total yield of crystalline pseudaconitine, 27 g.

Bikhaconitine

The crystalline perchlorate obtained from the first base eluted from the chromatogram was recrystallized from ethanol from which it separated as colorless needles, m.p. 240–242°, $[\alpha]_D$ −5.2° (*c*, 1.6 in $CHCl_3$). Found: C, 55.75; H, 6.62. Calc. for $C_{36}H_{51}O_{11}N.HClO_4$: C, 55.83; H, 6.77%.

The base recovered from the purified perchlorate crystallized from ether or dilute ethanol as colorless needles. From either solvent the crystalline base was hydrated, m.p. 105–110°,[4] $[\alpha]_D$ +16° (*c*, 1.6 in EtOH). For bikhaconitine the literature (1) gives m.p. 118–123° or 113–116°, $[\alpha]_D$ +12.21°, in EtOH. Found: C, 62.34; H, 7.66; N, 2.29. Calc. for $C_{36}H_{51}O_{11}N.H_2O$: C, 62.50; H, 7.72; N, 2.02%.

Bikhaconitine formed a hydrobromide which crystallized from ethanol as colorless prisms, m.p. 174–175°, and the air-dried sample had $[\alpha]_D$ −8.5° (*c*, 1.2 in H_2O). The literature (1) gives m.p. 173–175°, $[\alpha]_D$ −12.4°, in water.

Acetylbikhaconitine

Bikhaconitine (150 mg) in acetic anhydride (3 ml) containing *p*-toluenesulphonic acid (100 mg) was heated on a steam-bath for 1 hour. The reaction mixture was poured into ice water, alkalized, and repeatedly extracted with ether. The combined ether extract was washed, dried, and evaporated to dryness. The residual crystalline acetylbikhaconitine (150 mg) was crystallized from methanol from which it separated as colorless prisms, m.p. 197–199°, $[\alpha]_D$ +21.6° (*c*, 1.5 in $CHCl_3$). Found: C, 63.70; H, 7.28; N, 2.11. Calc. for $C_{38}H_{53}O_{12}N$: C, 63.77; H, 7.46; N, 1.96%. In the n.m.r. spectrum, δ 1.30, 2.04 ($COCH_3$).

[4]*Bikhaconitine can be converted, by oxidative dealkylation followed by methylation, into the N-methyl-N-desethyl derivative which crystallizes readily. Seeding a solution of bikhaconitine in n-hexane with a small crystal of the derivative induced crystallization of bikhaconitine as stout prisms which were not hydrated and melted at 163.5–164°. Found:* C, *63.69;* H, *7.47;* N, *2.11. Calc. for* $C_{36}H_{51}O_{11}N$: C, *64.09;* H, *7.57;* N, *2.08%. We are indebted to Dr. O. Achmatowicz, Jr. for this observation.*

For personal use only.

Hydrolysis of Bikhaconitine

Bikhaconitine perchlorate (75 mg) in 5% methanolic sodium hydroxide (10 ml) was refluxed for 1½ hours. The methanol was evaporated under reduced pressure, the residue was dissolved in water, and the solution extracted with chloroform. The extract was washed, dried, and evaporated to dryness. There was left a gummy residue of bikhaconine (46 mg) which in thin layer chromatography appeared to be homogeneous and showed no carbonyl absorption in the infrared spectrum; n.m.r. triplet centered at δ 1.07 (N—Et) and $4OCH_3$ at δ 3.22, 3.28 (6H), 3.40, $[\alpha]_D$ +33.4° (*c*, 3.2 in EtOH). For bikhaconine the literature (1) reports $[\alpha]_D$ +33.9° in ethanol.

The aqueous solution that had been extracted with chloroform was acidified with hydrochloric acid and extracted repeatedly with ether. The combined ether extract yielded a solid acid which was crystallized from aqueous ethanol from which it separated as colorless prisms, m.p. 184–186°, either alone or in admixture with an authentic sample of veratric acid. The infrared spectra of the two were superimposable.

Triacetylbikhaconine

Bikhaconine (100 mg) and *p*-toluenesulphonic acid (100 mg) in acetic anhydride (5 ml) were heated on a steam bath for 1½ hours. The mixture was poured into ice water, rendered alkaline with sodium carbonate, and the solution extracted with ether. Evaporation of the dried extract left a solid which was dissolved in benzene, and chromatographed on a column of alumina. The eluate on evaporation left the solid triacetylbikhaconine (95 mg) which crystallized from *n*-hexane as colorless needles, m.p. 149–150°, $[\alpha]_D$ −8.1° (*c*, 1.7 in $CHCl_3$). Found: C, 62.65; H, 7.81; N, 2.54. Calc. for $C_{31}H_{47}O_{10}N$: C, 62.71; H, 7.98; N, 2.36%. In the n.m.r. spectrum the signals δ 1.96, 2.05, 2.09 designate the acetyl group protons. Triacetylbikhaconine is dimorphous and, when kept for some time in contact with *n*-hexane, melts at 159–161°. Slow crystallization from *n*-hexane gives the high-melting form as colorless prisms. Either form can be obtained by cross seeding.[5]

Pyrobikhaconitine

Bikhaconitine (2.2 g) was heated *in vacuo* (10^{-2} mm) at 190–195° (air bath) for 5 minutes. The cooled product was dissolved in benzene, and chromatographed on a column (2 × 7 cm) of alumina. The pyrobikhaconitine (1.81 g) obtained by evaporation of the benzene eluate was crystallized from ether from which it separated as clusters of colorless needles, m.p. 155–157°, $[\alpha]_D$ +198.4° (*c*, 1.3 in $CHCl_3$). Found: C, 66.39; H, 7.65. Calc. for $C_{34}H_{47}O_9N$: C, 66.54; H, 7.72%.

Pyrobikhaconine

Pyrobikhaconitine (0.29 g) was refluxed in 3% methanolic sodium hydroxide (10 ml) for 2 hours. The methanol was evaporated, the residue dissolved in water, and the solution extracted with chloroform. Evaporation of the extract left the product as a gum (0.21 g) which by thin layer chromatography was homogeneous. Infrared spectrum of this product showed no carbonyl absorption, and had an absorption at 1620 cm^{-1} attributable to a double bond.

Isopyrobikhaconine

Pyrobikhaconine (90 mg) in methanol (10 ml) containing a few drops of 70% perchloric acid was heated under reflux for 1 hour. The reaction mixture was evaporated under reduced pressure, the residue was dissolved in water, and the solution alkalized with sodium hydroxide and extracted with chloroform. Evaporation of the extract after washing with water and drying gave isopyrobikhaconine (90 mg) which crystallized on trituration. When recrystallized from methanol it consisted of colorless prisms, m.p. 189–192°, $[\alpha]_D$ +33.8° (*c*, 0.7 in $CHCl_3$). Found: C, 66.82; H, 8.67. Calc. for $C_{25}H_{39}O_6N$: C, 66.79; H, 8.75%.

Demethoxyisopyrobikhaconine

A mixture of pyrobikhaconitine (1.8 g) and lithium aluminum hydride (1.2 g) in tetrahydrofuran (30 ml) was stirred for 16 hours at room temperature. After decomposition of the excess hydride by the addition of a few drops of water, the mixture was diluted with methylene chloride and filtered. The material on the filter was washed repeatedly with methylene chloride and the combined filtrate and washings evaporated to dryness. The residue was dissolved in 5% hydrochloric acid, the solution washed with ether, made alkaline with sodium carbonate, and extracted with chloroform. The dried chloroform extract on evaporation left a colorless gum (1.2 g) which was dissolved in benzene and chromatographed over alumina. Elution with methylene chloride and chloroform gave demethoxyisopyrobikhaconine which crystallized from ether–*n*-hexane as colorless fine needles, m.p. 147–150°, $[\alpha]_D$ +66.7° (*c*, 0.8 in $CHCl_3$). Found: C, 68.68; H, 8.58. Calc. for $C_{24}H_{37}O_5N$: C, 68.70; H, 8.89%. Those fractions of the eluate which did not yield a pure product were chromatographed again and an additional crop of the pure compound was obtained. Total yield, 1.0 g.

Acetylation of Demethoxyisopyrobikhaconine

Demethoxyisopyrobikhaconine (1.0 g) in acetic anhydride (5 ml) and pyridine (10 ml) was kept overnight at room temperature. The mixture was poured into ice water, the solution made basic with sodium carbonate, and extracted with methylene chloride. The extract was washed with water, dried over magnesium sulphate, and evaporated under reduced pressure. A residual gum (1.0 g) was left which was dissolved in benzene–

For personal use only.

hexane (1:2) and chromatographed over alumina. The benzene–hexane and benzene eluates yielded the diacetyl compound (0.175 g) which crystallized from *n*-hexane–ether as colorless prisms, m.p. 161–163°, $[\alpha]_D$ +31.9° (*c*, 1.2 in $CHCl_3$). Found: C, 66.35; H, 7.84. Calc. for $C_{28}H_{41}O_7N$: C, 66.77; H, 8.21%. In the n.m.r. spectrum the signals at δ 2.01, 2.06 indicated the protons of the two acetyl groups.

Further elution of the chromatogram with benzene and methylene chloride yielded a monoacetyl derivative (0.75 g) which crystallized from pentane as colorless prisms, m.p. 94–97°, $[\alpha]_D$ +66.1° (*c*, 1.1 in $CHCl_3$) Found: C, 67.83; H, 8.70. Calc. for $C_{26}H_{39}O_6N$: C, 67.65; H, 8.52%; (n.m.r., δ 2.07). When further acetylated with acetic anhydride and pyridine, the monoacetyl derivative gave rise to diacetyl-demethoxyisopyrobikhaconine, m.p. 161–163°.

Dihydrodiacetyl-demethoxyisopyrobikhaconine

Diacetyl-demethoxyisopyrobikhaconine (60 mg) in ethanol (10 ml) containing a few drops of acetic acid was hydrogenated over platinum oxide (50 mg) for 10 hours at room temperature. The catalyst was filtered off and the filtrate evaporated to dryness. The residual gum was dissolved in water, the solution made basic with sodium carbonate and extracted with ether. The extract was concentrated to a small volume and allowed to stand at room temperature. It deposited the crystalline dihydro-compound which was recrystallized from ether-*n*-hexane from which it separated as colorless prisms, m.p. 172–174°, $[\alpha]_D$ −57.8° (*c*, 0.9 in $CHCl_3$). Found: C, 66.66; H, 8.62. Calc. for $C_{28}H_{43}O_7N$: C, 66.51; H, 8.57%.

Anhydropseudaconitine

Pseudaconitine (5 g) in thionyl chloride (30 ml) was heated on a steam bath for 4 hours. The excess thionyl chloride was evaporated off under reduced pressure and the residue dissolved in water. The solution was made basic with ammonia and extracted with ether. The extract was washed with water, dried over magnesium sulphate, and evaporated to dryness. It left a gum which was dissolved in benzene and chromatographed on alumina. The benzene eluate yielded an amorphous product which formed a crystalline perchlorate. After several recrystallizations from ethanol, the salt consisted of colorless needles (3.9 g), m.p. 235–236° (decomp.), $[\alpha]_D$ +16.1° (*c*, 1.8 in $CHCl_3$). Found: C, 56.11; H, 6.52. Calc. for $C_{36}H_{49}O_{11}N.HClO_4$: C, 55.99; H, 6.53%. Anhydropseudaconitine recovered from the pure salt remained amorphous and could not be induced to crystallize.

Anhydropseudaconine

Anhydropseudaconitine perchlorate (70 mg) was hydrolyzed in 5% methanolic sodium hydroxide (10 ml) by refluxing for 1 hour. The solvent was evaporated, water added, and the solution extracted with chloroform. The extract yielded anhydropseudaconine as a gum (48 mg) having no carbonyl absorption in the infrared spectrum that failed to crystallize, but was shown by thin layer chromatography to be homogeneous. In the n.m.r. spectrum it showed the complex signal for two olefinic protons (δ 5.9).

Hydrogenation of Anhydropseudaconitine

Anhydropseudaconitine recovered from the pure perchlorate (1.04 g) was dissolved in ethanol (35 ml) and stirred at room temperature for 10 hours in a hydrogen atmosphere in contact with platinum oxide (0.165 g). The catalyst was removed by filtration and the filtrate evaporated to dryness under reduced pressure. There was left a colorless gum which failed to crystallize; in thin layer chromatography it showed only one spot which had the same mobility as bikhaconitine.

The colorless gummy product was dissolved in ethanol and converted to the perchlorate which separated as colorless needles (0.93 g). This perchlorate (A), recrystallized once from ethanol, melted at 227–233°, either alone or in admixture with bikhaconitine perchlorate (m.p. 242°). Further recrystallization did not improve the melting point and in some cases lowered it.

A quantity of perchlorate (A) (0.6 g) was recrystallized three times and converted into the free base which crystallized from ethanol–water. After several recrystallizations from the same solvent, the base consisted of colorless leaflets (50 mg), m.p. 175–182°. The n.m.r. spectrum of this base showed the presence of only three aliphatic methoxyl groups (δ 3.16, 3.28, 3.52) and two aromatic methoxyls (δ 3.90, 3.92). This base was again converted to a perchlorate (perchlorate B); it was crystallized twice from ethanol from which it separated as colorless elongated prisms, m.p. 170–175° (decomp.). Found: C, 53.93; H, 6.45. Calc. for $C_{35}H_{49}O_{10}N.HClO_4.2H_2O$: C, 53.87; H, 6.97%. The salt is that of the new base demethoxydeoxypseudaconitine (demethoxybikhaconitine) which has the same R_F value as bikhaconitine.

The remainder of perchlorate A (which had been crystallized twice only) was refluxed with 5% methanolic sodium hydroxide for 1½ hours. The alkamine isolated from the reaction mixture was acetylated as described above for the preparation of triacetylbikhaconine. The product (0.625 g) was chromatographed in benzene on an alumina column (2 × 15 cm). The first eluate (102 mg) showed two spots in thin layer chromatography and remained amorphous. Further elution with benzene gave a crystalline substance (402 mg) which was homogeneous in thin layer chromatography. This fraction, after crystallization in *n*-hexane, consisted of colorless needles, m.p. 147–150°, $[\alpha]_D$ −8.0° (*c*, 1.9 in $CHCl_3$). Admixture with triacetylbikhaconine failed to depress the melting point, and the infrared spectra of the two samples were superimposable. Both the acetylated product and triacetylbikhaconine had the same mobility in thin layer chromatography.

QUADRUPOLE RELAXATION FOR A SPIN $I = 3/2$

THE F^{19} N.M.R. SPECTRA OF BF_3 AND ClO_3F

J. BACON, R. J. GILLESPIE, AND J. W. QUAIL
Department of Chemistry, McMaster University, Hamilton, Ontario
Received July 23, 1963

ABSTRACT

An expression is derived for the broadening of the components of the quartet obtained for the n.m.r. spectrum of nuclei coupled to a nucleus of spin 3/2 undergoing electric quadrupole relaxation. It is shown that the F^{19} spectra of BF_3 and ClO_3F at various temperatures may be satisfactorily interpreted by means of this expression. Activation energies for molecular reorientation of 1.4 kcal/mole for BF_3 and 1.0 kcal/mole for ClO_3F are obtained.

INTRODUCTION

In general, the spectra of protons or fluorine nuclei spin–spin coupled to a nucleus of spin I (where $I > 1/2$) would be expected to have a multiplet structure of $2I+1$ lines. Often, however, since nuclei with a spin I greater than 1/2 have quadrupole moments which usually couple strongly, by means of molecular reorientations, to local electric fields, relaxation of the nucleus having the quadrupole moment occurs and the multiplet structure of the H^1 or F^{19} resonance is collapsed to a single line. The expected multiplet structure will therefore be seen only if the high-spin nucleus has a small quadrupole moment or if the high-spin nucleus is in an environment which is highly symmetric electrically. Examples of the first case are the proton spectra of diborane (1, 2) and ammonia (3), B^{11} and N^{14} having relatively small nuclear quadrupole moments (4); examples of the second case are the fluorine spectra of MoF_6 (5) and of SF_6 (6), Mo^{95}, Mo^{97}, and S^{33} having relatively large quadrupole moments but being situated in highly symmetric environments.

While the general cases of very slow relaxation and very rapid relaxation have been treated by various authors (7, 8, 9), the case of an intermediate rate of relaxation which gives rise to a partially collapsed multiplet has been treated only for $I = 1$ (8).

THEORY

A spin of 3/2 can exist in the states $m = 3/2, 1/2, -1/2, -3/2$. Pople (8) has derived a series of expressions for the transition probabilities due to quadrupole relaxation which can be summarized as follows: the probability that a nucleus in state m will undergo a 1 quantum transition (i.e., to state $m\pm1$) is

$$[1] \qquad P_{m,m\pm1} = \frac{3}{20}\frac{(2m \pm 1)^2(I \pm m + 1)(I \mp m)}{4I^2(2I-1)^2}\left(\frac{e^2qQ}{\hbar}\right)^2\tau_q$$

and for the 2 quantum transition the probability is

$$[2] \qquad P_{m,m\pm2} = \frac{3}{20}\frac{(I \mp m)(I \mp m - 1)(I \pm m + 1)(I \pm m + 2)}{4I^2(2I-1)^2}\left(\frac{e^2qQ}{\hbar}\right)^2\tau_q,$$

where e = the charge on an electron
eq = the electric field gradient at the nucleus
eQ = the quadrupole moment of the nucleus
τ_q = the correlation time for molecular reorientation

and $e^2qQ/\hbar$ is the quadrupole coupling constant in radians/sec. Transitions due to electric quadrupole moments occur only for $\Delta m = \pm 1$ or ± 2. For $I = 3/2$ we find from the above expressions that

$$[3] \qquad P_{3/2,\pm 1/2} = P_{\pm 1/2,3/2} = P_{-3/2,\pm 1/2} = P_{\pm 1/2,-3/2} = \frac{1}{20}\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_q$$

and

$$[4] \qquad P_{3/2,-3/2} = P_{-3/2,3/2} = P_{1/2,-1/2} = P_{-1/2,1/2} = 0.$$

The inverse lifetime of each state m is given by

$$[5] \qquad \frac{1}{\tau_m} = \sum_{\substack{n \\ n \neq m}} P_{m,n}.$$

For $I = 3/2$ we find therefore that

$$[6] \qquad \frac{1}{\tau_{3/2}} = \frac{1}{\tau_{1/2}} = \frac{1}{\tau_{-1/2}} = \frac{1}{\tau_{-3/2}} = \frac{1}{\tau} = \frac{1}{10}\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_q,$$

a result also obtained by Pople (8). It has been shown (9) that in the extreme narrowing case the nuclear spin – lattice relaxation time T_1, due to quadrupole coupling for a nucleus of spin $I = 3/2$ is given by

$$[7] \qquad \left(\frac{1}{T_1}\right) = \frac{1}{10}\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_q.$$

If the quadrupole moment is small, or if the high-spin nucleus is in a symmetrical environment (eq small), then τ will be long and the resonance of the spin 1/2 nucleus will be a quartet of equal intensities, each line having width $1/\pi\tau$. The line width of the individual components of the resonance of the high-spin nucleus should be $1/\pi T_1$, which is equal to $1/\pi\tau$ in this case.

It has been shown (9) that the line shape for intermediate rates of quadrupole relaxation (assuming other relaxation mechanisms to be insignificant) is given by the following expression:

$$[8] \qquad I(\omega) \propto \text{Re}\ \{\mathbf{W}.\mathbf{A}^{-1}.\mathbf{1}\}$$

where Re { } denotes "the real part of"

$\mathbf{W}$ is the vector $\begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}$

$\mathbf{1}$ is the vector $[1, \ldots, 1]$

$\mathbf{A}^{-1}$ is the inverse of the complex matrix $\mathbf{A}$ that is defined by the relationships

$$[9] \qquad A_{m,m} = i[(\omega_0 - \omega) + m \cdot 2\pi J] - \frac{1}{\tau_m},$$

$$[10] \qquad A_{m,n} = P_{m,n}, \qquad m \neq n,$$

ω_0 being the center of the unperturbed multiplet and J the coupling constant in c/sec. Using the previously derived relationship [6] for $1/\tau_m$ and expressing the transition probabilities $P_{m,n}$ in terms of τ we obtain the following expression:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

$$\mathbf{A} = \begin{bmatrix} i[(\omega_0-\omega)+3\pi J]-\frac{1}{\tau} & \frac{1}{2\tau} & \frac{1}{2\tau} & 0 \\ \frac{1}{2\tau} & i[(\omega_0-\omega)+\pi J]-\frac{1}{\tau} & 0 & \frac{1}{2\tau} \\ \frac{1}{2\tau} & 0 & i[(\omega_0-\omega)-\pi J]-\frac{1}{\tau} & \frac{1}{2\tau} \\ 0 & \frac{1}{2\tau} & \frac{1}{2\tau} & i[(\omega_0-\omega)-3\pi J]-\frac{1}{\tau} \end{bmatrix}$$

Inserting the inverse of **A** in equation [7], we find that the line shape is given by the expression

[11] $$I(x) \propto \tau f(\eta,x)$$

where $$f(\eta,x) = \frac{320+16\eta^2(25x^2+17)+\eta^4(80x^4+56x^2+45)}{1024x^2+64\eta^2(36x^4-20x^2+25)+16\eta^4(96x^6-160x^4+110x^2+45)+\eta^6(256x^8-1280x^6+1888x^4-720x^2+81)}$$

$$\eta = 2\pi J\tau, \quad x = \frac{\omega_0-\omega}{2\pi J}$$

Line shapes calculated from equation [11] with various values of η^2 from 100 to 0.1 are shown in Fig. 1. In the collapse of the quartet the outer lines move inward, but the inner lines move outward, resulting in a broad doublet-like structure at values of η^2 near 2. Finally, the "doublet" collapses to a single line.

RESULTS AND DISCUSSION

The Spectrum of Boron Trifluoride

The F^{19} n.m.r. spectrum of BF_3 at room temperature has previously been reported by Muetterties and Phillips (5) and by Coyle and Stone (10) as a broad 1:1:1:1 quartet with $J = 15$ c/sec due to coupling of the fluorine with the 81.2% abundant B^{11}. The F^{19} on the 18.8% abundant $B^{10}(I = 3)$ gives some unresolved underlying structure. We have observed both the F^{19} and B^{11} n.m.r. spectra of BF_3 in the gas phase at room temperature. Since both the F^{19} 1:1:1:1 quartet and the B^{11} 1:3:3:1 quartet are only slightly collapsed at room temperature, the multiplet separations are taken as $J_{B^{11}F}$. The F^{19} resonance gives a value for $J_{B^{11}F}$ of 18.3±0.6 c/sec and the B^{11} resonance gives $J_{B^{11}F} = 18.5\pm0.2$ c/sec.

The BF_3 sample used condensed to a liquid at about −17° C. The F^{19} spectrum of the liquid at four lower temperatures is shown in Fig. 2. At −21° C the value of $J_{B^{11}F}$ (allowing for the partial collapse of the spectrum) was found to be 20.0±0.5 c/sec. Since the quadrupole moment of B^{10} is three times as large as that of B^{11} and since $J_{B^{10}F}$ is much smaller than $J_{B^{11}F}$ (due to the smaller magnetogyric ratio of B^{10}), the spectrum of the fluorine on B^{10} is more collapsed than that of fluorine on B^{11}. By matching spectra calculated from equation [11] with the experimental spectra and making due allowance for the underlying broad fluorine on B^{10} lines, approximate values of η have been obtained for temperatures in the range − 100° to −21° C.

If the suggestion of Moniz and Gutowsky (11) that the reorientation is a thermally activated process described by the usual rate equation

12] $$\tau_q = \tau_q^0 \exp(E_a/RT)$$

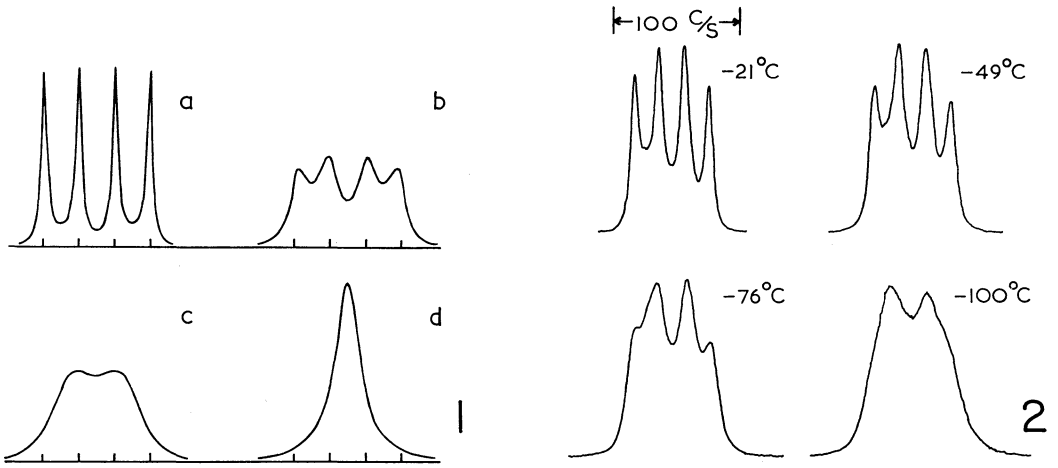

FIG. 1. Theoretical line shapes for the spectra of nuclei of spin 1/2 coupled to a nucleus of spin 3/2 according to equation [11]. (*a*) $\eta^2 = 100$, (*b*) $\eta^2 = 10$, (*c*) $\eta^2 = 1$, (*d*) $\eta^2 = 0.1$. The vertical lines indicate the positions of the quartet in the absence of quadrupole relaxation.

FIG. 2. F^{19} resonance spectra of liquid BF_3.

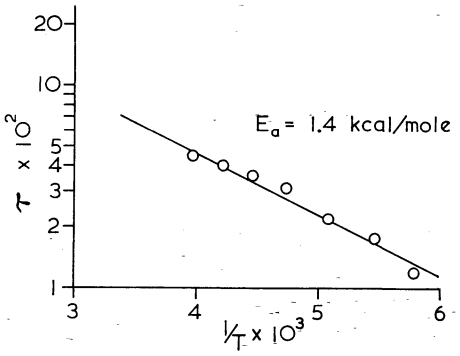

FIG. 3. The temperature dependence of the B^{11} τ estimated from the F^{19} resonance of liquid BF_3.

is accepted, we find from equations [6] and [12] that a plot of log τ vs. $1/T$ should be a straight line of slope $-E_a/2.3R$. The plot of the experimental data is shown in Fig. 3. The plot does not appear to be linear. Nevertheless, a straight line was drawn through the points as shown in Fig. 3. The slope of the line gave a mean activation energy of 1.4 kcal/mole.

The line widths of the F^{19} and B^{11} resonances of BF_3 in the gas phase at room temperature were pressure dependent. However, for any one sample the F^{19} and B^{11} line widths were the same, as predicted by equations [6] and [7].

It is clear from the asymmetry of the BF_3 spectra that there is an isotope effect associated with the two boron isotopes. As would be expected (12), the fluorine on B^{11} resonance occurs at slightly higher field than that of fluorine on B^{10}. The isotope effect was estimated as approximately 3 c/sec at 56.4 Mc/sec or approximately +0.05 p.p.m.

The Spectrum of Perchloryl Fluoride

Studies of the infrared vibrational and rotational spectra (13, 14) and the microwave spectrum (15) indicate that the perchloryl fluoride molecule possesses a nearly regular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tetrahedral structure about the central chlorine atom, the fluorine atom being bonded directly to chlorine. The molecule possesses no observable dipole moment (16) and it is evident therefore that the electrical environment of the chlorine is highly symmetric: hence a slow rate of quadrupole relaxation would be expected.

The F^{19} n.m.r. spectrum of perchloryl fluoride has previously been recorded by Brownstein (17) and by Agahigian *et al.* (18). Both authors found the F^{19} resonance at room temperature to have a broad, poorly resolved doublet-like structure. Brownstein interpreted the spectrum using a rough qualitative treatment only.

The F^{19} n.m.r. spectrum of perchloryl fluoride recorded at six temperatures over the range −131° C to 24° C is shown in Fig. 4. The theory given above can be used to inter-

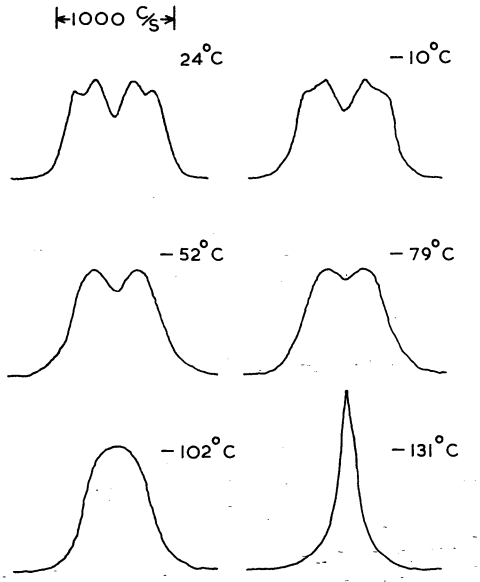

FIG. 4. F^{19} resonance spectra of liquid ClO_3F.

pret these spectra. This task is complicated by the fact that two chlorine isotopes are present, both with spin 3/2. We have therefore considered the ClO_3F spectrum as the sum of two spectra: one due to the molecule $Cl^{35}O_3F$ and the other to the molecule $Cl^{37}O_3F$. The equation to describe this system takes the form

$$I(ClO_3F) = I(Cl^{35}O_3F)+I(Cl^{37}O_3F)$$

and therefore

$$I(ClO_3F) \propto A_{35}\tau_{35}f(\eta_{35},x_{35})+A_{37}\tau_{37}f(\eta_{37},x_{37}),$$

where

$$A_{35} = \text{relative abundance of } Cl^{35}$$
$$A_{37} = \text{relative abundance of } Cl^{37}$$
$$\eta_{35} = 2\pi J_{35}\tau_{35}$$
$$\eta_{37} = 2\pi J_{37}\tau_{37}$$
$$x_{35} = \frac{\omega_0-\omega}{2\pi J_{35}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and $$x_{37} = \frac{\omega_0 - \omega}{2\pi J_{37}}$$

Since $$\frac{J_{35}}{J_{37}} = \frac{\mu_{35}}{\mu_{37}}$$

in this case, where μ_{35} and μ_{37} are the magnetic moments of the Cl nuclei, it follows that

$$x_{37} = \frac{\mu_{35}}{\mu_{37}} x_{35}.$$

Assuming that the electrical asymmetries (eq) and the correlation times (τ_q) are the same for both molecules, and applying equation [6], we obtain

$$\tau_{37} = \left(\frac{Q_{35}}{Q_{37}}\right)^2 \tau_{35}$$

and $$\eta_{37} = \frac{\mu_{37}}{\mu_{35}} \left(\frac{Q_{35}}{Q_{37}}\right)^2 \eta_{35}$$

Substituting the known values (4) for μ and Q, the final expression for the line shape becomes

[13] $$I(ClO_3F) \propto f(\eta_{35}, x_{35}) + .537\, f(1.371\eta_{35}, 1.201x_{35})$$

where $f(\eta,x)$ is given in equation [11].

Equation [13] was evaluated at small intervals of x over the range $x = 0 \rightarrow x = 3.0$ for different values of η_{35}. The calculated line shape for $\eta_{35}^2 = 5.15$, showing the individual contributions of the two isotopes, is reproduced in Fig. 5. This was the closest fit that could

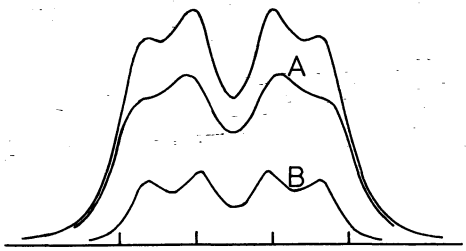

FIG. 5. Calculated line shape for $\eta_{35}^2 = 5.15$, showing the individual contributions of the two isotopes, Cl^{35} (A) and Cl^{37} (B), and their sum. The vertical lines indicate the positions of the Cl^{35} quartet in the absence of quadrupole relaxation.

be obtained for $T = 24°$ C. The splitting between the inner peaks in the experimental spectrum at this temperature was observed to be 289±5 c.p.s. From a comparison of the observed and calculated spectra a value of $J_{Cl^{35}F} = 278 \pm 5$ c.p.s. was obtained. Using this value and by comparing experimental and calculated spectra, values for τ_{35} at each temperature were found.

A plot of log τ_{35} vs. $1/T$ is shown in Fig. 6. It is a reasonably good straight line with a slope corresponding to an activation energy of approximately 1.0 kcal/mole. This energy is less than the corresponding activation energy for any of the 12 nitrogen compounds studied by Moniz and Gutowsky (11). Such a result is expected for perchloryl fluoride, due to the high symmetry and relatively small size of the molecule.

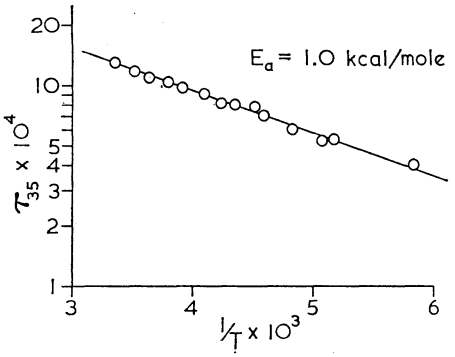

FIG. 6. The temperature dependence of the Cl^{35} τ estimated from the F^{19} resonance of liquid ClO_3F.

EXPERIMENTAL

The boron trifluoride used was obtained from Matheson of Canada, Ltd., Whitby, Ontario. The gas was distilled into 5 mm O.D. silica n.m.r. tubes on a vacuum line and the tubes sealed off under vacuum. The samples were gaseous at room temperature, but condensed to give an adequate volume of liquid for n.m.r. studies at temperatures from −17° C to −25° depending on the pressure of the sample.

Perchloryl fluoride was obtained from Pennsalt Chemicals Corporation, Philadelphia 2, Pa. The gas was distilled into 5 mm O.D. pyrex n.m.r. tubes and the tubes were sealed under vacuum. The compound was a liquid at room temperature under its own vapor pressure (about 12 atm at 24° C). Spectra of ClO_3F were obtained with non-spinning samples, because at the high power level required to observe the F^{19} resonance (50 db below 0.5 w) the noise induced by spinning the sample actually decreased resolution.

The fluorine n.m.r. spectra were obtained using a Varian Associates' high resolution n.m.r. spectrometer and electromagnet operating at a frequency of 56.4 Mc/sec. B^{11} n.m.r. spectra were obtained at 10.3 Mc/sec. The spectra were calibrated using audio sidebands generated with a Muirhead Wigan D-890-A Decade Oscillator.

The low temperature F^{19} studies were performed using a Varian V-4340 variable temperature n.m.r. probe cooled by means of cold air from a liquid air boiler. A copper–constantan thermocouple and a Leeds and Northrup No. 8692 temperature potentiometer were used to measure the sample temperature. After each change in temperature, about one half hour was allowed for thermal equilibrium to be reached. The temperature of the sample was maintained constant to ±0.5° C while each spectrum was recorded.

The mathematical expressions for the line shapes were evaluated using a Bendix G-15 computer.

ACKNOWLEDGMENTS

We thank the Directorate of Chemical Sciences of the United States Air Force Office of Scientific Research for financial support of this work. One of us (J.W.Q.) thanks the National Research Council of Canada for the award of a Studentship.

TETRAHYDROFURANS

II. SPIRO COMPOUNDS CONTAINING THE TETRAHYDROFURAN RING

B. K. Wasson, J. A. Kernan, and J. M. Parker
Research Laboratories, Charles E. Frosst and Co., Montreal, Que.

Received June 26, 1963

ABSTRACT

2-Allyl-2-methallyl-1,3-propanediol (IV) and 2,2-dimethallyl-1,3-propanediol (V) were cyclized in the presence of mineral acid to give 3,3,8-trimethyl-2,7-dioxaspiro(4.4)nonane (VIII) and 3,3,8,8-tetramethyl-2,7-dioxaspiro(4.4)nonane (IX), respectively. Similarly, 2-methallyl-2-(3-methyl-2-butenyl)-1,3-propanediol (VI) afforded 3,3,8,8-tetramethyl-2,7-dioxaspiro(4.5)decane (X). The diol VI was derived from diethyl methallylmalonate by condensation with 3-methyl-2-butenyl bromide, followed by reduction of diethyl methallyl(3-methyl-2-butenyl)malonate (III) with lithium aluminum hydride. The assigned structures of the spiro compounds were supported by infrared and nuclear magnetic resonance spectral analyses.

DISCUSSION

In a previous paper (1), the synthesis of 2,2-dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (VII) from 2-allyl-2-methallyl-1,3-propanediol (IV) was described. It was noted that during the distillation of VII a forerun contained material which exhibited no infrared absorption for the primary hydroxyl groups or the terminal double bonds present in IV and VII. It would appear that further cyclization occurred between the allyl and

IX

X

the hydroxymethyl group of VII affording the bicyclo compound 3,3,8-trimethyl-2,7-dioxaspiro(4.4)nonane (VIII). This has now been confirmed. A sample of VII was heated 20 hours on the steam bath with concentrated hydrochloric acid to afford an excellent yield of VIII. Furthermore, VIII was obtained directly in high yield when IV was treated with 0.6 molar equivalents of concentrated hydrochloric acid.

A search of the literature failed to reveal a prior synthesis of methylsubstituted-2,7-dioxaspiro(4.4)nonanes. The Patterson, Capell, and Walker Ring Index (2) lists the parent 2,7-dioxaspiro(4.4)nonane but the actual reference (3) described the preparation of the dilactone 1,6-dioxo-2,8-dimethyl-2,7-dioxaspiro(4.4)nonane by treatment of diallylmalonic acid with hydrobromic acid.

3,3,8,8-Tetramethyl-2,7-dioxaspiro(4.4)nonane (IX), a second member of this series, has now been prepared in excellent yield by the acid-induced ring-closure of 2,2-dimethallyl-1,3-propanediol (V). The diol V was obtained by reduction (4) of diethyl dimethallylmalonate (II) with lithium aluminum hydride (5). The ring-closure was vigorously exothermic, even with only a trace of acid present, requiring a solvent to modify the reaction temperature. This confirms the greater activity of the methallyl double bond over that of the allyl double bond. It has already been shown (1) that a molecule containing a methallyl group and a hydroxymethyl group attached to the same carbon atom will condense, according to Markownikoff's rule, to form a tetrahydrofuran rather than a tetrahydropyran ring. Therefore, during the cyclization of 2,2-dimethallyl-1,3-propanediol (V) two tetrahydrofuran rings are formed yielding the 2,7-dioxaspiro(4.4)nonane ring system.

Investigation of the above cyclization was extended to include one member of the methylsubstituted-2,7-dioxaspiro(4.5)decanes. The preparation of 3,3,8,8-tetramethyl-2,7-dioxaspiro(4.5)decane (X) was accomplished by treating the sodio derivative of diethyl methallylmalonate with 3-methyl-2-butenyl bromide to give diethyl methallyl-(3-methyl-2-butenyl)malonate (III). Reduction of III with lithium aluminum hydride afforded 2-methallyl-2-(3-methylbutenyl)-1,3-propanediol (VI) and acid treatment of VI gave X. The crystalline dicarbamate was obtained from VI in high yield.

No information is available concerning the methyl derivatives of 2,7-dioxaspiro(4.5) decane. The literature of related compounds is very scanty, however, one reference (6) was discovered which described a ketolactone, 9,9-bis(hydroxymethyl)-2,7-dioxaspiro-(4.5)decane-3,10-dione. 3,3,8,8-Tetramethyl-2,7-dioxaspiro(4.5)decane (X) represents the first member of this series to be synthesized. The structure X was assigned rather than the isomeric 3,3-dimethyl-8-isopropyl-2,7-dioxaspiro(4.4)nonane or 3,9,9-trimethyl-2,8-dioxaspiro(5.5)undecane, since the ring-closure between the 3-methyl-2-butenyl- and hydroxymethyl groups would follow the normal Markownikoff rule of addition.

Assignment of structures to the cyclized products was supported by infrared absorption and nuclear magnetic resonance (n.m.r.) data. The cyclization of each of the three diols, IV, V, and VI, to the dioxaspiro compounds, VIII, IX, and X, required an increase in the number of methyl groups, the formation of cyclic ether, and the loss of terminal unsaturation and of hydroxyl groups. An inspection of the infrared spectra of IV, V, VI, VIII, IX, and X showed that these changes did occur. They were exhibited by the appearance of a doublet (*gem*-dimethyl) in the 7.25–7.35 μ region in place of the single band at 7.3 μ attributed to each starting diol, by the loss of the two bands at 3.25 and 6.1 μ (terminal unsaturation), the loss of the band at 11.2 μ (methallyl), the absence of the band at 10.95 μ (allyl) from the spectrum of VIII which was originally present in that of IV, the loss of the band at 3 μ (hydroxyl) and the shifting and narrowing of the

For personal use only.

9.6–9.8 μ band (hydroxyl) to 9.5 μ (cyclic ether) (7). In addition, the spectra of VIII, IX, and X possessed a strong band at 12.9–13.0 μ (believed to be *gem*-dimethyl). The infrared spectrum of X showed a strong band at 9.25 μ. This was attributed to the C—O vibration in the tetrahydropyran ring, since the C—O vibration for the tetrahydrofuran ring occurred at 9.5 μ for VIII, IX, and X. It is believed that the above-described cyclizations have general application and will be discussed in future publications.

Nuclear magnetic resonance data, given for 3,3,8-trimethyl-(VIII) and 3,3,8,8-tetramethyl-2,7-dioxaspiro(4.4)nonanes (IX) in the experimental section, has proved that only tetrahydrofuran rings were formed to provide spiro compounds containing methyl groups. Similarly the n.m.r. spectrum of X confirmed the presence of the 2,7-dioxaspiro-(4.5)decane skeletal system containing one tetrahydrofuran and one tetrahydropyran ring. Since this spectrum has shown that neither two tetrahydrofuran nor two tetrahydropyran rings were present, the two alternate isomeric structures 3,3-dimethyl-8-isopropyl-2,7-dioxaspiro(4.4)nonane and 3,9,9-trimethyl-2,8-dioxaspiro(5.5)undecane are eliminated.

3,3,8-Trimethyl-2,7-dioxaspiro(4.4)nonane (VIII) was effective as an anticonvulsant. The pharmacological activities of the 2,7-dioxaspiro(4.4)nonanes and the 2,7-dioxaspiro-(4.5)decanes will be reported elsewhere.

EXPERIMENTAL

Boiling points and melting points (Fisher–Johns apparatus) are uncorrected. Analytical samples of liquids were prepared by distillation through a 24-in., 8-mm diameter Nester and Faust spinning band column. Infrared absorption spectra were obtained with a Beckman IR-5 spectrophotometer equipped with a sodium chloride prism. Solids were examined as potassium bromide pellets, and liquids as thin films. The n.m.r. spectra were taken on a Varian 60 Mc high resolution spectrophotometer. In all cases integration of areas was carried out and the number of protons corresponding to each signal is indicated. Values are given in parts per million (p.p.m.) with tetramethylsilane used as the standard.

Preparation of Diethyl Mono- and Di-substituted Malonates

Diethyl methallylmalonate and diethyl allylmethallylmalonate (I) were prepared by standard methods from the literature (5). Methallyl chloride and diethyl methallylmalonate afforded diethyl dimethallylmalonate (II) in an 80% yield, b.p. 153–158° at 15–20 mm. 3-Methyl-2-butenyl bromide and diethyl methallylmalonate gave diethyl methallyl(3-methyl-2-butenyl)malonate (III) in an 84% yield. Redistillation afforded an analytical sample, b.p. 149–150° at 14 mm, n_D^{25} 1.4581. Anal. Calc. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28. Found: C, 67.67; H, 9.14. Infrared: λ_{max} 3.25, 6.1 (terminal unsaturation), 5.75 (carbonyl), 7.25–7.32 (methyl), 8.3–8.5 (ester), 11.15 μ (methallyl).

Preparation of 3,3,8-Trimethyl-2,7-dioxaspiro(4.4)nonane (VIII)

Method A

From 2,2-Dimethyl-4-allyl-4-hydroxymethyltetrahydrofuran (VII).—Distilled VII (25 g) was treated dropwise with 6.5 ml of concentrated hydrochloric acid. The temperature of the reaction mixture rose from 25° to 35° and was accompanied by faint discoloration. The mixture was allowed to stand for 30 minutes and was warmed overnight on a steam bath. After it had been cooled, the reaction mixture was made alkaline with 6 *N* sodium hydroxide and extracted with ether. The ethereal extract was washed with water, dried, and evaporated to give 23 g of a liquid residue. Distillation of this residue afforded 20.8 g (83%) of VIII, b.p. 68–74° at 6–8 mm, n_D^{25} 1.4439. An analytical sample had a boiling point of 70.5–71.0° at 6 mm, n_D^{25} 1.4436. Anal. Calc. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66. Found: C, 70.29; H, 10.64. The infrared spectrum of VIII showed the presence of two bands in the methyl region and the absence of bands associated with unsaturation and hydroxyl groups. N.m.r. signals: multiplet centered at 3.60 p.p.m. (—CH—O—CH_2—C—CH_2—O—, area = 5H), multiplet centered at 1.77 p.p.m. (—C—CH_2—C—CH_2C—, area = 4H), triplet at 1.20, 1.16, 1.10 p.p.m. (methyls, area = 9H).

Method B

From 2-Allyl-2-methallyl-1,3-propanediol (IV).—Distilled IV (25 g) was treated with 6.5 ml of concentrated hydrochloric acid. The temperature of the cooled solution rose rapidly to 80°. The reaction mixture was warmed 7 hours on the steam bath and was worked up as described in method A. Distillation afforded 20.2 g (81%) of VIII, b.p. 77–83° at 8–10 mm, n_D^{25} 1.4438. The infrared absorption of this product was identical with that from the product obtained by method A.

Preparation of 2,2-Dimethallyl-(V) and 2-Methallyl-2-(3-methyl-2-butenyl)-1,3-propanediol (VI)

A solution of 214.5 g of diethyl dimethallylmalonate (II) in 500 ml of anhydrous ether was added dropwise to a vigorously stirred mixture of 45.6 g of lithium aluminum hydride in 1250 ml of anhydrous ether maintained at 5–20°. The reaction mixture was stirred for 2 hours, cooled, and decomposed by successive additions of methanol–ether, methanol–water, and water. The solids were triturated several times with ether. The combined ethereal extracts were washed with water and evaporated to give an oily residue. Distillation of this residue afforded 136.5 g (93%) of V, b.p. 162.5–172° at 15–20 mm. Infrared: λ_{max} 3.0 (hydroxyl), 3.25, 6.1 (terminal unsaturation), 9.6–9.8 (hydroxyl), 11.2 μ (methallyl).

A similar reduction of diethyl methallyl(3-methyl-2-butenyl)malonate (III) with lithium aluminum hydride gave a 94% yield of VI, b.p. 148–165° at 9 mm, which crystallized as white needles, m.p. 54.5–55.0°. Anal. Calc. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18. Found: C, 72.74; H, 11.22. Infrared: λ_{max} 3.0 (hydroxyl), 3.22, 6.1 (terminal unsaturation), 6.9 (methylene), 7.25 (methyl), 9.5–9.8 (hydroxyl), 11.25 μ (methallyl). The dicarbamate of VI was prepared (1) in an 85% yield as white crystals, m.p. 140.5–146°. Recrystallization from aqueous methanol afforded an analytical sample having a melting point of 145–146°. Anal. Calc. for $C_{14}H_{24}N_2O_4$: C, 59.13; H, 8.51; N, 9.85. Found: C, 59.17; H, 8.24; N, 9.95. Main infrared bands: λ_{max} 2.93, 2.97, 5.9, 6.25, 7.1, 7.45, 9.4, 11.1, and 12.75 μ.

Preparation of 3,3,8,8-Tetramethyl-2,7-dioxaspiro(4.4)nonane (IX)

A solution of 83.9 g of the diol V in 59.5 ml of tetrahydrofuran was treated with 1.9 ml of concentrated hydrochloric acid. The temperature of the solution rose spontaneously to 60°. The solution was cooled, left 1 hour at room temperature, and refluxed for 2 hours. The solvent was evaporated and the residue dissolved in ether. The ethereal solution was washed with dilute alkali, then with water, and dried. The solvent was evaporated to give 73.7 g of a pale yellow residue. Distillation of this residue afforded 68.3 g (81%) of IX, b.p. 115–121° at 21 mm. An analytical sample of IX had a boiling point of 109–110° at 30–31 mm, n_D^{25} 1.4404. Another specimen had a boiling point of 207.5–208° at atmospheric pressure. Anal. Calc. for $C_{11}H_{20}O_2$: C, 71.69; H, 10.94. Found: C, 72.05, 72.13; H, 11.43, 11.19. The infrared spectrum of IX showed the absence of unsaturation and of hydroxyl groups and the presence of two bands in the methyl region. N.m.r. signals: quartet centered at 3.73 p.p.m. (—O—CH_2—C—CH_2—O—, area = 4H), 1.81 p.p.m. (C—CH_2—C—CH_2—C—, area = 4H), doublet at 1.19 and 1.16 p.p.m. (methyls, area = 12H).

Preparation of 3,3,8,8-Tetramethyl-2,7-dioxaspiro(4.5)decane (X)

A solution of 30 g of the diol VI in 110 ml of tetrahydrofuran was treated dropwise during 15 minutes with 28 ml of 6 *N* hydrochloric acid. The temperature of the solution rose from 22° to 33°. The solution was refluxed for 3 hours and the solvents evaporated to give 31.9 g of crude X. An analytical sample had a boiling point of 94.0–94.5° at 6 mm, n_D^{25} 1.4505. Anal. Calc. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18. Found: C, 72.66; H, 11.14. The infrared spectrum indicated the absence of unsaturation and hydroxyl groups and the presence of methyl groups (7.25, 7.35 μ). N.m.r. signals: quartet centered about 3.63 and 3.41 p.p.m. (—O—CH_2—C—CH_2—O—, area = 4H), multiplet centered at 1.50 p.p.m. (—C—CH_2—CH_2—C—CH_2—C—, area = 6H), doublet at 1.17 and 1.12 p.p.m. (methyls, area = 12H).

A NEW TYPE OF CARBOHYDRATE ORTHOESTER

SIDE REACTIONS OF THE KÖNIGS-KNORR SYNTHESIS[1]

C.-S. GIAM,[2] H. R. GOLDSCHMID,[3] AND A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received August 6, 1963

ABSTRACT

A trisaccharide orthoester (IV) is one of the products formed by decomposition of 2,3,4,6-tetra-*O*-acetyl α-D-mannopyranosyl bromide in the presence of silver oxide. This new type of carbohydrate derivative contains three units of D-mannose linked together through the functional groups of a molecule of acetoacetic acid. The carboxyl group of the latter takes part in the orthoester structure of IV, with one D-mannose unit closing a 1,2-orthoester ring, and another unit comprising the —OR group through its anomeric center; the keto group of the acetoacetate forms a 1,2-ketal structure with the third D-mannose unit. The n.m.r. spectra characteristics of the trisaccharide and some related compounds are described. The following sequence of reactions is consistent with formation of the trisaccharide: 1,2-*trans*-acetoxyl bromide $\xrightarrow{Ag^+}$ 1,2-cyclic acetoxonium ion (IX) $\xrightarrow{-H^+}$ 1,2-cyclic ketene-acetal; ion IX and 2,3,4,6-tetra-*O*-acetyl D-mannose then added to the ketene derivative.

Selective degradation of trisaccharide IV yields a novel type of ketal, i.e., 1,2,*O*-[1-(carbomethoxymethyl)-ethylidene]-β-D-mannose.

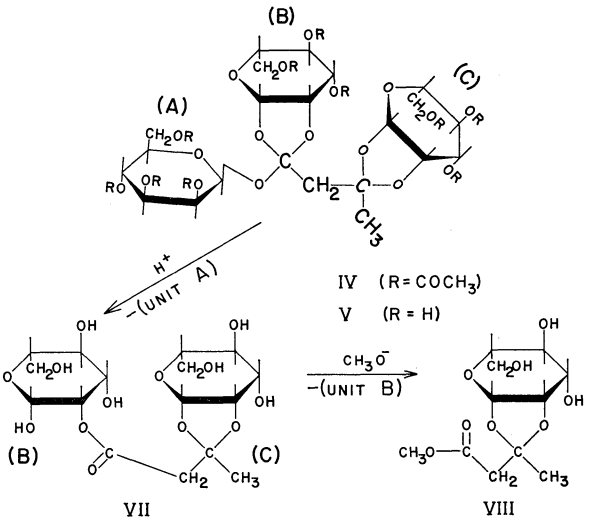
Glycosyl halides decompose readily in the presence of silver oxide or carbonate under conditions generally used for the Königs-Knorr synthesis (1) of glycosides and oligosaccharides (2). This "side reaction" therefore adversely affects the yield of the desired condensation product, particularly when formation of the glycosidic linkage involves an unreactive hydroxylic component. Several products have been isolated (2) from a reaction mixture of 2,3,4,6-tetra-*O*-acetyl α-D-mannopyranosyl bromide (I) and silver oxide in benzene, including 2,3,4,6-tetra-*O*-acetyl D-mannose (II) and a 1,2,1′-linked disaccharide orthoacetate heptaacetate (III). Also isolated, in 10% yield, was a product (IV) which appeared to be a second dimeric orthoester. This last product has now been found to be a novel type of trisaccharide, the structure of which is represented by formula IV. It contains three units of D-mannopyranose linked together through the functional groups of a molecule of acetoacetic acid (the carbon chain of which is shown in heavy type). The carboxyl group of the acid and two D-mannose units (A and B) are combined in the form of a 1,2,1′-orthoester structure, and a 1,2-ketal structure serves to bind the ketone group with the third D-mannose unit (C). Evidence for the structure proposed is presented below.

Deacetylation of IV yielded a crystalline material (V) which on reacetylation, with acetic anhydride – pyridine or – sodium acetate, afforded the original product (IV). In this way a more highly purified sample of IV was obtained, as shown by an increase in the estimated molecular weight from the earlier value (2) of 700 to the value of about 1000 required by the trimeric structure. This procedure showed also that none of the interunit linkages was of the normal ester type. On methylation of V a crystalline derivative (VI) was obtained which on methanolysis gave a 2:1 mixture of 3,4,6-tri- and 2,3,4,6-tetra-*O*-methyl methyl glycoside. When V was treated with lead tetraacetate in pyridine

[1]*Presented before the Division of Organic Chemistry, Chemical Institute of Canada, Toronto, June 8, 1963. Issued as N.R.C. No. 7600.*

[2]*National Research Council of Canada Postdoctoral Fellow, 1962–1963.*

[3]*National Research Council of Canada Postdoctoral Fellow, 1958–1960.*



(3, 4), it consumed 4.9 moles of oxidant per mole in 1.5 hours, this uptake being consistent with the presence of four *vic*-diol groups and the release of about 1 mole of formic acid, as seen from comparative oxidations of orthoesters of known structure (5, and experimental section).

Compounds IV and V showed the marked acid-lability of orthoesters (6). As found with other 1,2-orthoesters of D-mannose triacetate, IV was rapidly degraded in cold acidic methanol yielding 3,4,6-tri-*O*-acetyl D-mannose, among other products (2). Treatment of V with dilute sulphuric acid resulted in the release of D-mannose (presumably unit A), and also the formation of an amorphous ester the properties of which correspond to those of structure VII. Both of these products are to be expected from the hydrolysis of V, by analogy with the known behavior of mono- and di-saccharide D-mannose orthoesters (6, 7). A second D-mannose unit (presumably B) was then liberated on addition of sodium methoxide to VII, and the methyl ester of ketal VIII was isolated and characterized as a crystalline triacetate.*

Evidence for the presence of the acetoacetate structure in trisaccharide IV was obtained first by the isolation of acetone from an acid hydrolyzate of the deacetylated material (V). Although acetoacetic acid is very easily decarboxylated to yield acetone, the well-known ethyl ester appears to be substantially more stable, and direct evidence for the acetoacetate moiety was provided by ethanolysis of IV. Ethyl acetoacetate produced in this way was detected in 38% yield by gas–liquid phase chromatography, and characterized as the dinitrophenylhydrazone.

Proton magnetic resonance characteristics of IV and V are consistent with the structures proposed. For example, three non-equivalent anomeric proton signals are evident in the region 5.0 to 6.0 p.p.m. (9) (Figs. 1A and 2A). Other signals in this region are due to protons located α- to secondary acyloxy groups, as shown by their absence from the spectrum of the deacetylated compound (V) (Fig. 2A). The doublet at about 5.7 p.p.m. is close to that expected for the anomeric proton of a D-mannose 1,2-orthoester (5), and is

**Cyclic ketals of type VIII have not been prepared previously. Although analogous ketal derivatives are formed readily by acid-catalyzed condensation, the reaction of acetoacetate and other β-keto esters with a sugar leads under similar conditions to elimination of an extra mole of water and the formation of a 2-substituted furoic acid derivative, the heterocyclic ring of which incorporates C-1 and C-2 of the sugar (8).*

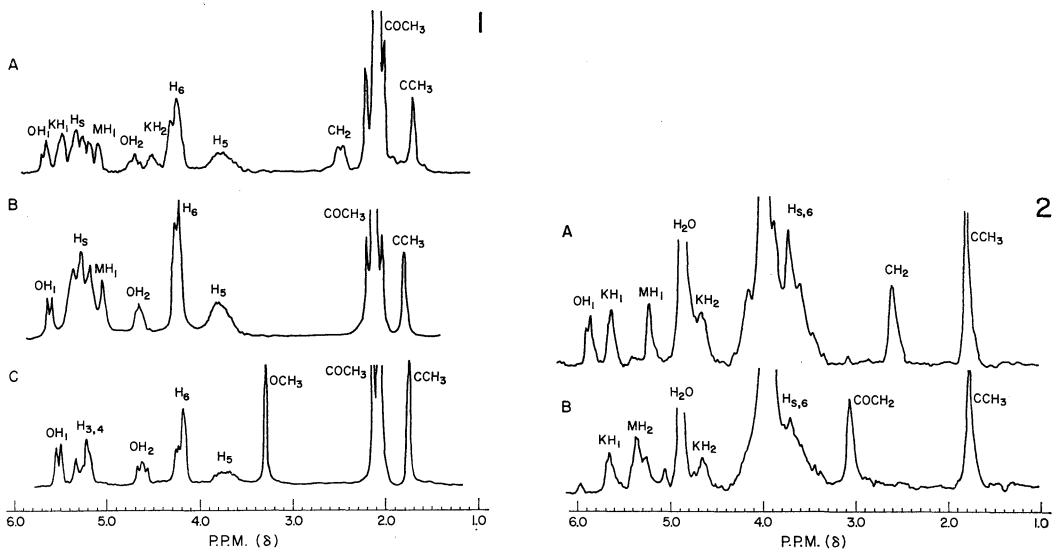

FIG. 1. Proton magnetic resonance spectra (chloroform solution) of (A) trisaccharide acetate IV; (B) disaccharide acetate III; (C) β-D-mannose-1,2-(methyl orthoacetate) 3,4,6-triacetate (*exo*-diastereomer (5)). OH, proton of orthoester unit; KH, proton of ketal unit; MH, proton of mannosyl unit; H_s, proton on secondary carbon atoms.

FIG. 2. Proton magnetic resonance spectra (deuterium oxide solution) of (A) trisaccharide V; (B) hydrolysis product VII. OH, proton of orthoester unit; KH, proton of ketal unit; MH, proton of mannosyl unit; H_s, protons on secondary carbon atoms.

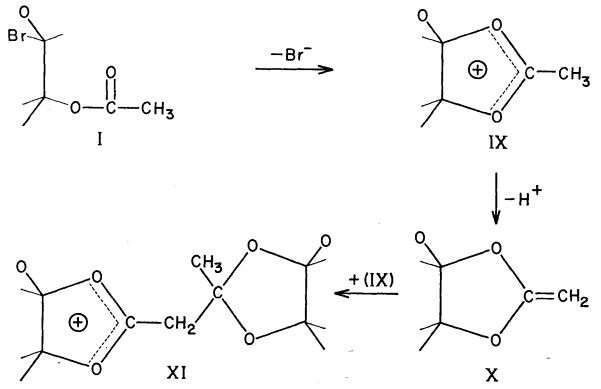
ascribed to H_1 of unit B(OH_1); this assignment is supported by the fact that when acid is added to a solution of V, the signal (OH_1, Fig. 2A) disappears and is replaced by a doublet at lower field (MH_2 in Fig. 2B). The same properties are shown by D-mannose 1,2-orthoacetates on acid hydrolysis (7) and are consistent with opening of the 1,2-orthoester ring of unit B and formation of an *O*-acyl derivative (VII). The doublet (Fig. 1A) having a chemical shift of about 5.5 p.p.m. is ascribed to the anomeric proton (KH_1) of the 1,2-ketal unit, since it is affected neither by deacetylation (Fig. 2A) nor by the acid treatment (Fig. 2B). Although the one-proton signal at 5.1 p.p.m. (Fig. 1A) is not disturbed by removal of neighboring acetyl groups (Fig. 2A), it may no longer be detected after acid hydrolysis (Fig. 2B), and hence can be ascribed to the anomeric proton (MH_1) of the D-mannosyl unit.

Presence of the C-methyl group in IV and V is clearly evident in the three-proton signal at about 1.8 p.p.m., and of the methylene group, in the two-proton signal at about 2.6 p.p.m. (Figs. 1A and 2A). Although the chemical shift for the C-methyl group is the same as that for the C-methyl group of the dimeric orthoacetate (III) (Fig. 1B), it is not materially affected by acid (Fig. 2B) and hence is not indicative of an *orthoacetate* structure in IV and V. By contrast, the acid hydrolysis results in a considerable paramagnetic shift in the signal for the methylene protons (Fig. 2B), consistent with generation of a carbonyl group α- to the methylene on formation of VII from V. In VI, the *O*-acyl linkage likely is through the 2-position of the D-mannose unit, by analogy with the hydrolysis of D-mannose 1,2-orthoacetates to 2-*O*-acetyl D-mannose (7). Thus signal MH_2 (Fig. 2B) which becomes detectable after hydrolysis is closely equivalent to that of H_2 in the *O*-acetate (7), but probably is at relatively too high field for a 1-*O*-acyl derivative (9).

A possible route to formation of IV, consistent with generally-accepted mechanisms,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

could be as follows: on dissociation of the 1,2-*trans*-acyl bromide (I), participation of the 2-*O*-acetyl group leads to the cyclic 1,2-carbonium ion (IX) (10, 11) which, by loss of a proton, may give the cyclic ketene-acetal (X) (12, 13). The latter can then suffer electrophilic attack by IX, as in the normal addition reactions of ketenes and related ketene-acetals (14), with elaboration of the four-carbon chain of the acetoacetate portion (e.g., as in XI). Addition of the elements of a tetra-*O*-acetyl D-mannosyloxy residue to the electron-deficient center of XI then leads to completion of the trimeric structure IV.



Most probably, the latter step involves 2,3,4,6-tetra-*O*-acetyl D-mannose (II), a major constituent of the reaction mixture (2).

The stereochemistry of three asymmetric centers in the trisaccharide remains to be considered, i.e., of the tertiary carbons in the orthoester and ketal rings and of the D-mannosyl anomeric carbon. The 1,2-orthoester unit appears to be related sterically to the corresponding unit of the disaccharide orthoacetate (III) and to D-mannose 1,2-orthoacetates in which the OR group is thought to be oriented *exo-* to the fused ring system (5). Thus, as noted earlier, protons OH_1 and OH_2 of the trisaccharide (Fig. 1A) are closely equivalent to those of the pertinent diastereoisomeric methyl derivative (Fig. 1C) and of the disaccharide (Fig. 1B). Hence, insofar as the assignment of an *exo*-orientation for the —OR group of the mono- and di-saccharide orthoesters is valid (5), the same orientation may be tentatively assigned for the orthoester structure of the trisaccharide. An *exo*-orientation for the mannosyloxy residue in IV and II is favored also on kinetic grounds, since a group of this magnitude in attacking X or XI is more likely to approach from the side *exo-*, rather than *endo-*, to the fused ring structure (15). Consistent with this possibility is the apparent absence of isomers of the tri- and di-saccharide in the reaction mixture, making it likely that diastereoisomers of only one type predominate.

The molecular rotation of the disaccharide (III) (M_D −16,000), when compared with additive M_D values (16, 17) for β-D-mannose 1,2-(methyl orthoacetate) 3,4,6-triacetate (having −OR *exo* (5)) and penta-*O*-acetyl β-D-mannopyranose (−7860 − 9840 = −17,700) or penta-*O*-acetyl α-D-mannopyranose (−7860 + 21,470 = +13,600) is strongly indicative of a β-configuration for the D-mannosyl unit.* A similarly strongly negative M_D value for the trisaccharide (IV) (−29,200) is clearly consistent with a β-configuration for the D-mannosyl unit in this compound as well. Allowance for the rotatory contribution

**The additive M_D value for the syrupy —OR endo-diastereoisomer of the methyl orthoacetate (5) and penta-O-acetyl-β-D-mannopyranose (+ 4350 − 9840 = − 5490) is less satisfactory than if the —OR exo-orientation is considered.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by the third, ketal, unit is provided by degradation product VIII. The sum of the molecular rotations for VIII, β-D-mannose pentaacetate and the pertinent methyl 1,2-orthoacetate (−1370 − 9840 − 7860 = −19,070) is then in reasonable agreement with the observed value for IV.

The absence of model compounds having a closely related type of structure eliminates the possibility at present for considering the relative orientation of the C-methyl and C-methylene groups of the cyclic 1,2-ketal structure.

A further item of note in the n.m.r. spectrum of IV is the splitting of the signal for the methylene protons. This inference of restricted rotation about the carbon–carbon bonds involving the methylene group is not unexpected, in view of the presence of three bulky groups in close proximity. However, splitting of the methylene protons' signal is not detected in the spectrum of the deacetylated material, although its absence may be due here to inadequate resolution or, perhaps, to solvent effects. The chemical shift for the methylene group in IV or V also may be noted. In the absence of adjacent free carbonyl groups its location is at relatively high field (2.45 p.p.m.). On release of the carboxyl–carbonyl group by hydrolysis of V to VII a paramagnetic shift of 0.6 p.p.m. is observed, as noted above. With both carbonyl groups present, i.e., in acetoacetate itself, the chemical shift for the methylene group is found an additional 0.5 p.p.m. towards lower field (at 3.5 p.p.m.).

EXPERIMENTAL

Melting points are corrected. Optical rotations were measured at 25±2° C. Evaporations were carried out *in vacuo* at 40–45° C. The n.m.r. spectra were prepared with a Varian A-60 high-resolution spectrometer. The concentration of solute was generally about 10%, and tetramethylsilane was used as the reference standard internally (for chloroform) or externally (for deuterium oxide).

Trisaccharide IV

Penta-*O*-acetyl α-D-mannopyranose (17.1 g) in ethylene chloride (10 ml) was treated for 12 hours with hydrogen bromide in acetic acid (35 ml, 30–35%). Benzene (100 ml) was added, the solution was washed thoroughly with ice water and cold sodium bicarbonate, and dried with anhydrous calcium sulphate. This crude preparation of 2,3,4,6-tetra-*O*-acetyl α-D-mannosyl bromide (I) was added to a suspension of silver oxide (50 g) and anhydrous calcium sulphate (90 g) in sodium-dried benzene (100 ml), the mixture was shaken for 12 hours, filtered, and the filtrate concentrated. The syrupy residue, on being taken up in ethanol–ether, deposited a white powder (1.2 g), m.p. 198–201° C. Recrystallized from acetone–hexane, the product had m.p. 213–215° C, undepressed by admixture with IV prepared from crystalline I; $[\alpha]_D$ −29° (*c*, 1, $CHCl_3$). Calculated for $C_{42}H_{56}O_{28}$: C, 50.00%; H, 5.59%; acetyl, 43.5%; C-methyl, 27.2%; mol. wt., 1008. Found: C, 50.09%; H, 5.57%; acetyl, 42.8%; C-methyl, 27.5%; mol. wt., 980 (by thermometric vapor pressure measurement in acetone solution of a sample prepared by acetylation of V). The n.m.r. spectrum is reproduced in Fig. 1A.

Deacetylated Trisaccharide (V)

Compound IV was deacetylated catalytically with sodium methoxide under reflux, as described previously (2), affording a crystalline product; m.p. 156–157° C, $[\alpha]_D$ −5.4° (*c*, 1.1, H_2O). Calculated for $C_{22}H_{36}O_{18}$: C, 44.90%; H, 6.18%; C-methyl, 4.6%. Found: C, 45.15%; H, 6.42%; C-methyl, 5.8%. The product obtained in another experiment was hygroscopic and, after equilibration with atmospheric moisture, had m.p. 180° C. Calculated for $C_{22}H_{36}O_{18}.H_2O$: C, 43.60%; H, 6.32%. Found: C, 43.68%; H, 6.42%. The n.m.r. spectrum is reproduced in Fig. 2A. On acetylation with acetic anhydride, using either pyridine or sodium acetate as catalyst, IV was regenerated as shown by mixed melting point tests.

Lead Tetraacetate Oxidation of V and Deacetylated III

Trisaccharide IV (15.6 mg) and disaccharide III (2) (12.0 mg) were each deacetylated catalytically in methanol, and the solutions were neutralized with carbon dioxide. After removal of the methanol, pyridine (3 ml) was added and the solution treated at 0° C with lead tetraacetate (50 mg) in pyridine (3 ml). The uptake of oxidant in moles/mole min) measured iodometrically as described elsewhere (4) was: 3.1 (10), 3.9 (50), and 4.9 (90) for the trimer; 2.3 (15), 3.1 (30), and 3.7 (80) for the dimer. Required for cleavage of four and three *vic*-diol groups (trisaccharide and disaccharide, respectively) and oxidation of 1 mole of formic acid released: 5 moles/mole and 4 moles/mole, respectively.

Methylated Trisaccharide (VI)

(*a*) To a solution of acetate IV (120 mg) in acetone (5 ml) potassium hydroxide (3 ml, 10%) and dimethyl sulphate (1 ml) were added slowly, excess of the alkali always being present. A second treatment with these reagents was then carried out, the solution was extracted with chloroform, and the extracted material was methylated twice with methyl iodide and silver oxide. The final syrupy product (60 mg) was found by thin-layer chromatography to contain three components, one of which corresponded to methyl tetra-*O*-methyl-D-mannoside and a second, travelling on the chromatogram at a rate expected for a methylated disaccharide. The third, slowest-moving, component (12 mg) was obtained in crystalline form from a solution of the mixture in hexane and, after recrystallization from ether–hexane, had m.p. 163–164° C. Calculated for $C_{32}H_{56}O_{18}$: C, 52.74%; H, 7.75%. Found: C, 52.51%; H, 7.72%.

(*b*) Product V (150 mg) was taken up in liquid ammonia (7 ml) and potassium was added until a stable blue coloration of the solution resulted. The ammonia was evaporated off, methyl iodide (5 ml) was added, the suspension was refluxed for 3 hours, and concentrated. This methylation treatment was repeated twice and the final syrupy product extracted into chloroform. Removal of the solvent afforded crystalline material (150 mg) which was recrystallized from *n*-hexane, m.p. 165–166° C, undepressed by admixture with the product described in section (*a*).

Methanolysis of VI

The methylated trisaccharide (5 mg) was refluxed with methanolic hydrogen chloride (0.6 ml, 1%) for 19 hours, excess ethereal diazomethane was added, and the solution was concentrated. The syrupy residue was examined by gas–liquid phase chromatography using temperature programming (50–205° C in 11 minutes), a column (8 ft × 1/4 in.) of ethylene glycol – *o*-phthalate (18) on firebrick (C-22, 60–80 mesh) (1:4.5) and helium as the carrier gas (60 ml/min). Only two methyl ethers were detected as significant components of the methanolyzate, their retention times being the same as those of methyl 2,3,4,6-tetra-*O*-methyl α-D-mannoside and methyl 3,4,6-tri-*O*-methyl α-D-mannoside. Using the known methyl ether methyl glycosides as standards the ratio of the two products was estimated to be 1:2. After acid hydrolysis of the methanolyzate, products corresponding to 2,3,4,6-tetra-*O*-methyl D-mannose and 3,4,6-tri-*O*-methyl D-mannose were detected by paper chromatography, the latter being readily oxidized by lead tetraacetate in acetic acid.

3,4,6-Tri-O-acetyl-1,2-O-[1-(carbomethoxymethyl)-ethylidene]-β-D-mannose (VIII)

Trisaccharide V was hydrolyzed with 0.1 *N* sulphuric acid yielding mannose and an amorphous product (VII), as described previously (2). The n.m.r. spectrum of the hydrolyzate is reproduced in Fig. 2B; the spectrum of isolated VII is closely similar, differing mainly in that the relative intensity of signals for secondary and C_6 protons (H_s, H_6) is lower than for that of the mixture. When treated with a slight excess of sodium methoxide in methanol, VII yielded mannose and a non-reducing product. (In the earlier experiment (2) two non-reducing products having closely similar R_F appeared to be detectable by paper chromatography.)

The latter product (99 mg), isolated as a syrup by preparative paper chromatography, was treated with acetic anhydride (3 ml) and sodium acetate (100 mg) for 1 hour on the steam bath, the reaction mixture was decomposed with ice-water, and benzene-extractable, neutral, material was recovered: yield, 130 mg of syrup. The latter, on being distilled (120–140° C at 0.01 mm, bath temperature) afforded a solid product which was recrystallized from *n*-hexane; m.p. 100.5–101.5° C, $[\alpha]_D$ −3.4 (*c*, 1.1, $CHCl_3$). Calculated for $C_{17}H_{24}O_{11}$: C, 50.49%; H, 5.98%; saponification equivalent, 101. Found: C, 50.64%; H, 6.08%; saponification equivalent, 100.

Formation of Acetone by Hydrolysis of IV

Trisaccharide IV (5 mg), suspended in 10% sulphuric acid (2 ml), was heated at 100° C for 1 hour under a stream of nitrogen, the effluent gas being passed through a solution of sodium bisulphite (2%). Color tests with sodium nitroprusside or salicylaldehyde on portions of the bisulphite solution were positive for the presence of acetone. On addition of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid to the bisulphite solution a crystalline precipitate was obtained, m.p. 124–126° C, indistinguishable by infrared spectroscopy and by paper chromatographic behavior from acetone-2,4-dinitrophenylhydrazone.

Ethyl Acetoacetate by Ethanolysis of IV

Trisaccharide IV (15 mg) was heated under reflux for 2 hours with ethanolic hydrogen chloride (0.1 ml, 5%). The solution was examined by gas–liquid phase chromatography, using a column (2 ft × 1/4 in.) of butanediol-succinate on Celite (1:6) (18), a column temperature of 108° C, and helium as the carrier gas (40 ml/min). A compound having the same emergence time as ethyl acetoacetate was detected; based on the chromatographic behavior of the authentic ester, the yield was found to be 38%.

Trisaccharide IV (0.54 g) was heated under reflux for 2 hours with ethanolic hydrogen chloride (4 ml, 5%). Ether (200 ml) was added to promote precipitation of methyl mannoside, the filtrate was concentrated to a small volume, and the residue treated with 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid. The acid solution was extracted with carbon tetrachloride, and a concentrate of the extract was chromatographed preparatively on thin layers of Silica Gel G (Stahl) using benzene (containing about 1.5% of ether). A major

For personal use only.

zone, corresponding to the hydrazone of ethyl acetoacetate (R_F 0.33) was extracted with ethanol, the extract affording crystalline material, m.p. 94–95° C, undepressed by admixture with the 2,4-dinitrophenylhydrazone of ethyl acetoacetate; the X-ray powder diagram was indistinguishable from that of the authentic specimen. A second zone, corresponding on the chromatogram to the acetone 2,4-dinitrophenylhydrazone (R_F 0.58), also was extracted with ethanol, affording acetone 2,4-dinitrophenylhydrazone, m.p. 126–127° C, undepressed.

ACKNOWLEDGMENTS

The authors express their thanks to Mr. M. Mazurek and Mr. W. C. Haid for microanalyses and for preparation of proton magnetic resonance spectra, infrared spectra and X-ray powder diagrams. Facilities for determining proton magnetic resonance spectra were kindly made available by the Chemistry Department, University of Saskatchewan.

ABSTRACT

An investigation of the kinetics of the protodeboronation of benzeneboronic acid in water in the pH range 2.0 to 6.7 is described. In addition to the acid-catalyzed reaction studied earlier a reaction whose rate is independent of pH and one whose rate increases linearly with hydroxide ion concentration have been observed. The effect of malonate buffer concentration at low pH confirms the earlier observations of general acid catalysis. Changes in buffer concentration at pH 6.70 have no effect on rate indicating specific hydroxide ion catalysis. Effect of substituents in the ortho, meta, and para position of the benzene ring on the rate of protodeboronation have been examined. Ortho–para ratios for this reaction are high; possible reasons for this are discussed. The Hammett equation using σ correlates the rates for meta and para substituents.

Among the reactions of areneboronic acids in which the dihydroxyboron group is subjected to electrophilic displacement the simple hydrolysis or protodeboronation (eq. [1]) is particularly interesting. Ainley and Challenger (1)

$$ArB(OH)_2 + H_2O \rightarrow ArH + B(OH)_3 \qquad [1]$$

showed that the hydrolysis of boronic acid proceeds in water at 150°, and is catalyzed by concentrated sodium hydroxide, concentrated hydrochloric acid, as well as zinc and cadmium bromides. Ammoniacal silver nitrate has been shown to be an effective catalyst for the protodeboronation of benzeneboronic acid and others of the arene series (2, 3, 4). An understanding of the mechanisms by which these catalysts function would be desirable, and we have embarked upon a series of kinetic investigations toward this end.

A fairly extensive and detailed study of the kinetics of acid-catalyzed protodeboronation has been described (5, 6, 7). Observation of the variation of rate constants in several acidic media, and in deuterium, as well as protium, solvents, along with determination of substituent effects led to the conclusion that the reaction is an electrophilic displacement in which the rate-determining step is the transfer of a proton from an acid to the boronic acid. In view of this an examination of the same reaction catalyzed by base was in order, especially because the strongest electrophile which might be present in significant concentration in aqueous base might well be water. The possibility that a SE1 type of reaction (eqs. [2–4]) might be involved also provided some attraction.

$$ArB(OH)_2 + HO^- \rightleftarrows ArB(OH)_3^- \qquad [2]$$

$$ArB(OH)_3^- \xrightarrow{\text{slow}} Ar^- + B(OH)_3 \qquad [3]$$

$$Ar^- + H_2O \rightarrow ArH + HO^- \qquad [4]$$

RESULTS AND DISCUSSION

Exploratory kinetic experiments were carried out with *o*-methoxybenzeneboronic acid at 60° in aqueous borate buffers at pH 8.7. Several difficulties were encountered. First-order rate plots indicated very rapid initial reaction followed by a pronounced decrease to what appeared to be a linear plot. Rate plots could not be reproduced with satisfactory precision. In the presence of oxygen the expected product, anisole, was accompanied by guaiacol, formed by oxidative replacement of the dihydroxyboron group by hydroxyl. When the pH was decreased below 7, it was possible to eliminate these difficulties provided appropriate precautions described in the Experimental part were taken.

Most of the kinetic runs were conducted in aqueous malonate buffer solutions at pH 6.70 at 90°. At this temperature the buffers showed a detectable change in pH after about six days due, presumably, to decarboxylation of the malonic acid. Agreement of the ultraviolet spectrum of the product with that expected was taken as confirmation that the reaction took the expected course. In the cases of *o*-methoxy-, 2,6-dimethoxy-, and *p*-methoxy-benzeneboronic acids a small amount of brown material appeared in the reaction mixture after several half-lives. It apparently functioned as a catalyst for the reaction, but generally made its presence felt in this way late enough in the course of the kinetic run so that satisfactory rate constants could be obtained from initial slopes. Figure 1 shows a typical first-order rate plot for 2,6-dimethoxybenzeneboronic acid;

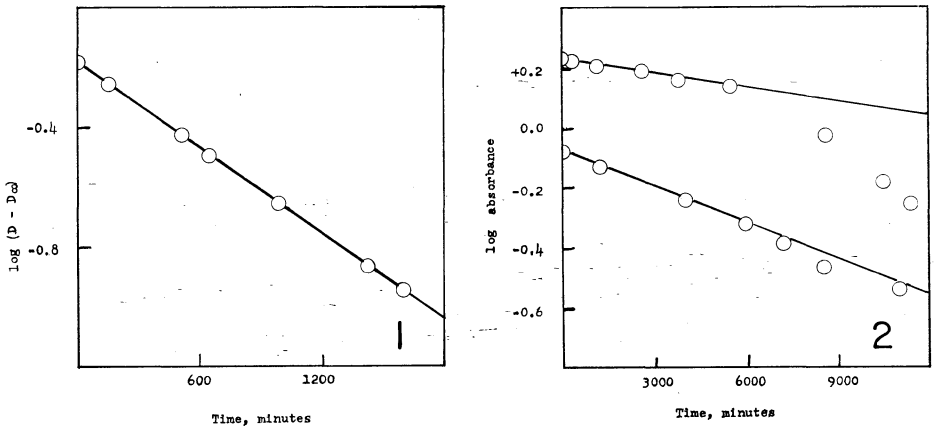

FIG. 1. Pseudo first-order rate plot for the base-catalyzed protodeboronation of 2,6-dimethoxybenzeneboronic acid at 90.0°, pH 6.70; ionic strength 0.14; malonate buffer.

FIG. 2. Pseudo first-order rate constants for base-catalyzed protodeboronation at 90.0°, pH 6.70; ionic strength 0.14; malonate buffer. Upper curve *p*-methoxybenzeneboronic acid. Lower curve *o*-methoxybenzeneboronic acid.

Fig. 2 shows a curved plot for *o*-methoxybenzeneboronic acid and the most extreme case of curvature observed with *p*-methoxybenzeneboronic acid. The other boronic acids gave good linear plots. As shown in Table I (runs 130 and 131), the first-order rate law is valid over at least a 10-fold variation in initial concentration of 2,6-dimethoxybenzeneboronic acid.

Effect of pH and Buffer Concentration

As a test of general base catalysis versus specific lyate ion catalysis the effects of variation of buffer concentration and pH on the rate coefficients were examined. Pertinent results are presented in Tables II and III. The data in Table II are at pH 6.70 and clearly

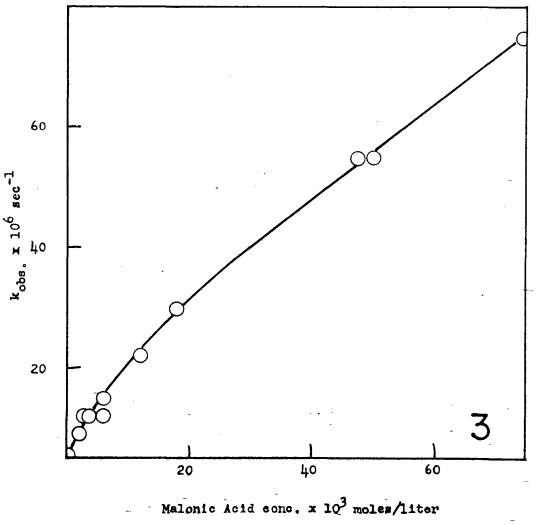
indicate that there is no noticeable effect of malonate ion concentration on rate. Phosphate buffers, on the other hand, revealed an increase in rate with buffer concentration. This was attributed to the presence of catalytic impurities in the buffers because buffers of the same pH at the same concentration made from different reagents gave different rate coefficients.

The data presented in Table III were obtained with a buffer containing the malonate monoanion and malonic acid in a ratio of about 7, resulting in a pH of 3.60. A very pronounced increase in rate results as the buffer concentration is increased. This is a clear-cut indication of general acid catalysis, and confirms the results obtained earlier in the study of the acid-catalyzed reaction. A plot of the data is shown in Fig. 3. A linear relationship between rate and buffer concentration would be expected. The reason for the non-linear plot is not clear at this time.

The effect of pH on the rate of reaction was examined, providing the data presented in Table IV and plotted in Fig. 4. Above pH 6.0 the plot has unit slope as would be



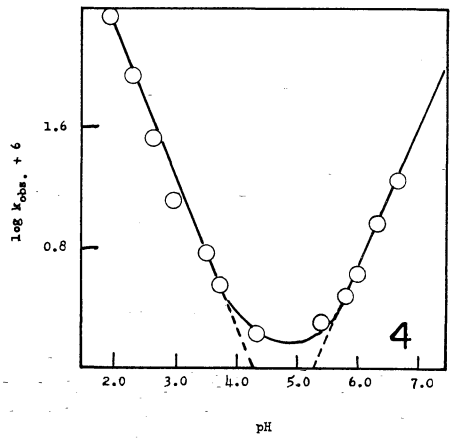


FIG. 3. Test of Brönsted catalysis law for 2,6-dimethoxybenzeneboronic acid at 90.0° with malonate buffers; pH 3.60; ionic strength 0.14.

FIG. 4. pH – log k profile for protodeboronation of 2,6-dimethoxybenzeneboronic acid at 90.0°; ionic strength 0.14.

required for a reaction whose rate is directly dependent upon hydroxide ion concentration. Below this value the slope drops to a minimum near pH 4.85 and then rises again to a negative unit slope below pH 3.5 as the acid-catalyzed reaction comes into prominence. In the pH region around the minimum the rate constants are larger than the sum of the expected contributions from the base- and acid-catalyzed reactions. This means that there is also a pH-independent reaction which predominates in this region. The value of the uncatalyzed rate constant is 0.630×10^{-6} sec^{-1}. This value has been used in constructing the solid line between pH 3.8 and 5.8.

In the pH range between about 6.0 and 6.7 the linear relationship between pH and log k_{obs} suggests the following two-step mechanism as a reasonable working hypothesis.

$$ArB(OH)_2 + H_2O \underset{\text{fast}}{\overset{K_a}{\rightleftharpoons}} ArB(OH)_3^- + H^+ \qquad [5]$$

$$ArB(OH)_3^- + H_2O \xrightarrow[\text{slow}]{k'} ArH + B(OH)_3 + OH^- \qquad [6]$$

23m	2.00*	230	2.362

*These runs were carried out in the absence of buffer; perchloric acid was used to adjust acidity.

Now,

[7] $$K_a = \frac{[BA^-][H^+]}{[BAH]} = \frac{[BA^-][H^+]}{[BAH]_S - [BA]^-}$$

where $[BA^-]$ is the concentration of boronate anion, [BAH] and $[BAH]_S$ are the actual and stoichiometric concentrations of boronic acid. Solving for $[BA^-]$,

[8] $$[BA^-] = \frac{K_a[BAH]_S}{[H^+]+K_a} = \frac{K_a[BAH]_S}{[H^+]}$$

if K_a is much smaller than the hydronium ion concentration. This is true, since pH in these experiments is below 6.8 and the pK_a values for the boronic acids are greater than 8.25. The expression for the overall reaction velocity is given by

[9] $$V = k_{obs}[BAH]_S = k'[BA^-][H_2O] = k'[H_2O]\frac{K_a}{[H^+]}[BAH]_S.$$

Whence

[10] $$k_{obs} = 55.5\, k'\frac{K_a}{[H^+]} \text{ or } \log k_{obs} = \text{pH} + \text{const.}$$

and

[11] $$k' = k_{obs}[H^+]/55.5\, K_a.$$

The logarithmic form of eq. [10] describes the linear portion of the rate profile in Fig. 4, indicating that this analysis is reasonable. If the mechanism is correct, knowledge of the pH and the value of pK_a in conjunction with the experimentally determined rate coefficient, k_{obs}, permits evaluation of the specific rate constant k' for reaction [6].

Effect of Ionic Strength

When the ionic strength is increased beyond 0.140 by the addition of sodium perchlorate, the specific rate constant decreases as can be seen from the last column in Table V. This would imply a negative salt effect. However, addition of the salt has the effect of decreasing the pK_a of the acid; the rate constant expected as a result of the change in

*Calculated by assuming that $k_{obs} = 18.1 \times 10^{-6}$ at pH 6.70 and that the reaction is first order in hydroxide ion.

pH is shown in the penultimate column. Comparison of the values in the two columns shows that the primary kinetic salt effect is actually positive since the observed rate constants are larger than those calculated at each pH.

Effect of Added Boric Acid

The possibility that boric acid formed in the reaction might have an effect on the rate was tested. The result of run 139 in Table I reveals that no effect is observed when the acid is present in concentration of the order of magnitude of the initial boronic acid.

Effect of Oxygen

In view of the difficulties encountered in preliminary work at high pH values when oxygen was in contact with reaction solutions, its effect was tested at the lower pH. The reaction solutions of runs 116 and 117, Table I, were thoroughly degassed by alternate freezing and thawing at reduced pressure and sealed *in vacuo* before being placed in the constant temperature bath. Oxygen clearly has no effect on the reaction under these conditions.

Effects of Substituents

Rates of protodeboronation of several meta- and para-substituted benzeneboronic acids were measured at pH 6.70. In order to ascertain whether the reaction followed was only the one whose rate coefficient increases linearly with hydrogen ion concentration the rates were also measured at pH 6.42 in several cases. The values found at these two pH values are shown in Table VI, second and third columns. In the fourth column are shown the values which would be expected at the lower pH assuming linear dependence of rate coefficient on hydroxide ion concentration. The agreement between the expected and observed values is satisfactory, and assures that the rate of the same reaction is being measured in each case. Because of the very slow reactions in the case of meta substituents it was not practical to make the same check, but it is probably safe to assume that the result would be the same.

Examination of the values in the second column of Table VI reveals that all substituents increase the value of k_{obs}. Obviously no simple linear free energy relationship will correlate these data with other electrophilic aromatic substitutions. However, if values of k' of equation [11] are estimated, the pattern changes, as seen below.

It is not feasible to determine pK_a values of many boronic acids in water because of their limited solubility. However, values in 25% methanol have been determined by Polevy (8). Another limitation is that the pK_a values were determined at 25° while the

kinetic experiments were conducted at 90°. Thus, absolute values of k' cannot be accurately obtained with the data at hand, but relative values should be significant, and sufficient for our purposes. The last three columns in Table VI contain, respectively, values of K_a, k', calculated according to equation [11], and log (k'/k_0'). Inspection of these values shows that the normal pattern for electrophilic aromatic substitution emerges. When these are plotted against Brown's σ^+ values (9) the point for *p*-methoxy falls considerably below the line; when they are plotted against $\sigma + 0.5\ (\sigma^+ - \sigma)$ (10) the plot is improved somewhat, but considerable scatter results. On the other hand, when the ordinary σ values are used in the plot a good line with a slope of −2.32 results as can be seen in Fig. 5.

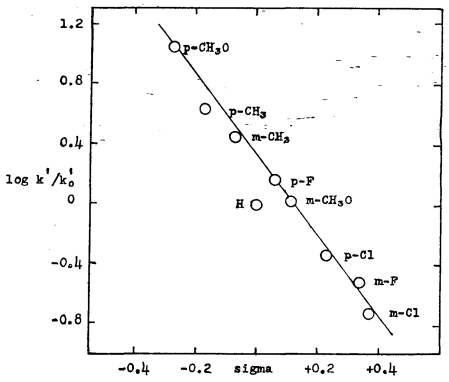

FIG. 5. Hammett plot for protodeboronation of benzeneboronate anions at 90.0°; ionic strength 0.14.

Interestingly enough, the only pronounced deviation from the line is the point for benzeneboronic acid. The negative value of rho indicates that a positive charge develops in the benzene ring in the transition state. The magnitude of the charge is a relatively small one for electrophilic aromatic substitutions which generally have rho values larger than four (11). Displacements of silicon, germanium, tin, and lead from the benzene ring by the proton have rho values of −5.0, −4.6, −3.8, and −2.5, respectively (12–15). Protodeboronation of benzeneboronic acid in 6.3 *N* sulphuric acid at 60° has a rho value of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

−5.0, and the rates are correlated best by σ^+ (7). The decrease in rho when the more reactive boronate anion is the substrate would be expected because the negative charge on the boronate anion decreases the electron demand at the seat of reaction.

The Taft equation for ortho-substituted benzenes (16) can be used as a device for detecting influences on reactivity other than inductive and resonance effects. A plot of k' for the ortho-substituted benzeneboronic acids is not linear; therefore, other factors do indeed play a role in this series.

The methyl and chloro substituents, which have similar steric but opposite electronic effects, produce about the same rate acceleration. Although *o*-fluoro usually has a larger partial factor than *o*-chloro in electrophilic aromatic substitution the reverse is true in the present case.

The ortho–para ratios shown in Table VII are striking in that no simple trend is dis-

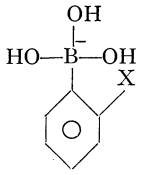
TABLE VII

Ortho–para ratios (k'_{ortho}/k'_{para}) for protodeboronation of areneboronic acids in aqueous malonic acid – sodium malonate buffers (pH 6.70) at 90.0° C

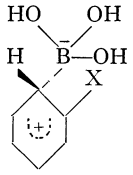
Substituent	k'_{ortho}/k'_{para}
CH_3O	3.02
CH_3	4.06
F	7.34
Cl	37.3

cernible. In each case the value is greater than the statistical value of two, in marked contrast to acid-catalyzed protodeboronation in which case only *o*-methyl has a value greater than two (8). Furthermore, methyl and chloro have different values although they have similar bulk; chloro and fluoro have different values although they have similar electronic effects.

These observations may be interpreted as resulting from a combination of steric effects, hydrogen bonding, and electrostatic interactions and will be discussed in terms of the transition state for the formation of a pentadienate intermediate (B) by the attack of a water molecule on a boronate anion (A). Thus the carbon to which the proton becomes



(A)



(B)

attached is in the process of changing hybridization from sp^2 to sp^3. Since the C—X and C—B bonds are eclipsed in (A), but staggered in (B), release of strain accompanying this change in dihedral angle in the order methyl > chloro > methoxy ≃ fluoro would be expected. This may be a major factor for all substituents but the fluoro. The distance between the negative charge and the C—X dipole will increase in going from (A) to (B), with a resultant decrease in electrostatic repulsion. The introduction of a positive charge into the ring will decrease the magnitude of the C—X dipoles involving chlorine and fluorine, because the negative end is toward the halogen in the ground state. This will

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

lead to further decrease in electrostatic repulsion. The carbon bonded to boron decreases in electronegativity due to decreasing *s* character in the orbital involved, but increases in electronegativity due to the positive charge developing in the ring. The net result is probably a negligible change in the magnitude of charge on boron, and the electrostatic effect is very probably rate-enhancing for chloro and fluoro.

The oxygen in the methoxy group has a relatively high electron density and is at the the negative end of two dipoles. The electrostatic effect should be similar to that for chloro and fluoro. It is to be noted that the introduction of one methoxy group ortho to the boronic acid function increases the rate of reaction by a factor of 38.7 and the introduction of second methoxy increases the rate by a factor of 85.3 beyond that of the first. This kind of enhancement is frequently encountered in steric effects.

The methyl group is at the positive end of the X—C dipole in the boronic acid. As a result the electrostatic repulsion due to change in the bond moment will increase in going to the transition state. This will be counteracted by the change in dihedral angle and leads to the conclusion that the deactivating effect of the methyl group due to electrostatic factors will be smaller than the activating effect of fluoro and chloro.

The effects of hydrogen bonding are difficult to evaluate. Polevy (8) has shown that intramolecular hydrogen bonding occurs to ortho-methoxy, -chloro, and -fluoro in the free boronic acids. Loss of conjugation between substituent and boron, and development of the negative charge on boron in conversion to the anion must diminish the strength of the hydrogen bonds substantially. Whatever remains can be expected to be decreased further due to the electrostatic and geometric changes occurring in going to the transition state.

The resultant of these effects for the four substituents may be summarized as follows. Fluoro activates because of the electrostatic effect; methyl activates mainly because of the relief of steric strain; chloro and methoxy activate because of both effects. In the case of methoxy the reason for activation is not quite clear, since only the steric effect would seem to activate and this should be little larger than that for fluoro.

Mechanism

In the earlier papers of this series on acid-catalyzed protodeboronation it was established that the reaction involves a rate-determining proton transfer from acid to boronic acid. This conclusion was based primarily on the observation of a kinetic isotope effect and general acid catalysis. The base-catalyzed reaction, on the other hand, appears not to be subject to general base catalysis. The mechanism represented by equations [5] and [6] with reaction [6] rate-determining is consistent with this observation. An increase in base concentration results in an increase in rate only when it leads to an increase in the concentration of the boronate anion through an increase in pH. Reaction [6] might very well be subject to general acid catalysis, but this possibility has not yet been examined explicitly. Satisfactory correlation of the rate constants by the "normal" sigma constants and the small value of rho suggests that the positive charge in the benzene ring is not highly developed.

The SE1 type of mechanism (equations [2–4]) can be eliminated as a possibility because it would be expected to have a positive value of rho, whereas a negative value is actually observed.

The uncatalyzed reaction must have a transition state which is neutral overall. This could result from attack on a boronic acid molecule by water, or from attack on a boronate anion by hydronium ion. Rate constants for 2,6-dimethoxybenzeneboronic acid at 90° have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

been calculated assuming these two possibilities, and these are given below along with those for the acid- and base-catalyzed reactions. Perhaps the only conclusions which can

$$ArB(OH)_2 + H_3O^+: \quad 2.12\times10^{-2}\ \text{l. mol}^{-1}\text{sec}^{-1}$$
$$ArB(OH)_2 + H_2O: \quad 1.15\times10^{-8}$$
$$ArB(OH)_3^- + H_3O^+: \quad 2.35\times10^{4}$$
$$ArB(OH)_3^- + H_2O: \quad 2.23\times10^{-3}$$

be drawn from these data with any confidence are that the boronate anion is about a million times as reactive as the boronic acid molecule and the hydronium ion is about a million times as powerful an electrophile as water in aromatic protodeboronation.

EXPERIMENTAL

Materials

All of the boronic acids used in this investigation have been described previously, and the wavelength at which the analytical determinations were made have also been reported (5–8). In view of the sensitivity of the reaction to adventitious materials dissolved in ordinary distilled water all of the water used was redistilled. Recrystallization of the boronic acids and of the buffer substituents were from redistilled water. All pH measurements were made at 25° and are reported as measured.

Kinetics

(A) Base-catalyzed hydrolysis.—An appropriate amount of areneboronic acid was transferred to a 100-ml volumetric flask. The malonate buffer solution was added and the solution diluted to the mark with redistilled water. After all of the areneboronic acid was dissolved, aliquots were transferred to ampoules, which were sealed and placed in the constant-temperature bath at 90.0±0.02° for appropriate intervals. The ampoules were removed from the bath and chilled in ice water, the contents were transferred to a volumetric flask containing sufficient hydrochloric acid to neutralize the buffer base and analyzed spectrophotometrically.

(B) Acid-catalyzed hydrolysis.—The procedure was substantially the same with the exception that sodium acetate was used in the final dilution procedure to neutralize the perchloric acid.

ACKNOWLEDGMENT

It is a pleasure to express our appreciation for support of this research by the U.S. Air Force Office of Scientific Research (Contract AF 49(638)-312).

LYCOPODIUM ALKALOIDS

PART VIII. NEW ALKALOIDS FROM JAMAICAN LYCOPODIUM SPECIES[1]

R. H. BURNELL, C. G. CHIN, B. S. MOOTOO, AND D. R. TAYLOR
Instituto Venezolano de Investigaciones Científicas (IVIC) Apartado 1827, Caracas, Venezuela
and
University of the West Indies, Kingston, Jamaica
Received June 25, 1963

ABSTRACT

Four more alkaloids have been isolated from *Lycopodium fawcettii*. Lycodine and des-N-methyl-α-obscurine have been found in other *Lycopodium* species but base L, $C_{18}H_{31}NO_4$, and base R, $C_{16}H_{24}N_2O_2$, are new. Some transformations of base L are described including its conversion to the previously described base O. An unstable base from *L. clavatum* has been characterized as the picrate $C_{15}H_{25}NO_3.C_6H_3N_3O_7$. Further characterization of the two bases fawcettidine (base F) and fawcettimine (base A) is reported.

Many alkaloids have been reported (1 (*a*,*b*)) from *L. fawcettii*; most of these possess the lycopodine (2) type of skeleton, although neither lycopodine itself nor any of its simple relatives (those with one or no oxygen functions) have been isolated. Three bases have more recently been isolated from this Jamaican plant, all of which contain two nitrogen atoms. Two of these (from the weaker bases), lycodine (3) and des-N-methyl-α-obscurine (4), have been previously isolated and are of known structure but the other, obtained from countercurrent distribution of the stronger base fraction, is not previously described. The latter, base R, $C_{16}H_{24}N_2O_2$, forms only a monoperchlorate (B. $HClO_4$) and from infrared spectra its structure includes carbonyl and secondary amino groups. Acetylation of base R affords a neutral oily compound showing N-acetyl absorption in the infrared.

Another new strong base containing only one nitrogen atom has also been found. Base L, which analyzes best for $C_{18}H_{31}NO_4$, is shown from its infrared spectrum to contain an O-acetyl residue and two hydroxyl groups. Since the methiodide prepared from base L is normal (B. MeI) the nitrogen is presumably tertiary and this is confirmed by acetylation which gives the diacetate $C_{20}H_{33}NO_5$, identical with base O described elsewhere (1 (*b*)). Further acetylation of base O is ineffective so the other hydroxyl grouping was thought to be tertiary and this suspicion is strengthened by the chromium trioxide oxidation of base L to the hydroxy-keto-acetate, $C_{18}H_{29}NO_4$. The latter is readily hydrolyzed to the dihydroxy-ketone (desacetyldehydro-base L), $C_{16}H_{27}NO_3$, which shows infrared absorption attributable to a six-membered (or larger) ring ketone. Neither hydroxyl in desacetyl-dehydro-base L is suitably placed relative to the ketone for ready elimination.

Base L hydrolyzes to a trihydroxy compound, desacetyl-base L, $C_{16}H_{29}NO_3$, which consumes no periodic acid implying that it contains no cis α-glycol system. Acetylation of desacetyl-base L at room temperature gives rise to the diacetate, base O, but at low temperature (5°) a monoacetate is obtained which is not base L and must be the positional isomer, isobase L (cf. fawcettimine (5) and lycofoline (6)), since on further acetylation it also affords base O. These preliminary results suggest that base L is a tricyclic tertiary base possessing a tertiary hydroxyl, a secondary equatorial hydroxyl, and a secondary axial O-acetyl grouping.

[1]*Part VII. R. H. Burnell and D. R. Taylor. Tetrahedron,* ***18****, 1467 (1962).*

For personal use only.

Further characterization of fawcettimine (7), $C_{16}H_{25}NO_2$, shows that both oxygen atoms are present as carbonyl groups. While the base itself shows only one carbonyl peak in the infrared, the crystalline neutral N-acetyl derivative, the N-nitrosamide, and the fawcettimine methiodide all show two peaks attributable to carbonyls (the N-acetyl derivative also shows the amide peak at 1620 cm^{-1}).

The action of sodium borohydride on N-acetylfawcettimine results in the reduction of only one of the carbonyls; the product, dihydro-N-acetylfawcettimine, $C_{18}H_{29}NO_3$, must contain a hindered carbonyl, the N-acetyl group, and a secondary hydroxyl. Reduction of N-acetylfawcettimine with sodium and isobutanol gives rise to this same dihydro compound.

Fawcettidine, base F (1(*a*)), $C_{16}H_{23}NO$ has been reduced to dihydrofawcettidine with sodium borohydride. The infrared spectra of these compounds (and that of acetyldihydrofawcettidine) show that the ketone in the parent base is in a six-membered (or larger) ring, the molecule contains a carbon–carbon double bond and that the secondary hydroxyl is probably axial. From the n.m.r. spectra only one olefinic proton is shown to be present as well as a secondary C-methyl group. The pK_a of fawcettidine is low (6.2) and that of the reduction product is still low (7.9) for a tertiary lycopodium base. The inference drawn is that both the double bond and the carbonyl are sufficiently close to the nitrogen as to greatly affect its basicity.

The unstable base referred to in an earlier report on the bases obtained from Jamaican *L. clavatum* (7) has now been obtained as the picrate, $C_{15}H_{25}NO_3.C_6H_3N_3O_7$. The free base, however, is extremely labile and rapidly develops a brown color in air.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectral values are for Nujol mulls unless otherwise stated and pK_a determinations were done in 50% methanol.

Bases from L. fawcettii Lloyd and Underwood

The mixture of weak bases from *L. fawcettii* (1(*b*)) (2.2 g) was chromatographed over alumina in benzene affording first fawcettidine (base F: 150 mg), pK_a 6.2, $[\alpha]_D$ 161° (*c*, 0.6 EtOH).

Fawcettidine Methiodide

From methanol–acetone, m.p. 223–225°. Calc. for $C_{16}H_{23}NO.CH_3I$: C, 52.7; H, 6.8; I, 32.8; $(N—Me)_1$ 3.9%. Found: C, 52.6; H, 6.6; I, 32.8; N—Me, 4.1%.

Dihydrofawcettidine

A methanolic solution of $NaBH_4$ was added to fawcettidine (40 mg) in methanol and the mixture was left standing at room temperature for 6 hours. Dilution with water and chloroform extraction gave the dihydro base (40 mg) $[\alpha]_D$ 137° (*c*, 1.0 EtOH) which showed hydroxyl (3200 cm^{-1}) and double bond (1666 cm^{-1}) absorption in the infrared but no carbonyl peak. A sample was sublimed for analysis, m.p. 153–156°, pK_a 7.9. Calc. for $C_{16}H_{25}NO$ requires: C, 77.7; H, 10.2%. Found: C, 77.6; H, 10.5%.

Acetyldihydrofawcettidine

Acetylation of dihydrofawcettidine in acetic anhydride – pyridine gave the O-acetate in the normal manner. The base was converted to the perchlorate, m.p. 220–221°. Calc. for $C_{18}H_{27}NO_2.HClO_4$: C, 55.5; H, 7.2; N, 3.6%. Found: C, 55.9; H, 7.5; N, 3.9%.

Lycodine

The next fraction (180 mg) eluted with benzene gave a crystalline hydrochloride which was recrystallized from methanol–acetone. Calc. for $C_{16}H_{22}N_2.2HCl.H_2O$: C, 57.7; H, 7.9; N, 8.4; Cl, 21.3%. Found: C, 57.7; H, 8.1; N, 8.4; Cl, 21.3%.

The base, m.p. 117–118°, regenerated from the salt showed ultraviolet absorption at 268 mμ (log ϵ = 3.73) and 276 mμ (log ϵ = 3.61). On comparison (mixed melting point, infrared and ultraviolet spectra) with authentic lycodine (for which we thank Dr. W. A. Ayer, Alberta) the two were shown to be identical.

Des-N-methyl-α-obscurine

Closely associated with base I (1(*b*)) in the weak base mixture was a small amount of a crystalline base,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

m.p. 270–272° (sealed tube), showing ultraviolet absorption at 252 mμ (log ε = 3.75). Calc. for $C_{16}H_{24}N_2O$: C, 73.8; H, 9.3; N, 10.8%. Found: C, 74.1; H, 9.3; N, 10.7%.

The infrared spectrum, with a peak at 3250 (NH)cm^{-1} and a complex band centered at 1675 cm^{-1}, was identical with that of des-N-methyl-α-obscurine. A mixed melting point with the latter showed no depression (we thank Dr. W. A. Ayer for the authentic sample).

Base R

The fraction (4.25 g) of the *L. fawcettii* strong bases (1(*b*)) containing fawcettiine was distributed between chloroform and aqueous phosphate buffer, pH 7.4 for 20 transfers. The first five fractions contained weaker bases, including fawcettimine (base A: 140 mg perchlorate). Fractions 6–10 contained fawcettiine (1.24 g) and fractions 11–14 gave a new crystalline perchlorate (101 mg) which crystallized from acetone, m.p. 198–199°. Calc. for $C_{16}H_{24}N_2O_2.HClO_4$: C, 51.0; H, 6.7; O, 25.4; N, 7.4; Cl, 9.4%. Found: C, 51.2; H, 6.7; O, 25.5; N, 7.4; Cl, 9.2%.

The base crystallized from a concentrated acetone solution, m.p. 129–130°, pK_a 7.05. Calc. for $C_{16}H_{24}N_2O_2$: C, 69.5; H, 8.8; O, 11.6; $(C—Me)_1$, 5.4%. Found: C, 69.8; H, 8.8; O, 11.9; C—Me, 4.5%.

The infrared spectrum showed peaks at 3420, 3310, 3120, and 1720 cm^{-1}.

Base L

Fractions 19–20 of the distribution (above) gave a crystalline perchlorate, m.p. 290–294° (decomp.). Calc. for $C_{18}H_{31}NO_4$: C, 50.8; H, 7.6; O, 30.1; N, 3.3; Cl, 8.3%. Found: C, 50.6; H, 7.7; O, 30.4; N, 3.3; Cl, 8.1%.

The base, pK_a 9.7, obtained from the perchlorate, was an oil showing infrared absorption at 3450 (OH), 1723, and 1250 cm^{-1} (OAc).

The *methiodide*, m.p. 281–282° (from acetone). Calc. for $C_{18}H_{31}NO_4.CH_3I$: C, 48.8; H, 7.3; N, 3.3; O, 13.7%. Found: C, 48.6; H, 7.3; N, 3.3; O, 13.6%.

Acetylation of Base L (Base O)

Base L (108 mg) was acetylated in acetic anhydride (4 ml) and pyridine (4 ml) at room temperature for 20 hours. The mixture was then poured into iced water, basified with ammonia, and chloroform extracted giving a white solid (103 mg) which was sublimed twice for analysis, m.p. 179°. Admixture with base O (1(*b*)) (m.p. 180–181°) caused no depression in melting point and the two samples have identical infrared spectra. Calc. for $C_{20}H_{33}NO_5$: C, 65.4; H, 9.0; O, 21.8; $(OAc)_2$, 23.4%. Found: C, 65.5; H, 8.6; O, 21 9; OAc, 23.4%.

Desacetyl-base L

To base L perchlorate (92 mg) in methanol (5 ml) was added 3 *N* sodium hydroxide solution (1 ml). After 21 hours at room temperature the mixture was diluted with water and the chloroform was extracted, affording a crystalline solid (58 mg). Recrystallization was from acetone, m.p. 189–190°, pK_a 9.4. Calc. for $C_{16}H_{29}NO_3$: C, 67.8; H, 10.3; O, 16.9%. Found: C, 67.9; H, 10.4; O, 17.0%.

The base showed no carbonyl absorption in the infrared.

Acetylation of Desacetyl-base L (Isobase L)

Desacetyl-base L (106 mg) was acetylated in acetic anhydride and pyridine at 5° C. The white solid (100 mg) obtained by extraction was sublimed for analysis, m.p. 189–192°. Calc. for $C_{18}H_{31}NO_4$: C, 66.4; H, 9.6; O, 19.7; $(O—Ac)_1$, 13.2%. Found: C, 66.5; H, 9.4; O, 19.7; O—Ac, 12.9%.

The infrared spectrum differed from that of base L and seeding concentrated solutions of the latter with this product caused no crystallization.

Oxidation of Base L (Dehydro-base L)

To a cooled solution of base L (250 mg) in pyridine (5 ml) was added a cold mixture of chromium trioxide (1 g) in pyridine (5 ml). After 90 minutes at 5° the mixture was poured into ice water and made basic with ammonia. Chloroform extraction and evaporation gave a pale brown solid, affording crystals from acetone. A sample was sublimed for analysis, m.p. 196–197°. Calc. for $C_{18}H_{29}NO_4$: C, 66.9; H, 9.0%. Found: C, 66.9; H, 9.1%.

Desacetyldehydro-base L

Dehydro-base L (187 mg) was hydrolyzed in methanol with sodium hydroxide (75 mg) at room temperature for 5 hours. Extraction gave a white solid (124 mg) which was recrystallized from acetone and sublimed for analysis, m.p. 199–200°. Calc. for $C_{16}H_{27}NO_3$: C, 68.6; H, 9.6; O, 16.8%. Found: C, 68.3; H, 9.7; O, 17.0%.

L. clavatum—weak base

The weak base residues from *L. clavatum* (7) were chromatographed over alumina in benzene. The first eluate proved to be extremely labile, colored rapidly when exposed, but afforded a relatively stable picrate, m.p. 125–127°. Calc. for $C_{15}H_{25}NO_3.C_6H_3N_3O_7$: C, 50.8; H, 5.7; N, 11.3; O, 32.2%. Found: C, 51.1; H, 5.7; N, 11.1; O, 32.2%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Further elution of the column gave the previously described weak bases (7) and then a substantial amount of fawcettimine (base A).

Acetylation of Fawcettimine (N-Acetylfawcettimine)

To fawcettimine (950 mg) in pyridine (11 ml) was added acetic anhydride (11 ml). After 20 hours at room temperature the volatile materials were removed on a rotary evaporator and the residue taken up in chloroform. After washing thoroughly with dilute hydrochloric acid, dilute ammonium hydroxide, and water, the neutral product (856 mg), obtained on evaporation of the solvent, was recrystallized from acetone–ether, m.p. 144–145°. Calc. for $C_{18}H_{27}NO_3$: C, 70.8; H, 8.9; N, 4.6; O, 15.7%. Found: C, 70.7; H, 9.1; N, 4.7; O, 15.7%.

Infrared peaks were at 1735 (C=O), 1710 (C=O), and 1620 (N—$COCH_3$) cm^{-1}.

Sodium–Isobutanol Reduction of N-Acetylfawcettimine

N-Acetyl fawcettimine (400 mg) was dissolved in toluene (40 ml) containing isobutanol (1 ml) and the solution added to a fine dispersion of sodium (600 mg) in toluene (50 ml) under purified nitrogen. The mixture was stirred for 24 hours, the undissolved sodium decomposed with ethanol, and then the solution was poured into water, shaken, and separated. The aqueous portion was extracted with chloroform. The organic layers were combined, washed with dilute hydrochloric acid and then water, dried, and evaporated to give an oil (359 mg). A crystalline product (90 mg), which was obtained by being dissolved in a small volume of acetone and then cooled, was sublimed for analysis, m.p. 205–206°. Calc. for $C_{18}H_{29}NO_3$: C, 70.3; H, 9.5; O, 15.6; N, 4.6%. Found: C, 70.6; H, 9.5; O, 15.4; N, 4.5%.

The infrared spectrum (Nujol) showed peaks at 3370 (OH), 1735 (C=O), and 1620 (N—$COCH_3$) cm^{-1}.

The material from the mother liquors above slowly crystallized when they were left standing and gave an infrared spectrum identical with that of the sublimed dihydro-N-acetylfawcettimine.

This same reduction product was obtained when N-acetylfawcettimine was treated with sodium borohydride in methanol, but crystallization was only possible after chromatography over alumina.

ACKNOWLEDGMENTS

The authors are indebted to Dr. W. R. Chan (University of the West Indies) for the n.m.r. spectra and one of us (D. R. T.) thanks Geddes Grant Ltd., Kingston, for a Postgraduate Scholarship during part of this work.

PHASE TRANSITIONS OF WATER AND XENON ADSORBED IN POROUS VYCOR GLASS[1]

G. LITVAN[2] AND R. MCINTOSH[3]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received June 14, 1963

ABSTRACT

Measurements of the expansion of porous Vycor glass containing fixed quantities of adsorbed water indicate that in every instance a phase transition starts below −50° C, with the main change occurring below −160° C. Two other anomalies of the length variation were observed near −22° C and −7° C when the amount of adsorbed water exceeded the value equivalent to two monolayers. The length of the adsorbent after completion of a temperature cycle was different from the initial length. This is thought to be due to damage suffered by the glass and to the fact that the length of the adsorbent is different for adsorption and desorption although the quantity adsorbed may be the same.

The phase transition of adsorbed xenon takes place below the normal triple point and is a function of surface concentration as shown by length variations and equilibrium pressures for fixed quantities adsorbed. All transitions are gradual and hysteresis is exhibited by the isosteres. The adsorption isotherms for xenon – Vycor glass show a decreasing adsorptive capacity and a contraction of the hysteresis loop with lower temperature. The inadequacy of the capillary condensation theory of adsorption in relation to these results is discussed.

The capillary condensation theory assumes that the free energy of the adsorbate is less than that of bulk material at the same temperature because it is held under concave menisci in the pores of the adsorbent. The vapor pressure of the condensed substance is calculated by the relationship due to Kelvin. The theory implies that the adsorbent is inert, and only the shape and size of the pores play any role in determining the adsorptive characteristics. It follows also that the adsorbate has bulk properties except the lowered free energy arising from the presence of the concave meniscus.

There is, however, ample experimental evidence to the contrary. The observed dimensional changes of the adsorbents (0.3% in the case of Vycor glass – water system (1)) during the adsorption process indicate that the solid is perturbed by the presence of the adsorbate. Similarly, the infrared spectra of the adsorbate contain lines caused by forbidden transitions normally observable only in the Raman spectra (2, 3) showing that the adsorbed liquid is in a state different from the bulk state. The crystal structure of the frozen adsorbate, too, has been found by X-ray diffraction methods to differ from the one of the bulk crystal (4). Accordingly, solidified adsorbates failed to nucleate undercooled bulk liquid of the same composition (5).

These findings are to be expected in view of the fact that adsorption is the result of molecular interaction between adsorbate and adsorbent, and this interaction perturbs both.

On applying the equation due to Kelvin the question arises: is it permissible to use the relationship even as an approximation when most of the quantities involved are not only unknown quantitatively but are meaningless on a molecular scale? Surface tension (or even the term surface itself) of a liquid consisting of 30–40 molecules, the radius of an irregularly shaped void, the wetting angle formed by a few molecules on an irregular surface, the molar volume of the adsorbate, and so on, have no significance and one has to

conclude that the relationship deduced and valid for macroscopic systems cannot be applied for microscopic systems without important reservations.

The contradictions of the capillary condensation theory were realized at an early stage although some of the experimental evidence supporting the criticism was obtained only recently. In spite of this fact some phenomena are explained by the theory. The hysteresis exhibited by the adsorption isotherms of porous adsorbents is probably the most important. In addition, the concept has been applied to explain the features of the expansion isotherms, the freezing point lowering of adsorbates, etc. The lack of another general concept and the apparent success of the theory have helped it to survive on a pragmatic rather than on a theoretical basis. But even so, the number of experimental results not explicable by the theory is growing and it seems desirable to examine its applicability under various conditions. One means of testing the theory has been shown to be the study of phase transitions of adsorbates (6, 7). The present work is a continuation of that investigation.

EXPERIMENTAL

The measurements were carried out using a volumetric adsorption apparatus incorporating a capacitance-type extensometer (1) which was redesigned in order to decrease the 1500 ml dead space of the chamber to 134 ml. Length changes of ± 0.01 to 0.4 μ could be detected depending on the separation of the plates with an estimated error of less than 2%. The temperature of the cell could be varied between -190 and $+200°$ C, and controlled from liquid nitrogen temperature to $+8°$ C. The system was pumped down to less than 10^{-6} mm pressure. Only soft annealed pure gold o-rings sealed satisfactorily throughout the wide temperature range.

The pressure was measured using either a mercury or a dibutyl phthalate manometer (depending on the range) which were isolated from the cell by a bellows type pressure gauge (8) used as a null instrument so that contamination of the adsorbent by the vapors of the manometer fluids was avoided.

Completely metal valves were used to avoid distillation of stopcock grease vapors to the cold adsorbent. During pumping the system was protected by a liquid air trap.

The porous Vycor glass (No. 7930) was supplied by Corning Glass Works and was in the form of an 11.5 cm long rod of 0.70-cm diameter. The effective length of the rod for expansion was 10.0 cm.

Before a run was started the cell containing the adsorbent was heated to above $+150°$ C and pumped at this temperature until "stick vacuum" was obtained.

The water before adsorption was purified several times by vacuum distillation. The xenon used was supplied by the Matheson Co. The research grade gas had less than 0.05 mole% total impurities and was used as obtained.

Because of the large range of the experimental temperatures it was necessary to take into account the coefficient of thermal expansion of the extensometer. The data given are corrected accordingly unless stated otherwise.

The results of the expansion isosteres are expressed in terms of fractional length changes, relative to the length of the rod at $+5°$ C. After the temperature was changed, the system was allowed to come to apparent equilibrium, and this took about 12 to 24 hours. The duration of a run was between 3 and 6 weeks.

RESULTS

Water Expansion Isosteres

The water isosteres (Figs. 1–4) show anomalies mainly in three temperature regions: (*a*) below $-50°$ C the length of the rod does not change in spite of the decrease of temperature and below $-150°$ C it increases. Above a critical water concentration the anamolous variation of length occurs at (*b*) around $-22°$ C, and (*c*) around $-7°$ C. The absence of any discontinuity indicates that the phase changes are gradual. The anomalies occur at higher temperatures on warming than the corresponding ones on cooling. The cooling and warming curves do not coincide. Pronounced hysteresis is exhibited even on repeated cycling. The length of the glass rod at $+5°$ C before and after a freezing–thawing cycle is, in general, not the same.

Xenon Vapor Pressure and Expansion Isosteres

The changes observed in the dimensions of the adsorbent and in the pressure of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

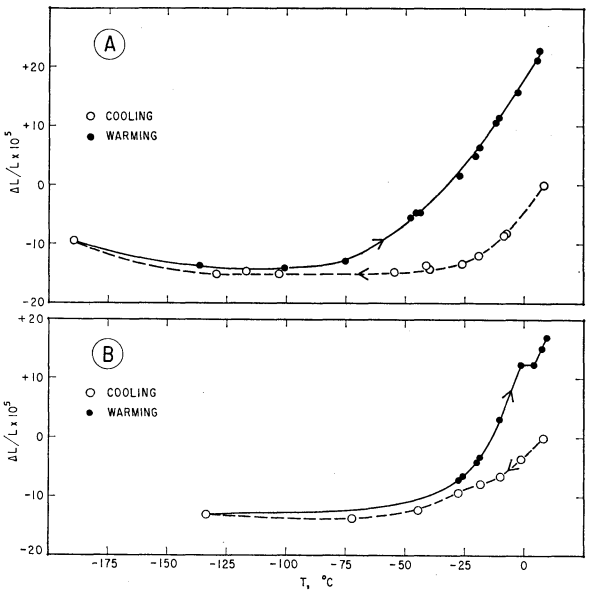

FIG. 1. Expansion isostere. Water content *A* 0.0263 g/g; *B* 0.0480 g/g.

adsorbate due to temperature variation are represented in Figs. 5 and 6. The diagrams in these cases show not only the "corrected" values computed by considering the coefficient of thermal expansion of the extensometer, but the "uncorrected" values as well which represent the apparent length changes of the system.

In order to eliminate the effect of condensation from the vapor phase on cooling or evaporation from the adsorbent on warming, thus maintaining isosteric conditions, in run 17 (Fig. 6) appropriate amounts were withdrawn from or admitted to the system. The amount of xenon to be withdrawn or admitted for a given change of temperature was computed from the values of the isotherms taken at different temperatures (Fig. 7).

The isosteres show that, on cooling, expansion takes place below the freezing point of bulk xenon. The temperature region of the length anomaly seems to be a function of the amount adsorbed, as at smaller concentrations the anomaly occurs at a lower temperature. The peak of the expansion versus temperature plot is at −114.0° C with 600 ml S.T.P. xenon adsorbed and at −128.5° C with 514 ml S.T.P., adsorbed. The log p versus $1/T$ plot consists of two linear sections. The sudden changes of the slope take place at −114.5 and −134.0° C, respectively. The cooling and warming branches of the expansion isosteres are displaced in the temperature region of the expansion anomaly. Below this region the two curves coincide and indicate expansion of the adsorbent. In the case of xenon as with water, the transition is gradual. The lengths of the glass rod at −109° C before and after the temperature cycle are the same.

Isothermal Expansion and Isotherms Using Xenon

The isotherms obtained above and below the bulk freezing temperature of xenon are shown in Fig. 7. The adsorption isotherms indicate a sharp decrease of the adsorptive capacity with decreasing temperature and at the same time a narrowing of the hysteresis loop. The inception of the hysteresis loop occurs essentially at the same value of relative pressure for all temperatures. The amount adsorbed approaches the line for $p/p^0 = 1$

asymptotically at the temperature of −110.1° C, when p^0 is the value (p_l^0) of the vapor pressure of the liquid at that temperature. At −136.3° C and −143.4° C the same is true if (p_s^0), the vapor pressure of the solid, is employed. At −125.6° C the isotherm is considered to cut the $p/p_s^0 = 1$ axis. These facts are interpreted as showing liquid adsorbate down to −125.6° C, but solid adsorbate at −136.3° C and below. The concomitant expansion isotherms indicate small dimensional changes even at relatively high temperatures

when compared with other systems investigated, and become even smaller with decreasing temperatures. The hysteresis loop of the high temperature isotherm narrows and finally vanishes at low temperature. No pronounced contraction can be detected on desorption as was observed with other adsorbates on Vycor glass.

DISCUSSION

Water Expansion Isosteres

It is apparent at once that the results obtained with the water – Vycor glass system do not support the capillary condensation concepts. According to this theory a sharp freezing point should be observed which is a function of the amount adsorbed. The opposite of these predicted facts is found; that is, the transition is not sharp nor much dependent upon the quantity absorbed. The results, however, can be explained by considering the possible events taking place in the adsorbed layer during the phase transition of the adsorbate.

Freezing in a bulk phase occurs when the kinetic energy of the molecules decreases to such an extent that an order of the species favored by the crystal lattice of the forming solid can develop. If the molecules in the liquid are subjected to external forces which are not present under ordinary conditions the phase transition will take place at a different and lower temperature than the normal freezing point. Adsorbate molecules on the surface are in such a force field. Since the field is not homogeneous its value varies from site to site and from layer to layer. The individual adsorbate molecules are perturbed in different ways depending on their location in the surface. The strongest interaction can be assumed to exist between the sorbent and the first layer and therefore the phase transition of such a layer is expected to occur, if it does at all, at very low temperatures. The transition temperature of the second and subsequent layers approaches the value of the bulk freezing temperature.

Length Anomalies below −50° C

Hodgson and McIntosh (6) found no length anomaly with the water – Vycor glass system between 0° C and −50° C if the water content was less than 0.138 g/g. The present investigation confirms this result (Fig. 1). On further cooling, however, some sort of solidification of the adsorbate seems to take place if indicated by the horizontal portion of the isosteres (Figs. 1 to 4) beginning around −50° C. The contraction of the system due to cooling is compensated for and at around −150° C, is overcome by an expansion effect. It seems reasonable to associate the continuous expansion with the gradual redistribution of the firmly bound molecules in the first layers. The phase transition was prevented from taking place by the strong interaction between the sorbate and substrate at high temperatures but at very low temperatures crystalline or, more probably, amorphous solid forms.

This observed expansion could not have been caused by condensation of water from the vapor phase since, in the case depicted in Fig. 1, 0.54×10^{-4} g water/g glass condensed on the adsorbent during cooling, which could cause only an estimated $\Delta L/L = 1\times10^{-6}$ expansion compared with the observed fractional expansion of 6×10^{-5}. Furthermore, it has to be noted that the condensation process was practically complete at around −100° C, at which temperature ice has a vapor pressure of about 10^{-5} mm. Another possible cause of expansion will be discussed in a later paragraph.

Length Anomalies at −22 and −7° C

It has been reported previously that the adsorbed water begins to freeze at around −22° C regardless of the water concentration if it is higher than a critical value. It can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

be seen from Figs. 1 and 2 that this value is between 0.0480 and 0.0839 g/g water content, which is equivalent to 1.3 and 2.3 monolayers.

Several workers have observed sudden changes in the properties of the adsorbate at a critical surface concentration. Morrison and Drain (10) found the onset of the large increase of heat capacity in the argon–rutile system occurring between 1.6 and 2.2 V_m. Similar results were obtained by other authors (11, 12) with various systems. Studies of the dielectric properties showed that a plot of the dielectric loss versus adsorbed amounts had a discontinuity of slope at a value corresponding to $V_m = 1$ (Ebert and Langhammer (13)). Karagounis (5) observed that organic substances adsorbed on metal oxide powder will not seed the undercooled liquids in bulk state unless V_m is greater than 2. The heat of adsorption usually falls rapidly with coverage and approaches the heat of liquification at twice the monolayer coverage (14).

The results obtained by the various methods show that the first layer or layers of the adsorbate are in a distinctly different state from that of higher layers or of the substance in bulk phases, which explains why adsorbates in these layers have unusual properties, among others a very low freezing point.

The results of the present investigation indicate the existence of two length anomalies above −50° C, namely at around −22° C and −7° C. Since the temperature of the beginning of phase transition is −22° C, and since it is independent of the quantity adsorbed, comparison of the mechanism of the transition is invited with that of the transition water – ice I – ice III. To do so, however, requires the postulate of a pressure in the adsorbed layer of 2115 atm and, if that is assumed, an explanation of why such a pressure exists and does not destroy the glass.

If the pores are blocked by some means the approximate 10% increase of volume occurring on formation of ice I from water can be considered to be the cause of the existence of high pressures as has been assumed by Powers and Helmuth (15) who explained the expansion of porous adsorbents on cooling by this mechanism. Expansion on freezing, however, has been observed with other systems, in which the solid specific volume is less than that for liquid, e.g. the xenon – Vycor glass system (see Figs. 5 and 6).

There are indications that high pressures do exist in the adsorbate layers and are caused not by mechanical reasons but by the force field of the adsorbent which pulls the sorbate molecules toward the surface. The adsorbate molecules are perturbed as though under externally applied pressure.

Several authors such as Goldman and Polanyi (16), Mastrangelo (17), Long and Meyer (18), Schaeffer, Smith, and Wendell (19) have assumed high pressures to exist in the adsorbed layers.

The expansion occurring at −7° C was observed previously (6) in one instance and was suspected to be caused by condensation of water from the vapor phase on cooling. Since the decrease of the dead space did not eliminate this result it can be concluded that it is caused by changes in the adsorbate.

Although the scarcity of experimental data prevents generalization, it seems that the height of the peak at −7° C is inversely proportional to the amount adsorbed (Figs. 2, 3, 4) and disappears on repeated cycling (Fig. 3). These facts suggest that the expansion may be associated with the formation of an amorphous type of ice.

Burton and Oliver (20) detected by X-ray diffraction that semicrystalline—(neither hexagonal nor cubic)—ice formed on a cooled metal surface at below −90° C. It recrystallized into ordinary ice at high temperatures. Recently these findings were confirmed (21) and it was shown by Brazhan (4) that water adsorbed on silica gel froze at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

−9° C in a well defined but unusual structure as determined by X-ray diffraction methods.

The presence of amorphous ice or water with unusual structure in the surface layers is suggested by the dielectric measurements of Dransfield, Frisch, and Wood (22) and Ebert and Langhammer (13).

Such results, obtained by employing various experimental methods, demonstrate the existence of amorphous ice and it seems reasonable to associate the expansion occurring at −7° C with the formation of this structure.

Xenon Vapor Pressure and Expansion Isosteres

The xenon isosteres are similar to the ones obtained for other systems, for example benzene, inasmuch as the temperature at which the phase transition occurs is a function of the amount adsorbed. It is noteworthy, however, that the freezing of the adsorbate caused the system to expand, demonstrating that other factors than an increase of the molar volume can be responsible for this effect.

For both the xenon and water systems the transitions were gradual, which fact contradicts the capillary condensation theory in its usual form. The sharp change of slope of the vapor pressure isosteres does not prove that the transition is sharp as has been pointed out (7). The existence of a freezing range is to be expected according to the molecular picture of phase changes in adsorbed layers.

Both the xenon and water systems exhibited marked hysteresis; the water – Vycor glass system over the entire experimental temperature range; the xenon – Vycor glass, however, only in the region where the phase transition takes place. On examining the experimental results on the basis of the capillary condensation theory the following may be noted.

According to the theory the menisci are the sole reason for the lowering of the freezing point. Because of the equilibrium with the vapor phase the curvature of every meniscus is the same and the liquid in every capillary should freeze at the same temperature. For the solidified adsorbate one may assume either flat (meniscus destroyed) or curved surface (meniscus retained).

In the first case, on warming, the melting should take place at the bulk melting temperature since no concave menisci are present. Although there are indications that the melting point of the adsorbate is usually higher than the freezing point, it is still very much lower than the bulk transition temperature. Furthermore, one should not observe hysteresis in the adsorption isotherm below the adsorbate transition temperature. This is the case for xenon but not for water. In addition, the relative vapor pressure of the solid adsorbate should be unity, which condition is not met by the xenon–glass system according to Fig. 6.

If one assumes the second case to be valid, i.e. concave menisci exist, the freezing and melting points of the adsorbate should coincide and no hysteresis is to be expected in any region. The experimental findings are not in accordance with these predictions. Thus, the capillary condensation theory does not explain the hysteresis phenomenon of the isostere.

$\Delta(\Delta L/L)$ *at* $+5°$ *C*

In the case of the water isosteres the Vycor glass rod exhibits a different length after a temperature cycle than it did before. It is apparent that the length difference $\Delta(\Delta L/L)$ at +5° C is a function of the water content (Table I).

The fact that with zero water content and with xenon adsorbate $\Delta(\Delta L/L) = 0$ establishes that the results are not due to a mechanical error of the extensometer.

change during the temperature cycle. The values given represent the change in length of the rod with no water present, under standard conditions, measured between runs.

If the rod suffered permanent damage in every instance, presumably due to the formation of microfissures, resulting in greater length, negative $\Delta(\Delta L/L)$ at +5° C with high water contents would have been obtained only if an opposing contraction occurred. One explanation may be the following.

In spite of the fact that the dead space of the cell was small some adsorption took place during cooling due to lowering of the vapor pressure. Although the amount adsorbed in itself was not sufficient to cause any observable change in length the process took place and the system could be described as being on the adsorption branch of the water isotherm. On warming, the opposite effect, desorption, occurred and the system was on the desorption branch. Since lengths corresponding with the desorption branch are less than those of the adsorption branch it can be understood why $\Delta(\Delta L/L)$ is negative for systems with higher water content than at the inception of the hysteresis loop. Thus reversing the direction of the temperature change results in altering the state of the system from the one of adsorption to the one of desorption.

In order to test this assumption the following experiment was carried out. With a fixed amount of water adsorbed the length of the rod was measured at +2.50° C. After the temperature of the system was changed (raised, lowered, or both) the original temperature, +2.50° C, was restored as closely as possible (within 0.5° C) and the length measured again. The results are shown in Table III. The $\Delta L/L$ data at temperatures other than the reference are omitted being non-equilibrium values. The observed changes were of the order of -30 to $+20\times10^{-5}$.

It can be seen that when the reference temperature was restored by heating (desorption

branch), as in points No. 1, 4, 8, and 11, the rod appears to have the same length and about $\Delta L/L = -11\times10^{-5}$ units lower than in cases when the temperature was restored by cooling (adsorption branch), points No. 6 and 13.

Xenon Isotherms

Since the heat of adsorption is always positive the adsorptive capacity should increase with decreasing temperature and, in fact, this is the case in general. There are only a few exceptions known. Kiselev and Kulichenko (23) obtained the isotherms for the benzene – silica gel and benzene–charcoal systems and found a decrease in the adsorptive capacity at temperatures below the bulk freezing point of the adsorbate. Amberg, Everett, Ruiter, and Smith (24) observed the same phenomenon with CO_2 – Vycor glass and N_2O – Vycor glass systems. An explanation of the phenomenon which has already been advanced by several authors (23, 24) is the following. If the state of the adsorbed film resembles that of an undercooled liquid, the saturation pressure of the liquid will exceed that of the solid by an increasing margin as temperature is decreased below the transition temperature. In the experimental assembly, however, the upper limit of pressure which can be generated is the vapor pressure of solid which would form on the walls of the adsorption vessel. In practice, therefore, a relatively smaller part of the adsorption isotherm can be examined as the temperature is lowered. Indeed, it may come about that relative pressures above the value for the inception of the hysteresis loop (about 0.45 p/p^0 at ordinary temperatures) cannot be generated. Thus the adsorptive capacity will decrease with decreasing temperature, the pore spaces may appear to be inactive, and the phenomenon of adsorption hysteresis may disappear. This is essentially the case with xenon. However, this explanation does not explain all the facts. On the basis of what has been said, one would expect that the beginning of the hysteresis loop would be found at higher values of the relative pressure based upon the saturation pressure of solid, that is, at higher values of p/p_s^0, as temperature is decreased. There is no evidence of this.

In addition, the drastic change in the shape of the xenon isotherms is apparent at and below −136.3° C in which case $p/p_s^0 = 1$ was reached with 450 ml S.T.P. adsorbed. The expansion isostere with 514 ml S.T.P. xenon content (Fig. 6) indicates freezing at −128.5° C and the vapor pressure isostere at −134° C, which facts contradict the assumption that the adsorbate is in a liquid state. The isotherms at −136.3° C and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

−143.4° C approach $p/p_s^0 = 1$ asymptotically and this too—as pointed out by Hodgson and McIntosh—suggests the presence of solid adsorbate.

The decrease of adsorptive capacity raises the question as to what conditions obtain during isosteric cooling. On the basis of the low temperature isotherms, much more adsorbed matter is contained within the porous solid for certain conditions of cooling than one would expect. Moreover, the film, although containing more matter than predicted by the isotherms, has a lower equilibrium pressure than the bulk phase. It would seem that some adsorbate is "locked" into the adsorbent on cooling. Such a situation may be the reason for the expansion which is noted in the case of xenon, and at very low temperatures in the case of water. No direct evidence of decreased adsorptive capacity of water at lower temperatures has been obtained by us, but the decreased capacity may be anticipated by analogy with the behavior of xenon.

Xenon Expansion Isotherms

The xenon – Vycor glass system shows, even at high temperatures above the bulk freezing point, relatively small dimensional changes compared to other adsorbate – Vycor glass systems (9). Particularly important is the absence of a pronounced contraction along the desorption branch of the isotherm. Since the surface tension of liquid xenon is estimated to be 15 dynes/cm, a value comparable to those of other adsorbates investigated such as butane, the small dimensional changes are unexpected, and seem to contradict the proposed mechanism of dimensional changes based on the meniscus theory. The fact that the system does not contract on desorption indicates that either there are no menisci present or the contractive forces of the menisci are not the reason for the contraction as assumed in explaining the behavior of butane (9).

The differentiation of the expression for the spreading force ϕ with respect to temperature T gives the following result

$$\left(\frac{\partial \phi}{\partial T}\right)_{A,P,n_s} = \frac{Rn_s}{A}\left(\frac{\partial \ln p}{\partial \ln T}\right)_{A,P,n_s},$$

where the symbols n_s, A, p, P stand for the number of moles adsorbed, the surface area of the adsorbent, the vapor pressure of the adsorbate and the hydrostatic pressure respectively. Since the temperature coefficient of the vapor pressure is positive, such should be the case for the spreading force. Because $\Delta L/L$ is directly proportional to the spreading force, the observed decrease of the length changes with decreasing temperature is expected.

CONCLUSION

The capillary condensation theory in conjunction with assumptions concerning the shape of the voids has been used extensively to explain adsorption hysteresis, to analyze pore sizes, and to explain dimensional changes of the adsorbate–adsorbent system, e.g. (1). It has been employed also to predict the temperature of phase transitions, e.g. (25). However, the amount of experimental evidence which has accumulated and which cannot easily be fitted into the framework of the theory is becoming substantial. It is worthwhile to summarize this evidence, as well as other unexplained results characteristic of porous adsorbents. First, phase transitions are found not to be sharp. Second, the temperature of the beginning of a phase transition depends upon the amount adsorbed for some adsorbates, but not for others. Third, the marked contraction associated with the reversible part of the desorption branch of the isotherm, explained by the decreasing radius of curvature of the menisci, is not found in the case of xenon. The adsorption isotherms are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

similar to those of water, butane, ethylchloride, and so on, but the contraction in the appropriate pressure range is not found.

Under the classification of unexplained results for porous adsorbents may be placed the following observations. The adsorptive capacity of the adsorbent in several cases is known to diminish with decreasing temperature. Although this fact might be explained on the basis of the similarity of the film near saturation to an undercooled liquid, there is evidence that the film is more likely to resemble solid. Second, the expansion of the system found with water on Vycor glass, and which might be anticipated by knowing the densities of bulk ice and water, is revealed also in the case of xenon. The density of solid xenon is, of course, greater than that of liquid. Additionally, a transition of adsorbed benzene brings about contraction of the glass–benzene system. Third, it has been shown that the measured expansion of glass–benzene, glass–water, glass–ethylchloride, etc., is not dependent solely upon the calculated spreading force derived from the Gibbs adsorption equation (9). If the viewpoint is adopted that changes of the chemical potential of the solid are being evaluated rather than spreading forces, the finding is then that expansion is not equal in the various systems for equal changes of the chemical potential of the solid (see Table IV). It is clear that this isolated fact may be rationalized by supposing that the sites of

TABLE IV

Proportionality constants for variation of ϕ with $\Delta L/L$

Adsorbate	K, cal
Water	-2.96×10^4
Butane	-1.06×10^4
Ethylchloride	-0.238×10^4
Xenon	-20×10^4

NOTE: K is defined by the equation $\Delta F_{S_0} = \phi = K\Delta L/L$.

adsorption vary from one adsorbate to the other, and thus the point of application of internal stress also varies. However, there is no independent confirmation of this view.

Thus we find that the capillary condensation theory and the behavior, both reversible and irreversible, which might be considered to result from the presence of menisci, will explain some of the known phenomena admirably. Other findings are not consistent with that theory. In addition there are experimental facts which remain unsatisfactorily explained on the basis of all current theories. The situation is not surprising in view of the complex nature of the adsorbent structure, but it is becoming clear that other theoretical bases must be established before an understanding of physical adsorption in porous bodies can be regarded as achieved.

INVESTIGATION OF THE INFLUENCE OF SPACE CHARGE ON THE ANODIC OXIDATION OF ALUMINUM, A TYPICAL VALVE METAL

M. J. DIGNAM AND P. J. RYAN
Department of Chemistry, University of Toronto, Toronto, Ontario
Received July 16, 1963

ABSTRACT

Measurements of the time derivative of the anodic overpotential of superpurity aluminum during anodic oxidation were made at various constant current densities. The data have been interpreted in terms of the variation of electric field strength with position in the oxide film. The analytic form of the profile of the electric field strength in the oxide film was deduced, assuming the high field Frenkel defect model. The data were found to be incompatible with the theoretical profile, providing, therefore, evidence against this model. The data are only consistent with a model for the transport process in which the concentration of ionic current carriers at a position in the oxide remote from the metal interface is independent of the field strength. A new model, proposed recently by Dignam to explain transient ionic conduction phenomena, is consistent with this conclusion.

INTRODUCTION

The influence of space charge on the oxidation of metals and semiconductors has been the subject of a number of theoretical and experimental investigations. In a recent paper by Butler (1), the space charge distribution in a metal oxide – oxygen system under equilibrium conditions is discussed in detail. His approach to the problem, however, is not applicable to any case where the conditions depart seriously from those at equilibrium. Such non-equilibrium conditions clearly obtain during the steady-state anodic oxidation of the valve metals, so that consideration of space charge in these systems must rest on kinematic rather than equilibrium arguments. Information concerning the nature of space charge effects within such anodic oxide films can therefore be used to judge the relative merits of different kinematic models.

If a space charge exists, it will give rise to a variation of electric field strength with position in the oxide film, thus providing a means for its detection. The experiments described herein consist of measurements of the time derivative of the aluminum anode potential, $\dot{\varphi}$, under conditions of constant anodizing current. Ignoring for the moment the problem of charging current and transient effects associated with the ionic current, these measurements can provide information concerning the variation of the electric field strength with position in the oxide film. Details of the assumptions involved are discussed in a later section.

Measurements of the influence of space charge on the steady-state anodic oxidation of aluminum have been carried out in the above manner for a range of current densities, and the results interpreted and compared with predictions based on the high field Frenkel defect model (2). The results indicate that the concentration of ionic current carriers is independent of the electric field strength for steady-state conditions, in direct conflict with the fundamental postulate of the above model.

EXPERIMENTAL

Apparatus

The circuit, designed to maintain the anodizing cell current constant and measure the time derivative of the potential of the aluminum anode with respect to that of a reference electrode, is depicted in Fig. 1. The triangular symbols represent high-gain, d.c., inverting, operational amplifiers, number 3101 made by Donner Scientific Co.; the square symbol, a Keithley Instruments Inc., number 610A electrometer amplifier.

The resistors are all 0.1%, wire-wound; the capacitors, high quality polystyrene. The circuit design can be readily understood in terms of conventional electronic analogue computer circuits. Amplifier 1 maintains a constant current of magnitude e_1/R_1 through the anodizing cell. The reference electrode potential is fed from the electrometer amplifier through amplifier 2 which changes the sign of the potential. The output of amplifier 3 is five times the difference between the potentials of the reference and aluminum electrode. Amplifier 4 is connected as a limited frequency response differentiator, R_3 being chosen to give a few hundred millivolts output for the maximum rate of change of the anode potential encountered for the run in question. R_2 and C were chosen to introduce time constants ($R_2 \times 10$ μf and R_3C) of magnitude 0.1 sec to 1 sec, depending on the conditions of the run. The time constants were chosen as large as possible, without sacrificing accuracy, in order to suppress background noise. The error introduced in this way was in no case the limiting factor. The signal from amplifier 4 is fed through amplifier 5 to a 100-mv strip-chart recorder. The 10-turn potentiometer was used to adjust the output calibration for a known rate of voltage rise into amplifier 4, and e_2 was chosen to offset the zero a known amount, hence providing greater sensitivity. With this arrangement, rates of voltage rise in the range 0.1 to 0.005 volt/sec could be measured with an accuracy of 0.1%, and a sensitivity of 0.02%.

The electrolysis cell, constructed of Lucite, is shown diagrammatically in Fig. 1. The electrolyte used

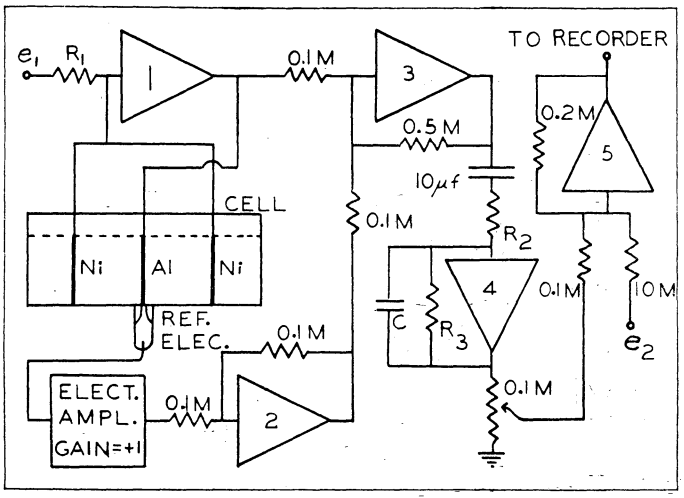

FIG. 1. Electronic circuit employed to measure the time derivative of the anode potential at constant current.

was a 30% solution of ammonium pentaborate in ethylene glycol (3), as it has been shown by Bernard and Cook to lead to 100% current efficiencies for the formation of Al_2O_3. The working cathodes were made of high purity nickel. The reference electrode was a saturated calomel electrode in a cracked glass envelope, which in turn was placed in a tube connected to the cell through a capillary tipped side arm adjacent to the anode.

Experimental Procedure

Superpurity (99.996%) aluminum sheet (0.04 inch thick) was formed into paddle-shaped electrodes of dimensions 1 inch × 0.25 inch for the paddle, 1 inch × 0.06 inch for the tab. Following routine cleaning procedures, the electrodes were electropolished at about 0.2 amp/cm^2 and 25° C in 5 parts ethyl alcohol to 1 part 70% perchloric acid by volume (4). The electrodes were rinsed briefly in ethyl alcohol, then for 1 minute in running distilled water, being dried in a clean air jet and stored in a desiccator over activated alumina. In order to ascertain the influence of surface treatment on the results, a few electrodes were treated by: (*a*) etching in 1:1 nitric acid at 60° C for ½ hour; (*b*) electropolishing, then treated as in (*a*); (*c*) etching in aqueous 10% NaOH at 25° C for 1 minute; (*d*) electropolishing, then treated as in (*c*); (*e*) immersion in chromic-phosphoric acid stripping solution at 25° C for 2 hours; (*f*) electropolishing followed by treatment as in (*e*). In all cases the electrodes were rinsed in distilled water and dried as before.

A typical experimental run was carried out as follows. The cell was filled to just above the shoulders of the paddle-shaped aluminum electrode and was then connected into the circuit with e_1 set at zero and left for 2 to 10 minutes. The appropriate value of e_1 was then switched on and the output of amplifier 5 recorded as a function of time.

A few runs were carried out using electrodes with "tabs" insulated with a thick anodic oxide film.

Experimental Results

Figure 2 represents the data obtained from a typical run, Δ' being the fractional deviation of the time derivative of the anode potential from its limiting value for thick films ($\Delta' = [\dot{\varphi}(t) - \dot{\varphi}(\infty)]/\dot{\varphi}(\infty)$). The reference point for zero incremental charge passed was chosen as the point at which the aluminum electrode reached a potential of +1.000 volt against the saturated calomel electrode. This potential, although quite arbitrary, was chosen since the data at this point and beyond were quite reproducible. The initial features of the runs, however, were subject to random variations. These features usually resemble in form those depicted by the solid curve, the broken curve representing a limiting case sometimes found.

The most important observation concerning these results is the lack of any appreciable dependence of curve shape, when the results are plotted against charge passed, on the current density employed. A systematic decrease in the height of the broad peak with increasing current density does occur, as can be inferred from the logarithmic plots shown in Fig. 3. It is apparent that the graphs of log Δ' versus charge

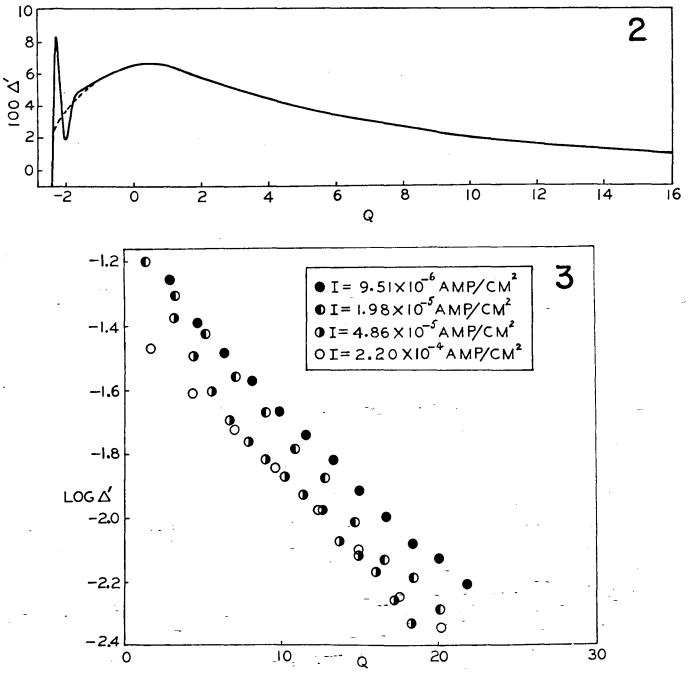

FIG. 2. Experimental data: $100\Delta'$ as a function of total charge passed (Q in mcoul/cm²).
FIG. 3. Dependence of log Δ' vs. Q on current density (Q in mcoul/cm²).

passed are nearly straight lines with the slopes independent of current density. The theoretical significance of these observations will be discussed in the following sections.

INTERPRETATION OF RESULTS

In the introduction it was stated that measurements of the time derivative of the anodic potential against a reference electrode could be interpreted under certain conditions in terms of the variation of field strength with position in the oxide. It is the purpose of this section to examine the arguments leading to this interpretation.

On making the following assumptions:

(1) 100% current efficiency for the formation of the oxide film;
(2) film density independent of the film thickness;
(3) overpotential associated with the reactions at the oxide interfaces independent of the total film thickness;
(4) field strength at a position x in the film is independent of the total film thickness, X; it follows immediately that:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[1] $$E(x, I) = (F\rho/IW_e)\dot{\varphi}(t,I)$$

where x is calculated from the relation

$$x = (IW_e/F\rho)t + X_0.$$

$E(x, I)$ is the field strength at a distance x from the metal-oxide interface during steady-state formation conditions at a current density I; $\dot{\varphi}(t,I)$ is the time derivative of the anodic potential against a reference electrode measured at time t for steady-state formation conditions at a current density I; W_e is the electrochemical equivalent weight of the oxide; F is Faraday's constant; ρ is the oxide density; and X_0 the film thickness at $t = 0$. Thus, providing the assumptions are valid and that true steady-state conditions can be achieved, the field strength as a function of position in the film may be calculated from $\dot{\varphi}$ as a function of time. Setting aside for the moment the question as to whether true steady-state conditions can in fact be achieved, the four assumptions will be examined.

The first assumption may be examined on the basis of the data of Bernard and Cook (3). These authors measured the weight gain of aluminum anodes anodically oxidized to 150 v at current densities from 10^{-7} to 10^{-3} amp/cm^2. They found that the current efficiencies for oxide formation ranged from 99% to 102%, with the estimated error in their experiments being 1%. Heating the film to 600° C gave no change in weight, indicating the absence of water or glycol in the film. Further, the presence of borates in the film was not detected by chemical analysis, there was no apparent oxygen evolution during formation and no aluminum was detected in the electrolyte after formation. For the present experiments where the same electrolyte was employed, at anode overpotentials well below 150 v, and at current densities of 10^{-5} to 2×10^{-4} amp/cm^2, within the range studied by Bernard and Cook, it is concluded that the current efficiency for oxide formation was not less than about 99%. During an experimental run, the current efficiency can therefore not decrease by more than about 1%, whereas the observed drop in $\dot{\varphi}$ would require more than a 6% decrease in current efficiency with increasing thickness to be explained in this manner.

Concerning the second assumption, significant variation in film density is expected over the first few molecular layers of oxide, but certainly not beyond about 30 Å film thickness.

Concerning the third assumption, if the field strength is a function of position in the film, x, then the defect concentration will also be a function of position. It then follows that the defect concentration in the oxide at the oxide–electrolyte interface will be a function of film thickness. In general, therefore, the overpotential associated with the oxide–electrolyte interface will also be a function of film thickness. Because of the very high field strength ($\sim 10^6$ to 10^7 v/cm) present in the film, however, the contribution of this field to $\dot{\varphi}$ will almost certainly dominate beyond the first few molecular layers of oxide.

Assumption (4) will be valid if all the mobile defects involved in the rate controlling transport process bear a positive charge and are present in low concentration, since for high-field transport conditions diffusion against the field is negligible so that the field strength and defect concentration at x_1 is not influenced by the field or defect concentration at x_2, where $x_2 > x_1$.* If all the mobile defects involved bear a negative charge,

Strictly speaking, we should include the further condition that the dimensions of the oxide–electrolyte interfacial region be small compared with that of the space charge zone, since the above statement is clearly not valid for x_1 within the interfacial region. For the present case, where the space charge zone is about 100 Å thick, this condition is almost certainly fulfilled.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

assumption (4) will still be valid provided that the x-axis direction is reversed, the position $x = 0$ being defined to coincide with the oxide–electrolyte interface. The space charge in this case will be associated with the oxide–electrolyte, rather than with the metal–oxide interface region.

If we define the "excess field", $\Delta = [E(x) - E_\infty]/E_\infty$ where E_∞ is the limiting value for E at large values of x (i.e. the value of E beyond the space charge region), it follows from our previous definition of Δ' and from equation [1] that $\Delta(x,I) = \Delta'(t,I)$ where $x = (IW_e/F\rho)t + X_0$, providing Δ' was obtained from steady-state measurements.

Examining the results from a typical run (Fig. 2) it is apparent that the equality $\Delta = \Delta'$ cannot be applied over the entire curve since electronic charging effects, responsible for the initial rapid rise in Δ', prevent the establishment of a constant ionic current density. The final fall-off of Δ' cannot be ascribed to charging effects, however, since the direction of its change is in the wrong sense. Nor can it be explained by assuming a reduction of true surface area during anodic oxidation, for the same reason. A further possibility eliminated on the same grounds is that the initial oxide film, formed by electropolishing in a chloride-containing solution, causes the current efficiency to be initially low, increasing as anodic oxidation proceeds.

The following possible causes for the final decay of Δ' cannot be eliminated on the above grounds. These are: (1) that the effect is brought about by electrolyte creeping up the electrode tab, thus reducing the current density; and (2) that the effect is the manifestation of transient ionic conduction phenomena. These possibilities will now be examined.

The principal evidence against the acceptance of the first explanation is the fact that the results obtained for electrodes whose tabs were insulated with a thick anodic film did not differ in any systematic way from the results obtained for uninsulated electrodes. In addition, the observed decay of Δ' amounts to over 6%, an effect far too large to be explained in this way.

The possibility that the decay of Δ' arises as a result of transient ionic transport processes must be examined carefully. On interrupting a run at, for example, 10 mcoul/cm^2 (Fig. 2), and starting the run again with the same sample, Δ' assumes values which form a continuation of the previous curve after a time period corresponding to only a fraction of a mcoul/cm^2. The effect of interest does not arise, therefore, as a result of simple ionic transient phenomena. Furthermore, it can be shown that the decay in Δ' is more than a factor of 10 slower than that found for ionic transients. The possibility that some unusual process, associated with the film produced during electropolishing, is responsible for the effect is also ruled out by the results obtained for the different surface treatment procedures. Only electrodes treated finally in chromic-phosphoric acid solutions gave significantly different results, this difference arising almost certainly as a consequence of specific adsorption of chromate ion on the oxide (5).

Finally, the possibility that the effect might arise from the instrumentation was eliminated by conducting suitably designed dummy runs. In addition, runs of a different nature, carried out using independent equipment, produced a very similar phenomenon. In these runs the anodic potential was increased at a constant rate, and the current recorded as a function of charge passed. The current is initially low (as expected) by about 6%, approaching the limiting value in much the same way as $\dot{\varphi}$ approaches its limiting value.

On the basis of the evidence presented, it is eminently reasonable to interpret the final decay of Δ' in terms of a real variation of the field strength with position in the film.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Assuming the rate controlling transport process to involve mobile defects of one kind only, the equality $\Delta = \Delta'$ may therefore be applied to this region. The initial features of Δ', however, most certainly cannot be interpreted in this way. They probably arise as a result of a combination of a number of the factors which have been discussed.

THEORY AND DISCUSSION

High Field Frenkel Defect Model

For comparison with the data, the theoretical influence of space charge will be calculated on the basis of the above-mentioned model (2). According to this model, interstitial metal ions are transported through the oxide film in accordance with the following equation:

$$I = 2q\, a\, \nu\, n \exp\left[-(U - Eaq)/kT\right] \qquad [2]$$

where I = ion current density in the film;
q = charge on the cation;
ν = vibrational frequency of an interstitial cation;
n = concentration of interstitial cations;
U = activation energy for the migration of interstitial cations in the absence of an electric field;
a = activation distance corresponding to U;
E = electric field strength in the oxide.

To account for transient conduction phenomena, the concentration of interstitial cations is assumed to be a function of the electric field strength and time. The simplest specific model is that suggested by Bean, Fisher, and Vermilyea (6) and by Dewald (7). They proposed that interstitial cation – cation vacancy pairs (i.e. Frenkel defects) are produced by the action of the field on lattice cations, and destroyed by their recombination. The net rate of formation of interstitials and vacancies is given by:

$$\left(\frac{\partial n}{\partial t}\right)_x = \left(\frac{\partial m}{\partial t}\right)_x = (N-m)\nu' \exp\left[-(W - E\lambda q)/kT\right] - I\sigma m/q \qquad [3]$$

where N = concentration of cation lattice sites;
m = concentration of cation vacancies;
t = time;
ν' = vibrational frequency of a lattice cation;
W = activation energy for formation of a Frenkel defect in the absence of an external electric field;
λ = activation distance corresponding to W;
σ = capture cross-section of a vacancy for an interstitial cation.

On applying this theory, it has previously been assumed that n, m, E, and I are independent of position in the film. Although this should be true some distance from the metal–oxide interface, as Dewald points out there must be, in general, a space charge near the metal–oxide interface, thereby making n, m, and E functions of position. The necessity for postulating this space charge can be seen from the following considerations. For steady-state conditions, the ion current density at the interface must be equal to that within the film some distance from the interface. Since transport of ions across the interface and transport within a space charge free oxide are distinct and independent kinetic processes, the rates can in general only be equal providing the field strengths are different. The difference in field strength can only be sustained if the intervening space contains a net charge.

Profile of Electric Field Strength

Only the cases corresponding to steady-state anodic oxidation will be considered. Under these conditions, the following relations hold:

$$[4] \qquad \left(\frac{\partial I}{\partial x}\right)_t = \left(\frac{\partial I}{\partial t}\right)_x = \left(\frac{\partial n}{\partial t}\right)_x = \left(\frac{\partial m}{\partial t}\right)_x = \left(\frac{\partial E}{\partial t}\right)_x = 0$$

where x is the distance in the oxide measured from the metal–oxide interface. In the zone of the oxide where the space charge is negligible (i.e. at sufficiently large x) we may set $m = n = n_\infty$. The variation of current with field in the space charge free zone, E_∞, under steady-state conditions is then obtained from equations [2] to [4].

$$[5] \qquad I = \alpha \exp \beta E_\infty$$

where $\alpha = q(2aN\nu\nu'/\sigma)^{1/2} \exp\left[-(W + U)/2kT\right]$

and $\beta = q(\lambda + a)/2kT$.

Equation [5] is of the form found experimentally for the valve metals for films thicker than about 100 Å (2).*

An expression for the variation of n with field strength within the space charge zone is obtained from equation [2].

$$[6] \qquad n = n_\infty \exp[(E_\infty - E)\, aq/kT]$$

Similarly, the variation of m with field strength within the space charge zone is obtained from equations [3] and [4], and assuming $N \gg m$.

$$[7] \qquad m = n_\infty \exp[(E - E_\infty)\lambda q/kT]$$

From Poisson's equation we also have:

$$[8] \qquad \frac{dE}{dx} = \frac{4\pi q}{\epsilon}(n - m)$$

where ϵ, the dielectric constant of the oxide, is assumed to be independent of x. Substituting for n and m in equation [8], the resulting equation can be written:

$$[9] \qquad dy/ds = (1 - y^\gamma)/\gamma$$

where y, s, and γ are dimensionless parameters defined as follows:

$$y = \exp\left[-|E - E_\infty|(\lambda + a)\, q/\gamma kT\right]$$

$$s = [4\pi q^2(\lambda + a)n_\infty/kT\epsilon]x$$

for $n_0 > m_0$, $\quad \gamma = (\lambda + a)/a$ and $E_\infty > E$

for $n_0 < m_0$, $\quad \gamma = (\lambda + a)/\lambda$ and $E_\infty < E$

where n_0 and m_0 are the values of n and m at $x = 0 = s$.

Equation [9] can be solved in terms of simple functions for certain values of γ only. Asymptotic solutions for any value of γ, however, can be found. One such solution is easily deduced for the case $y^\gamma \ll 1$. This corresponds, however, to very large deviations of E from E_∞, under which conditions the equations used to obtain equation [9] probably represent poor approximations. In addition, only relatively small deviations of E from

**Strictly speaking, the exponential factor should contain a term in E^2 (8). However, its omission here will cause no serious error.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

E_∞ are apparent from the experimental results. The asymptotic solution for the other extreme case, $1-y \ll 1$, will be considered in the following development.

The general solution of equation [9] can be expressed as follows:

$$s + s_0 = f(\gamma,y) - \ln (1-y) \quad [10]$$

where

$$f(\gamma,y) = \int_0^y \left(\frac{\gamma}{1-y^\gamma} - \frac{1}{1-y}\right)dy$$

and s_0 is the integration constant.

The important property of $f(\gamma,y)$ is that it approaches a finite value as y approaches unity (see Fig. 4). Equation [10] can be rearranged to give:

$$\ln y = \ln (1-\exp [f(\gamma,y)-(s+s_0)]). \quad [11]$$

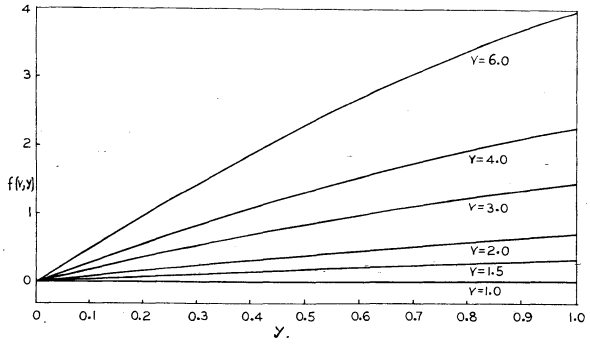

FIG. 4. The function $f(\gamma,y)$ vs. y for various values of γ.

On substituting for y according to its definition, and for E_∞ according to equation [5], equation [11] becomes:

$$|\Delta| = -\gamma \ln (1-\exp [f(\gamma,y)-(s+s_0)])/\ln (I/\alpha) \quad [12]$$

where Δ is $(E-E_\infty)/E_\infty$ as before.

For $1-y \ll 1$ (i.e. E almost equal to E_∞) it follows that $1 \gg \exp [f(\gamma,y)-(s+s_0)]$ and $f(\gamma,y) \simeq f(\gamma,1) = f(\gamma)$, so that equation [12] reduces to the following approximate relation:

$$|\Delta| \simeq \gamma \exp [f(\gamma)-(s+s_0)]/\ln (I/\alpha). \quad [13]$$

Equation [13] represents, therefore, the field profile in the region of the film where the effect of the space charge has almost vanished. In this region, a plot of $-\ln |\Delta|$ versus distance from the metal–oxide interface, x, should yield a straight line:

$$-\ln |\Delta| \simeq \left(\frac{4\pi q^2(\lambda+a)n_\infty}{kT\epsilon}\right)x + \left(\ln\left[\frac{\ln (I/\alpha)}{\gamma}\right] - f(\gamma) + s_0\right) \quad [14]$$

It is seen from equation [14] that the slope, and hence the rate of fall of the space charge effect with distance, is proportional to n_∞, the concentration of defects in the space charge free zone of the film. This is certainly an expected result, which leads to the further expectation that the slope should be an increasing function of current density, since n_∞ increases with increasing current density. Substituting for n_∞ the relation obtained from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

equations [2] and [5], the expression for the slope becomes:

$$[15] \qquad \text{slope} = \left(\frac{2\pi q\alpha^{2a/(\lambda+a)}}{kT\epsilon\nu \exp(-U/kT)}\right)\left(\frac{\lambda+a}{a}\right)\cdot I^{(\lambda-a)/(\lambda+a)}.$$

From the steady-state data for aluminum obtained by Bernard and Cook (3), $\lambda+a \simeq 7.8$ Å, and from transient data obtained in this laboratory (9), $a = 1.25$ Å. For aluminum, therefore, the slope should vary proportionately to $I^{0.7}$, a factor of 20 change in I causing about a factor of 8 change in the slope. The results shown in Fig. 3 clearly do not confirm this prediction, the slope being independent of current density within experimental error. After allowing for the maximum possible errors in the evaluation of $(\lambda+a)$ and a, the results and theory are still irreconcilable. In a recent publication by Ryan and Dignam, a modification of the high-field Frenkel defect model was proposed in order to explain certain transient ionic conduction measurements. It turns out, however, that the modified model leads to identically the same variation of the slope with I as does the original model. The conflict between the results and the theory is basic, in that the results indicate no observable dependence of the concentration of charged defects on the current density (and hence also on the field strength) in contradiction the fundamental postulate of the high-field Frenkel defect model. It is necessary, therefore, either to discard the model completely, or else to reinterpret the data. As the validity of the present interpretation of the data has been carefully examined, the only conclusion justified at present is the rejection of the model.

Further evidence against this model is provided by the calculations illustrated in Fig. 5.

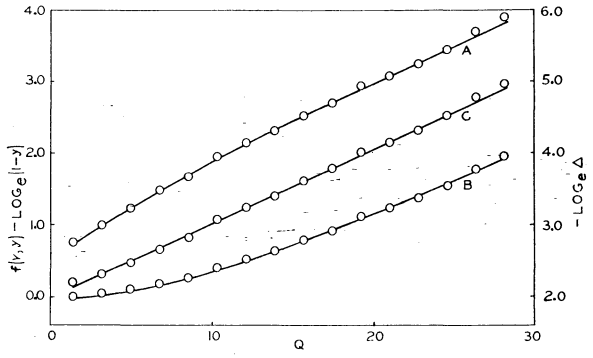

FIG. 5. Space charge data plotted according to: A, equation [14]; B, equation [10] with $\lambda + a = 7.8$ Å and $a = 1.25$ Å; C, equation [10] with $\lambda = a = 7.8/2$ Å. Q in mcoul/cm² in all cases.

The data obtained from one of the most reliable runs is plotted first (curve A) in accordance with the approximate equation [14] (i.e. $-\ln \Delta$ vs. charge passed), then in accordance with the more precise equation [10] (i.e. $f(\gamma,y) - \ln(1-y)$ vs. charge passed), the latter for two sets of values for the parameters ($\lambda+a = 7.8$ Å, $a = 1.25$ Å for curve B, $\lambda = a = 7.8/2$ Å for curve C). In order to calculate the results for curves B and C, the actual field strengths were required. These were calculated from $\dot{\varphi}$ values using the data obtained by Bernard and Cook (3). If the high-field Frenkel defect model were correct, curve B should be linear. It is, in fact, the least linear of the three curves. It is important to determine the significance of the excellent linearity of curve C, calculated assuming only a single activation distance equal to that obtained from steady-state measurements,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

particularly since for $\lambda = a$ the slope of the log Δ' versus Q plots previously discussed will be independent of current density as observed. Its significance, however, is not immediately obvious, since for $\lambda = a$ the high field Frenkel defect model cannot give rise to transient ionic conduction.

One of us (M. J. D.) has recently proposed a new model for the anodic oxidation of the valve metals (10) in which the transient phenomena arise not as a result of a change of defect concentration, but as a result of time dependent polarization phenomena within the film. The theory was proposed initially to explain anomalies relating to conventional steady-state and transient kinetic results, but it appears to contain the essential ingredients to be in accord with the present results, and with recent results relating to transport numbers (11).

The detailed predictions arising from this model have not as yet been worked out, but preliminary investigation has led to a relation formally identical with equation [10], with "λ" and "a" equal to one another and to the empirical steady-state activation distance, which is about 3.9 Å for aluminum (3).

SUMMARY AND CONCLUSIONS

Measurements of the time derivative of the aluminum overpotential versus film thickness during anodic oxidation show no appreciable dependence on formation current density. Analyzed in terms of the high-field Frenkel defect theory, this means that the defect concentration is independent of the steady-state current density, in direct conflict with the basic postulate of this theory. It seems likely, although it is difficult to prove, that these results show the concentration of charged defects in the film to be independent of current density for any assumed mechanism involving mass transport through the film as a rate controlling process. Specifically, therefore, the data are in direct conflict with the high-field Frenkel defect model or any reasonable modification of it, and most likely in conflict with any theory which predicts a dependence of defect concentration on current density.

Alternatively, one can choose to interpret the data in terms of spurious phenomena totally unrelated to space charge effects. All of the data obtained mitigate against such an interpretation. In addition, the data are in excellent accord with a theory already postulated (10) to explain data of an entirely different sort. We prefer at the moment, therefore, to support the above conclusions.

Detailed analysis of space charge effects in relation to the new model (10) will be presented in a future publication.

The authors are grateful to The National Research Council of Canada for supporting this research and for a scholarship (P. J. R.).

ENERGETICS AND MECHANISM OF HYDRONIUM ION FORMATION BY ELECTRON IMPACT

D. VAN RAALTE AND A. G. HARRISON[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received August 12, 1963

ABSTRACT

The reactions leading to formation of the hydronium ion in the mass spectra of a number of alcohols and formate esters have been elucidated through a study of appearance potentials and metastable transitions and by the use of deuterium labelling. The results lead to $\Delta H_f(H_3O^+) = 157 \pm 3$ kcal/mole corresponding to a proton affinity of the gaseous water molecule of 151 ± 3 kcal/mole.

INTRODUCTION

The generally accepted value for the proton affinity of the gaseous water molecule is 182 kcal/mole (1) based on calculations from crystal lattice energies by Sherman (2). More recently Sokolov *et al.* (3) have recalculated P.A. (H_2O) from lattice energies and, taking into account the effect of hydrogen bonding, have obtained P.A. (H_2O) = 168 ± 7 kcal/mole. This latter value is in essential agreement with an independent estimate obtained by Tal'roze and Frankevich (4) from a study of gas-phase ion–molecule reactions involving H_3O^+ as the product ion. The reaction

$$H_2S^+ + H_2O \rightarrow H_3O^+ + HS \qquad [1]$$

was observed and therefore must be exothermic or thermoneutral. Thermochemical calculations led (4) to a maximum value $\Delta H_f(H_3O^+) \leq 141$ kcal/mole. Using a more recent value (5) for $\Delta H_f(HS)$ this upper limit is raised to 145 kcal/mole, leading to a minimum value P.A. (H_2O) ≥ 163 kcal/mole. On the other hand, the reaction

$$C_2H_2^+ + H_2O \rightarrow H_3O^+ + C_2H \qquad [2]$$

was not observed and was therefore assumed to be endothermic (4). On this basis a minimum value $\Delta H_f(H_3O^+) \gtrsim 136$ kcal/mole (P.A. (H_2O) ≤ 172 kcal/mole) was obtained. This limit must be accepted with reservation, since other factors may be responsible for the non-occurrence of reaction [2].

Although the hydronium ion has been observed as a rearrangement ion in the mass spectra of alcohols (6, 7, 8) and esters (9) no systematic investigation of the energetics and mechanism of formation has been undertaken. An early study (10) of the appearance potential of H_3O^+ from ethyl alcohol has been used (11) to derive $\Delta H_f(H_3O^+) = 172$ or 196 kcal/mole, depending on the mechanism of formation chosen. More recently, Bernecker and Long (12) have measured the appearance potential of H_3O^+ from ethyl formate and have reported $\Delta H_f(H_3O^+) = 207$ kcal/mole, corresponding to P.A. (H_2O) = 100 kcal/mole.

In view of the conflict in the reported values for $\Delta H_f(H_3O^+)$ and the paucity of data concerning the mechanism of formation of this rearrangement ion in the mass spectra of alcohols and esters, we have undertaken a detailed study of the energetics and mechanism of formation of H_3O^+ by electron impact.

EXPERIMENTAL

All results were obtained using an Associated Electrical Industries MS-2 mass spectrometer. The mass spectra were obtained with 50 volts electron energy, 20 μamp ionizing current and 3 volts repeller (~7 volts/cm field strength). The appearance potentials were obtained as previously described (13), using xenon or krypton as the calibrating gas.

The mass-to-charge ratios of the "low mass" metastables of interest in the present work were measured by comparison with the C^+ ion using electrostatic scanning and making accurate comparison with the voltage necessary to bring the two ion beams into focus. The necessary circuitry and potentiometer are built into the mass spectrometer.

The non-deuterated compounds were commercial samples with the exception of the isopropyl formate which was prepared by standard procedures. All samples were carefully dried and distilled before use to remove traces of water. In all cases the peak attributable to H_2O impurity was scarcely above the normal small instrument background.

The ethyl-1,1-d_2 alcohol, 2-propyl-1,1,1,3,3,3-d_6 alcohol, ethyl formate-*d*, and isopropyl formate-*d* were obtained from Merck, Sharp, and Dohme. The detailed mass spectra of the two esters have been presented previously (14). The deuterated ethyl alcohol initially contained impurities thought to be acetone and diethyl ether. These were removed by careful distillation. The isopropyl-d_6 alcohol also showed diethyl ether impurities which were removed by gas chromatography. Low energy analysis of both alcohols indicated approximately 99% isotopic purity.

RESULTS AND DISCUSSION

The appearance potential of H_3O^+ was measured from ethanol, *n*-propanol, *s*-propanol, *s*-butanol, *s*-pentanol, 3-methyl-2-butanol, diethyl ether, ethyl formate, and isopropyl formate. The measured appearance potentials, postulated neutral products, and the resultant $\Delta H_f(H_3O^+)$ for each compound are given in Table I. The evidence leading to the assignment of the neutral fragments, and thus the details of the ionization mechanism, will be discussed below.

TABLE I

Appearance potentials and heats of formation of H_3O^+

Compound	$A(H_3O^+)$ kcal/mole ±3	Postulated neutral products	$\Delta H_f(H_3O^+)$ kcal/mole ±3
s-Propanol	310	$CH_3 + C_2H_2$	158
s-Butanol	308	$C_2H_5 + C_2H_2$	158
s-Pentanol	308	$n\text{-}C_3H_7 + C_2H_2$	156
3-Me-2-butanol	304	$i\text{-}C_3H_7 + C_2H_2$	154
Ethanol	277	C_2H_3	156
n-Propanol	292	$C_3H_3 + H_2$	155
Diethyl ether	304	$C_2H_5 + C_2H_2$	164
Ethyl formate	302	$HCO + C_2H_2$	159
Isopropyl formate	317	$CH_3 + CO + C_2H_2$	159

The heats of formation of neutral species necessary for the calculations in Table I were taken from the recent compilations of Bernecker and Long (12) and Green (15) with a few exceptions. The heats of formation of the propyl radicals are in some doubt and the values used were based on $D(n\text{-Pr-H}) = 99$ kcal/mole (16) and $D(i\text{-Pr-H}) = 96.5$ kcal/mole, an average of two values 94 kcal/mole (17) and 99 kcal/mole (18). $\Delta H_f(C_3H_3) = 75$ kcal/mole (19) was used in preference to the value quoted by reference (12). The heats of formation of *s*-pentanol, 3-methyl-2-butanol, and isopropyl formate have not been reported and were estimated by comparison with related compounds to be: −75.9, −76.2, and −98 kcal/mole respectively. Calculations using group contributions (20) gave very similar values for the two alcohols; the error for these cases is likely to be small, however the value for isopropyl formate may be in error by ±3 kcal/mole.

Formation of H_3O^+ from $RCH(CH_3)OH$

The most extensive and conclusive evidence for the dissociation mechanism was obtained for secondary alcohols $RCH(CH_3)OH$ where R = CH_3, C_2H_5, *n*-C_3H_7, and *s*-C_3H_7. The mass spectra of these alcohols all show (8) the largest peak at mass 45* (CH_3CHOH^+) corresponding to loss of the group R. For *s*-propanol (21, 22) and *s*-butanol (23) deuterium labelling has shown that the group R is lost without isotopic mixing. Each of the four alcohols showed a pronounced metastable at mass 8.02 corresponding to the transition

$$CH_3CHOH^+ \rightarrow H_3O^+ + C_2H_2 \quad m^* = 19^2/45 = 8.02. \qquad [3]$$

The intensity of the metastable was directly proportional to the sample pressure indicating that reaction [3] was not a collision-induced dissociation. These facts suggest a common mechanism, reaction [4], for the four alcohols.

$$RCH(CH_3)OH \rightarrow R + CH_3CHOH^+ \rightarrow C_2H_2 + H_3O^+ \qquad [4]$$

Calculations assuming this mechanism lead to mutually consistent values for $\Delta H_f(H_3O^+)$ as summarized in the first four rows of Table I.

For *s*-propanol it has been suggested (24) that formation of H_3O^+ would occur by reaction [5] with C_3H_5 (allyl) as the neutral fragment

$$(CH_3)_2CHOH \rightarrow C_3H_5 + H_3O^+. \qquad [5]$$

The experimental appearance potential, 310 kcal/mole, leads to $\Delta H_f(H_3O^+) = 213$ kcal/mole assuming reaction [5]. This value is in disagreement with other values obtained in this work. Furthermore, reaction [5] does not lead to the observed metastable, nor does it explain the observed deuterium labelling to be discussed below.

To provide further information on the detailed mechanism of reaction [4] the mass spectrum of 2-propyl-1,1,1,3,3,3-d_6 alcohol was examined. The spectrum obtained was in good agreement with that previously reported (22). The intermediate mass 45 has moved to mass 48 indicating the formula CD_3CHOH^+. The observed relative intensities for H_2DO^+, HD_2O^+, and D_3O^+ are given in Table II and compared with relative intensities calculated on the following four models:

(i) complete scrambling in parent ion,
(ii) retention of hydroxyl hydrogen and scrambling of remainder in parent ion,
(iii) complete scrambling in CD_3CHOH^+ intermediate,
(iv) retention of hydroxyl hydrogen and scrambling of remainder in CD_3CHOH^+ intermediate.

The results of Table II show that the only model which comes close to predicting the

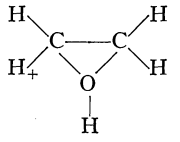
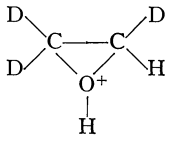
observed relative intensities is model (iv) involving retention of the hydroxyl hydrogen and scrambling of the remainder in the CD_3CHOH^+ intermediate. There does not appear to be any reasonable model involving direct decomposition of the parent ion (reaction [5]) which can explain the observed label distribution. A simple interpretation of the label distribution is the formation of a symmetrical protonated ethylene oxide intermediate having the structures I and II for the unlabelled and labelled alcohols respectively.



I



II

Transfer of one hydrogen (or deuterium) from each carbon to the oxygen would explain the product formation and the deuterium labelling. The small ion current for D_3O^+ suggests a small amount of exchange of the hydroxyl hydrogen with the other hydrogens in the intermediate ion. The appearance potentials of the H_2DO^+ and HD_2O^+ ions were identical with the appearance potential of H_3O^+ from the unlabelled alcohol within experimental error. The abundance of the D_3O^+ ion was too low to permit appearance potential measurements.

The deuterium labelling in *s*-butanol (23) provides results in good agreement with those obtained for *s*-propanol. Table III shows the abundance of the relevant ions, as percentage

are compared in Table IV with relative intensities calculated on the following four models:

(i) complete scrambling in parent ion,
(ii) retention of hydroxyl hydrogen and scrambling of remainder in parent ion,
(iii) complete scrambling in CD_3CHOH^+ intermediate,
(iv) retention of hydroxyl hydrogen and scrambling of remainder in CD_3CHOH^+ intermediate.

The experimental results are practically identical with the label distribution found for the isopropanol-d_6 and clearly are only in accord with model (iv). The formation of D_3O^+ in low abundance again probably represents a small amount of hydroxyl hydrogen exchange in the intermediate II.

In *s*-butanol-d_6 the intermediate CD_3CDOH^+ should lead only to HD_2O^+ by the mechanism proposed. The partial spectrum in Table III shows, as expected, the largest ion current at mass 21, however, the ion current at mass 22 (D_3O^+) indicates again some scrambling in the intermediate.

Formation of H_3O^+ from Ethyl Alcohol

Two reactions, [6] and [7], must be considered as possibilities for the formation of H_3O^+ from ethyl alcohol.

$$CH_3CH_2OH \rightarrow C_2H_3 + H_3O^+ \quad [6]$$

$$\rightarrow H + CH_3CHOH^+ \rightarrow C_2H_2 + H_3O^+ \quad [7]$$

The mass spectrum of ethyl alcohol shows an appreciable ion current for CH_3CHOH^+ and, in addition, a metastable ion at mass 8.02 (reaction [3]) corresponding to the second step in the overall reaction [7]. However, the measured appearance potential, 277 kcal/mole, leads to $\Delta H_f(H_3O^+) = 115$ kcal/mole assuming reaction [7] and 156 kcal/mole assuming reaction [6]. The agreement of this latter value with the values obtained from the secondary alcohols indicates quite conclusively that the lowest energy process occurring is reaction [6]. Reaction [7], which is of higher energy requirement, is shown to occur by the metastable transition at mass 8.02. Attempts were made to detect breaks in the ionization efficiency curve by the method of Morrison (25). Although a rather large initial curvature was observed, no definite breaks could be identified.

In an attempt to obtain information on the relative importance of reactions [6] and [7] the mass spectrum of CH_3CD_2OH was examined. As has been found previously (26, 27), the mass 45 moves exclusively to mass 46, indicating loss of the α-deuterium. The observed spectrum in the region of the hydronium ion (Table V) is in reasonable agreement with

TABLE V

that reported by Momigny (26). The appearance potentials for H_3O^+ and H_2DO^+ were 273±3 and 274±3 kcal/mole respectively, in good agreement with the value of 277

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

kcal/mole obtained for the undeuterated alcohol. The relative intensities for H_3O^+ and H_2DO^+ are close to that expected for decomposition of the CH_3CDOH^+ intermediate; the small amount of D_2HO^+ must originate by reaction [6]. No significant variation of the ratio H_3O^+/H_2DO^+ was observed as the electron energy was decreased to near the threshold. This probably means that the label distributions obtained from reactions [6] and [7] do not differ significantly. On the basis of the present evidence we cannot assess the relative importance of the two reactions.

Formation of H_3O^+ from n-Propyl Alcohol

The mass spectrum of *n*-propyl alcohol shows only a very small ion current for mass 45 and no metastable corresponding to reaction [3]. The following three reactions must be considered.

$$CH_3CH_2CH_2OH \rightarrow C_3H_5 + H_3O^+ \quad [8]$$

$$\rightarrow C_3H_4 + H + H_3O^+ \quad [9]$$

$$\rightarrow C_3H_3 + H_2 + H_3O^+ \quad [10]$$

The measured appearance potential, $A(H_3O^+) = 292 \pm 3$ kcal/mole leads to $\Delta H_f(H_3O^+) =$ 199 kcal/mole assuming [8], 144 kcal/mole assuming [9] and 155 kcal/mole assuming [10]. Although reaction [10] appears rather unlikely, it gives the best fit for $\Delta H_f(H_3O^+)$ and is, accordingly, the reaction chosen.

Formation of H_3O^+ from Diethyl Ether

The H_3O^+ ion is of moderate abundance (0.8% of total ionization) in the mass spectrum of diethyl ether. A sizeable ion current at mass 45 and a metastable at mass 8.02 (reaction [3]) suggested decomposition through the mass 45 intermediate. $A(H_3O^+) = 304$ kcal/mole leads to $\Delta H_f(H_3O^+) = 164$ kcal/mole assuming reaction [11].

$$C_2H_5OC_2H_5 \rightarrow C_2H_5 + C_2H_2 + H_3O^+ \quad [11]$$

If this reaction is the only one contributing to H_3O^+ formation it must be responsible for the metastable transition, thus suggesting that the mass 45 is $C_2H_5O^+$ formed with C_2H_5 as the neutral fragment. It is probable, however, that the majority of the mass 45 ions are formed by the rearrangement reaction indicated below (28).

$$CH_2{-}CH_2O{-}CH{-}CH_3 \rightarrow H + C_2H_4 + HO\overset{+}{C}HCH_3 \quad [12]$$

The appearance potential of mass 45 was found to be 272 ± 3 kcal/mole in the present work, which leads to an ionic heat of formation of 147 ± 3 kcal/mole, assuming reaction [12], in excellent agreement with best estimates of $\Delta H_f(CH_3CHOH^+) = 145$ kcal/mole derived from simple alcohols. This indicates that reaction [12] is the lowest energy process producing mass 45 and, since decomposition of CH_3CHOH^+ is known to produce H_3O^+ (see above), we conclude that reaction [13], which is of higher energy requirement than reaction [12], also contributes to H_3O^+ formation.

$$C_2H_5OC_2H_5 \rightarrow H + C_2H_4 + C_2H_2 + H_3O^+ \quad [13]$$

Formation of H_3O^+ from Ethyl Formate

The H_3O^+ ion is approximately 1.2% of the total ionization in ethyl formate. In the present work $A(H_3O^+)$ was found to be 302 ± 3 kcal/mole, considerably lower than the value of 334 kcal/mole reported by Bernecker and Long (12). Reactions [14] to [16] must be considered in a discussion of these results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$HCOOC_2H \rightarrow C_2H_3 + CO + H_3O^+ \quad [14]$$

$$\rightarrow C_2H_2 + HCO + H_3O^+ \quad [15]$$

$$\rightarrow C_2H_2 + H + CO + H_3O^+ \quad [16]$$

Table VI records the values calculated for $\Delta H_f(H_3O^+)$ for each of these reactions using

TABLE VI

Appearance potential and calculated $\Delta H_f(H_3O^+)$ in ethyl formate

	$A(H_3O^+)$ (kcal/mole)	$\Delta H_f(H_3O^+)$ (kcal/mole)		
		Reaction [14]	Reaction [15]	Reaction [16]
This work	302	175	159	133
Bernecker and Long	334	207	191	166

both our result and that of Bernecker and Long. It is apparent that the present result gives a satisfactory ionic heat of formation only if reaction [15] is assumed to be the lowest energy process occurring. Reaction [14], which was assumed by Bernecker and Long, does not give results in agreement with other estimates in the present work. The ionization efficiency curve showed a rather large tailing, suggesting that more than one reaction was occurring, and it is possible that Bernecker and Long's appearance potential corresponds to reaction [16].

The mass spectrum of ethyl formate shows a large mass 45 ion current and a metastable at mass 8.02 (reaction [3]). The mass spectrum of ethyl formate-*d* (14) shows that approximately 65% of the mass 45 ion incorporates the formyl hydrogen to give CH_3CHOD^+. In addition, in ethyl formate-*d* a metastable was observed at mass 8.70 indicating the transition

$$DOCHCH_3^+ \rightarrow H_2DO^+ + C_2H_2. \quad [17]$$

Since the mass spectrum of ethyl formate-*d* shows predominantly H_2DO^+ formation (1.2% compared to 0.3% H_3O^+), and since it has been established (14) that the ion CH_3CHOD^+ is formed with H+CO as the neutral fragment, it was thought that the DH_2O^+ formation should give a measure of the fraction of the reaction proceeding by reaction [16]. However, the appearance potential of DH_2O^+ was found to be 306±3 kcal/mole compared to 302±3 kcal/mole for H_3O^+ from the undeuterated ester. One must therefore assume HCO+C_2H_2 (reaction [15]) as the neutral fragments. Obviously, incorporation of the formyl hydrogen in the H_3O^+ ion with formation of HCO as one of the neutrals must involve considerable hydrogen scrambling in the parent ion. The mechanism by which this occurs is unknown.

Formation of H_3O^+ from Isopropyl Formate

The largest peak in the mass spectrum of isopropyl formate is mass 45. In isopropyl formate-*d* the peak moves to mass 46 indicating retention of the formyl hydrogen (14). The rearrangement is given by reaction [18]:

$$HCOOCH(CH)_2 \rightarrow CO + CH_3 + HOCHCH_3^+ \quad [18]$$

The mass spectrum of isopropyl formate also shows a metastable at mass 8.02, moving to mass 8.70 in the formate-*d*. The complete reaction for formation of H_3O^+ would thus appear to be reaction [19] proceeding through the CH_3CHOH^+ intermediate.

$$HCOOCH(CH_3) \rightarrow CO + CH_3 + C_2H_2 + H_3O^+ \quad [19]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$A(H_3O^+) = 317 \pm 3$ kcal/mole leads to $\Delta H_f(H_3O^+) = 159$ kcal/mole assuming this mechanism, in good agreement with other results obtained in this work.

In isopropyl formate-*d* the intermediate hydroxycarbinyl ion contains the formyl deuterium probably attached to the oxygen, i.e. $DOCHCH_3^+$. The labelling results for the secondary alcohols were explained on the basis of retention of the hydroxyl hydrogen in the decomposition of this intermediate. In the present case this should lead exclusively to DH_2O^+ formation. The mass spectrum of isopropyl formate-*d* shows (14) the relative intensities mass 20:mass 19 = 1.86:0.34. It is clear that the major part of the hydronium ion does incorporate the deuterium label as required. The small amount of H_3O^+ probably again represents a small amount of scrambling in the intermediate ion.

SUMMARY

The present results lead to an average value $\Delta H_f(H_3O^+) = 157 \pm 3$ kcal/mole yielding a value of 151 ± 3 kcal/mole for the proton affinity of water. The value of 157 kcal/mole for $\Delta H_f(H_3O^+)$ is considerably higher than the maximum value of 145 kcal/mole indicated by the reported occurrence (4) of the ion–molecule reaction

$$H_2S^+ + H_2O \rightarrow H_3O^+ + HS. \quad [1]$$

The reason for this discrepancy is not obvious. The mechanisms proposed for most of the decomposition reactions in the present work appear to be well substantiated by metastable and labelling evidence. The appearance potentials and resultant ionic heats of formation are therefore not likely to be in error unless excess energy is involved in each ionization process. This would necessitate the same amount of excess energy in each case, and thus appears unlikely. The ion–molecule reactions occurring in the high-pressure mass spectrum of H_2O–H_2S mixtures are numerous and include (4) reactions [20] and [21] in addition to reaction [1].

$$H_2O^+ + H_2S \rightarrow H_3O^+ + HS \quad [20]$$

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH \quad [21]$$

In these circumstances it is not clear that it has been clearly established that reaction [1] involves an H_2S^+ ion in the ground state. Reaction of an H_2S^+ ion with a minimum of 12 kcal/mole excitational energy could lead to H_3O^+ formation even if reaction of a ground state ion were endothermic.

In any event, the present results combined with the results of Tal'roze and Frankevich (4) clearly indicate that $\Delta H_f(H_3O^+)$ is in the range 145–157 kcal/mole rather than 207 kcal/mole, as had been suggested by previous electron impact work (12).

AROMATIC SUBSTITUTION

PART V.[1] THE MECHANISM OF THE REACTION OF PHENYLLITHIUM WITH PYRIDINES. DEUTERIUM ISOTOPE EFFECT STUDIES

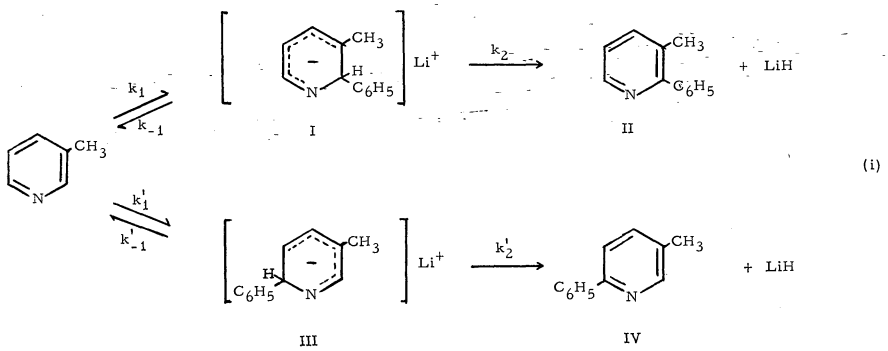
R. A. ABRAMOVITCH AND CHOO-SENG GIAM
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received May 17, 1963

ABSTRACT

The ratios of isomers formed in the reaction of 3-alkylpyridines with phenyllithium under various conditions appear to be invariant within the limits of experimental error. A number of experiments, including the reaction of phenyllithium with 3-picoline-2*d* and with an excess of a mixture of pyridine and pyridine-2*d*, are described which establish that the hydride ion elimination stage in these nucleophilic aromatic substitutions is not important in determining the observed orientation and that the addition stage is either virtually irreversible or that the equilibrium lies far on the product side and is not rapidly reversible. A convenient new procedure is described for working up the reaction mixtures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In previous parts of this series (1, 2) the reaction of 3-substituted pyridines with phenyllithium has been studied, particular emphasis being placed upon the determination of the orientation of the entering phenyl group and the isomer ratios. It was shown that in the case of most 3-substituents the main product formed was the 2,3-disubstituted pyridine derivative, the 2,5-isomer usually being formed in lesser amounts. In no case was any attack at C_4 of the pyridine ring observed. A number of possible explanations for the observed orientation were considered (1). Among other possibilities it was pointed out that if the second stage in these reactions, the elimination of hydride ion, is rate-determining, and *if it is assumed that the addition step is rapidly reversible* the results might be explained as follows (3-picoline is taken as an example):



The aromatization step in (i) probably involves the abstraction by the lithium cation of the hydrogen atom with its bonding pair of electrons. The energy of activation for this step would probably be lowered more by an electron-repelling ortho-methyl than by a para-methyl group. This effect might well be greater than the opposing steric effect favoring hydride expulsion from III over that from I.* If this is so, k_2 would be greater

[1]*Part IV: R. A. Abramovitch, W. A. Hymers, J. B. Rajan, and R. Wilson. Tetrahedron Letters, 1507 (1963).*
**If the transition state resembles product there would be appreciable 1,2-alkyl:phenyl repulsion in the case of I → II.*

than k_2' and more II would be formed than IV even though K_1' were greater than K_1, provided the addition step is rapidly reversible. It is to be noted that whereas the addition step is exothermic, heat is required to cause the elimination to take place. In addition, the formation of intermediates such as (I) and (III) finds support in the oxidation of the pyridine–phenyllithium adduct with benzophenone (3), when a by-product, probably 4-diphenylhydroxymethyl-2-phenylpyridine (V), is also formed. This presumably arises by the addition of the 2-phenyl-1,2-dihydropyridyllithium intermediate to benzophenone followed by oxidation and a molecular rearrangement (3).

In order to test the above possibility the reactions of phenyllithium with deuterated pyridine and deuterated picoline were examined. Before doing so, however, it was decided to re-examine the ratios of isomers formed in the reaction between phenyllithium and a 3-alkylpyridine when the phenyllithium solution was added to an excess of the 3-alkylpyridine (which was, therefore, always present in excess throughout the reaction) instead of the other way around (when phenyllithium was present in excess, at least in the initial stages). In this way, it was hoped to get a better indication if possible of the relative discrimination of the attacking reagent towards C_2 and C_6. The results are summarized in Table I. The reaction mixtures were worked up in the usual way by heating with

TABLE I

Addition of phenyllithium to an excess of 3-R-pyridine

R	Overall yield* of phenyl-3-R-pyridine (%)	Ratio of 2,3- to 2,5-isomer

toluene at ca. 110°. The ratios of the 2,3- to the 2,5-phenylalkylpyridines are the same, within experimental error, as those obtained when the addition was carried out in the reverse order (1).

During the course of this work a much more convenient procedure for the working up of the reaction mixture resulting from the addition of an organo-lithium compound to pyridines was developed. After the addition was completed and the mixture had been stirred at room temperature for varying lengths of time dry oxygen was slowly bubbled through the ethereal suspension: oxidation of the dihydropyridyllithium intermediate occurred readily (3) to give the required reaction products and probably lithium hydroxide. The isomer ratios were essentially unchanged, but the overall yields of products are usually somewhat higher—this may well be due to the fact that extensive polymerization of the dihydropyridyllithium intermediate takes place, particularly when it is heated.

The isomer ratio for the addition of phenyllithium to 3-picoline also remained unchanged when the reaction was carried out in dry light petroleum or in dry benzene instead of in ether. When an ethereal solution of the 3-picoline–phenyllithium adduct was stirred at room temperature for various intervals of time (from 6 to 90 hours) before being worked up, again no change in the isomer ratio was observed but the yield of products rose from

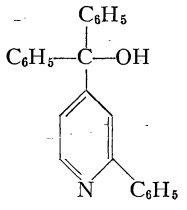
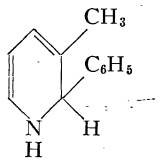
For personal use only.

20.5 to 42.9%. The reactions with 3-picoline and with 3-ethylpyridine with phenyllithium in ether were also carried out in the presence of an excess of anhydrous lithium bromide. The reactions appeared to proceed more slowly under these conditions (as indicated by the evolution of heat) than when one equivalent of lithium bromide was present (which normally arises from the method of preparation of phenyllithium using bromobenzene and lithium in dry ether), and the overall yields of products were somewhat lower; on the other hand, the 2,3- to 2,5-isomer ratios were unchanged within the limits of accuracy of the experiments (±2%). Finally, the reactions were carried out using halide-free phenyllithium from diphenylmercury and lithium metal (6): once again the isomer ratios remained constant.

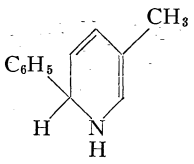
In order to test whether the possible reversibility of the addition step had any influence upon the isomer ratios observed, the reaction of phenyllithium with an excess of 3-picoline was interrupted by the addition of water after only a small percentage of the addition had occurred. The 1,2-dihydrophenylpicolines (VI) and (VII) thus formed (4) cannot revert to starting material and, if oxidized, should give the isomeric phenylpicolines in a ratio indicative of the actual orientation in the addition step. Thus, one might then expect that if equations (i) hold and $K_1' > K_1$ (the inductive effect of the methyl group would render attack at C_6 more likely than at C_2) one would get more 2,5- than 2,3-isomer. When the suspension of the dihydropyridines obtained after treatment with water was either oxidized directly with chloranil (5) or extracted with ether and the ethereal extract oxidized and the products analyzed by gas chromatography, the ratio of 3-methyl-2-phenylpyridine to 5-methyl-2-phenylpyridine was still found to be about 94:6. These results would indicate that the addition reactions are virtually irreversible, or that the equilibria as in (i) lie far on the side of the addition products and that equilibration of I and III via starting material is so slow as not to be of importance here.



V



VI



VII

This has been confirmed in two ways. The importance of the hydride ion elimination step upon the orientation of the products formed was determined by measuring the ratio of isomers formed in the reaction of halide-free phenyllithium with 3-picoline-2*d*. Since k_H/k_D in hydride ion eliminations is of the order of 1.8–2.6 (7) then if scheme (i) is applicable one would expect the 2,3- to 2,5-isomer ratio to be substantially higher with 3-picoline than when 3-picoline-2*d* was used. This was not found to be the case, the observed isomer ratio being 95:5 in both cases (under otherwise identical conditions). It is clear, therefore, that the rate of hydride ion elimination is not important in determining the observed orientation.

Finally, an excess of a mixture of pyridine and pyridine-2*d* was allowed to react with a small amount of phenyllithium in the presence of an excess of anhydrous lithium bromide. Unreacted pyridine–pyridine-2*d* mixture was recovered from this competitive reaction and analyzed for pyridine-2*d* using an infrared spectroscopic method (see Experimental). A blank run was carried out using identical conditions except that the phenyllithium was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

left out; the concentration of the pyridine-2*d* in the recovered pyridine–pyridine-2*d* mixture was taken as the "original" concentration in the actual runs. Since the hydride ion elimination step is the slow step in scheme (i) and k_H/k_D should be about 2, one would expect the recovered mixture of starting materials to contain a larger proportion of pyridine-2*d* than it did initially—provided the addition step is readily reversible. In actual practice, the composition of the recovered pyridine–pyridine-2*d* was no different from the initial one.

There seems to be no doubt, therefore, that the second stage in the reactions of phenyllithium with 3-alkylpyridines, namely the elimination of hydride ion does not decide the 'abnormal' orientations observed (1) in these reactions, and that the first step, the addition giving rise to a dihydrophenylpyridyllithium intermediate is not readily reversible. It has been assumed, and the present results, showing the constancy of the isomer ratios produced under various conditions, seem to bear out amply, that there is no, or almost no, selective removal of the isomeric dihydropyridyllithium intermediates due to disproportionation and (or) polymerization but that both isomers undergo these side-reactions at virtually the same rate. It is hoped to submit more evidence supporting this point soon. One must look elsewhere for an explanation of the orienting influence of alkyl groups in such nucleophilic substitution reactions.

EXPERIMENTAL

Starting Pyridines

Commercial 2° pyridine (Reilly Tar and Chemical Co.) was dried (KOH) and fractionally distilled, the fraction, b.p. 110–112° at 720 mm being used. Commercial synthetic 3-picoline was similarly treated; the fraction, b.p. 138–140° at 720 mm was used.

3-Ethylpyridine, b.p. 165–166° at 720 mm, was obtained in 80–87% yield by the reduction of 3-acetylpyridine with hydrazine hydrate and potassium hydroxide according to the procedure of Fand and Lutomski (8). 3-Isopropylpyridine was prepared as described previously (1).

"Ordinary" Phenyllithium

This was prepared as usual and its concentration estimated by titration with 0.1 *N* hydrochloric acid using methyl orange as indicator.

Halide-free Phenyllithium (6)

Diphenylmercury (3.6 g) was added with stirring to a suspension of finely cut lithium (0.4 g) in anhydrous ether (75 ml) under dry, oxygen-free, nitrogen. The mixture was stirred vigorously at room temperature for 24 hours, the clear supernatant liquid was decanted under nitrogen through glass wool, and the clear solution was analyzed for phenyllithium content by acid titration.

Ethereal solutions of anhydrous lithium bromide were prepared either from lithium and 1,2-dibromoethane in ether solution (9) or by dehydrating 'anhydrous' lithium bromide ($LiBr,xH_2O$; Matheson, Coleman, and Bell) at 155° at 1 mm for 12 hours, dissolving it in dry ether and decanting the supernatant liquid from some insoluble material. In either case, the concentration of bromide was determined by Volhard titration.

Addition of Phenyllithium to an Excess of a 3-Alkylpyridine

The procedure will be described only for the case of 3-picoline.

(a) The toluene method.—A solution of 3-picoline (2.79 g, 0.03 moles) in dry ether (25 ml) was treated dropwise and with vigorous stirring in a nitrogen atmosphere with an ethereal solution of phenyllithium (12.5 ml ≡ 0.01 moles of phenyllithium). At the end of the addition the ether was distilled and simultaneously replaced with dry toluene. The mixture was then boiled gently under reflux for 6.5 hours, cooled, treated with water, made strongly alkaline with potassium hydroxide, and extracted with several portions of ether. The ethereal extracts were washed with concentrated hydrochloric acid and the aqueous acid layer was basified and extracted with ether. The combined ether extracts were dried (KOH), evaporated, and analyzed by gas chromatography. The columns, conditions, retention times, and identification of the various peaks have already been described in detail (1).

(b) The oxygen method.—The addition of phenyllithium solution (8.5 ml ≡ 0.01 moles) to 3-picoline (2.79 g, 0.03 moles) was carried out as before. At the end of the addition, the reaction mixture was boiled gently under reflux for 30 minutes and cooled, and oxygen gas was bubbled through until a white suspension had formed. The mixture was then treated with water and worked up as under (*a*) above. The combined yield of 3-methyl- and 5-methyl-2-phenylpyridine was 57% and the molar ratio of these two isomers was 95:5.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(c) In the presence of an excess of lithium bromide.—The procedure was essentially the same as that described under (*a*) or (*b*), respectively, except that two molar equivalents of anhydrous lithium bromide in dry ether were added per mole of pyridine used. No appreciable evolution of heat was observed when the phenyllithium solution was added. Some typical results are summarized in Table I.

(d) Using halide-free phenyllithium.—The procedure was identical with that used under methods (*a*) or (*b*). A vigorous exothermic reaction took place when the phenyllithium solution was added to the pyridine. A few of the results are given in Table I.

Reaction of Halide-free Phenyllithium with 3-Picoline-2d

The addition of halide-free phenyllithium was carried out as described under (*a*) above except that 3-picoline-2*d* (10) (0.2 g, 0.0021 moles; 11.67 atom % D) was used. To this was added 0.001 moles of phenyllithium in dry ether. The yield of products was 18.6% and the ratio of 2,3- to 2,5-isomer was 95:5.

Oxidation of Dihydrophenylpicolines

(a) A solution of phenyllithium (0.023 moles) in ether (30 ml) was added dropwise with stirring under nitrogen to a solution of 3-picoline (5.58 g, 0.06 moles) in ether (10 ml), at such a rate that the temperature of the reaction mixture did not rise appreciably. It was then immediately cooled to −10°, treated cautiously with an excess of iced water, the ether layer separated, and the aqueous layer extracted with ether. The combined ether extracts were added with stirring to a solution of chloranil (14.6 g) in benzene (600 ml) and filtered. The residue was washed with ether and the combined washings and filtrate were concentrated down to a small volume (2 ml) and analyzed by gas chromatography. The combined yield of 3-methyl- and 5-methyl-2-phenylpyridine was 19.0%; the isomer ratio was 96:4.

(b) In this experiment the mixture obtained above after treatment with water was not extracted with ether but was treated directly with a benzene solution of chloranil and analyzed. The ratio of 2,3- to 2,5-isomer was 94:6 and the combined yield was 22.5%.

Reaction of Phenyllithium with Pyridine–Pyridine-2d Mixture

A solution of 'ordinary' phenyllithium (0.018 moles) in anhydrous ether (66 ml) was added dropwise at 24°, and under oxygen-free dry nitrogen to a well stirred solution of anhydrous lithium bromide (0.076 moles), pyridine (0.0179 moles), and pyridine-2*d* (10) (0.0201 moles) in anhydrous ether (150 ml). At the end of the addition, stirring was continued for another 2 hours, oxygen was bubbled through the mixture for 5–10 minutes, the suspension treated with an excess of water, and the mixture of recovered pyridine and pyridine-2*d* isolated and purified by preparative gas-chromatography on columns of silicone oil (25%) on Fisher Columnpak (60–80 mesh) at 70°. The mixture was then dried (KOH pellets) and distilled.

A blank run was carried out similarly except that the phenyllithium was omitted. The composition of the recovered pyridine–pyridine-2*d* was used for comparison with the recovered material from the actual runs.

The quantitative analyses for pyridine-2*d* were carried out by determining the infrared spectra of authentic mixtures of known concentration of pyridine and pyridine-2*d* (as pure liquids) in matched 1-mm fixed-thickness cells. A calibration curve for the pyridine-2*d* concentration was obtained by plotting log T (where T = % transmission) of the C—D stretching band at 2260 cm^{-1} against the corresponding known concentration of pyridine-2*d*, and was a straight line, thus making it unnecesssary to measure the areas under the C—D band.

In all runs, the composition of the recovered pyridine–pyridine-2*d* mixture was identical with that of the starting material.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by C.-S. G.) of a National Research Council Studentship, and was supported financially by a grant from the National Research Council. Some preliminary experiments were carried out by Dr. B. Staskun.

NOTES

THE INFRARED AND RAMAN SPECTRA OF CYANOACETYLENE

V. A. Job and G. W. King

The infrared spectrum of cyanoacetylene H—C≡C—C≡N in the vapor, liquid, and solid phases has been investigated by Turrell, Jones, and Maki (1). They were able to assign five of the seven fundamental frequencies of the linear molecule to bands observed in the vapor phase spectrum. Of the two missing fundamentals, $\nu_4(\sigma^+)$ was assigned to a band of medium intensity observed at 875 cm^{-1} in the spectrum of the liquid; $\nu_7(\pi)$ was calculated to be 230 cm^{-1} from the observed combination bands, this frequency being beyond the range of the spectrometer employed in the work.

During the course of a study of the electronic spectrum of cyanoacetylene, we have measured the infrared and Raman spectra of both the hydrogenic and the deuterated compound. The results confirm and extend the assignments of the previous workers. We have also observed in the Raman spectrum the two fundamentals that are missing from the infrared spectrum of the vapor.

The cyanoacetylene was prepared from commercial propiolic acid by the method of Moureu and Bongrand (2), and subjected to repeated trap-to-trap distillation under vacuum until weak bands due to impurities had disappeared from the infrared spectrum. The deuterated compound was prepared by the repeated exchange of propiolamide in slightly alkaline D_2O and the subsequent dehydration of the deuterated propiolamide with phosphorous pentoxide (2). A sequence of 10 exchanges, with D_2O of 99.8% purity being used in the final stages, gave a product estimated to contain ~98% deuterocyanoacetylene from the infrared spectrum. Infrared spectra were recorded in the region 400–4000 cm^{-1} on a Perkin–Elmer model 21 spectrophotometer with CaF_2, NaCl, and KBr optics. The Raman spectrum of the liquid was excited by the filtered 4358 Å line emitted by a spiral Toronto type mercury arc and recorded with a Hilger double prism spectrograph type E612 on Kodak type IIaO photographic plates.

The observed frequencies and their assignments are given in Table I. At a vapor pressure of 290 mm Hg and an absorption path of 10 cm in the vapor, some of the combination bands observed by Turrell, Jones, and Maki only in the spectrum of liquid and solid HCCCN were obtained, as well as some additional weak combination bands which are definitely not due to impurities. A very weak parallel-type band observed at 885 cm^{-1} in the infrared spectrum of HCCCN vapor could possibly be the $\nu_4(\sigma^+)$ fundamental, but a corresponding band was not observed in the DCCCN spectrum and the assignment as the combination $\nu_5+\nu_7$ appears more plausible. The product rule ratios agree well with the theoretical values calculated from the moments of inertia of the molecule (3). The ratios are 1.39 (obs.) and 1.40 (calc.) for the σ^+ stretching vibrations and 1.35 (obs.) and 1.35 (calc.) for the π bending vibrations.

We wish to thank Dr. K. Ramaswamy for assistance in recording the Raman spectra, Dr. R. H. Tomlinson for supplying the deuterium oxide, and the Ontario Research Foundation for financial support.

METHYL α-FURANOSIDE DERIVATIVES OF FULLY METHYLATED GALACTOSE AND GALACTURONIC ACID

H. G. WALKER, JR., AND R. M. MCCREADY

It was noted earlier that direct *O*-methylation of D-galactose or D-galacturonic acid by the Kuhn procedure (1) (silver oxide and methyl iodide in dimethyl formamide) gives predominantly α-furanoside product (2). This statement was based on the fact that the main product isolated by gas–liquid chromatography (GLC), was a strongly positive rotating substance whose retention volume did not correspond with that of the α-pyranoside derivative. Hydrolysis of the fully *O*-methylated galactoside gave a substance with a negative rotation similar to that reported for the fully *O*-methylated α-β-D-galactofuranose. In the present work, the furanose structure of the products was confirmed by chemical means.

The fully *O*-methylated β-furano- and α- and β-pyrano derivatives of both D-galactose

For personal use only.

and D-galacturonic acid are well known (3, 4). Greene and Pacsu prepared pure methyl 2,3,5,6-α-D-galactofuranoside (5), but preparation of the fully *O*-methylated derivative has not been reported subsequently. The specific rotations of the new compounds, methyl 2,3,5,6-tetra-*O*-methyl-α-D-galactofuranoside (I) and methyl (methyl 2,3,5-tri-*O*-methyl-α-D-galactofuranoside) uronate (II) are reported in Table I, along with that of methyl 2,3,5,6-tetra-*O*-methyl-β-D-galactofuranoside (III) as determined during this study.

TABLE I

Specific rotations of fully *O*-methylated furanoside derivatives

Compound	Rotation[a]
Methyl 2,3,5,6-tetra-*O*-methyl-α-D-galactofuranoside (I)	+108.2
Methyl (methyl 2,3,5-tri-*O*-methyl-α-D-galactofuranoside) uronate (II)	+82.3
Methyl 2,3,5,6-tetra-*O*-methyl-β-D-galactofuranoside (III)	−104.5[b]

[a]All rotations measured in H_2O in a 1-dm tube at 25°. Compound I, C = 1.97; II, C = 2.05; III, C = 1.80.
[b]Reported: −45.2 (*c* 1.42 H_2O), see ref. 7.

The values in Table I were obtained from samples isolated by preparative scale GLC. It is believed that II and III are essentially pure. Analytical scale GLC and thin layer chromatography on silica gel G (TLC) (6), show that I may contain 1–2% of isomeric β-pyranoside impurity. Hydrolysis of I and III leads to the same 2,3,5,6-tetra-*O*-methyl-α,β-D-galactofuranose. Previous data on III would indicate contamination with isomeric impurities (7).

The relationship between I and II was established by reducing and remethylating II to give a product identical with I by GLC and TLC. To confirm the furanose structure, II was converted to the known *N*-methyl-bis-amide of 2,3,5-tri-*O*-methyl mucic acid (4).

Room temperature nuclear magnetic resonance spectral measurements (n.m.r.) on I and III did not reveal useful anomeric conformational information, because of lack of splitting of the resonance from the C-1 proton. Presumably, the methoxyl groups on the furanose ring are not bulky enough to fix the conformation rigidly.

Mass spectrometric analysis of I and the isomeric fully *O*-methylated α-pyranoside isomer showed significant quantitative spectral differences, even though the general fragmentation pattern was similar for both.

EXPERIMENTAL

Preparation and Isolation of Samples

Crude I and II were prepared by direct methylation of D-galactose and D-galacturonic acid, respectively (2). Crude III was prepared by methylation of the reaction product obtained from room temperature glycosidation of galactose using methanolic hydrogen chloride (7).

I, II, and III were obtained by GLC from crude preparations by collecting appropriate peaks with a commercial GLC apparatus; column, 3/8 in. O.D. × 10 ft aluminum tubing; liquid phase, a mixture of fluorosilicone (QF-1) and neopentyl glycol succinate (10 and 12.5 wt% of support, respectively); solid support, Chromosorb W, 60–80 mesh; carrier gas, helium; flow rate, 200 ml per minute; temperature, isothermal, 160–170° range.

Adequate samples were obtained by repeatedly injecting 100–150 mg of crude product and collecting the peak corresponding to the component of interest. Pooled collected fractions were repurified by GLC.

Purity of Samples

Carbon–hydrogen analyses on the purified samples were satisfactory for empirical composition, but indicated nothing about isomeric composition. High isomeric purity of II and III was evident from the homogeneous appearance of these materials on an efficient analytical GLC column (8). Isomeric purity of I was estimated at 98–99%, by analytical scale GLC and TLC. Complete purification of I by GLC was not achieved. Trace amounts of the β-pyranoside isomer persisted as a minor shoulder on the main peak even after several repurifications. Absence of III and the α-pyranoside isomer in purified I was easily shown

by TLC. The relative retention volumes in the fully methylated galactoside series at 135°, using a 1/8 in. O.D. × 9 ft aluminum column, packed with 5% NPS on Chromosorb W (60–80 mesh) with a flow rate of 25 ml of helium per minute, were as follows: III, 1.00; I, 1.21; methyl 2,3,4,6-tetra-*O*-β-D-galactopyranoside (IV), 1.10; methyl 2,3,4,6-tetra-*O*-methyl-α-D-galactopyranoside (V), 1.16. Relative mobilities by TLC were: III, 1.00; I, 0.66; IV, 0.64; V, 0.48 (6).

Hydrolysis of I and III

Compounds I (39.46 mg) and III (36.03 mg) were hydrolyzed overnight at 100° in sealed tubes in 0.05 *N* H_2SO_4. The $[\alpha]_{25}^{D}$ of product from I was −29.7°; from III, −30.0 (*c* approximately 2, 0.05 *N* H_2SO_4) (reported, −21.2, *c*, 2.12 H_2O) (7). After ion exchange treatment and evaporation, the free 2,3,5,6-tetra-*O*-methyl-α-β-D-galactofuranoside could be purified by GLC at temperatures below 200° C, ($[\alpha]_D^{25} = -30.0$; *c* 1.25 H_2O).

Conversion of II to I

Compound II (264 mg) was reduced with sodium borohydride (152 mg) in methanol at room temperature, overnight, on a mechanical shaker (9). After neutralization of the solution with acetic acid, followed by treatment with Dowex 50 (H^+ form) and Duolite A 4 (OH^- form) ion exchange resins, and evaporation, the residue was methylated. The reduced methylated II was identical with I by GLC and TLC.

Conversion of II to the N-methyl-bis-amide of 2,3,5-tetra-O-methyl-mucic Acid

Compound II (40 mg) was treated with nitric acid and the mucic acid derivative esterified with methanolic hydrogen chloride (4). The product obtained in this manner was not distilled, but was converted to the *N*-methyl-bis-amide which was recrystallized from ethanol; m.p. 228.5–229.5° (micro m.p. (Kofler)); reported m.p. 232° (4). If II had had the pyranose configuration, the *N*-methyl-bis-amide of 2,3,4-tri-*O*-methyl-mucic acid, m.p. 205° (4), would have been obtained.

THE PREPARATION OF SOME FLUORO-NITRO-ANTHRAQUINONES AND THEIR REDUCTION TO AMINO-FLUORO-ANTHRAQUINONES

G. Valkanas

Mononitration of 1-fluoro-, 2-fluoro-, and 2,6-difluoro-, and 1,5-difluoro-anthraquinones (1) can be effected by adding the stoichiometric amount of well dried potassium or sodium nitrate to solutions in sulphuric acid (2). Complete reaction of the α-substituted compounds occurs during 12 hours at 0°; higher temperatures lead to partly solvolyzed products. For the β-substituted compounds a further 2 hours heating at 40–45° is necessary to complete the reaction. Satisfactory analyses were obtained except for the nitration product of 1,5-difluoro-anthraquinone. Nitration of anthraquinone itself gives mainly the α-nitro compound together with some β-nitro compounds and some dinitration (3), whereas 1-substituted anthraquinones with *ortho–para* directing substituents appear to

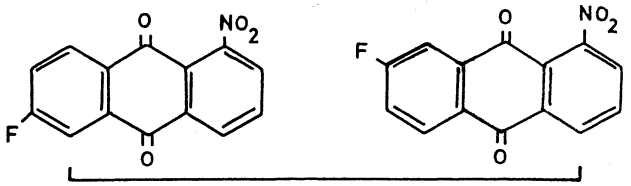
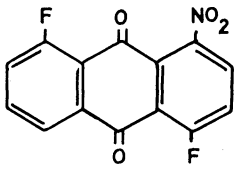
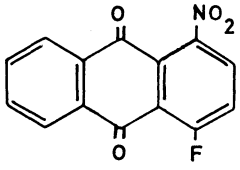
I



II



III



IV

undergo only 4-nitration (4). The nitration product of 2-fluoro-anthraquinone on reduction gives an amine identical with that obtained by the sulphonamide process and described as a mixture of two isomers (II) (5). 1,5-Difluoro-anthraquinone can only give one α-nitration product (III). 2,6-Difluoro-anthraquinone gives a product, presumably (I), from which one fluorine can readily be displaced by treatment with sodium sulphide (Table I); nitration *meta* to fluorine should not give a product with activated fluorine.

TABLE I

Reduction of fluoro-nitro-anthraquinones with sodium sulphide (8) at 70°

	Fluorine, %		
		Found	
Anthraquinone	Calc.*	In 40 min	In 90 min
I 1-Nitro-2,6-difluoro-	14.65	7.25	7.20
II 1-Nitro-6 or 7-fluoro-	7.90	7.55	7.45
III 1-Nitro-4,8-difluoro-	14.65	4.20	None
IV 1-Nitro-4-fluoro-	7.90	1.30	None

*Calculated on the corresponding amine.

1-Fluoro-anthraquinone gives a product different from the fluoro compound prepared from 1-amino-4-nitro-anthraquinone by the fluoroborate process (1). Unlike the reported exclusive 4-nitration of 1-chloro-anthraquinone (6) the nitration of 1-fluoro-anthraquinone seems to lead to a mixture of isomers.

Some typical results concerning the sodium sulphide reduction of the different fluoro-nitro-anthraquinones are included in Table I.

The α-fluoro-compounds (III, IV) readily lose fluorine when reduction with stannous chloride, sodium hydrosulphide (7), or sodium sulphide (8) is attempted. The β-fluoro-compounds (I, II) are more resistant; reduction of compound (II) with all reagents gives 1-amino-6 or 7-fluoro-anthraquinone (5) but compound (I) easily loses the fluorine *ortho* to the nitro group.

EXPERIMENTAL

The Nitration of 2-Fluoro-anthraquinone

2-Fluoro-anthraquinone (10 g) was dissolved in concentrated sulphuric acid (100 ml). The solution was cooled to 0° and a quantity of well ground, dry sodium nitrate (3.8 g) was added while the solution was well stirred. After 12 hours the solution was heated to 40–45° for 2 hours and then poured onto ice. During the reaction a noticeable change in color to grey-yellow was observed. The grey-yellow precipitate was recrystallized from chlorobenzene to give *1-nitro-6 or 7-fluoro-anthraquinone* (8.2 g, 66.2%), m.p. 222–223°. Anal. Found: C, 62.15; H, 2.2; F, 6.9; N, 5.15%. $C_{14}H_6FNO_4$ requires: C, 62.1; H, 2.25; F, 6.9; N, 5.15%.

Similarly, 2,6-difluoro-anthraquinone (10 g) was nitrated to give *1-nitro-2,6-difluoro-anthraquinone* which on recrystallization from chlorobenzene (7.75 g, 66.3%), had m.p. 207–209°. Anal. Found: F, 13.00; N, 4.9%. $C_{14}H_5F_2NO_4$ requires: F, 13.15; N, 4.85%.

The Nitration of 1-Fluoro-anthraquinone

1-Fluoro-anthraquinone (10 g) was dissolved in sulphuric acid (100 ml) and to the red solution maintained at 0° was added sodium nitrate (3.7 g) with stirring. The reaction mixture was kept at 0° (12 hours) and then poured onto ice to precipitate the grey nitration product (6.7 g, 55.7%), which was recrystallized from chlorobenzene, m.p. 213–214°. Anal. Found: F, 6.95; N, 5.15%. $C_{14}H_6FNO_4$ requires: F, 6.9; N, 5.15%.

Similarly, 1,5-difluoro-anthraquinone (10 g) was nitrated to *1-nitro-4,8-difluoro-anthraquinone.* Recrystallization from chlorobenzene gave a grey product (6.65 g, 60.8%), of m.p. 235–240°. Anal. Found: F, 11.9; N, 4.9%. $C_{14}H_5F_2NO_4$ requires: F, 13.15; N, 4.85%.

1-Fluoro-4-nitro-anthraquinone

1-Amino-4-nitro-anthraquinone (50 g) was converted by treatment with nitrosyl – sulphuric acid solution to *1-diazonium fluoroborate-4-nitro-anthraquinone* (1) (yield, 60.9 g, 89%), decomposition temperature 171-173°. The well dried salt was heated to decomposition in a round-bottomed flask equipped with a reflux condenser. The decomposition was followed by sublimation of the product which was recrystallized from chlorobenzene and further purified by sublimation, m.p. 226–227°. Anal. Found: F, 6.95; N, 5.15%. $C_{14}H_6FNO_4$ requires: F, 6.9; N, 5.15%.

1-Amino-6 or 7-Fluoro-anthraquinone

The nitration product of 2-fluoro-anthraquinone (5 g) was ground to a paste with sodium sulphide nonahydrate (10 g), suspended in hot water at 70–80°, and stirred. The complete reaction occurred in 40 minutes. The solution turned to violet and was filtered hot. The red product recrystallized from anisole gave red needles (yield 4.2 g, 94.2%), m.p. 199–201°. Reduction with sodium hydrosulphide in benzene in the presence of calcium chloride (7) gave similar results; from 5 g of starting material, 4.4 g (98.5%) of amine were obtained which on recrystallization from anisole had m.p. 203–204°. Found: C, 69.6; H, 3.3; F, 7.55; N, 5.8%. Calc. for $C_{14}H_8FNO_2$: C, 69.7; H, 3.3; F, 7.9; N, 5.8%.

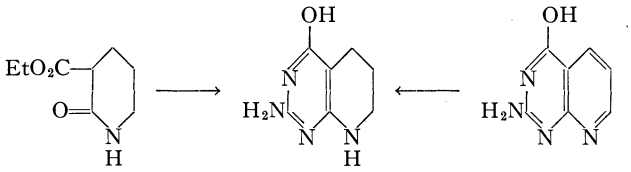
method for preparing II can be elaborated to provide 6-substituted derivatives of II useful for the synthesis of 5-deazatetrahydrofolic acid.

The condensation of guanidine with a β-keto ester represents probably the most useful general method for preparing 2-amino-4-hydroxypyrimidines. As an extension of this method the condensation of guanidine with 3-carbethoxy-2-piperidone (I) (2) was



I II III

investigated for the synthesis of II. The reaction, carried out at 150° in methanol with sodium methoxide, afforded the pyrimidopiperideine (II) in 38% yield. This appears to be the first such example of the condensation of guanidine with a β-amidoester to form a pyrimidine ring.

In order to provide a proof of structure for the condensation product and as a second preparative method for II, the catalytic reduction of 2-amino-4-hydroxypyrido[2,3-*d*]-pyrimidine (III) (3) was investigated. When an aqueous suspension of III was treated with hydrogen at atmospheric pressure over platinum oxide, approximately 2 moles of hydrogen were absorbed. The product (II) was identical with that prepared by the condensation method with respect to infrared and ultraviolet spectra and paper chromatographic behavior.

The further utility of these methods for the ultimate synthesis of 5-deazatetrahydrofolic acid is currently under investigation.

EXPERIMENTAL

3-Carbethoxy-2-piperidone (I) was prepared in a two-step reaction sequence as follows. Malonic ester was reacted with acrylonitrile to afford ethyl 2-carbethoxy-4-cyanobutyrate in a 56% yield according to the procedure of Mikeska (4). The cyano ester was catalytically reduced over platinum oxide at atmospheric pressure to yield 3-carbethoxy-2-piperidone (I), essentially following the method described by Koelsch (2). 2-Amino-4-hydroxypyrido [2,3-*d*]pyrimidine (III) was prepared in 51% yield by the procedure of Price *et al.* (3).

2-Amino-5,6,7,8-tetrahydro-4-hydroxypyrido[2,3-d]pyrimidine (II)

A. Condensation of Guanidine and 3-Carbethoxy-2-piperidone

A 1-liter autoclave was charged with 14.4 g (84 mmoles) of 3-carbethoxy-2-piperidone (I), 15.7 g (0.29 mole) of sodium methoxide, 16.4 g (0.172 mole) of guanidine hydrochloride, and 200 ml of absolute methanol. The mixture was stirred at 150° for 8 hours and allowed to cool for another 15 hours. The mixture was evaporated to dryness *in vacuo* and the residue was triturated with 100 ml of water. The insoluble material was collected, washed with water, and dried to leave 5.3 g (38%), m.p. 245–255°. An analytical sample, m.p. 260–270°, was obtained by recrystallization from water; $\lambda_{max(m\mu)}^{pH\,1}$ 280 (ϵ 16150), $\lambda_{max(m\mu)}^{pH\,13}$ 274 (ϵ 8900), R_f 0.70 in *n*-butanol/acetic acid/water, 5/2/3.

Anal. Calc. for $C_7H_{10}N_4O \cdot \frac{1}{4}H_2O$: C, 49.3; H, 6.20; N, 32.8. Found: C, 49.3; H, 6.60; N, 32.6. The material was quite hygroscopic and samples showing various degrees of hydration were encountered; the samples were dried *in vacuo* at 120° for 15 hours prior to analysis.

B. Hydrogenation of 2-Amino-4-hydroxypyrido[2,3-d]pyrimidine

To 10 ml of water were added 0.50 g (2.8 mmoles) of 2-amino-4-hydroxypyrido[2,3-*d*]pyrimidine (III) and 50 mg of platinum oxide. The mixture was stirred under an atmosphere of hydrogen for 21 hours. An uptake of 1.91 moles of gas was observed and the product deposited from solution. The mixture was heated to 95–100° and quickly filtered by suction. The residue was retreated with 5 ml of hot water, filtered, and the combined filtrates were chilled for 30 minutes. The white crystals which formed were collected, washed

THE EFFECT OF ALKYL GROUP VARIATION ON THE RATES OF SOLVOLYSIS OF ALKYL SULPHONIUM HALIDES

J. B. Hyne and H. S. Golinkin

Tertiary butyl and amyl dimethylsulphonium salts have been the standard examples of the sulphonium salt series used in neutral solvolytic rate studies of this type of compound in the past (1). Apart from these cases the apparent hygroscopic nature of the sulphonium salts has limited the study of their solvolytic behavior. In the course of our studies of sulphonium salt solvolysis we have prepared and characterized α-phenethyldimethylsulphonium and benzyldimethylsulphonium bromides. The solvolytic rate behavior of these two compounds together with comparative data on the *t*-butyldimethylsulphonium salt are reported here.

RESULTS

Approximately 10^{-3} M solutions of the various sulphonium salts in the desired solvent media were prepared by weight. Solvolytic kinetics were followed using the conductimetric technique described previously (2) and due to Robertson (3). While the iodide salt was used in the *t*-butyl case the bromides of both the α-phenethyl and benzyl sulphonium ions were employed. Since 0.325 mole fraction ethanol in water was the lowest polarity solvent used the anion does not enter the rate determining step as was shown previously (2, 4). Consequently the change from iodide to bromide does not invalidate the comparison of rates. In both the α-phenethyl and benzyl cases difficulty was encountered in obtaining reproducible results in pure water. In the benzyl case only those rates measured in higher ethanolic compositions were of satisfactory reproducibility. In Table I the rates for the

three sulphonium salts studied under various solvent and temperature conditions are recorded.

DISCUSSION

The availability of the rates of solvolysis for the three sulphonium salts in Table I enables a comparison to be made with the rate behavior of the corresponding alkyl chlorides. Using the date of Winstein and Fainberg (5) and Hyne, Wills, and Wonkka (6) the relative rates of solvolysis of the t-butyl, α-phenethyl, and benzyl chlorides and dimethylsulphonium salts may be compared. Conditions chosen for the comparison were 0.204 mole fraction ethanol (approx. 45% ethanol by volume in water) at 50° C for the chloride and 78.4° C for the sulphonium salts. These conditions were dictated largely by the availability of results. The temperature difference is unlikely to have a significant effect since the comparisons are internal within a given set at the same temperature. Use of a mixed solvent medium is perhaps not the best condition in view of the established selective solvation effects (6, 7). Since free energies of activation are being compared, however, the likelihood of gross errors being introduced by such effects is minimized. The rate comparisons are shown in Table II.

TABLE II

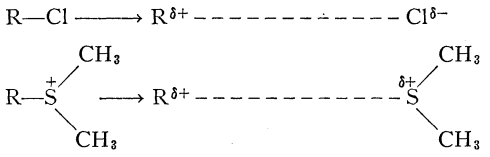
Relative rates of solvolysis of alkyl halides and sulphonium salts in 0.204 mole fraction EtOH–H_2O

Leaving group		Alkyl group		
		t-Bu	PhCHCH$_3$	PhCH$_2$
$-S(CH_3)_2$	$k_{78.4°}$ sec^{-1}	4.42×10^{-4}	2.72×10^{-4}	1×10^{-6}
	Relative log k (ΔF^*)	1	1.07	1.79
—Cl	$k_{50.0°}$ sec^{-1} [a]	1.32×10^{-2}	9.80×10^{-3}	1.89×10^{-5}
	Relative log k (ΔF^*)	1	1.07	2.51

[a] NOTE: Rates in this row interpolated from data of refs. 5 and 6.

Comparison of the free energies of activation (ratio of log k) for the two types of solvolysis shows immediately that structural changes in the alkyl group have the same effect on the solvolysis rates of both the halide and the sulphonium salts. Although the two reactions have opposite charge character on activation—one involving charge delocalization while the other requires charge creation—in both cases an incipient alkyl carbonium ion develops on activation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



The similar effects of structural change in the alkyl group must imply that the stabilization of the incipient carbonium ion in the transition state is the dominant factor affecting the rate as a function of the alkyl group. This is particularly interesting in view of the fact that we are dealing here with two reactions having leaving groups of entirely different character. Clearly the stabilization of the transition state—or lack of it in the sulphonium case—brought about by solvation of the leaving group does not appear to vary significantly as the nature of the alkyl group is varied. If it did one would imagine that the effect of the alkyl group variation in the case where leaving group solvation was important would be very much different from that in the case where leaving group solvation was minimal.

The data in Table I also shows that the rate dependence on solvent composition is considerably less for the α-phenethylsulphonium salt than for the *t*-butyl compound. This should be compared with the very similar rate dependence on solvent exhibited by the two corresponding alkyl chlorides (5). While the solvent dependence for all three sulphoniums is in the opposite sense from the alkyl halides, as would be expected from the charge character of the activation process, the smaller dependence in the α-phenethyl case probably reflects a smaller change in polarity of the solute on activation. Whether this is due to a lowering of the polarity of the ionic initial state thus approaching the polarity of the transition state or to a more polar transition state closer to the ionic character of the initial state can only be resolved by studies of the relative physical properties of the *t*-butyl and α-phenethyl initial states.

The data recorded in Table I permits the calculation of both enthalpies and entropies of activation for the *t*-butyl and α-phenethyl cases. These parameters are remarkedly insensitive to structural changes. Values of activation energy vary between 32.4 and 33.0 kcal/mole for both salts over the range of solvents used. The entropy values lie in the range of +15 to +18 e.u. in keeping with the charge delocalization on activation resulting in "desolvation" of the transition state compared with the ionic initial state.

Synthesis of Sulphonium Halides

The following refers particularly to the α-phenethyl and benzyl sulphonium salts; the *t*-butyl salt is readily synthesized and isolated from *t*-butyl iodide and dimethyl sulphide in nitromethane. The method is a modified form of that reported by Siegel and Graefe (8). Dimethyl sulphide and the corresponding alkyl halide were mixed in a 1:1 mole ratio. The reaction vessel was stoppered with an aluminum foil covered rubber stopper, and was covered with aluminum foil to omit light. The mixture was allowed to stand at room temperature until the bottom of the flask was covered with crystals. The remaining liquid was deep red in color possibly due to bromine formation. The mixture was washed with 50 ml anhydrous ether to remove any unreacted starting materials. The ether was decanted, but enough was left so that the crystals were not exposed to the atmosphere; 5 to 10 ml absolute ethanol was added to dissolve the crystals. Gentle heating was sometimes necessary for solution to occur. Warm tap water generally sufficed. The solution was then treated with norite A to decolorize it, after which it was filtered over a celite bed on a sintered glass funnel to remove the norite and any undissolved residue. The clear filtrate was placed in a 50-ml standard taper flask, equipped with a vacuum adapter,

which was previously evacuated and weighed. The flask was then filled with dry ether to precipitate the salt and placed in the refrigerator overnight. The liquor was decanted using an aspirator, but enough was left behind to keep the crystals covered. The remaining liquid was removed under vacuum. The white salt was then dried over phosphorous pentoxide under vacuum. α-Phenethyldimethylsulphonium bromide—reaction time 96 hours; yield 10.1%; m.p. 91.7–92.8° C (lit. m.p. 76–80° C ref. N.M.R. STUDIES OF BRIDGED RING SYSTEMS. I. CARBON–HYDROGEN SPIN COUPLING CONSTANTS IN BICYCLO[2,2,1]HEPTANE DERIVATIVES

K. Tori, R. Muneyuki, and H. Tanida

The carbon–hydrogen spin coupling constants, $J_{C^{13}-H}$, are considered as useful tools for the investigation of *s*-character of the carbon atomic orbital participating in the C—H bond (1–4). Muller and Pritchard (1) suggested that decrease of the ring size of cycloalkanes with their C—C—C angles increased $J_{C^{13}-H}$ with the percentage of *s*-character of the C—H bond, and, for example, the $J_{C^{13}-H}$ of cyclopropane exhibited the comparable value to that of the sp^2 bond.

It has been known that bicyclo[2,2,1]heptane derivatives have considerably smaller bond angles on their sp^3-tetrahedral and sp^2-trigonal carbons than the respective ordinal angles due to the contribution of ring strain.* Musher (7) proposed that the unusual behavior of the bicyclo[2,2,1]heptane ring toward the magnetic shielding and the proton coupling constant might be due to the π-character in the ring.

**Few data relating to the molecular geometry of this ring system have appeared; however, Schomaker, using an electron diffraction method, has shown the geometry of norbornadiene to be (5): $<C_1C_2C_3 = 109.1°$, $<C_2C_1C_7 = 96.4°$, $<C_2C_1C_6 = 102.2°$, $<C_1C_7C_4 = 96.7°$, $C_1—C_2 = 1.522$ Å, $C_2—C_3 = 1.333$ Å, $C_1—C_7 = 1.558$ Å. There are other data based on the dipole moment studies of bridged bicyclic molecules (6).*

N.M.R. STUDIES OF BRIDGED RING SYSTEMS. I. CARBON–HYDROGEN SPIN COUPLING CONSTANTS IN BICYCLO[2,2,1]HEPTANE DERIVATIVES

K. Tori, R. Muneyuki, and H. Tanida

The carbon–hydrogen spin coupling constants, $J_{C^{13}-H}$, are considered as useful tools for the investigation of *s*-character of the carbon atomic orbital participating in the C—H bond (1–4). Muller and Pritchard (1) suggested that decrease of the ring size of cycloalkanes with their C—C—C angles increased $J_{C^{13}-H}$ with the percentage of *s*-character of the C—H bond, and, for example, the $J_{C^{13}-H}$ of cyclopropane exhibited the comparable value to that of the sp^2 bond.

It has been known that bicyclo[2,2,1]heptane derivatives have considerably smaller bond angles on their sp^3-tetrahedral and sp^2-trigonal carbons than the respective ordinal angles due to the contribution of ring strain.* Musher (7) proposed that the unusual behavior of the bicyclo[2,2,1]heptane ring toward the magnetic shielding and the proton coupling constant might be due to the π-character in the ring.

**Few data relating to the molecular geometry of this ring system have appeared; however, Schomaker, using an electron diffraction method, has shown the geometry of norbornadiene to be (5): $<C_1C_2C_3 = 109.1°$, $<C_2C_1C_7 = 96.4°$, $<C_2C_1C_6 = 102.2°$, $<C_1C_7C_4 = 96.7°$, $C_1—C_2 = 1.522$ Å, $C_2—C_3 = 1.333$ Å, $C_1—C_7 = 1.558$ Å. There are other data based on the dipole moment studies of bridged bicyclic molecules (6).*

In order to obtain some information about the ring strain and π-character in connection with our work from other standpoints in this ring system, we investigated the proton magnetic resonance spectra of C^{13}—H (in natural abundance) in the bicyclo[2,2,1]heptane series, such as norbornane (I), norbornene (II), norbornadiene (III), benzonorbornene (IV), benzonorbornadiene (V), and quadricyclene (VI). The values of $J_{C^{13}-H}$ determined by the observable C^{13}-satellites are shown in Table II.

*The presence of impurity which interfered in the signal gave the estimated value.
†Recent observations (15) showed that J_{gem}'s have, in many cases, the opposite sign to the vicinal coupling constants. Since the J_{gem}'s in this table were determined by first order approximation, they are given with no sign.

larger than that of the usual sp^3 bond, so the C—H bonds on these positions should have much increased *s*-character. Also, considerably larger $J_{C^{13}-H}$ values were recognized in the bridge methylene and about the double bond. The introduction of double bonds and (or) benzene ring into the bicyclo[2,2,1]heptane system increased the $J_{C^{13}-H}$ value with the ring strain, as would be expected. From these data, we can reasonably assume that carbon atoms in these series have extraordinary high *s*-character in the C—H bonds and accordingly some π-character in the C—C bonds. The large substituent effect observed by us on a carbonium ion reaction at the 7-position of benzonorbornene derivatives (8) might bear some relation to these results.

The proton spin coupling constants of methylene protons, J_{gem}'s, at the 7-position, which were determined by first order approximation from the C^{13}—H or normal C^{12}—H spectra and listed in a column of $\lvert J_{7a,\,7s}\rvert$ of Table II, were considerably smaller than that of methane (12.4 c.p.s.) (9). This observation may have a relationship to more opening of the corresponding H—C—H angles.*† Non-equivalent values of coupling constants between a proton on the bridge head carbon and a proton on the carbon-7, $J_{1,7a}$, and $J_{1,7s}$ in the compounds, II, IV, and V, were observed. Furthermore, the fact that the coupling constants, $J_{1,2}$, $J_{2,3}$, and $J_{1,3}$, about the protons on the double bond are considerably smaller than usual, would have some relation to the "bent" of the double bond due to the strain in these ring systems.‡

All the spectra were taken with a Varian A-60 spectrometer. Calibration of the spectrometer was checked by using the signal peaks of *p*-anisaldehyde (4.0% solution in carbontetrachloride) (12). The C^{13}—H spectra, except for norbornane and norbornene, were measured in the pure liquid form. For the measurements of the spectra of norbornane and norbornene, a small quantity of deuterochloroform was added to those crystals to make a liquid form, because it is considered that no appreciable errors may be detectable owing to the presence of impurities in this case (1). Technical errors are approximately ±0.5 c.p.s. in $J_{C^{13}-H}$ and ±0.3 c.p.s. in J_{H-H}.

The J_{gem}'s of the bridge methylene in bicyclo[2,1,1]hexane derivatives were about 5.4 ~ 8.4 c.p.s., indicating the angle is much larger (11).

†The relation between J_{gem} and H—C—H angle was discussed by Gutowsky et al. (10). The contrast findings have appeared recently (15).

‡Added in proof: Since the submission of our first draft, the following papers have described the parallel relation between ring size of cycloalkenes and J_{H-H} (cis), and $J_{C^{13}-H}$ of the compounds II and III. TRITIUM RECOIL LABELLING OF LITHIUM ALUMINUM HYDRIDE

Constanţa Măntescu and Ana Genunche

Lithium aluminum hydride ($LiAlH_4$) is an extremely powerful reducing agent. Although its violent reaction with water does not permit its use for the reduction of water-soluble compounds, it reacts readily, and in many cases quantitatively, with substances soluble in ethers such as diethyl ether and tetrahydrofuran.

By the preparation of $LiAlH_4$-*t* it was possible to obtain a large variety of tritiated organic compounds; $LiAlH_4$-*t* is usually prepared by the reaction of lithium hydride-*t* (1, 2) and aluminum chloride (3). The direct exchange of $LiAlH_4$ with a hydrogen–tritium mixture at 100° C could not be carried out (1).

We tried to prepare $LiAlH_4$-*t* using the recoil tritium resulting from the $Li^6(n,\alpha)T$ nuclear reaction. Preliminary results are reported in this note. The proportion of $LiAlH_4$ in the samples before the irradiation was established (4) using the hydrolitic and pyrolitic methods for analysis. Samples of 30–50 mg of $LiAlH_4$ sealed in quartz tubes were irradiated in high vacuum in the I.F.A. reactor with an integral thermal neutron flux of 7.2×10^{15} n/cm² to 7.5×10^{17} n/cm². The irradiated samples were again analyzed in order to determine the chemically active $LiAlH_4$ contained in the samples after irradiation.

The total amount of tritium introduced in the sample during irradiation was determined by measuring the activity of the hydrogen gas evolved on hydrolysis and pyrolysis.

The labelling of $LiAlH_4$ was tested by preparing methanol-T and 2-propanol-2T. The reaction of 1 mole carbon dioxide with 0.75 moles of $LiAlH_4$ in ethereal solution was used to prepare methanol-T. Non-labelled methanol was employed for the decomposition of excess $LiAlH_4$ and for the liberation of methanol-T by alcoholysis (5). The average radiochemical yield was 77% as compared with the stoichiometric reaction. 2-Propanol-2T

[e]The average radiochemical yield.

was obtained by reducing 1 mole of acetone with 0.25 moles of $LiAlH_4$, using 2-propanol for the decomposition of excess $LiAlH_4$ and the liberation of 2-propanol-2T by alcoholysis (6). The average radiochemical yield was 75% as compared with the stoichiometric reaction. The fact that tritium was not attached to the hydroxyl groups was established by the alcoholysis of samples of non-labelled $LiAlH_4$ with the methanol-T and 2-propanol-2T prepared by us; the hydrogen evolved was not radioactive.

The activity of the tritiated compounds was determined by introducing them into two compensated Geiger–Müller counters by means of a vacuum line (7). In all experiments reported in this note the fraction of tritium which had left the crystalline lattice of $LiAlH_4$ during irradiation without participating in the labelling process of $LiAlH_4$ was not determined.

The results shown in Table I, indicate a variation of the contents of chemically active $LiAlH_4$ versus the nominal and (or) integral neutron flux, to which the sample had been exposed. The differences between the data given in the columns G and I on one hand, and those given in the columns H and J, on other hand, seem to show an advanced radiation damage of the crystalline lattice of $LiAlH_4$ to a chemical form non-active in the chemical reduction, especially for sample No. 3.

In this note we have succeeded in demonstrating qualitatively the formation of $LiAlH_4$-*t* by irradiation of $LiAlH_4$ with thermal neutrons, and in showing the possibility of tritiation of organic compounds by using $LiAlH_4$-*t* thus prepared. The labelling of $LiAlH_4$ as a result of neutron irradiation via substitution of recoil T atoms from the $Li^6(n,\alpha)T$ nuclear reaction is a simple and fast procedure. The usual methods (1–3) are more complicated requiring two reactions although at the first sight they are more favorable because of the higher specific activities obtained.

In forthcoming experiments we shall try to study the phenomenon quantitatively in order to explain the influence of neutron flux, and of the irradiation temperature etc., and at the same time to find the best conditions for obtaining a maximum specific activity for a minimum damage of the crystalline lattice of $LiAlH_4$.
