Considerable interest has centered recently on the dependence of cis, trans, and gem coupling constants for vinyl compounds upon the electronegativity of the substituent group. Schaefer (1) has reported a linear correlation of J_{cis}, J_{trans}, J_{gem} and their sum with electronegativities of the substituent group for a wide range of vinyl compounds. Similar correlations have also been observed independently by Waugh and Castellano (2) and Banwell and Sheppard (3). The significance of correlations of this type in sorting out unacceptable values for coupling constants in the analysis of proton resonance spectra is readily apparent. For example, Castellano and Waugh (4) recently utilized the constancy of $J_{cis}+J_{trans}+J_{gem}$ as a criterion for rejection of spectral assignments for tetravinylsilane which yielded spacings whose sum was significantly different from 38.2 c/s.

Relatively few proton resonance measurements have been reported for vinyl-metallic compounds and the coupling constants for several vinyl-metallics (5) included in Schaefer's correlations are open to question (6). Since electronegativities for many of the metals fall in the range 1.5 to 2.0 additional data for compounds of this type would provide a further test of the empirical correlations. In particular, no spectra have been published for vinylgermanes and in this note we wish to report the proton resonance spectrum, coupling constants, and chemical shifts for hexavinyldigermane.

Spectra were measured with a Varian A-60 spectrometer at room temperature (23±1° C) with a drop of tetramethylsilane serving as internal reference. A commercial sample of hexavinyldigermane (Metallomer Labs, Maynard, Mass.) was used without further purification. A small amount of vinyl impurity (estimated as less than 5%) was noted. Spectra were measured for the neat compound and for 5 vol% solutions in carbon tetrachloride, acetone, and acetonitrile. No detectable changes were observed for the vinyl protons in these solvents and only a very slight change, amounting to shifts of 1 c/s, was noted for the strong peaks when the concentration was varied from 0 to 100% in acetone.

Figure 1 shows the spectrum for hexavinyldigermane in acetone (10%) and indicates a

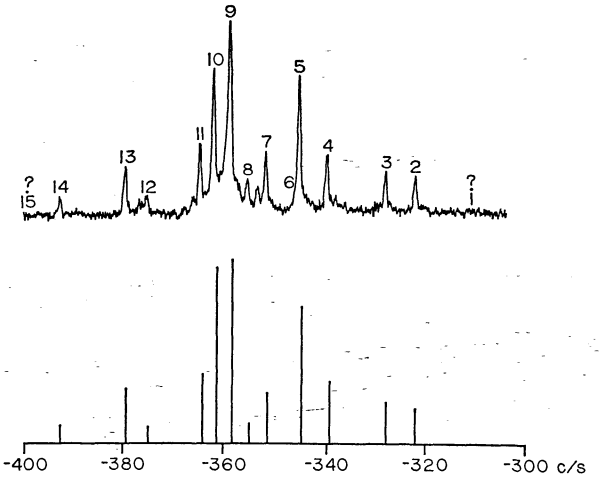

FIG. 1. Observed and calculated proton resonance spectrum for 10 vol% hexavinyldigermane in acetone (relative to tetramethylsilane as internal standard).

partially collapsed ABC pattern for the vinyl protons. A summary of the chemical shifts and coupling constants is given in Table I along with a comparison of observed and calculated frequencies. The structural parameters were computed by an iterative procedure* and are precise to ±0.001 p.p.m. for δ's and ±0.08 c/s for the J's. Very good agreement is obtained between calculated and observed frequencies—the latter representing the mean value of five spectra. Similar agreement is noted for the intensities (Fig. 1) except for the peaks at −361.35 and −358.12 c/s. The discrepancies can be attributed to vinyl impurities present in the hexavinyldigermane. A satisfactory fit of the spectrum could not be obtained if the peaks at 352.5 and 376.0 c/s were incorporated in the calculations and these are therefore ascribed to impurities.

The magnitudes of the coupling constants are almost identical, within experimental error, with those observed for tetravinylgermane and triphenylvinylgermane (7). Both

$J_{AB} = 2.93 \pm 0.08$ c/s $\quad \delta_A = -335.56 \pm 0.10$ c/s

$J_{AC} = 20.07 \pm 0.09$ c/s $\quad \delta_B = -357.46 \pm 0.10$ c/s

$J_{BC} = 13.32 \pm 0.09$ c/s $\quad \delta_C = -371.61 \pm 0.10$ c/s

J_{gem}, 2.93 ± 0.08 c/s, and the sum of the three coupling constants, 36.32 ± 0.09 c/s, for hexavinyldigermane are significantly lower than the corresponding values for the vinyl-silanes, 3.6 to 3.9 c/s (7, 8) and 38.8 c/s (4, 8) respectively. This decrease in the sum of the J's parallels the slight increase in electronegativity in going from Si ($E_n = 1.90$) to Ge ($E_n = 2.00$) (9). A good fit of both J_{gem} and $J_{gem} + J_{cis} + J_{trans}$ to Schaefer's empirical correlations (1) is noted for hexavinyldigermane. This provides a further check on the correctness of the three coupling constants obtained in the numerical analysis.

The chemical shifts are all considerably lower than those for alkenes (10) and vary in the same order as observed for vinyl-silanes (8) and other vinyl-germanes (7), i.e., $\alpha <$ trans $<$ cis.* The insensitivity of the shifts to polar solvents (acetone, acetonitrile) indicates that the shielding is not due to any permanent electric field within the molecules as has been proposed for alkenes (10). Nor is it possible to attribute the low-field shifts to inductive interaction of the trigonal C atom with the Ge since the lower electronegativity of Ge would lead to shifts in the opposite direction. Similar low-field shifts (relative to alkenes) for substituted vinyl-silanes (8) have been attributed qualitatively to $d_\pi - p_\pi$ interaction between Si and the trigonal C. Although an analogous interaction is possible in hexavinyldigermane further work is required to sort out the magnitude of this contribution.

SYMMETRIZATION OF SPIN FUNCTIONS FOR THREE EQUIVALENT SPIN 1/2 NUCLEI BY MEANS OF THE POINT GROUP C_3

T. SCHAEFER AND F. HRUSKA

As is well known, group theoretical methods are very useful in simplifying calculations involving the diagonalization of operator matrices. The analyses of high-resolution nuclear magnetic resonance spectra are no exception (1). Whenever the spin system under consideration is symmetrical, additional factoring of the Hamiltonian will occur if the zero-order spin functions are chosen properly. Often the correct spin functions can be obtained by simple considerations. In general, it is necessary to apply the group theory which allows one to form linear combinations of product spin functions which are basic functions for irreducible representations of the group to which the spin system belongs. The Hamiltonian matrix then factors because the matrix elements of the type $\langle\psi_m|\mathcal{H}|\psi_n\rangle$ are zero unless ψ_m and ψ_n are both basis functions for the same irreducible representation (2, 3).

As pointed out, for instance by Corio, the point groups required in n.m.r. spectroscopy are usually simpler than those needed for the same molecule in other connections (4). He takes as an example three equivalent nuclei (the protons in a methyl group, for instance) and shows that the group C_{3v} will do, although in considering the normal vibrational modes the correct group would be D_{3h}. One might use D_{3h} but the calculations would involve much more work since D_{3h} has twice as many elements as C_{3v}. We show here that the use of the rotation group C_3, with only three elements, will suffice to derive the basis functions of proper symmetry for three magnetically equivalent nuclei of spin 1/2.

There are $2^3 = 8$ basic spin product functions $\alpha\alpha\alpha$, $\alpha\alpha\beta$, $\alpha\beta\alpha$, $\beta\alpha\alpha$, $\beta\beta\alpha$, $\beta\alpha\beta$, $\alpha\beta\beta$, and $\beta\beta\beta$. α and β are defined by $I_z\alpha = (1/2)\alpha$ and $I_z\beta = (-1/2)\beta$ where I_z is the z-component of the nuclear spin angular momentum vector operator I. These functions are eigenfunctions of the operator $F_z = I_z(1)+I_z(2)+I_z(3)$ which commutes with the Hamiltonian operator (1).

If the three spins are considered to lie at the corners of an equilateral triangle with a 3-fold symmetry axis through its center then the effect of the three symmetry operations of the group C_3 on the basis functions is as shown in Table I. E is the identity operator, C_3 is a counterclockwise rotation by $2\pi/3 = 120°$, and C_3^2 is a clockwise rotation by the same amount. Note that the functions have been blocked into groups with the same eigenvalue of F_z. There is, of course, no mixing between the different blocks. Notice also that

SYMMETRIZATION OF SPIN FUNCTIONS FOR THREE EQUIVALENT SPIN 1/2 NUCLEI BY MEANS OF THE POINT GROUP C_3

T. SCHAEFER AND F. HRUSKA

As is well known, group theoretical methods are very useful in simplifying calculations involving the diagonalization of operator matrices. The analyses of high-resolution nuclear magnetic resonance spectra are no exception (1). Whenever the spin system under consideration is symmetrical, additional factoring of the Hamiltonian will occur if the zero-order spin functions are chosen properly. Often the correct spin functions can be obtained by simple considerations. In general, it is necessary to apply the group theory which allows one to form linear combinations of product spin functions which are basic functions for irreducible representations of the group to which the spin system belongs. The Hamiltonian matrix then factors because the matrix elements of the type $\langle\psi_m|\mathcal{H}|\psi_n\rangle$ are zero unless ψ_m and ψ_n are both basis functions for the same irreducible representation (2, 3).

As pointed out, for instance by Corio, the point groups required in n.m.r. spectroscopy are usually simpler than those needed for the same molecule in other connections (4). He takes as an example three equivalent nuclei (the protons in a methyl group, for instance) and shows that the group C_{3v} will do, although in considering the normal vibrational modes the correct group would be D_{3h}. One might use D_{3h} but the calculations would involve much more work since D_{3h} has twice as many elements as C_{3v}. We show here that the use of the rotation group C_3, with only three elements, will suffice to derive the basis functions of proper symmetry for three magnetically equivalent nuclei of spin 1/2.

There are $2^3 = 8$ basic spin product functions $\alpha\alpha\alpha$, $\alpha\alpha\beta$, $\alpha\beta\alpha$, $\beta\alpha\alpha$, $\beta\beta\alpha$, $\beta\alpha\beta$, $\alpha\beta\beta$, and $\beta\beta\beta$. α and β are defined by $I_z\alpha = (1/2)\alpha$ and $I_z\beta = (-1/2)\beta$ where I_z is the z-component of the nuclear spin angular momentum vector operator I. These functions are eigenfunctions of the operator $F_z = I_z(1)+I_z(2)+I_z(3)$ which commutes with the Hamiltonian operator (1).

If the three spins are considered to lie at the corners of an equilateral triangle with a 3-fold symmetry axis through its center then the effect of the three symmetry operations of the group C_3 on the basis functions is as shown in Table I. E is the identity operator, C_3 is a counterclockwise rotation by $2\pi/3 = 120°$, and C_3^2 is a clockwise rotation by the same amount. Note that the functions have been blocked into groups with the same eigenvalue of F_z. There is, of course, no mixing between the different blocks. Notice also that

TABLE I

Transformation properties of product spin functions for three spins 1/2 under the C_3 point group

3/2	1. $\alpha\alpha\alpha$	$\alpha\alpha\alpha$	$\alpha\alpha\alpha$	$\alpha\alpha\alpha$
1/2	2. $\alpha\alpha\beta$	$\alpha\alpha\beta$	$\beta\alpha\alpha$	$\alpha\beta\alpha$
	3. $\alpha\beta\alpha$	$\alpha\beta\alpha$	$\alpha\alpha\beta$	$\beta\alpha\alpha$
	4. $\beta\alpha\alpha$	$\beta\alpha\alpha$	$\alpha\beta\alpha$	$\alpha\alpha\beta$
−1/2	5. $\beta\beta\alpha$	$\beta\beta\alpha$	$\alpha\beta\beta$	$\beta\alpha\beta$
	6. $\beta\alpha\beta$	$\beta\alpha\beta$	$\beta\beta\alpha$	$\alpha\beta\beta$
	7. $\alpha\beta\beta$	$\alpha\beta\beta$	$\beta\alpha\beta$	$\beta\beta\alpha$
−3/2	8. $\beta\beta\beta$	$\beta\beta\beta$	$\beta\beta\beta$	$\beta\beta\beta$

the symmetry operators convert a function in one of the blocks into another function in the same block.

It follows that we need to apply symmetry principles only to the two blocks containing three functions each in our effort to further factor the Hamiltonian matrix. Consider the three functions ψ_2, ψ_3, and ψ_4. They clearly form a basis for a reducible representation of the group C_3 (they do not form a basis for a representation of the group C_{3v}). The reducible representation consists of the three transformation matrixes

$$\begin{pmatrix}1&0&0\\0&1&0\\0&0&1\end{pmatrix} \quad \begin{pmatrix}0&0&1\\1&0&0\\0&1&0\end{pmatrix} \quad \begin{pmatrix}0&1&0\\0&0&1\\1&0&0\end{pmatrix}$$

which are associated to the operators E, C_3, and C_3^2 respectively. It is easily checked that these matrices have the same multiplication table as the symmetry operators and therefore they are a faithful, actually the regular, representation of the group.

Since the order of the group is three, it follows that this representation can be reduced to three one-dimensional irreducible representations. The reduction by means of similarity transformations is carried out by standard methods and the three irreducible representations are found to be Γ_1, Γ_2, and Γ_3:

	C_3	C_3	C_3^2
Γ_1	1	1	1
Γ_2	1	w	w^2
Γ_3	1	w^2	w

where $w = \exp(2\pi i/3)$, $w^2 = \exp(-2\pi i/3)$, $i = \sqrt{-1}$, $1+w+w^2 = 0$.

This is, of course, the character table for the group C_3. It follows (3) that the three normalized linear combinations of ψ_2, ψ_3, and ψ_4 belonging to the three irreducible representations are

$$\psi(\Gamma_1) = \frac{1}{\sqrt{3}}(\alpha\alpha\beta+\alpha\beta\alpha+\beta\alpha\alpha)$$

$$\psi(\Gamma_2) = \frac{1}{\sqrt{3}}(\alpha\alpha\beta+w\alpha\beta\alpha+w^2\beta\alpha\alpha)$$

$$\psi(\Gamma_3) = \frac{1}{\sqrt{3}}(\alpha\alpha\beta+w^2\alpha\beta\alpha+w\beta\alpha\alpha).$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The last two functions are accidentally degenerate as can easily be checked in the usual way (1). This degeneracy is not required by the dimensionality of the representations but is a consequence of time reversal (5). These functions do not have the same form as those derived by Corio (4) and McConnell *et al.* (6). Because of the degeneracy, however, linear combinations of the two functions are also acceptable. We find

$$\frac{1}{\sqrt{2}}\{\psi(\Gamma_2)+\psi(\Gamma_3)\} = \frac{1}{\sqrt{6}}(2\alpha\alpha\beta-\alpha\beta\alpha-\beta\alpha\alpha)$$

and

$$\frac{1}{\sqrt{2}i}\{\psi(\Gamma_2)-\psi(\Gamma_3)\} = \frac{1}{\sqrt{2}}(\alpha\beta\alpha-\beta\alpha\alpha).$$

These functions have the same form as those normally used and are also degenerate.

The same procedure can be applied to the functions ψ_5, ψ_6, and ψ_7 to find the proper symmetry combinations, although they can now be found by analogy to ψ_2, ψ_3, and ψ_4. The present approach is considerably shorter than that involving the group C_{3v}. The simplification arises by considering separately those starting spin functions with the same eigenvalue of F_z.

TEMPERATURE AND SOLVENT EFFECTS ON THE PROTON MAGNETIC RESONANCE SPECTRUM OF BIS(2,2-DICHLOROCYCLOPROPYL) ETHER

H. M. HUTTON[1] AND T. SCHAEFER

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

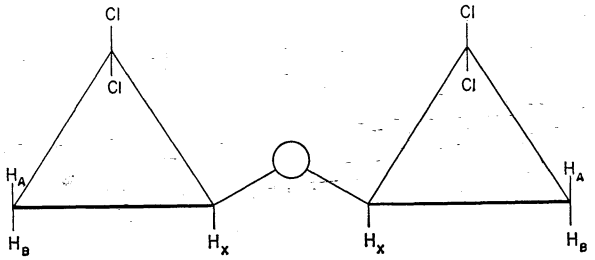
Received March 22, 1963

ABSTRACT

The proton magnetic resonance spectrum of bis(2,2-dichlorocyclopropyl) ether consists of two partially overlapping ABX spectra due to the meso and *d,l* isomers. A study of the temperature dependence of the spectra in different solvents demonstrates the existence of complex formation with benzene. It is found that for the most abundant isomer the heat of formation of the complex is -1700 ± 100 cal/mole, the entropy of formation is -6.2 ± 0.3 e.u. The association shifts are 52 ± 2 c.p.s., 64 ± 5 c.p.s., and 88 ± 5 c.p.s. at 60 Mc/s for the three protons situated at different points in the molecule.

INTRODUCTION

The proton magnetic resonance spectrum of bis(2,2-dichlorocyclopropyl) ether (I) consists of two slightly shifted ABX spectra arising from the meso and *d,l* isomers.* The shifts



I

of the three protons in each ABX spectrum relative to one another and to an internal tetramethylsilane (TMS) reference depend markedly on solvent and temperature. We have examined our experimental data in terms of internal rotation effects, effective inversion of the oxygen atom, and association effects. It appears that the latter is consistent with experiment.

EXPERIMENTAL

The spectra were recorded on a Varian V4302 DP 60 Mc/s spectrometer. A sample of about 0.1 g of bis(2,2-dichlorocyclopropyl) ether (1) was obtained from Dr. Bernard T. Gillis. The spectra were taken at room temperature in carbon tetrachloride, benzene, carbon disulphide, and in a series of mixed solvents of benzene and carbon disulphide. Measurements were made with benzene as solvent over a temperature range of +18° C to +138° C using a temperature probe built by Mr. G. Ensell.

[1]*Holder of a C.I.L. Fellowship, 1962–1963.*

**We thank Dr. B. T. Gillis for pointing this out to us.*

Since carbon disulphide offers a wide liquid range for temperature studies the spectrum was studied from −85° C to +101° C in this solvent. The solution with the mixed solvent 0.59 mole fraction carbon disulphide and 0.41 mole fraction benzene was also observed from +18° C to +132° C. The solutions were prepared by dilution with 0.5 ml of reagent grade solvent and represent an ether concentration of about 8 mole% in benzene, 7 mole% in carbon tetrachloride, and 5 mole% in carbon disulphide. The ether was isolated by evaporation of the solvent from each solution and used again. Tetramethylsilane was the internal reference in all solutions. Other solvents such as cyclohexane and *n*-hexane, useful for the comparison of chemical shifts, were not used because of the interference of their proton resonances in the region of interest.

The results represent an average of 10 calibrated spectra for those taken at room temperature and of 6 to 8 spectra at other temperatures. Spectra were taken with an increasing and decreasing magnetic field sweep.

Temperatures were measured with a precalibrated Varian G-11A recorder using a thermocouple placed near the sample in the exit stream of the spinning and heating gas. The temperature control was approximately ±1° C over the period of time necessary to run the calibrated spectra.

RESULTS

Figure 1 shows the proton resonance spectrum in benzene at room temperature and

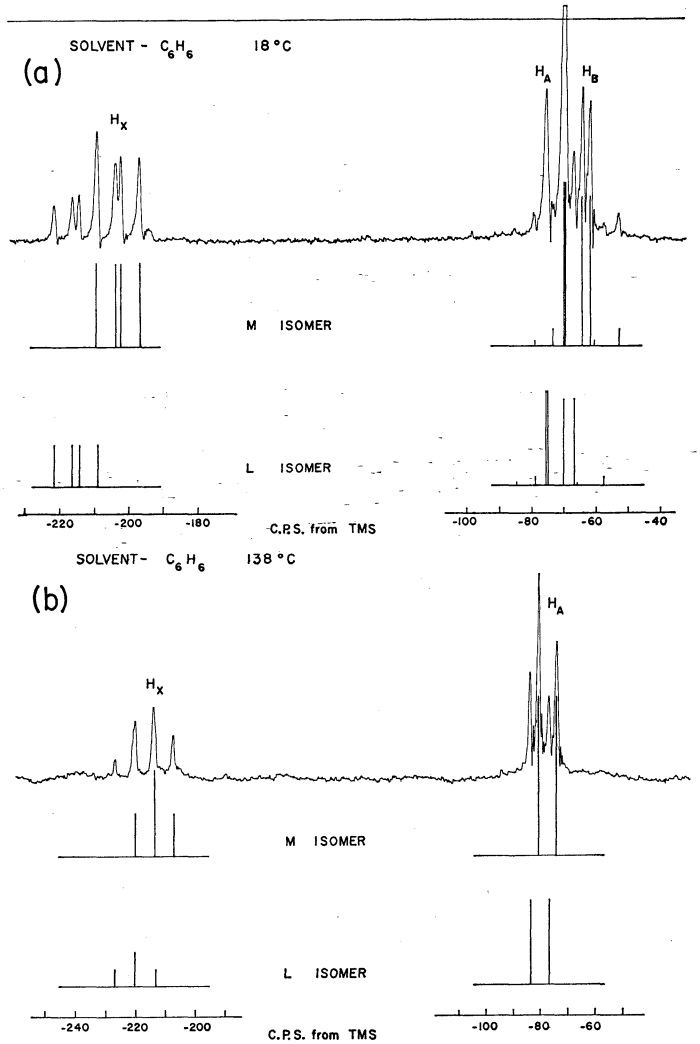


FIG. 1. Proton magnetic resonance spectrum at 60 Mc/s of bis(2,2-dichlorocyclopropyl) ether in benzene (*a*) at 18° C and (*b*) at 138° C; calibration is with respect to internal TMS.

at 138° C. From the relative intensities of the two ABX spectra one isomer (M) is seen to be about twice as abundant as the other isomer (L). The former is probably the meso isomer (2) although there is no way of deciding this from the spectrum.

The chemical shifts relative to internal TMS and the proton coupling constants are given in Tables I, II, and III. Graphs of the chemical shifts as a function of temperature in benzene and in a mixed benzene – carbon disulphide solution are shown in Figs. 2 and 3. Figure 4 shows the chemical shifts of the protons of the M isomer as a function

FIG. 3. Plot of proton resonance shifts of bis(2,2-dichlorocyclopropyl) ether in 0.41 mole fraction benzene + 0.59 mole fraction carbon disulphide (in c.p.s. at 60 Mc/s) against temperature; calibration is with respect to internal TMS.

of the benzene concentration in the mixed solvent system. The shifts of the protons in the L isomer could not always be obtained with any accuracy because of overlapping peaks.

For the benzene solution the shift between the benzene peaks and the TMS peaks

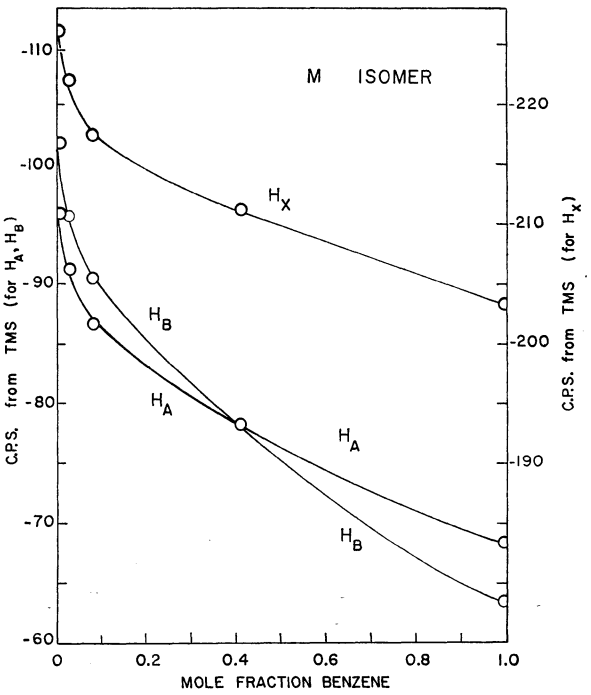

FIG. 4. Plot of proton resonance shifts of bis(2,2-dichlorocyclopropyl) ether in mixed benzene – carbon disulphide (in c.p.s. at 60 Mc/s) against mole fraction benzene at 18° C; calibration is with respect to internal TMS.

was 430.4±0.1 c.p.s. at 18° C and 431.0±0.2 c.p.s. at 102° C. For the mixed solvent (Fig. 3) these shifts were 429.1±0.1 c.p.s. at 18° C and 429.6±0.1 c.p.s. at 145° C.

DISCUSSION

(a) Coupling Constants

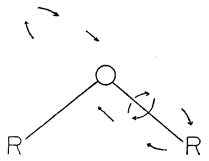
From a series of measurements (3–6) we are almost certain that geminal proton coupling constants in cyclopropane derivatives are negative. The vicinal couplings are then positive with the trans smaller than the cis (7–9). The labelling in Fig. 1 and in the other figures and tables assumes this relationship and that the B proton resonates at a higher field than the A proton in benzene solution.

From the tables we then have that for isomer M: $J_{AB} = J_{gem} = -8.7_7 \pm 0.25$ c.p.s.; $J_{AX}+J_{BX} = 12.8\pm0.2$ c.p.s. with $J_{AX} = J_{trans} = 5.0\pm0.5$ c.p.s. and $J_{BX} = J_{cis} = 7.8 \pm0.5$ c.p.s. For the L isomer: $J_{AB} = J_{gem} = -8.7\pm0.2$ c.p.s.; $J_{AX}+J_{BX} = 13.0\pm0.2$ c.p.s. with $J_{AX} = J_{trans} = 4.8\pm0.5$ c.p.s. and $J_{BX} = J_{cis} = 8.2\pm0.5$ c.p.s. The individual errors in J_{AX} and J_{BX} are considerably larger than in their sum because of the way in which these quantities depend on peak separations (10). For those solutions where the shift between A and B protons was zero the average of J_{AX} and J_{BX} could be determined quite accurately and was equal to half the sums given above, within experimental error. Also, within error, the couplings are independent of solvent and temperature.

(b) Chemical Shifts and Internal Rotational Effects

The internal rotational motions of the molecules about the carbon – oxygen bonds is indicated schematically in II, where R represents the substituted cyclopropyl group.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



II

From Dreiding models it appears unlikely that rotations about these bonds will result in an averaging process such that the shifts of the A and B protons will become identical. This hypothesis is supported by the shift behavior of these two protons as a function of temperature in carbon disulphide and in benzene. The dielectric constants of these two solvents are almost identical and the population of the various rotational isomers should have the same temperature dependence in the two solvents. As can be seen in the tables this is not the case at all. The same objection can be levelled against a more complex motion consisting of combined rotation and an effective inversion of the oxygen atom.

(c) Chemical Shifts and Association in Benzene

Association between benzene and polar molecules has been investigated for relatively simple molecules by a number of workers (11–14). Such an association usually results in a high-field shift of the solute protons due to the disk-shaped molecules of the diamagnetically anisotropic benzene (13). A temperature increase should break up the association and result in a shift to low field of the solute proton peaks. This is exactly what we find. If the A and B protons have different association shifts, as is reasonable, the high-temperature shift equivalence must be looked upon as accidental.

The temperature dependence of the shifts in carbon disulphide is consistent with very weak association between the rod-shaped diamagnetically anisotropic carbon disulphide molecules and the solute. Such an association results in a low-field shift (13) and as the temperature increases a high-field shift is predicted. This we find, although it is small (1–3 c.p.s.) and therefore consistent with very weak association.

In this discussion we have ignored dispersion (van der Waals) effects and density effects. However, the use of an internal reference minimizes these effects. Reaction field effects (15) should be almost the same in both carbon disulphide and in benzene. The excess shifts we observe therefore can be put down to specific interactions with the solvent. The negligible change with temperature of the benzene peaks relative to the TMS peaks indicates no drastic change in packing of molecules which do not specifically interact.

We postulate that the complex formation between the ether and the benzene can be represented by

$$\text{A—H} + \text{B} \rightleftarrows \text{A—H}\cdots\text{B}$$

with an equilibrium constant

$$K = \frac{[\text{A—H}\cdots\text{B}]}{[\text{A—H}][\text{B}]} = \exp\left(\frac{\Delta S}{R}\right)\exp\left(\frac{-\Delta H}{RT}\right),$$

where [A—H] is the concentration of the ether, [B] is the concentration of the benzene, and [A—H- - -B] is the concentration of the complex. ΔS is the entropy of formation and ΔH the heat of formation of the complex. If we write K in units of mole fraction and assume our shifts to differ by a negligible amount from those of an infinitely dilute solution, the benzene concentration becomes unity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Then

$$[1] \qquad \frac{p}{1-p} = \frac{[\text{A—H - - - B}]}{[\text{A—H}]} = \exp\left(\frac{\Delta S}{R}\right)\exp\left(\frac{-\Delta H}{RT}\right),$$

where p is the fraction of the ether in the complex form. The measured shift of the solute protons δ is the weighted mean of the shift of the unassociated solute δu and that in the complex δc. We have

$$[2] \qquad \delta = p\delta c + (1-p)\delta u.$$

From equations [1] and [2] we can find δ as a function of ΔH, ΔS, δc, δu, and the known temperature.

Following Abraham (14) we argue that at a high temperature, where $\Delta H \ll kT$, all the solute protons will be in the unassociated form. In this state the shift from internal TMS will be due to the different chemical nature of the solute and reference and to the reaction field of the benzene. Since carbon disulphide and benzene have almost the same dielectric constant we can take the high-temperature shift in carbon disulphide as the unassociated shift δu (we have ignored any small effects due to slight differences in dispersion forces). The high-temperature shift in carbon disulphide was taken in order to eliminate association effects with this solvent as far as possible. This effect is very small since we find at most a 3 c.p.s. shift with respect to internal TMS over a 200° C range (Table II).

At low temperatures, $\Delta H \gg kT$, all the solute molecules will be associated with the benzene and the shift will now be δu plus that due to complex formation. We take δu to be the origin and measure all chemical shifts from it.

Then it follows that $\delta = p\delta c$ and that

$$[3] \qquad \delta = \delta c\left\{1 + \exp\left(\frac{-\Delta S}{R}\right)\exp\left(\frac{\Delta H}{RT}\right)\right\}^{-1},$$

which is the equation given by Abraham (14). δ is now a function of three unknowns only.

We apply equation [3] to the most abundant isomer M where the individual proton shifts are most reliable. δu is taken from Table II. The experimental points in Fig. 2 can be fitted with the following values for the parameters within the error limits given:

Proton	δu (c.p.s.)	δc (c.p.s.)	ΔH (cal)	ΔS (e.u.)
H_X	−226.2	52±2	−1700±50	−6.2±0.1
H_B	−101.2	88±5	−1700±100	−6.2±0.2
H_A	− 95.0	64±5	−1700±100	−6.2±0.3

The values are reasonable in that ΔH and ΔS are the same for all three protons while δc is different. δc depends on the structure of the complex and may therefore very well be different for protons situated at different positions in the solute molecule.

CONCLUSIONS

Hydrogen bonding has been postulated to explain interactions of methyl iodide and iodoform with toluene (14) and of chloroform with mesitylene (11). Whether the interaction we have found for this ether with benzene can be similarly explained is open to speculation. We feel that an association such that the benzene molecules tend to avoid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

electron-rich centers (oxygen and chlorine) is probably just as reasonable if not preferable (16). H_X would then be expected to have the smallest association shift and this we find. It is interesting to note that the dilution shifts of protons A and B in the mixed solvent (Fig. 4) have a ratio $H_A/H_B = 0.71$ while the ratio of the association shifts is 0.73. Since the former are measured against internal TMS they should also be a measure of the association dependence of the proton shifts.

ACKNOWLEDGMENTS

We are grateful to Dr. B. T. Gillis for the gift of the last 0.1 g of his ether and for his comments. The helpful discussions with many colleagues were very useful. H. M. H. would like to thank Canadian Industries Limited for fellowship support. This work was supported by the National Research Council.

HEATS OF VAPORIZATION OF A SERIES OF ALIPHATIC ALCOHOLS

K. G. McCurdy and K. J. Laidler
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received February 22, 1963

ABSTRACT

Heats of vaporization of 14 alcohols, having from one to five carbon atoms, have been determined in a Calvet microcalorimeter, using a special technique. The method consisted of allowing the alcohol to vaporize into a vacuum, the heat required for the vaporization being provided by passing a current through a resistance wire which was immersed in oil in a U-tube surrounded by the alcohol. The additivity scheme previously devised by Laidler for heats of formation and related properties was applied to the results, and the agreement with experiment was within a few tenths of a percent.

INTRODUCTION

A considerable amount of experimental work has been done on heats of combustion of compounds in the liquid and solid states, but relatively little accurate work has been done on heats of vaporization. Such heats are required for the conversion of heats for the liquid state into heats relating to the gaseous state. It was therefore decided to adapt the Calvet microcalorimeter for the determination of such heats of vaporization, and a special technique for this purpose has been developed. It was considered of particular interest to attempt to interpret the heats of vaporization in terms of additivity schemes, such as the one previously developed by Laidler (1). The work was done on a homologous series of aliphatic alcohols.

EXPERIMENTAL

Materials

The alcohols used were Fisher certified reagents. They were dried by refluxing over freshly ignited calcium oxide for 4 hours, followed by fractionation through a 40-cm column packed with short lengths of 4-mm glass tubing. Only the middle fractions were retained.

Calorimetry

The heats of vaporization were measured at 25° C using a differential microcalorimeter of the Calvet type, described in previous papers from this laboratory (2, 3). The apparatus for carrying out the vaporization, shown in Fig. 1, consists of a U-tube which contains the purified alcohol. This tube, after being loaded with the appropriate amount of alcohol, was sealed directly to a vacuum line. It was then subjected to freeze-drying to remove air that had become dissolved during loading. The U-tube was then evacuated to a pressure of approximately 0.5 mm, with the alcohol frozen in liquid air. The U-tube was then sealed off from the vacuum line by collapsing the walls of the tube.

The receiver consisted of a calibrated glass bulb of approximately 5-ml capacity connected to the U-tube by means of a calibrated capillary tube. The U-tube was placed in the calorimeter, and when it and the calorimeter had attained thermal equilibrium the distillation was started by raising a Dewar vessel of coolant on the receiving end of the U-tube. This was done by means of a raising and lowering device controlled from the exterior of the calorimeter cabin. The coolant consisted of liquid air, dry ice – acetone, or iced water, according to circumstances.

The heat required to cause vaporization was compensated for by the application of a potential across a resistance wire immersed in an oil bath, which was encased in glass and was surrounded by the alcohol. An electric timing device was used to record the duration of the passage of the current; the current was passed for 100 to 200 minutes, depending on the vapor pressure and the coolant. It was possible, by means of the elevating device, to control the rate of evaporation so that it would closely match the rate of heat delivered by the coil; in this way the amount of heat measured in the calorimeter was kept to a minimum, and the accuracy of the measurements was thereby greatly increased. The rates of evaporation ranged from about 2×10^{-4} mole/min to 5×10^{-4} mole/min.

When sufficient alcohol had been vaporized, so that the surface of the liquid was in the calibrated capillary tube, the coolant was lowered sufficiently to stop vaporization but only to such an extent that the alcohol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

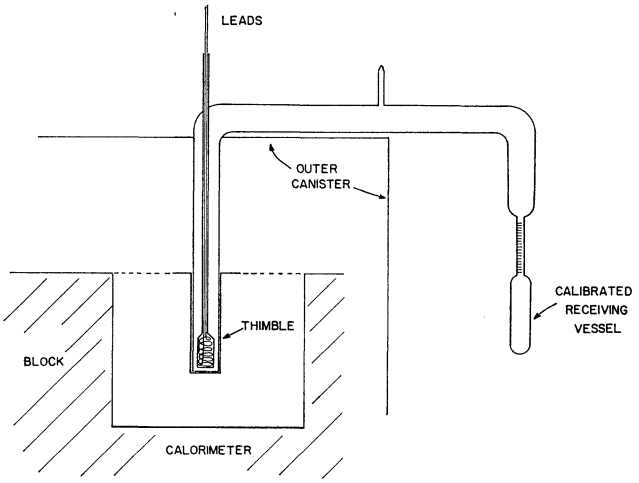

FIG. 1. Apparatus for the measurement of heats of vaporization of liquids in the microcalorimeter (schematic, not drawn to scale).

in the receiver did not distill back into the U-tube. The heater was then turned off and the calorimeter allowed to come back to thermal equilibrium. During this period part of the alcohol in the calorimeter was vaporized, with the result that the conditions in the U-tube were the same as the initial conditions. The coolant was then further lowered and the alcohol in the receiver allowed to return to 25° C; this was done in the thermostatted cabin, the temperature of which was controlled to 0.1° C. The volume was then recorded, and from a knowledge of its density it was then possible to calculate the weight of alcohol distilled.

The conditions were always adjusted so that there was a positive amount of heat evolved, indicated by a positive area on the record. This area was reproduced by passing an electric current through the resistance in the cell for a known period of time. This excess heat was usually less than 1% of the total heat absorbed in the vaporization process.

Experiments with the U-tube empty and evacuated showed that there was negligible conduction of heat along the U-tube when the coolant was placed around the receiver. Experiments in which the amount of alcohol in the U-tube was varied showed no effect on the calculated heat of vaporization, indicating that there was negligible heat loss from the tube. Experiments in which the rate of vaporization was varied, by using a different coolant and varying the potential across the resistance, gave results in good agreement with one another. This indicates negligible entrainment of liquid during the vaporization.

RESULTS

A typical set of measurements is given in Table I and the final results obtained are summarized in Table II. An estimate of the overall accuracy of the heat determinations may be arrived at as follows. The error in the measurement of time can be ignored as being much smaller (<1 in 10,000) than the other errors. An average current was 0.0750 amp, and the uncertainty in this is 0.0001 amp. The total resistance was 73.675

$CH_3(CH_2)_3OH$	$3P+6S+A^1$	117	0.8059	12,190	12,190	3	±10
$(CH_3)_2CHCH_2OH$	$6P+2S+T+A^1$	107	0.7979	11,910	11,890	4	± 6
$CH_3CH_2(CH_3)CHOH$	$6P+2S+T+A^2$	119.8	0.8025	11,590	11,590	4	±27
$(CH_3)_3COH$	$9P+A^3$	82	0.7810	10,720	10,710	4	±19
$(CH_3)_2CH(CH_2)_2OH$	$6P+4S+T+A^1$	131	0.8054	12,980	12,950	2	± 1.9
$CH_3CH_2(CH_3)CHCH_2OH$	$6P+4S+T+A^1$	127.5	0.8110	12,920	12,950	2	±16
$CH_3(CH_2)_2(CH_3)CHOH$	$6P+4S+T+A^2$	119.3	0.8052	12,670	12,650	2	±10
$(CH_3CH_2)_2CHOH$	$6P+4S+T+A^2$	115	0.8150	12,650	12,650	3	± 7
$(CH_3)_2CH(CH_3)CHOH$	$9P+2T+A^2$	112	0.8150	12,350	12,350	3	±15
$CH_3CH_2(CH_3)_2COH$	$9P+2S+A^3$	101.4	0.8069	11,750	11,760	3	±10

ohms, and the uncertainty in this is about 0.010 ohms. These figures lead to an uncertainty of 2.9 cal in the electrical heat, or of 0.3%. The volume vaporized was approximately 5 ml, and the uncertainty 0.01 ml or 0.2%. The heat of vaporization per mole is the ratio of a measured heat to the volume, and this leads to an overall uncertainty of 0.5%.

The calculated heats of vaporization were obtained by the use of an additivity scheme of the same kind as previously given (1) for heat of formation. The contributions for the various bonds, obtained on the IBM 650 computer by the method of least squares, are as follows:

P	(primary C—H bond)	606 cal/mole
S	(secondary C—H bond)	530 cal/mole
T	(tertiary C—H bond)	0 cal/mole
A^1	(C—O—H, in which C is primary)	7196 cal/mole
A^2	(C—O—H, in which C is secondary)	6894 cal/mole
A^3	(C—O—H, in which C is tertiary)	5250 cal/mole

There is no contribution for a C—C bond.

DISCUSSION

The standard deviations of the experimental heats of vaporization are in all cases less than 0.3%, and in most cases are 0.1 to 0.2%. The technique employed therefore seems to provide a very reliable method of measuring the heats of vaporization.

The values obtained for methanol, ethanol, and *n*-propanol may be compared with the values given by Green (4), which are 9,070±10, 10,180±20, and 11,360±10 cal/mole respectively. For higher members of this straight-chain series of aliphatic alcohols Green suggests the same increment per CH_2 unit for the heat of vaporization as is found per CH_2 unit in the straight-chain aliphatic hydrocarbon series. This value is 1200±50 cal/mole per CH_2 unit; our value for the CH_2 unit increment is 1060 cal/mole.

Parks and Barton (5) obtained values for the heats of vaporization of *i*-propyl alcohol and *t*-butyl alcohol at 25° C from vapor pressure measurements; application of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Clausius–Clapeyron equation gives the values 10,600±150 and 10,900±200 cal/mole respectively, in good agreement with our experimental values.

Two methods most frequently employed in the calculation of the heat of vaporization at one temperature from the heat of vaporization at another temperature are due to Su (6) and Watson (7). These two methods have been applied to the data of Mathews (8), Ingle and Cody (9), Williamson and Harrison (10), and Weltner and Pitzer (11); the critical constants from the "International Critical Tables" (12) were used. The resulting values for the heats of vaporization at 25° C are shown in Tables III and IV.

TABLE IV

Calculated heats of vaporization at 25° C

Temperature of measurement	Calculated value at 25° C	
	Su	Watson
Data of Weltner and Pitzer (11) for methanol		
40	8,970	9,010
55	8,980	9,090
65	9,080	9,130
Data of Williamson and Harrison (10) for n-propanol		
60	11,310	11,420
73	11,310	11,390
81	11,300	11,420
Data of Williamson and Harrison (10) for i-propanol		
51	10,800	10,810
70	10,790	10,840
80	10,690	10,380

Pitzer and Williamson have determined the heats of vaporization of certain aliphatic alcohols at several temperatures. Results of the application of the method of Su and Watson to their data are given in Table IV.

For the lower-boiling aliphatic alcohols both temperature-dependent relationships predict heats of vaporization which are too high. The data of Pitzer lead to a value in better agreement with our value when the temperature of the measurement is closer to 25° C, that is, when the amount of correction is small. This is not the case with the data of Williamson and Harrison, where the predicted heat of vaporization is too high for both n-propyl and i-propyl alcohol, and the predicted value at 25° C is independent of the temperature of the measurement. For the higher-boiling alcohols both approximation methods give values that are too low. Adjustment of the exponent in Watson's equation allows one to fit different members of the series, but one cannot predict the heats of vaporization of a number of aliphatic alcohols using a constant exponent.

The agreement between our observed and calculated heats is very satisfactory, and is usually well within the standard deviation. This can be taken as confirming the accuracy of the measurements, and shows that the additivity scheme is as good as can be developed on the basis of the present experimental results.

Strictly speaking, an additivity scheme in terms of atoms or groups, rather than of bonds, would be preferable in the case of heats of vaporization. Simple atom schemes can, however, be shown to be equivalent to bond schemes. The use of the present bond scheme has the practical advantage that it is equivalent to the scheme used for heats of formation (1), so that gases and liquids can be treated in a uniform manner.

THE INTERACTION OF HYDRAZINE WITH BORON AND ALUMINUM HALIDES[1]

W. G. PATERSON[2] AND M. ONYSZCHUK
Inorganic Chemistry Laboratory, McGill University, Montreal, Que.
Received February 26, 1963

ABSTRACT

The interaction of boron halides BX_3 (where X is Cl or Br) or aluminum halides Al_2X_6 (where X is Cl, Br, or I) with hydrazine is characterized by the elimination of hydrogen halide and the formation of substances with boron– (or aluminum–) nitrogen linkages. The hydrogen halide appears in the products as hydrazine hydrohalide, which can be separated by a hydrazine washing technique, leaving a polymeric material with empirical formula MN_4H_5 (where M is Al or B). A reaction scheme is proposed and possible structures of this polymeric product are discussed.

INTRODUCTION

Hydrazine, like ammonia, is an electron-pair donor capable of forming coordination compounds with borane (1–3), boron trifluoride (4), and trimethylborane (5). Ammonia reacts with the other boron trihalides, BCl_3 (6, 7), BBr_3 (6), and BI_3 (8), without yielding stable adducts, but forming ammonium halide and boron amide or imide instead, by condensation reactions. Hydrazine might be expected to give similar condensation products. The experiments reported in this paper were made to examine this possibility. Since ammonia forms a series of addition compounds with aluminum trihalides (9, 10), it was also particularly interesting to determine the nature of the interaction between hydrazine and aluminum trihalides.

RESULTS AND DISCUSSION

Boron trichloride reacted with excess hydrazine in a vacuum, yielding a product in which the ratio of trichloride to hydrazine was 1:4. This suggests that the overall reaction was:

$$BCl_3 + 4N_2H_4 \rightarrow (NH_2NH)_2BCl + 2N_2H_4 \cdot HCl.$$

In tetrahydrofuran solution, however, the combining ratio was 1:6, suggesting the reaction

$$BCl_3 + 6N_2H_4 \rightarrow (NH_2NH)_3B + 3N_2H_4 \cdot HCl.$$

The products from both reactions did not have definite melting points and their infrared spectra contained bands characteristic of hydrazine hydrochloride (11) in addition to bands which could not be unambiguously assigned. Attempts were made to separate the product mixtures by fractional sublimation; these were unsuccessful due to simultaneous thermal decomposition.

Although hydrazine hydrochloride is insoluble in all dry hydrocarbon solvents, it is appreciably soluble in anhydrous hydrazine. Accordingly, the 1:4 product mixture was extracted with hydrazine until the extracts gave negative tests for chloride ion. The remaining insoluble substance, after being dried in a vacuum, contained B, N, and H, but no Cl. Reproducible analyses were obtained for B but not for N and H. The boron

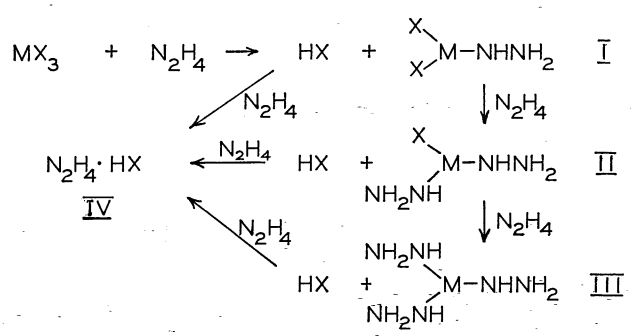
value indicates that the substance contains 4 g-atoms of N per g-atom of boron. The most likely empirical formula, as suggested by the reaction scheme to be proposed, appears to be BN_4H_5, although other formulas containing less H cannot be ruled out because analyses for H were not reproducible. The substance did not melt or decompose when it was heated to 300°, and its infrared spectrum consisted of broad unresolved bands with centers at frequencies characteristic of N—H and B—N stretching vibrations. These properties strongly suggest that it is polymeric, but this could not be confirmed by molecular weight measurements because of its insolubility. The same substance was also ultimately obtained from the interaction of boron tribromide with excess hydrazine. The aluminum analogue, AlN_4H_5, was isolated from the reaction of hydrazine with aluminum chloride, bromide, or iodide.

We suggest that boron trichloride and tribromide and aluminum trichloride, tribromide, and triiodide each react with hydrazine initially to produce an unstable 1:1 molecular adduct. This adduct splits out hydrogen halide, which immediately forms hydrazine hydrohalide. The dihalohydrazinoborane (or alane), I, produced simultaneously reacts further with hydrazine, yielding more hydrazine hydrohalide and halodihydrazinoborane (or alane), II. The latter ultimately forms trihydrazinoborane (or alane), III, the analogue of boron amide, $B(NH_2)_3$. The overall reaction is depicted in the following scheme in which X is Cl or Br when M is B, and X is Cl, Br, or I when M is Al:



However, there was no evidence for the formation of the intermediates I, II, and III.

The above condensation reactions are similar to those briefly reported by Nöth (12) for the interaction of organoboron halides (R_3BCl) or borazenes (R_2BNR') with hydrazines, producing hydrazinoboranes and such condensation products as $R_2BNH—NHBH_2$, $R_2BNH—NHR'$, $R_2BNH—BR_2'$, and $B(NHNR_2')_3$. The details of this work have not yet been described. More recently, Holliday *et al.* (13) reported that diborontetrachloride reacts with hydrazine in a 1:5 mole ratio, which they attribute to:

$$B_2Cl_4 + 5N_2H_4 \rightarrow 4N_2H_5Cl + B_2N_2.$$

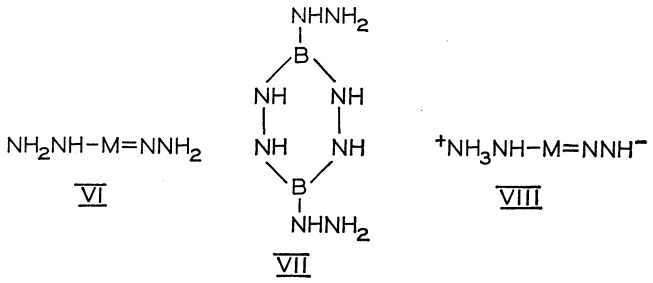
We could not isolate trihydrazino-borane and -alane, (III), presumably because they undergo rapid intermolecular condensation when dried in a vacuum at room temperature, producing hydrazine and substances with empirical composition MH_4N_5 (V), as represented by:

$$n\mathrm{M(NHNH_2)_3} \rightarrow (\mathrm{MN_4H_5})_n + n\mathrm{N_2H_4}.$$

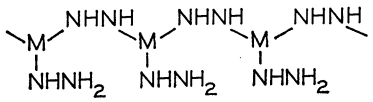
V

Substance V cannot be a double-bonded simple molecule (VI), a six-membered ring (VII), or a zwitterion (VIII) because these structures are not compatible with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

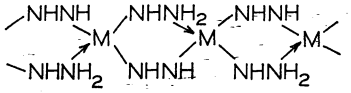


following observed properties: insoluble, non-volatile, high melting point, broad and unresolved infrared absorption bands. These properties indicate that V is probably a highly condensed polymer. One possible structure is:



in which nitrogen and boron (or aluminum) atoms are trivalent. Polymeric structures containing trivalent Al and N have been proposed by Fetter and Bartocha (14) for the Al—N polymers formed in the reactions of methylhydrazines with trimethylaluminum or trimethylaluminum–trimethylamine. Similar bonding is proposed by the same authors for the polymeric substance $[—Al(C_2H_5)—N(C_2H_5)—]_n$ produced when $(C_2H_5)_2Al—N(CH_3)_2$ is heated at 80° C (15).

It seems more likely that B and Al attain their maximum covalency of 4 in polymeric compounds (16–19). Thus, Laubengayer *et al.* (18) found that pyrolysis of 1:1 amine – aluminum alkyl or amine – alkyl aluminum chloride additioncom pounds yields Al—N polymers for which they postulate structures assuming tetrahedral bonding of Al and N. Similar bonding in MH_4H_5 might result in the following structural pattern:



With the object of obtaining further information about B—N and Al—N polymers, we are now investigating the interaction of monomethyl- and N,N-dimethyl-hydrazine with boron and aluminum halides. These reactions might produce methyl analogues of MN_4H_5 which might be soluble in organic solvents and hence more amenable to structural determinations than the MN_4H_5 substances.

EXPERIMENTAL

The experimental techniques have been described previously (4, 5). Reagent grade samples of aluminum chloride, bromide, and iodide were used without purification. Boron trichloride and tribromide were purified by low-temperature distillations in a vacuum. Anhydrous hydrazine was prepared by refluxing the 95+% material over sodium hydroxide flakes, followed by distillation. The fraction boiling at 111–112° was used; it was 100±0.2% pure by the iodate method (20).

Reaction of Boron Trichloride with Hydrazine

(a) In the Absence of a Solvent

When BCl_3 (11.90 mmoles) and N_2H_4 (94 mmoles) were condensed together at liquid air temperature and then warmed slowly to 25°, a very vigorous exothermic reaction produced a white solid which dissolved almost completely in the excess hydrazine. The direct reaction of the two materials should be done with small quantities, otherwise there is a considerable risk of explosion. The solid contained BCl_3 and N_2H_4 in a mole ratio of 1:4. (Found: N_2H_4, 51.4, 52.5%. Calc. for $BCl_3N_8H_{16}$: N_2H_4, 52.3%.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(b) In Tetrahydrofuran Solution

The interaction of N_2H_4 (310 mmoles) with BCl_3 (46.8 mmoles) in anhydrous tetrahydrofuran (250 ml) at 25° yielded a pale yellow tacky solid which became white and crystalline after it was washed several times with anhydrous diethyl ether. This substance contained BCl_3 and N_2H_4 in a mole ratio of 1:6. (Found: Cl, 38.7, 38.6%. Calc. for $BCl_3N_{12}H_{24}$: Cl, 38.9%.) It dissolved in water, giving a neutral solution, but was insoluble in boiling pyridine. A comparison of its infrared spectrum with that of hydrazine monohydrochloride revealed that the latter was one of the principal constituents of the product.

An attempt to separate the product into its components by fractional sublimation was unsuccessful. A sample of the product, heated at 160–165° in a vacuum, gave N_2H_4, $N_2H_4 \cdot HCl$, and an unidentified non-volatile residue containing hydrazine (found: 50.6, 50.7%), chlorine (13.2, 13.6%), and boron.

The reaction product $BCl_3N_{12}H_{24}$ was extracted 21 times with anhydrous N_2H_4 in a nitrogen-filled "dry-box". The extracts were separated from the solid each time by centrifugation. The residual material, a white solid, after being dried in a vacuum at 25°, contained 15.61% boron and no chlorine. This suggested that the substance contained 4 g-atoms of nitrogen per g-atom of boron, i.e. 80.8% nitrogen. The remaining few percent were presumed to be hydrogen. The most reasonable empirical formula appeared to be BN_4H_5 (calc. B, 15.05%). This substance did not melt when heated to 300°. It was soluble in water, giving an alkaline solution. Its infrared spectrum contained strong and very broad bands centered at 3350 (N—H stretching), 1620 (N—H deformation), 1330 (B—N stretching), 1050 (NH_2 wagging), and 700 cm^{-1} (unassigned).

Reaction of Boron Tribromide with Hydrazine

The reaction of BBr_3 (0.104 mole) with N_2H_4 (1.25 moles) in tetrahydrofuran (250 ml) gave a product composed of BBr_3 and N_2H_4 in a 1:6 mole ratio. (Found: Br, 53.9%. Calc. for $BBr_3N_{12}H_{24}$: Br, 54.2%.) This product was extracted 12 times with N_2H_4, leaving a white solid residue which contained 15.31% boron and no bromine. (Calc. for BN_4H_5: B, 15.05%.) Its infrared spectrum was identical with that of the corresponding product obtained from the reaction of BCl_3 with N_2H_4.

Reaction of Aluminum Chloride with Hydrazine

Aluminum chloride (16.5 mmoles) and hydrazine (150 mmoles) reacted at 25° in a 1:4 mole ratio, producing a white solid. (Found: N_2H_4, 51.8%; Cl, 39.2%. Calc. for $AlCl_3N_8H_{16}$: N_2H_4, 49.1%; Cl, 40.7%.) The same product was obtained when the reaction was done in carbon tetrachloride suspension. (Found: Al, 10.09, 10.14%; Cl, 39.8, 39.2%. Calc. for $AlCl_3N_8H_{16}$: Al, 10.33%; Cl, 40.7%.)

When a sample of $AlCl_3N_8H_{16}$ (1.002 g) was heated in a vacuum at 160–170° until the evolution of volatile material had ceased, the only volatile materials were hydrazine monohydrochloride (0.109 g; found: m.p. 91°, required for N_2H_5Cl: m.p. 89°) and hydrazine (0.220 g). The non-volatile residue (0.613 g) contained aluminum (15.4%), chlorine (50.2%), nitrogen, and hydrogen; analyses for the last two could not be obtained. Extraction of a sample of $AlCl_3N_8H_{16}$ 11 times with hydrazine at 25° gave a white solid containing aluminum (30.4, 30.7%) and hydrogen, but no chlorine. Its empirical formula was thought to be AlN_4H_5 (calc. Al, 30.7%). This substance did not melt when heated to 350° in a sealed tube. It dissolved readily in nitric and hydrochloric acids and only slightly in hydrazine. Water partly hydrolyzed the substance, yielding an alkaline solution. Its infrared spectrum contained broad unresolved bands centered at 3450 (N—H stretching), 1630 (N—H deformation), 1480 (N—H deformation), 1385 (N—H rocking), 1200 (N—H wagging), and 750 cm^{-1} (Al—N stretching).

Reaction of Aluminum Bromide and Iodide with Hydrazine

Hydrazine (250 mmoles) and aluminum bromide (44 mmoles) in CCl_4 (300 ml) yielded a white precipitate which, after being dried and then extracted with N_2H_4 10 times, contained aluminum (31.5%) but no bromine. This substance was the same as that obtained by the same method from the reaction of $AlCl_3$ with N_2H_4, i.e. AlN_4H_5 (calc. Al, 30.7%). Similar results were obtained for the reaction of aluminum iodide (21 mmoles) with hydrazine (220 mmoles) in diethyl ether (250 ml). The product contained aluminum, nitrogen, hydrogen, and no iodine. (Found: Al, 31.4. Calc. for AlN_4H_5: Al, 30.7%.)

THE SYNTHESIS OF 3-HEXULOSES

PART II. DERIVATIVES OF 1-DEOXY-L-*arabo*-3-HEXULOSE (SYN. 6-DEOXY-L-*lyxo*-4-HEXULOSE)

J. W. BIRD AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received March 18, 1963

ABSTRACT

Oxidation of 1,3:2,5-di-*O*-methylene-L-rhamnitol yielded 2,5:4,6-di-*O*-methylene-1-deoxy-L-*arabo*-3-hexulose, which was characterized as its 2,5-dichlorophenylhydrazone and by reduction to derivatives of L-rhamnitol and of 6-deoxy-L-talitol. Oxidation of 2,5-*O*-methylene-L-rhamnitol 1-benzoate yielded a syrupy 3,4-diketose which was characterized as the crystalline quinoxaline derivative. Attempts to convert 1,2:4,5-di-*O*-isopropylidene-D-mannitol 6-benzoate to a ketose were unsuccessful.

INTRODUCTION

The chemistry of the 3-ketose sugars has attracted attention during recent years because of their possible formation as intermediates in the breakdown of sugars (1); because a 3-pentulose derivative is postulated as an intermediate in the fixation of carbon dioxide during photosynthesis (2); and because of their potential value as intermediates in the synthesis of branched-chain sugars (3) and amino sugars (4). The first 3-hexulose was prepared by oxidation of L-fucitol with *Acetobacter suboxydans* to yield 1-deoxy-D-*xylo*-3-hexulose (Richtmyer *et al.* (5)). The first chemical synthesis of a 3-hexulose, from L-ascorbic acid, was described in Part I of this series (6). Oxidation of sugar alcohols to 3-hexuloses has been achieved by Sugihara and Yuen (7), who oxidized an isopropylidenated D-mannitol to a D-*lyxo*-3-hexulose derivative, and by Yuen and Sugihara (8), who oxidized a substituted D,L-galactitol and isolated from the product a crystalline *xylo*-3-hexulose. Stoodley (9) oxidized ribitol with mercuric acetate and obtained *erythro*-3-pentulose. A crystalline 3-heptulose was prepared by Schaeffer (10), who oxidized a branched-chain octose with periodate. The present work describes the preparation of 1-deoxy-L-*arabo*-3-hexulose derivatives from L-rhamnitol. This ketose is valuable as a possible intermediate in the preparation of L-streptose and other branched-chain sugars (11).

L-Rhamnitol condenses with formaldehyde in the presence of an acid catalyst to yield 1,3:2,5-di-*O*-methylene-L-rhamnitol (I) (12). This compound possesses a hydroxyl grouping on C_4 which is readily oxidized by chromium trioxide in glacial acetic acid – benzene (13) mixture to yield the crystalline ketose derivative 2,5:4,6-di-*O*-methylene-1-deoxy-L-*arabo*-3-hexulose (II), which gave a crystalline 2,5-dichlorophenylhydrazone. The ketose was readily reduced by sodium borohydride to yield the original di-*O*-methylene derivative and 1,3:2,5-di-*O*-methylene-6-deoxy-L-talitol. The latter material was produced in 55% yield when the reduction was carried out in absolute methanol solution (14) by addition of a methanolic sodium borohydride solution stabilized by sodium methoxide. The identification of the 6-deoxy-L-talitol was confirmed by its rate of movement on paper chromatographs and by comparing the retention time of the derived acetate with that of an authentic specimen on gas–liquid chromatograms (15).

Acetolysis of 1,3:2,5-di-*O*-methylene-L-rhamnitol followed by saponification of the product yielded 2,5-*O*-methylene-L-rhamnitol (12), which formed a 1-benzoate derivative. This compound, which possesses hydroxyl groups on C_3 and C_4, is readily oxidized

to a syrupy α-diketo compound (III) which with *O*-phenylenediamine yielded a quinoxaline compound (IV). Attempts to convert the α-diketo derivative to a streptosonic acid (11) analogue by a benzilic acid type rearrangement did not lead to the isolation of any identifiable products but tests indicated an α-hydroxycarboxylic acid was present.

It is likely that the hydroxyl group on C_4 of di-*O*-methylene-L-rhamnitol is oxidized easily because it is present in a relatively strain-free seven-membered ring in which the hydroxyl group is readily accessible. The oxidation of the axial 3-hydroxyl group in 2,4-*O*-methylene-xylitol 1,5-dibenzoates has been successfully achieved by Sera (16)but the oxidation of the equatorial 3-hydroxyl group on the corresponding ribitol derivative is difficult (unpublished results). It was considered likely that an isolated exocylic hydroxyl group would be more easily oxidized. To test this hypothesis 1,2:4,5-di-*O*-isopropylidene-D-mannitol 6-benzoate (17, 18) was prepared and submitted to oxidation. Unfortunately, no 3-hexulose derivative could be isolated from this reaction, perhaps because of the benzoate group on C_6 with which the hydroxyl group on C_3 may form a hydrogen bond. The 1,2:4,5-di-*O*-isopropylidene-D-mannitol gave a crystalline dibenzoate which on hydrolysis yielded the 1,4-di-*O*-benzoyl D-mannitol. This material was oxidized by periodate to a 2,5-di-*O*-benzoyl D-arabinose which is a potentially useful intermediate in the synthesis of disaccharides.

EXPERIMENTAL

All evaporations were carried out under reduced pressure and below 50°. Optical rotations were measured at 22±2°. Qualitative chromatography was carried out using the descending method (19) on Whatman No. 1 filter paper in the following solvents system (v/v): (A) butan-1-ol/ethanol/water, 3:1:1; (B) butan-1-ol/pyridine/water, 10:3:3; (C) ethyl acetate/acetic acid/formic acid/water, 18:3:1:4.

Ketoses were detected on paper chromatograms by the orcinol – trichloroacetic acid spray reagent (20) or with the *p*-anisidine hydrochloride spray reagent (21). Non-reducing compounds were detected by either the alkaline silver nitrate spray reagent (22) or by the ceric spray reagent (23). Rates of movement are quoted relative to L-rhamnose (R_{Rh}). Infrared spectra were measured using a Perkin–Elmer model 21 spectrophotometer or a Beckman IR-5B machine, as a 6% (w/v) chloroform solution or as a dispersion (0.8%) in a potassium bromide pellet. Ultraviolet spectra were measured using a Beckman DK-1 recording spectrometer.

2,5:4,6-Di-O-methylene-1-deoxy-L-arabo-3-hexulose (Cf. Ref. 13)

To a solution of 1,3:2,5-di-*O*-methylene-L-rhamnitol (12) (8.42 g) in benzene (160 ml) was added a hot solution of chromium trioxide (5.0 g, 1.1 mole equiv) in glacial acetic acid (440 ml) and water (4.44 ml). The mixture was heated at 85° for 40 minutes under reflux. The resultant solution was evaporated to a dark green syrup, which was dissolved in chloroform (200 ml). The solution was extracted with portions of cold *N* potassium carbonate solution until no further color was removed (1800 ml). Each extract was counterextracted with chloroform and the chloroform extracts were combined, washed with water, and dried (Na_2SO_4). Evaporation of the chloroform solution yielded the ketose (II) (5.64 g, 67%), which after recrystallization from ethanol had m.p. 151–152° and $[\alpha]_D$ +3.3° (*c*, 1.0, $CHCl_3$). The infrared spectrum showed a strong C=O stretching band at 1720 (approx.) cm^{-1}. The ketose gave a weak reaction with *p*-anisidine hydrochloride spray but a strong response to the alkaline silver nitrate spray. It gave a positive test for a ketose, a positive Molisch test, and reduced cold Fehling's solution. It had R_{Rh} 2.0 in solvent A and showed an absorption in the ultraviolet in aqueous solution at 297 mμ. Analysis: Calc. for $C_8H_{12}O_6$: C, 51.1%; H, 6.4%. Found: C, 50.9%; H, 6.45%.

When the ketose (0.225 g) was heated with 2,5-dichlorophenylhydrazine (0.23 g) in methanol (10 ml) a pale yellow crystalline hydrazone was produced. This, after three recrystallizations from ethyl acetate – chloroform, had m.p. 221° and $[\alpha]_D$ −154° (*c*, 1.0 in $CHCl_3$). Analysis: Calc. for $C_{14}H_{16}O_4Cl_2N_2$: C, 48.4%; H, 4.65%; Cl, 20.4%; N, 8.1%. Found: C, 48.2%; H, 4.7%; Cl, 20.7%; N, 8.1%.

Reduction of the Ketose

Reduction of the ketose with sodium borohydride yielded a mixture of the 1,3:2,5-di-*O*-methylene derivatives of L-rhamnitol and of L-talitol, the relative proportions of which were determined by the reaction conditions. Experimental details of a typical reduction are given below.

The ketose (II) (0.05 g) in 50% methanol (10 ml) was reduced by the dropwise addition at 0° of a sodium borohydride solution in 50% methanol (0.19 g, 10 ml). After 13 hours acetone was added to destroy excess borohydride, and sodium ions were removed from solution (IR-120 H resin). The acidic reaction mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was evaporated to dryness and boric acid was removed by distillation of methanol from the residues. The solid was then hydrolyzed by hot *N* hydrochloric acid (10 ml) and the cooled solution was deionized (Duolite A-4 OH) and concentrated to a syrup, which was acetylated (pyridine, acetic anhydride, 1 ml of each). The acetylated product was analyzed by gas–liquid chromatography. It contained L-rhamnitol and 6-deoxy-L-talitol acetates in the approximate ratio of 2 to 1. When the reaction was repeated, but substituting 50% ethanol for 50% methanol, the ratio of L-rhamnitol to 6-deoxy-L-talitol was 85:15.

When the reduction was carried out in absolute methanol plus sodium methoxide a much greater proportion of the 6-deoxy-L-talitol derivative was produced which could be isolated in a crystalline form. A typical experiment is given below.

1,3:2,5-Di-O-methylene-6-deoxy-L-talitol

2,5:4,6-Di-*O*-methylene-1-deoxy-L-*arabo*-3-hexulose (II) (0.87 g) in absolute methanol (15 ml) was reduced at 0° by the addition of sodium borohydride (0.9 g) in sodium methoxide solution (6 ml, 0.33 *N*); after 19 hours the product was isolated as described above. The crystals were recrystallized from acetone–petrol (b.p. 35–60°) and were obtained in 53% yield (0.46 g). The product had m.p. 122°, depressed to 96–97° on admixture with the L-rhamnitol derivative, and $[\alpha]_D$ +78° (*c*, 0.86 in $CHCl_3$). The infrared spectra of the L-rhamnitol and 6-deoxy-L-talitol derivative were different. Analysis: Calc. for $C_8H_{14}O_5$: C, 50.5%; H, 7.4%. Found: C, 50.5%; H, 7.4%. On hydrolysis (*N* HCl) the 2,5:4,6-di-*O*-methylene-6-deoxy-L-talitol yielded the syrupy sugar which was not separable from authentic material on paper chromatograms and the acetate was indistinguishable from an authentic specimen in the gas–liquid chromatographic apparatus.

1-Deoxy-L-arabo-*3-hexulose*

Attempts to prepare the sugar from the dimethylene compound either by acidic hydrolysis or by acetolysis were unsuccessful. In a typical experiment the di-*O*-methylene ketose (0.1 g) was hydrolyzed with *N* hydrochloric acid (20 ml) for 1 hour at 100°. Chromatographic analysis of the product showed the presence of seven components of R_{Rh} 0.33, 0.78, 1.02, 1.2, 1.95, 2.15, and 2.58. All except the component at R_{Rh} 1.02 gave a yellow color with the *p*-anisidine hydrochloride reagent. No crystalline derivative could be isolated.

Acetolysis Experiments

To the ketose derivative (II) (2 g) in 5 ml of a mixture of acetic acid (7.5 ml) and acetic anhydride (17.5 ml) was added 5.5 ml of an ice-cold acetolyzing mixture composed of sulphuric acid (1 ml), acetic anhydride (35 ml) and acetic acid (15 ml). The ketose derivative (II) dissolved at once and the solution gradually developed a violet color. After 1 hour it was poured onto ice and the mixture became green in color. The product was isolated by chloroform extraction in the usual way. Concentration of the chloroform extract yielded a syrup which did not crystallize. Two components were detected chromatographically (solvent A) with R_{Rh} 1.6 (positive test with alkaline silver nitrate) and R_{Rh} 1.78 (positive test with *p*-anisidine hydrochloride spray). Catalytic saponification (Zemplen) yielded a syrupy mixture which contained a major component at R_{Rh} 2.32 (solvent A).

2,5-O-Methylene-L-rhamnitol 1-Benzoate

To 2,5-*O*-methylene-L-rhamnitol (12) (4.4 g) in dry pyridine (20 ml) at 0° was added benzoyl chloride (3.15 ml, 1.1 mole equiv) dropwise during 5 minutes. After 20 hours at 21° the solution was poured onto ice (35 g). The product was extracted with chloroform in the usual way. Evaporation of the solvent left a crystalline residue which was recrystallized from acetone–petrol (b.p. 36–60°). Yield 4.4 g of m.p. 102° and $[\alpha]_D$ +69° (*c*, 1.0 in $CHCl_3$). Analysis: Calc. for $C_{14}H_{18}O_6$: C, 59.6%; H, 6.4%. Found: C, 59.3%; H, 6.3%.

Oxidation of 2,5-O-Methylene-L-rhamnitol 1-Benzoate to 2,5-O-Methylene-6-deoxy-L-threo-3,4-hexulodiose 1-Benzoate

The benzoate (0.86 g) in a mixture of benzene (15 ml), acetic acid (61 ml), and water (0.61 ml) was oxidized with chromium trioxide (0.67 g, 2.2 mole equiv). The mixture was heated at 80° for 35 minutes and the product (III, 0.39 g) was isolated as a yellow syrup by the procedure described above. Infrared examination of the syrup showed the absence of OH groups and a slight shift in the wavelength of the C=O stretching hand.

Characterization of the Oxidation Product

The syrupy diketose (0.1 g) was dissolved in ethanol (3 ml) and the solution was added to a solution of *O*-phenylenediamine (0.1 g) in ethanol (3 ml). The mixture was heated at 75° for 20 minutes and cooled. The resulting buff-colored crystals were collected and recrystallized from ethanol. The small needle-like crystals (50 mg) had m.p. 149°. Analysis: Calc. for $C_{20}H_{18}O_4N_2$: C, 68.6%; H, 5.2%; N, 8.0%. Found: C, 68.4%; H, 5.1%; N, 8.3%. The syrupy diketo compound (III, 0.804 g) was mixed with water (10 ml) and sodium hydroxide (4 ml, *N*); to aid solution methanol (7 ml) was added. After 2¼ hours the solution had become deep orange in color. After a further 5 minutes at 80° the cooled solution was extracted with chloroform to remove methyl benzoate. The residual aqueous layer was deionized (Amberlite IR-120 H) and the lemon yellow effluent was evaporated to yield a crystalline solid, identified as benzoic acid, m.p. 120°. The residual syrup gave tests for an α-hydroxy acid ($FeCl_3$) and showed absorption in the infrared

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

characteristic of a hydroxy carboxylic acid. Attempts to prepare a crystalline methyl ester by refluxing the syrup with methanolic hydrogen chloride were unsuccessful.

Derivatives of 1,2:4,5-Di-O-isopropylidene-D-mannitol

2,3:5,6-Di-*O*-isopropylidene-D-mannose was synthesized by the method of Van Grunenberg *et al.* (24). The product (5 g) was reduced by adding its solution in aqueous methanol to an ice-cold, stirred solution of sodium borohydride (5 g) in water (150 ml). (Note: If the order of addition is reversed very poor yields are obtained.) After 24 hours the solution gave a negative Molisch test for hexoses and excess of borohydride was destroyed by the addition of acetone (150 ml). The solution was evaporated and the residue was extracted with ether. The product was recrystallized with difficulty from ether–petrol. It had m.p. 50° (literature 52° (17)) and was obtained in a yield of 3.5 g. When the reduction was made with lithium aluminum hydride a similar yield was obtained.

1-O-Benzoyl 2,3:5,6-Di-O-isopropylidene-D-mannitol

A solution of 1,2:4,5-di-*O*-isopropylidene-D-mannitol (2.3 g) in dry pyridine (15 ml) was cooled at 0° and to it benzoyl chloride (1.1 ml) was added dropwise and with stirring and cooling during 15 minutes. After 24 hours at 20° the mixture was poured onto ice and the solution was extracted with ether. The extracts were washed successively with *N* hydrochloric acid, sodium bicarbonate solution, and water and then dried (Na_2SO_4). Evaporation of the ether left a syrup which rapidly crystallized. The product (2.03 g) was crystallized from ethanol and had m.p. 109°, $[\alpha]_D$ +6° (*c*, 2.5 $CHCl_3$). Analysis: Calc. for $C_{19}H_{26}O_7$: C, 62.3%; H, 7.15%. Found: C, 62.2%; H, 6.8%.

1-O-Benzoyl D-Mannitol

The 1-*O*-benzoyl 2,3:5,6-di-*O*-isopropylidene-D-mannitol (6.5 g) was dissolved in 30% acetic acid (10 ml) and the solution was heated at 86° for 15 minutes. Evaporation of the solution yielded crystalline 1-*O*-benzoyl D-mannitol (0.221 g) of m.p. 178°. Analysis: Calc. for $C_{13}H_{18}O_7$: C, 54.5%; H, 6.3%. Found: C, 54.15%; H, 6.3%. On prolonged oxidation this product consumed 5.15 mole of periodate and produced 1.05 mole of formaldehyde and 3.4 mole of formic acid per mole. Theory requires the formation of 1 mole of formaldehyde and 3 moles of formic acid per mole. The high results are due to overoxidation.

1,4-Di-O-benzoyl 2,3:5,6-Di-O-isopropylidene-D-mannitol

To dry 1,2:4,5-di-*O*-isopropylidene-D-mannitol (2 g) dissolved in dry pyridine (20 ml) was added benzoyl chloride (6 ml) with stirring at 0° during 40 minutes. The product was isolated in the usual way by extraction with ether. Evaporation of the ether yielded the 1,4-di-*O*-benzoyl derivative (3.01 g) of m.p. 136° and $[\alpha]_D$ −34° (*c*, 2.5 $CHCl_3$) after recrystallization from ethanol. Analysis: Calc. for $C_{26}H_{30}O_8$: C, 66.4%; H, 6.4%. Found: C, 66.1%; H, 6.4%.

1,4-Di-O-benzoyl D-Mannitol

Acetic acid (40%, 10 ml) was added to 1,4-di-*O*-benzoyl 2,3:5,6-di-*O*-isopropylidene-D-mannitol (1.0 g) and the mixture was heated at 85° for 30 minutes. Because the compound had not all dissolved 50% acetic acid (10 ml) was added and the solution was heated for a further 30 minutes. The solution was cooled, unchanged material (0.179 g) was collected by filtration, and the filtrate was evaporated to an oil which solidified. It had m.p. 111° and $[\alpha]_D$ −12° (*c*, 1.0 acetone) and was difficult to recrystallize. Analysis: Calc. for $C_{20}H_{22}O_8$: C, 61.5%; H, 5.7%. Found: C, 61.2%; H, 5.8%.

Periodate Oxidation

The product gave the following yields of formaldehyde (A) uptake of periodate (B) in moles per mole at the times indicated. (A): 0.94 (0.17 hr); 0.98 (0.67 hr); 0.98 (2.67 hr); and 0.98 (20.17 hr). (B): 0.91 (0.27 hr); 1.33 (1.15 hr); 1.39 (2.8 hr); 1.47 (8.5 hr); and 1.75 (22.5 hr). Attempts to oxidize 2,3:5,6-di-*O*-isopropylidene-D-mannitol 1-benzoate with chromium trioxide in pyridine or in glacial acetic acid led to recovery of starting material.

THE Co^{60} γ-RADIOLYSIS OF AQUEOUS CYSTINE SOLUTIONS

I. THE EFFECT OF CHLORIDE ION ON THE AMMONIA YIELD[1]

W. A. ARMSTRONG AND D. W. GRANT
Defence Research Chemical Laboratories, Ottawa, Canada

Received March 19, 1963

ABSTRACT

Sodium chloride has been found to increase the ammonia yield from Co^{60} γ-irradiated cystine in 0.02 M H_2SO_4. The effect is attributed to the participation of chlorine atoms, which deaminate the amino acid to a greater extent than hydroxyl radicals. The ratio of the rate constants $k_{OH + cystine}/k_{OH + Cl^-}$ is determined to be 24 in 0.02 M H_2SO_4.

INTRODUCTION

A paper chromatographic study of the products from the Co^{60} γ-radiolysis of aqueous 3×10^{-4} M cystine solutions revealed that the type of product formed was sensitive to the presence of chloride ions (1). In particular hydrochloric acid appeared to favor the production of cysteine and an unidentified compound, while sulphuric acid appeared to favor the production of cysteic acid and cystine disulphoxide. The results suggested that hydroxyl radicals and chlorine atoms formed through the reaction

$$OH + H^+ + Cl^- \rightarrow H_2O + Cl \qquad [1]$$

degrade cystine by different mechanisms. The ammonia yields from Co^{60} γ-irradiated cystine solutions were determined to see if the deamination process is sensitive to chloride ion concentration.

EXPERIMENTAL

Materials

L-Cystine was M.A. grade from Mann Research Laboratories ($[\alpha] = -216°$ in 1 M HCl). All other chemicals were reagent or analytical grade. All solutions were made using triply distilled water, the second distillation being from alkaline $KMnO_4$ and the final distillation from dilute H_2SO_4.

Irradiations

All irradiations were carried out in Pyrex vessels which had been cleaned using chromic acid, repeatedly rinsed with triply distilled water, and given a final steaming-out with steam from boiling alkaline $KMnO_4$. The γ-ray source was a nominal 200 c of cobalt-60, housed at the bottom of a water-filled well. The radiation doses received by the cystine solutions were determined using the Fricke dosimeter (2) assuming $G(Fe(III))$ to be 15.5 and the ferric ion extinction coefficient to be 2196 at 25° C for the 304 mμ band (3). Air-saturated solutions and degassed solutions were irradiated at dose rates of about 3.5×10^{16} ev/ml min and 4.5×10^{16} ev/ml min respectively.

Deaeration of Solutions

Solutions were degassed in a high-vacuum system ($<10^{-5}$ mm Hg) using the usual method of repeated cycles of freezing, pumping, and thawing. The vessels were flame-sealed while the solutions were frozen.

Ammonia Analysis

Ammonia was determined by a method based on its reaction with hypochlorite and phenol to give a colored indophenol. It is noteworthy that aliphatic amines do not undergo this reaction (4). Numerous methods based on this reaction have been described previously (4, 5). However, all those investigated suffered from a lack of reproducibility, color instability, or unacceptably high "blanks". The procedure adopted combines what are considered the best features of the methods of Bolleter, Bushman, and Tidwell (4) and Scheurer and Smith (5). The color is developed rapidly and is stable for at least 1 hour. As the color intensity depends to some extent on the age of the reagents, ammonia concentrations in irradiated samples were determined by a direct comparison of the optical densities of the indophenol produced from these

[1]*Issued as D.R.C.L. Report No. 407.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solutions and suitable standard ammonium chloride solutions. In order to obtain low "blank" readings it was found essential to use water distilled from dilute H_2SO_4 for the preparation of all solutions, and to absorb the ammonia, liberated on steam distillation, in water rather than in boric acid as is usually recommended. The detailed procedure is outlined below.

To a 25.0-ml aliquot of irradiated solution was added 0.5 g MgO. The ammonia was removed by a 5-minute steam distillation, absorbed in water, and the distillate made up to 25 ml with water. Three aliquots of unirradiated cystine solution, two containing different standard concentrations of ammonium chloride (in the range 10^{-5}–1.4×10^{-4} M), were similarly treated. To 10.0 ml of each distillate was added 1.0 ml of saturated chlorine water prepared by bubbling chlorine into ice-cold water until solid chlorine hydrate formed. After 5 minutes 1.0 ml of 8% aqueous phenol and 0.05 ml of 0.003 M manganous chloride solution were added. Five minutes later 0.5 ml of 2 M NaOH was added and the color allowed to develop for about 10 minutes. The optical density of each colored solution was measured at 627 mμ. The ammonia concentration in the irradiated solution was taken as the mean of the results obtained using the two "standards". The concentration of "standards" always approximated to the ammonia concentrations in irradiated solutions within a factor of two.

RESULTS AND DISCUSSION

The deamination of 3×10^{-4} M and 10^{-3} M cystine solutions is sensitive to chloride ions since the initial yields of ammonia are increased four- to five-fold when the acid is changed from 0.02 M H_2SO_4 to 0.04 M HCl (Fig. 1). There is also a pH effect since the

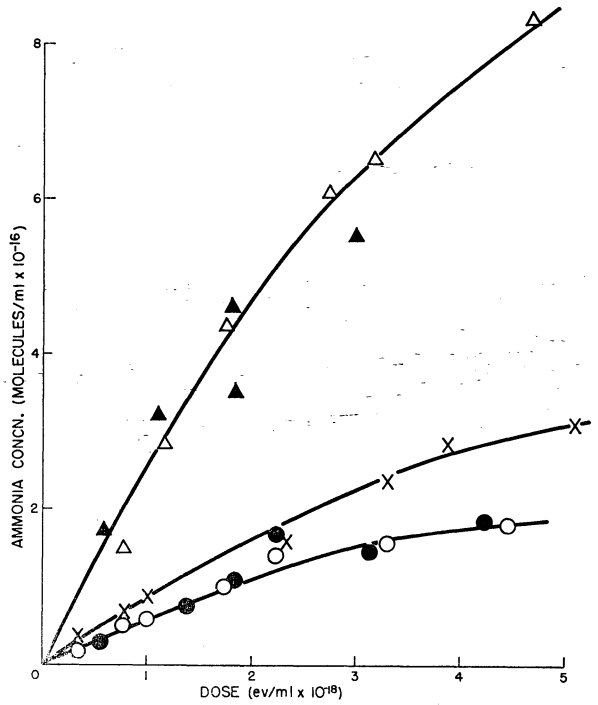

FIG. 1. Ammonia production in irradiated aerated cystine solutions. ○ 3×10^{-4} M in 0.02 M H_2SO_4; ● 10^{-3} M in 0.02 M H_2SO_4; × 3×10^{-4} M, no added acid; △ 3×10^{-4} M in 0.04 M HCl; ▲ 10^{-3} M in 0.04 M HCl.

initial ammonia yield is greater in solutions without added acid than in 0.02 M H_2SO_4 solutions of the amino acid (Fig. 1). The chloride ion effect was examined in more detail in 3×10^{-4} M cystine – 0.02 M H_2SO_4 solutions with sodium chloride concentrations varying from 10^{-3} to 0.25 M. The results (Fig. 2) show that $G_0(NH_3)$, the initial ammonia yield, increases from 0.8 to 2.75 as the chloride ion concentration is increased from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

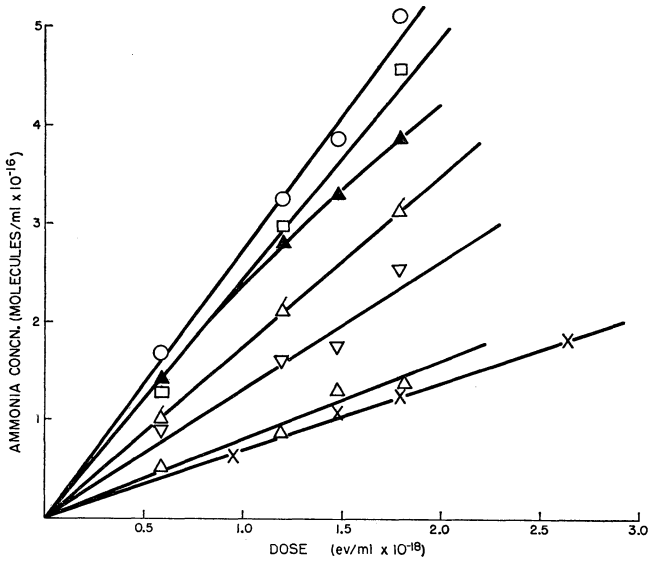

FIG. 2. Effect of sodium chloride on ammonia production in irradiated aerated 3×10^{-4} M cystine solutions. × 4×10^{-2} M NaCl, no added acid; △ 10^{-3} M NaCl – 0.02 M H_2SO_4; ▽ 5×10^{-3} M NaCl – 0.02 M H_2SO_4; △ 10^{-2} M NaCl – 0.02 M H_2SO_4; ▲ 4×10^{-2} M NaCl – 0.02 M H_2SO_4; □ 0.25 M NaCl – 0.02 M H_2SO_4; ○ 0.1 M NaCl – 0.02 M H_2SO_4.

10^{-3} to 10^{-1} M. A further increase in chloride ion concentration to 0.25 M reduced $G_0(NH_3)$ to 2.5.

The actual number of radicals available for deamination would actually tend to increase with increasing chloride ion concentration, since chloride ions have been shown (6) to scavenge hydroxyl radical precursors of the "molecular" hydrogen peroxide yield. The magnitude of this effect has not been determined at the acid concentration used in the present research. However, from Sworski's data (6) at pH 2 and in 0.8 N H_2SO_4 solutions, it is probable that even in 0.1 M sodium chloride the actual increase in radicals from this effect would not exceed 0.3 radical per 100 ev. Therefore, the magnitude of the increase in $G_0(NH_3)$ induced by chloride ions (Fig. 2) cannot be explained on the basis of a scavenging of "molecular" hydrogen peroxide precursors.

The chloride ion effect can be explained qualitatively on the basis of reactions [1], [2], and [3] if it is assumed that chlorine atoms deaminate cystine (RSSR) to a greater

$$RSSR + OH \rightarrow \text{ammonia} + \ldots \quad [2]$$

$$RSSR + Cl \rightarrow \text{ammonia} + \ldots \quad [3]$$

extent than hydroxyl radicals. Thus with sodium chloride concentrations $\geqslant 0.10$ M, it is assumed that virtually all hydroxyl radicals are scavenged by chloride ions to produce chlorine atoms (via reaction [1]), which degrade cystine predominantly in deamination reactions. In the absence of chloride ions hydroxyl radicals are scavenged by cystine and lower ammonia yields result. At intermediate chloride ion concentrations cystine and chloride ions compete for hydroxyl radicals. The slight decrease in $G_0(NH_3)$ when the sodium chloride concentration exceeds 0.1 M (Fig. 2) is not understood, since a small increase is to be expected on the basis of increased scavenging of hydroxyl radical precursors of "molecular" hydrogen peroxide. The low ammonia yield ($G_0(NH_3) = 0.7$) in aqueous cystine solutions (pH 4.1) containing 0.04 M sodium chloride (Fig. 2) supports

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the view already expressed (7) that chloride ions are inefficient scavengers of hydroxyl radicals at pH > 4 possibly because the reaction

$$OH + Cl^- \rightarrow OH^- + Cl \qquad [4]$$

is endothermic.

The effect of solution deaeration prior to irradiation is seen to produce little or no change in the initial ammonia yields in the case of cystine solutions containing 5×10^{-3} *M* NaCl and 0.04 *M* HCl (C and D curves, Fig. 3), but produces a significant decrease in

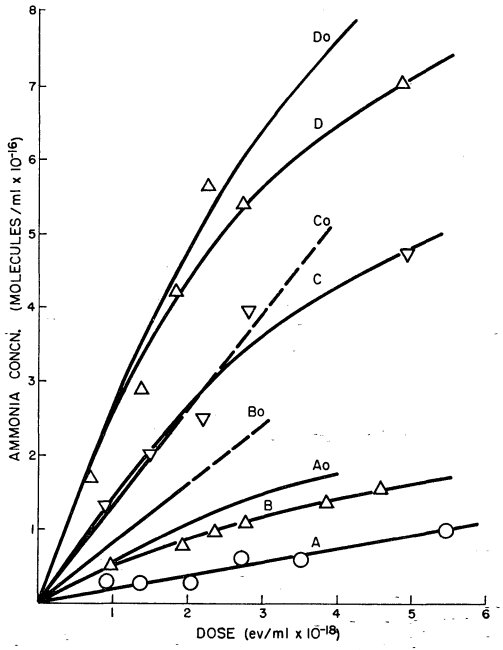

FIG. 3. Effect of deaeration on ammonia production in irradiated 3×10^{-4} *M* cystine – 0.02 *M* H_2SO_4 solutions. A deaerated, no added NaCl; A_0 aerated, no added NaCl. B deaerated, 10^{-3} *M* NaCl; B_0 aerated, 10^{-3} *M* NaCl. C deaerated, 5×10^{-3} *M* NaCl; C_0 aerated, 5×10^{-3} *M* NaCl. D deaerated, 4×10^{-2} *M* NaCl; D_0 aerated, 4×10^{-2} *M* NaCl.

the initial yields from solutions containing 10^{-3} *M* NaCl or no sodium chloride (B and A curves, Fig. 3). Deaeration of 3×10^{-4} *M* cystine solutions (pH 4.1) prior to irradiation was found (not shown) to produce a fractional decrease in the initial ammonia yield similar to that noted for 3×10^{-4} *M* cystine in 0.02 *M* sulphuric acid. These results in deaerated solutions suggest that the actual *mechanism* of deamination of cystine by chlorine atoms and hydroxyl radicals is different, the former process being oxygen independent and the latter process oxygen dependent.

Hydrogen peroxide is normally produced in irradiated aerated aqueous solutions via the reactions

$$H_2O \xrightarrow{\sim} H_2O_2,\ H_2,\ OH,\ H \qquad [5]$$

$$H + O_2 \longrightarrow HO_2 \qquad [6]$$

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2. \qquad [7]$$

For aerated unbuffered 3×10^{-4} *M* cystine solutions the initial hydrogen peroxide yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

is 2.0 (8). Hydrogen peroxide can compete with cystine and chloride ions for radicals according to the reactions

$$Cl + H_2O_2 \rightarrow HO_2 + HCl \quad [8]$$

$$OH + H_2O_2 \rightarrow HO_2 + H_2O. \quad [9]$$

Although HO_2 radicals could conceivably participate in deamination reactions it is generally recognized (9, 10) that they are relatively unreactive, particularly toward saturated organic substances.

The Determination of the Rate Constant Ratio k_2/k_1

The ratio of the rate constants for reactions [2] and [1], i.e. k_2/k_1 may be determined from the data of Fig. 2 if the change in ammonia yield with chloride ion concentration is due solely to competition between reactions [1] and [2] for hydroxyl radicals. The participation, if any, of the HO_2 radical in deamination reactions is not likely to affect the treatment given below, since the initial ammonia yield due to this radical would presumably be a constant independent of chloride ion concentration. With regard to reaction [8], its effect on the ammonia yield is determined by $k_8[H_2O_2]/k_3[RSSR]$, which again is virtually independent of the chloride ion concentration. However, reaction [9] merits further consideration because in principle it can compete with reactions [1] and [2] for hydroxyl radicals. From the treatment of Schwarz (11) it may be deduced that the rate constant ratio $k_{OH + Br^-}/k_{OH + Cl^-}$ is approximately 40 at pH 2, and is therefore presumably about 10 in 0.02 *M* H_2SO_4. Since the experiments of Hummel and Allen (12) and Rabani and Stein (13) yield the rate consant ratios $k_{OH + Br^-}/k_{OH + EtOH} = 0.6$ and $k_{OH + EtOH}/k_{OH + H_2O_2} = 9.2$, it follows that $k_{OH + H_2O_2}/k_{OH + Cl^-} \simeq 2$ in 0.02 *M* H_2SO_4. Consequently, since $[Cl^-] \gg [H_2O_2]$ at low doses, reaction [9] cannot compete effectively with reaction [1] or presumably for that matter with reaction [2].

The initial ammonia yield is given by

$$G_0(NH_3) = \begin{bmatrix}\text{fraction of OH radicals} \\ \text{scavenged by } Cl^-\end{bmatrix} G_{max} + \begin{bmatrix}\text{fraction of OH radicals} \\ \text{scavenged by RSSR}\end{bmatrix} G_{min},$$

where G_{max} is the maximum initial ammonia yield observed, i.e. when all OH radicals are scavenged by Cl^-, and G_{min} is the minimum initial ammonia yield, i.e. when all OH radicals are scavenged by cystine.

$$G_0(NH_3) = \frac{k_1[Cl^-]\cdot G_{max}}{k_1[Cl^-]+k_2[RSSR]} + \left[1 - \frac{k_1[Cl^-]}{k_1[Cl^-]+k_2[RSSR]}\right]\cdot G_{min}$$

$$= \frac{G_{max}}{1 + \dfrac{k_2[RSSR]}{k_1[Cl^-]}} + G_{min} - \frac{G_{min}}{1 + \dfrac{k_2[RSSR]}{k_1[Cl^-]}} \quad [A]$$

The ratio k_2/k_1 may be determined using equation [A] provided the initial ammonia yields (Fig. 2) are corrected for "molecular" precursor scavenging by chloride ions. It may be assumed that hydroxyl radical scavenging within "spurs" by chloride ions results in a chlorine atom and a hydroxyl radical which diffuse out into the body of the solution. Each chlorine atom can be assumed to produce approximately one molecule of ammonia by reaction with cystine since $G_{max} \simeq G_{OH}$, and each hydroxyl radical is assumed to be scavenged by either cystine or chloride ions. When the hydroxyl radical is scavenged by cystine it is assumed that approximately 0.2 molecule of ammonia results, since $G_{min} \simeq 0.2G_{max}$. The ammonia yield due to scavenging within "spurs" is then given by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$\Delta G(NH_3) = \Delta G_{H_2O_2} + \Delta G_{H_2O_2} \times f + \Delta G_{H_2O_2} \times 0.2(1-f), \quad [B]$$

where $\Delta G_{H_2O_2}$ is the decrease in the "molecular" peroxide yield produced by chloride ions (6) and f is the fraction of OH radicals diffusing out of "spurs" which are scavenged by chloride ions, i.e.

$$\frac{k_1[Cl^-]}{k_1[Cl^-]+k_2[RSSR]}.$$

The corrected initial ammonia yields $G(NH_3)_{corr}$ (Table I) were obtained by means of equation [B] using Sworski's data (6) for $\Delta G_{H_2O_2}$ and a value of 24 for k_2/k_1. The values

TABLE I

Calculated values for the rate constant ratio k_2/k_1 in 0.02 M H_2SO_4

[NaCl] (M)	$G_0(NH_3)$ (aerated)	$G_0(NH_3)_{corr}$	k_2/k_1
—	0.5_5 (G_{min})		
10^{-3}	0.8_0	0.7_7	26
5×10^{-3}	1.3_5	1.2_9	27
10^{-2}	1.7_5	1.6_6	25
4×10^{-2}	2.4_5	2.2_8	17
10^{-1}	2.7_5	2.5_0 (G_{max})	

thus derived for k_2/k_1 are listed in Table I. Since cystine reacts approximately 24 times as fast as chloride ions with hydroxyl radicals, it must be presumed to scavenge hydroxyl radicals from the "spurs" at a correspondingly faster rate than chloride ions. However, since the amino acid concentration was fixed at 3×10^{-4} M throughout the competition kinetic study, this scavenging effect will not change the values calculated for k_2/k_1.

CONCLUSION

Two points appear noteworthy. This paper demonstrates clearly that results obtained using amino acid hydrochlorides in hydrochloric acid are not necessarily comparable with results obtained either in sulphuric acid or in the absence of added acid. The results reported previously (1) and in the present paper suggest that chlorine atoms preferentially attack cystine at the amino group leading to deamination, while hydroxyl radicals preferentially attack cystine at the disulphide bond leading to the formation of cysteic acid in oxygenated solutions. Experiments are in progress to identify deaminated products in irradiated hydrochloric acid and sulphuric acid solutions of cystine in order to elucidate the mechanism of the different deamination processes.

OCCURRENCE OF *trans*-9-*trans*-12-OCTADECADIENOIC ACID AS A SEED OIL COMPONENT[1,2]

MARY J. CHISHOLM AND C. Y. HOPKINS
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received March 29, 1963

ABSTRACT

trans-9-*trans*-12-Octadecadienoic acid was found to be a component of the glyceride oil of the seeds of *Chilopsis linearis* (Cav.) Sweet. It was isolated by fractional crystallization of the acids at low temperatures and removal of conjugated acids as their adducts with maleic anhydride. Identification was made by absorption spectra and by preparation of derivatives and degradative products. The acid is estimated to constitute about 15% of the total fatty acids of the oil. Linoleic acid was also identified.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The occurrence of one or more positional isomers of linoleic acid in natural oils and fats has been suspected for a long time but was established only recently by the isolation of 10,12-octadecadienoic acid from a seed oil (1, 2). It has been considered less likely that geometric isomers of linoleic acid would be found in seeds since nearly all monoene and diene fatty acids of vegetable oils so far discovered have had the cis configuration. However, in the present work, examination of the seed oil of *Chilopsis linearis* provided infrared spectral evidence for the presence of a fatty acid containing isolated trans double bonds. It proved to be a geometric isomer of linoleic acid.

The freshly extracted oil had infrared absorption at 986 cm^{-1}, mainly due to the conjugated triene acid component, *trans,trans,cis*-9,11,13-octadecatrienoic acid (2). The subsidiary peak at 960 cm^{-1}, however, was more intense than would be expected for a trans–trans–cis acid. The conjugated trans–trans diene acid also known to be present (2) would not contribute to the absorption in the 960 cm^{-1} region. It was presumed, therefore, that part of this absorption must be due to an isolated trans linkage. This was confirmed by fractional crystallization of the mixed fatty acids at low temperatures, which effected a substantial separation of the various components. Three fractions were shown by infrared spectra (Fig. 1) to consist of concentrates of conjugated diene acid (F21), isolated trans-unsaturated acid (F22), and conjugated triene acid (F23).

Fraction F22 was crystallized further until free of conjugated triene acid but it continued to retain a little conjugated diene acid. It was found that the conjugated diene acid could be removed as its adduct with maleic anhydride. This treatment left the acid with isolated trans bonds unchanged. The latter acid melted when pure at 26.5–27.0° and was free of conjugated material as determined by ultraviolet absorption. Its infrared spectrum, max. 963 cm^{-1}, also showed the absence of conjugated diene and triene linkages since there was no peak or shoulder in the region of 986 cm^{-1} (Fig. 2). The intensity of the peak at 963 cm^{-1} was approximately double that of the same peak in the spectrum of elaidic acid; hence the substance must contain two isolated trans double bonds.

Hydrogenation of the acid resulted in the absorption of 2 moles of hydrogen and formation of stearic acid. Oxidative splitting of the acid gave two fragments identified by gas chromatography as hexanoic and azelaic acids, showing that the diene grouping is 9,12. These reactions, along with the spectral data, established the structure and configuration of the substance as *trans*-9-*trans*-12-octadecadienoic acid. To confirm its

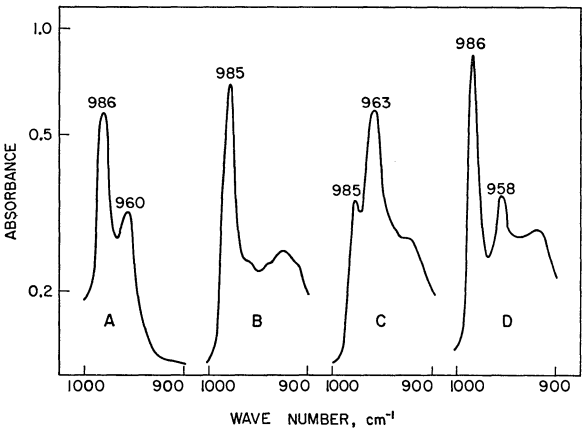

FIG. 1. Infrared absorption at 900–1000 cm^{-1}. A, chilopsis oil. B, fatty acids fraction F21, mainly trans–trans conjugated diene. C, fraction F22, mainly trans–trans non-conjugated diene. D, fraction F23, mainly trans–trans–cis conjugated triene.

identity an authentic sample was prepared by stereomutation of linoleic acid to the trans–trans form (linelaidic acid). This substance and the chilopsis acid had the same melting point and mixed melting point. The *p*-phenylphenacyl esters were also identical. The natural acid was converted by alkaline permanganate to di-*threo*-9,10,12,13-tetrahydroxystearic acid, m.p. 148°, and this was identical with an authentic sample.

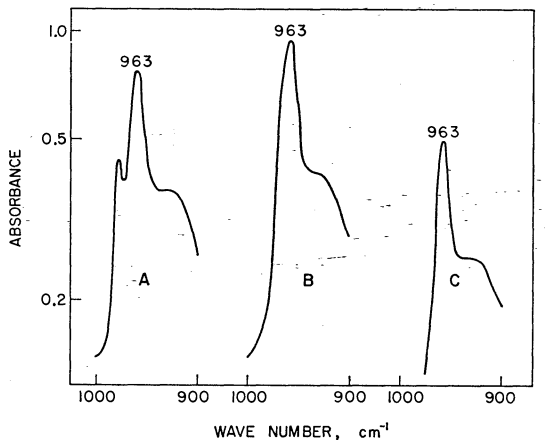

FIG. 2. Infrared absorption at 900–1000 cm^{-1}. A, fatty acids fraction, mainly trans–trans non-conjugated diene. B, pure *trans*-9-*trans*-12-octadecadienoic acid from chilopsis oil. C, *trans*-9-octadecenoic (elaidic) acid.

The most soluble fraction of the fatty acids of the oil (F4) was examined (as methyl esters) by gas chromatography. The emergence time of the major constituent was identical with that of methyl linoleate. Its identity as linoleate was confirmed by oxidizing a part of fraction F4 by alkaline permanganate. The product was the expected di-*erythro*-9,10,12,13-tetrahydroxystearic acid, m.p. 173–174°.

EXPERIMENTAL

Ultraviolet absorption measurements were made in cyclohexane solution with a Beckman DU spectrophotometer. Infrared spectra were determined in carbon disulphide in a Perkin–Elmer Model 21 spectrophotometer with sodium chloride prism. Melting points were determined in capillary tubes and are corrected. Petroleum ether refers to the fraction of b.p. 30–60°.

Chilopsis Seed Oil

Seed of *C. linearis* (Cav.) Sweet was obtained from a reliable commercial source. It was ground and extracted by stirring with petroleum ether at 25°. The solvent was removed at 25–30° in a current of nitrogen. The oil had iodine value 149, refractive index 1.4923 at 25°, and 1.3% of free fatty acid as oleic. Ultraviolet absorption maxima were at 233, 263, 272, and 283 mμ; infrared maxima were at 960 s and 986 vs cm^{-1}.

Isolation of trans-9-trans-12-Octadecadienoic Acid

The oil (54 g) was hydrolyzed at 25° by allowing it to stand for 18 hours with 6% ethanolic sodium hydroxide under nitrogen. The unsaponifiable matter was removed by extraction with petroleum ether. The fatty acids were collected in petroleum ether and the solvent was removed under reduced pressure at 25° in a current of nitrogen. The acids (47 g) were dissolved in acetone (20 ml/g) and the solution was cooled stepwise to −15, −50, and −70°. Fatty acid crystals were collected at each stage and their infrared spectra were taken (Table I).

TABLE I

Crystallization of acids of chilopsis oil

Fraction	Crystallizing temp., °C	Yield, g	Main component, as shown by infrared absorption
F1	−15	2.6	Saturated acids
F2	−50	17.8	Acid with isolated trans bonds
F3	−70	12.5	Conjugated triene acid
F4	(Filtrate)	11.3	Ordinary cis-unsaturated acids
F2 recrystallized:			
F21	−19	3.7	Conjugated trans–trans diene
F22	−40	7.1	Isolated trans–trans diene
F23	(Filtrate)	6.7	Conjugated trans–trans–cis triene
F22 recrystallized:			
F221	−20	3.4	Isolated trans–trans diene
F222	−45	2.6	Isolated trans–trans diene

Fractions F221 and F222 were mainly isolated trans–trans diene acid. The ultraviolet spectra showed that they were free of conjugated triene acid but there was 27% of conjugated diene acid in F221 and 11% in F222. Fraction F222 (2.6 g) was treated with maleic anhydride in benzene (3) to form the adduct of the conjugated acid. The benzene was evaporated in a current of nitrogen and the residue was leached with pentane. The pentane solution, cooled to −20°, yielded 1.96 g of *trans*-9-*trans*-12-octadecadienoic acid, m.p. 26.5–27.0°, n_D^{27} 1.4655; (lit. m.p., 25° (4), 27.8–28.4° (5); n_D^{27} 1.4641 (4)). The melting point was unchanged in admixture with linelaidic acid prepared by stereomutation of pure linoleic acid with Poutet's reagent (6) or with selenium. The ultraviolet spectrum had no peaks in the regions 233 mμ or 272 mμ and the content of conjugated acids was calculated to be less than 0.3%. The infrared spectrum had ν_{max} 963 vs cm^{-1} and no other peaks in the region 900–1000 cm^{-1} except the carboxyl peak at 930 cm^{-1} (Fig. 2). The intensity of the peak at 963 cm^{-1} was approximately twice that of pure elaidic acid, determined under the same conditions.

Linelaidic acid, prepared by the usual stereomutation of linoleic acid with selenium, was found by ultraviolet absorption to contain about 16% of conjugated acids. They were removed by adduction with maleic anhydride. It was necessary to start with linoleic acid entirely free from oleic acid, otherwise the product was contaminated with elaidic acid, which is very difficult to remove by crystallization.

The amount of *trans*-9-*trans*-12-octadecadienoic acid isolated initially was 4% of the total fatty acids of chilopsis oil. More was obtained by working up other fractions, especially fraction F221. The intensity of the infrared peak at 963 cm^{-1} for fractions containing little or no conjugated triene gives an indication of their content of the *trans*-9-*trans*-12 acid. Taking these into account and allowing for losses in crystallization, it is estimated that the oil contains about 15% of this acid.

Hydrogenation and Oxidative Splitting

The diene acid (0.12 g) was hydrogenated in ethanol with Adams catalyst. It absorbed 2 moles of hydrogen. The resulting solution was concentrated and cooled, giving stearic acid, m.p. and mixed m.p. 68.5–69.5°.

A portion of the diene acid (0.14 g) was subjected to oxidative splitting by permanganate–periodate (7). The acidic products were recovered and esterified by our usual procedure (8) and the methyl esters were examined by gas chromatography. Large peaks corresponding to hexanoate and azelate were observed. There were no other peaks of significant area.

p-Phenylphenacyl Ester

The diene acid (0.2 g) was treated with 2-bromo-4′-phenylacetophenone by the ordinary method (9). The product, crystallized from ethanol and then from acetone, was *p*-phenylphenacyl-*trans*-9-*trans*-12-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

octadecadienoate, m.p. 51.5–52.5°. The melting point was unchanged in admixture with an authentic sample prepared from linelaidic acid. Anal. Calc. for $C_{32}H_{42}O_3$: C, 80.97; H, 8.92. Found: C, 80.86; H, 8.94. The melting point of 73–75° reported by earlier workers (10) is considered to be incorrect. Their sample, prepared from linelaidic acid, was not characterized by analysis.

p-Phenylphenacylelaidate was prepared and analyzed. It melted at 71.5–72.5° (lit. 72–73° (10)). Anal. Calc. for $C_{32}H_{44}O_3$: C, 80.61; H, 9.30. Found: C, 80.67; H, 9.12.

Tetrahydroxy Derivative

The diene acid (1.0 g) was oxidized by alkaline permanganate (11) for 20 minutes at 10° and the product was crystallized twice from ethanol, giving the higher-melting racemic form of di-*threo*-9,10,12,13-tetrahydroxystearic acid, m.p. 148°. The melting point was unchanged in admixture with an authentic sample of the acid prepared from pure linelaidic acid.

Linoleic Acid

Fraction F4 (see Table I), containing the most soluble acids from the oil, was freed from conjugated diene and triene acids by treating it twice with maleic anhydride in benzene and discarding the adducts. Two grams of the remaining acids, which were soluble in petroleum ether, was oxidized by alkaline permanganate for 10 minutes at 7°. The crude product was washed with hot ethyl acetate, crystallized from ethanol, and washed successively with ethyl acetate and acetone. The product was pure di-*erythro*-9,10,12,13-tetrahydroxystearic acid, m.p. 173–174°, alone and mixed with an authentic sample.

DISCUSSION

Although most unsaturated fatty acids in seed oils occur in the cis form, exceptions are known. Until recently, all of the exceptions were acids which had one or two trans bonds in a conjugated system, e.g. α-eleostearic acid. In 1962, however, Bagby and co-workers (12) reported the occurrence of two acids having a trans bond but not having conjugated unsaturation. They were *trans*-5-octadecenoic acid and *trans*-5-*cis*-9-*cis*-12-octadecatrienoic acid, both found in the seed oil of *Thalictrum polycarpum*.

The present work describes the occurrence of an acid containing two non-conjugated trans bonds, viz. *trans*-9-*trans*-12-octadecadienoic acid. It is notable that this acid and *trans*-10-*trans*-12-octadecadienoic acid (2) are the only two isomers of linoleic acid known so far to occur in seed oils and that both are found in the oil of *C. linearis*, along with linoleic acid itself. Hilditch has pointed out (13) that seeds containing conjugated triene acid (eleostearic) do not seem to synthesize the corresponding non-conjugated acid, linolenic. It is evident that this apparent incompatibility does not extend to the diene acids since chilopsis oil is shown to have both conjugated and non-conjugated octadecadienoic acids.

The *trans*-9-*trans*-12-acid is considered to be a natural component of the glycerides and not an artefact, for the following reasons. The seed showed no evidence of deterioration. The oil was freshly extracted and had a normal content of free fatty acid, 1.3%. The infrared spectrum of the oil showed the presence of isolated trans unsaturation when examined immediately after extraction. Furthermore, the oil and its acids were handled under very mild conditions throughout the work. The estimated content of *trans*-9-*trans*-12-octadecadienoic acid is about 15% of the total fatty acids, hence most or all of it must have been in combination in the glycerides.

A rough calculation of the composition of the total fatty acids of the oil, based mainly on the spectral analysis of the various fractions, gives the following percentages: saturated acids, 5; *trans*-10-*trans*-12-octadecadienoic, 12; *trans*-9-*trans*-12-octadecadienoic, 15; *trans*-9-*trans*-11-*cis*-13-octadecatrienoic, 25; linoleic, 25; undetermined, 18.

THE STRUCTURE OF "METACHLORAL" (2,4,6,8-TETRAKIS-(TRICHLOROMETHYL)-1,3,5,7-TETROXACANE), A NEW CYCLIC TETRAMER OF CHLORAL

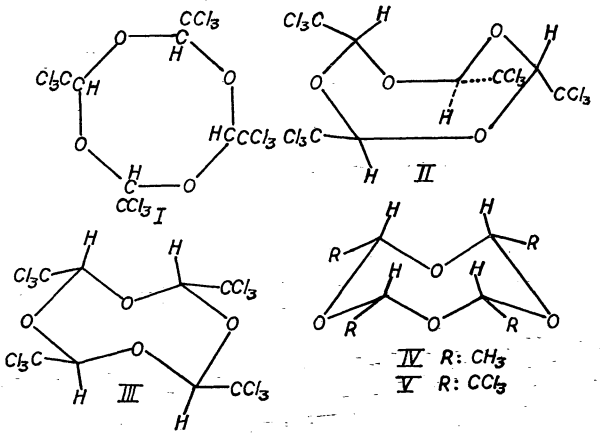
MÁXIMO BARÓN, O. BRIEUX DE MANDIROLA,[1] AND J. F. WESTERKAMP[2]
Laboratorio de Investigaciones, Atanor S.A.M., Munro, F.C.N.G.B., Argentina
Received November 21, 1962

ABSTRACT

The structure of metachloral is established by n.m.r., infrared, and dipole moment studies.

INTRODUCTION

It has been previously reported (1) that treatment of chloral hydrate with cold concentrated sulphuric acid gives a polymeric compound, hitherto unreported in the literature, shown to be a cyclic tetramer of formula I. Eight-membered rings of this type (with



four carbon and four oxygen symmetrically distributed atoms) are very rare. Staudinger (2) isolated 1,3,5,7-tetroxacane but did not study its structure. Pauling and Carpenter (3), continuing previous work by Hassel and Marks (4), established the structure of metaldehyde (2,4,6,8-tetrakis-(methyl)-1,3,5,7-tetroxacane), IV, by means of X-ray diffraction, finding it to be in the crown conformation with four axial protons and four equatorial methyl groups (C_{4v} symmetry).

More recently much work has been reported on cycloöctane and its derivatives by Allinger and co-workers (5), Chiurdoglu (6), and Bellis and Slowinski (7), the general conclusion being that cycloöctane seems to exist in only one conformation: the crown (that is also the case of metaldehyde). It is therefore reasonable to expect a similar situation for the tetramer under study and evidence is now provided in support of conformational structure V. Nuclear magnetic resonance and infrared spectra were obtained and the dipole moment in solution was measured.

RESULTS AND DISCUSSION

For eight-membered rings in general, there are basically three conformational structures: boat (II), chair (III), and crown (IV). In the present case only those will be considered where the protons are either directly or closely axial, since others are much less likely on steric grounds. These three possibilities have the following symmetries: C_2, the boat (II); C_i, the chair (III), and C_{4v}, the crown (V).

The proton magnetic resonance spectrum in deuterated chloroform shows only one signal at 359 c.p.s. (δ: 5.98 p.p.m. with reference to tetramethylsilane). The four protons are therefore structurally equivalent. This could correspond to structures III or V, both with four equatorial trichloromethyl groups. The four hydrogen atoms, although axial in each case, would be distributed with reference to the equatorial plane as follows: two above and two below in the chair (III) and all four above in the crown (V). The boat conformation (II) may then be ruled out since its protons would not be structurally equivalent and the n.m.r. spectrum could not show only one signal.

The dipole moments of the two remaining possibilities (III and V) were calculated by vector addition. For the chair conformer (III), with C_i symmetry (center of inversion), it is evident that $\mu = 0.0$ D regardless of the bond moment chosen. As for the crown conformer (V), using the values 0.2, 0.9 (8), and 1.57 (9) for the C—H, C—O, and C—Cl bond moments in preference to others reported in the literature, because of their usefulness in the study of the related parachlorals (10), a $\mu = 3.2$ D was obtained. The calculation was made by adding the four vectors at each carbon atom  and projecting the resultant vector on the fourfold axis.

The experimental value 1.40 ± 0.1 D is therefore too far removed from both calculated values to be comparable with them. However, it does indicate the existence of a dipole moment for the crown that cannot be expected in the case of the chair conformer, due to the presence of a center of symmetry. Consequently both n.m.r. and dipole moment results tend to point towards the crown conformation as the most probable of the three.

Additional evidence was obtained by establishing the molecular symmetry from the infrared spectra. In C_2, C_i, and C_{4v} symmetries, the frequencies corresponding to the normal modes of vibration may be expected in the 3500–400 cm^{-1} region and can be divided into C—H and skeletal. At a first approximation the trichloromethyl group may be considered as a single mass R (11). Thus the molecule would consist of 16 particles and there would be 42 normal vibrations: 12 C—H, 24 skeletal, 4 R—C, and 2 torsion vibrations of the ring.

For the C—H vibrations (stretching (ν), bending (δ), and wagging (γ)) it is convenient to use the following internal coordinates: four C—H, four R—C—H angles, and four H—C out-of-plane vibration angles. As for the skeletal vibrations 24 internal coordinates were used: 8 stretching (ν) C—O, 8 bending (δ) of the rings' internal angles (4 C—O—C and four O—C—O), and 8 bending (δ') of the H—C—O angle.

In the case of the crown conformer, the characters for these vibrations are represented, according to Wilson (12), by

$$\text{(C—H)} \qquad \Gamma = 2A_1+A_2+2B_1+B_2+3E$$
$$\text{(skeletal)} \qquad \Gamma = 4A_1+2A_2+3B_1+3B_2+6E.$$

There are 12 (C—H) frequencies, of which 8 are infrared active: $2A_1+3E$. Five bands

should then be expected in the spectrum, since the E vibrations are degenerate. Of the 24 skeletal vibrations only 16 are infrared active: $4A_1+6E$. Therefore 10 bands may be expected in the spectrum, making a total of 15 bands for the C—H and skeletal vibrations only.

In the case of the chair and boat conformers, through similar reasoning (12) the characters of the C—H and skeletal vibrations are represented by

$$\Gamma \text{ (chair, } C_i) = 18A_g+18A_u, \text{ where the 18 } A_g \text{ are infrared active;}$$
$$\Gamma \text{ (boat, } C_2) = 18A+18B, \text{ with all 36 infrared active.}$$

Since the spectrum shows only 24 bands, it is evident that the boat conformation can be definitely discarded in favor of a choice between the chair and the crown. In both cases it would appear possible to assign all active fundamental frequencies and still have bands left to be assigned to the remaining vibrations (C—C, C—Cl, etc.). As can be seen in Table I the 15 bands expected for the crown are readily identified and

TABLE I

Band assignment

Wave number (cm^{-1}) and strength		Assignment	Type	Wave number (cm^{-1}) and strength		Assignment	Type
2880	Medium	ν(C—H)	A_1	1000	Medium	C—C	
2840	Weak	ν(C—H)	E	970	Medium	Skeletal	
1380	Strong	δ(R—C—H)	A_1	890	V. weak	Perhaps C—C	
1340*	Medium	δ(R—C—H)	E	850	V. strong	Skeletal	
1320	Strong	δ(R—C—H)	E	812	V. strong	Skeletal	E
1162	V. strong	Skeletal		805*	Medium	Skeletal	E
1140	V. strong	Skeletal		720	Strong	ν(C—Cl)	Asym.
1090	Medium	Skeletal		670	Strong	ν(C—Cl)	Sym.
1070	Medium	(H—C—H′) "wagging"	E	638	Strong	Skeletal	
				591	Strong	Skeletal	
1045	Weak	Probably harmonic of 554 cm^{-1}		554	Strong	Skeletal	
				481	Weak	δ(C—Cl_2)	
1020	Strong	Skeletal		458	Weak	δ(C—Cl_2)	

*These bands disappear in solution, indicating that they very likely correspond to a degenerate vibration and that there are probably two molecules per unit cell (see refs. 10 and 13).

the two remaining, which are somewhat doubtful (1045 and 890 cm^{-1}), are too weak to be safely included among the fundamentals. On the other hand if the chair conformation is postulated with 9 C—H (3 stretching (ν), 3 bending (δ), and 3 wagging (γ)) and 9 skeletal vibrations, and the 2 above-mentioned bands are included among the fundamentals, there would still be 1 band missing of the calculated 18. This absence occurs in the well-known stretching region where only two (2880 and 2840 cm^{-1}) instead of three bands appear in the spectrum.

Furthermore, the fact that two of the bands appearing in the solid (1340 and 890 cm^{-1}) disappear in solution could be explained through the existence of degenerate vibrations. This was found to be the case when there is more than one molecule per unit cell (13), as was also suggested by Novak and Whalley (10) for α-parachloral and confirmed by Abeledo and co-workers (14) through X-ray diffraction. Thus if the existence of degenerate vibrations is accepted, C_i and C_2 symmetries can be ruled out since none would appear in either case.

Summing up, the boat conformation can be rejected on the basis of n.m.r. evidence and the large difference between the number of expected active fundamentals and that actually observed in the spectrum. The chair conformation, although more acceptable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

regarding the number of vibrations despite a difference that cannot be readily explained (absence of a band in the stretching region and existence of degenerate vibrations), must also be rejected since it requires the absence of a dipole moment. Therefore the crown conformation (V) is the only one consistent with all the experimental results, and bands can be assigned as follows: the 5 C—H vibrations are very likely those near 2880, 2840, 1380, 1320, and 1070 cm^{-1} (the lines at 1340 cm^{-1} could be a splitting of the E type bending vibration at 1320 cm^{-1}) and the 10 bands appearing near 1162, 1140, 1090, 1020, 970, 850, 812, 638, 591, and 554 cm^{-1} would be those expected for the skeletal vibrations (11, 15, 16).

Finally, it should be said that the determination of symmetry based principally on the stretching (ν) and bending (δ) modes of CH groups is justified in this case since the corresponding bands appear in a region where other fundamentals are not expected, as also happens with the parachlorals (10).

After a suggestion of Whalley (17) the trivial name metachloral is proposed for the tetramer here described, since it would be in accordance with the name metaldehyde for the tetramer of acetaldehyde (which it resembles closely). And also because the same author proposed (18) to call the linear polymers of chloral "polychlorals".

EXPERIMENTAL

Preparation of the Tetramer (1, 19)

Chloral hydrate (400 g) was mixed with 2000 g sulphuric acid (d: 1.84) at room temperature and shaken till completely dissolved. After 3–4 days a white solid separated, which was filtered, washed with hot water, and extracted with ethanol (100 ml/50 g) in a Soxhlet apparatus. On cooling, small white needles separated (occasionally mixed with the larger chloralide crystals), which when recrystallized from absolute ethanol gave 2.0 g (0.5% yield) of m.p. 219–220° C (corr.). Anal.: Calc. for (CCl_3CHO): C, 16.28; H, 0.68; Cl, 72.17. Found: C, 16.43; H, 0.73; Cl, 71.78. M.W. (Rast): Calc. for $(CCl_3CHO)_4$: 589.5. Found: 614; 616; 571 (average 600.3).

Nuclear magnetic resonance spectrum.—The n.m.r. spectrum was determined by Varian Associates on a Model A-60 spectrometer operating at 60 Mc. The sample was dissolved in deuterated chloroform, tetramethylsilane being used as internal reference.

Infrared spectra.—The compound was examined in KBr pressings in a model 221 P & E spectrophotometer from 4000 to 400 cm^{-1}.

Dipole moment.—The dipole moment was determined in benzene solutions at 25° using the Cole–Gross bridge and a test cell (20) consisting of three coaxial nickel cylinders in a glass jacket (Table II).

TABLE II

Measurements in benzene

w	ϵ_{12}	d_{12}
0.00211	2.275	0.8746
0.00334	2.276	0.8749
0.00466	2.276	0.8749
0.00597	2.277	0.8759
0.00827	2.278	0.8771
$\epsilon_1 = 2.274$; $d_1 = 0.8733$; $\mu = 1.40 \pm 0.1$ D		

For the dilute solutions studied, both the density change Δd and the dielectric constant increment $\Delta\epsilon$ were linear functions of the weight fraction of solute w, within experimental error. The best value of $\Delta\epsilon/w$ and of $\Delta d/w$ were used to calculate the solute polarization P_2, and the dipole moment μ, by the relation (21)

$$P_2 = \frac{3}{(\epsilon_1+2)^2}\left(\frac{M_2}{d_1}\right)\left(\frac{\Delta\epsilon_{12}}{w}\right) - \left(\frac{\epsilon_1-1}{\epsilon_1+2}\right)\left(\frac{M_2}{d_1}\right)\left(\frac{1}{d_1}\right)\left(\frac{\Delta d_{12}}{w}\right) + \left(\frac{\epsilon_1-1}{\epsilon_1+2}\right)\left(\frac{M_2}{d_1}\right)$$

and

$$\mu = 0.0127\sqrt{\{(P_2 - P_{e2})T\}},$$

where 1 and 2 refer to solvent and solute respectively, M is molecular weight, T absolute temperature, and $P_{e2} = 101.88$ electronic polarization, calculated from bond refractivity values, with no approximation being made for the atomic polarization (usually less than 5% of P_{e2}).

ACKNOWLEDGMENTS

The authors wish to thank the Argentine Atomic Energy Commission (C.N.E.A.) for allowing one of them (O. B. M.) to use its facilities to carry out part of this work; the Argentine National Research Council for partial support of the work; Dr. Hans Schumacher (Universidad Nacional de La Plata) for some of the infrared spectra; and Mr. Richard Nealey (Brown University, R.I.) for the determination of the dipole moment. They also wish to offer their thanks to Dr. R. A. Labriola (this department) for helpful discussions, to Professors J. F. Bunnett and M. R. Nace (Brown University, R.I.) for their kind cooperation, and to Dr. E. Whalley (National Research Council, Canada) for commenting on the manuscript.

SYNTHESIS OF L-ARABINOSE-5-C^{14}

R. K. HULYALKAR AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario
Received March 21, 1963

ABSTRACT

L-Arabinose-5-C^{14} was synthesized by the following route: D-xylose → D-gulono-1,4-lactone-1-C^{14} → 2,3:5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} → 2,3-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} → 3,4-*O*-isopropylidene-2,5-L-arabino-urono-lactone-5-C^{14} → methyl-α,β-L-arabinofuranosido-methyl uronate-5-C^{14} → methyl-α,β-L-arabinofuranoside-5-C^{14} → L-arabinopyranose-5-C^{14}. The overall radiochemical yield of L-arabinose-5-C^{14} was about 14% based on $KC^{14}N$ used in the first step. The structures of the isopropylidene derivatives of D-gulono-lactone have been clarified.

INTRODUCTION

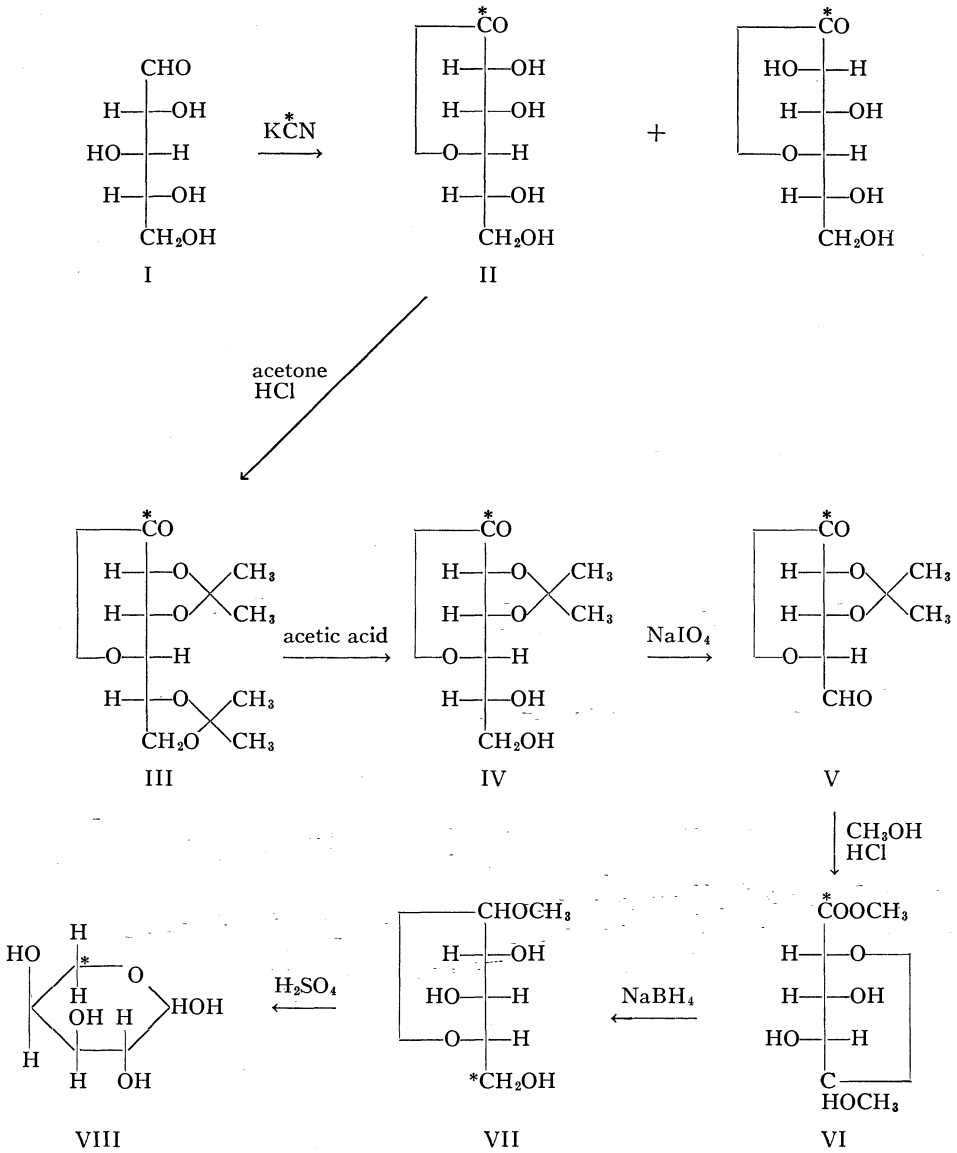
C^{14}-Labeled sugars have attained a great importance in recent years due to their extensive application in studies of chemical and especially biochemical reaction mechanisms. Uniformly labeled sugars are made available by biological syntheses (1, 2, 3). General synthetic methods applicable to C_1 labeling include the nitromethane (4) and cyanohydrin (5) syntheses. No general synthetic method is available for the preparation of sugars with specific labeling in positions other than C_1.

L-Arabinose, a biologically important sugar, is found in many polysaccharides of bacterial and plant origin. L-Arabinose-1-C^{14} has been made in yields of about 3% (6) by the nitromethane synthesis and the corresponding D-arabinose-1-C^{14} was prepared in yields of about 30% (7) by the cyanohydrin synthesis. D-Arabinose-5-C^{14} is known (8), but L-arabinose-5-C^{14} is not known. The present paper describes the synthesis of this sugar. The reaction sequence employed is shown in the accompanying scheme, where C* represents C^{14}.

RESULTS

The following method was first standardized with nonradioactive materials to attain the optimum experimental conditions. It was shown by Isbell and co-workers (9) that the ratio of epimers obtained in the cyanohydrin synthesis varied with the pH of the reaction mixture. In the present synthesis sodium acetate was used as a buffer to obtain larger yields of the D-*gulo* epimer from D-xylose. Hydrolysis of the resulting cyanohydrins was carried out at a relatively low temperature according to the conditions of Isbell and co-workers (9). The deionized hydrolyzate was concentrated in the presence of acetic acid and a trace of hydrochloric acid to effect lactonization. The crystalline D-gulono-1,4-lactone-1-C^{14} (II) was obtained from D-xylose (I) in 43% radiochemical yield based on the activity of $KC^{14}N$ used. 2,3:5,6-Di-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} (III) was obtained in about 69% radiochemical yield from D-gulono-1,4-lactone-1-C^{14}. 2,3-*O*-Isopropylidene-D-gulono-1,4-lactone-1-C^{14} (IV) was obtained in 83% radiochemical yield from 2,3:5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} by treatment with 88% acetic acid at 35°. Its identity was proved by periodate oxidation and estimation of the formaldehyde (10) produced. In the hydrolyzate small quantities of D-gulono-1,4-lactone-1-C^{14} and unchanged starting material were also present. The hydrolyzate was concentrated and the residue was extracted with benzene, which removed the unhydrolyzed di-*O*-isopropylidene derivative. The residue was then extracted with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



a mixture of acetone – ethyl acetate (50:50), which dissolved 2,3-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14}, leaving the insoluble D-gulono-1,4-lactone-1-C^{14}. The acetone – ethyl acetate extracts were evaporated to dryness and the residue was recrystallized from ethyl acetate.

The 2,3-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} was oxidized with 1 mole of sodium periodate and the reaction mixture was evaporated to dryness at room temperature. The residue was repeatedly extracted with chloroform. The chloroform extracts were dried and evaporated to a syrup which did not crystallize. The syrupy 3,4-*O*-isopropylidene-2,5-L-arabino-urono-lactone-5-C^{14} (V) was converted to the syrupy methyl-α,β-L-arabinofuranosido-methyl uronate-5-C^{14} (VI), which was reduced to the corresponding methyl-α,β-L-arabinofuranoside-5-C^{14} (VII) with sodium borohydride. The mild

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

experimental conditions under which sodium borohydride reduces sugars (11) and sugar acid lactones (12, 13) are admirably suited for the reduction of the alkali-sensitive methyl-α,β-L-arabinofuranosido-methyl uronate-5-C^{14}. L-Arabinose-5-C^{14} (VIII) was finally obtained by the hydrolysis of methyl-α,β-L-arabinofuranoside-5-C^{14}. The carrier method was used at each stage to increase the radiochemical yields. The overall radiochemical yield of L-arabinose-5-C^{14} was about 14% based on $KC^{14}N$ used in the first step.

The activity in C_5 of L-arabinose-5-C^{14} was determined by the preparation of formaldehyde dimedon from the formaldehyde produced by the periodate oxidation of L-arabinose-5-C^{14} and comparison of its specific activity with that of L-arabinose-5-C^{14}. It was found that all the activity was in C_5.

L-Arabinose-5-C^{14} should be a useful starting material for the preparation of L-rhamnose-6-C^{14} via the following intermediates: L-arabinose-5-C^{14} → L-mannose-6-C^{14} → L-rhamnose-6-C^{14}. L-Galactose-2-C^{14} might also be made by the following intermediates: methyl α,β-L-arabinofuranosido-methyl uronate-5-C^{14} → L-arabinofurano-uronic acid-5 C^{14} → L-lyxono-lactone-1-C^{14} → L-lyxose-1-C^{14} → L-galactose-2-C^{14}.

It was observed that when different catalysts were used to prepare the isopropylidene derivatives of D-gulono-1,4-lactone, different yields of isopropylidene derivatives were obtained. With sulphuric acid, zinc chloride, and hydrochloric acid 2,3:5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone was obtained in yields of 53%, 34%, and 70% respectively. When anhydrous copper sulphate was used as a catalyst, 5,6-*O*-isopropylidene-D-gulono-1,4-lactone (10%) and 2,3:5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone (25%) were obtained. Iwadare (14) has isolated 5,6-*O*-isopropylidene-D-gulono-1,4-lactone from the reaction mixture using hydrogen chloride as a catalyst. Mitchell (15) has also reported 5,6-*O*-isopropylidene-D-gulono-1,4-lactone but with different constants. In the present work the structures of these isopropylidene derivatives were clarified by the study of periodate oxidation results. The di-*O*-isopropylidene derivative did not consume any periodate. The 2,3-*O*-isopropylidene-D-gulono-1,4-lactone consumed 2 moles of sodium periodate, liberating 1 mole each of formic acid and formaldehyde. The 5,6-*O*-isopropylidene-D-gulono-1,4-lactone consumed 3 moles of sodium periodate and liberated no formaldehyde.

EXPERIMENTAL

Melting points were determined on a Kofler hot stage and are uncorrected. Optical rotations were measured at 22±3°. Solutions were concentrated under reduced pressure below 50°. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the following solvent systems (v/v): (*a*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4); (*b*) butan-1-ol, pyridine, benzene, water (10:6:2:6). Sugars were located on chromatograms with *p*-anisidine hydrochloride (16) or alkaline silver nitrate (17) sprays.

Determination of Radioactivity

Dilute solutions of sugar samples were plated on aluminum plates and counted at infinite thinness in a proportional methane gas flow counter and the activities were converted into microcuries (μc) assumingly 50% counting efficiency.

D-*Gulono-1,4-lactone-1-*C^{14}

An ice-cold solution of D-xylose (0.3 g) in water (15 ml) was added to a solution of $KC^{14}N$ (140 mg; 450 μc) and sodium acetate (205 mg) in water (15 ml) at 0°. The solution was kept at 0° for 3 hours and then at 5° for 5 days. Sodium hydroxide solution (5 ml, 2 *N*) was added to it and the solution was heated at 65° with aeration for 12 hours. The solution was passed through IR 120 (H^+) resin and the eluate was collected until its activity was no more than that of the background. The eluate was concentrated to a syrup with the addition of a trace of hydrochloric acid. The syrup was dissolved in methanol (20 ml), treated with activated charcoal, filtered, and concentrated to about 2 ml. A few drops of ethyl acetate were added and the solution kept at 0°. The crystals of D-gulono-1,4-lactone-1-C^{14} were collected by filtration after 24 hours. Further crops of crystalline D-gulono-1,4-lactone-1-C^{14} were obtained by using the carrier method. The results are recorded in Table I. The total radiochemical yield of D-gulono-1,4-lactone-1-C^{14}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

TABLE I

Yields of D-gulono-1,4-lactone-1-C^{14} and their activities

Fraction	Wt. of carrier added (mg)	Wt. of D-gulono-1,4-lactone recovered (mg)	Total activity (μc)
I	Nil	95	115.00
II	200	215	50.20
III	200	215	12.34
IV	200	210	9.53
V	200	205	5.90
		940	192.97

was 43% based on KC^{14}N used. The D-gulono-1,4-lactone-1-C^{14} was found to be chromatographically pure and to have R_f values indistinguishable from those of an authentic sample in solvents *a* and *b*; m.p. 181–182°; $[\alpha]_D$ −53° (*c*, 2.7 in water).

Experiments with Unlabeled Compounds

Isopropylidene Derivatives of D-*gulono-1,4-lactone**

Four experiments were carried out to obtain the isopropylidene derivatives of D-gulono-1,4-lactone using (1) hydrochloric acid (1.2%), (2) sulphuric acid (3%), (3) zinc chloride (4%), and (4) a suspension of anhydrous copper sulphate in acetone as catalysts. The results are recorded in Table II.

TABLE II

Yields of isopropylidene derivatives obtained by using hydrochloric acid, sulphuric acid, zinc chloride, and anhydrous copper sulphate

Catalyst used	Di-*O*-isopropylidene-D-gulono-1,4-lactone yield (%)	5,6-Isopropylidene-D-gulono-1,4-lactone yield (%)	M.p. (°C)	$[\alpha]_D$ (deg)
Hydrochloric acid (1.2%)	70	—	153–154	−64 (in acetone)
Sulphuric acid (3%)	53	—	153–154	−64 (in acetone)
Anhydrous zinc chloride (40%)	34	—	153–154	−64 (in acetone)
Anhydrous copper sulphate suspension (10%)	25		153–154	−64 (in acetone)
		10	168–170	−21 (in acetone)

*The Structure of 2,3-O-Isopropylidene-*D-*gulono-1,4-lactone*

2,3-*O*-Isopropylidene-D-gulono-1,4-lactone was prepared from non-radioactive materials. It had m.p. 142–143°, $[\alpha]_D$ −76° (*c*, 2.7 in acetone). Analysis: Calc. for $C_9H_{14}O_6$: C, 49.5%; H, 6.4%. Found: C, 49.4%; H, 6.4%.

*Periodate Oxidation of 2,3-O-Isopropylidene-*D-*gulono-1,4-lactone*

2,3-*O*-Isopropylidene-D-gulono-1,4-lactone (8 mg) was dissolved in water (49 ml), and sodium metaperiodate solution (1 ml, 0.3 *M*) was added to it. The solution was stored at room temperature in the dark. Samples (5 ml) were removed at intervals for the determination of periodate uptake (18) and for formic acid production (19). Formaldehyde (10) was determined on 1-ml aliquots. The results are recorded in Table III.

*Periodate Oxidation of 5,6-O-Isopropylidene-*D-*gulono-1,4-lactone*

5,6-*O*-Isopropylidene-D-gulono-1,4-lactone (8 mg) was dissolved in phosphate buffer pH 8 (49 ml), and

**Experimental details for the preparation of these derivatives are given in the text.*

2,3:5,6-Di-O-isopropylidene-D-gulono-1,4-lactone-1-C^{14}

D-Gulono-1,4-lactone-1-C^{14} (930 mg) was stirred with acetone (50 ml) containing hydrogen chloride (1.2%) for 18 hours at room temperature, when a clear solution was obtained. The acid was neutralized with solid potassium carbonate and filtered. The filtrate was concentrated to dryness and the residue was recrystallized from alcohol–petrol (b.p. 40–60°). The carrier method was employed to obtain further crops of crystals. The yields and the activities of the products with m.p. 152–153° and $[\alpha]_D$ −64° (*c*, 2.8 in acetone) (14) are recorded in Table V. The total radiochemical yield of 2,3:5,6-di-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} is 69%, based on the activity of D-gulono-1,4-lactone-1-C^{14}.

2,3-O-Isopropylidene-D-gulono-1,4-lactone-1-C^{14}

2,3:5,6-Di-*O*-isopropylidene D-gulono-1,4-lactone-1-C^{14} (2.554 g) was dissolved in glacial acetic acid (16 ml) at 45° and to this solution water (2.25 ml) was added drop by drop with stirring; the solution was then kept at 35° for 20 hours, and evaporated to dryness at 30°. The residue was dissolved in absolute alcohol (15 ml) and again evaporated to dryness. After two more evaporations with ethanol as above,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the residue was extracted with benzene three times to remove the unhydrolyzed di-*O*-isopropylidene derivative. The residue was then extracted with acetone – ethyl acetate mixture (50:50). The insoluble residue (27 mg) was found to be D-gulono-1,4-lactone-1-C^{14} of m.p. 181–182° and $[\alpha]_D$ −53° (*c*, 2 in water). The benzene extract gave the di-*O*-isopropylidene derivative (195 mg). On recrystallization it had m.p. 151–153° and $[\alpha]_D$ −64° (*c*, 2.5 in acetone). This product was further treated with acetic acid as above and the ethyl acetate – acetone (50:50) extract was added to the main extract. The ethyl acetate – acetone (50:50) extracts were evaporated to dryness and the residue was recrystallized from ethyl acetate. The carrier method was employed to increase the radiochemical yield as shown in Table VI. The total radiochemical yield of 2,3-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} of m.p. 142–143° and $[\alpha]_D$ −76.5° (*c*, 2.8 in acetone) was 82.5%.

TABLE VI

Yields of fractions of 2,3-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} and their activities

Fraction	Wt. of carrier (mg)	Wt. of 2,3-*O*-isopropylidene-D-gulono-1,4-lactone-1-C^{14} (g)	Total activity (μc)
I	Nil	1.801	107.2
II	200	0.185	3.6
		1.986	110.8

L-Arabinose-5-C^{14}

2,3-*O*-Isopropylidene-D-gulono-1,4-lactone-1-C^{14} (1.985 g) was dissolved in water (50 ml) and a molar equivalent of a solution of sodium periodate (1.95 g) in water (25 ml) was added to it. The solution was kept at room temperature for 1½ hours and then evaporated to dryness at 30°. To the residue anhydrous sodium sulphate (2 g) was added, and the solid was extracted repeatedly with chloroform. The chloroform extracts were concentrated to a syrup which did not crystallize. The syrup was refluxed at 90° with methanolic hydrogen chloride (66 ml, 1%) for 24 hours. The cooled solution was deionized by passing it through Duolite A4 (OH^-) resin (moistened with methanol) at 5°. The eluate was concentrated to a syrup which was dissolved in methanol (50 ml), and a solution of sodium borohydride (1 g) in water (5 ml) was added drop by drop to it under stirring at 0° during 5 minutes. The solution was stirred at 0° for 2 hours and then at room temperature for 12 hours. Resin IR 120 (H^+) was added to the solution and the suspension was stirred for 1 hour to destroy the excess of sodium borohydride and to remove the sodium ions. The resin was removed by filtration and washed well with water. The filtrate and the washings were evaporated to a white residue, which was dissolved in methanol, and the solution reconcentrated. After three evaporations with methanol a clear syrup was obtained (1.6 g) which did not crystallize. The syrupy methyl-α,β-L-arabinofuranoside-5-C^{14} was hydrolyzed with sulphuric acid (15 ml, 0.8 *N*) at 90° for 3 hours. The hydrolyzate was deionized by passing it through Duolite A4 (OH^-) resin, and concentrated to a syrup (1.4 g). Chromatographic examination of the syrup showed the presence of L-arabinose mainly, with a trace of faster-moving substance in solvent systems *a* and *b*. The autoradiogram of the above syrup showed the presence of traces of two faster-moving components besides L-arabinose-5-C^{14} as a main product. L-Arabinose-5-C^{14} was crystallized from the syrup by dissolving it in a small quantity of methanol and adding a few drops of 2-propanol. Three crops of crystals were isolated as follows:

Crop	Yields (mg)	Total activity (μc)
I	640	
II	60	53.9
III	35	
	735	

The three crops of crystals of L-arabinose-5-C^{14} were combined and recrystallized from methanol–isopropanol (710 mg, 53.6 μc). The product had m.p. 158° and $[\alpha]_D$ +105° (*c*, 3.1 in water). L-Arabinose-5-C^{14} (490 mg, 9.9 μc) was further recrystallized from the residues after addition of 500 mg of carrier.

L-Arabinose-5-C^{14} p-Nitrophenylhydrazone from the Residues

The residue left after removal of the crystalline L-arabinose-5-C^{14} was dissolved in methanol (20 ml)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and a methanolic solution (20 ml) of *p*-nitrophenylhydrazine (200 mg) was added to it and the solution was refluxed at 90° for 2 hours. The solution was concentrated to about 5 ml and ethyl acetate was added to it drop by drop until a slight turbidity was observed. The solution was kept at 5° and the crystals of L-arabinose-5-C^{14} *p*-nitrophenylhydrazone were collected after 20 hours (120 mg, 1.26 μc). The product had m.p. 179–180°. The mixed melting point with an authentic sample was not depressed. The total radiochemical yield was 14.4% based on the activity of $KC^{14}N$ used in the first step.

Determination of C^{14} in C_5 of L-Arabinose-5-C^{14}

L-Arabinose-5-C^{14} (2.5 mg) was dissolved in water (1 ml), and a solution of sodium periodate (18 mg) in 0.5 *N* sodium carbonate solution (1 ml) was added to it. After the solution had been kept at room temperature for 3 hours barium acetate (80 mg) solution in water (1 ml) was added. The precipitated barium salts were removed by filtration and washed with water (3 ml). To the combined filtrate, acetic acid (0.1 ml) and dimedon solution in alcohol (1 ml, 1%) were added. The formaldehyde dimedon was collected by filtration after 20 hours and was recrystallized from aqueous alcohol (3.8 mg). It had m.p. 189–190° with a specific activity of 0.892 μc/mmole C. The specific activity of L-arabinose-5-C^{14} was 0.940 μc/mmole C. Thus the specific activity (μc/mmole C) of formaldehyde dimedon amounted to 95% of that of L-arabinose-5-C^{14}.

The filtrate left after removal of the formaldehyde dimedon was acidified with sulphuric acid, and formic acid was distilled from it. The formic acid in the distillate was ozidized with mercuric acetate (20) to carbon dioxide, which was precipitated as barium carbonate by absorbing it in alkaline barium chloride. The barium carbonate thus obtained was found to be completely non-radioactive, which proved that radioactivity was only in C_5.

THE BUTYLLITHIUM-INITIATED POLYMERIZATION OF METHYL METHACRYLATE

PART II. MOLECULAR WEIGHT DISTRIBUTIONS[1, 2, 3]

B. J. COTTAM,[4] D. M. WILES, AND S. BYWATER
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received April 4, 1963

ABSTRACT

Samples of poly(methyl methacrylate) have been made in toluene solution at −30° C with *n*-butyllithium initiator. Different monomer and initiator concentrations were used to obtain products of different overall molecular weights; polymerization times were varied to achieve partial as well as complete polymerization. The polymer samples were divided into fractions which were examined as to molecular weight and microstructure. It was found that the whole polymers have unusually wide molecular weight distributions which can be attributed to a combination of two narrower distributions, one of which occurs at a low and the other at a higher molecular weight region. This "double peak" phenomenon was observed for polymers at lower conversions as well as for polymers representing complete conversion of monomer. Proton magnetic resonance measurements showed that the degree of isotacticity of various fractions of a whole polymer is not the same at all molecular weights.

In one case a second portion of monomer was polymerized after the complete polymerization of a first portion. Comparison of the molecular weight distribution before and after the second addition of methyl methacrylate indicated that polymer chains in all molecular weight regions, above a very low minimum value, are capable of further addition of monomer.

INTRODUCTION

It has been reported that the anionic polymerization of methyl methacrylate results in polymers with unusually wide molecular weight distributions. A variety of organometallic initiators has been used, including Grignard reagents and organolithium compounds. Many different $\bar{M}_w/\bar{M}_n$ ratios have been found, the values depending to a large extent on whether all or only part of the product is considered as well as on polymerization conditions. Glusker and co-workers (1) accounted for a wide molecular weight range on the basis of variable rates of polymerization, caused by the changing configuration of the growing polymer molecules. Weakley *et al.* (2) suggested that the broad molecular weight distribution could be explained in terms of a combination of two much narrower distributions, produced by simultaneously occurring mechanisms. Nevertheless, no systematic study of the effect of polymerization conditions on the molecular weight distribution of the entire product has been published.

This paper describes a study of the fractionation of a number of polymers prepared by the *n*-butyllithium initiation of methyl methacrylate in toluene at −30° C. The molecular weights of the fractions have been measured and weight distribution diagrams have been derived. The tacticity of many of the fractions has been measured.

EXPERIMENTAL

Poly(methyl methacrylate) samples were prepared in a scaled-up version of the apparatus described in Part I (3). Variations in monomer and initiator concentrations and in the degree of conversion provided samples of different overall molecular weight. The quantities used in this work were sufficiently large that approximately 10 g of material were available for a precipitation fractionation.

The organic liquids used during the fractionation and characterization experiments were reagent grade wherever possible.

Preliminary work indicated that not all of the petroleum-ether-soluble product (3) was separated from insoluble polymer during the original precipitation of the reaction mixture. Hence the soluble portion was recombined with the insoluble polymer prior to each fractionation. It was convenient to dissolve the polymer in a minimum amount of chloroform and then to dilute to the required concentration with acetone. The concentrations used were, in general, approximately 5% in chloroform diluted to 0.5% by the addition of acetone. The fractionations were carried out at 25° C by slowly adding petroleum ether (boiling range 30–80° C) to the solution, with vigorous stirring, until the mixture became cloudy. The temperature was raised to 40° C to redissolve the fraction, then lowered very slowly to 25° C, and the fraction was separated by centrifugation. Each fraction was dissolved in chloroform, precipitated in petroleum ether, and dried in a vacuum desiccator operating at 50° C. The polymer was normally separated into 8–10 fractions and all but the smaller ones were subsequently refractionated.

The molecular weights of the fractions of molecular weight above 20,000 were derived from their viscosities measured in chloroform solution at 25° C, with Cannon–Ubbelohde dilution viscometers having negligible kinetic energy corrections. The viscosity – molecular weight relationship used was

$$[\eta] = 6.48\times10^{-5}M^{0.78},$$

deduced from some of the results of Schulz *et al.* (4), Bischoff and Desreux (5), and Chinai *et al.* (6) and from light scattering measurements made in these laboratories (7) on both normal and highly isotactic polymers.

The molecular weights of fractions less than 2×10^4 were estimated with an ultracentrifuge using the short column, sedimentation equilibrium method. A Spinco model E ultracentrifuge equipped with phase plate Schlieren optics and a rotor temperature control unit was used to examine 1% solutions of the fractions in butyl chloride at 36° C.

The number-average molecular weights of the precipitant-soluble products and a few of the products of slightly higher molecular weight were measured using a Mechrolab vapor pressure osmometer.

The microstructure of a selected number of fractions in chloroform solution was examined with a proton magnetic resonance apparatus under conditions similar to those described by Bovey and Tiers (8). The amounts of the three types of sequences were calculated from measurements of relative areas of the peaks in the spectra due to α-methyl protons.

RESULTS

Two series of polymers were fractionated, one prepared using a low monomer/initiator ratio (0.125 M/7.6 mM; series A) and the other using a higher monomer/initiator ratio (0.25 M/3.85 mM; series B). Series A consisted of two samples. The first (G9) was prepared by terminating the reaction after 100% conversion and the second (G5) was prepared by terminating the reaction after the addition and polymerization of a second equal portion of monomer, following the complete polymerization of a first portion. A third sample (G1; monomer/initiator, 0.25 M/7.6 mM) has been included with this series in order that the effect of the initial monomer/initiator ratio on the molecular weight distribution may be seen. Series B consisted of three samples prepared by terminating reactions after conversions of 100% (G6), 31.4% (G8), and 17.8% (G10).

The integral weight distribution values were determined from the fractionation results using the relationship

$$W_j = \sum_{i=j-1} w_i + \tfrac{1}{2}w_j,$$

where W_j is the integral weight and w_j the weight of the jth fraction. The results for the two series are shown in Figs. 1 and 2.

The differential weight distributions, w_x, obtained by graphical determination of the gradient at chosen points on the integral curves, are illustrated in Figs. 3 and 4.

The fractions of linkages that are isotactic (p_1), have been calculated from the amounts of the three types of sequences, according to the method of Braun *et al.* (9) and are plotted as a function of molecular weight in Fig. 5.

Butyllithium analyses were made in systems in the presence and absence of monomer, under the conditions used for the polymerizations. Methanol was added to react with residual butyllithium and the reaction products were examined by gas chromatography.

For personal use only.

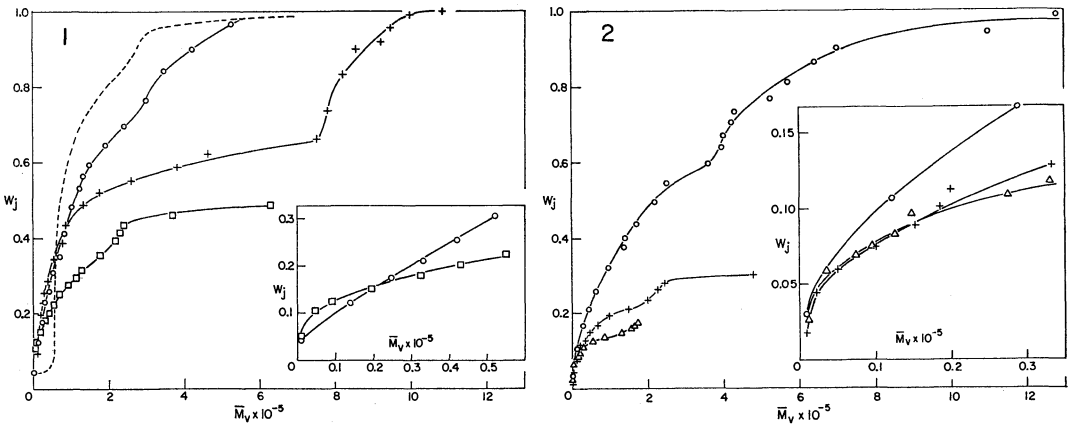

Fig. 1. Integral weight distributions for series A polymers, [BuLi] = 7.6 mM: (□) G9 [MMA] = 0.125 M; (○) G5 [MMA] = 0.125 M + 0.125 M, double addition; (+) G1 [MMA] = 0.25 M; (---) calculated from G9 assuming equal reactivity of chains during polymerization of second portion of monomer (cf. G5).

Fig. 2. Integral weight distributions for series B polymers, [BuLi] = 3.85 mM, [MMA] = 0.25 M: (○) G6 100% conversion; (+) G8 31.4% conversion; (△) G10 17.8% conversion.

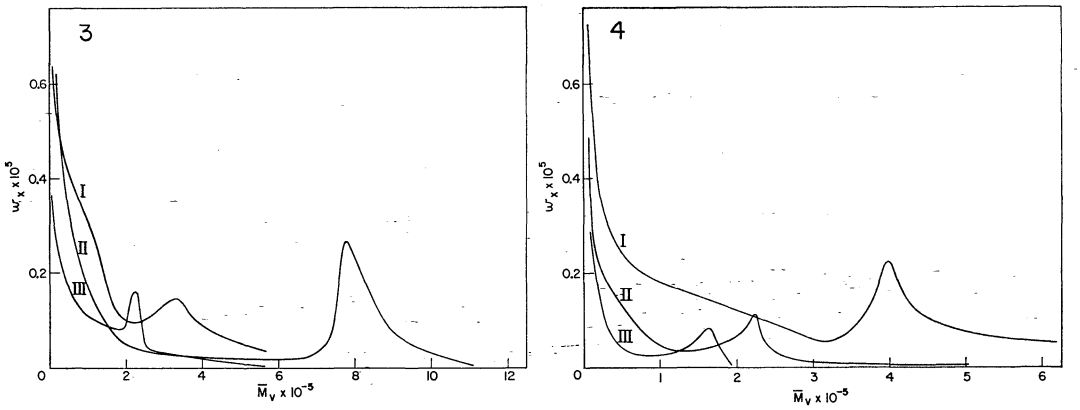

Fig. 3. Differential weight distributions for series A polymers, [BuLi] = 7.6 mM: (I) G5 [MMA] = 0.125 M + 0.125 M, double addition; (II) G1 [MMA] = 0.25 M; (III) G9 [MMA] = 0.125 M.

Fig. 4. Differential weight distributions for series B polymers, [BuLi] = 3.85 mM, [MMA] = 0.25 M: (I) G6 100% conversion; (II) G8 31.4% conversion; (III) G10 17.8% conversion.

In the absence of monomer the expected amount of butane was found. In the presence of monomer, no butane could be detected after only a few seconds of reaction, indicating that butyllithium reacts very rapidly with the nonomer.

DISCUSSION

Several interesting points emerge from the molecular weight distribution and n.m.r. results presented above. If it is assumed that each mole of product corresponds to 1 mole of butyllithium then quantitative recovery of all the added initiator was never obtained. The accuracy of this calculation is almost entirely dependent on the measurement of the yield and molecular weight of the final petroleum-ether-soluble product, which accounts for 85–90% of the chains counted.

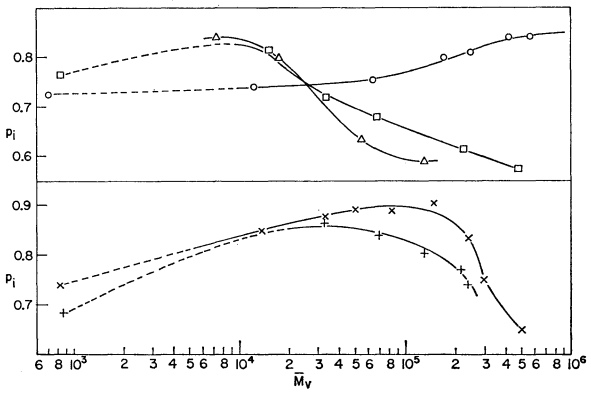

FIG. 5. Isotacticity of fractions. Series A polymers, [BuLi] = 7.6 mM: (+) G9 [MMA] = 0.125 M; (×) G5 [MMA] = 0.125 M + 0.125 M, double addition. Series B polymers, [BuLi] = 3.85 mM: [MMA] = 0.25 M; (○) G6 100% conversion; (□) G8 31.4% conversion; (△) G10 17.8% conversion.

The three experiments of series B carried out by interruption of a normal reaction process showed that at 17.8% conversion (G10) only 40% of the initiator was recovered as products but at 100% conversion (G6) over 70% was accounted for. The difference is due to an apparent increase in the number of chains in the petroleum-ether-soluble fraction. The most plausible explanation for this result is that some very low molecular weight material is lost in the drying procedure on isolation of the polymer from interrupted experiments, and that in the later stages of reaction, some of this material of very low molecular weight grows to produce material of low but now recoverable molecular weight.

A moderate chain deficiency still existed, however, at complete conversion (G6) in series B. Similarly in the two experiments of series A (G9 and G5) only about 40% of the added initiator could be accounted for. The soluble product changed neither in amount nor in measured molecular weight on the addition of the second portion of monomer and is presumed to be almost entirely inactive towards further addition of monomer at the end of a normal reaction period. Thus, in addition to the possibility of loss of very low molecular weight material through evaporation, it seems likely that some of the chain deficiencies observed at complete conversion for both series result from an attack of butyllithium on the ester function of the monomer.

Butyllithium reacts completely in less than 10 seconds to form petroleum-ether-soluble product and after only 2 minutes some insoluble polymer is formed. The broad molecular weight distributions reported by other workers for other anionic initiators appear in the present system. In addition to the petroleum-ether-soluble product, there seem, at less than 20% conversion, to be two distinct bands of insoluble polymer. This peculiar distribution continues to exist during a normal polymerization process and persists during the complete conversion of an added second portion of monomer. In series B, the $\bar{M}_w/\bar{M}_n$ ratio of the petroleum-ether-insoluble polymer stays relatively constant at about 4.6 in the three experiments, whereas it should decrease during polymerization if all the chains are equally reactive. There must be a wide variation in reactivity of different polymer chains in the first few minutes of reaction to produce this wide distribution and some of the difference persists even in later reaction stages where the higher molecular weight material seems to be still adding monomer at a faster rate. In series A, the effect can be seen more clearly. The addition of an extra portion of monomer at the end of a normal polymerization has shifted the distribution bodily even at very low molecular weights.

For personal use only.

Polymer originally of molecular weight between 40,000 and 200,000 has added uniformly about 400 monomer units since a good fit to the final curve (G5) can be obtained by this assumption. However, the high molecular weight band seems to be adding monomer at about twice this rate and polymer originally below a molecular weight of 40,000 at a somewhat lower rate. The $\bar{M}_w/\bar{M}_n$ ratio has, however, decreased during the polymerization of this second portion of monomer but not as much as expected for a uniform growth rate. An integral weight distribution curve, the broken line shown in Fig. 1, has been calculated from G9 on the assumption that all chains are equally reactive during the polymerization of the second portion of monomer. The difference between this curve and the actual one observed (G5) is obviously greater than any probable experimental error.

Previous kinetic evidence (3) had indicated that in the later reaction stages a steady concentration of reactive ends is present. This steady concentration is, however, mainly determined by the large number of chains in the low molecular weight range, as they account for most of the monomer added. Nevertheless, there seem to be persistent differences in intrinsic reactivity between chains of different molecular weight.

The very large differences between the molecular weight distributions for G5 and G1 (Figs. 1 and 3) show that the initial monomer/initiator ratio is much more important than the overall ratio in determining the nature of the product. Not only is the viscosity average molecular weight higher for G1 but, also, the distribution of molecular weights, although of the same general type as G5, is not related in any simple way.

The tacticity measurements produce rather surprising results. In series B (varying conversion) it can be seen that below 32% conversion the more rapidly growing chains have a markedly lower isotactic content. The highest isotactic content occurs in the chains found in the molecular weight range 10,000–20,000. Nevertheless, even the petroleum-ether-soluble fraction of very low molecular weight has an appreciable content of isotactic sequences. Its inability to add additional monomer does not seem likely to be caused by a failure to achieve a favorable (i.e., isotactic) configuration as suggested by Glusker *et al.* (1). At complete conversion the dependence of tacticity on molecular weight has changed completely, since the highest molecular weight material is now the most highly isotactic. Kinetic evidence (3) had indicated that a more rapid monomer consumption was attained after 32% conversion (G8). This reaction period must therefore be associated with a change in the environment of the polymer chains since the high molecular weight chains now add with a very high isotactic probability.

In series A, experiment G9 shows that at slightly different initial monomer and initiator concentrations, even at complete conversion, the intermediate range of molecular weights has the highest isotacticity. It seems reasonable to suppose that this is the result of lower isotacticity at higher molecular weight in the early stages of reaction and that later in the reaction there has been a phase of growth of higher isotacticity, which has not been sufficient to radically change the initial molecular weight – tacticity dependence. Addition of a second portion of monomer (G5) has changed the relationship to a minor extent in that the middle ranges of molecular weight have gained in isotacticity whilst the extremes have changed little.

It seems that the polymer molecules must be divided into several species. The distinct band of material soluble in petroleum ether must be considered entirely or almost entirely inactive after complete conversion and may possibly correspond to material which has cyclized at low molecular weights (1, 10). In addition there are at least two bands of polymer where the chains are still active and probably are of different intrinsic reactivity. The difference in reactivity starts at a very early stage in the reaction, persists to complete

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

polymerization and even during the subsequent polymerization of further monomer. It seems also that the two reaction stages as measured kinetically (3), namely a period of slow growth followed by a period of rapid growth, correspond to changes in environment at the polymer chain ends, since at the same time there is a sharp increase in isotacticity. The exact nature of the reactive ends cannot be stated unequivocally but it is known (11) that, in the case of styrene, association of the reactive end groups with tetrahydrofuran does produce differences in reactivity which depend on the number of polar molecules associated with the growing end. In the present case, polar or charged species (e.g., lithium methoxide) can be formed in the reaction directly by side reaction of butyllithium with the monomer (12), or later during propagation (1, 10, 13). Their formation during initiation would also help to explain the apparent loss of initiator molecules in the reaction. It is therefore suggested that, in addition to the normal uncomplexed ion-pair form, the structures of the reactive ends of the polymer chains could exist in the form of normal ion pairs complexed with one or even more molecules of methoxide. These complexed ion pairs could presumably react at different rates and with different probabilities of isotactic placement.

ACKNOWLEDGMENTS

The authors are grateful to Dr. S. Brownstein for the proton magnetic resonance measurements, to Dr. J. M. G. Cowie for light scattering and ultracentrifuge measurements, and to Dr. D. J. Worsfold for helpful discussions.

THE THERMAL DECOMPOSITION OF TETRAMETHYLTETRAZENE AND TETRAETHYLTETRAZENE[1]

B. G. GOWENLOCK,[2] P. PRITCHARD JONES,[3] AND D. R. SNELLING[4]
Department of Chemistry, University of Birmingham, Birmingham, England

Received April 11, 1963

ABSTRACT

The thermal decompositions of tetramethyltetrazene (TMT) and tetraethyltetrazene (TET) have been studied using a flow system. It is shown that both the decompositions occur at, or above, the limiting pressure for unimolecularity, and Arrhenius parameters for both decompositions are obtained. The decomposition mechanism is discussed in relation to the Arrhenius parameters and theories of three-fragment decompositions. Preliminary values of some kinetic parameters for some reactions of dialkylamino radicals are presented.

INTRODUCTION

The thermal decomposition of tetraalkyltetrazenes may take place either by the two-stage mechanism [1], [2]:

$$R_2N{-}N{=}N{-}NR_2 \rightarrow R_2N + \cdot N{=}N{-}NR_2 \quad \text{(slow)} \qquad [1]$$

$$\cdot N{=}N{-}NR_2 \rightarrow N_2 + R_2N \quad \text{(fast)} \qquad [2]$$

or by a three-fragment decomposition, i.e. simultaneous splitting, [3], of the two dialkylamino radicals:

$$R_2N{-}N{=}N{-}NR_2 \rightarrow R_2N + N_2 + R_2N. \qquad [3]$$

Thermochemical data for these routes have been given (1) and discussed together with the data for the analogous azoalkanes (2). We have reported elsewhere (3) the results of a preliminary study for the flow pyrolysis of TMT, and have related this to the gas phase static measurements by Watson and Waring (4), and the single value for the decomposition in cumene solution (5).

EXPERIMENTAL

I. Materials

TMT was prepared from an ethereal solution of *unsym*-dimethylhydrazine by oxidation using either mercuric oxide (6) or silver oxide (7). After filtration, drying, and removal of the bulk of the ether, the product was fractionally distilled *in vacuo* and further purified by bulb-to-bulb distillation. The purity of the product was established by gas–liquid chromatography (GLC) and by production of a reproducible mass spectrometric cracking pattern. TET was prepared and purified in similar manner: the *unsym*-diethylhydrazine was unavailable commercially and was synthesized from diethylnitrosamine by reduction. Carrier gases were purified as described by Billinge and Gowenlock (8). Other materials used for confirmation of products were tetramethylhydrazine (TMH), dimethylnitrosamine (DMN), diethylnitrosamine (DEN), diethylamine (DEA), diethylmethylamine (DEMA), 1,3,5-triethylhexahydro-*s*-triazine (ET), ethylethylideneamine (EEA), and tetraethylhydrazine (TEH). TMH was a gift of Dr. B. J. Aylett, DEA was commercially available, DMN and DEN were prepared from nitrosation of the corresponding amine, DEMA was prepared by reductive methylation (9), ET was prepared from condensation of formaldehyde with ethylamine (10), EEA from reaction of acetaldehyde with ethylamine (11), and TEH was obtained from fractional distillation of the products of a TET pyrolysis run. It is possible that the TEH may not be completely pure and this would be reflected in wider error limits of the ratios of products for any run. The only detailed preparation of the pure compound (12) was not attempted.

II. Apparatus

A conventional flow apparatus (8) was employed. TMT or TET was entrained by passing a stream of carrier gas over a pool of the liquid maintained at constant temperature in a cylindrical vessel. The amounts of permanent gases resulting from thermal decomposition were measured by pressure measurement in a

known volume: these gases could also be toeplered into small tubes for mass spectrometric analysis. Samples of the pyrolysis products were taken from the trap system and subjected to mass spectrometric and gas–liquid chromatographic analyses. Internal standards were run with each set of GLC analyses. Unless stated, the GLC systems used were those given elsewhere (13). A Cary 14 recording spectrophotometer was used to obtain optical densities of TET–DEN mixtures. The two reaction vessels employed were of different shape and reaction zone volume. One had a volume of about 110 cc and constant diameter throughout the reaction zone, the other had a volume of about 75 cc and the diameter increased by a factor of 50% in the center of the reaction zone. A reaction vessel of dimensions identical with those of the first was constructed and packed regularly with silica fibers: the surface/volume ratio was thereby increased by a factor of 10.

RESULTS

I. TMT

Residence times were calculated assuming the ideal gas law to be obeyed by all substances within the reaction zone. The velocity constants were calculated from the first-order equation, the throughput of TMT being obtained by weighing, and the amount of decomposition from (*a*) the quantity of nitrogen produced (carrier gases CO_2, SF_6, and some runs without carrier gas), or (*b*) GLC estimation of TMH formed and TMT undecomposed (carrier gas N_2, and some runs without carrier gas), or (*c*) mass spectrometric analysis of TMH formed and TMT undecomposed (carrier gas CO_2). GLC and mass spectrometric calibrations were carried out with samples of pure material. When the mixed carrier gas, NO–CO_2, was employed, the fraction of decomposition was estimated from GLC analysis of the liquid products using a 20-ft column packed with firebrick coated with 10% Apiezon L, and operated at 120°. The liquid products were DMN, TMH, and TMT. Peak area ratios of standard mixtures were employed and compared with those of the products so that the ratios DMN:TMT and DMN:TMH could be obtained, and hence the percentage decomposition calculated. Carrier gas throughput was measured by the change in pressure in a known volume at a measured temperature.

The first-order velocity constants were independent of carrier gas, and presence of nitric oxide. Alteration of reaction vessel, packing of reaction vessel, variation of total pressure in reaction vessel (6–12 mm), TMT pressure (by a factor of up to 50), contact time (0.5–3 sec) produced no alteration in velocity constants within the limits of reproducibility (±5%) of these values. The temperature variation of the rate constants is shown in Fig. 1, and in Fig. 2 the results of other workers (4, 5) are compared with the extrapolated best straight line of Fig. 1. Figure 2 is thus a representation of the figure in our preliminary communication (3) with the static technique velocity constants (4) corrected to their true value by multiplication by 2.303[2] (14). The agreement is enheartening. Our best straight line gives $\log_{10}(A) = 14.4 \pm 0.5$ and $E_{act} = 36.1 \pm 1.0$ kcal/mole: these values lie within the wider error limits of the preliminary results ($\log_{10}(A) = 13.8 \pm 1.7$, $E_{act} = 34.5 \pm 3.0$ kcal/mole) (3). The temperature range was 193–266° C (preliminary study (3) 204–244° C).

In a large number of the runs qualitative analyses of the products were made using GLC and mass spectrometry. Over the temperature range 193–260° C the only products (in the absence of nitric oxide) were TMH and nitrogen. In the range 260–266° C two further peaks appeared in the GLC trace: subsequent trapping and mass spectrometry were employed and these served to identify the compounds trimethylamine and tetramethylmethylenediamine. This identification was confirmed by GLC analyses of the pure compounds. Discussion of the formation of these compounds is given elsewhere (13).

II. TET

For the cases of CO_2 and SF_6 carrier gases combined with unpacked reaction vessels the method is identical with that used for TMT decomposition. When the packed reaction

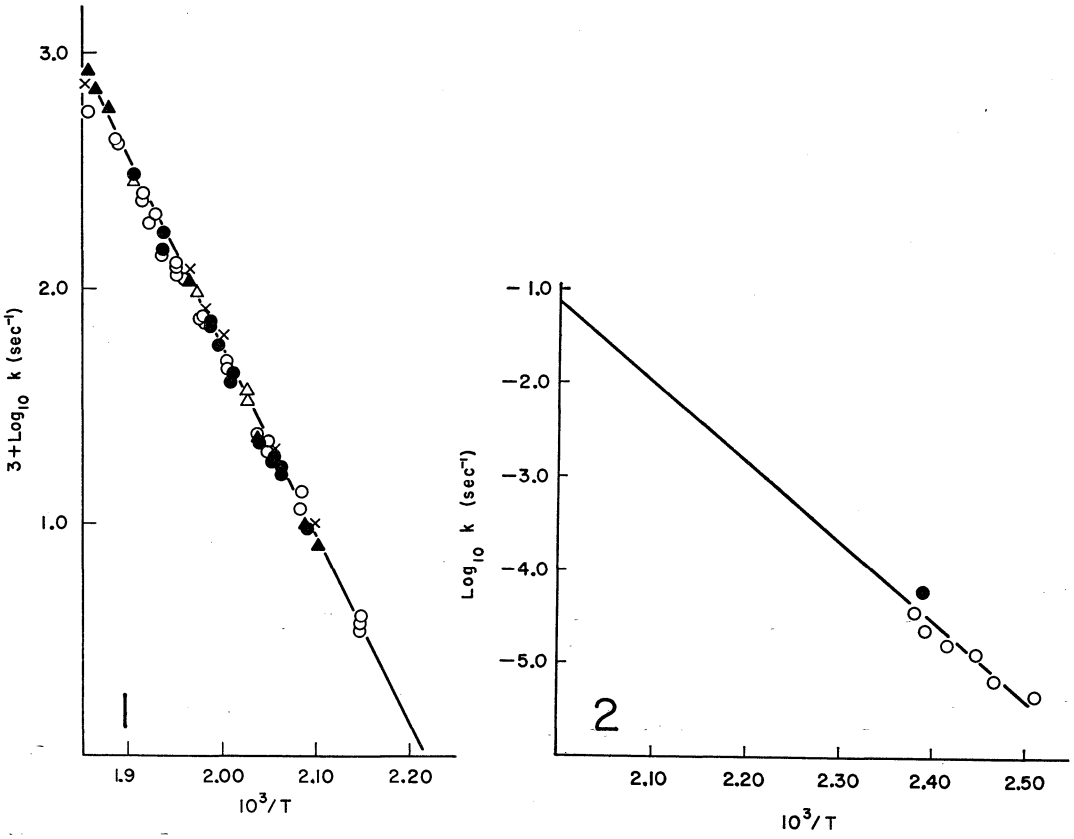

FIG. 1. Arrhenius plot for the thermal decomposition of TMT. ○ CO_2, ● SF_6, △ CO_2 + NO, ▲ pure TMT, × packed reaction vessel. Many of the points are coincident and cannot be distinguished.
FIG. 2. Comparison of our best straight line for TMT with results of other investigators. ○ references 4, 14, ● reference 5.

vessel (CO_2 carrier gas) was used, the permanent gas sample contained small quantities of methane and ethane. The following modification was employed: the reaction products were passed through three traps cooled respectively to −160°, −183°, and −210° C. The last trap removed ethane, and the proportions of methane and nitrogen present in the permanent gases were determined by mass spectrometry. Ethane was determined by vaporization into a known volume, carbon dioxide was removed from the contents of the −183° cooled trap by absorption (8) and the contents of this and of the −160° cooled trap were mixed with a known volume of ether and analyzed by GLC. Identification of the products was first made by mass spectrometry, the cracking patterns compared with the pure compounds, and the GLC analyses then confirmed by measurement of relative retention times of the pure compounds for which relative molar responses had also been obtained. Compounds present included DEA, DEMA, ET (small amounts), TEH, EEA, and two other unidentified materials.

Product analysis for runs using the mixed carrier gas (CO_2–NO) was confined to spectrophotometric analysis of the liquid products (previously condensed out at −160° C) at 350 mμ, where the molar extinction coefficients are 89.4 (DEN) (literature value (15) 90) and 0.82 (TET), and at 283.5 mμ, where they are 45 (DEN) and 7850 (TET). Comparison of the percentage decomposition based on DEN:undecomposed TET with that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

based on nitrogen produced gave good agreement and suggests that no other products were formed. The contents of the trap cooled to −183° were treated to remove CO_2 (8) and no remainder was observed.

First-order velocity constants were independent of carrier gas and unaltered by nitric oxide. Alteration of reaction vessel, packing af reaction vessel, and variation of total pressure in the reaction vessel (9–29 mm), TET pressure (up to a factor of 15), and contact time (0.6–4.2 sec) produced no alteration within the limits of reproducibility (±5%) of these values. The temperature variation of velocity constants is shown in Fig. 3. Our best

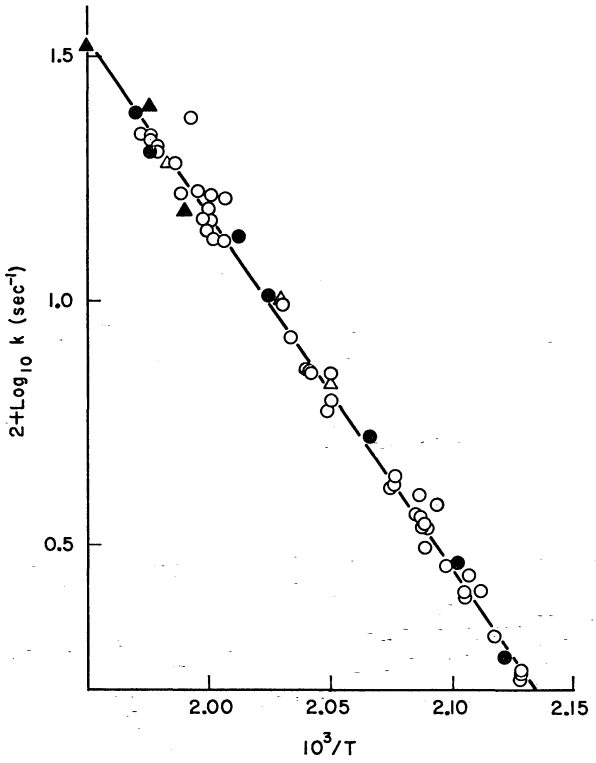

FIG. 3. Arrhenius plot for the thermal decomposition of TET. ○ CO_2, ● SF_6, △ CO_2 + NO, ▲ packed reaction vessel.

straight line gives $\log_{10}(A) = 13.7 \pm 0.9$ and $E_{act} = 33.0 \pm 2.0$ kcal/mole. The temperature range for the majority of the runs is 198–235° C and the estimated error limits are wider than those for TMT in consequence of this smaller temperature range.

DISCUSSION

For both the tetrazenes, the invariance of the velocity constants at any fixed temperature with changes in total pressure, carrier gas, and partial pressure of reactant is evidence that the decomposition is being studied at or above the limiting pressure for unimolecularity. The pressure of TMT is, in almost every case, greater than 0.1 mm, which has been shown (16) to be the limiting pressure for azoisopropane. It would be expected that TMT would have a limiting pressure at or slightly below that for azoisopropane. The evidence from nitric oxide addition shows that the decomposition is non-chain, and the packing of the reaction vessel indicates that the primary decomposition reaction is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

predominantly homogeneous. As we have emphasized elsewhere (13) there are heterogeneous contributions to the radical reactions at higher temperatures and discussion of this problem is postponed until further results are available.

Batten (17) has emphasized the importance of avoiding channelling of the reaction vessel by the streaming gas in flow systems where the flow is laminar. These considerations are of particular importance when considerable changes in reaction vessel diameter take place within the heated reaction zone. The good agreement in our velocity constants for both the tetrazenes when differently shaped reaction vessels are used is good evidence for the absence of channelling. The changes in reaction vessel diameter (and hence in linear flow rate) within our reaction vessels are much less than in those used by Batten. A further feature which diminishes channelling is the centrally mounted thermocouple tube which penetrates along the whole length of the reaction vessel. This was absent in Batten's first study (17) but later work (18) indicates that the flow patterns are modified by this insertion. In addition, we employ only a short calming length prior to entry to the heated zone and entry to this calming length is tangential. These considerations indicate that there will be only a smaller tendency to channelling in our system.

We have drawn attention (2) to the pattern of thermochemical parameters for three azoalkanes and TMT, namely $E_{act} > D_1 > D_1+D_2$ (where D_1 and D_2 are the respective endothermicities of reactions [1] and [2], i.e. first and second bond dissociation energies to the azo group). It seems probable that this will be general for azoalkanes and tetraalkyltetrazenes. The similarity of thermochemical pattern is an argument in favor of proposing identical decomposition mechanisms for azoalkanes and tetrazenes. In Fig. 4 we give a simplified picture of the energy surfaces for decomposition of these molecules, the numerical values for azomethane (2, 19) being used to illustrate the general case. This

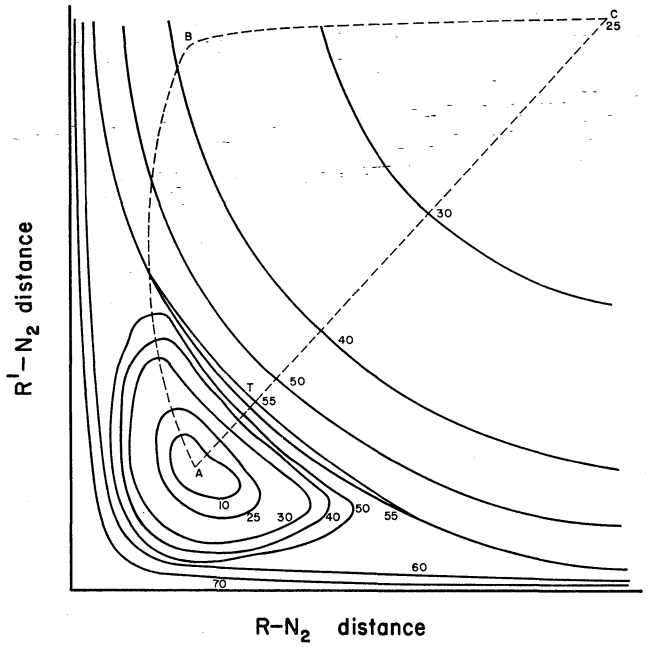

FIG. 4. Contour map for the thermal decomposition of an azocompound R′—N=N—R. Path AC corresponds to three-fragment decomposition, path ABC corresponds to two-fragment decomposition, T indicates the transition state, and the numbers indicate the energy values (in kcal/mole) for R and R′ = CH_3.

figure corrects that used by Steel and Laidler (20) and may be compared with those given by Szwarc (21). There is a marked difference between this energy surface and that for mercury dialkyls (22) because the fragment HgR decomposes endothermically in contrast to the exothermic decomposition of N_2R. It has been suggested (23) that there is an essential similarity in the decomposition mechanisms for azocompounds, ketones, and mercury dialkyls, and that all these molecules can be represented by R_2M, M being a divalent/zerovalent group. However, this classification ignores the different symmetry classes of the molecules and the different thermochemical patterns. The former of these will obviously be important if the reason for high-frequency factors be the contribution of more than one vibrational mode to the decomposition coordinate. Pritchard (24) has shown that more vibrational modes can participate in the three-fragment decomposition mechanism for mercury dialkyls than in the two-fragment mechanism. Hence, *in this case*, the multiple critical oscillator explanation of high-frequency factors is consistent with a three-fragment decomposition. However, the symmetry of an azocompound is different, and the number of vibrational modes contributing to the two-fragment decomposition is the same as the number contributing to the three-fragment decomposition. Hence, we cannot use the value of the frequency factor in this case as a diagnostic test of the number of fragments produces in the primary decomposition reaction. This contrasts with our previous assumption (2, 25). We suggest that azoalkanes and tetraalkyltetrazenes will decompose by a three-fragment mechanism and that the governing factor lies in the common thermochemical pattern. The values of the frequency factors ("high" for azoalkanes and "normal" for tetrazenes (25)) are not therefore relevant to our choice of most probable decomposition path. The relevant data are given in Table I. In these

*It has been noted (30, 31) that Ramsperger's values are probably too low.

pyrolyses, the exothermic decomposition of N_2R is probably effected in one vibration. Consequently there appears to be little or no meaning in the concept of a two-fragment decomposition. For azoalkanes, where "high" (25) frequency factors occur, we consider the best available explanation to be that of a "softening" of vibrations in the activated complex (20). This implies little softening for the tetrazenes, and we suggest tentatively that this is related to the lower energy barrier. Such a suggestion is supported by the available data for the decomposition of 1,4-dimethyl-1,4-diphenyltetrazene in hydrocarbon solvents (log $(A) = 14.7$, $E = 33.0$ kcal/mole (5); log $(A) = 14.2$, $E = 31.6$ kcal/mole (32)) and of dibenzylhyponitrite in a range of solvents (log $(A) = 12.6$, $E = 23.6$ kcal/mole (32); log $(A) = 13$–14, $E = 24.0$–25.4 kcal/mole (33)), where the activation

For personal use only.

energy is less than that for the compounds listed in Table I and, in general, the frequency factors also are lower.

We have summarized elsewhere (13) our evidence for the reactions of dimethyl- and diethyl-amino radicals. We shall therefore only discuss modifications and extensions to that discussion. A direct value for the recombination rate of amino radicals has recently become available (34). If we assume that the rates of recombination of amino and dimethylamino radicals are equal, and use our relative yields of TMH and DMN together with the average concentration of nitric oxide in the reaction vessel, we can obtain a value of $k_4 = 3 \pm 1 \times 10^7$ l./mole sec, i.e. a steric factor of approximately 10^{-4}. This assumes that reaction [4] is bimolecular. If this reaction is, in fact, termolecular as is the case for the

$$(CH_3)_2N + NO \rightarrow (CH_3)_2NNO \qquad [4]$$

corresponding reaction [5], then the steric factor reflects the termolecularity. It seems

$$CH_3 + NO + M \rightarrow CH_3NO + M \qquad [5]$$

less likely that this termolecularity should occur under our reaction conditions, as the resultant DMN contains more atoms than nitrosomethane. If the reverse reaction of [4] is in the region of falloff from unimolecularity at these pressures, then reaction [4] is presumably termolecular. Studies of DMN decomposition (35) are in progress, but surface effects complicate the interpretation of results.

Reactions [6]–[12] represent some probable reactions of diethylamino radicals and products derived therefrom. The presence of TEH, DEA, EEA, ET, DEMA, and ethane

$$2(C_2H_5)_2N \rightarrow (C_2H_5)_2NN(C_2H_5)_2 \qquad [6]$$

$$2(C_2H_5)_2N \rightarrow (C_2H_5)_2NH + C_2H_5N{=}CHCH_3 \qquad [7]$$

$$(C_2H_5)_2N \rightarrow C_2H_5N{=}CH_2 + CH_3 \qquad [8]$$

$$3C_2H_5N{=}CH_2 \rightarrow (C_2H_5N{=}CH_2)_3 \qquad [9]$$

$$(C_2H_5)_2N + CH_3 \rightarrow (C_2H_5)_2NCH_3 \qquad [10]$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \qquad [11]$$

$$(C_2H_5)_2N + CH_3 \rightarrow C_2H_5N{=}CHCH_3 + CH_4 \qquad [12]$$

in the reaction products could be accounted for by reactions [6]–[11], and reaction [12] represents a route for methane production which does not necessitate a metathesis with TET and subsequent chain reaction. Approximate ratios of some of the products have been obtained from GLC, and some product ratios at 254° C are given in Table II. If we

TABLE II

Product ratios in TET pyrolysis at 254° C

*Not estimated.

use our product ratios to calculate $k_{10}/(k_{11}k_6)^{1/2}$ values (36), then the results fall within the range 2–3.3. If the more accurate ratio $(k_{10}+k_{12})/k_{11}^{1/2}(k_6+k_7)^{1/2}$ (37) be used, then the results fall within the range 1.1–2.2. We emphasize that these results are not absolute, and claim only that the agreement with the established trend for alkyl radicals is encouraging. No other semiquantitative data for substituted amino radicals have yet been published. The reaction scheme [6]–[12] is not complete: other unidentified products

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

have been obtained in small quantity and in general DEA is in excess of EEA. In contrast to dimethylamino radicals (13), disproportionation is preferred to dimerization. Further investigations are proceeding.

ACKNOWLEDGMENTS

We wish to thank the Department of Scientific and Industrial Research for a maintenance grant (P. P. J.) and the University of Birmingham for a research scholarship (D. R. S.). We are also indebted to Dr. J. R. Majer for mass spectrometric analyses, Dr. B. J. Aylett for a gift of pure tetramethylhydrazine, and Dr. J. K. Brown for helpful discussions.

THE ALKALOIDS OF EUPATORIUM MACULATUM L.[1]

Y. TSUDA[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received April 10, 1963

ABSTRACT

The root of *Eupatorium maculatum* L. has been examined and found to contain at least four alkaloids. The major base was found to be echinatine, while the second one in importance has been identified as the non-esterified trachelanthamidine. The remaining two alkaloids are probably also of the pyrrolizidine type, but their structures could not be determined due to paucity of material.

Pyrrolizidine alkaloids are known to cause chronic poisoning associated with haemorrhage in the liver which forms the starting point for cirrhosis (1). Some species of *Eupatorium* (Compositae) have been suspected to cause liver damage in stock and this prompted a search for alkaloids in *Eupatorium maculatum* L., a plant which is widely distributed in Canada.[3] The root has yielded a number of water-soluble bases. Chromatography of the hydrochlorides of the crude bases on cellulose powder effected the separation of four distinct alkaloids.

Base A was obtained as a colorless gum by passing the methanolic solution of its hydrochloride through a column of amberlite IRA-401-OH. It could not be induced to crystallize, but it formed a crystalline picrolonate, $C_{15}H_{25}O_5N.C_{10}H_8O_5N_4$, m.p. 212–214°, and a methopicrate, $C_{16}H_{28}O_5N.C_6H_2O_7N_3$, m.p. 153–155°. An attempt to distill the base *in vacuo* caused pyrolysis, and a substance sublimed which proved to be a carboxylic acid ($C_7H_{14}O_4$) containing three C—CH_3 groups (infrared and n.m.r. spectra). This acid, which was obtained in better yield by the pyrolysis of base A hydrochloride, had properties that corresponded closely to those of viridifloric acid (II) (2, 3, 4), and a direct comparison with an authentic sample kindly sent by Dr. C. C. J. Culvenor proved the identity of the two acids.

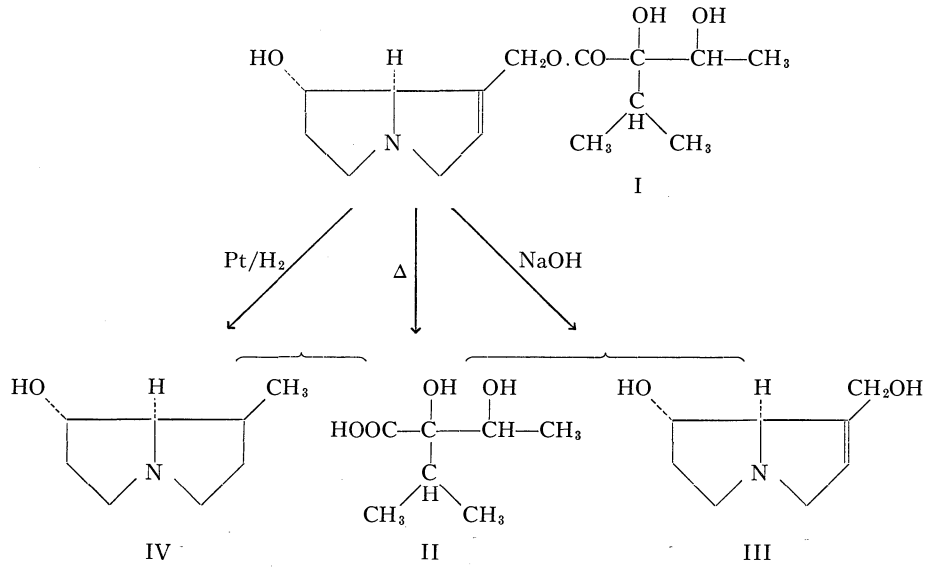
The formation of an acid on pyrolysis together with the empirical formula of base A led to the assumption that it was an esterified pyrrolizidine base, and this was confirmed by its saponification, which gave rise to viridifloric acid (II) and a necine, $C_8H_{13}O_2N$ (III), m.p. 116.5–118°. On acetylation the necine produced a diacetyl derivative and hence contained two hydroxyl groups.

The base A when hydrogenated catalytically absorbed 1 mole of hydrogen and underwent hydrogenolysis with the addition of a second mole of hydrogen. The products of the reaction were viridifloric acid and a base, $C_8H_{15}ON$, isolated as its picrate, m.p. 198–200°. The hydrogenolyzed base had properties which coincided with those of hydroxyheliotridane (IV) reported in the literature (5).

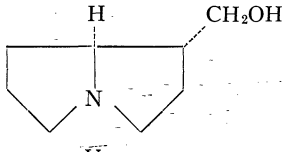
These results strongly indicated that the necine III might be identical with heliotridine, and base A with echinatine (I). Indeed the necine and base A picrolonate respectively proved to be identical by direct comparison with authentic specimens of heliotridine and echinatine picrolonate kindly supplied by Dr. C. C. J. Culvenor. Echinatine was first isolated from *Rindera echinata* (Boraginacae) by Men'shikov and Denisova (6), and the

[1]*Issued as N.R.C. No. 7397.*
[2]*National Research Council of Canada Postdoctoral Fellow.*
[3]*The plant was collected by Mr. J. N. Chabot, Division des Cultures Spéciales, Ministère de l'Agriculture, Québec, and we acknowledge our indebtedness to him.*

structure of heliotridine was established by Men'shikov and Kuzovkov (7) and Warren and Klemperer (8).



A second alkaloid (base B) was obtained in smaller quantity than echinatine. It could not be induced to crystallize but formed crystalline salts, i.e., a hydrochloride, a picrate, and a picrolonate. From the analysis of the salts its empirical formula was $C_8H_{15}ON$. The properties of the three salts were in agreement with those of the corresponding salts of trachelanthamidine (V) (9). The optical rotation of base B, $[\alpha]_D$ $-13.8°$, was approximate-



V

ly the same as that of trachelanthamidine, $[\alpha]_D$ $-12.9°$, and its n.m.r. spectrum contained no signal for an olefinic proton, but showed a doublet (δ 6.5, $J \sim 6$ c/s) indicative of the CH_2 in the grouping CH—CH_2—O—. Trachelanthamidine was originally obtained as the necine of trachelanthamine (9, 10). Since the ester alkaloid echinatine was isolated from the plant under the same conditions without undergoing hydrolysis, it is probable that trachelanthamidine is not an artifact and exists as such in the plant. Hence trachelanthamidine and its enantiomorph laburnine (11) are the only two simple pyrrolizidine alkaloids found so far to occur in nature as non-esters, although the latter has never been reported as part of an ester alkaloid.

The third alkaloid, base C, obtained as the crystalline picrate, $C_9H_{13}O_3N.C_6H_3O_7N_3$, and the fourth, base D, also isolated as the picrate, $C_8H_{13}ON.C_6H_3O_7N_3$, were present in quantities too small to permit their structural investigation. Neither base C nor base D picrate showed carbonyl absorption in the infrared.

EXPERIMENTAL

The ground root of *Eupatorium maculatum* was extracted with methanol and the concentrated extract worked up as usual into a basic, an acid, and a neutral fraction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The strong base fraction (16 g), which on a paper chromatogram appeared to contain more than four components, was dissolved in methylene chloride (300 ml) and shaken with three portions of 7% sulphuric acid each of 100 ml. The organic layer yielded a neutral brown gum (6 g). The combined acidic extract was filtered, neutralized by the addition of ammonia to the point (pH 5) of turbidity, and extracted with two portions of 200 ml of ether (extract A). More ammonia was added to the aqueous solution (to pH 9) which was again extracted first with three portions of 200 ml of ether (extract B) and then repeatedly with methylene chloride (extract C). The aqueous solution still gave a strong test with Meyer's reagent. It was neutralized with acetic acid and sulphuric acid added to pH 3 followed by the addition of a saturated solution of ammonium reineckate until precipitation was complete. The precipitated reineckate was filtered, washed with water, and dried in air, 13.5 g.

Extract A on evaporation left a slightly yellow oil, 0.12 g. Extract B yielded a yellow oil, 0.54 g, and extract C a brown gum, 1.83 g.

The reineckate (13.5 g) was dissolved in acetone (100 ml), the solution filtered, and the insoluble material (0.7 g) washed with acetone (50 ml). To the combined filtrate previously diluted with acetone (350 ml) and water (100 ml) a hot saturated aqueous solution of silver sulphate (6 g) was added and the precipitate removed by filtration. A solution of barium chloride was added to the filtrate and the precipitate removed by centrifugation. The cleared solution was evaporated to dryness under reduced pressure at 40–50°, the residue extracted with absolute ethanol, and the extract evaporated to dryness. The residue was treated twice more as above. Evaporation of the final extract left a greenish, gummy hydrochloride (6 g). Paper partition chromatography on Whatman No. 1 filter paper with butanol – acetic acid – water (10:1:4) revealed the hydrochloride to be a mixture of at least three components (R_f 0.51, 0.31, 0.11). The same mixture of hydrochlorides was also obtained directly by passing the solution of the reineckate through a column of Amberlite IRA-401-Cl.

The greenish gummy hydrochloride (ca. 7 g) was dissolved in methanol (50 ml), thoroughly mixed with cellulose powder (50 g), and dried *in vacuo* for 2 days. This was placed on the top of a cellulose powder (600 g) column (6×56 cm) and developed and eluted with butanol – acetic acid – water (10:1:4). The eluate (3.3 l.) was collected in 32 fractions, and the column was washed with methanol (1 l.—fraction 33). Fractions 1–6 (1 l.) yielded 0.28 g of neutral product which was discarded. Fractions 10–18 (500 ml) gave base A hydrochloride (5.4 g) which on standing for several weeks crystallized as colorless elongated prisms, but failed to recrystallize because of its hygroscopic nature (R_f 0.50). Base A was also obtained from extract C (above).

Fractions 21–25 (500 ml) yielded base B hydrochloride (0.32 g, R_f 0.32). Fractions 28–31 (500 ml) on evaporation left a mixture of hydrochlorides (0.21 g) from which base C was isolated as the picrate. The methanol eluate (fraction 33) also yielded a mixture of hydrochlorides (0.34 g) from which a fourth alkaloid, base D, was isolated as the picrate.

Echinatine (Base A)

Base A hydrochloride was dissolved in methanol and passed through a column of Amberlite IRA-401-OH. Evaporation of the solution left the free base as a colorless gum which gave only one spot on a paper chromatogram. The homogeneity of the base was also confirmed by chromatography over alumina (grade III) since each fraction of the eluate yielded a base having an infrared spectrum identical with that of the original base. The pure amorphous base A has pK_a 8.2 measured in aqueous solution. Its n.m.r. spectrum in chloroform indicates the presence of —$CH(CH_3)_2$ (two doublets corresponding to six protons centered at δ 0.9) and —$CH(OH)CH_3$ (δ 1.27; J = 7 c/s) groups and one olefinic proton, while the infrared spectrum (in $CHCl_3$) shows a band at 1720 cm^{-1} attributable to an ester carbonyl.

The perchlorate and picrate of base A failed to crystallize but the picrolonate crystallized from ethanol as yellow prisms, m.p. 212–214°, ν_{max} 1730 cm^{-1} (in nujol mull). For echinatine picrolonate the literature (6) gives m.p. 206°. An authentic sample of echinatine picrolonate, kindly sent by Dr. C. C. J. Culvenor, had the same melting point either alone or in admixture with base A picrolonate and both salts had superimposable infrared spectra. Found: C, 53.49; H, 5.81; N, 12.31. Calc. for $C_{15}H_{25}O_5N.C_{10}H_8O_5N_4$: C, 53.28; H, 5.90; N, 12.43%.

Echinatine (base A) was also characterized as the methopicrate. Base A liberated from 90 mg of the hydrochloride was kept overnight at room temperature in benzene (5 ml) and methyl iodide (1 ml). The methiodide separated as a gum which after decantation of the solvent was dissolved in water and the solution poured into a saturated aqueous solution of sodium picrate. The solution was concentrated to half volume by heating to 40° under reduced pressure. On cooling, the methopicrate crystallized. After recrystallization from water it consisted of yellow needles, m.p. 153–155°, ν_{max} (nujol mull) 1707 cm^{-1}. Found: C, 48.29; H, 5.48; N, 10.54. Calc. for $C_{16}H_{28}O_5N.C_6H_2O_7N_3$: C, 48.71; H, 5.57; N, 10.33%.

Pyrolysis of Echinatine (Base A)

When echinatine (60 mg) was heated in a vacuum (10^{-3} mm) pyrolysis took place and two fractions distilled over, a sublimate at 110°, 3 mg, and a pale yellow glass at 120–170°. The sublimate was resublimed at 90–95° under 5×10^{-4} mm. It consisted of an acid crystallizing as colorless needles, m.p. 130–131°. The same acid was obtained in better yield in the pyrolysis of the base hydrochloride (9 mg acid from 44 mg salt) and also from the saponification of the base, as well as in its hydrogenolysis.

Hydrolysis of Echinatine (Base A)

Base A hydrochloride (0.835 g) was added to 10% aqueous sodium hydroxide (20 ml) and heated on the steam bath for 2 hours. The cooled solution was then passed through a column of Amberlite IR-120-H (1.5×20 cm) and the column washed with water (500 ml). The eluate (combined with the washings) was evaporated to dryness under reduced pressure. There was left a crystalline acid (0.419 g) which was dissolved in boiling ether. The solution was filtered and evaporated to dryness. The residue consisted of colorless needles; it was recrystallized from chloroform, from which it separated as colorless needles of pure viridifloric acid, 0.381 g, m.p. 119–121°.[4] The literature (2) reports m.p. 121°. The acid, which was identical with that obtained in the pyrolysis of the base, had the same melting point either alone or in admixture with an authentic sample of viridifloric acid kindly supplied by Dr. C. C. J. Culvenor and both had superimposable infrared spectra. Found: C, 51.82; H, 8.62. Calc. for $C_7H_{14}O_4$: C, 51.84; H, 8.70%.

The Amberlite column from which the acid had been eluted was further eluted with 10% hydrochloric acid (500 ml), and the eluate was evaporated to dryness under reduced pressure. The residue was heated with absolute ethanol, and the filtered solution was evaporated to dryness. This residue was treated twice more as above. It finally consisted of a gummy hydrochloride which was dissolved in methanol and the solution passed through a column (1.5×20 cm) of Amberlite IRA-401-OH. The column was washed with methanol (300 ml) and the combined eluate and washings evaporated to dryness. The residue (0.362 g) crystallized on standing. It was purified by distillation, b.p. 115° (air bath) at 0.3 mm, and crystallized from acetone, from which it separated as colorless prisms, m.p. 116–118°, $[\alpha]_D$ +30.4° (*c*, 2.5 in EtOH). Heliotridine (12) has m.p. 116.5–118°, $[\alpha]_D$ +31° (in MeOH). Found: C, 61.89; H, 8.37; N, 9.20. Calc. for $C_8H_{13}O_2N$: C, 61.91; H, 8.44; N, 9.03%. The infrared spectrum of the base was superimposable on that of an authentic specimen of heliotridine kindly supplied by Dr. C. C. J. Culvenor. The melting points of the two were identical either alone or in admixture.

The hydrolytic base (heliotridine) formed a picrate which was recrystallized from ethanol–ether, from which it separated as yellow needles, m.p. 104–105°. Found: C, 43.66; H, 4.27; N, 14.51. Calc. for $C_8H_{13}O_2N.C_6H_3O_7N_3$: C, 43.75; H, 4.20; N, 14.58%.

Diacetylheliotridine

Heliotridine (20 mg) in acetic anhydride (2 ml) was heated on a steam bath for 2 hours and the reaction mixture evaporated to dryness *in vacuo*. The residue was dissolved in water, the solution filtered, and the filtrate evaporated to dryness. There was left a pale yellow oil (25 mg) which was dissolved in the minimum quantity of water and to the solution was added a saturated aqueous solution of picric acid. Diacetylheliotridine picrate precipitated; it was crystallized from ethanol, from which it separated in yellow needles, m.p. 129–130°. Found: C, 46.33; H, 4.39; N, 11.98. Calc. for $C_{12}H_{17}O_4N.C_6H_3O_7N_3$: C, 46.15; H, 4.30; N, 11.96%. Infrared in nujol mull: 1732 cm^{-1}. Nuclear magnetic resonance in chloroform: δ 7.78 and 7.79, indicative of two acetyl groups.

Hydrogenolysis of Echinatine

Echinatine (base A) hydrochloride (800 mg) in acetic acid (7 ml) and ethanol (17 ml) was shaken with Adams' catalyst (75 mg) in the presence of hydrogen at room temperature for 4 hours. The catalyst was filtered off and the filtrate evaporated to dryness under reduced pressure. The residue dissolved in water was passed through a column (1.5×25 cm) of Amberlite IR-120-H and the column washed with water (500 ml). Evaporation of the filtrate left a residue of viridifloric acid (374 mg), m.p. 120–122°, either alone or in admixture with an authentic sample.

The Amberlite column was further washed with 15% hydrochloric acid (600 ml). These washings, on evaporation, left a residual hydrochloride (330 mg) which was dissolved in a small volume of water. The solution was made strongly basic with sodium hydroxide and extracted several times with ether. Evaporation of the extract, previously dried over sodium carbonate, left a residual oil (300 mg) which was distilled, b.p. 125° (air bath) at 10 mm, wt. of distillate 250 mg, $[\alpha]_D$ −10.6° (*c*, 1.8 in EtOH). For hydroxyheliotridane the literature (5) gives $[\alpha]_D$ −14.5° in water. Hydroxyheliotridane formed a picrate which crystallized from ethanol as yellow needles, m.p. 198–200°. The literature (5) gives m.p. 196°. Found: C, 45.73; H, 4.90; N, 15.83. Calc. for $C_8H_{15}ON.C_6H_3O_7N_3$: C, 45.40; H, 4.90; N, 15.13%.

Base B (Trachelanthamidine)

Base B hydrochloride (320 mg) mentioned above consisted of greenish crystals. It was purified by being dissolved in ethanol–acetone and chromatographed on a column of acid alumina.[5] The pure trachelanthamidine hydrochloride thus obtained crystallized from methanol – ethyl acetate as colorless elongated prisms, m.p. 114–115° (lit. (9), m.p. 110–112°). The salt, which was hygroscopic, was dried at 60°, 0.03 mm, prior to analysis. Found: C, 54.73; H, 8.73. The sample used for nitrogen analysis was kept overnight after

[4] *Viridifloric acid seems to occur in dimorphic forms since it sometimes has the higher melting point. It has been described as having m.p. 117–119° and* $[\alpha]_D$ *0° (3), but also with m.p. 127.5° and* $[\alpha]_D$ *+1.8° (4). The racemate has m.p. 150° (4).*

[5] *Woelm alumina (grade I) suspended in 2 N hydrochloric acid was heated with stirring on the steam bath for 2 hours, filtered, thoroughly washed with water until the washings were only faintly acid, and dried for 10 hours at 110°.*

drying and had become solvated. Found: N, 6.74. Calc. for $C_8H_{15}ON.HCl$: C, 54.49; H, 9.08; N, 7.88%. For $C_8H_{15}ON.HCl.H_2O$: N, 7.16 and for the dihydrate: N, 6.56%.

The hydrochloride, dissolved in methanol, was passed through a column of Amberlite IRA-401-OH and the column washed with methanol. The combined solution and washings was evaporated to dryness and the residual trachelanthamidine distilled: colorless oil, b.p. 60–65° (air bath) at 7×10^{-2} mm, $[\alpha]_D$ −13.8° (*c*, 1.28 in 95% EtOH) (lit. (9), $[\alpha]_D$ −12.9°). The n.m.r. spectrum in D_2O contains a doublet (δ 6.5, J = 6 c/s) but no signal corresponding to an olefinic proton.

The base formed a picrate which crystallized from ethyl acetate – ether as yellow needles, m.p. 178–179° (lit (9), m.p. 174°). Found: C, 45.50; H, 4.88; N, 14.71. Calc. for $C_8H_{15}ON.C_6H_3O_7N_3$: C, 45.40; H, 4.90; N, 15.13%. The picrolonate prepared in ether solution and crystallized from methanol consisted of yellow prisms, m.p. 182–183° (lit. (9), m.p. 182°).

Base C

The brown gum (mixture of hydrochlorides) obtained from fractions 28–31 was dissolved in methanol and chromatographed on a column of acid alumina. The almost colorless solid obtained from the eluate was redissolved in methanol and the solution passed through a column of Amberlite IRA-401-OH. Evaporation of the eluate yielded the gummy free base, which was treated with picric acid. The picrate, after several crystallizations from ethanol, consisted of yellow prisms, m.p. 194–195°. Found: C, 44.47; H, 4.07; N, 13.46. Calc. for $C_9H_{13}O_3N.C_6H_3O_7N_3$: C, 43.69; H, 3.91; N, 13.59%.

Base D

Fraction 33 of the eluate from the original chromatogram of the crude base left on evaporation a residue of base hydrochlorides which was contaminated with inorganic salts. It was washed repeatedly with methanol and the combined methanol extract passed through a column of Amberlite IRA-401-OH. The eluate was evaporated to dryness under reduced pressure, the residue dissolved in water, and the filtered solution evaporated to dryness. The residue (52 mg) was dissolved in methanol and poured into a saturated solution of picric acid in methanol. The precipitated picrate was crystallized first from acetone and then from methanol, from which it separated as yellow needles, m.p. 165–167°. Found: C, 45.52; H, 4.22; N, 14.75. Calc. for $C_8H_{13}ON.C_6H_3O_7N_3$: C, 45.65; H, 4.38; N, 15.21%.

ACKNOWLEDGMENTS

We wish to express our thanks to Dr. C. C. J. Culvenor, C.S.I.R.O., Melbourne, for his kindness in sending authentic specimens; also to acknowledge our indebtedness to Mr. M. Lesage for the n.m.r. spectra, to Mr. R. Lauzon for the infrared spectra, and to Mr. H. Seguin for the microanalyses.

ABSTRACT

The lithium aluminum hydride reduction of nitriles in the aromatic resin acid series to aldimines and the conversion of the products to other derivatives are described. The effect of the stereochemistry of the nitriles on the rate of reduction is noted. The transformation of dehydroabietane into a dehydro product is indicated. The syntheses of a desoxydecarboxy-5,6-dehydro-7-keto derivative of podocarpic acid and its optical antipode are discussed. The stereochemistry of hydrogenation of 5,6-dehydro derivatives of podocarpic acid is reported. The effect of a 7-keto group on the rate of hydrolysis of methyl esters of aromatic resin acids is illustrated. The reactions of 6-bromo-7-keto derivatives of methyl podocarpate with bases are portrayed.

Throughout our continuing studies directed toward the total synthesis of diterpenic natural substances (1) tangential chemical problems of synthetic and/or mechanistic interest have arisen and drawn our attention. The present communication constitutes a description of our experiences with a variety of these subjects.

Reduction of Nitriles

In connection with our total synthesis of *d*-podocarpic acid (I*a*) (2) a fair quantity of desoxypodocarpic acid enantiomer (II*a*) was needed. Whereas its nitrile (II*b*) could be prepared in a few steps from dehydroabietonitrile (I*b*) (3), it had not been hydrolyzed to the acid (II*a*). It could be anticipated that such hydrolysis would take place only with extreme difficulty in view of the highly sterically hindered, axial nature of the nitrile group (and, more importantly, of the intermediate amide function). Furthermore, the last step in the reaction sequence leading to the nitrile II*b*, hydrogenation of the enol acetate III*a*, had afforded low yields of II*b* and had generated mostly the acetoxynitrile (II*c*). While the latter had been converted into II*b*, the resultant circuitous route represented an extra obstacle in a large-scale preparation of the desired acid II*a*. However, this impediment now has been overcome by the discovery of the fact that the use of an excessive amount of palladium–charcoal catalyst in the hydrogenation of III*a* changed the ratio of the products II*b* and II*c* heavily in favor of the former.

When preliminary experiments corroborated the predicted resistance of the nitrile II*b* to hydrolysis, an alternate route for its conversion into the acid II*a* was investigated. It was reasoned that a controlled hydride reduction of the nitrile might lead to an aldimine whose acid hydrolysis to an aldehyde and subsequent oxidation would yield the desired acid. While lithium aluminum hydride reduction of nitriles is known to produce amines, reactions with lithium triethoxyaluminum hydride have been shown recently to stop at the imine stage and thus serve as a method of preparation of aldehydes (4). However, the steric environment of the nitrile function of II*b* seemed to preclude the need of a special hydride. As a consequence, II*b* was reduced with lithium aluminum hydride and the product hydrolyzed with aqueous acid (2). Permanganate oxidation of the resultant aldehyde (II*d*) yielded the acid II*a* (2).

The above nitrile reduction was shown recently to be of importance in the steroid field (5, 6) and in the synthesis of nimbiol (7). Extension of this reduction to the equatorial nitrile I*b* and the conformationally flexible cyano compound IV*a* led to the desired aldehydes, I*c* and IV*b*, respectively. However, in these cases only control over the amount of reducing agent or over the length of reaction time prevented the formation of appreciable quantities of amines (I*d* and IV*c*, respectively). The striking contrast in the reactivity of the nitriles was revealed most sharply in the aldehyde–amine ratios of products of reductions under identical conditions (refluxing of a tetrahydrofuran solution of the nitrile and three-quarters of a mole of lithium aluminum hydride for 1 hour) and work-up. The axial nitrile II*b* yielded a 10:1 ratio, while that for I*b* and IV*a* was 1:1. Nevertheless, carefully controlled reduction of dehydroabietonitrile (I*b*), followed by Wolff–Kishner reduction of the intermediate aldehyde (I*c*), has led to a high (70%) overall yield of dehydroabietane (I*e*).[3] Similarly, a Wolff–Kishner reduction of the aldehyde IV*b* afforded the hydrocarbon IV*d* needed in another study. When during preliminary experiments designed to produce IV*b* the lithium aluminum hydride reductions were carried out in ether and followed by mild acid hydrolyses, a weakly basic solid constituted the sole isolable product. While its full characterization proved not to be feasible, its infrared spectrum supported an imine structure. Since the mere mixing of aldehyde IV*b* and amine IV*c* in ether solution led to the same compound, it appears to be the aldimine derived

from these substances. This unusual result is reminiscent of a similar experience in the steroid field (5, 6).

In view of the recently aroused interest in the total synthesis of diterpene alkaloids (8–11) it is noteworthy that the readily obtainable compounds of structure II represent the absolute configuration of the natural bases. As a consequence, two substances have been converted into nitrogenous compounds which, in principle, are within one or two steps of construction of the all-important piperidine ring of the diterpene alkaloids. Treatment of desoxypodocarpic acid enantiomer (II*a*) with thionyl chloride and thereafter with hydrazine yielded II*e*. Irradiation of the acyl azide related to II*e* would be of interest (8, 11). Base hydrolysis of the ester II*c* yielded the hydroxynitrile II*f*. Treatment of the latter with nitrosyl chloride gave a nitrite (II*g*) whose Barton rearrangement (12) would be worthy of study.

Dehydroabietane Derivatives

In connection with our need for the dehydroabietane derivative I*f* the following chemical operations were performed. Chromic acid oxidation (1, 13, 14) of dehydroabietane (I*e*) yielded a mixture of ketoacetate V*a* and diketone V*b*. Wolff–Kishner reduction and simultaneous hydrolysis of the former produced the carbinol I*g*, whose alternate synthesis from the second oxidation product (V*b*) proceeded as follows. Treatment of the diketone with iodine and pyridine (14), followed by alkaline hydrolysis, gave a keto acid which was characterized as its methyl ester (V*c*) and which could be converted to the acid I*h* upon Wolff–Kishner reduction. Reaction of the methyl ester (I*i*) of the latter with methyl magnesium iodide yielded carbinol I*g*. Dehydration of the alcohol with phosphorous oxychloride transformed it into the olefin I*f*.

Ring-B Oxidized Derivatives of Dehydroabietic and Podocarpic Acids

(*a*) As part of their proof of the structures of the products of aluminum-chloride-induced deisopropylation of dehydroabietic acid Ohta and Ohmori (15) converted the substances into ketone III*b* and its antipode (VI*a*). These compounds were of interest since they seemed to offer a reasonable opportunity of entry into the unsubstituted ring A of the diterpene system. An alternate method of preparation was devised. 5-Iso-7-ketodesoxypodocarponitrile enantiomer (IV*e*) (3) and methyl O-acetyl-7-ketopodocarpate (V*d*), prepared by the chromic acid oxidation (3) of methyl O-acetylpodocarpate (I*j*) (16), served as model compounds.

Compounds IV*e* and V*d* were exposed to selenium dioxide oxidation, a reaction which has been shown recently to convert 7-keto compounds to their 5,6-dehydro derivatives (1, 17). While the A/B cis compound (IV*e*) yielded a mixture of unsaturated ketone

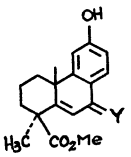
VI*a*, R = Y = H
b, R = CO_2Me, Y = OAc
c, R = CO_2Me, Y = H
d, R = CO_2Me, Y = OH
e, R = H, Y = OH
f, R = CO_2Me, Y = OMe

(III*c*) and α-diketone (IV*f*) (3), the trans system (V*d*) gave only the desired unsaturated ketone (VI*b*). This result is reminiscent of the difference of reactivity of stereochemically diverse diterpenic structures toward chromic acid oxidation (3). The low yield of III*c* and its lack of reaction in a subsequent attempt of hydrolysis of its cyano group led to the abandonment of this representative of the podocarpic acid enantiomer series in favor of its ester (III*d*), previously prepared by Ohta (15). Conversely, success in the podocarpic series led to the application of the method of oxidation to methyl 7-ketodesoxypodocarpate (V*e*) (3). This yielded the unsaturated ketone VI*c*, the antipode of III*d*. Whereas the latter had been converted to III*b* by alkali treatment, it was of interest to ascertain whether esters of this type are susceptible to dealkylation and thereafter to decarboxylation by the elegant new procedure of demethylation of methyl esters by lithium iodide – collidine treatment (18, 19). Indeed, exposure of III*d*, VI*c*, and VI*d* (*vide infra*) to these reagents yielded decarbomethoxylated products III*b*, VI*a*, and VI*e*, respectively.

(*b*) While the catalytic hydrogenation of 5,6-dehydro derivatives of dehydroabietic acid has led consistently to A/B trans compounds (20), little is known about the steric course of hydrogenation of similarly constituted podocarpic acid derivatives. For this reason the hydrogenation of VI*d* and its 7-desoxy derivative (VII*a*) came under scrutiny. The latter was synthesized from the former compound. The unsaturated ketone VI*d* was converted into its ethylene thioketal (VII*b*) by standard means. While Raney-nickel-induced desulphurization of the latter led to methyl podocarpate (I*k*), its treatment with deactivated Raney nickel yielded the desired 5,6-dehydro product VII*a*. Unfortunately this substance was exceedingly air-sensitive and could not be fully characterized. Hydrogenation of VI*d* and VII*a* produced the A/B trans methyl podocarpate (I*k*).



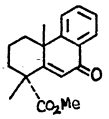
VII*a*, Y = H_2
b, Y = $(SCH_2)_2$

(*c*) Incidental observations during our studies of the chemistry of dehydroabietic and podocarpic acids over the span of several years have suggested that the rates of saponification of their difficultly hydrolyzable esters were affected by ring B substituents. While sterically properly oriented C(5) or C(6) substituents could be expected to exert some influence on the reactivity of the proximate (C4)-carboxylic esters, little effect would be predicted from C(7) substituents in rigid A/B trans ring systems. Since, as a consequence, the C(7) derivatives appeared as the most interesting compounds, it was decided to set

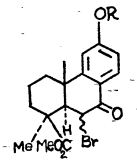
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

up a qualitative, comparative study of the speed of alkaline hydrolysis of four representative substances—methyl dehydroabietate (I*l*), its 7-keto derivative (V*f*), methyl desoxypodocarpate (I*m*), and its 7-keto compound (V*e*). Solutions of 80 mg of each of these esters and 0.6 ml of 10% potassium hydroxide in 4 ml of ethylene glycol were refluxed for 4 hours. After standard work-up the acid products as well as the unreacted neutral esters were identified by their characteristic infrared spectra. While 49% of methyl dehydroabietate (I*l*) had undergone hydrolysis (100% total recovery), its 7-keto compound (V*f*) was hydrolyzed in 99% yield (93% total recovery). Similarly, whereas methyl desoxypodocarpate (I*m*) was converted to its acid in only 5% of yield (100% total recovery), its 7-keto derivative (V*e*) was transformed to 22% acid (94% total recovery). Thus it appears that the 7-keto function has a striking effect on the reactivity of C(4) esters. This long-range phenomenon represents an example of conformational transmission, an effect investigated recently by Barton (21).

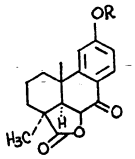
(*d*) Prior to our use of selenium dioxide oxidation as the last step of the preparation of 5,6-dehydro-7-keto compounds (VI) (*vide supra*) some of these substances had been synthesized by bromination of 7-keto compounds and base-induced dehydrobromination of the resultant 6-bromo-7-ketones. Thus Ohta and Ohmori (15) had prepared the unsaturated ketones III*d* and VIII by bromination of methyl 5-iso-7-ketodesoxypodocarpate enantiomer (IV*g*) and methyl 7-ketodeisopropyldehydroabietate (I*n*), respectively, and hydrogen bromide elimination of the bromoketones in pyridine solutions of silver nitrate, while we had synthesized a podocarpic acid derivative (VI) by a similar scheme but with the use of sodium methoxide as dehydrobromination agent. Since our results appeared inconsistent with the reported action of collidine on methyl 6-bromo-7-keto-O-methylpodocarpate (IX*a*) (22), a general study of the behavior of bromoketones in the podocarpic acid series toward bases was undertaken.



VIII



IX*a*, R = Me
b, R = OAc
c, R = OH



X*a*, R = Me
b, R = OAc
c, R = OH

Chromic acid oxidation of methyl O-methylpodocarpate (I*o*) and methyl O-acetylpodocarpate (I*j*) yielded the 7-keto compounds V*g* (22) and V*d*, respectively. Mild acid or base treatments or, to some extent, even absorption chromatography of the acetates V*d* and IX*b* produced the phenols V*h* and IX*c*, respectively. Bromination of the ketones led to the 6-bromo derivatives IX*a* (22) and IX*b*, respectively. Sodium methoxide treatment of the bromoketones resulted in the formation of unsaturated ketones. Thus IX*a* was transformed into VI*f*, while IX*b* and IX*c* gave VI*d*. The two enones VI*d* and VI*f* were interrelated by the conversion of phenol VI*d* to compound VI*f* by alkylation with methyl sulphate and base. Collidine treatment of the bromoketones led to mixtures of unsaturated ketones and ketolactones. The bromo derivative IX*a* led to the lactone X*a*, as reported (22), as well as ketone VI*f*; compound IX*b* yielded X*b* and VI*b*; and bromoketophenol IX*c* gave VI*d* and an oily lactone (X*c*) which on acetylation afforded crystalline acetate X*b*.

Interpretation of the unusual dehydrobromination results depends on the stereochemistry of the bromoketones IX to some extent. While the orientation of the bromine atom in these compounds cannot be considered as fully established, all available evidence points to an α-configuration. An equatorial conformation and, hence, α-configuration are indicated by the spectral properties of the 7-keto function. The 17 cm^{-1} shift to higher frequency in the infrared carbonyl absorption of the bromo compound IX*b* as compared to the ketone (V*d*) and the bathochromic shift of only 5 mμ in the ultraviolet absorption maximum of IX*b* from that of V*d* are in agreement with the general understanding of the spectral behavior of equatorial α-bromoketones (23, 24) and with the properties of a recently described β-bromo-α-tetralone (25), a simple model of IX*b*. Finally, a priori consideration of the mode of formation of compounds of structure IX also is in favor of a 6α-bromo orientation. The customary axial approach of the brominating agent to the 6,7-enol would be expected to be highly unfavorable because of strong steric interference by the axial substituents at C(4) and C(10). Furthermore, while equatorial approach of the reacting species toward the enol is less favored normally because of insufficient π-orbital overlap in the transition state, it is reasonable in the present cases since only slight bond distortions would permit full overlap with the enols in the fairly planar rings B.

If a 6α-bromo configuration be assumed for all compounds IX, their sodium-methoxide-induced dehydrobrominations appear to take a cis course. While bimolecular cis elimination and ionization of the bromide followed by proton loss represent possible reaction paths, some type of inversion at C(6), permitting a trans elimination to take place, seems more likely. Three routes of inversion of the C(6) leaving group are apparent: (*a*) base-induced isomerization of C(6)—H; (*b*) methoxide attack on the 7-keto function and bromide displacement by the resultant hemiketal anion leading to a 7α-methoxy-6β,7β-epoxide (XI); (*c*) bromide displacement by the aromatic ring leading to a cyclopropanone intermediate (XII) (particularly in the case of compounds IX*b* and IX*c*). However, a fourth and most probable reaction path for the elimination is suggested by the conformation of lactones X in the collidine reactions. The transition state (XIII) of the first step of the lactonization requires the creation of a part bond between C(6) and the C(4) methyl ester's oxygen, oriented trans diaxially with respect to C(5)—H. Consequently, a merged nucleophilic substitution – elimination (23) can be envisaged wherein transition state XIII turns to elimination product VI or to displacement intermediate XIV, which, in turn, produces the lactones X by demethylation by the base or, conceivably, leads to VI by trans elimination.[4] The difference of the steric requirements of the bases for proton abstraction may be a major factor in the dissimilar behavior of sodium methoxide and collidine in the elimination reactions.

The possible aryl participation in the bromide extrusion process and the consequent intermediacy of XII in the reaction led to a search for the interesting Favorskii rearrangement product XV among the products of the reaction of IX*b* with sodium methoxide. Along with the aforementioned product VI*d* an oily substance could be isolated in less than 1% yield from large-scale reactions. While its infrared and ultraviolet spectra were in accord with structure XV, its lack of ready availability prevented its full characterization. Sodium methoxide treatment of the model substance XVI*a* yielded merely the non-Favorskii product XVI*b* (24, 25).

[4]*Part structures XIII and XIV depict the carbonyl oxygen of the methyl esters as the intramolecular nucleophile responsible for the bromide displacement. However, in the absence of more revealing data no preference of these structures over those portraying the involvement of the ether oxygen of the esters in the displacement can be made at this time.*

EXPERIMENTAL

All melting points were observed on a Kofler microscope hot-stage. Ultraviolet spectra were run on 95% ethanol solutions on a Cary model 12 spectrophotometer. Infrared spectra were taken on chloroform solutions, unless noted otherwise, on a Perkin–Elmer model 21 spectrophotometer. Optical rotations were measured on chloroform solutions, unless stated differently, in a O. C. Rudolph polarimeter.

Derivatives of Desoxypodocarpic Acid Enantiomer (IIa)

Chromic acid oxidation of 5-isodesoxypodocarponitrile enantiomer (IV*a*) according to our previous procedure (3) gave improved yields (up to 35%) of the 6,7-diketone IV*f*. A mixture of 2.36 g of its enolacetate (III*a*) prepared as previously (3), 1.2 ml of conc. sulphuric acid, and 1.6 g of 10% palladium–charcoal in 120 ml of ethyl acetate was shaken for 8 hours under 10 lb of hydrogen. Then the catalyst was filtered, the solvent evaporated, water added, and the mixture extracted with ether. The extract was washed with saturated sodium bicarbonate solution and with water and was dried over anhydrous magnesium sulphate. Evaporation of the solvent yielded 1.82 g of residue. Alumina chromatography of 3.20 g of the crude product from several hydrogenations and elution with hexane gave 2.05 g of desoxypodocarponitrile enantiomer (II*b*), m.p. 87–88° (3). Further elution with 4:1 hexane–ether yielded 455 mg of 6β-acetoxydesoxypodocarponitrile enantiomer (II*c*), m.p. 117–118° (3).

A mixture of 600 mg of II*b* and 65 mg of lithium aluminum hydride in 40 ml of anhydrous tetrahydrofuran was refluxed for 1 hour. Water was added and the solvent mixture removed under reduced pressure. A mixture of the residue and 30 ml of 10% hydrochloric acid was refluxed for 4 hours, then cooled and extracted with ether. The extract was washed with water, dried over magnesium sulphate, and evaporated. Crystallization of the residue, 549 mg, from methanol yielded pure desoxypodocarpal enantiomer (II*d*), m.p. 91–94°; $[\alpha]_D^{22}$ −86.1° (EtOH); μ (in CCl_4) 3.71 (w, C—H), 5.82 (s, C=O). Anal. Calc. for $C_{17}H_{22}O$: C, 84.25; H, 9.15. Found: C, 84.18; H, 8.69.

The aqueous solution from which the aldehyde had been extracted was made basic and extracted with ether. Drying of the extract over magnesium sulphate, evaporation and distillation of the residue, 52 mg, gave desoxypodocarpyl amine enantiomer (II*h*), b.p. ca. 95° at 0.7 mm; $[\alpha]_D^{22}$ −7.8° (*c*, 3.0, EtOH). Anal. Calc. for $C_{17}H_{25}N$: C, 83.89; H, 10.35; N, 5.76. Found: C, 83.63; H, 10.54; N, 6.04.

A solution of 325 mg of potassium permanganate in 15 ml of water was added with stirring over a 5-hour period to a solution of 500 mg of II*d* in 15 ml of acetone. After the addition of sodium sulphite for the destruction of the excess permanganate as well as aqueous hydrochloric acid the solution was extracted with ether. The organic solution was extracted with 10% sodium hydroxide solution, the aqueous solution acidified and extracted with ether once again. Drying (sodium sulphate) of the extract, evaporation of the solvent, and crystallization of the residue yielded 501 mg of acidic product. Recrystallization from aqueous methanol gave desoxypodocarpic acid enantiomer (II*a*), m.p. 194–195.5°; $[\alpha]_D^{24}$ −141.0° (EtOH);[5] μ (in CCl_4) 5.75 (s) and 5.89 (w) (both C=O). Anal. Calc for $C_{17}H_{22}O_2$: C, 79.03; H, 8.58. Found: C, 79.33; H, 8.62.

An ether solution of 42.5 mg of II*a* and excess diazomethane was left 1 hour at room temperature. Upon addition of acetic acid the solution was washed with 10% sodium carbonate solution and with water and was dried (sodium sulphate). Evaporation of the solvent gave 45.3 mg of solid which on crystallization from aqueous methanol yielded crystalline platelets of methyl desoxypodocarpate enantiomer (II*i*), m.p. 140–141°; $[\alpha]_D^{25}$ −149.4° (EtOH); μ (in CCl_4) 5.77 (s, C=O). Anal. Calc. for $C_{18}H_{24}O_2$: C, 79.37; H, 8.88. Found: C, 79.62; H, 9.13.

A solution of 50 mg of II*a*, 1 ml of thionyl chloride, and 2 drops of pyridine was left standing at room temperature for 2 hours. The solution was evaporated under reduced pressure, the residue dissolved in 10 ml of ether, and 0.3 ml of 95% hydrazine hydrate in 10 ml of absolute ethanol was added at 0°. The mixture was shaken for 5 minutes, poured into water, and extracted with ether. Drying (magnesium sulphate) of the extract and evaporation of the solvent yielded 52 mg of a solid, m.p. 162–168°. Crystallization from ethyl acetate and sublimation afforded desoxypodocarpic hydrazide enantiomer (II*e*), m.p. 169–170°; $[\alpha]_D^{22}$ −127.8° (*c*, 0.80, EtOH); μ 2.91 (m), 3.04 (w, NH), 6.03 (s), 6.16 (s, C=O). Anal. Calc. for $C_{17}H_{24}ON_2$: C, 74.96; H, 8.88; N, 10.29. Found: C, 74.77; H, 8.68; N, 10.26.

A solution of 1.00 g of 6β-acetoxypodocarponitrile enantiomer (II*c*) and 50 ml of 10% sodium hydroxide in 100 ml of ethanol was stirred for 19 hours at room temperature under nitrogen. The solvent was removed under reduced pressure, water was added, and the mixture extracted with ether. The extract was washed with water, dried (magnesium sulphate), and evaporated. Crystallization of the residue, 843 mg, from ethyl acetate – chloroform gave 6β-hydroxypodocarponitrile enantiomer (II*f*), m.p. 204–205°; $[\alpha]_D^{23}$ −32.1° (*c*, 1.11); μ (Nujol) 2.88 (m, OH), 4.51 (m, C≡N). Anal. Calc. for $C_{17}H_{21}ON$: C, 79.96; H, 8.29; N, 5.49. Found: C, 80.15; H, 8.44; N, 5.36.

Nitrosyl chloride gas was bubbled through a stirred solution of 100 mg of II*f* in 15 ml of dry pyridine at −20° to −30°. When the solution appeared to have a persistent reddish brown color, water was added and the crystalline precipitate filtered and washed with water. Crystallization of the solid, 108 mg, from methylene chloride – hexane yielded 6β-hydroxypodocarponitrile nitrite enantiomer (II*g*), m.p. 189–191°; $[\alpha]_D^{23}$ −26.6° (*c*, 1.07); μ (Nujol) 4.50 (w, C≡N), 6.06 (s, N=O). Anal. Calc. for $C_{17}H_{20}O_2N_2$: C, 71.80; H, 7.09; N, 9.85. Found: C, 72.09; H, 7.34; N, 10.03.

Derivatives of 5-Isodesoxypodocarponitrile Enantiomer (IVα*)*

A lithium aluminum hydride reduction of 600 mg of IV*a* and a follow-up acid treatment were carried out in exactly the manner described for II*b* (*vide supra*). The crude products were 277 mg of aldehyde and 291 mg of amine. Distillation gave 5-isodesoxypodocarpal enantiomer (IV*b*), b.p. 85° at 0.7 mm; $[\alpha]_D^{22}$ 1.8° (*c*, 1.60, EtOH); μ 3.70 (w, C—H), 5.82 (s, C=O). Anal. Calc. for $C_{17}H_{22}O$: C, 84.25; H, 9.40. Found: C, 83.78; H, 9.40.

Crystallization of its 2,4-dinitrophenylhydrazone from ethanol gave needles, m.p. 203–204°. Anal. Calc. for $C_{23}H_{26}O_4N_4$: C, 65.38; H, 6.20; N, 13.26. Found: C, 65.56; H, 6.19; N, 13.13.

Crystallization of the basic product of the hydride reduction from ether yielded 5-isodesoxypodocarpyl amine (IV*c*), m.p. 80–81°; $[\alpha]_D^{22}$ 3.4° (*c*, 1.33, EtOH); μ 2.90 (m, NH). Anal. Calc. for $C_{17}H_{25}N$: C, 83.89; H, 10.35; N, 5.76. Found: C, 83.88; H, 10.52; N, 5.63.

A mixture of 502 mg of IV*a* and 25 mg of lithium aluminum hydride in 20 ml of ether was stirred at room temperature for 20 minutes. Water was added cautiously until hydrogen evolution had ceased and concentrated hydrochloric acid was added until the mixture was of pH < 1. After vigorous stirring for 20 minutes the ether layer was removed and the aqueous solution extracted three times with ether. The combined extracts were washed with 10% hydrochloric acid solution and with water and dried (magnesium sulphate). Solvent removal, chromatography of the crystalline residue (181 mg) on 3 g of silica, and elution with 9:1 hexane–ether yielded 150 mg of starting nitrile (IV*a*). Further elution gave only 24 mg of a mixture which was not investigated any further. The aqueous acid solution of reaction products was basified and extracted with ether. The extract was washed with minimum amounts of water, dried (magnesium sulphate), and evaporated. Upon standing, the residual oil, 297 mg, turned partly crystalline. Washing with small quantities

[5]*The optical rotation of desoxypodocarpic acid (I, R = CO_2H, R′ = Me, R″ = Y = H), the antipode of II*a*, has been recorded (16) erroneously as 40.8° (EtOH). It actually was observed as 140.8°.*

For personal use only.

of cold ether and ether–hexane mixtures freed the crystals from surrounding oil. Crystallization of the solid from ether, in which it was quite soluble, gave a crystalline product, m.p. 136–140° (moistening at 127°); μ (Nujol) no OH, NH, CN, or CHO absorption bands, 6.02 (s, C=N). Standing out of contact with ether changed the crystalline imine to an oil, while crystallization from methanol or aqueous methanol led to gels. Gradient elution chromatography of 110 mg of the compound on 3 g of silica (250 ml of solvent changing from hexane to 1:1 hexane–ether, collected in 20-ml fractions) converted the imine to 50 mg of IV*b* and 48 mg of IV*c*. A mixture of 14 mg of aldehyde IV*b* and 14 mg of amine IV*c* was heated on a steam bath for 3 minutes and then triturated with ether and left standing for 18 hours. Evaporation of the solvent and seeding with a crystal of imine led to 17 mg of crystalline solid. Additional quantities of product were obtained upon washing of the residual oil with ether and hexane. The product had an infrared spectrum (Nujol) identical with that of the above imine.

A solution of 216 mg of IV*b* and 3 ml of hydrazine in 5 ml of anhydrous ethylene glycol was heated at 140° for 1 hour. Potassium hydroxide pellets, 2 g, were added to the cooled solution, whereupon the mixture was kept at 200° for 4 hours. Water was added and the mixture extracted with ether. The extract was washed with 10% hydrochloric acid and with water and dried (magnesium sulphate). Evaporation of the solvent and distillation of the oily residue, 153 mg, yielded 5-isodesoxypodocarpane enantiomer (IV*d*), b.p. 70° at 0.7 mm, m.p. 47–50° (lit. (15) m.p. 53–54°). Anal. Calc. for $C_{17}H_{24}$: C, 89.41; H, 10.59. Found: C, 89.48; H, 10.61.

Derivatives of Dehydroabietane (Ie)

Exposure of a tetrahydrofuran solution of 600 mg of dehydroabietonitrile (I*b*) to lithium aluminum hydride reduction in the manner described above yielded 262 mg of dehydroabietal (I*c*), m.p. 90–91° (lit. (7, 26) oil), and 317 mg of dehydroabietyl amine (I*d*), b.p. ca. 130° at 2.5 mm (lit. (27) b.p. ca. 250° at 12 mm, m.p. 41°).

Lithium aluminum hydride, 1.25 g, was added in small portions over a period of 2 minutes to a stirred cold solution of 25.0 g of nitrile I*b* in 250 ml of ether. After the mixture had been stirred for 10 minutes, during which time a white precipitate had formed, the excess hydride was decomposed by the dropwise addition of water, 50 ml of 5% hydrochloric acid solution was added and then enough concentrated hydrochloric acid was added until the mixture was acidic. Thereupon the mixture was stirred for a half hour, the layers separated, and the ether solution washed with 5% hydrochloric acid and with water and dried over magnesium sulphate. Evaporation of the solvent gave 24.9 g of oily aldehyde (I*c*). A mixture of the latter and 100 g of 95% hydrazine in 300 ml of diethylene glycol was refluxed for 6 hours. Excess hydrazine was removed by distillation when the solution was heated up to 200°. After 150 g of potassium hydroxide had been dissolved in the cooled solution, the mixture was refluxed for 3 hours. One liter of water was added and the mixture extracted with ether. The extract was washed with water, dried (magnesium sulphate), and evaporated. A hexane (100 ml) solution of the residual oil, 22.0 g, was passed through 100 g of alumina and eluted with 500 ml of hexane. Evaporation of the eluates yielded 17.4 g of dehydroabietane (I*e*), m.p. 38–42° (lit. (26) m.p. 41–44°), which required no further purification for the subsequent reactions.

Chromium trioxide, 15 g, was added over a 7-hour period to a solution of 10 g of dehydroabietane in 100 ml of acetic acid and 80 ml of acetic anhydride kept at 20–25°. After being stirred at room temperature for 18 hours the mixture was poured onto 320 g of ice and 8 g of sodium acetate and stirred for 2 hours. The preciptated gum as well as the decanted solution were extracted with ether and the combined extracts washed with water and dried (magnesium sulphate). Evaporation of the solvent, chromatography of the residue on alumina and elution with hexane yielded 6.7 g of non-crystalline ketoacetate V*a* (μ 5.78 (s), 5.95 (s, C=O)). Elution with 9:1 hexane–benzene gave 2.4 g of an oil which crystallized on standing. Crystallization from methanol yielded 7-keto-13-acetyldeisopropyldehydroabietane (V*b*), m.p. 143–145°; $[\alpha]_D^{25}$ 31.8° (*c*, 1.33); μ 5.95 (s, C=O). Anal. Calc. for $C_{19}H_{24}O_2$: C, 80.24; H, 8.51. Found: C, 80.22; H, 8.16.

A solution of 4.0 g of the ketoacetate V*a* and 50 ml of hydrazine in 100 ml of diethylene glycol was heated at 100° for 1.5 hours. After 30 g of potassium hydroxide had been added to the cooled solution, the mixture was heated to 200° and then refluxed for 4 hours. Water was added to the cooled solution and the latter extracted with ether. The extract was washed with water and with dilute hydrochloric acid and dried (magnesium sulphate). Evaporation gave 3.2 g of an oil which crystallized on trituration with hexane. Crystallization from hexane afforded the carbinol I*g*, m.p. 99–100°; $[\alpha]_D^{27}$ 52.5° (*c*, 1.70). Anal. Calc. for $C_{20}H_{30}O$: C, 83.86; H, 10.56. Found: C, 83.69; H, 10.47.

A solution of 5.0 g of diketone V*b* and 4.5 g of iodine in 100 ml of pyridine was refluxed for 3 hours and left standing for 18 hours. Water was added and the mixture extracted with chloroform. The extract was washed with 2 *N* hydrochloric acid and saturated brine solution. The solvent was evaporated, 45 ml of 10% sodium hydroxide solution and 100 ml of ethanol were added to the residue, and the mixture was refluxed for 3 hours. Much of the ethanol was distilled and the solution made acidic and extracted with ether. The extract was washed, dried (magnesium sulphate), and evaporated. Crystallization of the residue, 3.2 g, from methanol and sublimation yielded a keto acid, m.p. 222–223°; $[\alpha]_D^{23}$ 41.0° (*c*, 0.21). Anal. Calc. for $C_{18}H_{22}O_3$: C, 75.49; H, 7.74. Found: C, 75.39; H, 7.48.

Diazomethane treatment of 100 mg of this keto acid in 10 ml of ether led to 100 mg of product. Crystallization of the latter from methanol yielded 7-keto-13-carbomethoxydeisopropyldehydroabietane (V*c*), m.p. 105–107°; $[\alpha]_D^{23}$ 10.7° (*c*, 1.08); μ 5.81 (s), 5.95 (s, C=O), 6.21 (s, C=C).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Wolff–Kishner reduction of the keto acid was carried out in the manner described above. Sublimation of the product gave acid I*h*, m.p. 215–218° (softening at 113–115°); $[\alpha]_D^{23}$ 25.9° (*c*, 0.39); μ 5.82 (s, C=O). Diazomethane treatment of this acid and sublimation of the product yielded 13-carbomethoxydeisopropyldehydroabietane (I*i*), m.p. 110–111°; $[\alpha]_D^{23}$ 56.4° (*c*, 1.35). Anal. Calc. for $C_{19}H_{26}O_2$: C, 79.68; H, 9.15. Found: C, 79.40; H, 9.29.

The ester I*i*, 25 mg, was dissolved in a Grignard solution, prepared from 85 mg of magnesium and 0.5 ml of methyl iodide in 50 ml of tetrahydrofuran and the mixture refluxed for 4 hours. Aqueous ammonium chloride was added and the mixture extracted with ether. The extract was dried (magnesium sulphate) and evaporated. Crystallization of the residue from hexane yielded the carbinol I*g*, m.p., m.m.p. 99–100°; infrared spectrum identical with that of an authentic sample (*vide supra*).

A solution of 1.6 g of alcohol I*g* and 2 ml of phosphorous oxychloride in 15 ml of dry pyridine was left standing for 18 hours. Water was added and the solution acidified with dilute hydrochloric acid and extracted with ether. The extract was washed with water and saturated brine solution and dried over magnesium sulphate. Evaporation left 0.65 g of an oil whose passage through alumina and distillation yielded the olefin I*f*, b.p. 105° at 3 mm. Anal. Calc. for $C_{20}H_{28}$: C, 89.49; H, 10.51. Found: C, 89.54; H, 10.45.

Unsaturated Ketones III, VIa, VIc, and VIe

A solution of 400 mg of 5-iso-7-ketodesoxypodocarponitrile enantiomer (IV*e*) (3) and 1.50 g of freshly sublimed selenium dioxide in 35 ml of acetic acid and 5 ml of water was refluxed for 2 hours. After filtration through Celite and removal of the solvent under reduced pressure water was added and the mixture extracted with ether. The extract was dried (magnesium sulphate) and evaporated. Addition of hexane–benzene yielded 97 mg of yellow crystals identical in all respects with authentic 5-iso-6,7-diketodesoxypodocarponitrile enantiomer (IV*f*) (3). Chromatography of the mother liquor on alumina and elution with 9:1 hexane–ether gave 150 mg of crystalline solid whose crystallization from benzene–hexane and sublimation yielded 5,6-dehydro-7-ketodesoxypodocarponitrile enantiomer (III*c*), m.p. 213–214°; $[\alpha]_D^{23}$ −112.9° (*c*, 1.24); μ 4.49 (w, C≡N), 6.03 (s, C=O), 6.23 (m, C=C). Anal. Calc. for $C_{17}H_{17}ON$: C, 81.24; H, 6.82; N, 5.57. Found: C, 81.20; H, 6.90; N, 5.50.

A similar oxidation of 2.8 g of V*e* (3) with 5.0 g of selenium dioxide, 80 ml of acetic acid, and water for 6 hours yielded 2.8 g of solid product whose crystallization from methanol yielded methyl 5,6-dehydro-7-ketodesoxypodocarpate (VI*c*), m.p. 146–147° (lit. (15), its optical antipode, m.p. 147–148°); $[\alpha]_D^{23}$ 164.9° (*c*, 0.69); μ 5.81 (s), 6.03 (s, C=O), 6.24 (m, C=C). Anal. Calc. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 75.76; H, 7.21.

Oxidation of 12.0 g of I*j* (16) with 14.0 g of chromic acid in 210 ml of acetic acid and 50 ml of water according to a published procedure (3) led to an oil whose benzene solution was passed through an alumina column (slow chromatography led to partly deacetylated product). Evaporation of the filtrate and crystallizations of the residue, 12.9 g, from hexane–benzene and aqueous methanol yielded methyl *O*-acetyl-7-ketopodocarpate (V*d*), m.p. 132–136°; $[\alpha]_D^{25}$ 70.0°; μ 5.68 (s), 5.81 (s), 5.96 (s, C=O), 6.23 (m, C=C); λ_{max} 255 mμ (log ϵ 4.22), λ_{min} 227 mμ (log ϵ 3.88). Anal. Calc. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.39; H, 6.97.

Oxidation of 200 mg of V*d* with 680 mg of selenium dioxide in 20 ml of acetic acid in the manner described above yielded an oil which on crystallization from aqueous methanol gave 130 mg of solid, m.p. 130–144°. Several recrystallizations from aqueous methanol afforded methyl O-acetyl-5,6-dehydro-7-ketopodocarpate (VI*b*), m.p. 143–146°; $[\alpha]_D^{25}$ 147°; μ 5.68 (s), 6.03 (s, C=O), 6.23 (m, C=C); λ_{max} 255 mμ (log ϵ 4.20), $\lambda_{shoulder}$ 274 mμ (log ϵ 4.10), λ_{min} 222 mμ (log ϵ 3.90). Anal. Calc. for $C_{20}H_{22}O_5$: C, 70.20; H, 6.44. Found: C, 70.22; H, 6.52.

A solution of 2.00 g of VI*c* and 5 g of anhydrous lithium iodide in 60 ml of dry collidine was refluxed for 10 hours under nitrogen. Water was added to the cooled solution and the latter extracted with ether. The extract was washed with 10% hydrochloric acid and with water and dried over magnesium sulphate. Removal of the solvent under reduced pressure left 1.59 g of solid which on sublimation afforded ketone VI*a*, m.p. 119–120° (lit. (15) m.p. 120–121°); $[\alpha]_D^{23}$ 54.7° (*c*, 0.51). Anal. Calc. for $C_{16}H_{18}O$: C, 84.91; H, 8.02. Found: C, 85.19; H, 8.43.

Similar decarbomethoxylation of III*d* (15), the optical antipode of VI*c*, yielded III*b* (15), m.p. 119–120°, the enantiomer of VI*a*.

Similar treatment of 790 mg of VI*d* (*vide infra*) produced a brown solid, the passage of whose chloroform–methanol solution through an alumina column gave 200 mg of pale yellow crystals. Several crystallizations from aqueous methanol and sublimation yielded colorless platelets of ketone VI*e*, m.p. 234–237° (change to needles at 200°); $[\alpha]_D^{25}$ 115.0°; μ 3.10 (m, broad, OH), 6.08 (s, C=O), 6.28 (m), 6.35 (m, C=C); λ_{max} at 242 mμ and 301 mμ. Anal. Calc. for $C_{16}H_{18}O_2$: C, 79.35; H, 7.44. Found: C, 79.05; H, 7.96.

Hydrogenation of Compounds VII

A mixture of 300 mg of ketoester IV*d* in 6 ml of glacial acetic acid and 0.3 ml of ethanedithiol in 0.6 ml of boron trifluoride etherate was left standing at room temperature for 48 hours. Then water was added and the precipitated solid, 272 mg, m.p. 234–239°, crystallized several times from aqueous methanol. This yielded the ketal VII*b*, m.p. 237–241° (decomp.); $[\alpha]_D^{20}$ 128.5°; μ 2.80 (w), 3.02 (w, broad, OH), 5.82 (s, C=O), 6.05 (w), 6.18 (m), 6.22 (m, C=C); $\lambda_{shoulder}$ 231 mμ (log ϵ 4.35) and 282 mμ (log ϵ 3.74). Anal. Calc. for $C_{20}H_{24}O_3S_2$: C, 63.79; H, 6.38. Found: C, 63.39; H, 6.34.

A mixture of 19 mg of the ketal VII*b* and 0.2 g of W-2 Raney nickel in 4 ml of absolute ethanol was refluxed for 6 hours. The solvent was removed under vacuum, the residue extracted with chloroform, and the extract dried over sodium sulphate. Evaporation of the solvent and two crystallizations of the crystalline solid from aqueous methanol yielded methyl podocarpate (I*k*), m.p., m.m.p. 209–211°; infrared spectrum identical with that of an authentic sample.

A mixture of 59 mg of thioketal VII*b* and 0.6 g of W-2 Raney nickel in 10 ml of acetone was refluxed for 2 hours. The catalyst was filtered through Celite and the filtrate evaporated under reduced pressure. The yellow residual oil was unstable to air, changing to a deep red liquid, and resisted all attempts at crystallization. Presumably VIII*a*, μ 2.80 (w), 3.00 (w, broad, OH), 5.82 (s, C=O), 6.10 (w), 6.23 (m, C=C); $\lambda_{shoulder}$ 231 mμ (log ϵ 4.34), 256 mμ (log ϵ 4.10), 280 mμ (log ϵ 3.91), it was used for subsequent reduction without further purification. The difference of these spectral data as well as $[\alpha]_D^{25}$ 108° from the physical constants of the $\Delta^{6,7}$ derivative of methyl podocarpate (m.p. 172–176°; $[\alpha]_D^{20}$ −75°; μ 2.78 (w), 2.97 (w, broad, OH), 5.82 (s, C=O), 6.23 (m), 6.36 (w, C=C); λ_{max} 270 mμ (log ϵ 4.30), λ_{min} 241 mμ (log ϵ 3.94)) (24) showed the oil to be the $\Delta^{5,6}$ derivative (VII*a*) (cf. also the difference between the physical data for ferruginol and its $\Delta^{6,7}$ derivative (28)). The oil was hydrogenated (2 drops of conc. sulphuric acid and 10 mg of palladium–charcoal in 5 ml of ethyl acetate). The reaction ceased after a ca. 1 mole hydrogen uptake and the yellow color had disappeared. The catalyst was filtered and the solution washed with 5% sodium bicarbonate and saturated brine solution and dried over sodium sulphate. Evaporation of the solvent yielded 40 mg of methyl podocarpate (I*k*), m.p., m.m.p. 207–209° after crystallization from aqueous methanol; infrared and ultraviolet spectra identical with those of an authentic sample. A similar hydrogenation of 76 mg of VI*d* (50 mg of palladium–charcoal and 8 ml of ethanol) yielded 61 mg of methyl podocarpate (I*k*).

Bromoketones IX

Chromic acid oxidation of 1.00 g of methyl O-methylpodocarpate (I*o*) according to the procedure of the Bible patent (22) yielded 906 mg of crystalline product, m.p. 117–123°. Crystallization from aqueous ethanol gave methyl O-methyl-7-ketopodocarpate (V*g*), m.p. 121–123° (crystal change at 108–110°); $[\alpha]_D^{25}$ 79°; μ 5.84 (s), 6.03 (s, C=O), 6.28 (s), 6.40 (s, C=C); λ_{max} 226 mμ (log ϵ 4.42), 276 mμ (log ϵ 4.32), λ_{min} 243 mμ (log ϵ 3.89). Anal. Calc. for $C_{19}H_{24}O_4$: C, 72.15; H, 7.60. Found: C, 72.36; H, 7.60.

Bromination of 732 mg of V*g* according to the procedure in the Bible patent (22) produced 861 mg of solid, m.p. 118–122°, whose crystallization from aqueous methanol yielded methyl 6-bromo-7-keto-O-methylpodocarpate (IX*a*), m.p. 123–126°; $[\alpha]_D^{25}$ 87°; μ 5.80 (s), 5.97 (s, C=O), 6.25 (s), 6.35 (m, C=C); λ_{max} 231 mμ (log ϵ 4.49), 291 mμ (log ϵ 4.18).

Chromic acid oxidation of 12.0 g of methyl O-acetylpodocarpate (I*j*) by our previous general procedure (3) yielded a crude product whose benzene solution was passed rapidly through an alumina column and then evaporated. Crystallization of the residual solid, 12.9 g, from aqueous methanol and benzene–hexane yielded methyl O-acetyl-7-ketopodocarpate (V*d*), m.p. 136–138°; $[\alpha]_D^{25}$ 70°; μ 5.69 (s), 5.83 (s), 5.98 (s, C=O), 6.25 (m), 6.35 (w, C=C); λ_{max} 225 mμ (log ϵ 4.20), λ_{min} 228 mμ (log ϵ 3.89). Anal. Calc. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.93; H, 7.01.

Slower chromatography of the reaction mixture of the oxidation or the following hydrolysis procedure led to ketophenol V*h*. A solution of 100 mg of the diester V*d*, 10 ml of 5% sodium hydroxide solution, and 1 ml of ethanol was stirred at room temperature for 3 hours. After the addition of 10 ml of saturated brine solution and enough conc. hydrochloric acid to bring the solution to pH 2 the latter was extracted with chloroform. The extract was washed with brine solution and dried over magnesium sulphate. Evaporation of the solvent and crystallization of the residual oil from aqueous methanol yielded 75 mg of solid, m.p. 220–238°. Recrystallizations afforded methyl 7-ketopodocarpate (V*h*), m.p. 237–241°; $[\alpha]_D^{25}$ 53°; μ 2.79 (w), 3.05 (m, broad, OH), 5.82 (s), 6.01 (s, C=O), 6.22 (s), 6.27 (s), 6.35 (s, C=C); λ_{max} 229 mμ; (log ϵ 4.52), 282 mμ (log ϵ 4.32), λ_{min} 245 mμ (log ϵ 4.12). Anal. Calc. for $C_{18}H_{22}O_4$: C, 71.52; H, 7.28. Found: C, 71.23; H, 7.20.

A solution of 2.9 g of bromine in 10 ml of glacial acetic acid was added dropwise to a stirred solution of 2.00 g of the diester V*d* and 2 drops of 15% hydrobromic acid in 10 ml of glacial acetic acid. The mixture was maintained at room temperature for 10 minutes and then evaporated under reduced pressure. Crystallization of the residual oil from methanol produced 1.97 g of solid, m.p. 120–125°, whose recrystallizations led to methyl 6-bromo-7-keto-O-acetylpodocarpate (IX*b*), m.p. 130–132°; $[\alpha]_D^{25}$ 59°; μ 5.69 (s), 5.82 (s), 5.92 (s, C=O), 6.24 (s), 6.35 (w, C=C); λ_{max} 260 mμ (log ϵ 3.92), λ_{min} 236 mμ (log ϵ 3.70). Anal. Calc. for $C_{20}H_{23}O_5Br$: C, 56.74; H, 5.48; Br, 18.88. Found: C, 57.11; H, 5.67; Br, 18.65.

A solution of 200 mg of the diester IX*b* in 5 ml of absolute ethanol, into which dry hydrogen chloride gas had been bubbled, was refluxed for 2 hours, and then evaporated under reduced pressure. Crystallization of the residue from aqueous methanol yielded 158 mg of solid, m.p. 193–200° (decomp.), whose recrystallization from methanol afforded methyl 6-bromo-7-ketopodocarpate (IX*c*), m.p. 200–204° (decomp.); $[\alpha]_D^{25}$ 61°; μ 2.80 (w), 2.08 (w, broad, OH), 5.82 (s), 5.96 (s, C=O), 6.22 (s), 6.26 (s), 6.35 (s, C=C); λ_{max} 234 mμ (log ϵ 3.91), 300 mμ (log ϵ 4.01), λ_{min} 254 mμ (log ϵ 3.14). Anal. Calc. for $C_{18}H_{21}O_4Br$: C, 56.71; H, 5.51. Found: C, 56.46; H, 5.72.

The same bromo compound was the product, 380 mg, of the reaction of a solution of 435 mg of IX*b* in 10 ml of conc. sulphuric acid for 4 hours at room temperature. Furthermore, it was the product, 265 mg, of the reaction of 500 mg of IX*b* in 5 ml of absolute methanol with sodium methoxide, 35 mg of sodium in 5 ml of absolute methanol, for 1 minute.

Unsaturated Ketones VIb, VId, and VIf

A solution of 3.00 g of bromoketone IX*b* in 10 ml of anhydrous methanol, in which 0.38 g of sodium had been dissolved, was refluxed for 5 hours. After the addition of 30 ml of saturated brine solution and 1.5 ml of conc. hydrochloric acid the mixture was extracted with chloroform. The extract was washed with saturated brine, dried over sodium sulphate, and evaporated. Crystallization of the residue from aqueous methanol gave 1.90 g of a solid, m.p. 205–215°, whose recrystallizations and sublimation led to methyl 5,6-dehydro-7-ketopodocarpate (VI*d*), m.p. 223–224°; $[\alpha]_D^{25}$ 143°; μ 2.85 (w), 3.15 (w, broad, OH), 5.82 (s), 6.12 (s, C=O), 6.31 (s), 6.39 (s, C=C); λ_{max} 242 mμ (log ϵ 4.27), 308 mμ (log ϵ 4.10), λ_{min} 269 mμ (log ϵ 3.60). Anal. Calc. for $C_{18}H_{20}O_4$: C, 71.98; H, 6.71. Found: C, 72.00; H, 6.67.

A solution of 200 mg of phenol VI*d* and 100 mg of sodium acetate in 5 ml of acetic anhydride was refluxed for 2 hours. The solution was concentrated under reduced pressure, 10 ml of water was added, and the mixture extracted with chloroform. The extract was washed with water, dried over sodium sulphate, and evaporated. Crystallization of the residue from aqueous methanol gave 211 mg of solid, m.p. 143–146°, whose recrystallization afforded methyl 5,6-dehydro-7-keto-O-acetylpodocarpate (VI*b*), m.p. 143–146°; $[\alpha]_D^{25}$ 147°; μ 5.70 (s), 5.81 (s), 6.06 (s, C=O), 6.24 (s, C=C); λ_{max} 255 mμ (log ϵ 4.20), $\lambda_{shoulder}$ 273 mμ (log ϵ 4.10), λ_{min} 222 mμ (log ϵ 3.90). Anal. Calc. for $C_{20}H_{22}O_5$: C, 70.20; H, 6.44. Found: 70.22; H, 6.52.

A solution of 200 mg of the phenol VI*d*, 0.1 ml of dimethyl sulphate, and 52 mg of sodium hydroxide in 3 ml of 50% aqueous ethanol was heated at 120° for 20 minutes. Water was added and the mixture extracted with ether. The extract was dried over magnesium sulphate and evaporated. The residue, 89 mg, was crystallized from benzene–hexane. Recrystallization of the product, m.p. 169–174°, and sublimation led to methyl 5,6-dehydro-7-keto-O-methylpodocarpate (VI*f*), m.p. 173–175°; $[\alpha]_D^{25}$ 153°; μ 5.80 (s), 6.08 (s, C=O), 6.25 (s), 6.35 (w, C=C); λ_{max} 235 mμ (log ϵ 4.45), 302 mμ (log ϵ 4.18), λ_{min} 270 mμ (log ϵ 4.01). Anal. Calc. for $C_{19}H_{22}O_4$: C, 72.50; H, 7.01. Found: C, 72.63; H, 7.11.

When a reaction between 261 mg of bromoketone IX*a* and sodium methoxide (20 mg of sodium in 5 ml of absolute methanol) was carried out and worked up in the manner described for the dehydrobromination of IX*b* (*vide supra*), there was produced 175 mg of crystallized product, m.p. 170–175°, whose recrystallization from aqueous methanol led to VI*f*, m.p. 173–175°, undifferentiable from the sample above.

Lactones X

A solution of 396 mg of bromoketone IX*b* in 3 ml of collidine was refluxed for 2 hours. Water, 14 ml, and conc. hydrochloric acid (up to pH 2) were added and the mixture extracted with chloroform. The extract was washed with saturated brine solution, dried over sodium sulphate, and evaporated. The residual oil, 383 mg, was chromatographed on a 4:1 Bentonite–Celite (6 g) column. Elution with carbon tetrachloride – benzene yielded 169 mg of solid whose crystallization from aqueous methanol led to VI*b*, m.p., m.m.p. 141–145°; spectra identical with those of the above sample. Further elution with benzene–chloroform gave 131 mg of solid whose crystallizations from aqueous methanol resulted in needles of 6β-hydroxy-7-keto-O-acetylpodocarpic lactone (X*b*), m.p. 161–164°; $[\alpha]_D^{25}$ 84°; μ 5.60 (s), 5.90 (s, C=O), 6.24 (s, C=C); λ_{max} 260 mμ (log ϵ 4.00), λ_{min} 232 mμ (log ϵ 3.29). Anal. Calc. for $C_{19}H_{20}O_5$: C, 69.51; H, 6.10. Found: C, 69.63; H, 6.50.

Treatment of 265 mg of bromoketone IX*c* in identical manner, chromatography of the oily reaction product, 250 mg, and elution with carbon tetrachloride – benzene, benzene, and benzene–chloroform yielded 80 mg of crude VI*d*, while elution with 2:1 benzene–chloroform and chloroform gave 150 mg of oily lactone X*c* (μ, 2.80 (w), 3.05 (w, broad, OH), 5.60 (s), 5.92 (s, C=O), 6.25 (s), 6.35 (m, C=C); λ_{max} 233 mμ (log ϵ 3.94), 299 mμ (log ϵ 4.10), λ_{min} 250 mμ (log ϵ 2.75)) which could not be induced to crystallize. Acetylation of the latter with acetic anhydride and sodium acetate afforded crystalline lactone acetate X*b*, m.p., m.m.p. 161–164°; spectra identical with those of the above sample.

Treatment of 310 mg of bromoketone IX*a* in the same manner and elution of a chromatogram of the reaction products with carbon tetrachloride and with chloroform yielded 110 mg of a solid whose crystallization from aqueous methanol afforded keto ester VI*f*, m.p., m.m.p. 171–173°; spectra identical with those of the above sample. The later chloroform eluates contained 110 mg of a solid whose crystallizations from aqueous methanol gave methyl 6β-hydroxy-7-keto-O-methylpodocarpic lactone X*a*, m.p. 195–197.5° (lit. (22) m.p. 198–200.5°); $[\alpha]_D^{25}$ 89°; μ 5.61 (s), 5.95 (s, C=O), 6.25 (s), 6.38 (m, C=C); λ_{max} 230 mμ (log ϵ 3.96), 291 mμ (log ϵ 4.12), λ_{min} 245 mμ (log ϵ 3.01). Anal. Calc. for $C_{18}H_{20}O_4$: C, 72.00; H, 6.67. Found: C, 72.15; H, 6.66.

ULTRAVIOLET IRRADIATION OF PYRIMIDINE DERIVATIVES

IV. ANIONIC EFFECTS ON THE PHOTOLYSIS OF CYTOSINE AND O-METHYLCYTOSINE

A. M. MOORE[1]

ABSTRACT

The course of the photochemical reactions involved in the photolysis of O-methylcytosine is strongly affected by the presence of various anions. Similar anionic effects were noted during the photolysis of cytosine but the products of this reaction appeared to be less suitable for further investigation. Ultraviolet irradiation of O-methylcytosine in water leads to destruction of the characteristic absorption bands, while irradiation in phosphate leads to the production of a new compound with marked absorption at 300 mμ, and irradiation in pyrophosphate, glycerophosphate, citrate, or cacodylate leads to the production of compounds with marked absorption at 274 mμ. The phosphate-dependent photolysis of O-methylcytosine has been studied in some detail and the product has been isolated and purified. Apparently the $H_2PO_4^-$ ion acts as a catalyst in a reaction which involves the loss of 1 mole of ammonia and the addition of 2 moles of water to O-methylcytosine.

RESULTS

Recent investigations of the chemical effects of ultraviolet light on pyrimidine derivatives have disclosed three types of reaction, namely, (*a*) nucleophilic addition of water, ethanol, or hydrogen cyanide at the 5,6-double bond (1–5), (*b*) dimerization by addition at the same double bond (6), and (*c*) ring cleavage (7). All three were encountered in studies of derivatives of uracil and thymine, in which the products of the photochemical reaction have been isolated and identified. Derivatives of cytosine have previously proved less satisfactory as subjects of investigation, the immediate products of irradiation being so unstable as to make their isolation very difficult. Spectrophotometric and other evidence in the case of cytidine and cytidylic acid indicate that addition of water to the 5,6-double bond is probably the main reaction occurring on irradiation of buffered, neutral, aqueous solutions (4). However, some anomalies have been observed. Wang (8) has reported that the product of irradiation of cytosine in water reverts spontaneously to cytosine on standing, but that the reaction is largely irreversible when a neutral buffer (nature unspecified) is used as solvent.

This observation was confirmed in the present investigation. The spectrophotometric results also provided some indication that the course of the photochemical reaction with cytosine was influenced by the nature of the anions present in the solution during irradiation (Fig. 1). However, some of the products appeared to be unstable. Earlier work in this laboratory (3) had shown that it was easier to isolate and identify the products of irradiation of 1,3-dimethyluracil than of uracil itself. Further, Shugar and Wierzchowski (9) had reported that irradiation of O-methylcytosine gave stable products with a characteristic absorption spectrum. For these reasons, O-methylcytosine (2-methoxy-4-aminopyrimidine; MAP) was selected for study in the hope that it might prove more tractable than cytosine itself.

The course of the reaction induced in MAP by ultraviolet light (253.7 mμ) was strongly influenced by the anionic constituents of the medium. When the compound was irradiated

in water at pH 7, the spectral change was characterized by a disappearance of the absorption maximum at 270 mμ, together with a general decrease in absorbance at all wavelengths between 210 and 286 mμ, and the transient appearance of a small shoulder above 286 mμ (Fig. 2). The same result was observed when MAP was irradiated at pH 7 in sodium

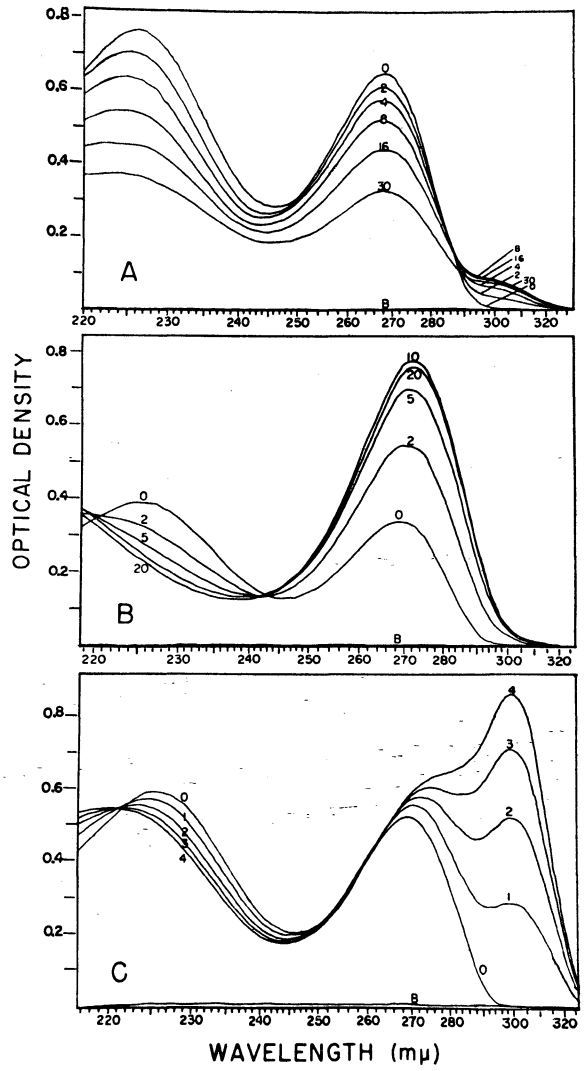

FIG. 2. Spectrophotometric changes during ultraviolet irradiation of 2-methoxy-4-aminopyrimidine (MAP). (A) 1×10^{-4} *M* MAP in water at pH 7.0 after irradiation for 0, 2, 4, 8, 16, and 30 minutes. (B) 0.5×10^{-4} *M* MAP in 0.05 *M* pyrophosphate buffer pH 7.0, after irradiation for 0, 2, 5, 10, and 20 minutes. (C) 0.77×10^{-4} *M* MAP in 0.05 *M* phosphate buffer pH 7.0, after irradiation for 0, 1, 2, 3, and 4 minutes. The concentrations of MAP were chosen for convenience of presentation. All irradiations were carried out at room temperature in the apparatus described in reference 3.

chloride or sodium sulphate solutions (0.05 *M*). These changes were not reversed by heating or on standing at room temperature, in contrast to the hydration reaction which occurs during irradiation of uracil, cytosine, or N-substituted cytosine derivatives such as cytidine and cytidylic acid.

A second pattern was observed when MAP was irradiated in pyrophosphate buffer at pH 7. Here the original absorption peak of MAP increased in optical density to more than twice the initial value, while the position of the peak shifted from 270 to 274 mμ (Fig. 2). The effects of several other anions (citrate, glycerophosphate, phosphite, cacodylate) were superficially similar to those of pyrophosphate.

In phosphate buffer at pH 7, however, a third type of reaction occurred. This resulted in the appearance of a new absorption maximum at 300 mμ with an increased optical density (Fig. 2). The only other anion that showed this effect was arsenate, which is similar to phosphate in structure and properties. However, arsenate was less efficient in producing the 300 mμ absorption band and it appeared to share some of the properties of pyrophosphate because a mixture of products with absorption maxima at 274 mμ and at 300 mμ was obtained.

The phosphate-dependent reaction appears to be a new type of photodecomposition in the pyrimidine series. In their review of the photochemistry of nucleic acids (9), Shugar and Wierzchowski noted that irradiation of MAP in phosphate buffer at pH 7 gave rise to a product with a new absorption band near 300 mμ, and that under similar conditions the spectrum of 2-ethyluracil showed an analogous shift in the absorption peak to longer wavelengths. They did not remark, however, that this reaction was obtained only in the presence of phosphate.

Paper chromatography of the photolytic products from MAP in solutions of various buffers provided further evidence for a specific effect of phosphate in directing the course of the reaction. Four products were identified; the anion present during irradiation of MAP appeared to determine which particular product was formed predominantly (Table I).

TABLE I

Paper chromatography of the products from the ultraviolet irradiation of MAP in various buffers

Buffer during irradiation	(A) Butanol–water R_f: 0.26	0.47	0.55	0.83	(B) Butanol – water – acetic acid R_f: 0.28	0.36	0.73
Pyrophosphate	++	++	+	−	++	+	++
Cacodylate	++	++	(+)	−	++	+	++
Arsenate	+	+	+	+	+	+	++
Phosphate	+	−	(+)	+++	+	−	+++

NOTE: Spots were located on the paper chromatograms by the ultraviolet print method. All R_f values are approximate and varied over a range of 0.05 from one experiment to another. The R_f of MAP in solvent A was 0.74 and in solvent B 0.48. The spot at R_f 0.73 in solvent B appears to represent two different compounds which exhibited similar mobilities in this solvent (see text).

The specific effect of phosphate on the photolysis of MAP appeared to be of particular interest and was studied in more detail. As the concentration of phosphate was increased, the rate of formation of the 300 mμ product approached a maximum, with half the maximal rate being reached at approximately 0.007 *M* phosphate (Fig. 3). The type of curve obtained is reminiscent of the dissociation curve for a complex between two ions or molecules (e.g. phosphate and MAP, or phosphate and an intermediate product) when the concentration of one of the ions is altered. However, the presence of phosphate had no measurable effect on the absorption spectrum of MAP itself. Continuous-flow experiments also failed to demonstrate measurable amounts of other products with ultraviolet absorption during the irradiation of MAP in phosphate buffer.

The yield of product with an absorption maximum at 300 mμ was strongly influenced

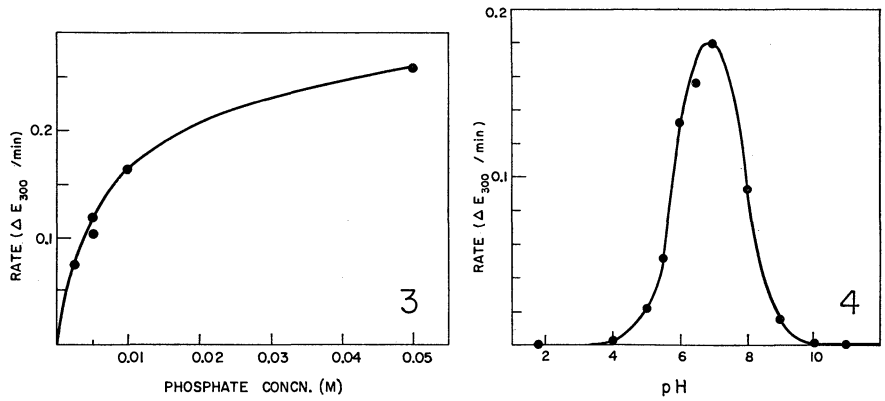

FIG. 3. Effect of phosphate concentration on the initial rate of formation of the 300 mμ product during ultraviolet irradiation of 10^{-4} *M* MAP in aqueous solution at pH 7.0. The rate is expressed as increase in optical density at 300 mμ per minute.

FIG. 4. Effect of pH on the initial rate of formation of the 300 mμ product during ultraviolet irradiation of 10^{-4} *M* MAP in 0.05 *M* phosphate. The rate is expressed as increase in optical density at 300 mμ per minute.

by the pH of the solution during irradiation (Fig. 4). Maximum rate of formation was found near pH 6.8–7.0. Since the p*K* of the second hydrogen of phosphoric acid is known to be 7.2, and the p*K* of the amino group of MAP was found by experiment to be 5.5, one might predict an optimum pH of 6.35 for a reaction involving these two molecules if the rate of reaction was determined by the relative concentrations of undissociated and dissociated ions. A more rigorous mathematical treatment, based on one model for the reaction (see below), introduces a correction factor to allow for competing reactions, which brings the theoretical value for optimum pH up to 6.8. The variation of yield with pH could not be explained by destruction of the product in slightly acid or alkaline solutions. These results (Fig. 4) suggest, therefore, that the reacting species are the unionized amino form of MAP and the singly ionized form ($H_2PO_4^-$) of phosphate.

The product with absorption maximum at 300 mμ did not contain phosphorus, nor was there any phosphorus in the other minor products formed during irradiation of MAP in phosphate. This was demonstrated by paper chromatography of MAP solutions after irradiation in the presence of phosphate labelled with radioactive P-32; no radioactivity was detected in any of the ultraviolet-absorbing spots on the chromatogram. Further, the 300 mμ peak did not appear when phosphate was added immediately after irradiation to an irradiated solution of MAP in water, showing that phosphate did not react with some long-lived irradiation product. The 300 mμ product was itself destroyed by further irradiation with ultraviolet light; however, its rate of destruction was essentially the same in the presence and absence of phosphate, thus demonstrating that the role of phosphate was not the stabilization of the 300 mμ product. We are thus left with the conclusion that phosphate acts as a catalyst in the photolysis of MAP to the 300 mμ product by some reaction mechanism as yet unknown.

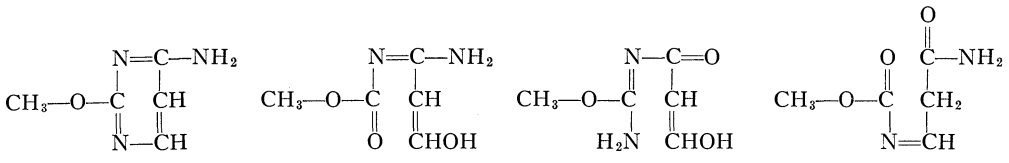
Identification of the 300 mμ Product

Fifty-milligram quantities of this product were prepared by irradiation of large volumes of MAP solution containing phosphate in a specially designed apparatus, followed by subsequent chromatography of the products on a cation-exchange resin. The 300 mμ product was extracted from the eluate with chloroform and recrystallized from ethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acetate – hexane. The pure material was a faintly yellow, crystalline solid which melted at 153.5° C, had a molecular weight of 144, and analyzed for $C_5H_8N_2O_3$. This empirical formula suggests that in the photolysis of MAP ($C_5H_7N_3O$), one molecule of ammonia is lost and two molecules of water are added.

Three alternative structures were considered; these are indicated below in the same configuration as MAP. All three structures could, in their enol forms, exhibit the system of conjugated double bonds which is necessary to account for the high extinction coefficient (24.4×10^3) of the purified product at 300 mμ.



MAP I II III

The production of ammonia during irradiation of MAP in phosphate solution was verified by two separate methods (see below). The presence of one methoxyl group in the purified product was also verified. The absorption peak at 300 mμ was suppressed by treatment with hydrogen cyanide, permanganate, or semicarbazide, indicating the presence of an aldehyde group. The compound reacted readily both with bromine and with iodine, but these reactions appeared to be of a complex nature. Infrared spectra gave evidence of the presence of primary amino, hydroxyl, and carbonyl groups in the purified product. The free amino group appeared to have a pK of 3.5, as compared with the pK of 5.5 for the amino group of MAP.

The cumulative evidence suggests that the correct structure of the purified product is represented by compound I, which, in the enol form, might be designated as N-carbomethoxy-β-hydroxyacrylamidine. This conclusion remains to be proved by synthesis of compound I.

EXPERIMENTAL

2-Methoxy-4-aminopyrimidine (MAP)

MAP was synthesized according to Hilbert *et al.* (10, 11) and purified by repeated recrystallization from hot water; m.p. 170–171° C; lit. m.p. 170° (10), 174° (11). The 2,4-dichloropyrimidine used in this synthesis was prepared from uracil by two methods (10, 12). MAP was also purchased from Applied Science Laboratories, Inc., State College, Pa.; m.p. 164–167° C. All melting points were determined with a Fisher–Johns heated-stage apparatus.

The ultraviolet spectrum of an aqueous solution of MAP at pH 7.0, either in water or phosphate buffer, exhibited two maxima at 270 mμ and 225 mμ, with an intervening minimum of absorption at 245 mμ (Fig. 2). The molecular extinction coefficient was 6820 at 270 mμ and 7510 at 225 mμ. At the same pH, cytosine itself exhibited a single absorption maximum at 267 mμ (Fig. 1) with an extinction coefficient of 6130 (13). The values given above for MAP are slightly different from those reported by Shugar and Wierzchowski (9), but both the identity of the compound and the position of the absorption maxima have been carefully checked in the present experiments.

The addition of alkali had no effect on the spectrum of MAP, while the repeated addition of 10-μl portions of 0.01 N HCl to 3 ml of 10^{-4} M MAP in water resulted in a series of spectral curves with isosbestic points at 268.5, 224, and 217.5 mμ. At pH 4.5, the absorption maxima were at 259 and 229.5 mμ, with the absorption minimum at 242 mμ. The pK of the primary amino group can be calculated from a plot of these spectral changes as a function of pH (cf. ref. 13); the average value from four experiments was 5.6. Two experiments, in which a 10^{-2} M solution of MAP was titrated directly with acid, provided pK values of 5.4 and 5.5. An average pK of 5.5 has been used in mathematical calculations.

Ultraviolet Irradiation

In most experiments, solutions of MAP or of cytosine in water or in appropriate buffers were irradiated in the apparatus previously described (3) using low-pressure mercury-vapor lamps as the light source. A

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

0.1 *M* KBr solution was circulated through the jacket of the double-walled quartz sample chamber in order to filter out ultraviolet radiation of wavelengths below 230 mμ, and maintain a constant temperature. The wavelength of the incident radiation was preponderantly 253.7 mμ. Irradiated samples were withdrawn at various periods of time and their ultraviolet absorption spectra determined with a Beckman DK-2 recording spectrophotometer. In experiments on irradiation at different pH values (Fig. 4), the samples were neutralized before the spectra were recorded. During irradiation of MAP in 0.05 *M* phosphate at pH 7, the rate of formation of the 300 mμ product was found to be independent of MAP concentration over the range 10^{-4} to 2×10^{-3} *M*, indicating that most of the incident light was being absorbed under the experimental conditions (Table II).

TABLE II

Effect of MAP concentration on the initial rate of the photochemical reaction in 0.05 *M* phosphate buffer at pH 7.0

MAP concentration (*M*)	Rate of formation of 300 mμ product (ΔE_{300}/min)	MAP concentration (*M*)	Rate of formation of 300 mμ product (ΔE_{300}/min)
2×10^{-3}	0.260±0.037 (3)	1×10^{-4}	0.253±0.019 (8)
1×10^{-3}	0.277±0.026 (12)	5×10^{-5}	0.163±0.024 (3)
5×10^{-4}	0.270±0.050 (2)		

NOTE: Average values are given together with the standard error of the mean followed by the number of determinations in parentheses. The differences between the average rates are not statistically significant until the concentration of MAP is decreased to 5×10^{-5} *M*.

Quantum yields were measured in a modification of the same apparatus (3) using a smaller-diameter quartz chamber insert fitted with a mechanical stirrer to provide continuous mixing during irradiation. Using values of 0.0013 for 10^{-4} *M* cytosine and 0.037 for 10^{-2} *M* uridylic acid as standards (1), the quantum yield for disappearance of the absorption maximum at 270 mμ during irradiation of 10^{-4} *M* MAP in water proved to be 0.00065, while the quantum yield for formation of the 300 mμ peak during irradiation of 10^{-4} *M* MAP in 0.05–0.2 *M* phosphate at pH 7 was 0.0017. The initial rate of increase in optical density at 300 mμ during irradiation of MAP in water at pH 7 was approximately 100 times slower than the corresponding rate in phosphate buffer.

In order to look for spectrophotometric evidence of short-lived intermediates during the photolysis of MAP in phosphate buffer, a special apparatus was designed by which the MAP solution was continuously circulated from the irradiation chamber to the spectrophotometer and back again. By this means, the time between irradiation and spectrophotometric recording was reduced from several minutes to a few seconds. However, the spectra showed no evidence of ultraviolet-absorbing compounds other than those detected in previous experiments. A record of change in absorption at 300 mμ with time of irradiation also failed to show any appreciable lag between the time that irradiation was started and the time that the absorption at 300 mμ began to increase. These experiments indicate that (*a*) short-lived intermediates in the reaction mixture must be present in very low concentrations, (*b*) their half-lives are considerably less than a few seconds, or (*c*) their spectra are very similar to the spectra of MAP or the 300 mμ product.

Paper Chromatography

Solutions containing 10^{-3} *M* MAP in 0.05 *M* buffer (phosphate, pyrophosphate, arsenate, or cacodylate) at pH 7.0 were irradiated for 90–120 minutes. Ten-milliliter samples of the irradiated solutions were evaporated to dryness under a stream of air at room temperature and the residue redissolved in 1 ml water. Small amounts (20 to 50 μl) were applied to Whatman No. 1 paper, using 20 μl of 10^{-2} *M* MAP as a reference spot on each chromatogram. The chromatograms were developed for 6–16 hours with an ascending solvent consisting either of (A) butanol saturated with water, or (B) 9 volumes of butanol saturated with water plus 1 volume of glacial acetic acid. The chromatograms were subsequently dried in air and ultraviolet-absorbing spots located by the ultraviolet print method of Markham and Smith (14). R_f values were measured on the ultraviolet prints in the usual manner (Table I).

In some experiments, small portions of the chromatogram, corresponding to the ultraviolet-absorbing spots, were cut out and eluted with 4 ml of phosphate buffer. The ultraviolet spectrum of the eluates could then be recorded. In this way, it was possible to show that the products with R_f 0.26 and 0.47 in solvent A both exhibited absorption maxima in the region of 272–274 mμ, while the product with R_f 0.83 in solvent A exhibited an absorption maximum at 300 mμ. One of the above products, possibly the one with R_f 0.26, acquired a much higher mobility in solvent B and travelled with approximately the same R_f as the 300 mμ product in solvent B. Thus the product with R_f 0.73 in solvent B exhibited maximum absorption at 274 mμ when irradiation had been carried out in pyrophosphate buffer, but exhibited maximum absorption at 300 mμ when irradiation had been carried out in orthophosphate. The absorption spectrum of the product with R_f 0.55 in solvent A could not be properly defined owing to the small amounts of material present, but appeared to have a maximum near 269 mμ.

Formation of Ammonia

Ammonia was measured first by distillation at room temperature from irradiated solutions of MAP. Air was drawn through an acid trap containing 0.1 N H_2SO_4, then into an irradiated MAP solution to which an equal volume of saturated K_2CO_3 had been added, and finally into a solution of 2% boric acid. The amount of ammonia carried over into the boric acid was determined by titration with standard HCl. No ammonia was detected in MAP solutions prior to irradiation; after irradiation of MAP in 0.05 M phosphate, approximately 1 mole of ammonia was recovered per mole of MAP lost during the irradiation. Since the K_2CO_3 had no effect on the ultraviolet spectrum of the irradiated solution at room temperature, it seems probable that this ammonia must have been liberated during the irradiation.

A second method for determination of ammonia was based on determination of optical density at 420 mμ after addition of Nessler's reagent (15). On irradiation of 10^{-3} M MAP in 0.05 M phosphate at pH 7, a linear 1:1 molar relationship between ammonia production and formation of the 300 mμ product was found during the first 30 minutes of irradiation. Further irradiation resulted in a molar excess of ammonia over 300 mμ product, presumably because this product was susceptible to photodecomposition during prolonged irradiation.

Isolation of the 300 mμ Product

An apparatus was constructed whereby MAP solution from a reservoir was sprayed onto the top of two vertical glass plates and allowed to run down the surface of these plates, past a vertical bank of 10 mercury-vapor lamps, to the reservoir again. Using this apparatus, 1 liter of 10^{-3} M MAP in 0.05 M phosphate buffer pH 7.0 was irradiated for 6 hours at 5° C; this length of time provided a maximum yield of the 300 mμ product under these experimental conditions. The irradiated solution was acidified to pH 4.5–4.6 with concentrated HCl and applied under suction to an ion-exchange column (Dowex 50 W-X 8, Na form; column 4×9 cm). The column was washed under suction with 1 liter of water acidified to pH 4.5 with acetic acid and then with another liter of the same solution by gravity feed. These washings contained unchanged MAP and other ultraviolet-absorbing materials but none of the 300 mμ product; the pH of this solution, it might be noted, was below the pK of MAP (4.5) but greater than the pK of the 300 mμ product (3.5; see below). When the eluate was free of ultraviolet-absorbing materials, a solution of 1 M NaCl – sodium acetate buffer at pH 4.5 was applied to the column. The 300 mμ product was eluted almost immediately and was usually collected in a volume of 1 liter. This eluate was neutralized to pH 7 and extracted four to six times with an equal volume of chloroform (the partition coefficient of the product in a chloroform/water system being 1.12). The combined chloroform extracts were evaporated *in vacuo* almost to dryness and the last few milliliters of solvent were removed under a stream of air at room temperature.

The product was dissolved in 15 ml of boiling ethyl acetate and the resulting solution was allowed to cool to room temperature, at which point a few crystals formed. Hexane was added to opalescence and crystallization was allowed to continue. The crystals were washed twice with hexane and dried in a vacuum desiccator over P_2O_5 to eliminate residual water. The weight of crystalline material was usually 35–50 mg, representing a 25–35% yield of product from the original amount of MAP. After repeated recrystallization, the melting point of the product was 153.5° C.

Properties of the 300 mμ Product

Elementary analysis was carried out at National Research Council, Ottawa, through the kindness of Dr. Léo Marion. Found: C 41.49%, H 5.43%, N 19.38%, O (by difference) 33.70%. Calculated for $C_5H_8N_2O_3$: C 41.67%, H 5.56%, N 19.44%, O 33.33%. The molecular weight for a monomer of this elementary composition should be 144. *Molecular weight* was estimated from the decrease in vapor pressure of a solvent caused by the presence of a known amount of compound, using a Mechrolab Model 301 osmometer for this determination and 1,3-dimethyluracil as standard. The molecular weight of the 300 mμ product was found to be 144 (individual measurements 145.8 and 143.3).

The ultraviolet spectrum at pH 7.0 exhibited a maximum in absorption at 300 mμ with a molecular extinction coefficient (ϵ) of 24,400, and a second maximum at 212 mμ with an extinction coefficient of 8,300 (Fig. 5). The molecular extinction at 300 mμ was 3.6 times the molecular extinction of MAP at 270 mμ but was of the same order of magnitude as that observed with compounds such as 2,4-hexadienal (16) or 2,4-hexadienoic acid (17). The spectrum of the purified product in chloroform solution was essentially identical with that in a neutral aqueous solution.

The position and height of the absorption peak at 300 mμ were not appreciably altered by the addition of alkali, but this peak disappeared in acid without the appearance of a new peak anywhere in the region 220–330 mμ (Fig. 5). The effect of acid on the absorption spectrum was reversible on neutralizing the solution. Determination of the pK from the change in spectrum with pH gave a value of 3.5.

Ultraviolet irradiation of a 2.5×10^{-5} M solution of the purified 300 mμ compound resulted in a rapid destruction of the compound, the absorption maxima at 300 mμ and at 212 mμ both being extinguished. The average time for 50% destruction of a 2×10^{-5} M solution was 10 minutes in water at pH 7 and 8 minutes in 0.05 M phosphate at pH 7. The rate of destruction at pH 9 was similar to that at pH 7, while one experiment at pH 5 suggested a slower rate. By way of comparison it might be noted that approximately 1.2 minutes were required for the production of a 1.25×10^{-5} M concentration of 300 mμ compound during the irradiation of 10^{-4} M MAP in 0.05 M phosphate pH 7 under the same experimental conditions.

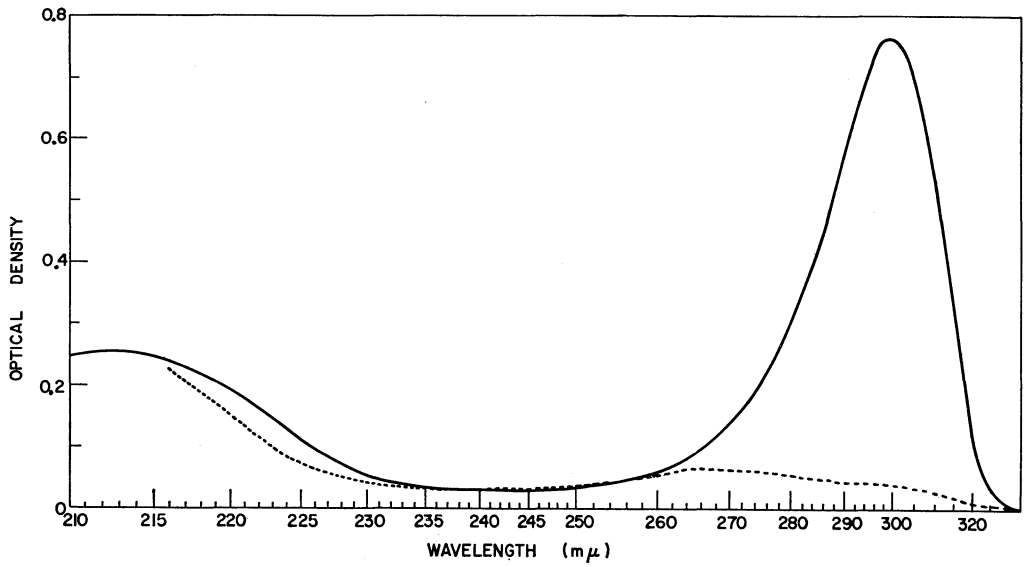

FIG. 5. The ultraviolet absorption spectrum of a 3.1×10^{-5} *M* solution of the purified 300 mμ product. The solid line represents the spectrum at pH 7 while the broken line represents the spectrum at pH 2.

Stability of the 300 mμ product in aqueous solution was limited. The absorption at 300 mμ disappeared with a half-life of 35 hours on standing at room temperature (20–22° C) in 0.05 *M* phosphate buffer at pH 7.0, and was extinguished when the same solution was heated to 100° C for 20 minutes. The stability at room temperature was not appreciably affected by exposure to visible light. Heating the compound in 0.01 *N* HCl at 100° C for 5 minutes resulted, after neutralization of the solution, in the disappearance of the absorption maximum at 300 mμ and the formation of a new maximum at 283 mμ. Preliminary experiments indicated the loss of one molecule of ammonia in hot acid solutions. Heating the compound in 0.1 *N* NaOH at 100° C for 20 minutes resulted in complete loss of ultraviolet absorption bands, with the transient appearance of a small absorption maximum near 280 mμ after shorter periods of heating.

Methoxyl content was determined by a slight modification of the method described by Clark (18), using vanillin as a standard and nitrogen as the carrier gas. Found: 21.76 and 21.63%. Calculated (for one methoxyl per 144 g): 21.53%.

The presence of an aldehyde group in the 300 mμ product was suggested by a number of observations. Reaction with hydrogen cyanide was followed spectrophotometrically. The maximum at 300 mμ decreased by approximately 40% within 20 minutes after addition of 0.017 *M* NaCN to a 2.5×10^{-5} *M* solution of the compound in 0.05 *M* phosphate.

Reaction with $KMnO_4$ was measured titrimetrically. Five milliliters of 10^{-3} *M* MAP in 0.05 *M* phosphate was irradiated for 60 minutes, then acidified with 1 ml 1 *N* H_2SO_4, warmed to 60° C, and titrated with 0.01 *N* $KMnO_4$. The irradiated solution reacted with 1.03 equivalents of permanganate, whereas the MAP solution before irradiation failed to react. Reaction with permanganate eliminated the absorption peak at 300 mμ.

The addition of 0.01 *M* semicarbazide (neutralized) to a dilute solution of impure 300 mμ product in 1 *M* sodium acetate resulted in complete disappearance of the 300 mμ absorption peak within 15–30 minutes. The semicarbazone derivative was obtained by reaction of 10 mg of purified product with excess semicarbazide, followed by evaporation of the solvent and recrystallization of the product from ethyl acetate – hexane; m.p. 90° C. No reaction of semicarbazide with MAP was observed.

A reaction with 2,4-dinitrophenylhydrazine was demonstrated by spraying this compound onto a paper chromatogram of irradiated MAP (developed with butanol–water saturated with SO_2). When the chromatogram was subsequently exposed to ammonia vapor, the 300 mμ product showed up as a dark brown spot.

Bromination was followed spectrophotometrically as in previous investigations (19). Successive additions of 10-μl samples of Br_2–H_2O, containing approximately 2.5×10^{-3} *M* bromine, were mixed with solutions containing known amounts of MAP or the 300 mμ product (3×10^{-5}–8×10^{-5} *M*) and the ultraviolet absorption spectra were recorded after each addition. The exact concentration of bromine was calculated from its optical density at 390 mμ in 0.1 *N* HCl, the molecular extinction coefficient being 175.

Bromination of MAP resulted in the formation of a new absorption maximum at 282 mμ, the optical density at this wavelength being slightly smaller than the optical density of the original MAP solution at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

270 mμ. Slightly more than 1 mole of bromine per mole of MAP was required to complete this reaction. Since the bromo-MAP still exhibited a strong ultraviolet absorption band, it seems probable that the overall reactions led to the substitution of one bromine atom for hydrogen on carbon-5 of the pyrimidine ring, in much the same manner as demonstrated previously with uracil derivatives following bromination and heating (19).

Bromination of the 300 mμ product from irradiated MAP eliminated the absorption peak at 300 mμ. An unstable intermediate with maximum absorption at 320 mμ appeared during the reaction, but ultimately only an absorption peak at 241 mμ (with approximately one-third the original optical density at 300 mμ) remained. The total reaction consumed on the average 2.3 moles of bromine per mole of 300 mμ product. Irradiation of bromo-MAP in 0.05 *M* phosphate did not lead to formation of the same product but simply to disappearance of the absorption maximum at 282 mμ. Treatment of the 300 mμ compound with iodine–water produced much the same effect as with bromine–water; the 300 mμ peak disappeared with transient formation of a labile compound absorbing near 320 mμ and finally of a compound with maximum absorption at 224 mμ. These results suggest that the reactions with bromine and iodine might involve oxidation of the aldehyde group as well as addition to a double bond.

Infrared spectra were determined on a Perkin–Elmer infrared recording spectrophotometer Model 21 (NaCl prism) through the courtesy of W. M. Thurston. In most experiments, 0.5–0.6 mg of test compound was dissolved in 1 ml chloroform, mixed with 200 mg of KCl, dried, and pressed into disks at 12,000 p.s.i. for 10 minutes; these disks were then used for recording the infrared spectrum of the test compound in its solid state (Fig. 6). Both MAP and the 300 mμ product were deuterated by refluxing 0.5–0.6 mg of compound either with 0.5 ml of D_2O (99.7% isotopic purity; supplied by Development Chemistry Branch, Atomic Energy of Canada Limited) or with 0.5 ml of CH_3OD (Merck, Sharpe and Dohme Limited, Montreal) for 40–60 minutes. The compounds were then dried, mixed with chloroform and 200 mg of KCl, redried, and pressed into disks as described above. The infrared spectra of the deuterated compounds (Fig. 6) proved to be essentially identical with either D_2O or CH_3OD as deuterium source.

The infrared spectrum of MAP exhibited two absorption bands due to the —NH_2 group at 3.00 and 3.16 μ. Following deuteration, these bands shifted to 3.97 and 4.29 μ; similar results have been reported for cytosine and cytidine (20). Another absorption maximum at 6.05 μ, which shifted to 6.7 μ following deuteration, was also presumed to represent the —N—H bond (21). The series of five major absorption bands in the region between 6.3 and 7.6 μ are similar to those reported for 2-methoxypyrimidine but have not been further characterized.

The infrared spectrum of the purified 300 mμ product exhibited a similar absorption band at 6.03 μ, which shifted to 6.7 μ following deuteration. However, the corresponding absorption maxima at 2.95 and 3.14 μ for the undeuterated compound were no longer symmetrical. The increase in relative absorption at 2.95 μ may have been due to superposition of hydroxyl and amino bands; this is suggested by the fact that this band split into two components at 4.0 and 3.94 μ following deuteration. The series of overlapping absorption bands in the region between 3.3 and 3.8 μ shifted to 4.5–4.9 μ following deuteration; this shift may indicate that some of the —C—H bonds in the 300 mμ product exchanged readily with deuterium whereas a similar exchange did not occur in MAP (Fig. 6). The 300 mμ compound also exhibited an absorption band at 5.78 μ, representing a carbonyl group, which was not present in the infrared spectrum of MAP. A strong absorption band at 8.1 μ was tentatively assigned to a C—O ester linkage (21).

A hydrochloride of the 300 mμ compound was made by passing dry HCl through 1 ml of chloroform containing 0.5 mg of compound, followed by drying, mixing with KCl, and pressing into a disk as described above. The amino absorption bands at 2.95 and 3.14 μ were shifted to 3.4 and 3.5 μ, in the same manner as described for other amines (21), leaving a broad low peak at 3.0 μ. The absorption maxima at 5.74, 6.04, and 8.2 μ were scarcely altered by conversion of the compound to its hydrochloride.

The infrared spectra appeared to be consistent with structures I or II as indicated in the text above. If the absorption maximum at 8.1 μ were due to C—O ester linkage (21), the spectrum would indicate structure I. It might be noted that the infrared spectrum of crude samples of MAP that had been irradiated in phosphate buffer did not exhibit any unusual characteristics except for a small absorption peak at 4.55 μ. This absorption peak suggests the presence of a triple bond, either C≡N or C≡C, in one of the by-products of the photolytic reaction.

Nuclear magnetic resonance spectra were determined by W. G. Schneider, Division of Pure Chemistry, National Research Council, Ottawa, using $CDCl_3$ and CH_3OD as solvents. The data confirmed the presence of amino and methoxyl groups in the 300 mμ compound as well as in MAP. The spectrum of the 300 mμ product exhibited an additional low-field signal which was probably due to a hydroxyl group.

Mass spectrum was determined by J. A. Stone, Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River. In the mass spectrometer, a sample of crystalline material was exposed to an electron beam *in vacuo*; the mass and relative amount of the ionized fragments of the molecule were measured. The major peaks appeared at masses 14, 15, 16, 17, 28, 29, 31, 32, 43, and 44 with three minor peaks at masses 61, 70, and 73. On comparing the possible atomic composition of these fragments (22) with the proposed structures, it appeared probable that mass 17 must represent OH, mass 31 a methoxyl group, mass 43 either CHNO or C_2H_3O (e.g. —CH=CHOH), mass 61 either $C_2H_5O_2$ or CHO_3 (which could be formed if the carbonyl group of structure I were hydrogen bonded to the hydroxyl group), while the only probable

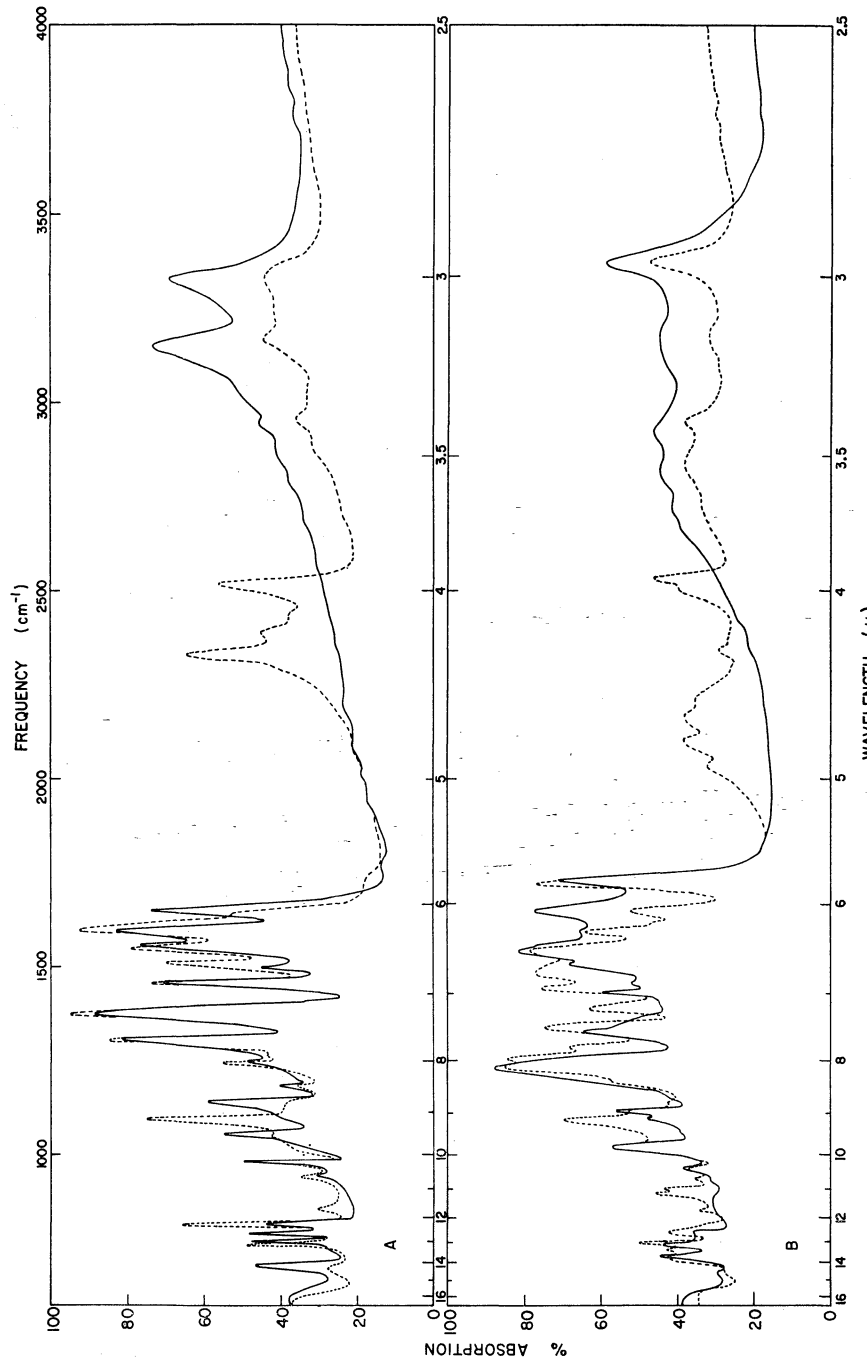

FIG. 6. Infrared spectra of MAP and of the 300 mμ product in the solid state. (A) Solid line: 0.28% MAP in a KCl disk. Broken line: approximately 0.3% deuterated MAP, formed by refluxing MAP with CH_3OD. Similar results were obtained after refluxing with D_2O. (B) Solid line: 0.25% purified 300 mμ product in a KCl disk. Broken line: approximately 0.25% deuterated product, formed by refluxing with CH_3OD.

fragment of mass 73 was $C_2H_3NO_2$ (e.g. CH_3—O—CO—N=). These fragments appear to be consistent with structure I.

Calculation of Optimum pH

Consider the hypothetical reactions

$$M + h\nu \xrightarrow{k_1} M^*$$

$$M^* + H_2O \xrightarrow{k_2} M, L, K, \text{etc.}$$

$$M^* + P \xrightarrow{k_3} MP^* \xrightarrow{k_4} Z + P$$

where M represents MAP; M* represents activated MAP after absorption of a quantum of ultraviolet light; P represents inorganic phosphate; MP* represents some undefined complex between activated MAP and phosphate (perhaps only two molecules in collision); Z represents the 300 mμ product; while L, K, etc. are by-products. Square brackets are used below to indicate molar concentrations. Using the conventional equation (23) for rate of formation of M* where I_o = incident intensity of ultraviolet radiation at 254 mμ; $D_M = \epsilon_M[M]$ = optical density of M in the solution at 254 mμ; and D = total optical density of M plus L plus K, etc.; then

[1] $$d[M^*]/dt = \text{rate of formation of } M^* - \text{rate of breakdown to other products} - \text{rate of formation of } MP^*$$
$$= k_1 I_o \frac{D_M}{D}(1 - 10^{-D}) - k_2[M^*] - k_3[M^*][P].$$

Assuming equilibrium conditions, where $d[M^*]/dt = 0$ and $d[MP^*]/dt = 0$, then

[2] $$[M^*] = \frac{k_1 I_0 D_M (1-10^{-D})}{D(k_2+k_3[P])} = \frac{A[M]}{k_2+k_3[P]}$$

where $A = k_1 I_o \epsilon_M (1-10^{-D})/D$. Since the optical density D at 254 mμ is relatively constant during irradiation of MAP in phosphate buffer (Fig. 2) and equal to D_M at zero time, A can be taken as a constant in any given experiment. From one experiment to another, A will depend on light intensity, on the concentration of MAP at zero time, and also on pH since ϵ_M varies with pH.

Under the same equilibrium conditions, the rate of formation of Z can be written as

[3] $$R = k_4[MP^*] = k_3[M^*][P]$$
$$= \frac{k_3 A[M][P]}{k_2+k_3[P]}.$$

This equation indicates that R will equal half the maximal rate when $[P] = k_2/k_3$ in experiments where [P] is varied while other experimental conditions are constant. Thus the data of Fig. 3 would indicate $k_2/k_3 = 0.007$ M.

The effect of variation in [M] on the rate will be determined by the factor $A[M]$ in equation [3]. If we substitute $D = D_M$ at zero time and consider the initial rate of reaction where [M] is approximately equal to $[M]_0$, the only important variable left in $A[M]$ is the factor $(1-10^{-D})$. This factor has a value of 0.8 when D is 0.7 and approaches 1 as D is increased to infinity. Since ϵ_M at 254 mμ is 3500 and the depth of solution in the irradiation chamber is 1.7 cm (3), a 1.2×10^{-4} M solution of MAP should provide an optical density of 0.7 at pH 7. Thus the initial rate of the reaction should be almost independent (within 20%) of $[M]_0$ when $[M]_0$ is equal to or greater than 1.2×10^{-4} M MAP at pH 7. This agrees with the experimental results; the measured rate appeared to be relatively independent of $[M]_0$ down to 1×10^{-4} M MAP and only decreased appreciably (35%) on going from 1×10^{-4} to 0.5×10^{-4} M MAP (Table II).

The effect of decrease in pH on factor A will be an increase in D_M and thus an increase in $(1-10^{-D})$. The optical density of MAP solutions at 254 mμ is almost exactly doubled when the pH is decreased from neutrality to pH 4. However, this change cannot account for the observed variations in rate between pH 7 and pH 6 (Fig. 4). First, the increase in D_M between pH 7 and pH 6 is relatively small; secondly, even a doubling in D_M due to pH changes will have little effect on the initial rate when the rate is independent of $[M]_0$ as described above.

Equation [3] can be modified to allow for the effect of pH on ionization of MAP and phosphate by introducing the fractional dissociation factors:

X_M = fraction of MAP in unionized amino form,
X_P = fraction of phosphate in doubly ionized form,

where $\log (1-X)/X = pK - pH$ for both compounds. Assuming that only the free amino form of MAP (X_M) and the singly ionized phosphate ion ($1-X_P$) are reactive (see Fig. 4), then equation [3] becomes

[4] $$R = \frac{k_3 A[M]X_M[P](1-X_P)}{k_2+k_3[P](1-X_P)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This equation can be used directly for the calculation of relative rates at different pH values by inserting the appropriate theoretical values for X_M and X_P. The equation can also be solved for optimum pH by differentiating with respect to $[H^+]$, using the expressions

$$X_M = \frac{K_M}{K_M+[H^+]},$$

$$(1-X_P) = \frac{[H^+]}{[H^+]+K_P},$$

$$\frac{dX_M}{d[H^+]} = \frac{K_M}{(K_M+[H^+])^2},$$

and

$$\frac{d(1-X_P)}{d[H^+]} = \frac{K_P}{(K_P+[H^+])^2}.$$

Putting $dR/d[H^+] = 0$ at the optimum pH, the differential of equation [4] can be simplified down to

$$\frac{1}{[H^+]^2} = \frac{1}{K_P K_M}\frac{(k_2+k_3[P])}{k_2}$$

or

[5] $$pH_{opt} = \frac{(pK_P+pK_M)}{2} + \frac{1}{2}\frac{\log\,(k_2+k_3[P])}{k_2}.$$

Inserting the values $pK_P = 7.2$, $pK_M = 5.5$, $k_2/k_3 = 0.007$ M, and $[P] = 0.05$ M as in the experiments shown in Fig. 4, then $pH_{opt} = 6.35+0.46 = 6.8$. This value is close to the experimentally determined value for optimum pH (Fig. 4). The calculation is based on the measured value of k_2/k_3 at a single pH (Fig. 3) close to the optimum pH. The value of k_2/k_3 may well vary with pH but examination of equation [5] shows that moderate changes in this ratio will not alter the calculated value for optimum pH greatly; variations in the ratio k_2/k_3 with pH can therefore be ignored for the present calculation of the approximate optimum pH value.

ACKNOWLEDGMENTS

After Dr. Moore's death, the manuscript of this paper was prepared from his notes and submitted for publication by G. C. Butler and D. K. Myers, with the assistance of Mrs. Catherine A. Vivian. Mrs. Vivian, P. E. Spencer, and Miss Joan N. Smith assisted Dr. Moore in the experiments described. A preliminary report of these experiments was presented to the Radiation Research Society on May 22, 1962 (24).

Received March 20, 1963

ABSTRACT

La^{127}, La^{128}, La^{129}, and La^{131} were produced by the reaction of C^{12} ions with antimony. Half-lives of 3.5±0.5, 4.6±0.6, 8.6±1.8, and 56±3 min respectively, were obtained from the observed growth of the respective barium daughters. The half-life for Ba^{128} was found to be 2.43±0.05 days. La^{129} and La^{130} were produced and identified by the reactions $Ba^{130}(p,2n)$ and $Ba^{130}(p,n)$ respectively, carried out with targets enriched in Ba^{130}. In the proton bombardments half-lives of 10.0±0.5 min and 8.7±0.1 min were found for La^{129} and La^{130} respectively.

The identification of La^{128} and La^{130}, with half-lives of 6.5±1.0 and 9.0±1.0 min respectively, was recently made by Sheline, Sikkeland, and Chanda (1). In their work lanthanum was radiochemically separated from various targets bombarded at the Berkeley Heavy Ion Linear Accelerator (HILAC). The tentative mass assignment of La^{128} was made on the basis of cross bombardments. The assignment of the observed activity to La^{130} was made on the basis of the occurrence of a very strong 356±4 kev gamma ray presumed to be identical with the 359 kev gamma ray observed in the Coulomb excitation of Ba^{130}.

It was felt that verification of the mass assignment of La^{128} could be made by a 'milking' experiment in which the growth of the well-known 2.4-day Ba^{128} daughter (2) was measured. La^{127} and La^{129} were unknown when these experiments were begun, and the same type of experiments was expected to establish their assignments by the growth of the Cs^{127} granddaughter (3) and the 2.5-hr Ba^{129} daughter (4) respectively. The mass assignment of La^{131} has been made only on the basis of a rough mass spectrometric separation (5) without any genetic verification. The mass assignment could be confirmed by a similar 'milking' experiment to observe the growth of the 12-day Ba^{131} daughter (6). It was also decided that a study of the reactions $Ba^{130}(p,n)La^{130}$ and $Ba^{130}(p,2n)La^{129}$ with targets of naturally occurring barium, and of barium enriched in Ba^{130}, would help to confirm the La^{130} mass assignment of Sheline *et al.* (1) and to cross-check the La^{129} assignment made by the HILAC irradiations.

While this work was in progress, Preiss, Strudler, and Wolfgang of Yale University were kind enough to make available to us their recent results on La^{127}, La^{128}, and La^{129}. A comparison between the two sets of data is included later under Results.

EXPERIMENTAL

(a) La^{131} (Experiment 1)

A thick target of antimony powder (99.999% pure), packaged in 0.00025-in. foil, was fastened to the target holder of the HILAC and irradiated with C^{12} ions of incident energy of 124 Mev in order to induce the reaction $Sb^{123}(C^{12},4n)La^{131}$. The irradiated antimony powder was dissolved in hot aqua regia containing 5 mg La carrier. Ba and Cs carriers (1 mg each) were added. Lanthanum fluoride was precipitated by the addition of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

concentrated hydrofluoric acid. The precipitate was centrifuged, and dissolved in 2 ml of a mixture of saturated boric acid and hydrochloric acid. Lanthanum hydroxide was then precipitated by the addition of concentrated ammonia. The precipitate was dissolved in 6 *M* hydrochloric acid, following which the fluoride was again precipitated, dissolved, and converted to the hydroxide. The final precipitate of lanthanum hydroxide was dissolved in 6 *M* hydrochloric acid and an accurately determined amount (~10 mg) of Ba carrier added. After a period of about 1 hour had elapsed, barium chloride was precipitated by bubbling gaseous hydrogen chloride into the ice-cold solution.

This barium chloride was separated and set aside as the first daughter-fraction. An additional, accurately measured amount of barium carrier was added to the supernatant solution. After 1 hour this solution was chilled and resaturated with hydrogen chloride. The precipitate of barium chloride was set aside as daughter-fraction 2. This process was repeated until six daughter-fractions were removed at 1-hour intervals.

An auxiliary experiment with La^{140} tracer, carried out under identical conditions, showed that less than $\frac{1}{2}\%$ of the lanthanum is coprecipitated with barium chloride under these conditions.

The barium daughter-fractions were purified by double reprecipitations as barium chloride and a final precipitation as barium nitrate from ice-cold fuming nitric acid. Cs and La carriers were present during the chloride reprecipitations, while Cs alone was present during the precipitation of barium nitrate. The chemical yield was determined by weighing the final barium nitrate precipitate.

The activity of the barium samples was measured by a scintillation counter consisting of a 3 in.×3 in. sodium iodide crystal coupled to a 400-channel pulse-height analyzer. The photopeak intensity of the 373 kev gamma ray (8), characteristic of Ba^{131}, was compared for the various samples.

(b) La^{129} and La^{130} (Experiments 5 and 6)

Irradiations of naturally occurring barium and of barium enriched in Ba^{130} (130-fold enrichment) as barium nitrate were made in the circulating beam of the McGill University proton synchrocyclotron. The barium nitrate was placed in thin aluminum tubing and clamped to the target holder on the cyclotron probe. This probe was placed at radii corresponding to 12 Mev and 20 Mev protons—roughly the calculated peaks of the (p,n) and $(p,2n)$ excitation functions, respectively.

After bombardment the barium nitrate was dissolved in dilute hydrochloric acid containing La carrier. The solution was boiled with a few milligrams of ammonium carbonate (to remove C^{11} as CO_2) and then lanthanum hydroxide was precipitated with ammonia. The precipitate was dissolved, reprecipitated, washed, and redissolved. The activity was measured with a 3 in.×3 in. sodium iodide crystal coupled to a 100-channel pulse-height analyzer.

(c) La^{127}, La^{128}, La^{129}

(1) Procedure Used in Experiments 2 and 3

Antimony powder was irradiated with C^{12} ions in the Berkeley HILAC. After bombardment the target was dissolved in hot aqua regia, La and Ba carriers were added, and barium chloride was precipitated by bubbling gaseous hydrogen chloride into the ice-cold solution. This precipitate was discarded. After 2 or 3 minutes a known amount of barium carrier was added to the solution and a barium chloride precipitate was centrifuged out and removed exactly 4 minutes after the initial 'clean-up' precipitation. Fresh barium was added in order to form a second daughter-fraction 4 minutes later. This process was repeated at 4-minute intervals until eight daughter-fractions were obtained.

Each of the eight daughter-fractions was purified by reprecipitation of the barium, first as the chloride then as the nitrate. Chemical yields were determined by weighing barium nitrate. The beta activity in these samples was measured in a proportional counter through a 0.005-in. aluminum absorber.

(2) Procedure Used in Experiment 4

The antimony target was dissolved in hot aqua regia, and lanthanum carrier precipitated as the fluoride. The precipitate was dissolved in saturated boric acid solution and lanthanum hydroxide precipitated in the presence of barium holdback carrier. The hydroxide was dissolved in hydrochloric acid, reprecipitated, and redissolved in hydrochloric acid containing an accurately known amount of barium carrier. After an interval of exactly 8 minutes lanthanum hydroxide was precipitated and separated by centrifugation. The supernatant solution was set aside as the first Ba–Cs daughter-fraction. The lanthanum hydroxide was dissolved in hydrochloric acid and fresh barium carrier was added. After exactly 8 minutes lanthanum hydroxide was again precipitated and a second daughter-fraction set aside. The procedure was repeated until eight daughter-fractions had been separated. The Ba–Cs fractions were individually evaporated with aqua regia to destroy NH_4^+, which would interfere with the later separation of cesium, then taken up in hydrochloric acid. After about 2 hours the solution was cooled, then gaseous hydrogen chloride bubbled in. The barium chloride was washed, recentrifuged, and mounted on filter paper for activity measurements.

Preliminary tests of this procedure with Ba^{140} tracer showed that only 3% of barium activity was removed from the solution with the lanthanum hydroxide precipitate.

Cesium granddaughter activity was isolated from the mother liquor of the barium chloride precipitation in the following way (9). Two drops of 0.4 *M* solution of silicotungstic acid was added and the ice-cold solution saturated with gaseous hydrochloric acid. Free silicotungstic acid was precipitated out, carrying with it the carrier-free cesium activity. The precipitate was separated by centrifugation and dissolved in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

water. The cesium was adsorbed on a short column of Dowex-50 cation resin to separate it from the silicotungstic acid carrier. The column was washed with water, after which the cesium was eluted with dilute hydrochloric acid and evaporated on a platinum plate which was mounted for activity measurements. Chemical yields were not measured but repeated preliminary test runs with Cs^{137} tracer showed that the recovery was consistently 85–90%.

(d) Activity Measurements

The activity of all barium samples from the HILAC bombardments, except those specifically designed to measure Ba^{131}, was measured by a series of intercalibrated end-window gas flow proportional β^- counters through aluminum absorbers (32.4 mg/cm²) which cut out any contribution of conversion electrons from the cesium daughters. The thickness of the samples was so nearly uniform that no self-absorption corrections were necessary. The relative activity of the cesium samples was measured by an integral gamma counter (sodium iodide) biased to record all events above the 60 kev level. The gamma activity of the lanthanum samples resulting from the cyclotron experiments was measured by a sodium iodide crystal coupled to a 100-channel pulse-height analyzer. As described previously, the 373 kev gamma rays from the Ba^{131} samples were measured by a 3 in.×3 in. sodium iodide crystal coupled to a 400-channel pulse-height analyzer.

RESULTS

Experiment 1 performed by the procedure outlined in (*a*) above was designed to confirm properties of La^{131}. The activity measurements of the barium daughter-fractions showed that the areas of the 373 kev photopeak decreased with time with the 12-day half-life expected for Ba^{131}. The half-life of the parent La^{131} was shown to be 56±3 min, in good agreement with the value of 58 min found previously by a direct determination (5). The decay curve of the parent found from various 'milkings' is shown in Fig. 1.

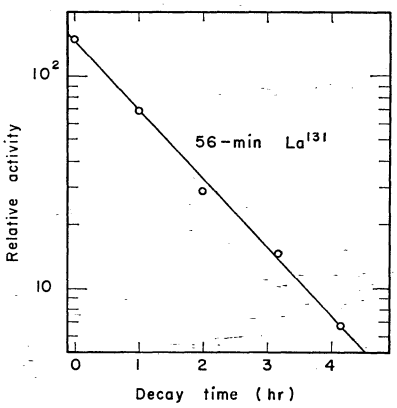

FIG. 1. Decay of La^{131} obtained by successive 'milkings' of Ba^{131}.

Experiments 2 and 3 were carried out according to procedure (*c*1) and experiment 4 according to procedure (*c*2). The decay curves of the activity in the barium daughter-fraction in all three experiments could be resolved cleanly into two components attributable to Ba^{128} and Ba^{129}. The presence of the 3 Mev β^--radiation from the 3.5-min Cs^{128} daughter (2) of Ba^{128} was confirmed by an aluminum absorption measurement. The half-life of Ba^{129} was found to be 2.20±0.05 hr from the analysis of 14 of our decay curves. Arbman and Haller (10) report two isomeric states in Ba^{129}—a β^+-form decaying with a half-life of 2.61±0.02 hr and various conversion electrons with half-lives between 2.00± 0.10 and 2.37±0.08 hr. We made no detailed examination to determine whether our Ba^{129} activity was a mixture of isomers.

The 2.4-day component of Ba^{128} was seen in every barium fraction. The best value of this half-life was determined from one sample which was followed for 22 days after the decay of Ba^{129}. This one-component decay curve gave a value of 2.43±0.05 days for the half-life of Ba^{128}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When the resolution of the barium decay curves was complete, the amounts of Ba^{128} and Ba^{129} in each sample at the time of the separation from the lanthanum parent was plotted against the time of the separation. Suitable corrections were made for chemical yield. Since the growth times were identical, this method of plotting reveals the decay of the La^{128} and La^{129} parents. The data points are shown in Fig. 2, and the half-life values are listed in Table I.

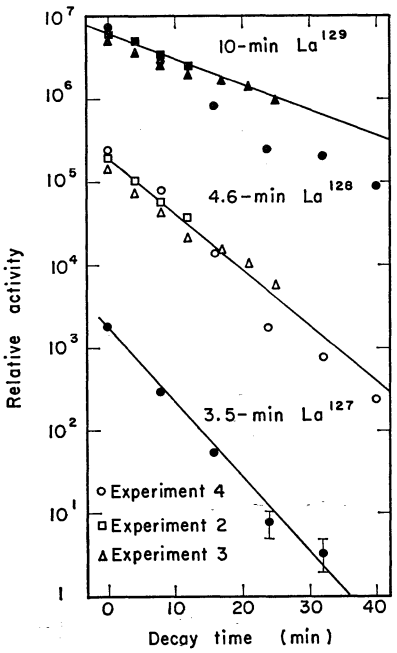

FIG. 2. Decay of La^{127}, La^{128}, and La^{129} obtained by successive 'milkings' of the daughters.

TABLE I

Summary of experimental results

Expt.	Growth time (min)	No. separations	Half-lives (min)				
			La^{127}	La^{128}	La^{129}	La^{130}	La^{131}
$Sb+C^{12}$							
1	60	5					56±3
2	4	4		4.5	9.4		
3	4	7		5.4	10.6		
4	8	6	3.5	3.8	5.8		
$Ba^{130}+p$							
5, 6					10.0±0.5	8.7±0.1	
		Best values	3.5	4.6±0.6	10.0±0.5	8.7±0.1	56±3

In experiment 4 the decay curves obtained for the cesium granddaughter fractions were easy to resolve into 6.2-hr-Cs^{127} and 32-hr-Cs^{129} components. The relative amount of Cs^{127} and Cs^{129} at the time of separation is plotted in Fig. 2. Those plots correspond to a half-life of 3.5 min and 5.8 min for La^{127} and La^{129}, respectively.

In experiment 5 barium was bombarded with 12 Mev protons to maximize the yield of La^{130} produced by the $Ba^{130}(p,n)La^{130}$ reaction. Measurements with a 3 in.×3 in.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

sodium iodide scintillation crystal spectrometer showed a prominent 360 kev gamma ray decaying cleanly with a half-life of 8.7±0.1 min to a background 1 part in 10^4 of the initial counting rate. The amount of this gamma ray present in the lanthanum fraction from the targets enriched in Ba^{130} was higher by the ratio of the Ba^{130} content in both targets. This establishes the correctness of the mass assignment of Sheline *et al.* (1).

In experiment 6 barium targets were bombarded with 20 Mev protons to maximize the reaction $Ba^{130}(p,2n)La^{129}$. The decay curves of X-ray and 511 kev annihilation radiation were measured. The assignment of a 10-min activity to La^{129} was consistent with the Ba^{130} content of the samples irradiated. The 110 kev and 511 kev radiation decayed with half-lives of 10.0 and 10.5 min, respectively, into a 2.6-hr background. The shape of the composite curve and the relative amounts of 10-min and 2.6-hr activity were consistent with the decay of 10.0-min La^{129} into 2.6-hr Ba^{129}. The X-ray activity decayed initially with a 9.4-min slope which later lengthened to 4.75 hr. This longer-lived activity is probably a mixture of La^{132} and La^{133} produced from higher-mass barium isotopes in the target.

All results are summarized in Table I. 'Best' values are quoted in the last line. Our values for the half-lives of La^{127}, La^{128}, and La^{129}, determined by 'milking' experiments, agree quite well with those of Preiss *et al.* (7), who obtained values of 3.8±0.5, 4.2±0.5, and 7.2±0.5 min respectively. The most accurate determination of the half-life of La^{129} (10.0±0.5 minutes) was obtained from direct observation of La^{129} produced by the reaction Ba^{130}(20 Mev $p,2n$)La^{130}. Our results are also close to those of Sheline *et al.* (1), who obtained half-lives of 6.5±1.0 and 9.0±1.0 min, for La^{128} and La^{130} respectively.

ACKNOWLEDGMENTS

One of us (L. Y.) wishes to express his sincere appreciation to Professor I. Perlman and the members of the Chemistry Department, Lawrence Radiation Laboratory, University of California at Berkeley, for their hospitality during the summer of 1962. The authors wish to express their appreciation to Dr. R. E. Bell, Director, Radiation Laboratory, McGill University, for his ready cooperation in making the cyclotron facilities available. They also thank the HILAC crew for their able assistance, and R. S. Tilbury for assisting with the chemical separations in those experiments dealing with proton bombardments.

A STUDY OF $Cd^{115m,g}$ FORMED IN THE FISSION OF NATURAL URANIUM BY PROTONS OF ENERGIES 8 TO 60 MEV[1]

R. S. TILBURY[2] AND L. YAFFE
Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.
Received April 10, 1963

ABSTRACT

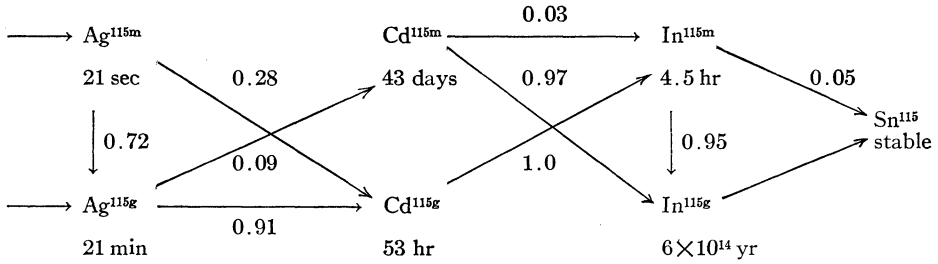
Excitation functions have been measured for the formation of Cd^{115m}, Cd^{115g}, and Ag^{115g} produced in the fission of natural uranium induced by protons of energies 8 to 60 Mev. The isomer yield ratio for $Cd^{115m,g}$ was found to increase with increasing proton bombarding energy over the range 20 to 60 Mev in contrast to the published results for the deuteron fission of uranium, for which a minimum was found.

INTRODUCTION

High-energy fission studies leading to nuclear isomers have been mostly concerned with the yields of Cd^{115m} and Cd^{115g}. Hicks and Gilbert (1) measured the ratio of isomer cross sections σ_m/σ_g, for the deuteron fission of U^{238} from 50 to 150 Mev, whilst Sharp and Pappas (2) measured the same ratio for deuterons of energy 10 to 25 Mev. Their combined results show a striking minimum at 25 to 50 Mev in the energy dependence of σ_m/σ_g. Unfortunately the energy range at which this minimum occurs is inaccessible to the present deuteron accelerators, lying above the range of the C.F. cyclotrons and below that at which large F.M. machines can be operated conveniently. Sharp and Pappas suggested that it would be of interest to see whether a similar minimum is obtained in proton fission with one of the 10–100 Mev proton cyclotrons which can bridge the energy gap. Munzel (3) has since measured $Cd^{115m,g}$ isomer yield ratios for the α-particle fission of U^{238} over the energy range 25 to 45 Mev and reports a less pronounced minimum.

We have examined the reaction $U^{238}(p,f)Cd^{115m,g}$ using the McGill synchrocyclotron to provide protons of energies between 8 and 60 Mev. At the same time, by including a monitor for the proton beam in the target assembly, it was possible to measure the formation cross sections of Cd^{115m}, Cd^{115g}, and that of the precursor Ag^{115g}.

The decay scheme of the mass 115 fission product chain was taken to be:



This is identical with the decay scheme used by Sharp and Pappas and is reproduced here for easy reference. By separating cadmium from silver as soon as possible after bombardment (about 20 minutes was required in the present work) it is possible to correct for the amount of $Cd^{115m \text{ and } g}$ which has grown in from Ag^{115g} during the bombardment and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

subsequent decay. Ag^{115m} is too short lived to allow a correction to be made for it. On the basis of the above decay scheme, equations have been derived for the formation cross sections of $Cd^{115m \text{ and } g}$ and for Ag^{115g}, and from these an equation for the isomer yield ratio for $Cd^{115m,g}$:

$$\frac{\sigma_m^i}{\sigma_g^*} = \frac{\lambda_g}{\lambda_m} \frac{[A_1 Y_o - A_3 Y_a F']}{[A_2 Y_o - A_4 Y_a F']}$$

where σ_m^i is the cross section for the independent formation of Cd^{115m},

σ_g^* is the cross section for the independent formation of Cd^{115g} + 0.28 of the cross section for the cumulative formation of Ag^{115m}, σ^c,

λ_m and λ_g are the decay constants,

A_1 and A_2 are the activities due to Cd^{115m} and Cd^{115g} respectively at end of bombardment in the organic phase of the separation process,

A_3 and A_4 are the activities due to Cd^{115m} and Cd^{115g} respectively in the aqueous phase of the separation process,

Y_o and Y_a are the chemical yield factors for cadmium in the organic and aqueous phases respectively of the separation of silver from cadmium, and

$$F' = \frac{1-[e^{-\lambda t_2} - e^{-\lambda(t_1+t_2)}]}{[e^{-\lambda t_2} - e^{-\lambda(t_1+t_2)}]}$$

where t_1 and t_2 are the times of bombardment and separation respectively, and λ is the decay constant for 21-min Ag^{115g}.

Sharp and Pappas obtained a λt_1 term in place of 1, due to slightly different approximations in the simplification, but this makes only a minor difference in the calculated isomer yield ratios.

EXPERIMENTAL

The target consisted of three foils of natural uranium (0.0006 in. thick) placed beside two foils of copper monitor (0.002 in. thick) in the cyclotron target holder. The leading edge was carefully aligned and the target irradiated in the circulating beam of the McGill synchrocyclotron for about 30 minutes.

After bombardment the first 1/4 in. of the leading edge was cut off, the first copper foil was used as a monitor, and the middle uranium foil as target. The other foils served to protect the monitor and target foils from contamination by recoil atoms. The extra foils did not significantly degrade the energy of the proton beam.

As soon as possible after bombardment the middle uranium foil was dissolved in 12 *N* hydrochloric acid, to which a drop of hydrogen peroxide solution had been added. Cadmium was extracted from this solution, and the remaining four foils were later weighed in order to ascertain the weights of target and monitor.

The procedure for the chemical separation of cadmium was taken from Sharp and Pappas (2) with certain modifications. The method depends on the extraction of cadmium dithizonate into chloroform solution from strongly basic solution. Sandell (4) lists tellurium as one of the metals reacting with dithizone. Te^{132} (78 hr) and Te^{129m} (33 days) would interfere with the resolution of 53-hr Cd^{115g} and 43-day Cd^{115m}. In addition to the carriers added by Sharp and Pappas, tellurium carrier was added. Examination of separated samples on a gamma-ray spectrometer showed the gamma-ray peaks of Te^{132} present in those extractions in which Te carrier had not been added, while only the photon peaks due to Cd^{115} were observed with the modified procedure.

The β^--activity of the cadmium samples was measured with a $4\pi\beta$ proportional counter (5). Corrections were applied for absorption in the source and source mount, and for coincidence loss. Cd^{115g} decays to In^{115m} which is in transient equilibrium, and In^{115m} decays 5.5% by β^--emission to Sn^{115} and 94.5% by a 335 kev isomeric transition to the ground state. The 335 kev gamma ray is largely internally converted with a total conversion coefficient of 0.90±0.06 (6). The energies of these conversion electrons are sufficiently great (~300 kev) to be efficiently detected in the 4π counter. It was calculated that the 53-hour counting rate must be divided by 1.55 to correct for the betas due to In^{115m}.

The branching ratio of the decay of Ag^{115g} to Cd^{115m} and Cd^{115g} was checked by measuring the Cd^{115} activities, since all the Cd^{115} occurring in the aqueous phase should be due to the decay of Ag^{115g} alone if the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

chemical separation of cadmium from silver had been adequate. The results found agreed with the branching ratios of 9% and 91% determined by Wahl and Bonner (7). This also provided a check on the efficiency of the separation procedure for each run.

The reaction used to monitor the proton beam was $Cu^{65}(p,pn)Cu^{64}$, and the cross-section data were those of Meghir (8). After bombardment, the copper foil was dissolved and copper separated by ion exchange, using a method due to Kraus and Moore (9) in the presence of suitable holdback carriers. The 12.8-hr Cu^{64} activity was measured by means of its positron annihilation radiation, using a calibrated gamma-ray spectrometer.

Chemical yields were determined spectrophotometrically, cadmium by dithizone in chloroform (10), and copper by diethyldithiocarbamate, extracting the complex into isoamyl alcohol (11).

RESULTS AND DISCUSSION

Table I shows the cross-section values obtained in this work. Figures 1, 2, and 3 show these results plotted graphically, together with the estimated experimental errors. At 15 Mev no Cd^{115m} was detected and at 8 Mev neither Cd^{115m} nor Cd^{115g} was detected.

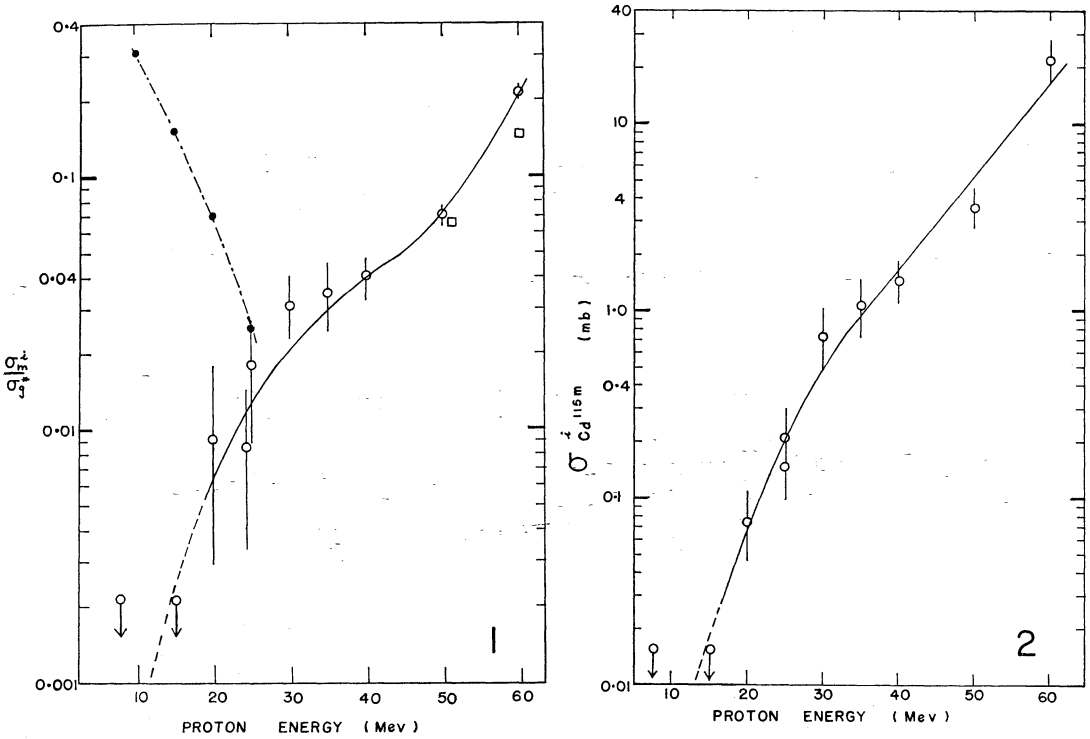

FIG. 1. Variation of σ_m^i/σ_g^* with proton bombarding energy for the reaction $U^{238}(p,f)Cd^{115m,g}$, where $\sigma_g^* = \sigma^i_{Cd^{115g}} + 0.28\sigma^c_{Ag^{115m}}$. ○ = this work; ● = Sharp and Pappas (2); □ = Hicks and Gilbert (1).

FIG. 2. Excitation function for the reaction $U^{238}(p,f)Cd^{115m}$.

The isomer yield ratio for $Cd^{115m,g}$ was found to increase from the lowest energy at which both Cd^{115m} and Cd^{115g} were detected to the highest proton energy used. No minimum in the curve was detected, in contrast to that shown in the deuteron fission of uranium. At 50 and 60 Mev the isomer yield ratios found in this work agree reasonably well with those of Hicks and Gilbert (1). The results of Sharp and Pappas for deuteron bombardments do not agree with the present results for proton bombardments at low energies. The reason for this may possibly be due to slight tellurium contamination in

their separation of cadmium as discussed previously. Te^{129} and Te^{132} have high fission yields in low-energy fission of uranium, whilst Cd^{115} occurs at the valley. Thus, at low energies, slight contamination with tellurium would have a large effect on the measurement of cadmium.

This difference in experimental observation between the proton and deuteron reactions at low energies would not be expected on the basis of different nuclear mechanisms. Oppenheimer-Phillips reactions do occur with deuterons at low energies, but this would merely tend to lower the threshold energy of the fission reaction. It may be that the deuteron, having a greater nuclear spin than the proton, brings in a relatively larger amount of angular momentum at low energies, but it is difficult to see why this should decrease and then start to increase above 30 Mev.

Although the cross-section values of Cd^{115m} are independent, those of the ground-state isomer are not, since they include 28% of the cumulative yield of Ag^{115m}. It has been shown that, at thermal energies, Z_p, the most probable nuclear charge, is about 3 charge units removed from stability. As the bombarding energy increases, however, Z_p moves towards stability (12, 13, 14). In the mass 115 chain, $_{47}Ag^{115}$ will be the most probable species formed directly in the fission process, at low energies, with relatively large yields of $_{46}Pd^{115}$ and $_{48}Cd^{115}$. As the bombarding energy increases, $_{48}Cd^{115}$ will be the favored product, so that at energies about 25 Mev most of the Cd^{115g} will be formed independently. Above 25 Mev, then, since the σ_m^1/σ_g^* ratio for $Cd^{115m,g}$ increases with increasing energy, the higher the bombarding energy the more is the high-spin state favored compared with the low-spin state, in agreement with what might be expected from the conclusion that high-energy fission is a high angular momentum process. Davies and Yaffe (15), however, have recently found, in the case of the Cs^{134} isomers, that increasing bombarding energy decreases the yield of the high-spin isomer, adding to the complexity of the situation.

ACKNOWLEDGMENTS

The authors wish to thank Dr. R. E. Bell and Mr. R. H. Mills for their cooperation during the cyclotron bombardments, and Mr. D. M. Marsden for his help in elucidating some of the chemical separation difficulties. One of us (R. S. T.) thanks the International Nickel Company of Canada Limited for a Fellowship from 1960–1963.

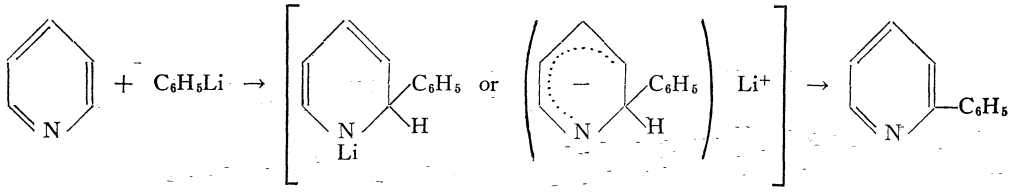
PHENYLLITHIUM–PYRIDINE ADDUCT AS A REDUCING AGENT FOR KETONES

R. A. ABRAMOVITCH AND B. VIG
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received March 19, 1963

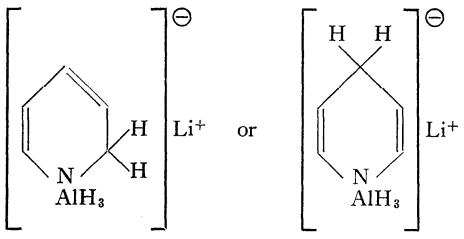
ABSTRACT

The reduction of ketones to the corresponding alcohols using 1,2-dihydro-2-phenylpyridyllithium has been studied. Benzophenone is reduced more readily than is acetophenone, which in turn is more readily reduced than cyclohexanone. It is suggested that the by-product formed in the reduction of benzophenone is 4-diphenylhydroxymethyl-2-phenylpyridine.

The reaction of phenyllithium with pyridine and substituted pyridines has been studied extensively in these laboratories (1–4). The reaction is thought to proceed in two stages: the first is the addition leading to the formation of 1,2-dihydro-2-phenylpyridyllithium, which has been formulated either as I*a* or I*b*; this, on heating, splits off lithium hydride to give 2-phenylpyridine (II). Alternatively, it may be treated with water and the 1,2-dihydro-2-phenylpyridine formed oxidized *in situ* to II. It occurred to us that the adduct I might well behave as a selective reducing agent and it was proposed to examine the possibility of reducing a number of ketones making use of this intermediate. While this work was in progress Lansbury and Peterson (5) reported the results of their interesting work carried out using the adduct III formed between pyridine and lithium aluminum hydride, a reagent similar in many ways to the one used in the present work.



I*a* I*b* II



III

Dihydropyridines play an important role in biological oxidation–reduction systems and many dihydropyridine derivatives have been reported to reduce a variety of substances non-enzymically: nitro groups (6, 7), olefinic double bonds (7, 8), ketones (9), keto acids (10), quinones (7, 11), and other functional groups. The reduction of hexachloroacetone proceeds readily to give a reasonably good yield (53–60%) of the alcohol (9), but chloral only gives a 3% yield of 2,2,2-trichloroethanol with 1-benzyl-1,4-dihydronicotinamide.

Acetone is not reduced by this reagent (9) whereas alloxan is reduced rapidly by 1-methyl or 1-*n*-propyl-1,4-dihydronicotinamide (12).

The reduction of benzophenone by the intermediate I in pyridine–ether solution was investigated in detail. A solution of phenyllithium was prepared in the usual manner and added to a solution of a large excess of pyridine in ether. To this was added the benzophenone and the products worked up by column chromatography. The yield of benzhydrol varied according to the amount of phenyllithium used relative to that of benzophenone, maximal yields being obtained when the molar ratio of I to benzophenone was 2 (Table I). Yields were lowered appreciably if pyridine was not used in excess. A

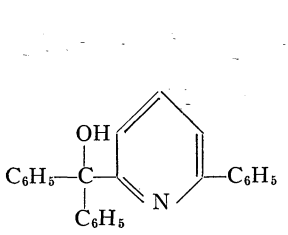
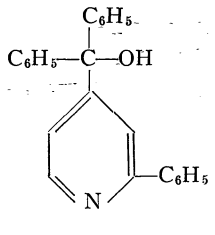
Yield of by-product A (%)	Not determined	10	12.5

*Assuming that one equivalent of I is present for every equivalent of phenyllithium used. This is undoubtedly not the case since I undergoes polymerization quite readily (13).

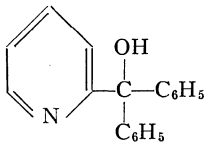
by-product (A) was also obtained in these reactions. The by-product A had the molecular formula $C_{24}H_{19}ON$. It formed a hydrochloride only with difficulty (it was not extracted easily from ether solution with dilute acid), but readily gave a picrate. The infrared spectrum of A indicated the presence of a hydroxyl group, but no —NH— group. Bands characteristic of a monosubstituted phenyl group were also present. Attempts to prepare an acetyl derivative were unsuccessful, suggesting that the hydroxyl group may be tertiary. The compound could not be reduced catalytically at room temperature and pressure. On the basis of these observations, and taking into account the nature of the reactants, two plausible structures for A are 2-diphenylhydroxymethyl-6-phenylpyridine (IV) and 4-diphenylhydroxymethyl-2-phenylpyridine (V). An attempt was made to synthesize IV by



IV



V



VI

the action of phenyllithium on diphenyl-2-pyridylmethanol (VI) (prepared by the action of 2-pyridyllithium on benzophenone): only starting material was recovered. 2-Bromo-6-phenylpyridine was obtained from 2-phenylpyridine via 2-amino-6-phenylpyridine (14). Reaction of 2-lithio-6-phenylpyridine with benzophenone gave the required tertiary alcohol (IV), which was different from the by-product A. That A probably has structure V was confirmed by the comparison of its n.m.r. spectrum (measured on a solution of the compound in carbon tetrachloride, at an oscillator frequency of 60 Mc/s and with tetramethylsilane as an internal standard) with that of authentic IV. The latter exhibited no peaks characteristic of a pyridine α-proton; instead, a multiplet centered at 484 c.p.s. was observed and is attributed to H_γ of the pyridine ring (1, 15). On the other hand, A exhibited a single-proton doublet centered at 524 c.p.s., which is characteristic of an H_α

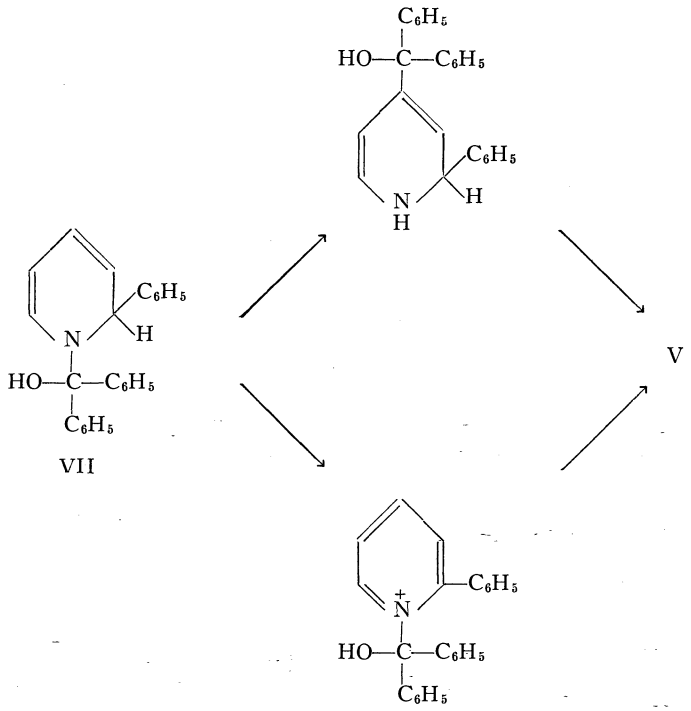
For personal use only.

proton in a pyridine ring (1, 15) and is consistent with the proposed structure (V). This by-product could arise in one of two ways: (i) by direct nucleophilic attack of benzophenone by intermediate I*b*, or (ii) by the reaction of I*a* with benzophenone to give an unstable dihydropyridine derivative (VII), which can then undergo a molecular rearrangement followed by dehydrogenation, or dehydrogenation followed by rearrangement, the



latter being similar in character to the Ladenburg rearrangement of 1-alkylpyridinium salts (16). It is not possible at this stage to distinguish between these two alternatives.

The reduction of acetophenone was investigated next. Using a 2:1 molar ratio of phenyllithium to acetophenone a low yield (14.5%) of α-phenylethanol was obtained, which could not be improved upon by varying the reaction conditions. Though a number of by-products could be isolated in a crude state by column chromatography of the reaction products none could be purified sufficiently for analysis. The reduction of cyclohexanone was also investigated: gas-chromatographic analysis of the reaction products indicated the formation of cyclohexanol in 6.5% yield. It would, therefore, appear that diaryl ketones are more readily reduced by I than are either arylalkyl or dialkyl ketones. The same conclusion was reached when the reducing agent used was III (5).

In a preliminary run in which I was used to reduce nitrobenzene no aniline could be detected gas chromatographically. An orange product was formed whose retention time was identical with that of azobenzene. A small amount of this product was collected but its infrared spectrum was different from that of azobenzene. It was not investigated further at this time.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured on a Perkin–Elmer Model 21 spectrometer equipped with sodium chloride optics, and n.m.r. spectra on a Varian A60 instrument.

Reduction of Benzophenone

The general procedure used to carry out this reaction will be described for the case in which the phenyllithium:benzophenone ratio is 2.

A solution of phenyllithium in dry ether was prepared from bromobenzene and lithium under nitrogen according to a standard procedure (3). The normality of the phenyllithium solution was determined by titration with standard hydrochloric acid solution. An ethereal solution of phenyllithium (0.018 mole, 50 ml) was added to a cooled solution of pyridine (18 g) in dry ether (20 ml) under dry, oxygen-free nitrogen at such a rate that the temperature of the mixture did not rise. A solution of benzophenone (1.6 g, 0.009 mole) in dry ether (12 ml) was now added dropwise and stirring continued at room temperature under nitrogen for another 12 hours. The reaction mixture was decomposed with dilute hydrochloric acid (which removed unchanged pyridine and the 2-phenylpyridine which was formed), the ether layer washed repeatedly with water and evaporated. The residue was chromatographed on a column of alumina. Elution with benzene – light petroleum (b.p. 40–60°) (1:1 v/v) and then with benzene gave benzhydrol (1.02 g), m.p. 63°, undepressed on admixture with an authentic sample (the infrared spectra of product and authentic sample were identical). Elution with ether:benzene (1:1 v/v) gave *4-diphenylhydroxymethyl-2-phenylpyridine* (0.300 g), m.p. 156–157° (after recrystallization from dilute ethanol). (Calc. for $C_{24}H_{19}ON$: C, 85.43; H, 5.68; N, 4.15; M.W., 337. Found: C, 85.60; H, 5.95; N, 4.32; M.W. (osmometer), 343.) The *picrate* was recrystallized from benzene and had m.p. 190–191°. (Calc. for $C_{24}H_{19}ON,C_6H_3O_7N_3$: C, 63.60; H, 3.91. Found: C, 63.43; H, 3.91.)

Reduction of Acetophenone

An ethereal solution (80 ml) of phenyllithium (0.049 mole) was added to a solution of pyridine (30 g) in dry ether as described above. A solution of acetophenone (2.95 g, 0.024 mole) in dry ether was then added and the mixture worked up as for benzophenone. Evaporation of the ether extract gave a mixture of products, which was distilled up to 150° at 20 mm to give a mixture of unreacted acetophenone and of α-phenylethanol (1.54 g). This was analyzed by gas chromatography on a 6-ft×1/4-in. column packed with silicone nitrile (17%) on Chromosorb W (80–100 mesh). The column temperature was 80° and the helium inlet pressure 40 p.s.i. Two peaks corresponding to acetophenone and α-phenylethanol were observed. The yield of α-phenylethanol was 14.5% based on the amount of acetophenone used (not taking into account the recovered acetophenone).

Reduction of Cyclohexanone

This was carried out as for the reduction of acetophenone using phenyllithium (0.030 mole) and cyclocyclohexanone (0.015 mole), and the gas-chromatographic analysis performed as above. The yield of cyclohexanol (not taking into account recovered cyclohexanone) was 6.5%.

Diphenyl-2-pyridylmethanol

2-Bromopyridine (3.16 g) in dry ether (20 ml) was added dropwise with stirring to a solution of *n*-butyllithium (0.03 mole) in dry ether (30 ml) under nitrogen at −62° over a period of 1 hour and the mixture stirred for another 30 minutes. A solution of benzophenone (3.64 g) in dry ether (15 ml) was added during 10 minutes while the temperature was kept at −62°. Stirring at this temperature was continued for a further hour after which the temperature was allowed to rise to room temperature. The mixture was treated with dilute hydrochloric acid, the ether layer removed, and the aqueous acid layer extracted with ether. The acid layer was neutralized with sodium bicarbonate, extracted with ether, the ether dried (Na_2SO_4) and evaporated to give *diphenyl-2-pyridylmethanol* (3.0 g), m.p. 105° after recrystallization from methanol. (Calc. for $C_{18}H_{15}ON$: C, 82.73; H, 5.79. Found: C, 82.57; H, 5.68.)

A number of attempts were made to phenylate this alcohol with phenyllithium in various molar proportions (including a large excess of phenyllithium). In all cases, unchanged carbinol was recovered. The failure of this reaction to occur might be due to the formation of an insoluble O-Li salt with the starting material.

2-Diphenylhydroxymethyl-6-phenylpyridine

A solution of 2-lithio-6-phenylpyridine was prepared as described above for 2-pyridyllithium using 2-bromo-6-phenylpyridine (1 g, 0.0043 mole) in dry ether (15 ml) and *n*-butyllithium (0.005 mole) in dry ether (30 ml). To this solution was added benzophenone (0.80 g) in dry ether (10 ml) and the reaction mixture worked up as above to give a crude product (2.58 g) which was purified by chromatography on a column of alumina (70 g). Elution with benzene – light petroleum (b.p. 40–60°) (1:4 v/v) gave *2-diphenylhydroxymethyl-6-phenylpyridine* (0.535 g), m.p. 135–136° after recrystallization from ethanol. (Calc. for $C_{24}H_{19}ON$: C, 85.43; H, 5.60. Found: C, 84.97; H, 5.68.) The infrared spectrum of this compound was different from that of by-product A.

CATALYTIC HYDRODESULPHURIZATION OF THIOPHENE

IV. THE METHYLTHIOPHENES[1, 2]

P. DESIKAN[3] AND C. H. AMBERG
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received March 28, 1963

ABSTRACT

The hydrodesulphurization of 2- and 3-methylthiophene was studied over a sulphided, alumina-supported cobalt molybdate catalyst in a microreactor permitting the use of both pulse and steady-state flow techniques. The higher rates obtained with the 3-isomer were interpreted in terms of involvement of the α-carbon. The results were found to conform to the predominant reaction sequence proposed earlier for thiophene: C—S bond fission followed by diene and monoolefin formation and complete saturation. Some ancillary experiments on the hydrogenation of C_5-olefins were reported.

INTRODUCTION

In three previous publications from this laboratory (1–3) studies of the hydrodesulphurization of thiophene on a commercial cobalt molybdate catalyst and a sulphided chromia catalyst were described. By making use of the microreactor technique it was possible to examine the adsorption–desorption behavior of reactants and products on the surface of these catalysts under reaction conditions. It was argued that the rate-determining step in the reaction was either hydrogen chemisorption or a surface reaction. No thiolane or mercaptans were found among the products and it was demonstrated that ring hydrogenation was not the initial step; the latter was more likely to be C—S bond fission. Though butadiene was identified only in the products from reactions over chromia, it was assumed to have been an intermediate also with the cobalt molybdate catalyst. This has since been verified in this laboratory by infrared transmission studies of the catalyst during the reaction (4). An excess of 1-butene over the amount expected from the isomerization equilibrium in the vapor phase was noted over chromia catalyst (1). It was shown to be the initial isomer formed in a later investigation by Vernon and Richardson (5), who studied the effects of varying the amount of cobalt promoter on the activity of molybdenum sulphide catalysts for thiophene hydrogenolysis. The experiments of Kirsch *et al.* (6, 7) with cobalt molybdate catalysts are in good agreement with those of the present series in several respects, notably in their consistency with the concept of a dual function catalyst.

In extending the use of the microcatalytic reactor to the desulphurization of the methylthiophenes it was hoped to examine the effect of the methyl group in different positions on the behavior of the thiophene ring in the reaction and thus to throw further light on the detailed mechanism of hydrogenolysis. The hydrogenation and isomerization reactions of the resulting C_5-olefin products were also expected to be of interest.

EXPERIMENTAL

Essentially the same apparatus was used as in the earlier work. Variations in feed rate were effected by adjustment of the temperature of the methylthiophenes in a liquid saturator.

The commercial cobalt molybdate catalyst (Girdler G 35A, 32–65 mesh) previously described (1) was

[1]*Issued as N.R.C. No. 7432.*
[2]*For Parts I–III, see references 1–3.*
[3]*National Research Council Postdoctoral Fellow 1961–1963.*

employed in beds of 0.47 g, 1.0 g, and 5.4 g, the smallest weight being used in all the single-shot runs to avoid the long pulse delays otherwise encountered. The catalyst was again stabilized with thiophene carried in a stream of hydrogen at 400°. This sulphiding process was repeated for occasional reconditioning.

Chromatographic and mass-spectrometric estimates of impurities contained in the thiophenes used yielded the following approximate results. Thiophene (Eastman) contained 1% benzene as its major impurity, 0.1% CS_2, 0.02–0.04% methyl ethyl ketone, and two unknown species of similar concentration; with 2-methylthiophene (Aldrich) no impurity bands were detectable, the lowest limit being ~0.01%; 3-methylthiophene (Aldrich) contained 0.9% 2-methylthiophene as its only detectable impurity. All three were used as received in continuous-flow experiments, but were purified by preparative gas chromatography for the single-shot and adsorption runs. The hydrocarbons employed were all Phillips research grade. Hydrogen from a cylinder was passed through a palladium catalyst and drying column to remove oxygen and water.

Most of the hydrocarbon analysis was carried out using a 25-ft propylene carbonate column (30% w/w on 30- to 48-mesh Chromosorb, in copper tubing). Satisfactory resolution of all C_5-isomers was obtained except for *trans*-2-pentene and 2-methyl-1-butene, which had identical retention times. Since hydrogenolysis of 2-methylthiophene gives rise predominantly to normal hydrocarbons and hydrogenolysis of 3-methylthiophene to branched hydrocarbons, i.e. without the occurrence of appreciable skeletal isomerization (Table I), this was not important. Nevertheless, it was possible by a series of successive approximations to estimate the concentration of the minor component of the olefin band in a given case on the basis of the above consideration and utilizing further product distribution data given in Table I. A 6-ft tricresyl phosphate column (40% w/w on 35- to 60-mesh Chromosorb, in glass tubing) was used at 70–90° in the determination of temperature coefficients and as a check on the percentage conversion calculated from results with the propylene carbonate column.

RESULTS AND DISCUSSION

As in the case of thiophene (1) no evidence was obtained of mercaptan or thiolane intermediates among the products. Dienes could likewise not be identified. The distribution of the products for 2-μl shots on a 0.47-g catalyst bed is shown in Table I at four different temperatures. From the table, the following conclusions can be drawn. Under the same conditions, 3-methylthiophene undergoes higher conversion than 2-methylthiophene, the activity ratio being approximately constant in the temperature range 277 to 362°, in which diffusion is not rate controlling.

The percentage of saturates in the products is always greater for 2-methylthiophene than for the 3-methyl compound. This conforms to the observation of Gaschke, Spector, and Heinemann (8) that the rate of hydrogenation of 2-pentene on a cobalt molybdate alumina catalyst is faster than that of 2-methyl-2-butene. Furthermore, there is a general tendency favoring isomerization to branched rather than normal hydrocarbons. Thus, the

percentage of skeletal rearrangement of the (branched) products of hydrogenolysis of 3-methylthiophene varies from 0 to 10% in the temperature range examined, while it remained fairly constant at about 40% for the (normal) products from the 2-isomer. Both the preferential hydrogenation of normal olefins and their tendency to isomerize to branched olefins can be rationalized if acid sites are responsible for the reactions. There is reason to believe such to be the case. A few experiments in this laboratory using cobalt molybdate catalysts containing varying amounts of sodium (deposited from aqueous sodium carbonate) showed that both hydrogenolysis and olefin hydrogenation were suppressed by the alkali. The different sites, or the different functions of the same type of site, were also shown to be selectively poisoned by H_2S (1, 7). From other investigations in cracking and isomerization (9) it is reasonable to deduce that the carbonium ion from a normal olefin is more reactive and can either isomerize to a branched carbonium ion or hydrogenate to form a saturated hydrocarbon. The branched carbonium ion is more stable and gives the branched olefin without skeletal rearrangement.

The effect of sample size on conversion is similar to that found for thiophene and is demonstrated in Fig. 1. The C_5 analysis for the experiments at 414° (diffusion-controlled

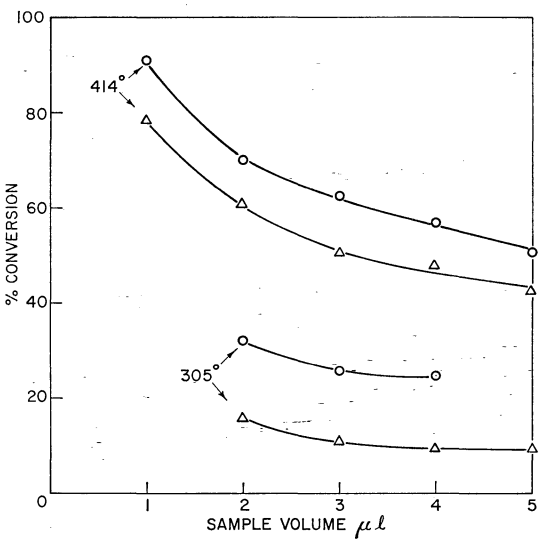

FIG. 1. The effect of sample size on conversion of the methylthiophenes on 0.47-g catalyst. △ 2-methylthiophene, ○ 3-methylthiophene.

region) was made using the tricresyl phosphate column and for those at 305° the propylene carbonate column. The effect is sufficiently marked to demonstrate that, as before (1), steady-state conditions are to be preferred for strict quantitative measurements (see e.g. Table II).

Figure 2(*a*) shows the preferential hydrogenation of 1-pentene over 2-methyl-1-butene. Hydrogenation experiments were carried out with 2-μl samples of the olefins in the absence of thiophene and H_2S, and once again the normal olefin was found to be hydrogenated to a greater extent. Also, skeletal rearrangement favored the formation of branched olefins, as indicated by Fig. 2(*b*).

In order to determine temperature coefficients of the rates of hydrogenolysis for thiophene and its homologues, continuous-flow experiments were carried out in the

conversion vs. reciprocal temperature, which were obtained by the method of least squares; slopes and hence temperature coefficients (apparent activation energies *E*) were computed at the 95% confidence level. The energy value for thiophene proved to be the same, within experimental accuracy, as that for a 5.4-g catalyst bed and similarly agreed with that quoted in an ealier publication (1). Changing the flow and hence the feed rate did not alter the value appreciably.

It can be seen from Table II that there is little difference in the temperature coefficients of hydrogenolysis for the two methylthiophenes, in contrast to the much higher value for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

thiophene. On the other hand the conversion of 3-methylthiophene is consistently more than double that of the 2-isomer. Thiophene reacts at rates similar to those of 2-methylthiophene at the lower temperatures and tends to approach its 3-methyl homologue in activity at higher temperatures.

An explanation for the higher rates of conversion of 3-methylthiophene compared to the 2-methyl compound has to be consistent with the behavior of thiophene. If hydrogen chemisorption were to be the only rate-determining step, changes in the structure of the other reactant such as introduction of a methyl group in the aromatic ring or change of its position would not affect the rates and energies of activation significantly. That the slow step could be the adsorption of the thiophene would also seem to be ruled out. Heats of adsorption of thiophene and the methylthiophenes were measured by the peak delay technique (1–3) on the 1-g catalyst sample in the range of reaction temperatures, and were found to be 8.7 ± 0.5 kcal/mole for thiophene and 11.0 ± 1.2 kcal/mole for each of the two methylthiophenes. If these are the heats of chemisorption, then the difference in the activities of the two methylthiophenes cannot be explained on the basis of differences in adsorption energy.

It is very likely then that the slow step is a surface reaction such as C—S bond fission on the catalyst surface. The surface species involved in the fission should be different for thiophene and the methylthiophenes, and different again for 2- and 3-methylthiophene. This makes it unlikely that the slowly reacting surface species is bonded to the catalyst surface through a π-bond to the aromatic ring, although the latter might be a precursor in the reaction sequence. A π-complex of this type between chromium tricarbonyl and thiophene has been characterized, for instance, by Fischer and Öfele (10). The electron density at the α-carbon atom is most probably the determining factor. The combined inductive and hyperconjugative effects of the methyl group in the 3-position can enrich the α-carbon atom of the 3-methylthiophene and impart to it greater affinity for a proton or an acidic surface site. If the α-hydrogen atom is replaced by a methyl group, however, the hyperconjugation would oppose the interaction of the aromatic double bond with the sulphur atom. There would still remain a smaller activation of the unsubstituted α-carbon. The thiophene molecule without any localizing substituent effects should then require higher activation for the C—S bond scission. The difference in activity of the 2- and 3-methylthiophenes is not reflected in their apparent activation energies possibly because of the limited accuracy of the measurements. Thus by assuming the "compensation effect" to be operative it can be estimated that a variation in rates by a factor of 2 will result in activation energy changes of the same magnitude as the uncertainty in the measured E values.

It is of interest to consider possible gas-phase intermediates. By analogy with thiophene itself, it is reasonable to expect C_5-dienes to be intermediates in the reaction of the methyl thiophenes over cobalt molybdate catalyst. A few shot runs with n-pentadienes and isoprene in a stream of hydrogen showed that, if they were initially formed in the hydrogenolysis, they would be hydrogenated too fast to be detected among the products under the conditions used. On the other hand using alumina alone, dienes were positively identified among the hydrogenolysis products arising from both thiophene and the methylthiophenes. A highly pure and acidic alumina was prepared for this purpose by the method of Pines (11) (conversions were less than 2% at 300–400° C). The insignificant departure from gas phase equilibrium (9) among the pentene and also the methylbutene isomers in the reaction products unfortunately precluded identification of the initial monoolefin formed from either of the two methylthiophenes. Previously, 1-butene had been so

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

identified in the case of thiophene itself (1). Cyclic intermediates with partial or complete saturation of the aromatic double bonds have apparently no place in the thiophene hydrogenolysis scheme. Desulphurization of dihydro- and tetrahydro-thiophene is being investigated and the results, to be published later, indicate the reaction pattern to be quite different. Also, the differences between the activities of thiophene and its immediate homologues depend on the retention of the thiophene double bonds before the rate-determining step, which, in turn, is consistent with a mechanism involving the α-carbon atom.

ACKNOWLEDGMENTS

The authors are grateful to M. Bednas for purification of the methylthiophenes by preparative gas chromatography.

THE EXISTENCE OF THE FLEXIBLE CONFORMATION IN SIX-MEMBERED RINGS

F. LAUTENSCHLAEGER AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 11, 1963

ABSTRACT

From consideration of electrical polarization and nuclear magnetic resonance measurements, 1,4-dimethylenecyclohexane and its exo-tetramethyl and tetraphenyl analogues have been assigned the flexible ring conformation, as have also 1,4-dithiane and *cis*-1,4-dithiane-1,4-dioxide. However, the magnitudes of the moments indicate that uniform flexibility is not prevalent, the stretched form being predominant. In contrast to these flexible forms the conformation of dithiane monoxide is thought to be chair and that of 2,5-diphenyl-1,4-dithiin a fixed boat.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

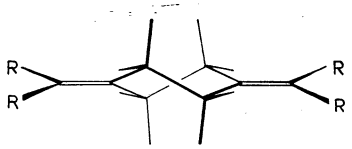
Evidence is accumulating to show that the Sachse-Mohr chair conformation for six-membered rings is not universal (1), and in some instances is less likely than the so-called "flexible" form of conformation (2). It has been shown by Kumler and Huitric (3) that the electric dipole moments of α-halogenocyclohexanones are best explained by some contributions from flexible forms. Correlation of dipole moments with nuclear magnetic resonance spectra of N,N′-disubstituted piperazine seems to show that these substances are entirely in the flexible form. Indeed the moment of 1,4-cyclohexanedione (μ = 1.3 D) (4), which has been interpreted in terms of an equilibrium mixture of cis and trans forms (boat and chair in the conformational sense), might better be included among substances in which a dynamic structure (flexible form) is operative. At least this is our interpretation of the fact that only one peak is found in the n.m.r. spectrum of this substance, whereas rigid-boat and chair conformations both ought to display distinctive axial and equatorial hydrogen resonance if they persist longer than 0.01–0.02 second.

The carbonyl groups in the cyclohexanones and cyclohexanedione would contribute 120° angularity to the six-membered rings of which they are a part in consequence of their sp^2 bond distribution.



I

It seems to be worthwhile to examine analogues with this structural feature so we have synthesized 1,4-dimethylenecyclohexane (I, R = H), its exo-tetramethyl homologue (I, R = CH_3), and have included the already known 1,4-bis-diphenylmethylidene-cyclohexane (5) (I, R = C_6H_5). Structure I depicts these molecules in the non-boat (the stretched) mode of the flexible six-membered ring.

The preparation of 1,4-dimethylenecyclohexane, II, by pyrolysis of the 1,4-diacetoxy-methylcyclohexane, II, has been effected according to Bailey's method (6) for synthesis of the 1,2-structural isomer. Bailey's recommended use of the primary rather than the tertiary dialcohol minimizes the isomers which are ring unsaturated but it cannot prevent dehydrogenation and hydrogen redistribution. Notwithstanding a low yield of acetic acid

(61%) at a pyrolysis temperature of 500°, this temperature has been chosen in order to minimize the formation of xylene and other aromatic hydrocarbons.

Although the complexity of the crude product precludes separation of the ring-unsaturated isomers of 1,4-dimethylenecyclohexane (I, R = H), the presence of the conjugated isomers is readily discernible because I is transparent throughout the ultraviolet range to 215 mμ. Moreover the conjugated diene impurities can be removed by use of diethyl azodicarboxylate, with which they form Diels–Alder complexes. The fortuitous boiling point (122°) of I makes separation from toluene and xylene by fractional distillation a relatively simple operation. If 1,4-dimethyl-2,5- or -1,4-hexadienes were present in the system they have escaped detection by us.

Except for a tendency toward slow polymerization, which might be expected in view of similarity with isobutylene, the purified substance is stable under neutral conditions, especially in absence of oxygen. Upon ozonization only formaldehyde and 1,4-cyclohexanedione can be isolated. On the other hand extensive isomerization occurs upon treatment with acid; among the isomer products the thermodynamically more stable 1,4-dimethyl-1,3-hexadiene has been identified by its ozonization product, acetonylacetone.

The infrared spectrum of 1,4-dimethylenecyclohexane contains all the expected absorptions of the exo unsaturation. The CH_2-hydrogen out-of-plane deformation is indicated strongly by the absorption at 893 cm^{-1} and, weakly, by what is probably its overtone at 1780 cm^{-1}. The C—H stretching of the double bonds is indicated at about 3080 cm^{-1}; the in-plane deformation is displaced to 1405 cm^{-1} from its expected position at 1420-1410 cm^{-1}, and the C=C stretch is strong at 1660 cm^{-1}.

It is of interest that this exocyclic unsaturation behaves typically toward iodine according to the spectral behavior reported by Long and Neuzil (7) for unsymmetrically disubstituted alkenes since only a single peak at 293 mμ is observed when 1,4-dimethylenecyclohexane is treated with iodine. Thus it would seem that the double bonds in 1,4-dimethylenecyclohexane are of themselves quite normal.

The exo unsaturation of 1,4-dimethylenecyclohexane can be preserved during bromine addition and elimination under conditions (exclusion of peroxides by diphenylamine) where the radical reaction is at least not excluded. Only one tetrabromide has been found in the product, indicating to us that an equilibrium mixture of chair and boat conformations is less likely than either a chair or a flexible conformation alone.

On the other hand methoxymercuration leads to two geometric isomers, approximately in equal amount. In view of the stereospecificity of this addition with simple alkenes the formation of two isomers, especially where one is not preponderant, is less to be expected from a chair conformation than from the flexible form since the median shape of this latter is essentially colinear with respect to alkene groups. It is of interest that the reversal of oxymercuration when it is accomplished with concentrated hydrochloric acid regenerates pure 1,4-dimethylenecyclohexane, thus indicating that the process is molecular rather than ionic.

In respect of nuclear magnetic resonance 1,4-dimethylenecyclohexane behaves like 1,4-cyclohexanedione in favor of a flexible conformation. Only two peaks are observed from an undiluted sample at 25°. The peak at 20 c.p.s. must represent the methylidene hydrogens because the area enclosed by it is half of that to be attributed to the ring methylene hydrogens which occurs at 107 c.p.s. in a 60 Mc field. We have been unsuccessful in the attempts to split this absorption into axial and equatorial hydrogen resonance by lowering the temperature of a solution in carbon disulphide to −120°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A similar study has been made with 1,4-diisopropylidenecyclohexane (I, R = CH_3) which we have prepared via the *cis*-1,4-glycol from methyl chloride Grignard reagent and diethyl 1,4-cyclohexanedicarboxylate (mainly cis). Mild acid treatment converts the cis glycol to trans with loss, whereas stronger treatment dehydrates it cleanly to the exo dialkene. This structure has been demonstrated by ozonization to acetone and 1,4-cyclohexanedione. Like its lower homologue it is ultraviolet-transparent down to 210 mμ and only one tetrabromide is obtained from it.

It is to be expected that this substance would show only two absorptions by n.m.r., and in fact in carbon disulphide one peak at 130 c.p.s. with area corresponding to the methyl hydrogens and the other peak of larger area at 97 c.p.s. have been observed. The hope that the latter peak would split when the temperature was lowered has not been realized because no suitable solvent has been found for the examination at low temperatures.

Equally unsuccessful has been the attempt to discover axial and equatorial absorption for 1,4-bis-diphenylmethylidenecyclohexane. This substance is so insoluble in appropriate organic solvents that its n.m.r. spectrum (40 Mc) can only be obtained in tetrachloroethane at 130°. The spectrum at this temperature consists of one peak at −53 c.p.s. characteristic of phenyl hydrogens and the other at +137 c.p.s. characteristic of the ring methylene hydrogens, both relative to the solvent. At room temperature tetrachloroethane has a peak 239 c.p.s. (at 40 Mc) below tetramethylsilane.

Because strongly polar groups are absent in these exo-unsaturated cyclohexanes the electrical polarizations are relatively meaningless but they have been studied. Firstly, the distortion polarizations have been determined when possible. Since 1,4-dimethylenecyclohexane is a liquid at room temperature the electric polarization (P_E) at optical frequencies has been used; likewise with dimethyl sulphoxide to be discussed later. The distortion polarizations ($P_D = P_E + P_A$) of the remainder (the solids) have been determined by the wafer technique (8, 9) and are listed among others in Table I together with

values calculated by the summation of atom (Eisenlohr) or bond (Vogel) polarizabilities. Only three items in the table warrant comment. It may be seen that additive MR_D for bis-1,4-diphenylmethylidenecyclohexane is appreciably higher than the P_D values obtained from the dielectric constant of wafers and absurdly so, as will be shown by comparison with total polarization of bis-diphenylmethylidenecyclohexane solutions. This discrepancy conforms with earlier studies (10) and it leads us to prefer the wafer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

technique for evaluation of P_D. This preference applies to a second item, P_D for dithiane. In this instance the agreement with additive polarizability by the Eisenlohr calculation is good, although inconsistent with the Vogel bond additivity.

The third item for comment in Table I is 2,5-diphenyldithiin, because the distortion polarization determined by dielectric constant is 8.1 cc higher than the average of the summation values for MR_D despite the presence of the phenyl groups which would be expected to cause P_D to be lower than MR_D by summation of atom or bond polarizabilities. One must presume in this instance that an appreciable exhaltation in electronic polarization (P_E) is operative, a situation not unexpected in view of the divinyl sulphide linkage in this substance.

The dipole moments and data from which they are derived are shown for the substances of this report in Table II. As would be expected from resemblance to isobutylene and tetramethylethylene the moments of dimethylenecyclohexane and diisopropylidenecyclohexane are indistinguishable from zero at our present precision. However, a small moment may be attributed to bis-diphenylmethylidenecyclohexane on the basis of the measured distortion polarization. The use of MR_D by summation would lead to an absurd result. But the assignment of flexible conformation to these exo-unsaturated cyclohexanes depends not upon the moment but upon the absence of axial–equatorial peaks in the n.m.r. spectra.

In earlier publications from this laboratory the flexibility of several six-membered ring systems has been attributed entirely on geometrical grounds to the 120° ring angles contributed by carbonyl or nitramino (11) linkages as a consequence of their sp_2 hybridization. To be sure, the same type of flexible conformation is required for explanation of the appreciable moments of 1,4-diphenyl- (12) and 1,4-dimethyl-piperazines (8) in which tertiary amino groups are involved in the ring. But the 110–111° R—N—R angle of amines is an extreme form of the group which is oscillating with inversion. The flexibility of the diphenyl- or dimethyl-piperazine may then be attributed to the 120° ring angles which amino nitrogen must contribute in the planar median of the oscillation if it is assumed that the nitrogen atom oscillation is approximate to that of conformational oscillation in a flexible ring. Since the oscillation rate of the flexible ring must be 10^3–10^4 c.p.s. and that of the substituted amino group will be less than 10^7 c.p.s. the assumption of an effective 120° angles is not unreasonable, especially since one frequency might be expected to "lock in" to the other.

The question arises whether the flexible conformation is likely in absence of sp_2 angularity. An answer may be provided by consideration of 1,4-dithiacyclohexanes since information about bond lengths and bond angles of 1,4-dithiane (13) and *trans*-1,4-dithiane-1,4-dioxide (14) is available. Although these data are based on diffraction studies which specify chair conformations in the crystalline state it may be assumed that they will be applicable if the substances exist in solution as flexible forms.

The dipole moments of the 1,4-dithiacyclohexanes and their oxides are listed in Table II. The apparent moment of 1,4-dithiane (μ = 0.51–0.56 D) is small but the precision of the determination of P_D (Fig. 1) and of total polarization (P_T, Fig. 2) in benzene solution from 20 to 40° C indicates that this moment is real and is temperature dependent. The existence of the meagre moment is not surprising in view of the comparable value (0.3–0.4 D) which has been found for the analogous dioxane (15, p. 299).

However, this low moment cannot be explained either by a chair or a completely flexible conformation in view of the observed moment of dimethyl sulphide (15, p. 303). On the other hand the low moment can be rationalized in terms of a limited flexibility in

*Calculated from refractive index and density.

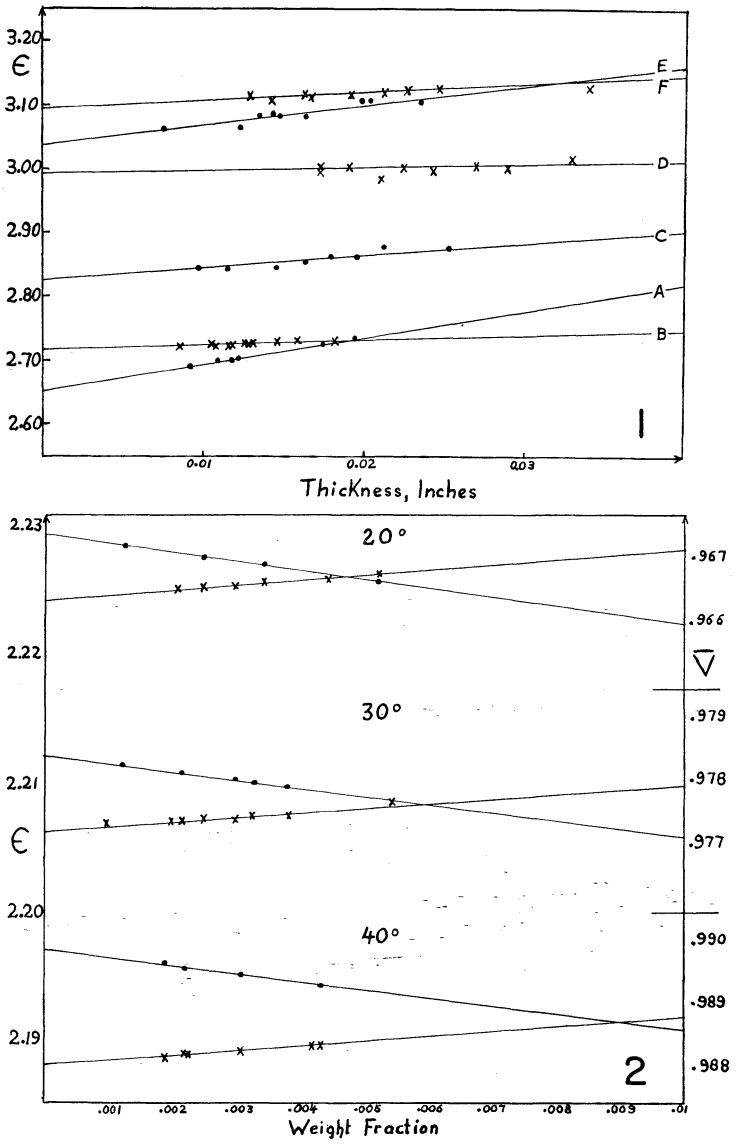

FIG. 1. Extrapolation of dielectric constants of solids. A: 1,4-Dithiane; B: 1,4-bis-diphenylmethylidene-cyclohexane; C: 1,4-dithiane monoxide; D: *trans*-1,4-dithiane dioxide; E: 2,5-diphenyldithiin; F: *cis*-1,4-dithiane dioxide.

FIG. 2. Extrapolations of dielectric constant (ϵ) and specific volume ($\bar{V}$) for dioxane solutions (weight fraction) of 1,4-dithiane.

which the molecule is largely in the "stretched" modes (II). In this connection it should be noted that unlike the isocyclic cyclohexane there will be two possibilities of "stretched" mode in dithiane of which the one where the hetero atoms tend toward the median positions should be more probable than the one where carbon rather than the sulphur occupies this median position. That is to say, II*a* is more probable than II*b*. Since the moment of II*a* would essentially be zero one must postulate on this basis that dithiane is flexible with an unequal conformational distribution favoring II*a*.

IIa IIb

Flexibility involving a frequency greater than the reading rate of an n.m.r. measurement is indicated by a single proton absorption for dithiane at room temperature. Confirmation of this evidence would be afforded if the flexible oscillation could be decreased at low temperature to an extent that it would be slower than the 116 c.p.s. downfield which Dr. S. S. Danyluk of this department has found at room temperature. When he cooled a 5% solution of dithiane to −120° in the 1:1 volume mixture of thionyl chloride – carbon disulphide (f.p. ca. −140°) he did not observe a splitting of the proton absorption band, but the marked broadening of this line toward virtual disappearance against the background at −120° is a strong indication of the complex spectrum to be expected at a relatively low oscillation rate. On balance of evidence the flexible form of dithiane is favored.

A contrasting rigidity in a six-membered ring is shown by the moment (Table II) of 2,5-diphenyldithiin. There is no possibility of a flexible form of this 1,4-dithiadiene; it must exist as a chair or boat. The observed moment (1.8 D) shows that the molecule has boat shape. If comparison with the moment of ethylene sulphide is valid (15, p. 299) the ethylene linkages in diphenyldithiin are not significantly distorted.

According to the X-ray diffraction analysis of March the C—S—C bond angle in 1,4-dithiane is 93°. This wide divergence from the 120° angle, which heretofore has seemed to characterize the flexible ring conformation, actually does not preclude flexibility. It is evident from geometry that the carbon atom in the ring is properly spaced for flexible behavior because of the greater bond length of C—S (1.81 Å) over that of C—C (1.51 Å) or C—N (1.46 Å) in exo-unsaturated cyclohexanes or piperazines. The equivalent angle in terms of the latter types would be about 115°.

According to Shearer the C—S—C bond angle in *trans*-1,4-dithiane-1,4-dioxide is 98°, which with the C—S bond length of 1.81 Å is practically equivalent to the 120° angle in exo-unsaturated cyclohexanes or piperazines. Therefore, on geometric grounds the flexible conformation is not excluded for dithiane dioxides in solutions, even though Shearer considers the trans isomers to be of chair conformation in the crystal.

It should be stressed that flexibility if it exists in the dithiane oxides is a consequence of favorable geometry due to the long C—S—C bond and not to inversion-oscillation which is characteristic of the C—N—C linkage. This is obvious in the fact that amines cannot be isolated as enantiomeric individuals because of inversion whereas the sulphoxides are configurationally stable.

In order to make a conformational evaluation from electric moment data the moment angle must be correlated with bond angle. In a substance such as 1,4-dimethylpiperazine the moment must evidently arise between the nitrogen nucleus and the non-bonded electrons of this atom. We presume that the non-bonded electrons in sulphoxides contribute little to the moment. If the contribution were appreciable the moments of *cis*- and *trans*-dithiane dioxides would not be so different as Table II shows them to be. The principal contribution must be due to the polar S→O linkage and we assume that its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

bond angle is approximately the same as the moment angle. The C—S→O bond angle has been specified as 107° by Shearer so the $=C_2=S\rightarrow O$ bond angle may be taken as 110°.

If dimethyl sulphoxide of moment 3.88 D is compared with 1,4-dithiane-1-oxide it is evident that the cyclic compound cannot exist in the flexible conformation because the mean value of the moments calculated for the extreme conformers would exceed the moment of dimethyl sulphoxide in benzene. Actually the observed moment of dithiane monoxide (in dioxane, which tends to enhance the apparent moment in benzene) is 0.63 D lower than that of dimethyl sulphoxide. This moment could be due only to a rigid "stretched form" or to a chair form, and the latter is energetically more probable.

Thus the chair conformation is assigned to the monoxide but a different situation may exist in the case of dioxides. Assuming that the bond angle $=C_2=S\rightarrow O$ and the moment angle are identically 110° the moment of the trans dioxide ought to be zero while the cis isomer ought to have a moment of 6.36 D.

The observed moment for the trans isomers apparently is 0.4 D, but this value is too low to be significant. Great precision and accuracy are necessary in order to attach any meaning to an apparent moment less than 0.5 D, and the trans dioxide because of its low solubility therefore is precluded. Because of this low solubility we have been unable to determine the n.m.r. spectrum in a suitable medium. Therefore it seems best to leave the question of *trans*-dithiane dioxide conformation in abeyance.

On the other hand the cis isomer is amenable for consideration. Clearly with an observed moment of 4.66 D *cis*-1,4-dithiane-1,4-dioxide cannot exist in a fixed chair conformation which should have a moment of 6.36 D. Alternatively with postulation of a flexible ring a calculation by the method of Hazebroek and Oosterhoff (2) has been made. If the observed moment of dimethyl sulphoxide is used as the group moment for $=C_2=S\rightarrow O$ (as before) then at a moment angle of 110° the μ of the cis isomer may vary from 0 to 7.36 D. The upper limit is sterically improbable because it represents the extreme boat form in which the oxygen atoms would overlap. The moment will therefore be comprised of three other "boat" aspects plus the stretched forms which are intermediate. The resultant is approximate to the observed moment of 4.66 D on the basis of equal contributions. While this assumption is unwarranted it does give reasonable agreement which is impossible for the chair conformation. Consequently the dynamic structure of limited flexibility is assigned to *cis*-1,4-dithiane-1,4-dioxide.

EXPERIMENTAL[1]

1,4-Dimethylenecyclohexane

Into the top of a quartz tube 600×30 mm packed with 0.2–1.0 cm² Vycor chips in the region 140 mm to 440 mm from the top and heated externally to show a temperature of 510° to a centrally located thermocouple was added at a rate of 100 g/hr a total of 1040 g (4.56 mole) of a cis–trans mixture of 1,4-bis-acetoxymethylcyclohexane. During this time a 50 cc/min stream of dry 99.8% nitrogen was passed downward through the pyrolysis tube and the dry, ice-chilled receiver which was connected to it. The top of the chip bed acted as a vaporizer for the diacetate.

A solution of the pyrolyzate in ether was water-washed to remove acetic acid (336 g, 61% according to titration) then dried by means of magnesium sulphate and distilled, finally through a Vigreux column at 20 mm Hg pressure to give 265 g, b.p. 28–75°. The chilled residue yielded 111 g, m.p. 65–72°, chiefly unchanged diacetate. The remainder was discarded.

The distillate, b.p. 28–75°, was fractionated through a 40-plate helix-packed column (r.r. 20:1 at 750 mm) to give a series of fractions which were complex according to gas chromatography; only toluene and xylene were identified besides the principal fraction (103 g, n_D^{20} 1.4727, boiling at 122–123°, 750 mm). This crude 1,4-dimethylenecyclohexane, m.p. −32° to −27°, absorbed slightly (E_{max}, 87) at 230 mμ so it was treated with 50-mg portions of diethyl azodicarboxylate until the color of the latter persisted for 8 hours. The volatile fraction was removed under reduced pressure and then was distilled at 750 mm, yield 90.5 g, b.p.

[1]*Melting points have been checked against reliable standards.*

121–122°, n_D^{20} 1.4717, d_4^{20} 0.821, capillary m.p. −28 to −26.5°. This pure material (single peak, retention time 16 minutes by gas chromatography on 20% carbowax firebrick) was transparent down to 215 mμ in methanol. Anal. Calc. for C_8H_{12}: C, 88.9; H, 11.2. Found: C, 88.9; H, 11.0. The infrared absorptions in carbon tetrachloride in cm^{-1} (E_{max}) are 3075 (54), 2930 (118), 2840 (73), 1780 (19), 1655 (100), 1440 (79), 1400 (34), 1315 (36), 1180 (25), 1160 (49), 980 (21), 893 (402), 692 (105) in carbon tetrachloride. An additional peak at 785 (54) was found in carbon disulphide or in an undiluted sample but no further absorption out to 300 cm^{-1}. Slight differences from the spectrum in carbon tetrachloride were found for the neat sample, i.e. 2940 vs. 2930, 1455 (new, shoulder), 1165 vs. 1160, 982 vs. 980, and 888 vs. 893.

The nuclear magnetic resonance spectrum (60 Mc) of an undiluted sample showed two simple peaks. The peak characteristics of the four methylene hydrogens at 20 c.p.s. included half of the area under the peak at 107 c.p.s. characteristic of the eight ring hydrogens. Neither peak showed any tendency toward splitting when the temperature of a carbon disulphide solution was lowered to −120° C.

Bis-1,4-bromomethyl-1,4-bromocyclohexane

To a solution of 10.8 g (0.1 mole) of 1,4-dimethylenecyclohexane in 100 ml of diethyl ether and 2 ml of amyl alcohol containing 10 mg of diphenylamine (to favor homopolar addition) was added bromine at −40° C until the color was permanent. After solvent evaporation the product was crystallized from commercial hexane – diethyl ether (2:1) to give 29.8 g (69%), m.p. 134–135°. Anal. Calc. for $C_8H_{12}Br_4$: C, 22.5; H, 2.83. Found: C, 22.4; H, 2.78.

This tetrabromide (12.8 g, 0.03 mole) was dissolved in 200 ml of dry diethyl ether and stirred under nitrogen with 1.5 g (0.062 g-atom) of Grignard-quality magnesium plus a grain of iodine for 10 minutes and then was refluxed for 1 hour. The supernatant phase, waterwashed and magnesium sulphate dried, was distilled, finally at 121°, yield 1.3 g (40%) with negligible residue. This 1,4-dimethylenecyclohexane was transparent down to 215 mμ and gave a single gas chromatograph peak. Addition of bromine as described above gave a 62% yield of tetrabromide, m.p. 133.5–135°, not depressed by admixture with the original.

1,4-Cyclohexanedione

A solution of 0.546 g (0.005 mole) of 1,4-dimethylenecyclohexane in 20 ml of carbon tetrachloride was saturated with 5% ozonized oxygen at −10°. After vacuum evaporation of the solvent the residue was heated with powdered zinc and water at 90° for 90 minutes and then was steam-distilled. The distillate, treated with dimedone, gave the formaldehyde derivative, 0.885 g (30%), m.p. 188–189°.

The steam distillation residue was exhaustively extracted with petroleum ether (b.p. 40–60°). Evaporation of this extract left 0.22 g (39%) of 1,4-cyclohexanedione, m.p. 74°. After three sublimations the melting point, 78.4°, was not depressed by admixture with an authentic sample. The 2,4-dinitrophenylhydrazone melted at 237° (lit 240°).

The n.m.r. spectrum of a methylene dichloride solution of the cyclohexanedione showed only a single peak for all ring hydrogens at 88 c.p.s.

Bis-1,4-chloromercurimethyl-1,4-methoxycyclohexane

To a stirred suspension of 63.6 g (0.2 mole) of crystallized mercuric acetate in 400 ml of pure methanol was added 10.8 g (0.1 mole) of 1,4-dimethylenecyclohexane at room temperature. After 35 minutes the suspension showed a negative test for mercuric ion and was cooled to 0° and poured into a stirred solution of 12.2 g (0.21 mole) of sodium chloride in 400 ml of water. After 20 minutes the precipitate was filtered and washed with a little cold methanol, yield 63 g (98%). This crude product was extracted with 4 liters of boiling chloroform, leaving 15.7 g, m.p. 196–200°. Vacuum evaporation of the extract gave a first fraction (12.0 g, m.p. 170–190° (decomp.)) and then a second (32.5 g, m.p. 166–180° (decomp.)). Crystallization with recombination from hot acetone, chloroform, methanol, and dioxane separated the mercurial into its two geoisomers; A, 21 g, decomp. 217°, slightly soluble in hot chloroform, fairly soluble only in hot dioxane. Anal. Calc. for $C_{10}H_{18}O_2Hg_2Cl_2$: C, 18.7; H, 2.87. Found: C, 18.7; H, 3.01. The infrared spectrum in potassium bromide (cm^{-1}) is 2950 (s), 2900 (s), 1460 (shld., m), 1450 (shld., m), 1443 (m), 1425 (m), 1405 (m), 1360 (m), 1312 (w), 1280 (m), 1243 (s), 1193 (w), 1166 (w), 1145 (m), 1110 (s) ,1090 (s), 1075 (shld., s), 1063 (s), 1042 (shld.), 963 (w), 912 (m), 886 (m), 860 (s), 763 (w), 755 (w), 709 (w). Geoisomer B, 24 g, decomp. 193°, is soluble in cold dioxane and easily soluble in hot methanol or chloroform. Anal. Calc. for $C_{10}H_{18}O_2Hg_2Cl_2$: C, 18.7; H, 2.87. Found: C, 18.8; H, 3.07. The infrared spectrum in potassium bromide (cm^{-1}) is 2940 (s), 2840 (shld., m), 1460 (shld., m), 1450 (m), 1430 (m), 1405 (m), 1360 (w), 1340 (w), 1318 (w), 1275 (m), 1255 (m), 1185 (shld., m), 1140 (s), 1060 (s), 1025 (m), 970 (m), 943 (w), 904 (m), 865 (m), 746 (s), 703 (w), 663 (w).

When 18 g of geoisomer A (0.028 mole, decomp. 216°) was suspended in 30 ml of pure *n*-hexane and stirred vigorously with 4.8 ml (0.06 mole) of conc. hydrochloric acid for 5 minutes a residue was still undissolved. However, the hexane layer was separated, washed with water, dried with magnesium sulphate, and distilled to give a slight first fraction boiling up to 121° and then 1.6 g (53%) b.p. 121–122°. The distillation residue weighed 0.6 g (20% also calculated as dimethylenecyclohexane), was unsaturated, and showed ultraviolet peaks at 271, 260, and 253 mμ. The 1.6-g portion, n_D^{20} 1.4721, melted at −28° to −26.5°, m.m.p. not depressed with 1,4-dimethylenecyclohexane. The aqueous layer on treatment with alkali gave 11.5 g (95%) of mercuric oxide.

Polymerization of 1,4-Dimethylenecyclohexane

(a) By Ultraviolet (Broad Peak at 360 mμ)

When the pure substance in a soft glass tube at +35° was irradiated for 14 days a yellow coating developed on the wall. The remaining liquid, distilled, contained 47% of unchanged dimethylenecyclohexane and also 16% (calc. as monomer) non-volatile syrup insoluble in methanol, benzene, and carbon tetrachloride with infrared spectrum (KBr pellet) in cm^{-1}: 3075 (vw), 2950 (s), 2850 (m), 1720 (s), 1658 (m), 1435 (s), 1165 (s), 887 (m). The solid material on the wall (12%) is a hard thermoplastic insoluble in carbon tetrachloride, methanol, benzene, and hexane with infrared spectrum in cm^{-1}: 2950 (s), 1720 (s), 1640 (s), 1440 (s), 1165 (s), 887 (s).

(b) By Benzoyl Peroxide

A 20% solution of dimethylenecyclohexane in dry benzene was refluxed for 3 days while 0.5 wt% portions of benzoyl peroxide were added at 10-hour intervals. The entire volatile portion was vacuum evaporated to a syrup which was washed with alkali and with water and dried at 100° (10 mm). The remainder (9%) is thermoplastic and soluble in carbon tetrachloride. The infrared spectrum, KBr pellet, in cm^{-1}, is 2950 (s), 1630 (m), 1443 (m), 1265 (s), 887 (w), 785 (m), 710 (m).

(c) By Aluminum Chloride

A violent reaction occurred when 1 g of the exo diene was treated with 0.5 g of freshly ground aluminum chloride. The carbon tetrachloride extract when washed with water and precipitated by 10-fold dilution with methanol gave 0.3 g of a brown thermoplastic solid, infrared absorption in KBr (cm^{-1}): 2950 (s), 2325 (w), 1620 (s), 1450 (s), 1370 (m), 785 (s), 740 (m). After the aluminum chloride was washed from the carbon tetrachloride insoluble residue there remained 0.2 g of a brown thermoplastic solid. By contrast no reaction of the exo diene occurred when it was treated with a solution of aluminum chloride in carbon tetrachloride.

Aromatization of 1,4-Dimethylenecyclohexane

When a 4.3 g of the exo diene was carried by nitrogen (25 cc/min) through a 15 mm dia. Vycor chip bed 5 cm long at 700–750° C the recovered material (70 wt%) was a mixture of benzene, toluene, and xylene in ratio 1:2:1 according to retention times on a carbowax–celite column at 140°. The collected fractions were identified by their ultraviolet and infrared spectra.

Isomerization of 1,4-Dimethylenecyclohexane

A solution of 7.7 g (0.07 mole) of the exo diene in 100 ml of peroxide-free dioxane plus 0.6 ml of 66 wt% aqueous sulphuric acid was refluxed for 3 hours and let stand for 8 hours more. The ethyl ether extract of the water-diluted system, washed acid free and dried by means of magnesium sulphate, was found to distill as follows: 1 g, 126–133° C; 2 g, 133–135° C (n_D^{20} 1.4745); 0.7 g, 135–136° C (n_D^{20} 1.4730); 2 g, 136–140° C; 0.2 g, 140–141° C; residue 0.7 g. All fractions showed olefinic unsaturation.

A solution of 0.54 g (0.005 mole as 1,4-dimethyl-1,3-cyclohexanediene) of the fraction b.p. 135–136° in 15 ml of absolute ethanol was treated with 6% ozonized oxygen at −40° to saturation and then at −10°, again to saturation. Then the system was treated with aqueous sodium borohydride until oxidizing agents were absent. The solution was acidified with dilute sulphuric acid, then treated with an acid solution of 2,4-dinitrophenylhydrazine. After 2 hours the precipitate was filtered off, 0.45 g after washing with ethanol, m.p. 235–245°, and was crystallized from *p*-xylene, 0.3 g (13%), m.p. 254–256°. A mixture melting point with the derivative of acetonylacetone (m.p. 257°) was not depressed, thus indicating the presence originally of 1,4-dimethyl-1,3-cyclohexadiene.

cis-1,4-Bis-isopropylolcyclohexane

To a magnesium-free methyl chloride Grignard reagent prepared from 2.1 g-atom of the metal in 1200 ml of diethyl ether (yield 69% by titration) was added 60 g (0.3 mole) of dimethyl 1,4-cyclohexanedicarboxylate (largely cis isomer, m.p. 0°) in 60 ml of diethyl ether at a rate sufficient to maintain reflux with the vessel being ice-cooled (1 hour). After 20 minutes of subsequent reflux the cooled system was poured into cold, stirred, saturated aqueous ammonium chloride. After 10 hours the system was filtered to remove scum and both the residue and the aqueous phase of the filtrate were extracted with diethyl ether. All of the ethereal portions, dried with magnesium sulphate, were evaporated, leaving a magma from which was filtered 32 g (49%) of the glycol, m.p. 110–112°. Crystallization from benzene – carbon tetrachloride (1:2 by volume) raised the melting point to 115.5–116.5°. Anal. Calc. for $C_{12}H_{24}O_2$: C, 72.0; H, 12.1. Found: C, 72.1; H, 12.1. The infrared spectrum (KBr pellet) in cm^{-1} is 3320 (s), 2975 (s), 2950 (s), 2860 (m), 1450 (m), 1445 (m), 1365 (s), 1355 (s), 1295 (w), 1230 (m), 1220 (m), 1155 (s), 1125 (s), 1105 (w), 945 (w), 935 (w), 912 (w), 898 (w), 872 (w), 830 (w), 808 (w), 780 (w); in chloroform solution 3550 (m), 3425 (m), 2940 (s), 2850 (s), 1460 (m), 1440 (m), 1380 (s), 1360 (s), 1320 (m), 1155 (s), 1125 (s), 940 (m), 905 (s), 870 (w), 840 (w).

trans-1,4-Bis-isopropylolcyclohexane

The cis glycol (4 g, 0.02 mole) was heated for 40 minutes with 8 g of anhydrous copper(II) sulphate at 130°. The system was then extracted with cold carbon tetrachloride to remove dehydration products, and subsequently with the same solvent hot. When the hot extract was cooled 0.8 g (20%) of trans isomer, m.p. 157–158°, crystallized out. Anal. Calc. for $C_{12}H_{24}O_2$: C, 72.0; H, 12.1. Found: C, 72.0; H, 12.1. The infrared spectrum (KBr pellet) showed absorption peaks at 2975 (s), 2950 (s), 2860 (m), 1445 (m), 1370 (s), 1360 (s),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

1305 (w), 1240 (m), 1225 (m), 1160 (m), 1130 (s), 1120 (s), 945 (s), 915 (s), 872 (m), 783 (w); in chloroform solution 3550 (w), 3400 (w), 2900 (s), 2850 (s), 1460 (m), 1440 (m), 1370 (s), 1360 (s), 1320 (w), 1285 (w), 1135 (s), 938 (w), 908 (s), 868 (w).

1,4-Bis-isopropylidenecyclohexane

The substance may be dehydrated over alumina at 300° but better yields were obtained using formic acid. A solution of 10 g of the cis diol (0.05 mole) in 5 ml of formic acid was heated at 90–100° until a second phase separated after 5 minutes. The non-aqueous layer in diethyl ether was water-washed until it was neutral. Vacuum evaporation of the ether left 7.3 g (90% calc. as diene) which was dissolved in 5 ml acetone. Needles separated at −80° C, 2.1 g (26%), m.p. 70–71° C, which upon crystallization from acetone, methanol and subsequent sublimation melted at 78.5–79.5° C. Anal. Calc. for $C_{12}H_{20}$: C, 87.7; H, 12.3. Found: C, 87.6; H, 12.4. This 1,4-bis-isopropylidenecyclohexane forms a tetrabromide, m.p. 205–206°, after crystallization from commercial hexane. Anal. Calc. for $C_{12}H_{20}Br_4$: C, 29.8; H, 4.17. Found: C, 29.2; H, 3.76. The 1,4-diene is transparent in the ultraviolet down to 210 mμ but absorbs strongly at shorter wavelengths. The infrared spectrum (KBr pellet) in cm^{-1} is 2930, 2850 (s), 28 (s), 1615 (w), 1430 (s), 1370 (shld., m), 1360 (s), 1195 (s), 1115 (w), 1095 (w), 970 (w), 720 (w).

The mother liquors from crystallization of the diene contained 5.6 g, b.p. 83–115° (10 mm). This oil absorbs at 281, 250, and 243 mμ and it slowly polymerizes.

1,4-Bis-diphenylmethylidenecyclohexane

To a magnesium-free Grignard reagent prepared from 1 mole of bromobenzene in 385 ml of diethyl ether was added a solution of 30 g (0.015 mole) of dimethyl 1,4-cyclohexanedicarboxylate (chiefly cis) in 60 ml of ether during 1 hour. After 20 minutes of subsequent reflux the system was poured into 300 ml of glacial acetic acid. After the addition of 2 ml of hydrochloric acid the solution was boiled for 5 minutes, cooled, and filtered, 23.4 g (91%). This diene was crystallized from dioxane (150 ml/g), m.p. 257–259°. It is also soluble in hot benzene, toluene, and carbon tetrachloride but is almost insoluble in methanol or ethanol. A dioxane solution absorbs in the ultraviolet at 246 mμ (E_{max} 27,000) comparable with the absorption by benzophenone at 250 mμ. The infrared spectrum (cm^{-1}, KBr pellet) is 3040 (m), 2950 (m), 2855 (m), 2825 (m), 1620 (w), 1590 (m), 1475 (s), 1460 (w), 1430 (s), 1210 (m), 1070 (m), 1030 (w), 995 (w), 980 (m), 915 (w), 880 (w), 765 (s), 755 (s), 730 (s), 697 (vs), 673 (w).

The substance shows strong green fluorescence in ultraviolet light but becomes permanently yellow after this irradiation. In carbon tetrachloride solution aerated with oxygen under ultraviolet irradiation the yellow color appears within 2 hours. The melting point of the recovered solid has decreased to 248–254°. In absence of light, ozonization in carbon tetrachloride does not produce a color change; the ozonide yields benzophenone (42%).

Electrical Measurements

The dielectric constants of the crystalline substances were determined by the method previously described (8, 9). The results of Table I have been calculated from the extrapolations shown in Fig. 1. All wafers were prepared from the pure compounds except in the case of bis-diphenylmethylidenecyclohexane, where it was necessary to use 2% of polyethylene wax in order to effect consolidation. The dielectric constant was corrected for this dilution. The specific volumes and dielectric constants of solutions, from which the total polarizations and moments of the dithiane oxides of Table II are calculated, are shown in Fig. 3.

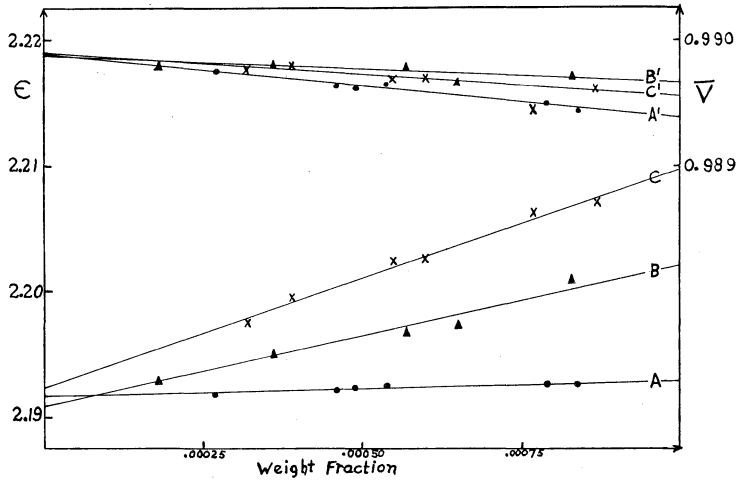

FIG. 3. Extrapolations of dielectric constant (ϵ) and specific volume ($\bar{V}$). A, A′: *trans*-1,4-Dithiane-1,4-dioxide; B, B′: dithiane monoxide; C, C′: *cis*-1,4-dithiane-1,4-dioxide.

KINETICS AND MECHANISMS OF THE PYROLYSIS OF DIMETHYL ETHER

I. THE UNINHIBITED REACTION

D. J. McKenney and K. J. Laidler
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received February 26, 1963

ABSTRACT

An experimental study has been made of the thermal decomposition of dimethyl ether, the temperature range being 500 to 550° C and the pressure range 100 to 700 mm Hg. A considerable surface effect was noted, and the results were not very reproducible. The reaction was of the three-halves order and the rate constant could be expressed as $2.98\times10^{14}e^{-54,900/RT}$ $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}. On the basis of the results obtained in the presence of hydrogen sulphide (D. J. McKenney and K. J. Laidler. Can. J. Chem. **41**, 2009 (1963)) it is concluded that the initiating step, the dissociation of CH_3OCH_3 into CH_3O and CH_3, is in its second-order region. In order for the overall order to be three-halves the main terminating step must be either of the type $\beta\beta M$ or $\beta\mu$. The concentrations of the various radicals, and the rates of the various chain-ending steps, are calculated from known or estimated kinetic parameters for the elementary processes. It is concluded that the predominant chain-ending step is probably $CH_3 + CH_3 + M \rightarrow C_2H_6 + N$, but that there may be a significant contribution from $CH_3 + CHO + M \rightarrow CH_3CHO + M$ and from $CH_3 + CH_2OCH_3 + M \rightarrow C_2H_5OCH_3 + M$.

INTRODUCTION

During recent years determinations have been made of the kinetic parameters for a large number of the elementary processes that occur in organic pyrolyses. As a result there has been a revival of interest in the problem of establishing the overall mechanisms for such reactions, and in confirming them quantitatively. Recent work of this kind in these laboratories has been concerned with the thermal decompositions of propylene (1), ethane (2), propane (3), and butane (4). In all cases it has been found that the reactions occur predominantly by free-radical mechanisms, the molecular mechanisms being of minor importance. In the cases of ethane and propane it was concluded that under the experimental conditions the initiating unimolecular dissociation of the reactant molecule was in its low-pressure second-order region; with the larger butane molecule, on the other hand, the initial reaction is first order. It is of considerable interest to come to a conclusion about this matter for other decomposing substances, and the present investigation is concerned with the pyrolysis of dimethyl ether. For this substance the evidence as to the order of the initiating step comes from an investigation of the reaction in the presence of hydrogen sulphide, and is discussed in Part III of this series. The present paper describes an experimental study of the uninhibited dimethyl ether decomposition, and considers in some detail the nature of the chain-ending steps.

A number of previous investigations have been made of the dimethyl ether pyrolysis, and the results may be referred to briefly. The reaction was first studied by Askey and Hinshelwood (5), who concluded it to be first order with respect to the ether. The formation of products could be represented by the equation

$$CH_3OCH_3 \rightarrow CH_4 + CH_2O \rightarrow CH_4 + CO + H_2.$$

The formaldehyde builds up in the system and its concentration goes through a maximum when the reaction is about half complete. Later workers (6–11) found a great deal of evidence indicating that the decomposition was a chain reaction and could be described by a mechanism of the Rice–Herzfeld (12) type.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Benson (13) analyzed existing data and found that the reaction was three-halves order with respect to ether. Benson and Jain (14) confirmed the three-halves order relative to ether and obtained a rate constant of $k = 1.3\times10^{15}\ e^{-55,600/RT}$ cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}. They found very little effect of added inert gas. The decomposition mechanism postulated by these authors involved first-order initiation, and termination involving two β radicals. They assumed that the CH_3OCH_2 radical is an important chain breaker and that the reaction

$$CH_3OCH_2 \rightarrow CH_2O + CH_3$$

is in its second-order region. Anderson and Benson (15) confirmed the presence of $CH_3OC_2H_5$ and $CH_3OCH_2CH_2OCH_3$ in the products of the pyrolysis. Their results also indicate that the reaction

$$CH_3 + CH_3OCH_2 \rightarrow CH_3OCH_2CH_3$$

is an important termination step.

Imai and Toyama (16) recently decomposed dimethyl ether in the temperature range of 360 to 440° C, and found that the rate constant could be represented as

$$k = 1.45\times10^{15}e^{-54,500/RT}\ \text{cc}^{1/2}\ \text{mole}^{-1/2}\ \text{sec}^{-1}.$$

This is in good agreement with that obtained by Benson and Jain (14).

EXPERIMENTAL

The apparatus and experimental procedure were essentially as described previously (1). Reactions were carried out in a quartz cylindrical tube of about 250-cc volume with a "dead space" of approximately 4 cc. The temperature was controlled to about 0.2° C by means of a Thermo Electric controller which was activated by means of a thermocouple in the copper furnace block. Another thermocouple in the reaction vessel was used to measure the temperature on a Thermo Electric Mini-Mite potentiometer.

Prior to a run the reaction vessel was pumped down to approximately 10 μ; this small residual pressure had no detectable effect on the rates. The pressure change as a function of time was recorded automatically by a Beckman photopen recorder in conjunction with a quartz spiral gauge, as described by Laidler and Wojciechowski (1). A pressure change of 18.6 mm Hg in the reaction vessel resulted in a deflection of 1 inch on the recorder. Pressures measured by means of the spiral gauge arrangement could be measured to $\pm$0.6 mm Hg.

RESULTS

The decomposition of dimethyl ether was studied in the temperature range of 500 to 550° C, and over a pressure range of approximately 100 to 700 mm Hg. A typical pressure–time curve for the reaction is shown as curve A of Fig. 1. Rates were calculated from the slopes of the pressure–time curves at the inflection point. The reaction was found to be three-halves order with respect to dimethyl ether over the complete range of pressure and temperature. It proved very difficult to obtain reproducible results, since the uninhibited reaction appeared to be influenced to a great extent by the condition of the surface of the reaction vessel. Greater reproducibility could be obtained after the surface had been exposed to nitric oxide either alone or mixed with ether. Enough reproducible data were accumulated by first treating the surface in this way, in order to verify the results of previous workers (14, 16). An Arrhenius plot of the data is shown in Fig. 2. Most of the points shown are the average of many and the approximate deviations are indicated (for the point at 500° C ($1/T\times10^3 = 1.294$) only a single value was obtained). The activation energy was 54.9 kcal mole^{-1}.

Because inflection-point rates were used rather than initial rates (rates at the inflection point were more reproducible), it was necessary to correlate the pressure change with the

For personal use only.

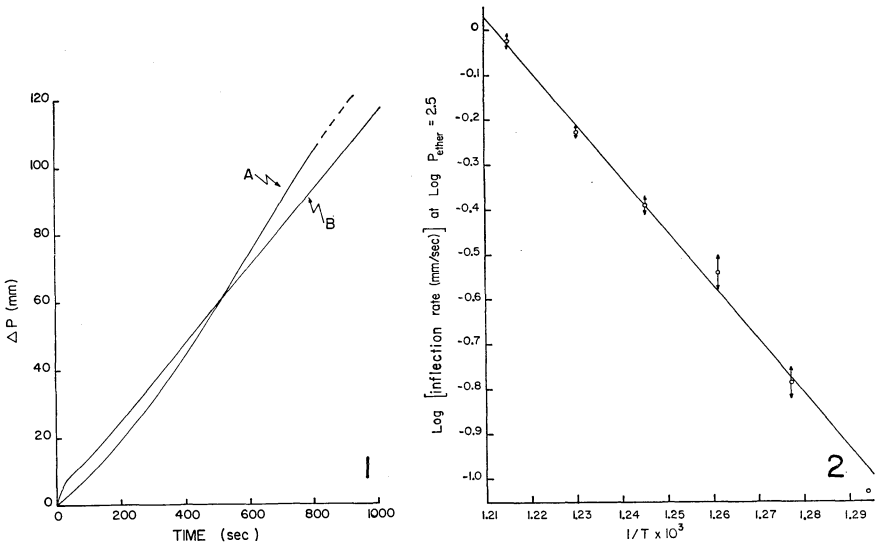

FIG. 1. Curve A: A typical pressure–time curve for the pyrolysis of dimethyl ether; this is a tracing of an actual record obtained at 520° C and at an initial pressure of 197 mm. Curve B: A pressure–time curve showing the effect of 0.4 mm of oxygen on the pyrolysis of dimethyl ether. All other conditions are the same as those for curve A.

FIG. 2. Arrhenius plot for the pyrolysis of dimethyl ether.

rate of disappearance of ether at decompositions of 20 to 30%. The data of Benson and Jain (14) were utilized for this purpose. Figure 1 of their paper is a plot of $\Delta CH_2O/\Delta CH_3OCH_3$ as a function of percentage decomposition. The overall reaction is represented by

$$\underset{(1-x)}{CH_3OCH_3} \rightarrow \underset{(x-y)}{CH_2O} + \underset{(x)}{CH_4} + \underset{(y)}{H_2} + \underset{(y)}{CO}$$

Benson and Jain have plotted $1-y/x$ against x. The change in pressure Δp, i.e. $x+y$, can thus be calculated from their data, and this can now be plotted against x. One can therefore obtain a plot of $\Delta p/p$ versus $\Delta E/p$, where ΔE is the change in partial pressure of ether. The experimental Δp can be calculated from the pressure–time curves obtained in the present work, and the corresponding value of ΔE can be estimated graphically. In all cases $\Delta E/\Delta p = 0.70 \pm 0.02$. The three-halves-order rate constant was therefore multiplied by 0.70, yielding

$$k = 2.98 \times 10^{14} e^{-54900/RT} \text{ cc}^{1/2} \text{ mole}^{-1/2} \text{ sec}^{-1}.$$

The activation energy is in good agreement with the values obtained by previous workers, and quoted above. The frequency factor and rates are, however, significantly lower than those obtained previously. This may be because our technique has minimized the surface-catalyzed reaction.

The shape of the pressure–time curve was found to be altered considerably by the addition of a small quantity (~0.2%) of oxygen. The initial rate of decomposition appeared to be greatly enhanced by the presence of oxygen, which in turn seems to be used up rapidly as suggested by the shape of the pressure–time curve shown in Fig. 1,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

curve B. These effects differ somewhat from those reported by Benson and Jain (14), who state that the reaction is relatively insensitive to surface effects and to small amounts of added oxygen. Professor Benson has, however, informed us that he and Jain did observe an initial effect of oxygen, which was rapidly consumed; there therefore seems to be agreement on this point.

The uninhibited decomposition of dimethyl ether exhibits a well-defined induction period, which is particularly evident at lower pressures. Figure 3 shows that this induction

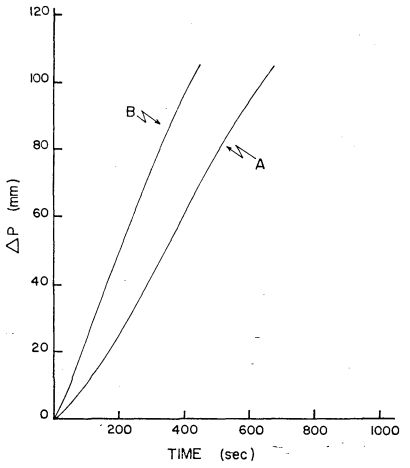

FIG. 3. Pressure–time curves for the ether decomposition at 540° C and an initial pressure of 122 mm. Curve A is for the reaction in the absence of formaldehyde; curve B for the reaction in the presence of 24 mm of formaldehyde.

period can be considerably shortened, and probably eliminated completely, by the addition of suitable amounts of formaldehyde. The formaldehyde also considerably increases the rate of the decomposition. An increase in rate on the addition of formaldehyde was also reported by Benson and Jain (14).

DISCUSSION

It is convenient to base a discussion of the mechanism of the dimethyl ether pyrolysis on that proposed by Benson and Jain (14):*

$$CH_3OCH_3 \rightarrow CH_3 + CH_3O \quad [1]$$

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3 \quad [2]$$

$$M + CH_2OCH_3 \rightarrow CH_2O + CH_3 + M \quad [3a]$$

$$CH_3O \rightarrow CH_2O + H \quad [4]$$

$$H + CH_3OCH_3 \rightarrow H_2 + CH_2OCH_3 \quad [5]$$

$$CH_3 + CH_2OCH_3 \rightarrow CH_3CH_2OCH_3. \quad [6]$$

The main features of this scheme are that the initiation reaction [1] is first order, that the decomposition of the radical (reaction [3a]) is in its second-order region, and that the main termination process involves CH_3 and CH_3OCH_2. If reaction [3a] is second order the radical CH_3OCH_2 is a β radical, as is CH_3. The termination is thus of the $\beta\beta$ type,

*The letter a in an equation number (e.g. [3a]) is used to emphasize the fact that the reaction is in its low-pressure region.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and this together with first-order initiation gives rise to three-halves-order kinetics. Following the terminology of Laidler, Sagert, and Wojciechowski (3) this mechanism may be denoted by $^1\beta\beta_{3/2}$, the initial superscript indicating the order of the initiation process, and the subscript 3/2 denoting the overall order.

It may be noted that three-halves-order overall kinetics are also obtained if the orders of reactions [1] and [3a] are reversed; i.e. if the reactions are

$$M + CH_3OCH_3 \rightarrow CH_3 + CH_2O + M \qquad [1a]$$

$$CH_2OCH_3 \rightarrow CH_2O + CH_3. \qquad [3]$$

Initiation is now second order and CH_2OCH_3 is a μ radical; this again gives rise to three-halves-order kinetics ($^2\beta\mu_{3/2}$).

Benson and Jain's main reason for preferring the $^1\beta\beta_{3/2}$ scheme is that the apparent first-order frequency factor for reaction [3], as calculated by Trotman-Dickenson (17) from the results of Marcus, Darwent, and Steacie (18), is $\sim 10^{10}$ sec^{-1}; this is much too low to be a true frequency factor for a unimolecular dissociation involving no change of multiplicity. An apparent way out of the difficulty is to suggest that the reaction is really in its second-order region. It might also be urged in favor of the Benson–Jain scheme that if the dissociation of CH_3OCH_3 were second order that of CH_2OCH_3 would be second order *a fortiori*, in view of its lower activation energy and smaller number of degrees of freedom.

Further consideration, however, reveals that these arguments are not as convincing as they appear at first sight. Thus the analytical methods on which the experimental results of Marcus *et al.* are based are not very reliable, and involved measuring amounts of CH_2O, CO, and 'dimer' ($CH_3OCH_2CH_2OCH_3$) produced from the radical CH_2OCH_3. It seems very possible that some of what was reported as 'dimer' was actually polymerized formaldehyde, since formaldehyde is known to polymerize readily under similar analytical conditions (19). This would have a very serious effect on the experimental results, and the frequency factor and activation energy for reaction [3] therefore cannot be relied upon.

Secondly, there is a precedent for suggesting that reaction [3] is second order and reaction [1] first order, since a similar situation exists in the ethane pyrolysis; the evidence (2) there seems conclusive that the dissociation of C_2H_6 is first order and that of C_2H_5 second order. Two explanations may tentatively be put forward to explain this apparently paradoxical result:

(1) The number of effective degrees of freedom may be larger in the radical (C_2H_5 or CH_2OCH_3) than in the corresponding molecule (C_2H_6 or CH_3OCH_3) because of less symmetry (cf. Laidler and Wojciechowski (20)).

(2) When a radical decomposes in the presence of a very large excess of its parent molecule there may exist an abnormally effective mechanism for energy transfer, involving atom abstraction. Some support for this interpretation is provided by the conclusion of Purnell and Quinn (21) that the ethyl radical decomposition is not in its first-order region when it is in the presence of butane and in the absence of the parent molecule ethane.

On the basis of these arguments there remains no valid objection to concluding that the reaction is of the type $^2\beta\mu_{3/2}$. Very strong evidence that the initiating reaction is in fact in its second-order region has been obtained from a study of the reaction in the presence of hydrogen sulphide, and is described in detail in Part III. This evidence excludes the Benson–Jain $^1\beta\beta_{3/2}$ mechanism. It is consistent with a mechanism in which the chain-ending step involves the recombination of two β radicals, in the low-pressure region ($^2\beta\beta M_{3/2}$), and also with a $^2\beta\mu_{3/2}$ mechanism. These are the only two possibilities if

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

initiation is second order. One can at once eliminate the second of these two possibilities by the fact that the reaction shows only a very slight effect of inert gases (14); the ${}^2\beta\mu_{3/2}$ mechanism would predict a substantial positive inert gas effect, since inert gases will increase the rate of initiation but will have no effect on the rate of termination. With a ${}^2\beta\beta M_{3/2}$ mechanism, on the other hand, no strong inert gas effect is to be expected, since both initiation and termination will be affected by the addition of inert gas, and the two effects will approximately cancel.

Chain-ending Steps

Initially, before any formaldehyde has decomposed, the radicals present in the system are CH_3, CH_3O, CH_2OCH_3, and H; only CH_3 and CH_2OCH_3 are involved in chain-propagating steps, and their concentrations are very much greater than those of the other two radicals. The CH_3 radical is certainly a β radical, and CH_2OCH_3 may be either β or μ and may indeed play both roles. The following chain-ending steps are therefore possible:

$$CH_3 + CH_3 + M \rightarrow C_2H_6 + M \quad [7]$$

$$CH_3 + CH_2OCH_3 + M \rightarrow CH_3CH_2OCH_3 + M \quad [8]$$

$$2CH_2OCH_3 + M \rightarrow CH_3OCH_2CH_2OCH_3 + M. \quad [9]$$

A decision between these possibilities can be made by carrying out calculations of the concentrations of the radicals, and finding out which chain-ending steps will occur with greatest velocity. Such calculations lead to the conclusion that reaction [7] occurs somewhat more rapidly than either of the other processes ([8] and [9]). The overall reaction mechanism is therefore concluded to be, for the most part,

$$M + CH_3OCH_3 \rightarrow CH_3 + CH_3O + M \quad [1a]$$

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3 \quad [2]$$

$$CH_2OCH_3 \rightarrow CH_2O + CH_3 \quad [3]$$

$$M + CH_3O \rightarrow CH_2O + H + M \quad [4]$$

$$H + CH_3OCH_3 \rightarrow H_2 + CH_2OCH_3 \quad [5]$$

$$CH_3 + CH_3 + M \rightarrow C_2H_6 + M. \quad [7]$$

It should be noted that reaction [4] is almost certainly in its second-order region, but this has no effect on the overall behavior. As discussed earlier, it is not certain whether reaction [3] is first order or second order, and this again makes no difference as far as the overall order is concerned.

Application of the steady-state treatment to the above mechanism gives rise to the following approximate expressions for the radical concentrations:

$$[CH_3] = \left(\frac{2k_{1a}}{k_7}\right)^{1/2} [CH_3OCH_3]^{1/2} \quad [i]$$

$$[CH_2OCH_3] = \frac{k_2}{k_3}\left(\frac{2k_{1a}}{k_7}\right)^{1/2} [CH_3OCH_3]^{3/2}. \quad [ii]$$

The overall rate is given by

$$v = k_2\left(\frac{2k_{1a}}{k_7}\right)^{1/2} [CH_3OCH_3]^{3/2}. \quad [iii]$$

Values of frequency factors and activation energies for the various elementary processes are given in Table I, which refers to a temperature of 800° K. The use of these values in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

TABLE I

Kinetic parameters

Reaction	Frequency factor (sec^{-1}, cc $mole^{-1}$ sec^{-1}, or cc^2 $mole^{-2}$ sec^{-1})	Activation energy (kcal $mole^{-1}$)	Rate constant at 800° K (sec^{-1}, cc $mole^{-1}$ sec^{-1}, or cc^2 $mole^{-2}$ sec^{-1})	Reference
[1a]	1×10^{18}	74.0	5.8×10^{-3}	Estimated (see Appendix)
[2]	3×10^{11}	9.5	7.8×10^{8}	Trotman-Dickenson and Steacie (22)
[3]	7×10^{10}	19.0	4.6×10^{5}	Marcus, Darwent, and Steacie (18); Trotman-Dickenson (17)
[7]	7×10^{14}	−13.5	3.5×10^{18}	Estimated (see Appendix)

the expressions for the radical concentrations leads to the conclusion that the concentrations at 800° K, and with [M] taken as 10^{-5} moles cc^{-1}, are as follows:

$$[CH_3] = 1.8\times10^{-13} \text{ moles } cc^{-1}; \quad [CH_2OCH_3] = 3.1\times10^{-15} \text{ moles } cc^{-1}.$$

The methyl radical is therefore predominant, and reaction [7] is therefore concluded to be the main chain-ending step. One cannot, however, exclude the possibility that reactions [8] and [9] also play a small role in the process. It may be noted that the value of 10^{-5} taken for [M] corresponds to the upper range of the pressures employed (~500 mm Hg); at lower pressures the methyl radicals are predominant *a fortiori*.

Except at the very beginning of the reaction there will be significant amounts of the formyl radical HCO, which arises from the decomposition of the formaldehyde produced as an intermediate. In a personal communication Professor S. W. Benson has suggested to us that for the main part of the reaction the principal chain-ending step is

$$CH_3 + HCO \rightarrow CH_4 + CO. \qquad [10]$$

According to Professor Benson this reaction will occur more rapidly than reaction [7] except at the very beginning of reaction. We are unable, however, to agree with this suggestion, for two main reasons. In the first place, our work with hydrogen sulphide (Part III) leads unequivocally to the conclusion that the initial dissociation of dimethyl ether is, under our experimental conditions, in its second-order region. This being so, reaction [10], being of the type $\beta\beta$, leads to second-order kinetics, in disagreement with experiment; only with a first-order initiation process does this lead to the correct three-halves-order kinetics. In the second place, our calculations of radical concentrations and rates lead us to the conclusion that reaction [7] actually occurs considerably more rapidly than reaction [10]. We calculate the third-order rate constant for reaction [7] to be, at 800° K, 3.5×10^{18} cc^2 $mole^{-2}$ sec^{-1} so that, with the concentration of M taken as 10^{-6}, the rate of reaction [7] can be expressed as

$$v_7 = 3.5\times10^{12}[CH_3]^2.$$

The concentration of CHO radicals is calculated to be somewhat less than that of CH_3, but for the purpose of the present estimate it will be assumed that the concentrations are the same. Since reaction [10] is a hydrogen atom abstraction reaction its frequency factor is expected to be about 10^{11} cc $mole^{-1}$ sec^{-1} and its activation energy will be at least 5 kcal $mole^{-1}$. On this basis we calculate that the rate of reaction [10] would be, at 800° K,

$$v = 4.3\times10^{9}[CH_3][CHO].$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Even with equal CH_3 and CHO concentrations the rate of reaction [10] is therefore considerably less than that of reaction [7]. It is to be noted that the high rate of reaction [7] is due to the fact that the complex formed from two methyl radicals has a very long life, so that the third-body recombination process occurs almost as rapidly as the second-order reaction with no activation energy.

The calculations do not, however, exclude the possibility that the recombination reaction

$$CH_3 + CHO + M \rightarrow CH_3CHO + M \qquad [11]$$

plays a significant role in the reaction. Our conclusion is, in fact, that chain ending may occur by reactions [7], [8], [9], and [11], with [7] being most important.

The Overall Reaction

As a check on the proposed mechanism, with [7] as the chain-ending step, calculations may be made of the absolute rate, frequency factor, and activation energy of the reaction on the basis of the mechanism. Using the parameters given in Table I the calculated overall values are

$$k = 0.045 \text{ cc}^{1/2} \text{ mole}^{-1/2} \text{ sec}^{-1}$$
$$A = 1.6 \times 10^{13} \text{ cc}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$
$$E = 53.3 \text{ kcal mole}^{-1}.$$

The calculated rate constant is less than the experimental value (0.27 $\text{cc}^{1/2}$ $\text{mole}^{-1/2}$ sec^{-1}), as is the frequency factor, but the activation energy is in good agreement with the experimental value of 54.9 kcal mole^{-1}. The error undoubtedly lies in the rather long extrapolations required to calculate the low-pressure rate constants for the initiation and termination steps.

APPENDIX

The basis for the values given in Table I for reactions [1a] and [7] is as follows. Gill and Laidler's analysis (23) of the data for the recombination of methyl radicals and for the reverse reaction,

$$2CH_3 + M \underset{k_{-7}}{\overset{k_7}{\rightleftharpoons}} C_2H_6 + M,$$

led to the following rate constants at 200° C:

$$k_7 = 3 \times 10^{20} \text{ cc}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$
$$= 1.67 \times 10^{17} e^{8000/RT} \text{ cc}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$
$$k_{-7} = 3 \times 10^{-16} \text{ cc mole}^{-1} \text{ sec}^{-1}$$
$$= 1.5 \times 10^{20} e^{-77{,}000/RT} \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

On the assumption that the temperature dependence of these rate constants is given by

the Hinshelwood formula, with $s = 9$ and $E_0 = 85$ kcal mole^{-1} as used by Gill and Laidler (23), the corresponding values at 800° K are:

$$k_7 = 3.5\times10^{18} \text{ cc}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$
$$= 7.0\times10^{14}e^{13,500/RT} \text{ cc}^2 \text{ mole}^{-2} \text{ sec}^{-1}$$
$$k_{-7} = 5\times10^{-2} \text{ cc mole}^{-1} \text{ sec}^{-1}$$
$$= 2.0\times10^{18}e^{-71,500/RT} \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

The parameters for k_7 are those given in Table I.

For the dissociation of CH_3OCH_3 in its second-order region we have assumed the same frequency factor as for the dissociation of ethane, namely 2×10^{18} cc mole^{-1} sec^{-1}. The low-pressure activation energy (74.0 kcal) was obtained by subtracting $8.5RT$ from 87 kcal, which is supposed to be the high-pressure value (24). It is quite possible that the value of 81 kcal reported by Rice and Johnston (6) actually corresponds to the fallen-off region, in which case their activation energy is too low.

In view of the rather long extrapolations involved (from 200° C to 800° K) there may well be considerable error in the estimated values for reactions [1a] and [7]. The present estimates seem, however, to be the best that can be made with the data available.

The parameters given in Table I for reaction [3] are also doubtful, as was noted in the main text.

KINETICS AND MECHANISMS OF THE PYROLYSIS OF DIMETHYL ETHER

II. THE REACTION INHIBITED BY NITRIC OXIDE AND PROPYLENE

D. J. McKenney, B. W. Wojciechowski, and K. J. Laidler
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received October 22, 1962

ABSTRACT

The thermal decomposition of dimethyl ether, inhibited by nitric oxide and by propylene, was studied in the temperature range of 500 to 600° C. About 1.5 mm of nitric oxide gave maximal inhibition, the rate then being approximately 8% of the uninhibited rate. With propylene, approximately 70 mm gave maximal inhibition, the rate being slightly higher than that using nitric oxide (~12.5% of the uninhibited rate). In both cases the degree of inhibition was independent of the ether pressure. In the maximally inhibited regions both reactions are three-halves order with respect to ether pressure. As the pressure of nitric oxide was increased beyond 10–15 mm, the overall rate increased, and in this region the reaction is first order with respect to both nitric oxide and ether. A 50:50 mixture of CH_3OCH_3 and CD_3OCD_3, with enough NO to ensure maximum inhibition, was pyrolyzed. Even at very low percentage decomposition the CD_3H/CD_4 ratio was approximately the same as that in the uninhibited decomposition, proving that the inhibited reaction is largely a chain process. Detailed inhibition mechanisms are proposed in which the inhibitor is involved both in initiation and termination reactions.

INTRODUCTION

Previous publications from this laboratory (1–6) have provided evidence for the view that maximally inhibited reactions proceed not by molecular mechanisms but by processes in which the inhibitor is involved both in initiation and in termination. Detailed mechanisms have now been worked out for the decompositions of ethane (4), propane (5), butane (6), and other substances, and a specific scheme has been proposed for the dimethyl ether decomposition (1). The present paper is concerned with an experimental study of the effects of nitric oxide and propylene on the decomposition of dimethyl ether, and with the formulation of reaction mechanisms. The mechanism previously proposed (1) has been found to require some revision.

A considerable amount of previous experimental work has been done on the inhibited dimethyl ether decomposition. The reaction inhibited by nitric oxide was first studied by Staveley and Hinshelwood (7), who found that the rate is very considerably reduced by small amounts of nitric oxide, and that a limiting rate is reached with nitric oxide pressures between about 0.5 mm and 12 mm. They reported an activation energy of 62 kcal $mole^{-1}$ for the maximally inhibited reaction, which they considered to be a molecular reaction. Gay and Travers (8) found, from a study of the products of the inhibited decomposition, that introduction of an increased quantity of nitric oxide into the reaction led to an increased amount of carbon monoxide in the products.

Thompson and Meisner (9) studied the absorption spectra of the products of the retarded decomposition of dimethyl ether, and found that during the course of the reaction the NO lines disappeared and that NH_3 lines appeared; they suggested the formation of formaldoxime (CH_2=NOH). A frozen mixture of the products gave a positive test for the nitroso group.

Recently Imai and Toyama (10) have studied the effect of nitric oxide on the pyrolysis of dimethyl ether. They found that the rate was first decreased by small amounts of nitric oxide, but that it increased linearly as larger quantities of nitric oxide were added. In this

accelerated region the order was unity with respect to both nitric oxide and ether. These authors suggested that the inhibited decomposition is a molecular process, and that large quantities of nitric oxide catalyze the molecular decomposition.

EXPERIMENTAL

The apparatus and methods were essentially the same as described previously (3; see also Part I). All gases used were research grade and were used without further purification except for the usual trap-to-trap distillation. In order to ensure complete mixing of the ether and inhibitor, and hence to eliminate any errors due to variation in reactant composition, the experimental procedure was as follows. A measured quantity of purified dimethyl ether was condensed on a cold finger in a 1-liter spherical flask. Only one stopcock was attached to this mixing vessel, and the connecting tubing was kept to a minimum. A known quantity of the inhibitor was then admitted to the mixing vessel, which contained the frozen ether. After all of the inhibitor was condensed, the stopcock was closed and the cold finger allowed to warm to room temperature. The warm gases were allowed to mix for about 15 minutes before being admitted to the reaction vessel.

Rates were calculated from the slopes of the pressure–time curves at the initial point and at the inflection point. The data obtained were fully reproducible.

The isotopic mixing experiments were carried out using equal amounts of CH_3OCH_3 and CD_3OCD_3. For the inhibited decomposition sufficient nitric oxide was added to ensure maximum inhibition. The reaction temperature was 550°, and the extent of the reaction varied from approximately 1 to 20%. The CD_3H/CD_4 ratio was determined by means of a mass spectrometer using samples from liquid-nitrogen non-condensable fractions of the reacted mixture.

Some runs were carried out at 500° C using mixtures containing approximately 10% CD_4, 90% dimethyl ether, and 0–1% nitric oxide (enough for maximum inhibition).

RESULTS

Isotopic Mixing

Table I summarizes the results obtained using 1:1 mixtures of CD_3OCD_3 and CH_3OCH_3.

TABLE I

Isotopic mixing experiments

Expt. No.	CH_3OCH_3 pressure (mm)	NO pressure (mm)	CD_4 pressure (mm)	Total pressure increase (mm)	Approx. % decomp.	Ratio CD_3H/CD_4 in products
1	314	0	0	141	22.2	2.44
2	312	0	0	96	15.4	2.53
3	311	0	0	58	9.3	2.52
4	308	0	0	35	5.7	2.51
5	305	0	0	18	3	2.44
6	299	5.5	0	115	19.2	2.41

12	436	0	43	105	12.1	0.03
13	427	4.5	46	18	2.1	0.0
14	428	4.5	51	6	0.7	0.03
15	422	4.7	50	3	0.4	0.03

NOTE: For experiments No. 1 to 11 inclusive the reaction temperature was 550° C, and for the remaining experiments the temperature was 500° C.

The average CD_3H/CD_4 ratio was 2.49±0.04 for the uninhibited runs and 2.44±0.03 for the inhibited runs. The extent of decomposition was determined from pressure measurements, and the methane ratios determined mass spectrometrically. The results from mixtures of ~10% CD_4 and ~90% CH_3OCH_3 in the absence of NO, and in the presence of ~1% NO (sufficient for maximal inhibition), are also shown in Table I.

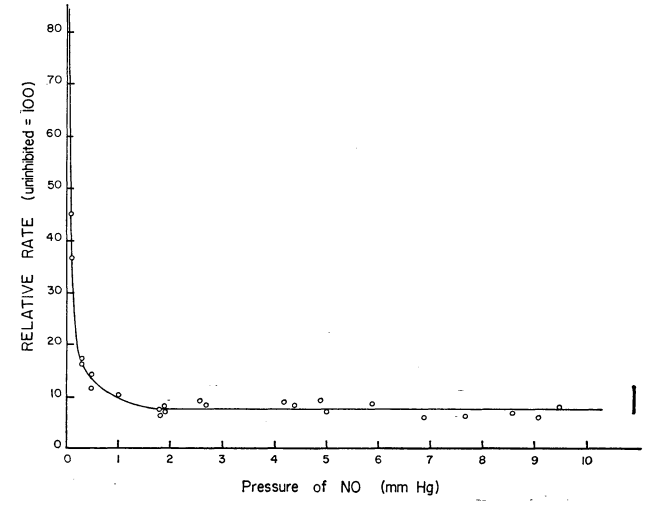
The Overall Kinetics of the Reaction Inhibited by Nitric Oxide

Preliminary experiments were carried out to determine the quantity of nitric oxide required to reduce the rate of decomposition of dimethyl ether to a minimum. The results are summarized in Fig. 1. The curve shows that the relative rate drops sharply to a minimum with the addition of about 1.5 mm of nitric oxide. Further addition of nitric oxide



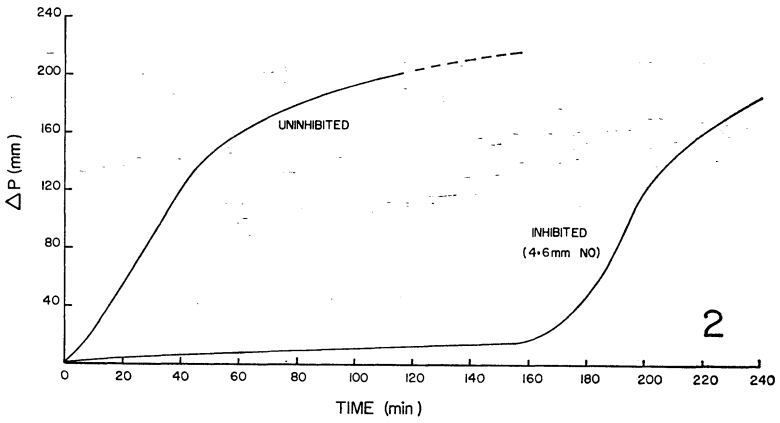


FIG. 1. Relative rate (uninhibited rate = 100) against nitric oxide pressure, at 520° C.
FIG. 2. Typical pressure–time curves for the uninhibited reaction and for the reaction maximally inhibited by nitric oxide, at 520° C. The initial ether pressure was 126 mm in each case.

has no effect on the rate until an amount greater than 10 mm has been added, and the rate then increases linearly with increasing nitric oxide pressure. Figure 1 also shows that no matter what pressure of ether was used the same minimum rate is obtained relative to the rate of the uninhibited reaction; ether pressures varying from 130 mm to 479 mm were used to obtain the points lying along the flat portion of the curve. Nitric oxide pressures between 2 mm and 10 mm were used in subsequent investigations of the maximally inhibited reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Figure 2 shows a typical pressure–time curve for the maximally inhibited decomposition and a similar curve for the uninhibited reaction. The ether pressure was the same (126 mm) in both cases. The curve for the inhibited reaction initially is completely different in shape from that of the uninhibited reaction. However, after a certain "inhibition time" the rate of the inhibited reaction increases and approaches that of the uninhibited reaction. This is apparently due to the fact that the nitric oxide has been used up.

Figure 3 shows plots of the logarithm of the initial rate versus the logarithm of the ether

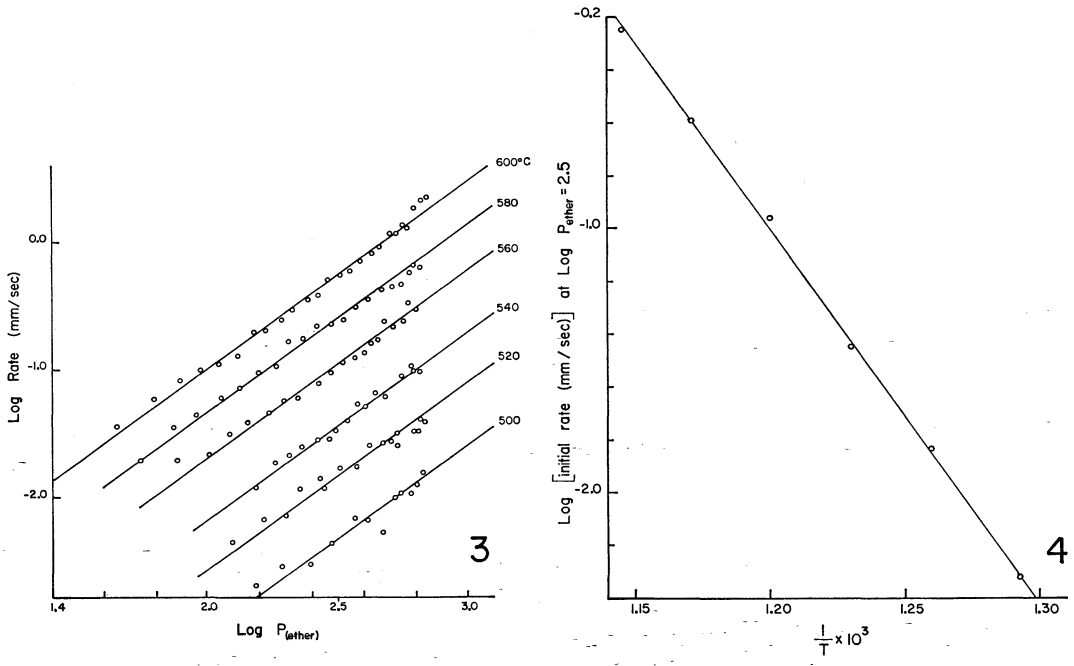

FIG. 3. Double logarithmic plots of initial rate against ether pressure, for the maximally inhibited reaction at various temperatures. The lines have slopes of 1.5.
FIG. 4. Arrhenius plot for the reaction maximally inhibited by nitric oxide.

pressure. About 5 mm of nitric oxide were used in all cases. The lines drawn have slopes of 1.5 at all temperatures. The initial rates become increasingly more difficult to measure as the temperature is lowered; the accuracy is therefore not as good at the lower temperatures, and the points become more scattered.

The activation energy, obtained from the Arrhenius plot shown in Fig. 4, was 64.6 kcal mole^{-1}. This is in satisfactory agreement with the activation energy of 62 kcal reported by Staveley and Hinshelwood (7). The three-halves-order rate constant may be expressed as

$$k = 1.2\times10^{16}e^{-64{,}600/RT}\ \text{cc}^{1/2}\ \text{mole}^{-1/2}\ \text{sec}^{-1}.$$

The effect on the "inhibition time" with varying amounts of nitric oxide is shown in Fig. 5. As the pressure of nitric oxide is increased the time required to reach the rate corresponding to the uninhibited rate steadily increases. More time is evidently required for the consumption of larger quantities of nitric oxide. The curves also demonstrate how the initial rate increases with large quantities (i.e. ~10 mm) of nitric oxide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

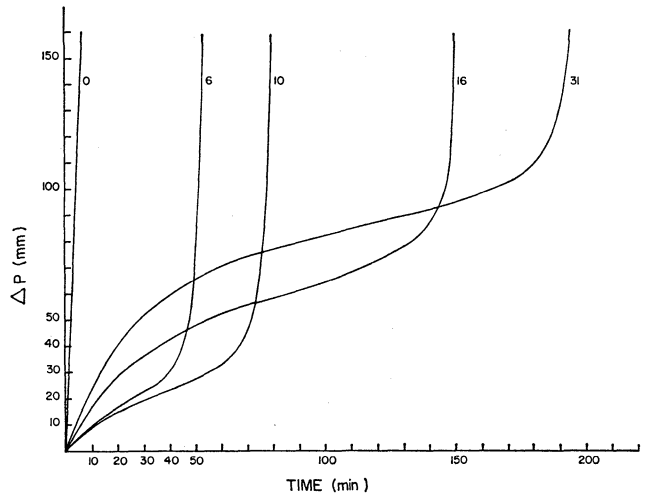

FIG. 5. Pressure–time curves for various pressures (mm Hg) of nitric oxide, which are indicated on the curves; the ether pressures were 470–485 mm, and the temperature 520° C.

The Reaction Accelerated by Nitric Oxide

Some runs were carried out using high pressures of nitric oxide. Figure 6 shows a plot of the logarithm of the initial rate against the logarithm of the pressure of nitric oxide.

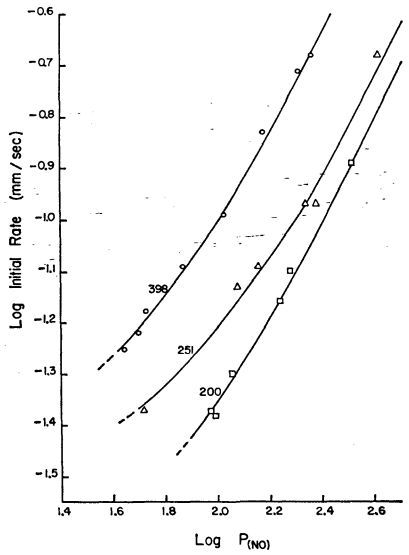

FIG. 6. Double logarithmic plot of initial rate against nitric oxide pressure, for the accelerated reaction using three different pressures of dimethyl ether, which are indicated on the curves.

The curves corresponding to different ether pressures all show some curvature at low nitric oxide pressures, but tend to linearity as the nitric oxide pressure is increased. The slopes of the linear portions of the curves are all unity. In the maximally inhibited region the order is obviously zero with respect to nitric oxide. The curvature therefore shows the gradual shift to first order in nitric oxide as the nitric oxide pressure is increased. In

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

subsequent studies in this region where the decomposition is sensitized by high pressures of nitric oxide, care was taken to ensure that at least 250 mm of nitric oxide (corresponding to log $P_{NO} = 2.4$ in Fig. 6) was used.

Rates were determined for the accelerated reaction for pressures of dimethyl ether varying from approximately 75 mm to 425 mm Hg, and over the temperature range from 510 to 570° C. As will be shown in the discussion, the overall rate expression for the inhibition by nitric oxide can be expressed by

$$v = k[CH_3OCH_3][NO] + k'[CH_3OCH_3]^{3/2}.$$

In the accelerated region, i.e. when [NO] is very large, the first term in the expression predominates and the reaction is first order with respect to both ether and nitric oxide; this was shown experimentally. To avoid the tedious procedure of maintaining a constant nitric oxide pressure, while studying the change in rate with variation of ether pressure, the logarithm of the rate minus the logarithm of the nitric oxide pressure was plotted against the logarithm of the ether pressure. Figure 7 shows the results of such plots. The

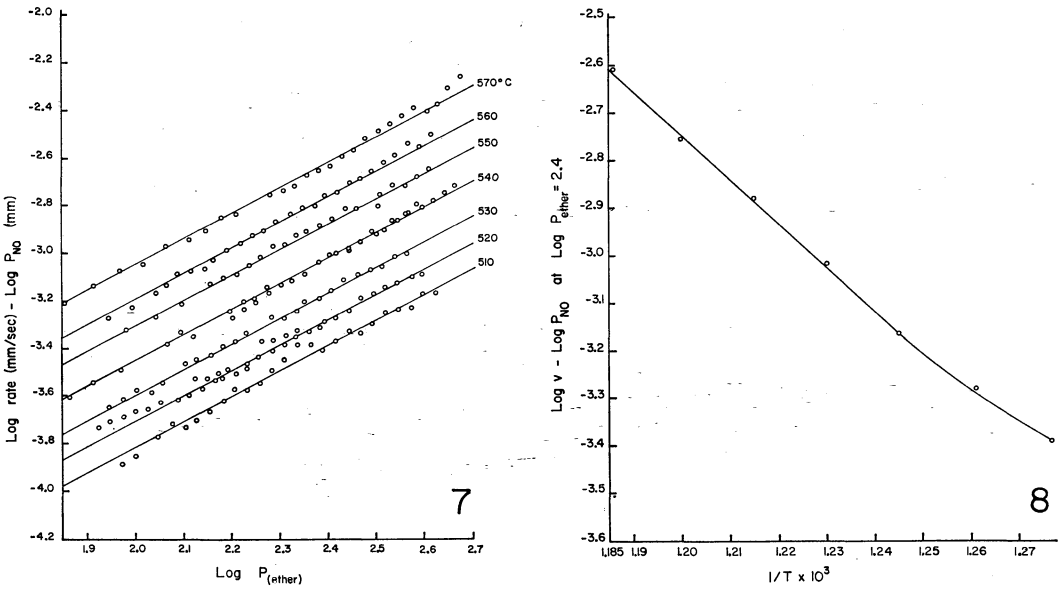

FIG. 7. Double logarithmic plots of initial rate against ether pressure, for the accelerated reaction.
FIG. 8. Arrhenius plot for the reaction accelerated by nitric oxide.

lines drawn all have slopes of approximately unity. The fact that the slopes are all slightly greater than unity (~1.1) shows that the second term in the above expression is not completely negligible even at nitric oxide pressures as high as 250 to 450 mm.

An Arrehenius plot of the data is shown in Fig. 8. The line drawn shows some curvature at the low temperatures, but is linear for temperatures above 530° C. The activation energy calculated from a least-squares treatment of the linear portion of the curve was found to be 43.5 kcal mole^{-1}, and the frequency factor was 9.6×10^{13} cc mole^{-1} sec^{-1}. This is an approximation to the true Arrhenius factor since, as was pointed out, the slopes of the curves of log v − log P_{NO} against log P_{ether} were slightly greater than unity. An approximate second-order rate expression can be written as $k \approx 1 \times 10^{14} e^{-43{,}400/RT}$ cc mole^{-1} sec^{-1}.

The Reaction Inhibited by Propylene

The inhibition curve showing the variation of relative rate with pressure of propylene is compared in Fig. 9 with the corresponding curve using nitric oxide as the inhibitor.

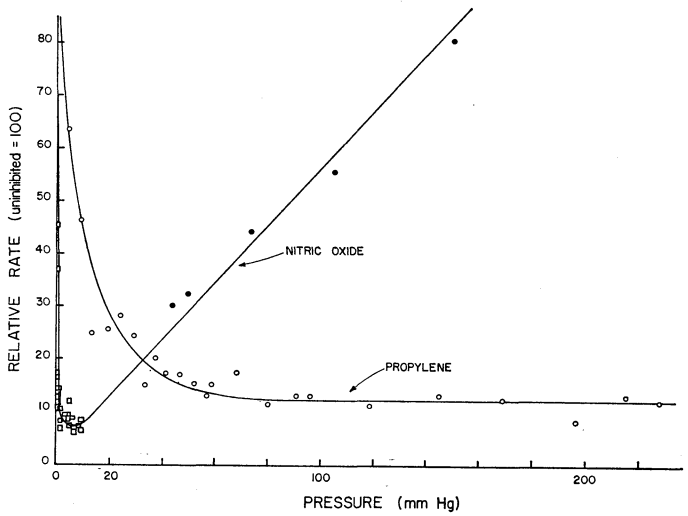

FIG. 9. Relative rate (uninhibited rate = 100) against propylene and nitric oxide pressures, at 520° C. The filled circles indicate an initial ether pressure of 398 mm. Points along the flat portions were obtained for various pressures of dimethyl ether.

About 70 mm of C_3H_6 is required at 520° to give a limiting rate. The relative rate in the maximally inhibited region is independent of ether pressure, as was also found in the case of inhibition by nitric oxide. In this case ether pressures varying from 168 mm to 513 mm are plotted along the flat portion; the variation was always well within the experimental error. The amount of propylene required to attain a limiting rate varied slightly with temperature. However, even at the highest temperature studied about 85 mm of propylene was found to be sufficient for maximal inhibition. The propylene inhibition curve differs in shape from the inhibition curve for nitric oxide in the region studied. Even pressures of propylene of about 200 mm failed to increase the rate of the decomposition, whereas pressures greater than 10–15 mm of nitric oxide produced a pronounced increase in rate. Care was taken in subsequent experiments in the fully inhibited region to maintain the propylene pressure at greater than 90 mm.

A typical pressure–time curve for the maximally inhibited reaction is shown in Fig. 10. The shape of the curve indicates that the system reaches equilibrium before an appreciable quantity of propylene is used up. The pressure–time relation for propylene therefore does not show the same behavior as does that for nitric oxide; this can be seen by comparing Fig. 10 with Fig. 2. The small quantity of nitric oxide necessary for maximal inhibition can be consumed before equilibrium is established between the ether and its products, but since much larger quantities of propylene must be used, a very long time would be required for all of the propylene to be used up, and the system comes to equilibrium before this can happen.

Figure 11 shows plots of the logarithm of the inflection-point rate against the logarithm of the ether pressure, at temperatures between 520 and 600° C. The inflection-point rates

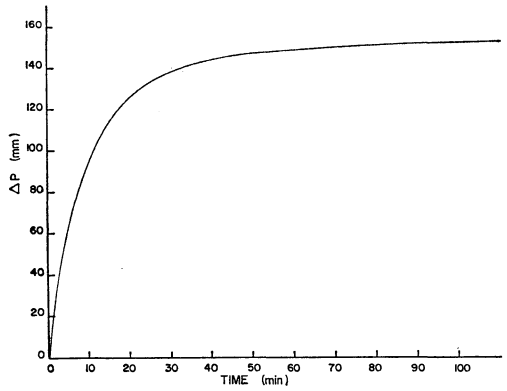

FIG. 10. A typical pressure–time curve for the reaction maximally inhibited by propylene; the initial ether pressure was 94 mm, and the temperature 600° C.

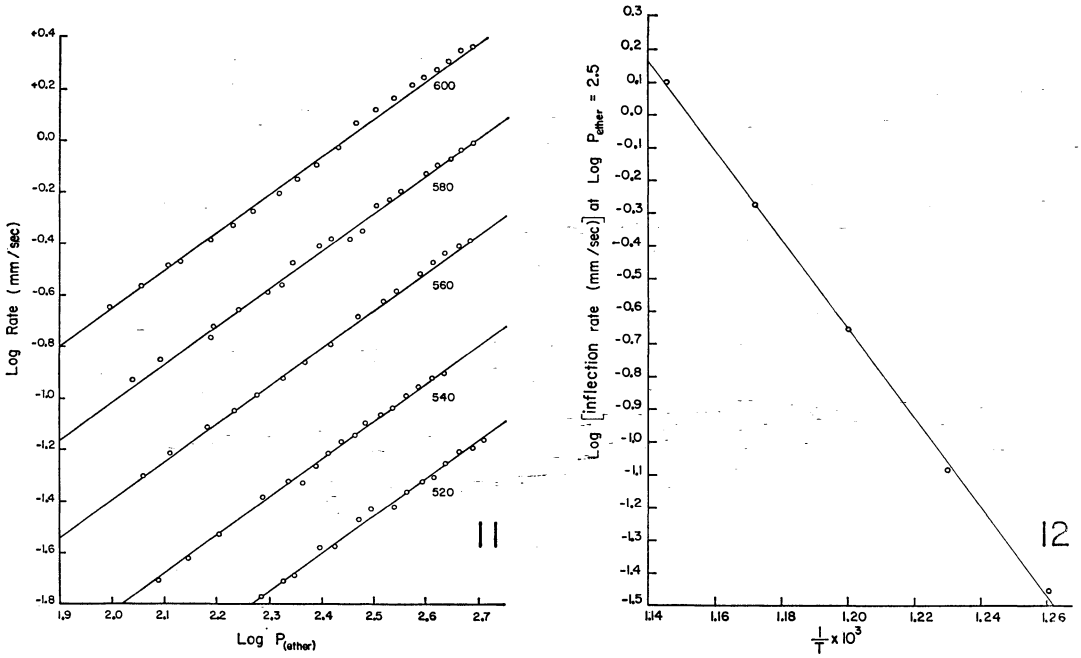

FIG. 11. Double logarithmic plots of inflection-point rate against ether pressure, for the reaction maximally inhibited by propylene.

FIG. 12. Arrhenius plot for the reaction maximally inhibited by propylene.

were used in this case because initial rates could not be measured very accurately especially at the higher temperatures.

The order, determined from the slopes of the lines in Fig. 11, was three-halves over the complete temperature and pressure ranges studied.

Figure 12 shows the Arrhenius plot for this system. The line drawn is the best fit determined by a least-squares treatment. The activation energy is 61.7 kcal mole^{-1} and the rate constant can be expressed as

$$k = 4.6\times10^{15}e^{-61{,}700/RT}\ \text{cc}^{1/2}\ \text{mole}^{-1/2}\ \text{sec}^{-1}.$$

DISCUSSION

Isotopic Mixing

Since the CD_3H/CD_4 ratio for the inhibited reaction is approximately the same as that for the uninhibited reaction (see Table I) it can be concluded that in the region of maximum inhibition the reaction is almost entirely a chain process. The suggestion made by previous workers (7, 10) that the inhibited reaction is entirely molecular must therefore be considered invalid for the dimethyl ether pyrolysis. The very low value obtained for the CD_3H/CD_4 ratio, in the case of CD_4, CH_3OCH_3, and NO mixtures, indicates that secondary processes are unimportant under these experimental conditions.

The Reaction Fully Inhibited by Nitric Oxide

The participation of nitric oxide in the initiation reaction in the dimethyl ether decomposition has been suggested by Wojciechowski and Laidler (1). Experimentally (see Fig. 2) nitric oxide effectively removes the induction period that is present in the uninhibited decomposition, and this suggests a direct reaction between NO and dimethyl ether. Initiation could therefore occur by either

$$CH_3OCH_3 + NO \rightarrow HNO + CH_3OCH_2 \qquad [1n]$$

or

$$CH_3OCH_3 + NO \rightarrow CH_3ONO + CH_3. \qquad [1n']$$

As far as the energetics of these reactions are concerned reaction [1n'] is favored. Reaction [1n] is endothermic by about 43 kcal (assuming $D(CH_3OCH_2—H)$ to be approximately 92 kcal $mole^{-1}$ as discussed later), while [1n'] is endothermic by about 39 kcal $mole^{-1}$. On the other hand [1n'] is a displacement reaction, while [1n] is an abstraction reaction and would probably be favored on steric grounds. Both reactions give similar rate expressions in the overall scheme, as will be shown below; for convenience it will be assumed that initiation is by [1n].

If reaction [1n] is the correct initiation reaction, the HNO will dissociate to produce H and NO. In hydrocarbon systems in which H atoms are present in large concentrations the reverse step also occurs. However in the decomposition of ether the hydrogen-atom concentration is quite low since the CH_3 radical is the principal chain carrier. The concentration of HNO is therefore low; the HNO largely dissociates and an equilibrium is established between CH_3, NO, CH_3NO, and CH_2NOH:

$$HNO \rightarrow H + NO$$

$$CH_3 + NO \rightleftarrows CH_3NO \rightleftarrows CH_2NOH.$$

If on the other hand reaction [1n'] is the correct one, the CH_3ONO can react with CH_3 radicals, as was shown by Jest and Phillips (11), as follows:

$$CH_3 + CH_3ONO \rightarrow CH_3NO + CH_3O.$$

The same equilibria as above would then be established.

The overall order being three-halves, the chain-ending steps must involve reaction between a β radical and either HNO or CH_3NO, of which the latter is present in much larger amounts. Isomerization of CH_3NO to $CH_2{=}NOH$ is known to occur (12), and the latter probably reacts with CH_3 more rapidly than does CH_3NO, since the process $CH_3 + CH_3NO \rightarrow C_2H_6 + NO$ probably involves a fairly high activation energy (see Appendix). The chain-ending step is therefore best written as

$$CH_3 + CH_2NOH \rightarrow CH_3CH_2—NOH \rightarrow C_2H_6 + NO.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This reaction is quite exothermic and can probably occur with no activation energy. The disappearance of nitric oxide is accounted for by the breakdown of CH_2NOH.

The mechanism to which these considerations leads is:*

$$CH_3OCH_3 + NO \rightarrow HNO + CH_2OCH_3 \qquad [1n]$$

$$CH_2OCH_3 \rightarrow CH_2O + CH_3 \qquad [3]$$

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_2OCH_3 \qquad [2]$$

$$M + HNO \rightarrow H + NO + M \qquad [11]$$

$$H + CH_3OCH_3 \rightarrow H_2 + CH_2OCH_3 \qquad [5]$$

$$M + CH_3 + NO \underset{[-12]}{\overset{[12]}{\rightleftharpoons}} CH_3NO + M$$

$$CH_3NO \underset{[-13]}{\overset{[13]}{\rightleftharpoons}} CH_2NOH \rightarrow \text{products (HCN, etc.)}$$

$$CH_3 + CH_2NOH \rightarrow CH_3CH_2NOH \rightarrow C_2H_6 + NO. \qquad [15]$$

Application of the conventional steady-state treatment yields the following expressions for the radical concentrations:

$$[H] = \frac{k_{1n}}{k_5}[NO]$$

$$[HNO] = \frac{k_{1n}}{k_{11}}[NO]$$

$$[CH_2NOH] = \left(\frac{k_{1n}k_{12}k_{13}}{k_{-12}k_{-13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{1/2}[NO]$$

$$[CH_3NO] = \left(\frac{k_{1n}k_{12}k_{-13}}{k_{-12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{1/2}[NO] + \frac{k_{1n}}{k_{13}}[CH_3OCH_3][NO]$$

$$[CH_3] = \left(\frac{k_{1n}k_{-12}k_{-13}}{k_{12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{1/2}$$

$$[CH_3OCH_2] = \frac{k_2}{k_3}\left(\frac{k_{1n}k_{-12}k_{-13}}{k_{12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{3/2} + \frac{2k_{1n}}{k_3}[CH_3OCH_3][NO].$$

The rate is given by

$$-\frac{d[CH_3OCH_3]}{dt} = 2k_{1n}[CH_3OCH_3][NO] + k_2\left(\frac{k_{1n}k_{-12}k_{-13}}{k_{12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

At low NO concentrations the first term can be neglected in comparison to the second term, and the rate expression then predicts three-halves-order kinetics with respect to ether. However, when the nitric oxide concentration is large the first term can no longer be neglected and in fact the rate becomes first order with respect to both NO and ether concentration. This is in agreement with the experimental facts.

A calculation can be made to determine whether CH_3 radicals or CH_3OCH_2 radicals are present in greater amounts:

$$\frac{[CH_3]}{[CH_3OCH_2]} = \frac{k_3}{k_2}\frac{1}{[CH_3OCH_3]}.$$

The reactions have been numbered so as to be consistent with Part I.

[12]*	1×10^{11}	0	1×10^{11}	Ref. 13
[−12]*	1×10^{15}	50	21	A from ref. 14 and E estimated (see Appendix)
[13]	1×10^{13}	40	1.2×10^{2}	Ref. 15
[−13]	1×10^{13}	55	9.1×10^{-3}	Estimated (see Appendix)
[15]	1×10^{10}	0	1×10^{10}	Assumed

*The values given relate to the high-pressure region.

cc^{-1}, gives rise to, at 600° C,

$$\frac{[CH_3]}{[CH_3OCH_2]} = 59.$$

Consequently the CH_3 radical should be involved in termination rather than the CH_3OCH_2 radical.

The activation energy for the maximally inhibited reaction predicted by the mechanism is:

$$E = E_2+\tfrac{1}{2}(E_{1n}+E_{-12}+E_{-13}-E_{13}-E_{15}).$$

Agreement with the experimental value of 64.6 kcal mole^{-1} is obtained if a value of 64.8 kcal is taken for $E_{-12}+E_{-13}-E_{12}-E_{13}$. The significance of this value is that it implies that formaldoxime, CH_2NOH, is 64.8 kcal more stable than $CH_3 + NO$. This is a reasonable conclusion; further discussion is to be found in the Appendix.

The predicted frequency factor is

$$A = A_2\left(\frac{A_{1n}A_{12}A_{-13}}{A_{12}A_{13}A_{15}}\right)^{1/2} = 3\times10^{15}\ \text{cc}^{1/2}\,\text{mole}^{-1/2}\,\text{sec}^{-1}.$$

This is in satisfactory agreement with the experimental value of 1.2×10^{16} ml$^{1/2}$ mole$^{-1/2}$ sec^{-1}.

The Reaction Accelerated by Nitric Oxide

When large quantities of nitric oxide are used the rate of decomposition of dimethyl ether is considerably enhanced. The reaction has been found to be first order with respect to both NO and CH_3OCH_3 in this region. This result is predicted by the mechanism given above for the fully inhibited reaction. As the quantity of NO is increased the first term in the overall rate expression (i.e. $2k_{1n}[CH_3OCH_3][NO]$) predominates. Thus the ratio of the two terms is given by

$$\frac{\text{term 1}}{\text{term 2}} = \frac{2k_{1n}[CH_3OCH_3][NO]}{k_2\left(\frac{k_{1n}k_{-12}k_{-13}}{k_{12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{3/2}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

This ratio is found to be approximately 73 after substitution of the values for the rate constants and the values $[NO] = [CH_3OCH_3] = 10^{-5}$ mole cc^{-1}. If $2k_{1n}[CH_3OCH_3][NO]$ is the dominant term when [NO] is large, a second-order rate constant can be calculated which corresponds to k_{1n}. The calculated second-order rate constant from Fig. 8 is given by

$$k_{1n} = 1 \times 10^{14} e^{-43{,}400/RT} \text{ cc mole}^{-1} \text{ sec}^{-1}.$$

The abstraction of a hydrogen atom from dimethyl ether by nitric oxide therefore has an activation energy of 43.4 kcal mole^{-1}, and the frequency factor is, to a good approximation, 1×10^{14} cc mole^{-1} sec^{-1}. The reason for the approximation is explained above. Using the value of 48.6 kcal for D(H—NO) (16), and the activation energy of 43.4 kcal determined above, an estimate of 92.0 kcal mole^{-1} for $D(CH_3OCH_2—H)$ can be made.

It is well established that increased quantities of nitric oxide increase the proportion of carbon monoxide in the products (8). This is also true in the decomposition of acetaldehyde (17) and diethyl ether (18). This result has previously been explained as being due to oxidation reactions, but it can be explained by the mechanism postulated above. Carbon monoxide is a major product in the decomposition of formaldehyde, which itself is one of the major products in the ether decomposition. From the mechanism postulated above the rate of formation of formaldehyde is given by

$$\frac{d[CH_2O]}{dt} = k_3[CH_3OCH_2]$$

$$= 2k_{1n}[CH_3OCH_3][NO] + k_2\left(\frac{k_{1n}k_{-12}k_{-13}}{k_{12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

The rate expression thus includes a term involving [NO], and therefore the proportion of formaldehyde (and hence of CO) should increase with increasing amounts of nitric oxide. On the other hand, the rate of formation of methane is not increased by adding nitric oxide, since

$$\frac{d[CH_4]}{dt} = k_2[CH_3][CH_3OCH_3]$$

$$= k_2\left(\frac{k_{1n}k_{-12}k_{-13}}{k_{12}k_{13}k_{15}}\right)^{1/2}[CH_3OCH_3]^{3/2},$$

which does not contain a term involving [NO].

The Reaction Fully Inhibited by Propylene

An analogous mechanism can be written for inhibition by propylene by assuming that the allyl radical (C_3H_5) is capable of abstracting hydrogen atoms and is therefore the counterpart of NO in the previous scheme. That C_3H_5 can abstract hydrogen atoms is well established experimentally (3, 19–22). Consequently, following the dissociation of propylene,

$$C_3H_6 \rightarrow C_3H_5 + H, \qquad [16]$$

the initiation reaction may be written as

$$CH_3OCH_3 + C_3H_5 \rightarrow C_3H_6 + CH_3OCH_2. \qquad [1p]$$

Experimentally there is an appreciable induction period in the propylene-inhibited reactions. This is required since an appreciable concentration of C_3H_5 radicals must first be formed. In the nitric oxide case the nitric oxide can abstract hydrogen atoms immediately and consequently there is no appreciable induction period.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The overall mechanism for the propylene-inhibited decomposition may therefore be written as:

$$CH_3OCH_3 + C_3H_5 \rightarrow C_3H_6 + CH_3OCH_2 \quad [1p]$$

$$CH_3OCH_2 \rightarrow CH_2O + CH_3 \quad [3]$$

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_3OCH_2 \quad [2]$$

$$C_3H_6 \rightarrow C_3H_5 + H \quad [16]$$

$$H + CH_3OCH_3 \rightarrow H_2 + CH_3OCH_2 \quad [5]$$

$$CH_3 + C_3H_6 \rightarrow CH_4 + C_3H_5 \quad [17]$$

$$CH_3 + C_3H_5 \rightarrow CH_4 + H_2C{=}C{=}CH_2. \quad [18]$$

The steady-state treatment yields the following expressions for the radical concentrations:

$$[H] = \frac{k_{16}[C_3H_6]}{k_5[CH_3OCH_3]}$$

$$[CH_3] = \left(\frac{k_{1p}k_{16}}{k_{15}k_{17}}\right)^{1/2}[CH_3OCH_3]^{1/2}$$

$$[CH_3OCH_2] = \frac{k_{16}}{k_3}[C_3H_6] + \frac{k_{17}}{k_3}\left(\frac{k_{1p}k_{16}}{k_{18}k_{17}}\right)^{1/2}[CH_3OCH_3]^{1/2}[C_3H_6] + \frac{k_2}{k_3}\left(\frac{k_{1p}k_{16}}{k_{18}k_{17}}\right)^{1/2}[CH_3OCH_3]^{3/2}$$

$$[C_3H_5] = \left(\frac{k_{16}k_{17}}{k_{18}k_{1p}}\right)^{1/2}\frac{[C_3H_6]}{[CH_3OCH_3]^{1/2}}.$$

The overall rate is

$$v = -\frac{d[CH_3OCH_3]}{dt} = \left(\frac{k_{1p}k_{16}k_{17}}{k_{18}}\right)^{1/2}[C_3H_6][CH_3OCH_3]^{1/2} + k_{16}[C_3H_6] + k_2\left(\frac{k_{1p}k_{16}}{k_{18}k_{17}}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

The second term in this expression is negligible in comparison to the third term. The ratio of the third term to the first term is, using the values in Tables II and III, and with $[CH_3OCH_3] = [C_3H_6]$,

$$\frac{\text{term 3}}{\text{term 1}} = \frac{k_2}{k_{17}}\frac{[CH_3OCH_3]}{[C_3H_6]} = 2 \text{ at } 800^\circ \text{ K}.$$

Consequently the third term will predominate and the overall order is predicted to be three-halves with respect to ether, in agreement with experiment.

TABLE III

Kinetic parameters for inhibition by propylene

Reaction	Frequency factor (sec^{-1} or cc mole^{-1} sec^{-1})	Activation energy (kcal mole^{-1})	k at 800° K (sec^{-1} or cc mole^{-1} sec^{-1})	Reference
[1p]	1.0×10^{12}	38.0	4.1	Estimated
[16]	1.0×10^{15}	78.0	4.7×10^{-7}	Estimated from Szwarc (23)
[17]	5.2×10^{10}	7.7	4.1×10^{8}	Trotman-Dickenson and Steacie (24)
[18]	1.0×10^{10}	3.0	1.5×10^{9}	Estimated

Reaction [18] shows that the allyl radical is used up in forming stable products. As pointed out above one cannot observe by direct pressure measurement when all of the C_3H_5 has been consumed, as is possible with NO, because a thermodynamic equilibrium is presumably established long before the very large quantity of allyl radicals has disappeared by reaction [18]. The propylene constitutes a reservoir supplying C_3H_5 radicals to the system by reaction [16].

The predicted activation energy is

$$E = E_2+\tfrac{1}{2}(E_{1p}+E_{16}-E_{17}-E_{18})$$
$$= 62.2 \text{ kcal mole}^{-1},$$

in good agreement with the experimental value of 61.7 kcal mole^{-1}.

The predicted frequency factor is given by

$$A = A_2\left(\frac{A_{1p}A_{16}}{A_{17}A_{18}}\right)^{1/2} = 4.2\times10^{14} \text{ cc}^{1/2} \text{ mole}^{-1/2} \text{ sec}^{-1}$$

whereas the experimental value is

$$A = 4.6\times10^{15} \text{ ml}^{1/2} \text{ mole}^{-1/2} \text{ sec}^{-1}.$$

The agreement is quite satisfactory in view of the uncertainties in the individual frequency factors.

Induction Period

The induction period in the uninhibited reactions is associated with a gradual increase in rate at the beginning of the reaction; this results in the familiar S-shaped pressure–time curves. This type of curve was observed in the uninhibited reaction (see Part I), in the reaction inhibited by propylene, and in the reaction accelerated by large quantities of nitric oxide. In the latter case an induction period was evident only at low pressures and temperatures. The situation is quite different in the case of the reaction fully inhibited by nitric oxide. Here there is no evidence of any induction period at high pressures and temperatures. However, as the pressures and temperature are lowered there is a pronounced time lag before there is any pressure change in the reaction vessel. Thus the pressure–time curve exhibits a flat portion initially, followed by a sudden increase; Fig. 13 shows this effect.

The S-shaped curves can perhaps be explained by assuming a gradual approach to steady-state conditions. For the nitric oxide inhibited reaction the shape of the pressure–

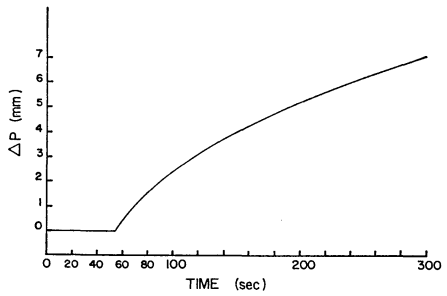

FIG. 13. Typical pressure–time curve for the reaction maximally inhibited by nitric oxide, particularly at low pressures and temperatures; this curve was obtained at 520° with an ether pressure of 591 mm and a nitric oxide pressure of 4.8 mm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

time curve suggests that there is a time delay before any ether decomposes, after which the reaction proceeds in the manner described above.

ACKNOWLEDGMENTS

The authors are grateful to Dr. F. P. Lossing of the National Research Council, for the mass spectrometric analyses, and to Drs. Margaret Back and W. A. Bryce for valuable suggestions.

The work was supported in part by a grant from the National Research Council, and in part by a grant from the Petroleum Research Fund.

APPENDIX

Figure 14 summarizes our conclusions with regard to the thermochemistry of processes related to the species HNO and CH_3NO. The main evidence for these values is as follows.

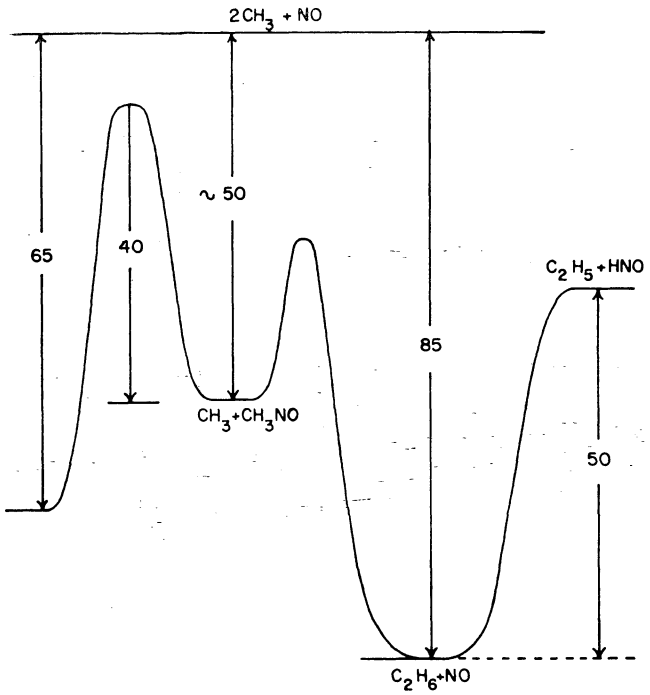

FIG. 14. Schematic energy-level diagram for the processes related to the species CH_3NO, CH_2NOH, C_2H_6, and HNO.

On the basis of their study of the ethane pyrolysis Laidler and Wojciechowski (4) concluded that the process $C_2H_6 + NO \rightleftarrows C_2H_5 + HNO$ is endothermic by 50 kcal $mole^{-1}$ and that the back reaction has no activation energy. The level of $2CH_3 + NO$ is higher than that of $C_2H_6 + NO$ by 85 kcal, the dissociation energy of the C—C bond in ethane.

The level of CH_3NO below that of $CH_3 + NO$ is not known with any certainty. Gray (25) has obtained a value of 57 kcal for $D(CH_3—NO_2)$, and Gowenlock, Trotman, and Batt (12) suggested that the value of $D(CH_3—NO)$ should be approximately the same. Gowenlock (26) now, however, favors a lower value, of about 30 kcal, on the grounds that the CH_3—NO dissociation energy should be about 15 kcal weaker than that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

H—NO. The dissociation of HNO, however, involves a predissociation (as may also that of CH_3NO), so that the evidence is not reliable. In Fig. 14 the value is about 50 kcal; the actual value has no bearing on the kinetics of the reaction. Ree, Yang, and Eyring (27), in a recent discussion of reactions inhibited by nitric oxide, have concluded that the value may be as high as 69.7 kcal mole^{-1}.

Since reaction between NO and C_2H_6 apparently gives $C_2H_5 + HNO$ (4) and not $CH_3 + CH_3NO$ it is postulated that there is a potential-energy barrier between $C_2H_6 + NO$ and $CH_3 + CH_3NO$, as shown in the diagram.

Batt and Gowenlock (15) have shown that CH_3NO isomerizes into formaldoxime, CH_2=NOH, with an activation energy of about 40 kcal mole^{-1}. The results of the present work indicate that the level of CH_2=NOH + CH_3 is 65 kcal below that of $CH_3 + CH_3 + NO$, and therefore significantly below that of $CH_3 + CH_3NO$. This is not unreasonable. Formaldoxime is expected to be a much more effective scavenger of radicals than is CH_3NO, and chain ending is therefore postulated to be

$$CH_3 + CH_2{=}NOH \rightarrow CH_3CH_2{-}NOH \rightarrow C_2H_6 + NO.$$

The breakdown of CH_2NOH accounts for the disappearance of nitric oxide in this reaction, in contrast to the situation with certain hydrocarbon decompositions (e.g. ethane, ref. 4), where CH_2NOH is not formed in significant amounts.

KINETICS AND MECHANISMS OF THE PYROLYSIS OF DIMETHYL ETHER

III. THE REACTION ACCELERATED BY HYDROGEN SULPHIDE

D. J. McKenney and K. J. Laidler
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received November 23, 1962

ABSTRACT

The thermal decomposition of dimethyl ether in the presence of hydrogen sulphide was studied in the temperature range of 480 to 530° C, and over the pressure range of 5 to 500 mm of Hg. For a given pressure of dimethyl ether the rate of decomposition increased with the addition of increasing quantities of hydrogen sulphide, reaching a plateau after approximately 30% H_2S had been added. The relative rate of decomposition then remained constant until more than 50% H_2S had been added. Further increase in the hydrogen sulphide concentration produced a linear increase in the relative rate. In the region between 30 and 50% added H_2S, the decomposition of dimethyl ether was three-halves order with respect to ether pressure, and zero order with respect to hydrogen sulphide pressure. In this region the three-halves-order rate constant can be expressed by $k = 1.06\times10^{14}e^{-53,200/RT}$ $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}. In the region beyond 50% added H_2S, the reaction was first order with respect to dimethyl ether, and one-half order with respect to hydrogen sulphide. In this region the three-halves-order rate constant is given by $k = 4.98\times10^{14}e^{-52,500/RT}$ $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}. The experimental facts are shown to be consistent with a mechanism involving hydrosulphide radicals as the principal chain carriers. These HS radicals are produced mainly from the reaction of methyl radicals with hydrogen sulphide. The work leads to a value of 85.6 kcal for the dissociation energy of H_2S into H + SH.

INTRODUCTION

A number of workers (1–7) have suggested that thiyl radicals (RS) are more reactive than alkyl radicals. Thus thiols generally accelerate free-radical reactions involving saturated aldehydes; this has been shown to be the case in the liquid phase (1), in photodecomposition reactions in the gas phase (2, 3) and in thermal decompositions in the gas phase (4–7). Birrell and co-workers (2) observed that various thiols (H_2S, CH_3SH, C_2H_5SH, etc.) catalyzed the photodecomposition of acetaldehyde, and in most cases the thiols increased the rate of the decomposition. The rates increased to a plateau with the addition of thiol and remained constant over a range of concentrations. When the thiol concentration was about three-quarters of the acetaldehyde concentration the relative rate (ratio of catalyzed to uncatalyzed rate) increased further. Hydrogen sulphide was found to be the most effective catalyst, and the catalytic effect decreased with increasing complexity of the thiol. The mechanism proposed for catalysis by methanethiol involved the chain transfer reaction

$$CH_3 + CH_3SH \rightarrow CH_3S + CH_4$$

followed by

$$CH_3S + CH_3CHO \rightarrow CH_3SH + CH_3 + CO$$

and termination by

$$2CH_3S \rightarrow CH_3SSCH_3.$$

Such a simple mechanism could not, however, explain the effects observed for other thiols.

More recently Imai and Toyama have postulated mechanisms to explain the acceleration by hydrogen sulphide and methanethiol of the decomposition of acetaldehyde (4, 5, 7). The effect of hydrogen sulphide on the decomposition of dimethyl ether was also studied (6). These workers suggest that the catalytic effect of hydrogen sulphide is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

essentially due to reaction of methyl radicals with hydrogen sulphide, with the production of hydrosulphide (SH) radicals which in turn abstract hydrogen atoms from the substrate. These reactions are suggested to be faster than the reaction between methyl radicals and the substrate. For the thermal decomposition of dimethyl ether in the presence of hydrogen sulphide the rate increased with increasing concentration of hydrogen sulphide and reached a limit where further addition of hydrogen sulphide had no effect. The maximum amount of hydrogen sulphide which was added was approximately 67%, and the reactions were carried out over the temperature range of 360 to 440° C. The mechanism suggested for the reaction in the presence of sufficient hydrogen sulphide to ensure "limiting" acceleration was as follows:*

$$CH_3OCH_3 \rightarrow CH_3 + CH_3O \quad [1]$$

$$CH_3O + H_2S \rightarrow CH_3OH + HS \quad [24]$$

$$CH_3 + H_2S \rightarrow CH_4 + HS \quad [21]$$

$$CH_3OCH_3 + HS \rightarrow H_2S + CH_3OCH_2 \quad [20]$$

$$CH_3OCH_2 \rightarrow CH_2O + CH_3 \quad [3]$$

$$HS + HS \rightarrow \text{products.} \quad [23]$$

The rate equation to which this mechanism leads is

$$-\frac{d[CH_3OCH_3]}{dt} = \frac{d[CH_4]}{dt} = k_{20}\left(\frac{k_1}{k_{23}}\right)^{1/2}[CH_3OCH_3]^{3/2}$$

and a three-halves-order dependence on ether concentration was obtained experimentally. The results led to a rate constant of $k = 1.82\times10^{15}e^{-51,800/RT}$ cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}.

In the light of recent work (Part II) in this laboratory on the action of inhibitors on the thermal decomposition of dimethyl ether, it was thought that a mechanism similar to inhibition mechanisms could be applied to the reaction accelerated by hydrogen sulphide. It also seemed necessary to extend the experimental investigation to higher temperatures and higher pressures of H_2S. The fact that there was an increase in relative rate at very high pressures of H_2S (>50% added H_2S) indicated that the mechanism postulated by Imai and Toyama (6) is not sufficient to describe the reaction completely.

EXPERIMENTAL

The apparatus used was essentially the same as described previously (8; see also Part I of this series). The dimethyl ether and hydrogen sulphide were 99.5% pure, and were used after three trap-to-trap distillations. The reactants were mixed thoroughly prior to a run, the procedure described earlier (Part II) being employed.

The reaction vessel was a cylindrical quartz tube of about 250-ml volume. A Thermo Electronic controller, activated by means of a thermocouple in the copper furnace block, maintained the temperature constant to about ±0.2° C. The temperature was measured by means of a thermocouple in the reaction vessel and a Thermo Electric Mini-Mite potentiometer.

Before each run the reaction vessel was pumped down to less than 10 μ. This small residual pressure had no detectable effect on the rates. A Beckman photopen recorder in conjunction with a quartz spiral gauge automatically recorded the pressure change as a function of time. The details of this arrangement have been described by Laidler and Wojciechowski (8).

Rates were calculated from the slopes of the pressure–time curves at the inflection point, and the results were found to be fully reproducible over the entire range of pressure and temperature. The induction period for the reaction in the presence of H_2S was generally quite short, so that the inflection point occurred in all cases at less than 10% decomposition. The rates can therefore be considered to be initial rates to a very close approximation.

**The numbering is written so as to be consistent with the mechanism postulated below, as well as with the numbering in Parts I and II of this series.*

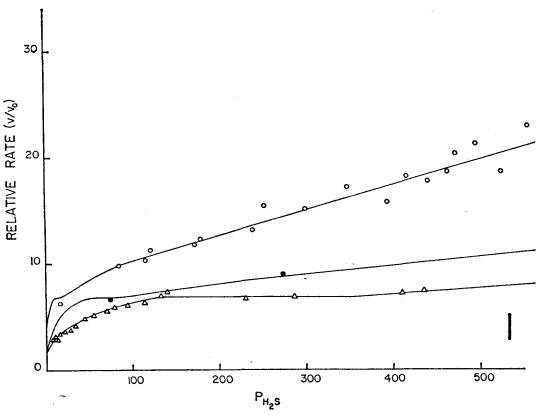
RESULTS

Preliminary experiments were carried out with hydrogen sulphide alone in the reaction vessel at 600° C. It was found that the total pressure decreased by approximately 1% to a limit. This slight pressure change is insignificant compared to the pressure change for the decomposition of dimethyl ether in the presence of H_2S, and was therefore ignored.

In order to verify the experimental results of previous workers (6) the rate of decomposition of dimethyl ether was measured for various added amounts of hydrogen sulphide. A plot of relative rate (i.e., the rate in the presence of H_2S divided by the rate in the absence of H_2S) is shown in Fig. 1. The curves drawn have been calculated from Fig. 2,



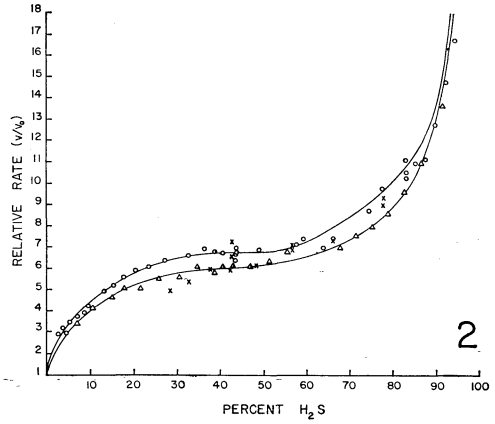


FIG. 1. Relative rate (v/v_0) against pressure of hydrogen sulphide for three different pressures of ether: △ 300 mm, ● 100 mm, and ○ 20 mm of ether. The solid lines have been calculated from Fig. 2.

FIG. 2. Relative rate (v/v_0) against the percentage of hydrogen sulphide for three different temperatures: △ 530° C, ○ 520° C, and × 480° C.

to be considered later. For a given pressure of ether the relative rate increases to a plateau with an increasing concentration of hydrogen sulphide. In this region the order with respect to hydrogen sulphide is obviously zero. As still greater quantities of H_2S are added the relative rate increases linearly. It is apparent from the curves shown in Fig. 1 that the length of the plateau depends on the pressure of ether; the lower the ether pressure, the shorter the plateau. This suggests that the effects depend only on the *proportion* of H_2S relative to ether, rather than on the absolute amount of H_2S. This result differs from that found in the nitric oxide inhibited decomposition of dimethyl ether (Part II). A plot of relative rate against the percentage of hydrogen sulphide (Fig. 2) shows this dependence more clearly. Points were determined at three different temperatures—480, 520, and 530° C. Within the experimental error, the plateau occurs at approximately the same relative rate in all cases, although there appears to be a slight increase with decreasing temperature, i.e. the plateau seems to be higher for the low temperatures.

Kinetic measurements were carried out with about 40% added H_2S, and with about 75 to 99% added H_2S. Hydrogen sulphide in the amount of 40% was sufficient to ensure "limiting" acceleration (independent of H_2S), while over 75% H_2S ensured that the reaction was in the region dependent on the percentage of hydrogen sulphide.

A typical pressure–time curve is shown in Fig. 3. Curve A is an actual tracing of the record obtained for the decomposition of 90 mm of dimethyl ether in the absence of H_2S. Curve B is a similar tracing showing the decomposition of 85 mm of dimethyl ether

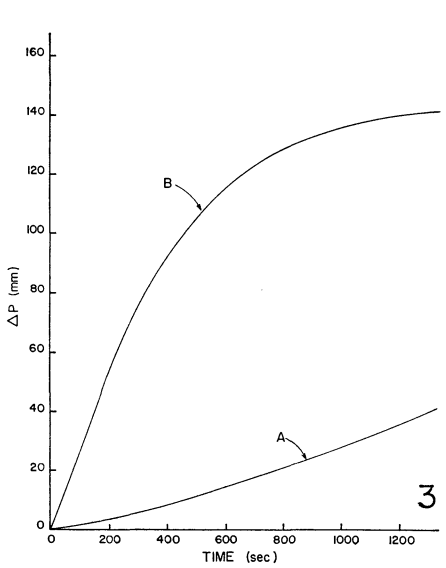

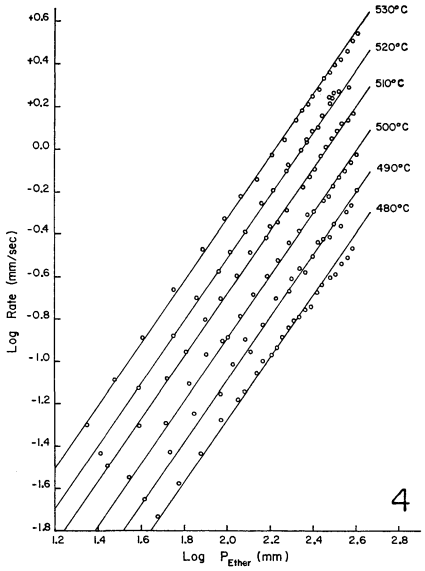

FIG. 3. Typical pressure–time curves. Curve A is a tracing of the record obtained for the decomposition of 90 mm of ether in the absence of hydrogen sulphide. Curve B is a similar tracing showing the decomposition of 85 mm of ether in the presence of 475 mm of H_2S. The temperature in both cases was 510° C.

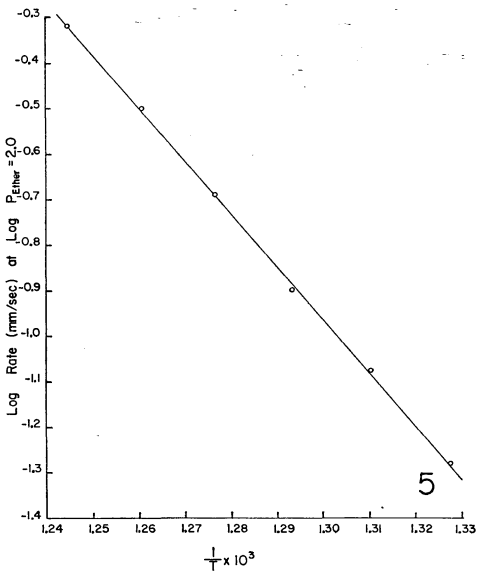
FIG. 4. Double logarithmic plot of inflection rate against ether pressure for various temperatures. The lines all have slopes of 1.5. These curves were determined for the decomposition in the presence of about 40% H_2S (i.e. the plateau region).

in the presence of 475 mm of H_2S. Both runs were carried out at 510° C. The accelerating effect of the added H_2S is readily seen.

Figure 4 shows plots of the logarithm of the rate against the logarithm of the ether pressure, for the reaction in the plateau region where about 40% H_2S was added. All of the lines have slopes of 1.5. The corresponding Arrhenius curve is shown in Fig. 5.



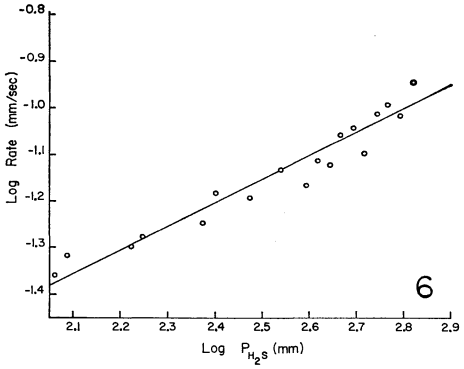


FIG. 5. Arrhenius plot for the decomposition in the presence of about 40% H_2S (i.e. the plateau region).

FIG. 6. Double logarithmic plot of inflection rate against pressure of hydrogen sulphide at 520° C. The ether pressure was constant at about 20 mm. The slope of the line is 0.5.

The three-halves-order rate constant may be expressed as $k = 1.06\times10^{14}e^{-53,200/RT}$ cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}. This is to be compared with $k = 1.82\times10^{15}e^{-51,800/RT}$ cc$^{1/2}$ mole$^{-1/2}$ sec^{-1} obtained by Imai and Toyama (6).

The kinetic measurements made with 75 to 99% H_2S are shown in Figs. 6, 7, and 8. Figure 6 is a double logarithmic plot of rate against pressure of hydrogen sulphide, for a

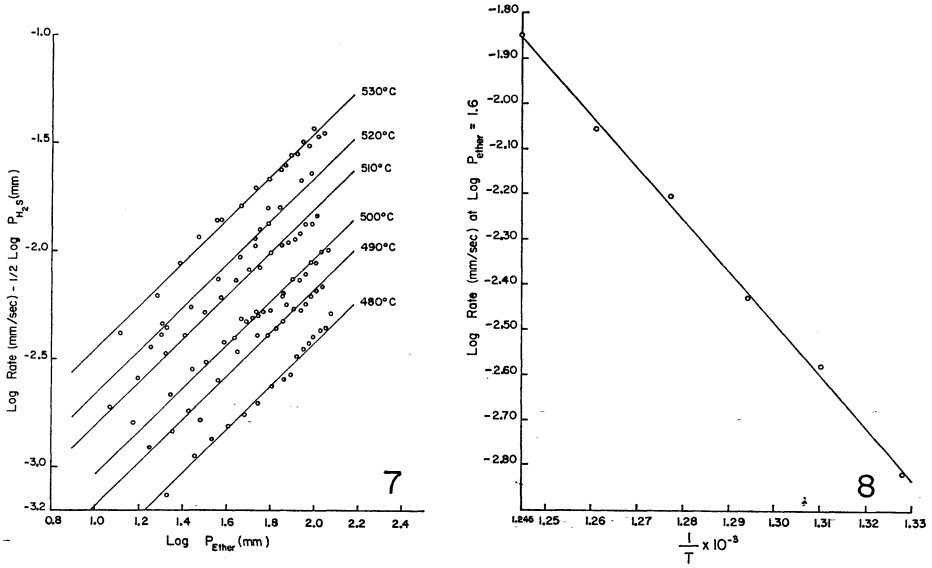

FIG. 7. Double logarithmic plot of inflection rate against ether pressure for various temperatures. The lines all have slopes of 1.5. These curves were determined for the decomposition in the presence of 75–99% H_2S.

FIG. 8. Arrhenius plot for the decomposition in the presence of 75–99% H_2S.

constant (~20 mm) pressure of dimethyl ether. The line drawn has a slope of 0.5, showing that the order with respect to H_2S pressure is one-half in the region of very high percentages of H_2S. The logarithm of the rate minus one-half the logarithm of the hydrogen sulphide pressure is plotted against the logarithm of the ether pressure in Fig. 7. A plot of this kind enabled the dependence on ether pressure to be determined, without the tedious task of holding the H_2S pressure constant. All of the lines drawn in Fig. 7 have slopes of unity. The corresponding Arrhenius plot is shown in Fig. 8. The calculated activation energy for the reaction accelerated by very high percentages of hydrogen sulphide is 52.5 kcal mole^{-1}. The rate constant may be expressed by $k = 4.98\times10^{14}$ $e^{-52,500/RT}$ cc$^{1/2}$ mole$^{-1/2}$ sec^{-1}.

DISCUSSION

The fact that the rate of decomposition of dimethyl ether in the presence of hydrogen sulphide relative to the rate in the absence of hydrogen sulphide depends on the proportion of H_2S to ether (see Figs. 1 and 2) suggests that competitive reactions are involved in the process. At these temperatures it is well known that dimethyl ether decomposes to form methyl and methoxy radicals. Hydrosulphide radicals are almost certainly formed from the decomposition of hydrogen sulphide. This is suggested by the fact that there is a slight decrease in pressure when H_2S alone is present in the reaction vessel at 600° C. The thermal decomposition of hydrogen sulphide has in fact been studied in the temperature range employed in this research (9). The evidence suggests that the decomposition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

proceeds mainly by heterogeneous processes at temperatures below 600° C. The radical HS would probably be formed in large quantities, and can also be produced from reactions such as

$$CH_3 + H_2S \rightarrow CH_4 + HS.$$

Consequently, during the decomposition of dimethyl ether in the presence of hydrogen sulphide, there should be a plentiful supply of hydrosulphide radicals. These could initiate the ether decomposition by abstraction of a hydrogen atom,

$$CH_3OCH_3 + HS \rightarrow H_2S + CH_3OCH_2.$$

The overall rate expression for the thermal decomposition of pure dimethyl ether is of the form (Part I and ref. 10)

$$v_0 = k[CH_3OCH_3]^{3/2}.$$

The shape of the curves shown in Figs. 1 and 2 suggests the following relationships:

$$v = k'[H_2S]^n[CH_3OCH_3]^m + k''[CH_3OCH_3]^{3/2}$$

or

$$\frac{v}{v_0} = \frac{k'[H_2S]^n[CH_3OCH_3]^m + k''[CH_3OCH_3]^{3/2}}{k[CH_3OCH_3]^{3/2}}.$$

This reduces to

$$\frac{v}{v_0} = \frac{k'}{k}\frac{[H_2S]^n}{[CH_3OCH_3]^{3/2-m}} + \frac{k''}{k}.$$

Thus on a plot of relative rate (v/v_0) against the percentage of hydrogen sulphide a plateau would be observed when the proportion of H_2S to CH_3OCH_3 is small and k''/k is the dominant term. However, as the ratio of H_2S to CH_3OCH_3 becomes larger the relative rate should then increase with increasing percentage of hydrogen sulphide.

The rate expression for the reaction in the presence of H_2S should therefore involve two terms—one predicting three-halves-order behavior with respect to dimethyl ether and no dependence on hydrogen sulphide, the second predicting dependence with respect to both hydrogen sulphide and dimethyl ether. Figures 6, 7, and 8 show that the order is one-half in H_2S and first in CH_3OCH_3, i.e. $n = 1/2$ and $m = 1$, for the reaction with high percentages of H_2S.

The mechanism to which these considerations lead can be written as:

$$M + CH_3OCH_3 \rightarrow CH_3 + CH_3O + M \quad [1a]$$

$$M + H_2S \rightarrow H + HS + M \quad [19]$$

$$H + CH_3OCH_3 \rightarrow H_2 + CH_3OCH_2 \quad [5]$$

$$HS + CH_3OCH_3 \rightarrow H_2S + CH_3OCH_2 \quad [20]$$

$$CH_3OCH_2 \rightarrow CH_2O + CH_3 \quad [3]$$

$$CH_3 + H_2S \rightarrow CH_4 + HS \quad [21]$$

$$M + CH_3O \rightarrow CH_2O + H + M \quad [4]$$

$$HS + HS \underset{[-22]}{\overset{[22]}{\rightleftharpoons}} H_2S + S$$

$$M + HS + HS \rightarrow H_2S_2 + M \quad [23a]$$

where M represents a third body. Application of the conventional steady-state approximation yields for the radical concentrations:

$$[HS] = \left(\frac{2k_{19}}{k_{23a}}\right)^{1/2}[H_2S]^{1/2} + \left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{1/2}$$

$$[CH_3O] = \frac{k_{1a}}{k_4}[CH_3OCH_3]$$

$$[H] = \frac{k_{19}}{k_5} + \frac{k_{1a}}{k_5}[CH_3OCH_3]$$

$$[CH_3OCH_2] = \frac{k_{20}}{k_3}\left(\frac{2k_{19}}{k_{23a}}\right)^{1/2}[CH_3OCH_3][H_2S]^{1/2} + \frac{k_{20}}{k_3}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{3/2} + \frac{k_{1a}}{k_3}[CH_3OCH_3][M] + \frac{k_{19}}{k_3}[H_2S][M]$$

$$[CH_3] = \frac{k_{1a}}{k_{21}}\frac{[CH_3OCH_3][M]}{[H_2S]} + \frac{k_{20}}{k_{21}}\left(\frac{2k_{19}}{k_{23a}}\right)^{1/2}\frac{[CH_3OCH_3]}{[H_2S]^{1/2}} + \frac{k_{1a}}{k_{21}}\frac{[CH_3OCH_3]}{[H_2S]} + \frac{k_{20}}{k_{21}}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}\frac{[CH_3OCH_3]^{3/2}}{[H_2S]} + \frac{k_{19}}{k_{21}}[M].$$

The rate is given by

$$v = 2k_{1a}[CH_3OCH_3][M] + k_{20}\left(\frac{2k_{19}}{k_{23a}}\right)^{1/2}[H_2S]^{1/2}[CH_3OCH_3] + k_{20}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{3/2} + k_{19}[H_2S][M].$$

The first and fourth terms in this expression are small in comparison to the second and third terms, and hence may be neglected. The rate can therefore be written as

$$v = k_{20}\left(\frac{2k_{19}}{k_{23a}}\right)^{1/2}[H_2S]^{1/2}[CH_3OCH_3] + k_{20}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

A crude estimate of the percentage of H_2S at which the change in order takes place can be made using the values for k_{1a} and k_{19} from Table I. The ratio of the first to the second term is

$$\left(\frac{k_{19}}{k_{1a}}\right)^{1/2}\frac{[H_2S]^{1/2}}{[CH_3OCH_3]^{1/2}} = 0.1103 \times \frac{[H_2S]^{1/2}}{[CH_3OCH_3]^{1/2}}.$$

This expression becomes greater than unity when the ratio $[H_2S]/[CH_3OCH_3]$ becomes greater than 9.1. Thus the first term in the rate expression predominates when the pressure of hydrogen sulphide exceeds 90%. The transition actually takes place with about 50–70% H_2S. The agreement is therefore quite satisfactory in view of the uncertainties in the rate constants. Consequently, to describe the rate for the plateau region the following expression can be written:

$$v = k_{20}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

This expression is identical with that postulated by Imai and Toyama (6). The reason

TABLE I

Kinetic parameters

Reaction	Frequency factor (sec^{-1}, cc $mole^{-1}$ sec^{-1}, or cc^2 $mole^{-2}$ sec^{-1})	Activation energy (kcal $mole^{-1}$)	k at 800° K (sec^{-1}, cc $mole^{-1}$ sec^{-1}, or cc^2 $mole^{-2}$ sec^{-1})	Reference
[1a]	1×10^{18}	74.0	5.8×10^{-3}	See Part I
[19]	1×10^{18}	81.0	7.0×10^{-5}	Estimated (see footnote)
[20]	1×10^{12}	13.0	2.8×10^{8}	Assumed
[3]	7×10^{10}	19.0	4.6×10^{5}	See Part I
[21]	2.5×10^{11}	2.6	1.9×10^{10}	Imai and Toyama (11)
[23a]	1×10^{14}	−5.6	2.9×10^{12}	Estimated (see footnote)
[2]	3×10^{11}	9.5	7.8×10^{8}	See Part I
[7]	7×10^{14}	−13.5	3.5×10^{18}	See Part I

NOTE: The values for reactions [19] and [23a] were calculated in the same manner as in the Appendix of Part I. Four effective degrees of freedom were assumed for HS + SH, by analogy with hydrogen peroxide, and three effective degrees of freedom were taken for $M + H_2S \rightarrow H + HS + M$.

for this is that reaction [19] is unimportant until large relative quantities of hydrogen sulphide are used. Thus with the neglect of reactions [19] and [5], the mechanism is essentially the same as that postulated by Imai and Toyama (6). The reaction in this region is therefore predicted to be three-halves order with respect to ether, in agreement with experiment. The predicted activation energy is given by $E = E_{20}+\frac{1}{2}(E_{1a}-E_{23a})$. Substitution of the appropriate values given in Table I yields $E = 52.8$ kcal $mole^{-1}$, in good agreement with the experimental value of 53.2 kcal $mole^{-1}$. The predicted frequency factor is $A = A_{20}(2A_{1a}/A_{23a})^{1/2} = 1.0\times10^{14}$ $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}. This is also in good agreement with the experimental value of 1.06×10^{14} $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}.

In the region of high percentages of H_2S the rate is given by

$$v = k_{20}\left(\frac{2k_{19}}{k_{23a}}\right)^{1/2}[H_2S]^{1/2}[CH_3OCH_3].$$

Experimentally the reaction is one-half order with respect to hydrogen sulphide and first order with respect to dimethyl ether in this region, in agreement with this rate expression. The predicted activation energy is $E = E_{20}+\frac{1}{2}(E_{19}-E_{23a}) = 56.3$ kcal $mole^{-1}$, in fair agreement with the experimental value of 52.5 kcal $mole^{-1}$. The predicted frequency factor is $A = A_{20}(2A_{19}/A_{23a})^{1/2} = 1.0\times10^{14}$ $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}, whereas the experimental value is $A = 4.98\times10^{14}$ $cc^{1/2}$ $mole^{-1/2}$ sec^{-1}.

The Termination Reaction

Darwent and Roberts (9) concluded, from a study the photolysis of H_2S, that about 13% of the HS radicals disappeared by the reaction $2HS \rightarrow S_2 + H_2$ while about 87% reacted by the process $2HS \rightarrow H_2S + S$ followed by $2S + M \rightarrow S_2 + M$.

In view of this evidence, the equilibrium process

$$HS + HS \underset{[-22]}{\overset{[22]}{\rightleftharpoons}} H_2S + S$$

has been included in the mechanism. The small quantity of S atoms produced may react with H_2S as shown or with CH_3OCH_3:

$$CH_3OCH_3 + S \rightarrow HS + CH_3OCH_2. \qquad [24]$$

It is suggested that reaction [−22] is faster than [24], and hence [24] can be ignored.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The concentration of HS radicals is large in this system and their combination will give rise to H_2S_2. This reaction will require a third body under these experimental conditions.

The Initiation Reaction

An important conclusion arises from this study with regard to the order of the initiation reaction: the dissociation of the ether molecule into the radicals CH_3 and CH_3O. Consideration of the steady-state equations shows that the only apparent way to obtain the correct pressure dependence in both H_2S and CH_3OCH_3 is by having the initiation in its low-pressure second-order region. This observation is important with reference to the mechanism of the uninhibited reaction, as discussed in Part I.

The Dissociation Energy of Hydrogen Sulphide

The present work provides a method of estimating the dissociation energy (D(H—SH)) of hydrogen sulphide. The difference between the activation energies for the reaction in the plateau region and the region of high H_2S percentages is given from the overall rate expression as

$$\begin{aligned}\Delta E &= [E_{20}+\tfrac{1}{2}(E_{1a}-E_{23a})]-[E_{20}+\tfrac{1}{2}(E_{19}-E_{23a})]\\ &= \tfrac{1}{2}[E_{1a}-E_{19}].\end{aligned}$$

The experimental difference is 0.7 kcal mole^{-1}. Since E_{1a} is known (Part I) E_{19} can be calculated as, at high pressures,

$$E_{19} = E_{1a}-2\Delta E = 85.6 \text{ kcal mole}^{-1}.$$

Previous work has led to conflicting values for this dissociation energy; values varying from 81 to 95 kcal mole^{-1} have been reported (12). Johns and Ramsay (13) recently determined the dissociation energy of the hydrosulphide radical and obtained D(H—S) = 81.4±2.9 kcal mole^{-1}. This can be used to calculate a value for D(H—SH), since the heats of formation of S, H, and H_2S are known (14). For the process SH → S + H,

$$\begin{aligned}D(\text{S—H}) &= \Delta H_f^0(\text{S})+\Delta H_f^0(\text{H})-\Delta H_f^0(\text{SH})\\ 81.4 &= 53.23+52.09-\Delta H_f^0(\text{SH}),\end{aligned}$$

whence

$$\Delta H_f^0(\text{SH}) = 23.9 \text{ kcal mole}^{-1}.$$

For $H_2S \rightarrow H + SH$

$$\begin{aligned}D(\text{H—SH}) &= \Delta H_f^0(\text{H})+\Delta H_f^0(\text{SH})-\Delta H_f^0(\text{H}_2\text{S})\\ &= 52.09+23.9-(-4.82)\\ &= 80.9 \text{ kcal mole}^{-1}.\end{aligned}$$

Cottrell (12) favors a more recent value of 57 kcal mole^{-1} for ΔH_f^0(S), and Ansdell and Page (15) support this value on the basis of their determination of the electron affinity of the sulphur atom. This value yields D(H—SH) = 84.65 kcal mole, in good agreement with our value. On the other hand, Mackle and McClean (16) prefer a value of 35.2 kcal mole^{-1} for ΔH_f^0(HS), which was determined from a calorimetric study of benzyl mercaptan. This yields D(H—SH) = 92 kcal mole^{-1}. Palmer and Lossing (17) recently determined $\Delta H_f^0(\text{HS}) \leqslant 33.7$ by mass spectrometric techniques, and this leads to an estimate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of $D(H—SH) \leqslant 90.6$ kcal mole^{-1}. The value is therefore still in doubt, but our value of 85.6 kcal mole^{-1} calculated from the difference in activation energies supports the lower values. Admittedly the experimental errors involved in this estimation are large. The value of 85.6 kcal mole^{-1} was taken for the calculations considered above.

The Effect of Temperature on the Relative Rate

The main features of the thermal decomposition of dimethyl ether can be represented by the following scheme (see Part I):

$$M + CH_3OCH_3 \rightarrow CH_3 + CH_3O + M \quad [1a]$$

$$CH_3 + CH_3OCH_3 \rightarrow CH_4 + CH_3OCH_2 \quad [2]$$

$$CH_3OCH_2 \rightarrow CH_2O + CH_3 \quad [3]$$

$$M + CH_3O \rightarrow CH_2O + H + M \quad [4]$$

$$H + CH_3OCH_3 \rightarrow H_2 + CH_3OCH_2 \quad [5]$$

$$M + CH_3 + CH_3 \rightarrow C_2H_6 + M. \quad [7]$$

The overall rate expression derived by means of the usual steady-state approximation is given by

$$v_0 = k_2\left(\frac{2k_{1a}}{k_7}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

It was shown above that the rate expression for the reaction in the plateau region (~30 to 50% added H_2S) can be written as

$$v = k_{20}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{3/2}.$$

The relative rate is therefore

$$\frac{v}{v_0} = \frac{k_{20}\left(\frac{2k_{1a}}{k_{23a}}\right)^{1/2}[CH_3OCH_3]^{3/2}}{k_2\left(\frac{2k_{1a}}{k_7}\right)^{1/2}[CH_3OCH_3]^{3/2}},$$

which reduces to

$$\frac{v}{v_0} = \frac{k_{20}}{k_2}\left(\frac{k_7}{k_{23a}}\right)^{1/2}.$$

The predicted activation energy for the relative rate in this region is therefore

$$E = E_{20} - E_2 + \tfrac{1}{2}(E_7 - E_{23a}).$$

Substitution of the appropriate values from Table I yields $E = -0.45$ kcal mole^{-1}. This is in good agreement with the experimental value determined by subtracting the activation energy for the reaction in the absence of H_2S from the activation energy for the reaction in the presence of 40% H_2S, i.e. $53.2 - 54.9 = -1.7$ kcal mole^{-1}. This explains why the relative rate seems to increase with decreasing temperature. The fact that -1.7 is so small is indicated from Fig. 2, which shows that the curves for the three temperatures fall very close to one another.

Similarly for the region using high percentages of hydrogen sulphide the relative rate is given by

$$\frac{v}{v_0} = \frac{k_{20}}{k_2}\left(\frac{k_{19}k_7}{k_{1a}k_{23a}}\right)^{1/2}\frac{[H_2S]^{1/2}}{[CH_3OCH_3]^{1/2}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The activation energy for the relative rate is predicted to be

$$E = E_{20} - E_2 + \tfrac{1}{2}(E_{19} + E_7 - E_{1a} - E_{23a})$$
$$= 3.85 \text{ kcal mole}^{-1}.$$

This is in fair agreement with the experimental value of -2.4 kcal mole^{-1}, considering the uncertainties in the individual activation energies.

THE METAL-CATALYZED AUTOXIDATION OF TETRALIN

I. INTRODUCTION. THE COBALT-CATALYZED AUTOXIDATION IN ACETIC ACID[1]

Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received April 23, 1963

ABSTRACT

The catalytic effect of transition metal salts on the rate of autoxidation of organic substances reaches a constant value at some critical catalyst concentration. Three possible explanations of this phenomena are critically examined. The cobalt acetate catalyzed autoxidation of tetralin in acetic acid has been reinvestigated and the limiting rate of oxidation at high cobalt concentrations has been shown to be due to the production of a steady-state concentration of hydroperoxide. The present results are in fair agreement with the experimental work of Woodward and Mesrobian (J. Am. Chem. Soc. **75**, 6189 (1953)) and are in excellent agreement with theoretical predictions.

INTRODUCTION

Although it has been known for many years that trace amounts of the salts of heavy metals, particularly transition metals, generally increase the rates of autoxidation of organic substances many details of the processes involved are still not fully understood (1, 2). In particular, it has frequently been observed, both in polar (3, 4) and non-polar (5–8) media, that the catalytic effect of metal salts reaches a constant value at some critical concentration, further increases in the concentration of the metal salt having no further effect on the rate. Three explanations have been advanced to explain this phenomena.

1. The Catalyst Produces a Steady-State Concentration of Hydroperoxide

Only this explanation has received experimental support, which has been provided by Woodward and Mesrobian (3) in their very fine work on the cobaltous acetate catalyzed oxidation of tetralin in acetic acid. Their work confirmed a suggestion made by Tobolsky in 1948 (9) that the limiting rate of oxidation is reached when the rate of formation of hydroperoxide is equal to its rate of decomposition to free radicals by the catalyst. This theory was presented in greater detail and was backed up with experimental results on the photochemically induced oxidation of rubber by Tobolsky, Metz, and Mesrobian in 1950 (10). Since the results obtained in this and the following paper are in good agreement with this theory it will be discussed in some detail and, so far as is possible, we shall use the same nomenclature as Woodward and Mesrobian to facilitate comparison of the two sets of data.

The kinetic scheme is represented by:

$$\mathrm{ROOH} + n\mathrm{CoAc_2} \xrightarrow{k_1'} \text{radical} \xrightarrow{\mathrm{RH}} \mathrm{R}^{\bullet} \qquad [1D]$$

$$\mathrm{R}^{\bullet} + \mathrm{O_2} \xrightarrow{k_2} \mathrm{RO_2}^{\bullet} \qquad [2D]$$

$$\mathrm{RO_2}^{\bullet} + \mathrm{RH} \xrightarrow{k_3} \mathrm{ROOH} + \mathrm{R}^{\bullet} \qquad [3D]$$

$$\mathrm{RO_2}^{\bullet} + \mathrm{RO_2}^{\bullet} \xrightarrow{k_6} \text{inactive products} + \mathrm{O_2}. \qquad [4D]$$

[1]*Issued as N.R.C. No. 7440.*
[2]*N.R.C. Postdoctoral Fellow 1962–1963.*
[3]*N.R.C. Summer Student 1962.*

The cobalt catalyst cycles continuously between its divalent and trivalent state by reacting with hydroperoxide and producing free radicals at each step. The reactions can be represented by:

$$ROOH + Co^{2+} \rightarrow RO^{\bullet} + HO^{-} + Co^{3+} \quad [1B]$$

$$ROOH + Co^{3+} \rightarrow RO_2^{\bullet} + H^{+} + Co^{2+} \quad [1C]$$

so that, under steady-state conditions,

$$k_{1B}[Co^{2+}] = k_{1C}[Co^{3+}] = \tfrac{1}{2}k_1'[Co].$$

When the rate of hydroperoxide decomposition is negligible compared with its rate of formation, the overall rate of oxidation is given by

$$\frac{-d[O_2]}{dt} = k_3\left(\frac{k_1'}{2k_6}\right)^{1/2}[RH][ROOH]^{1/2}[CoAc_2]^{n/2}. \quad [2]$$

As the hydroperoxide concentration increases with time its rate of decomposition will eventually equal its rate of formation. This steady-state concentration is given by

$$[ROOH]_\infty = \frac{k_3^2[RH]^2}{2k_1'k_6[CoAc_2]^n} \quad [3]$$

and, therefore, the maximum rate of oxidation is given by

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6}. \quad [4]$$

In actual fact, this derivation of equation [3] and [4] is oversimplified since no account is taken of the $RO^{\bullet}$ radicals produced in reaction [1B] nor of the oxygen evolved in reaction [4D]. Both reactions are, of course, of major importance in the limiting-rate region where every molecule of hydroperoxide decomposed produces only one new molecule of hydroperoxide. In this region, a more complete kinetic treatment including the reactions

$$RO^{\bullet} + RH \rightarrow R^{\bullet} + ROH \quad [3E]$$

and

$$RO^{\bullet} + RO^{\bullet} \rightarrow \text{inactive products} \quad [4E]$$

in addition to reactions [1B], [1C], [2D], [3D], and [4D] also gives equations [3] and [4] provided $k_{3E}^2[RH]^2 \gg 4k_1'k_{4E}[Co][ROOH]_\infty$. Moreover, this derivation shows that two molecules of oxygen oxidize three molecules of tetralin in the limiting-rate region, i.e. $(d[RH]/dt)/(-d[O_2]/dt)_\infty = 1.5$, and also shows that the rate of decomposition of hydroperoxides is equal to the rate of oxidation, i.e. $k_1'[Co][ROOH]_\infty = (-d[O_2]/dt)_\infty$.

Equations [3] and [4] were apparently verified experimentally by Woodward and Mesrobian. That is, it was shown that the rate of oxidation reached a constant value at, or above, a cobalt acetate concentration of 2.0×10^{-3} mole/l. However, our own results indicate that the true maximum rate is not achieved until the cobalt acetate concentration is more than 5.0×10^{-2} mole/l. The steady-state hydroperoxide concentration was shown to be proportional to the square of the cobalt acetate concentration from 1.0×10^{-3} to 4.0×10^{-3} mole/l. $[CoAc_2]$, i.e. $n = 2$ in equation [3], suggesting that the active catalyst is a dimer. At a cobalt acetate concentration of 2×10^{-3} mole/l., $[ROOH]_\infty$ was also shown to be proportional to the square of the tetralin concentration in the range 0.2 to 1.8

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mole/l. [RH]. The oxidation rate at 2.0×10^{-3} mole/l. [$CoAc_2$] was also stated to be proportional to the square of the tetralin concentration, but this might be a misprint. That is, this relationship is shown in Fig. 3 of Woodward and Mesrobian's paper and the order is given as 1.93, but actual measurement of the graph shows that the order is nearer 1.73, although it might be as high as 1.8. However, we have shown that at the true maximum rate the order is indeed 2.0 with respect to tetralin, as required by equation [4].

The theoretical limiting rate of oxidation can be obtained experimentally in the absence of cobalt acetate by measuring the rate of oxidation in the presence of a free-radical initiator such as 2,2′-azo-bis-isobutyronitrile (AIBN) or benzoyl peroxide. Again following Woodward and Mesrobian's kinetic scheme, we have,

$$\text{initiator} \xrightarrow{k_7} 2R'^{\bullet} \xrightarrow{RH} 2R^{\bullet}. \qquad [1A]$$

Hence,

$$\frac{-d[O_2]}{dt} = k_3\left(\frac{2e_1k_7}{2k_6}\right)^{1/2}[RH][\text{initiator}]^{1/2}; \qquad [1]$$

therefore,

$$\frac{\left(\frac{-d[O_2]}{dt}\right)^2}{2e_1k_7[\text{initiator}]} = \frac{k_3^2[RH]^2}{2k_6}, \qquad [7]$$

where e_1, the efficiency of initiation, was taken to have its maximum value of 1.0. With this assumption, which is by no means correct (see below), the theoretical limiting rate obtained with AIBN and benzoyl peroxide was in fairly good agreement with the measured rate at a cobalt acetate concentration of 2.0×10^{-3} mole/l.

Woodward and Mesrobian also showed that the rate of tetralin hydroperoxide decomposition by cobalt acetate in equimolar mixtures of benzene and acetic acid was roughly first order in hydroperoxide and was *approximately* proportional to the square of the cobalt concentration, i.e.,

$$\frac{-d[ROOH]}{dt} = k_1'[ROOH][CoAc_2]^2. \qquad [5]$$

In actual fact, this decomposition appears to be quite complicated and, in addition, its rate shows a strong solvent dependence (see later). However, these authors compared the value of k_1' determined by direct measurement under nitrogen in a 1:4 tetralin – acetic acid mixture (i.e. 40 $l^2/mole^2$ sec) with the value calculated from the ratio of equation [4] to equation [3], i.e.

$$\frac{\left(\frac{-d[O_2]}{dt}\right)_\infty}{[ROOH]_\infty} = k_1'[CoAc_2]^n. \qquad [6]$$

Their comparison is given in their Table IV for a tetralin concentration of 1.84 mole/l. and a cobalt acetate concentration of 2.0×10^{-3} mole/l. Although the agreement in k_1' appears to be fairly good some mistakes have apparently been made in this table. From the data given in their numerous figures it can readily be calculated that the table should

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

read as follows, where the numbers in parenthesis are the numbers given by Woodward and Mesrobian:

$(-d[O_2]/dt)_\infty$, mole/l. sec	$[ROOH]_\infty$, mole/l.	k_1' (calc.), $l^2/mole^2$ sec	k_1' (obs.), $l^2/mole^2$ sec
2.93×10^{-5}	~0.25	29.3*	†
(2.93×10^{-5})	(0.140)	(52)	(40)

*At $[ROOH]_\infty = 0.140$ mole/l., $(-d[O_2]/dt)_\infty = 1.5\times10^{-5}$ mole/l. sec, giving $k_1' = 26.8$ $l^2/mole^2$ sec.
†k_1' obtained from the data given at 2.0×10^{-3} mole/l. [$CoAc_2$] in the equimolar benzene – acetic acid mixture is 210 $l^2/mole^2$ sec.

In spite of the errors which seem to have slipped into Woodward and Mesrobian's calculations the agreement between their results and Tobolsky's theory is sufficiently close to confirm its major premise. Our own work has largely confirmed their data and, moreover, where our results differ they give an even better agreement with the theoretical predictions.

It should perhaps be added that Denisov and Emanuel (2) have pointed out that rather similar kinetic expressions can be obtained by including the catalyzed decomposition of hydroperoxides to non-radical products or by including a radical-induced hydroperoxide decomposition plus the formation of a new radical by the reaction of a peroxy radical with the catalyst. However, neither of these kinetic treatments predicts the agreement that is actually found between the measured maximum rate and the theoretical limiting rate.

2. Micelle Formation by the Catalyst

In hydrocarbon media metal salts of organic acids are normally associated into micelles (7) except at very low concentrations. Once the critical micelle concentration has been passed further increases in catalyst will tend to cause an increase in the size and number of micelles rather than an increase in the amount of catalyst in true solution. If the micelles are inactive catalysts the rate of oxidation will therefore reach a maximum value at the critical micelle concentration. This has been suggested by various authors (2, 7), but it seems probable that the catalyst in micelle form should have some activity and the rate of oxidation should therefore show a slow increase as the catalyst concentration is increased rather than reaching a true maximum. However, most transition metal salts are not very soluble in non-polar media at low temperatures and a comparatively inactive catalyst might therefore be too insoluble for its concentration in true solution or in micelles ever to rise to a value where the rate of hydroperoxide decomposition equalled the rate of the propagation reaction. In this way, an apparent steady limiting rate could be obtained. This cause of limiting rates is more likely to occur at low temperatures than at high temperatures where the catalyst would be more soluble.

3. Chain Termination by the Catalyst

In 1946, on the basis of a study of the cupric, ferric, and cobaltous stearate catalyzed oxidations of tetralin and stearic acid, George *et al.* (6) suggested the the metal catalysts both initiate and terminate free-radical chains. They represented the rate of oxidation by

$$R_m = \frac{(a+dm)}{(b+em)} \cdot p,$$

where a and b are the initiation and termination rates in the thermal oxidation, d and e are the rates of initiation and termination for unit catalyst concentration, p is the propagation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rate, and m the catalyst concentration. On this very simple basis it is obvious that the rate will be independent of the catalyst concentration when dm and em are much greater than a and b. More sophisticated kinetic treatments of chain termination by the catalyst indicate that the true rate expression is far more complicated than this simple derivation suggests (1). Moreover, it has been pointed out (2) that, at the high oxidation rates normally involved with metal catalysts, the peroxy radical concentration will be large and therefore the normal bimolecular termination reaction between two peroxy radicals is intrinsically more probable than a reaction between a peroxy radical and the catalyst.

In spite of these arguments, Kropf (8), has preferred to interpret his results on the copper, cobalt, nickel, and vanadium phthalocyanine catalyzed oxidation of cumene and some other alkyl benzenes in terms of this mechanism. Tobolsky's theory of limiting rates was dismissed without serious consideration mainly because there was an almost quantitative production of cumene hydroperoxide at temperatures below 105° C when copper phthalocyanin was used as the catalyst. It was therefore concluded that chain initiation did not occur primarily by reactions [1B] or [1C] and for this reason the limiting rate of oxidation could not be due to the formation of a steady-state concentration of hydroperoxide. However, the limiting rates of oxidation were obtained by extrapolation, to infinite catalyst concentrations, of the measured rates at two to four catalyst concentrations only, rather than by increasing the catalyst concentration until the limiting rate was achieved. The catalyst concentrations were in the range 7×10^{-4} to 5×10^{-3} mole/l. and if the chain length is fairly long in this concentration range hydroperoxide could form the major oxidation product. The Tobolsky theoretical limiting rate of oxidation at 60° C can be calculated from the data of Blanchard (11) on the AIBN-catalyzed oxidation of cumene by means of equation [7]. It is found to be about 5.4×10^{-4} mole/l. sec. At this temperature the rates of oxidation at infinite catalyst concentration can be calculated from Kopf's data to be 7.3×10^{-4} (Co), 2.6×10^{-4} (Ni), 4.7×10^{-5} (Cu), and 7.5×10^{-6} mole/l. sec (V). Considering the method by which the limiting rates were obtained these values strongly suggest that Tobolsky's theories are applicable to this system with cobalt phthalocyanine and, quite probably, also with nickel phthalocyanine.

In the liquid phase free radicals are never completely "free", that is, their reactivity is modified by the surrounding medium, decreasing reactivity with change of solvent being associated with the increasing stability of a radical–solvent complex. Recent work has shown that in both polar and non-polar solvents free radicals are even less "free" in the presence of heavy metals (1). For example, the decomposition of hydroperoxides and peroxides in the presence of heavy metals, particularly copper, yields radicals which are much less reactive than those obtained by thermal decomposition since they show a much greater stereospecificity in their subsequent reactions than do thermally produced radicals (1). As a result of the stabilization of peroxy radicals by metal salts the rate of chain propagation may be expected to decrease. The rate of chain termination might either increase or decrease. In general, the decrease in the rate of propagation more than outweighs any decrease in the rate of termination (12, 13) although the opposite effect has also been observed in the cobalt-catalyzed oxidation of cumene (14).* Since theory predicts a limiting rate equal to $k_3^2[RH]^2/2k_6$ and since both k_3 and k_6 will change if the radicals are complexed with the metal catalyst the measured limiting rate might be either larger or smaller† than the theoretical value depending on the relative influence of the catalyst on

*This result may possibly explain the fact that Kropf's limiting rate for the cobalt-catalyzed oxidation of cumene is larger than the theoretical value.

†In Part II of this series, it is shown that the measured limiting rate will also be smaller than the theoretical value if the catalyst decomposes some of the hydroperoxide to non-radical products.

For personal use only.

k_3 and k_6. This means that different metal catalysts could give different limiting rates even though the cause of the limiting rate is in all cases due to the production of a steady-state hydroperoxide concentration. The absolute value of a measured limiting rate is therefore not a criterion of the validity of Tobolsky's theory, the only sure criterion being a dependence of the limiting rate of oxidation on $[RH]^2$ and an agreement between k_1' measured directly and indirectly when this is possible. The limiting rates of oxidation of cumene obtained by Kropf for copper and even vanadium phthalocyanine do not, therefore, disprove the Tobolsky theory of limiting rates for these metals.

It is clear from the foregoing discussion that only the first theory of limiting rates has been properly confirmed and then only with the metal cobalt and under rather unusual oxidation conditions. That is, it has only been confirmed in a highly polar solvent in which both the catalyst and hydrocarbon are fully soluble up to quite high concentrations so that, even though polar media are known to reduce the efficiency of metal catalysts (15), solubilities do not affect the kinetics. As a preliminary to a study of the effect of high concentrations of various metal catalysts on oxidation rates in non-polar media we have repeated the work of Woodward and Mesrobian on the cobaltous acetate catalyzed oxidation of tetralin in acetic acid. The second paper in this series deals with the cobalt catalyzed oxidation of undiluted tetralin (16).

EXPERIMENTAL

The purification of tetralin and the oxygen absorption apparatus have been described previously (17). All the experiments described in this work were done at 50° C. The cell cleaning procedure was that of Chalk and Smith (18) with the addition of a final heating of the cell to the softening point of glass in a stream of dry air. Tetralin hydroperoxide was prepared and analyzed by the method of Woodward and Mesrobian (3). It was stored at −10° C. Acetic anhydride (1% by volume) was added to freshly opened bottles of glacial acetic acid 24 hours before use (3). Anhydrous cobaltous acetate was prepared by dehydrating the tetrahydrate and 2,2′ azo-bis-isobutyronitrile (AIBN) was carefully recrystallized from ethyl alcohol at tempratures below 40° C.

RESULTS AND DISCUSSIONS

Determination of the Theoretical Maximum Rate of Autoxidation

Measurements of the rate of nitrogen evolution from AIBN dissolved in tetralin under oxygen-free helium at 50° C gave

$$k_7 = 2.33\times10^{-6}\ \text{sec}^{-1},$$

in good agreement with previous work in benzene (19), toluene (19), and styrene (20). The efficiency of chain initiation by AIBN was calculated in the usual manner (20) by measuring the induction period produced in the AIBN-catalyzed oxidation of tetralin by a known concentration of the free-radical inhibitor 2,6 di-*tert*-butyl-4-methylphenol (BMP). It was found that the efficiency $e_1 = 0.65$, in good agreement with the value found in several other hydrocarbons (20). Measurements of the rate of oxidation of tetralin at several AIBN concentrations yield the relation

$$\frac{-d[O_2]}{dt} = 5.5\times10^{-5}[\text{AIBN}]^{1/2}\ \text{mole/l. sec}$$

at 50° C after correcting for the nitrogen evolution by the AIBN. From equation [7], the theoretical limiting rate of the metal-catalyzed oxidation of tetralin at 50° C is given by

$$\frac{k_3^2[RH]^2}{2k_6} = \frac{(5.5\times10^{-5})^2}{2\times0.65\times2.33\times10^{-6}} = 1.0\times10^{-3}\ \text{mole/l. sec.}$$

Oxygen Absorption and Hydroperoxide Formation

The absorption of oxygen and the buildup of hydroperoxide to a steady concentration in a typical experiment are shown in Fig. 1. At a given tetralin concentration the maximum rate of oxidation is independent of the cobalt acetate concentration in the range 5.0×10^{-2} to 1.0 mole/l. Within this range of catalyst concentrations the rate is exactly proportional to the square of the tetralin concentration from 0.4 to 4.0 mole/l. as required by equation [4]. Extrapolation of these measured maximum rates to obtain the maximum rate of oxidation of pure tetralin gives a value of $1.00\pm(0.05)\times10^{-3}$ mole/l. sec, in perfect agreement with the theoretical limiting rate. This agreement by itself provides convincing evidence of the validity of Tobolsky's theory of limiting rates. This limiting rate can be compared with the value of 3.3×10^{-4} mole/l. sec which is obtained by a linear extrapolation of Woodward and Mesrobian's data at a cobalt acetate concentration of 2.0×10^{-3} mole/l.

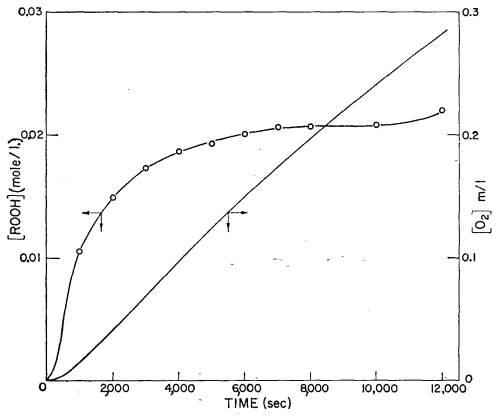

FIG. 1. Oxygen absorption and hydroperoxide formation during the oxidation of 1.22 mole/l. of tetralin in acetic acid catalyzed by 6.0×10^{-3} mole/l. of cobalt acetate.

At high catalyst concentrations the decrease in rate after the maximum fairly closely follows the oxygen consumption with a square dependence on the unconsumed tetralin. That is, the measured rate divided by the square of the tetralin concentration is approximately constant from the maximum-rate region up to at least a 20% consumption of the tetralin, provided it is assumed that two molecules of oxygen oxidize three molecules of tetralin. This provides an independent check on the reaction order with respect to [RH] in the limiting-rate region, and, furthermore, proves that cobalt is a true catalyst in this system, i.e., it is not deactivated in the reaction.

The induction period, defined as the intercept of the extrapolated maximum rate on the time axis, is about 1 minute at high cobalt concentrations. At lower cobalt concentrations the induction period increases remarkably and, at a given cobalt concentration, it increases with increasing dilution of the tetralin, i.e. with increasing dilution of the hydroperoxide which is initially present in the tetralin (normally about 10^{-3} mole/l.). At cobalt concentrations below 10^{-3} mole/l. it is necessary to add hydroperoxide at the start of the reaction in order to reach the maximum rate in a reasonable length of time. At a given tetralin concentration the reaction order with respect to tetralin decreases with decreasing cobalt concentration, probably to its limiting value of 1.0 defined by equation [2]. At a given cobalt concentration this reaction order tends to increase to its limiting value of 2.0

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(as defined by equation [4]) with decreasing tetralin concentration.* For example, with 10^{-2} mole/l. [Co] the rate is equal to the limiting rate at tetralin concentrations below 1.9 mole/l. (i.e. rate $\propto$ [RH]^2 in this region), but at a tetralin concentration of 3.67 mole/l. the rate is only 1.9×10^{-4} mole/l. sec compared with a limiting rate of 2.5×10^{-4} mole/l. sec. Therefore, the rate of oxidation of pure tetralin cannot be obtained by extrapolation except in the region of the limiting rate where the order in [RH] is constant. The oxidation rates found in this work at 2×10^{-3} mole/l. [Co] are about 50% greater than those reported by Woodward and Mesrobian.

Oxidation rates were measured over a range of cobalt acetate concentrations from 10^{-4} to 1.0 mole/l. For example, the following rates in mole/l. sec$\times10^4$ were obtained at a tetralin concentration of 3.67 mole/l., the cobalt concentration in mole/l. being given in parentheses: 2.5 (1.0, 10^{-1}, 5×10^{-2}), 1.9 (10^{-2}), 1.3 (10^{-3}), 0.20 (10^{-4}). At this tetralin concentration limiting-rate effects become comparatively unimportant below 10^{-3} mole/l. [Co] and the rate of oxidation becomes almost first order in cobalt. Therefore, $n = 2$ in equation [2] and the reaction chains are initiated by a cobalt acetate dimer.

It can be seen from Fig. 1 that the hydroperoxide concentration rises to a steady value during the cobalt-catalyzed oxidation of tetralin in acetic acid. The steady-state concentration of hydroperoxide obtained in this experiment, i.e., $[ROOH]_\infty = 0.021$ mole/l. at [Co] $= 6\times10^{-3}$ mole/l., [RH] = 1.22 mole/l., and $[ROOH]_0 = 2\times10^{-4}$ mole/l., is in excellent agreement with the value obtained by extrapolation of Woodward and Mesrobian's data at lower cobalt concentrations. An "initial rate" method was used by these authors to measure $[ROOH]_\infty$. That is, given amounts of the pure hydroperoxide were added to the other reagents previously placed in the reaction vessel. Reaction conditions identical with those used in oxygen absorption measurements were maintained but instead of recording oxygen uptake two aliquots of the reaction mixture were taken for hydroperoxide determination. The first aliquot, removed immediately after the addition of the hydroperoxide, served to establish $[ROOH]_0$ and the added hydroperoxide concentration was varied until this quantity became identical with the hydroperoxide concentration found in the second aliquot, which was removed at a later fixed time interval. This constant hydroperoxide concentration was taken to represent $[ROOH]_\infty$. These authors pointed out that the advantage of this technique is that the change in tetralin concentration during reaction is negligibly small and also any products of peroxide decomposition or tetralin oxidation which may impart an inhibiting effect to the reaction are held to a minimum.

The decomposition of tetralin hydroperoxide in benzene – acetic acid mixtures is a very complex reaction (see following section). After elucidating some of its complexities we realized that the simple dependence of $[ROOH]_\infty$ on [RH]^2 predicted by equation [3] and reported by Woodward and Mesrobian could not be an accurate representation of the kinetics during oxidation. Using Woodward and Mesrobian's method of determining $[ROOH]_\infty$ by varying $[ROOH]_0$, but removing several aliquots of the reaction mixture at varying time intervals to ensure that the true $[ROOH]_\infty$ was obtained, the variation of $[ROOH]_\infty$ with [RH] was measured at a cobalt concentration of 6×10^{-3} mole/l. The data are given in Table I and it is found that instead of $[ROOH]_\infty$ being proportional to [RH]^2 it is proportional to [RH]^2[AcH]^2, where [AcH] represents the acetic acid concentration. This relationship is in agreement with our results for the cobalt acetate catalyzed decomposition of the hydroperoxide in benzene – acetic acid mixtures. It should be noted, moreover, that the value of $[ROOH]_\infty$ determined by this technique is significantly lower

See following paper for a full discussion of the influence of limiting-rate effects on reaction order.

For personal use only.

than the value found when the hydroperoxide concentration is allowed to build up to its steady-state value during the oxidation, probably because a significant portion of the tetralin is oxidized at this point. For example, at [RH] = 1.22 mole/l. and [Co] = 6×10^{-3} mole/l., $[ROOH]_\infty$ = 0.0120 mole/l. by the initial method (Table I) but equals 0.021 mole/l. by the continuous oxidation method (Fig. 1). At the highest tetralin concentration (3.67 mole/l.) the hydroperoxide concentration is only constant for about 700 seconds and thereafter starts to increase, possibly because of a deactivation of the catalyst at this tetralin concentration (see following paper). At the other three tetralin concentrations the hydroperoxide concentration is constant for more than 3000 seconds.

NOTE: [RH] represents tetralin concentration and [AcH] acetic acid concentration.

The variation of $[ROOH]_\infty$ with [Co] at a tetralin concentration of 1.22 mole/l. is shown in Fig. 2. Over a range of cobalt concentrations from 1.0×10^{-3} to 8.0×10^{-3} mole/l.,

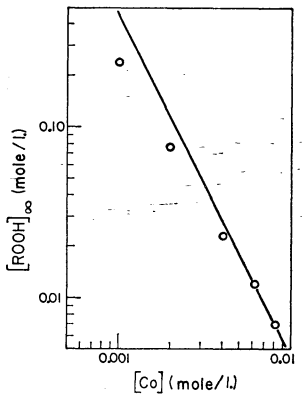

FIG. 2. Dependence of $[ROOH]_\infty$ on cobalt acetate concentration for 1.22 mole/l. of tetralin in acetic acid. The line drawn on the figure has a slope of 2.0.

$[ROOH]_\infty$ is approximately proportional to $[Co]^{-1.7}$ but the experimental points show some curvature and at cobalt concentrations above 6×10^{-3} mole/l., $[ROOH]_\infty$ appears to become approximately inversely proportional to the square of the cobalt concentration. The line that has been drawn in Fig. 2 has this limiting slope of 2.0. As the cobalt concentration is reduced, $[ROOH]_\infty$ becomes inversely proportional to a lesser power of the cobalt concentration. This effect is apparently due to the occurrence of a radical-induced decomposition of the hydroperoxide, a reaction which also causes the measured rate constant for the cobalt-catalyzed decomposition of tetralin hydroperoxide to increase as the cobalt concentration is decreased (see following section). It might be added that the

For personal use only.

determination of $[ROOH]_\infty$ at cobalt concentrations below 2×10^{-3} mole/l. is very time consuming since the rate of change of hydroperoxide concentration becomes very small. A great many experiments are therefore necessary to ensure that the initially added hydroperoxide concentration is very close to $[ROOH]_\infty$ and that at least two of the initial concentrations bracket $[ROOH]_\infty$ within $\pm10\%$.

It seems reasonable to assume that most of the cobalt acetate and most of the hydroperoxide will be associated with molecules of acetic acid in this system even in quite dilute acetic acid solutions. Making the further assumption that the catalytically active dimer of cobalt acetate contains one less molecule of acetic acid than the monomer and that this dimer reacts only with free hydroperoxide we can write

$$2(CoAc_2AcH) \rightleftarrows ((CoAc_2)_2AcH) + AcH \qquad [a]$$

$$(ROOHAcH) \rightleftarrows ROOH + AcH \qquad [b]$$

$$(CoAc_2)_2AcH + ROOH \rightarrow \text{radical} \qquad [1]$$

$$\text{radical} + RH \rightarrow ROOH + \text{radical} \qquad [3]$$

$$\text{radical} + ROOH \rightarrow \text{radical} \qquad [i]$$

$$\text{radical} + \text{radical} \rightarrow \text{inactive products.} \qquad [6]$$

This reaction scheme is only intended to be illustrative and not in any way exclusive of other similar reaction schemes. For example, the rate-controlling chain-initiation step could equally well involve a trivalent cobalt dimer or charged dimer without in any way affecting the resultant kinetics. Replacing $(CoAc_2AcH)$ by Co on the assumption that all the monomeric cobalt acetate is associated with acetic acid and applying the usual stationary-state approximation, we obtain

$$[\text{radical}] = \left(\frac{k_1K_aK_b}{2k_6}\right)^{1/2}\frac{[Co]}{[AcH]}[ROOHAcH]^{1/2}.$$

The steady-state concentration of hydroperoxide is given by

$$\frac{-d[ROOH]}{dt} = \frac{-d[ROOHAcH]}{dt} = 0 = \frac{k_1K_aK_b[Co]^2[ROOHAcH]_\infty}{[AcH]^2}$$
$$+ k_i\left(\frac{k_1K_aK_b}{2k_6}\right)^{1/2}K_b\frac{[Co]}{[AcH]^2}[ROOHAcH]_\infty^{3/2} - k_3\left(\frac{k_1K_aK_b}{2k_6}\right)^{1/2}\frac{[Co]}{[AcH]}[RH][ROOHAcH]_\infty^{1/2}.$$

This quadratic expression simplifies to

$$[ROOHAcH]_\infty = \frac{k_3^2[RH]^2[AcH]^2}{2k_6k_1K_aK_b[Co]^2} \qquad [3']$$

at high cobalt concentrations, provided $[Co]^2 \gg (2k_ik_3[RH][AcH])/(k_1k_6K_a)$. Under these conditions the induced decomposition becomes unimportant compared with the direct cobalt-catalyzed decomposition. The measured steady-state concentration of hydroperoxide corresponds to $[ROOHAcH]_\infty$ and is described by equation [3′] at cobalt concentrations of 6×10^{-3} mole/l. and higher (see Table I and Fig. 2).* In the cobalt con-

**An expression similar to equation [3′] is also obtained if it is assumed that either the hydroperoxide is not associated with acetic acid, or that the associated hydroperoxide reacts with the active cobalt dimer, provided the concentration of this dimer is inversely proportional to the square of the acetic acid concentration, e.g.*

$$2(CoAc_2AcH) \rightleftarrows (CoAc_2)_2 + 2AcH.$$

However, in this case the kinetics derived for the cobalt-catalyzed decomposition of the hydroperoxide do not fit the observed results in acetic acid – benzene mixtures quite as well as the kinetics derived from the equations outlined above.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

centration range where this equation applies, the limiting rate of oxidation will be achieved and is given by

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6} \qquad [4]$$

as is found experimentally. At lower cobalt concentrations, $[ROOHAcH]_\infty$ will become inversely proportional to a power of the cobalt concentration which will decrease from its maximum value of 2.0 as the cobalt concentration is reduced (see Fig. 2). Under these conditions, there is, of course, too low a concentration of cobalt acetate for the oxidation rate to reach its limiting value. Moreover, at these low cobalt concentrations the maximum rate of oxidation appears to be unaffected by the initial hydroperoxide concentration. This suggests that reaction [1] occurs by way of an intermediate complex, as has already been suggested by several workers (6, 18, 21, 22, 23), i.e.

$$(CoAc_2)_2AcH + ROOH \rightleftarrows ((CoAc_2)_2AcHROOH) \xrightarrow{k_1} \text{radical.}$$

Dividing equation [4] by equation [3′] we obtain

$$\left(\frac{-d[O_2]}{dt}\right)_\infty \Big/ [ROOHAcH]_\infty = \frac{k_1K_aK_b[Co]^2}{[AcH]^2}. \qquad [6']$$

At a cobalt concentration of 6×10^{-3} mole/l. and a tetralin concentration of 1.224 mole/l., $[ROOHAcH]_\infty = 0.0120$ mole/l. (Table I). At this tetralin concentration the limiting rate of oxidation is 2.8×10^{-5} mole/l. sec and because the tetralin is fairly dilute this rate is achieved with 6×10^{-3} mole/l. [Co].* Substituting these values into equation [6′] we obtain

$$k_1K_aK_b = 13{,}740 \text{ sec}^{-1}.$$

Hydroperoxide Decomposition

In our study of the cobalt acetate catalyzed decomposition of tetralin hydroperoxide in acetic acid – benzene mixtures we first repeated Woodward and Mesrobian's experiment with $[ROOH]_0 = 0.04$ mole/l. and $[CoAc_2] = 2.0\times10^{-3}$ mole/l. in a 1:1 by volume acetic acid – benzene solution. Half-lives of 690 and 730 sec were obtained in two experiments. These values are in fair agreement with a value of about 820 sec which can be read from Fig. 6 in Woodward and Mesrobian's paper for the same $[ROOH]_0$ and $[CoAc_2]$ in an equimolar acetic acid – benzene solution. Assuming that the active catalyst is dimeric, the rate constant for hydroperoxide decomposition would be

$$k_1' = \frac{\log_e 2.0}{710\times(2\times10^{-3})^2} = 244 \text{ l}^2/\text{mole}^2 \text{ sec},$$

which is in very poor agreement with the values obtained indirectly from the limiting rate of oxidation and $[ROOH]_\infty$; e.g. from equation [6], at $[CoAc_2] = 6\times10^{-3}$ mole/l., $[RH] = 1.224$ mole/l.,

$$k_1' = \frac{2.8\times10^{-5}}{0.012\times(6\times10^{-3})^2} = 64.8 \text{ l}^2/\text{mole}^2 \text{ sec}.$$

However, further experiments soon showed that not only was the decomposition not exactly second order in cobalt and first order in hydroperoxide but that its rate decreased very noticeably as the ratio of acetic acid to benzene in the solvent was increased. It was

**At higher tetralin concentrations the limiting rate is not achieved at this cobalt concentration.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

found, in fact, that at a given [Co] and $[ROOH]_0$ the rate was inversely proportional to the square of the acetic acid concentration.

In all the solvent mixtures studied the cobalt-catalyzed decomposition of the hydroperoxide is only pseudo first order in hydroperoxide. That is, a plot of log ($[ROOH]/[ROOH]_0$) against time is only linear until about 50% of the peroxide has been decomposed, thereafter the rate of decomposition decreases. Moreover, in a given solvent at a fixed cobalt concentration the initial rate of hydroperoxide decomposition decreases as $[ROOH]_0$ is decreased. Changes in rate of this type have been observed during the decomposition of many peroxides and they are known to be due to the occurrence of a radical-induced decomposition of the peroxide, that is, the changes are due to reaction [*i*]. The theoretical rate of peroxide decomposition obtained from reactions [*a*], [*b*], [1], [*i*], and [6] is given by

$$\frac{-d[ROOH]}{dt} = \frac{k_1K_aK_b[Co]^2[ROOH]}{[AcH]^2} + k_i\left(\frac{k_1K_aK_b}{2k_6}\right)^{1/2}K_b\frac{[Co]}{[AcH]^2}[ROOH]^{3/2}.$$

Therefore,

$$\frac{-d[ROOH]}{dt}\frac{[AcH]^2}{[Co]^2[ROOH]} = k_1K_aK_b + k_iK_b\left(\frac{k_1K_aK_b}{2k_6}\right)^{1/2}\frac{[ROOH]^{1/2}}{[Co]}$$

and a plot of the left-hand side of this equation against $[ROOH]^{1/2}/[Co]$ should give a straight line with an intercept equal to $k_1K_aK_b$ and a slope of $k_iK_b(k_1K_aK_b/2k_6)^{1/2}$. The results obtained in several benzene – acetic acid mixtures and in pure acetic acid are shown plotted in this manner in Fig. 3. A straight line through the experimental points is consistent with an intercept of 13,740 sec^{-1} as required for the value of $k_1K_aK_b$ obtained from the limiting rate and $[ROOHAcH]_\infty$ at a cobalt concentration of 6×10^{-3} mole/l. The points cover a range of cobalt concentrations from 5×10^{-4} to 6×10^{-3} mole/l., a range of $[ROOH]_0$ from 0.01 to 0.08 mole/l., and an acetic acid to benzene ratio from 1:3 by volume to pure acetic acid. The scatter of the points is probably due mainly to experimental error but the possibility that other reactions affecting the decomposition rate are also occurring cannot be excluded. In particular, the results suggest that some of the hydroperoxide may be present as a reactive hydroperoxide dimer.

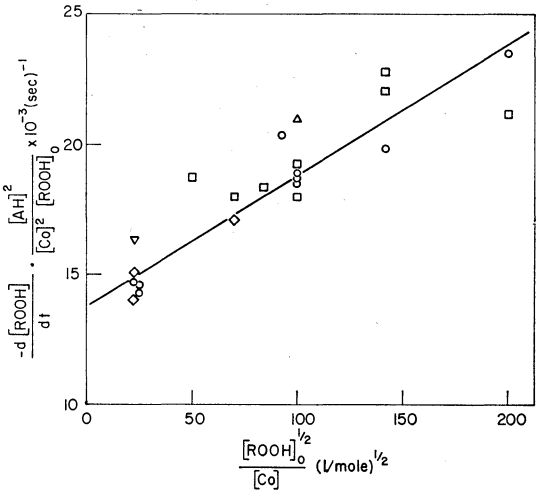

FIG. 3. The measured rate constant for the cobalt acetate catalyzed decomposition of tetralin hydroperoxide in acetic acid – benzene mixtures plotted against $[ROOH]_0^{1/2}/[Co]$. Solvents: ◇ pure acetic acid; ▽ 5:1 by volume acetic acid – benzene; ○ 3:1; □ 1:1; and △ 1:3.

The contribution of the radical-induced decomposition of the hydroperoxide to the measured rate constant should be eliminated by the addition of a free-radical inhibitor in sufficient concentration to pick up all the radicals before they have a chance to react with the hydroperoxide (24). It is, of course, essential that the inhibitor does not catalyze the decomposition of the hydroperoxide, and the highly hindered phenol 2,6-di-*tert*-butyl-4-methylphenol (BMP) generally appears to satisfy this requirement (24). Peroxide decomposition rates were therefore measured in the presence of 0.2 mole/l. [BMP] with various concentrations of cobalt and hydroperoxide in several different benzene – acetic acid mixtures. The measured rate constants, i.e. $(-d[\mathrm{ROOH}]/dt)([\mathrm{AcH}]^2/[\mathrm{Co}]^2[\mathrm{ROOH}])$, were independent of $[\mathrm{ROOH}]_0$ as was expected, but they were all less than 13,740 sec^{-1} and they decreased as the cobalt concentration was increased from 5×10^{-4} to 6×10^{-3} mole/l. (see Fig. 4). Extrapolation of the data to zero cobalt concentration gives the required rate constant of 13,740 sec^{-1}, which suggests that in the presence of the inhibitor the measured rate constant should be either of the form $k_1K_aK_b-f[\mathrm{Co}]$ or possibly $k_1K_aK_b/(1+f[\mathrm{Co}])$. This aspect of the decomposition was not studied in detail, but the observed kinetics might possibly result from a cobalt-catalyzed oxidation of a product of the inhibitor–radical reaction to re-form hydroperoxide.

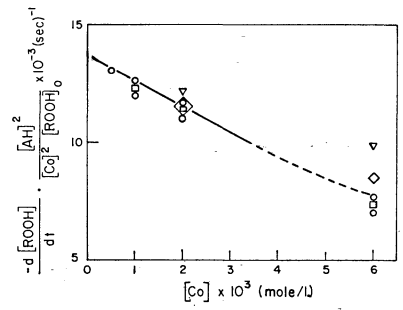

FIG. 4. The measured rate constant for the cobalt acetate catalyzed decomposition of tetralin hydroperoxide in acetic acid – benzene mixtures in the presence of 0.2 mole/l. of 2,6-di-*tert*-butyl-4-methylphenol plotted against the cobalt concentration. Solvents: ◇ pure acetic acid; ▽ 5:1 by volume acetic acid – benzene; ○ 3:1; □ 1:1.

In conclusion, the present results afford a striking confirmation of Tobolsky's steady-state theory. That is, the limiting rate of the cobalt-catalyzed oxidation of tetralin in acetic acid is achieved when the rate of formation of hydroperoxide in the propagation step becomes equal to its rate of decomposition to free radicals by the catalyst.

THE METAL-CATALYZED AUTOXIDATION OF TETRALIN

II. THE COBALT-CATALYZED AUTOXIDATION OF UNDILUTED TETRALIN AND OF TETRALIN IN CHLOROBENZENE[1]

Y. KAMIYA,[2] S. BEATON,[3] A. LAFORTUNE, AND K. U. INGOLD

ABSTRACT

The catalysis of the autoxidation of tetralin by the cobalt salts of 10 organic acids has been examined at 50° C over a concentration range from 2×10^{-6} to 1.0 mole/l. of cobalt. The measured rate of oxidation reaches a limiting value at cobalt concentrations above 2×10^{-2} mole/l., which is about half the expected limiting rate. The cobalt salt catalysts are deactivated during the oxidation, probably in the initiation reaction with hydroperoxide, each cobalt atom being capable of decomposing about 100 molecules of hydroperoxide. Upon correcting the measured limiting rate for cobalt deactivation and for the amount of tetralin consumed at the point where the rate reaches a maximum value an extrapolated limiting rate about equal to the expected value is obtained. Although no steady concentration of hydroperoxide occurs during the oxidation the results suggest that the limiting rate of oxidation is basically due to the same phenomena that produce a limiting rate for the cobalt-catalyzed autoxidation of tetralin in acetic acid (Y. Kamiya *et al.* Can. J. Chem. **41**, 2020 (1963)).

INTRODUCTION

In the preceding paper (1), it has been shown that the limiting rate of the cobalt-catalyzed autoxidation of tetralin in acetic acid is in agreement with theoretical predictions (2, 3, 4). Although the reaction appears to be a lot more complicated in the absence of acetic acid, the same theory still gives a very satisfactory explanation for the experimental results.

EXPERIMENTAL

The catalytic effects of the cobalt salts of the following acids were examined: acetic, hexanoic, octanoic, decanoic, myristic, stearic, behenic, pivalic, *p*-toluic, and 12-hydroxystearic. These salts were prepared by the method of Heaton and Uri (5), the concentration of the reactants being increased for the more water soluble salts. The salts were dehydrated by heating to 60° C or more under a high vacuum and were stored under vacuum in the dark to prevent their autoxidation. In general, for experiments with cobalt concentrations of 10^{-2} mole/l. and greater the cobalt salt was weighed directly into the cell, which was then evacuated and heated to 60–90° C for half an hour before it was cooled and the tetralin was added. At lower concentrations the cobalt salt was dissolved in a benzene – ethyl alcohol mixture, an aliquot of this solution was added to the cell, the solvent was removed under vacuum, and this was followed by heating under vacuum as for the solid samples. During the course of this work it was found that these cobalt salt solutions deteriorated very rapidly unless oxygen was rigidly excluded from the solvents. This continued loss of catalytic activity was overcome by making a fresh solution for each experiment.

Reagent grade chlorobenzene was used as a solvent to study the cobalt-catalyzed decomposition of tetralin hydroperoxide since this compound appears to act merely as an inert diluent in the oxidation experiments, although it appears that the cobalt salts are rather less soluble in chlorobenzene than in tetralin. The following procedure was employed: 15 ml of chlorobenzene, previously warmed to 50° C, was added to a cell containing a known amount of the dried cobalt salt. After half a minute, 5 ml of a tetralin hydroperoxide solution ($\sim4.0\times10^{-2}$ mole/l.), previously warmed to 50° C, was added with vigorous shaking of the reaction flask and the first sample was removed for hydroperoxide determination (4) after 10 seconds. Subsequent samples were taken at time intervals dependent on the rate of reaction. Hydroperoxide concentrations were also followed during autoxidations by withdrawing samples for titration at appropriate time intervals.

α-Tetralol was prepared by the sodium borohydride reduction of α-tetralone (Eastman).

RESULTS AND DISCUSSION

Oxygen Absorption

The effect on the rate of autoxidation of tetralin at 50° C of the 10 cobalt salts listed in the experimental section was examined over a range of cobalt concentrations from 2.0×10^{-6} to 1.0×10^{-1} mole/l. In addition, the decanoate and stearate were examined up to 1.0 mole/l. As normally used, the tetralin contained about 10^{-3} mole/l. of hydroperoxide. Some typical oxidation curves are shown in Figs. 1, 2, and 3. In general, the curves are sigmoidal in shape and, with the exception of the acetate, the maximum rate was found to be virtually independent of the anion over the entire concentration range. The $\log_{10}$ of the measured maximum rate (ρ_m) has been plotted as the solid curve against $\log_{10}$ [Co] in Fig. 4. Over the main part of the graph, i.e. from 2.5×10^{-5} to 1.0×10^{-1} mole/l. [Co], the majority of the experimental points lie within 10–20% of the curve. It can be seen that at cobalt concentrations between 2.0×10^{-2} and 1.0×10^{-1} mole/l., ρ_m reaches a limit of about 5.3×10^{-4} mole/l. sec, which is just over half the theoretical limit of 1.0×10^{-3} mole/l. sec (1).

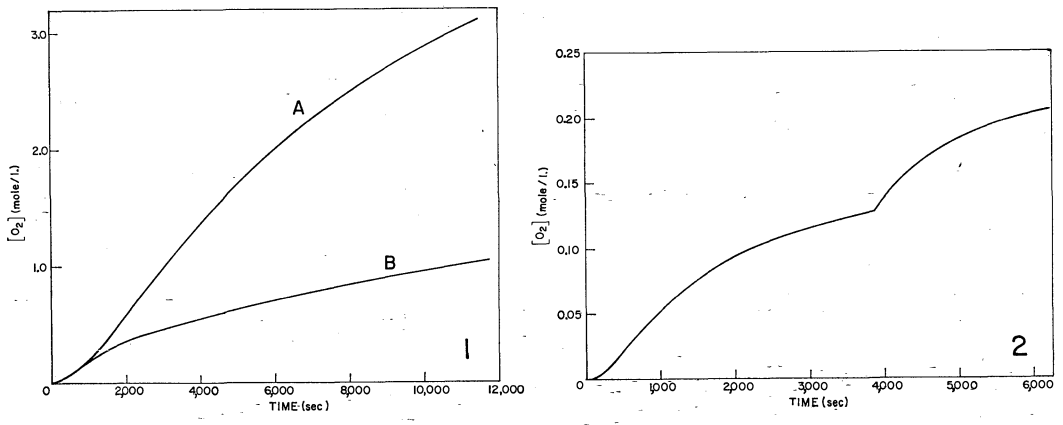

FIG. 1. Oxygen absorption by tetralin. A. Cobalt decanoate at 5.1×10^{-2} mole/l. B. Cobalt decanoate at 9.7×10^{-4} mole/l.

FIG. 2. Oxygen absorption by tetralin at a cobalt decanoate concentration of 1.0×10^{-4} mole/l. A fresh sample of cobalt decanoate at the same concentration was added at 3900 seconds.

In contrast to ρ_m, the induction period (which was defined as the intercept of the extrapolated maximum rate on the time axis) shows a noticeable dependence on the anion which appears to be connected with the solubility of the cobalt salt. That is, the more soluble cobalt salts (pivalate, *p*-toluate, octanoate, and decanoate) gave induction periods of between 100 and 300 seconds at cobalt concentrations below 3×10^{-3} mole/l. The less soluble salts (acetate, stearate, behenate, and 12-hydroxystearate) gave induction periods of about 500 to 1000 seconds while the hexanoate and myristate fall between these two groups. From 5×10^{-3} to 10^{-1} mole/l. [Co] the induction period changes to between 700 and 1000 seconds for all the salts except the acetate, where it is much longer.

One of the most interesting features of the oxidation curves shown in Figs. 1, 2, and 3 which helps to explain several aspects of the overall reaction is the way the rate decreases after reaching its maximum value at lower extents of oxidation the lower the cobalt concentration. This decrease in rate after the maximum is due to deactivation of the catalyst at low concentrations of cobalt and to the oxidation of a significant fraction of the tetralin

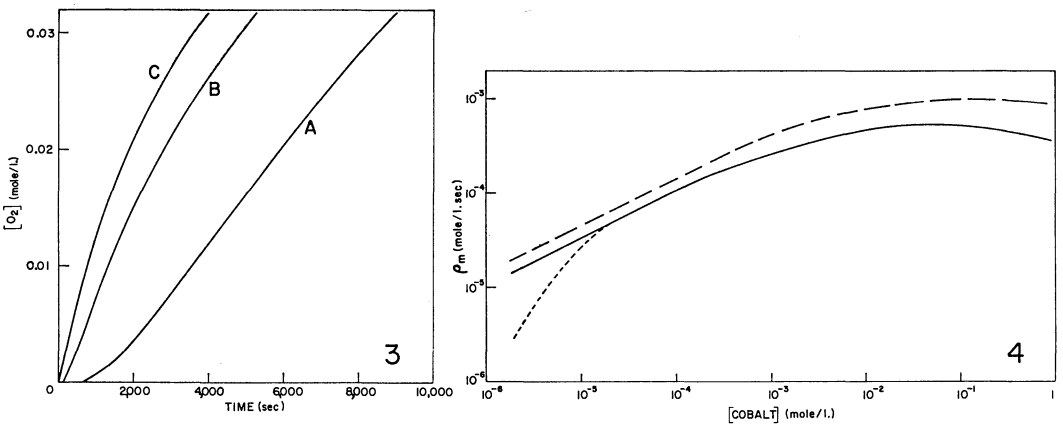

FIG. 3. Oxygen absorption by tetralin at a cobalt toluate concentration of 3×10^{-6} mole/l. A. No detectable hydroperoxide at the beginning of the reaction. B. $[ROOH]_0 = 1.0\times10^{-3}$ mole/l. C. $[ROOH]_0 = 3.2\times10^{-2}$ mole/l. and 1.0×10^{-1} mole/l.

FIG. 4. The variation in the maximum rate of oxidation of tetralin (solid curve) and the extrapolated maximum rate (broken curve) with cobalt concentration.

at high concentrations. The fact that the cobalt is deactivated during the oxidation is shown conclusively in Fig. 2. In this experiment, tetralin was oxidized in the presence of 10^{-4} mole/l. of cobalt decanoate until the rate had fallen to a small fraction of its maximum value. A portion of this oxidized tetralin was transferred to a new cell containing an amount of cobalt decanoate sufficient to give a fresh 10^{-4} mole/l. solution. The initial rate of oxidation, even after allowance is made for the residual rate due to the first sample of cobalt decanoate, is within 10–15% of the original maximum rate. However, the second oxidation curve is not exactly superposable upon the first since its rate decreases slightly more rapidly. Metal catalyst deactivation has also been observed by previous workers during the catalyzed autoxidation of *n*-decane (6), ethylbenzene (7), and cumene (8).

The results suggested that the deactivation of the cobalt was dependent on the amount of oxygen absorbed and this was confirmed by plotting the amount of oxygen absorbed when the rate has fallen to half its maximum value (i.e. $\log_{10}[O_2]\rho_{m/2}$) against $\log_{10}[Co]$ (Fig. 5). The points for all the cobalt salts examined in the present work fell very close (greatest deviation 20%) to a single straight line of slope 0.5 over a range of cobalt concentrations from 2.5×10^{-5} to 1.3×10^{-2} mole/l. and they are therefore not shown in the figure. The equation describing this line is

$$[O_2]\rho_{m/2} = 12.8[Co]^{1/2} \text{ mole/l.} \qquad [8]$$

The initial decrease of the rate from its maximum value generally occurs between one half and one third of $[O_2]\rho_{m/2}$.

Since the deactivation process is half order in cobalt it suggests that the initiation reaction is first order in cobalt and that the cobalt is occasionally deactivated in either the initiation or termination reaction. Alternatively, the cobalt might be deactivated by a product of these reactions. That is, assuming the rate-determining initiation process is either

$$ROOH + CoA_2 \rightarrow RO^{\cdot} + CoA_2OH \qquad [1a]$$

or

$$ROOH + CoA_2OH \rightarrow RO_2^{\cdot} + CoA_2 + H_2O, \qquad [1b]$$

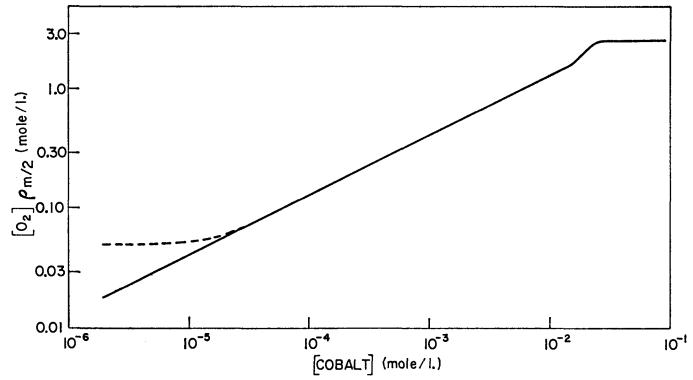

FIG. 5. Amount of oxygen absorbed when the rate reaches half its maximum value as a function of the initial cobalt concentration.

then, using the same nomenclature as in Part I (1), under stationary-state conditions,

$$\frac{-d[O_2]}{dt} = k_3\left(\frac{k_1[Co]}{2k_6}\right)^{1/2}[RH][ROOH]^{1/2}, \qquad [2a]$$

where A represents the anion attached to the cobalt and n in equation [2] (1) is equal to 1.0. Therefore, if the cobalt concentration is decreased by a factor m, the amount of intiation and termination also decreases by the same factor but the rate decreases by a factor of $m^{1/2}$. If unit concentration of cobalt requires x units of initiation or termination for the rate to reach half its maximum value, than $1/m$ units of cobalt will only require x/m units of initiation or termination. Since the rate is decreased by $(1/m)^{1/2}$, for the same amount of oxygen consumed there will have been $x/m^{1/2}$ effectively deactivating initiation or termination steps. Therefore, x/m effectively deactivating steps will occur when the oxygen absorbed is $(1/m)^{1/2}$ of the amount required at unit cobalt concentration. That is, to reach a given degree of deactivation of the cobalt requires an amount of oxygen proportional to the square root of the initial cobalt concentration.

Deactivation in the termination process might occur in two different ways. Firstly, by the reaction sequence (9)

$$RO_2^{\bullet} + RO_2^{\bullet} \rightarrow \alpha\text{-tetralone} + \alpha\text{-tetralol} + O_2 \qquad [4d]$$

$$CoA_2 + \begin{cases}\alpha\text{-tetralone}\\ \alpha\text{-tetralol}\end{cases} \rightarrow \text{inactive cobalt} \qquad [4e]$$

and, secondly, directly in the termination reaction

$$CoA_2 + RO_2^{\bullet} + RO_2^{\bullet} \rightarrow \text{inactive cobalt} + \text{inactive products.} \qquad [4f]$$

The first possibility can be discarded since the addition of 10^{-1} mole/l. of α-tetralone and α-tetralol to a reaction catalyzed by 10^{-4} mole/l. of cobalt had virtually no effect on the maximum rate of oxidation.* The second alternative cannot be completely discarded but seems improbable in view of the fact that there is good agreement between the extrapolated maximum rate and the theoretical limiting rate (see below). Moreover, the fact that the extrapolated maximum rate is independent of [Co] at high concentration indicates that reaction [4f] and similar reactions, e.g.

$$CoA_2 + RO_2^{\bullet} \rightarrow \text{inactive cobalt} + \text{inactive products,} \qquad [4g]$$

**The induction period was, however, increased by a factor of about 5 with α-tetralol but this is probably due to the production of some phenolic material from impurities in the α-tetralone during its reduction.*

can play no more than a minor part in the oxidation. It must therefore be concluded that deactivation occurs in the initiation process and again there are two possibilities. Water is produced in reaction [1*b*] and there is no doubt that water has a slight inhibiting effect on the reaction at low cobalt concentrations. For example, in one experiment at 5×10^{-5} mole/l. [Co] the rate was reduced by a factor of 5 by the addition of 10% by volume of water (6.1 mole/l.) and in a second experiment at 4×10^{-5} mole/l. [Co] the rate was reduced by a factor of 7 by the addition of 0.2 mole/l. of water.* The inhibiting effect of water is probably due to its addition to the coordination shell of the cobalt (i.e. to hydration of the cobalt salt) which will greatly reduce the ease with which a molecule of hydroperoxide can approach the cobalt in order to react with it. In fact, it is likely that a coordinated water molecule has to be replaced by a hydroperoxide molecule before reaction can occur. The large amounts of water added to the present system therefore probably represent the limiting inhibiting effect of water in this system. It is, therefore, not surprising to find that at 1.3×10^{-2} mole/l. [Co] (where ρ_m is independent of [Co]) 25% by volume of water has no effect on the maximum rate. The magnitude of the inhibiting effect of water is sufficiently large that water cannot be ruled out as a major cause of catalyst deactivation. However, the second alternative by which cobalt is deactivated during the initiation reaction appears to give a more satisfactory explanation of the results. The following reaction scheme, leading to the formation of insoluble basic salts and hydroxides of cobalt, is suggested:

$$\mathrm{ROOH} + \mathrm{CoA_2OH} \rightarrow \mathrm{CoAOH}\downarrow + \mathrm{AH} + \mathrm{RO_2}^{\bullet} \qquad [1c]$$

$$\mathrm{ROOH} + \mathrm{CoAOH} \rightarrow \mathrm{CoA(OH)_2}\downarrow + \mathrm{RO}_{\bullet} \qquad [1d]$$

$$\mathrm{ROOH} + \mathrm{CoA(OH)_2} \rightarrow \mathrm{Co(OH)_2}\downarrow + \mathrm{AH} + \mathrm{RO_2}^{\bullet} \qquad [1e]$$

$$\mathrm{ROOH} + \mathrm{Co(OH)_2} \rightarrow \mathrm{Co(OH)_3}\downarrow + \mathrm{RO}^{\bullet}. \qquad [1f]$$

Reactions [1*c*] and [1*e*] must occasionally replace reaction [1*b*].

The cobalt is undoubtedly precipitated during the reaction since a very fine black or brownish-black precipitate is always produced during extensive oxidation at intermediate cobalt concentrations. In one experiment, the precipitate produced by the oxidation for 8 hours of a liter of tetralin containing 514 mg of cobalt myristate (i.e., 10^{-3} mole/l.) was examined. It weighed 171 mg and contained about 25% cobalt by weight (determined both by ignition and by reprecipitation from solution with sodium anthranilate). Because of its very small particle size it is probable that not all the precipitate was collected and, therefore, not less than 73% of the cobalt was precipitated. X-Ray examination in a focusing camera using monochromatic Cu K_α radiation showed that the precipitate was completely amorphous and its infrared spectrum in a nujol mull contained only the broad bands corresponding to hydrogen-bonded hydroxyl groups.

Organic acids are produced by this deactivation scheme and they apparently have a small accelerating effect on the oxidation rate at low cobalt concentrations (e.g., at 10^{-4} mole/l. [Co] the rate was increased by a factor of 2–3 on the addition of 7×10^{-2} mole/l. of decanoic acid) but they have no effect on the limiting rate. This catalytic activity may be partly due to a decrease in the efficiency of catalyst deactivation (11). However, it is probably mainly due to an increase in the rate of the cobalt-catalyzed decomposition of

**Michaels (10) has studied the cobalt naphthenate catalyzed oxidation of tetralin at 70° C by an induction period method in which, after allowing 15 minutes for the system to reach equilibrium, the amount of oxygen consumed in 1 hour was measured. At 9.5×10^{-6} mole/l. [Co] he reported that the rate of oxidation was inversely proportional to $[H_2O]^{0.11}$ over a range of water concentrations from 5.5×10^{-3} to 5.5×10^{-2} mole/l. Although in this work it does not appear to have been realized that the catalyst was probably deactivated during the oxidation, the order might possibly have been closer to 0.5 if water were mainly responsible for deactivation.*

hydroperoxide since 10^{-1} mole/l. of decanoic acid increased the rate of decomposition of tetralin hydroperoxide (10^{-2} mole/l., catalyzed by 2×10^{-3} mole/l. [Co]) by a factor of about 5. In this respect, therefore, decanoic acid appears to function somewhat differently to acetic acid since the latter decreases the rate of the cobalt–hydroperoxide reaction. The water produced during oxidation probably causes a relatively slight inhibition of the reaction and it may account for the fact that there was a slightly more rapid decrease in rate in the second stage of the experiment shown in Fig. 2. This deactivation scheme may also, in part, account for the fact that porphin complexes of heavy metals appear to be more powerful catalysts of autoxidation than the corresponding heavy metal soaps at very low concentrations (12, 13) since it is possible that the complexed metal will be less susceptible to deactivation than the uncomplexed metal in the soaps. However, deactivation does occur with some complexed metal catalysts since cobalt phthalocyanine is deactivated during the autoxidation of cumene (14). The absence of cobalt deactivation in acetic acid as a solvent (1) is also to be expected since any cobalt oxide or hydroxide which is formed will be immediately reconverted to cobalt acetate.

Equation [8] is obeyed from 1.3×10^{-2} to 2.5×10^{-5} mole/l. [Co] for the tetralin as normally used, and is obeyed down to 2×10^{-6} mole/l. [Co] in the presence of a sufficiently large initial concentration of hydroperoxide (see below). Over this range of cobalt concentrations the measured maximum rate of oxidation is very roughly proportional to the square root of the initial cobalt concentration as predicted by equation [2*a*] (see Fig. 4). It therefore follows that approximately 75% of the cobalt will have been deactivated when the rate falls to half its maximum value or, more accurately, 75% of the cobalt which is still present in the region of the maximum rate. This will, of course, be more than 75% of the initial cobalt since our results indicate that the cobalt is deactivated throughout the entire oxidation. When the rate falls to half this value again, i.e. to $0.25\rho_m$, then 75% of the remaining 25% will have been deactivated and this should require the further absorption of half the amount of oxygen required to give the half maximum rate. That is, all the cobalt should be deactivated when the oxygen absorption equals $2[O_2]\rho_{m/2}$ and further oxidation should cease at this point. A plot of the measured rate (ρ) divided by ρ_m against absorbed $[O_2]/[O_2]\rho_{m/2}$ should therefore give a straight line of slope -0.5, intercepting the ρ/ρ_m axis at 1.0 and the $[O_2]/[O_2]\rho_{m/2}$ axis at 2.0. When plots of this kind are made (see Fig. 6 for a typical example) they give a rather poor fit to the predicted relation. That is, between 10^{-5} and 10^{-2} mole/l. [Co] the plots are horizontal to a value of $[O_2]/[O_2]\rho_{m/2} = 0.4\sim0.6$ (corresponding to the linear maximum-rate region), they then decrease more rapidly than predicted and finally tail off more slowly than expected, generally at about 15–30% of ρ_m. The residual thermal reaction initiated by the non-catalyzed decomposition of hydroperoxide contributes very little to this tailing since 1.5×10^{-1} mole/l. [ROOH] gives a rate of less than 10^{-6} mole/l. sec in the absence of cobalt. Instead, the tailing is due to the fact that the cobalt is not totally deactivated but is merely altered to a much less active form. This was shown by an experiment in which cobaltous oxide was ground to pass through a 400-mesh screen: 10^{-1} mole/l. of this oxide gave a maximum rate of oxidation which was about 14% of that obtained with a cobalt soap. This finding that even an insoluble cobalt compound has some catalytic activity is in agreement with the results of Chalk and Smith (15) on the copper sulphate catalyzed oxidation of cyclohexene. These authors showed that the catalytic activity of the solid was proportional to its surface area. The tailing in Fig. 6 suggests that the finely divided cobalt precipitate formed at first slowly agglomerates into larger particles.

The main portion of the ρ/ρ_m against $[O_2]/[O_2]\rho_{m/2}$ plots can be most readily explained

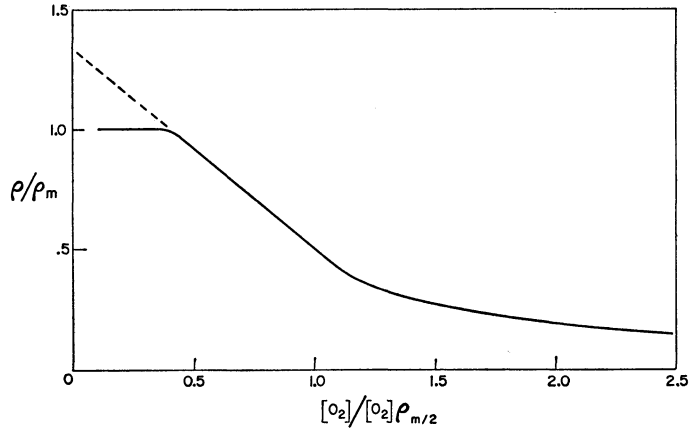

FIG. 6. The oxidation rate as a function of the amount of oxygen absorbed at a cobalt decanoate concentration of 9.7×10^{-5} mole/l.

on the assumption that the cobalt is being deactivated throughout the oxidation since it seems improbable that no cobalt will have been deactivated until the rate starts to fall below its maximum value. That is, a certain fraction of the initial cobalt will have been deactivated by the time the rate reaches its maximum value and more will be deactivated while the maximum rate is maintained. At cobalt concentrations where the active cobalt becomes completely dissolved by the time the maximum rate is reached the true maximum rate will be obtained by extrapolating the sloping linear region in Fig. 6 to zero oxygen absorption (broken line). Extrapolated maximum rates obtained by this method, after applying one or two other corrections the importance of which depend on the cobalt concentration (see below), are shown as the broken curve in Fig. 4. These extrapolated maximum rates are also independent of the anion. It can be seen by comparison of the two curves that this correction amounts to about 40% at low cobalt concentrations where this is the only correction factor of importance.

The second correction that must be made to ρ_m arises from the fact that at high cobalt concentrations an appreciable fraction of the tetralin has been consumed while the rate is still at its maximum value (see Fig. 1). According to equation [4], i.e. (1, 4),

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6}, \qquad [4]$$

the limiting theoretical rate should be proportional to $[RH]^2$. This has been confirmed both directly and indirectly. In the direct determination the tetralin was diluted with chlorobenzene, which appears to be chemically inert in this system, and ρ_m was measured at four tetralin concentrations with 1.0×10^{-2} and 2.0×10^{-2} mole/l. [Co]. In both cases ρ_m is proportional to $[RH]^2$ for mixtures containing more than about 50% tetralin (see Fig. 7). The small increase in order with more dilute tetralin solutions is probably due to a lower solubility of the catalyst in chlorobenzene than in tetralin. That is, insufficient cobalt is dissolved by the dilute mixtures for them to give a measured limiting rate directly comparable with the more concentrated tetralin solutions. The reaction order was also derived indirectly from the fact that at cobalt concentrations above 1.3×10^{-2} mole/l. equation [8] is no longer obeyed. It is found instead that from 1.3×10^{-2} to 2.5×10^{-2} mole/l. [Co], $[O_2]\rho_{m/2}$ increases more rapidly than expected but that it then levels off at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

about 2.4 mole/l. (see Fig. 5). Assuming one molecule of oxygen oxidizes one molecule of tetralin* this levelling off corresponds to a tetralin consumption of 32.7% and, therefore, to a calculated rate = $(0.673)^2\rho_m = 0.453\rho_m$. The slight discrepancy from the expected value of 0.50 is due both to inaccuracies in this assumption and to the oxidation of some of the tetralin before the maximum rate is reached (see Fig. 1). The sharp increase in $[O_2]_{\rho_{m/2}}$ from 1.3×10^{-2} to 2.5×10^{-2} mole/l. [Co] is probably due to the fact that the rate is independent of the cobalt concentration in this region for which reason appreciably more than 75% of the cobalt must be deactivated before the rate falls to half its maximum value.

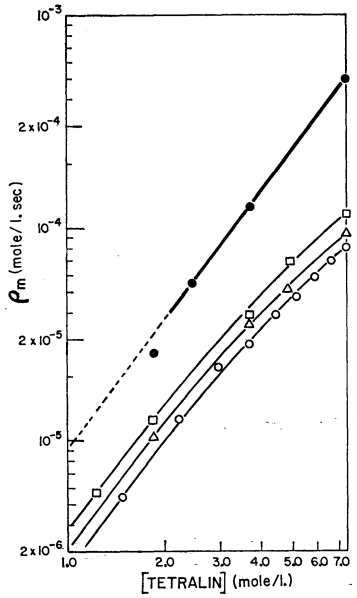

FIG. 7. The maximum rate of oxidation as a function of tetralin concentration. Key: ● [Co] = 1.0×10^{-2} mole/l. and 2.0×10^{-2} mole/l.; □ [Co] = 7.9×10^{-5} mole/l., $[ROOH]_0 = 4.6\times10^{-3}$ mole/l.; △ [Co] = 4.9×10^{-5} mole/l., $[ROOH]_0 = 1.0\times10^{-3}$ mole/l.; ○ [Co] = 2.4×10^{-5} mole/l., $[ROOH]_0 = 2.0\times10^{-2}$ mole/l.

The correction for tetralin consumption is of major importance in obtaining the true maximum rate at cobalt concentrations above 10^{-3} mole/l. It must, of course, be applied before the correction relating to cobalt deactivation.† Moreover, in the limiting-rate region the correction must be based on the assumption that two molecules of oxygen oxidize three molecules of tetralin (1), i.e. $(d[RH]/dt)/(-d[O_2]/dt) = r = 1.5$. The magnitude of this correction factor is about 6% at 10^{-3} mole/l. [Co] ($r = 1.0$), 45% at 10^{-2} and 10^{-1} mole/l. [Co] ($r = 1.5$, or 30% if $r = 1.0$), and as high as 135% ($r = 1.5$) for finely divided cobalt acetate at 10^{-1} mole/l. (see below). The importance of this factor can be further illustrated by reference to curve A in Fig. 1. The rate appears to drop below the maximum value at $[O_2] = 0.9$ mole/l. at which point the correction factor = 1.45 for $r = 1.5$ (i.e. extrapolated rate = $1.45\rho_m$); at $[O_2] = 1.9$ mole/l. the rate has dropped 46% but the corrected rate is still 1.45 times ρ_m; at $[O_2] = 3.0$ mole/l. the rate has dropped 64% but the corrected rate is still 1.16 ρ_m.

**In the region of the maximum rate this assumption is incorrect since two molecules of oxygen oxidize three molecules of tetralin (1). However, once the rate starts to decrease from its maximum value the amount of hydroperoxide formed increases rapidly (see Fig. 8). The chain length is, therefore, no longer unity and this assumption will not be too inaccurate for fairly extensive oxidation.*

†*The correction for cobalt deactivation becomes negligible above 5×10^{-2} mole/l.* [Co].

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

One further correction has been applied at cobalt concentrations above 3×10^{-2} mole/l. to make allowance for the dilution of the tetralin by the catalyst. The magnitude of this correction naturally depends on the molecular weight of the acid with which the cobalt is combined. As an example, this correction is about 6.5% with 10^{-1} mole/l. of cobalt stearate and is proportionately larger at higher concentrations.

After applying all the necessary correction factors, the extrapolated maximum rate for all the cobalt salts examined in this work is $(1.0\pm0.1)\times10^{-3}$ mole/l. sec in the range from 10^{-2} to 10^{-1} mole/l. [Co], which is in gratifying agreement with the predicted limiting rate of 1.0×10^{-3} mole/l. sec (1). The fact that the measured limiting rate is only about half of its theoretical value is, in all probability, basically due to the low solubility in tetralin of all the cobalt catalysts studied in this work. The oxygen-containing reaction products help to solubilize the cobalt catalysts and the tetralin must therefore be oxidized to a significant extent in order to dissolve sufficient catalyst to give a high oxidation rate. However, in the course of solubilizing the catalyst some of it is destroyed and also the tetralin concentration is decreased. Correction of the measured limiting rate for these two effects gives an extrapolated limiting rate in very satisfactory agreement with the theoretical value. It is obvious that with a less active metal catalyst than cobalt the measured rate at the highest practical catalyst concentrations could be very much less than the theoretical limiting value. Incidentally, the agreement between extrapolated and theoretical rates with cobalt catalysts indicates that any reaction between the cobalt catalyst and the hydroperoxide to give non-radical products (rate constant k_1*) must be unimportant compared with the reaction giving free radicals (rate constant k_1). That is, the inclusion of such a reaction in the kinetic scheme leads to the prediction that the measured limiting rate will be smaller than the theoretical value, i.e., it predicts that

$$\left(\frac{-d[O_2]}{dt}\right)_\infty = \frac{k_3^2[RH]^2}{2k_6}\frac{k_1}{k_1+k_1^*}. \qquad [4a]$$

The theories of Tobolsky (2, 3) give a very satisfactory explanation of our data. It would appear that none of the following factors have any appreciable effect on the measured limiting rate: (i) the solubility (within reasonable limits) of the cobalt salt; (ii) the mild steric protection afforded to the cobalt atom in cobalt pivalate; (iii) minor changes in the oxidation–reduction potential of the cobalt caused by the various anions. However, it should be added that solubilities may play a minor role in determining the rate in the range from 5×10^{-4} to 5×10^{-3} mole/l. [Co] since the extrapolated ρ_m values for the less soluble salts fall slightly, although perhaps not significantly, below the curve shown in Fig. 4. If this effect is real, it suggests that cobalt is micelle form has only a slightly lower catalytic activity than free cobalt, which seems rather unlikely. On the other hand, the variation in the amount of hydroperoxide produced at a given extent of oxidation shows a smaller dependence on the cobalt concentration than would be expected in the range 1.0×10^{-2} to 4.0×10^{-2} mole/l. [Co] (see following section). This suggests that above 10^{-2} mole/l. [Co] the effective concentration of even the more soluble cobalt salts increases rather slowly with increasing catalyst concentration.

It is convenient at this point to consider the efficiency of the cobalt deactivation process. At cobalt concentrations where the limiting rate of oxidation is achieved the reaction chain length must be very close to unity, i.e., one molecule of hydroperoxide is decomposed for each molecule of oxygen absorbed (1). The maximum concentration of cobalt at which $\rho_{m/2}$ is reached because of cobalt deactivation rather than because of tetralin consumption is 2.5×10^{-2} mole/l. [Co]. For the measured rate to fall to half the measured maximum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rate it can be seen from Fig. 4 that the amount of cobalt remaining at this point will be 10^{-3} mole/l. Therefore, from Fig. 5, 2.4 mole/l. $[O_2]$ deactivated $2.5\times10^{-2}-1.0\times10^{-3} = 2.4\times10^{-2}$ mole/l. of cobalt. Assuming unit chain length over the whole of this concentration range 2.4×10^{-2} mole/l. cobalt is deactivated by reaction with 2.4 mole/l. of hydroperoxide. That is, each atom of cobalt is capable, on average, of decomposing 100 molecules of hydroperoxide.

As has already been mentioned, ρ_m for cobalt acetate is somewhat smaller than that for the other cobalt salts apparently because of its low solubility in unoxidized tetralin. It is considerably more soluble in oxidized tetralin (like the other cobalt salts) and therefore tends not to exert its full catalytic effect until a rather large amount of oxygen has been absorbed and therefore a rather large amount of cobalt acetate has been deactivated. This effect showed up very noticeably at 10^{-1} mole/l. $[CoAc_2]$ where ρ_m was found to depend on the state of subdivision of the solid. A maximum rate of 4.4×10^{-4} mole/l. sec (which is still 20% below ρ_m for the other salts at this concentration) was only obtained by grinding the hydrated salt to pass through a 400-mesh screen and then dehydrating it rapidly under vacuum to increase further its state of subdivision. Even with these steps, the induction period was about 5000 seconds and the maximum rate was not reached until 1.7 mole/l. $[O_2]$ was absorbed, corresponding to a correction factor of 2.35 and an extrapolated ρ_m of $1.0_3\times10^{-3}$ mole/l. sec.

Although the results obtained with cobalt decanoate and stearate at concentrations above 10^{-1} mole/l. were markedly different only these two salts were examined since it is not clear how much significance should be attached to the results in view of the pasty consistency of such mixtures. The curves shown in Fig. 4 represent the results obtained with cobalt stearate. The measured rates with cobalt decanoate follow these curves up to a concentration of 0.40 mole/l., but at 0.48 mole/l., less than 0.10 mole/l. $[O_2]$ was absorbed in 15,000 seconds to give an induction period $\geqslant$ 5,200 seconds and $\rho_m \geqslant 1.0\times10^{-5}$ mole/l. sec. Similar very sudden increases in induction periods at high catalyst concentration have been reported previously for the copper stearate catalyzed oxidation of *n*-decane at catalyst concentrations of 0.6 mole% (16). This phenomena of a "critical catalyst concentration" was attributed to chain termination by the catalyst (16). The difference in the behavior of cobalt stearate and decanoate suggests that, in addition to the metal, the anion plays a very important role in this phenomena.

In the initial work the maximum rates obtained at catalyst concentrations of less than 2.5×10^{-5} mole/l. [Co] were rather irreproducible and consistently fell well below the rate expected on the assumption that it should be proportional to $[Co]^{1/2}$, and the overall oxidation rate curve appeared to have the form

$$\frac{-d[O_2]}{dt} = \frac{a[Co]}{b+c[Co]}.$$

Furthermore, $[O_2]\rho_{m/2}$ levelled off at about 0.05 mole/l. at low cobalt concentrations. The broken curves in Figs. 4 and 5 represent these results which were obtained with tetralin containing an initial hydroperoxide concentration $[ROOH]_0$ of 10^{-3} mole/l. At cobalt concentrations above 2.5×10^{-5} mole/l., ρ_m does not alter as $[ROOH]_0$ is varied from 10^{-3} to 2.0×10^{-1} mole/l., although the induction period is reduced slightly at the higher initial peroxide levels. However, if the tetralin is carefully freed from hydroperoxide by passing it through alumina in the complete absence of oxygen ($[ROOH]_0 < 10^{-6}$ mole/l.) the induction period is significantly increased and, at cobalt concentrations below 5×10^{-3} mole/l., ρ_m is decreased. For example, at a cobalt toluate concentration of 1.7×10^{-4}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mole/l., ρ_m was reduced by a factor of 4 and the induction period was increased by a similar factor. Moreover, the maximum rate was not reached until 0.05 mole/l. $[O_2]$ had been absorbed whereas with the normal tetralin, ρ_m was reached after the absorption of 0.01∼ 0.02 mole/l. $[O_2]$. This suggested that, provided the cobalt concentration was above 2.5×10^{-5} mole/l., the normal tetralin contained sufficient hydroperoxide for ρ_m to be reached before a significant fraction of the cobalt was deactivated, but that below this cobalt concentration it would be necessary to add hydroperoxide to the tetralin to obtain the true maximum rate only slightly affected by cobalt deactivation. In order to compare rates obtained at low cobalt concentrations with the values at higher concentrations it was therefore necessary to add hydroperoxide before the start of the reaction. A typical series of experiments at 3×10^{-6} mole/l. [Co] is shown in Fig. 3. In the absence of initial hydroperoxide it is obvious that the cobalt is in a rather inactive form by the time the maximum rate is reached. At the two highest initial hydroperoxide concentrations (3×10^{-2} and 1.0×10^{-1} mole/l.) the oxidation curves are identical and ρ_m occurs at the very beginning of the reaction (i.e., the cobalt is immediately and completely soluble at this concentration). Moreover, this value of ρ_m agrees perfectly with the value predicted from the rate data at higher cobalt concentrations on the assumption that $\rho_m \propto [Co]^{1/2}$. In addition, $\rho_{m/2}$ is now reached at, or even slightly before, the oxygen absorption predicted by a similar extrapolation, i.e. the continuation of the straight line in Fig. 5. At these very low cobalt concentrations it is rather difficult to estimate the extrapolated maximum rate since a not insignificant fraction of the cobalt will have been deactivated before any measurements can be made. However, within the limits of error, the extrapolated ρ_m values also depend on $[Co]^{1/2}$. That is, provided allowance is made for cobalt deactivation, the curves in Fig. 4 show that ρ_m and the extrapolated ρ_m depend on $[Co]^{1/2}$ from 2×10^{-6} to 1.0×10^{-3} mole/l. [Co], in agreement with the dependence predicted by equation [2*a*]. This means that chain initiation in this system is first order in cobalt and chain termination is bimolecular in peroxy radicals.

The importance of catalyst deactivation in determining kinetics in this and in other similar systems cannot be overemphasized. Errors are particularly likely to arise when kinetics are determined by an induction period method. Several cases where unusual kinetics have been reported in the literature can readily be explained on the basis of catalyst deactivation. For example, Michaels (10) has reported that the rate of oxidation of tetralin at 70° C catalyzed by cobalt naphthenate is proportional to $[Co]^{0.6}$. His experimental technique was to measure the decrease in oxygen pressure over the tetralin that occurred in 1 hour, but after first allowing 15 minutes for the system to reach equilibrium. The oxidation that occurs during this equilibrium period and the consequent deactivation of the cobalt will naturally tend to give a somewhat higher order than the true one (see e.g., broken curve in Fig. 4). Michaels also reports that the reaction is inhibited by added hydroperoxide and therefore, following a suggestion of Uri (12), suggests that the main initiation reaction is

$$Co^{2+} + O_2 \rightarrow Co^{2+}O_2^{\cdot}. \qquad [9]$$

However, with a 15-minute equilibrium period, particularly at 70° C, it is clear from Fig. 3 that in the presence of added hydroperoxide the reaction will be largely over before any measurements are made. That is, the effective cobalt concentration after 15 minutes will be much smaller if hydroperoxide is added initially than if the hydroperoxide is absent. This is bound to cause an *apparent* inhibition of the reaction by added hydroperoxide.

The importance of catalyst deactivation has also, perhaps, been overlooked in the work of Heaton and Uri (5) on the cobalt stearate catalyzed oxidation of 0.10 *M* linoleic acid in benzene and cyclohexane at 37° C. The kinetics in this case were determined by measuring the hydroperoxide concentration in solution after a fixed time interval. These authors report that from 4×10^{-5} to 2×10^{-4} mole/l. [Co] the rate is proportional to [Co], but their experimental points from which this conclusion is derived show a curvature which is not dissimilar to that shown by the broken line in Fig. 4. As we have shown, this apparent increase in order with decreasing cobalt concentration at low initial hydroperoxide levels is due to catalyst deactivation. This effect possibly occurs at higher cobalt concentrations in the work of Heatin and Uri since great precautions were taken to remove all hydroperoxides from their starting materials. Heaton and Uri also report some very unusual kinetic results at cobalt concentrations below 4×10^{-5} mole/l. In these experiments, the solvents containing the catalyst were aerated by bubbling air through them prior to the oxidation reaction. As has already been mentioned, it has been found in the present work that the activity of cobalt salt catalysts in benzene solution decreases very rapidly unless oxygen is excluded from the solvent, so these results could also perhaps be due to catalyst deactivation. Moreover, the conclusion of these authors that reaction [9], or some modification of this reaction, is responsible for the kinetic peculiarities at low cobalt concentrations is contrary to our own finding that ρ_m is independent of the oxygen pressure (from 300 to 760 mm) over our entire cobalt concentration range. One further point is that the absence of any measurable catalytic effect at [Co] $< 10^{-6}$ mole/l. has led Uri (5, 12) to conclude that the so-called residual thermal reaction in the absence of initial hydroperoxide in many organic substances is initiated by trace metal contaminants by way of reaction [9]. However, in view of the very small amounts of absorbed oxygen which would probably be required to deactivate such contaminants unless they are present in a form which cannot be deactivated, and in view of the work of Russell (17) and Denisov (18) on the initiating reactions

$$RH + O_2 \rightarrow R^{\cdot} + HO_2^{\cdot} \qquad [10]$$

and

$$2RH + O_2 \rightarrow 2R^{\cdot} + H_2O_2, \qquad [11]$$

we can see no evidence to support this conclusion. The recent work of Privett and Blank (19) on the initial stages of the autoxidation of the methyl esters of unsaturated fatty acids also throws considerable doubt on the importance of reaction [9] as a chain-starting process.

Many other examples exist in the literature of metal-catalyzed autoxidations where rather complex reactions have been suggested on what appears to us to be an inadequate kinetic foundation. We should like to suggest that such reactions be treated with considerable reserve until they have withstood the test of more rigorous examination.

The observation that the initial hydroperoxide concentration only affects ρ_m up to a certain limiting concentration implies, of necessity, that the rate-controlling chain-initiation reaction between cobalt and hydroperoxide is not a simple bimolecular reaction. Instead, the rate-controlling step must involve the slow decomposition of a rapidly formed complex. In non-polar media most workers are agreed that reaction [1*a*] is much faster than reaction [1*b*]. Moreover, visual observation of our own system shows the green color of trivalent cobalt once oxidation commences. It is therefore probable that the rate-controlling initiation reaction can be written:

$$ROOH + CoA_2OH \underset{\text{fast}}{\rightleftharpoons} [ROOHCoA_2OH] \xrightarrow[\text{slow}]{} RO_2^{\cdot} + CoA_2 + H_2O. \qquad [1b']$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The conclusion that chain initiation occurs by way of an intermediate complex is in agreement with similar conclusions reached by other workers (15, 20).

At sufficiently low initial hydroperoxide concentrations reaction [1b'] implies that the rate of oxidation should be proportional to $[ROOH]^{1/2}$. Although, at low cobalt concentrations, the initial rates of oxidation are not inconsistent with this relationship, it could not be properly verified because hydroperoxide is the major oxidation product and also because of the necessity of correcting for cobalt deactivation during the oxidation.

According to equation [2a], ρ_m should be proportional to [RH] provided limiting-rate effects do not come into play. One of the most interesting features of metal-catalyzed autoxidations uncovered in this work is the discovery that limiting-rate effects become very important in determining reaction order with respect to [RH] even at quite low cobalt concentrations. The reason for this can be illustrated by reference to Fig. 7. The heavy line represents the limiting rate obtained with 1×10^{-2} and 2×10^{-2} mole/l. [Co] as a function of [RH] in chlorobenzene. As already described, this line has a slope of 2.0 for fairly concentrated tetralin solutions and no rate can ever lie above this line. As the cobalt concentration is decreased, the rate in pure tetralin will decrease, but any decrease in reaction order can only occur over a rather limited range of tetralin concentration, after which the order must increase towards 2.0 as [RH] is further decreased. This means that there should be a family of curves which approach the limiting rate line at sufficiently low [RH], the detailed shape of each curve depending on the cobalt concentration. The expected family of curves was obtained at three cobalt concentrations and is shown in Fig. 7. The true reaction order in [RH] must be obtained from the limiting slope at low cobalt and high tetralin concentrations. The measured limiting slope is about 1.35–1.4 at the lowest cobalt concentration at which ρ_m could be measured with reasonable accuracy over a range of tetralin concentrations without the difficulties associated with catalyst deactivation, i.e. $[Co] = 2.4\times10^{-5}$ mole/l. and $[ROOH]_0 = 2\times10^{-2}$ mole/l. The question therefore arises as to whether limiting-rate effects are still influencing the reaction order even at this low cobalt concentration and, if they are not responsible for the reaction order, then the question arises as to whether the order is really 1.5 or whether it lies between 1.0 and 1.5 for some other reason. It is not possible to answer these questions on the basis of Fig. 7 alone. However, if ρ_m is proportional to $[RH]^{1.5}$ it implies that the complex formed in reaction [1b'] is decomposed to radicals by reaction with a molecule of tetralin (cf. the ferric ion – hydrogen peroxide catalyzed oxidation of ethyl alcohol (21)) and if the order is between 1.0 and 1.5 it suggests that this reaction is in competition with the unimolecular decomposition of the complex. Solution of the appropriate kinetic equations shows that the expression for the limiting rate of oxidation is unaffected (i.e., it is still given by equation [4]) but that in the first case,

$$[ROOH]_\infty = \frac{k_3^2[RH]}{2k_6K k_1'[Co]}, \qquad [3a]$$

and in the second case,

$$[ROOH]_\infty = \frac{k_3^2[RH]^2}{2k_6K[Co](k_1'+k_1''[RH])}, \qquad [3b]$$

where it has been assumed there is an equilibrium constant (K) for the complex and k_1' is the rate constant for its unimolecular decomposition. k_1'' is the rate constant for the reaction

$$[ROOHCoA_2OH] + RH \rightarrow \text{radicals}. \qquad [1b'']$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

If limiting-rate effects are responsible for the observed reaction order, then

$$[\mathrm{ROOH}]_\infty = \frac{k_3^2[\mathrm{RH}]^2}{2k_6Kk_1'[\mathrm{Co}]}. \qquad [3]$$

In spite of the difficulty of measuring $[\mathrm{ROOH}]_\infty$ with any precision in this system (see following section) it appears that, with chlorobenzene as the diluent, the measured hydroperoxide concentration at a given extent of oxidation is proportional to the square of the tetralin concentration at low cobalt concentrations ($\sim 5\times10^{-3}$ mole/l.). At higher cobalt concentrations the apparent order decreases but this seems to be due to a lower solubility of the catalyst in tetralin–chlorobenzene mixtures compared with that in pure tetralin. It must therefore be concluded that $[\mathrm{ROOH}]_\infty$ can be best represented by equation [3] and that reaction [1b''] is probably unimportant compared with the unimolecular decomposition of the catalyst–hydroperoxide complex. The measured dependence of the oxidation rate on [RH] is therefore still influenced by limiting-rate effects even at a cobalt concentration of 2.4×10^{-5} mole/l. Incidentally, decomposition of the complex by reaction with a second molecule of hydroperoxide (cf. refs. 22, 23) (rate constant k_1''') also leads to the same expression for the limiting rate of oxidation but in this case,

$$[\mathrm{ROOH}]_\infty = \frac{k_3[\mathrm{RH}]}{(2k_6Kk_1''')^{1/2}[\mathrm{Co}]^{1/2}}, \qquad [3c]$$

which does not describe the dependence of $[\mathrm{ROOH}]_\infty$ on [RH] nor on [Co] in the concentration region where the cobalt salts are soluble (see following section). In a similar way, analysis of the kinetics indicates that initiation is not due to a reaction between two of the complexes.

It should perhaps be pointed out that although a reaction order of 1.5 with respect to [RH] might appear to be accounted for at low cobalt concentrations by the slow reaction

$$\mathrm{CoA_2OH} + \mathrm{RH} \rightarrow \mathrm{CoA_2} + \mathrm{H_2O} + \mathrm{R}^\bullet \qquad [12]$$

the inclusion of this reaction at high cobalt concentrations precludes the occurrence of a limiting rate of oxidation equal to the theoretical value calculated on the basis of the Tobolsky theory. That is, at low cobalt and high hydroperoxide concentrations reaction [12] could be rate determining, with reaction [1a] becoming rate controlling as the hydroperoxide concentration is reduced. To account for the limiting rate of oxidation equalling the theoretical value one is forced to conclude that reaction [1a] is also rate determining at high cobalt concentrations. However, at high cobalt concentrations the addition of large amounts of hydroperoxide at the start of the reaction merely reduces the induction period very slightly (presumably by helping to solubilize the catalyst) but has no effect on the maximum rate. This is true even when more than sufficient hydroperoxide is added to convert all the cobalt to the trivalent state (see Fig. 8). This leads to the conclusion that at high cobalt concentrations reaction [1a] is rate controlling irrespective of the hydroperoxide concentration, a result diametrically opposed to the conclusion that was drawn at low cobalt concentrations. Reaction [12] can therefore play no important role in the oxidation.

In view of the shapes of the curves in Fig. 7 it is obvious that considerable caution should be exercised in deducing reaction mechanisms on the basis of incomplete kinetic analysis. That is, for any substrate and solvent in which the rate of a metal-catalyzed autoxidation is really first order with respect to the substrate the apparent reaction order over a limited concentration range will lie between 1.0 and 2.0. In particular, at low

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

[RH] or comparatively high [catalyst] an apparent order of 1.5 might be obtained. Such an order could lead to the incorrect conclusion that the substrate was involved in the rate-controlling initiation reaction. This conclusion has in fact been drawn by several authors (24, 25) but the kinetic basis appears to be rather weak in much of the work. The initiating reaction generally proposed to account for these kinetics is

$$M^{(n+1)+} + RH \rightarrow M^{n+} + H^+ + R^\cdot \qquad [12a]$$

leading to an oxidation rate proportional to $[M]^{1/2}[RH]^{3/2}$. While there is no doubt that this reaction can occur with a variety of substrates and metal catalysts in aqueous media (24) it appears less probable in non-polar media. An example which may possibly illustrate this effect is contained in the work of Heaton and Uri referred to previously (5). Their experimental evidence for reaction [12] was obtained at an initial hydroperoxide concentration of 0.10 mole/l. and a cobalt stearate concentration of 10^{-4} mole/l. over a range of linoleic acid concentrations from 0.05 to 0.4 mole/l. in benzene. The experimental rates indicate an average order of 1.5 in [RH] but they show a considerable curvature in the direction to be expected if limiting-rate phenomena are coming into play. Their data could therefore be accounted for either by reaction [12], or by reaction [1*b*′] if limiting-rate effects are coming into play, or by reaction [1*b*″], and no definite choice can be made between these three possibilities. This discussion of reaction [12] is not intended to imply that it never occurs in non-polar media since some of the extensive data collected by Denisov and Emanuel in their review article (25) indicate that aldehydes and possibly some other very readily oxidized substances may undergo such a reaction at elevated temperatures. However, at low temperatures, kinetic evidence alone which has been obtained over a small range of substrate concentration should not be taken as giving unequivocal proof that reaction [12] is the rate-determining initiation process.

Hydroperoxide Formation

The formation of tetralin hydroperoxide during the cobalt-catalyzed (1.9×10^{-2} mole/l. [Co]) oxidation of tetralin containing an initial concentration of 1.0×10^{-3} and 4.1×10^{-2} mole/l. [ROOH] is shown in Fig. 8. It can be seen that within a comparatively short time the hydroperoxide concentration at a given extent of oxidation is independent of its initial concentration. The hydroperoxide concentration increases fairly steadily throughout the region of the steady maximum rate of oxidation and then starts to increase more rapidly as the oxidation rate decreases because a large fraction of the cobalt has been deactivated at this point. There is no truly steady concentration of hydroperoxide (i.e. no $[ROOH]_\infty$) such as occurs in acetic acid as the solvent (1). This is apparently due both to the continuous deactivation of the cobalt and to the fact that, even with the more soluble cobalt salts, not all the cobalt will dissolve in the tetralin at this high cobalt concentration until some oxidation has occurred. That is, the oxygen-containing products of the reaction help to solubilize the cobalt salt. It is extremely difficult to correct for these two factors so that it is not really possible to obtain $[ROOH]_\infty$ in this system. However, at the same cobalt concentration it should be permissible to compare hydroperoxide concentrations for different tetralin concentrations in chlorobenzene by measuring [ROOH] at the same extent of oxidation of the tetralin and therefore at the same extent of cobalt deactivation. This was first done with 2×10^{-2} mole/l. [Co] in pure tetralin and in a 50% and a 25% by volume solution of tetralin in chlorobenzene. It was found that the measured [ROOH] depended on a power of the tetralin concentration lying between 1.0 and 2.0, in apparent agreement with equation [3*b*]. However, the measured order not only increased during

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the oxidation but also increased as the tetralin concentration was increased. That is, with 25% tetralin and 50% tetralin, respectively, the measured orders with respect to undiluted tetralin increased from 1.15 and 1.3 at a 2% oxidation of the tetralin to 1.5 and 1.9 at 16% oxidation. It has already been mentioned that the cobalt catalysts appear to be more soluble in tetralin than in tetralin–chlorobenzene mixtures since measured oxidation rates at high cobalt concentrations decrease more rapidly than expected as the tetralin concentration in chlorobenzene is reduced, i.e. the apparent order in [RH] increases (see Fig. 7). The catalyst solubility will also affect the hydroperoxide concentration in tetralin–chlorobenzene mixtures. That is, since there is relatively less catalyst in solution the more dilute the tetralin is, the measured hydroperoxide concentration does not decrease as rapidly as expected as the tetralin concentration is reduced. The correct dependence of [ROOH] on [RH] is therefore given under conditions where comparable amounts of catalyst are dissolved in the system. The approach to a limiting order of 2.0 as the oxidation proceeds and the catalyst becomes solubilized by the products together with the increase in order at a given extent of oxidation as the tetralin concentration is increased (i.e. the opposite of the effect predicted by equation [3*b*]) both suggest that under strictly comparable conditions [ROOH] would be proportional $[RH]^2$ as required by equation [3]. This conclusion was verified at a lower cobalt concentration where catalyst solubility effects are greatly reduced. That is, with 5×10^{-3} mole/l. [Co] it was found that the hydroperoxide concentration at a given extent of oxidation was exactly proportional to $[RH]^2$ over almost the entire course of the oxidation (i.e. from 0.5% to 12% tetralin consumption) for a range of tetralin concentrations from pure tetralin to a 60% by volume solution of tetralin in chlorobenzene. The complex formed by reaction of the cobalt with hydroperoxide therefore undergoes a first-order decomposition and, at sufficiently low [Co] and high [RH], the rate of oxidation should become directly proportional to [RH].

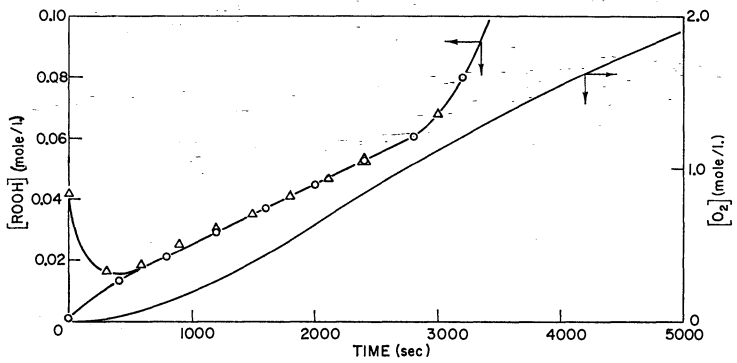

FIG. 8. Oxygen absorption and hydroperoxide formation at a cobalt decanoate concentration of 1.9×10^{-2} mole/l. Key: ○ $[ROOH]_0 = 1.0\times10^{-3}$ mole/l.; △ $[ROOH]_0 = 4.1\times10^{-2}$ mole/l.

At a given extent of oxidation the amount of active cobalt remaining in the system, although not necessarily in solution, can be very roughly calculated from equation [8] (see previous section). By comparing measured hydroperoxide concentrations at extents of oxidation where the same fraction of the cobalt should have been deactivated it appears that the hydroperoxide concentration decreases rather more slowly than expected at cobalt (decanoate) concentrations above 1.0×10^{-2} mole/l. (cf. [ROOH] at 1500 seconds in Figs. 8 and 9). This suggests that the effective cobalt concentration in solution increases rather

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

slowly with increasing cobalt concentration in this range. However, at cobalt concentrations below 10^{-2} mole/l. (and at the same relative extents of cobalt deactivation) [ROOH] becomes roughly inversely proportional to the initial cobalt concentration as required by equation [3]. The measured hydroperoxide concentrations can be roughly corrected to allow for cobalt deactivation during an oxidation and when this is done the increase in [ROOH] during an oxidation is greatly reduced, as can be seen in Fig. 9. This figure shows the measured [ROOH] during the oxidation of undiluted tetralin containing 5.0×10^{-3} and 9.0×10^{-3} mole/l. of cobalt decanoate and the calculated [ROOH] based on equation [8], i.e., based on the assumption that with 5×10^{-3} mole/l. [Co], $12.8(5\times10^{-3})^{1/2} = 0.91$ mole/l. [O_2] deactivates $0.75\times5\times10^{-3} = 3.75\times10^{-3}$ mole/l. [Co] and with 9×10^{-3} mole/l. [Co], 1.2 mole/l. [O_2] deactivates 6.8×10^{-3} mole/l. [Co]. Although the corrected [ROOH] still does not reach a true steady state it is not too far from one in the region of the maximum rate of oxidation (~1500 seconds). At cobalt concentrations below 1.0×10^{-2} mole/l. the corrected hydroperoxide concentration in the region of the maximum rate can perhaps be used as a very approximate measure of the steady-state hydroperoxide concentration which should exist were it not for the low solubility of the catalyst at the beginning of the reaction and its continuous deactivation during the reaction. That is, taking $[ROOH]_\infty \approx 0.07$ mole/l. at 5×10^{-3} mole/l. [Co], we can calculate the rate constant for chain initiation by cobalt in pure tetralin from equation [6] (1), using, of course, the extrapolated limiting rate of oxidation since this also allows for cobalt deactivation, i.e.

$$\left(\frac{-d[O_2]}{dt}\right)_\infty \Big/ [ROOH]_\infty = k[Co]. \qquad [6]$$

Therefore,

$$k \approx \frac{1.0\times10^{-3}}{7\times10^{-2}\times5\times10^{-3}} \approx 2.9 \text{ l./mole sec},$$

where k is either Kk_1' or k_1' depending on whether the complex in reaction [1b'] is formed by a reversible or irreversible process.

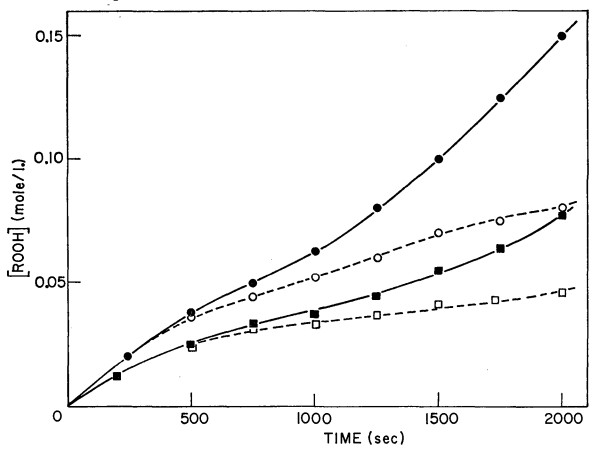

FIG. 9. The formation of hydroperoxide during the oxidation of tetralin. Key: Measured hydroperoxide at [Co] = 9.0×10^{-3} mole/l. (■), and at [Co] = 5.0×10^{-3} mole/l. (●); calculated hydroperoxide corrected for cobalt deactivation given by □ and ○.

Hydroperoxide Decomposition

The measurement of the rate of the cobalt-catalyzed decomposition of tetralin hydroperoxide in chlorobenzene solution is complicated by the deactivation of the cobalt and this reaction was not studied in as much detail as the decomposition in the benzene – acetic acid mixtures (1). The reaction is much faster in chlorobenzene than in the mixture containing acetic acid possibly because the cobalt is not very strongly associated with the solvent, and hydroperoxide molecules therefore have ready access to the cobalt. At a given [Co] and $[ROOH]_0$ the reaction is pseudo first order in hydroperoxide for a limited extent of decomposition but the measured rate constant increases with increasing concentration of peroxide and with decreasing concentration of cobalt. This increase in rate constant is probably not due to a reaction that is bimolecular in peroxide since the addition of the free-radical inhibitor, 2,6-di-*tert*-butyl-4-methylphenol (BMP), greatly reduces the variation in the measured rate constant. This implies that in the uninhibited reaction a radical-induced decomposition, [*i*], is superposed on the main decomposition reaction, i.e.,

$$\text{radical} + \text{ROOH} \rightarrow \text{radical} + \text{products.} \qquad [i]$$

The rate of hydroperoxide decomposition is therefore given by

$$\frac{-d[\text{ROOH}]}{dt} = Kk_1'[\text{Co}][\text{ROOH}] + k_i[\text{ROOH}]\left(\frac{Kk_1'[\text{Co}][\text{ROOH}]}{2k_6'}\right)^{1/2},$$

where k_6' is the rate constant for the self-termination of the radicals produced in the decomposition. The induced decomposition and cobalt deactivation were kept to a minimum by working with as large a cobalt concentration and as small an initial hydroperoxide concentration as was practical. With $[ROOH]_0 = 10^{-2}$ mole/l. the apparent rate constants were 9.4, 8.8, 8.0, and 7.2 l./mole sec at cobalt concentrations of 2.5, 3.5, 5.5, and 10.0×10^{-4} mole/l. When these values are plotted against $1/[\text{Co}]^{1/2}$ an excellent straight line is obtained with an intercept of 5.0 l./mole sec at infinite cobalt concentration which should correspond to the complete suppression of the induced chain decomposition, i.e., it should represent Kk_1' in chlorobenzene. This value is in satisfactory agreement with the value of 2.9 l./mole sec obtained in tetralin from the limiting rate of oxidation and $[ROOH]_\infty$ when the difficulties associated with the determination of the rate constant in the two systems are considered.

At the same initial hydroperoxide concentration the rate constant becomes very difficult to measure at cobalt concentrations below 2.5×10^{-4} mole/l. owing to the fact that a significant fraction of the cobalt is deactivated when comparatively little of the peroxide has been decomposed. The first-order plots of peroxide decomposition therefore show a very marked curvature and since it is not possible to obtain the initial rate accurately the measured rate constant may appear to decrease rather than increase as the cobalt concentration is reduced. This phenomenon may perhaps account for the greater than first order dependence on [Co] which has been reported by Dyer *et al.* (26) for the cobaltous 2-ethylhexanoate catalyzed decomposition of tetralin hydroperoxide in xylene at comparatively low cobalt concentrations ($\sim0.5\times10^{-4}$ to 1.0×10^{-4} mole/l.). That is, the reported order was about 2.0 at 25.5° C (cf., however, reference 27) and about 1.5 at 50.5° C.*

Under conditions where the initial hydroperoxide concentration is large relative to the cobalt concentration the rate of hydroperoxide decomposition rapidly drops to almost

**At 50.5° C the measured rate constant at 1.07×10^{-4} mole/l. [Co] was 77×10^{-5} sec^{-1}, i.e., 7.2 l./mole sec, which is in fairly good agreement with the value of 11.7 l./mole sec obtained by extrapolation from our own data at higher cobalt concentrations (where deactivation is less important and the rate can be more accurately measured).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

zero. For example, with 10^{-4} mole/l. [Co] and 4×10^{-2} mole/l. $[ROOH]_0$ the reaction ceases after 30% of the hydroperoxide has been decomposed. In chlorobenzene, each cobalt salt molecule is therefore capable of decomposing about 120 molecules of hydroperoxide, which is in fairly good agreement with the value of 100 calculated from equation [8] at high cobalt concentrations in tetralin.

The true rate constant for the catalyzed decomposition of the hydroperoxide was also obtained by suppressing the induced decomposition by the addition of the inhibitor BMP. With 10^{-2} mole/l. $[ROOH]_0$ and 10^{-3} mole/l. [Co] the measured rate constants in the presence of 1.2×10^{-2}, 2.4×10^{-2}, and 3.6×10^{-2} mole/l. [BMP] were 5.6, 5.2, and 5.1 l./mole sec respectively. Extrapolation to infinite BMP concentration where the induced decomposition should be completely eliminated gives a true rate constant of 4.8 l./mole sec, in good agreement with the value of 5.0 l./mole sec obtained by extrapolation to infinite cobalt concentration.

SUMMARY AND CONCLUSIONS

The extrapolated limiting rate of the cobalt-catalyzed oxidation of undiluted tetralin is in good agreement with the theoretical value even though there is no steady-state concentration of hydroperoxide formed during the oxidation. Upon dilution with chlorobenzene the limiting rate of oxidation shows the expected dependence on the square of the tetralin concentration provided the tetralin is not too dilute. Cobalt salt catalysts are deactivated during the oxidation, probably in the chain-initiation process, each atom of cobalt being able to decompose about 100 molecules of hydroperoxide. The rate of oxidation at low cobalt concentrations shows the expected dependence on the square root of the cobalt concentration, chain initiation most probably occurring by the unimolecular decomposition of a cobalt–hydroperoxide complex. There is no evidence for initiation by either a direct reaction of trivalent cobalt with the substrate or by a reaction of divalent cobalt with oxygen.

ACKNOWLEDGMENT

IONIZATION AND DISSOCIATION OF FORMATE ESTERS BY ELECTRON IMPACT

D. VAN RAALTE AND A. G. HARRISON[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 19, 1963

ABSTRACT

The mass spectra of methyl formate-*d*, ethyl formate-*d*, and isopropyl formate-*d* are compared with the mass spectra of the undeuterated compounds. By use of the deuterium labelling and appearance potential studies the dissociation reactions leading to a number of the oxygen-containing ions have been elucidated. The proton affinity of formic acid is estimated to be 157 kcal/mole from the appearance potential of the $HC(OH)_2^+$ ion in the mass spectra of ethyl formate and isopropyl formate.

INTRODUCTION

A survey of the mass spectra of aliphatic esters by Sharkey and co-workers (1) has established the main dissociation reactions on electron impact and has pointed out a number of important rearrangement processes. Beynon *et al.* (2) have extended this work by using high-resolution mass spectrometry to determine the empirical formulae of the ions formed. Some information on the energetics and mechanism of ion formation has been obtained by King and Long (3) in a detailed study of C^{13}-labelled methyl formate and methyl acetate, while more recently Godbole and Kebarle (4) have studied some of the rearrangement processes in various deuterated ethyl and isopropyl acetates and ethyl formate. The present paper reports the mass spectra of methyl formate-*d*, ethyl formate-*d*, and isopropyl formate-*d*. The use of deuterium labelling combined with appearance potential studies has permitted the elucidation of the mechanism of a number of the important rearrangement processes.

EXPERIMENTAL

The mass spectra were obtained with an Associated Electrical Industries MS-2 mass spectrometer. The operating conditions were 50 v electron energy, 20 μa ionizing current, and 3 v repeller ($\sim$7 v/cm field strength). The appearance potentials were determined as previously described (5) using xenon as the calibrating gas.

The deuterated compounds were obtained from Merck, Sharp and Dohme of Canada. The isotopic purity was checked by low-energy analysis as will be discussed below. The mass spectra showed no other detectable impurities. The unlabelled methyl and ethyl formates were commercial samples which were distilled before use. The isopropyl formate was prepared by standard methods and purified by distillation.

RESULTS AND DISCUSSION

The major peaks in the mass spectra of the deuterated and undetuerated esters are presented in Table I. The intensities are expressed as percentage of the total ion yield and ion currents less than 0.5% have not been listed unless they are of special interest. The spectra have all been corrected for C^{13} isotope contribution and in the case of methyl formate-*d* for 0.5% undeuterated methyl formate as determined by low-energy analysis. Low-energy analysis of ethyl formate-*d* and isopropyl formate-*d* showed less than 1% isotopic impurity in each case; no correction for this has been made. The isotopic analysis of the isopropyl formate was carried out in the mass 45–46 region due to the low intensity of the parent ion.

*Intensities expressed as percentage of total ion yield.

Table II lists the appearance potentials of some of the more important ions for the three esters. In general, the agreement with previously published results is within experimental error.

Of particular interest in the mass spectra are the oxygen-containing ions at masses* 73, 59, 47, 45, 31, and 19, and their counterparts in the deuterated isomers. These ions can be divided into two classes, those which are formed by direct dissociation and those which are formed by a rearrangement reaction.

Ions Formed by Direct Dissociation

(a) Loss of H

The small ion current at mass 73 (loss of deuterium) in ethyl formate-*d* indicates that loss of the formyl hydrogen occurs to a significant extent in ethyl formate. The mass spectrum of $HCO_2CD_2CH_3$ showed (4) a much larger loss of H than can be accounted for by loss of the formyl hydrogen. Since Godbole and Kebarle (4) also observed loss of deuterium, it is apparent that all hydrogens are lost to some extent from ethyl formate.

**Since doubly charged ions are not discussed, the mass-to-charge ratio will be referred to as the mass throughout.*

	45	11.55	
$HCOOCH(CH_3)_2$	47	10.87	
	45	11.53	
	31	13.45	
$DCOOCH(CH_3)_2$	32	13.53	

The mass 59 ion of methyl formate corresponds to loss of hydrogen. The observation of both mass 59 (loss of D) and mass 60 (loss of H) in the mass spectrum of methyl formate-*d* indicates that both the formyl and the methyl hydrogens are lost, with loss of the methyl hydrogen accounting for approximately 20% of the ion current. The observation of loss of the methyl hydrogen is in contrast to the results of Renaud and Leitch (6), who concluded, from the mass spectrum of $HCOOCD_3$, that only the formyl hydrogen was lost. It should be noted, however, that their reported spectra gave mass 63/mass 62 = 0.0456 for $HCOOCD_3$ compared to mass 60/mass 59 = 0.0186 for $HCOOCH_3$. This suggests an appreciable impurity of $HCOOCD_2H$ in the $HCOOCD_3$ and makes interpretation of the results difficult.

(b) Loss of CH_3

The mass 73 ion in isopropyl formate corresponds to loss of CH_3. The observation of this ion at mass 74 in the deuterated compound indicates that the formyl hydrogen is retained. It is probable that the methyl is lost without isotopic mixing.

The mass 59 ion of ethyl formate has been shown (2) to have the empirical formula $C_2H_3O_2^+$, formed by loss of CH_3. In $DCOOC_2H_5$ this ion is observed at mass 60, while in $HCOOCD_2CH_3$ the ion is observed (4) at mass 61. These results indicate the structure $HCOOCH_2^+$, the methyl group being lost without isotopic mixing.

(c) Formation of $C_2H_5O^+$ from Ethyl Formate

High-resolution work by Beynon *et al.* (2) has shown that the mass 45 ion in ethyl formate has the empirical formula $C_2H_5O^+$ with negligible contribution from HCO_2^+.

Both masses 45 and 46 are found in the mass spectrum of ethyl formate-*d*. The former must be $C_2H_5O^+$, consisting of the original ethoxy group of the ester, while the latter ion, incorporating the formyl hydrogen, is presumably the $DOCHCH_3^+$ ion. The relative intensities indicate that in ethyl formate approximately 65% of the mass 45 ion is a rearrangement ion incorporating the formyl hydrogen. Godbole and Kebarle (4) observed both $CH_3CD_2O^+$ and CH_3CDOH^+ in the mass spectrum of $HCOOCD_2CH_3$. From the relative intensities they assigned, one calculates 43% retention of the two deuteriums. This is significantly higher than the 35% retention of the total ethoxy group calculated in the present work and suggests that some of the mass 45 ion may be formed by loss of one of the methyl hydrogens with transfer of the formyl hydrogen.

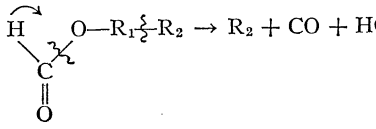
For personal use only.

The appearance potential of mass 45 ($C_2H_5O^+$) in the ethyl formate-*d* is in agreement with *A*(mass 45) = 11.55 ev. in the undeuterated compound. Using ΔH_f(ethyl formate) = −88 kcal/mole (7) this appearance potential leads to $\Delta H_f(C_2H_5O^+)$ = 152 kcal/mole assuming H + CO as the neutral fragments and 178 kcal/mole assuming HCO as the neutral fragment. The lower value is only slightly higher than $\Delta H_f(CH_3CHOH^+)$ = 145 kcal/mole, obtained from appearance potential studies of the simple alcohols (8, 9). Although no reliable value for $\Delta H_f(C_2H_5O^+)$ has been established, both the values 152 and 178 kcal/mole are too low by comparison with $\Delta H_f(CH_3O^+)$ = 212 kcal/mole (7). It appears likely that the ion has rearranged to the more stable carbinyl structure and is formed with H + CO as the neutral fragments.

Ions Formed by Rearrangement

A number of the major rearrangement reactions which occur can be represented by the following general reaction first suggested by King and Long (3):



$$\rightarrow R_2 + CO + HOR_1^+. \qquad [1]$$

The main driving force for this rearrangement is undoubtedly the stability of the CO produced and the stability of the hydroxycarbinyl ion.

(a) Loss of H + CO (R_2 = H)

The loss of H + CO from isopropyl formate leads to the formation of mass 59, which has been shown (2) to have the empirical formula $C_3H_7O^+$. In isopropyl formate-*d* this ion has moved to mass 60, indicating retention of the formyl hydrogen. The ion is thus not the original isopropoxy group of the ester but is a rearrangement ion formed by reaction [1], the hydrogen lost probably being the tertiary hydrogen of the isopropyl group.

As discussed above the large intensity at mass 46 in ethyl formate-*d* indicates approximately 65% retention of the formyl hydrogen in formation of the $C_2H_5O^+$ ion. The ion probably has the structure $HOCHCH_3^+$ formed by rearrangement reaction [1].

A(CH_3CHOD^+) from ethyl formate-*d* is in agreement with *A*(mass 46) reported by Bernecker and Long (7). The appearance potential leads to $\Delta H_f(CH_3CHOD^+)$ = 162 kcal/mole assuming the neutral fragments H + CO. This is considerably higher than the best value for this ion and implies the presence of excess energy in the rearrangement process.

The mass 31 ion in methyl formate has been postulated (3) to be the original methoxy group formed with HCO as the neutral fragment. The large intensity at mass 32 in methyl formate-*d* indicates that the major fraction of this ion incorporates the formyl hydrogen and is thus the CH_2OH^+ ion formed by reaction [1] with H + CO as neutral fragments. Comparison of the mass 32 intensity in $DCOOCH_3$ with the mass 31 intensity in $HCOOCH_3$ indicates 95% formyl hydrogen retention neglecting any isotope effects.

The appearance potential of mass 31 from methyl formate leads to $\Delta H_f(CH_2OH^+)$ = 176±3 kcal/mole, using $\Delta H_f(HCOOCH_3)$ = −83.7 kcal/mole (7) and assuming H + CO as the neutral fragments. This is in reasonable agreement with $\Delta H_f(CH_2OH^+)$ = 180±3 kcal/mole obtained from simple alcohols (8, 9).

(b) Loss of CH_3 + CO (R_2 = CH_3)

Mass 45 in isopropyl formate corresponds to loss of CH_3 + CO. In isopropyl formate-*d* this ion has moved quantitatively to mass 46, indicating retention of the formyl hydrogen. The ion is thus formed by rearrangement reaction [1] with R_2 = CH_3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The appearance potential of CH_3CHOH^+ from isopropyl formate leads to $\Delta H_f(CH_3CHOH^+) = 163$ kcal/mole using ΔH_f(isopropyl formate) $= -97$ kcal/mole as estimated from the heats of formation of other formate esters. Again this is considerably higher than the best estimates for this ion and implies the involvement of excess energy in the rearrangement process.

The mass 31 in ethyl formate has moved to mass 32 in $DCOOC_2H_5$. This result, in conjunction with the observation of the ion at mass 33 in $HCOOCD_2CH_3$ (4), clearly shows retention of the formyl hydrogen and loss of the terminal methyl group without isotopic mixing in the rearrangement reaction. The appearance potential of mass 31 from ethyl formate obtained in the present work is slightly lower than that obtained previously and leads to $\Delta H_f(CH_2OH^+) = 183 \pm 3$ kcal/mole, in reasonable agreement with the best value of 180 kcal/mole (8, 9).

(c) Formation of Mass 31 from Isopropyl Formate

In contrast to the above results, the rearrangement to form mass 31 in isopropyl formate follows a somewhat different mechanism. As shown in Table I the ion has moved to mass 32 in isopropyl formate-*d*, indicating retention of the formyl hydrogen. The most reasonable mechanism for formation of this ion is through the mass 59 ($(CH_3)_2COH^+$) as follows:

$$HCOOCH(CH_3)_2^+ \rightarrow H + CO + HOC(CH_3)_2^+ \rightarrow C_2H_4 + HOCH_2^+. \qquad [2]$$

Deuterium labelling (11) has shown that formation of mass 31 from isopropyl alcohol occurs with retention of the hydroxyl hydrogen and complete loss of the tertiary hydrogen, while recent work in this laboratory (9) indicates that the reaction proceeds through the mass 59 intermediate as indicated by the above mechanism and in agreement with the labelling evidence.

The appearance potential of CH_2OH^+ from isopropyl formate was found to be 13.45 ev compared to 13.53 ev for $A(CH_2OD^+)$ from isopropyl formate-*d*. The average value, 13.49 ± 0.1 ev, leads to $\Delta H_f(CH_2OH^+) = 177 \pm 3$ kcal/mole assuming the above mechanism. Considering the possible errors in the estimation of the heat of formation of the ester this is in satisfactory agreement with the best value of 180 kcal/mole. This result affords further support for the mechanism of formation proposed.

It is apparent from the above results that mass 31 in methyl formate and in ethyl formate, mass 46 in ethyl formate-*d*, and masses 45 and 59 in isopropyl formate arise by similar rearrangement reactions represented by the general reaction [1]. Three possibilities must be considered when discussing the time sequence by which the reaction occurs. These are:

(*a*) CO leaves first;

(*b*) R_2 leaves first;

(*c*) concerted rearrangement in which R_2 and CO leave simultaneously.

Sequence (*a*) should lead to significant ion currents for the corresponding alcohol ions in the case of methyl and ethyl formates. For methyl formate a significant ion current for CH_3OH^+ is observed. Subsequent loss of $R_2 = H$ would be consistent with the labelling results, since the mass spectra of deuterated methanols show predominantly methyl hydrogen loss (9, 10). The mass 31 intensity in methyl formate is greater than might be expected from decomposition of the methanol ion and it is probable that one or both of sequences (*b*) and (*c*) contribute.

The absence of the $CH_3CH_2OH^+$ ion in the spectrum ethyl formate would argue against the occurrence of reaction [1] by sequence (*a*) in this case. For the formation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

CH_2OH^+ from ethyl formate the observation (4) of a metastable form at mass 16.3 corresponding to the transition

$$HCOOCH_2^+ (59) \rightarrow CH_2OH^+ (31) + CO (28); m^* = \frac{31^2}{59} = 16.3 \quad [3]$$

indicates for this ion a significant occurrence of the rearrangement [1] by a time sequence in which R_2 is lost first. For the other cases the present results do not permit decisions as to the time sequence of the rearrangement.

Mass 19

The mass spectra of ethyl formate and isopropyl formate both show significant ion currents at mass 19 corresponding to the hydronium ion. For both esters the spectra of the deuterated isomers show that the major part of this ion incorporates the formyl hydrogen. The energetics and mechanism of hydronium ion formation in esters and alcohols will be discussed in a further communication.

Proton Affinity of Formic Acid

The mass sepctra of ethyl and isopropyl formates show significant ion currents at mass 47 which must correspond to a protonated formic acid molecule. The spectra of the deuterated molecules show that this ion incorporates the formyl hydrogen. The three reported appearance potentials for $HC(OH)_2^+$ from ethyl formate (Table II) agree within experimental error. The average value, 11.66±0.1 ev, leads to $\Delta H_f(HC(OH)_2^+) = 115\pm3$ kcal/mole assuming C_2H_3 ($\Delta H_f = 65$ kcal/mole (7)) as the neutral fragment. $A(HC(OH)_2^+) = 10.87\pm0.1$ ev from isopropyl formate leads to $\Delta H_f(HC(OH)_2^+) = 122\pm3$ kcal/mole assuming C_3H_5 ($\Delta H_f = 30$ kcal/mole (7)) as the neutral fragment. This mechanism is similar to that proposed by McLafferty and Hamming (12) for the similar rearrangement in isobutyl esters. Although the agreement of the two estimates is barely within experimental error the results suggest that $\Delta H_f(HC(OH)_2^+) = 118$ kcal/mole is not in serious error. Combination of this value with $\Delta H_f(HCOOH) = -90$ kcal/mole and $\Delta H_f(H^+) = 365$ kcal/mole (7) leads to 157 kcal/mole for the proton affinity of formic acid in the gas phase. This is substantially less than the estimate of 177 kcal/mole by Godbole and Kebarle (4) for the proton affinity of acetic acid, but is not unexpected in view of the stabilizing effect of the methyl group compared to hydrogen.

INTENSITIES OF EMISSION LINES IN FLAMES OF METAL HALIDES WITH ACTIVE NITROGEN

L. F. PHILLIPS
Chemistry Department, University of Canterbury, Christchurch, New Zealand
Received April 3, 1963

ABSTRACT

The intensities of spectral lines emitted by flames of a number of metal halides with active nitrogen have been found to vary as the square of the nitrogen atom concentration. When the total energy required for simultaneous dissociation of the halide and excitation of the metal atom is less than about 200 kcal/mole the energy transfer process is too efficient to be attributed to the termolecular reaction of a halide molecule with a pair of nitrogen atoms. The observations are consistent with the hypothesis that in this case energy is transferred to the halide molecule during collision with a nitrogen molecule in the $^5\Sigma_g^+$ state. Possible excitation mechanisms are discussed for less intense lines which would require up to 276 kcal/mole for simultaneous dissociation and excitation.

INTRODUCTION

In a previous communication (1) it was shown that in flames of thallous halides with active nitrogen the intensity of the 5350 Å thallium line is proportional to the first power of the halide concentration and to the square of the nitrogen atom concentration. The rate of the overall reaction, calculated from the absolute intensity of the 5350 Å line and also from the rate of consumption of halide, was approximately 2×10^{-29} cm^{6}molecule^{-2}sec^{-1}, whereas the largest value to be expected for a termolecular reaction is about 10^{-31} cm^{6}molecule^{-2}sec^{-1} (2).

Thallium lines were observed photographically down to 3230 Å, for which the energy required in the case of TlF is 221 kcal/mole. The results were discussed in terms of the transfer of energy to the halide during a collision with an electronically excited nitrogen molecule (equation [1]), the excited molecule being produced during nitrogen atom recombination. In the steady state the concentration of N_2^* is proportional to the square of the nitrogen atom concentration. It was suggested that the excited molecule involved was in the $^5\Sigma_g^+$ state, since the amount of energy required appeared to be too great to be provided by other metastable species.

$$N_2^* + TlX \rightarrow Tl^* + X + N_2 \qquad [1]$$

In the present paper the intensity measurements are extended to all of the thallium lines and to flames of active nitrogen with some halides of other metals. For all of the emission lines the intensity varies as the square of the nitrogen atom concentration, proportionality to the halide concentration also being observed over the range of partial pressures used. The lines may be divided into three classes, depending on whether the total energy required to dissociate the halide and excite the metal atom is less than about 200 kcal/mole, between 200 and 225 kcal/mole, or greater than 225 kcal/mole. For lines in the first class the efficiency is in general too high for the termolecular mechanism [2]

$$N + N + MX_n \rightarrow N_2 + M^* + nX \qquad [2]$$

X = halogen atom, M = metal atom of valency n

and the arguments of the previous paper (1) may be applied, leading to the conclusion that energy is probably transferred from a nitrogen molecule in the $^5\Sigma_g^+$ state. For lines

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

in the second class either of these mechanisms may operate. For lines in the third class both mechanisms may be ruled out on energetic grounds, while a termolecular mechanism involving one ground state and one excited nitrogen atom may be eliminated on grounds of efficiency because of the small proportion of excited atoms in discharged nitrogen (3). There are two other alternatives for this case, one involving a higher metastable state of N_2 and the other using consecutive excitation processes similar to [1] or [2] to overcome the high energy requirement. Of these alternatives the latter is favored since it leads more readily to a dependence of intensity on the square of the atom concentration.

This work is essentially a continuation of the series of observations of Strutt (4) on flames supported by active nitrogen, with the advantage that in the intervening 50 years a reasonably complete theory of active nitrogen has developed (5). In the current theory most of the activity of discharged nitrogen is attributed to the presence of ground-state nitrogen atoms; however, the role of metastable nitrogen molecules has been stressed by a number of investigators (6–9, 1). Mulliken (10) has listed most of the known or predicted states of N_2, together with their theoretical dissociation products and important spectroscopic constants, including the known or predicted energy of the ground vibrational level. Table I, selected from Mulliken's data, contains those states which are expected to be metastable or long lived. As pointed out by Kenty (11), a state may be slightly above another to which transition is allowed yet have a long lifetime because of smallness of the factor ν^3 in the expression for the transition probability. Where a state is expected to be long lived for this reason the nearby state to which a transition is allowed is given in the right-hand column of Table I. As in Mulliken's table, square brackets indicate predicted states or values, parentheses indicate doubtful values.

TABLE I

Long-lived electronic states of N_2

State	Energy ($v = 0$), kcal/mole	D^0, kcal/mole	Dissociation products	Allowed transition
$X^1\Sigma_g^+$	0	225	$^4S+^4S$	—
$A^3\Sigma_u^+$	142	83	$^4S+^4S$	—
$[^3\Delta_u]$	[172]	[107]	$^4S+^2D$	$\rightarrow B^3\Pi_g$ at 170 kcal
$a^1\Pi_g$	196	138	$^2D+^2D$	—
$a'^1\Sigma_u^-$	(202)	(132)	$^2D+^2D$	$\rightarrow a^1\Pi_g$ at 196 kcal
$^5\Sigma_g^+$	(222)	(3)	$^4S+^4S$	—
$[^1\Sigma_g^+]$	[(280)]	[(182)]	$^4S+(s^2p^2.3S)^4P$	$\rightarrow [^1\Pi_u]$ at [(279)] kcal
(Possibly other states, of high multiplicity, above this)				

EXPERIMENTAL

The reaction vessel and flow system were as previously described (1) except that an improved heating jacket enabled the reaction vessel to be heated to 550° C. This higher temperature was necessary for flames with sodium iodide, a temperature of 400±10° C being used with the other halides. The reaction vessel consisted of a length of 34 mm o.d. quartz tubing having one end window at right angles to the length of the tube and two parallel side windows. In the present work photometric observations were made through the side windows. Active nitrogen from a microwave discharge was pumped through the reaction tube with a linear velocity of 1.2 m/sec at 3.0 mm Hg, the majority of the experiments being carried out at this pressure. Metal halides were carried from a small, independently heated oven by a stream of argon, and entered the reaction vessel through a 0.2 mm jet at the end of a 3 mm o.d. quartz tube. This jet could be moved over a range of 6 cm along the axis of the reaction vessel. Nitrogen atom flows were determined by visual titration with nitric oxide (12). Typical partial pressures of atomic nitrogen and metal halide were 0.05 mm and 0.0005 mm respectively.

Thallous halides were as used previously. The other halides were A.R. grade or else the best reagent grade available. The process of vacuum sublimation involved in producing a flame appeared to be sufficient to eliminate the effects of most impurities, especially since the greatest source of this kind of error would be

the presence in the reaction vessel of traces of halides from previous experiments. Prolonged cleaning of the vessel with 20% hydrofluoric acid was not sufficient to entirely free the walls of metals or metal halides. Measurements were carried out in an order which would minimize the effect of this contamination; for example TlF was studied before TlI, the intensity of emission at all wavelengths being greater for the latter. In every case the background intensity was measured with the argon flow cut off and a suitable correction applied.

Photometric measurements were carried out using a Hilger medium quartz spectrograph fitted with an E720 scanning unit and a 1P28 photomultiplier. The output of the photomultiplier was taken to a 0–250 μa meter through a cathode follower. The variation of photometer sensitivity with wavelength was determined from the response to a tungsten strip filament lamp of known temperature and emissivity (13).

RESULTS

The four thallous halides, lead (II) chloride, bromide, and iodide, cuprous iodide, and sodium iodide were studied. The spectral features observed were thallium lines at 5350, 3776, 3530, 3519, and 3230 Å, lead lines at 4058, 3683, and 3639 Å and visible bands of PbX, copper lines at 3247 and 3274 Å with visible bands of CuI, and sodium lines at 5890, 5896, and 3302 Å with the respective halides. Flames of this sort have often been used as sources of MX bands for spectroscopy (14). Flames of sodium and thallous halides were short and tended to be spherical at low halide flows. Those of the other halides were much more elongated and sometimes extended well beyond the heated portion of the flow system. This suggests that the reactions leading to consumption of the latter halides are comparatively slow, and perhaps proceed in stages. Dark-colored deposits, similar to those noticed previously with thallous halides, were formed in cool parts of the reaction system with all of the halides except sodium iodide, where a white deposit was formed. Hydrofluoric acid removed the metallic appearance of the deposits, leaving solids which were similar to the original halides and which could be removed with hot water.

The effect of variation of nitrogen atom concentration on the intensity of the emission lines is shown in Fig. 1. All of the observed lines vary in intensity as the square of the nitrogen atom concentration. The MX bands that appeared with halides of lead and copper were superimposed on some moderately intense afterglow emission; however it was noticed that the total intensity varied more slowly than $[N]^2$. Since the intensity of the afterglow alone is proportional to $[N]^2$ (8) this suggests that the MX-band intensity depends on a lower power of the nitrogen atom concentration.

For the measurements of Fig. 1 the power supplied to the discharge was varied, the atom concentration at each power level being determined by NO titration in absence of halide. The end point of the titration is difficult to locate at high temperatures, apparently because of reduced efficiency of the light-emitting reactions, so the calibrations of power level in terms of atom concentration were carried out near room temperature. The amount of nitric oxide required to extinguish the halide flame at the high temperature was invariably the same as that required to titrate the nitrogen atoms at the low temperature.

In order to determine the relative efficiencies of the various excitation processes the intensities of emission lines were measured for each flame under as nearly the same conditions as possible. Observations were made at 2 cm from the halide inlet jet and the intensities were corrected to the same partial pressures of halide and atomic nitrogen. The same argon flow (12.1 μmoles/sec), nitrogen flow (265 μmoles/sec), total pressure (3.0 mm Hg), and temperature ($400\pm10°$ C) were used in every case except that of sodium iodide where the temperature was 550° C.

The results of the intensity measurements, normalized to a value of 200 for the rate of production of Tl($7.^2S_{\frac{1}{2}}$) atoms from TlI, are given in Table II. On this scale the nominal upper limit for the rate of a termolecular reaction is unity and emission lines which have

relative intensities which exceed this by an order of magnitude are almost certainly excited by a different kind of process. Also listed in Table II are the excitation energies E of the emission lines (15) and the dissociation energies D of the halides (16, 17). For lead halides the energies for dissociation into atoms at 400° C were calculated from a thermodynamic cycle using data from Lewis, Randall, Pitzer, and Brewer (18). These dissociation energies will be slightly high because heats of fusion of the halides were neglected and heats of vaporization were calculated directly from vapor pressure data (19) without allowance for the possible presence of polymeric species in the vapor. The results are entered in Table II in order of increasing $D+E$.

DISCUSSION

The results in Table II show a steady trend with increasing value of the sum $(D+E)$, the only marked exception being found with cuprous iodide. It is well known that in this case the vapor contains a large proportion of dimer Cu_2I_2 and extrapolation of the vapor pressures of the two species (19) indicates that at 400° C the ratio of dimer to monomer is of the order of 100, which is sufficient to explain the low intensity.

The criterion that the intensity in Table II should be more than about 10 for a process to be too efficient to be accounted for by the termolecular mechanism [2] leads to an

3683 Å Pb	100	$PbCl_2$	175	275	0.16
4058 Å Pb	101	$PbCl_2$	175	276	0.34

NOTE: E = excitation energy of atomic line, D = dissociation energy of halide (at 0° K for all except lead halides, where they are calculated for 400° C; see text).

approximate lower limit for this mechanism at $D+E = 200$ kcal/mole. There is no theoretical reason to expect a lower limit for process [2]; however, it is still not possible to rule out mechanism [2] for $D+E$ greater than 200 kcal. This is not necessarily an upper limit for the bimolecular process [1], and there is nothing to imply that the same mechanism does not operate over the whole range of $D+E$ below 222 kcal/mole. Apart from the $^5\Sigma_g^+$ state the only metastable states of N_2 which might be present in appreciable concentrations and which could supply 200 kcal/mole are the a and a' states (Table I). With both of these states the available energy is on the low side, and a further point against them is that the $^5\Sigma_g^+$ state is probably required to be their precursor if they are to be formed from ground-state atoms. Unfortunately little is known about the relevant crossing probabilities, but the strength of the Lewis–Rayleigh afterglow suggests that most $^5\Sigma_g^+$ molecules prefer to cross into the B state. The observed quenching of the afterglow in the presence of metal halides also favors the choice of $^5\Sigma_g^+$ as the state of the excited N_2 in equation [1].

With lead halides the energy required for simultaneous dissociation and excitation of the emission lines is equal to or greater than 225 kcal/mole, which is the maximum which can be supplied by recombination of ground-state nitrogen atoms. Another kind of mechanism is therefore required. As mentioned in the introduction, a termolecular reaction of the halide with one ground state and one excited nitrogen atom would not be efficient enough to account for the observed intensities because of the small proportion of excited atoms in active nitrogen (3). It is also difficult to see how this mechanism could lead to a dependence of intensity on the square of the (ground-state) nitrogen atom concentration. In this respect the results of Fig. 1 were surprising because it had been anticipated that with lead halides the intensity would vary as some higher power of the atom concentration. The bimolecular mechanism [1] might explain the observations if the excited nitrogen molecule were in the predicted $^1\Sigma_g^+$ state, but here again it is difficult to see how a dependence on $[N]^2$ could arise. The only remaining possibility is that of excitation by consecutive energy transfer steps. This mechanism can lead to a dependence of intensity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

on $[N]^2$, as is shown below, taking lead chloride as an example. In this mechanism the

$$PbCl_2 + N_2^* \rightarrow PbCl^* + Cl + N_2 \quad [3]$$

$$PbCl^* + N_2^* \rightarrow Pb^* + Cl + N_2 \quad [4]$$

$$PbCl^* + N_2 \rightarrow PbCl + N_2 \quad [5]$$

$$PbCl^* \rightarrow PbCl + h\nu \quad [6]$$

$$PbCl + N_2^* \rightarrow Pb^* + Cl + N_2 \quad [7]$$

$$Pb^* \rightarrow Pb + h\nu' \quad [8]$$

part of N_2^* could equally well be taken by a pair of uncombined nitrogen atoms. Recombination of PbCl and Cl has been neglected because of the low halide partial pressure, while quenching of excited lead atoms should be negligible because of their short lifetime (ca. 10^{-8} sec). Halogen atoms are expected to be removed at the walls of the reaction vessel (20). At the steady state

$$[PbCl^*] = k_3[PbCl_2][N_2^*]/(k_4[N_2^*]+k_5(N_2]+k_6) \quad [9]$$

$$[PbCl] = (k_5[N_2]+k_6)[PbCl^*]/k_7[N_2^*] \quad [10]$$

$$[Pb^*] = k_3[PbCl_2][N_2^*]/k_8. \quad [11]$$

The intensity of PbCl emission bands is given by $k_6[PbCl^*]$. The observation that the intensity of these bands varies more slowly than $[N]^2$ suggests that $k_4[N_2^*]$ is comparable in magnitude with the other terms in the denominator of equation [9]. The total intensity of Pb lines is given by $k_8[Pb^*]$ and is equal to the rate of the primary process [3] when recombination and quenching of Pb* are not taken into account. It is probable that in the present experiments a completely stationary state was not reached in the short time spent by the reactants in the reaction vessel, since it was found that the Pb-line intensity increased steadily with increasing distance from the halide inlet jet.

A similar consecutive excitation mechanism for thallium halides is ruled out by the observation of finite spherical flames at low halide flows. Thallium nitride is unknown and thallium metal has been found as a reaction product (1), so from the fact that no Tl emission occurs in the region immediately following the flame, where both thallium and active nitrogen are certainly present, it follows that the efficiency of excitation of metallic thallium by active nitrogen under the conditions of the present experiments is very low. This conclusion was tested by mixing thallium vapor with active nitrogen in a simple reaction vessel which had a fixed inlet jet and a single end window and which was able to be taken to temperatures approaching 1000° C. At a cherry red heat (ca. 800° C) the vapor pressure of the metal is similar to that of thallous iodide at 400° C. The emission at 5350 Å with the metal at this temperature was less than 1% of that which was observed in a subsequent experiment with the iodide at 400° C. The behavior of lead should be similar to that of thallium in this respect, and in the mechanism just given no allowance is made for the possibility of excitation of lead atoms by N_2^*.

ACKNOWLEDGMENTS

The author is grateful to the New Zealand University Research Grants Committee for financial support and to Mr. C. G. Freeman for assistance with many of the measurements. In addition it is a pleasure to acknowledge the contribution of discussions and correspondence with Dr. A. N. Wright of McGill University to both this and the previous paper.

DETERMINATION OF α OR β SUBSTITUTION OF THE INDOLE NUCLEUS BY NUCLEAR MAGNETIC RESONANCE[1]

R. V. JARDINE AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received April 5, 1963

ABSTRACT

Marked differences in chemical shift of the signal for the α proton in indole and substituted indoles occur when spectra are obtained in non-polar and polar solvents. In contrast, using polar and non-polar solvents, only small differences are observed in the chemical shift of the signal for the β proton in indoles. The utility of the solvent effect on the chemical shift to distinguish between α and β substitution of the indole nucleus is pointed out.

INTRODUCTION

Witkop *et al.* (1) have shown that nuclear magnetic resonance can be used to determine substitution at the *alpha* or *beta* position of the indole nucleus. In carbon tetrachloride or deuterochloroform solution the signal for the α protons of indole, N-methylindole, skatole, and tryptamine was at the respective τ value (referred to the internal standard, tetramethylsilane) of 3.32 (triplet), 3.18 (doublet), 3.20 (poorly resolved doublet), and 3.08 (doublet). The β proton signal in indole, N-methylindole, and 2-methylindole was at a τ value of 3.62 (triplet), 3.52 (doublet), and 3.87 (broad single peak) respectively. Thus the β proton gave a signal at higher field than that found for the α proton, the difference in chemical shift for these two protons lying between 0.3 and 0.8 τ units. The signals for the α and β protons were quite clearly discernible, well separated, and at higher field than those for the remaining protons in the indole nucleus, except for the case of quebrachamine, whose signal for the α proton was buried in the more complicated absorption due to the aromatic ring protons in the region approximately between 2 and 3 τ.

We have had occasion to determine whether the α or β position of certain indole nuclei was substituted by groups other than alkyl, and hence turned to n.m.r. for assistance in this problem. When groups more electronegative than alkyl substituents were introduced into the α position, the signal for the remaining β proton, normally found well isolated at about 3.5 to 3.9 τ (1), occurred considerably farther downfield, at approximately 2.8 to 3.2 τ, in the region where the α proton absorption is shown to occur in indole and 3-alkylated indoles (3.08–3.32 τ). Hence, observation of a signal in this region is not conclusive proof that the β, rather than the α, position has been substituted.

Among the factors listed by Roberts (2) which affect the extent of chemical shift of protons is that due to solvent. It occurred to us that, because of the obvious difference in electron environment at the α and β protons, change in solvent from one of non-polar character to one of highly polar character might affect one of the protons (α or β) to a greater extent than it did the other. Hence solvent shift or lack of solvent shift might be used as a means to determine whether we were dealing with the α- or β-substituted indole nucleus.

Accordingly a number of indole derivatives were synthesized in which substitution at the α or β position was known. These, along with indole itself, were subjected to n.m.r. analyses on a 60 Mc Varian spectrometer using a variety of solvents. Tetramethylsilane

[1]*Taken from the thesis of R. V. Jardine to be submitted to the Faculty of Graduate Studies at the University of Alberta as part of the requirements for the degree of Doctor of Philosophy.*

was used as an internal standard and all values were expressed on the τ scale (3). To aid in determining the position of the α and β proton resonance signals, use was made of the fact that the doublet or multiplet, caused by spin–spin coupling between the proton on the nitrogen atom and the α or β proton, collapses to a singlet or to a simpler system when the >N—H is converted to >N—D (1). Where the complexity of signals for the aromatic protons interfered, the greater resolving power of the 100 Mc Varian spectrometer (HR-100) was found to be helpful in locating α or β proton resonance signals. The results of the analyses are shown in Table I.

RESULTS AND DISCUSSION

The signal for the β proton in either indole or 2-methylindole is quite well discernible in all the seven solvents employed. Its position, ranging from 3.52 τ to 3.71 τ ($\Delta\tau = 0.19$) for indole and 3.86 τ to 4.10 τ ($\Delta\tau = 0.24$) for 2-methylindole, lies well beyond and at higher field than the absorption peaks of the aromatic protons (2.0 τ to 3.0 τ). There is a slight downfield shift of the signal in polar solvents as compared with its position in non-polar solvents.

The signal for the α proton of indole is found between 2.70 and 3.46 τ, a range ($\Delta\tau$) of 0.76 τ units, whereas for 3-methylindole the signal is found between 2.94 and 3.65 τ, over a range ($\Delta\tau$) of 0.71 τ units.

It is clearly seen that the signal position of the α proton in the indole nucleus is influenced to a much greater extent by the nature of the solvent than is that of the β proton. In more polar or more basic solvents, the chemical shift of the α proton is sufficient to place it in the region assigned to the aromatic proton absorption. In some solvents (acetone, dimethylsulphoxide, dioxane, and triethylamine) the assignment of the signal for the α proton of indole was not certain and hence is tentative, as indicated by the values in parentheses in Table I. However, from the simplification of multiplets caused by the conversion of >N—H to >N—D, and with the aid of high-resolution spectra, it was quite definitely ascertained that the α proton signal must lie *below* certain τ values as indicated in the table. In only one solvent, acetone, was a similar ambiguity found for the signal position of the α proton in 3-*methyl*indole.

It is of interest to note that the methyl group in both 2- and 3-methylindole caused greater shielding of the β *and* α protons than that found for indole itself, as indicated by the shift to higher field of the signals for these protons in the alkylated indoles. This is apparent in both cases only when one *compares the spectra obtained in the same solvent.* Witkop *et al.* (1) have noted the greater shielding effect on the β proton in 2-methylindole caused by the introduction of the methyl substituent, but their data indicate that a similar increased shielding of the α proton is not found in 3-methylindole. In fact the α proton in *3-methylindole* was found to give a signal at 3.20 τ while the α proton of *indole* absorbed at 3.32 τ. However, their use of CCl_4 as solvent for indole but $CDCl_3$ for the methylindole accounts for this inconsistency. From our observations it is now clear that the more polar solvent, $CDCl_3$, will cause a significantly greater decrease in shielding for the α proton than for the β proton in indole and any increase in shielding due to the methyl substituent is not sufficient to compensate for the large downfield shift of the α proton signal due to the solvent effect.

Substitution of the α or β proton of indole by an electron-withdrawing group such as acetyl, carbonyl, carbethoxy, and benzoyl shifts the absorption of the remaining β or α

TABLE I

The effect of change of solvent on the position of the resonance signals for the α or β protons in β- or α-substituted indoles

proton as much as 0.7 to 1.2 τ units downfield from the corresponding position of the signals of indole itself. Here again one must compare spectra of compounds in the same solvent. A greater shift occurs for the α than for the β proton: The $\Delta\tau$ ranges from 0.95 to 1.2 for the α proton as compared with 0.7 to 1.1 for the β proton. Thus, for ethyl indole-3-carboxylate, the α proton signal in $CDCl_3$ is a doublet at 2.15 and 2.21 τ, while that of the α proton in 3-methylindole and indole in the same solvent occurs at 3.39 τ and 3.26 τ respectively. On the other hand, for ethyl indole-2-carboxylate, the β proton signal is found at 2.80 τ in dioxane solution while in the same solvent, the β proton signal for 2-methylindole and indole is at 3.88 τ and 3.52 τ respectively.

For compounds in which the β proton was replaced by either sulphur or halogen, the deshielding effect on the α proton due to these substituents was less than that found for the carbonyl compounds.

In dimethylsulphoxide, for the two compounds ethyl indole-3-carboxylate and 3-acetylindole it was noted that the normally expected doublet for the α proton, due to spin–spin coupling with the proton on the adjacent nitrogen atom, did *not* occur. Instead, a sharply defined singlet was observed at 1.88 τ and 1.66 τ respectively. Deuteration produced an unchanged singlet at the same position. The carboxylate exhibited the same phenomenon in triethylamine. The insolubility of the 3-acetylindole in triethylamine thwarted attempts to detect a similar observation. In other solvents (e.g. acetone and dioxane) doublets due to spin–spin coupling were clearly shown. When the spectral grade acetone solvent was treated with a small amount of water or dilute hydrochloric acid, 3-acetylindole still showed a doublet, unchanged; for the α proton. In reagent pyridine the spectrum of 3-acetylindole gave a closely spaced doublet at 1.75 τ which collapsed to a singlet when the compound was deuterated.

We have assigned the α proton absorption of 3-acetylindole to the doublet appearing at 1.80 and 1.83 τ on the basis of the collapse of this doublet to a singlet in the N-deuterated compound. Additional evidence to support the assignment was obtained from the fact that this signal disappeared completely when the α hydrogen was substituted by a methyl group.

From the data in Table I it is clear that the greater solvent dependence of the chemical shift of the α proton as compared with that of the β proton is a useful means of determining or corroborating α or β substitution in the indole nucleus. The limited solubility or the insolubility of the compounds in some of the solvents normally employed for n.m.r. spectra determinations restricts the utility somewhat. However, considering a *pair of solvents* such as acetone and dimethylsulphoxide, in which most of the compounds are soluble, the position of the β proton signal is nearly the same in either solvent, with a maximum difference of 0.03 τ. But for the α proton, a difference in signal position of 0.08 to 0.17 τ occurs. A larger difference in the chemical shift for the α proton is found when one compares signal position in a non-polar or slightly polar solvent ($CDCl_3$) and highly polar solvent (acetone or dimethylsulphoxide).

It is of interest to note that the signal position for the proton attached to the nitrogen atom of the indole ring is influenced even more strongly by the solvent employed than is the α proton. Table II summarizes the information obtained.

Where the signals are clearly discernible they are found generally to be broad, but less so in dimethylsulphoxide.

In non-polar, or relatively non-polar solvents (CCl_4, $CDCl_3$, CS_2), the N—H signals of indole and alkylated indoles are buried in the complex absorption due to the aromatic protons, roughly in the region 2.9 to 3.1 τ. Approximate locations of the signal are given

TABLE II

The effect of solvent on the position of the resonance signal for the proton on the nitrogen atom of indole and substituted indoles

	Position of the signal for the N—H proton in the solvents (τ)						
	CCl_4	$CDCl_3$	Acetone	Dimethyl sulphoxide	Dioxane	CS_2	$(C_2H_5)_3N$
Indole	(3.0)	(2.9)	0.00	−1.01	+0.48	(3.1)	−0.08
2-Methylindole	(3.1)	(3.0)	+0.33	−0.82	+0.84	(3.1)	+0.08
3-Methylindole	(3.1)	(2.9)	+0.48	−0.69	+0.91	(3.1)	−0.59
Ethyl indole-2-carboxylate	Insol.	+0.44	−0.79	−1.87	−0.51	Insol.	?
3-Bromoindole	Insol.	(2.8)	−0.61	−1.46	+0.22	(2.9)	−1.01
β,β′-Diindolyldisulphide	Insol.	Insol.	−0.46	−1.54	+0.13	Insol.	Insol.
3-Benzoylindole	Insol.	Insol.	Insol.	−2.00	Insol.	Insol.	Insol.
2-Benzoylindole	Insol.	+0.08	−1.06	?	?	?	?
3-Acetylindole	Insol.	Insol.	Insol.	−1.92	Insol.	Insol.	Insol.
3-Acetyl-2-methylindole	—	—	—	−1.8	—	—	—

NOTE: Figures in parentheses are approximate locations of the signals. The term "insol." means that the compound was either insoluble or insufficiently soluble for satisfactory n.m.r. analysis. A question mark indicates that the signal for the N—H proton could not be detected.

by the figure in parentheses, and are obtained from the decrease in integrated areas for the N-deuterated compounds. The disappearance of the signal upon N-methylation, in the case of indole, supports the assignment of this signal to the N—H proton. Electronegative substituents in the α or β positions cause a pronounced downfield shift also.

Polar solvents and those which associate with the indole compound (i.e. ethers) cause a larger chemical shift to lower field in the order dimethylsulphoxide > triethylamine > acetone > dioxane.

EXPERIMENTAL

Nuclear magnetic resonance spectra were obtained at a temperature of 40° using a Varian A-60 spectrometer. Wherever possible the concentration employed was that obtained by dissolving 100 mg of the substance in 0.35 to 0.40 ml of spectral grade solvent. In a few cases (diindolyl disulphide in dioxane, indole-2-carboxylic acid in dioxane, 3-acetylindole in actone, and ethyl indole-2-carboxylate in $CDCl_3$ and in $(C_2H_5)_3N$) saturated solutions were used unavoidably. High-resolution spectra, using a Varian HR-100 spectrometer, were obtained at 29.2° with solutions containing 20 mg of solute in 0.40 ml of the respective solvent.

Deuteration

General Procedure

The following general procedure was employed in all deuterations. About 120 mg of the indole compound was dissolved in 8 ml of reagent acetone and then 2 ml of D_2O (99.7%) was added. The resulting solution was freed of solvent in a rotary evaporator under vacuum. This treatment was repeated two or three times. Final drying was carried out in a desiccator over P_2O_5. Care was taken to protect the solutions from direct light.

The extent of deuteration was determined by infrared spectrometry and by n.m.r. Disappearance of the >N—H peak between 3100 and 3500 cm^{-1} in the infrared and the appearance of a new peak due to >N—D at a frequency of about 0.75 of that of the >N—H stretching gave a measure of the amount of deuteration. N-Deuteration was more rapid for the indoles containing electronegative substituents in the α or β positions. For indole and 2-substituted indoles, considerable deuteration occurred at the β position, as detected by the lower integrated area for β proton signal in the N-deuterated compounds.

*De*deuteration, both at the nitrogen atom and at the β carbon, occurred readily when the compounds were dissolved in 95% ethanol and the solvent evaporated.

N-Deutero-3-bromoindole.—Since 3-bromoindole (5) decomposes spontaneously when its solution is completely freed of solvent, the following procedure was employed. A quantity of 3-bromoindole (4) (5.0 g, 0.025 mole) was treated with 2 ml of D_2O (99.7%). The solution was concentrated at room temperature under vacuum by rotary evaporator almost to dryness, then acetone and D_2O added again and the process repeated. The concentrated solution now was poured into 100 ml of *n*-heptane to which 5 g of anhydrous

magnesium sulphate was then added. After addition of decolorizing charcoal, the mixture was stirred vigorously and heated to the boiling point. As long as the 3-bromoindole was *in solution* it could be heated above its normal decomposition temperature (67°) with no ill effect. The boiling solution was quickly filtered into a *cooled* receiver. Cooling is essential since 3-bromoindole deposited at a temperature close to or above its decomposition point will spontaneously decompose. The N-deutero-3-bromoindole crystallized as plates in a yield of 80%, melting at 65–66° (decomp.).

N,β-Dideuteroindole.—A solution of indole (11.7 g, 0.1 mole) in ether (50 ml) was added slowly to an ether solution of 0.2 mole of ethyl magnesium iodide (from 4.8 g, 0.2 mole, of magnesium and 31.2 g, 0.2 mole, of ethyl iodide in 250 ml of ether). When reaction was complete the solution, protected from moisture, was cooled to 0° and then stirred rapidly while 10 ml of D_2O (99.7%) in 50 ml of anhydrous tetrahydrofuran was added dropwise. When addition was complete, the solution was refluxed overnight. The cooled mixture was then filtered rapidly to minimize admission of water since this causes rapid *de*deuteration. The solvent was then removed completely by rotary evaporator under vacuum. Sufficient hot *n*-heptane was then added to dissolve the indole which had precipitated. The resulting clear solution was dried ($MgSO_4$) and filtered. When the solution was cooled and allowed to stand overnight the dideuteroindole separated. The solid was quickly isolated by filtration, and dried under nitrogen in a desiccator. Yield, 6 g (51%). The n.m.r. analysis indicated that the β position was deuterated approximately to the extent of 50%. Infrared analysis showed that the nitrogen atom was deuterated approximately to the extent of 50%.

2-Benzoylindole

Thionyl chloride (22 ml) was slowly added to 12.3 g (0.075 mole) of solid, powdered indole-2-carboxylic acid (6). When the initial vigorous reaction had subsided, the mixture was heated for 20 minutes on a steam bath. Excess thionyl chloride was removed under vacuum. The solid product was taken up in 50 ml of dioxane and the solution then slowly added to 50 g (0.19 mole) of diphenyl cadmium (7) dissolved in 300 ml of benzene. The reaction mixture was then heated under reflux for 12 hours. The cooled solution was poured slowly, with stirring, onto 2 kg of ice, while sufficient acetic acid was added to maintain approximately a pH of 7 (hydrion paper). The benzene layer was separated and treated with ether to precipitate the 2-benzoylindole. The crude precipitate was extracted with pentane for 24 hours in a Soxhlet apparatus. The pentane extract was freed from solvent and the residue crystallized from a mixture of ethanol and water. There was obtained 5.4 g (32%) of colorless needles melting at 146–148°. The infrared spectrum in $CHCl_3$ showed N—H stretching at 3452 cm^{-1}, bonded N—H at 3325 cm^{-1}, and carbonyl stretching at 1625 cm^{-1}.

Anal. Calculated for $C_{15}H_{11}NO$: C, 81.45; H, 4.88; N, 6.33; O, 7.24. Found: C, 81.19; H, 5.37; N, 6.36; O, 7.21.

3-Acetyl-2-methylindole

The procedure for the preparation of this compound as described in the literature (8) failed to give satisfactory results. Accordingly the following method was devised. A solution of 4 g (0.033 mole) of 2-methylindole (9) in ether was added slowly to ethyl magnesium iodide (from 1.6 g, 0.067 mole, of magnesium metal and 9.6 g, 0.065 mole, of ethyl iodide) in 100 ml of ether. When addition was complete, the resulting solution was cooled to 0° and then 2.6 g (0.033 mole) of acetyl chloride in 10 ml of ether was added dropwise so that the temperature of the mixture remained below 5°. Then the mixture, continually stirred, was allowed to come to room temperature overnight. The contents of the reaction vessel was poured onto ice (200 g) along with sufficient acetic acid to react with the magnesium hydroxide produced. The precipitated 3-acetyl-2-methylindole was removed by filtration and crystallized from aqueous ethanol to yield 3.2 g (56.5%) of pure product melting sharply at 204° (lit., 195–196° (8)). An n.m.r. spectrum in dimethylformamide indicated acetyl methyl at 7.44 τ, α-methyl buried in the signal due to solvent at about 7.08 τ, and a broad signal at −2.24 τ due to N—H. In pyridine the respective τ values for acetyl methyl and α-methyl were clearly separated and discernible at 7.34, 7.22. Infrared spectra in halo oil showed N—H stretching at 3082 cm^{-1}, and carbonyl absorption at 1605 cm^{-1}.

Ethyl Indole-2-carboxylate

A solution of indole-2-carboxylic acid (5.0 g, 0.31 mole) (6) in 50 ml of anhydrous ethyl alcohol, saturated with anhydrous hydrogen chloride, was allowed to stand overnight. The mixture was poured into water and made slightly basic with dilute caustic soda. The cold, basified solution was twice extracted with 100-ml portions of ether. Removal of the ether and crystallization of the residue from aqueous ethanol gave long needles melting at 125°. Lit., 125–126° (10). Yield, 74.5%. Infrared spectra in nujol showed N—H stretching at 3310 cm^{-1} and carbonyl absorption at 1685 cm^{-1}.

THE SULPHUR–OXYGEN BOND IN SULPHURYL AND THIONYL COMPOUNDS: CORRELATION OF STRETCHING FREQUENCIES AND FORCE CONSTANTS WITH BOND LENGTHS, BOND ANGLES, AND BOND ORDERS

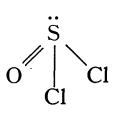
ABSTRACT

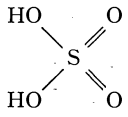
It is shown that the bond length of an SO bond and the bond angle of an SO_2 group may be very satisfactorily correlated with the SO stretching frequency. The bond-length – stretching-frequency relationship is used to predict some bond lengths that have not been measured and the OSO angles in some sulphuryl compounds are also calculated. The problem of defining and measuring the bond order of sulphur–oxygen bonds is discussed. It is shown that there is a linear relationship between the force constant and the bond order and a non-linear relationship between the bond length and the bond order.

INTRODUCTION

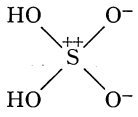
The nature of the SO bond in $XYSO_2$ and XYSO molecules has long been a subject of controversy. Classically the structures of molecules such as $SOCl_2$ and H_2SO_4 were written with double bonds between sulphur and oxygen (I and II). In order to make the electronic



I



II



III

configuration of sulphur in these compounds conform to his octet rule Lewis (1) suggested that they should be written with single bonds only (III). Such structures were accepted for many years and, indeed, are still widely used.

However the bond lengths of SO bonds (2) and the angle in the SO_2 group (3) provide strong support for the double-bond structures. By analogy with the familiar σ–π description of multiple bonds between carbon atoms, double bonding in SO bonds has been described in terms of π-bonds formed between oxygen $2p$ orbitals and $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals on sulphur (4–8). Recently Cruickshank (9) has given a detailed discussion of this type of description of the sulphur–oxygen double bond.

We expect that SO bonds will in general be intermediate between IV and V. The former is meant to indicate two completely covalent bonds in which both electron pairs forming

IV

V

the bond are equally shared and hence neither atom has any resultant charge. This would necessitate that the other atoms attached to sulphur had electronegativities sufficiently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

great to raise the effective electronegativity of sulphur to that of oxygen. This situation is probably approached in SO_2F_2 and SOF_4. With decreasing electronegativity of the attached groups the double bond becomes polar and the electron pairs are no longer shared equally between the S and O atoms. If a double bond is described in terms of σ- and π-components it is generally assumed for C=C and C=O bonds that the π-bond is more polarizable than the σ-bond. It seems reasonable to assume that this is also the case for SO bonds and that therefore the greater part of the polarity may be ascribed to the π-bond (5). There will, of course, be an accompanying but smaller change in the polarity of the σ-bond; we assume that to a first approximation this does not vary independently of the bond order. In the limiting case, where the π-bond electron pair resides essentially wholly in a p-orbital on oxygen, structure V is obtained. If we define the bond order simply as the average number of electron pairs available per bond IV has a bond order of two and V has a bond order of unity. Evidently the situation in real molecules may be reasonably well described as being intermediate between IV and V and the bond order increases while the bond polarity simultaneously decreases with increasing electronegativity of the ligands.

Cruickshank (9) assumes that whenever oxygen ligands are attached to sulphur both the $3d_{z^2}$ and the $3d_{x^2-y^2}$ orbitals of sulphur are fully utilized in double bonding and thus he ascribes bond orders of 1.5 to the sulphate ion and 2.0 to $XYSO_2$ compounds in general. He further assumes that there is a linear relationship between bond length and bond order determined by the single bond length of 1.69 Å deduced from the Schomaker–Stevenson equation (10) and the observed length of 1.49 Å for the sulphate ion. However, there is no theoretical justification for the Schomaker–Stevenson rule or for the linear relationship between bond length and bond order, which in any case seems unlikely, since for carbon–carbon bonds, for example, this relationship is certainly non-linear (11). Cruickshank's linear relationship predicts an improbably short bond length of 1.30 Å for a bond order of 2.0. The observed length of 1.43 Å for dimethyl sulphone (12) implies a very low bond order and is ascribed by Cruickshank to "the smaller electronegativity of the group R than of oxygen, and to the asymmetry of the σ-bonding about sulphur so that the effective nuclear charge, $Z_{eff}(3d)$, for the $3d$ orbitals is lowered with loss of bonding strength". However, this cannot be the case for SO_2F_2, where the bond length is 1.405 Å (13) and the bond order of the SO bond order must surely be close to 2.0. This is confirmed by the arguments given in this paper and it is also shown that the bond-order – bond-length relationship is very probably not linear.

It is the purpose of this paper to present the experimental evidence for some definite correlations between the various different properties of SO bonds. On the basis of the correlations an attempt is made to estimate SO bond orders.

CORRELATION OF STRETCHING FREQUENCIES WITH BOND LENGTHS AND BOND ANGLES

Recently one of us showed (14) that the linear correlation between the symmetric and asymmetric stretching frequencies of the sulphuryl group that was first demonstrated by Bellamy and Williams (15) is valid for a large number of sulphuryl compounds and that it also applies to the anions XSO_3^- and SO_4^{2-}. It was noted that the frequencies of these stretching vibrations increase with increasing electronegativity of the groups X and Y in the sulphones. Thus the highest observed frequencies (1270 and 1502 cm^{-1}) are found for SO_2F_2 while the lowest (980 and 1104 cm^{-1}) are those of the sulphate ion. Similarly in the case of the sulphoxides X_2SO the highest SO stretching frequency is observed for SOF_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(1308 cm^{-1}). In the case of SOF_4 (16) the SO stretching frequency of 1379 cm^{-1} is higher than that in SOF_2, which is consistent with the presence of two additional highly electronegative ligands. Since increasing the electronegativity of the groups X and Y should increase the order of the SO bond, it seems reasonable to assume that there is a correlation between the bond order and stretching frequency and to suppose that the stretching frequency may be used as a measure of the bond order. Thus SO_2F_2 has the highest bond order and the SO_4^{2-} ion the lowest bond order of the sulphuryl compounds considered. The bond orders for molecules with intermediate frequencies must lie between these limits.

In order to find SO bonds with orders smaller than that of the sulphate ion it is necessary to consider molecules which have formally single bonds between sulphur and oxygen, such as the RO—S bonds in sulphates of the type $(RO)_2SO_2$. However, in such cases the mass of the R group will in general introduce the complication that it will not be possible to make a satisfactory assignment of an observed vibrational frequency to the S—O bond alone, and if this is attempted as Simon and Kriegsmann have done (17) the observed frequency will depend on the mass of R. However, there is one case where the mass of R is unimportant, namely when R is hydrogen, and it is reasonable to suppose that the small increase in mass produced by the hydrogen atom has a relatively unimportant effect on the frequency compared with changes in the SO bond order. Some confirmation of this supposition is provided by the fact that the $S(OH)_2$ symmetric and asymmetric stretching frequencies (910 and 976 cm^{-1}) for H_2SO_4 (18) fit the straight-line correlation previously established for the SO_2 symmetric and asymmetric stretching frequencies. These frequencies indicate that the order of these bonds is lower than that of the S—O bonds in the sulphate ion.

It is interesting to note that although the S—O bond in a sulphoxide could be formally regarded as a triple bond formed by the use of both the $d_{x^2-y^2}$ and d_{z^2} sulphur orbitals the vibrational frequencies 1308 cm^{-1} and 1109 cm^{-1} for dimethyl sulphoxide show that the bond order is somewhat less than that in the sulphuryl compounds with the same ligands. This may be ascribed to an effect of the lone pair of electrons on sulphur in reducing its electronegativity.

Since the lengths of SO bonds are presumably also related to their bond order there would be expected to be a correlation of bond length with stretching frequency. That such a correlation does indeed exist was first demonstrated by Barnard, Fabian, and Koch (19), who showed that for seven compounds there is a general increase of stretching frequency with decrease of bond length. We have found that the correlation can be extended to include many more compounds, including both neutral molecules and ions, and S—OH as well as S—O frequencies. For sulphuryl compounds Barnard, Fabian, and Koch (19) used the mean of the symmetric and asymmetric stretching frequencies as a measure of the frequency that the SO vibration would have in the absence of coupling between the two SO bonds. A similar procedure has been used by Simon and Kriegsmann (17) in their discussion of the force constants of sulphuryl compounds. Barnard, Fabian, and Koch justified the approximation by showing that for the sulphur dioxide molecule a bond stretching force constant of 9.86×10^5 dynes cm^{-1} is obtained on the basis of this method while a value of 9.97×10^5 dynes cm^{-1} is obtained by rigorous methods (20). Lehmann (21) has recently pointed out that the assumption of a simple valence-force field leads to the result that for a linear AB_2 molecule the stretching frequency of the AB group is the root mean square of the symmetric and asymmetric stretching frequencies. For most purposes the arithmetic mean is a good approximation for the root mean square. Lehmann has shown that this "average rule" is also a good approximation for the A—B stretching

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

frequency of an angular AB_2 group if the bending force constant is small, if the symmetric stretching frequency is appreciably larger than the bending frequency, and if the coupling of the AB_2 group with the rest of the molecule is small. Lehmann also shows that for an AB_x group where the asymmetric stretch has a degeneracy $(x-1)$ the average rule becomes

$$[1] \qquad \nu_{AB} = (1/x)[\nu_{sym}+(x-1)\nu_{asym}].$$

The "average rule" has also been shown by Bernstein to be a very good approximation in the special case of X—H bonds (22). SO stretching frequencies ν_{SO} were obtained from the experimental data by means of equation [1].

The available data which is collected in Table I and Fig. 1 shows that there is a reasonably good correlation between bond length and stretching frequency. The frequencies are

in general more accurate than the bond lengths and the scatter of the points is in most cases not greater than ±0.02 Å, which is approximately the experimental error in many of the bond-length determinations. The SO bond length given for the sulphite ion is evidently incorrect and would merit reinvestigation. The SO bond length in sulphamide is probably also somewhat in error. It is possible to use this stretching-frequency – bond-length correlation to predict SO bond lengths in molecules where these have not been measured, to a probable accuracy of ±0.02 Å. Some examples are given in Table II.

With increasing bond order the electron density in the SO bonds increases, hence the repulsion between the SO bonds in the SO_2 group will increase and the bond angle should increase accordingly (23). Although the data available on bond angles (Table III) is

[1]$S(OH)_2$ group.

rather scanty and not always very accurate Fig. 2 shows that there does appear to be an approximately linear correlation between the bond angle and the SO stretching frequency.

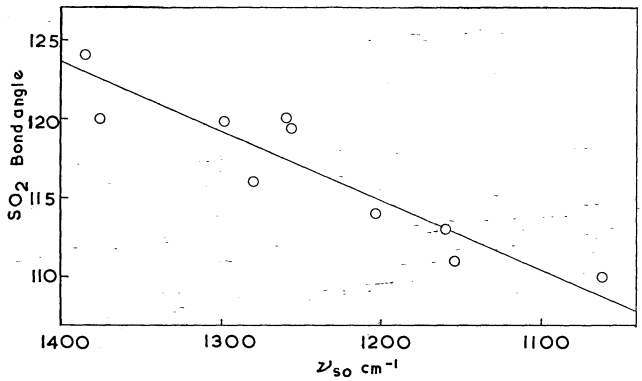

FIG. 2. Correlation of SO stretching frequencies with bond angles.

By making use of the approximations involved in Lehmann's "average rule", namely that the bending force constant, d, is much smaller than the stretching force constant, k, and that the symmetric stretching frequency is appreciably larger than the bending frequency the following relation between the bond angle 2α and the SO stretching frequencies can be obtained for SO_2 groups:

$$[2] \qquad \nu_{sym}/\nu_{asym} = [(1 + \cos^2 \alpha)/(1 + \sin^2 \alpha)]^{\frac{1}{2}}.$$

A comparison is made in Table III of bond angles predicted in this way from the stretching frequencies and the experimentally determined values. The agreement is rather better than might have been expected in view of the approximations involved. Table II gives some predicted OSO bond angles in some species where this angle has not been measured, obtained both by interpolation from Fig. 2 and from equation [2].

FORCE CONSTANTS

Reasonably rigorous calculations of force constant have been made for only a few of the molecules we are considering (24, 25, 26), and in many cases they cannot be made at present because complete assignments have not been given for the vibrational spectra and the bond angles and bond lengths have not been measured. However, if it is assumed that there is negligible coupling between the vibrations of the SO_2 or SO group and the other vibrations of the molecule then an approximate value for the force constant of the SO bond may be obtained by treating the SO group as a simple diatomic molecule and the SO_2 group as a simple triatomic molecule. An SO_2 group can also be treated as a diatomic SO group if the appropriate SO stretching frequency is first calculated using Lehmann's average rule (17). Hence we have

$$[3] \qquad k_{SO} = \frac{5.889\nu_{SO}^2 \times 10^{-2}}{(1/m_S + 1/m_O)} = 0.6282\nu_{SO}^2,$$

where m_S and m_O are the atomic weights of sulphur and oxygen, respectively. Values of the stretching force constants obtained from equation [3] and those of other workers are shown in Table IV. The general agreement between our approximate force constants and

the limited number of more precise values provides some justification for our use of these approximate force constants.

Figure 3 shows that there is a linear relationship between log k_{SO} and log r_{SO}, where k_{SO} and r_{SO} are the stretching force constant and bond length, respectively, which may

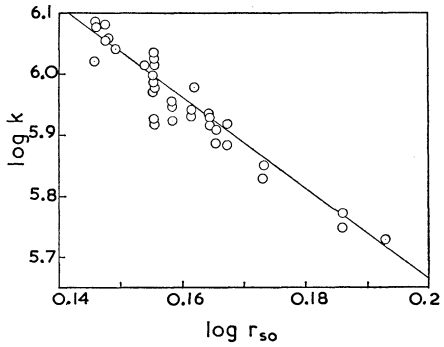

FIG. 3. Linear relation between log k and log r_{SO}.

be expressed by the equation

[4] $$\log k_{SO} = -7.41 \log r_{SO} + 7.15$$

or

$$k_{SO} r_{SO}^{7.4} = 1.41 \times 10^7,$$

where r_{SO} is in angstroms and k_{SO} in dynes cm^{-1}. This relation is of the general form

$$kr^n = C$$

which was suggested by Linnett (27) as being the best general relation between force constant and bond length. This is a modified form of the relation $kr^6 = C$ originally proposed by Douglas-Clark (28).

If we substitute for k_{SO} in terms of ν_{SO} in equation [2] we obtain the expression

[5] $$\log \nu_{SO} = -3.7 \log r_{SO} + 3.68$$

or

$$\nu_{SO} r_{SO}^{3.7} = 4.79 \times 10^3.$$

The line determined by this equation is shown in Fig. 1.

BOND ORDERS

In order to determine the relationship between the bond properties we have been discussing and bond orders it is necessary to know the bond orders in at least two and preferably several molecules containing SO bonds. An apparently obvious method would be to calculate the lengths of SO single and double bonds from tables of covalent radii. For the SO single bond Pauling's covalent radii (29, p. 224) give a value of 1.70 Å while the Schomaker–Stevenson rule (10) gives 1.69 Å. For a double bond Pauling's covalent radii give 1.49 Å and the Schomaker–Stevenson rule 1.47 Å. In fact no compound is known in which the S—O bond is as long as the predicted single-bond values. The longest bonds that have been found are 1.66 Å in SF_5OOSF_5 (30); 1.645 Å for the SOS bridge bonds in the $S_2O_7^{--}$ ion (32), and 1.64 Å in SF_5OF (31) and the bridge bonds in $HS_2O_7^-$ (33) and SO_3 polymer (34). It is reasonable that the longest SO bonds are formed in these molecules

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

since the sulphur 3*d* orbitals normally used for double bonding with oxygen are largely used up in forming single bonds to fluorine or double bonds to other oxygen atoms. However, even for these long SO bonds there is evidence that there is a small amount of delocalization of oxygen lone-pair electrons into the partially available $3d_{x^2-y^2}$ or $3d_{z^2}$ orbitals or possibly into the other *d* orbitals which form considerably weaker π-bonds (9, 35). Hence these bonds may be expected to be slightly shorter than a true single bond, and it seems reasonable to take the value of 1.70 Å as the bond length of an SO single bond. The predicted double bond lengths are, however, much less satisfactory since many SO bonds are known with lengths shorter than either of the above values and there is no reason to assume that the bond orders are considerably greater than two. It can only be concluded that either the double-bond radii are incorrect or that the simple additivity rule and the Schomaker–Stevenson rule are invalid for the SO double bond. The Pauling single-bond radii are reasonably satisfactory as they are derived from a large number of experimental determinations of bond lengths but the values of the double-bond radii are based on many fewer experimental data and the additivity relationship has not been so well tested. Hence these double-bond radii may not be correct. The shortest observed SO bond lengths* are 1.405 Å in SO_2F_2 (12), 1.412 Å in SOF_2 (36), and 1.40 Å in S_3O_9 (33). These short SO bonds are also the strongest as measured by the stretching frequencies and force constants and it seems reasonable to make the assumption that they have an order of two. In view of the high electronegativity of fluorine it is unlikely that bonds of a higher order than those in SO_2F_2 and SOF_4 will be found. Unfortunately the bond length in SOF_4 is not known but the SO stretching frequency in this molecule is very close to that in SO_2F_2, suggesting that the bond length will be close to 1.40 Å. Since replacement of an oxygen in SO_2F_2 by two fluorines in SOF_4 fails to raise the value of SO stretching frequency we assume that in both of these molecules the effective electronegativity of sulphur is large enough to achieve essentially complete double-bond formation. Extrapolation of the log k – log r and ν_{SO}–r plots in Figs. 3 and 1 then gives $\nu = 655$ cm^{-1} and $k = 2.7\times10$ dynes cm^{-1} for a single bond and $\nu = 1385$ cm^{-1} and $k = 11.7$ dynes cm^{-1} for a double bond.

In order to determine the form of the relationship between force constant and bond order it is necessary to have at least one and preferably several additional pairs of force-constant and bond-order values. Assuming that fluorine substituents on sulphur cause the SO bond order to achieve its maximum value of 2.0, as in SOF_2 and SOF_4, it seems reasonable to assume that in the fluorosulphate ion, FSO_3^-, the bond order of the SO bonds has the maximum possible value of 1.67. In the case of anions of the general formula XSO_3^- the SO stretching frequencies are all close to the SO stretching frequency of FSO_3^-. Hence the bond orders in anions of the type XSO_3^- are all very close to the maximum theoretical value of 1.67, suggesting that the group X has a much smaller effect on the SO stretching frequency than in $XYSO_2$ compounds. This may be attributed to the effect of the negative charge. Using the force constant for FSO_3^- and a bond order of 1.67 together with the values for SO single and double bonds given above it may be seen in Fig. 4 that they exhibit a linear relationship. It is interesting to note that the force-constant – bond-order relationship is also linear for C—C single, double, and triple bonds (39). Some confirmation of this linear relationship for SO bonds is provided by the force constant for the SO_4^{2-} ion, which, if a bond order of 1.5 is assumed, fits the straight line relationship well. Because of the high negative charge of the sulphate ion we consider that the electronegativities of

**Although equally short bonds are also reported for $SO_2(NH_2)_2$ (37) and SO_3^{2-} (38) these are quite inconsistent with the other properties of these bonds and they must be considered to be of doubtful accuracy.*

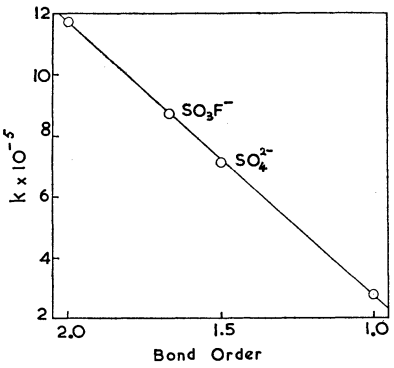

FIG. 4. Linear relation between bond order and force constant.

the groups attached to sulphur will be even less important in determining the bond order than was found to be the case for the anions XSO_3^- and thus the bond order of 1.5 is reasonable for the sulphate ion. The straight line in Fig. 4 is determined by the equation

$$n = 1.11\times10^{-6}k+0.7, \qquad [6]$$

where n is the bond order.

This equation may now be used in conjunction with equation [4] to obtain the relationship between bond length and bond order:

$$n_{SO} = \frac{15.65}{r_{SO}^{7.4}}+0.7. \qquad [7]$$

This curve is plotted in Fig. 5 and is not a straight line as Cruickshank assumed (9), but has a shape similar to the corresponding curve for C—C bonds (11).

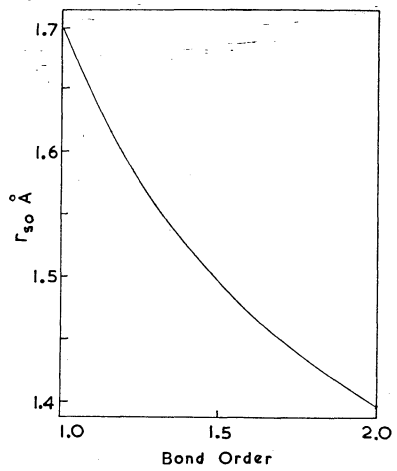

FIG. 5. Bond-length – bond-order relationship.

Pauling and Coulson (29, p. 236; 40) have deduced the following general expression for the length r_n of a bond of order n intermediate between a single and double bond, where r_1

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[8] $$r_n = r_1 - \frac{r_1 - r_2}{1 + \left(\frac{2-n}{n-1}\right)\frac{k_1}{k_2}}.$$

and r_2 are the single and double bond lengths and k_1 and k_2 the corresponding force constants. On the basis of the SO single- and double-bond distances and the bond length in the sulphate ion ($n = 1.5; r = 1.49$ Å), equation [8] becomes

[9] $$r_n = 1.70 - \frac{0.30}{1+0.46\left(\frac{2-n}{n-1}\right)}$$

for SO bonds. Bond lengths calculated from both equations [7] and [9] agree exactly to two decimal places. This would appear to lend some support to our choice of single- and double-bond lengths given above.

Bond orders interpolated from Fig. 4 for most of the compounds for which data is available are given in Table IV.

REACTIONS OF PHENYL-SUBSTITUTED HETEROCYCLIC COMPOUNDS

III. FREE-RADICAL PHENYLATION OF 1-PHENYLPYRAZOLE[1]

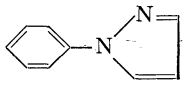
Received January 29, 1963

ABSTRACT

Phenyl radicals furnished by benzoyl peroxide attack both rings of 1-phenylpyrazole, and the orientation of substitution has been examined using gas–liquid partition chromatography. Substitution occurs at all positions of the phenyl ring, although predominantly at the ortho positions, while attack in the pyrazole ring is confined to the 3-position. The results are in agreement with the suggestion that the *free valence* at a given position is a major factor in determining the orientation of free-radical phenylation of 1-phenylpyrazole, but in conflict with predictions from resonance theory.

In earlier papers of this series (1, 2), we have examined some electrophilic substitutions of N-phenylazoles. The present work is concerned with the attack of free radicals on 1-phenylpyrazole (I), where the phenyl and benzoate radicals liberated by benzoyl peroxide



I

effect nuclear substitution. Reactions were carried out by allowing benzoyl peroxide to decompose in 20% solution in 1-phenylpyrazole at 80° C, and the products were separated and isolated using standard procedures (3, 4). The yields obtained in the various experiments are listed in Table I.

1-Phenylpyrazole behaves typically towards benzoyl peroxide, in that the predominant reaction paths are the nuclear phenylation and benzoyloxylation reactions, i.e.,

$$(Ph\cdot CO_2)_2 + X\cdot H \begin{cases} Ph\cdot CO_2H + CO_2 + Ph\cdot X \\ Ph\cdot CO_2H + Ph\cdot CO_2\cdot X \end{cases} \qquad (X = C_9H_7N_2)$$

Since the molar yields of free benzoic acid are appreciably higher than the combined yields of substitution products, it is possible that some direct N-oxidation of 1-phenylpyrazole by benzoyl peroxide occurs (compare the pyridine – benzoyl peroxide system (5)).

The distribution of products is fairly similar to that observed in the reactions of benzoyl peroxide with biphenyl (6), although the benzoyloxylation:phenylation ratio (an index of reactivity towards radical attack (3)) is somewhat higher for 1-phenylpyrazole.

‡Calculated as hydroxy-1-phenylpyrazoles.

Phenylations are usually unselective processes (for reviews listing isomer ratios, see Augood and Williams (7) and Williams (8)), and we expected that each of the six possible phenylated 1-phenylpyrazoles would be present in the reaction products. Consequently, authentic samples of each isomer were prepared as follows: 1,3- and 1,5-diphenylpyrazoles by previously reported cyclizations (9, 10); and 1,4-diphenylpyrazole, 1-*o*-, 1-*m*-, and 1-*p*-biphenylylpyrazoles from the appropriate nitro-1-phenylpyrazoles (by reduction, diazotization, and Gomberg arylation (cf. Khan *et al.* (2))). The latter two biphenylylpyrazoles were also synthesized using the standard cyclization of the appropriate substituted hydrazine and 1,1,3,3-tetramethoxypropane (11). Attempted cyclization using *o*-hydrazinobiphenyl gave carbazole and biphenyl, with no evidence for the formation of 1-*o*-biphenylylpyrazole: this reaction, which is reminiscent of a Fischer indole cyclization, is under further study.

The mixtures of phenylation products from the various experiments were examined by gas–liquid partition chromatography, and the presence of 1,3-diphenylpyrazole and the three 1-biphenylylpyrazoles was established by comparison of the retention times observed for the components of the reaction mixtures with those of authentic samples of the various isomers. The ratios of these isomers in the phenylation products were evaluated by direct comparison of the peak areas found for the various isomers, after it was established that the response of the detector to corresponding quantities of each of the isomers was identical. The results are shown in Table II. The infrared spectra of the phenylation products isolated from the various experiments were consistent with the results from the gas–liquid partition chromatography, as bands diagnostic of each of the three 1-biphenylylpyrazoles and 1,3-diphenylpyrazole were observed, while absorption was absent at frequencies noted in the spectra of authentic samples of 1,4- and 1,5-diphenylpyrazoles.

Unusual features of the isomer distribution are the marked preference for ortho substitution in the phenyl ring, the apparently selective attack of the 3-position in the pyrazole ring, and the consequence that the total phenylation is greater in the phenyl ring than in the pyrazole ring. The high ortho:para ratio, and the isomer distribution for phenylation

in the phenyl ring of 1-phenylpyrazole, appear quite similar to results observed for free-radical substitution of other molecules with substituent groups having unshared $2p$ electron pairs (i.e., +T substituents): this is illustrated by Table III, where isomer percentages in the phenylation, methylation, and phenoxymethylation of anisole, the

phenylation of phenetole, and the phenylation of pyridine N-oxide are compared with the corresponding quantities for attack on the phenyl ring of 1-phenylpyrazole. Preferred ortho, para orientation in free-radical substitution of benzenoid compounds is often rationalized in terms of the additional resonance stabilization of the σ-complexes formed by attack ortho or para to a substituent, as a result of delocalization of the unpaired electron into the substituent group (8, 17–20): such stabilization cannot be important for the σ-complex formed by attack meta to a substituent. However, it does not appear to have been realized that interaction with an unpaired electron cannot involve delocalization onto the key atom of the substituent if the substituent is a +T group derived from a first-row element. For such a substituent, depicted as Y in structures II*a–d* and III*a–d*,* interaction must involve unpairing of $2p$ electrons, and generation of an electron pair at the carbon atom carrying the substituent: this electron pair is then subject to delocalization, as indicated in structures II*b–d* and III*b–d*. Although this type of electron delocalization might appear novel, it is closely analogous to the delocalization occurring in the

**In the structures II through VII, lines (—) adjacent to atoms (the lines may be horizontal, vertical, or at 45°) denote unshared electron pairs.*

diphenylpicrylhydrazyl radical, where the five-line pattern noted in the hyperfine structure of the electron paramagnetic resonance spectrum shows conclusively that the odd electron is shared equally between the two central nitrogen atoms (cf. ref. 20(*a*)).

Other treatments of the effects of +T substituents have suggested contributing structures such as IV*b* for the σ-complex IV*a* formed by attack para to the methoxy substituent

IVa IVb

of anisole (19–21), but since contributing structures with more than eight electrons in the outer shells of first-row elements would involve use of high-energy 3*d* orbitals, we consider that structures of type IV*b* should be disregarded. Even if structures of types II*b–d* and III*b–d* are assumed to be important in determining the relative stabilities of the σ-complexes formed from ortho, para, or meta attack, and if the relative stabilities are taken to determine the orientation of the final substitution products, interpretation on this basis is at best qualitative, and offers no explanation for the high ortho:para ratios, since there are no obvious differences in energy between the type II and type III structures. In other words, treatment based on resonance theory gives no quantitative account of the results listed in Table III.

Furthermore, it is doubtful whether the relative stabilities of the various σ-complexes can be regarded as controlling orientation, since the minor differences in the relative reactivities of different positions of substituted benzenes, and the absence of appreciable steric effects, indicate that the transition states for phenylations involve weak bonding of the phenyl radical to the carbon atom being attacked, with this atom still partly conjugated with the residual molecule (cf. refs. 4, 22). The σ-complexes are better regarded as reaction intermediates, persisting long enough to dimerize under favorable circumstances (23, 24).

These considerations of the suggested nature of the transition states indicate that quantities characteristic of the isolated reactant molecules (such as the free valence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(25–27) at a given position) might be more relevant in discussions of orientation. There is, in fact, remarkable agreement between the orientations calculated for free-radical substitution in aniline and phenol, where the partial rate factors are deduced from the appropriate free valences (Sandorfy (28)), and the isomer percentages listed in Table III. The partial rate factors are related to the free valences by the expression

$$ {}^{X}_{H}k_r = \exp\,(34{,}000({}^{X}F_r - 0.398)/RT), $$

where ${}^{X}_{H}k_r$ is the partial rate factor for position r of a benzene derivative C_6H_5X, ${}^{X}F_r$ is the free valence at position r, 0.398 is the free valence for a benzene position, and T is the temperature (see Augood and Williams (7), Williams (8)). The calculated orientations for a temperature of 80° C are summarized in Table IV, together with the appropriate

TABLE IV

Free valences, partial rate factors, and predicted orientation of free-radical substitution in phenol and aniline

Para	0.406	1.47	15.4	Para	0.412	1.97	14.4

free valences and partial rate factors. It is apparent that aniline and phenol may be regarded as satisfactory models for prediction of the orientation of radical substitution in the phenyl ring of N-phenylpyrazole and in anisole, phenetole, and pyridine N-oxide respectively.

The predominant 3-phenylation in the pyrazole ring is in direct conflict with qualitative predictions from resonance theory. If the σ-complexes (V*a*, VI*a*, VII*a*) for phenyl radical

attack at the 3-, 4-, and 5-positions are compared, it is apparent that delocalization of the unpaired electron in the σ-complexes for 3- or 4-substitution must involve charge separation (compare the contributing structures V*b*, V*c*, VI*b*, VI*c*), while uncharged contributing structures (VII*a* $\leftrightarrow$ VII*b*) can be written for the σ-complex for 5-substitution. If the relative stabilities of the σ-complexes govern the yields of phenylation products, then these should lie in the order $5 > 3 > 4$, since charged contributing structures are generally of higher energy than uncharged ones, while contributing structures with a negative charge on nitrogen (e.g., V*b*) should be more stable than those with a negative charge on carbon (e.g., VI*b*).

In view of the successful correlation of the orientation of substitution in the phenyl ring of 1-phenylpyrazole with the free valences at the ring carbons in aniline (which is regarded as a suitable model for 1-phenylpyrazole because of the +T character of the amino group, and its possession of an identical key atom in the substituent), it appeared possible that a similar correlation might be found between the free valences at the various positions of *pyrazole* and the orientation of substitution in the pyrazole ring of 1-phenylpyrazole. The relevant free valences, calculated from recently published π-bond orders for pyrazole (29), are: (position, free valence) 3-, 0.440; 4-, 0.286; 5-, 0.393. The predicted order of reactivity towards radicals is therefore 3- $\gg$ 5- $\gg$ 4-, and is consistent with the observed orientation in the pyrazole ring of 1-phenylpyrazole. The observed preponderance of substitution in the phenyl ring can be attributed to the low free valences at the 4- and 5-positions of the pyrazole ring.

Reservations have been expressed about the validity of the assumption that free valence can be regarded as an index of reactivity towards free radicals, particularly for non-alternant hydrocarbons, heteroaromatic compounds, and substituted benzenes (8, 26, 27). The main justification of the use we have made of this assumption in the present study is its success in predicting the orientation of substitution in each ring. In view of the approximations inherent in regarding aniline and pyrazole as suitable models for the two rings of 1-phenylpyrazole, and in neglecting inter-ring conjugation, the agreement with experiment is remarkably good. Since the approach we have adopted can be used to predict the orientation of substitution of other phenyl-substituted heterocycles by free radicals, we have initiated studies of free-radical substitution in 1-phenylpyrrole, 1-phenylimidazole, and 2-phenyl-1,2,3,2H-triazole, in order to test these predictions.

The nuclear benzoyloxylation products (isolated as mixed hydroxy-1-phenylpyrazoles after saponification in the standard isolation procedure (3, 4)) were examined briefly. The mixtures of hydroxy compounds were methylated, and their infrared spectra were compared with those of authentic samples of 1-*o*- and 1-*p*-methoxyphenylpyrazole: marked resemblances were evident (see Experimental), indicating that the pattern of benzoyloxylation qualitatively resembles that of phenylation. However, no attempt was made to evaluate accurate isomer ratios, or to establish the occurrence of benzoyloxylation in the pyrazole ring.

In the course of this work, we recorded the ultraviolet spectra of the various phenylated 1-phenylpyrazoles, and noted that the wavelengths of maximum absorption and the molecular extinction coefficients of correspondingly substituted arylbenzenes and arylpyrazoles resembled one another closely. This is shown in Table V (the data for the arylbenzenes are taken from the compilations by Kamlet (30) and Ungnade (31)). Resemblances between the electronic spectra of arylbenzenes and analogously substituted heterocycles, or between correspondingly substituted derivatives of different heterocyclic

aromatic compounds, can be of obvious assistance in assignments of structure (for an example, see Lynch and Chan (1)).

EXPERIMENTAL

General

Analyses are by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A. Melting points were observed using a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded using a Unicam SP100 spectrophotometer equipped with an SP130 grating accessory. Unless noted otherwise, samples were examined using the potassium chloride disk technique. Ultraviolet spectra were recorded in 95% ethanol using a Beckman DK-2A spectrophotometer. A Beckman GC-2A gas chromatograph, with a Beckman No. 70008 column (Apiezon "L" on C-22 firebrick), helium as carrier gas (flow rate, 70 ml/min), and a column temperature of 220° C, was used for the gas–liquid partition chromatography.

Starting Materials

Benzoyl peroxide was purified by repeated precipitation from chloroform solution by methanol, and had minimum purity 98% (iodometric estimations). 1-Phenylpyrazole, m.p. 11°, b.p. 246°, n_D^{25} 1.5957, was prepared by reaction of phenylhydrazine hydrochloride with 1,1,3,3-tetramethoxypropane in ethanol solution (2, 11).

Reference Samples

(a) Phenylated 1-Phenylpyrazoles

1,3-Diphenylpyrazole, m.p. 84° (lit. 84°), and 1,5-diphenylpyrazole, m.p. 55° (lit. 55–56°), were prepared by cyclization of hydroxymethyleneacetophenone with phenylhydrazine (9, 10). 1,4-Diphenylpyrazole, m.p. 97° (lit. 97°) (anal. calc. for $C_{15}H_{12}N_2$: C, 81.80; H, 5.50%; found: C, 81.72; H, 5.50%); 1-*o*-biphenylylpyrazole, b.p. 208° at 20 mm (anal. calc. for $C_{15}H_{12}N_2$: N, 12.72%; found: N, 13.03%); 1-*m*-biphenylylpyrazole, b.p. 205° at 20 mm (anal. found: C, 81.84; H, 5.72%); and 1-*p*-biphenylylpyrazole, m.p. 126° (lit. 126°), were prepared from the appropriate nitro-substituted 1-phenylpyrazoles by reduction to the corresponding amines with tin and hydrochloric acid, followed by diazotization and reaction of the buffered diazonium salt solutions with benzene (Gomberg arylation). Full details of this method have been given (2) for the synthesis of 1-*p*-biphenylylpyrazole. Overall yields from 10-g quantities of the respective nitro-1-phenylpyrazoles were 32, 33, 32, and 52%. 1-*m*-Biphenylylpyrazole and 1-*p*-biphenylylpyrazole are also available in good yields by cyclization of the appropriate hydrazinobiphenyls (prepared by diazotization of the appropriate aminobiphenyl, followed by reduction with stannous chloride (32)) with 1,1,3,3-tetramethoxypropane. However, when *o*-hydrazinobiphenyl (5 g) and 1,1,3,3-tetramethoxypropane (5 g) were heated under reflux in 3 *N* ethanolic hydrochloric acid (100 ml), carbazole (1 g), m.p. and mixed m.p. 246°, and biphenyl (1 g), m.p. and mixed m.p. 70°, were the only products obtained.

(b) 1-Methoxyphenylpyrazoles

1-*o*-Methoxyphenylpyrazole, b.p. 280°, n_D^{25} 1.5883 (anal. calc. for $C_{10}H_{10}N_2O$: C, 68.95; H, 5.79%; found: C, 69.15; H, 5.98%), was prepared from *o*-methoxyphenylhydrazine and 1,1,3,3-tetramethoxypropane (2, 11). 1-*p*-Methoxyphenylpyrazole, m.p. 33–35°, b.p. 130° at 5 mm (lit. b.p. 138–142° at 0.5 mm (33)) (anal. found: C, 69.00; H, 5.42%), was obtained as follows: 1-*p*-aminophenylpyrazole (8.5 g), m.p. 45° (lit. 45°), was diazotized in 3 *N* hydrochloric acid at 5°, and the resulting solution was boiled with excess of water until the evolution of nitrogen ceased. The phenolic material was recovered by standard methods, and methylated with dimethyl sulphate – sodium hydroxide; distillation yielded 1-*p*-methoxyphenylpyrazole (1.84 g).

General Procedure for Reactions

Benzoyl peroxide and 1-phenylpyrazole were heated together at 80° C as indicated in Table I. The various products were separated and isolated following previously outlined procedures (3, 4).

Examination of Reaction Products—Phenylated Fractions

(a) Gas–Liquid Partition Chromatography

Retention times for the various isomeric phenyl-substituted 1-phenylpyrazoles were established with authentic samples of each compound, using the standardized operating conditions noted above. Trial experiments using ethyl ether or acetone as solvents for the compounds, and sample volumes from 0.02–0.05 ml, showed that the peak areas were directly proportional to the amounts of each isomeric compound taken, and that the molar response of the detector was identical for all of the isomers. The following retention times were observed: 1-*m*-biphenylylpyrazole, 6.70 min; 1-*o*-biphenylylpyrazole, 8.20 min; 1,3-diphenylpyrazole, 9.80 min; 1,5-diphenylpyrazole, 12.00 min; 1,4-diphenylpyrazole, 12.60 min; 1-*p*-biphenylylpyrazole, 15.00 min. Preliminary examination of the mixtures of phenylation products from expts. 1–4 failed to reveal any evidence for the presence of 1,4- or 1,5-diphenylpyrazole, although peaks were observed at the characteristic retention times of each of the other four isomers. By addition of varying amounts of 1,4- and 1,5-diphenylpyrazole to samples of the reaction products, and examination of the resulting peak areas, it was estimated that the lower limit of detection was 3% of either of these isomers. Detailed comparisons of the peak areas corresponding to the four isomers detected in the phenylation products gave the results summarized in Table II. The identification of the various peaks was checked by making artificial additions of each isomer to separate samples of the experimental reaction mixtures, when increments in the areas of the appropriate peaks were observed.

(b) Infrared Spectra

The infrared spectra of capillary films of the various phenylated fractions from Expts. 1–4 were recorded, and showed no absorption bands other than those assignable to the 1-biphenylylpyrazoles or to 1,3-diphenylpyrazole: thus, the results are consistent with those from the gas–liquid partition chromatography. However, the spectra of the various 1-biphenylylpyrazoles and 1,*x*-diphenylpyrazoles resemble one another closely: only in the 650–1000 cm^{-1} regions are bands present which allow qualitative identification of a single isomer in a mixture of several, and many bands in this region are common to more than one isomer. Typical spectra of reaction mixtures showed the following medium or strong bands in this region (letters in parentheses following the frequency (cm^{-1}) and intensity (m or s) of an absorption band indicate that bands at this frequency are observed in the spectra of a pure isomer, as follows: A, B, C: 1-*o*-, 1-*m*-, and 1-*p*-biphenylylpyrazoles; D, E, F: 1,3-, 1,4-, and 1,5-diphenylpyrazoles): 660 m (ABC), 680 m (AB), 690 s (DEF), 702 vs (ABCDEF), 755 vs (DEF), 760 vs (ABCE), 790 m (B), 840 m (C), 887 m (ABC), 920 m (C), 940 s (ABCD), 955 s (D). Strong absorption bands noted at 804, 867, 904, and 960 cm^{-1} for 1,4-diphenylpyrazole, and at 674, 765, 834, 880, 925, and 960 cm^{-1} for 1,5-diphenylpyrazole, were absent from the spectra of the mixtures of phenylation products from the various experiments. Full details of the spectra of the isomeric phenyl-substituted 1-phenylpyrazoles are available on request.

(c) Direct Isolation by Adsorption Chromatography

When samples of reaction mixtures were chromatographed on alumina using benzene as eluant, 1-*p*-biphenylylpyrazole was the most readily eluted material, in agreement with the suggestion that the order of elution in a series of isomeric compounds follows the reverse order of dipole moments (34). Fair agreement (within ±10%) was found between the quantities of 1-*p*-biphenylylpyrazole isolated directly from the reaction mixtures and the amounts calculated from the gas–liquid partition chromatography.

Examination of Reaction Products—Hydroxyphenylpyrazole Fractions

These mixtures were methylated with dimethyl sulphate – sodium hydroxide, and the infrared spectra were recorded and compared with those of authentic 1-*o*- and 1-*p*-methoxyphenylpyrazole. Of 20 strong bands observed between 650 and 1600 cm^{-1} in the spectra of the methylated hydroxyphenylpyrazole fractions, all are found in the spectra of one or other of the authentic 1-methoxyphenylpyrazoles. Full details of these spectra are available on request.

ACKNOWLEDGMENTS

We thank the National Research Council for generous support through Operating and Major Equipment Grants, and Misses D. A. Chalker and J. Murphy for skilled technical assistance in spectrophotometry.

NOTES

GAS CHROMATOGRAPHIC SEPARATION OF DEUTERIUM-SUBSTITUTED OLEFINS BY UNSTABLE COMPLEX FORMATION[1]

R. J. Cvetanović, F. J. Duncan,[2] and W. E. Falconer

The increasing use of deuterium-substituted hydrocarbons in gas kinetic investigations creates an important need for methods of analysis of small amounts of the deuterated reaction products. Wilzbach and Riesz (1) first indicated the possibility of separating extensively isotopically substituted hydrocarbons by gas–liquid chromatography in 1957. Falconer and Cvetanović (2) separated fully and partially deuterated hydrocarbon isomers from each other and from their non-deuterated counterparts by partition chromatography using a non-polar column for which retention times increase linearly with boiling points. This method proved suitable only for the heavier hydrocarbon gases; *n*-butane, *n*-butane-d_{10} was the lowest-boiling pair that could be separated under the conditions used. Techniques to extend the range of separations to include the low-boiling hydrocarbons are badly needed.

Columns prepared from silver nitrate – ethylene glycol solutions on firebrick have been found to be particularly selective for olefins (3), and Muhs and Weiss (4) have related the equilibrium complexing constants calculated from the retention times for a large number of olefins to steric and strain characteristics of the olefins. The retention times of olefins on silver nitrate – ethylene glycol – firebrick columns are also strongly affected by deuterium substitution.

EXPERIMENTAL

Saturated silver nitrate – ethylene glycol solution was prepared by stirring an excess of finely ground silver nitrate together with ethylene glycol at ~40° C, and decanting the supernatant liquid after the mixture had stood overnight at room temperature. Two column packings were made: (1) 17 ml of saturated solution mixed with 100 ml (39 g) 30/60 mesh firebrick (Johns-Manville Chromosorb P), and (2) 5 ml of saturated solution mixed with 100 ml of the same firebrick. After thorough mixing, both packings appeared dry and flowed easily. Packings (1) and (2) were loaded respectively into 16- to 48-ft lengths of 4 mm I.D. and 2.5 mm I.D. Pyrex tubing.

Samples (~1 μmole) were flushed onto the columns from a U-shaped bypass injector. Helium was used as carrier gas, and linear flows were 2–3 cm sec^{-1}. Detection was with a Gow-Mac thermal conductivity cell for the 4-mm columns, and with a flame ionization detector for the 2.5-mm columns. A 10:1 bypass system was inserted between the injection system and the column when the narrower columns were used, to reduce the effective injection time.

The deuterated olefins used were obtained as follows: ethylene-d_4 and *cis*-2-butene-d_8, kindly supplied by Dr. L. C. Leitch of these laboratories; *cis*- and *trans*-ethylene-d_2 and propylene-d_6, commercial samples from Merck, Sharp and Dohme, Ltd; *trans*-2-butene-d_8, produced by the mercury-photosensitized isomerization (5) of *cis*-2-butene-d_8; *cis*- and *trans*-2-pentene-d_8, 2-methyl-2-butene-d_8, and 3-methyl-1-butene-d_8, produced by the reaction of non-deuterated triplet methylene (6) with *cis*-2-butene-d_8.

RESULTS

Figure 1 shows the separation of propylene-d_0, propylene-d_6 and of ethylene-d_0, ethylene-d_2, ethylene-d_4 on a 40-ft, 2.5 mm I.D. silver nitrate – ethylene glycol – firebrick column (packing (2)) at −16° C. This column was most effective for this separation. Although the column performance did not depend critically on operating parameters, slight improvements in separation were observed upon lowering the column temperature.

[1]*Issued as N.R.C. No. 7403.*

[2]*National Research Council Postdoctoral Fellow 1961–1963.*

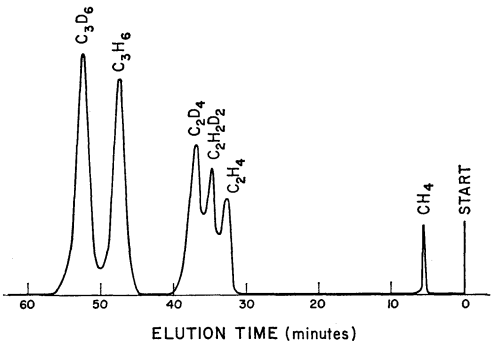

FIG. 1. Separation of ethylene and propylene isomers on a 40-ft silver nitrate – ethylene glycol column at −16° C.

For this reason, and because retention times were more convenient, most measurements were made below room temperature. Column efficiencies per unit length were similar for both types of columns used, and were not affected greatly by temperature change. Efficiencies increased markedly from ~50 theoretical plates per foot for short retention times (e.g. *trans*-2-butene, ethylene) to ~150 plates per foot for long retention times (e.g. *cis*-2-pentene). For a given retention time, the longer, more lightly loaded columns gave better peak resolution than shorter columns, with more stationary phase per gram of firebrick. The former are therefore recommended for analytical applications.

The adjusted retention times of deuterated olefins relative to their light isomers ($r_{H,L}$) are given for various temperatures in Table I. These values are independent of the column

TABLE I

Retention times for deuterated olefins, relative to their light isomers, at various temperatures

	−16±3° C	1±1° C	23±1° C	58±1° C
Ethylene-1,2-d_2	1.07_5	1.07		
Ethylene-d_4	1.15	1.14	1.11_5	1.09
Propylene-d_6	1.12	1.11	1.08	
trans-2-Butene-d_8	1.11	1.09		
cis-2-Butene-d_8	1.10	1.08		
2-Methyl-2-butene-d_8	1.10	1.07		
3-Methyl-1-butene-d_8	1.11	1.10		
trans-2-Pentene-d_8	1.10	1.08_5		
cis-2-Pentene-d_8	1.08	1.07		

used for their measurement. They show a slight increase with decreasing temperature, but the significance of this trend is questionable since the change is of the same order as the error in measurement.

DISCUSSION

Silver–olefin complexing provides a gas chromatographic technique of general applicability for the separation of olefin isomers differing only in the extent of deuterium (and no doubt tritium) substitution. The application is particularly interesting because it permits the separation of ethylene and propylene isomers which have not been resolved by partition methods. The increase in $r_{H,L}$ observed on going from 2-butene-d_8 to propylene-d_6 to ethylene-d_4 suggests that deuterium substitution at the double bond has the greatest effect. That the contributions from substitution elsewhere in the molecule are smaller but not negligible can be seen by a comparison of the $r_{H,L}$ values for 2-butene-d_8 and ethylene-d_2.

It is noteworthy that the isotope effect observed here is in the direction *opposite* to that for a conventional stationary phase in partition chromatography (1, 2). The isotope effects on the silver–olefin equilibrium complexing constant are still larger than those listed in Table I for the overall effect on relative retention times, since the partition coefficient of the olefin in ethylene glycol, which is probably lowered by deuterium substitution (2), affects the overall retention time (4).

Attempts to obtain greater resolution by preparing high-resolution capillary columns by coating polyethylene, nylon, or stainless steel narrow bore tubing with either saturated silver nitrate – ethylene glycol solution or silver nitrate – ethylene glycol solution diluted with water have so far been unsuccessful.

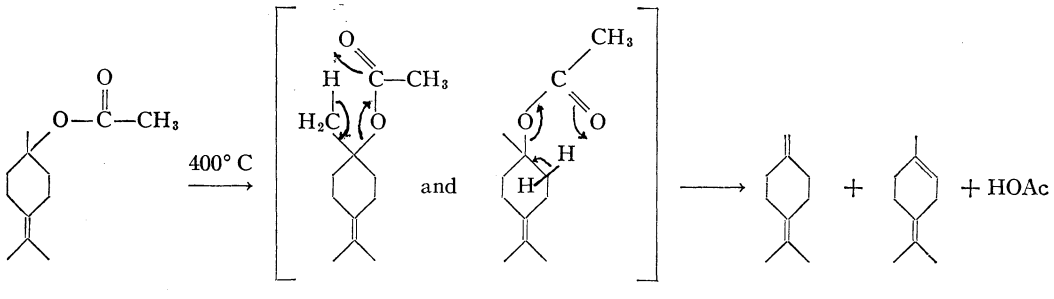
1(7),4(8)-*p*-MENTHADIENE

B. M. Mitzner, E. T. Theimer, and S. Lemberg

1(7),4(8)-*p*-Menthadiene (I) has not been reported previously, neither as found in nature[1] nor as a synthetic compound.

We have observed that when gamma-terpinyl acetate (II) is pyrolyzed at 400° C, it eliminates acetic acid to form I and terpinolene (III), presumably by the usual concerted mechanism involving IV*a* and IV*b*.



II IV*a* IV*b* I III

Nuclear magnetic resonance and infrared analyses support the structure of the 1(7),4(8)-*p*-menthadiene, I. The n.m.r. spectrum of I indicates the following (in tau values, tetramethylsilane, $\tau = 10.00$):

[1]*A terpene called crithmene has been obtained from Oil of Samphire, and assigned structure I (1). The same hydrocarbon was later isolated by other workers from French Oil of Samphire (2). Subsequently, a new hydrocarbon (called moslene) was isolated from the essential oil Mosla Japonica Maxim, and assigned structure I (3). It has been conclusively shown that crithmene and moslene are, in fact, gamma-terpinene (4).*

It is noteworthy that the isotope effect observed here is in the direction *opposite* to that for a conventional stationary phase in partition chromatography (1, 2). The isotope effects on the silver–olefin equilibrium complexing constant are still larger than those listed in Table I for the overall effect on relative retention times, since the partition coefficient of the olefin in ethylene glycol, which is probably lowered by deuterium substitution (2), affects the overall retention time (4).

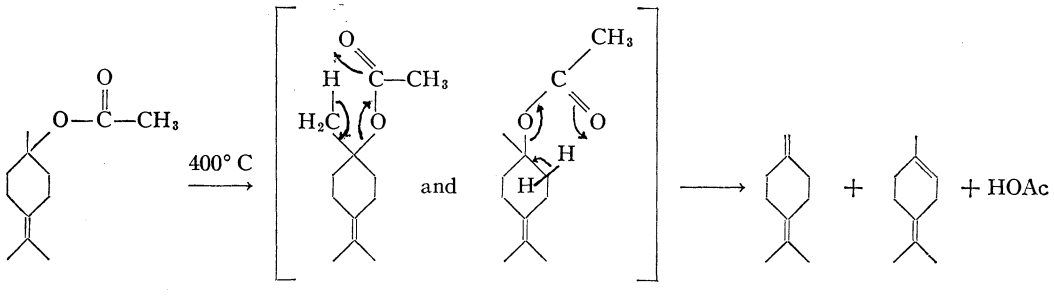
1(7),4(8)-*p*-MENTHADIENE

B. M. Mitzner, E. T. Theimer, and S. Lemberg

1(7),4(8)-*p*-Menthadiene (I) has not been reported previously, neither as found in nature[1] nor as a synthetic compound.

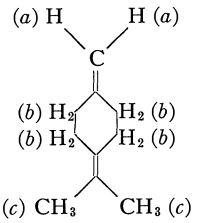
We have observed that when gamma-terpinyl acetate (II) is pyrolyzed at 400° C, it eliminates acetic acid to form I and terpinolene (III), presumably by the usual concerted mechanism involving IV*a* and IV*b*.



II IV*a* IV*b* I III

Nuclear magnetic resonance and infrared analyses support the structure of the 1(7),4(8)-*p*-menthadiene, I. The n.m.r. spectrum of I indicates the following (in tau values, tetramethylsilane, $\tau = 10.00$):

[1]*A terpene called crithmene has been obtained from Oil of Samphire, and assigned structure I (1). The same hydrocarbon was later isolated by other workers from French Oil of Samphire (2). Subsequently, a new hydrocarbon (called moslene) was isolated from the essential oil Mosla Japonica Maxim, and assigned structure I (3). It has been conclusively shown that crithmene and moslene are, in fact, gamma-terpinene (4).*



(*a*) τ = 5.41, singlet, 2 hydrogens
(*b*) τ = 7.82, allylic methylene, singlet, 8 hydrogens
(*c*) τ = 8.30, singlet, 6 hydrogens

The following are the pertinent n.m.r. signals of the compound: $\tau = 8.30$, $(CH_3)_2C{=}C$; 7.82, allylic methylene; 5.41, $>C{=}CH_2$. It is interesting to note that all the allylic methylenes give rise to one sharp signal at 7.82.

The infrared spectrum of the 1(7),4(8)-*p*-menthadiene is characterized by a strong absorption at 886 cm^{-1} due to the $>C{=}CH_2$ group; this absorption is also found in 1(7)-*p*-menthene.[2] A medium intensity band is present at 1237 cm^{-1} which we attribute to the $R_1R_1C{=}CR_2R_2$ configuration. The same absorption is present in 4(8)-*p*-menthene.[2] The absence of the *gem*-dimethyl split (ca. 1375 cm^{-1} and 1385 cm^{-1}), which is also absent in 4(8)-*p*-menthene, supports the proposed structure.

The terpinolene (III) was identical with that of authentic terpinolene isolated from a natural source[3] by the congruency of the n.m.r. and infrared spectra.

EXPERIMENTAL

Terpinyl acetate[4] is a mixture of alpha-, beta-, and gamma-terpinyl acetate. A vapor-phase chromatogram of this material (obtained on a 10 ft×1/4 in. O.D.×3/16 in. I.D. copper column packed with 20% Reoplex 400 on 60- to 80-mesh silane-treated celite at a column temperature of 140° C and an inlet pressure of 30 p.s.i. helium with a flow rate of 55 ml/min) yielded an excellent separation of the beta isomer and only a slight separation of the gamma isomer, actually appearing as a shoulder on the front of the alpha-terpinyl acetate peak. (If the alpha-terpinyl acetate can be considered to have a retention volume of 1.0, then the relative retention volume of beta-terpinyl acetate is 0.64 and that of gamma-terpinyl acetate is 0.95.) Therefore, the front side of the alpha-terpinyl acetate peak was trapped on a preparative unit to concentrate the gamma isomer. (The preparative unit contained a 1/2 in. O.D.×7/16 in. I.D. copper column 9 ft long and packed with 20% Reoplex 400 on 60- to 80-mesh silane-treated celite at 150° C. An inlet pressure of 20 p.s.i. helium was used and a flow of 175 ml/min was obtained.) Ten grams of material was obtained by means of 30 repeated trappings using 1-ml samples. The starting material contained 15% gamma- and 12% beta-terpinyl acetate. The first trapping contained approximately 35% of the gamma isomer and the beta isomer was completely eliminated. The 10 grams of material was retrapped, again using 1-ml samples, yielding 3 g of gamma-terpinyl acetate which was 65% pure. The structures of the alpha-terpinyl acetate and gamma-terpinyl acetate were confirmed by n.m.r. analysis.[5] This was then passed through a 1-ft×1/8 in. O.D.×2/32

[2]*The infrared spectra of 1(7)-p-menthene, 4(8)-p-menthene, and 1(7),4(8)-p-menthadiene have been reported (5).*

[3]*Sample of terpinolene from pure stump oil was generously supplied by the Hercules Chemical Co., Wilmington, Delaware.*

[4]*Prepared by the acetylation of commercial terpineol, a mixture of the alpha, beta, and gamma isomers.*

[5]*The proof of the structures of the gamma and alpha isomers is based primarily on n.m.r. analysis. Briefly, the assignments are made as follows: An olefinic ring proton appearing at τ = 4.68 p.p.m. is attributed to the alpha isomer. This signal is then correlated quantitatively with the acetoxy methyl group, τ = 8.07 p.p.m., of the gamma isomer; the acetoxy methyl group of the alpha isomer appears at slightly higher fields, τ = 8.12 p.p.m., thus making these measurements possible. Moreover, the ratio of the acetoxy methyl group signals corresponds to the ratio of the two peaks, gamma and alpha, obtained via v.p.c. measurements. The methyls on a double bond, τ = 8.38 p.p.m., are attributed to the methyls of the isopropylidene and the ring methyl on the double bond, but the chemical shifts here are identical and allow no distinction between the isomeric species. In view of the fact that a mixture is being analyzed, the authors are aware that the structures cannot be assigned unequivocally; however, the compounds resulting from the pyrolysis have been isolated pure and their structures established with certainty (which indirectly supports the structure of gamma-terpinyl acetate and of alpha-terpinyl acetate).*

in. I.D. stainless steel tube heated to 400° C, at a flow rate of approximately 1 ml/min, a small flow of nitrogen being used as the carrier. The pyrolyzate (2 g) was separated into its components on a preparative v.p.c. unit using a 3/8 in. O.D.×5/16 in. I.D. copper column packed with 20% Reoplex 400 on 60- to 80-mesh silane-treated celite at a temperature of 110° C and an inlet pressure of 20 p.s.i. helium with a flow rate of 90 ml/min. In this way, the 1(7),4(8)-*p*-menthadiene and terpinolene were easily separable; the former, which eluted first, was pure by v.p.c. analysis. Since the pyrolysis products of alpha-terpinyl acetate (which was present to the extent of 35% in the pyrolyzed material) are terpinolene and dipentene, it was not possible to obtain a quantitative ratio of the pyrolysis products of the gamma-terpinyl acetate.[6]

[6]*The pyrolyzate components elute in the following order in the gas chromatographic columns previously described: dipentene, 1(7),4(8)-p-menthadiene, followed by terpinolene. If dipentene is considered to have a retention volume of 1.0, then 1(7),4(8)-p-menthadiene has a relative retention volume of 1.20 and terpinolene has a relative retention volume of 1.55 when using a Reoplex 400 column.*

THE PHOTOLYSIS OF SOME α-SUBSTITUTED CYCLOHEXANONES[1]

H. G. Ferguson, P. de Mayo, F. L. M. Pattison, and T. Tabata

The photolysis of cyclohexanones in alcoholic solution to give, by cleavage, saturated esters is well known. It occurred to us that the cleavage of α-fluorocyclohexanones might provide a route to fluoro esters. To this end 2-fluoro-, 2-fluoro-4-methyl-, and 2-fluoro-3,5-dimethyl-cyclohexanone were prepared and photolyzed in methanol.

Vapor phase chromatography revealed that methyl 6-fluorohexanoate was indeed produced in the photolysis of 2-fluorocyclohexanone, but in insignificant yield. No trace of the 2-fluoro ester, available by another route in these laboratories, could be detected. An ester, presumably ω-substituted because of the ester carbonyl frequency (~1740 cm^{-1}), was similarly obtained in small yield from the 3,5- and 4-methyl derivatives.

The photolysis of 2-formyloxycyclohexanone was also investigated. In an inert solvent this could proceed, in principle, by ejection of the formyloxy group, or by a cyclic process involving γ-hydrogen (1, 2) abstraction. Since the latter would result in the formation of carbon dioxide, the two steps formylation and irradiation might have provided a useful procedure for the conversion of ketols to ketones. Irradiation of 2-formyloxycyclohexanone did give cyclohexanone, but in yields (up to 30%) inferior to those obtained by other methods available for the reduction of the ketol.

EXPERIMENTAL

The α-Fluorocyclohexanones (Method of Kissman, Small, and Weiss (3))

(*a*) A mixture of cyclohexanone (49.7 g) and diethyl oxalate (63 g) was added at 10° to a solution of sodium

To this end 2-fluoro-, 2-fluoro-4-methyl-, and 2-fluoro-3,5-dimethyl-cyclohexanone were prepared and photolyzed in methanol.

Vapor phase chromatography revealed that methyl 6-fluorohexanoate was indeed produced in the photolysis of 2-fluorocyclohexanone, but in insignificant yield. No trace of the 2-fluoro ester, available by another route in these laboratories, could be detected. An ester, presumably ω-substituted because of the ester carbonyl frequency (~1740 cm^{-1}), was similarly obtained in small yield from the 3,5- and 4-methyl derivatives.

The photolysis of 2-formyloxycyclohexanone was also investigated. In an inert solvent this could proceed, in principle, by ejection of the formyloxy group, or by a cyclic process involving γ-hydrogen (1, 2) abstraction. Since the latter would result in the formation of carbon dioxide, the two steps formylation and irradiation might have provided a useful procedure for the conversion of ketols to ketones. Irradiation of 2-formyloxycyclohexanone did give cyclohexanone, but in yields (up to 30%) inferior to those obtained by other methods available for the reduction of the ketol.

EXPERIMENTAL

The α-Fluorocyclohexanones (Method of Kissman, Small, and Weiss (3))

(*a*) A mixture of cyclohexanone (49.7 g) and diethyl oxalate (63 g) was added at 10° to a solution of sodium

[1]*This work was supported in part by a grant (No. 2020–29) from the Defence Research Board of Canada. We wish to thank Mr. F. H. Dean for help in preparing the α-fluorocyclohexanones.*

For personal use only.

ethoxide (from 11.5 g sodium) in absolute ethanol (150 ml). After 1 hour at this temperature and 6 hours at room temperature, dimethylformamide (100 ml) was added and the mixture cooled to 10°. After displacement of oxygen in the system by nitrogen, perchloryl fluoride (55 g) was bubbled in. After standing overnight at room temperature, the product was isolated, dissolved in aqueous ethanol (80%; 350 ml) containing potassium acetate (196 g), and refluxed for 4 hours. Isolation of the product in the usual way gave 2-fluorocyclohexanone, 7.2 g (12%), b.p. 71–72° at 13 mm, n_D^{25} 1.4422 (lit. (4): b.p. 83–83.5° at 20 mm, n_D^{25} 1.4432); 2,4-dinitrophenylhydrazone m.p. 138–141° (lit. (4): m.p. 139–140°).

(*b*) 2-Fluoro-3,5-dimethylcyclohexanone was prepared from the appropriate ketone by the above method. The final product was purified by V.P.C. on 12-ft diethylene glycol succinate columns and was obtained in 12% overall yield, b.p. 62–63° at 2.3 mm, n_D^{25} 1.4401, d_4^{20} 1.070. Calc. for $C_8H_{13}FO$: C, 66.63; H, 9.08. Found: C, 66.73; H, 8.95%. The 2,4-dinitrophenylhydrazone had m.p. 186–189°. Calc. for $C_{14}H_{17}FN_4O_4$: C, 51.85; H, 5.29; N, 17.28. Found: C, 52.02; H, 5.34; N, 17.41%.

(*c*) 2-Fluoro-4-methylcyclohexanone was obtained similarly in 12% yield, b.p. 75–76° at 5 mm, n_D^{25} 1.4386, d_4^{20} 1.054. Calc. for $C_7H_{11}FO$: C, 64.57; H, 8.52. Found: C, 64.64; H, 8.67%. The 2,4-dinitrophenylhydrazone had m.p. 135–139°. Calc. for $C_{13}H_{15}FN_4O_4$: C, 50.32; H, 4.87; N, 18.06. Found: C, 50.55; H, 5.15; N, 18.20%.

2-Formyloxycyclohexanone

To a solution of 2-hydroxycyclohexanone (5.04 g) in monoglyme (85 ml) and pyridine (30 ml) was added 8–9 ml formyl fluoride (5) and the mixture left at −70° for 40 hours and at 0° for 30 minutes. After filtration the product was isolated with ether in the usual way. The crude formate was filtered through a silica gel column and the material eluted with ether – light petroleum (1:9) and distilled to give the ester, b.p. 78° at 0.8 mm, n_D^{25} 1.4643, ν_{max} 1738, 1717 cm^{-1}. Calc. for $C_7H_{10}O_3$: C, 59.14; H, 7.09. Found: C, 59.11; H, 7.19%.

Irradiations

(a) 2-Fluorocyclohexanone

The ketone (5 g) in methanol (170 ml) was irradiated in a quartz immersion apparatus (6) with an 80-w medium-pressure lamp for 20 hours. The neutral material, isolated with ether, was distilled (12 mm). Analysis of the distillate on a 17% 3/8-in.×10-ft diethylene glycol succinate column on firebrick at 145° (He at 25 p.s.i.) revealed the presence of methyl 6-fluorohexanoate (retention time = 8.3 minutes). A portion was isolated by the same procedure and identified by comparison of retention time, infrared spectrum, and refractive index with an authentic specimen.

(b) 2-Fluoro-3,5-dimethylcyclohexanone

Irradiation of this ketone as described for 2-fluorocyclohexanone gave, on similar isolation, methyl 6-fluoro-3,5-dimethylhexanoate, n_D^{25} 1.4171, ν_{max} 1741, 1012 cm^{-1}. Calc. for $C_9H_{17}FO_2$: C, 61.34; H, 9.73. Found: C, 61.25; H, 9.82%. The FCH_2— group appeared as a pair of doublets centered at 250 c.p.s.* (from TMS) with $J_{HF} \sim 47$ and $J_{HH} \sim 7$ c.p.s.

(c) 2-Fluoro-4-methylcyclohexanone

Irradiation of this ketone and isolation as described above gave methyl 6-fluoro-4-methylhexanoate, n_D^{25} 1.4141, ν_{max} 1741, 996 cm^{-1}. Calc. for $C_8H_{15}FO_2$: C, 59.24; H, 9.32. Found: C, 59.53; H, 9.48%.

The Irradiation of 2-Formyloxycyclohexanone

A 0.5% solution of the ester in cyclohexane was placed in a vycor flask and irradiated with an 80-w medium-pressure mercury lamp for 5 hours. The yield of cyclohexanone was estimated by V.P.C. on a 20-ft 20% carbowax column by calibration with standard solutions. Isolation of a portion of the ketone and conversion to the 2,4-dinitrophenylhydrazone gave material identical in melting point and infrared spectrum with an authentic specimen; the mixed melting point gave no depression.

DERIVATIVES OF MONOGERMANE
PART III. INFRARED SPECTRA OF THREE DIHALOGERMANES

T. N. Srivastava,* J. E. Griffiths,† and M. Onyszchuk

In an earlier publication (1) we reported the vibration–rotation spectra of germyl fluoride and bromide. The infrared spectra of dihalogermanes have not yet been described, although there is much information about the spectra of dihalosilanes (2–4) and dihalomethanes (5). We now report the infrared spectra of difluoro-, dichloro-, and dibromogermane in the 4000–650 cm^{-1} range and compare them with those of the corresponding dihalosilanes.

EXPERIMENTAL

Difluoro-, dichloro- and dibromo-germane were obtained in low yield (10–20%) as by-products in the preparation of the corresponding monohalogermanes (6–8). Crude samples were purified by fractional distillation in vacuum until tensimetrically pure. Vapor pressures (v.p.) and molecular weights (M) were: (i) for GeH_2F_2: v.p. 18.6 mm at 0°, M 112.8 (calc. 112.6); (ii) for GeH_2Cl_2: v.p. 29.0 mm at 0°, M 146.0 (calc. 145.6); (iii) for GeH_2Br_2: v.p. 6.2 mm at 0°, M 233.5 (calc. 234.4). An attempt to prepare diiodogermane was unsuccessful because the compound appears to be too unstable at room temperature to be isolated in the pure form (7).‡

Spectra (Fig. 1) were recorded in the range 4000–650 cm^{-1} by a Perkin–Elmer Model 21 spectrometer

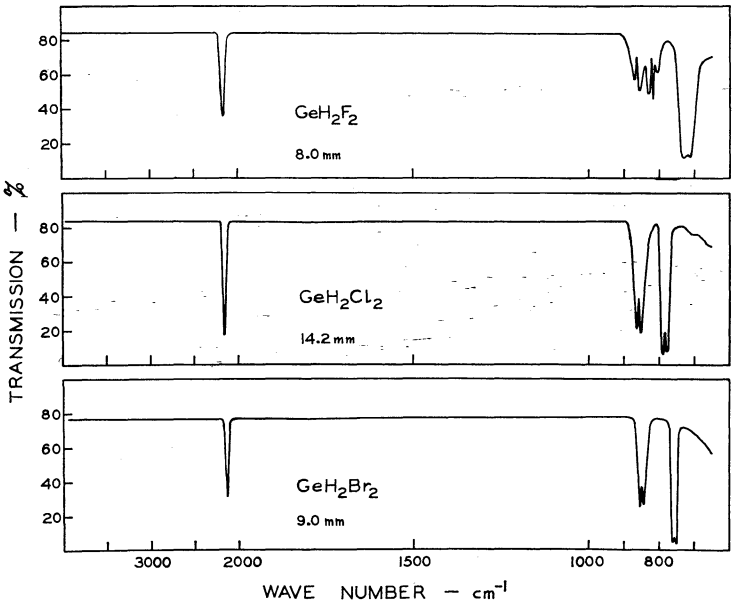

Fig. 1. Vapor-phase infrared spectra of difluoro-, dichloro-, and dibromo-germane.

equipped with a sodium chloride prism. The instrument was calibrated using water vapor and polystyrene. Measurements were made on compounds in the gas phase in a glass cell of 10-cm length and 5-cm diameter

with 5 mm thick sodium chloride end-plates. The frequency assignments given in Table I are based on those previously reported for dihalosilanes (2–4). The wave numbers reported are accurate to ± 3 cm^{-1} in the range 2000–650 cm^{-1}, and to ± 10 cm^{-1} above 2000 cm^{-1}.

TABLE I

Infrared vibration frequencies (cm^{-1}) of dihalogermanes

GeH_2F_2	GeH_2Cl_2	GeH_2Br_2	Assignment
2175, s	2150, s	2130, s	$\nu_1(a_1)$ GeH_2 stretching
2175, s	2150, s	2130, s	$\nu_6(b_1)$ GeH_2 stretching
870, *R*, m	862, *R*, s	853, *R*, s	
(863), *Q*, m	(856), *Q*	(848), *Q*	$\nu_2(a_1)$ GeH_2 bending
855, *P*, m	850, *P*, s	844, *P*, s	
828, *R*, m	788, *R*, s	760, *R*, s	
815, *Q*, m	(780), *Q*	(756), *Q*	$\nu_8(b_2)$ GeH_2 wagging
805, *P*, m	773, *P*, s	752, *P*, s	
730, *R*, s			
(722), *Q*	—	—	$\nu_9(b_2)$ GeF_2 stretching
714, *P*, s			

NOTE: s = strong; m = medium.

DISCUSSION

Dihalogermanes, like dihalosilanes, belong to the symmetry group C_{2v} and hence should have nine fundamental vibrations including the torsional mode $\nu_5(a_2)$ which is forbidden in the infrared. The GeH_2 stretching vibrations, $\nu_1(a_1)$ and $\nu_6(b_1)$, are unresolved and located between 2130 and 2175 cm^{-1}. There is a gradual shift toward lower frequencies as the mass of the halogen atom increases.

The GeH_2 bending vibration, $\nu_2(a_1)$, occurs as a strong doublet in dichloro- and dibromogermane, about 90 cm^{-1} lower than the similar doublet observed in the corresponding dihalosilanes. The GeH_2 wagging vibration, $\nu_8(b_2)$, is also found as a strong doublet in GeH_2Cl_2 and GeH_2Br_2, again about 90 cm^{-1} below those in the analogous silicon compounds.

In difluorogermane the GeH_2 bending and wagging modes give five peaks of moderate intensity. These peaks may be attributed to the *P*, *Q*, and *R* branches of $\nu_2(a_1)$ and $\nu_8(b_2)$, with the *P* branch of the former overlapping slightly with the *R* branch of the latter, giving increased intensity to the bands at 855 and 828 cm^{-1}. The strong doublet centered at 722 cm^{-1} is assigned to the GeF_2 antisymmetric stretching vibration $\nu_9(b_2)$. The $GeCl_2$ and $GeBr_2$ antisymmetric stretching frequencies occurred below 650 cm^{-1}, which is the limit of spectrometer, and hence were not observed. The remaining vibrations $\nu_7(b_1)$, $\nu_3(a_1)$, and $\nu_4(a_1)$ also occurred below 650 cm^{-1}.

ACID-CATALYZED REACTIONS OF VINYL COMPOUNDS
PART II. PRODUCTS OF THE REACTION OF VINYL ACETATE AND BENZENE

J. M. Pepper and B. P. Robinson

In Part I (1) of this series, preliminary studies were reported on the nature of the aluminum chloride catalyzed reaction of vinyl acetate and benzene. A more thorough investigation of the products of this reaction, using the molar ratio 3:1:10 respectively, has revealed that, in addition to the compounds reported previously (acetophenone, *p*-ethylacetophenone, 1,1-diphenylethane, and 9,10-dimethylanthracene), ethylbenzene, *o*-ethylacetophenone, 2,4- and 3,4-diethylacetophenone, and 1,1-diphenylethene were also produced. They have been isolated and characterized. Except for 9,10-dimethylanthracene, which was isolated and weighed (1), the yield of each product was determined by gas–liquid chromatographic analysis. These data are given in Table I.

TABLE I

6	29.6	146–148, 15 mm	93.13	7.08	184	For $C_{14}H_{12}$:	93.29	6.71	180

*The compounds are numbered as they were in Table II, Part I of this series (1).

Compounds 1 and 3 had already been shown to be acetophenone and *p*-ethylacetophenone respectively (1). Compound 2 ($C_{10}H_{12}O$) gave a positive iodoform test and its infrared spectrum indicated that it was an ortho-substituted aromatic ketone. The preparation of *o*-ethylacetophenone from *o*-ethylaniline by the Beech reaction (2) and its proved identity with compound 2 confirmed the structure of compound 2.

The analysis ($C_{12}H_{16}O$) of compound 4 indicated that this compound was a diethylacetophenone. Oxidation by alkaline potassium permanganate gave an acid, m.p. 213–215°, which, by comparison with the three benzenetricarboxylic acids (obtained by the alkaline permanganate oxidation of the corresponding trimethylbenzenes), was shown to be identical with benzene-1,2,4-tricarboxylic acid. To distinguish whether compound 4 was the 2,4-, 3,4- or 2,5-diethylacetophenone, these compounds were synthesized by the Friedel–Crafts acylation reaction from *o*-, *m*-, and *p*-diethylbenzene respectively. The structure of each of these ketones was confirmed by its oxidation to the previously prepared benzene-1,2,4-tricarboxylic acid. By direct comparison, compound 4 was shown to be identical with the previously unreported 2,4-diethylacetophenone. Similarly, by a comparison of gas chromatographic retention times and infrared spectra, compound 4A was shown to be 3,4-diethylacetophenone.

Compounds 5 and 6, although previously reported (1) as constituents of the carbonyl-containing fraction, have now been shown to be hydrocarbons. By a comparison of retention times and infrared spectra, compound 5 ($C_{14}H_{14}$) was shown to be identical with an authentic sample of 1,1-diphenylethane, and compound 6 ($C_{14}H_{12}$) was shown to be identical with 1,1-diphenylethene.

The ethylbenzene reported, in Table I, as a product of the benzene – vinyl acetate reaction was detected only by the gas chromatographic study of the crude reaction product. Its identity was indicated by a comparison of its retention times with those of authentic ethylbenzene when measured under a variety of chromatographic conditions as shown in Table III.

This note describes the isolation and characterization of five compounds, namely: ethylbenzene, *o*-ethylacetophenone, 2,4- and 3,4-diethylacetophenone, and 1,1-diphenylethene, which had not been reported previously as products of the aluminum chloride interaction of benzene and vinyl acetate. The significance of the relative abundance of these and the other reported reaction products, as well as a discussion of the mechanism of their formation, will be the subject of a subsequent publication.

	105	90	66.7	7.7	7.7

EXPERIMENTAL

Melting points are uncorrected. The infrared spectra were measured using a Perkin–Elmer Model 21 instrument with sodium chloride optics. Gas–liquid chromatography was effected using a Beckman GC-2 chromatograph, with a thermal conductivity detector unit, and which had been modified by placing the injection system as close as possible to one end of the column and by making it more comparable electronically to the GC-2A.

Reaction of Vinyl Acetate and Benzene

To obtain the data recorded in Table I the following procedure was followed. Vinyl acetate (8.6 g, 0.1 mole) was added slowly over a period of 1 hour to a well-stirred mixture of benzene (78 g, 1.0 mole) and sublimed, anhydrous aluminum chloride (40 g, 0.3 mole) in a 200-ml 3-necked flask equipped with reflux condenser, dropping funnel, and mechanical stirrer. Both the condenser and dropping funnel were fitted with calcium chloride drying tubes. Throughout the addition, the flask was cooled in an ice bath, but after the addition was complete, the reaction mixture was refluxed for 3 hours. The complex was decomposed by its addition to a mixture of concentrated hydrochloric acid (75 ml) and crushed ice (75 g). The aqueous layer was extracted with benzene (3×25 ml), the benzene extract dried over anhydrous sodium carbonate, and the excess solvent removed to leave a brownish orange oil which crystallized on cooling. The yellow precipitate, after filtering and washing with methanol (10 ml), was dried, weighed, and recorded as 9,10-dimethylanthracene, m.p. 179–181° (reported 180–181° (3)). The filtrate and the methanol wash were combined and diluted to 25 ml with methanol. By gas–liquid chromatography, using a Beckman No. 17449 silicone column (6 ft), with a column temperature of 230° and a helium flow of 40 ml/min, and comparison of the peak areas with standard curves previously prepared from authentic samples, the abundance of each product was obtained.

To obtain the analytical samples on which the data recorded in Table II were found, a similar reaction procedure was followed with the exception that the crude reaction product, obtained from the benzene extract, was distilled and the fraction b.p. 90–140 at 12 mm was collected. From this fraction the samples of the compounds 2, 3, 4, 4A, 5, and 6 that are reported in Table II were obtained by gas–liquid chromatography.

Synthesis of Reference Compounds

o-Ethylacetophenone.—The procedure used was similar to that described by Beech (2) for the synthesis of *p*-chloroacetophenone. Condensation of the diazonium salt obtained from *o*-ethylaniline (22.0 g) with acetaldoxime (16.5 g) and subsequent hydrolysis gave *o*-ethylacetophenone (2.45 g, 9.1%), b.p. 100° at 10 mm (reported 99–103° at 13 mm (4)). Reduction using the Wolff–Kishner method (Huang–Minlon modification) gave a hydrocarbon which was identical with an authentic sample of *o*-diethylbenzene.

2,4-, 3,4-, and 2,5-Diethylacetophenones.—Into a 15-ml, three-necked flask equipped with a mechanical stirrer and with a condenser and dropping funnel each fitted with a calcium chloride guard tube was placed light petroleum (b.p. 37–49°) (5 ml) and anhydrous aluminum chloride (1.80 g, 0.0135 mole). After cooling in an ice bath, a mixture of the appropriate diethylbenzene (1.74 g, 0.013 mole) and acetyl chloride (1.10 g, 0.014 mole) was added over a period of 1 hour while the mixture was stirred vigorously. After standing overnight, this reaction mixture was added to crushed ice (10 g) and concentrated hydrochloric acid (2 ml). The required ketones were recovered from the organic phase and by ether extraction of the aqueous phase. In each case, distillation of the product, b.p. ca. 240° at 720 mm (reported for 2,5-diethylacetophenone 246–247° at 769 mm (5)), gave a colorless oil. The resulting 2,4-diethylacetophenone was found to be chromatographically pure. The 2,5- and 3,4-isomers were about 97% pure and were purified by gas–liquid chromatography followed by distillation. Calc. for $C_{12}H_{16}O$: C, 81.77; H, 9.15%. Found: for 2,4-diethylacetophenone, C, 81.88; H, 9.47%; for 3,4-diethylacetophenone, C, 81.33; H, 9.23%; and for 2,5-diethylacetophenone, C, 81.22; H, 9.66%. In two earlier reports the preparation of 3,4-diethylacetophenone had been indicated (6, 7) but few details were given.

1,1-Diphenylethane.—To a solution of 1,1-diphenylethene (5.4 g) in absolute ethanol (70 ml), sodium (5 g) was added in small portions. The resulting solution was poured into water (100 ml) and thoroughly extracted with benzene. This extract was dried over anhydrous sodium sulphate, and concentrated to a yellow liquid residue (6.1 g). Distillation of this product yielded 1,1-diphenylethane (4.1 g, 83%), b.p. 144–147° at 15 mm (reported 136–137° at 11 mm (8)). This product was chromatographically pure.

THE ELECTRON SPIN RESONANCE SPECTRA OF GAMMA-IRRADIATED THIOSULPHATE

R. L. Eager and D. S. Mahadevappa

In a study of the effect of Co^{60} γ rays on various alkali thiosulphates the electron spin resonance (e.s.r.) spectra of the irradiated salts has been obtained.

Reagent grade $Na_2S_2O_3.5H_2O$ was used without further purification. Crystalline anhydrous $Na_2S_2O_3$ was obtained by evaporating to dryness at 80° C (1) a saturated solution of sodium thiosulphate pentahydrate. The potassium salt $3K_2S_2O_3.5H_2O$ was obtained by dissolving the C.P. grade reagent in water followed by repeated recrystallizations from a hot solution. All three of the salts were microcrystalline.

The irradiation source was a "Gamma Cell 220 Co^{60} Irradiation Unit" manufactured by Atomic Energy of Canada Ltd. The unit provides a dose rate of 10^5 r/hr.

The e.s.r. spectra were obtained with a Varian 4500 spectrometer. Magnetic field modulation of 200 c/s was used. The magnetic field survey in the region of $g = 2.00$ was calibrated by obtaining spectra of the semiquinone ion. The g values were determined by calibration of the spectra with signals from microcrystalline diphenylpicrylhydrazyl (D.P.P.H.) included with each sample. Electron spin concentrations were measured by graphical double integrations of the recorded spectra and comparison, through a substandard of gamma-irradiated barium dichloracetate, with solutions of D.P.P.H. in benzene.

Most of the spectra were obtained with the samples at room temperature and are free of power-saturation effects. A few spectra of the three salts were also obtained at liquid nitrogen temperature. At this temperature the samples could readily be power saturated.

THE ELECTRON SPIN RESONANCE SPECTRA OF GAMMA-IRRADIATED THIOSULPHATE

R. L. Eager and D. S. Mahadevappa

In a study of the effect of Co^{60} γ rays on various alkali thiosulphates the electron spin resonance (e.s.r.) spectra of the irradiated salts has been obtained.

Reagent grade $Na_2S_2O_3.5H_2O$ was used without further purification. Crystalline anhydrous $Na_2S_2O_3$ was obtained by evaporating to dryness at 80° C (1) a saturated solution of sodium thiosulphate pentahydrate. The potassium salt $3K_2S_2O_3.5H_2O$ was obtained by dissolving the C.P. grade reagent in water followed by repeated recrystallizations from a hot solution. All three of the salts were microcrystalline.

The irradiation source was a "Gamma Cell 220 Co^{60} Irradiation Unit" manufactured by Atomic Energy of Canada Ltd. The unit provides a dose rate of 10^5 r/hr.

The e.s.r. spectra were obtained with a Varian 4500 spectrometer. Magnetic field modulation of 200 c/s was used. The magnetic field survey in the region of $g = 2.00$ was calibrated by obtaining spectra of the semiquinone ion. The g values were determined by calibration of the spectra with signals from microcrystalline diphenylpicrylhydrazyl (D.P.P.H.) included with each sample. Electron spin concentrations were measured by graphical double integrations of the recorded spectra and comparison, through a substandard of gamma-irradiated barium dichloracetate, with solutions of D.P.P.H. in benzene.

Most of the spectra were obtained with the samples at room temperature and are free of power-saturation effects. A few spectra of the three salts were also obtained at liquid nitrogen temperature. At this temperature the samples could readily be power saturated.

The e.s.r. spectra (the first derivative of the absorption curve) for the three irradiated salts are shown in Fig. 1. The vertical line shown in each of these spectra indicates the

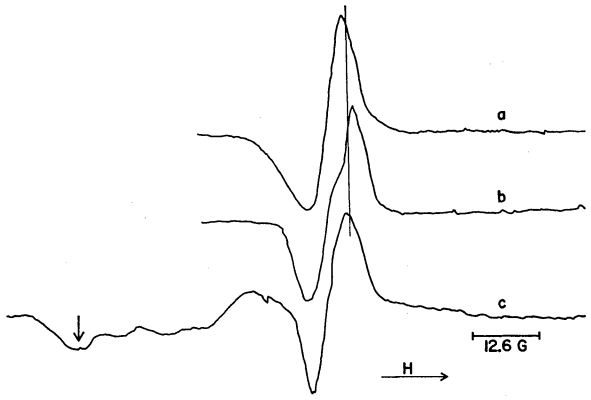

FIG. 1. Electron spin resonance spectra for samples at room temperature: (*a*) $Na_2S_2O_3.5H_2O$; (*b*) $3K_2S_2O_3.5H_2O$; (*c*) $Na_2S_2O_3$ anhydrous. The vertical line indicates the position of the D.P.P.H. spectrum. The vertical arrow is at a *g* value of 2.032. The magnetic field increases from left to right.

position of the D.P.P.H. spectrum. The magnetic field increases from left to right. The spectra for each of the salts appears to be essentially a single absorption line, except for anhydrous $Na_2S_2O_3$, where there is in addition a low-field structure. No hyperfine splitting was observed. The results for the three salts after they had been irradiated for 144 hours are given in Table I. The results are from spectra of samples which were at room tempera-

TABLE I

$Na_2S_2O_3$	5.94	5.9	2.006	6.6
$Na_2S_2O_3.5H_2O$	6.96	5.1	2.005	8.8
$3K_2S_2O_3.5H_2O$	6.54	4.0	2.005	9.1

*The width between the points of maximum slope, taken from the first derivative plots of the e.s.r. spectra.

ture. The electron spin concentrations were found to increase at first with an increase in absorbed dose but became almost constant for higher doses. The results shown in Table I are from samples with nearly the maximum electron spin concentrations.

The above results by themselves are not sufficient to enable an identification of the species responsible for the spectra. Gardner and Fraenkel (2) made the tentative suggestion that polyatomic free radicals in which the odd electron is primarily associated with a sulphur atom would be expected to have a *g* value of about 2.02. However, if the odd electron is in a sulphur-containing compound and is not primarily localized on a sulphur atom, the *g* value would normally be closer to the free-spin value of 2.0023. The *g* values recorded in Table I would suggest that the odd electron is not primarily on a sulphur atom.

The presence of sulphite free-radical ions, SO_3^-, in the irradiated salts would account for the products obtained when the irradiated salts are dissolved in water. Chantry *et al.* (3) have reported on the optical and e.s.r. spectra of γ-irradiated single crystals of sodium dithionate, sulphamic acid, potassium sulphamate, potassium amine sulphonate, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

potassium methane disulphonate. The e.s.r. spectra are similar for all these compounds, consisting of a single absorption line with a g value of 2.004. The authors (3) present evidence indicating that the e.s.r. spectra are due to the presence of sulphite free-radical ions. The g values found in the present work are significantly higher than the value of 2.004 reported by Chantry *et al.* Hence it would appear that if the interpretation of these authors is correct the spectra obtained in the present work are not due to sulphite free-radical ions.

Clark *et al.* (4) suggested that the SO_2^- free-radical ion was responsible for the e.s.r. spectra obtained by them from X-irradiated sodium and potassium dithionites. The spectra obtained in the present work for γ-irradiated thiosulphates are similar to those obtained by Clark *et al.* As a check, a sample of sodium dithionite was irradiated with Co^{60} γ rays. The e.s.r. spectra of the irradiated sample, at room temperature and at liquid nitrogen temperature, were obtained. At the lower temperature the sample could be readily power saturated. At both temperatures the g value of the peak was 2.005 and the line width was 10.4 gauss. The values reported by Clark *et al.* are 2.005 and 11.5 gauss, respectively.

On the basis of the similarity of the e.s.r. spectra of irradiated dithionites and thiosulphates it seems safe to tentatively assume that SO_2^- free-radical ions are produced in the gamma irradiation of thiosulphates.

The g value for the low-field shoulder of the low-field structure observed in the e.s.r. spectra of anhydrous $Na_2S_2O_3$ is 2.032. Free radicals in which the odd electron is mainly involved with the sulphur atom may be responsible for this structure (2). Low-field structures at a similar g value have been noted in the e.s.r. spectra of sulphur dissolved in oleum (5) and of chilled sulphur vapor (6). Such a conclusion is consistent with the observation that colloidal sulphur is formed when gamma-irradiated thiosulphates are dissolved in water.

PREPARATION OF ANTIDOTES FOR ANTICHOLINESTERASE POISONING
II. TERTIARY AND QUATERNARY SALTS OF PARPANIT AND PARPANIT ANALOGUES*

R. A. B. BANNARD, J. H. PARKKARI, AND I. W. COLEMAN

In connection with a study of the analogues of Parpanit (2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride) as cholinolytics for treatment of Sarin poisoning

*Issued as D.R.C.L. Report No. 411.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(1, 2) it became necessary to obtain a variety of salts of this compound as well as a series of quaternary derivatives of it and certain other cholinolytics. The preparation of the compounds required is described herein.

2-Diethylaminoethyl 1-phenylcyclopentanecarboxylate nitrate, bromide, and methanesulphonate were prepared from the hydrochloride by ion exchange using Amberlite IRA-400 resin in the appropriate anionic form (see Table I). Attempts to obtain the sulphate in the same manner, by metathesis of Parpanit with silver sulphate, or by interaction of the free base with sulphuric acid, led instead to good yields of the bisulphate, due presumably to a solubility effect.

For preparation of anionic variants of a given quarternary ammonium salt, most workers still appear to prefer the more classical metathetical reactions to ion exchange (3–10). However, it seemed to us that the latter procedure had much to recommend it in the present application from the standpoint of manipulative convenience and ease of purification, since only small quantities of the compounds were required. Accordingly, the Parpanit quaternary salts shown in Table II were prepared from the methiodide by ion exchange. Parpanit methylacetate, methylcitrate, methyllactate, and methyltartrate were not obtained as crystalline salts from the methiodide by ion exchange or by metathesis with the appropriate silver salt.

For preparation of quaternary ammonium salts from tertiary bases, only two basic methods are in common use. These are, interaction of the neat dry halide and base, and treatment of the base with a halide in the presence of a dry solvent. Although the first of these is commonly used to prepare methiodides as derivatives for characterization of amines (11), the second has recently been used with increasing frequency for synthesis of alkyl, benzyl, and substituted benzyl quarternary ammonium salts (3–5, 7, 10, 12–21). Both methods have been conducted at room temperature (14, 16, 19), at the reflux temperature of the halide (21) or solvent (4, 5, 7, 12, 14–18, 20), or in sealed vessels at elevated temperatures (3, 13, 16, 18–20). The solvent which has been used most frequently is benzene (7, 12, 16–18), but ethanol (4, 10, 13, 16), ether (5, 7, 14), methyl ethyl ketone (3, 4, 20), methanol (13, 15), nitromethane (10, 20), acetone (19), and chloroform (22) have also been employed. For preparation of Parpanit methobromide and methiodide and the quaternary salts given in Tables III, IV, and V it was necessary to use a variety of conditions, details of which are given in the Experimental section.

Interaction of Parpanit free base with excess isopropyl bromide at 130° in a sealed tube furnished Parpanit hydrobromide in 66% yield, due presumably to unfavorable competition between the substitution reaction and an elimination reaction which leads to dehydrohalogenation of the alkyl halide (4, 10, 23). Attempts to increase the S_N to E ratio by operating at low base concentration (0.1 *M*), low temperature (0°), and in polar solvents (acetonitrile) (23) failed to yield Parpanit isopropylbromide. This substance was, however, obtained in 38% yield by the action of ethyl bromide on 2-isopropylethylaminoethyl 1-phenylcyclopentanecarboxylate (24).

EXPERIMENTAL*†

Preparation of Parpanit Tertiary Salts by Ion Exchange

The method used for preparation of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrogen nitrate is typical. A 2% aqueous solution of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride (3.26 g, 10 meq) was passed through Amberlite IRA-400 resin (50 ml, 50 meq) in the nitrate form, followed by water (500 ml). The eluate was evaporated to dryness *in vacuo* and the residue was dried at

					Found	60.85	7.52	3.35	20.20

Method H described in Experimental used throughout.

0.001 mm pressure. Two recrystallizations from ethanol–ether gave 3.05 g (86.7%) of Parpanit nitrate as colorless needles, m.p. 105–105.5°.

Preparation of Quaternary Ammonium Salts of Parpanit

Method A: Parpanit Methobromide

Parpanit (1.00 g, 0.00307 mole), dissolved in water (25 ml), was neutralized with 10% aqueous sodium hydroxide and extracted with ether (4×25 ml). The extract was dried over magnesium sulphate and filtered. Removal of the ether *in vacuo* followed by drying at 0.001 mm pressure gave 0.840 g (94.7%) of 2-diethylaminoethyl 1-phenylcyclopentanecarboxylate as a colorless mobile oil. The flask was fitted with a dry-ice condenser, and methyl bromide (10 ml, 17 g, 0.18 mole) was added. A precipitate began to form almost immediately. After 2 hours the excess methyl bromide was allowed to evaporate and the residue was dried at 0.001 mm pressure. Two recrystallizations from acetone–ether gave 1.05 g (89.0%) of Parpanit methobromide as colorless flakes, m.p. 117–117.5°.

Method B: Parpanit Methiodide

Parpanit (5.00 g, 0.0153 mole) was converted to the free base as described in Method A. The free base was dissolved in acetone (50 ml), methyl iodide (10 ml, 23 g, 0.16 mole) was added, and the solution was heated under reflux with stirring for 30 minutes. Removal of volatiles *in vacuo* followed by two recrystallizations from acetone–ether gave 6.34 g (96.0%) of Parpanit methiodide as colorless needles, m.p. 139–140°. Mndzhoyan *et al.* (25) report m.p. 136°.

Method C: Preparation of Parpanit Methyl Quaternary Ammonium Salts by Ion Exchange

The procedure followed was identical with that given for conversion of Parpanit to the nitrate salt except that Parpanit methiodide was used as starting material. Yields are given in Table II.

Method D: Parpanit n-Alkylbromides

The preparation of Parpanit ethobromide is typical. Parpanit (1.00 g, 0.00307 mole) was converted to the free base as described in Method A. The free base was heated in a sealed tube for 16 hours at 100° with ethyl bromide (5.0 g, 0.046 mole) which had been freshly dried over phosphorus pentoxide. The precipitate was removed from the tube by dissolving it in acetone, the solvents were removed *in vacuo*, and the solid residue was twice recrystallized from acetone–ether, yielding 0.95 g (78%) of Parpanit ethobromide as colorless needles, m.p. 150–150.5°. Van Campen and Tilford (26) report m.p. 150–152°. When the reactants were merely heated under reflux for 48 hours, a 25% yield was obtained.

Method E: Parpanit Benzylbromide

A mixture of Parpanit free base (0.87 g, 0.0030 mole) and freshly distilled and dried benzyl bromide (0.77 g, 0.0045 mole) was kept at room temperature for 24 hours. Anhydrous ether (25 ml) was added and the resultant precipitate was collected by filtration. Two recrystallizations from acetone–ether gave 0.88 g (64.0%) of Parpanit benzylbromide as colorless needles, m.p. 108–108.5°. When the reaction was conducted in ether as solvent under otherwise identical conditions, the yield decreased to 4%. The use of benzene as solvent, when the same proportions of reactants were heated under reflux for 2 hours, gave only a 12% yield.

Method F: Parpanit Benzylchloride

A mixture of Parpanit free base (0.87 g, 0.0030 mole) and freshly distilled and dried benzyl chloride (0.57 g, 0.0045 mole) was kept at 110° for 24 hours. Anhydrous ether (25 ml) was added, causing separation of an oil which crystallized on standing. The solid was recrystallized twice from acetone–ether, yielding 0.65 g (52.0%) of Parpanit benzylchloride as colorless needles, m.p. 129.5–130°.

Method G: Parpanit p-Phenylbenzylbromide

A mixture of Parpanit free base (1.26 g, 0.0044 mole), *p*-phenylbenzylbromide (2.20 g, 0.0088 mole) (prepared according to the method of Zervas and Dilaris (27)), and anhydrous ether (50 ml) was heated under gentle reflux for 3 days. Removal of the solvent *in vacuo* followed by two recrystallizations of the oily residue from ethanol–ether gave 1.98 g (84.5%) of Parpanit *p*-phenylbenzylbromide as colorless needles, m.p. 157–157.5°. The yield was reduced to 37% when the period of reflux was shortened to 16 hours.

Preparation of Methobromides of Parpanit Analogues

Method H: 2-Isopropylethylaminoethyl 1-Phenylcyclopentanecarboxylate Methobromide

2-Isopropylethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride (24) (1.70 g, 0.0050 mole) was converted to the free base (1.49 g, 97.4%) by the procedure described in Method A. A mixture of the latter, methyl bromide (10 ml, 17 g, 0.18 mole), and acetone (25 ml) in a flask fitted with a dry-ice condenser was magnetically stirred for 1 hour under reflux. Removal of the excess halide *in vacuo* followed by three recrystallizations from *n*-propanol–ether gave 1.27 g (64.0%) of 2-isopropylethylaminoethyl 1-phenylcyclopentanecarboxylate methobromide as colorless needles, m.p. 154.5–155.5°.

ACKNOWLEDGMENTS

We are indebted to Geigy Pharmaceuticals Ltd., Montreal, for kindly providing the Parpanit used in preparation of the Parpanit tertiary and quaternary salts, and to Miss Anne Fairhurst for technical assistance.

NUCLEAR SPIN–SPIN COUPLING IN C^{13}-ENRICHED ACETYLENE, ETHYLENE, AND ETHANE

D. M. GRAHAM AND C. E. HOLLOWAY

The application of Ramsay's theory of nuclear spin–spin coupling (1) has been limited by lack of knowledge of the coupling constants of simple molecules where, because of symmetry, the effect of nuclear spin coupling does not appear in the transition energies. H^2 substitution has been used to circumvent the symmetry selection rules. However this technique may lead to complicated spectra, particularly when several nuclei are present, due to the greater multiplicity of energy levels arising from the spin of the deuteron. In many cases C^{13} substitution should be preferable in spite of greater synthetic difficulties since this may allow the determination of H^1–H^1 as well as C^{13}–H^1 and C^{13}–C^{13} coupling parameters. Such information should afford and indeed has afforded an additional means for evaluating different approaches for calculation of molecular wave functions.

NUCLEAR SPIN–SPIN COUPLING IN C^{13}-ENRICHED ACETYLENE, ETHYLENE, AND ETHANE

D. M. GRAHAM AND C. E. HOLLOWAY

The application of Ramsay's theory of nuclear spin–spin coupling (1) has been limited by lack of knowledge of the coupling constants of simple molecules where, because of symmetry, the effect of nuclear spin coupling does not appear in the transition energies. H^2 substitution has been used to circumvent the symmetry selection rules. However this technique may lead to complicated spectra, particularly when several nuclei are present, due to the greater multiplicity of energy levels arising from the spin of the deuteron. In many cases C^{13} substitution should be preferable in spite of greater synthetic difficulties since this may allow the determination of H^1–H^1 as well as C^{13}–H^1 and C^{13}–C^{13} coupling parameters. Such information should afford and indeed has afforded an additional means for evaluating different approaches for calculation of molecular wave functions.

EXPERIMENTAL

Acetylene was prepared from C^{13}-enriched barium carbonate (59.7%) by reduction to the carbide with excess calcium followed by reaction with water. Ethylene was obtained by reduction of the acetylene with chromous chloride. Reduction of ethylene by hydrogen on palladium – barium carbonate catalyst gave enriched ethane.

Proton spectra were obtained with a Varian V 4302 spectrometer at 60 Mc; carbon spectra at 15.1 Mc. All measurements were made on pure liquid samples at −70° C. The peak positions were measured by the audio side-band technique, and the modulation frequency was determined by a Hewlett–Packard 522 B frequency counter. By varying the audio-modulation frequency as the spectrum was scanned a side band of one of the stronger lines could be used to provide a base-line frequency calibration. In the case of ethylene and acetylene averaging a number of such spectra gave line positions to ±0.1 c/s in most cases. With ethane, however, field instability increased the average deviation to ±0.5 c/s. In all cases, the position of certain lines which were critical in the analysis of the spectrum was determined to better than ±0.1 c/s by the wiggle-beat method or by a combination of these two techniques.

To a certain extent for ethylene and particularly with ethane the C^{13} spectrum was more useful than the proton spectrum since the line spacings were greater and hence the lines were more readily resolved and their positions could be determined more precisely.

RESULTS

The enriched compounds prepared are actually mixtures of species containing zero, one, and two C^{13} atoms. Resolution of the spectra into contributions from each isotopically substituted species was aided by observations on the "C^{13}-satellite" spectra of the unenriched compounds. The resulting proton and carbon spectra were analyzed as follows.

Acetylene (Fig. 1).—The spectrum is obviously a superposition of an ABX pattern due to $HCC^{13}H$ and an A_2X_2 pattern arising from $HC^{13}C^{13}H$. Calculation of the spin-coupling

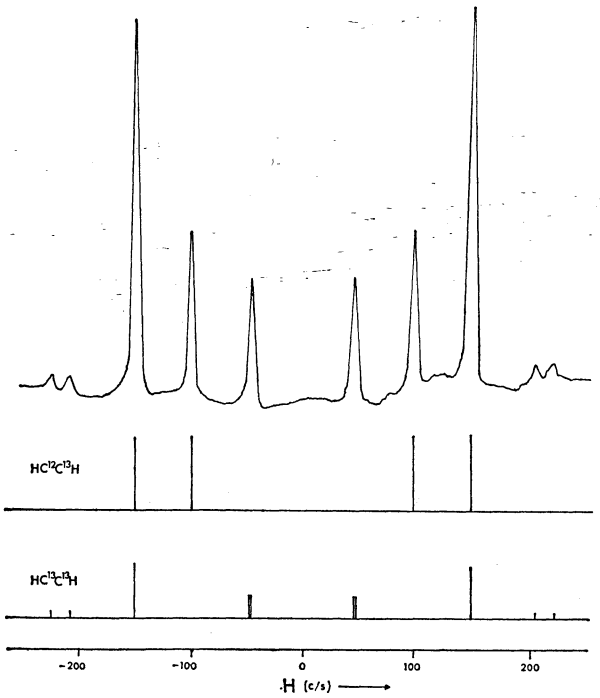

FIG. 1. Observed and calculated C^{13} n.m.r. spectra of enriched acetylene.

constants was readily carried out using the published energy levels and transitions for these spin systems (2).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Ethylene (Fig. 2).—The lines in the spectrum resulting from the mono-enriched species were obtained in terms of an A_4X system using spin functions of C_2 symmetry. The transitions arising from the other species were obtained from an A_4X_2 analysis using spin functions of D_2 symmetry. Separation of the lines due to each species in the observed spectra was aided by the chemical shift due to isotopic substitution; $\delta_{HC^{13}} - \delta_{HC^{12}} = 0.0102 \pm 0.003$ p.p.m.; $\delta_{C^{13}C^{12}} - \delta_{C^{13}C^{13}} = 0.30 \pm 0.001$ p.p.m. It proved possible using both the H^1 and C^{13} spectra to obtain directly all the coupling constants except that between the gem protons and the carbon–carbon coupling. Here it was necessary to solve 4×4 secular determinants and to determine the constants by successive approximations.

Ethane (Fig. 3).—The $H_3C^{13}C^{12}H_3$ spectrum was calculated using a set of spin functions formed from the carbon spin function and the product of two sets of D_3 symmetry spin functions corresponding to the two groups of three equivalent protons. The symmetry of the resulting functions was assigned by the application of standard group theory operations and rules (3). Further simplification of the secular equation was obtained by taking linear combinations of wave functions within each symmetry group which were degenerate as a result of free internal rotation of the methyl groups. A similar procedure was used for the $H_3C^{13}C^{13}H_3$ transitions; in this case carbon spin functions of C_2 symmetry were used. The only parameter that could be obtained directly from the spectra was the sum of the long- and short-range C^{13}–H^1 coupling constants. The remaining constants were obtained by an iterative procedure. Since the protons within each methyl group are equivalent, the gem coupling constant could not be obtained.

The results obtained are summarized in Table I. Shortly before completion of this work the results of a similar study became available (4). Since this work was based on proton

*From proton resonance spectra of C^{13}-enriched compounds (4).
†The authors of ref. 4 have pointed out in a private communication that the observed C^{13} spectrum of ethylene can arise only if the C—C and H—H coupling constants have the same sign, thus confirming their deduction that the contact term is dominant in J_{CC}. We have recently shown that this is also the case for ethane.
‡From proton "C^{13}-satellite" spectrum (6).
§From deuteration (7).

spectra and the work reported here was primarily (but not entirely) based on C^{13} resonance measurements, the excellent agreement obtained independently tends to confirm the spectral analyses. This is particularly important for ethylene and ethane where the large number of possible transitions presented a formidable problem in arriving at a reasonable and unique assignment.

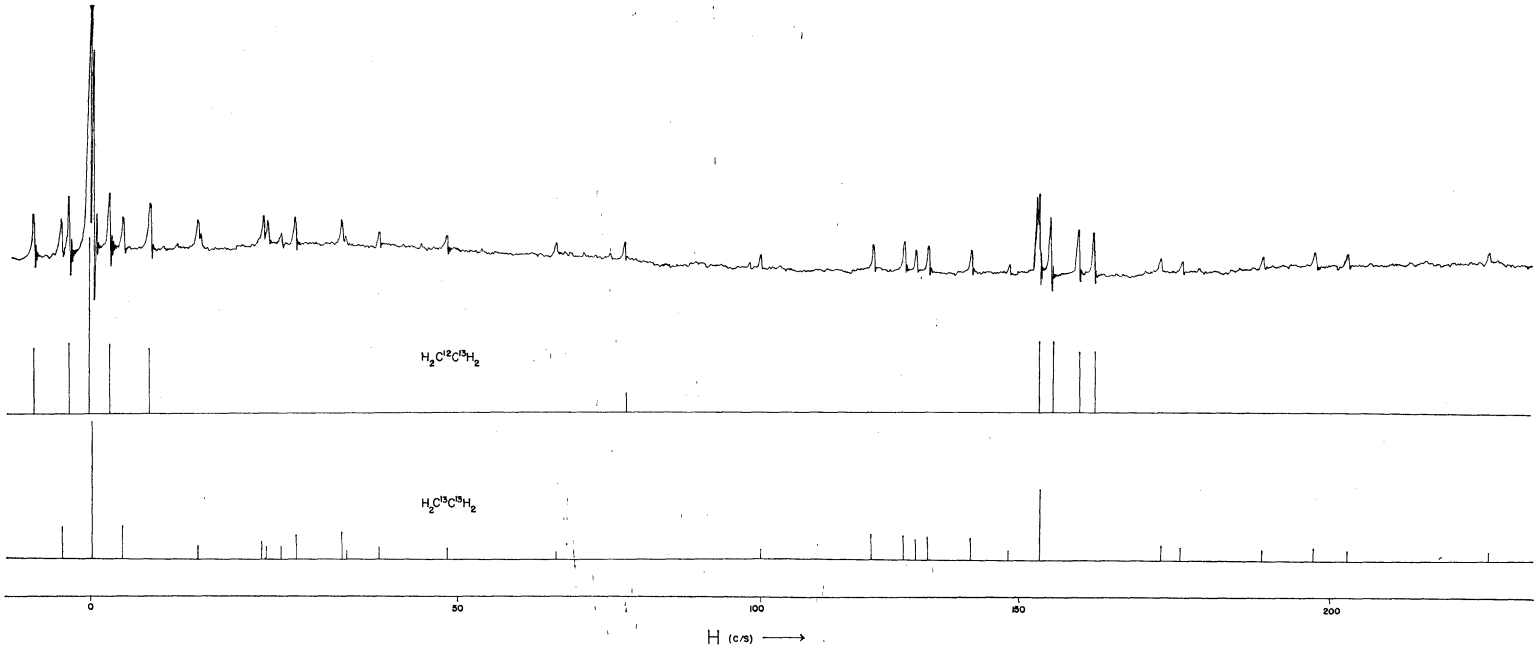

FIG. 2. Observed and calculated C^{13} n.m.r. spectra of enriched ethylene.

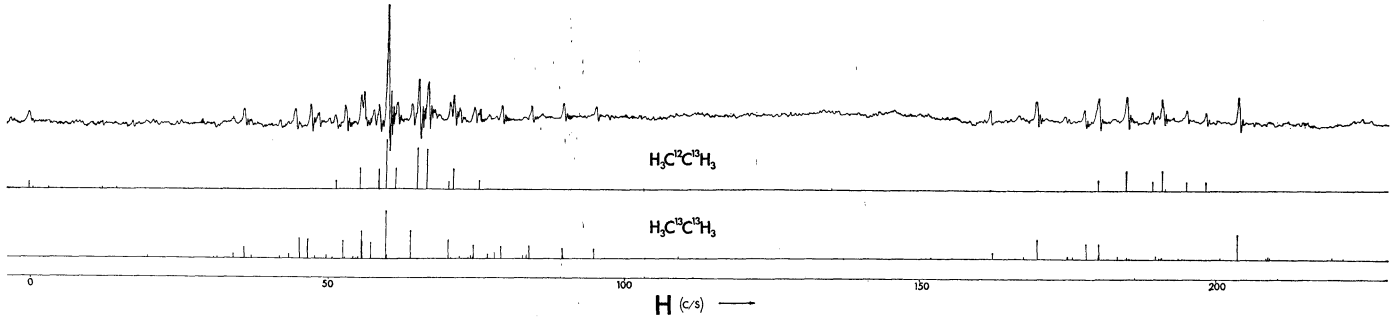

FIG. 3. Observed and calculated C^{13} n.m.r. spectra of enriched ethane.

The data also provide additional verification of the linear relation between C^{13}–H^1 short-range coupling constants and the fractional *s*-character of the C—H bond (ρ_{CH}) (5). Making the reasonable assumption that the hybridization in acetylene is pure *sp*, the relation is $\rho_{CH} = 0.201 J_{CH}$. This gives 0.315 and 0.251 for the fractional *s*-character in ethylene and ethane, respectively, consistent with the bond angles and lengths reported for these molecules.

The carbon–carbon coupling constants also appear to follow a similar trend. Extension of the argument of reference 5 to carbon–carbon coupling predicts a linear dependence of J_{CC} on the square of the fractional *s*-character. The experimental values do not fit such a relation and it appears probable that the simple picture used is not applicable to carbon–carbon coupling in general, and also that there may be appreciable contributions to J_{CC} from π electrons in the unsaturated compounds. Further work is in progress which it is hoped will resolve this problem.

SOLVOLYSIS IN LIGHT AND HEAVY WATER
V. EFFECT OF DIOXANE ON THE SOLVENT ISOTOPE EFFECT WITH *t*-BUTYL CHLORIDE[1]

WM. G. CRAIG,[2] LEO HAKKA,[2] P. M. LAUGHTON, AND R. E. ROBERTSON[3]

In paper I of this series (1), we reported data for the solvolytic rate ratio k_{D_2O}/k_{H_2O} for a few alkyl halides, including *t*-butyl chloride. This part of the work was motivated by a paper of Swain, Cardinaud, and Ketley (2) which reported a large difference in the ratio between methyl halides and *t*-butyl chloride. Our work essentially confirmed their data for the latter, but changed the values for the former. Dr. Swain has since informed us that redetermination of the methyl halide values in his laboratories confirmed our results.

Since that time, our view of the origin of this solvent effect in water has been developed in a series of papers both on k_{D_2O}/k_{H_2O} (3–6) and in extensive work by one of us (R. E. R.) on the apparent heat capacity of solvolysis, $\Delta C_p^{\ddagger}$ (7). Central to our interpretation is the concept that water forms a solvation shell of the gas-hydrate type about the initial-state substrate (8). This solvation shell undergoes rearrangement near the reaction site in the activation process. The slight differences in the work required to rearrange the initial-state solvation shell in the two solvents (H_2O and D_2O) provide the source of the difference in the solvolysis rates in the two media. As might have been anticipated, these differences closely parallel comparable differences which have been observed where some physical test involves the disruption of the water structure in the two media (9).

Just as the viscosity of water is reduced by an increase in temperature, the *difference* in viscosity between light and heavy water is reduced proportionately. Similarly, the addition of a hydrogen-bonding solvent such as dioxane will modify the structure of bulk water and particularly the solution properties, which are among the more striking consequences of water structure. The gas-hydrate type of initial-state solvation shell characteristic of aqueous solution of neutral molecules will, as a consequence of this modification, be modified toward a less organized structure in the solvent mixture. There should be a corresponding reduction in the work to break down this structure in the activation process and hence a reduction in the difference due to isotopic substitution (6).

It was therefore a source of continuing concern for us that Swain, Cardinaud, and Ketley (2) reported no perceptible change in k_{D_2O}/k_{H_2O} from 10% to 80% dioxane solution. We decided to re-examine this system, choosing a dioxane mole fraction between 0.1 and 0.2 because of evidence from many sources that aqueous solvolytic parameters go through maxima or minima in this region (10).

EXPERIMENTAL

Rate determinations were made using a conductometric method (11). Concentration resistance relationships were determined empirically with a precision rod displacement titrimeter (one counter unit = 8.33×10^{-4} ml (12) with a precision of this order for 1-ml displacement). The reactions were studied in stirred cells of 80-ml volume with shiny platinum electrodes and a cell constant of approximately 0.1. The cells were filled under dry nitrogen and the substrate was introduced through a serum cap and silicone plug mounted on a 10/30 standard taper joint. Temperature control was ±0.003° C as indicated by a platinum resistance thermometer.

Dioxane was purified by the method of Vogel (13), distilled in a 5-ft Vigreux column under nitrogen, and subjected to partial freezing, n_D^{25} 1.4213, single VPC peak. When distilled with a 2-ft saddle-packed column from sodium, it was found to be strongly basic. Conductivity water was boiled under nitrogen before use. Liquid transfers were carried out in glass and Teflon systems under dry nitrogen, the dioxane by weight, the conductivity water by volume. The solvent was 40 vol% water or D_2O, 60% dioxane (86.77 mole% water), n_D^{25} 1.3750 and 1.3700, respectively. The *t*-butyl chloride was a center cut from Eastman Kodak white label material. Convenient aliquots were 0.1 ml of solution made up from 5 μl of substrate in 1 ml of solvent.

Rates were calculated by the Guggenheim method, resistance readings being converted to counter readings corrected for volume change in the titration calibration, which preceded the kinetic study.

RESULTS

At 20.099°, replicate values for the rate of hydrolysis of *t*-butyl chloride in 60 vol% dioxane in light water were 4.64×10^{-4} and 4.62×10^{-4} sec^{-1}, and at 20.106°, 4.66×10^{-4} sec^{-1}. The corresponding values at 20.106° when D_2O replaced H_2O were 4.53×10^{-4} and 4.36×10^{-4} sec^{-1} with slight scatter. These results indicate a ratio k_{D_2O}/k_{H_2O} of 0.94–0.97. Our best value in the pure waters is 0.70 at 4°, which, when extrapolated to 20° according to the temperature correlations of papers III and IV (4, 6), would change to 0.73–0.75. Thus, even if the scatter of our values in heavy water conceals a systematic error of as

TRITIATION OF AROMATICS BY HTO-PROMOTED ALUMINUM CHLORIDE

CONSTANŢA MĂNTESCU AND ALEXANDRU T. BALABAN

In the search for a better tritiation agent for aromatics we investigated the action of tritiated water on derivatives of benzene and pyridine in the presence of aluminum chloride. As known (1) water-promoted aluminum chloride contains the complex acid $H[AlCl_3OH]$, one of the strongest Brönsted acids, which is able to abstract hydride ions from alkanes and thus to cause isomerization (2).

Benzene and pyridine derivatives were selected for investigation; in order to find out the limitations of the method, compounds less reactive than benzene were tested. The reaction consisted of the addition of 0.05 mole tritiated water (specific activity 3.96×10^9 disintegrations sec^{-1} $mole^{-1}$) to a stirred mixture of aromatic (0.1–0.3 mole) and 0.1 mole anhydrous aluminum chloride. In some cases methylene chloride was used as solvent. Temperatures up to 100° and reaction times up to 12 hours were employed. After completion of the reaction the mixture was poured into ice water and the product was purified by repeated washing with water, drying, and distillation.

Pyridines were purified by strong alkalinization of the hydrolyzed reaction mixture, extraction with ether, repeated washing with concentrated alkali, drying, and distillation.

After counting, the products were again washed, dried, distilled, and counted, in order to verify if all activity due to water had been removed.

Activities were determined (3) by introducing from a vacuum line the labeled products

as quenching agents admixed with ethanol in known amounts into two compensated Geiger–Müller counters of identical characteristics except their lengths.

Results are presented in Table I. As it may be seen, although the specific activities

TABLE I

Tritiation of aromatics by 0.05 mole HTO (3.96×10^9 disintegrations sec^{-1} $mole^{-1}$) in the presence of 0.1 mole $AlCl_3$

Aromatic		CH_2Cl_2, ml	Temp., °C	Time, hr	Specific activity, disintegrations sec^{-1} $mole^{-1}$
Compound	Moles				
Benzene	0.1	—	25	0.5 1 1.5	2.2×10^9 4.5×10^9 6.7×10^9
Fluorobenzene	0.1	—	86	3	1.85×10^9
Chlorobenzene	0.1	—	100	3	3.6×10^8
2,4,6-Collidine	0.1	20	41–42	3 7	7.5×10^6 1×10^7
2,6-Lutidine	0.1	20	41–42	7	4.8×10^6
Pyridine	0.1	25	41–42	12	5×10^5
Nitrobenzene	0.15	25	41–42	12	8×10^4
2,6-Di-*t*-butyl-4-picoline	0.1	20	41–42	3 7	2.5×10^7 4×10^7

obtained refer neither to comparable conditions nor to equilibrium composition (excepting benzene which reaches equilibrium in 1.5 hours), they reflect the order of decreasing reactivity towards electrophilic substitution: benzene ~ fluorobenzene > chlorobenzene > 2,4,6-collidine > 2,6-lutidine > pyridine > nitrobenzene.

Other tritiated acids that were used as electrophilic tritiation agents, namely sulphuric acid (4, 5), trifluoroacetic acid (6), and the recently described complex acid $T[F_3BOPO_3H_2]$ (7), give lower reaction rates, since they are weaker acids. In order to be able to make a comparison with published rate constants, the tritiation of benzene by THO-promoted aluminum chloride was investigated at 25°. The first-order rate constant is 10 times larger than that in the presence of $T[F_3BOPO_3H_2]$ (7) and 2000 times larger than that in the presence of $THSO_4$ (4). Moreover, the present method allows the tritiation of pyridine, while tritiated sulphuric acid is unable to tritiate pyridine even at 200° C during 40 hours (5).

The tritiation of 2,6-di-*t*-butyl-4-picoline (8) is the most rapid of all pyridines studied, despite the fact that the substitution in position 3 is retarded by an ortho effect due to the *t*-butyl group; this is explained by the fact that, unlike all other pyridines, this compound is not protonated (9) and is therefore substituted as a pyridine more easily than as a pyridinium salt.

HIGH-YIELD SYNTHESES OF N-MONO- AND N,N-DI-SUBSTITUTED UREAS AND THIOUREAS FROM SILICON PSEUDOHALIDES

Roy G. Neville[1] and John J. McGee

Department of Chemistry, Aerospace Corporation, El Segundo, California, U.S.A.

Received March 22, 1963

ABSTRACT

This study demonstrates that N-mono- and N,N-di-substituted ureas and thioureas may expediently be synthesized, in essentially theoretical yield, by reacting primary or secondary aliphatic, alicyclic, aralkyl, aromatic, and heterocyclic amines with silicon tetraisocyanate or tetraisothiocyanate, or the corresponding methyl-substituted analogues. The method fails with aromatic amines possessing bulky (e.g. phenyl, bromo), or strongly electronegative (e.g. trifluoromethyl), substituents in the 2-, or 2,6-positions of the aromatic nucleus. Data on several new substituted ureas and thioureas are reported, and improved preparative procedures for the silicon pseudohalides are described.

It has long been known that organic isocyanates and isothiocyanates react readily with primary and secondary aliphatic and aromatic amines to produce substituted ureas and thioureas. Indeed, these reactions are commonly employed to characterize amines and to prepare urea derivatives (1, 2). Despite the large amount of literature available on compounds containing the carbon–isocyanate and carbon–isothiocyanate groups, very few studies have been published on the reactions of amines with compounds containing the silicon–isocyanate (Si–NCO) and silicon–isothiocyanate (Si–NCS) groups.

In 1951, Anderson (3) reported that silicon tetraisocyanate and several alkyl- and arylsilicon mono-, di-, and tri-isocyanates and isothiocyanates react readily with aniline, but the products resulting from these reactions were not characterized. Later, O'Brien (4) showed that trimethylsilicon isocyanate in benzene solution reacts with *n*-, *i*-, *s*-, and *t*-butylamines to produce butylureas. In 1958, Neville (5) demonstrated that silicon tetraisocyanate and isocyanates of empirical formula $R_xSi(NCO)_{4-x}$ (R = Me, Ph; x = 0, 1, 2, 3) reacted alone or in benzene solution with allylamine, diallylamine, aniline, benzylamine, and *o*- and *p*-toluidines to produce essentially theoretical yields of the corresponding N-mono- or N,N-di-substituted ureas. In every case the isocyanates and amines reacted in stoichiometric proportions and intermediate silylureas were not isolated. That these reactions do, in fact, involve silylurea intermediates was shown by Goubeau and Heubach (6), who reacted aniline and several secondary aliphatic amines with methylsilicon isocyanates, $Me_xSi(NCO)_{4-x}$ (x = 0, 1, 2, 3), in petroleum ether.* The silylureas isolated

[1]*All inquiries, including requests for reprints, should be addressed to this author.*

**It is significant that these workers specifically state that trimethylsilicon isocyanate does* not *react with aniline. In the present study we found that trimethylsilicon isocyanate reacts readily with aniline to produce phenylurea upon hydrolysis of the trimethylsilylurea intermediate.*

were extremely readily hydrolyzed by moisture to a silicon-containing moiety and a substituted urea:

$$4RR'NH + Si(NCO)_4 \rightarrow Si(NHCONRR')_4 \xrightarrow{2H_2O} 4H_2NCONRR' + SiO_2.$$

The extreme reactivity of the readily prepared silicon tetraisocyanate and tetraisothiocyanate with amines, coupled with the essentially theoretical yields of ureas obtained upon hydrolysis of the products, prompted us to investigate the scope and limitations of these reactions to ascertain whether they might furnish a preparatively useful general synthetic method for N-mono- and N,N-di-substituted ureas and thioureas. Usually, substituted ureas and thioureas of this type are prepared by reacting an amine hydrochloride in *aqueous* solution with cyanic or thiocyanic acid (7). An alternative procedure is the reaction of ammonia with the rather inaccessible dialkyl- or diaryl-carbamyl chlorides (1). The obvious advantage of silicon tetraisocyanate and tetraisothiocyanate (and their methylsilicon analogues) is that these reagents are very soluble in benzene, chloroform, and many other non-prototropic solvents in which amines are also soluble. Reaction is thus carried out in a homogeneous medium and the urea and thiourea products, which are insoluble in the solvent, immediately precipitate. Since essentially theoretical yields (usually $>95\%$) are obtained there are no organic by-products, and the gelatinous silica remaining is easily separated by filtration.

Silicon Isocyanates and Isothiocyanates

Silicon tetraisocyanate (8) and methylsilicon isocyanates (9) were prepared in 75–90% yields by reacting the appropriate chlorosilanes with dry silver cyanate in anhydrous benzene. Forbes and Anderson (8, 9) state that lead cyanate reacts with chlorosilanes to produce low yields of silicon isocyanates. We have found that lead cyanate, when *freshly* prepared and dried, consistently gives 52–71% yields of the silicon isocyanates and can, therefore, advantageously replace the more expensive silver cyanate.

Silicon tetraisothiocyanate (10) and the three methylsilicon isothiocyanates (11) were prepared in 80–86% yields by reaction of the corresponding chlorosilanes with freshly prepared, anhydrous silver thiocyanate or ammonium thiocyanate (12) in anhydrous benzene. Although the use of silver thiocyanate has been found to produce approximately 5% higher yields, ammonium thiocyanate gives purer silicon isothiocyanates.

Reactions with Amines

To determine the scope and limitations of this novel procedure approximately 60 primary and secondary amines, of widely differing structure, were reacted with silicon tetraisocyanate and tetraisothiocyanate, and in certain cases with methylsilicon isocyanates and isothiocyanates. In the aliphatic series unbranched- and branched-chain alkyl and alkenyl, and certain alicyclic, amines were investigated. In the aromatic series representative aryl, aralkyl, and heterocyclic amines were studied.

In all cases aliphatic unbranched- and branched-chain primary and secondary amines were found to react very readily, and usually exothermically, with silicon tetraisocyanate and tetraisothiocyanate. Methylsilicon isocyanates and isothiocyanates behaved similarly. In almost all cases the urea or thiourea derivative rapidly crystallized (1–2 minutes) in essentially 100% yield on cooling the solution to room temperature. To ensure that the silylurea intermediates were completely hydrolyzed, the products were dissolved in dilute isopropyl alcohol and refluxed for a few minutes. Gelatinous silica was easily removed by filtering the hot solution through a sintered-glass funnel containing Celite, and the urea or thiourea derivative was obtained by evaporating the filtrate. Alicyclic amines

(e.g. cyclohexylamine) reacted very readily and exothermically. In the case of a few short-chain aliphatic amines (e.g. diallylamine, cyclopropylamine) some difficulty was experienced in isolating a high (>90%) yield of the urea or thiourea. This difficulty was possibly due to tenacious occlusion of the urea or thiourea derivative by the gelatinous silica. Most aliphatic amines investigated could be quantitatively converted to the corresponding urea or thiourea derivative in 5–10 minutes and the entire preparation of the purified product could be completed within 1 hour. The method is greatly superior to earlier published procedures (employing *aqueous* cyanic or thiocyanic acids) in that it is simple, rapid, and produces high yields.

Primary aromatic amines (e.g. aniline, toluidines, naphthylamines) and aralkylamines (e.g. benzylamine) reacted exothermically, or occasionally without noticeable exotherm, in benzene or chloroform solution to produce essentially theoretical yields of urea and thiourea derivatives. Heterocyclic primary amines (e.g. 2-aminopyridine) behaved similarly. Secondary aromatic amines (e.g. N-methylaniline, N-ethylaniline) reacted slowly with silicon tetraisocyanate, or tetraisothiocyanate, and required longer reflux periods (1–2 hours) depending upon the amine. Diphenylamine, for example, yielded N,N-diphenylurea in theoretical yield only after refluxing for 4 hours with silicon tetraisocyanate. In the case of silicon tetraisothiocyanate a 6-hour reflux period was required to produce a theoretical yield of N,N-diphenylthiourea.

To determine the effect of steric hindrance on the reactivity of arylamines with silicon tetraisocyanate, or tetraisothiocyanate, a series of 2-mono-, 2,4-di-, and 2,4,6-tri-substituted amines was studied. Although 2-chloro-, 2-bromo-, and 2-iodo-anilines readily yielded the 2-halophenylureas or thioureas, 2-fluoroaniline reacted slowly to produce 2-fluorophenyl derivatives. 2,6-Dibromoaniline was extremely slow to react with silicon tetraisocyanate and, under the experimental conditions employed, a pure derivative could not be isolated. Both 2,6-dimethylphenylurea and 2,6-dimethylphenylthiourea were readily obtained from 2,6-dimethylaniline, but 2-trifluoromethylaniline was totally unreactive. 2-Nitroaniline and 2-methoxyaniline yielded the corresponding urea and thiourea derivatives without difficulty.

In general, theoretical yields were readily obtainable from anilines substituted in the ortho or diortho positions, provided that the substituents were not too bulky (e.g. C_6H_5 groups), or that they deactivated the amino group by inductive withdrawal of electrons as in the case of 2-trifluoromethylaniline.

The reactivities of amines with silicon tetraisocyanate or tetraisothiocyanate and their methylsilicon analogues may be summarized as follows:

$$RNH_2 > R_2NH > ArNH_2 \gg ArNHR \gg Ar_2NH$$

(R = alkyl, aralkyl; Ar = aryl)

In the course of this investigation, several new compounds were prepared. These, and the other compounds synthesized, are listed in Tables I, II, and III.

Silicon tetraisocyanate and tetraisothiocyanate were reacted with ethylenediamine and *o*- and *p*-phenylenediamines to demonstrate that the method can be extended to synthesize diureas and dithioureas, although the preparation of these compounds was not studied in detail.

Ureas and thioureas were characterized by their melting point, Kjeldahl nitrogen analysis, and infrared spectra. The following infrared absorption characteristics were observed: NH stretching at 3390–3470 cm^{-1}; NH_2 vibration at 3180–3370 cm^{-1}; NH_2

EXPERIMENTAL

Silicon Isocyanates

These compounds were synthesized by employing modifications of the procedures of Forbes and Anderson (8, 9).

The synthesis of silicon tetraisocyanate is typical. Freshly prepared, dry, finely powdered silver cyanate (660 g; 4.4 moles; 10% theoretical excess) was stirred with anhydrous (sodium dried) benzene (800 ml). Silicon tetrachloride (170 g; 1.0 mole) was added, dropwise, over a 45-minute period, to the rapidly agitated suspension. As the reaction was strongly exothermic, the temperature was maintained below 45° by immersing the flask in ice water. The vigorously stirred suspension was heated at gentle reflux for 3 hours, then cooled to room temperature. After the mixture was filtered, the silver salts were washed with five 70-ml aliquots of anhydrous benzene, pressed, and drained. The benzene was distilled at atmospheric pressure, and the fraction of the residue boiling at 185–189° was collected. Upon redistilling, using a 50-cm Vigreux

column, 167 g (85.3%) of colorless liquid silicon tetraisocyanate, b.p. 185.6°, was obtained. This compound was stored in the refrigerator, where it froze to colorless crystals, m.p. 26°.

When dry, finely powdered lead cyanate (642 g; 2.2 moles; 10% theoretical excess) was employed in the above procedure, the yield of silicon tetraisocyanate was 121 g (61.8%).

The three methylsilicon isocyanates (9) were similarly prepared from the appropriate methylchlorosilanes and silver cyanate. Approximately 30% lower yields of these compounds were obtained when lead cyanate was employed. The boiling points and yields (by the silver and lead cyanate methods, respectively) were: trimethylsilicon isocyanate, b.p. 91.0° (91%, 71%); dimethylsilicon diisocyanate, b.p. 139.2° (84%, 52%); methylsilicon triisocyanate, b.p. 170.8° (88%, 60%).

Silicon tetraisocyanate and the three methylsilicon isocyanates were stored in tightly stoppered bottles to prevent hydrolysis (by atmospheric moisture) to gelatinous silica and cyanic acid. When sealed in glass ampoules these isocyanates could be stored indefinitely.

Silicon Isothiocyanates

These compounds were synthesized by employing modifications of previously published (10–12) procedures. Although silver thiocyanate gave approximately 5% higher yields, the resulting products were less pure than those obtained using ammonium thiocyanate.

The preparation of silicon tetraisothiocyanate is typical of the procedure employed to obtain the purest isothiocyanates.

Finely powdered ammonium thiocyanate (190 g; 2.5 moles; 25% theoretical excess) was stirred with anhydrous benzene (800 ml). Silicon tetrachloride (85 g; 0.5 mole) was added, over a 5-minute period, to the rapidly stirred suspension. The mixture was refluxed, with stirring, for 3 hours, cooled to 70°, and filtered through a coarse-grade sintered-glass funnel. After the solids were washed with hot benzene until the characteristic odor of the isothiocyanate could no longer be detected, the combined filtrates were distilled to a residual volume of approximately 200 ml. The hot contents of the flask were immediately transferred to a 400-ml beaker, and the flask was rinsed with 30 ml of benzene. When cold, the crystalline silicon tetraisothiocyanate was *rapidly* filtered through a coarse-grade sintered-glass funnel, washed with a few milliliters of cold benzene, pressed, and drained. Silicon tetraisothiocyanate was thus obtained as 112 g (86%) of colorless crystals, m.p. 144°. An additional 10 g of less pure isothiocyanate was obtained by evaporating the mother liquor to dryness in a rotary evaporator.

When silver thiocyanate was employed, the silicon tetraisothiocyanate obtained was bright yellow.

The three methylsilicon isothiocyanates were prepared using the appropriate methylchlorosilanes and a 25% theoretical excess of ammonium thiocyanate. The following data were obtained: trimethylsilicon isothiocyanate, b.p. 143–143.5° at 760 mm (80%); dimethylsilicon diisothiocyanate, b.p. 64° at 1.0 mm (86%); methylsilicon triisothiocyanate, m.p. 72.5° (83%).

All the silicon isothiocyanates were rapidly hydrolyzed to gelatinous silica and thiocyanic acid on contact with moist air or water. They could be stored without change in tightly stoppered glass bottles or sealed ampoules.

N-Mono- and N,N-Di-substituted Ureas and Thioureas

The following typical synthetic procedure was employed, although in certain instances more solvent was required to dissolve the amine.

A solution of the primary or secondary amine (0.04 mole)* in anhydrous (sodium dried) benzene (10 ml) was added, dropwise, to a solution of silicon tetraisocyanate (1.96 g; 0.01 mole)† in benzene (60 ml). As the addition of many amines resulted in a strongly exothermic reaction, it was occasionally necessary to cool the reaction flask in ice water. The mixture was then heated at reflux for 15–30 minutes, after which the benzene was removed on the steam bath or rotary evaporator. Dilute isopropyl alcohol (45 ml *i*-PrOH: 5 ml H_2O) was added to the residue, the mixture refluxed for 15–30 minutes, then filtered hot through a coarse-grade sintered-glass funnel. The gelatinous silica was washed with two 15-ml aliquots of acetone, and the combined filtrates evaporated on the steam bath or rotary evaporator. The crude product was then recrystallized twice from isopropyl alcohol. To obtain pure ureas or thioureas from certain of the aromatic amines, it was necessary to employ activated charcoal during their recrystallization from alcohol. Using this procedure essentially theoretical (97–100%) yields of the ureas and thioureas were obtained.

The compounds listed in Tables I, II, and III were prepared by this procedure, and analyzed correctly for nitrogen.

It should be noted that no reaction occurred when attempts were made to react silicon tetraisocyanate, or tetraisothiocyanate, with the following amines: 2-trifluoromethylaniline, 2,6-dibromoaniline, and diisobutylamine.

Large-scale Preparations

This general synthetic procedure was employed to prepare large amounts (0.4 *M*) of the following compounds (yields in parentheses): *t*-butylurea (95%), cyclohexylurea (97%), benzylurea (96%), phenylurea (95%), N-(2-benzothiazolyl)urea (95%), *t*-butylthiourea (98%), dibenzylthiourea (95%), 2,6-dimethylphenylthiourea (99%), and 2,4,6-trimethylphenylthiourea (99%). The following preparations are typical.

Benzylurea.—A solution of benzylamine (42.8 g, 0.4 mole) in 100 ml anhydrous benzene was added to a mechanically stirred solution of silicon tetraisocyanate (19.6 g, 0.1 mole) in benzene (150 ml). The mixture was heated at reflux for 0.5 hour, the benzene removed using a rotary evaporator, dilute isopropyl alcohol (200 ml; i.e. 180 ml *i*-PrOH:20 ml H_2O) added, and the mixture refluxed a further 0.5 hour. The hot mixture was filtered through a coarse-grade sintered-glass funnel containing a 0.5-inch layer of Celite. After the gelatinous silica was washed with acetone and the solvents evaporated the crude benzylurea (57.6 g; 96%) was recrystallized from isopropyl alcohol as pearly white platelets, m.p. 148°. Anal.: Calc. for $C_8H_{10}N_2O$: N, 18.65. Found: N, 18.88.

2,4,6-Trimethylphenylthiourea.—Silicon tetraisothiocyanate (26.0 g; 0.10 mole) was finely ground under anhydrous benzene (100 ml) and rapidly added to a well-stirred solution of 2,4,6-trimethylaniline (54.0 g;

**Only 0.02 mole of a diamine is required.*

†When silicon tetraisothiocyanate was used in this procedure, 2.60 g (0.01 mole) was triturated under benzene and quickly transferred to the flask.

0.4 mole) in benzene (100 ml). The procedure was then exactly the same as that employed in the preparation of benzylurea. The yield of white acicular crystals was 76.8 g (99%), m.p. 220°. Anal.: Calc. for $C_{10}H_{14}N_2S$: N, 14.57. Found N, 14.38.

COORDINATION COMPLEXES OF GROUP (IV) HALIDES

PREPARATION AND INFRARED SPECTRA OF COORDINATION COMPOUNDS OF TITANIUM TETRACHLORIDE, TITANIUM TETRABROMIDE, ZIRCONIUM TETRACHLORIDE, AND TIN TETRACHLORIDE WITH α,ω-DINITRILES AS LIGANDS[1]

SUMER CHAND JAIN AND ROLAND RIVEST
Department of Chemistry, University of Montreal, Montreal, Que.

Received March 25, 1963

ABSTRACT

Coordination complexes between dinitriles of dicarboxylic acids and tetrahalides of titanium, zirconium, or tin have been prepared. The analytical results and the infrared spectra indicate that on working under different experimental conditions three types of compounds are obtained: $2MX_4.L—L$, $MX_4.L—L$, and $MX_4.2L—L$ where MX_4 is a Lewis acid and L—L a bidentate ligand. The compounds $2MX_4.L—L$ are explained by the formation of halogen bridging between the two metal atoms. The compounds $MX_4.L—L$ are considered to be either coordination polymers or chelates of variable ring size and the compounds $MX_4.2L—L$, ordinary addition compounds where no chelation takes place because of the mutual interaction of the two CN groups in a dinitrile of a short chain length.

INTRODUCTION

The compounds $TiCl_4$, $TiBr_4$, $ZrCl_4$, and $SnCl_4$ are all strong Lewis acids. The reactions of $TiCl_4$ with donor molecules have been summarized in a review paper (1). Very little work has been published on the reactions of nitriles with the above mentioned Lewis acids. Emeléus and Rao (2) reported that $TiCl_4$ reacted with two mononitrile molecules to give the 1:2 addition compound. Physicochemical measurements carried out on benzene solutions of these addition compounds (3) led to the conclusion that in dilute solution the 1:2 complexes are dissociated into the 1:1 complexes and the free nitriles. Coerver and Curran (4), reporting on the infrared absorption of the C≡N group in addition compounds, indicated that coordination involving the nitrile group could be evidenced by infrared spectra measurements because of the positive shift of the C≡N stretching frequency on addition-compound formation. It has been recently established (5) that halogen bridging is possible in multinuclear complexes of titanium tetrachloride.

The present work was undertaken to study the possibility of chelate formation and halogen bridging, when dinitriles of increasing chain length react with $TiCl_4$, $TiBr_4$, $ZrCl_4$, and $SnCl_4$. With a short carbon chain the possible interaction between the two CN groups was expected to reduce the donor ability of the second CN group involved in coordination. In such cases compounds of the general formulae $MX_4.2L—L$ are expected.

EXPERIMENTAL

Material and Manipulations

Reagent grade titanium tetrachloride was purified by the method of Gilchrist (6) and the middle fraction of the distillate used in complex formation. Tin tetrachloride was purified by the method patented by Pittsburg Plate Glass Company (7). Commercial zirconium tetrachloride was sublimed in nitrogen atmosphere at 200° C. The compound so obtained was a white powder. Titanium tetrabromide was purified by distilling the commercial product at low pressure. The dinitriles were obtained from Fisher Scientific Company and used as such. The solvents used were purified and made anhydrous by suitable methods. The experimental methods and the methods of analysis for metal and halogens are essentially the same as described previously (8, 9). All the analytical results are included in Table I. The setup used to prepare the complexes was the same as the one used in previous experiments (10).

The spectrophotometric measurements were carried out on a Perkin–Elmer Infrared spectrophotometer, model 21, using sodium chloride prism in nujol mulls.

The molecular weights of the complexes were determined by cryoscopic method using anhydrous acetic acid as solvent.

Preparation of the Complexes

The preparation of these complexes was performed in methylene chloride. Three types of compound were prepared. The $MX_4.L$—L compounds were prepared with solutions of the reactants in 1:1 molar ratio.

In all cases powders were obtained which were washed with dry methylene chloride and dried in vacuum at room temperature. The $TiCl_4$ complexes yielded yellow powders; $TiBr_4$, dark red powders; and $SnCl_4$, white powders. Zirconium tetrachloride being insoluble in common solvents, its complexes were prepared by adding excess dinitrile to a suspension of zirconium tetrachloride in the same solvent and the reaction allowed to proceed for about a week. The excess ligand could then be washed out and the white precipitates so obtained dried under vacuum as usual. The $2MX_4.L$—L complexes could be obtained only with $TiCl_4$, and were prepared by adding a dinitrile solution to an excess of the Lewis acid. The yellow powders so obtained were filtered on a sintered-glass filter, washed with the solvent, and dried under vacuum. The $MX_4.2L$—L complexes were obtained only with malononitrile when reacted either with titanium tetrachloride, tin tetrachloride, or zirconium tetrachloride.

The $TiCl_4.2CN—CH_2—CN$ complex is obtained when excess malononitrile is reacted with $TiCl_4$ in solution. The yellow powder is then washed and dried as usual. The $SnCl_4.2CNCH_2CN$ crystalline white compound is always obtained even if the reactants are made to react in a 1:1 molar ratio.

The results of elementary analysis and of infrared spectra measurements are included in Table I.

INFRARED SPECTRA AND STRUCTURAL DISCUSSION

The infrared absorption frequencies of the pure dinitriles and their complexes are included in Table I and illustrated in Fig. 1. As it was observed by Coerver and Curran

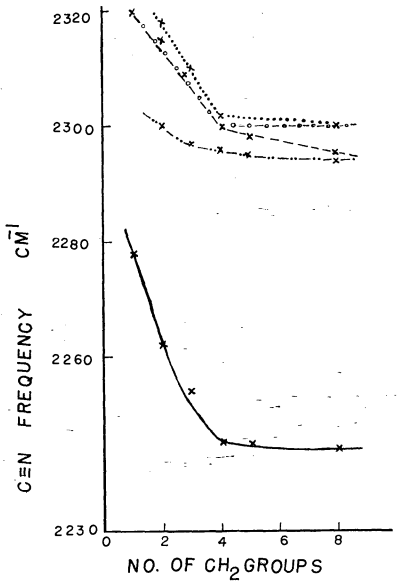

FIG. 1. Variation of the C≡N stretching frequency with respect to the number of CH_2 groups in the dinitrile: ··· 2:1 $TiCl_4NC(CH_2)_nCN$ compounds; o– 1:1 $TiCl_4NC(CH_2)_nCN$ compounds; – – 1:1 $TiBr_4$-$NC(CH_2)_nCN$ compounds; –·· 1:1 $SnCl_4NC(CH_2)_nCN$ compounds; — pure dinitriles.

(4), Kharitonov, Chiang, and Babaeva (11), as a result of complex formation the C≡N stretching frequency increases instead of decreases as in the complexes of carbonyl donors (12). The fact that coordination in nitrile complexes takes place through the nitrogen atom and not through the triple bond of CN group has been confirmed by X-ray examination (13, 14). In all the dinitrile complexes an increase in —C≡N stretching frequency varying from 12 to 56 cm^{-1} has been observed. This suggests that the shift of free electron pair from nitrogen atom of CN group towards metal ion would decrease the mutual repulsion and favor an increase in electron density between the carbon and the nitrogen of the triple bond. The above discussion explains the reason for an increase in —C≡N stretching frequency on coordination.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In Fig. 1 is represented the —C≡N stretching frequencies of the pure dinitriles as a function of the number of CH_2 groups in the chain. The decrease in —C≡N stretching frequency with increase in chain length shows that with short chain length one C≡N group markedly influences the spectroscopic and chemical behavior of the second C≡N group in the same molecule. But as the chain length increases this mutual influence fades away and in the later members of the series the two C≡N groups in the molecule coordinate independently without influencing each other. This can be observed from the plots of C≡N stretching frequencies of the complexes as a function of CH_2 groups (Fig. 1). The shape of the curves is similar to the pure dinitrile one.

In Fig. 2 the shift in C≡N stretching frequencies has been plotted as a function of the number of CH_2 groups in the dinitrile complexes of the 1:1 composition. From these

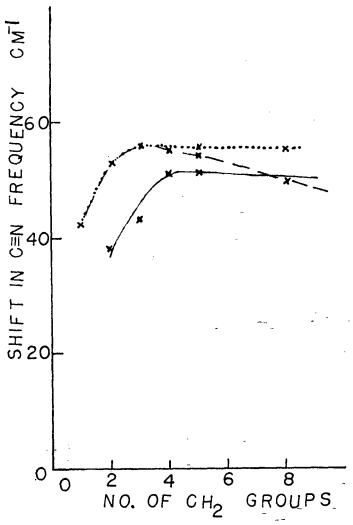

FIG. 2. Variation of the bathochrome effect as a function of the number of CH_2 groups in the dinitrile: ··· 1:1 $TiCl_4NC(CH_2)_nCN$ compounds; – – 1:1 $TiBr_4NC(CH_2)_nCN$ compounds; — 1:1 $SnCl_4NC(CH_2)_nCN$ compounds.

results it is observed that after the number of CH_2 group reaches three and four the curve becomes almost flat, showing that after the chain has reached a certain length, the interaction between the two CN of the same dinitrile is small. From previous experience (8) it seems that if these 1:1 complexes were chelates of variable ring size, it should be evident from the curves of Fig. 2. The fact that compounds of the 1:1 composition are obtained with malononitrile and succinonitrile where ring closure, on the same titanium atom, is almost impossible due to rigid nature of C—C≡N group led us to believe that at least for these specific cases we have polynuclear complexes, which could be cyclic dimers, trimers, or linear coordination polymers.

The formation of $MX_4.2L$—L complex with malononitrile with one CH_2 group is favored where one CN group is coordinated, leaving another C≡N group free. This interpretation is further supported by the infrared spectra of such complexes, where both the shifted peak due to coordination and the unshifted original peak are obtained (Fig. 3).

In the complexes $2MX_4.L$—L we assume that the two metal ions are held together through halogen bridging (Fig. 4).

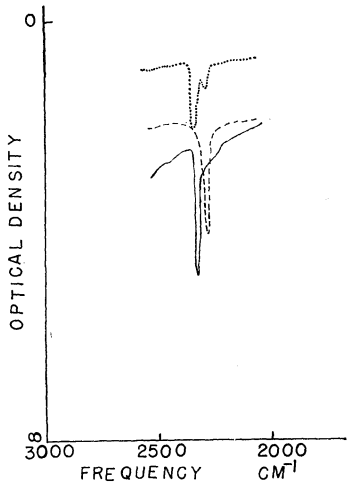

FIG. 3. Infrared spectra of the malononitrile complexes with $TiCl_4$: ···1:2 $TiCl_4NCCH_2CN$ compounds; — 1:1 $TiCl_4NCCH_2CN$ compounds; – – pure $NCCH_2CN$.

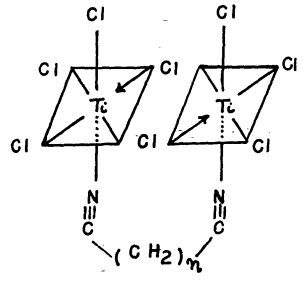

FIG. 4. Chloride bridging in $2TiCl_4NC(CH_2)_nCN$ compounds.

An attempt to determine the molecular weight of these compounds was made. The 1:1 $TiCl_4$, $TiBr_4$, and $SnCl_4$ complexes gave yellow, dark red, and colorless solutions respectively in dry acetic acid. The infrared spectra of some of these solutions indicated that there was dissociation leading to some uncoordinated C≡N group. The amount of dissociation was found to increase with dilution. Conductivity measurements on these solutions indicate about 100-fold increase in conductivity of the solutions as compared to the conductivity of the pure solvent. The increase in conductivity shows that ionization is not very important. The dissociation effect is much harder to assess since the infrared absorption of C≡N frequency is much more intense when this group is coordinated. We have attempted to recover the complex from the solution by evaporating the solvent and observed the formation of a white precipitate the analysis of which confirms the composition $TiCl_2(CH_3COO)_2$.

The molecular weight determinations by cryoscopy on these solutions are included in Table II. They were found to be about half that of the theoretical values. It is to be noticed that the molecular weight found increased with concentration and this is in conformity with the dissociation hypothesis. The fact that the acetate complex mentioned above is very slightly soluble in CH_3COOH and the fact that the observed molecular weight depends upon the dinitrile used strongly suggest that if the complexes are polymers they are probably decomposed by the very polar solvent.

$SnCl_4NC(CH_2)_5CN$	0.0881	234.6	382.7

CONCLUSION

From the previous discussion one can draw the following conclusions:

(1) The interaction of Lewis acids with dinitriles can lead to two main types of compounds: $MX_4.L—L$ and $2MX_4.L—L$.

(2) The compounds $2MX_4.L—L$ cannot be polymeric in nature, but can be best explained by assuming halogen bridging between the two titanium atoms of the binuclear complex. It is also possible that in these compounds titanium exhibits a coordination number of 5. To prove this we have prepared the compound $TiCl_4.CH_3CN$, which is very stable and can even be sublimed under low pressure without decomposition. The infrared spectrum of this last complex does not indicate that the triple bond is involved in coordination since the CN stretching frequency is increased by about 40 cm^{-1} through coordination. Attempts to determine the molecular weight of this compound have failed due to the lack of suitable solvents. So there are only two possibilities left for this compound, it is either a single addition compound where the titanium atom has a coordination number of 5, or it is a dinuclear complex where halogen bridging takes place.

(3) The compounds $MX_4.L—L$ can be either coordination polymers or chelated complexes. We have no definite experimental evidence to prove any one of these two possibilities. However, the observations made on solutions in dry acetic acid would give a slight indication that in solutions we are not dealing with coordination polymers.

ACKNOWLEDGMENT

The authors gratefully acknowledge the continued financial support from the National Research Council of Canada.

SOMMAIRE

Des complexes de coordination entre les dinitriles dérivés des acides α,ω-dicarboxyliques et des tétrahalogénures de titane, de zirconium ou d'étain ont été préparés. Les résultats analytiques et les spectres infrarouges montrent que suivant les conditions expérimentales, on peut obtenir les trois sortes de composés suivants: $2MX_4.L—L$, $MX_4.L—L$ et $MX_4.2L—L$ où MX_4 est un acide de Lewis et L—L un ligand bidentate. On explique la formation des composés $2MX_4.L—L$ par la présence de ponts halogénés entre les deux atomes de métal. On considère que les composés $MX_4.L—L$ sont ou bien des polymères de coordination ou des chélates de dimension variable et les composés $MX_4.2L—L$ des composés d'addition ordinaire où il n'y a pas chelation, à cause de l'interaction mutuelle des deux groupes CN du même dinitrile.

THERMAL DECOMPOSITION OF MOLECULAR COMPLEXES

II. β-QUINOL CLATHRATES

H. G. McAdie

Department of Physical Chemistry, Ontario Research Foundation, Toronto, Ontario

Received March 1, 1963

ABSTRACT

The β-quinol clathrates of nitrogen, carbon dioxide, methanol, and methyl cyanide decompose at temperatures well below the melting point of the host quinol lattice. The accompanying endothermal effect is broad, indicating that the decomposition occurs gradually over a considerable temperature range. The clathrate decomposition was verified by measurement of the gas evolved. The enthalpy change accompanying decomposition correlates closely with the energy of interaction of the guest molecule with the β-quinol lattice, and the decomposition of the clathrate is suggested to occur by a lattice distortion mechanism in which the size and shape of the guest molecule are important.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The formation of three dimensionally closed networks of quinol molecules, capable of containing individual molecules of a variety of relatively small species, was first elucidated by the structural work of Powell and collaborators (1). The cavities produced within the quinol network are capable of a limited deformation to accept certain molecules having non-spherical symmetry, and generally not all cavities are filled with guest molecules, the vacancies being stabilized by neighboring units.

Unlike some other types of inclusion compounds, the guest molecules are completely enclosed by the host clathrate lattice. At room temperature interactions between the guest molecules and the quinol network contribute to the overall stability of the clathrate (2), the heat of formation increasing linearly with the fraction of available cavities filled.

Since the quinol cavities can only be filled during their formation, it was of interest to determine whether the guest molecules remained trapped until the melting point of the quinol cage was reached, or whether a process prior to melting was responsible for the thermal decomposition of these materials. Isothermal studies (3) have indicated that clathrates have a measurable decomposition pressure at temperatures well below the melting point of quinol. The evident reversibility of the process

$$\text{clathrate (s)} \rightarrow \text{quinol (s)} + \text{guest (g)}$$

implies reference to the β-modification of the quinol lattice and an increasing ease of interchange between a guest molecule in the cavity and one in the surroundings as temperature increases.

EXPERIMENTAL

Samples of the quinol clathrates of carbon dioxide and nitrogen were obtained from the National Lead Company. Clathrates of methanol and methyl cyanide were prepared by slow crystallization from warm solutions of quinol in these solvents. α-Quinol was recrystallized from distilled water and dried over P_2O_5. γ-Quinol was prepared by sublimation of α-quinol under vacuum at about 160° C.

The fraction of filled cavities in the clathrates was determined by dissolving known weights in ethanol, evaporating the solvent under vacuum at room temperature, and measuring the weight loss. The lattice structures were confirmed by Debye–Scherrer powder patterns obtained using Cu $K\alpha$ radiation with a nickel filter.

For differential thermal analysis, −100-mesh samples were diluted to 20% by weight in ignited α-alumina. Differential thermograms were obtained with an apparatus described earlier (4), having provision

for purging the furnace by a controlled stream of a desired gas. Temperatures were calibrated against the fusion endotherm of a National Bureau of Standards calorimetric sample of benzoic acid. Thermograms were obtained at heating rates of 1.2 and 3.0° C min^{-1}.

In a separate series of experiments samples of undiluted clathrates were placed in a small bulb of known volume attached to a mercury manometer. The sample was heated at 1° C min^{-1} and the pressure within the system continuously measured. After correcting for the air present in the system the results were calculated as the fraction of available guest molecules liberated at a given temperature.

RESULTS

The thermograms of α- and γ-quinol obtained at 3.0° C min^{-1} are shown in Fig. 1. Corrected fusion peak temperatures for these two modifications were found to be 172.7

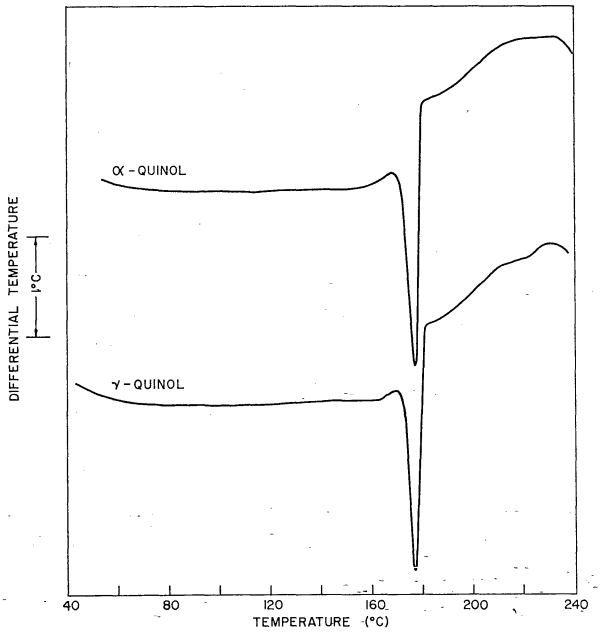

FIG. 1. Differential thermograms of non-clathrate forms of quinol.

and 172.4° C respectively. No transitions were observed below approximately 155° C, where a drift in the base line commenced, interrupted by the sharp quinol fusion peak and followed by a marked displacement of the base line. The initial base-line drift appeared to be slightly less in the case of the γ-quinol. The displacement of the base line is attributed to decomposition of the quinol on melting, forming gaseous products (5) which alter the specific heat of the sample with respect to the reference. No attempt was made to determine these decomposition products, but even under inert atmospheres the samples were found to be completely charred at 200° C. The formation of gaseous decomposition products was also indicated in the case of α-quinol by an increase in pressure beginning at about 150° C.

The base-line displacement was characteristic also of all the clathrates, thus being independent of the original crystal modification of the quinol. It was also found to be unaffected by the nature of the furnace atmosphere, the same effect being noted in carbon dioxide, nitrogen, or argon atmospheres as well as in air. It appears, therefore, that quinol begins to degrade near its melting point, the fusion endotherm being superimposed upon this degradation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Thermograms of the clathrates, also obtained at 3.0° C min^{-1}, appear in Fig. 2. The quinol fusion peak temperatures for the range of clathrates studied was found to be

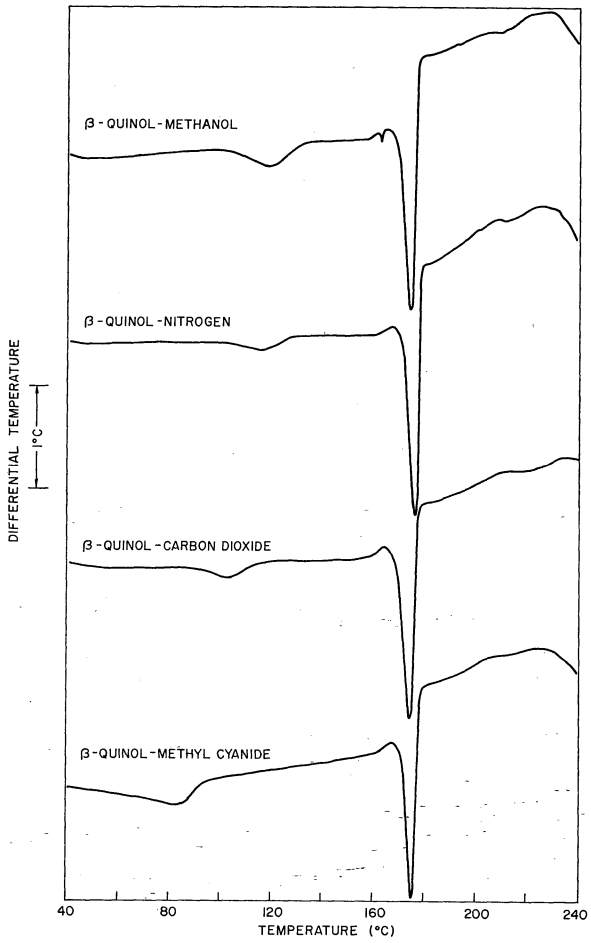

FIG. 2. Differential thermograms of quinol clathrates.

172.0±0.5° C. Changing the furnace atmosphere from one of air to one of the pure guest species (in the cases of the nitrogen and carbon dioxide clathrates) tended to sharpen the quinol fusion endotherm slightly without altering its peak temperature.

Clathrate thermograms also exhibited a broad shallow endotherm at temperatures considerably below the fusion temperature of the host quinol lattice. This endotherm was somewhat more accentuated when obtained at 3° C min^{-1} than at 1.2° C min^{-1}. The gas evolution curves, obtained at 1.2° C min^{-1} and shown in Fig. 3, indicate that these low-temperature endotherms correspond to the decomposition of the clathrate, and a further estimate of the decomposition temperature could be obtained by extrapolating the linear portions of these curves to the temperature axis. The results obtained are compared with the peak temperatures of the decomposition endotherms in Table I.

To estimate the enthalpy change associated with the decomposition endotherm, comparison was made of the areas under this endotherm and under the quinol fusion endotherm. Because of the base-line displacement, it was difficult to define the latter accurately;

N_2	114.5	115.5
CO_2	101.0	94.5
MeCN	80.0	73.0

however, an estimate was made based on the construction of Berg (6). The heat of decomposition of the clathrate having all available cavities filled can be calculated from the relation

$$\Delta H_d = (3/x) \cdot (a_C/a_Q) \cdot \Delta H_f,$$

where

ΔH_d = heat of clathrate decomposition (kcal mole^{-1} guest),
x = fraction of available cavities filled,
a_C = area of clathrate decomposition endotherm,
a_Q = area of quinol fusion endotherm,
ΔH_f = heat of fusion (kcal mole^{-1} quinol) (7).

The theoretical composition of a clathrate is 3 moles quinol per mole guest (1), so that the ratio $3/x$ is equivalent to the actual molar ratio prevailing in the experimental sample. Table II compares the data obtained in this way with reported values for heat of decomposition (2).

The various modifications of quinol were confirmed by Debye–Scherrer powder patterns, the results agreeing with accepted values (8). The principal differences between these structures, first reported by Caspari (9, 10) and subsequently modified by Powell

(1), are indicated by their *d*-spacings in Table III. Clathrates of most species exhibited *d*-spacings very similar to those shown for β-quinol from methanol. However, the methyl cyanide clathrate appeared to have *d*-spacings considerably different from any other clathrate lattice examined, or any other modification of quinol. This may be associated with the considerable distortion of the quinol lattice necessary to accommodate this essentially linear guest molecule.

Diffraction patterns of the γ-quinol indicated this material to be metastable and to revert to the α-modification on storage.

DISCUSSION

The crystalline modifications of quinol behave similarly on heating, there being no sharp transitions between room temperature and the melting point. Once formed, each lattice appears to be stable, although the clathrate modification (β-quinol) is capable of sufficient distortion or rearrangement to permit the trapped guest molecules to evolve. Since it is not presently possible to undertake an X-ray examination of the quinol lattice remaining following the clathrate decomposition, it is uncertain whether loss of the guest molecules is accompanied by a change in quinol lattice, say from β- to α-quinol. The enthalpy change between these two modifications is only 0.17 kcal mole^{-1} (2).

At 25° C the energy of interaction of guest molecules with the β-quinol lattice, corresponding to the process

$$\text{clathrate (s)} = \beta\text{-quinol (s)} + \text{guest (g)},$$

has been determined (2), and the results compare well with heats of decomposition determined from the differential thermograms (Table II). Thus, energetically the quinol clathrates evidently decompose according to the process stated above. The range of values for the heats of decomposition may be ascribed to differences in dipole–dipole

For personal use only.

interactions between the guest and the β-quinol lattice. These are absent in the case of the nitrogen clathrate, but increase with the polarizability of guest molecules containing C—O, O—H, and C—N bonds. The result is that the interaction of the guest molecule with the β-quinol lattice exceeds the mutual interactions of the pure species in its liquid or solid state (2), i.e. more energy is required to remove a single molecule from the clathrate cavity than to remove it from its own crystal lattice.

The symmetry of the guest molecule plays an important part in the thermal decomposition of its clathrate. Of the species examined, nitrogen is easily accommodated without distortion of the β-quinol network. Methanol, carbon dioxide, and methyl cyanide, in this order, progressively extended the cavity along the *c*-direction (11), with corresponding decrease in the *a*-direction. This reduces the possible rotation of the guest molecule within the cavity (12, 13) and the strain introduced into the lattice appears to cause these clathrates to decompose at progressively lower temperatures, suggesting that the mechanism responsible for the thermal decomposition of quinol clathrates is basically one of lattice distortion. At a suitable temperature the lattice may possess sufficient thermal motion between the two interpenetrating quinol networks to allow distortion of the cavity, perhaps producing a bottleneck type of opening through which the guest molecule can escape. Such distortion would occur gradually and continuously with temperature rather than at some discrete temperature. The existence of initial distortion due to the presence of a non-spherical guest molecule would facilitate this process, causing the clathrate to decompose at a lower temperature.

Reduction of the ambient pressure causes the clathrates to decompose at lower temperatures and the effect of pressure is not the same for each clathrate (14). This is to be expected if the reversible nature (3) of the decomposition process

$$\text{clathrate (s)} \rightarrow \beta\text{-quinol (s)} + \text{guest (g)}$$

is correct. Such reversibility may better be understood in terms of a distortion of the β-quinol lattice to the extent that the guest molecule may pass between the cavity and the surroundings. Since vacant normal cavities can be stabilized by their occupied neighbors, it is suggested that distorted cavities may also be stabilized due to the long-range interpenetration of the two quinol networks. Thus a cavity once distorted sufficiently to allow the guest to escape would remain so, permitting the re-entry required by a truly reversible process.

In general, the heats of decomposition increase with the size of the guest molecule, although methyl cyanide again appears to be somewhat anomalous. Since the diffraction pattern of this clathrate is markedly different from the others, it is possible that the distortion inherent in this material has altered the interaction of these molecules with the quinol network. It is further interesting that the gas evolution curves for nitrogen and carbon dioxide are similar and quite steep, while those for methyl cyanide and methanol have a similar but much lower slope. This could be interpreted as due to the guest molecule having to escape through a bottleneck opening in the cavity wall, the relatively large methyl group in each case requiring more time to diffuse through. It appears that clathrates of guest molecules having roughly similar size and shape tend to decompose at the same rate, so that the overall decomposition characteristics are determined by the extent of initial distortion of the lattice by the guest molecule and the size and shape of this guest, which determines the extent of further distortion required and the rate of eventual decomposition.

For personal use only.

One further endothermal effect was observed only in the case of the methanol clathrate. This occurred just prior to the quinol fusion endotherm (Fig. 1) and was quite sharp, although small in magnitude. Since the clathrate is decomposed by this temperature, the magnitude of this endotherm suggests it could be associated with a transition in the quinol lattice from the β- to the α-modification, although this could not be detected in any other clathrate or quinol modification examined.

A more detailed examination of the quinol lattice structure following clathrate decomposition, and of the gas evolution characteristics during thermal decomposition, is expected to resolve some of these interesting features.

ACKNOWLEDGMENTS

This research was carried out under a research grant to the Ontario Research Foundation from the Province of Ontario, received through the Department of Economics and Development.

The author wishes to thank the National Lead Company for making available samples of the nitrogen and carbon dioxide clathrates, and Messrs. G. C. Cranton and D. Cobb for their technical assistance.

THERMAL DECOMPOSITION OF MOLECULAR COMPLEXES

III. UREA INCLUSION COMPOUNDS OF MONOSUBSTITUTED ALIPHATIC SERIES[1]

H. G. McAdie

Department of Physical Chemistry, Ontario Research Foundation, Toronto, Ontario

Received April 24, 1963

ABSTRACT

Examination of the thermal decomposition of urea inclusion compounds has been extended to complexes of the even-numbered members of the following aliphatic series: *n*-alcohols, *n*-alkylamines, *n*-alkyl bromides, and *n*-carboxylic acids. The decomposition has been studied primarily by differential thermal analysis and an attempt made to correlate the observed decomposition temperatures and heats of decomposition with the particular guest species. The decomposition mechanism appears to involve acquisition of sufficient energy by the guest molecule to permit its diffusion from the canal, the decomposition temperature being related to the activation energy required for this diffusion process.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Many of the urea–*n*-paraffin inclusion compounds have been shown to endothermally decompose below the melting point of urea, with a concurrent change in the crystal lattice of urea and loss in weight (1). Energetically, the decomposition involves the process

$$\text{complex (s)} = \text{urea (s)} + \text{guest (liq.)}$$

and it was suggested that this decomposition was similar to the fusion of the pure long-chain species. For the complex to decompose, the guest molecule must achieve a certain level of vibrational–rotational energy before it is sufficiently mobile to escape the canal. In the case of complexes stable up to the melting point, the host urea cage simply melts, liberating the entrapped guest molecule.

It was of interest to extend these studies to urea inclusion compounds of other even-numbered, long-chain series, having one terminal group different from hydrogen. The stability of the complex should be influenced by the size of this group and its ability to associate with other guest molecules either through dipole–dipole interaction or through hydrogen bonding. The present work describes the thermal decomposition of complexes having as guest molecules the even-numbered *n*-alcohols, *n*-carboxylic acids, *n*-alkylamines, and *n*-alkyl bromides. In these cases a maximum of two guest molecules can be mutually associated within the urea canal, while it is hoped a future paper will report the extension of this work to some α,ω-disubstituted long-chain guest molecules in which the number of guest molecules consecutively associated within the canal may be higher.

EXPERIMENTAL

Preparation of the various inclusion compounds was by methods described previously (1). All guest materials were Eastman white label grade or equivalent, while other materials were reagent grade. The presence of the hexagonal urea complex lattice was confirmed in each case by Debye–Scherrer powder patterns obtained using Cu $K\alpha$ radiation with a nickel filter.

Differential thermograms of the complexes were obtained by the method described earlier (1), except that samples were ground to pass only a 100-mesh screen prior to dilution with ignited α-alumina. Visual microscopy was not found to yield reproducible decomposition temperature data and was not used to any extent. Thermogravimetric analysis was carried out on the urea–*n*-alcohol series of complexes only, because of the high decomposition temperatures found.

[1]*Presented in part at the 144th Meeting of the American Chemical Society, Los Angeles, California, March–April, 1963.*

RESULTS

Differential Thermal Analysis

The differential thermograms of the various series of complexes are shown in Figs. 1 to 4, inclusive. In all cases a low-temperature endotherm was observed, corresponding

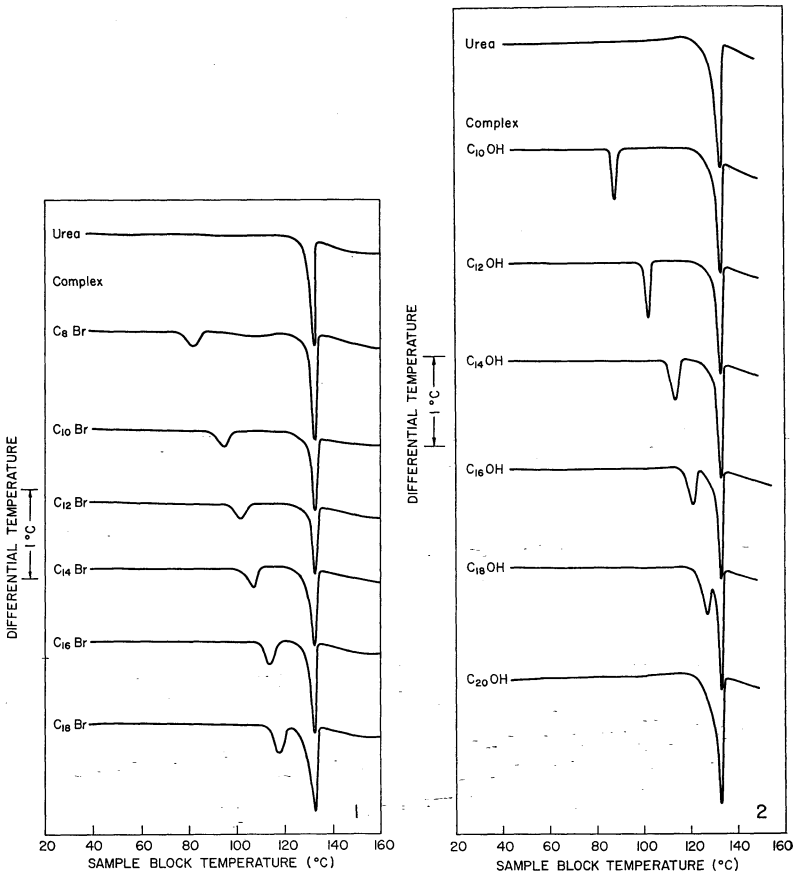

FIG. 1. Differential thermograms of urea–*n*-alkyl bromide complexes.
FIG. 2. Differential thermograms of urea–*n*-alcohol complexes.

to the complex decomposition, which progressed steadily towards the urea fusion endotherm as the carbon chain length of the guest molecule increased. The urea fusion endotherm allowed each system to be internally calibrated with respect to temperature and to the enthalpy change equivalence of peak area.

Complexes of the *n*-alcohols (Fig. 2) and the *n*-carboxylic acids (Fig. 3) decompose over a narrower temperature range than those of the other series studied, although the point of incipient decomposition is less well defined in the case of the *n*-carboxylic acid complexes. Thermograms of the *n*-alkylamine complexes (Fig. 4) exhibit an exotherm immediately following the urea fusion endotherm. This is attributed to the reaction of the molten urea with the liquid *n*-alkylamine liberated at a lower temperature, producing substituted ureas (2). The decyl- and dodecyl-amine complexes give only traces of this exotherm since these guest molecules volatilize more readily in the interval between

complex decomposition and urea fusion. There was some evidence of further reactions between 160° and 200° C, but no attempt was made to investigate these further.

The decomposition temperatures of the various complexes are given in Table I as the peak temperature of the decomposition endotherms corrected to a value of 132.7° C for

TABLE I

the peak of the urea fusion endotherm. This is a procedural decomposition temperature corresponding to about 50–80% of decomposition, depending upon the reaction rate, but in a given system it is more reproducible than incipient temperatures defined in a variety of ways. Further, by calibrating over a reasonably short temperature interval with another, known peak temperature, the influence of heating rate upon peak temperature is substantially reduced. Redetermined data for the urea–*n*-paraffin complexes are included and correlate satisfactorily with earlier measurements (1).

Enthalpy changes accompanying the decomposition process were calculated from peak areas by the method previously used (1) and are given in Table II. In all cases, these

TABLE II

enthalpy changes increased linearly with carbon chain length and compared favorably with those obtained from equilibrium data (3, 4) for the process

$$\text{complex (s)} = \text{urea (s)} + \text{guest (liq.)}.$$

No such data were available in the literature for the urea–*n*-alkylamine complexes, which decompose at temperatures intermediate to complexes of the *n*-alcohols and *n*-carboxylic acids. Experimental heats of decomposition were generally slightly lower than heats of reaction for the above process, due to the presence of coprecipitated urea.

Thermogravimetric Analysis

The loss in weight following decomposition of the urea–*n*-alcohol complexes is shown in Fig. 5. Decompositions in excess of 100% correspond to thermal degradation of the urea which begins to show a detectable weight loss at about 125° C. Since the decomposition temperatures of all the complexes examined were greater than those for the urea–*n*-paraffin complexes (1), it was impractical to carry out extensive thermogravimetric analysis because of the poor resolution of the two-stage decomposition process. As seen from Fig. 5 only complexes of the two shorter chain length *n*-alcohols could be so resolved.

DISCUSSION

It is convenient to divide the complexes studied into two groups, one in which the end-group influence may be predominantly related to size and the other where intermolecular association between successive guest molecules is the principal feature. Neither group can be completely exclusive of the other and in each case comparison will be made with the urea–*n*-paraffin complexes as reference.

Group I

The *n*-alkyl bromides were selected as representative of a large terminal group which could be readily accommodated within the hexagonal urea canal. Comparison of this series

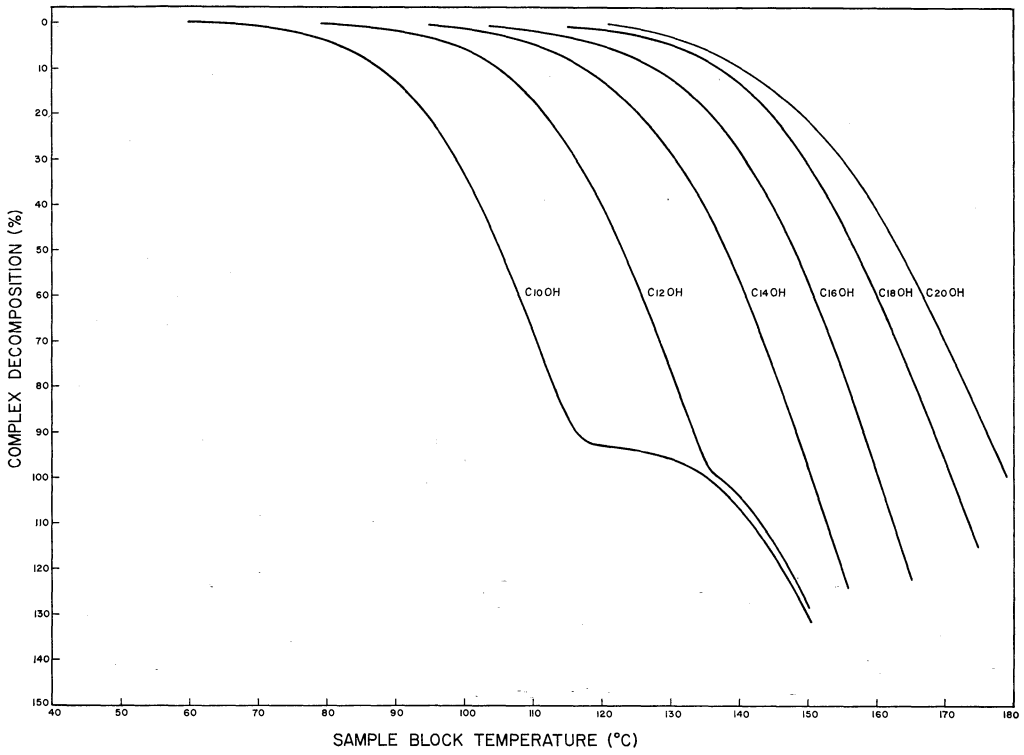

FIG. 5. Thermogravimetric analysis curves for urea–*n*-alcohol complexes.

of complexes with those of the *n*-paraffins is displayed in Fig. 6. The *n*-alkyl bromide complexes decompose at higher temperatures than the *n*-paraffin complexes, although the two pure species melt at virtually the same temperature (5, 6). Evidently the volume of a terminal bromine atom, compared to a terminal hydrogen atom, has increased the stability of the complex by occupying a larger portion of the available canal cross section. Calculation of the increase in effective area occupied suggests that there may be a limited strain introduced into the canal walls adjacent to the bromine atom.

The greater molecular volume of the *n*-alkyl bromides is reflected in an increased ratio of urea to guest (3, 4, 7, 8) compared with *n*-paraffin complexes of the same chain length. If the only difference were due to replacement of a hydrogen by a bromine, it would be expected that the reported comparative molar ratios should increase in parallel fashion with carbon chain length. However, this is not the case, the molar ratio of urea:bromide increases faster than that of urea:paraffin. This divergence of molar ratios appears to be a peculiarity of complexes in which the guest molecule has a cross section close to, or slightly greater than, the available canal cross section (4) and may be associated with the longitudinal packing of the guest molecules within the canal. Since the C—Br bond is at an appreciable angle to the axis of the carbon chain, dielectric evidence (9, 10) suggests that this grouping may occupy preferred sections of the canal where the potential energy of stable sites and the strain induced into the canal walls are at a minimum. The C—Br bond is likely directed towards one of the corners of the hexagonal canal with the polar groups located in planes normal to the longitudinal axis containing the oxygen

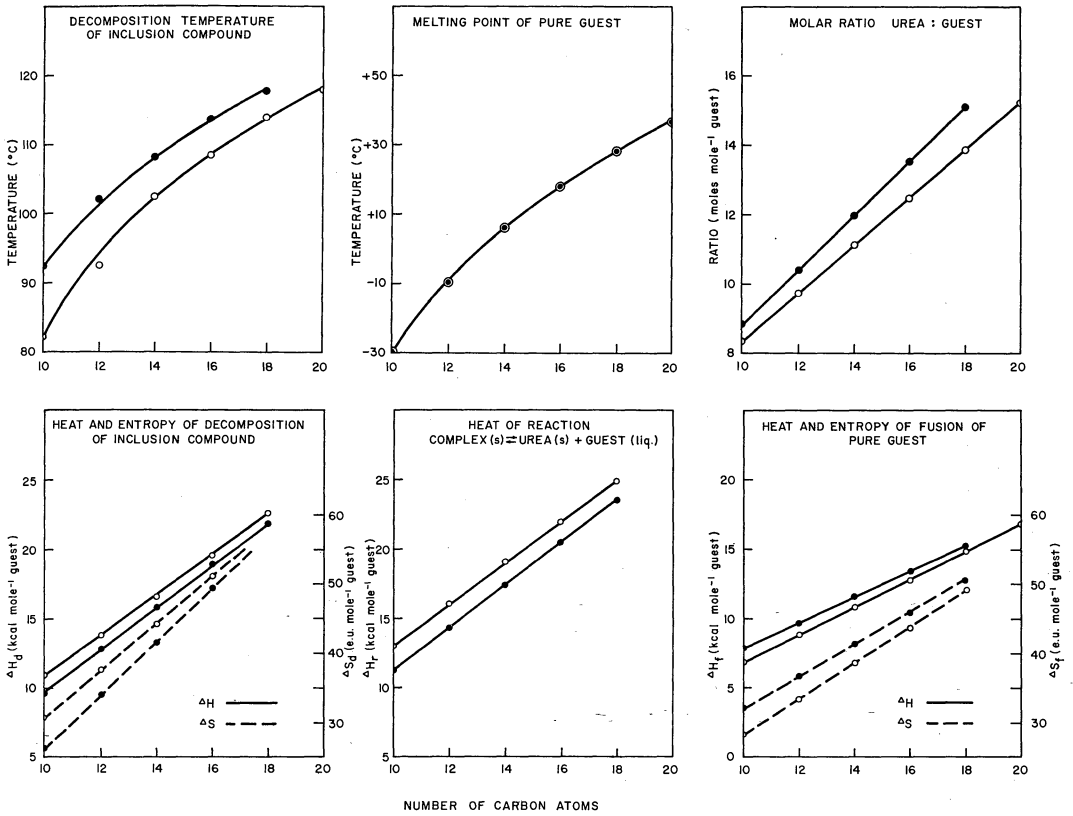

FIG. 6. Comparisons of the *n*-paraffin (○) and *n*-alkyl bromide (●) systems.

atoms of urea molecules. The introduction of such preferred locations for guest molecules within the canal would affect the regularity with which guest molecules could be accommodated.

Considering the energetics of the two systems, the heats and entropies of fusion of the pure guest species converge (5, 11). The heats and entropies of decomposition of their complexes also converge, but in opposite array, the *n*-paraffin complexes absorbing more energy on decomposition and undergoing a larger entropy change than those of the *n*-alkyl bromides. The same features are shown in the heats of reaction calculated from equilibrium data in the literature (3, 4).

The melting of a long-chain species is generally associated with increased rotation of the molecule (12, 13) and it appears that the same holds true for the decomposition of the complex. Nuclear magnetic resonance (14) and infrared (15) evidence have shown the long chains to be capable of considerable motion within the canal, including restricted rotation as well as other possible modes. Since the urea lattice is capable of slight expansion with temperature (10) it is suggested that at the decomposition temperature the overall energy of the chain becomes adequate to render it sufficiently mobile to diffuse out of the canal. This does not necessarily mean there has to be complete dynamic rotation of all guest molecules, but rather that these have acquired sufficient energy of rotational vibration to permit frequent passage over the potential barriers situated at 60° intervals around the canal (9) and now have required a translational component along the axis of the canal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Energetically the decomposition follows a process which yields the guest molecule in the liquid state, as expected since the decomposition temperatures of the complexes all lie above the melting points of the pure guest species, and accounts for the heat of decomposition of the *n*-alkyl bromide complexes being less than that for the corresponding *n*-paraffin complexes. Dielectric evidence (9) indicates that in the liquid state more association of the *n*-alkyl bromides is possible than in the urea canal. Therefore, when the *n*-alkyl bromide chains are liberated from the canal and aggregate into the liquid state there should be an energy *release* not present when the *n*-paraffin chains undergo the same process. This energy release, corresponding to an increased dipole association among the *n*-alkyl bromide molecules, and superimposed upon the energy absorption required to place these guest molecules in an adequately mobile state within the canal, results in an experimental heat of decomposition below that for the *n*-paraffin complexes.

Once the guest molecule is sufficiently mobile, there is still the problem of its removal from the canal. This may occur by a diffusion mechanism and as such would have an activation energy associated with it. It would then be expected that the size of the bromine atom would result in a higher activation energy for diffusion of this species from the canal. Since the complex does not decompose until a given section of the canal is vacant, this results in the *n*-alkyl bromide complexes decomposing at higher temperatures than the *n*-paraffin complexes.

At present it has not been feasible to estimate activation energies for the diffusion of long-chain molecules from the urea canal. Although under certain circumstances it is possible to estimate such data from the results of both DTA and TGA experiments, neither of these techniques, as presently applied, uniquely measures the diffusion process. If activation energies are based upon DTA endotherms, they will refer to the energy absorption process which consists to a large measure in changes in the N—H···O bond lengths in urea involved in the transition from the hexagonal to the tetragonal lattice (8, 16). If activation energies are based upon TGA weight loss data, they will be associated with the ultimate volatilization of the long-chain molecule *after* it has escaped the canal and aggregated into the liquid state. If the long-chain molecules escaped the canal and volatilized immediately, higher overall heats of reaction should have been found.

Group II

This group represents guest molecules which are capable of extensive intermolecular association through the formation of hydrogen bonds, and includes complexes of the *n*-alcohols, *n*-carboxylic acids, and *n*-alkylamines. In their urea complexes, it is known that the *n*-carboxylic acids exist as dimers within the canal so that the molecules lie alternately head-to-head and tail-to-tail (17), terminal methyl group interactions alternating with hydrogen-bonded carboxyl groups. It is probable that the *n*-alcohols and *n*-alkylamines may also exist to a large extent in this alternating arrangement within the canal. The possibility of ring-type polymers involving the guest molecules is precluded by the spatial characteristics of the hexagonal urea lattice.

Since the capacity for hydrogen-bond formation involving urea molecules is satisfied within the hexagonal lattice structure by sets of two different N—H···O bonds (8), it is unlikely that there will be any further hydrogen-bond formation between guest molecules and the walls of the urea canal. It is possible, however, that some dipole interactions may exist in the case of polar guest molecules, although the general freedom of guest molecules indicated by dielectric (9), n.m.r. (14), and spectroscopic (15) evidence suggests that the extent of such additional association would be slight.

For personal use only.

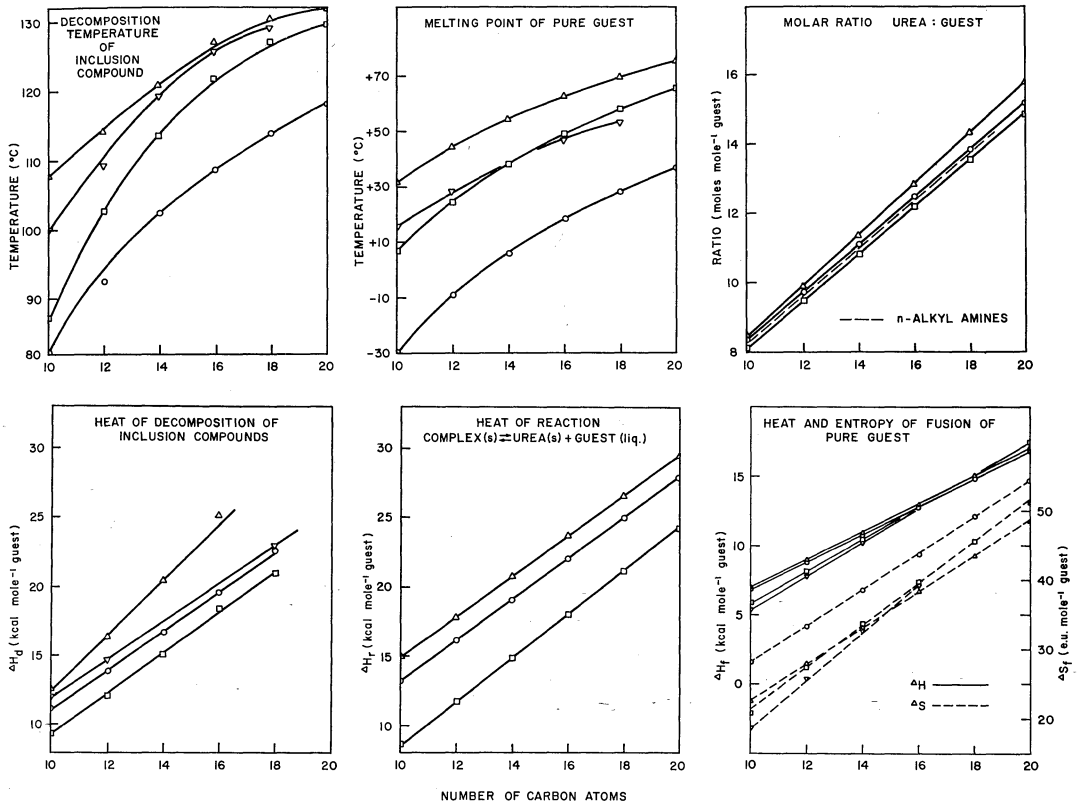

FIG. 7. Comparisons of the *n*-paraffin (○), *n*-alcohol (□) *n*-alkylamine (▽), and *n*-carboxylic acid (△) systems.

Comparison of these three systems with the *n*-paraffins, Fig. 7, shows that their complexes progressively increase in thermal stability with carbon chain length and, for a given carbon chain length, in the order paraffin < alcohol < amine < acid. For comparison, the *n*-alkyl bromide complexes decompose at temperatures intermediate to those of the *n*-paraffins and *n*-alcohols. The melting points (17) of the pure guest species, for a given carbon chain length, increase in the same order as the decomposition temperatures of their complexes except for the *n*-alkylamines, which cross the *n*-alcohols at about C_{14}. It therefore appears that many of the molecular properties responsible for the sequence of melting points in the pure solids may be retained within the urea canal.

Literature data for the molar ratios of urea to guest (3, 4, 7, 8) show this ratio to be greatest in the case of the urea–*n*-carboxylic acid complexes due to the size of the hydrogen-bonded dimer produced. While a similar association of the *n*-alcohols and *n*-alkylamines within the canal will not markedly affect the overall cross section of the guest at this point, the carboxyl group dimer, being somewhat larger than the available canal diameter, produces a "bump" in the middle of each long-chain pair. This causes the *n*-carboxylic acids to behave somewhat like the *n*-alkyl bromides and show a molar ratio which diverges from other series. The effect is not so marked in this case, however, since there is effectively only one bulky group per two molecules, rather than one for each molecule. Again, it appears to be a matter of accommodating this bulky group at positions where the strain induced into the canal wall and the potential energy of the site are minimal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Since no data were available for the urea–*n*-alkylamine complexes, the molar ratio in this case was calculated from the measurement of molecular models, assuming the alternate terminal NH_2 groups participate in an N—H···N bond with its counterpart on the succeeding guest molecule.

All complexes studied decompose according to the same energetic process, viz.

$$\text{complex (s)} = \text{urea (s)} + \text{guest (liq.)},$$

although the values for heats of decomposition obtained from thermograms are not as well separated as the heats of reaction reported in the literature (4). There are no equilibrium data for the urea–*n*-alkylamine complexes which appear to have energies of decomposition, as determined from thermograms, close to those for the urea–*n*-paraffin complexes of the same chain length.

The heats of decomposition of the urea–*n*-alcohol complexes are lower than those of any other series. Infrared studies (18) have shown that long-chain alcohols decrease in hydrogen bonding on passing from the solid to the liquid state. In the crystal lattice each OH group participates in two O—H···O bonds (19) so that in the pure liquid the average number of hydrogen bonds per *n*-alcohol molecule must be somewhat less than two. In the case of the urea–*n*-alcohol complexes, the dimensions of the canal constrain the guest molecules to form not more than one hydrogen bond per two molecules. Thus, when the *n*-alcohol molecules are liberated from the canal and aggregate into the liquid state, there may be expected to be an *increase* in intermolecular hydrogen bonding, relative to the condition of these molecules in the urea canal, with a consequent release of energy. This energy release, superimposed upon the energy absorption accompanying the decomposition process, would result in a net experimental energy change lower than that for the corresponding *n*-paraffin complexes.

Because the literature appears to be lacking in adequate heat of fusion data for the *n*-alcohols and *n*-alkylamines, estimations of these were made from solubility data (20, 21) assuming solutions of these materials in chloroform to be approximately ideal. More extensive data were available for the *n*-paraffins (5) and the *n*-carboxylic acids (22, 23, 24).

Heats and entropies of fusion of the *n*-carboxylic acids indicate that these materials behave similarly to the *n*-paraffins on melting, the lower entropy of fusion for the acids indicating the melt is less disordered than that of the *n*-paraffins. Until better thermodynamic data are available for the *n*-alcohols only speculation can be made about the position of heats and entropies of fusion of these materials relative to the *n*-paraffins. Since *n*-alcohols undergo some hydrogen-bond rupture on melting, this would be expected to raise the heat of fusion. However, in the liquid *n*-alcohol there exists a long-range order which results in less change in the orientation of the carbon chains relative to the solid state, thereby producing lower values for the heats and entropies of fusion. As the carbon chain length increases, the slopes of these curves suggest that the effect of this long-range ordering diminishes somewhat. A similar situation may occur in the case of the *n*-alkylamines, although the hydrogen bonds involved are weaker and the long-range order in the liquid state somewhat less than that for the *n*-alcohols.

The above considerations appear to be consistent with the mechanism for complex decomposition presented earlier. The decomposition temperature of the complex is determined by the temperature at which the guest molecule becomes sufficiently mobile to pass frequently over the potential barriers in the canal, and possesses sufficient activation energy for the translational diffusion out of the canal. The larger the end group, or the stronger its interaction with a succeeding guest molecule, the higher will be the energy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

requirement for the guest molecule to achieve adequate freedom within the canal. However, because of differences in the relative association in the canal and in the pure liquid guest, the measured overall energy changes may not lie in the same order as the decomposition temperatures.

Once the guest molecule has departed a section of the canal and is not replaced by another guest molecule, the hexagonal urea lattice collapses and reverts to the tetragonal form. By this means the complexes decompose from the "inside out". Where guest molecules are sufficiently large that the complex is stable up to the melting point of urea, the host cage melts away from the trapped guest thus decomposing from the "outside in".

THE CARBONYL-STRETCHING VIBRATION OF ARYLALIPHATIC ESTERS

KEITH BOWDEN,[1] N. B. CHAPMAN, AND J. SHORTER
Chemistry Department, The University, Hull, England
Received April 1, 1963

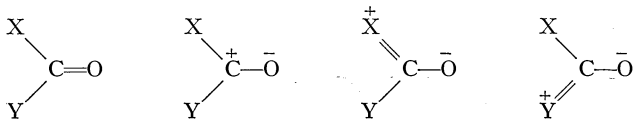
ABSTRACT

The infrared spectra in the carbonyl-stretching region of certain arylaliphatic esters, RCOOMe, have been examined. The stretching frequencies and absorption intensities are presented and are discussed in terms of polar and α-mass effects and the occurrence of conformational isomers.

INTRODUCTION

As carbonyl vibrations are considered rarely to be perturbed by coupling with other vibrations, the corresponding absorption band and its variation with structure has been widely studied. Several factors may affect this vibration, of which the most important, for the present work, are polar, α-mass, and steric effects.

Thompson and his co-workers (1) have suggested that the force constant is primarily determined by the relative contributions of the canonical structures I, II, III, and IV to the structure of the carbonyl group. The relative importance of these structures is



I II III IV

determined by the ability of X and Y either to interact with the carbonyl bond (cf. III and IV), or to alter the relative contributions of I and II by an electrostatic effect (i.e. inductive or direct field). Since the value of the frequency indicates the energy needed to produce a dipolar state, a reduction in the part played by structures II, III, and IV will increase the frequency.

The effect on the frequency of increasing the mass of α-substituents is significant for small masses but reaches a limit for group X or Y in XYC=O with higher masses (e.g., Halford (2) considers the effects to be constant above about 27 atomic weight units for X or Y). Substitution of deuterium for α-hydrogen atoms in esters or ketones has been found to give fairly large α-mass effects (3).

A reduction in the X—C—Y intervalency angle in X—CO—Y will increase the frequency as has been observed for the carbonyl vibrations of strained ring ketones (4, cf. ref. 2). In the absence of any change in the steric environment of the motion, successful correlations have been obtained of the carbonyl frequencies of substituted ethyl benzoates and acetophenones with substituent constants of the Hammett type (5). Similar correlations involving the carbonyl-stretching frequencies of substituted aliphatic esters and ketones have been made with varying success. Correlations of doubtful value for intensities, due to the narrow range of intensities covered and the small number of substituents involved (6), have also been attempted.

A number of investigators have observed the splitting of the carbonyl bands of ketones

[1]*Present address: Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia.*

and esters. Possible explanations of this phenomenon are the occurrence of rotational isomers (7), Fermi resonance (8), and a solvation effect (9). Fermi resonance can be discounted in normal cases, as the effect of solvent, temperature, and concentration change is not that expected. However, the occurrence of Fermi resonance in five-membered ring ketones has been suggested (8). The solvation effect cannot easily explain the occurrence of splitting in such solvents as cyclohexane. Rotational isomers are considered to be the cause in most known cases. Brown (10, 17) has examined the spectra of a number of substituted ethyl acetates (in carbon tetrachloride) and has attempted to explain the integrated absorption coefficients and the vibrational frequencies of the carbonyl groups by reference to Taft's polar substituent constants (11) and the existence of conformational isomers.

EXPERIMENTAL

(a) Preparation of Esters

The preparation of the esters has been described elsewhere (12); their purity was determined by vapor phase chromatography. No significant impurity was found in any samples of esters subsequently used for measurements.

(b) Infrared Spectra

The carbonyl-stretching vibrations of the esters were examined by use of a Unicam S.P. 100 double-beam infrared recording spectrophotometer, operating with a nitrogen atmosphere. A 0.55-cm cell was used and the cell-well temperature was 30±1°. The calibration was checked by using a solution of acetone in carbon tetrachloride (band at 1719 cm^{-1}). The bands were normally scanned at 8 cm^{-1} min^{-1}. "Analar" carbon tetrachloride or cyclohexane (Hopkin and Williams, Ltd., "Spectrosol" grade) was used as the solvent and the solutions were approximately 0.01 *M*. At least two independent measurements were made on each ester.

The values of ν_{max} (wave number at the absorption maximum), the apparent molecular extinction coefficients at the maximum, the partial band widths, and the apparent integrated absorption intensities were determined. Intensities were measured from a solvent–solvent base line superimposed on the record of the absorption of the solution (determined with solvent in reference beam). Peaks were symmetrical unless otherwise stated.

The absorption curves were integrated graphically using an "Allbrit" planimeter to give the apparent integrated absorption intensities, A^a. The integration interval chosen was 50 cm^{-1} on each side of the peak maximum, or, in the case of split peaks, from 45 cm^{-1} on the low-frequency side of the lower-frequency peak to 45 cm^{-1} on the high-frequency side of the higher-frequency peak. Approximation formulae (13) can be used to give $A^a = 2.303 N E^a_{max}$, where N is a function of the partial band widths, such that $N = \pi\Delta\nu_{\frac{1}{2}}/2$, $\pi\Delta\nu_{\frac{1}{4}}/2\sqrt{3}$, or $\pi\Delta\nu_{\frac{1}{8}}/2\sqrt{7}$, where $\Delta\nu_x$ is the partial band width at $x \times$ the optical density. In using these formulae it is assumed that symmetrical absorption curves of a Lorentz shape are involved. Mean values obtained from them were about 5% higher than the values obtained by the graphical method.

EXPERIMENTAL RESULTS

The apparent integrated absorption intensities, apparent molecular extinction coefficients, the partial band widths, and values of ν_{max} are shown in Table I. The accuracy of the measurements is considered to be ±1 cm^{-1} in the wave number (relative to the standard); ±0.5 cm^{-1} in the partial band widths; ±1.5% in the apparent molecular extinction coefficient; and ±2.0% in the apparent integrated absorption coefficient.

DISCUSSION

(a) Stretching Frequencies

The factors which may affect the carbonyl-stretching vibration frequency are shown in Table II. The values of ν_{max} in Table I are conveniently discussed by reference to a plot of ν_{max} (carbon tetrachloride solutions) against the values of the Taft polar substituent constant σ^* obtained previously (12) (Fig. 1).

The band splitting observed for ester 7, methyl fluorene-9-carboxylate, suggests the occurrence of two conformers. (The abnormally great band spreading for esters 2, 4, 5,

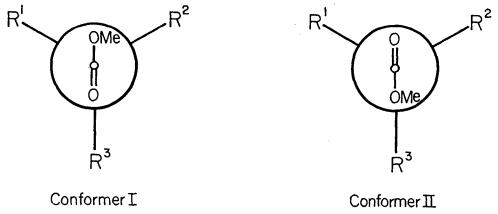
10, and 13 and asymmetry of the band for esters 10 and 13 indicate the occurrence of 'hidden' conformers.) The most likely conformations for these are shown below, with



R^1 and R^2 together denoting the fluorene system, and R^3 = H. The higher value of ν_{max} may be attributed to conformer II. Steric interaction between the methoxyl group and the fluorene system in conformer I will be greater than that between carbonyl–oxygen and the fluorene system in II, because of the greater steric requirements of the methoxy group. In conformer I the 'X·CO·Y' angle (see above p. 2154) will therefore be greater than that in conformer II, and so II will have the higher value of ν_{max} (4).

For esters 8 to 12 there is good correlation between ν_{max} and σ^*, and the lower value for ester 7 lies on the same line. These esters apparently occur as conformer I and the effect of structure upon ν_{max} is due to the polar effect of the 9-substituent. The slope of the line (a 'reaction constant', ρ^*, see ref. 11) is 18.0, and this agrees fairly well with values of 19.6 to 19.9 found for similar series of compounds in previous studies (6). The 'X·CO·Y' angle is constant in the series, since the steric environment of the methoxyl group does not alter, and it appears that even with the largest 9-substituents there is no effect on ν_{max} due to compression of the carbonyl group. Variations in 'α-mass' are not significant in the series since the systems are very massive (see below). When the hydrogen atom in the 9-position is replaced by an alkyl or a phenyl group the interaction between these and the methoxyl group in conformer II is evidently so great that this conformer does not occur to an appreciable extent.

Ester 6, methyl triphenylacetate, gives ν_{max} lying on the line discussed above and therefore exists as conformer I with all R's = Ph. In this conformer steric interaction of the methoxy group with the phenyl substituents will be minimal. If the interaction of carbonyl–oxygen with the phenyl group R^3 is significant, however, rotation of the ester group will occur so as to separate these two slightly. The 'X·CO·Y' angle must be about the same in conformer I of ester 6 as in ester 7 to 12.

In esters 4 and 5 steric interactions involving the methoxyl group should be minimal in conformer I, with R^1 = R^3 = Ph, and R^2 = Me or Et, although appreciable interaction between carbonyl–oxygen and phenyl might twist the ester group to bring the methoxyl group slightly closer to R^2. At all events, steric interaction involving the methoxyl group should be less than in the main series already discussed, leading to a decrease in the 'X·CO·Y' angle, and to an increase in ν_{max} relative to the main series, as actually found.

Since ν_{max} for ester 3, methyl diphenylacetate, is close to the higher value for ester 7, it is likely that ester 3 exists as conformer II, with R^1 = R^2 = Ph, and R^3 = H. For ester 1 conformer I would be expected, with all R's = H. In ester 2 interaction between the phenyl group and carbonyl–oxygen may be relatively important. Analogy with halogeno- and cyano-acetic esters (10, 14) suggests conformer I with R^1 = Ph and R^2 = R^3 = H. Dipole interaction which is dominant in halogeno- and cyano-esters

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

should be less important in methyl phenylacetate. However, conformer I with R^1 = Ph and R^2 = R^3 = H (giving less interaction involving the methoxy group) appears also sterically more probable. In esters 1, 2, and 3 the methoxy group is thus involved in little steric interaction, as in conformer II of ester 7. The 'X·CO·Y' angle in these esters should be approximately constant, but the effect of polar substituents on ν_{max} should be observed. The figure shows a line drawn through the points for esters 3 and 7, and parallel to that for the main series. The point for ester 1 is well off the line, and that for 2 is slightly displaced. This is doubtless due to the smaller 'α-mass' of esters 1 and 2 leading to an increase in ν_{max}.

Like ester 7, ester 13 might be expected to occur in both conformers I and II, where R^1 and R^2 together denote the dihydro-anthracene system and R^3 = H. The band is wide and asymmetric, and may be an unresolved doublet with an apparent value of ν_{max} at a frequency intermediate between those characteristic of the conformers.

The factors influencing ν_{max} can now be tentatively evaluated. In Table III estimates of the relative contributions of α-mass and polar effects to the change in ν_{max} (relative

[c]Obtained by difference.

to methyl acetate) are given. The polar effect is calculated by use of σ^* values and the above value of ρ^*. It is assumed that for esters 3 and 7 (conformer II) there is no steric contribution, so that the α-mass effect may be evaluated by subtracting the polar contribution from the observed ν_{max}. The α-mass effect thus found for ester 7 (conformer II) is assumed to apply to all the esters except 2. The estimates are reasonable in the light of pertinent data (2, 3). The steric effect is now calculated by difference.

(b) Intensities

The electronic ground state of a carbonyl compound has contributions from the canonical structures I, II, III, and IV. When the carbonyl carbon–oxygen bond distance increases, the ionic structure becomes more important. Carbonyl stretching is therefore an electron-demanding process and will be assisted by electron-releasing and hindered

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

by electron-withdrawing substituents. The intensity (A) varies linearly with $(\partial\mu/\partial r)^2$ and will fall for electron-withdrawing substituents (16).

Attempts have been made to correlate the intensities by use of the following alternative relations (6, 15) which are similar to those of Hammett and Taft:

$$A/A_0 \quad \text{or} \quad \log(A/A_0) \quad \text{or} \quad A^{1/2}/A_0{}^{1/2} = \rho\sigma \quad \text{or} \quad \rho^*\sigma^*.$$

The results obtained in this study give a very poor correlation with the Taft polar substituent constants. The only reasonably meaningful correlation is that using $A^{1/2}/A_0{}^{1/2}$. The results, with the exception of those for esters 8, 9, and 11, give ρ^* equal to -0.150 and A_0 equal to 1.68_5. The correlation coefficient is 0.764, a very low value. However, the correlation is as good as that found by other workers (6, 15) for similar series. The four alkyl fluorene esters show in fact a regression of opposite sign to that expected. Brown, in a recent study (17), concludes that the steric size and conformation, rather than the polar effect, is of greatest importance in determining the carbonyl intensity. In the series of substituted fluorene esters studied there does appear to be a steady decrease in intensity with size of the substituent group.

ACKNOWLEDGMENTS

The authors are indebted to Dr. C. W. Gray and Mrs. D. Strickland for making the measurements and Dr. T. L. Brown for helpful suggestions.

THE NEAR-ULTRAVIOLET SPECTRA OF SOME 9-ALKYLPHENANTHRENES

F. A. L. ANET
Chemistry Department, University of Ottawa, Ottawa, Canada
AND
P. M. G. BAVIN
Smith Kline & French Laboratories Ltd., Welwyn Garden City, England
Received March 25, 1963

ABSTRACT

The ultraviolet spectra are reported of a series of 9-alkylphenanthrenes. The bathochromic shifts relative to phenanthrene of the longest-wavelength (α) band are not explicable in terms of hyperconjugation. It is suggested that the band envelope is influenced by the rotameric forms of the alkyl substituents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The effect of alkyl substituents upon the near-ultraviolet spectra of polycyclic aromatic hydrocarbons is not fully understood (see ref. 1), and few systematic studies have been made. Theoretical studies have shown that in alternant hydrocarbons such substitution can lead only to bathochromic shifts, provided that strong steric effects are absent (2,3). In non-alternant hydrocarbons the shifts may be either bathochromic or hypsochromic, depending on the position of substitution (3). These results were obtained by treating the inductive and hyperconjugative effects separately but additively, and agree with experiment for some methylated azulenes and fulvenes. Similar results have been obtained using Hückel's method (4, 5).

The near-ultraviolet spectra of benzene, toluene, ethylbenzene, *i*-propylbenzene, and *t*-butylbenzene have been measured in the vapor phase and in solution (6). The results were interpreted as showing that the spectral shifts relative to benzene were due to the differing hyperconjugative powers of the alkyl groups (6; 7, pp. 667–675).

We now report the near-ultraviolet spectra of the following 9-alkylphenanthrenes: methyl, ethyl, propyl, *i*-propyl, butyl, *s*-butyl, *i*-butyl, *t*-butyl, *t*-amyl, benzyl, cyclopentyl, cyclohexyl. Comparison of the spectra, summarized in Table I, has revealed certain interesting regularities.

The spectrum of phenanthrene has been reported by several authors (8, 9, 10; see also footnote, page 230, ref. 11) and has recently been discussed in some detail (12). The low extinction coefficients and high resolution of the longest-wavelength band system (α-band (13) or series III band (14)), little improved at $-170°$ (8; cf. $-100°$ (12)), suggest that it has its origin in a single electronic transition. Since in addition the extinction coefficients are only slightly affected by overlap with neighboring band systems, we have confined our discussion to the α-band system.

The shifts of the longest-wavelength peak relative to phenanthrene follow the usual order (6) for the methyl, ethyl, *i*-propyl, and *t*-butyl substituents. The data for the other substituents show that the shifts are not explicable in terms of relative hyperconjugative powers alone, a view previously expressed in more general terms by Jones (1) for alkyl-substituted polycyclic aromatic hydrocarbons, and more forcibly by Dewar (15, p. 79).

Variations of the extinction coefficients revealed in Table I are of greatest interest. The spectra are divisible into two groups. In the first, the α-band shows six peaks, with

NOTE: N.R., not recorded.

the first and third particularly well resolved. Phenanthrene and the methyl, *t*-butyl, and *t*-amyl derivatives belong to this group. The second group shows only five peaks in the α-band, the first and third being broader and having lower extinction coefficients. Differences between the two groups are well illustrated in Fig. 1 by the spectra of $M/500$

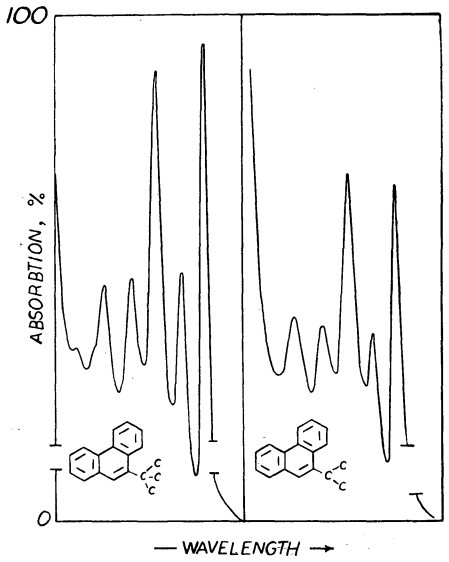

FIG. 1. Spectra of $M/500$ solutions of 9-*t*-butylphenanthrene and 9-*i*-propylphenanthrene in ethanol

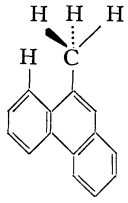
solutions of 9-*i*-propyl- and 9-*t*-butyl-phenanthrenes in ethanol. Contrary to the view expressed elsewhere (16, p. 326) the 9-monoalkylphenanthrenes retain fine structure in the α-band.

We can explain our results in terms of the symmetry of the alkyl group about the axis of the bond joining it to the ring system. Methyl and *t*-butyl and, to a first approximation, *t*-amyl have trigonal symmetry so that only a single rotamer, I (18), exists in each case.



I

The other alkyl groups are less symmetrical so that at least two rotamers can exist. Since the corresponding bands of the rotamers in any one compound would not be expected to coincide exactly, a slight broadening should be observed (cf. refs. 17, 19).

EXPERIMENTAL

The alkylphenanthrenes were prepared either by heating the 9-alkyl-9-fluorenylmethanol with phosphorus pentoxide under xylene (method A (20), where references are given to earlier work) or by decomposing the tosylate in formic acid (method B (20)). 9-Methyl-, -ethyl-, -*i*-propyl-, -*t*-butyl-, and -benzyl-phenanthrenes were available from earlier work (20).

9-t-Amylphenanthrene (Method B)

Methyl 9-t-amylfluorene-9-carboxylate crystallized as needles (76%) from methanol, m.p. 56–57°. Found: C, 81.81; H, 7.40. Calc. for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%. The *acid* formed colorless needles from benzene–hexane, m.p. 200–204° with decomposition. Neutralization equivalent found: 277; calc.: 280. *9-t-Amyl-9-fluorenylmethanol* separated from hexane as colorless needles (91%), m.p. 104–106°. Found: C, 86.56; H, 7.63. Calc. for $C_{19}H_{20}O$: C, 86.32; H, 7.63%. The tosylate crystallized from benzene, slightly yellow prisms, m.p. 105–118° varying with the rate of heating, with decomposition to 9-*t*-amylphenanthrene.

9-t-Amylphenanthrene crystallized from methanol as lustrous plates, more rarely as prisms, m.p. 87–88°. Found: C, 92.05; H, 8.17. Calc. for $C_{19}H_{20}$: C, 91.88; H, 8.12%.

9-s-Butylphenanthrene (Methods A and B)

Methyl 9-*s*-butylfluorene-9-carboxylate (20), carefully purified by repeated crystallization, was reduced ($LiAlH_4$) and the alcohol esterified with tosyl chloride. Neither the alcohol nor the tosylate could be induced to crystallize.

9-*s*-Butylphenanthrene was obtained as an oil by either of the methods A or B. After distillation at 4 mm from sodium, the *1,3,5-trinitrobenzene adduct* was prepared as bright yellow needles from methanol, m.p. 124–125°. Found: C, 63.78; H, 4.25; N, 9.81. Calc. for $C_{24}H_{21}N_3O_6$: C, 64.42; H, 4.73; N, 9.39%. Decomposition of the adduct by passing its solution in hexane through a column of activated alumina gave the pure hydrocarbon as a colorless oil, which has not crystallized. Found, after redistillation: C, 92.44; H, 7.63. Calc. for $C_{18}H_{18}$: C, 92.26; H, 7.74%. The ultraviolet spectrum was not changed by further attempts at purification through adducts with trinitrobenzene or picric acid.

9-i-Butylphenanthrene (Method B)

Methyl 9-i-butylfluorene-9-carboxylate formed colorless prisms from methanol (71%), m.p. 67–69°. Found: C, 81.42; H, 7.18. Calc. for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%. Reduction ($LiAlH_4$) and esterification gave the *tosylate*, colorless needles from hexane, m.p. 104–105°. Found: C, 74.12; H, 6.40. Calc. for $C_{25}H_{26}O_3S$: C, 73.86; H, 6.45%. 9-*i*-Butylphenanthrene formed colorless needles from acetone–methanol, m.p. 98–99° (lit. m.p. 96–97° (21)).

9-n-Butylphenanthrene (Method B)

Methyl 9-butylfluorene-9-carboxylate (20), purified by distillation at 0.1 mm and subsequent crystallization from methanol, was reduced ($LiAlH_4$) and esterified to give the *tosylate*, prisms from hexane, m.p. 104–105°, depressed when mixed with the *i*-butyl isomer. Found: C, 74.12; H, 6.46.

9-Butylphenanthrene crystallized from acetone–methanol as colorless needles, m.p. 78–79° (lit. m.p. 78.5–79.0° (22); 80–81° (23)).

9-n-Propylphenanthrene (Method A)

Methyl 9-propylfluorene-9-carboxylate (20) was converted via the alcohol to 9-propylphenanthrene, which crystallized as lustrous plates from methanol, m.p. 62–63° (lit. m.p. 59° (22); 57–58° (23); 58.5–59.5° (24)). The picrate separated as orange needles from methanol, m.p. 94–95° (lit. m.p. 95.5–96.0° (24); 98–99° (23)).

9-Cyclopentylphenanthrene (Method A)

Methyl 9-cyclopentylfluorene-9-carboxylate (25) was converted through the alcohol to 9-cyclopentylphenanthrene, colorless needles from methanol, m.p. 125–126°. Lit. m.p. 124–125.5° (25).

9-Cyclohexylphenanthrene (Method A)

Methyl 9-cyclohexylfluorene-9-carboxylate (20) was converted through the alcohol to 9-cyclohexylphenanthrene, colorless prisms from methanol, m.p. 113–114°. Found: C, 92.05; H, 7.96. Calc. for $C_{20}H_{20}$: C, 92.26; H, 7.74% (lit. m.p. 112–113° (27)).

A sample of phenanthrene was purified by treatment with maleic anhydride (11, 28), spectroscopic examination confirming the absence of anthracene (9).

The spectra were taken with a Beckmann DK-2 recording spectrophotometer. Solutions were initially *M*/500 in ethanol, secondary solutions being prepared by volume dilution. Estimated errors are ± 0.2 mμ for the α-band, $\pm 5\%$ for ϵ_{max} values.

ACKNOWLEDGMENTS

P. M. G. Bavin is indebted to the National Research Council of Canada for a Postdoctoral Fellowship (1954–1956) at The University of Ottawa. Miss E. V. Eggington (Smith Kline & French Laboratories Ltd.) recorded some of the spectra. Dr. Cammille Sandorfy kindly read the manuscript at an early stage.

THE HEARTWOOD EXTRACTIVES OF PINUS BANKSIANA LAMB.[1]

E. VON RUDLOFF AND A. SATO[2]
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received April 22, 1963

ABSTRACT

The heartwood of jack pine was analyzed by various chromatographic techniques and countercurrent distribution. The major components were found to be isopimaric, abietic, dehydroabietic, and neoabietic acids, as well as glycerides of oleic, linoleic, and linolenic acids. Smaller amounts of pimaric, sandaracopimaric, myristic, palmitic, stearic, palmitoleic, and four unidentified acids were recorded, as well as fatty acid esters of β-sitosterol, α-terpineol, and four unidentified volatile alcohols. Of the phenols, pinocembrin, pinobanksin, and pinosylvin monomethyl ether predominated. Pinosylvin was isolated and several minor constituents including lignan-like compounds were detected in the acetone extract. The methanol extract was composed mainly of polymeric lignan-like fractions. From one of these a trimer, $C_{60}H_{66}O_{24}$, m.p. 186–188° C, $[\alpha]_D$ +3.2°, was isolated. The small amount of steam-volatile material consisted mainly of α- and β-pinene, benzoic acid, and α-terpineol. Traces of methyl benzoate, camphene, limonene, β-phellandrene, *cis-p*-menthan-8-ol, and nine unidentified trace components were recorded.

INTRODUCTION

Jack pine (*Pinus banksiana* Lamb.) is a medium- to large-sized conifer found from Nova Scotia to northern British Columbia and the MacKenzie River valley (1). This pine is used extensively in the lumber industry and in Kraft pulping. In 1931 Hibbert and Phillips (2) made a thorough study of the resins found in green and seasoned jack pine wood and reported the presence of abietic, pimaric, oleic, and linoleic acids as well as smaller amounts of linolenic acid, saturated fatty acids, resenes, phytosterol, and α-pinene. More recently, Buchanan *et al.* (3) confirmed that oleic and linoleic acids are the major fatty acids, and found, in addition to the above, small amounts of lignoceric acid, these fatty acids occurring mainly as triglycerides. Erdtman (4) isolated from the heartwood the two flavanones pinocembrin and pinobanksin and the hydroxystilbene pinosylvin monomethyl ether. Lindstedt and Misiorny (5) confirmed the presence of these three polyphenols by paper chromatography and found also pinosylvin and three unidentified minor constituents. Haagen-Smit *et al.* (6) investigated the volatile oil from the oleoresin of jack pine and reported the major constituents to be *dl*- and *l*-α-pinene (ca. 85%) and *l*-β-pinene (ca. 10%).

These various studies have shown that the composition of the wood extractives of jack pine is very complex and that separation into individual components or groups of related compounds by the conventional techniques is very tedious and only partially successful. Furthermore, procedures which involve heating in alkaline or acidic media undoubtedly lead to some isomerization and polymerization (2). No complete analysis of the heartwood extractives with more modern techniques appears to have been published. In the present study an attempt was made to obtain as comprehensive as possible an analysis by employing countercurrent distribution (7) and chromatographic techniques.

The heartwood was milled and extracted first with acetone and then with methanol. These extracts were analyzed as shown in the flow sheet (Fig. 1). In a separate experiment the steam-volatile components (0.05%) were recovered and analyzed by gas–liquid chromatography (GLC) (8, 9). The major components were found to be α- and β-pinene,

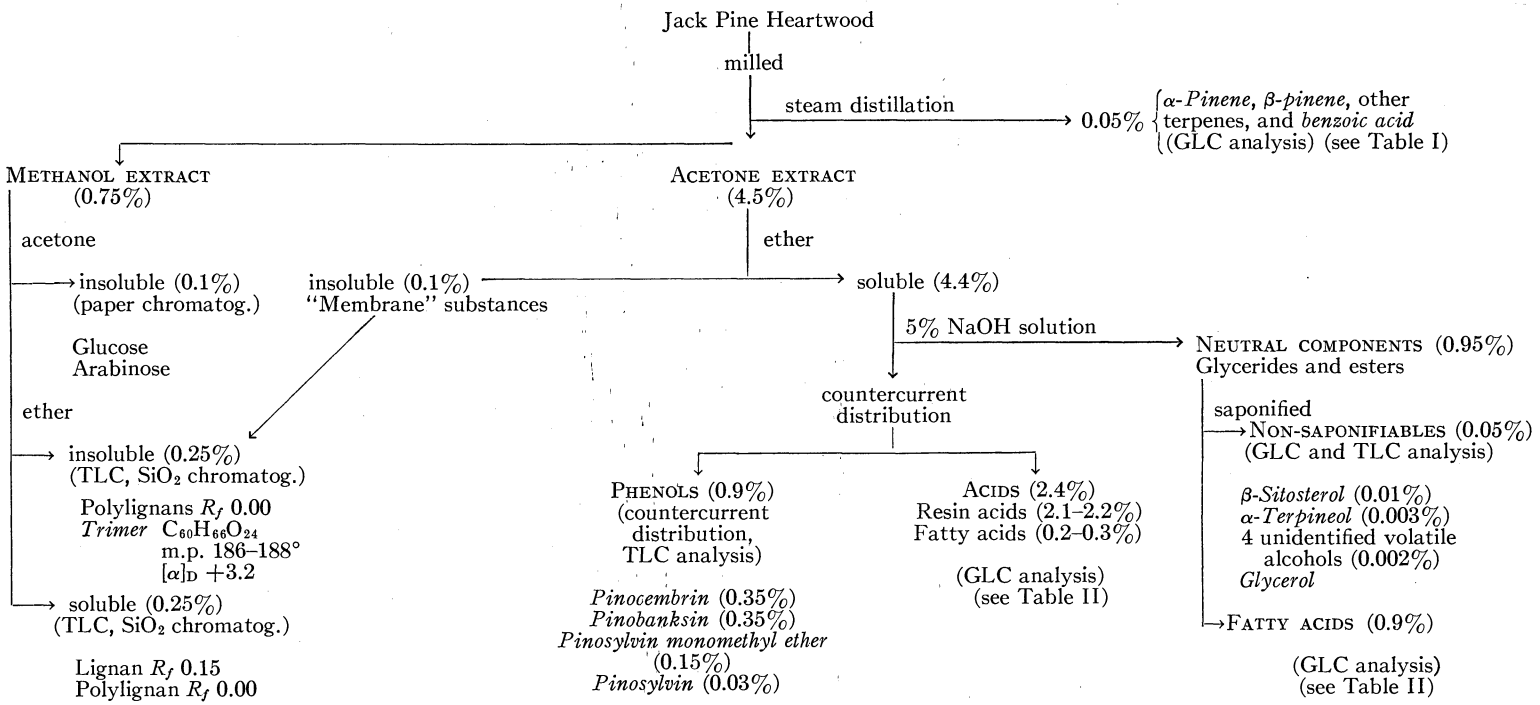

FIG. 1. Fractionation scheme for the wood extractives of jack pine.

confirming the findings of Haagen-Smit *et al.* (6). Thus, jack pine could be used for turpentine production, although the yield is low. In addition to the pinenes, smaller amounts of α-terpineol and benzoic acid were isolated, and camphene, limonene, β-phellandrene, *cis*-*p*-menthan-8-ol, and methyl benzoate were tentatively identified by retention characteristics (see Table I). Nine unidentified trace components were also

TABLE I

Composition of steam-volatile fraction from jack pine wood

Compound	Percent	RRT*
(*a*) Hydrocarbons†

NOTE: Names in parentheses refer to compounds identified by retention times only.
*RRT = relative retention time on 6 ft×1/4 in. polyethylene glycol column (PEG 20 M).
†Hydrocarbons at 65° C (limonene = 1.00).
‡Oxygenated monoterpenes at 120° C (camphor = 1.00).

recorded in the monoterpene range, but α-terpinyl acetate, propionate, or sesquiterpenoid constituents were not detected.

The acetone-soluble portion (4.5%) of the wood was divided into petrol- and ether-soluble material. Only a small amount (see Fig. 1) was insoluble in these two solvents (so-called "membrane" substances (4)). Initially, fractionation into neutral, phenolic, and acidic constituents was attempted by extraction with aqueous alkali of different strength. However, the separation into distinct groups of compounds was incomplete, and the material was, therefore, divided only into neutral and total acidic material. The neutral components were almost exclusively esters, and after saponification β-sitosterol, α-terpineol, four unidentified steam-volatile alcohols, and a mixture of long-chain fatty acids were isolated (see Fig. 1). Glycerol, the major non-saponifiable constituent, was identified by GLC as the triacetate. The fatty acid mixture was analyzed qualitatively and quantitatively by GLC (10) after conversion to the methyl esters. The quantitative data (see Table II) confirm that oleic and linoleic acids are the major acidic constituents of the glycerides (3), but appreciable amounts of linolenic acid were also recorded. Lignoceric acid was not detected; instead a number of minor acids, including three unidentified ones, were recorded in the C_{14} to C_{20} range. When an aliquot of the neutral material was chromatographed on a column of silicic acid, a partial separation of the triglycerides from the β-sitosteryl esters was obtained, some of the latter being obtained as waxy material melting in the 65 to 80° range (see Experimental).

*A: Apiezon N (5% on Anakrom ABS 60–70 mesh) at 210° C. B: Neopentyl glycol adipate polyester (1% on Chromosorb W 60–80 mesh) at 190° C. C: QF-1 fluorinated silicone polymer (5% on Anakrom ABS) at 185° C. D: Polyethylene glycol 20 M (3% on Anakrom ABS) at 190° C.

Initially the phenolic (and acidic) fractions were analyzed by paper chromatography, using Lindstedt's technique (5, 11). However, it was found that the material from jack pine streaked and that R_f values fluctuated excessively. Employing different solvent systems did not give improved results and thin-layer chromatography (TLC) (12) was investigated. Using silica gel G and chloroform – acetic acid (9:1) or toluene–dioxane–water (1:1:1) satisfactory separation and well-defined spots were obtained with a variety of polyphenols, acids, and lignans (see Table III). R_f values were reproducible within narrow limits when measured relative to a reference compound (e.g. chrysin). This technique also gave satisfactory results for the analysis of the phenolic heartwood constituents of jack pine (cf. Fig. 2). However, resin and fatty acids were not resolved sufficiently. Since methyl esters of fatty acids are conveniently and accurately analyzed by GLC (cf. e.g. ref. 10), this technique was employed for identification and estimation of acidic constituents. Hudy (13) has reported satisfactory separation of the methyl esters of a number of resin acids using Apiezon N and polyester GLC columns. However, the use of temperatures of 225° C and higher resulted in a partial isomerization of methyl levopimarate and palustrate to methyl abietate and dehydroabietate. In the present study, other liquid phases were investigated, and by employing a higher ratio of solid support to liquid phase, operating temperatures were reduced sufficiently to reduce isomerization to a negligibly small amount. Relative retention times (RRT) were measured with respect to methyl arachidate (see Table II), which was also used as internal standard for the quantitative data. The results obtained show the major acidic constituents to be isopimaric

TABLE III

R_f values of lignans, polyphenols, β-sitosterol, and some acids on thin-layer chromatograms*

Compound	Chloroform – acetic acid (9:1 v/v)	Toluene–dioxane–water (1:1:1)	Color with acidic $KMnO_4$ reagent
Polylignan (unknown 1)	0.00	0.00	Brown
Olivil	0.05	0.06	Violet-brown
Isolariciresinol	0.09	0.11	Pink
Secoisolariciresinol	0.10	0.17	Brown
Unknown 2	0.15	0.21	Brown
Lariciresinol	0.18	0.23	Brown
Unknown 3	0.32	0.42	Brown
Pinosylvin	0.37	0.46	Brown
α-Conidendrin	0.49	0.38	Pink
Pinoresinol	0.49	0.42	Grey-brown
Unknown 4	0.50	0.46	Brown
Pinobanksin	0.56	0.59	Yellow
Chrysin	0.57	0.61	Yellow
Unknown 5	0.60	0.50	Brown
Pinocembrin	0.68	0.69	Yellow
Pinosylvin monomethyl ether	0.71	0.72	Yellow-brown
β-Sitosterol	0.76	0.56	Brown
Abietic acid	0.82	0.68	Brown
Stearic acid	0.83		Weak
Oleic acid	0.85	0.51	Light yellow
Pinostrobin	0.84	0.64	Yellow
Pinosylvin dimethyl ether	0.86	0.67	Yellow-brown
Benzoic acid	0.86		None

and abietic acids, with lesser amounts of dehydroabietic, neoabietic, pimaric, sandaracopimaric, and unsaturated fatty acids also being recorded (see Table II). A fairly large

For personal use only.

peak of RRT 1.00 was also recorded, and, since no arachidic acid was detected in the mixture of acids from the triglycerides, this component could be palustric acid (13).

Countercurrent distribution (7) was found to be a suitable method for separating the phenolic components from resin and fatty acids. The major phenolic constituents were fractionated sufficiently to permit estimation and isolation when 200 transfers were employed. Pinocembrin and pinobanksin were found to be the major polyphenols, smaller amounts of pinosylvin monomethyl ether and pinosylvin also being isolated (see Fig. 1). TLC indicated that five other minor constituents were present. Of these, two (R_f 0.00 and 0.15) were lignan-like constituents found in larger amounts in the methanol extract (see below). No pinosylvin dimethyl ether, dihydropinosylvins, or chrysin was detected. These findings are in good agreement with the work of Erdtman (4) and Lindstedt and Misiorny (5). The unidentified compound F described by the latter authors may have been benzoic acid, but their compounds D and E could not be correlated with any of the above minor components. The ether-insoluble portion of the acetone extract ("membrane" substances) had R_f 0.00 (TLC) and was very similar to the major fraction obtained from the methanol extract.

The methanol extract (0.75%) was divided into ether-soluble and -insoluble material. The former was chromatographed on silicic acid and elution with chloroform gave a trace of the compound with R_f 0.15. Its infrared spectrum was very similar to that of lariciresinol (R_f 0.18), but the melting point (135.5–137° C) and molecular weight (573) differed from those of this lignan. Elution of the chromatogram with more polar solvents did not yield other crystalline components. All fractions appeared to contain lignan-like material of higher molecular weight. The ether-insoluble portion was taken up in hot acetone and the insoluble carbohydrate material was filtered off. Paper chromatography of the latter gave spots corresponding to glucose and arabinose. Erdtman (14) reported arabinose to be a constituent of jack pine and other pine species. The acetone-soluble portion was fractionated by crystallization and column chromatography, when several sharp-melting, amorphous fractions were obtained. One of these (m.p. 164–165° C, R_f 0.00) gave on recrystallization a small amount of a polylignan, $C_{60}H_{66}O_{24}$, m.p. 186–188° C, $[\alpha]_D$ +3.2°, λ_{max}^{MeOH} 281 mμ, which had an infrared spectrum resembling very closely that of lariciresinol. Acetylation gave an acetate, m.p. 101–102.5° C, $[\alpha]_D$ −1.0°, but methylation gave intractable material. It is noteworthy that the oxygen content of this polylignan is 4 atoms per phenylpropanoid unit as compared with 3 in lignans of the lariciresinol type. Recently Freudenberg (15), in discussing a soluble oligomeric lignan-like material which Brauns (16) found in spruce wood (native lignin), pointed out that alcoholic solvents may react with lignin during isolation and that alcohols or sugars may add to dehydration polymerizates during lignin formation. Similarly, the higher oxygen content of the polylignan isolated in the present study suggests that the material may be the product of the addition of methanol to a reactive lignan-like compound. Two other fractions having similar properties, but with melting points of 124–125° C and 148–151° C, were also isolated. The nature and the source of these polylignans will be investigated further.

Benzoic acid and its methyl ester are not considered to be typical pine heartwood extractives (14). It is possible that these are artefacts, produced for example by oxidative degradation of the pinosylvins or flavanones. From a crude sample of pinobanksin, which had been standing several months, benzoic acid was isolated. However, benzoic acid was found in the steam-volatile fraction, and if it is a degradation product, it must have been produced during the milling or steam distillation of the wood.

EXPERIMENTAL

Melting points were determined with a Leitz hot-stage microscope. Countercurrent distribution was carried out with a modified 100-tube E.C. Apparatus Co. instrument (20-ml volume lower phase, 5- to 30-ml variable upper phase for each tube). Gas–liquid chromatograms were obtained with an instrument of conventional design (10), having a thermal conductivity cell as detector and using helium as carrier gas. A 1-mv Honeywell recorder was used with a chart speed of 0.5 in./min. Columns were made of 6 ft×1/4 in. (6 mm) O.D. copper or stainless steel tubing. The liquid phase was applied to the solid support (Chromosorb W 60–80 mesh) by means of the tray method in the ratio of 1 to 6, unless otherwise stated. Individual fractions were collected at the heated outlet in glass traps which were externally cooled. Infrared spectra were recorded with a Perkin–Elmer Model 21 double-beam spectrophotometer, liquids being mounted as films between sodium chloride plates and solids as KBr disks. Molecular weights were determined by means of a Mechrolab Model 301 osmometer.

Paper-partition Chromatography (PPC)

Initially, Lindstedt's technique (5, 11) was used for the separation of phenols. However, it was found that with benzene–ligroin–methanol (50:50:1 v/v) saturated with water as solvent R_f values fluctuated and spots streaked frequently even when the paper (Whatman No. 4) was allowed to equilibrate with the solvent in the chamber for 8 hours. R_f values (measured at the top of the spot) for pinosylvin, its monomethyl ether, pinobanksin, pinocembrin, and chrysin varied from 0.08 to 0.15, 0.71 to 0.84, 0.13 to 0.21, 0.35 to 0.44, and 0.15 to 0.25 respectively in different runs. The spray reagent was diazotized benzidene and ultraviolet fluorescence or absorption was also used. With some of the phenolic fractions from jack pine heartwood extractives excessive streaking was obtained. Other solvent systems, including *n*-butanol – acetic acid – water (4:1:1.8), chloroform – acetic acid – water (13:6:1), benzene–ligroin–methanol (5:5:1), and benzene–ligroin–acetic acid – methanol – water (5:5:1:1:5, upper phase), were tried without marked improvement.

Sugars were chromatographed on Whatman No. 1 paper using *n*-butanol – acetic acid – water (4:1:5, upper phase) and *n*-butanol–pyridine–water (3:3:1) as solvent and aniline phthalate as spray reagent. The R_f values for glucose, arabinose, and xylose were 0.12 and 0.16, 0.18 and 0.21, and 0.19 and 0.27 respectively.

Thin-layer Chromatography (TLC)

To solve the above difficulties with phenolic constituents TLC according to Stahl (12) was tried. Well-defined spots and good resolution were obtained on silica gel G (Merck, Darmstadt, Germany) and either chloroform – acetic acid (9:1) or toluene–dioxane–water (1:1:1, upper phase) as developing solvent. Phenolic compounds were detected by use of ultraviolet light, diazotized benzidene, or $FeCl_3$–$K_3Fe(CN)_6$ (1% aqueous solutions, 1:1) spray. Equally good separation was obtained with some lignans and the technique could also be used for the detection of resin acids, fatty acids, β-sitosterol, and benzoic acid. The spray reagents used were: 0.1 *M* $KMnO_4$ and 10% H_2SO_4 (1:3, heated 5 minutes at 105° C), rhodamine B (0.05% in 10% aqueous acetone), and antimony trichloride (0.05% in chloroform). The glass plates were 5×20 cm or 13×13 cm in dimension, the support was applied in about 250-μ thickness and development time was about 30 minutes, when the solvent had travelled about 10 cm. R_f values for individual compounds varied by about 0.05 unit between different runs, but when measured with respect to a reference compound (e.g. chrysin) they were constant to within ±0.02 unit. The R_f values of lignans, polyphenols, some acids, and β-sitosterol, as well as those of the unidentified components of the jack pine heartwood extractives, are shown in Table III. A two-dimensional chromatogram obtained with phenolic and acidic components from the jack pine wood extract is shown in Fig. 2.

Gas–Liquid Chromatography (GLC)

Steam-volatile components were analyzed by the GLC technique described by one of us for the analysis of terpenes (8) and essential oils (9, 17). Monoterpene hydrocarbons were analyzed at 65° C (flow rate 120 ml/min) on polyethylene glycol 20 M (PEG 20 M) and adipate polyester (APEG, NGA) columns. Relative retention times (RRT) were measured with respect to limonene. Oxygenated monoterpenes and methyl benzoate were chromatographed on the same columns at 120° C and RRT values were measured with respect to camphor. When separation was incomplete, analysis was also carried out on ethylene glycol bis(propionitrile) or QF-1 fluorinated silicone polymer columns. The percentage composition was obtained by the triangulation method, the error being ±(1–3)% for large- to medium-sized peaks and ±(3–10)% for medium- to small-sized ones.

Free fatty acids were methylated with freshly prepared diazomethane and the resulting methyl esters were analyzed by GLC at 160–190° C on Apiezon N (5% on Anakrom ABS, 60–70 mesh), QF-1 (5% on Anakrom ABS 60–70 mesh), neopentyl glycol adipate polyester (NGA, 1% on Chromosorb W, 60–80 mesh), and polyethylene glycol (PEG 20 M, 3% on Anakrom 60–70 mesh) columns. Resin acids were similarly methylated, but in the presence of some methanol in order to ensure complete esterification. A mixture of abietic acid (48%) and arachidic acid (52%) methylated in this manner gave peaks (at 185° to 210° C) which had corresponding areas (±(2–3)%) on the Apiezon N, QF-1, and SE-30 columns. On the polyester and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

polyethylene glycol columns the area of the peak recorded for methyl abietate was 5 to 15% smaller than the theoretical value. Therefore, all quantitative data were calculated from data recorded on the former columns. For methyl esters of fatty acids correction factors for acids of different chain length were required. Taking methyl arachidate as 1.00, the factors for stearate, oleate, linoleate, and palmitate were 0.95, 0.96, 0.96, and 0.90 (±0.02) respectively. All retention times were measured with respect to methyl arachidate and the various RRT values obtained are shown in Table II.

Extraction of the Wood and Preliminary Fractionation

The logs of jack pine wood came from the Candle Lake district of Northern Saskatchewan.* The bark and sapwood was removed and the heartwood was milled in a hammer and a Wiley mill. The air-dried wood (5.0 kg) was extracted with acetone (15 liters) in a Soxhlet extractor for 30 to 36 hours. Excess solvent was removed by evaporation *in vacuo* on a rotatory evaporator. The residual wood meal was extracted similarly with methanol.

The brown, viscous residue from the acetone extract (226 g, 4.5%) was poured with stirring into petrol (b.p. 40–60° C; 2 liters), and after decantation of the petrol solution and washing with fresh solvent (2×250 ml), the insoluble residue (80 g, 35.4%) was taken up in a minimum of acetone and poured similarly into ether (2 liters). The ethereal solution was filtered to remove the insoluble precipitate ("membrane" substances, 4.3 g, 1.9%).

When small aliquots of the petrol and ether solutions were extracted successively with saturated sodium bicarbonate, 5% sodium carbonate, and 5% sodium hydroxide solution, the separation into neutral, phenolic, and acidic components was incomplete (TLC analysis). The insoluble resin acid salt layer (4), after acidification and chromatography on silicic acid gave a number of fractions with sharp melting points (0.5 to 1.5° spread) in the 70 to 90° C range. Subsequent analysis showed these to be mixed crystals of resin acids, fatty acids, and esters (see also below). A trace (1.5 mg) of a white, crystalline compound, m.p. 199.5–200° C, was isolated from the first fraction eluted with chloroform. The infrared spectrum had strong adsorption bands at 3400, 1730, 1268, 1200, 1080, 1065, and 700 (triplet) cm^{-1} and medium-intensity ones at 1600, 1508, 1453, 1023, 968, 880, 800, and 752 cm^{-1}, indicating that the compound may be an aromatic ester having free hydroxyl groups. This compound was not isolated again by the techniques described below.

In subsequent work the petrol- and ether-soluble material was extracted exhaustively with aqueous sodium hydroxide solution to remove all acidic and phenolic components. The ether layer was washed with water, dried (Na_2SO_4), and evaporated to dryness to give the neutral constituents (47.8 g, 21.2%; 15.2% from the petrol-soluble portion). The aqueous alkaline solutions and washings were combined, acidified, and extracted with ether to give the combined acidic and phenolic constituents (171.2 g, 75.7%; 46.3% from the petrol-soluble portion).

Steam-volatile Components

Fresh wood meal (200 g) was steam-distilled for 2 hours and the distillate was extracted with ether. After drying, the solvent was evaporated on a steam bath, using a small flask having a long neck. The residual oil (0.10 g, 0.05%) contained about 3% ether and had n_D^{25} 1.4680, $[\alpha]_D$ −18.2° (*c*, 1.2, $CHCl_3$). Aliquots (1–10 μl) were analyzed by GLC for monoterpenes as described above. The average composition is shown in Table I. The identity of α-pinene, β-pinene, and α-terpineol was confirmed by isolation and comparison of infrared spectra. The optical rotation of both pinene fractions was negative.

GLC analysis at higher temperatures (120–180° C) showed no peaks corresponding to α-terpinyl acetate or propionate, nor were any peaks in the sesquiterpene range recorded. When the steam-volatile product was treated with diazomethane a substantial peak (about 10%) corresponding to methyl benzoate (RRT 1.57) was observed. The presence of free benzoic acid was confirmed when steam distillation of the acidic portion of the wood extract gave crystalline benzoic acid, m.p. 117.5–120° C, which was undepressed on admixture with an authentic sample (m.p. 120–121° C). Steam distillation of the neutral portion of the acetone extract gave a very small amount of an oil similar in composition to the one obtained by direct steam distillation of the wood.

Countercurrent Distribution

An aliquot of the acetone extract (4.0 g) was distributed equally between the first four tubes of the apparatus, using 70% aqueous ethanol equilibrated with petrol (b.p. 60–70° C) as lower and upper phase (20 ml each per tube). After applying 100 transfers, the contents of each tube were withdrawn, the solvent evaporated, and the residual material weighed. By plotting weight against tube number the distribution curve was obtained. Tubes 0 to 25 contained about 20% of the extract, which was distributed in two overlapping peaks. Tubes 26 to 68 were practically devoid of material, whereas tubes 69 to 95 contained the balance of the extract. From tubes 79 and 82 crystalline material of m.p. 87–88° C and 73–74° C was obtained. The infrared spectra resembled those of β-sitosteryl esters, with free acids as contaminants. Removal of the acidic material (resin acids, GLC analysis) gave waxy ester fractions, m.p. 70–74° and 67–72° C respectively, which were saponified. β-Sitosterol, m.p. 135–137° C (TLC R_f 0.76), was isolated from the non-saponifiable portion, whereas GLC analysis showed the saponifiable portion to contain a mixture of C_{18}

**Identified and supplied by Dr. W. B. Denyer, Department of Forest Pathology, Forestry Department, Saskatoon.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

fatty acids (see also below). TLC analysis of the material in tubes 0 to 25 showed it to be composed of pinocembrin, pinobanksin, pinosylvin monomethyl ether, and several unidentified phenolic components.

From this experiment it was concluded that a fairly low number of transfers would suffice to separate the phenolic constituents completely from resin acids and neutral components, but that a very high number of transfers would be required to obtain fractionation into individual components. Since the neutral and acidic components were analyzed more conveniently by other techniques, only the phenolic constituents were fractionated by this means (see below).

Neutral Components

The infrared spectrum of the neutral portion indicated that it was composed mainly of esters. An aliquot (20 g) was saponified by heating under reflux with sodium hydroxide solution (5% in 80% aqueous ethanol) for 2 hours. After diluting with water, the non-saponifiables (0.2 g) were extracted with ether. GLC analysis showed the presence of five volatile components with RRT (camphor = 1.00, PEG 20 M column at 120° C) values of 0.88, 1.31, 1.90, 2.08, and 2.24 in the area ratios of 2:5:1:1:24. These RRT values correspond to those of some of the oxygenated terpenes found in the steam-volatile fraction (Table I). The component with RRT 2.24 was isolated and its infrared spectrum agreed in all respects with that of α-terpineol. The peak at RRT 1.31 may correspond to *cis*-*p*-menthan-8-ol. TLC analysis showed the non-volatile component to be β-sitosterol (R_f 0.76). The non-saponifiable material was steam-distilled and the volatiles were extracted with ether. On concentrating the ether solution a small amount of crystalline β-sitosterol, m.p. 136–137° C, was obtained. The soluble material was fractionated by GLC and the major component with RRT 2.24 was isolated pure in small amounts. The infrared spectrum agreed with that of α-terpineol in all respects. From the non-volatile portion (0.12 g) crystalline β-sitosterol, m.p. 135–136° C, $[\alpha]_D^{25}$ −24.2° (*c*, 2.5, $CHCl_3$), was obtained after recrystallization from ethanol. TLC analysis gave a single spot of R_f 0.76. The acidic components (17 g) were recovered from the saponification mixture in the usual manner. After methylation with diazomethane these were analyzed by GLC. The average composition is shown in Table II. The residual aqueous solution was deionized by treatment with ion-exchange resin and evaporated to a sirupy residue (3 g). An aliquot was acetylated and the ether-soluble product was analyzed by GLC (PEG 20 M column at 160° C), when a peak corresponding to glycerol triacetate, RRT 7.07 (camphor = 1.00), was recorded.

An aliquot (1.0 g) of the neutral portion was chromatographed on a column of silicic acid (25 g). Elution with chloroform gave two waxy fractions (mg amounts) having m.p. 67–72° C and 78.5–82° C respectively. The infrared spectra resembled that of β-sitosteryl stearate. Saponification gave β-sitosterol (TLC R_f 0.75) and a mixture of oleic, linoleic, and stearic acids (GLC).

Acidic Constituents (77.6%)

The total acidic material was fractionated into phenolic and acidic components by countercurrent distribution. Applying 50 transfers with 75% aqueous ethanol–petrol (b.p. 60–70° C) as solvent pair, an aliquot (5 g) was resolved into phenols (1.3 g; tubes 0 to 18) and resin and fatty acids (3.6 g; tubes 26 to 49).

Aliquots of the free acids were taken up in a mixture of ether and methanol (1:1) and were methylated with excess diazomethane solution. The average composition of the mixture of methyl esters as determined by GLC analysis is shown in Table II.

The phenolic material was analyzed by two-dimensional TLC (see Fig. 2). This, together with earlier paper chromatograms, showed that the major components were most likely pinocembrin, pinobanksin, and pinosylvin monomethyl ether. Spots corresponding to pinosylvin and five unidentified minor components were also detected (see Table III). To obtain an estimate of the relative amounts and to isolate pure components, an aliquot (5 g) was fractionated in a 200-transfer countercurrent experiment, using 75% aqueous ethanol–petrol (b.p. 60–70° C) as solvent pair. The distribution curve showed two main peaks with maxima at tube 6 (K = 0.031) and tube 18 (K = 0.099) respectively, and shoulders at tubes 2, 9, and 28. Calculation of theoretical curves (7) gave values of about 35% for the two major components, about 20% for that giving a shoulder at tube 28, and about 3% each for the other two components. Using TLC, these were tentatively identified as pinobanksin, pinocembrin, pinosylvin monomethyl ether, pinosylvin, and an unknown respectively. From tubes 5 to 7, pinobanksin, m.p. 177–180° C (from ethanol), $[\alpha]_D^{25}$ −6.4° (*c*, 1.1, MeOH), was obtained; from tubes 16 to 20, pinocembrin, m.p. 203.5–204° C, $[\alpha]_D^{25}$ −16.9° (*c*, 1.0, $CHCl_3$); and from tubes 27 to 30, pinosylvin monomethyl ether, m.p. 112.5–114° C. When pinobanksin was crystallized from aqueous solvents, it was obtained as the monohydrate, m.p. 174.5° C. Found: C, 61.60; H, 4.75%. Calculated for $C_{15}H_{12}O_5 \cdot H_2O$: C, 62.10; H, 4.86%. Pinosylvin was obtained as mixed crystals with pinobanksin from tubes 1 to 3, m.p. 156–170° C. Column chromatography on silicic acid gave practically pure pinosylvin, m.p. 154–156° C. The identity of each compound was confirmed by mixed melting points and comparison of infrared spectra. Attempts to obtain the unidentified components (cf. Fig. 2) in the crystalline state failed, and it was not possible to obtain crude products which were free from the above major constituents. It is noteworthy that crude fractions of pinobanksin gave crystalline benzoic acid (sublimed at the top of test tubes) on standing for several months in the cold.

Ether-insoluble Material (1.9%)

The ether-insoluble portion of the acetone extract was a brown, amorphous material having R_f 0.0 (TLC). Using acetic acid – hydrochloric acid – water (30:3:1 v/v) as developing solvent a single spot of R_f 0.77 was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

obtained, which gave an orange-brown color with diazotized benzidene. The infared spectrum of the crude material was similar to that of the material R_f 0.0 (TLC) obtained from the methanol extract (see below).

Methanol Extract

The residue (9.0 g) from the methanol extract (0.75%) was extracted with ether and the ether-soluble portion (4.0 g) was fractionated by column chromatography on silicic acid. Elution with chloroform gave a very small amount (8 mg) of an amorphous compound, m.p. 135.5–137° C, having an infrared spectrum similar to that of lariciresinol (m.p. 169.5–170.5° C). The R_f value (TLC) was 0.15, i.e. that of unknown 2 (Fig. 2), which is close to that of lariciresinol (R_f 0.18). However, the molecular weight was found to be 573, which is about 1.6 times that of lariciresinol. Further elution of the chromatogram with more polar solvents did not produce fractions of sharp melting points.

The ether-insoluble portion (5.0 g) was taken up in hot acetone and the mixture was filtered hot. The insoluble residue (1.0 g) was taken up in water and analyzed by paper chromatography. Two spots, corresponding in R_f values (see above) to glucose and arabinose, were detected. The acetone solution was allowed to cool slowly overnight, when an amorphous precipitate, m.p. 164–165° C, was obtained. Recrystallization from ethanol gave a microcrystalline powder, compound A (61 mg), m.p. 186–188° C, λ_{max}^{MeOH} 281 mμ, $[\alpha]^{23}_D$ +3.2° (*c*, 1.2, dioxane). The infrared spectrum was similar to that of lariciresinol, but the R_f value (TLC) was 0.0. Found: C, 61.03; H, 5.65; CH_3O, 17.39%; mol. wt., 1167. Calculated for $C_{60}H_{66}O_{24}$: C, 61.53; H, 5.68; CH_3O, 15.3%; mol. wt., 1171.4. Acetylation with acetic anhydride in the presence of sodium acetate gave a compound, m.p. 101.5–102.5° C, $[\alpha]_D^{25}$ −1.0° (*c*, 1.0, acetone). Found: C, 61.84; H, 5.64; CH_3O, 11.42; AcO, 26.83%; mol. wt., 1558. Calculated for decaacetate: C, 60.8; H, 4.84; CH_3O, 11.4; AcO, 25.9%; mol. wt., 1581.41. Calculated for nonaacetate: C, 59.3; H, 4.91; CH_3O, 11.7; AcO, 26.6%; mol. wt., 1540.38. Methylation with dimethyl sulphate gave intractable, viscous material. Treatment with diazomethane gave an amorphous compound of mol. wt. 1460. The parent compound gave a single spot of R_f 0.86 on TLC analysis, using acetic acid – hydrochloric acid – water (30:3:1) as solvent. The acetone-soluble (cold) portion was chromatographed on silicic acid (30 g), eluting successively with ether, chloroform, 2-butanone, and methanol. Elution with 2-butanone gave an amorphous material (240 mg), compound B, m.p. 124–125° C, after precipitation with water from a solution in dioxane. Elution with 2-butanone–methanol (1:1) gave another amorphous fraction, compound C, m.p. 148–151° C, $[\alpha]_D$ +3.2° (*c*, 1, dioxane). Both compounds had R_f values of 0.0 (TLC) and had infrared spectra similar to those of compound A and lariciresinol.

ACKNOWLEDGMENTS

We wish to thank Dr. W. B. Denyer for procuring the jack pine wood, Professor H. Erdtman for samples of pine polyphenols, Professor K. Freudenberg for samples of lignans, and Dr. E. O. Edwards and the Hercules Powder Co., Wilmington, U.S.A., for samples of resin acids. Microanalyses were carried out by Mr. M. Mazurek and infrared spectra were recorded by Mr. W. C. Haid. The technical assistance of Mr. M. Granat is also gratefully acknowledged.

ISOTOPE EFFECTS IN X-RAY-IRRADIATED ACIDIFIED H_2O–D_2O SOLUTIONS

CHAVA LIFSHITZ[1]
Department of Physical Chemistry, The Hebrew University of Jerusalem, Israel
Received February 13, 1963

ABSTRACT

H_2O–D_2O mixtures containing 0.1–1 *N* H_2SO_4 were irradiated by 200-kv X rays. The molecular isotope effect, $\alpha_M = (H/D)_{H_2}/(H/D)_{H_2O}$, was determined from experiments on KBr solutions. The atomic isotope effect, $\alpha_A = (H/D)_H/(H/D)_{H_2O}$, was determined from experiments on ethanol solutions. At 96% D_2O, $\alpha_A = 3.7\pm0.5$ and $\alpha_M = 4.0\pm0.2$. The isotope effects are discussed in connection with the radiation-chemical reaction $H_3O^+ + eH_2O \rightarrow H + 2H_2O$. The connection between the atomic and molecular hydrogen is discussed. It is concluded that the relation between the observed atomic and molecular isotope effects is *not* contrary to a hydrogen atom recombination reaction leading to the molecular product. Isotope effects due to the oxidation of Fe^{+2} ions by hydrogen atoms in acid solutions were measured and the mechanism of this reaction is discussed.

INTRODUCTION

The primary chemical act taking place when aqueous solutions are subjected to ionizing radiations is represented schematically as follows:

$$H_2O \rightarrow H, OH, H_2, H_2O_2. \qquad [1]$$

When suitable solutes are present (e.g. methanol, $Fe^{+2}(H^+)$), the hydrogen atoms lead to further hydrogen molecule production, in addition to the molecular hydrogen produced by the primary chemical reaction [1].

When H_2O–D_2O mixtures are irradiated, the hydrogen atoms and molecules formed via [1] are enriched with light hydrogen with respect to the water (1–5). A study of the dependence of these isotope effects on various factors, such as type of solute, deuterium concentration of the water, etc., is important for the understanding of the mechanism of formation of the primary products as well as the secondary reactions between the reactive intermediates formed (e.g. hydrogen atoms) and the solutes present. Such a study is of particular interest, since none of the mechanisms which were proposed for the radiation-chemical decomposition of water was found consistent with all the observed isotope effects (4–6).

The present paper presents results on the isotopic enrichment of hydrogen gas evolved from irradiated acidified solutions of various solutes, in particular, KBr, $FeSO_4$, and ethanol. The dependence of the isotope effects on the deuterium concentration of the solution is presented. The results obtained are compared with existing data, and possible reaction mechanisms leading to the observed isotope effects are discussed.

EXPERIMENTAL

Air-free solutions were irradiated with 200-kv X rays and the isotopic composition of the gas was determined mass spectrometrically. The detailed experimental procedure was described in a previous paper (7).

RESULTS

The Molecular Isotope Effect

The effect of solute concentration and deuterium content of the water on $\alpha_M = (H/D)_{H_2}/(H/D)_{H_2O}$ was examined for two basically different types of solute: (*a*) non-oxidizing solutes and (*b*) oxidizing solutes.

(*a*) Acidified aqueous solutions of KBr and KI of various D_2O concentrations were irradiated and the isotopic composition of the hydrogen evolved was determined. The Br^- ion was chosen as a solute in a principal series of experiments carried out to determine the molecular isotope effect, since it is an efficient hydroxyl radical scavenger yet does not react with hydrogen atoms. In these experiments one thus gets the full molecular hydrogen yield, via [1], and this molecular hydrogen is protected from further attack of OH by the Br^- (8). The isotopic separation observed is then the initial separation characteristic of the molecular product and unaffected by secondary reactions.

Values of α_M in the presence of various solutes at low deuterium concentrations were compared, in order to examine the dependence of α_M on the type of solute. The radiation-chemical behavior of I^- was found to be slightly different from that of Br^- (9, p. 108). α_M values obtained from KBr and KI solutions of low deuterium concentration are presented in Table I. The hydrogen yields in these experiments are equal, within the experimental error. (The molecular yield, in terms of the number of hydrogen molecules formed per 100 ev absorbed, is $G_M = 0.7 \pm 0.1$.)

TABLE I

α_M at low deuterium concentrations (0.8 N H_2SO_4)

% D in solution	Solute	α_M
2.95	—	2.0_5
2.1	1×10^{-4} M KBr	2.2_6
1.0	1×10^{-4} M KBr	1.9_8
1.0	1×10^{-2} M KBr	1.9_7
3.0	1×10^{-2} M $CuSO_4$; 7×10^{-4} M $FeSO_4$	2.2_0
1.0	1×10^{-2} M KI	2.0_5
1.0	5×10^{-1} M KI	2.1_5

From the experiments on 1% D_2O solutions of KBr (Table I) one observes that α_M is independent of KBr concentration. The addition of 10^{-4} M KBr to a solution containing no KBr increases α_M slightly, but any concentration change beyond that has no effect.

The dependence of α_M on the deuterium content of acidified KBr solutions is presented in Fig. 1. An increase in α_M is observed with increasing deuterium concentration. α_M in

Fig. 1 shows an additional upward trend at high deuterium concentrations. Several experiments were carried out on 99.8% D_2O solutions. Great care was taken not to contaminate the D_2O with light hydrogen. The results obtained are summarized in Table II. Since

TABLE II

α_M values at 99.8% D_2O (neutral solutions)

% D	Solute	$(HD/D_2)_{gas}$	α_M
96.5	1×10^{-2} *M* KBr		3.6 (7)
97.0	1×10^{-1} *M* KNO_2		4.3 (7)
99.8	1×10^{-3} *M* KBr	0.020	5.0

Standard (99.8% D in the gas)		0.004	

these experiments were carried out on neutral solutions, we included two of our previous results (7) on lower D_2O concentrations in neutral solutions. The ratio of HD to D_2 in the gas evolved from 99.8% irradiated D_2O solutions, as well as the HD-to-D_2 ratio for the standard (99.8%) gas used, is presented in Table II. No $m/e = 2$ was observed in these mass spectrometric measurements, beyond that due to the background and to the D^+ contribution. HD/D_2 values are thus the true values for the gas originating in these highly concentrated D_2O solutions. It should be emphasized, however, that a minute H_2O contamination, of the irradiated water, may lead to values of α_M considerably higher than the true values in this concentration region. (For example, if the irradiated water is 99.7% D_2O instead of 99.8%, D/H is not 500 but 330 and α_M observed is greater than the true value by a *factor* of 1.5, since the value 500 was used in the computation.) The α_M values for 99.8% D_2O should thus be treated with some caution. Nevertheless, some genuine further increase in α_M is believed to occur at high deuterium concentrations.

(*b*) Acidified aqueous solutions of Cu^{+2} and Ce^{+4} of various D_2O concentrations were irradiated and the isotopic composition of the hydrogen evolved was determined. Oxidizing solutes are capable of reacting with hydrogen atoms and affecting the molecular yield (9). Oxidizing solutes may thus affect α_M. α_M at low Cu^{+2} concentration and low D_2O content is included in Table I. It is seen that, under limiting low solute concentrations, α_M is independent of the type of the solute.

Figure 2 shows the dependence of α_M on $CuSO_4$ concentration for 0.1 *N* H_2SO_4. Contrary to the behavior found for non-oxidizing solutes (Table I), a marked decrease in α_M is observed when the $CuSO_4$ concentration is increased. A similar decrease in α_M was found for neutral solutions of NO_3^- containing 10^{-3} *M* KBr and 1.5–2% D_2O. α_M decreased upon increasing the NO_3^- concentration as follows:

NO_3^- concn., *M*	1.1×10^{-3}	1.1×10^{-2}	1.1×10^{-1}	8.8×10^{-1}
α_M	1.8_0	1.6_3	1.2_9	$1._0$

The increase of α_M with deuterium concentration observed for KBr in Fig. 1 was also observed in experiments with oxidizing solutes. The pair Cu^{+2}/Fe^{+2} ($[Cu^{+2}] > [Fe^{+2}]$) was previously studied at 84.5% D and in 0.1 *N* H_2SO_4 (2). Additional experiments were carried out with these ions at 0.8 *N* H_2SO_4 and high deuterium concentrations and the

results are given in Table III. Ce^{+4} was also among the ions studied previously at low deuterium concentrations and in 0.8 N H_2SO_4 (1, 10). Further results at higher deuterium concentrations are also included in Table III. Previously published values on Cu^{+2}/Fe^{+2} and Ce^{+4} are given for comparison. The increase in α_M with increasing deuterium concentrations is also observed in neutral solutions of oxidizing solutes as is seen from the experiments with NO_2^- (Table II and ref. 7).

The Atomic Isotope Effect

The enrichment in light hydrogen, of the hydrogen atoms produced in reaction [1], was studied using mainly ethanol solutions. When a suitable organic solute is present in the irradiated water, the hydrogen atoms formed by reaction [1] react with it to abstract a further hydrogen atom and form molecular hydrogen. The isotopic composition of the evolved hydrogen gas was studied by us, in order to determine $\alpha_A = (H/D_{atoms}/(H/D)_{water}$, in this system. If the abstracted hydrogen atoms have a known isotopic composition, then the isotopic composition of the atoms, formed from the water, can be computed. (Contribution from the molecular product, via [1], to the total hydrogen yield has to be taken into account.) When ethanol is dissolved in water its hydroxylic hydrogen exchanges with the water. It has been shown that the hydroxylic hydrogen is not attacked, however, by hydrogen atoms and that the main abstraction reaction occurs at the α-hydrogen of the ethanol (11, 12). The hydrogen atoms of the ethanol, participating in the reaction, are thus of a known isotopic composition. Furthermore, although electron transfer from an alcohol molecule to H_2^+ at acid pH's was suggested to occur in photochemical systems

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(13), no evidence for this reaction could be found in the present case (14). The composition of the hydrogen atoms from irradiated H_2O–D_2O mixtures containing ethanol is thus directly obtained from the composition of the hydrogen molecules, since the abstracted hydrogen atoms are all light. Similarly, in formic acid, the hydrogen atoms react with the hydrogen attached to the carbon (15) and since these do not exchange with the water, they are also light hydrogens only.

α_A was determined at low deuterium concentrations on 0.1 N and 0.8 N H_2SO_4 solutions of ethanol and formic acid and the results are given in Table IV. The method for calcu-

*The total hydrogen yield in this experiment is quite low. This is characteristic for relatively low concentrations of carboxylic acids in acid solutions (16) and the interpretation of $(D/H)_{gas}$ in terms of the given α_A may be incorrect.

lating α_A from the isotopic results, as well as the notations used in Table IV, was explained in a previous paper (7). α_M values, needed for computing α_A, were taken from the KBr experiments.

The values for α_A obtained from the ethanol experiments are slightly higher than those from the formic acid experiments (Table IV). It is doubtful whether any significance should be attached to this, since the relative arbitrariness in the choice of the value of the molecular yield used for computing α_A introduces a considerable uncertainty into the results (7), at low deuterium concentrations. α_A at low deuterium concentrations in acid solution is thus 3.0 ± 0.5. Previous results for α_A at low deuterium concentrations are from experiments on neutral solutions and are as follows: 2.7 (4), 2.4 (5), and 3.1 (7).

The dependence of α_A on the deuterium concentration of the water was studied using 0.1 N H_2SO_4 and 1 N H_2SO_4 solutions of ethanol in water. The results are given in Table V. Notations used are as in reference 7. G_M denotes the molecular hydrogen yield. Since at high deuterium concentrations there is no contribution to $G(H_2)$ from the molecular product, one can compute α_A directly from α_M without assuming any value for G_M; in fact G_M is computed at the same time. α_A and G_M values in experiments 3–9 of Table V were computed as previously explained (7). α_M values used for the calculations of Table V are from the KBr experiments (Fig. 1). If the deuterium concentration is low, as in experiments 10–13, so that there is a contribution to $G(H_2)$ from the molecular product, the computation of α_A is based on assumed values for both α_M and G_M. α_A values given in experiments 10–13 were computed using the G_M values given in parentheses. These G_M values are obtained by simple interpolation from G_M values in the pure solvents. G_M values computed in experiments 6–9 (Table V) are higher than the ones computed for experiments 3–5, since the ethanol concentration is lower. In experiments 1 and 2 the concentration of ethanol is comparable to that of experiments 6–9, yet $G(D_2)$ is lower

than G_M of experiments 6–9. The possibility exists that even at the very high deuterium concentrations employed in experiments 1 and 2 there is a contribution to HD from the molecular product.

The value of α_A obtained at high deuterium concentrations is thus 3.7 ± 0.5. Previous values for α_A at similar D_2O concentrations are: 4.1 in acid solution (2) and 4.3 for the "residual" yield in neutral solution (7) or 1.6 for the total yield in neutral solution (5). The present values for α_A are higher than α_M at low deuterium concentrations and lower than α_M at high deuterium concentrations. At 50% D α_M and α_A are approximately equal.

Isotope Effects in Secondary Reactions

Solutions of 10^{-2} M $FeSO_4$, 0.8 N H_2SO_4 were studied. The isotopic composition of hydrogen gas evolved from H_2O–D_2O mixtures was determined. Cr^{+2} was run once at low deuterium concentration for comparison with the Fe^{+2}. Both of these ions give high hydrogen yields (equal to the "atomic" plus "molecular" yields) and $\alpha = (H/D)_{gas}/(H/D)_{water}$ for 1% D_2O was 3.53 from Fe^{+2} and 3.71 from Cr^{+2}. When Cu^{+2} is added to ferrous solutions the hydrogen yield is decreased. Figure 3 presents the dependence of α upon the total

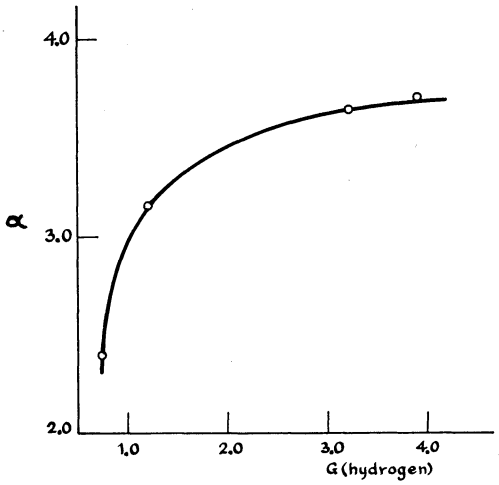

FIG. 3. α dependence on hydrogen yield from 0.8 N H_2SO_4 solutions of varying Cu^{+2}/Fe^{+2} ratios and 3% D_2O.

For personal use only.

hydrogen yield as the ratio $[Cu^{+2}]/[Fe^{+2}]$ is varied at constant low deuterium concentration of the solution. Similar concentration effects were observed on a 34% D_2O solution, where α changes from 2.7 to 3.05 and 3.95 as the yield changes from the molecular one (no Fe^{+2} present) to $G = 0.93$ and $G = 4.25$, respectively.

Various deuterium concentrations were studied in the $FeSO_4$ case and the dependence of α on deuterium concentration is presented in Table VI. Several initial Fe^{+3} ion yields

TABLE VI

are presented. These were measured on analogous experiments given low total doses. To determine the isotopic composition of the gas, one needs relatively high conversions and the hydrogen yields presented are the ones measured at the end of the total irradiation period. Both hydrogen and Fe^{+3} yields exhibit the expected increase of hydrogen *atom* yield (light + heavy) with increasing deuterium concentration. The initial Fe^{+3} yield is a measure of the initial hydrogen yield, atomic plus molecular, since $G(Fe^{+3}) = 2G(\text{hydrogen})$ in this system (9, p. 36). The contribution of the molecular yield to the total hydrogen yield is minor and the increase observed in $G(Fe^{+3})$ reflects the increase in the atomic yield. $\alpha_{Fe^{+2}}$ are computed values obtained when the contribution of the molecular product via [1] with its α_M is subtracted, in the usual manner (2).

DISCUSSION

Isotope effects encountered in water radiolysis are incompatible with the simple Samuel–Magee model (17). In addition to the isotopic separations observed in irradiated H_2O–D_2O mixtures, another type of effect occurs, namely the radical and molecular yields are different in light and heavy water (2, 5, 18–20); $G(D)$ in D_2O is larger than $G(H)$ in H_2O, while G_{D_2} is smaller than G_{H_2}. A broader initial distribution of D atoms in D_2O was suggested, in order to explain this phenomenon (21). However, previous attempts to reconcile this suggestion with the observation $\alpha_A > \alpha_M$ (at low deuterium concentrations) were unsuccessful (4).

Contributions from isotopic exchange reactions and diffusion processes to the observed isotope effects in H_2O–D_2O mixtures have been discussed previously (3). It was concluded that any contribution from isotopic exchange reactions (e.g. between hydrogen atoms and hydrogen molecules, water molecules, etc.) to the observed isotope effects is ruled out, since these are too slow to compete with hydrogen atom recombination. Diffusion processes of the hydrogen atoms cannot contribute to the isotopic separation either, since any difference in atomic diffusion rates out of the spurs is counterbalanced by the difference in rates of the diffusion-controlled atom recombination reactions (3). Thus, any difference between α_M and α_A reflects a difference in the mechanisms of production

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the molecular and atomic species. Furthermore, any variation of solute concentration should have no effect upon α_A or α_M, unless more than one radiation-chemical process is operative. α_A was found by Baxendale and Hughes to be independent of solute (methanol) concentration in the concentration range of 0.2–1 *M* (2).

In the following discussion we will try to explain the observed isotope effects, taking into account the effects on *yields* as well. We will also attempt to explain observed differences between α_A and α_M as well as effects of solute concentration on α_M.

α_A and the Mechanism of Hydrogen Atom Formation in Acid Solutions

It has been shown recently (22–24) that most or all of the reducing species are formed in water radiolysis as aquated electrons. Reaction [1] has to be modified, therefore, in the following way:

$$H_2O \rightarrow e^-_{aq}, OH, H_2, H_2O_2. \qquad [1']$$

The aquated electrons are transformed in acid solution to hydrogen atoms by the reaction (22–24)

$$H_3O^+ + e^-_{aq} \rightarrow H + H_2O. \qquad [2]$$

It has been shown that reaction [2] may give rise to $\alpha_A > 2$ at $\sim$100% D (4) and indeed the experimental results of Baxendale and Hughes (2) in this direction are verified by our results (Table V). It should be pointed out, here, that the value of α_A is not proof for the occurrence of [2]; it is possible that another reaction could be found leading to the observed α_A. What this rather means is that α_A is *compatible* with [2], while it is not so with several other reactions which have been proposed previously for the mechanism of hydrogen atom formation. (For a discussion of this point see references 4 and 7.)

Another question is whether reaction [2] is compatible with the observation $G(D), D_2O > G(H), H_2O$. It has been suggested that, as a result of the greater relaxation time of D_2O compared to that of H_2O, electrons are trapped and react with water farther away from the positive ion in D_2O than in H_2O (21) and this causes the observed difference in atomic and molecular yields. It is now suggested that the electron in acid solution does not react with H_2O but with H_3O^+ (reaction [2]). Yet, since reaction [2] occurs with aquated electrons (22), the position at which the electrons are trapped still determines the degree of recombination reactions versus reactions with the solute. It is important to note, however, in this connection, that $G(D)/G(H)$ is larger in neutral than in acid solutions (5), a result which suggests that trapping of the unaquated electron by H_3O^+ occurs in strongly acid solutions and suppresses this isotope effect. On the other hand solutes such as H_2SO_4 decrease the relaxation time of water. This decrease is a linear function of solute concentration.* If the decrease in the relaxation time D_2O due to the addition of sulphuric acid is greater than the similar effect in H_2O, this may provide a more plausible explanation for the reduced isotope effects on the yields in acid solution.* Until further data are available for D_2O this question must be left open. The "residual" atomic yield in neutral solutions, obtained when electron scavengers are present, is smaller in D_2O than in H_2O (7), showing that the major part of the "residual" yield is due to a track reaction, the contribution of which is smaller in D_2O than in H_2O.

α_M and the Mechanism of Production of Hydrogen Molecules

Since α_M and α_A were found to have different values for the same initial deuterium concentration, it was suggested that the mechanisms of production of the atomic and

*J. B. Hasted, D. M. Ritson, and C. H. Collie. J. Chem. Phys. **16**, 1 (1948). This point was suggested by the referee.*

molecular products are different (2, 4). On the other hand, from independent experiments on the dependence of the molecular hydrogen yield upon solute concentration, it was believed that most or all of the molecular product is due to hydrogen atom recombination (9, p. 63). In this connection let us observe first of all that the difference between α_M and α_A at any deuterium concentration is much smaller than the previously observed difference. Secondly, the molecular product may be due to a recombination of hydrogen atoms, but of such atoms formed by a mechanism different than the ones reacting with the solute. Reaction [2] itself may be viewed in either of two ways—either as an acid-catalyzed reaction of the electron with a water molecule:

$$eH_2O + H_3O^+ \rightarrow H\cdots OH^- + H^+\cdots H_2O \rightarrow H + 2H_2O \qquad [2']$$

or as a capture of the electron by the H_3O^+:

$$H_3O^+ + e(e^- \text{ or } e_{aq}^-) \rightarrow H + H_2O. \qquad [2'']$$

The captured electron in [2''] may be a thermalized *un*aquated electron, although such an electron cannot react with H_2O to give a hydrogen atom (24). However, for the electron to be unaquated in reaction [2''] there has to be a very high local concentration of H_3O^+ in the track, so that this reaction can compete effectively with the process of aquating the electron.

Although [2'] and [2''] both lead to hydrogen atoms by reaction of the electron with H_3O^+, they involve quite different isotope effects.

It has been suggested lately that the molecular yield is due to a recombination reaction of aquated electrons (25), according to

$$e_{aq}^- + e_{aq}^- \rightarrow H_2 + 2OH^-. \qquad [3]$$

The dependence of the molecular yield on scavenger concentration may in some cases be explained better by a scavenging of the electrons (2, 26). Recent experiments with C_2H_5OD in D_2O at pH 13, utilizing pulse techniques, establish that the product of the bimolecular reaction of two aquated electrons is a molecule of hydrogen (27(*a*)).

If the molecular product is formed from hydrogen atoms via H_3O^+ (reaction [2]), the isotopic enrichment will be, in part, due to the enrichment of H_3O^+ relative to the water. If it is formed via e_{aq}^-, the isotopic enrichment of the latter is involved. The curve F.F. in Fig. 1 represents the isotopic enrichment of H_3O^+ with respect to the water, as computed by Fiquet-Fayard (4). No attempt has yet been made to compute the isotopic enrichment of e_{aq}^-. The experimental results for α_M and its dependence on deuterium concentration follow the similar behavior of the "residual" atomic yield in neutral solutions (7). We suggest that they have similar origins and that the molecular yield is formed mainly by hydrogen atom recombination, the atoms being formed by the track reaction [2]. (The aquated electron has been shown to disappear even in neutral water, containing no added solute, by more than one process (27(*b*)).) Scavengers may reduce the molecular yield either by preventing reaction [2], i.e. reacting with the electrons prior to their being transformed into hydrogen atoms, or by preventing the recombination reaction

$$H + H \rightarrow H_2. \qquad [4]$$

There may be some contribution to the molecular yield from reaction [3] and this may cause the difference between α_A and α_M.

As is seen from the experiments on Cu^{+2} in Fig. 2 and on NO_3^-, α_M itself is not uniform. Since the concentration of the solute should have no effect on α_M, if only one process contributes to the molecular yield, the dependence observed must be due to the occurrence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of more than one process. From the dependence of the molecular hydrogen yield on NO_3^- concentration, it was concluded that two processes lead to the molecular product (28). These may be [2] (followed by [4]) and [3]. The occurrence of another process was considered recently (25(*b*)):

$$H_2O^* \rightarrow H + OH \qquad [5]$$

(where H_2O^* is an excited water molecule) followed by [4]. Reactions [2] and [3] can lead to α_M values larger than 2 at high deuterium concentrations, as is observed, but reaction [5] cannot. (This is in the line of the usual statistical argument (4, 7).) Reaction [5] cannot be, therefore, a major process leading to the molecular product. Increased solute concentrations can affect α_M without affecting the hydrogen yield very much, by providing an alternative route for hydrogen molecule production. For example, one explanation given for the track effects of doubly and triply charged metal ions was electron capture. The excited metal ions formed in this way can react with water to give hydrogen atoms (2). The hydrogen atoms thus formed may then recombine via [4] as usual.

In the previous section we have seen that since the deuterium atom has a greater chance of escaping recombination reactions in pure D_2O than the hydrogen atom has in pure H_2O, $G(D) > G(H)$. The question which arises, in connection with the relation of the molecular to the atomic product, is whether the deuterium atom has a greater chance of escaping recombination reactions in an H_2O–D_2O *mixture* than the hydrogen atom has. This has been suggested, so that if the molecular product is due to hydrogen atom recombination, one should always have $\alpha_M > \alpha_A$, which is contrary to what is observed at low deuterium concentrations (4). We do believe that the hydrogen molecules are formed by atomic recombination, but according to the present picture, the chance of escaping recombination is determined by the distance at which the electron is trapped. This distance depends upon the deuterium concentration of the water, so that in a mixture of light and heavy water the *total* hydrogen atom yield (light and heavy) is intermediate between the yields in pure light or pure heavy water. (This agrees with the observed trend, Table VI.) The competition is between recombination reactions and reactions with the solute and one gets less recombination the higher the D_2O content is, since the hydrogen atom distribution, light or heavy, is wider (depending upon where the electron was trapped). Nevertheless, the separation is always in favor of light hydrogen and, observing that $\alpha_M \leqslant \alpha_A$, is not contrary to hydrogen atom recombination.

Some additional effects are observed at high deuterium concentrations (Tables II and V). In a previous paper (11) we have observed a decrease in D_2 yield for irradiated ethanol–D_2O solutions as H_2SO_4 increased from 0.1 *N* to 0.8 *N*. Since the sulphuric acid in these experiments was H_2SO_4 rather than D_2SO_4, this change in acid concentration involved a slight decrease in deuterium concentration of the solution. Thus, the decrease in D_2 may not be due to a genuine decrease in molecular yield, but rather to a considerably higher α_M value in this concentration region, where part of the molecular yield is in the form of HD. Isotope effects in highly concentrated irradiated D_2O solutions were measured previously. Some measurements utilizing the e.s.r. technique were carried out on irradiated ice containing D_2O at 4.2° K (29–31). Careful analysis of the results showed that no isotope effect is observed for 50% and 80% D_2O; however, D_2O ice containing trace amounts of HDO (0.2%) exhibits a very large isotope effect in favor of H atom production (31). The authors suggest a model of delocalization of electronic energy, where the HDO acts as a defect in the solid, which is strongly coupled by hydrogen bonding. They suggest that trace amounts of HDO in H_2O should act similarly. Our results on α_M (Fig. 1) show that there is a further *decrease* of α_M in solutions of very low D_2O concentrations. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

overall dependence of α on deuterium concentration of the liquid may thus be due to a superposition of the effects observed in ice at limiting ($\sim$0% and $\sim$100%) deuterium concentrations (since the liquid water is also hydrogen bonded to some extent) over the general dependence of α on the deuterium concentration of the liquid. The effects at limiting concentrations may be due to electron transfer, rather than energy transfer. Since these large effects at $\sim$100% D were not observed in liquid water previously (5), when hydrogen was the only solute in the irradiated water, it seems worthwhile to study further the isotope effect at high deuterium concentrations.

Isotope Effects in Secondary Reactions

The ion Fe^{+2} was studied at first in order to obtain α_A (1). Later it was shown that $\alpha_{Fe^{+2}}$ obtained is not α_A (2), since the hydrogen formed in [6]:

$$Fe^{+2} + H^+ + H \rightarrow Fe^{+3} + H_2, \qquad [6]$$

originates partly in the H atoms (with their characteristic isotopic separation) and in part in H^+ (with another characteristic isotopic separation). $\alpha_{Fe^{+2}}$ is the isotopic enrichment of H_2 formed via [6], with respect to the irradiated water.

Two mechanisms are kinetically possible for the oxidation of Fe^{+2} by H (32, 33):

$$H + H^+ \rightleftharpoons H_2^+;\ H_2^+ + Fe^{+2} \rightarrow H_2 + Fe^{+3} \qquad [6']$$

$$H + Fe^{+2} \rightleftharpoons H\cdots Fe^{+2};\ H\cdots Fe^{+2} + H^+ \rightarrow H_2 + Fe^{+3}. \qquad [6'']$$

Reaction [6] takes place in the photochemical oxidation of Fe^{+2} as well and isotope effects in that system have been measured recently for low deuterium concentrations (34). The numerical results are very similar to our radiation-chemical results for α_A as well as for $\alpha_{Fe^{+2}}$. Since α_A is known, one can compute the enrichment of H^+ in reaction [6] from the observed $\alpha_{Fe^{+2}}$ (this means going in a reverse order to that taken by Fiquet-Fayard (4)). This was done for low deuterium concentrations in the photochemical system (34), and the isotopic enrichment of H^+ in the oxidation reaction [6] was calculated to be $\alpha_{H^+} = 5 \pm 0.5$. Since this is a relatively high separation, it was decided that this reflects the isotopic enrichment of H_3O^+ so that the mechanism for reaction [6] is the hydride formation reaction [6''].

If we take α_A to be 3.0 at low deuterium concentrations and 3.5 at high ones, we calculate from our results for $\alpha_{Fe^{+2}}$ (4.0 and 4.5, respectively) that α_{H^+} is $6._0$ and $5._5$ for low and high deuterium concentrations. The value at high deuterium concentrations points indeed to mechanism [6'']. In H_2^+ (which is the species involved in mechanism [6']) the enrichment of the proton is that of the bare H^+, although H_2^+ is probably hydrated; at the time of reaction with Fe^{+2} the H^+ is bound to an H atom and only that H can go over to the H_2 which is formed. On the other hand, the proton in mechanism [6''] involves the enrichment of H_3O^+ (34) and any of the three hydrogen atoms of H_3O^+ can eventually be incorporated into the H_2. If we make use of the computed isotopic enrichment of H_3O^+ ($\alpha_{H_3O^+}$) at low and at high deuterium concentrations (ref. 4 and Fig. 1), 1.66 and 3.2 respectively, α'_{H^+} is computed, according to (where α'_{H^+} is the corrected separation factor S'_{ox} of ref. 34)

$$\alpha'_{H^+} \cdot \alpha_{H_3O^+} = \alpha_{H^+}. \qquad [I]$$

We find α'_{H^+} equal to $3._6$ and $1._7$ at low and high deuterium concentrations, respectively. Equation [I] is valid only if the different H_3O^+ isotopic species (e.g. H_3O^+ and H_2DO^+, at low deuterium concentrations) react with the ferrous hydride at the same rate. If this is so, then fractionation will occur owing to the different rates at which D and H escape the isotopic H_3O^+ in the activated complex. Let the relative rates at which H and

For personal use only.

D escape such an activated complex be k_H/k_D. Taking into account statistical factors, such as having two H atoms to one D atom in H_2DO^+ (4), we compute k_H/k_D to be equal to 4.9 and 2.6 at low and high deuterium concentrations, respectively. Since these two values are not equal, the model and/or experiment need further refinement. The computed k_H/k_D cannot be compared for the time being with the relative rates of oxidation of Fe^{+2} in light and heavy water, which was found to be 2.4 (2).

CONCLUSIONS

Isotope effects in acidified H_2O–D_2O mixtures are compatible with the radiation-chemical reaction $H_3O^+ + e^-_{aq} \rightarrow H + H_2O$. The molecular product is formed by hydrogen atom recombination. The lowering effect that high Cu^{+2} concentrations have on α_M is due to the interaction of Cu^{+2} with the electron, which forms a different path for hydrogen atom formation.

ACKNOWLEDGMENTS

This research was sponsored by the Israel Atomic Energy Commission. The author wishes to thank Professors G. Stein and E. D. Bergmann for their continued interest in this work. The author also thanks Mrs. V. Fishoff at the Isotope Department of the Weizman Institute, Rehovoth, for carrying out most of the mass spectrometric measurements and Dr. C. M. Stevens, Argonne National Laboratory, for the measurements at 99.8% D.

REACTION MECHANISM STUDIES

1. THE DIAXIAL → DIEQUATORIAL REARRANGEMENT OF BROMOHYDRIN SULPHONATE ESTERS[1]

J. F. KING, R. G. PEWS,[2] AND R. A. SIMMONS
Department of Chemistry, University of Western Ontario, London, Ontario

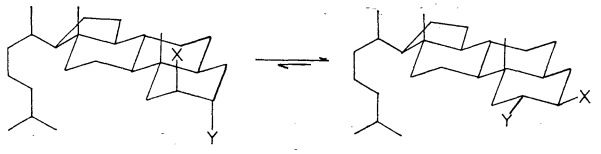
Received April 24, 1963

ABSTRACT

3α-Bromocholestan-2β-yl *p*-toluenesulphonate on heating in solution rearranges to an equilibrium mixture in which the diequatorial isomer, 2α-bromocholestan-3β-yl *p*-toluenesulphonate, predominates. 2β-Bromocholestan-3α-yl *p*-toluenesulphonate and the corresponding diaxial benzenesulphonate and *p*-nitrobenzenesulphonate rearrange analogously. These are the first examples of the diaxial → diequatorial rearrangement with sulphonic esters. Replacement of the para methyl group of 2β-bromocholestan-3α-yl *p*-toluenesulphonate by more electrophilic substituents is accompanied by an increase in the rate of rearrangement. It is concluded that in the transition state the bromine atom is positively charged and the sulphonate group negatively charged relative to the starting material.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The diaxial → diequatorial rearrangement (1), illustrated in the general case by I ⇌ II, has been shown to proceed readily with dihalides (e.g. I*a*) (2, 3) and halohydrin carboxylic esters (I*b*) (4). As part of a study of the relation between rearrangement, solvolysis, and reduction of 1,2-dihalides and related compounds, we became interested in the possibility of a diaxial → diequatorial rearrangement of bromohydrin sulphonates.



I II

(a) X,Y = Br

(b) X = Br, Y = O-C-R

(c) X = OSO_2—C$_6$H$_4$—CH_3, Y = Br

(d) X = Br, Y = OSO_2—C$_6$H$_4$—CH_3

(e) X = Br, Y = OSO_2—C$_6$H$_5$

(f) X = Br, Y = OSO_2—C$_6$H$_4$—NO_2

We chose as substrates for initial work the two diaxial bromohydrin *p*-toluenesulphonates (tosylates) I*c* and I*d*. Preliminary experiments indicated that when heated in the melt, I*d* decomposed, yielding no readily identified products, but further investigation showed that when heated in a high-boiling solvent, I*c* and I*d* underwent mutarotation without extensive decomposition. A triglyme (triethylene glycol dimethyl ether) solution of 3α-bromocholestan-2β-yl tosylate (I*c*, diaxial) on heating for 16 hours or more at 135° showed a change in specific rotation from +50° to 0°. The major product was identified

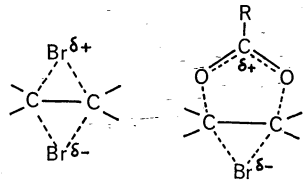
as the diequatorial isomer, 2α-bromocholestan-3β-yl tosylate (II*c*), by comparison with a sample prepared from 2α-bromocholestan-3β-ol (5, 6). The specific rotation of the diequatorial compound (II*c*) on similar heating changed from $-27°$ to $-12°$. The equilibrium mixture is estimated (see Experimental) to consist of $85\pm8\%$ of the diequatorial compound (II*c*) and $15\pm8\%$ of the diaxial isomer (I*c*). In addition an uncharacterized, dextrorotatory, probably olefinic material which separates into at least three components on thin-layer chromatography was also formed in these pyrolyses.

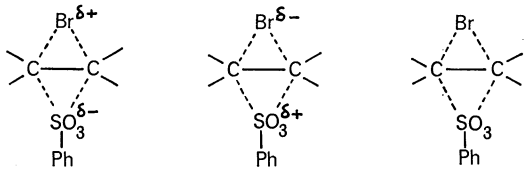
The other diaxial bromohydrin tosylate (I*d*) also mutarotated on heating in triglyme. The product proved difficult to purify by recrystallization because of a strong tendency to form gels. An authentic sample of the diequatorial compound (II*d*) was prepared from the corresponding alcohol, 3β-bromocholestan-2α-ol, the latter compound being obtained by acid hydrolysis of the acetate (II*b*, R = CH_3) (4). The tosylate so obtained also yielded gels on attempted crystallization but a few precipitations from petroleum ether gave a white powder which gave satisfactory elemental analyses. Comparison of infrared spectra and behavior on thin-layer chromatography clearly established that II*d* is the major product of the pyrolysis of I*d*; the equilibrium mixture of I*d* and II*d* is estimated to contain $95\pm5\%$ of the diequatorial isomer (II*d*).

In previous studies of the rearrangement of dibromides (7) and bromohydrin carboxylic esters (4) it was concluded that there is, in general, separation of charge in the transition states of these reactions. These conclusions may be summarized by representing the midpoint of each reaction (i.e. the species in which the migrating groups are bonded as strongly to one carbon as to the other) by structures III and IV. In addition, Grob and Winstein (7) have suggested that as the reaction is carried out in various solvents the magnitude of "δ" in III may vary with the ionizing power of the solvent.

For the rearrangement of the bromohydrin tosylates three such half-way species are conceivable: V, VI, and VII, the last being the special case in which $\delta = 0$ (compared with



III IV



V VI VII

starting material). Species V would seem the most likely of these, both on (*a*) general considerations of the relative reactivities of bromine and tosyl functions as leaving groups and as neighboring groups in heterolyses, and on (*b*) the specific example of the

reaction of *trans*-2-bromocyclohexyl tosylate with concentrated hydrobromic acid. In the latter case the product is *trans*-1,2-dibromocyclohexane, formed, apparently, via the bromonium ion (8); this reaction and the present rearrangement, however, are carried out in media of greatly different ionizing power and acidity. To provide direct evidence to decide between the possibilities V, VI, and VII we have studied the effect of para substituents on the rate of rearrangement. As can be seen from Table I, the benzenesulphonate (I*e*) rearranges nearly twice as fast as the tosylate (I*d*), in triglyme at 135°. The *p*-nitrobenzenesulphonate (I*f*) was not sufficiently soluble in triglyme for rate studies, but in phenetole at 99° the rearrangement of I*f* is about 20 times as fast as that of the tosylate under the same conditions. These results clearly exclude either VI or VII and are only compatible with a reaction proceeding through a transition state in which there is separation of charge in the sense of V.

TABLE I

Rates of rearrangement of diaxial cholestanyl bromohydrin sulphonates

Compound	Solvent	Temp. (°C)	$k \times 10^6$	k/k_{Id} (under same conditions)*
3α-Bromocholestan-2β-yl tosylate (I*c*)	Triglyme	135	45±5	0.38
2β-Bromocholestan-3α-yl tosylate (I*d*)	Triglyme	135	120±15	1.00
2β-Bromocholestan-3α-yl tosylate (I*d*)	Phenetole	99	5.6±0.3	1.00
2β-Bromocholestan-3α-yl benzenesulphonate (I*e*)	Triglyme	135	220±30	1.8
2β-Bromocholestan-3α-yl benzenesulphonate (I*e*)	Phenetole	99	(6±1)†	1
2β-Bromocholestan-3α-yl *p*-nitrobenzenesulphonate (I*f*)	Phenetole	99	130±20	23

*Rate relative to that of I*d* under identical conditions.
†Average value from three measurements only.

It is interesting to contrast these conclusions with those from the study of carboxylic esters (4). Though it might appear contradictory to propose that the bromine is negatively charged in one case and positively charged in the other, such behavior is well established in, respectively, unimolecular solvolysis of alkyl bromides and reactions involving participation of bromine in solvolysis at a neighboring carbon. The studies on carboxylic and sulphonic esters of bromohydrins, by showing that bromine may be either positively or negatively charged in the transition state of a diaxial → diequatorial rearrangement, agree with the proposal (7) that the rearrangement of *dibromides* takes place through a species in which one bromine is positively and the other negatively charged.

EXPERIMENTAL

Unless otherwise stated optical rotations refer to chloroform solutions at room temperature. Melting points were determined on a Kofler block and are uncorrected. Infrared spectra were obtained using Beckman IR-5 or IR-7 spectrophotometers equipped with sodium chloride optics; all values quoted for the infrared maxima positions were determined with the IR-7 instrument. Petroleum ether refers to the fraction of boiling range 35–60°. Thin-layer chromatography was carried out using Camag Kieselgel D5; unless otherwise specified the developing solvent was petroleum ether – benzene (1:1).

For the pyrolyses, commercial triglyme (triethylene glycol dimethyl ether) supplied under the designation Ansul Ether 161 by Ansul Chemical Company, Marinette, Wis., U.S.A., was heated at 140–150° in a nitrogen atmosphere with sodium and benzophenone until the dark purple color of the benzophenone

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ketyl was produced. The triglyme was then distilled under reduced pressure. It was tested for peroxides before use; if these were found to be present the triglyme was redistilled from lithium aluminum hydride. The phenetole used in the rate measurements was obtained by distilling B.D.H. Analar grade from lithium aluminum hydride.

Rate Measurements

The rearrangements were carried out either in sealed Pyrex ampoules or in a test tube with a standard taper male joint in the middle and a female joint at the top, as previously described (4). The sample was weighed into the tube and a measured volume of solvent added. The tube was then flushed with nitrogen, closed, and, if necessary, warmed to dissolve the compound. The tube was then inserted into a three-necked flask containing a refluxing liquid so that the portion of the tube which contained the solution was well heated by the vapor of the liquid. Ethylbenzene was the refluxing liquid for the experiments at 135±1° and water for those at 99±1°. The extent of reaction was determined by quickly cooling the solution and determining the optical rotation. The rate constants in Table I were calculated from the half-life estimated graphically from a plot of 5 to 10 values of $\log \alpha-\alpha_{eq}/\alpha_0-\alpha_{eq}$ vs. reaction time (α is the measured specific rotation after a certain reaction time, α_0 the specific rotation of the starting material, and α_{eq} the specific rotation of the equilibrium mixture—see Table II and accompanying text).

Determination of the Composition of the Pyrolytic Equilibrium Mixtures

Table II summarizes much of the data on the pyrolyses. In addition the following separate experiments were carried out.

TABLE II

Pyrolytic equilibration experiments

Reaction	Starting material	Solvent	Temp. (°C)	Time (hr)	$[\alpha]_D$ of diaxial isomer (I)	$[\alpha]_D$ of di-equational isomer (II)	$[\alpha]_D$ of pyrolysis product	α_{eq}	Estimated % of II at equilibrium

*Calculated from the estimated percentage of IIc and Ic in the equilibrium mixture.

(a) 3α-Bromocholestan-2β-yl Tosylate (Ic) ⇌ 2α-Bromocholestan-3β-yl Tosylate (IIc)

Compound Ic (22 mg) was heated at 135° for 25 hours in triglyme (1 ml). The reaction product ($[\alpha]_D$ −2°) was poured into ether and the ether layer washed six times with water, dried with sodium sulphate, and the solvent evaporated. Recrystallization from ether–methanol gave white crystals melting at 135–165°; the infrared spectra of this material and pure 2α-bromocholestan-3β-yl tosylate (IIc) were identical.

As can be seen from Table II the rotation of the reaction mixtures from Ic and IIc differ by about 10°. Thin-layer chromatography, however, showed that the product from either Ic or IIc contained Ic and IIc in apparently identical proportions. In a comparison with mixtures of known content the relative intensities of the spots due to Ic and IIc were indistinguishable from those containing either 85% IIc and 15% Ic or 90% IIc and 10% Ic. Thin-layer chromatography (using either petroleum ether – benzene, 1:1, or petroleum ether alone) also showed that, in addition to Ic and IIc, the pyrolysis products contained a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

small amount of other material which appeared as three spots (two were only partially resolved) near the solvent front. The three spots were distinctly more intense in the product of pyrolysis of I*c*, though the identical spots were nonetheless present in the product of the pyrolysis of II*c*; in the pyrolysis product from I*c* the two partially resolved spots appeared, when taken together, to be more intense than that due to I*c* itself. Pyrolysis of II*c* (400 mg) at 180° for 2 hours in triglyme, followed by extraction as above, gave a product which on chromatography on alumina (Woelm Grade III basic) yielded a material (25 mg) eluted rapidly with petroleum ether. The remaining fractions (total 386 mg) were found to consist of II*c* mixed with a little I*c*. The 25 mg eluted first with petroleum ether showed three intense spots on thin-layer chromatography (with petroleum ether) corresponding exactly to those from the crude products. This material had a specific rotation of +45° and in the infrared spectrum did not show the characteristic tosylate bands at 1185 and 1175 cm^{-1} but did show bands at 3030, 700, and 665 cm^{-1}, suggesting the presence of olefinic hydrogen.

The infrared spectra (IR-7) of the pyrolysis products from I*c* and II*c* were virtually identical and were indistinguishable from that of a mixture containing 90% II*c* and 10% I*c*. The spectrum of pure II*c* showed distinct differences from those of the pyrolysis products or the 90:10 mixture, in particular the latter all showed a small but distinct peak at 862 cm^{-1} which is absent in that of II*c* but present as a moderately strong band in the spectrum of pure I*c*.

The polarimetric, chromatographic, and infrared data, taken together, lead to the estimate that the equilibrium mixture of I*c* and II*c* contains 85±8% of II*c*.

(b) 2β-Bromocholestan-3α-yl Tosylate (Id) ⇌ 3β-Bromocholestan-2α-yl Tosylate (IId)

Workup, as in part (*a*), of the product of pyrolysis of I*d* gave a material whose infrared spectrum was virtually superimposable on that of an authentic sample of II*d* (see below). Thin-layer chromatography, however, showed the presence of a little I*d* (estimated by comparison with mixtures of known content to amount to less than 1/10 of the amount of II*d*) and also a small proportion of fast-moving decomposition products. From the chromatographic and polarimetric data the equilibrium mixture is estimated to contain 95±5% of II*d*.

(c) Other Equilibria

The pyrolysis products of one run each from I*e* (in both triglyme and phenetole) and I*f* (in phenetole) were worked up by pouring into water and extracting with chloroform. The extracts were washed with water, dried over sodium sulphate, and the solvent evaporated. The infrared spectrum in each case clearly showed the product to consist principally of the diequatorial isomers.

3α-Bromocholestan-2β-ol

The following procedure was found to be more convenient than that of Alt and Barton (3). A solution of N-bromosuccinimide (1.50 g) in ethylene glycol dimethyl ether (150 ml) was added slowly to a solution of cholest-2-ene (3.0 g) in a mixture of ethylene glycol dimethyl ether (300 ml) and 0.5 *N* aqueous perchloric acid (20 ml). The reaction mixture was allowed to stand at room temperature for 2 hours and was then poured into water and extracted with ether. The ether extract was washed with dilute potassium bicarbonate solution and water and dried with sodium sulphate, and the solvent evaporated. The crude product was dissolved in petroleum ether and poured onto a column of silica gel (50 g, BDH "for chromatographic adsorption"). Elution with petroleum ether gave cholest-2-ene (500 mg), elution with benzene gave 3α-bromocholestan-2β-ol (2.5 g), m.p. 130–132°, $[\alpha]_D$ +59°, identified by comparison of its infrared spectrum, melting point, and optical rotation with those of an authentic sample prepared as previously described (3).

2β-Bromocholestan-3α-ol

This compound was prepared from cholestan-2α,3α-epoxide as described by Alt and Barton (3); m.p. 115–118°, $[\alpha]_D$ +44°; reported m.p. 115–118°, $[\alpha]_D$ +44°.

2α-Bromocholestan-3β-ol

This compound was prepared by reduction of 2α-bromocholestan-3-one with sodium borohydride as previously described (5, 6); m.p. 113°, $[\alpha]_D$ +12°; reported m.p. 113–114°, $[\alpha]_D$ +12°.

3β-Bromocholestan-2α-yl Acetate

This compound was prepared by diaxial → diequatorial rearrangement of 2β-bromocholestan-3α-yl acetate as previously described (4): m.p. 117–119°, $[\alpha]_D$ −20°; reported m.p. 118–119°, $[\alpha]_D$ −22°.

3β-Bromocholestan-2α-ol

A suspension of 3β-bromocholestan-2α-yl acetate (1.10 g) in a mixture of methanol (90 ml) and 70% perchloric acid (2 ml) was stirred for 36 hours. The mixture was then poured into water and extracted with ether, the extract washed with dilute potassium bicarbonate solution and water and dried with sodium sulphate, and the solvent evaporated. Recrystallization of the crude product from ether–methanol gave 3β-bromocholestan-2α-ol (886 mg), m.p. 102–103°, $[\alpha]_D$ +17°. Calculated for $C_{27}H_{47}OBr$: C, 69.35%; H, 10.13%; Br, 17.09%. Found: C, 69.51%; H, 9.92%; Br, 17.02%.

Preparation of the Sulphonate Esters

About 1 to 2 equivalents of the sulphonyl chloride was added to a solution of the alcohol in about 5 to 10 times its weight of dry pyridine and the mixture allowed to stand for 3 to 5 days. It was then poured into ether or chloroform and washed with dilute potassium bicarbonate solution, dilute sulphuric acid and water, respectively. The organic layer was then dried and evaporated and the product recrystallized (or precipitated).

3α-Bromocholestan-2β-yl p-Toluenesulphonate (Ic)

Recrystallized four times from acetone, m.p. 174–177°, $[\alpha]_D$ +49°. Calculated for $C_{34}H_{53}O_3SBr$: C, 65.68%; H, 8.59%; S, 5.16%; Br, 12.85%. Found: C, 65.61%; H, 8.59%; S, 5.15%; Br, 12.81%. Infrared maxima below 1400 cm^{-1} (0.1 mm, CCl_4 solution): 1377 (s), 1188 (s), 1177 (s), 1096 (m), 966 (w), 922 (m), 905 (m), 896 (m), 880 (m), 862 (m), 674 (m).

2β-Bromocholestan-3α-yl p-Toluenesulphonate (Id)

M.p. 168–170°, $[\alpha]_D$ +49°; reported m.p. 168–170°, $[\alpha]_D$ +49° (4). Infrared maxima below 1400 cm^{-1} (0.1 mm CCl_4 solution): 1377 (s), 1188 (s), 1178 (s), 1095 (m), 967 (m), 944 (w), 912 (m), 900 (s), 892 (s), 867 (m), 848 (w), 825 (w), 817 (w), 716 (m), 673 (m).

2β-Bromocholestan-3α-yl Benzenesulphonate (Ie)

Recrystallized four times from acetone, m.p. 159–161°, $[\alpha]_D$ +59°. Calculated for $C_{33}H_{51}O_3SBr$: C, 65.23%; H, 8.40%; S, 5.24%; Br, 13.16%. Found: C, 65.46%; H, 8.43%; S, 5.15%; Br, 13.14%. Infrared maxima below 1400 cm^{-1} (0.1 mm, $CHCl_3$ solution): 1377 (s), 1185 (s), 1175 (m), 1094 (m), 966 (m), 943 (w), 912 (m), 900 (s), 891 (s), 865 (w), 822 (w), 686 (m), 665 (m).

2β-Bromocholestan-3α-yl p-Nitrobenzenesulphonate (If)

Recrystallized four times from chloroform–methanol, fine white needles, m.p. 159–161°, $[\alpha]_D$ +47°. (The recrystallization was apparently accompanied by rearrangement. Attempts to obtain a second crop yielded only a gelatinous precipitate.) Calculated for $C_{33}H_{50}O_5NSBr$: C, 60.68%; H, 7.72%; S, 4.97%. Found: C, 60.30%; H, 7.76%; S, 4.77%. Infrared maximum at 1536 cm^{-1} (vs) and the following maxima below 1400 cm^{-1} (0.1 mm, $CHCl_3$ solution): 1378 (s), 1366 (m), 1350 (s), 1313 (w), 1184 (s), 1044 (m), 1013 (w), 964 (w), 898 (s), 852 (m), 820 (w), 685 (w).

2α-Bromocholestan-3β-yl p-Toluenesulphonate (IIc)

Recrystallized five times from ether–methanol, $[\alpha]_D$ −38.5°, apparently dimorphous: partly melts around 135° then resolidifies slowly finally melting at 165°. Calculated for $C_{34}H_{53}O_3SBr$: C, 65.68%; H, 8.59%; S, 5.16%; Br, 12.85%. Found: C, 65.64%; H, 8.20%; S, 5.23%; Br, 12.85%. Infrared maxima below 1400 cm^{-1} (0.1 mm, CCl_4 solution): 1374 (s), 1188 (s), 1177 (s), 1096 (m), 990 (m), 955 (s), 922 (m), 902 (m), 841 (s), 830 (m), 717 (w), 685 (m), 669 (m).

3β-Bromocholestan-2α-yl p-Toluenesulphonate (IId)

Precipitated three times from petroleum ether, apparent m.p. 134–138°, $[\alpha]_D$ −28.5°. Calculated for $C_{34}H_{53}O_3SBr$: C, 65.68%; H, 8.59%; S, 5.16%. Found: C, 65.97%; H, 8.44%; S, 4.89%. Infrared maxima below 1400 cm^{-1} (0.1 mm, CCl_4 solution): 1376 (s), 1191 (s), 1180 (s), 1098 (m), 988 (w), 968 (s), 947 (m), 933 (m), 916 (s), 848 (s), 824 (w), 716 (w), 672 (m).

3β-Bromocholestan-2α-yl Benzenesulphonate (IIe)

Precipitated three times from petroleum ether, apparent m.p. 133–135°, $[\alpha]_D$ −20.4°. Calculated for $C_{33}H_{51}O_3SBr$: C, 65.23%; H, 8.40%; S, 5.24%. Found: C, 64.70%; H, 8.47%; S, 5.25%. Infrared maxima below 1400 cm^{-1} (0.1 mm, $CHCl_3$ solution): 1385 (s), 1187 (s), 1177 (s), 1156 (m), 1098 (m), 988 (w), 968 (s), 948 (m), 933 (m), 848 (s), 820 (m), 719 (m), 685 (m), 666 (w).

3β-Bromocholestan-2α-yl p-Nitrobenzenesulphonate (IIf)

Precipitated three times from petroleum ether, apparent m.p. 187–189° (decomp.), $[\alpha]_D$ −39.5°. Calculated for $C_{33}H_{50}O_5NSBr$: C, 60.68%; H, 7.72%; S, 4.97%. Found: C, 60.84%; H, 7.49%; S, 5.12%. Infrared maximum at 1540 cm^{-1} (vs) and the following maxima below at 1400 cm^{-1} (0.1 mm, $CHCl_3$): 1386 (s), 1353 (s), 1318 (m), 1189 (s), 1179 (s), 1097 (m), 1082 (w), 1014 (w), 989 (w), 962 (m), 941 (s), 917 (w), 856 (s), 849 (s), 820 (m), 685 (m).

INTERACTION OF VANADIUM WITH PROTONS OF ENERGIES UP TO 84 MEV[1]

S. HONTZEAS[2] AND L. YAFFE

Radiochemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.

Received March 25, 1963

ABSTRACT

Radiochemical techniques have been used to determine absolute excitation functions for 17 nuclides formed as spallation products from the irradiation of vanadium by protons of energy up to 84 Mev. The shape of the excitation functions and classical threshold calculations showed evidence of contribution of heavy-particle emission in the reactions of the type $(p,3pxn)$, $(p,5pxn)$, and $(p,7pxn)$. The Barr method for analysis of the cross-section distribution was modified and applied at 60 and 80 Mev bombarding energies. The experimentally measured cross sections for 16 nuclides at 60 and 80 Mev bombarding energies were fitted to the four-parameter Rudstam equation $\sigma(A,Z) = \exp\ [PA-Q-R(Z-SA)^2]$. Comparison of the results obtained at 8 Mev bombarding energy with the predictions of the weak and strong absorption models showed better agreement with the predictions obtained by using the surface absorption Fernbach–Bjorklund potential.

INTRODUCTION

The study of nuclear reactions initiated by various particles incident on different target nuclei is one of the experimental approaches to the elucidation of nuclear structure. Because of the present condition of theories of nuclear structure, it is desirable to study a simple system. Vanadium may be considered such a system, since it is virtually a monoisotopic element (99.75% V^{51}, 0.25% V^{50}). In addition, it belongs to the range of medium-weight elements where there is no severe Coulomb barrier. The energy range studied in this paper bridges the low-energy region where simple reactions are treated by the compound nucleus theory and the high-energy region where nuclear transparency becomes important.

In the present work, absolute excitation functions for protons of energy up to 84 Mev incident on vanadium have been measured by radiochemical techniques. These results are compared with those obtained by other workers (1–6) in this and other energy ranges.

EXPERIMENTAL METHODS

(a) Targets and Irradiations

All the bombardments were done in the circulating beam of the McGill synchrocyclotron. The target materials were vanadium foils of normal isotopic composition (0.002 in.) obtained from the Electrometallurgical Co., Toronto, Ontario. Spectrographic analysis of the foils showed the following impurities to be present: Al, 0.02%; Ba, 0.02%; Ca, 0.04%; Fe, 0.01%; Zn, 0.04%. The following reactions were used to monitor the proton beam—$Cu^{63}(p,n)Zn^{63}$ at proton energies less than 16 Mev and $Cu^{65}(p,pn)Cu^{64}$ at higher energies. Ghoshal's (7) values were used for the former reaction while Meadows' values (8), corrected by Meghir (9), were taken for the latter reaction. The copper foils (0.002 in.) were carefully aligned with the vanadium at the leading edge since this part of the target intercepted most of the beam.

At the end of the irradiation, the first 1/8 in. of the leading edge of the foil stack was cut off and used. Initially three foils of copper and two of vanadium were used in the foil stack. The degradation of the beam was estimated using the values of Sternheimer (10). Usually the degradation of the beam was less than the energy spread of the McGill cyclotron (±2 Mev) and the degradation has been neglected (except in one case). In the later bombardments, one foil of copper and one of vanadium were used as targets for bombarding energies up to 30 Mev. At higher bombarding energies two vanadium foils (the first vanadium foil acting as guard foil to prevent contamination of the second target foil by the copper spallation products) were used.

For personal use only.

This arrangement was reasonable since it has been shown (11) that, in the range of the McGill cyclotron (up to 90 Mev), recoil losses in the monitor copper foil (0.002 in.) were negligible.

(b) Chemical Separations

The number of elements to be separated depended upon the energies at which a particular bombardment was made. The separation and purification procedures for the different elements are given below.

(1) Chlorine (12)

The vanadium target was transferred to a microdistillation apparatus and dissolved in dilute nitric acid containing 5 mg of Cl^- carrier. The target solution was boiled to distill the hydrochloric acid into a receiver containing a few drops of nitric acid and sufficient silver nitrate to precipitate the Cl^- as silver chloride. The precipitate was removed by centrifugation, washed with dilute nitric acid and then dissolved in 5 *N* ammonia. The solution was scavenged with ferric hydroxide, acidified with nitric acid, and more silver nitrate was added to complete the precipitation. The chemical yield (50–60%) was determined gravimetrically.

(2) Chromium–Vanadium

The vanadium target was dissolved in dilute nitric acid containing 5 mg of chromium carrier, and the hydroxides were precipitated with ammonia and ammonium chloride. The precipitate was washed with dilute ammonia and then boiled with 1 *N* sodium hydroxide and hydrogen peroxide. The supernate (chromates–vanadates) was evaporated to remove peroxide, neutralized, and dissolved in 0.1 *M* hydrochloric and 0.1 *M* oxalic acids. The solution was then passed through a column of Dowex-1 (×10, 100–200 mesh) anion exchange resin which had been previously washed with the hydrochloric–oxalic eluant. The chromium was eluted initially while vanadium was later eluted with a mixture of 0.4 *M* hydrochloric and 0.1 *M* oxalic acids. The chromium chemical yield (50–80%) was determined colorimetrically by diphenylcarbohydrazide (13). The peroxide method (13) was used for the colorimetric determination of the chemical yield of vanadium (40–50%).

(3) Titanium–Scandium

The vanadium target was dissolved in dilute nitric acid containing 4 mg of titanium and 5 mg of scandium carriers, and the solution was made ammoniacal. The precipitate was washed twice with dilute ammonia and then boiled with 1 *N* sodium hydroxide and hydrogen peroxide. The precipitate was washed, dissolved in hydrochloric acid, and more vanadium carrier, sodium hydroxide, and hydrogen peroxide were added. The precipitate was boiled, centrifuged, washed, and dissolved in 0.4 *M* hydrochloric acid. After complete dissolution an equal volume of 0.1 *M* oxalic acid was added and the solution passed through a Dowex-1 (×10, 100–200 mesh) anion exchange resin column which had been washed with 0.4 *M* hydrochloric acid and 0.1 *M* oxalic acid. Scandium appeared at the beginning (14) and titanium was eluted with 0.4 *M* hydrochloric acid. The chemical yields were determined colorimetrically (13) for both titanium and scandium (30–50%).

(4) Potassium–Calcium

The vanadium target was dissolved in dilute nitric acid containing 5 mg K^+ and 5 mg Ca^{++} carriers. Iron scavenger was added, the solution made ammoniacal, and the supernate again scavenged with a ferric hydroxide precipitation, evaporated, and ammonia and hydrogen peroxide added. The solution was boiled to remove peroxide and passed through a cation exchange column (D-50, ×12, 200–400 mesh) in NH_4^+ form. The column was washed with 10 ml of water, and potassium and calcium were eluted with 2.2 *N* hydrochloric acid. The acidic solution was concentrated, made ammoniacal, and calcium oxalate precipitated with ammonium oxalate. The precipitate was washed with a solution containing ammonium oxalate and then dissolved in dilute nitric acid. The calcium yield (10–20%) was determined by direct EDTA titration (15) with phthaleincomplexone indicator. The potassium yield (20–30%) was determined gravimetrically by the cobaltinitrite method (16).

(5) Copper

The copper monitor foil was dissolved in nitric acid, the solution evaporated and redissolved in hydrochloric acid (4.5 *M*) and passed through a D-1 anion exchange column previously washed with 4.5 *M* hydrochloric acid. Elution with 4.5 *M* hydrochloric acid removed nickel and cobalt impurities. The copper was eluted with 1.5 *M* hydrochloric acid (17). The chemical yield (50–90%) was determined colorimetrically with diethyldithiocarbamate (17) by a modified procedure (18).

(c) Activity Measurements

The gamma activity of the samples was measured by a 3 in.×3 in. NaI(Tl) crystal in conjunction with a 100-channel pulse-height analyzer. Background radiation was reduced by placing the crystal and photomultiplier tube assembly inside a cylinder of lead 1½ in. thick. Fluorescent X rays from the lead were attenuated by lining the lead shielding with 1/4 in. of iron and 1/8 in. of lucite.

The radioactive nuclides were identified by means of their half-lives and gamma-ray energies. These half-lives were usually obtained graphically from the decay curves, but a few half-life determinations were made using the method of least squares. The gamma-ray energies were determined from a calibration curve obtained by measuring well-known gamma energies of long-lived standards (Na^{22}, Cs^{137}, Co^{60}, etc.). Sc^{43}

For personal use only.

and Sc^{44} have identical half-lives and the mixture of their activities was analyzed by measuring the 511-kev annihilation photopeak common to both and obtaining an independent determination of the disintegration rate of Sc^{44} from its 1.16-Mev γ ray which is in 100% abundance. Sc^{44} may be formed independently or from the decay of the 2.4-day Sc^{44m} isomer. The decay of Sc^{44m} was determined by measuring the distinctive 270-kev γ ray. The independent yield of Sc^{44} was corrected for the isomer contribution.

EXPERIMENTAL RESULTS

(a) Calculations

The observed gamma emission rate was converted to a disintegration rate, $D_\gamma{}^0$, by using the equation

$$[1] \qquad D_\gamma{}^0 = N_\gamma{}^0 \cdot \frac{1+\alpha_T}{R} \cdot \frac{1}{Y} \cdot \frac{1}{F},$$

where $N_\gamma{}^0$ = the absolute photon emission rate; α_T = total internal conversion coefficient; R = branching ratio; Y = chemical yield; and F = dilution factor. Since the energy degradation was negligible in general, the target was assumed to be thin. The independent cross section for the formation of shielded nuclides was calculated by the equation

$$[2] \qquad \sigma_x = \sigma_m \frac{A_m}{A_t} \cdot \frac{W_t}{W_m} \cdot \frac{B_m}{B_t} \cdot \frac{D_x{}^0}{D_m{}^0} \cdot \frac{(1-e^{-\lambda_m T})}{(1-e^{-\lambda_x T})}.$$

The subscripts m and t refer to the monitor and target respectively; σ = cross section; A = natural abundance; W = atomic weight; B = weight used, $D_x{}^0$ and $D_m{}^0$ = disintegration rates of the nuclide under consideration and monitor at end of bombardment, respectively; and λ = decay constant. For unshielded nuclides, a correction for the contribution from the parent was applied, if the parent half-life was known. Where the parent contribution was not known, the cross sections are reported as cumulative.

(b) Estimation of the Error (Standard Deviation) of the Cross-Section Calculation

Equation [2] may be written in the form

$$[3] \qquad \sigma_x = \sigma_m \cdot K_n \cdot \frac{D_x{}^0}{D_m{}^0} \cdot \frac{f(t_m)}{f(t_x)}.$$

$K_n = (A_m/A_t) \cdot (W_t/W_m) \cdot (B_m/B_t)$, where t and m refer to vanadium target and copper monitor respectively, and $f(t_m) = 1-e^{-\lambda_m T}$ and $f(t_x) = 1-e^{-\lambda_x T}$. Since the errors associated with the different terms in equation [3] are independent, the standard deviation of σ_x is obtained by taking the square root of the sum of the squares of the standard deviations of the different terms for the yield of each nuclide. The standard deviation of σ_m was taken as $\pm 13.5\%$ as reported by Meghir (9).

A probable error of $\pm 1\%$ was assigned to the terms K_n, $f(t_m)$, and $f(t_x)$ respectively. The error associated with the term $D_m{}^0$ was found experimentally to be $\pm 13.5\%$. For $D_x{}^0$, the error for each nuclide was: $\pm 11.5\%$ for Cr^{51}, Cr^{49}, Cr^{48}, Ti^{45}, Sc^{47}, Sc^{46}, Sc^{44m}; $\pm 7\%$ for V^{48}; $\pm 16.3\%$ for V^{46}; $\pm 29\%$ for Sc^{43}, Sc^{44}, Ca^{47}; and $\pm 23.6\%$ for Cl^{34m}, Cl^{38}, Cl^{39}, K^{42}, K^{43}.

However, the errors shown in the following figures do not include the errors in the measurement of the absolute cross section of the monitor, but only those present in this series of experiments. The errors thus associated with the absolute value of the various nuclides are as follows: $\pm 17.5\%$ for Cr^{51}, Cr^{49}, Cr^{48}, Ti^{45}, Sc^{47}, Sc^{46}, Sc^{44m}; $\pm 15\%$ for V^{48}; $\pm 21\%$ for V^{47}; $\pm 32\%$ for Ca^{47}, Sc^{44}, Sc^{43}; and $\pm 27\%$ for Cl^{39}, Cl^{38}, Cl^{34m}, K^{43}, K^{42}.

RESULTS AND DISCUSSION

The nuclides which were identified and measured are given in Table I. The yield is characterized as independent when the measured nuclides are shielded by stable or relatively long-lived isobars. Cr^{51}, for our purposes, may be considered as shielded since its parent nuclide, Mn^{51}, cannot be formed by the proton bombardment of vanadium. The same applies for Cl^{38} since the parent, S^{38}, is not formed in the energy range of interest. The yield of Sc^{47} is characterized as independent since the parent, Ca^{47}, is formed in very low yield and only above bombarding energies of 50 Mev. In the case of V^{48}, the parent, Cr^{48}, was measured and the yield corrected for the parent contribution. The yields were characterized as cumulative when the short half-life of the parent made its contribution difficult to determine. The experimentally determined values of the formation cross sections are given in Tables II and III.

The excitation functions obtained are given in Figs. 1–5 inclusive. The spread in the bombarding energy (~2 Mev) is indicated in the excitation function graphs by horizontal

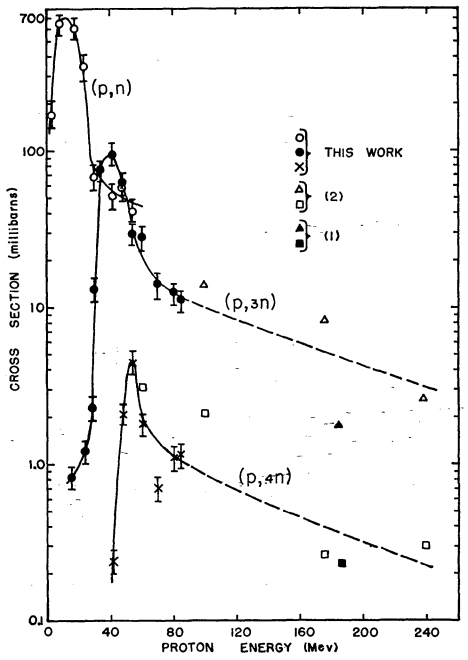

FIG. 1. Excitation functions for (p,xn) reactions.

bars through the experimental points. The vertical bars are the standard deviations estimated in this experiment. The results of other workers (1–6) are also plotted where feasible for purposes of comparison. In general, the agreement between the results obtained in this work and other authors is satisfactory.

(a) Qualitative Analysis

(1) (p,xn) Reactions (Fig. 1)

In the (p,n) reaction, the rapid rise above the threshold to a maximum yield, followed by a rapid decline as other reactions begin to compete, can be accounted for by compound nucleus theory. The yield of this reaction does not fall to a negligible value but tails off

at higher bombarding energies, indicating that the knock-on cascade mechanism is of importance here. The excitation functions of the $(p,3n)$ and $(p,4n)$ reactions show the same general shape with the difference that the knock-on mechanism predominates at higher energies. The unusually low yield for the $(p,4n)$ reaction can be explained by assuming a low-level density (20) for even–even Cr^{48}.

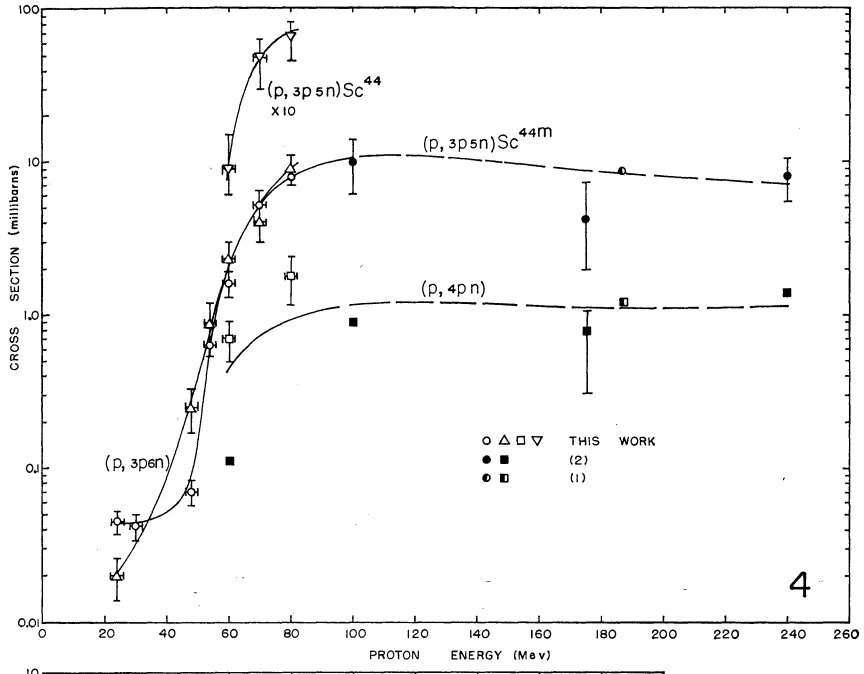

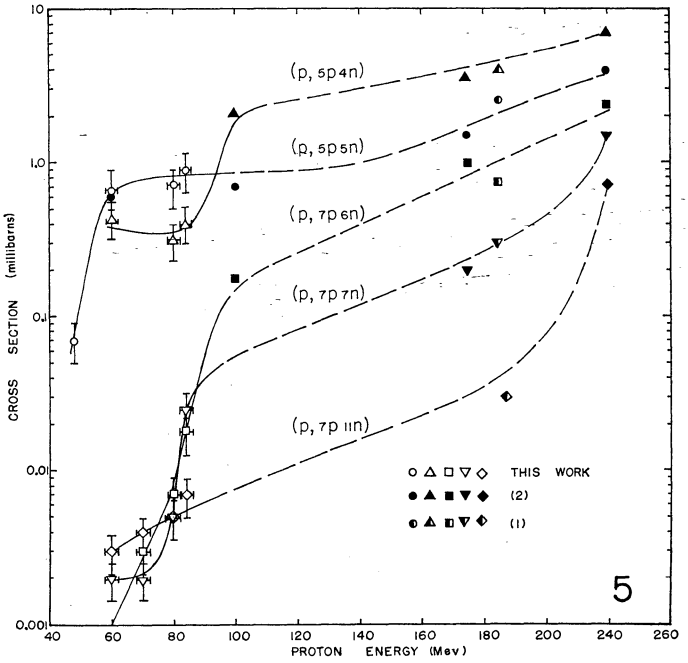

FIG. 4. Excitation functions for $(p,3pxn)$ and $(p,4pn)$ reactions.
FIG. 5. Excitation functions for $(p,5pxn)$ and $(p,7pxn)$ reactions.

(2) (p,pxn) Reactions (Fig. 2)

The excitation functions of these reactions show the same general characteristics as the $(p,3n)$ and $(p,4n)$ excitation functions. Comparison of the $(p,4n)$ and $(p,p3n)$ reactions

indicates that the relative yield of the $(p,4n)$ reaction may be explained according to the statistical model by virtue of the position of Cr^{48} and V^{48} with respect to the valley of the stability (Fig. 6). The sharp decrease in yield as the distance from the stable valley

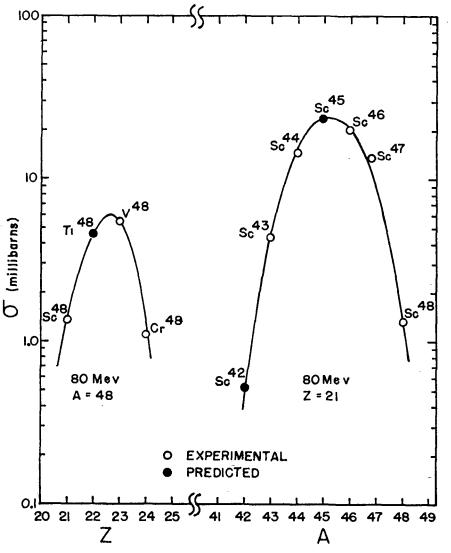

FIG. 6. Formation cross sections of isobars of $A = 48$ and isotopes of $Z = 21$ at 80 Mev.

increases is strong evidence for the importance of the evaporation mechanism which favors de-excitation modes leading towards the stable valley (21). The low value of the ratio of the $(p,4n)/(p,p3n)$ yields suggests that, if sufficient energy is available for four-particle emission, the proton is favored to be among the particles emitted.

(3) (p,2pxn) Reactions (Fig. 2)

The only reaction of this type observed is the $(p,2p5n)$ reaction. The shape of the excitation function supports the Serber mechanism.

(4) (p,3pxn) Reactions (Figs. 3 and 4)

For the reactions (except for $x = 2, 3$) the excitation functions increase monotonically up to the highest bombarding energy available at the McGill cyclotron.

The low yield of the $(p,3pn)$ reaction to produce Sc^{48} may be explained by its position with respect to the stability valley (Fig. 6). When energy is available for single-particle emission (3 protons, 1 neutron) the ratios of the $(p,4n)/(p,3pn)$ and $(p,p3n)/(p,3pn)$ reactions suggest that Sc^{48} is formed mainly by an evaporation process in the energy region of interest. This can be ascertained from Table IV.

TABLE IV

Ratio of formation cross sections

	60 Mev	80 Mev
$\frac{p,4n}{p,3pn} = \frac{Cr^{48}\text{ (even–even)}}{Sc^{48}\text{ (odd–odd)}}$	3.0	0.85
$\frac{p,p3n}{p,3pn} = \frac{V^{48}\text{ (odd–odd)}}{Sc^{48}\text{ (odd–odd)}}$	133	42.5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The shapes of the $(p,3p2n)$ and $(p,3p3n)$ excitation functions show that many of the reactions observed cannot possibly be due to single-particle emission only.

Table V lists $-Q$ values obtained, using the Seeger (22) semiempirical mass formula, for a number of possible mechanisms for the formation of the nuclides Sc^{43}, Sc^{44}, Sc^{46}, etc.

*Obtained from measured isotopic mass of Ca^{40} and calculated mass of Cl^{34m}.
†Obtained from calculated masses of Ca^{40} and Cl^{34m}.

In the case of formation of Sc^{47}, $(p,3p2n)$ reaction, all possible mechanisms are listed. Only $(p,\alpha p)$, (p,td), and $(p,t2p)$ mechanisms can explain the yield below 30 Mev. A mixture of these mechanisms contributes to the yield over most of the excitation curve. From other experimental evidence (23–25) it is known that alpha particles are produced in high yield in reactions of this type and that protons, deuterons, and tritons are also emitted. Therefore it is probable that the first maximum in the Sc^{47} excitation function represents a large contribution from α-particle emission, while the second maximum is probably due to the emission of protons, deuterons, and tritons.

The $(p,3p3n)$ excitation function shows the same characteristics as that of the $(p,3p2n)$. The only difference is that the yield of Sc^{46} (odd–odd) is significantly greater than that of Sc^{47} (odd–even). Energetic considerations indicate that only the first five mechanisms (Table V) could explain the yield of $(p,3p3n)$ reaction below 40 Mev. The higher yield of Sc^{46} compared with Sc^{47}, in spite of the fact that the reaction leading to the formation of Sc^{47} might be expected to be more probable than the reaction leading to the formation of Sc^{46}, can be explained by assuming that the odd–odd nuclide Sc^{46} has a higher-level density than odd–even Sc^{47}, in agreement with the statistical model. The odd–odd, odd–even, even–even effect is shown in Table VI. The $(p,3p3n)$ excitation function could also be explained on the same grounds as the $(p,3p2n)$ excitation function. Excitation functions

showing two maxima in the energy range of interest and of the same type have previously been observed in spallation studies of Cu (20) and Co (26) by protons.

The excitation functions of Sc^{43}, Sc^{44}, and Sc^{44m} also provide evidence for multiple-charged-particle emission. The high-spin state of Sc^{44m} is formed far below 60 Mev bombarding energy, while the low-spin ground-state Sc^{44} only begins to be formed in measurable amounts at 60 Mev.

The yield ratios at different bombarding energies indicate that the high-spin state is favored (Table VII). The result may be explained by assuming that the residual nucleus

TABLE VII
Yield differences of Sc^{44m} and Sc^{44} at various bombarding energies

Bombarding energy (Mev)	Sc^{44m} cross section (millibarn)	Total angular momentum J ($\hbar$)	Sc^{44} cross section (millibarn)	Total angular momentum J ($\hbar$)	Ratio $\frac{Sc^{44m}}{Sc^{44}}$
24	0.04	6, 7	—	2, 3	—
48	0.07		—		—
60	1.60		0.90	—	1.78
70	5.30		4.80		1.10
80	8.00		6.50		1.23

formed from a fast process (cascade) containing a large amount of excitation energy has a high spin and may tend to retain this state while it de-excites by evaporation preferentially forming the high-spin state of the isomeric pair.

(5) (p,4pxn) Reactions (Fig. 4)

Ca^{45} was observed but, because of the very low count rate and the high self-absorption (due to the separation chemistry) in the 4π counting, the results were discarded and no cross-section calculations were performed. The yield of Ca^{47} is depressed, as was expected, due to shell effects ($Z = 20$).

(6) (p,5pxn) Reactions (Fig. 5)

The examination of the $(p,5pxn)$ ($x = 4, 5$) excitation functions leads to the following considerations. The energetics of these reactions would predict that the $(p,5p4n)$ reaction is more favored than that of $(p,5p5n)$. The latter leads to the formation of K^{42} ((O–O) type) (high-level density) while the $(p,5p4n)$ leads to the formation of odd–even K^{43}. The de-excitation mode, according to the evaporation model, suggests that K^{42} should have a higher yield than K^{43} because of its position with respect to the stability valley. The data show that the yield of K^{42} is significantly lower than the yield of K^{43} up to 80 Mev bombarding energy. On the other hand, the energetics suggest that the K^{43} yield at 48 Mev

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

cannot be explained by single-particle emission but only under the assumption of multiple-charged-particle emission.

(7) (p,7pxn) Reactions (Fig. 5)

The production of complex particles like Li^8, Be^8, etc. has been found (27–32) mostly at very high excitation energies. The reaction mechanism for the production of these particles was first investigated by Camerini *et al.* (33) and since then in more detail (34, 35). Multiple-charged-particle emission (statistical model) in general is militated against by high barriers and $-Q$ values, but, on the other hand, is favored by statistical factors (36).

The $(p,7p11n)$ reaction leads to the production of Cl^{34m}. The threshold for this reaction is above 150 Mev. Cl^{34m} was at first identified at 60 Mev bombarding energy. Spectrographic analysis of the vanadium target has shown calcium impurities of the order of 0.04%. This is the only impurity which could produce chlorine by reaction with protons (Ca^{40}, 97.01%). If Cl^{34m} were indeed being produced by reactions on calcium, one would have expected the appearance of Cl^{34m} at lower energies, as indicated in Table V. It is energetically possible for it to have been produced by a reaction like $(p,N^{17}n)$.

(b) Cross-Section Distribution and Application of a General Cross-Section Equation

Spallation studies on medium-weight elements at very high energies (37, 38) have shown that:

(i) the independent yields across an isobar or an element are largest in the region of the stable isotopes and fall rapidly on the wings of those isolines;

(ii) along isodiapheric lines, originating at the various isotopes of the target element, the measured cross sections seem to vary in a smooth manner.

Since there are not enough measurable cross sections across any of the isobars below the vanadium target, the Barr (38) method was first applied to scandium isotopes in a slightly modified manner. Figure 6(*b*) shows the distribution of scandium isotopes at 80 Mev. The cross-section distribution, within experimental error, followed the assumed shape. The cross sections for three scandium isotopes (Sc^{44}, Sc^{46}, Sc^{48}) ((O–O) type) were fitted to an equation of the form

$$\ln \sigma = aA^2+bA+c, \quad [4]$$

where σ = measured cross section of the isotope in millibarns; A = mass number for that isotope.

The parameters a, b, c were determined and the cross sections for the nuclides of the (O–E) type were calculated and compared with the predicted values (80 Mev bombarding energy, Sc^{47}, predicted/measured = 0.55; Sc^{43}, predicted/measured = 0.86). The quantity $-b/2a$ was calculated. This corresponds to the most probable A for a given Z. It was assumed that the quantity $-b/2a$ for each element of interest should fall on the line defined by the origin and the value $-b/2a$ for scandium. The assumption was tested by predicting measured cross sections for the elements potassium and chlorine, from the isodiapheric lines. The values of $-b/2a$ for K and Cl indeed fall on the assumed straight line (Fig. 7). The ratios for K^{43} and Cl^{39} respectively are not of course very satisfactory because of the previously mentioned discrepancy due to multiple-charged-particle emission for K^{43}.

The measured cross sections for the elements Cl, K, Ca, Sc, Ti, V, and Cr were determined in this way as long as there was one measured cross section for the element under consideration. Three yields for each mass number were fitted to an equation of the form

$$\ln \sigma = aZ^2+bZ+c, \quad [5]$$

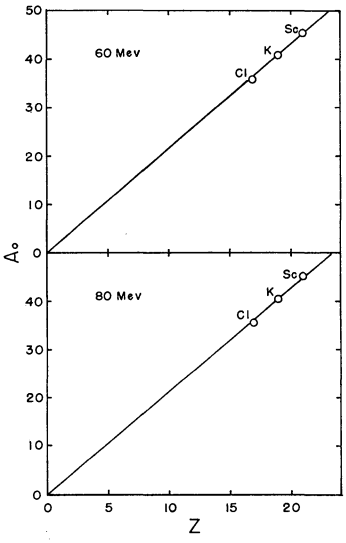

FIG. 7. Most probable maximum number for a given Z at 60 and 80 Mev.

where Z is the atomic number of the isotope with cross section σ. The validity of the parabolic distribution was therefore tested. The parameter a remained essentially constant. A plot of the most probable Z for a given A was made (Fig. 8) from the value $-b/2a$. The cross section for each mass number was summed and Fig. 9 was constructed for 60

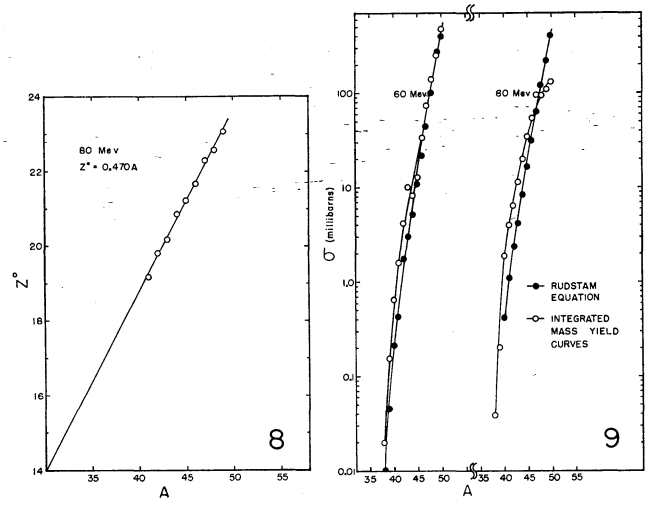

FIG. 8. Most probable Z for a given A at 80 Mev.
FIG. 9. Comparison of integrated maximum yield curves with values predicted by Rudstam at 60 and 80 Mev.

and 80 Mev respectively. The overall shape of the curves suggested that the relationship may be approximated by the four-parameter Rudstam equation (1). The slope of the curves in Fig. 8 represents the parameter S in the Rudstam equation:

$$\sigma(A,Z) = \exp\,[P-Q-R(Z-SA)^2]. \qquad [6]$$

The parameters P, Q, R were obtained by fitting the data for the nuclide measured to equation [7] by the method of least squares. The values obtained are consistent with the systematics for the parameters established by Rudstam (37). Table VIII gives the comparison of the cross sections calculated from equation [7] with those actually measured for the nuclides of interest.

TABLE VIII

Comparison of calculated and measured cross sections

Nuclide	Cross section measured (millibarn) 60 Mev	80 Mev	Cross section calculated (millibarn) $\ln \sigma = PA-Q-R(Z-SA)^2$ 60 Mev	80 Mev
Cr^{49}	28.90	12.80	30.0	23.8
Cr^{48}	1.80	1.10	2.9	4.80
V^{48}	79.80	54.50	41.10	61.30

found to be 0.849 and 0.887 at 60 and 80 Mev bombarding energies respectively. The expression $e^{\pm m} = 2.327$ and 2.427, for 60 and 80 Mev respectively, gives the average ratio between the experimental and calculated cross sections. However, the empirical equation is more useful when it covers as wide a range of mass numbers as possible.

(c) Quantitative Analysis of Experimental Results at 8 Mev Bombarding Energy

To compare reaction cross sections with the optical model, the quantities $\sigma(p,n)$, $\sigma(p,\gamma)$, $[\sigma(p,p')+\sigma(p,\alpha)]$, and σ_{ce} (compound elastic scattering) must be added. The quantity $\sigma(p,n)$ was determined experimentally in this work (647 millibarns). The other quantities were taken from the literature (6), giving a total of 799 millibarns for total absorption cross section. The theoretical (Fig. 11) (surface and volume) absorption curves were

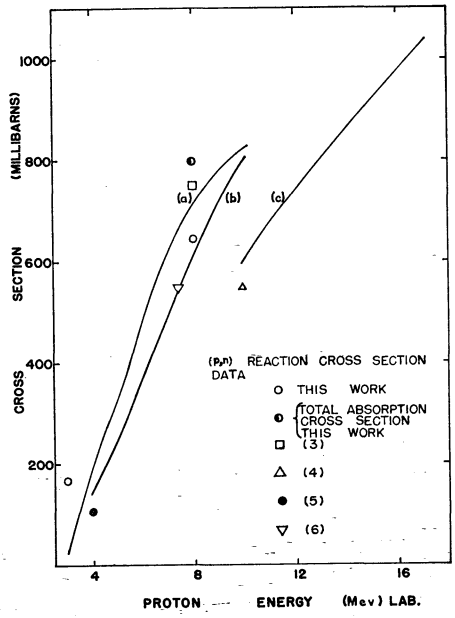

FIG. 11. Agreement between theoretical and experimental cross sections at 4 and 8 Mev bombarding energies: (*a*) strong absorption model; (*b*) weak absorption model (surface absorption Fernbach–Bjorklund potential); (*c*) weak absorption model (volume absorption Woods–Saxon potential).

derived using the results of Fernbach and Bjorklund (39), Albert (40), and Melkanoff *et al.* (41). The value $r_0 = 1.36\times10^{-13}$ was obtained using the equation $\pi R^2 = \pi(r_0\times 10^{-13}\times A/3)^2 = 799$ millibarns. The results rather support the surface absorption model. The strong absorption model curve was obtained using Shapiro's (42) approximation for the calculation of compound nucleus formation. The best value of r_0 for the fit (1.5×10^{-13}) was used for the calculations. However, this is misleading since the calculations based on the strong absorption model assume that at this bombarding energy there is one de-excitation channel (p,n) in the compound nucleus sense, and the theory does not take into account the quantities $\sigma(p,\gamma)$, $[\sigma(p,p')+\sigma(p,\alpha)]$, and σ_{ce}.

ACKNOWLEDGMENTS

We wish to express our gratitude to Professor R. E. Bell, Director of the Radiation Laboratory, McGill University, for his kind cooperation in making the cyclotron readily available to us.

AUTOMATIC ADIABATIC SOLUTION CALORIMETER USING THERMISTORS

LAWRENCE BENJAMIN
The Procter and Gamble Company, Miami Valley Laboratories, Cincinnati, Ohio, U.S.A.
Received February 27, 1963

ABSTRACT

A calorimeter is described, of capacity 40–50 ml, which is suitable for the investigation of solutions between 0° C and 70° C. Temperatures are measured to better than 0.0001° C using thermistors and the latter are also used to provide automatic adiabatic control. A novel mechanism is used for opening sample cells and the associated heat effect can be measured with a precision of 0.01 cal or better. Stirring of the calorimeter is achieved by continuous rocking of the vessel through 180°. The performance of the calorimeter is illustrated by results obtained for the heat of solution of NaCl at 25° C.

I. INTRODUCTION

An accurate study of enthalpy changes occurring in dilute solutions, where the amount of heat to be measured is of the order of a calorie, is difficult to carry out. The calorimeter to be described is intended for use in such studies with aqueous surfactant systems. Since solution of these materials is not always rapid, an adiabatic instrument is to be preferred in the experiments. Thermistor bridge circuits are used for temperature measurement and adiabatic control, stirring of the calorimeter being achieved by continuous rocking through 180°.

One of the limitations to the accuracy attainable in the measurement of small heat changes is the reproducibility of the blank heat change occurring on opening an empty sample cell, q_b. Factors associated with the magnitude of q_b have been discussed in some detail (1) together with a number of general features pertaining to the design of solution calorimeters. A novel breaking mechanism is employed in the present instrument which enables an accurate allowance for q_b to be made in solution and dilution experiments.

After a description of the calorimeter is given, its use is illustrated by results obtained for the heat of solution of sodium chloride in water at 25° C. (The calorimeter is designed and constructed to operate over a considerable temperature range. Heat capacity determinations using water have been successfully carried out up to 70° C with no apparent loss of accuracy.)

II. CALORIMETER DESCRIPTION

In some respects the calorimeter is similar to those described by Benson and co-workers (1, 2) but uses an immersed submarine mounted in a thermostat bath to contain the calorimeter vessel, in a manner similar to that employed by Gunn (3). The assembly is shown schematically in Fig. 1 while Fig. 2 shows a photograph of the polished stainless steel calorimeter vessel suspended by nylon loops and light springs in a cradle made of 1/16 in. mild steel rods. A nine-pin connector collects the leads from the vessel components and fits a socket sealed in the cap of the glass submarine with an epoxy resin. The submarine is constructed from freeze-drying flasks (Virtis, 500 ml) and can be evacuated using the stopcock shown. A bright aluminum coating is applied to its inside surfaces in order to reduce heat transfer by radiation. The flexible nature of the cradle allows it to

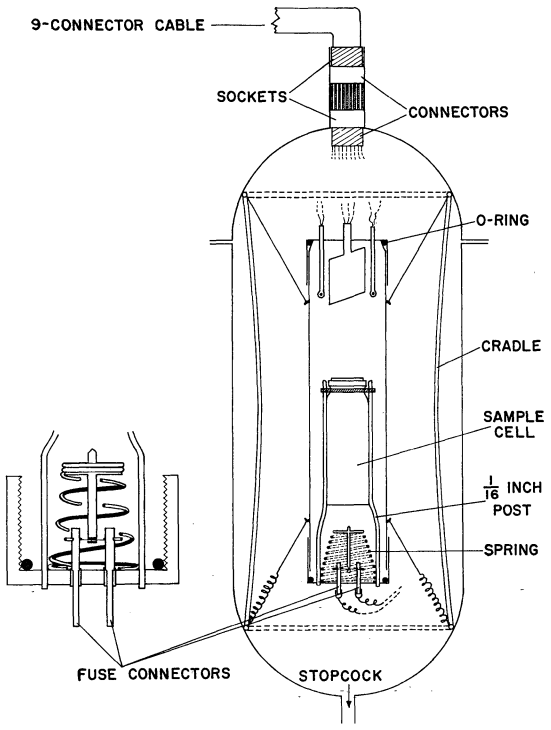

FIG. 1. Diagram of calorimeter assembly.

be held rigidly in the submarine when the cap is in position, the parts of the cradle coming in contact with the glass being covered with tape or coated with Tygon (see Fig. 2).

Stainless steel is used for all metal parts of the calorimeter vessel, which consists of a 1 in. diameter tube, 4 in. long, sealed by caps tightening on neoprene O-rings. Fairly loose threads are used on the caps and no pressure is therefore developed during sealing. The capacity of the vessel is approximately 50 ml. Epoxy resin is used to seal two thermistors (for temperature measurement and control) and a heater in the top cap and fuse connectors in the lower cap, silver solder being preferred for holding the 1/16 in. diameter posts in position. The solder is only required on the outside of the cap, however, and does not come into contact with the vessel contents. The heater consists of approximately 100-ohm manganin wire, 40 gauge, wound non-inductively on a mica form attached to a porcelain tube, together with a similar length of 38-gauge copper wire on the form to act as a heat trap. A third lead for potential measurements is attached just as the leads leave the vessel. Following a thin coating of epoxy resin, the heater is plated with copper and then gold. Since the electrical insulation of this heater deteriorated with use, as had also been found with epoxy-resin coatings, a final layer of a heat-curing epoxy resin (Hysol 4102) was applied to the gold. This has given quite satisfactory insulation during subsequent use.

Sample cells are made from standard female tapered joints (12/30) by grinding away most of the taper and cutting the attached tube to the required length. This cut end is ground flat and sealed with a 15 mm diameter cover glass, 0.006 in. thick, attached with the Hysol resin. Sealing of the tubes can be achieved using tapered Teflon stoppers or

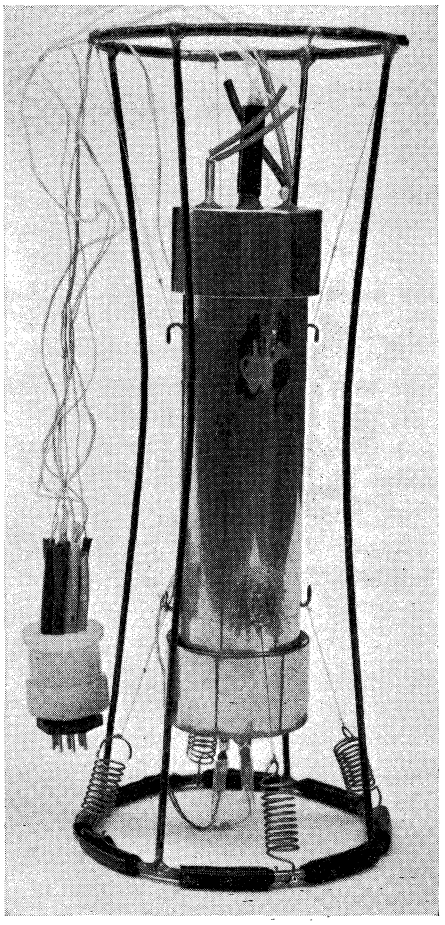

FIG. 2. Calorimeter vessel in flexible cradle.

quite conveniently with sections of neoprene stoppers. The sample cells are aligned with the supporting rods along two grooves in their sides. The coil spring (0.035 in. diam. wire) is held in compression by the 0.003 in. diameter stainless steel wire across the fuse connectors. Short plugs fitting tapered holes in the connectors keep the fuse wire in position and the cutting point is thus held about 1/4 in. from the cover glass. Larger-diameter copper leads (28 gauge) are used for making connection to the fuse to minimize the total resistance, the latter being 1 ohm. One of the fuse connectors is connected to the negative terminal of a 6-v storage battery which serves as the apparatus ground. A push-button switch allows opening of the sample cell by applying 6 v to the fuse wire when the latter is above the liquid level. It is not necessary to interrupt the rocking action to carry out this operation. Two calorimeter vessels are used, differing only in the volume of their sample cells, one being 2 ml and the other 5 ml.

The submarine, held in a metal clamp around its center, is attached by a set screw to a shaft passing through a graphitized-nylon bearing in the side of a temperature-controlled bath. The latter is kept as small as is possible yet allowing room for rotation of the submarine: the capacity of the bath is 35 l. A circulating pump provides rapid stirring and the bath can be heated electrically or cooled by passing cold tap water through an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

immersed copper coil; the flow of cold water is controlled by a solenoid-operated valve and a reducing valve. The bath is well insulated with Styrofoam to allow use of the calorimeter at elevated temperatures. Figure 3 shows a photograph of the external features of the calorimeter.

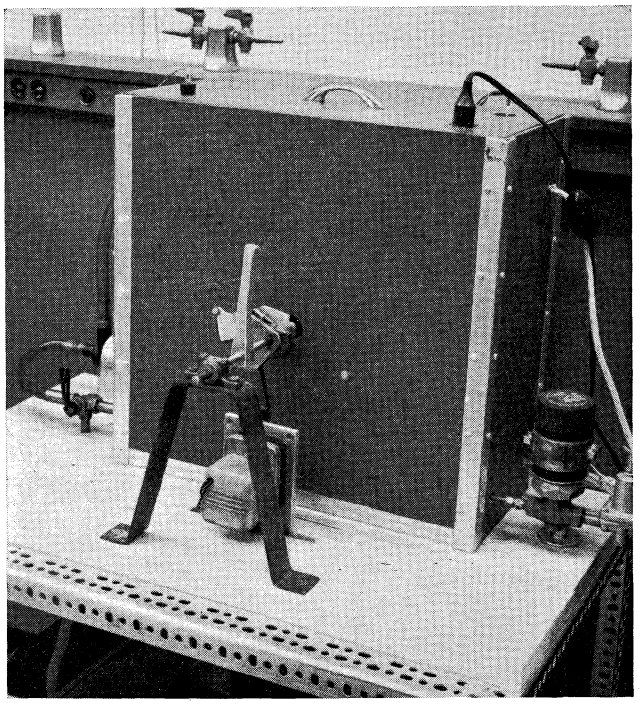

FIG. 3. External features of calorimeter showing rocking mechanism and bath.

A shielded nine-connector cable is soldered to a socket (female) which fits a connector sealed in the exit tube of the submarine cap (Fig. 1). It is necessary to minimize movement at the connection and this is achieved by fairly tight fitting of the socket in the glass tube. Also, the cable is bent at 90° just above the socket and the elbow made rigid up to the connector using epoxy resin. Rubber tubing is used to enclose the cable from its point of entry to the bath (through a metal tube in the wall) up to the glass tube of the submarine cap. This flexible connecting cable forms one coil adjacent to the side of the bath and is supported in its upper portion by very light springs. In this way the cable is kept clear of the submarine, rocking of which produces negligible strain on the electrical connections to the vessel.

Continuous rocking of the submarine through 180° is achieved using a rack and pinion movement (see Fig. 3). A brass arm attached to the shaft of a 7 r.p.m. motor is connected to the end of the rack, the point of connection describing a circle of diameter equal to half the circumference of the pinion. The latter is rigidly attached to the rotation shaft with a set screw but the brass mount, in which the rack moves linked to the pinion, is free to rotate about the shaft. The resulting motion is smooth and reliable, giving a slight dwell period at the vertical positions of the submarine. In this way good stirring of the calorimeter contents by the enclosed air bubble is obtained. Manual rotation can be readily accomplished by releasing the pinion set screw.

Electrical circuits connected with the instrument are shown schematically in Fig. 4. During electrical calibration of the calorimeter the current flowing through the heater

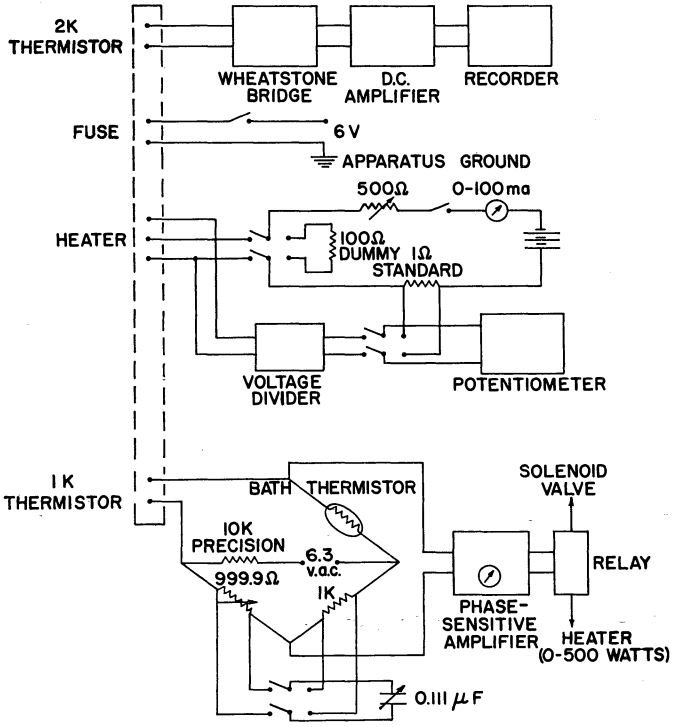

FIG. 4. Schematic diagram of electrical connections in the calorimeter.

and the e.m.f. applied across it are measured using a potentiometer (Honeywell–Rubicon Model 2781) and standard resistance in series with the heater. Five- or ten-minute heating periods are usually used and are timed to 0.02 second with an electric clock, the clutch of which is ganged with the heater circuit switch. The accuracy of timing using line frequency in this way has been checked by using a counter working in conjunction with an accurate crystal-controlled oscillator. The maximum difference in time interval recorded by the timer and by the counter, over a large number of heating periods, has been 0.01% and in the majority of cases agreement has been as good as the clock-reading error will allow. Current and e.m.f. readings are steady to better than 0.001% during a heating period, in which 20–50 cal are supplied to the vessel. Successive heat-capacity determinations usually agree within 0.05%. All calorimeter components are in a laboratory maintained at a constant temperature (±0.5° C) and 40% humidity. A regulated power supply is used for operating the calorimeter.

III. TEMPERATURE MEASUREMENT AND CONTROL

Temperature measurement is achieved by measuring the resistance of one of the thermistors (Veco A 60, approximately 2000 ohms at 25° C) with a Wheatstone bridge (Gray Instrument Co., E-1005 A) the off-balance signal from which is amplified and recorded (Leeds and Northrup microvolt amplifier 9835-B, Speedomax G Recorder, 1 mv full scale). Full scale of the recorder corresponds to 0.008° C with the sensitivity range

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

usually used. Under these conditions, electronic noise is negligible whereas a trace variation, synchronous with rocking of the vessel, is present. The width of the trace thus obtained is 0.1–0.2 μv (1–2% of recorder scale) and is regular. Some of this synchronous variation is no doubt due to motion of part of the measuring circuit in the earth's magnetic field and its magnitude can be greatly increased by a number of factors, such as loose-fitting connectors or poor electrical insulation of the heater. Periodic variation of the temperature of the medium adjacent to the thermistor will also occur during rocking because of its power dissipation, but this is minimized by applying as low a voltage as possible to the Wheatstone bridge; in the present case 0.2 v is used.

The thermistor is calibrated by finding its resistance at a number of points between 0 and 50° C using a calibrated thermometer (NBS certificate). Least-squares analysis of the data using a computer gives the constants in the equation

$$R_T = R_0 e^{\beta(1/T - 1/T_0)}, \quad [1]$$

where R_0 is the resistance at a standard temperature T_0, for which 298.15° K is chosen. Subsequent conversion of resistance values to temperatures is straightforward but requires the use of seven-figure logarithms to obtain values accurate to 0.00001° C. If a computer is not available, temperature changes, ΔT, can often be more readily computed using a differentiated form of equation [1]:

$$\frac{dR_T}{dT} = -R_T\beta\left[\frac{1}{T_0^2} + \frac{2}{\beta T_0}\ln\frac{R_T}{R_0} + \frac{1}{\beta^2}\left(\ln\frac{R_T}{R_0}\right)^2\right] \quad [2]$$

and

$$\Delta T \simeq \frac{\Delta R}{dR_T/dT} \text{ (using mean } R_T\text{)}. \quad [3]$$

These equations are accurately and readily applied to small temperature changes in the vicinity of T_0 since only the first term in eqn. [2] is then significant. The error introduced by ignoring the second term, roughly proportional to ΔT, is about 0.4% per degree ΔT, and a correction using the second term is not difficult to apply for greater precision (the third term can be ignored). Long-term drift rates in thermistor resistance values, following thermal shock, have recently been studied (4). The results are very pertinent to the use of thermistors in accurate calorimetry studies.

Automatic adiabatic control in the calorimeter is achieved using a circuit described by Cleland and Harding (5). Two thermistors, one in the calorimeter vessel and one in the bath, form arms of a resistance bridge, the other arms being a precision 1K resistance and a 4-dial decade resistance (cf. Fig. 4). A variable capacitance (3-dial decade) can also be connected in parallel to either of the resistance arms and allows good balancing of the bridge to be achieved without the care otherwise needed in mounting thermistors (5). The thermistors used (Veco 31A16, approximately 1000 ohms at 25° C) are chosen so that the ratio of their resistance is almost independent of temperature. In order to reduce power dissipation by the vessel thermistor, only 0.27 v A.C. is applied to the bridge and for this reason an extra amplification stage has been added to the original circuit together with a meter to record the amplified signal. The circuit is stable and actuates the solenoid valve and bath heater, giving a uniform sawtooth temperature control ($\pm$0.01° C). The bath temperature is monitored using another thermistor bridge circuit and recorder. Adiabatic conditions are maintained for all reasonable rates of temperature variation, exceptions being dealt with as outlined later.

IV. EXPERIMENTAL PROCEDURE

Before loading the calorimeter vessel, the contents are cooled below the desired temperature of solution or dilution. A partial vacuum is created in the submarine, heat transfer only being affected by a factor of 3 by the presence or absence of air around the vessel (1); under these conditions K, the thermal leakage modulus, is approximately 0.01° C per minute per °C head for a vessel having a heat capacity of 65 cal/°C and compares with values for similar calorimeters (1, 2). Unless a high vacuum can be continually maintained in the submarine, such as by installing another flexible connection, it is thought best to use only a partial vacuum in order to minimize desorption effects which might otherwise occur.

The calorimeter is brought to a steady state at the required temperature by heating the vessel and by finding the control bridge setting which then keeps the vessel virtually adiabatic. This setting is constant for a particular vessel and varies only slightly with the contents, except when the latter are poor thermal conductors. The calorimeter temperature is rarely exactly constant but varies linearly with time, the drift rate being usually less than 0.0001° C per minute. A regular variation of the vessel temperature, synchronous with the bath on–off cycle (about 1 minute), is just discernible (±about 0.00001° C).

After approximately 15 minutes of steady-state behavior, the sample cell is opened and the amplifier sensitivity reduced. For endothermic or exothermic changes, ice or hot water, respectively, is added to the bath at such a rate as to keep the bath and vessel temperatures nearly equal as indicated by the control circuit meter. This is only necessary during the initial rapid temperature change and the circuit is able to take over control again after some 10–20 seconds. Approximately 15 minutes after the heat change a steady state is again reached and, after adjusting the setting of the Wheatstone bridge, a linear drift rate, usually of a slightly different slope, is recorded. After a further period of time, sufficient for temperature-trace extrapolation, a heating period is carried out during which the calorimeter is kept adiabatic automatically. The recorder chart is calibrated in terms of resistance by obtaining a suitable shift of trace on altering the Wheatstone bridge setting.

Extrapolation of the temperature trace to the 'time of half-heating' allows estimation of ΔT. This value is usually found accurately since there is little change in drift rate before and after a heat change. With heating periods the 'time of half-heating' is well defined and most solution and dilution processes are virtually instantaneous.

V. THE HEAT ASSOCIATED WITH OPENING SAMPLE CELLS

The ultimate accuracy of the calorimeter, when measuring small heat changes, is limited by the reproducibility with which the blank heat change accompanying the opening of sample cells, q_b, can be measured. One of the main sources of variation in such values has been the heat change involved in fracture of glass cells (see reference 1), but in the method described this variation is minimized by using standard cover glasses, very thin, which are almost completely shattered and removed every time during breaking.

In a series of experiments using water in the vessels, q_b was found to be 0.032±0.003 cal (heating) and 0.006±0.007 cal (cooling) for the 2-ml and 5-ml cells, respectively. When the cells contained water prior to opening, the respective values of q_b were 0.046 cal and 0.035 cal (both heating). The differences for each cell when empty and when containing water correspond closely to the values calculated for the heat of evaporation from 40% to 100% relative humidity. The greater variation of q_b values for the larger cell is consistent with variations of room humidity. With sufficient information regarding the

For personal use only.

humidity at the time of loading and the vapor pressure of solutions it is therefore possible to make accurate allowance for q_b.

VI. THE HEAT OF SOLUTION OF SODIUM CHLORIDE AT 25° C

In order to assess the performance of the calorimeter, the integral heat of solution of sodium chloride in water was found in the concentration range 0.02 to 0.7 molal and the values compared with those found by other investigators as summarized in reference 1.

The water used for these studies was distilled and then passed through an ion-exchange column (Illco-way research model). No attempt was made to remove dissolved gases. The sodium chloride used was Baker Analyzed reagent (100.0% assay) which was dried at 110° C and stored in a desiccator over P_2O_5. The particle size was ~1 mm and should therefore exhibit negligible surface energy effects. The salt was considered sufficiently pure from its batch analysis to be used without further purification.

Only the small (2 ml) sample cell was used and 48 ml of water was weighed into the vessel. Weights were corrected to vacuum and results stated in terms of the defined calorie (4.1840 absolute joules). The vapor space in the vessel above the solution was approximately 5 ml and errors due to the heat effect associated with changes in water vapor pressure on solution were negligible. Solution was effected near 25.0° C and heat-capacity data of aqueous sodium chloride (6), water, and sodium chloride (7) were used to correct for small deviations from this temperature. Heat changes measured in these runs varied from 0.8 to 35 cal.

Results are shown in Table I. They are found to agree well with the smoothed values given by Benson and Benson (1) together with the heat of dilution data of Robinson below

TABLE I

The heat of solution of sodium chloride in water at 25.0° C

Molality	ΔH_S (cals/mole)	% deviation from smoothed values (1, 8, 9)	Molality	ΔH_S (cals/mole)	% deviation from smoothed values (1, 8, 9)

0.0656	1002.3	+0.15			

0.05 molal (8), summarized by Harned and Owen (9). Percentage deviations of the present results from these smoothed data are shown in Table I and it can be seen that agreement is almost exact above 0.1 molal with a mean deviation of the results equal to ±0.1%. Below 0.1 molal the results fall slightly lower (0.1% mean) than the smoothed values and agree within themselves to ±0.4%. The performance of the calorimeter, as judged by these results, is considered to be quite satisfactory and compares well with other adiabatic solution calorimeters (cf. Fig. 4, ref. 1) particularly in view of the relatively small volume of solution required. The reproducibility of q_b allows reasonable precision to be maintained in the measurement of small heat changes of the order of a calorie or less.

SPECTROPHOTOMETRIC STUDY OF XANTHATE AND DIXANTHOGEN SOLUTIONS

A. POMIANOWSKI[1] AND J. LEJA
Department of Mining and Metallurgy, University of Alberta, Edmonton, Alberta

Received March 29, 1963

ABSTRACT

Xanthate solutions of pH 6–10, prepared from "aged" potassium ethyl xanthate crystals, KEtX, were investigated spectrophotometrically in the region 190–400 mμ and showed coexistence of xanthate ions, EtX^-, dixanthogen, $(EtX)_2$, and carbon disulphide, CS_2. Optical density measurements on the spectra of dixanthogen solutions led to the evaluation of: molar absorptivities of dixanthogen at wavelengths corresponding to the two main bands in the xanthate ion spectrum, i.e. at 301 mμ—6130 liter/mole cm, and at 226 mμ—18,400 liter/mole cm; the solubility of dixanthogen, ca. 1.3×10^{-5} mole/liter; and the equilibrium constant, $k = 3\times10^{10}$, of the reaction $2(EtX)_2 + 4OH^- \rightarrow 4EtX^- + 2H_2O + O_2$, for solutions saturated with air at atmospheric pressure. Simultaneous reactions leading to decomposition of xanthate and/or dixanthogen species to alcohol and carbon disulphide have been detected by a strong band at 206.5 mμ due to CS_2 (with an estimated molar absorptivity of the order of 60,000–70,000 liter/mole cm).

The behavior of xanthates in solution (particularly their dissociation, decomposition on acidification, and oxidation) has been the subject of numerous investigations. Yet, owing to the complexity of the xanthate systems, many aspects have not been clarified. In the recent papers of Majima (1, 2) the relevant literature is reviewed and new data are presented (based on ultraviolet spectrophotometry) concerning the dissociation, decomposition, and stability constants of alkyl xanthates from methyl to amyl, and lead, nickel, and cobalt xanthate complexes. Solubilities of numerous metal xanthates have been correlated in great detail by Sheka and Kriss (3) while Wronski (4) discusses the effects of increased pH in xanthate solutions.

In investigating the kinetics of xanthate adsorption from mixed solutions containing quaternary ammonium compounds the use of ultraviolet spectrophotometric analyses of these mixed solutions necessitated a preliminary study of various products of xanthate decomposition. The most probable reactions involved in the decomposition of xanthate solutions are hydrolysis and formation of xanthic acid, [1]; decomposition to alcohol and CS_2, [2]; and oxidation to dixanthogen, [3]:

$$\begin{aligned} &ROCS_2^-K^+ + H_2O \rightarrow ROCS_2H + K^+OH^- \\ &ROCS_2^-K^+ + H^+Cl^- \rightarrow ROCS_2H + K^+Cl^- \end{aligned} \qquad [1]$$

$$\begin{aligned} &ROCS_2^-K^+ + H^+Cl^- \rightarrow ROH + CS_2 + K^+Cl^- \\ &ROCS_2H + H_2O \rightarrow ROH + CS_2 + K^+OH^- \end{aligned} \qquad [2]$$

$$2(ROCS_2^-K^+) + H_2O + \tfrac{1}{2}O_2 \rightarrow (ROCS_2)_2 + 2(K^+OH^-). \qquad [3]$$

Of these reactions, the production of xanthic acid and the subsequent decomposition to alcohol and CS_2, particularly in low pH regions, have been most recently studied by Iwasaki and Cooke (6), Klein *et al.* (7), and Majima (1). The oxidation to dixanthogen has been considered irreversible and of little interest, particularly since tests with O_2 bubbled through xanthate solutions indicated this to be a slow reaction (Iwasaki and Cooke (6), Rao and Patel (8)); dixanthogen itself has been considered insoluble in water and no analytical method appears to be available for accurate determination of small quantities of dixanthogen.

Klein *et al.* (7) recorded the infrared and ultraviolet spectra of xanthic acid, and evaluated the absorptivity of its pronounced absorption band at 270 mμ as 10,670 liter/mole cm, and at 301 mμ (the major band of xanthate anion) as 117 liter/mole cm. However, in their work on fast decomposition of xanthate in acid solutions only the region 310–260 mμ was scanned.

EXPERIMENTAL

Ultraviolet spectra in the region 190–400 mμ were recorded on a Perkin–Elmer 350 spectrophotometer, using 10 mm path length quartz cells for 10^{-5}–10^{-4} *M* solutions, and 0.8 mm path length microcells for 10^{-4}–2×10^{-3} *M* solutions.

Xanthate compounds (potassium salts of ethyl, butyl, hexyl, and nonyl xanthates) were prepared by the standard method of reacting the corresponding alcohols with KOH, treating the alcoholates with CS_2, and doubly recrystallizing the xanthates from acetone solutions. Their purity (over 99%) was checked by titration with iodine and by comparison of their infrared spectra with those obtained previously (5) on samples analyzed microchemically for individual elements. Ethyl dixanthogen was prepared by oxidation of potassium ethyl xanthate solutions with iodine, extraction of dixanthogen with ether, and evaporation of ether.

Aqueous solutions were prepared using water distilled once in presence of air; when necessary, the pH was adjusted using $Na_2CO_3.9H_2O$, $KHCO_3$, or NaOH.

RESULTS AND INTERPRETATION

The ultraviolet absorption spectra of freshly recrystallized potassium ethyl xanthate (KEtX) are given in Fig. 1. They show two strong maxima, at 301 mμ and 226 mμ, an

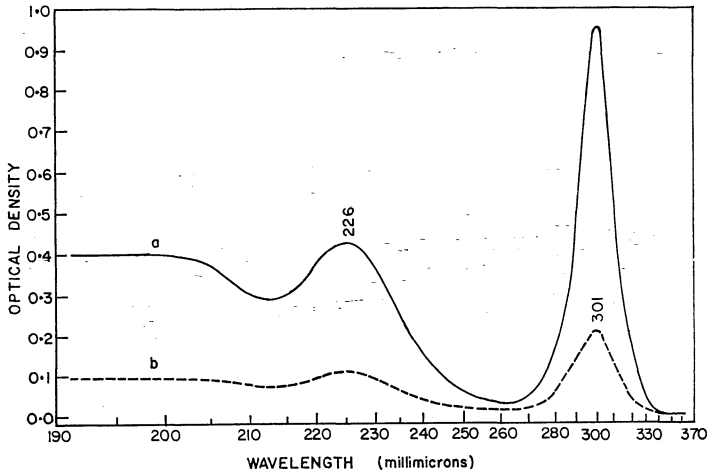

FIG. 1. Ultraviolet spectra of solutions of pure potassium ethyl xanthate (KEtX): (*a*) 1×10^{-4} mole/liter; (*b*) 2.3×10^{-5} mole/liter.

absorption plateau below approximately 200 mμ, and a very weak band at 380 mμ appearing only in concentrated solutions. Two deep minima are observed at 264 mμ and 213 mμ.

The applicability of Beer's law was established for KEtX concentrations of 3×10^{-5}–1.5×10^{-3} *M* solutions, Fig. 2, with the average molar absorptivities (extinction coefficients) equal to ϵ_{226} = 8,920 liter/mole cm and ϵ_{301} = 17,750 liter/mole cm (compared to ϵ_{226} = 8,780 and ϵ_{301} = 17,460 given by Majima (1)). The ratio of optical densities was d_{226}/d_{301} = 0.504 with an average deviation of ±0.005.

It was observed, however, that the optical densities in the region below approximately 280 mμ were affected by the length of the storage period since recrystallization of the

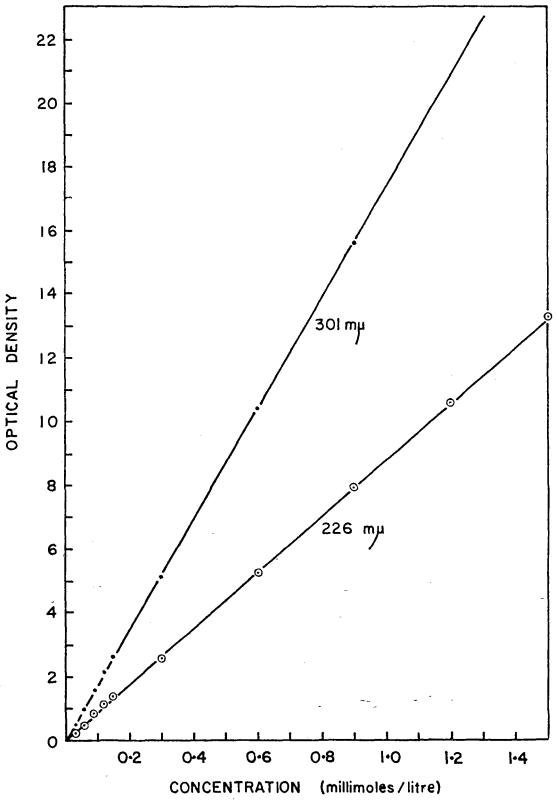

FIG. 2. Optical density vs. concentration of pure KEtX.

solid xanthate, and also by the method of preparation of the solutions. Spectra of dilute solutions (10^{-5}–10^{-4} M) obtained by dissolution of the required quantity of finely crystalline potassium ethyl xanthate (which was stored for prolonged time in dark) showed higher optical densities in the region below 280 mμ than the solutions obtained by dilution of 10^{-2} M stock solution or those obtained by dissolution of freshly recrystallized solid xanthate. The appearance of this "background" in the spectrum, chiefly responsible for an increase in the optical density of the 226 mμ maximum, resulted in the observed variations in the ratio of optical densities d_{226}/d_{301} ranging from 0.49–0.53. A more detailed investigation of xanthate solutions, and decomposition products, was undertaken with the view of uncovering the cause of this "background".

(a) Xanthic Acid

Comparison of several spectra obtained from solutions stored for several days or prepared from "aged" solid xanthates with the spectra of freshly recrystallized xanthates indicated that xanthic acid formation, with its pronounced maximum at 270 mμ, was not likely to be the primary cause of the general "background" at lower wavelengths. A spectrum of xanthic acid extracted by chloroform from acidified xanthate solution is shown in Fig. 3.

(b) Carbon Disulphide

At 22° C the solubility of CS_2 in water is given as 2.2 g/liter (9); because of its very

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

high absorptivity below about 380 mμ, CS_2 is not used as a solvent in ultraviolet spectrophotometry. The spectrum of a CS_2 solution (containing 3 ml of water saturated with CS_2 and diluted to 1000 ml) is shown in Fig. 3. Accepting the above figure for CS_2 solubility,

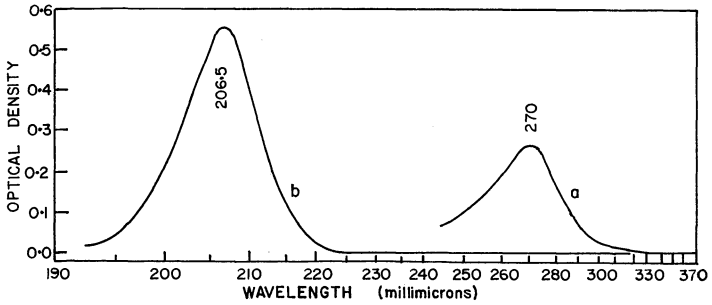

FIG. 3. Ultraviolet spectra of: (*a*) ethyl xanthic acid (EtXH) in chloroform extract from acidified KEtX solution; (*b*) carbon disulphide in water (3 ml of CS_2 saturated aqueous solution diluted to 1 liter).

the absorptivity at 206.5 mμ was estimated to be 60,000–70,000 liter/mole cm. Owing to high vapor pressure of CS_2 (400 mm Hg at 28° C) it easily volatilizes out of solution unless the cell is tightly corked.

(c) Dixanthogen

Ethyl dixanthogen was shaken with distilled water to obtain saturated solution, and its spectrum recorded; also, dixanthogen was dissolved in various solvents (chloroform, ethyl alcohol, ethyl ether) to determine its absorption bands. The spectra are shown in Fig. 4. It is seen that two wide absorption bands are present between 280–300 mμ and

220–250 mμ which, for the 4.1×10^{-5} *M* solutions of dixanthogen in ethyl ether, are more clearly defined at 286 mμ and 241 mμ. It is clear from these spectra that any formation of dixanthogen in xanthate solutions raises the optical densities of xanthate spectra at 301, 226, and below 200 mμ.

When distilled water (final pH 5.9–6.1) was kept in contact with dixanthogen (in well-stoppered flasks) for several days, the resultant spectrum, curve *a* in Fig. 5, indicated the presence of all three species: xanthate ion (301 mμ band), dixanthogen (~240 mμ band), and carbon disulphide (206.5 mμ). It was found that a stationary state was reached in this solution only after 15–20 days.

When the supernatant water (in a duplicate experiment) was decanted and centrifuged, then treated with NaOH to pH ~10, the sequence of spectra obtained after 15 minutes at 22° C, and after 2 hours at 40° C, showed a gradual transition of dixanthogen to xanthate with the concurrent appearance of CS_2, Fig. 6.

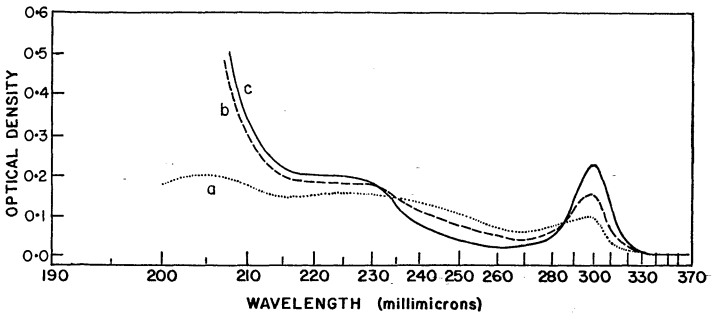

FIG. 6. Changes with time in the ultraviolet spectrum of ethyl dixanthogen aqueous solution at pH 10: (*a*) initial spectrum of aqueous dixanthogen (shaken with distilled water at pH 6, allowed to stand several hours in order to settle the suspension); (*b*) spectrum taken 15 minutes (at 22° C) after the addition of NaOH to raise the pH of solution (*a*) to pH 10; (*c*) the same solution as (*b*) after 2 hours at 40° C.

The reactions involved are:

$$2(EtX)_2 + 4OH^- + 4K^+ \rightarrow 4EtX^- + 2H_2O + O_2 + 4K^+; \quad [4]$$

which is the reverse reaction to [3], i.e. oxidation of xanthate in solution; and the simultaneous decomposition of either xanthate ions, or dixanthogen:

$$EtX^- + K^+ + H_2O \rightarrow EtOH + CS_2 + KOH \quad [5]$$

$$(EtX)_2 + H_2O \rightarrow 2EtOH + 2CS_2 + 2OH^-. \quad [6]$$

The stoichiometric overall reaction is, therefore,

$$2(EtX)_2 + 2OH^- + 2K^+ \rightarrow 2EtX^- + 2EtOH + 2CS_2 + 2K^+ + O_2. \quad [7]$$

The increase in the optical densities below 280 mμ observed in the spectra of solutions prepared from aged potassium ethyl xanthate was ascribed to the oxidation taking place on the surface of the solid xanthate, resulting in dixanthogen and carbonate:

$$2KEtX + \tfrac{1}{2}O_2 + CO_2 \rightarrow (EtX)_2 + K_2CO_3. \quad [8]$$

An attempt was made to obtain qualitative evidence for the existence of dixanthogen and carbonate on the surfaces of aged crystals, using infrared spectroscopy of mulls in hexachlorobutadiene. The band at ~1450 cm^{-1}, shown by all carbonates (10), was, however, masked by the C—H deformation band of the hydrocarbon radical in the xanthate. A weak band at ~1260 cm^{-1} indicated the presence of dixanthogen (5) on the surface of crystals.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

A solution of aged xanthate had its pH raised to 8.5 by $KHCO_3$ and was kept for 19 hours at 85° F. The spectra obtained from the initial and the final states of this solution, Fig. 7, show an increase in optical density at 301 mμ due to the formation of EtX^- anion

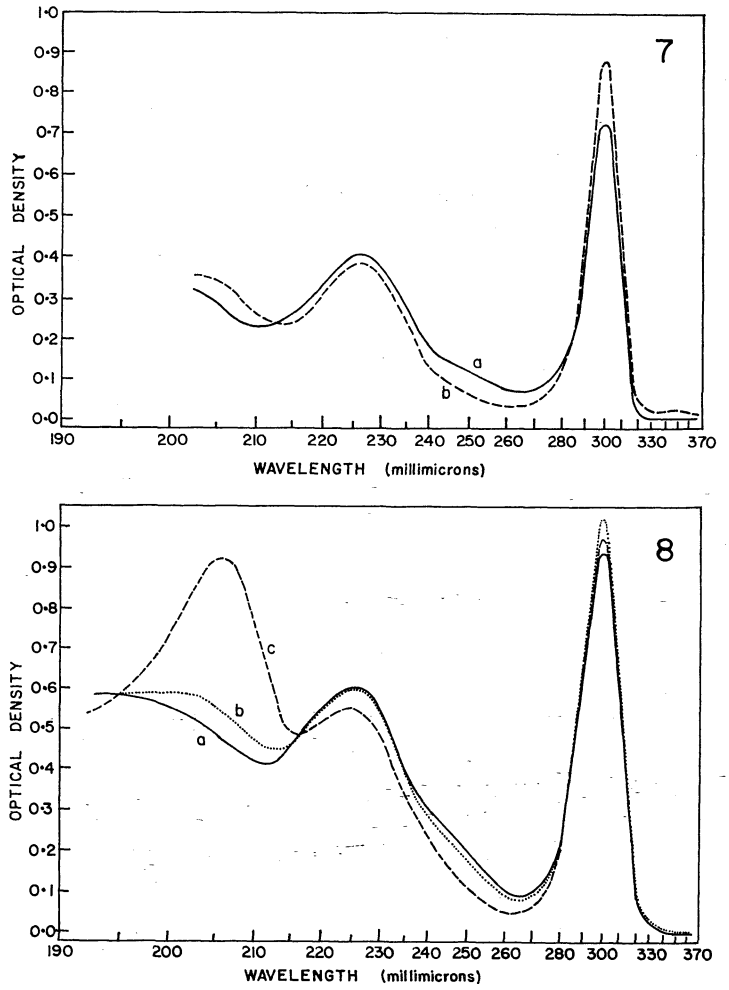

FIG. 7. Decomposition in xanthate solution: (*a*) the ultraviolet spectrum of pure potassium ethyl xanthate solution, ca. 0.9×10^{-4} mole/liter, freshly prepared in water of pH 8.5; (*b*) the same as (*a*) after 19 hours at 85° F.

FIG. 8. Ultraviolet spectra of 1.1×10^{-4} mole/liter ethyl xanthate solution at pH 6, kept in closed cell at 98° F for (*a*) 0 hours, (*b*) 7 hours, (*c*) 24 hours.

from dixanthogen decomposition, a reduction in optical densities in the range 216–280 mμ due to disappearance of some dixanthogen, and an increase in optical densities below 216 mμ caused by the formation of CS_2. Even freshly made ethyl xanthate solution of pH 6, kept at 98° F in a well-stoppered flask, indicated a progressive decomposition of dixanthogen initially present on the surface of the aged solid xanthate, Fig. 8. The sequence of changes in optical densities at 301 mμ, i.e. an increase after 7 hours followed by a decrease after 24 hours, may be significant and may indicate that, under the conditions of the experiment, the decomposition of dixanthogen to xanthate (shown by reaction [4]) is faster than the decomposition to carbon disulphide and alcohol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Using spectra of solutions contaminated by dixanthogen (reaction [8]), the measured optical densities were compared with those obtained on freshly recrystallized xanthate (Fig. 2) to evaluate the absorptivities of dixanthogen at 226 and 301 mμ (the major bands in the spectrum of pure xanthate solution); for this, an assumption was made that the ratio of absorptivities for dixanthogen is $\epsilon^{D}_{301} = \frac{1}{3}\epsilon^{D}_{226}$. This assumption is supported by the relative optical density measurements:

$$\frac{d_{226}}{d_{301}} = \sim 3 \text{ for water solutions of dixanthogen,}$$
$$\sim 3.2 \text{ for ethyl alcohol solutions of dixanthogen,}$$
$$\sim 2.8 \text{ for methyl alcohol solutions of dixanthogen,}$$
$$\sim 3.1 \text{ for ethyl ether solutions of dixanthogen.}$$

The calculation is given in the Appendix. The absorptivities of dixanthogen at 301 and 226 mμ thus evaluated were then used to calculate the solubility of dixanthogen in water (using spectra of appropriate solutions) and the equilibrium constant of reaction [4] (see Appendix). The results are listed in Table I with data from literature.

TABLE I
Summary of spectrophotometric data for dixanthogen and related compounds

	Wavelength, mμ	ε, liter/mole cm	Solubility, mole/liter (at 22° C)
Ethyl dixanthogen	226	18,300	1.3×10^{-5}
	301	6,100	
Ethyl xanthate ion	226	8,920	(~1–2)
	301	17,750	
Ethyl xanthic acid (6)	270	10,670	(Unstable, the monomolecular decomposition rate constant was determined to be 4.3 min^{-1})
	(301)	(117)	
Carbon disulphide (9)	206.5	>60,000	(ca. 3×10^{-2})

It was also of interest to study spectrophotometrically the standard method of titration of xanthate solution with iodine, according to the accepted reaction

$$I_3^- + 2EtX^- \rightarrow (EtX)_2 + 3I^-. \qquad [9]$$

At concentrations of iodine used (0.1 *M* in 2.5 *M* KI) the spectra of aqueous iodine solutions are free from maxima down to 250 mμ. (At higher concentration, two weak maxima at 355 mμ and 288 mμ appear.) Below 250 mμ, two strong iodide maxima at 226.5 mμ and 193.5 mμ make it practically impossible to interpret spectra of xanthates in this region.

When a dilute solution of potassium ethyl xanthate is titrated with iodine, a progressive lowering of optical density at 301 mμ is obtained with the appearance of an isosbestic point at 278 mμ for 5.2×10^{-5} *M* EtX^-.

The isosbestic point is shifted during the titration with I_2 towards the 301 mμ maximum of xanthate ion, as shown schematically in Fig. 9. This "shift in isosbestic point" is due to the formation of one molecule of dixanthogen from two ions of xanthate, hence the xanthate concentration falls off twice as fast as the dixanthogen concentration increases.

If the initial xanthate concentration used for titration is high, so that the dixanthogen formed on oxidation exceeds the solubility, the solution becomes opalescent as a result of formation of dixanthogen emulsion. Departures in optical density readings become evident, as shown in Fig. 10, where the points represent the actual readings and the line

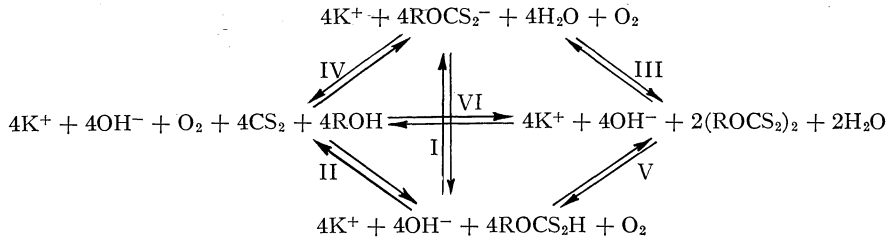
represents the theoretical optical densities of xanthate ions alone, based on stoichiometry of reaction.

DISCUSSION

The evidence obtained from spectrophotometric measurements on xanthate solutions containing dixanthogen shows not only the instability of dixanthogen but also the existence of other concurrent reactions. In order to describe an aqueous xanthate solution at a given pH, temperature, and pressure, at least the following six reactions have to be taken into consideration:



Of these reactions I, II, and III have been long recognized and studied, but both II and III have been generally considered irreversible, yielding CS_2 and dixanthogen, respectively. Spectra presented above show the reversibility of reaction III, and the appearance of the CS_2 band indicates the occurrence of either the reaction VI, IV, or II. Reaction IV is that employed in the standard method of xanthate production and its reversibility is not unexpected. The occurrence of xanthic acid in solutions of pH 6–10 has not been substantiated in this spectrophotometric work but it does not mean that reactions I, II, or V do not take place. Accepting the equilibrium constant derived by Iwasaki and Cooke (6) for reaction I, $K = ([EtX^-][H^+])/[EtXH] \simeq 2\times10^{-2}$, and applying it to pH 6 with activity of H^+ equal to concentration, the concentration of xanthic acid present in 10^{-5} M

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

solution of xanthate ions is found to be of the order of

$$[EtXH] = \frac{[EtX^-][H^+]}{K} \simeq \frac{10^{-5} \cdot 10^{-6}}{2 \cdot 10^{-2}} = \frac{1}{2} \cdot 10^{-9}\ M.$$

Using the molar absorptivity derived by Klein *et al.* (7), the optical density change expected from this concentration of xanthic acid would be $\Delta d_{270} = 10{,}670 \times 5 \times 10^{-10} = 5.3 \times 10^{-6}$, i.e. well outside the possibility of detection even when using a 10 cm optical path length cell.

Similarly, other reactions resulting in the formation of sulphides and trithiocarbonates, investigated by Klauditz (11) in highly alkaline xanthate solutions, may also be involved in the overall scheme of xanthate reactions, but could not be detected spectrophotometrically under the conditions employed.

The intermediate equilibrium constant for reaction [4], viz., $k = [EtX^-]^2/([OH^-]^2 \times [(EtX)_2]) \simeq 3.3 \times 10^{10}$ (see Appendix), evaluated from spectrophotometric measurements of dixanthogen solutions, can be used to calculate the approximate concentrations of ethyl dixanthogen in xanthate solution of different concentrations and at different pH (see Table II). It is seen that solutions of ethyl xanthate become saturated with respect

TABLE II

Approximate concentrations of ethyl dixanthogen, mole/liter, in equilibrium with xanthate ions at different pH values

to ethyl dixanthogen at different pH values depending on the concentration of xanthate ion; for 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6} M concentrations of xanthate ions in solutions, the saturation points are respectively just above pH 8, 7, 6, and 5.

For pH values lower than these saturation points the solutions exposed to air are supersaturated by dixanthogen, the excess of which forms an emulsion (or lenses at the air/water interface).

Figures in parentheses denote amounts of dixanthogen in excess of its saturation, ca. 1.3×10^{-5} M. Under the conditions of pH lower than the saturation pH, there is no tendency of the excess dixanthogen to be converted to xanthate since the equilibrium values (in parentheses) exceed the solubility value. However, if an excess of dixanthogen is initially present at a higher pH (where equilibrium values in Table II are smaller than the solubility), then the reaction of converting dixanthogen to xanthate takes place until the concentration of dixanthogen is reduced to the equilibrium value.

Using the constant K obtained by Iwasaki and Cooke (6), $K = ([EtX^-][H^+])/[EtXH] \simeq 2 \times 10^{-2}$, and the intermediate equilibrium constant k obtained in this work, $k = [EtX^-]^2/([OH^-]^2[(EtX)_2]) \simeq 3.3 \times 10^{10}$, together with $[OH^-][H^+] = 10^{-14}$, the ratio of dixanthogen to xanthic acid present in xanthate solutions at different pH values and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

different concentrations of xanthate ions (in solutions saturated with air at 1 atm pressure) can be expressed by:

$$\frac{[(EtX)_2]}{[EtXH]} = \frac{1}{k}\cdot\frac{[EtX^-]^2}{[OH^-]^2}\cdot\frac{K}{[EtX^-][H^+]} \simeq 6\times10^{15}[EtX^-][H^+].$$

It appears therefore that for the normal conditions employed in most flotation systems (10^{-5}–10^{-4} M xanthate solutions, pH 8–11) the concentration of dixanthogen is always greater than that of xanthic acid; in slightly alkaline xanthate solutions it is greater by several orders of magnitude. This would suggest that, in agreement with Cook's (12, 13) arguments for the adsorption of neutral molecules and Nixon's (14) deductions presented during discussion of hydrolytic adsorption, the active species in adsorption from xanthate solutions is the dissolved dixanthogen rather than xanthic acid. Infrared and ultraviolet spectrophotometric evidence, accumulated respectively by Poling (15) and Pomianowski (16), fully supports this supposition and will be published later.

It is significant that the ratio of dixanthogen to xanthic acid, derived above, reproduces the critical pH/concentration curves obtained by Wark and Cox (17) for various minerals and collectors; it has been pointed out by Barsky (18) that for each of these curves $[EtX^-][H^+]$ = constant.

ACKNOWLEDGMENTS

Grateful acknowledgment is made to the National Research Council for financial support of this work. The authors also wish to thank Miss Jean Begg for the preparations of xanthates used, and Mr. Colin Duncan for valuable assistance.

APPENDIX

Optical densities of pure xanthate solutions were compared with optical densities of xanthate solutions contaminated with dixanthogen in order to calculate the solubility of dixanthogen and the equilibrium constant of the reaction

$$2(EtX)_2 + 4OH^- \rightarrow 4EtX^- + 2H_2O + O_2. \qquad [3] \text{ or } [4]$$

$$K' = \frac{[EtX^-]^4[H_2O]^2[O_2]}{[OH^-]^4[(EtX)_2]^2} = k^2[H_2O]^2[O_2],$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where $k = [EtX^-]^2/([OH^-]^2[(EtX)_2])$ is an intermediate constant for solutions saturated with O_2 from the air under 1 atm total pressure.

(a) Evaluation of Dixanthogen Absorptivities

Pure KEtX (12.08 mg) dissolved in 1 liter would give 7.53×10^{-5} M solution, with optical densities $d_{301} = 1.34$ and $d_{226} = 0.67$, the absorptivities being $\epsilon_{301} = 17750$ liter/mole cm and $\epsilon_{226} = 8920$ liter/mole cm. The spectrum of 12.08 mg of "aged" KEtX dissolved in 1 liter showed the optical densities $d_{301} = 0.990$ and $d_{226} = 0.645$.

Assuming the applicability of Beer's law to the mixtures of xanthate ions and dixanthogen:

$$d_{301} = \epsilon^{X}_{301}\cdot C_X + \epsilon^{D}_{301}\cdot C_D = 0.990 \qquad [A]$$

and

$$d_{226} = \epsilon^{X}_{226}\cdot C_X + \epsilon^{D}_{226}\cdot C_D = 0.645, \qquad [B]$$

where X denotes xanthate ion and D dixanthogen. Using the ratio

$$\frac{d^{D}_{226}}{d^{D}_{301}} = 3 = \frac{\epsilon^{D}_{226}}{\epsilon^{D}_{301}} \qquad [C]$$

and substituting other known data to the above equations [A] and [B], the actual concentration C_X of xanthate ions was calculated.

The difference in the amounts of xanthate used and determined, $12.08-8.40 = 3.68$ mg, was due to the products of surface oxidation:

$$2KEtX + \tfrac{1}{2}O_2 + CO_2 \rightarrow (EtX)_2 + K_2CO_3 \qquad [7]$$

$$2\times160.3 + 16 + 44 \qquad 242.4 + 138.2$$

giving $(3.68\times10^{-3})/380.6 = 9.7\times10^{-6}$ M dixanthogen concentration. Substituting the evaluated concentrations, $C_D = 9.7\times10^{-6}$ M and $C_X = 5.24\times10^{-5}$ M, into eqn. [B] the absorptivities $\epsilon^{D}_{226} = 18{,}300$ liter/mole cm and $\epsilon^{D}_{301} = 6{,}100$ liter/mole cm (from eqn. [C]) were obtained.

(b) Evaluation of Dixanthogen Solubility and Equilibrium Constant k

Several spectra were recorded of distilled water, immediately after shaking with dixanthogen, after prolonged contact (in well-stoppered flasks) with a dixanthogen layer, and after additions of alkalies to establish equilibrium conditions between EtX^- ions and $(EtX)_2$. Interpretation of the spectrum recorded after prolonged contact with dixanthogen at 22° C, which indicated only negligible amount of CS_2 produced, led to the evaluation of dixanthogen solubility and equilibrium constant k:

$$\text{pH} = 6.0,\ [OH^-] = 10^{-8}\ \text{mole/liter}$$
$$d_{301} = 0.195 = 17{,}750C_X + 6{,}100C_D\ \text{(measured)}$$
$$d_{226} = 0.295 = 8{,}920C_X + 18{,}300C_D\ \text{(measured)};$$

hence

$$C_X = 7.0\times10^{-6}\ M$$

and

$$C_D = 1.3\times10^{-5}\ M.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

These two values correspond to 3.3×10^{-5} M of total EtX^- concentration, and the measurements at the "shifting isosbestic point" confirmed that the total concentration was between the limits

$$3\times10^{-5} < (C_X \text{ total}) < 4\times10^{-5} \text{ mole/liter.}$$

The value of $C_D = 1.3\times10^{-5}$ M was accepted as the solubility of dixanthogen in water at pH 6 and 22° C. The optical density d^D_{301} at saturation point of dixanthogen alone was, therefore,

$$d^D_{301} = 6100\times1.3\times10^{-5} = 0.079.$$

Using the above data, the intermediate equilibrium constant was obtained:

$$k = \frac{[EtX^-]^2}{[OH^-]^2[(EtX)_2]} = 3.3\times10^{10}.$$

(c) Titration of Xanthate Solution with Iodine

In titration with I_3^-, when the dixanthogen saturation point is exceeded, the concentration of xanthate cannot be directly evaluated from

$$C_X\cdot\epsilon^X_{301}+1.3\times10^{-5}\epsilon^D_{301} = 17{,}750\ C_X+0.079 = d_{301} \text{ (measured)} \qquad [D]$$

because of the unknown effect of emulsion. However, before the point of saturation is reached, the concentrations of xanthate and dixanthogen can be evaluated from

$$C_X\cdot\epsilon^X_{301} + \left(\frac{C^0_X}{2} - \frac{C_X}{2}\right)\epsilon^D_{301} = d_{301} \text{ (measured)},$$

where C^0_X is the initial concentration of pure xanthate.

The results of titration of a 20-ml xanthate solution with 5.56×10^{-4} N solution of I_3^- are given in Table III. The figures in parentheses have been calculated using eqn. [D];

TABLE III

Results of titration with I_3^- solution

	I_3^- solution added, ml						
	0	0.2	0.4	0.8	1.2	1.6	2.0
Measured d_{301}	0.990	0.905	0.802	0.640	0.427	0.270	0.172
Calculated C_X, 10^{-5} M	5.2	4.65	(4.05)	(3.15)	(1.96)	(1.07)	(0.5)
Calculated C_D, 10^{-5} M	0.95	1.28	Saturated solutions				

Fig. 10 shows the departure of measured optical densities from those for the residual concentration of pure xanthate ions, based on stoichiometry of the reaction.

A SYNTHESIS OF 3,3,3-TRICHLORO-1,2-EPOXYPROPANE FROM THE TETRAHALOPROPANE DERIVED FROM A CARBON TETRAHALIDE AND ETHYLENE[1]

WILKINS REEVE AND LEONARD W. FINE
Chemistry Department, University of Maryland, College Park, Maryland, U.S.A.

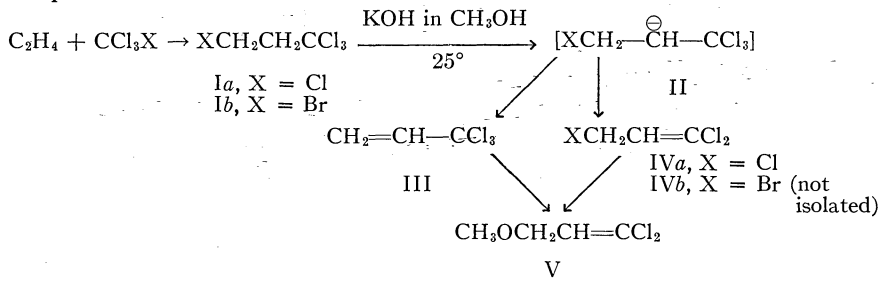
Received April 2, 1963

ABSTRACT

A study has been made of the reactions involving the addition of bromotrichloromethane to ethylene to give 3-bromo-1,1,1-trichloropropane, subsequent dehydrohalogenation of this to 3,3,3-trichloro-1-propene, and the isomerization of the latter to 1,1,3-trichloro-1-propene; the experimental conditions have been improved so that the minimum yield obtained in any one step is 78%. The 1,1,3-trichloro-1-propene is converted to a chlorohydrin in 36% yield by reaction with *tert*-butyl hypochlorite, and the chlorohydrin is converted in 61% yield to 3,3,3-trichloro-1,2-epoxypropane by treatment with base. The reaction of 3,3,3-trichloro-1-propene with methoxide ion to form 1,1-dichloro-3-methoxy-1-propene provides another example of an S_N2' reaction.

A convenient synthesis of 3,3,3-trichloro-1,2-epoxypropane was desired to make the compound available in relatively large amounts for another synthetic program. It had previously been prepared on a small scale by the reaction of diazomethane with chloral (1).

The synthesis which was developed involved the addition of carbon tetrachloride or bromotrichloromethane to ethylene to form the tetrahalopropane, which was then dehydrohalogenated and the resulting olefin isomerized and then converted to the epoxide via the chlorohydrin. Some of the reactions have been reported on previously, but significant improvements have been worked out for these steps and much new information has been developed.



Reaction of Carbon Tetrachloride with Ethylene

The addition of carbon tetrachloride to ethylene has been reported previously (2), but in our hands the reaction was quite unsatisfactory when carried out batchwise according to the published directions. A steel reaction vessel fitted with a glass liner was used and the latter was filled one eighth full with carbon tetrachloride. Ethylene was fed in at 7–10 atm pressure. At 80° and with 0.8% benzoyl peroxide as the free-radical initiator, about 11% of the theoretical yield was the most that could be obtained in one run, although this corresponded to a yield of 25% when allowance was made for the recovered carbon tetrachloride. As has been reported previously (2(*a*)), telomers were produced in addition to the desired product.

[1]*This investigation was supported in part by a Predoctoral Fellowship to L. W. F. from the Division of General Medical Studies, United States Public Health Service.*

A series of peroxides was studied, and it was found that *tert*-butyl perbenzoate was superior to benzoyl peroxide for this reaction when equal amounts of catalysts were used. The optimum conditions involved using 2.4% of *tert*-butyl perbenzoate; the yield was then 28% before allowing for recovered carbon tetrachloride. The results are summarized in Table I.

TABLE I

The reaction of ethylene with carbon tetrachloride and with bromotrichloromethane

	Catalyst	
	Benzoyl peroxide	*t*-Butyl perbenzoate
Conditions		
Reaction temperature, °C	80	115
Pressure of ethylene, atm	7 to 10	7 to 10
Volume of glass liner, ml	1125	1125
Volume of starting CCl_3X, ml	125	125
With CCl_4		
Moles catalyst/mole CCl_4	0.0048*	0.0192
Yield of 1:1 adduct, %	11	28
Yield of telomers, %	10	25
Recovered CCl_4, %	56	34
With $CBrCl_3$		
Moles catalyst/mole $CBrCl_3$	0.0048	0.0048
Yield of 1:1 adduct, %	78	78
Yield of telomers, %	0	0
Recovered $CBrCl_3$, %	4	6

*In larger runs, it was found that increasing the amount of catalyst did not increase the yield.

Peroxides which were less effective than the above included lauroyl peroxide, hydroxyheptyl peroxide, and *tert*-butyl hydroperoxide. All of the peroxides were used at reaction temperatures (70 to 130°) which corresponded to a half-life of 3 hours for the pure catalyst when decomposed thermally by heating alone in benzene at the given temperature (3).

Reaction of Bromotrichloromethane with Ethylene

As shown in Table I, bromotrichloromethane adds to ethylene to give a 78% yield of the 1:1 adduct with either benzoyl peroxide or *tert*-butyl perbenzoate as catalysts.* No telomers were formed and very little of the bromotrichloromethane was unreacted. Haszeldine previously observed that this addition reaction using benzoyl peroxide would occur in 60% yield (2(*d*)), and the reaction has also been reported to occur in unstated or lower yields by others (4). This provides an excellent example of a chain-transfer reaction, [1], taking precedence over the chain-propagation reaction, [2], observed with carbon

$$\cdot CH_2CH_2CCl_3 + BrCCl_3 \rightarrow BrCH_2CH_2CCl_3 + \cdot CCl_3 \quad [1]$$

$$\cdot CH_2CH_2CCl_3 + CH_2{=}CH_2 \rightarrow \cdot CH_2CH_2CH_2CH_2CCl_3 \quad [2]$$

tetrachloride because of the greater lability of the carbon–bromine bond in bromotrichloromethane as compared with the carbon–chlorine bond in carbon tetrachloride.

It was observed that the amount of catalyst required depended on the relative volumes of the gas and liquid phases inside of the glass liner. When the liner was filled 17% (50% more than the volume specified in Table I), the concentration of the *tert*-butyl perbenzoate catalyst had to be doubled in order to obtain a 78% yield.

The addition of bromotrichloromethane to ethylene at 120° and 50 atm pressure in the absence of peroxides has been used successfully by others as a preparative method. However, Elser and Saure (H. Elser and S. Saure. Angew Chem. **74, 253 (1962)) have recently reported the occurrence of a violent explosion under these conditions.*

Dehydrohalogenation of the Tetrahalopropanes

The base-catalyzed dehydrohalogenation of 1,1,1,3-tetrachloropropane has been previously studied and both of the olefins III and IV*a* have been reported to be obtained in yields of 31 and 12% (5), 50 and 30% (6), and 57 and 30% (2(*d*)) respectively. The dehydrohalogenation of 3-bromo-1,1,1-trichloropropane has been reported to give 57% of olefin III (7).

From the theoretical standpoint, this dehydrohalogenation of the 1,1,1,3-tetrachloropropane is of considerable interest since the intermediate carbanion II should be capable of forming either of the two olefins, III or IV. The conformation of the tetrahalopropane required for the formation of olefin III is given in Fig. 1. This conformation might be

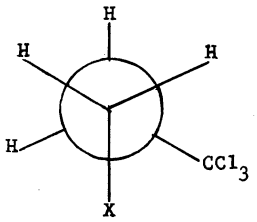

FIG. 1.

considered to be unlikely due to both steric interaction and dipole–dipole repulsion of the groups in this skew configuration. Therefore, formation of olefin III might be considered less likely than formation of olefin IV. The formation of the latter involves no steric problems and the developing double bond would have considerable resonance stabilization from the two vinylic chlorine atoms. Despite these considerations, the results in Table II show that the trichloromethyl group is so inert that the major reaction product is olefin III.

TABLE II

Percentage yields of products in dehydrohalogenation reaction*

Products	From $ClCH_2CH_2CCl_3$	From $BrCH_2CH_2CCl_3$
$CH_2{=}CHCCl_3$ (III)	55	80
$XCH_2CH{=}CCl_2$ (IV)	24	0
$CH_3OCH_2CH{=}CCl_2$ (V)	11	14

*Twofold excess of potassium hydroxide in methanol solvent at 25° for 90 minutes.

Our results are based on vapor phase chromatographic analysis of the reaction products before distillation, whereas the results of earlier workers are based on careful fractional distillation. It is now apparent that some isomerization of olefin III to olefin IV can occur under distillation conditions. Our procedure differed from the others also in that a twofold excess of methanolic potassium hydroxide was employed at 25° and the reaction was carried out in 90 minutes. Earlier workers used ethanolic potassium hydroxide at temperatures from 0 to 25°, base concentrations from 0 to 30% in excess of theory, and reaction times up to 6 hours.

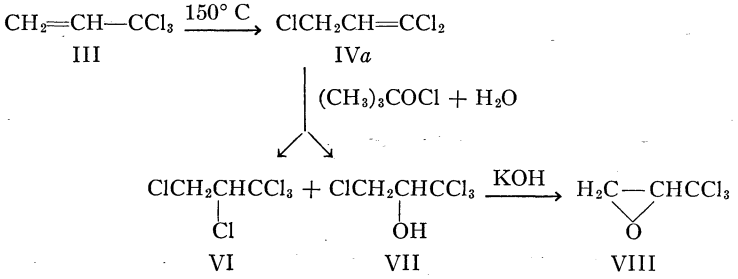
The increased amount of olefin III formed from the 3-bromo-1,1,1-trichloropropane is in accord with the known much greater tendency of alkyl bromides relative to alkyl chlorides to undergo an elimination reaction rather than a substitution reaction (8). It is probable that a small amount of 3-bromo-1,1-dichloro-1-propene (IV*b*) is also formed and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is converted completely to the unsaturated ether V. This unsaturated ether can be formed either by an S_N2 attack of methoxide ion on olefin IV or by an S_N2' attack of methoxide ion on olefin III. To determine which is the more likely route, separate portions of each of the pure olefins were reacted with potassium hydroxide in methanol at 80° and the reaction rates were determined semiquantitatively by withdrawing samples at various time intervals and analyzing for the ratio of olefin to unsaturated ether by vapor phase chromatography. At 80°, 1,1,3-trichloro-1-propene (IV*a*) was converted to the unsaturated ether (V) approximately six times as rapidly as was 3,3,3-trichloro-1-propene (III). If this same ratio of S_N2 to S_N2' attack holds at 25°, and if allowance is made for olefin III being present in larger amounts than olefin IV, then it would appear that approximately 20% of the unsaturated ether V arises by an S_N2' attack of methoxide ion on olefin III and the balance by an S_N2 attack of methoxide ion on olefin IV.

Isomerization of Olefin III to Olefin IV

This reaction has been previously studied (6) and shown to occur even at 0° with an acid catalyst but in relatively poor yield (2(*d*), 9); at 140° it occurs in 74% yield with no catalyst (2(*d*)). In the present work, a 95% yield was obtained by heating olefin III at 150° for 5 hours under pressure.



Formation of Chlorohydrin

The chlorohydrin 1,1,1,3-tetrachloro-2-propanol (VII) was first prepared by Meerwein by means of a Meerwein–Ponndorf reduction of tetrachloroacetone (10). Later Shelton and Lee prepared it in unstated yield from olefin IV*a* and hypochlorous acid (11). In the present work, it was prepared by reacting olefin IV*a* with a twofold excess of *tert*-butyl hypochlorite in 10% aqueous acetic acid. The chlorohydrin was obtained in 36% yield and 1,1,1,2,3-pentachloropropane (VI) was obtained in 42% yield. These were separated by distillation, but the purity of the chlorohydrin so obtained was estimated to be about 90% based on vapor phase chromatographic analyses; also the chlorine analysis was 4% high.

Formation of Epoxide

Chlorohydrin VII was converted to the epoxide VIII, 3,3,3-trichloro-1,2-epoxypropane, in 61% yield by "titrating" the chlorohydrin with slightly less than the theoretical amount of alcoholic potassium hydroxide solution at 25° to 35° in the presence of phenolphthalein indicator.

Attempts to synthesize the epoxide directly from olefin III and peracetic acid, perbenzoic acid, or *tert*-butyl hydroperoxide were unsuccessful.

EXPERIMENTAL

All melting and boiling points are corrected. Analyses are by Dr. Franz J. Kasler. The infrared spectra were determined on a Beckman IR-5. The liquids were measured as a film between sodium chloride plates.

3-Bromo-1,1,1-trichloropropane (Ib)

The apparatus used was a rocking-type steel autoclave (1640-ml volume) fitted with a glass liner (1125-ml inner volume). In the glass liner were placed 125 ml (1.3 moles) of freshly distilled bromotrichloromethane and 1.5 g (0.0062 mole) of dibenzoyl peroxide. The autoclave was flushed thoroughly with ethylene, the ethylene pressure raised to 100 lb/sq. in., and the autoclave then rocked and heated to the initiation temperature of 115°, at which point the pressure began to drop. Each time the pressure fell to 100 lb/sq. in., the autoclave was recharged to 175 lb/sq. in. The rate of pressure change was slow at first, reached a maximum, and then gradually tapered off with about 3 hours' reaction time required. Distillation yielded 230 g (78% yield) of 3-bromo-1,1,1-trichloropropane, b.p. 78–80° at 26 mm, n_D^{26} 1.5125. The physical constants are in agreement with the literature values (4(*a*)).

Dehydrohalogenation of 3-Bromo-1,1,1-trichloropropane

Over a 30-minute period, 56 g (1 mole) of potassium hydroxide dissolved in 130 ml of methanol was added with mechanical stirring to 112 g (0.5 mole) of 3-bromo-1,1,1-trichloropropane. The temperature was maintained at 25° with an ice-water bath. Stirring was continued for 1 hour, the reaction mixture then poured into 300 ml of cold water, the organic layer washed once with water, dried over anhydrous magnesium sulphate, and then distilled through a modified Widmer column. There was obtained 57 g (80% yield) of *1,1,1-trichloro-1-propene*, b.p. 100–100.5° at 760 mm, n_D^{25} 1.4684. The physical constants are in agreement with the literature values (5). Infrared spectrum, ν_{max}: 1890 (vinyl overtone), 1630 ($\rangle C{=}C\langle$ weak), 1410, 1125, 970, 945, and 813–770 cm^{-1}.

There was also obtained 12 g (14% yield) of *1,1-dichloro-3-methoxy-1-propene* (V), b.p. 132–133° at 760 mm. For preparative purposes, the preferred synthesis of this involved treating 1,1,3-trichloro-1-propene (IV*a*) according to the above procedure, but with refluxing at approximately 80° for 6 hours after the methanolic potassium hydroxide had been added to the reaction mixture. The yield was 80% of the theoretical. Infrared spectrum, ν_{max}: 2975, 2875, 1625, 1450, 1370, 1360, 1285, 1225, 1185, 1150, 1115–1065, 980–960, 912, 878–863, and 825 cm^{-1}. Anal Calc. for $C_4H_6Cl_2O$: C, 34.08; H, 4.29. Found: C, 34.25; H, 4.47.

1,1,3-Trichloro-1-propene (IVa)

Freshly distilled 3,3,3-trichloro-1-propene (146 g, 1.0 mole) was placed in the glass liner in the autoclave and heated for 5 hours at 150°. Shaking was not necessary. After cooling overnight, there was obtained on distillation 139 g (95% yield) of 1,1,3-trichloro-1-propene, b.p. 130–131° at 760 mm. The physical constants were in agreement with the literature values (6(*a*)). Infrared spectrum, ν_{max}: 3025, 2930, 1725, 1690, 1605, 1475, 1285, 1245, 1175, 1070, 945, 880–815, 740, and 695–675 cm^{-1}.

1,1,1,3-Tetrachloro-2-propanol (VII)

In a 500-ml 3-necked flask, equipped with a Hershberg stirrer and a thermometer, were placed 15 g (0.1 mole) of 1,1,3-trichloro-1-propene, 24 g of glacial acetic acid, and 250 ml of water. To this, 22 g (0.2 mole) of *tert*-butyl hypochlorite (12) was added dropwise over a 20-minute period with the temperature of the reaction mixture being maintained at 0°. After another 30 minutes, the reaction mixture was allowed to warm up to room temperature and was stirred for an additional 2 hours. The aqueous layer was separated and extracted with chloroform, the chloroform combined with the organic layer, washed once with water, dried, and distilled through a modified Widmer column. There was obtained 7 g (36% yield) of *1,1,1,3-tetrachloro-2-propanol* (VII), b.p. 98–100° at 17 mm, n_D^{25} 1.5165. Reported values are: b.p. 87–90° at 14 mm and n_D^{20} 1.5145 (10). Analysis by v.p.c. indicated the material to be 90% pure. Anal Calc. for $C_3H_4Cl_4O$: C, 18.21; H, 2.03. Found: C, 18.48; H, 2.20.

There was also obtained 12% of unreacted starting material, and 9 g (42% yield) of *1,1,1,2,3-pentachloropropane (VI)*, b.p. 81–83° at 17 mm, identified by analysis and by comparison with an authentic sample.

3,3,3-Trichloro-1,2-epoxypropane (VIII)

In a 250-ml 3-necked flask equipped with a dropping funnel, Hershberg stirrer, and a thermometer was placed 20 g (0.1 mole) of 1,1,1,3-tetrachloro-2-propanol. One milliliter of phenolphthalein indicator solution was added and a 1 *N* methanolic (or ethanolic) potassium hydroxide solution was introduced dropwise at such a rate that the reaction mixture never became highly colored. The temperature was maintained at 25 to 35°. Two to three hours were required for 80% of the stoichiometric amount of base to be added, at which point the reaction was stopped by adding 200 ml of water and separating the layers. The organic layer was washed twice with water, dried over anhydrous magnesium sulphate, and distilled. There was obtained 10 g (61% yield, based on the chlorohydrin), b.p. 47–49° at 17 mm, n_D^{26} 1.4783. Literature values are b.p. 39–40° at 11 mm and n_D^{25} 1.4768 (13). An authentic research sample from an industrial source had a boiling point of 147–149° at 760 mm, n_D^{25} 1.4768.

Infrared spectrum of the 10-g sample, ν_{max}: 3065, 3010, 2920, 1475, 1385, 1270, 1155, 1140, 1105, 1075, 955, 885, 848, and 830–770 cm^{-1}. Anal Calc. for $C_3H_3Cl_3O$: C, 22.32; H, 1.87; Cl, 65.90. Found: C, 22.10; H, 1.81; Cl, 66.15.

X-RAY DIFFRACTION DATA FOR AMMONIUM TETRATHIOTUNGSTATE

R. W. MOONEY AND C. W. W. HOFFMAN

Sylvania Electric Products Inc., Chemical and Metallurgical Division, Towanda, Pennsylvania, U.S.A.

Received May 9, 1963

ABSTRACT

The tetrathiotungstate salt of ammonia has been prepared. Zero-layer Weissenberg photographs have been used to establish that this material is orthorhombic with $a = 9.62_3$ Å, $b = 12.40_6$ Å, and $c = 7.05_5$ Å with space group $Pn2_1a$—C_{2v}^9 or $Pnma$—D_{2h}^{16}. The data have been used to index the Debye–Scherrer pattern.

INTRODUCTION

The preparation of ammonium thiotungstate, $(NH_4)_2WS_4$, has been known for about a hundred years (1). The preparation given by Corleis (2) yields substantially pure, crystalline $(NH_4)_2WS_4$. In 1885, Vater (3), from geometrical considerations, obtained the axial ratios $a:b:c = 0.7783:1:0.5675$. He described the crystal habit as rhombic bipyramidal, consistent with orthorhombic symmetry. Recently, Bernard and Tridot (4, 5) prepared some of the alkali and ammonium thiotungstates and studied the solutions spectrophotometrically. They observed three thiotungstate ions: $WO_2S_2^{2-}$, WOS_3^{2-}, and WS_4^{2-}, in solution, obtained successively by gassing tungstate solutions.

EXPERIMENTAL

Ammonium tetrathiotungstate, $(NH_4)_2WS_4$, was prepared in this laboratory by prolonged gassing of an ammonium tungstate solution with H_2S. $(NH_4)_2WS_4$ crystallized as orange, translucent crystals. These crystals showed a platy hexagonal habit. Cursory microscopic examination revealed, however, that these plates were usually elongated in what later was designated the *c*-direction. In addition, one pair of the opposite angles (the *c*-apices) was found to be very close to 60°. The other two pairs were found to be close to 59° and 61°. The chemical analysis of the crystals was: Found: W, 52.99%; S, 37.41%; NH_3, 9.6%. Theoretical, $(NH_4)_2WS_4$: W, 52.80%; S, 36.84%; NH_3, 9.78%. At room temperature, $(NH_4)_2WS_4$ is fairly stable but has a slight odor of H_2S; very slow decomposition may be taking place. At high temperatures, in air, it reacts, forming H_2S, NH_3, SO_2, and WO_3. Spectrographic qualitative analysis of the WO_3 obtained from firing showed 0.01% Mo and Si, and 0.001% Fe and Mg. The density obtained by ordinary pycnometric means was 2.71 g cm^{-3}.

Ni-filtered Cu $K\alpha$ ($\lambda = 1.5418$ Å) radiation was used to obtain zero-layer Weissenberg photographs taken about each of the three axes. The equi-inclination method was used to obtain the $h1l$ reflections. Inspection of the reciprocal lattice nets for each zone of reflection showed that the unit cell was orthorhombic with the approximate dimensions: $a = 9.6$ Å, $b = 12.4$ Å, and $c = 7.0$ Å. The $0kl$ reciprocal lattice net showed almost perfect hexagonal symmetry as a result of the absence of all reflections with $k+l = 2n+1$. A back reflection Laue photograph taken along the same *a*-axis also showed near-perfect 6-fold symmetry superimposed upon two mirror planes at right angles to each other. The Laue group must, however, be *mmm*. Twinning was observed parallel to the *b*-axis.

The unit cell dimensions were determined from high-order reflections on the single-crystal rotation photographs, tungsten ($a_0 = 3.1648$ Å) being used to correct for film shrinkage. The layer line photographs were then used to index the Debye–Scherrer pattern to a 2θ of 35° ($d = 2.50$ Å) as given in Table I.

RESULTS AND DISCUSSION

Extrapolation of single-crystal data to $2\theta = 180°$ refined the cell dimensions to: $a = 9.62_3 \pm 0.005$ Å, $b = 12.40_6 \pm 0.005$ Å, and $c = 7.05_5 \pm 0.005$ Å. Based on these figures, the ratio $b:c$ is very close to $\sqrt{3}$, namely 1.758, and with the absence of the $0kl$ reflections for which $k+l = 2n+1$ accounts for the near-hexagonal symmetry of the $0kl$ reciprocal lattice net. The cell dimensions lead to $a:b:c = 0.7757:1:0.5687$ ratios in excellent agreement with those of Vater. (Also, using Vater's ratios, the ratio $b:c$ is 1.762.)

vw	2.60	2.61	240
w	2.58	2.59	132
vw	2.53	2.54	330

The volume of the unit cell is 842.2 Å^3. Assuming four $(NH_4)_2WS_4$ units per unit cell, the calculated density is 2.75 g cm^{-3}, in satisfactory agreement with the experimental figure of 2.71 g cm^{-3}. The tetramolecular unit cell is consistent with the space group discussed below.

Lack of systematic absences in the $h1l$ reciprocal lattice net indicated a primitive unit cell. No systematic absences occurred in the $hk0$ zone. However, the systematic absence of $h0l$ when h was odd and of $0kl$ when $k+l$ was odd indicated the space group was either $Pn2_1a$—C_{2v}^9 or $Pnma$—D_{2h}^{16}. Vater's early observations, although unconfirmed in this work, support the latter space group. However, without more detailed information from a complete structure analysis the choice of a unique space group is unreliable.

In spite of the lack of definitive data, certain speculations concerning the structure of $(NH_4)_2WS_4$ are possible. There are two common structure types (6) having the A_2BX_4 stoichiometry that display a tetramolecular unit cell with pseudohexagonal orthorhombic symmetry, namely chrysoberyl (Al_2BeO_4) and the room-temperature form of potassium sulphate (K_2SO_4). Both of these compounds have the more probable space group $Pnma$—D_{2h}^{16}. The relative ratios of the unit cell dimensions of $(NH_4)_2WS_4$, K_2SO_4, and Al_2BeO_4 are: 0.776:1:0.569, 0.742:1:0.573, and 0.583:1:0.471, respectively. This tends to favor the isomorphism of $(NH_4)_2WS_4$ and K_2SO_4. However, such data by themselves are insufficient to establish an isomorphic relationship.

ACKNOWLEDGMENTS

The authors are indebted to V. Chiola and C. D. Vanderpool for the preparation of $(NH_4)_2WS_4$ crystals and to I. L. Ericson for the chemical analyses.

CONTRIBUTION CONCERNING THE PROBLEM OF THE INTRAMOLECULAR HYDROGEN BONDS IN ORTHO HALOPHENOLS

HENRIETTE BOURASSA-BATAILLE, P. SAUVAGEAU, AND C. SANDORFY
Département de Chimie, Université de Montréal, Montréal, Qué.
Received April 1, 1963

ABSTRACT

The infrared spectra of the four ortho halophenols were measured in carbon tetrachloride solutions containing variable amounts of ether. The integrated intensities of the stretching band corresponding to the intermolecularly hydrogen-bonded OH groups were determined and plotted against ether concentration. From the curves obtained in this manner it was possible to deduce the relative strengths of the *intra*molecular hydrogen bonds which are present in these molecules. They are, in order of increasing strength: F < I < Br < Cl. This result is compared to others, published in the literature, obtained using alternative methods.

INTRODUCTION

Ortho-substituted phenol derivatives have received a great deal of attention in recent years (1–9). In particular the nature of the intramolecular hydrogen bond in the ortho halophenols has been the subject of many publications since Wulf, Liddel, and Hendricks (10) found that these molecules have two OH stretching bands in the infrared; and since Pauling (11) suggested that for these compounds cis and trans isomers are possible, the cis isomer being stabilized by hydrogen bonding. Ferguson (12) pointed out that in this case the energies of the hydrogen bonds may not vary proportionally with the frequency shifts of the infrared OH stretching bands, because the hydrogen bonds must be bent to a large extent.

The shifts increase in the natural order of the halogens, F < Cl < Br < I, giving the impression that iodine forms the strongest hydrogen bond in this series. The following data were measured in this laboratory (13), but, of course, these bands were known long before.

	Free OH (trans)	Bonded OH (cis)
o-Fluorophenol	—	3591
o-Chlorophenol	3608	3545
o-Bromophenol	3604	3522
o-Iodophenol	3600	3499
Phenol	3610.5	—

If the frequency shifts were proportional to the hydrogen bond energies, it would be expected that the trans/cis ratio would decrease in the same order. This is, however, not so. Baker (1) and Baker and Kaeding (2) measured the integrated absorption intensities of the trans and cis bands for the four compounds; and also for 2,4,6-trisubstituted phenols with two different halogens in the 2 and 6 positions, where two bonded bands appear: they concluded from the relative intensities of the bands that the strength of the hydrogen bonds increases in the order I < F < Br < Cl, with chlorine giving the strongest hydrogen bond.

More recently Allan and Reeves (14) measured the nuclear magnetic resonance spectra of the *o*-halophenols. They determined equilibrium constants for the cis–trans conversion,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and from their temperature dependence they calculated ΔH, the heat of formation of the hydrogen bonds. They obtained:

	ΔH, cal/mole
o-Chlorophenol	2.356
o-Bromophenol	2.141
o-Iodophenol	1.651

Chlorine again gave the strongest hydrogen bond. For *o*-fluorophenol they concluded that no hydrogen bond formation takes place.

The dipole moments of the cis and trans forms are very different: this led Richards and Walker (15) to determine the trans/cis ratios by dipole moment measurements. The order was dependent on the solvent, but in CCl_4 it was $I > F > Cl = Br$, essentially the same as the order found by Baker and Kaeding.

The above-mentioned infrared studies suffer from the implicit assumption that the relative intrinsic intensity of the trans and cis bands remains the same for all the *o*-halophenols. The n.m.r. work of Allan and Reeves is free of this drawback, but their conclusion concerning *o*-fluorophenol does not seem to be well founded (see below). Those results of Richards and Walker which were obtained in CCl_4 are also somewhat uncertain, according to these authors themselves, because their calculations involve small differences of low dipole moments.

The present work is an attempt to supply additional infrared evidence concerning the order of the hydrogen bond energies of the ortho halophenols.

OUTLINE OF THE WORK

The intramolecular hydrogen bonds in ortho halophenols are relatively weak. Therefore, if we put a strong proton acceptor into the solution we might expect that the intramolecular hydrogen bonds will be broken in order to give rise to stronger intermolecular bonds. One such case has been described by Bellamy and Hallam (16), who examined the infrared spectra of pyrrole – pyrrole complexes in the presence of strongly associating solvent molecules; and Pople, Schneider, and Bernstein mention similar observations made with n.m.r. spectra (9, p. 412).

In our investigation we prepared dilute solutions of the *o*-halophenols in CCl_4 at a concentration (0.0189 *M*) where intermolecular hydrogen bonding is negligible, and then solutions in CCl_4 containing diethyl ether in concentrations varying from 0 to about 9 *M*. The intensity of the sharp "intramolecular" bands diminishes gradually and then disappears as the ether concentration increases; and at the same time a broad band appears at 3300 cm^{-1}, the integrated intensity of which increases gradually, indicating the formation of intermolecular hydrogen bonds.

We plotted curves of integrated intensities of the intermolecular bands against ether concentration. If a para or meta halophenol is used as solute the curve rises rapidly to reach a plateau at moderate ether concentrations. But for an ortho halophenol the rising is much slower, showing that the equilibrium is much less in favor of intermolecular bonds in the reaction: intramolecularly bonded *o*-halophenol + ether $\rightleftarrows$ intermolecularly bonded *o*-halophenol to ether (cf. ref. 17). Figure 1 illustrates this situation in the case of *o*-chlorophenol, the other three *o*-halophenols yielding similar sets of curves. On Fig. 2 the ortho curves are collected together.

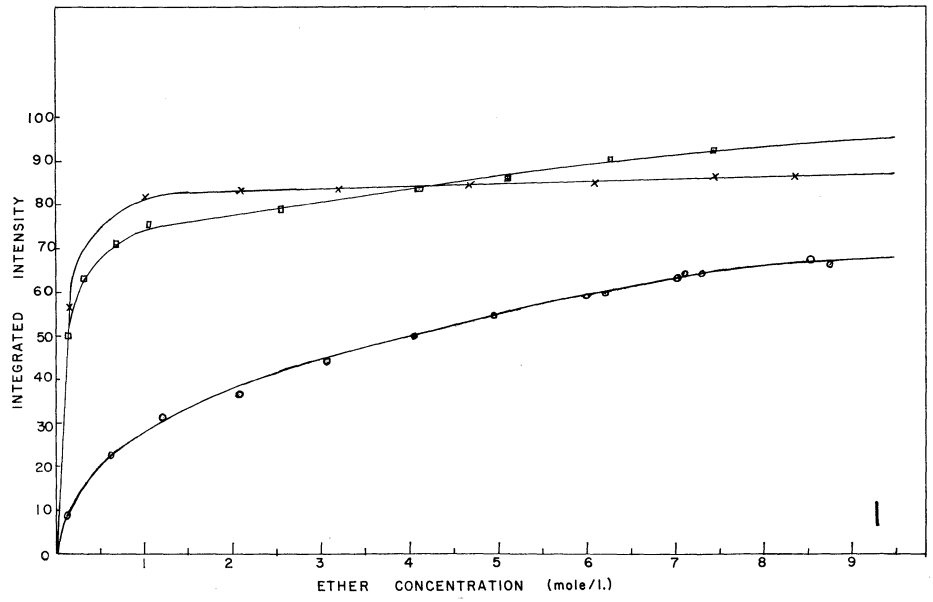

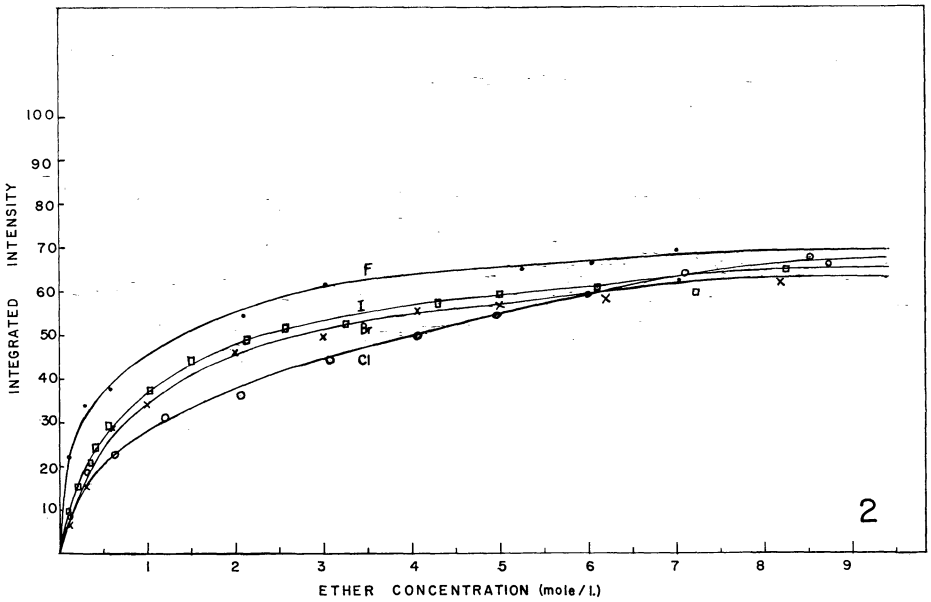

FIG. 1. Intensities (in arbitrary units) vs. ether concentration for *o*-chlorophenol (○), *m*-chlorophenol (×), and *p*-chlorophenol (□).
FIG. 2. Intensities (in arbitrary units) vs. ether concentration for *o*-chlorophenol (○), *o*-bromophenol (×), *o*-iodophenol (□), and *o*-fluorophenol (●).

Only the intermolecular band was used because the intensity of the intramolecular band is influenced too much by overlap with the other bands.

EXPERIMENTAL

The purity of the compounds is a rather important factor in spectroscopic studies of the halophenols, as has been emphasized by Rossmy, Lüttke, and Mecke (18). Our samples were reagent or highest purity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

grade commercial products; and we further purified them by vacuum distillation, sublimation in vacuum, or chromatographic methods according to the cases. We cannot claim that our compounds were of the same high degree of purity as those of Baker (1), but we calculated that they would have to contain a rather unreasonably high amount of phenol, the most probable impurity, in order to impair our conclusions.

A Perkin–Elmer model 21 spectrometer was used, mounted with a sodium chloride prism. For the lowest ether concentrations 1-mm cells were used, for the rest 0.1-mm cells. Ether absorbs heavily from 3100 cm^{-1} and, therefore, the parts of our curves above 5 M have to be interpreted with caution: no conclusions will be drawn from the occasional crossing between curves encountered at high ether concentrations.

The area under the intermolecular OH band was planimetered out between the center of the band ± 150 cm^{-1}. Since the center of these broad bands was always very close to 3300 cm^{-1}, and since their shapes were all very similar, we believe we have obtained reliable relative intensities. No attempt was made, however, to compute absolute intensities, and so the results are given in arbitrary units.

Although all the work was conducted in an entirely quantitative manner, only qualitative conclusions will be drawn from the results.

DISCUSSION

It may be inferred from the curves of Fig. 2 that the order of increasing intramolecular hydrogen bond strength is F < I < Br < Cl. Drawing this conclusion would, however, imply the supposition that the intrinsic intensity of the intermolecular band is the same for all four compounds. This may appear to be so since the frequency of the center of the band is in all cases very close to 3300 cm^{-1}, as far as it is possible to tell in view of its broadness. But, if this were really true, the intensity versus ether concentration curves of Fig. 2 should all attain the same height at high ether concentrations, when all the OH groups are intermolecularly bonded. But clearly this is not the case, and the differences may be great enough to affect our conclusions. In fact, if hydrogen bonding were the only important factor in determining the intensity of the intermolecular band at high ether concentrations, even the ortho, meta, and para curves should eventually reach a plateau of the same height. Figure 1 shows clearly that the electronic structure of the proton-donor molecule has a great influence on the intensity of the bands, even though it hardly affects their frequency.

The slope of the curves is, however, independent of the intrinsic intensities of the bands. Therefore we computed the change in ether concentration, $\Delta_{I'-I''}$, needed to raise the intensity from I' to I'' for all four molecules at a number of places that we considered to be the meaningful parts of the curves, say from about 0.2 to 4.5 mole/liter; I' and I'' are measured on the same arbitrary scale as used in Figs. 1 and 2. Here is a typical example:

	$\Delta_{(35-55)}$
Cl	3.43
Br	2.75
I	2.53
F	1.58

In every case the sequence turned out to be F < I < Br < Cl, which is actually the same as what would follow from a simple consideration of the order of the curves of Fig. 2.

This is the same order as the one found by Allan and Reeves (14), but differs by one inversion (F ↔ I) from the order given by Baker and Kaeding (2). According to our results Cl is further apart from the others than found by previous authors, but this may be due partly to some phenol impurity, phenol being more difficult to eliminate from *o*-chlorophenol than from the other three *o*-halophenols (1). In computing our results the trans isomers were disregarded since they could only influence the slope at very low ether concentrations, as can easily be shown by using trans/cis ratios which are certainly higher than the true ones.

o-Fluorophenol deserves some special comment. According to Baker and Kaeding there is an intramolecular hydrogen bond in this molecule, but according to Allan and Reeves there is not. We should like to support the opinion of the former authors since for *o*-, *m*-, and *p*-fluorophenol we obtained a set of curves similar to those shown on Fig. 1, even though the ortho curve runs closer to the meta and para curves than for the ortho halophenols. This means that the *o*-fluorophenol band at 3591 cm^{-1} is either entirely due to an intramolecularly bonded OH group and the trans band is too weak to show up or that the trans band is too close to the cis band and melted into it (see ref. 19). Actually this band is appreciably more intense and somewhat broader than the free OH bands of the other halophenols, although it is not unusually assymetrical. For example:

	A	h, cm^{-1}
o-Fluorophenol	8.64	24.1
m-Fluorophenol	6.28	18.6
p-Fluorophenol	5.97	17.1

A is the integrated intensity in absolute units multiplied by 10^7 and h is the half width (20).

We believe that F < I < Br < Cl is the reliable order of increasing hydrogen bond energies in the ortho halophenols. Nothing emerges from our work, however, to explain this order. The interorbital repulsion theory of Baker and Kaeding offers the only comprehensive explanation available, and it probably goes as far as might be hoped for from qualitative arguments. For a more thorough treatment we shall likely have to wait until the next stage in the development of quantum chemistry.

ACKNOWLEDGMENTS

We are grateful for financial support from the National Research Council of Canada and from the Petroleum Research Fund of the American Chemical Society.

Our thanks are due to Miss Ton-Nu-Thi-Nga for help in carrying out the experimental work.

We are indebted to Mr. David Davies for correcting the English of our manuscript.

REACTIONS OF CARBOHYDRATE DERIVATIVES DURING GAS–LIQUID CHROMATOGRAPHY[1]

C. T. BISHOP, F. P. COOPER, AND R. K. MURRAY[2]
Division of Applied Biology, National Research Council, Ottawa, Canada
Received May 10, 1963

ABSTRACT

The following reactions have been shown to occur during gas–liquid chromatography of carbohydrate derivatives: (*a*) deamidation, (*b*) change in size of the sugar ring, (*c*) rearrangement of acetal or ketal groups, (*d*) degradative rearrangement of acetylated amino sugars. The results emphasize that stability of a compound under conditions used in gas–liquid chromatography is a necessary prerequisite to the application of that technique; the precautions that should be followed to determine stability are indicated.

The polyhydroxylated carbohydrates are not sufficiently volatile for gas–liquid chromatography and must be converted into stable, volatile derivatives for the successful application of this method of separation. Derivatives that are sufficiently volatile include *O*-methyl ethers (1-4), *O*-acetyl esters (5–7), acetals and ketals (2, 8, 9), and *O*-trimethylsilyl ethers (10–12); through use of these derivatives gas–liquid chromatography has been applied to a number of problems in the chemistry of carbohydrates (13). Although much attention has been given to the search for easily prepared carbohydrate derivatives of sufficient volatility for gas–liquid chromatography, the stabilities of these drivatives under the conditions used have not been critically assessed in most instances. Column temperatures required for gas–liquid chromatography of carbohydrate derivatives range from 150° C to 250° C depending upon the compounds being examined and the injection port is usually kept at a temperature some 60° C higher than the column. Oxidative and hydrolytic processes are probably not operative, or are held to a minimum, in the atmosphere of inert gas (helium, argon, nitrogen) used as a mobile phase. However, among the various classes of organic compounds, carbohydrate derivatives are noted for their lability at high temperatures and for undergoing complex rearrangements under a variety of conditions. The possibility that a carbohydrate derivative may be modified during gas–liquid chromatography should not, therefore, be overlooked.

The present investigation draws attention to this possibility by describing four general types of modification that can occur during gas–liquid chromatography of carbohydrate derivatives. It also indicates those classes of derivatives for which caution should be observed in interpreting results of gas–liquid chromatography and describes methods for determining when modification has occurred. The four general types of modification are (*a*) deamidation, (*b*) change in size of the sugar ring, (*c*) rearrangement of acetal or ketal groups, (*d*) degradative rearrangement of *O*-acetyl esters of amino sugars.

The first modification was illustrated by the behavior of 2,3,5-tri-*O*-methyl-L-arabonamide and 2,3,5-tri-*O*-methyl-D-galactonamide during gas–liquid chromatography. Each amide yielded only ammonia, which emerged with the solvent peak, and the corresponding lactone. The lactones were identified by comparison of their retention volumes (R_v) with those of authentic samples and, after collection from the effluent gas stream, by the melting points of their mixtures with previously characterized specimens.

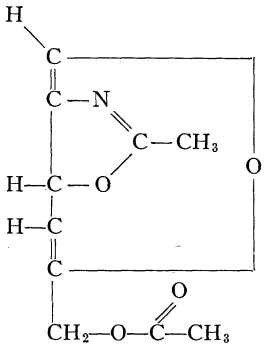
The change in size of the sugar ring was demonstrated by conversion of methyl 3,6-anhydro-α-D-mannopyranoside to methyl 3,6-anhydro-α-D-mannofuranoside. The pyranoside derivative gave four components on gas–liquid chromatography, the major one (75%) being identified as the corresponding furanoside by its R_v value and, after collection from the effluent gas stream, by the melting point of its mixture with an authentic sample. Methyl 3,6-anhydro-α-D-mannofuranoside showed only one component on gas–liquid chromatography and was recovered unchanged from the effluent gas stream. Identities of the other components arising from methyl 3,6-anhydro-α-D-mannopyranoside could not be established; when recovered from the effluent none of them proved to be the initial compound. These may have been caused by other rearrangements such as anomerization or ring cleavage, or they may have been present as impurities in the methyl 3,6-anhydro-α-D-mannopyranoside. Although the latter had the reported physical properties no other criterion of purity was available.

Rearrangements of acetal and ketal groups were found with the benzylidene glycerols and with di-*O*-isopropylidene-D-mannitols. The mixture of benzylidene glycerols obtained by acid-catalyzed condensation of glycerol with benzyldehyde showed four components on gas–liquid chromatography. These were undoubtedly the cis and trans isomers of 1,2-*O*- and 1,3-*O*-benzylidene glycerol. The four components were collected individually from the effluent gas stream and chromatographed again as a check on their purity. Three of the single components each gave the same four peaks found on the original chromatogram but in varying amounts, showing that equilibrium conditions were not established. The fourth component could be rechromatographed without change and was identified as the stable *cis*-1,3-*O*-benzylidene glycerol. Both 1,2:3,4-di-*O*-isopropylidene-D-mannitol and 1,2:5,6-di-*O*-isopropylidene-D-mannitol were well-characterized, crystalline specimens. Each isomer gave a single peak on gas–liquid chromatography but the retention volumes did not differ greatly and collection of the material from the effluent gas stream gave products with depressed melting points. The di-*O*-acetates of each di-*O*-isopropylidene-D-mannitol showed single peaks with widely differing retention volumes on gas–liquid chromatography and the products were recovered unchanged from the effluent gas stream. The products with depressed melting points, obtained by gas–liquid chromatography of the 1,2:3,4-di-*O*- and 1,2:5,6-di-*O*-isopropylidene-D-mannitols, were therefore acetylated and examined separately by gas–liquid chromatography. The results showed that the 1,2:3,4-di-*O*-isopropylidene-D-mannitol yielded 2% of the 1,2:5,6-di-*O*-isopropylidene isomer and two unknown products (1.5% and 0.5%) on gas–liquid chromatography; 96% of the initial product was recovered unchanged. The 1,2:5,6-di-*O*-isopropylidene-D-mannitol yielded 13% of the 1,2:3,4-di-*O*-isopropylidene isomer and two unknown products (3% and 8%) having the same R_v values as those obtained from the 1,2:3,4-di-*O*-isopropylidene-D-mannitol; 76% of the initial product was recovered unchanged. Identities of the two unknown products could not be established because of a paucity of material but their retention volumes indicated that they were probably di-*O*-isopropylidene hexitols.

An example of the degradative rearrangement of *O*-acetyl esters of amino sugars was obtained in attempts to find a derivative of 2-amino-2-deoxy-D-glucose (glucosamine) that was suitable for gas–liquid chromatography. Gas–liquid chromatography of *N*-acetyl-D-glucosamine tetraacetate (α- or β-anomer) yielded two products that were eluted at different temperatures. The faster-moving component was crystalline, m.p. 80–81° C, $[\alpha]_D^{27}$ −0.6° (*c*, 1.7% in methanol), and was obtained in yields of about 7%. It constituted about 50% of the volatile products. Analyses of the compound indicated the following

composition, $C_{10}H_{11(12)}O_4N$, which included two acetyl groups. Infrared spectroscopy indicated the presence of a C=N grouping, probably in an oxazoline ring. Nuclear magnetic resonance spectroscopy indicated that the following groupings were probably present:  .

The compound decomposed when warmed with acid or base and readily took up bromine. Although further work is required to establish the structure of this product it must be an unsaturated compound, probably containing an oxazoline ring, and quite possibly is a variant of the following structure:



The same two products were obtained from fully acetylated D-galactosamine (α, β mixture). The compound eluted at the higher temperature was not examined further except to show that it was not a fully acetylated hexosamine and therefore must have been another product of degradation.

The results described here could have been caused by the high temperatures of the columns or injection port; by the types of liquid phases or inert supports or any pretreatment of the latter; by the tubing used for the column; by the solvent used for injection of the sample; and no doubt by other parameters as well. No attempts were made to vary any of these parameters in order to reduce or increase the extent of any of the changes described. The conditions used were those normally employed for gas–liquid chromatography of carbohydrate derivatives and the results indicate that considerable modification can occur.

Obviously, amide groups must be regarded as unstable under conditions of gas–liquid chromatography. Similarly, the size of a glycoside ring may be changed in a molecule where that change is structurally favorable and is not forbidden by substituent groups. Acetal and ketal groups may undergo rearrangement on gas–liquid chromatography but it appears that such rearrangement can be prevented by prior substitution of all available hydroxyl groups. Thus, the two di-*O*-isopropylidene-D-mannitols were partially rearranged but their diacetates were completely stable. These three modifications can be anticipated or prevented and hence should not cause much difficulty in the application of gas–liquid chromatography. However, the degradation of *N*-acetyl-D-glucosamine tetraacetate not only showed that compound to be unsuitable for gas–liquid chromatography but raised a question about the propriety of using any *O*-acetyl derivatives for that purpose. Although the structure of the degradation product has not been established completely it is clear that double bonds were formed, most likely by elimination of the elements of acetic acid.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The effect of the *N*-acetyl group on this elimination is not clear but a similar degradation has been observed with the acetylated aminols, 2-acetamido-2-deoxy-D-glucitol pentaacetate and 2-acetamido-2-deoxy-D-galactitol pentaacetate; mixtures of these two derivatives on gas–liquid chromatography gave highly variable quantitative results that could be accounted for only by a random degradation of the products on the column (14). It may be that the higher temperature required for the gas–liquid chromatography of these amino sugar derivatives is alone responsible for the degradation because good quantitative separations of sugar alcohol acetates have been obtained at lower temperatures (5). However, the same workers have pointed out that *O*-acetyl esters must be injected directly onto the column packing to prevent decomposition of the samples and that discontinuities in the column packings should be avoided for satisfactory results (6).

Obviously, the utmost caution should be used when gas–liquid chromatography is applied to the separation of carbohydrate derivatives. It is essential that compounds be stable under the conditions used if erroneous results are to be avoided. A simple test that will show whether or not any compound is suitable for gas–liquid chromatography is its recovery, unchanged, from the effluent gas stream. Indeed, positive identification of a compound separated by gas–liquid chromatography can be achieved only by its recovery from the effluent gas and determination of its physical constants. The possibility that some products on a chromatogram are artifacts arising from another component can be checked by the collection and reinjection of each separated component in the mixture. The occurrence of partial decomposition of a compound can be detected by quantitative estimations of its mixtures with another compound that is known to be stable under the conditions used. Gas–liquid chromatography can be used safely to separate any derivatives that meet these checks satisfactorily.

EXPERIMENTAL

The following conditions were common to all gas–liquid chromatography experiments described below: apparatus—F and M model 500; column—1/4-inch coiled copper tubing; flow rate—60 ml helium/min; injection port temperature—265° C; detector—thermal conductivity cell.

Deamidation

2,3,5-Tri-*O*-methyl-L-arabonamide (15), m.p. 134–136° C, $[\alpha]_D^{26}$ +20° (*c*, 0.5% in ethanol), was dissolved in 95% ethanol for injection into the chromatogram through a silicone rubber septum by means of a Hamilton syringe. The column temperature was 200° C; the packing was 10% neopentyl glycol succinate polyester on Gas Chrom Z, 100–120 mesh; column length was 8 ft. Only one component was shown on the chromatogram and it had the same R_v value as 2,3,5-tri-*O*-methyl-L-arabonolactone. Samples were injected repeatedly (six to seven times 0.04 ml of a 10% solution) to provide enough of the single component for characterization. The product was collected for the effluent gas stream in a straight glass tube fitted to the outlet port through a silicone rubber *O*-ring. The sirupy product crystallized when cooled and had m.p. 25–26° C, unchanged on admixture with 2,3,5-tri-*O*-methyl-L-arabonolactone (16) having m.p. 27° C and $[\alpha]_D^{26}$ −26° equilibrium (*c*, 0.6% in water).

Gas–liquid chromatography of 2,3,5-tri-*O*-methyl-D-galactonamide (17), m.p. 143–144° C, $[\alpha]_D^{26}$ +5° (*c*, 2% in water), under exactly the same conditions also yielded only one component. It was identified, after collection from the effluent gas stream, as 2,3,5-tri-*O*-methyl-D-galactonolactone (17), m.p. 83–84° C, unchanged on admixture with a sample prepared according to Alexander *et al.* (18) which had m.p. 83–84° C and $[\alpha]_D^{23}$ −38°, 5 minutes (*c*, 1.44% in water).

Moist indicator paper, held at the outlet port, showed a strong basic reaction during emergence of the solvent peak for each of the foregoing samples. This reaction was not observed when solvent alone was passed through the chromatograph.

Change in Size of Sugar Ring

Methyl 3,6-anhydro-α-D-mannopyranoside (19) was prepared according to Foster *et al.* (20) and had m.p. 130–131° C and $[\alpha]_D^{20}$ +97° (*c*, 0.7% in water) in excellent agreement with the reported (19, 20) values. This compound, injected as a solution in ethanol, showed four components on the gas–liquid chromatogram. Except for a higher column temperature (225° C) the conditions of chromatography were exactly the same as those described for the deamidation. The major component (75% of the mixture) crystallized after being

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

collected from the effluent gas and had m.p. 84–85° C, unchanged on admixture with methyl 3,6-anhydro-α-D-mannofuranoside (19) having m.p. 84–85° C and $[\alpha]_D^{26}$ +157° (*c*, 3.06% in water), in agreement with reported values. The other three products were present in about equal quantities (each about 8% of the mixture) and none of them was the initial compound. Only one of those three products crystallized; its melting point of 102–103° C indicated that it might be methyl 3,6-anhydro-β-D-mannopyranoside but there was insufficient material to confirm this. Methyl 3,6-anhydro-α-D-mannofuranoside showed only one peak on gas–liquid chromatography and was recovered unchanged from the effluent gas stream.

Acetal and Ketal Migration

A mixture of benzylidene glycerols was prepared according to Baggett *et al.* (21) and examined by gas–liquid chromatography under the following conditions: column—8 ft, 20% Carbowax 20M on Gas Chrom A, 100–150 mesh, 250° C. Four components were revealed with relative retention volumes of 1.00, 1.07, 1.21, and 1.81. The most mobile component (R_v = 1.00) crystallized when collected from the effluent gas and had m.p. 84.5–85° C unchanged on admixture with an authentic sample of *cis*-1,3-*O*-benzylidene glycerol (m.p. 84–85° C) prepared as described previously (21). On rechromatography the *cis*-1,3-*O*-benzylidene glycerol gave only one peak and was recovered unchanged from the effluent gas. Each of the other three components gave all four peaks when rechromatographed.

1,2:3,4:5,6-Tri-*O*-isopropylidene-D-mannitol, m.p. 70° C, was prepared as described by Wiggins (22); 1,2:5,6-di-*O*-isopropylidene-D-mannitol (23), m.p. 123–124° C, was obtained as a water-soluble by-product from preparation of the tri-*O*-isopropylidene derivative; 1,2:3,4-di-*O*-isopropylidene-D-mannitol, m.p. 37° C, was prepared by partial hydrolysis of the tri-*O*-isopropylidene derivative (22).

The di-*O*-isopropylidene-D-mannitols were examined by gas–liquid chromatography using an 8-ft column of 20% QF-1 on Chromosorb-W, 100–120 mesh, at 225° C. Each di-*O*-isopropylidene derivative gave a single peak with similar retention volumes and the products, collected from the effluent gas stream, showed depressed melting points. These products were acetylated separately in pyridine – acetic anhydride and the acetates were examined by gas–liquid chromatography. The material from 1,2:3,4-di-*O*-isopropylidene-D-mannitol showed four components with retention volumes relative to tri-*O*-isopropylidene-D-mannitol of 2.87 (1.5%), 3.47 (96%), 3.79 (0.5%), and 4.06 (2.0%). The material from 1,2:5,6-di-*O*-isopropylidene-D-mannitol yielded products with the same R_v values in yields of 3%, 13%, 8%, and 76% respectively. The product with R_v 3.47 was characterized as 1,2:3,4-di-*O*-isopropylidene-D-mannitol 5,6-diacetate by isolation of 1,2:3,4-di-*O*-isopropylidene-D-mannitol, m.p. 37° C, after deacetylation with barium methoxide. The product with R_v 4.06 crystallized when collected from the effluent gas and did not depress the melting point of 1,2:5,6-di-*O*-isopropylidene-D-mannitol 3,4-diacetate (23), m.p. 123° C. Products with R_v 2.87 and 3.79 were not identified. Each of the known di-*O*-isopropylidene-D-mannitol diacetates gave only one peak when examined separately by gas–liquid chromatography and each was recovered unchanged from the effluent gas stream.

Degradation of Acetylated Amino Sugars

2-Acetamido-2-deoxy-1,3,4,6-tetra-*O*-acetyl-α-D-glucose (24), m.p. 133–134° C, $[\alpha]_D^{25}$ +84° (*c*, 1.21% in chloroform), was examined by gas–liquid chromatography under the same conditions used for the acetals and ketals. One product emerged when the column was maintained at 225° C, and a second product appeared when the column temperature was raised to 270° C. The same two products were obtained from gas–liquid chromatography of the β-anomer, of the mixture from acetylation of *N*-acetyl-D-glucosamine in pyridine – acetic anhydride, and of the mixture from acetylation of *N*-acetyl-D-galactosamine by the same procedure.

The first product crystallized when collected from the effluent gas, m.p. 80–81° C, $[\alpha]_D^{27}$ −0.6° (*c*, 1.7% in methanol). Anal: Calc. for $C_{10}H_{11}O_4N$: C, 57.4%; H, 5.27%; N, 6.70%; for $C_{10}H_{12}O_4N$: C, 57.2%; H, 5.72%; N, 6.67%. Found: C, 56.8%; H, 5.54%; N, 6.50%. Analysis for *O*-acetyl showed the presence of two such groups: 40.95%, calc. 41.1%.

The infrared spectrum in potassium bromide showed the following absorption bands, (S)—strong, (M) medium, (W)—weak; frequencies (cm^{-1}): 3420 (M), 3140 (W), 2930 (W), 1733 (S), 1695 (S), 1655 (S), 1592 (W), 1555 (M), 1412 (M), 1377 (S), 1332 (M), 1305 (M), 1267 (M), 1255 (S), 1185 (W), 1105 (S), 1050 (S), 987 (M), 977 (W), 907 (M), 860 (M), 835 (W), 792 (M), 720 (M), 633 (W). The band at 1695 cm^{-1} was attributed to the C=N bond in an oxazoline ring (25).

τ values	Tentative assignment	τ values	Tentative assignment
8.59 (1H)		5.14 (2H)	7.82 (3H)		3.20, 2.93, 2.61, 2.34 (2H, quartet)	7.52 (3H)		2.23 (1H)	
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The 60 Mc/s nuclear magnetic resonance spectrum, measured on a Varian A 60 spectrometer, had peaks at the τ values given in the table, for which the tentative assignments shown were made.

The unknown compound readily decolorized a solution of bromine in carbon tetrachloride and yielded black tars in warm acid or alkali. It readily reduced Fehling's solution in the cold and gave negative tests with ninhydrin and Elson–Morgan reagents.

The second compound, obtained when the column temperature was raised to 270° C, has not been examined. However, it failed to crystallize when seeded with any of the initial products and therefore could not be any of the fully acetylated hexosamines.

ACKNOWLEDGMENTS

The authors wish to thank Dr. O. E. Edwards and Dr. L. D. Hall for their assistance in determining and interpreting the nuclear magnetic resonance spectrum. Dr. P. E. Gardner, Industrial Cellulose Research Ltd., Hawkesbury, Ont., prepared the methyl 3,6-anhydro-D-mannosides in this laboratory in connection with another project. One of the authors (R. K. M.) gratefully acknowledges a grant from the National Research Council of Canada.

THE ELECTRON DENSITY DISTRIBUTIONS IN HYDRIDE MOLECULES

III. HYDROGEN FLUORIDE[1]

R. F. W. BADER[2] AND G. A. JONES[3]

Department of Chemistry, University of Ottawa, Ottawa, Canada

Received April 2, 1963

ABSTRACT

An electron density distribution is determined for the hydrogen fluoride molecule in its equilibrium configuration by requiring the distribution to predict the correct dipole moment and to exert forces on the nuclei equal and opposite to the nuclear forces of repulsion. The ability of the density function to give good estimates of the expectation values of other one-electron operators is found to be satisfactory. It is shown that an electron population analysis of the orbital densities, when interpreted in terms of the electronic forces which these densities exert on the nuclei, is of value in the understanding of chemical binding.

INTRODUCTION

In two previous papers (1, 2) we have given the electron density distributions for the equilibrium configuration of the water and ammonia molecules as determined by the requirement that the densities exert forces on the nuclei which are equal and opposite to the nuclear forces of repulsion. In each case the general characteristics, e.g., hybridization and bond polarity, of the densities so obtained are in good agreement with the results obtained from S.C.F. calculations. In addition, the densities determined by the requirement of zero resultant forces provide expectation values for the one-electron operators which are in as good, or better, agreement with experiment as the values predicted by wave functions obtained from S.C.F. calculations. This points to the main reason for carrying out such calculations. It was felt that a reliable picture of the one-electron density could be readily obtained by requiring the distribution to reproduce a property which is itself determined directly by the one-electron density, i.e., the forces on the nuclei. The wave function derived from a variational calculation is obtained by minimizing the energy with respect to the second-order density distribution. Therefore, the resulting one-electron density is not necessarily the best possible one obtainable from the given basis set of orbitals. This was elegantly demonstrated by Mukherji and Karplus in their use of a constrained wave function for hydrogen fluoride (3).

In the present paper we determine the electron density distribution for the hydrogen fluoride molecule by requiring that it balance the forces on the hydrogen and fluorine nuclei and, in addition, give the observed dipole moment. It is worth noting that the criteria of zero resultant forces fixes the electric field due to the density in the region of each nucleus while the requirement of reproducing the observed dipole moment governs the overall disposition of the density in the molecule. The present results substantiate the previous ones in that good estimates are obtained by this method for those molecular properties which depend on the density. In addition, however, we wish to illustrate the advantage gained in the understanding and interpretation of the binding in molecules (4). Since the molecular forces are determined by the one-electron density, their discussion is rigorously carried out in terms of classical electrostatics, thus affording an excellent medium in which to interpret the nature of the binding in a molecule.

The Determination of the Density Distribution

The electron density is obtained in terms of the single determinantal L.C.A.O. M.O. approximation. The basis set includes $1s$, $2s$, and $2p$ atomic orbitals on fluorine (denoted by s_o, s, and p respectively) and a $1s$ orbital on hydrogen (denoted by h). The set is later extended to include d orbitals on the fluorine atom. The orbitals are assigned the orbital exponents determined by Ransil (5) in a S.C.F. calculation for the hydrogen fluoride molecule. By using these values (termed the B.L.M.O. set) a meaningful comparison of the S.C.F. and the present results may be made. The molecular orbitals written in the equivalent orbital form are: the fluorine atom inner shell orbital

$$\phi_o = c_o s_o + c_1 s + c_2 p,$$

the bond orbital

$$\phi_b = \lambda[\cos \epsilon_b\, s + \sin \epsilon_b\, p + c_3 s_o] + \mu h_o,$$

and three doubly occupied lone pair orbitals which we write as one sigma lone pair orbital along the bond axis and two π orbitals

$$\phi_l = \cos \epsilon_l\, s - \sin \epsilon_l\, p$$
$$\phi_\pi = p_\pi.$$

These latter three orbitals may of course be combined to give three equivalent lone pair orbitals. The angle the equivalent lone pair orbitals make with the bond axis will be determined by the relative amount of $2s$ and $2p$ in the ϕ_l orbital.* The symbols h_o and s in the above expressions denote orbitals orthogonal to the s_o orbital of fluorine.

The orbitals embody three independent parameters: ϵ_b, the bond hybridization parameter, ϵ_l, the corresponding parameter for the lone pair orbital, and the polarity factor λ/μ. These three variables are fixed by requiring the density to balance the two nuclear forces and duplicate the dipole moment. The remaining orbital coefficients are uniquely determined by the orthogonality conditions which are listed in the Appendix. The values of the parameters which satisfy the three conditions are given in Table I together with the

TABLE I

Parameters for the electrostatic and S.C.F. molecular orbitals for HF

	ϵ_b	ϵ_l	λ/μ	Force on H (a.u.)*	Force on F (a.u.)	Dipole moment (D)
Electrostatic method	112°46′	−6°0′	1.6845	−0.004	0.000	1.82
S.C.F. (4)	100°23′	6°41′	1.377	−0.084	−2.944	1.44

*A negative force is one in the same direction as the force of nuclear repulsion.

values of the same parameters obtained from the transformed S.C.F. calculation of Ransil (5).†

These parameters succinctly characterize the density distribution. The value of ϵ_l for the electrostatic density indicates that the sigma lone pair orbital is 99% $2s$ and 1% $2p$

For example, when $\epsilon_l = 0$, the equivalent lone pair orbitals are sp^2 hybrids in a plane perpendicular to the bond axis through the fluorine nucleus, and when $\epsilon_l = 30°$, the orbitals are sp^3 hybrids which project out behind the fluorine nucleus symmetrically placed around the bond axis at an angle of 70°32′ with this axis.

†*Equivalent orbitals are obtained from the 2σ and 3σ symmetry orbitals of Ransil by an orthogonal transformation which yields one orbital with no hydrogen contribution (the lone pair) and another containing all of the hydrogen contribution (the bond orbital). This results in a unique set of orbitals.*

in character. Since ϵ_l is negative, the small amount of $2p$ character present actually projects density towards the hydrogen atom rather than away from it. This gives three equivalent lone pair orbitals of almost sp^2 character (1.00 part $2s$, 2.03 parts $2p$) which make an angle of 86° with the bond axis, and are directed towards the H atom. Conceivably, the sigma lone pair orbital could possess an orbital character of either $2s$ or $2p$ or any intermediate hybrid. As previously pointed out (1) only the limiting $2s$ form for this orbital will result in a balanced force on either the fluorine or hydrogen nuclei. Any lone pair s–p hybridization on the fluorine atom in the conventional direction results in a large force on the fluorine nucleus in a direction away from the hydrogen. This same s–p polarization removes density from the binding region and places it behind the fluorine nucleus, thus resulting in a greatly decreased shielding with respect to the hydrogen nucleus. Of the two possible limiting forms $2s$ and $2p$, the lone pair will become a $2s$ orbital and the bond orbital will then be primarily $2p$ in character. This form for the bond orbital exerts a much larger binding force than does the $2s$ form (1). Similar results were obtained for the water and ammonia molecules, both of which were predicted to possess lone pair orbitals with the maximum possible amount of $2s$ character.

To reach the limiting $2s$ form for the lone pair orbital orthogonality restrictions require the introduction of negative $2s$ character into the bond orbital, i.e., $\epsilon_b > 90°$. In the water and ammonia molecules the amount of negative $2s$ character so introduced was reduced to a minimum by delocalization of the hydrogen $1s$ orbitals. No such mechanism is possible in the case of hydrogen fluoride and consequently a larger percentage (actually 15%) of negative $2s$ character must be included in the bond orbital. It is interesting, however, that the nuclear force on hydrogen can still be balanced in spite of the density removed from the binding region by this adverse polarization of the fluorine density. Such is not the case for water and ammonia, where the forces on hydrogen cannot be balanced for large negative values of $\cos \epsilon_b$. Thus, where delocalization is possible, it is found to be essential, and where not possible, not necessary in order to achieve electrostatic equilibrium. Actually the slight projection of the sigma lone pair orbital towards the hydrogen atom in hydrogen fluoride compensates for the reverse polarization in the bond orbital.

A large bond polarity λ/μ is necessary to meet the observed dipole moment. There is a small positive atomic dipole contribution from the reverse hybridization in the bond orbital but the major contribution to the dipole moment is due to removal of charge from hydrogen (small μ) to the fluorine (large λ). This again is similar to the previous results for water and ammonia where the dipole was found to be due almost entirely to the bond polarity. A density contour map of the electron density for hydrogen fluoride by the electrostatic method is shown in Fig. 1.

The general features exhibited by the S.C.F. density distribution are similar to those found from the electrostatic approach. Lone pair hybridization is unimportant (although the small amount of hybridization, $\epsilon_l = 6°41'$, predicted by the S.C.F. function has a very adverse effect on the forces). The bond orbital contains 3% negative $2s$ character. Polarity is significantly smaller, as reflected in the low value of the predicted dipole moment.

Duncan and Pople (15) determined density distributions for the hydrogen fluoride, water, and ammonia molecules by requiring the density to duplicate only the observed dipole moment. In all three cases their results predicted a large degree of hybridization for the lone pair electrons (approaching overall sp^3 hybridization in all three molecules). We have previously shown (1, 2) these results to be untenable for water and ammonia,

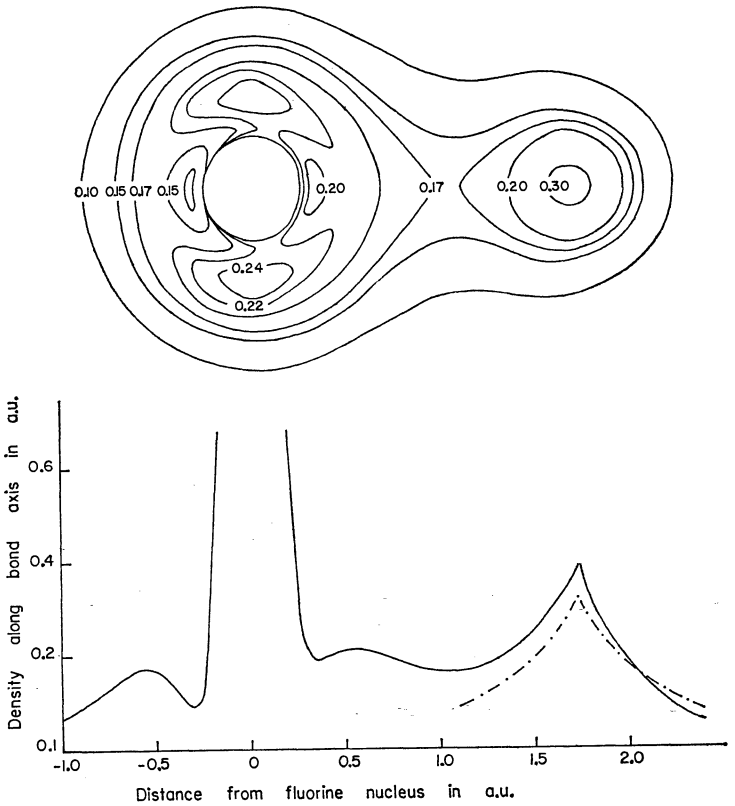

FIG. 1. The upper diagram gives lines of constant density in a plane through the hydrogen fluoride molecule, as determined by the electrostatic method. Only the valence orbital contributions are shown. The concentration of the lone pair electrons in p_π orbitals and in the $2s$ orbital leads to a pileup of density in the plane through fluorine perpendicular to the bond axis and an effective "hole" behind the fluorine nucleus. The lone pair density is concentrated toward the hydrogen nucleus, where it can exert a binding force on both nuclei.

Below the contour map is a graph showing the variation in electron density along the bond axis. The dotted line is the density distribution in an isolated hydrogen atom. It can be seen that the increased orbital exponent of the h orbital in the molecule tends to counteract the effect of a high bond polarity, so that the peak height at the proton is hardly changed on bond formation.

where such lone pair hybridization results in enormous forces of repulsion on all of the atoms in the molecule. The failure of their method in these two cases was due to their relating the degree of hybridization to bond geometry (i.e., not allowing for bent bonds or delocalization). In their treatment of hydrogen fluoride they exclude the possibility arrived at in this paper of three equivalent lone pair orbitals projected in a plane perpendicular to the bond axis through the fluorine nucleus (sp^2 hybridization). They do this on the grounds that such hybridization would of necessity lead to negative λ/μ values, i.e., correspond to an antibonding bond orbital. This is not a consequence, however, if one allows for negative values of cos ϵ_b as in the present treatment or as found in the S.C.F. wave function. (This can be seen from their equation number 4.2.) The distribution favored by Duncan and Pople has three lone pair orbitals of approximately sp^3 hybridization projected out behind the fluorine nucleus. This distribution results in large unbalanced forces of repulsion on both the hydrogen and fluorine nuclei. For the sp^3 case, the final force on the proton is -1 a.u. and on the fluorine nucleus is -13 a.u. These figures should be compared with those in Table I.

The electrostatic density distribution predicted for hydrogen fluoride agrees with the rule previously proposed (1): "in hydride molecules which possess at least one lone pair of electrons the bond orbitals will be primarily of p character and the lone pair orbitals will contain close to the maximum possible amount of s character". The "maximum possible amount of s character" corresponds in each case to the lone pair density being symmetrically placed with respect to a plane passing through the heavy nucleus and perpendicular to the main symmetry axis: sp^2 orbitals in HF, sp orbitals in H_2O, and an s orbital in NH_3. These forms for the orbitals do not exert any force on the heavy nucleus, and in addition they provide the maximum possible screening of the heavy nucleus from the protons. Any increase in p character from these lower limits displaces charge from the hydrogen side to the remote side of the F, O, and N nuclei and results in large imbalanced forces on both the hydrogen and heavy-atom nuclei.

It is always found that it is necessary to introduce inner shell polarization to an appreciable extent to balance the nuclear force of repulsion on the heavy atom in the hydride molecules with lone pair electrons. This polarization is brought about by including a $2p$ contribution in the inner shell orbital. In the present calculation the coefficient determining the amount of $2p$ so introduced (c_2) has a value of 0.069653.* This is larger than that predicted by variational calculations but it must be pointed out that the S.C.F. results for H_2O, NH_3, and HF all predict a resultant force on the heavy atom approximately equal to the full nuclear force of repulsion. Such a large discrepancy denotes a serious lack of flexibility in the basis orbitals chosen for the S.C.F. calculations. Because of the $1/r_i^2$ dependence of the forces, any inadequacy of the wave function in regions close to a heavy nucleus is emphasized more than in an energy calculation. The large value of c_2 found necessary for electrostatic equilibrium could be markedly reduced if an orbital which permitted polarization of the $1s$ density close to the heavy nucleus was included in the basis set. A good choice for such an orbital would be a "Kp" orbital, i.e. one of the form $\cos\theta\, e^{-\alpha r}$. Since this orbital, unlike the $2p$, has no pre-exponential radial dependence it peaks at the nucleus and, therefore, provides a much larger polarization and hence larger force than the same amount of $2p$. The present results and those for water and ammonia (1, 2) suggest that the inclusion of such an orbital will be necessary for obtaining wave functions from S.C.F. calculations which satisfy the criterion of electrostatic equilibrium.

Another form of polarization not represented in the basis set is that of $2p$ with $3d$. To be most effective these should be "shrunken" $3d$ orbitals, of the same radius as the $2p$ orbitals. In order to investigate the effect of $3d$ polarization by the present method it is necessary to ignore inner shell polarization as we have only three restraining conditions available. It is found that invoking $3d$ polarization cannot of itself enable the system to attain electrostatic equilibrium. The d_π or d_σ polarization removes density from the outermost regions of the fluorine atom and concentrates it in the region between the nuclei. This displaced density increases the force on the hydrogen nucleus as well as the force on fluorine. Regardless of the values assigned to the other parameters the amount of $3d$ polarization necessary to balance the force on fluorine always results in too large a force on the proton. On the other hand, inner shell polarization can be introduced to balance the force on fluorine without greatly changing the force on the proton and thus the system can attain electrostatic equilibrium. This is due to the fact that inner shell polarization displaces charge close to the fluorine nucleus rather than moving it into the overlap

*We previously reported values of c_2 for the water and ammonia molecules about a factor of 10 less than the present value. This is due to our neglect of the overlap between the heavy atom 1s orbital and the hydrogen 1s orbital. When this overlap is taken into consideration the c_2 values are comparable to that obtained for HF but the remaining parameters in the H_2O and NH_3 densities remain unchanged.

region. In a fuller treatment using this extended basis set, the $3d$ orbitals may provide part of the shielding obtained by negative lone pair hybridization in the present treatment. Sternheimer (6) has calculated the electric field at various nuclei in atoms and ions when they are subject to an external perturbing field. He concluded that inner shell polarization was very important for the alkali atoms (7), but in the negative fluoride ion (8) he found that the largest contribution to the electric field came from a p–d type perturbation. In the latter treatment the inner shell was approximated by a Slater $1s$ orbital as opposed to the Hartree-Fock orbitals employed for the valence electrons. Sternheimer estimated an error of $\pm 20\%$ in the inner shell contribution as a result (8), but since this contribution was small compared to those of the s–p, p–s, or p–d perturbations, the final result was not affected. It seems therefore that $3d$ polarization is much more important in the diffuse negative ion than in the neutral fluorine atom taking part in bond formation.

A Force Analysis of the Wave Functions for HF

An investigation of the forces exerted by an electron density distribution provides insight into the nature of molecular binding (4). When the L.C.A.O. approach is used in the construction of molecular orbitals the resulting density expression will consist of a sum of products of atomic orbitals of the form $c_i c_j \phi_{i\alpha}\phi_{j\beta}$ where c_i and c_j are the orbital coefficients and ϕ_i and ϕ_j denote the type of orbital ($1s$, $2s$, etc.) situated on nucleus α or β. We thus obtain the three basic electron populations, the atomic population terms $\phi_{i\alpha}\phi_{j\alpha}$ or $\phi_{i\beta}\phi_{j\beta}$ and the overlap population $\phi_{i\alpha}\phi_{j\beta}$. Each of these three electron populations gives rise to its own distinct contribution to the force acting on a particular nucleus.

Atomic Force

The atomic force is the force exerted on nucleus α by the density $\phi_{i\alpha}\phi_{j\alpha}$. If $\phi_{i\alpha}\phi_{j\alpha}$ possesses a center of symmetry, then this density will not exert a force on nucleus α. However, the introduction of any asymmetry, due to hybridization or polarization, gives rise to a force on nucleus α. Consequently the atomic force term is sensitive to the degree of charge polarization on a nucleus.

Penetration Force

The penetration force is the force exerted on nucleus α by the atomic charge density situated entirely on another nucleus, $\phi_{i\beta}\phi_{j\beta}$. It is a measure of the electronic shielding of nucleus β from nucleus α and the amount of this shielding is determined by the extent to which nucleus α penetrates the density around β. When $\phi_{i\beta}\phi_{j\beta}$ possesses spherical symmetry the penetration force has a particularly simple physical interpretation. It can be shown from a well-known theorem of electrostatics that the total force exerted on α by a spherical charge density on β is simply the force that would be exerted by that density contained within a sphere of radius d (the bond length) if all this charge was situated at nucleus β. Thus the penetration force due to spherical orbitals is numerically equal to the number of electrons contained in a sphere of radius equal to the bond length, all divided by d^2. As d decreases, a smaller fraction of the electrons is contained in the smaller sphere and nucleus β is less shielded from nucleus α. The density of tightly held inner shell electrons lies completely within the sphere defined by the bond length and thus they effectively screen an equal number of nuclear charges. The more diffuse valence shell electrons do not. The electron density in a p_σ orbital on β, since it places charge along the bond axis, exerts a shielding force greater than the same amount of density spherically disposed. Electrons in p_π orbitals, on the other hand, are less effective than s electrons at shielding since their density is principally directed perpendicular to the bond axis. As would be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

anticipated a closed shell in which all the orbitals have the same orbital exponent, i.e. a $ns^2np_\sigma^2np_\pi^4$, acts as a spherical distribution and the force is simply eight times that of a single electron in an ns atomic orbital.

Overlap Force

The overlap force is the force on nucleus α due to the density $\phi_{i\alpha}\phi_{j\beta}$ resulting from the overlap of the two atomic orbitals. This force term is a sensitive measure of the binding power of a molecular orbital. The binding is not simply proportional to the extent of overlap, of equal importance is where this density is placed. Thus a $2s1s$ overlap is larger than is a $2p1s$ overlap, but the latter is much more effective at binding since more of the overlap charge density is placed along the bond axis, where it exerts the maximum force.

We shall illustrate the advantages of a force analysis by applying the method to Ransil's S.C.F. results for hydrogen fluoride. We consider the forces exerted on the hydrogen atom first. The forces due to the atomic and overlap populations for each of the symmetry orbitals are given in Table II. Since the atomic density on hydrogen possesses spherical

TABLE II

Forces on the proton in HF (S.C.F. density) in a.u. of $(1/d^2)$

Orbital	Penetration force P_H	Overlap force O_H	Electronic force	Nuclear repulsion	Net force
1σ	2.00	0.00	2.00	−2.00	0.00
2σ	1.77	0.38	2.15	−2.00	+0.15
3σ	0.97	0.57	1.54	−1.00	+0.54

Total	7.81	0.95	8.76	−9.00	−0.24

symmetry ($1s$ orbital) there are no atomic force contributions in this case. Great simplification is achieved by omitting the factor $1/d^2$ from the numerical values of the forces. The nuclear repulsion is then simply $-Z_FZ_H = -9$. The sum of the electronic forces must equal minus this same number to attain electrostatic equilibrium. In the case of the separated atoms where there is no penetration each electron shields one unit of nuclear charge and the net force is zero.* We therefore break up the total nuclear repulsion of -9 into contributions for each orbital as determined by the shielding each orbital would exert in the case of the separated atoms. Consider the 1σ orbital. This orbital is made up almost entirely from the $1s$ orbital on fluorine. The pair of electrons in this orbital is very tightly held by the fluorine nucleus as is evidenced by the fact that the penetration force equals simply 2.000. Thus these two electrons effectively shield 2 units of positive charge on the fluorine nucleus from the hydrogen nucleus. The overlap force term in this case is insignificant and the net force due to this orbital and its share of the nuclear charge is zero. That is, in the separated atoms or in the molecule the inner shell orbital on fluorine simply acts to shield two units of nuclear charge, exerting no resultant force on the hydrogen nucleus. This is termed a *nonbinding* orbital in accordance with the definition previously proposed (4).

In the limit of separated atoms the 2σ orbital becomes the doubly occupied $2s$ orbital on fluorine and so is again assigned two units of the nuclear repulsion. The penetration of this charge density by the proton is much greater than in the 1σ case as evidenced by

**There would be a small quadrupole force operative due to the fact that fluorine does not have a closed-shell structure.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the value for $P_H(2\sigma)$ being less than 2. However, this loss is offset by the gain in force due to the density transferred to the overlap region. The net force is +0.15, which thus makes the 2σ orbital a *net-binding* orbital. The fluorine contribution to the 3σ orbital in the limit of separated atoms becomes a singly occupied $2p$ orbital. Thus it is assigned a corresponding nuclear repulsion of −1 unit. The molecular orbital of course contains two electrons, but of these one is gained from the hydrogen in bond formation. Thus the penetration for the 3σ orbital is to be measured against −1 and due to the large p character of this orbital it is seen to approach this limiting value quite closely. In addition, there is a large overlap force which points to this orbital as being the main source of the binding of the proton in the hydrogen fluoride molecule. An analysis of the 2σ and 3σ orbitals in terms of Mulliken's method of overlap populations (9) leads to the opposite conclusion. In such an analysis the bonding character of an orbital is related to the magnitude of the overlap population irrespective of where this overlap density is placed. The $2s$ orbital of fluorine, which is the main constituent of 2σ, has a larger numerical overlap with hydrogen than does the $2p_\sigma$ orbital found primarily in the 3σ orbital. Thus the 2σ orbital is found to have the highest overlap population and is thus rated as being the most strongly bonding orbital. As was pointed out in the discussion of the overlap forces, the $2p_\sigma$ overlap, while numerically less than the $2s$ overlap, concentrates the overlap density along the bond axis, where it exerts a much greater force on the proton than does the $2s$ overlap density. Thus the force analysis which relates the strength of binding not to the density itself but to the actual force exerted by the density leads to the conclusion that the 3σ orbital is the orbital principally responsible for binding the proton in the hydrogen fluoride molecule. The 3σ orbital is again a net-binding orbital, as the resultant force is one which draws the two nuclei together.

The degenerate p_π orbitals have no overlap with the hydrogen and are thus restricted to a penetration force. Out of the four units of nuclear charge they shield in the separated atoms, only approximately three of these are shielded at the equilibrium bond length. These orbitals thus give a net force of −1, which tends to push the two nuclei apart. The p_π orbitals are, therefore, net *antibinding*. Since Ransil's wave function does not predict a zero resultant force for the hydrogen nucleus the total electronic force does not equal the total nuclear force in this case as can be seen from the totals given in the last row of the table. The totals of the separate force contributions are of some interest. The density in the overlap population exerts 11% of the total electronic force which binds the proton in HF. The other 89% of the binding is due entirely to the density on the fluorine nucleus. It should be recalled that at infinite separation $P_H = 9.00$ and $O_H = 0.00$. Thus in forming the molecule the proton penetrates the fluorine atom density to the extent that effectively only 7.8 of the nuclear charges are screened but there is an accompanying transfer of density to the binding region which gives rise to the overlap forces and thus to the formation of a stable molecule. Table III gives the corresponding breakdown for the forces on hydrogen obtained in terms of equivalent orbitals by the electrostatic method. If Ransil's orbitals are transformed into equivalent orbitals, the 2σ and 3σ orbitals become the ϕ_l and ϕ_b orbitals. The ϕ_o and p_π orbitals give almost identical results in the two cases (the p_π's exactly so). Thus to compare the densities we may compare the sum of the contributions of ϕ_b and ϕ_l with those from 2σ and 3σ. The electrostatic density is seen to predict a greater shielding of the fluorine nucleus, actually giving a result of 3.21, which is greater than the 3 units of nuclear charge associated with these two orbitals in the separated atoms. This is obtained by a large λ/μ value, removing charge from hydrogen and placing it on the fluorine atom in the bonding orbital, and by

Total	−2.117	1.652	0.483	0.018

both the electrostatic and S.C.F. densities. As previously stated, the S.C.F. calculation falls far short of predicting a zero resultant force on the fluorine nucleus. The principal reason for this is the large negative atomic force due to the *sp* hybridization in the sigma lone pair orbital. In the electrostatic calculation this atomic force term is of positive sign (due to the negative value for ϵ_l). These figures illustrate the great sensitivity of the force on a heavy nucleus to atomic polarization of the charge density. Any hybridization must be proposed with care as it results in exceedingly large forces acting on the nucleus in question.

The Calculation of the Molecular Properties Determined by the One-electron Density

Many of the moments of hydrogen fluoride which can be compared to observed properties of the molecule have been calculated by Karplus and Lipscomb and co-workers (10–13). They found that wave functions which gave reasonable estimates of energies did not necessarily yield good estimates of these properties. A method of "constrained" variation calculations was suggested by Karplus and Mukherji (3). In this approach it was required that integrals of certain operators agreed with the known values for the corresponding properties. It was hoped that the resultant increase in energy would be more than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

compensated for by an increase in the accuracy with which other one-electron operator functions could be calculated. The method was applied to hydrogen fluoride, by modifying the 'best limited' wave function obtained by Ransil. Karplus and Mukherji chose as constraining functions the dipole moment and the electric field gradient at the deuteron in DF. They found that the diamagnetic and paramagnetic contributions to the susceptibility were in better agreement with experiment; the calculated diamagnetic proton shielding constant decreased, but no accurate measurement is available for comparison; the force on the hydrogen nucleus approached closer to zero, but the force on fluorine increased. The significance of their results is clear: for the first time it has been demonstrated that, starting with a given set of basis orbitals, that wave function which gives the best energy does not necessarily predict the best values of all other properties.

It was concluded from the anomalous value predicted for the force on the fluorine nucleus that "considerably greater distortion of the fluorine atom wave function than that permitted by limitations in the basis set appears to be required". However, the inner shell orbital was left unchanged in the constrained treatment on the grounds that a variation of its coefficients would result in a large increase in energy and only a small change in the dipole moment and field gradient. The present calculations indicate that the force on fluorine would greatly improve if such a variation was included.

It is possible to compare three wave functions using the same basis set of orbitals but derived under the following criteria:

(i) the minimum energy criterion of the variation method (Ransil);

(ii) the same, with the additional requirements that $\langle P_2/r_D^3 \rangle$ and $\langle P_1 r \rangle$ give the correct values (Karplus and Mukherji);

(iii) the criterion of electrostatic equilibrium, which requires $\langle P_1/r_H^2 \rangle$ and $\langle P_1/r_F^2 \rangle$ to be correct, with the dipole moment criterion of $\langle P_1 r \rangle$.

The properties calculated from these functions are listed in Table V. Two densities are given for the electrostatic method to illustrate how the properties change with lone pair hybridization. On transforming the constrained function it is found that $\epsilon_1 = 8.5°$ compared to 0° and $-6°$ for the best electrostatic densities. These latter three functions all have the correct dipole moment and therefore the same polarity of $\sim$1.6, compared to a λ/μ of 1.38 for the Ransil function.

Forces and Deuteron Quadrupole Coupling Constant

The forces for the electrostatic case are equal to or close to zero since they were used to fix the densities. The difference between the forces predicted by the other two functions can be explained in terms of the parameters describing them. Since more lone pair hybridization is predicted by the constrained function than by Ransil's, the force on fluorine increases. However, the force on hydrogen is more sensitive to the change of polarity than to this small increase in ϵ_1 and it consequently improves. The reason for this unfavorable change in the lone pair hybridization in the constrained function can be found in the criterion of meeting the deuteron quadrupole coupling constant.

Kolker and Karplus (12) have discussed the contribution to this constant from different atomic orbitals on fluorine in relation to the corresponding nuclear contributions. They found that the 1*s* electrons exactly shield their share of charge while the $2p_\pi$ electrons only shield about two-thirds of the corresponding nuclear charge. Thus both the field and the field gradient at the nuclei, as measured by the forces and the quadrupole coupling constants respectively, are sensitive to the same parameters. The same factors tend to increase or decrease the electronic contribution to both the field and the field gradient

*Apart from the deuteron quadrupole coupling constant, all moment results listed for the constrained function and for Ransil's function have been checked by an independent evaluation of integrals.

†J. W. C. Jones and R. F. Barrow. Proc. Roy. Soc. (London), Ser. A, **251**, 504 (1959).

‡R. Weiss. Abstracts of 6th Brookhaven Conference on Molecular Beams, June, 1962.

§The diamagnetic contribution was calculated from the fluorine nucleus as origin. R. P. Hurst, M. Karplus, and T. P. Das, J. Chem. Phys., **36**, 2786 (1962), calculated the corresponding paramagnetic term from the results of M. R. Baker, C. H. Anderson, J. Pinkerton, and N. F. Ramsey, Bull. Am. Phys. Soc., **6**, 19 (1961), on the rotational magnetic moment of HF. The total susceptibility was measured by P. Ehrlich, Z. Anorg. Allgem. Chem., **249**, 219 (1942). Combining these leads to the "experimental" value quoted.

‖The paramagnetic part of the shielding constant is −79.6±0.5 p.p.m. as determined by S. I. Chan and T. P. Das, J. Chem. Phys., **37**, 1527 (1962), from the spin rotational constants measured by N. F. Ramsay, Am. Scientist, **49**, 509 (1961). The proton was taken as the origin for the diamagnetic part.

¶Q_D was taken as 2.82×10^{-27} cm² (J. P. Auffray. Phys. Rev. Letters, **6**, 120 (1961)). The experimental determination of the coupling constant of DF was made by H. M. Nelson, J. A. Leavitt, M. R. Baker, and N. F. Ramsey, Phys. Rev., **122**, 856 (1961).

**The result for the force on fluorine for Ransil's function was slightly in error in the work of Karplus and Mukherji (3). The authors agree with the present value.

at the proton. As the lone pair hybridization decreases (other factors being equal) both these quantities decrease. At $\epsilon_1 = 8.5°$ the calculated coupling constant reproduces the experimental value, but the force on hydrogen is too large; at $\epsilon_1 = -6°$ the force on hydrogen is correct, but the calculated coupling constant is lower than the experimental value. The chosen value of the deuteron quadrupole coupling constant is subject to experimental error and the calculated value is subject to an uncertainty in Q_D (12). Thus the deuteron quadrupole coupling constant would seem to be a less reliable criterion of the density distribution than that of electrostatic equilibrium.

Diamagnetic Susceptibility

The diamagnetic contribution to the susceptibility of hydrogen fluoride (χ_d) is determined by $\langle r_F^2 \rangle$ and therefore by the density in the region of the proton, where r_F is large. Changes in hybridization of the fluorine atom would have little effect on this property. The factors which determine the density at the hydrogen nucleus are the polarity and the orbital exponent of the $1s$(H) orbital. A low polarity and a small orbital exponent both increase this density and, as a result, χ_d. The first effect is illustrated by the results in Table V. Both the constrained function and the electrostatic functions have the correct dipole moment and give very good estimates of χ_d. The S.C.F. density has a low polarity, as shown by the dipole moment, and predicts too large a value for χ_d. It can be concluded from these susceptibility calculations that the electrostatic function with $\epsilon_1 = 0$ gives the best representation of the density at hydrogen. However, the lack of an error estimate for the experimental determination detracts from the significance of the agreement with this particular point.

Proton Shielding Constant

No accurate measurement of the proton chemical shift of gaseous hydrogen fluoride is available, due to experimental difficulties (12). The shielding constant of gaseous methane is 3.01×10^{-5} and that of unassociated hydrogen fluoride is within 2 p.p.m. of this value. The results given in Table V indicate that the chemical shift is very small relative to methane. Perhaps this is the reason for the failure of Schneider and co-workers (14) to observe a signal due to gaseous HF relative to methane. Again the constrained density and electrostatic densities give very similar results while the S.C.F. density predicts a larger value. The latter can be attributed to the low polarity predicted by the straight energy calculation. Since the shielding constant measures the amount of density right at the nucleus, while the susceptibility is determined by that density in the general region of the proton, it is less sensitive to polarity than it is to choice of orbital exponent.

Dipole Moment

The importance of the dipole moment in determining molecular properties is apparent from these results, particularly if they are compared to those calculated from the simple "Slater atom" and "best atom" orbitals (11, 12) which predict very low dipole moments. A wave function predicting the correct dipole moment for which the hydrogen orbital exponent has been optimized might be expected to always yield good estimates of the diamagnetic susceptibility and proton-shielding constant. The field and field gradient are more sensitive than these properties to the details of the electron distribution on each nucleus, but still need an accurate estimate of the polarity to yield the correct results.

The calculations of the molecular properties support our thesis that the forces and dipole moment provide a good test of the overall density distribution. A density satisfying these criteria will also yield good estimates of the other one-electron properties discussed above.

ACKNOWLEDGMENTS

We wish to thank the Computing Centre at the University of Ottawa for their assistance and machine time on the I.B.M. 650 used in these calculations. We are also grateful to Mr. Peter Sefton for his mathematical assistance and to Professor Martin Karplus for the integrals used in the calculation of the deuteron quadrupole coupling constant.

APPENDIX

The requirement of orthogonality between the orbitals gives rise to three orthogonality conditions. In these, S_2 and S_3 are the overlaps of h_o with the s and p orbitals on fluorine.

Bond – lone pair condition:

$$[1] \qquad \tan \epsilon_1 = \frac{\lambda/\mu \cos \epsilon_b + S_2}{\lambda/\mu \sin \epsilon_b + S_3}.$$

Bond – inner orbital condition:

$$[2] \qquad \lambda[c_1 \cos \epsilon_b + c_2 \sin \epsilon_b + c_o c_3] + \mu[c_1 S_2 + c_2 S_3] = 0.$$

Lone pair – inner orbital condition:

$$[3] \qquad c_1 \cos \epsilon_1 - c_2 \sin \epsilon_1 = 0.$$

Normalizations of the inner orbital and bond orbital yield the additional equations

$$[4] \qquad c_o^2 + c_1^2 + c_2^2 = 1$$

and

$$[5] \qquad \lambda^2[1 + c_3^2] + \mu^2 + 2\lambda\mu[\cos \epsilon_b S_2 + \sin \epsilon_b S_3] = 1.$$

The limiting case of no inner shell polarization occurs when $c_2 = 0$. It follows from equations [2], [3], and [4] that $c_3 = c_1 = 0$ and $c_o = 1$. This set of orbitals was used by Duncan and Pople (15) in their calculations on hydrogen fluoride, with the difference that h was not orthogonal to the inner shell s_o orbital. As a result the overlap integrals were defined differently in the expression they gave for the bond orthogonality with an equivalent lone pair orbital.

Machine computation was employed to calculate the parameters and the resulting forces and dipole moment. The three variable parameters chosen for input data were ϵ_1, λ/μ, and c_3; then the above equations sufficed to find the remaining parameters. In order to solve for ϵ_b, the sin and cos terms in equation [2] were expressed in terms of tan $(\epsilon_b/2)$.

Integrals

All of the force integrals were obtained from analytical expressions listed in ref. 16. They are given in units of $1/d^2$ and therefore have to be divided by 3.00329 to obtain the absolute values. The symbols s' and h refer to Slater $2s$ and $1s$ orbitals on fluorine and on hydrogen respectively. In the overlap force integrals $O(\phi_\alpha,\phi_\beta)$ refers to the force on nucleus α.

Overlap integrals

$S(s_o,s') = 0.2332215$ $S(h,s_o) = 0.0487047$ $S(h,s') = 0.438805$
$S(h,p_\sigma) = 0.334687$

A NEW SYNTHETIC APPROACH TO THE BENZO[*c*]PHENANTHRIDINE SYSTEM: INTERNUCLEAR CYCLIZATION ONTO A PYRIDINE RING

R. A. ABRAMOVITCH AND G. TERTZAKIAN[1]
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan
Received April 5, 1963

ABSTRACT

Benzo[*c*]phenanthridine has been synthesized in low overall yield by the Pschorr cyclization of *trans*-α-(4-isoquinolyl)-*o*-aminocinnamic acid. The condensation of 4-isoquinolylacetonitrile with *o*-nitrobenzaldehyde gave the *cis*-cinnamonitrile. The preparation of a number of intermediates is described.

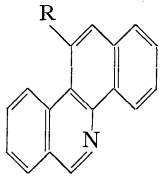
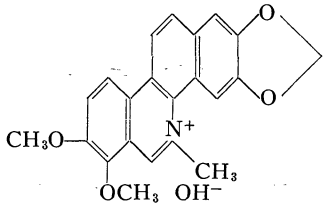
For personal use only.

The benzo[*c*]phenanthridine ring system (I) is found in a number of alkaloids such as chelidonine, chelerythrine, and sanguinarine (1). A number of these and their derivatives have been synthesized (2–4) starting from an alicyclic system, the nitrogen-containing ring being built up in the course of the synthesis. Current interest in chelerythrine (III) stems from its synergistic effect in enhancing the cancer chemotherapeutic action of colchicinamide (5). It was decided to develop a more flexible synthesis of the ring system which would permit the introduction of various substituents into the nucleus, and to use the Pschorr cyclization to achieve this end.

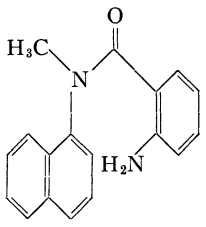


I, R = H
II, R = CO_2H

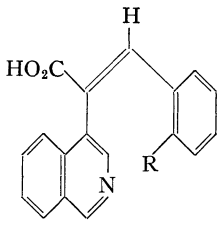


III

There have been a number of attempts made to apply a Pschorr type of ring closure to the synthesis of this ring system (6–8) but these failed in each case. The diazotization and subsequent decomposition of 2-amino-*N*-methylbenzo-1′-naphthalide (IV) was studied in detail by Hey and Turpin (9). No benzophenanthridone was formed, the only identifiable product being benzo-1-naphthalide, which results from the demethylation and deamination of IV. In the present work the cyclization of *trans*-α-(4-isoquinolyl)-*o*-aminocinnamic acid (V) to II, which would involve an internuclear attack onto a pyridine ring, has been studied.



IV



V, R = NH_2
VI, R = NO_2

It had been suggested (10) that the pyridine ring is more difficult to attack than a benzene ring in such reactions, a conclusion based on the fact that poor yields had been obtained in two examples studied (11, 12). It was shown, however, that under suitable conditions excellent yields of cyclized products resulting from attack onto a pyridine ring may be obtained (13). Another example of such a cyclization has been reported more recently (14). There seemed, therefore, to be no reason to suppose that the cyclization of V would not take place, provided the necessary amine having the right geometry could be prepared.

The route chosen initially for the preparation of V was the straightforward one involving the Perkin condensation of *o*-nitrobenzaldehyde with 4-isoquinolylacetic acid (VII) (15). Various attempts were made to prepare VII or its ethyl ester or anilide via an Arndt-Eistert homologation of isoquinoline-4-carboxylic acid. Though an acid chloride hydrochloride could be readily obtained from the latter and treatment of this with an excess of diazomethane gave a yellow crude diazoketone in no case could any of the required rearrangement products be obtained. This may be due to the fact that the acid chloride hydrochloride is insoluble in ether and is used in the form of a suspension. It could have been, then, that a coating of diazoketone was formed which prevented further reaction with the diazomethane. On the other hand, the infrared spectrum of the solid yellow product exhibited bands characteristic of a diazo group (2115 cm^{-1}) but not of the starting acid chloride hydrochloride. In any event, this route to the acetic acid had to be abandoned. An attempt was made to condense 4-bromoisoquinoline or its *N*-oxide with diethyl sodiomalonate under a variety of conditions: in no case did any reaction take place.

4-Isoquinolyl methyl ketone (VIII) could be prepared (in 20% yield) in one step from 4-aminoisoquinoline using the Beech reaction (16). This is a more convenient procedure than that which requires the preparation of the β-ketoester from ethyl isoquinoline 4-carboxylate followed by ketonic hydrolysis (17): the overall yields are of the same order of magnitude but many more steps are required in the latter procedure. When the methyl ketone (VIII) was subjected to a Willgerodt reaction only a low yield (9%) of ethyl 4-isoquinolylacetate was obtained. Other approaches were therefore investigated. Ethyl isoquinoline 4-carboxylate was reduced to the alcohol (IX) with lithium aluminum hydride and the latter oxidized to the corresponding aldehyde (X) with manganese dioxide in benzene. Various attempts were made to condense X with *o*-nitrophenylacetic acid but without success. Though condensation with oxindole took place no pure product could be obtained. A very low yield of 5-(4′-isoquinolylidene)-2-phenyloxazolone was obtained from the reaction of X with hippuric acid, so that this route was also not pursued further.

4-Isoquinolylmethanol (IX) was converted into its hydrochloride, which, with thionyl chloride, gave 4-chloromethylisoquinoline hydrochloride. The latter gave moderate yields of 4-isoquinolylacetonitrile (XI) when treated with sodium cyanide in either aqueous ethanol (18) or dimethyl sulphoxide (19). The moderate to low yields are probably due to a certain amount of polymerization of the free 4-chloromethylisoquinoline formed

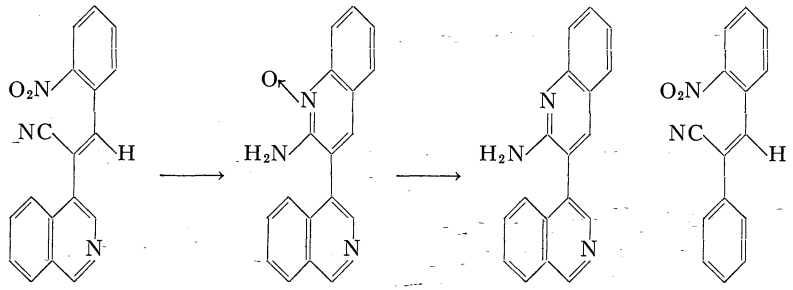
when its hydrochloride reacted with the basic sodium cyanide. The yields reported for the analogous synthesis of 3-pyridylacetonitrile are also not high (18, 20). The condensation of 4-isoquinolylacetonitrile with *o*-nitrobenzaldehyde in acetic anhydride in the presence of triethylamine gave the α-(4-isoquinolyl)-*o*-nitrocinnamonitrile, of unknown geometry, in good yield. Catalytic reduction of this led to absorption of two molar equivalents of hydrogen and the formation of a product, $C_{18}H_{13}N_3O$, m.p. 261°, in quantitative yield. The same substance was obtained when the cinnamonitrile was reduced with hydrazine and Raney nickel. This product was soluble in acid but not in base; it effervesced on attempted diazotization and the resulting solution did not give a coupling product with alkaline β-naphthol. It was unaffected by prolonged boiling with acid or with base. The absence of a cyano group was confirmed by the fact that no band was present in the infrared at about 2200 cm^{-1}; the bands observed at 3350 and 1625 cm^{-1} were attributed to N—H and C=N groups respectively. The reduction product gave a positive test for *N*-oxides (21), and on further reduction with stannous chloride in acetic acid saturated with hydrogen chloride, or on heating with ferrous oxalate (22), gave a primary amine, $C_{18}H_{13}N_3$, m.p. 253° (positive carbylamine test). The cinnamonitrile has, therefore, the undesired cis configuration (XII) and, on reduction, gives the amine oxide (XIII). Deoxygenation of this gives 2-amino-3-(4′-isoquinolyl)quinoline (XIV). That diazotization of the 2-amino group does not take place normally is now understandable. This sequence of reactions is not exceptional since Pschorr and Wolfe (23) found that reduction of the product (XV) of condensation of phenylacetonitrile and *o*-nitrobenzaldehyde gave



XII XIII XIV XV

2-amino-3-phenylquinoline; XV must thus also have the cis configuration. An attempt was made to isomerize XII to the trans form by irradiating its benzene solution in a quartz vessel with ultraviolet light. No isomerization appeared to take place.

The most convenient method for the conversion of the nitrile (XI) to the required acid (VII) was to hydrolyze XI to the amide, which, on treatment with nitrous acid, gave VII in good yield. Lower yields were obtained by ethanolysis or complete hydrolysis of XI. Condensation of VII with *o*-nitrobenzaldehyde gave the expected *trans*-cinnamic acid (VI), which was reduced to the amine (V) with ferrous sulphate and ammonia. Diazotization and cyclization in the presence of copper powder gave the expected benzo[*c*]phenanthridine-11-carboxylic acid (II) in 50% yield. The crude acid was readily decarboxylated to benzo[*c*]phenanthridine. The overall yield of I from 4-bromoisoquinoline was of the order of 1%, though the individual steps gave yields of at least 50%. Had the Arndt-Eistert reaction given the required acid this synthetic sequence would have been rendered much more attractive. The method should still be useful for the synthesis of substituted benzo[*c*]phenanthridines which may not be readily available using the Bailey–Robinson approach.

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were recorded on a Perkin–Elmer Model 21 spectrophotometer using sodium chloride optics. The main peaks only are reported. Unless otherwise specified, light petroleum refers to the fraction boiling between 36° and 48°, which was purified by stirring with concentrated sulphuric acid followed by distillation.

Attempted Arndt-Eistert Reactions

Isoquinoline 4-carboxylic acid (24) (3 g) was dissolved in warm ethanol (50 ml) and hydrogen chloride bubbled through the solution for 1 hour. The hydrochloride (3.6 g), m.p. 310°, was filtered, washed with absolute ethanol, dried, and boiled under reflux with thionyl chloride (12 ml) for 1½ hours. Benzene (30 ml) was added to the reaction mixture to precipitate isoquinoline 4-carboxylic acid chloride hydrochloride (3.8 g), m.p. > 310°. The solid was washed with dry benzene and dried. Infrared spectrum (KBr disk): 1745 (s), 1710 (s), 1580 (m), 1360 (m), 1225 (m), 1055 (m), 790 (w), 777 (w), and 745 cm^{-1} (m).

The acid chloride hydrochloride (1 g) was suspended in anhydrous ether (50 ml) and the suspension gradually added, with vigorous stirring, to a solution of diazomethane (from 4 g of *N*-nitroso-*N*-methylurea) in ether (50 ml) cooled to 5°. Nitrogen was evolved and initially some of the acid chloride dissolved, but most of the added solid turned yellow. The mixture was stirred for a further hour, the ether evaporated, and the yellow diazoketone used directly in the next step. Infrared spectrum (KBr disk): 2990 (m), 2115 (m), 1730 (m), 1685 (s), 1618 (s), 1465 (s), 1125 (m), 877 (m), and 760 cm^{-1} (m). The above diazoketone in ethanol (60 ml) was stirred and treated with a slurry of silver oxide (from 600 mg of silver nitrate) in ethanol (30 ml). The mixture was stirred at 60–70° for 4 hours, and then boiled under reflux for 1 hour. A silver mirror formed on the walls of the flask and the solution turned brown. The solvent was filtered and evaporated and the brown amorphous residue (0.50 g) extracted with benzene (0.15 g was insoluble). The solution was chromatographed on a column of alumina (30 g) but no pure product could be isolated. Similar intractable amorphous solids were obtained when, for instance, aqueous dioxane containing aniline was used to decompose the diazoketone.

4-Bromoisoquinoline 2-Oxide

A solution of 4-bromoisoquinoline (5 g) in acetic acid (10 ml) containing hydrogen peroxide (30%, 3 ml) was heated at 60–70° for 4 hours, a further amount of hydrogen peroxide (3 ml) was added, and heating continued for another 15 hours. The solution was evaporated under vacuum and the residue dissolved in chloroform (10 ml) and boiled under reflux with an excess of solid sodium carbonate for 30 minutes. The suspension was filtered, the solid washed with chloroform, and the combined filtrates evaporated to dryness. Ethyl acetate (0.5 ml) was added; when the sides of the flask were scratched with a glass rod nearly white crystals of *4-bromoisoquinoline 2-oxide* (0.5 g) separated which, after recrystallization from ethanol, had m.p. 182–183°. (Calc. for C_9H_6NOBr: C, 48.22; H, 2.68. Found: C, 48.47; H, 2.63.) Infrared spectrum (Nujol mull): 1597 (m), 1470 (m), 1355 (s), 1177 (s), 1130 (s), 765 (m), and 755 cm^{-1} (m). Evaporation of the ethyl acetate mother liquor gave 4-bromoisoquinoline (4.5 g) as a pale yellow oil which crystallized on standing and had m.p. 38–39°.

4-Isoquinolyl Methyl Ketone

Ice (6 g) was added with stirring to a solution of 4-aminoisoquinoline (2 g) in concentrated hydrochloric acid (4.5 ml) and water (4 ml) at 0–5°. To this was slowly added a solution of sodium nitrite (1 g) in water (2 ml) and the resulting deep red suspension neutralized to Congo red by the addition of sodium acetate (2 g) in water (3 ml). The diazonium salt solution was slowly introduced under the surface of a cold (10–15°) solution of acetaldoxime (1.3 g), copper sulphate (0.7 g), and sodium sulphite (0.055 g) in water (10 ml), with stirring. A solution of sodium acetate (9 g) in water (10 ml) was added and stirring was continued at room temperature for 1 hour, during which time nitrogen was evolved. The resulting suspension was acidified with enough hydrochloric acid to dissolve all the solid material. The red solution was boiled under reflux for 3 hours, cooled, basified with aqueous ammonia, and extracted with ether. The dried (Na_2SO_4) ether extract was evaporated and the brown tarry residue (0.88 g) dissolved in benzene and chromatographed on a column of alumina (60 g). Elution with benzene gave 4-isoquinolyl methyl ketone (0.40 g), m.p. 70–72°. Padbury and Lindwall (17) give m.p. 70–71° for this ketone.

Ethyl 4-Isoquinolylacetate (by the Willgerodt Reaction)

4-Isoquinolyl methyl ketone (0.189 g), sulphur (0.035 g), and morpholine (0.415 g) were boiled under reflux for 15 hours. Ethanolic sodium hydroxide (5%) (2 ml) was added to the black solution, which was boiled under reflux for a further 73 hours. The reaction mixture was poured into water (5 ml), the solution evaporated to about one third of its original volume under reduced pressure, water (5 ml) added, the solution saturated with salt and extracted with ether. The aqueous layer was taken almost to dryness, the dark oil remaining was treated with hydrochloric acid, and the mixture evaporated to dryness. The resulting light brown solid was warmed with absolute ethanol, filtered from any sodium chloride, and the filtrate poured into ether. A light brown flocculent precipitate which separated was filtered and dissolved in absolute ethanol

For personal use only.

saturated with dry hydrogen chloride, and the solution boiled under reflux overnight. It was poured into a saturated aqueous solution of sodium chloride, the solution basified with ammonia and extracted with ether. The dried (Na_2SO_4) ether extract was evaporated to give a brown gum which was sublimed at 100° at 15 mm. Colorless needles (0.020 g), m.p. 60–62°, of *ethyl 4-isoquinolylacetate* were obtained which, on recrystallization from light petroleum, had m.p. 62.5°. (Calc. for $C_{13}H_{13}NO_2$: C, 72.54; H, 6.09. Found: C, 72.33; H, 6.34.) Infrared spectrum (film): 1725 (s), 1627 (m), 1512 (m), 1299 (m), 1205 (s), 1115 (m), 800 (w), and 765 cm^{-1} (m).

4-Isoquinolylmethanol

Ethyl 4-isoquinoline carboxylate (7.9 g) in anhydrous ether (125 ml) was added dropwise to a stirred suspension of lithium aluminum hydride (1.9 g) in dry ether (250 ml) at 0°. The mixture was stirred for 1 hour and water (40 ml) added carefully. Carbon dioxide was bubbled through the mixture for 10 minutes, the ether layer removed, and the pasty aqueous phase washed with ether (5×100 ml). The combined ether layers were dried (Na_2SO_4) and evaporated to give an oil (5.6 g) which, on trituration with a small amount of ether, gave *4-isoquinolylmethanol* (4.3 g). Recrystallization from ether gave colorless crystals, m.p. 93–94°. (Calc. for $C_{10}H_9NO$: C, 75.45; H, 5.70. Found: C, 75.38; H, 5.84.) Infrared spectrum (Nujol mull): 3170 (s) (br), 1640 (m), 1475 (m), 1100 (s), 785 (w), and 755 cm^{-1} (m).

4-Formylisoquinoline

A solution of 4-isoquinolylmethanol (0.46 g) in benzene (100 ml) was shaken with activated manganese dioxide (1 g) (25) for 16 hours at room temperature, the mixture filtered and evaporated to dryness to give the aldehyde (0.40 g) as a white solid, m.p. 103.5–104.5°. (Calc. for $C_{10}H_7NO$: C, 76.42; H, 4.49. Found: C, 76.59; H, 4.69.) Angyal, Penman, and Warwick report m.p. 103° for 4-formylisoquinoline (26).

5-(4'-Isoquinolylidene)-2-phenyloxazolone

4-Formylisoquinoline (0.052 g), hippuric acid (0.060 g), fused sodium acetate (0.025 g), and acetic anhydride (0.153 g) were heated together at 140–145° for 15 minutes. Water (10 ml) was added to the hot melt, the brown solid was filtered and recrystallized from benzene to give the *azlactone* (0.009 g) as green hair-like crystals, m.p. 251–252°. (Calc. for $C_{19}H_{12}N_2O_2$: C, 75.99; H, 4.03. Found: C, 76.33; H, 4.60.)

4-Chloromethylisoquinoline Hydrochloride

4-Isoquinolylmethanol (4.3 g) in benzene (70 ml) was treated with dry hydrogen chloride gas and the solid hydrochloride which precipitated (4.63 g) was filtered, washed with benzene, and dried. It was then boiled under reflux with thionyl chloride (13 ml) for 1 hour. Benzene (35 ml) was added to the cold mixture and the white solid which precipitated was filtered, washed with benzene, and dried to give *4-chloromethylisoquinoline hydrochloride* (4.76 g), m.p. 225° (decomp.). (Calc. for $C_{10}H_8NCl,HCl$: C, 56.10; H, 4.25. Found: C, 56.18; H, 3.89.) Infrared spectrum (KBr disk): 2310 (s) (br), 2070 (s), 1645 (m), 1615 (m), 1375 (m), 1240 (m), 865 (m), 785 (s), and 755 cm^{-1} (m).

4-Isoquinolylacetonitrile

(i) Using aqueous ethanol as solvent.—4-Chloromethylisoquinoline hydrochloride (4.3 g) in 50% aqueous ethanol (30 ml) was added dropwise to a stirred, boiling solution of sodium cyanide (7 g) in water (12 ml) and ethanol (80 ml) over a period of 30 minutes. The resulting brown mixture was stirred and boiled under reflux for a further 40 minutes, evaporated to dryness under reduced pressure, and the black oily residue extracted with ether (6×70 ml). The dried (Na_2SO_4) ether extract was evaporated and the residual brown oil (3 g), which partially crystallized on cooling, was dissolved in benzene and chromatographed on a column of alumina (200 g). A mixture of benzene – light petroleum (2:1 v/v) eluted *4-isoquinolylacetonitrile* (1.45 g), m.p. 108–110°, which, on recrystallization from benzene – light petroleum (b.p. 60–80°), had m.p. 109–110°. (Calc. for $C_{11}H_8N_2$: C, 78.55; H, 4.79. Found: C, 78.54; H, 4.87.) Infrared spectrum (KBr disk): 2250 (w), 1625 (m), 1592 (m), 1391 (s), 870 (m), 780 (m), and 741 cm^{-1} (s).

(ii) Using dimethyl sulphoxide as solvent.—A suspension of 4-chloromethylisoquinoline hydrochloride (12 g) in dimethyl sulphoxide (110 ml) was added over 30 minutes to a stirred solution of sodium cyanide (6.2 g) in dimethyl sulphoxide (50 ml) at room temperature. The solution was stirred for 2½ hours, poured into water (1 l.), and the suspension extracted with ether (5×100 ml). The combined ether extracts were washed with water (3×100 ml), dried (Na_2SO_4), and evaporated to give a brown oil (8.9 g) which crystallized partly on standing. A small amount of ether was added, and the crystals of the nitrile (4.7 g), m.p. 107–109°, thus obtained were filtered and washed with a little ether.

cis-α-(4-Isoquinolyl)-o-nitrocinnamonitrile

4-Isoquinolylacetonitrile (1 g) and *o*-nitrobenzaldehyde (0.92 g) in acetic anhydride (12 ml) containing triethylamine (1.5 ml) were heated on a steam bath overnight and the reaction mixture cooled, when the *cis-cinnamonitrile* separated. Ether (1 ml) was added to the mixture and the solid (1.6 g) filtered, washed with a small amount of ether, and recrystallized from ethanol to give the pure product, m.p. 177–178°. (Calc. for $C_{18}H_{11}N_3O_2$: C, 71.75; H, 3.68. Found: C, 71.50; H, 3.78.) Infrared spectrum (KBr disk): 2220 (w), 1623 (w), 1570 (w), 1515 (s), 1355 (s), 907 (w), 850 (w), 780 (m), 755 (m), and 720 cm^{-1} (m).

2-Amino-3-(4'-isoquinolyl)quinoline 1-Oxide

cis-α-(4-Isoquinolyl)-*o*-nitrocinnamonitrile (0.20 g) in ethyl acetate (70 ml) was hydrogenated at room temperature and pressure over 10% palladium–charcoal (0.05 g) for 24 hours. Two equivalents of hydrogen were absorbed. The deep yellow solution was filtered and evaporated to give *2-amino-3-(4'-isoquinolyl)-quinoline 1-oxide* (0.185 g), m.p. 248–250° (decomp.), which, after recrystallization from acetone, had m.p. 260–261°. (Calc. for $C_{18}H_{13}N_3O$: C, 75.24; H, 4.56; N, 14.63. Found: C, 75.25, 75.20; H, 4.68, 4.56; N, 14.37.) Infrared spectrum (KBr disk): 3300 (s) (br), 1625 (s), 1590 (m), 1395 (m), 1360 (m), 753 (m), and 743 cm^{-1} (m).

2-Amino-3-(4'-isoquinolyl)quinoline

(i) 2-Amino-3-(4'-isoquinolyl)quinoline 1-oxide (0.10 g) was treated with a solution of stannous chloride in acetic acid saturated with dry hydrogen chloride (27) (2 ml) and the resulting solution boiled under reflux for 18 hours. Water (10 ml) was then added, the solution made alkaline with 40% aqueous potassium hydroxide and extracted with chloroform (3×15 ml), and the extracts dried (Na_2SO_4) and evaporated to give a waxy solid (0.085 g). Recrystallization from ethanol afforded the *amine* (0.055 g), m.p. 252–253.5°, as pale yellow crystals. (Calc. for $C_{18}H_{13}N_3$: C, 79.68; H, 4.83. Found: C, 79.28; H, 5.12.) Infrared spectrum (KBr disk): 3350 (s) (br), 1647 (s), 1613 (m), 1435 (s), 757 (s), and 745 cm^{-1} (s).

(ii) The *N*-oxide (0.10 g), ferrous oxalate dihydrate (0.11 g), and granulated lead (2 g) were mixed and heated at 330° for 20 minutes under air condenser to give 2-amino-3-(4'-isoquinolyl)quinoline (0.009 g), m.p. 250–253°, undepressed on admixture with a sample obtained as above.

Ethyl 4-Isoquinolylacetate (from the Nitrile)

4-Isoquinolylacetonitrile (0.10 g) was dissolved in a mixture of anhydrous ethanol (0.7 ml) and concentrated sulphuric acid (0.7 ml) and the solution boiled under reflux for 3 hours. The resulting dark brown solution was poured into ice and water, made alkaline by the careful addition of ammonia, and the precipitated ester (0.070 g), m.p. 62–64°, filtered. The melting point was undepressed on admixture with a sample prepared by the Willgerodt reaction, and the infrared spectra of the compounds were identical.

4-Isoquinolylacetamide

4-Isoquinolylacetonitrile (0.50 g) was dissolved in concentrated sulphuric acid (3 ml) and the solution kept at room temperature for 17 hours, poured into water, and made just basic with 20% aqueous sodium hydroxide solution. The solid (0.475 g), m.p. 219–220°, which precipitated was recrystallized from water to give *4-isoquinolylacetamide* as fine white needles, m.p. 232–232.5°. (Calc. for $C_{11}H_{10}N_2O$: C, 70.95; H, 5.41. Found: C, 70.75; H, 5.42.) Infrared spectrum (KBr disk): 3470 (s), 1628 (m), 1400 (m), 1256 (m), 790 (m), and 758 cm^{-1} (m).

4-Isoquinolylacetic Acid Hydrochloride

The amide (0.31 g) in 6 *N* hydrochloric acid (10 ml) was treated with a large excess of sodium nitrite in water and the solution kept at room temperature overnight, when *4-isoquinolylacetic acid hydrochloride* (0.32 g) separated as colorless rods. These were recrystallized from absolute ethanol and had m.p. 241–243° (decomp.). (Calc. for $C_{11}H_9NO_2,HCl$: C, 59.06; H, 4.47. Found: C, 59.09; H, 4.71.) Infrared spectrum (KBr disk): 3000 (s) (br), 2680 (s) (br), 2020 (w), 1723 (s), 1650 (m), 1378 (s), 1175 (s), and 788 cm^{-1} (s).

trans-α-(4-Isoquinolyl)-o-nitrocinnamic Acid

4-Isoquinolylacetic acid hydrochloride (1.41 g) and *o*-nitrobenzaldehyde (0.97 g) were boiled under reflux with acetic anhydride (16 ml) containing triethylamine (14 ml) and anhydrous sodium acetate (0.4 g) for 35 minutes. The mixture was poured into water (80 ml), heated, and filtered to remove some tarry material and the filtrate kept in the refrigerator overnight, when *trans-α-(4-isoquinolyl)-o-nitrocinnamic acid* (1.14 g) separated as orange-yellow crystals. Recrystallization from methanol gave the pure acid, m.p. 246–247°. (Calc. for $C_{18}H_{12}N_2O_4$: C, 67.50; H, 3.78. Found: C, 67.78; H, 3.98.) Infrared spectrum (KBr disk): 3400 (m) (br), 2400 (w) (br), 1700 (m), 1526 (s), 1316 (s), 1295 (m), 785 (m), and 752 cm^{-1} (m).

trans-α-(4-Isoquinolyl)-o-aminocinnamic Acid

trans-α-(4-Isoquinolyl)-*o*-nitrocinnamic acid (1 g) was dissolved in hot aqueous ammonia and the solution added to a rapidly stirred and boiling solution of ferrous sulphate (6 g) in water (17 ml). The reaction mixture was stirred for a further 10 minutes while ammonia was added to it to maintain it basic. It was then filtered, neutralized with acetic acid, and kept in the refrigerator for 3 hours, when the *amino acid* (0.40 g) separated as a yellow solid. This was recrystallized from ethanol and had m.p. 279–281° (decomp.). (Calc. for $C_{18}H_{14}N_2O_2$: C, 74.47; H, 4.86. Found: C, 74.02; H, 5.03.) Infrared spectrum (Nujol mull): 2400 (w) (br), 1685 (m), 1620 (m), 1460 (s), 1378 (m), 1256 (s), and 751 cm^{-1} (m).

Benzo[c]phenanthridine

trans-α-(4-Isoquinolyl)-*o*-aminocinnamic acid (0.250 g) in 5% hydrochloric acid (10 ml) was diazotized with a solution of sodium nitrite (0.070 g) in water (5 ml), the temperature being kept below 1°. The excess nitrous acid was decomposed by the addition of urea, and Gattermann copper powder (0.25 g) added to the mixture, which was stirred at room temperature for 5 hours. The mixture was made just acid with acetic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

acid, filtered, and the solid extracted with methanol in a Soxhlet extractor for 15 hours. The methanol solution was evaporated to dryness and the brown solid residue washed with a little cold methanol to give what is presumed to be benzo[*c*]phenanthridine-11-carboxylic acid (0.120 g), m.p. 270–272° (decomp.), as a nearly white solid. Several attempts to recrystallize this solid to obtain an analysis specimen were unsuccessful. Infrared spectrum (KBr disk): 3400 (s) (br), 1700 (s), 1620 (s), 1450 (m), 1285 (s), 1230 (s), 760 (s), and 730 cm^{-1} (m).

The acid (0.050 g) was dissolved in purified quinoline (5 drops), copper powder (0.010 g) was added, and the suspension was heated under reflux (metal bath). After the initial vigorous evolution of gas had subsided heating was continued for a further 10 minutes, water (1.5 ml) was added, and the quinoline removed by steam distillation. The residue was extracted with ether, the ether dried (Na_2SO_4) and evaporated to give a brown oil (0.033 g) which solidified on cooling. This was chromatographed through a column of alumina (7 g); elution with benzene – light petroleum (1:3 v/v) gave benzo[*c*]phenanthridine (0.020 g), m.p. 135–135.5° (after recrystallization from aqueous ethanol). (Calc. for $C_{17}H_{11}N$: C, 89.05; H, 4.84. Found: C, 89.02; H, 5.09.) λ_{max} 265, 312, 343, 361 mμ; $10^{-3} \times \epsilon$ 80.5, 8.75, 5.60, 6.72 (in $CHCl_3$). Infrared spectrum (KBr disk): 1625 (m), 1270 (m), 824 (m), 798 (s), 760 (s), and 681 cm^{-1} (s). Whaley and Meadow (28) give m.p. 135° for benzo[*c*]phenanthridine.

INTERBRANCH SEQUENCES IN THE WHEAT ARABINO-XYLAN

SELECTIVE ENZYMOLYSIS STUDIES[1]

H. R. GOLDSCHMID[2] AND A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received May 2, 1963

ABSTRACT

A *Streptomyces* xylanase degrades the soluble arabino-xylan of wheat with formation of polymeric fragments and several oligosaccharides. The overall data, together with information about the spatial requirements of the xylanase, show that (*a*) the arabino-xylan molecules are constituted predominantly of highly branched regions in which isolated and paired L-arabinosyl branches are separated by single D-xylosyl units; (*b*) at unequal intervals (averaging 20–25 main-chain units) this type of sequence is interrupted by "open regions" of at least two to five unbranched D-xylosyl units; and (*c*) infrequently, an L-arabinosyl branch is removed from other branches at either side by at least two D-xylosyl units.

A new tetrasaccharide isolated from the enzymic digest is shown to be *O*-α-L-arabinofuranosyl-(1 → 3)-*O*-[β-D-xylopyranosyl-(1 → 4)]-*O*-β-D-xylopyranosyl-(1 → 4)-D-xylose.

The soluble pentosans of wheat flour (1–6) comprise a group of closely related polysaccharides containing a linear chain of (1 → 4)-linked β-D-xylopyranosyl units to which L-arabinofuranosyl branches are appended by (1 → 2)- and (1 → 3)-bonds. The branches occur most frequently on isolated or on two consecutive D-xylosyl units (6), and a high proportion of these units contains two L-arabinosyl branches. Additional information about the structure of the arabino-xylans has now been obtained through enzymic degradation studies.

An enzyme preparation obtained from *Streptomyces* QMB 814 (7)* was found to partially degrade the pentosans. This preparation shows strong cellulolytic activity but, according to Reese (8), also contains a xylanase component. Chromatographic examination of the digest showed the presence of only traces of arabinose and xylose, but substantial quantities of at least five oligosaccharides. About 60% of the substrate was accounted for as a polymeric residue having an average molecular size less than one-tenth that of the original pentosan, which showed that most of the molecules had been degraded at least partially by the enzyme. The oligosaccharide mixture was chromatographed first on charcoal and then on cellulose, affording five fractions in a combined yield of about 15%. Two major oligosaccharides were the (1 → 4)-β-linked xylobiose (I) and xylotriose (II), each being characterized as the derived β-acetate. The three additional oligosaccharides (III, IV, and V) were amorphous and yielded both arabinose and xylose on acid hydrolysis; from their chromatographic mobilities they appeared to be tetra-, penta-, and hexa-saccharide components, respectively.

Of these latter mixed oligosaccharides, III has been examined in some detail. It was found to contain arabinose and xylose in a ratio of 1:3 and to have a molecular weight close to that of a tetrasaccharide. When hydrolyzed partially III yielded xylotriose, which was characterized as the β-octaacetate. On oxidation with lead tetraacetate – potassium acetate, III consumed 5 moles of oxidant and produced 2 moles of formic acid at the same rate as for xylotriose (9). Therefore, the tetrasaccharide consists of a unit of

III

xylotriose and the L-arabinofuranosyl unit is attached to the central D-xylosyl unit through position 2 or 3. A crystalline decaacetate (VI) was prepared from III, and the purified sample (VII) obtained by deacetylation of VI showed the same properties on partial hydrolysis and lead tetraacetate oxidation as did crude III.

Information about the point of attachment of the L-arabinosyl unit was obtained by degrading the tetrasaccharide with alkali. Xylotriose itself is degraded readily, unit by unit, from the reducing end of the molecule (10). However, if a branch is introduced at position 2 of the central xylosyl unit the erosion process should be interrupted with three-quarters of the molecule intact (11), whereas more extensive degradation should result if the branch is at position 3 (11, 12). When VII was treated with dilute lime water (10), its rate of decomposition was close to that for xylotriose. This behavior is indicative, therefore, of a (1 → 3)-bond between the L-arabinosyl branch and the central D-xylosyl unit of the tetrasaccharide, and hence favors the structure represented by formula III. Such a product is consistent with the fact that the parent polysaccharide on methylation and hydrolysis yields 2-*O*-methyl-D-xylose (2, 4). Also it provides direct evidence that single (2), isolated (6) L-arabinofuranosyl units are to be found attached to the main xylan chain.

The specific rotation of III and of acetate VI, when compared with rotatory data for pertinent reference compounds (Table I), indicates that the L-arabinofuranosyl unit

TABLE I

Rotatory values for arabinose-xylose oligosaccharides and related compounds

Compound	$[\alpha]_D$	M_D
1. Xylotriose	− 46.9 (21)	−19,420

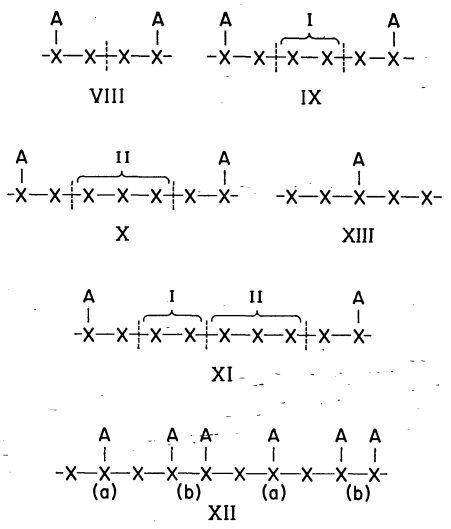
possesses the α-(1,2-*trans*)-configuration. This assignment agrees with conclusions reached recently by Marchessault (13), who examined the rotatory power of several arabino xylans including the wheat flour pentosans. Based on Marchessault's data, the calculated molecular rotation for III is 36,600, whereas the found value is 41,000. However, rotational data in this series are not always clearly indicative of configuration. Thus, a trisaccharide consisting of an L-arabinofuranosyl unit linked 3′ to a xylobiose unit (14, 15) has a molecular rotation which deviates about equally from values calculated to allow either for an α- or a β-L-arabinosyl branch (Table I, compound 10).

Since xylobiose and xylotriose are produced by the enzyme, but only traces of arabinose released, it is clear that these oligosaccharides represent interbranch segments of the xylan main chain. In fact, such segments are even larger than indicated by the dimensions of the oligosaccharides themselves, as shown by the recent finding (16) that the xylan chain is cleaved only when there are at least two unbranched β-D-xylosyl units in sequence. This follows from the fact that the polymeric residues (as well as the known oligosaccharide products) contain reducing and non-reducing end-units that are devoid of L-arabinosyl branches (16). Hence, a structure such as VIII appears subject to hydrolysis (broken



line) and the formation of xylobiose I can be envisioned from a sequence such as IX which involves a minimum of four interbranch xylosyl units. Similarly, at least five such units (as in X) are required for release of xylotriose II. The interbranch regions sometimes may be large enough, e.g., as in XI, to afford more than one oligosaccharide molecule or a large oligosaccharide which subsequently is degraded to I or II. However, the ready solubility of the arabino-xylan, when contrasted with the low solubility of xylans containing relatively low proportions of arabinosyl branches (2), suggests that few molecules are likely to have interbranch regions much larger than depicted in XI.

The incidence of branching in the pentosan is sufficiently high—i.e., two out of five D-xylosyl units contain L-arabinosyl branches (2)—that if the isolated and paired branches were distributed in a completely uniform fashion, there would be no sequence of four or more consecutive unbranched D-xylosyl units present from which D-xylose oligosaccharides could be derived. Since, however, the yield of I and II corresponds to about 13% of the xylan component of the polysaccharide, branching in the latter must deviate substantially from a uniform type of arrangement. About 22% of the xylan component is accounted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for by these oligosaccharides, by adjusting their yield to allow for two additional D-xylosyl units per segment (as in structures IX and X). Consequently, almost all of the arabinosyl branches are to be found concentrated in regions of the pentosan that involve barely three-quarters of the xylan chain. In these regions, therefore, about four in seven D-xylosyl units must be branched,* as compared with a figure of two in five for the overall molecule, and hence the distance between the isolated and paired branch points rarely can exceed one xylosyl unit. Since the minimum spatial requirement for enzymic hydrolysis is two adjacent unbranched D-xylosyl units (16), it is understandable that these highly branched regions of the polysaccharide are immune to attack by the *Streptomyces* enzyme.

The data available from the current and earlier studies now provide rather detailed information about the structure of the arabino-xylan. The molecules may be represented predominantly by XII, in which the incidence of branching is high (many of the D-xylosyl units even contain two branches): sometimes isolated D-xylosyl units serve as branch points (*a*), sometimes two (and less frequently more than two) consecutive branched units (*b*) occur between single unbranched units. At unequal intervals, averaging 20–25 units (average D.P. of the polymeric fragments), this type of sequence (XII) is interrupted by "open regions" in which at least two to five unbranched D-xylosyl units are found (as in VIII, IX, and X). An additional type of sequence is represented by the formation of tetrasaccharide III, in which an occasional arabinosyl branch is removed from other branches at either side by at least two D-xylosyl units (as in XIII). The relative distribution of these sequence types is not known. However, it was found earlier (1, 2) that the arabino-xylans comprise a series of polymers in which the arabinose-xylose ratio varies substantially. Therefore, some molecules probably contain a relatively large proportion of the highly branched type of sequence XII whereas others contain more "open regions".

EXPERIMENTAL

Melting points are corrected. Specific rotations were measured at 25±2°.

Evaporations were carried out *in vacuo* at 40–50° C.

Paper chromatography was carried out with Whatman No. 1 or 3 MM paper using ethyl acetate – pyridine – water (100:40:30) as solvent.

Pentose was estimated colorimetrically by the orcinol – ferric chloride reaction (17).

Preparation of Arabino-xylan

The procedure was essentially that described earlier (1): crude water-soluble pentosan (43.0 g) was acetylated in formamide with acetic anhydride and pyridine; the acetone-soluble fraction of the derived acetate was precipitated fractionally from acetone with ligroin. Each fraction was examined by deacetylation and acid hydrolysis, and those fractions containing arabinose and xylose predominantly were combined and again fractionally precipitated. A major final fraction (8.6 g) containing the two pentose sugars almost exclusively was deacetylated catalytically with sodium methoxide in boiling methanol, for use in the enzymolysis experiments.

Enzymic Degradation of Arabino-xylan

In preliminary experiments the arabino-xylan was incubated in water at 45° C with varying proportions of the *Streptomyces* enzyme preparation (7), ratios being varied from 27:1 to 3:1. Approximately the same degree of hydrolysis (copper-reducing power (18)) was reached within 24 hours' reaction time with each digest in which the substrate–enzyme ratio was 10:1 or less.

Arabino-xylan (4.74 g) in water (500 ml) was treated at 45° C with the enzyme preparation (470 mg) for 29 hours. The digest was then heated on the steam bath to inactivate the enzyme and the solution was concentrated to a volume of 60 ml.

Polymeric Fragments

Ethanol was added slowly with stirring to the digest concentrate, yielding, first, a brown precipitate which appeared to consist mostly of enzymic material (this fraction was not examined further). Further

**This increased incidence of branching is evident in the polymeric residues from a relatively high arabinose content and low periodate uptake.*

For personal use only.

increments of alcohol caused precipitation of three additional fractions (1, 2, and 3), each of which was centrifuged off. The supernatant solution was concentrated to a volume of 30 ml, and ethanol again added, yielding two more precipitated fractions (4 and 5). Yields of these five fractions were as follows: 1, 0.31 g; 2, 0.37 g; 3, 0.87 g; 4, 0.85 g; 5, 0.56 g. (Total yield, 62%.) In a separate experiment (16), these polymeric fragments were recovered in a total yield of 60% as two fractions (1A and 2A), the addition of alcohol to the digest concentrate in this experiment being less gradual.

The degree of polymerization of fractions 3, 4, 1A, and 2A, as estimated by copper-reducing power, was 22, 12, 28 and 15, respectively. The derived acetates of fractions 1A and 2A have molecular weights of 5100 and 2700, respectively (16).

Fractions 2, 5, 1A, and 2A, when hydrolyzed with 0.1 *N* sulphuric acid, each yielded arabinose and xylose; the arabinose:xylose ratios estimated by quantitative paper chromatography were 1.1, 0.7, 1.0, and 0.7, respectively. (In the original pentosan this ratio is about 0.6 (1, 2).)

On oxidation with excess sodium metaperiodate at 12° C fractions 1A, 2A, and 3 consumed 0.69, 0.77, and 0.71 mole of periodate per mole, respectively (18 hours' reaction time; constant value during succeeding 24 hours); the corresponding estimates of formic acid produced were 0.064, 0.115, and 0.084 mole per mole, making for corrected periodate uptake values of 0.63, 0.65, and 0.63 mole per mole, respectively. (The uptake of periodate by the original pentosan is about 0.7 mole per mole (2).)

Isolation of Oligosaccharides

The mother liquor remaining after precipitation of polymeric fragment fractions 1–5 was concentrated to a syrup (2.47 g) which was chromatographed on a column of coconut charcoal (19), aqueous ethanol solutions of 5, 10, 20, 30, and 40% ethanol being used successively as eluants. Oligosaccharide components contained in these eluates (detected by paper chromatography) were purified further by preparative chromatography on 3 MM paper sheets. This sequence of isolation steps afforded the following oligosaccharides in a chromatographically pure condition (listed in order of decreasing chromatographic mobility): xylobiose, 0.18; xylotriose, 0.16 g; oligosaccharide III, 0.19 g; oligosaccharide IV, 0.14 g; oligosaccharide V, 0.12 g.

Purification of Oligosaccharides

Each of the above oligosaccharides was acetylated with acetic anhydride, using anhydrous sodium acetate, on the steam bath for 2 hours. The derived products were isolated by precipitation with ice water and crystalline materials were recrystallized from ethanol, affording: *β-xylobiose hexaacetate*, m.p. 154–155° C, identity confirmed by X-ray powder diagram; *β-xylotriose octaacetate*, m.p. 106–108° C, identity confirmed by X-ray powder diagram; *oligosaccharide III decaacetate (VI)*, m.p. 179–180° C, $[\alpha]_D$ −85° (*c*, 1, chloroform); calculated for $C_{40}H_{54}O_{27}$: C, 49.69%; H, 5.63%; found: C, 49.64%; H, 5.73%. The acetates of oligosaccharides IV and V were syrupy products. Oligosaccharide V acetate was found by silicic acid column chromatography to contain at least two components.

Characterization of Oligosaccharide III

(*a*) The amorphous solid, $[\alpha]_D$ −75° (*c*, 1, water), was found by oxidation with alkaline hypoiodite (using xylotriose as standard) to have an equiv. wt. of 514 (pentose tetrasaccharide requires 546). A solution containing 37 γ of pentose was treated with excess of sodium borohydride for 4 hours, and then found to contain 28 γ of pentose; the latter value, being 75% of the original pentose value, agrees with formulation of III as a tetrasaccharide.

(*b*) The tetrasaccharide (2 mg) was hydrolyzed on the steam bath with 0.2 *N* sulphuric acid (0.2 ml) in a sealed tube for 15 hours, the hydrolyzate was neutralized with Dowex-1 (bicarbonate form). Arabinose and xylose were detected by paper chromatography and, by elution from the chromatograms, these sugars were estimated colorimetrically to be present in a ratio of 1 to 3.

(*c*) A solution of the tetrasaccharide (85 mg) in 0.05 *N* sulphuric acid (2 ml) was heated on the steam bath for 35 minutes, then neutralized with Dowex-1 (bicarbonate form). Arabinose and xylotriose were detected in the hydrolyzate by paper chromatography, and the latter product (47 mg) was isolated by use of 3 MM paper sheets and characterized as the derived acetate, m.p. 108–110° C; the X-ray powder diagram was indistinguishable from that of β-xylotriose octaacetate.

(*d*) The tetrasaccharide was oxidized with lead tetraacetate – potassium acetate in 90% acetic acid under conditions described elsewhere (9). In 5.5 hours' reaction time the consumption of lead tetraacetate was 6.5 moles per mole and the yield of formic acid (CO_2) was 1.8 moles per mole. Structure III requires 7.0 moles of lead tetraacetate and 2.0 moles of formic acid per mole. In a simultaneous oxidation of xylotriose, 5.7 moles of lead tetraacetate were consumed and 1.9 moles of formic acid released (requires 6.0 and 2.0 moles per mole, respectively). Both the tetrasaccharide and xylotriose released 1 mole of acid rapidly (15 minutes' reaction time) and the second mole slowly, chracteristic of oligosaccharides of the (1 → 4)-xylobiose series (9).

(*e*) The acetylated tetrasaccharide (VI) (1.9 mg) in methanol (0.4 ml) was treated with excess sodium methoxide for 6 hours. Acetic acid was added, the solvent evaporated off at room temperature, and the deacetylated product (VII) treated with lead tetraacetate – potassium acetate in 90% acetic acid. The consumption of lead tetraacetate, measured spectrophotometrically (20), reached a constant value of 6.5 moles per mole in 5–6 hours' reaction time (structure III requires 7.0 moles per mole). On partial acid hydrolysis, as in section *c*, VII yielded xylotriose and arabinose (paper chromatographic evidence).

(*f*) Acetate VI and xylotriose octaacetate were each (2-mg samples) deacetylated with sodium methoxide, the solutions were neutralized with carbon dioxide and concentrated *in vacuo*. Each product was taken up in 0.04 *N* lime water (previously saturated with oxygen-free nitrogen), and at intervals the pentose content

	% pentose remaining	
Time (hr)	Tetrasaccharide VII	Xylotriose

A GLUCAN PRODUCED BY CLAVICEPS PURPUREA[1]

A. S. PERLIN AND W. A. TABER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received May 23, 1963

ABSTRACT

A glucan is produced by pure cultures of *Claviceps purpurea* (Fr.) Tul., PRL 1980, and its formation appears to be related to the accumulation of other shunt products such as ergot alkaloids, polyols, and trehalose. The glucan consists of β-D-glucopyranosyl units, most of which constitute a (1 → 3)-linked main chain. Other units are attached as branches to units of the main chain by (1 → 6)-linkages and are distributed in a relatively uniform arrangement along the length of the polymer. The glucan is resistant to attack by an endo type of laminarinase but is degraded vigorously by one of the exo type, yielding D-glucose and gentiobiose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In attempting to relate the physiology of certain strains of *Claviceps purpurea* to production of ergot alkaloids, changes in content of mycelial and filtrate constituents of high- and low-alkaloid-producing cultures are being studied (1, 2). Alkaloid is produced in vitro when the media lack requirements for maximum cell growth (1) but do not simultaneously cause a noticeable inhibition of respiration (2). These imbalanced culturing conditions also influence markedly the formation and cellular accumulation of other shunt products (3) such as polyols, trehalose, and nucleotides (2).

When grown on a medium rich in D-glucose and phosphate, *Claviceps purpurea* (Fr.) Tul., PRL 1980, produces only traces of ergot alkaloid, but the cultures become unusually viscous, and addition of one-half to one volume of ethanol to the culture filtrate yields a fibrous polysaccharide (I). During earlier stages of growth (3–6 days) a substantial amount of polysaccharide (II) is associated intimately with the mycelium, from which it has been extracted with trichloroacetic acid, but none appears to be present in the mycelium of 7- to 8-day-old cultures. The polysaccharides from both sources are found to be closely related in structure, and hence I may not be elaborated by the fungus as an extracellular product but possibly is excreted into the medium as the mycelium ages. This loss of mycelial polysaccharide does not appear to be due to disintegration of cells for there is a commensurate drop in trehalose content but not in total polyol and dry weight (2), which suggests that a selective transport or utilization of carbohydrate reserves occurs within the culture. Under conditions that favor the production of more alkaloid the organism produces less polysaccharide, virtually all of which is present in the filtrate throughout the growth period. This polysaccharide shows characteristics notably different from those of I, and requires further examination. The present paper deals mainly with the structure of I isolated from filtrates of 8-day cultures.

Isolated polysaccharide I is water insoluble, but it dissolves readily in dilute alkali and remains in solution when excess acid is added. Gradual addition of ethanol to such a solution has afforded several fractions of the polymer, but no structural variations between these fractions have been detected. D-Glucose appears to be the sole sugar component of I, as shown by acid hydrolysis and other data reported below and, since solutions of the polymer in alkali are levorotatory, a predominance of β-D-glucosidic linkages is indicated.

On treatment with sodium metaperiodate the glucan consumed 0.6 mole of oxidant

[1]*Issued as N.R.C. No. 7489.*

per anhydroglucose unit, glycol cleavage resulting in the release of 0.25 mole of acid per unit. Hence virtually all of the oxidation was confined to about 25% of residues that contain a 1,2,3-triol grouping, i.e., to end-units and/or to 6-substituted D-glucopyranosyl units. The remaining three-quarters of the polymer appeared, therefore, to be linked by (1 → 3)-bonds. Accordingly, treatment of the oxidized material with hot phenylhydrazine acetate (4) afforded in high yield a polymeric product (III) virtually immune to further oxidation by periodate. This product, which was insoluble even in 1 *N* alkali, was obtained also by reducing the oxidized polysaccharide and then subjecting the derived polyol to partial acid hydrolysis (5). These results show the presence in I of a central chain of (probably several hundred, based on the low periodate uptake) 3-substituted D-glucopyranosyl units, and also suggest that the oxidizable units occur as end groups.

The presence of a high proportion of end groups in the polysaccharide is demonstrated more clearly by methylation data. Unfortunately, the glucan proved highly resistant to complete methylation and the derived ether was poorly soluble, making for a low recovery of methylated product. However, acid methanolysis of the polymeric methyl ether afforded a mixture of glucosides which, from gas–liquid phase chromatographic analysis, consisted of a tetra-, a tri-, and a di-methyl derivative. The yield of the tetramethyl glucoside was about 17%, showing that most of the formic acid liberated by periodate oxidation had been derived from end groups. The trimethyl fraction, constituting about 60% of the mixture, gave 2,4,6-tri-*O*-methyl D-glucose on acid hydrolysis, thus confirming that the 3-linked D-glucopyranosyl unit is the dominant structural type in the glucan. Units comprising the branch points are of this same type but are linked to other units also through position 6, the dimethyl ether derived from such units being the 2,4-isomer.

Although the glucan contains many 3-substituted β-D-glucopyranosyl units it is attacked in solution to only a small extent by the "*endo*-laminarinase" of *Rhizopus arrhizus* QM 1032 (6). However, *Basidiomycete* QM 866 "*exo*-laminarinase" (6) was found to degrade the polysaccharide (even as a suspension) rapidly and extensively, yielding D-glucose and the disaccharide gentiobiose. These products were formed in a ratio of 3:2 and accounted for 80% of the glucan. Isolation of gentiobiose confirms the methylation evidence that (1 → 6)-β-D-glucosyl linkages are present in the polymer, and the strong affinity of the β-D-glucosidase for the glucan provides a further indication that all (or nearly all) of the remaining glycosidic bonds possess the β-D-configuration. Polymeric product III, from which the end groups have been removed selectively, also is hydrolyzed by the exo enzyme but with production of glucose only, a clear indication that in glucan I the end groups constitute non-reducing end-units of the gentiobiosyl structures.

The *exo*-laminarinase provided a highly useful means for structural comparison of various samples of the glucan. Thus, polysaccharide II, extracted from the *Claviceps* mycelium, was found in this way to be closely similar to I since it was degraded readily by the enzyme to glucose and gentiobiose. Similarly, subfractions of I obtained by fractional precipitation each yielded glucose and gentiobiose in about the same ratio, which indicated strongly that any difference between fractions is mainly one of molecular size.

The overall data are consistent with a structure for the glucan represented by formula I. There is a main chain of (1 → 3)-linked β-D-glucopyranosyl units (Glp), and single β-D-glucopyranosyl units are attached as branches to (on the average) about every fourth unit of this main chain through (1 → 6)-linkages. The *Claviceps* glucan is thus closely related structurally to a new type of glucan described recently by Smith (7) that is produced by an unidentified fungus; however, this latter polysaccharide is more highly branched and readily soluble in water.

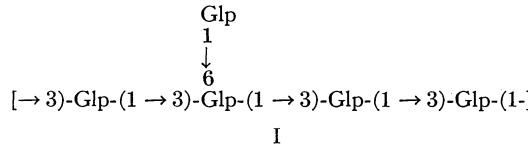
For personal use only.



I

As noted above, the *Rhizopus endo*-laminarinase effects very limited degradation of glucan I, as compared with its activity on laminarin. A similar comparison with polymer III was not possible because of the marked insolubility* of this material; however, a suspension of III was slowly degraded by the enzyme whereas there was no evidence of attack on I in suspension. These observations suggest, therefore, that the branch units in I limit accessibility of the enzyme to most of the 3-substituted β-D-glucosyl units of the main chain, and hence that branching is distributed along the length of the polymer in such a way that relatively few large interbranch regions are to be found.

EXPERIMENTAL

Melting points are corrected. Optical rotations were measured at 25±2°. Concentration of solutions was carried out *in vacuo* at 40–45° C.

Paper chromatography was carried out using as solvents (A) ethyl acetate – pyridine – water (10:4:3) or (B) butanol–ethanol–water (40:11:15). Gas–liquid phase chromatography was carried out with a temperature-programmed unit over the range 60–200° C using an 8 ft×3/16 in. column of phthalate – ethylene glycol polyester (9) on C-22 activated firebrick (ratio 4.5:1); helium flow rate 70 cc/min.

Formation of Polysaccharide by Claviceps purpurea PRL 1980

The medium consisted of D-glucose (65 g), D-mannitol (65 g), succinic acid (7.2 g), potassium dihydrogen phosphate (2 g), and various other salts per liter (1, 2); the pH of the medium was adjusted to 5.2 with ammonia. A washed and homogenized vegetative inoculum was added and the cultures were shaken at 24° C. At various intervals the mycelium was filtered off with suction on Whatman No. 2 paper and washed on the filter with water. The lyophilized mycelium was then extracted successively with cold and hot 5% trichloroacetic acid solution (TCA). Ethanol was added to each of these extracts and to the culture filtrate to promote turbidity, and the precipitates obtained were recovered by filtration, washed with ethanol and acetone, and dried *in vacuo*. The relative amounts of polysaccharide isolated from these three different sources are indicated by the following crude yields obtained from a series of cultures (mg/flask).

	Age of culture (days)					
	3	4	5	6	7	8
Filtrate	60	132	189	161	140	115
Cold TCA extract	26	50	53	46	0	0
Hot TCA extract	23	42	40	41	0	0

Each of the materials extracted by TCA at 5 days was readily degraded by *Basidiomycete* QM 866 *exo*-laminarinase (see below), yielding glucose and gentiobiose in a ratio of about 1:1 (paper chromatographic evidence).

Polysaccharide I

Polysaccharide I used for the detailed structural studies was obtained from clear filtrates of 8-day-old cultures by precipitation with one-half to one volume of ethanol. The highly gelatinous flocculus was centrifuged off, washed several times each with 50% aqueous ethanol and water, then it was suspended in water, and lyophilized. In a typical experiment 1.0 g of colorless, fibrous material was isolated from 1 liter of culture. Found: C, 41.3%; H, 6.5%; N, 1.1%; ash, 3.3%. Calculated for $C_6H_{10}O_5$: C, 44.4%; H, 6.2%. $[\alpha]_D$ −4° (*c*, 1 in 1 *N* NaOH).

The polysaccharide (0.1 g) in 1 *N* sulphuric acid (10 ml) was heated in a sealed tube on the steam bath for 18 hours. The hydrolyzate, which contained a small quantity of a gelatinous sediment, was neutralized and, on paper chromatographic examination, found to contain only glucose.

**This observed decrease in solubility associated with conversion of a branched to a linear polymer is thus similar to the effect found with the soluble arabino-xylan of wheat (8), i.e., removal of the* L-*arabinosyl branches of this latter polysaccharide yields an insoluble linear xylan.*

For personal use only.

Polysaccharide I (0.20 g) was dissolved in 1 *N* sodium hydroxide (20 ml), the solution was acidified with acetic acid, and then ethanol was added slowly with good stirring, four precipitated fractions being collected with increasing alcohol concentration: 1, 25 mg; 2, 140 mg; 3, 35 mg; 4, 40 mg.

Each fraction was hydrolyzed readily by *Streptomyces* QM 806 laminarinase at 45° C, a paper chromatogram of the hydrolyzates indicating that each yielded glucose and gentiobioise in about the same proportion as unfractionated glucan I.

Periodate Oxidation of I

The glucan (32 mg) was suspended in a solution of sodium metaperiodate (83 mg, 10 ml) in the absence of light; stirred magnetically, the suspension was stored first for 5 hours at 25° C and then at 12° C. Periodate uptake measured iodometrically was as follows (moles/mole (hour)): 0.43 (1), 0.54 (5), 0.61 (92); at 92 hours the yield of formic acid was 0.24 mole/mole.

Glucan I (0.30 g) was treated with sodium metaperiodate (0.65 g in 25 ml water) as above for 72 hours. Excess ethylene glycol was added, the sediment was centrifuged off and washed with 50% acetic acid until it gave a negative test for iodate, then it was suspended in water, and lyophilized (wt., 0.28 g).

Partially-degraded Glucan (III)

(*a*) Periodate-oxidized I (0.15 g) was treated according to Barry (4) with phenylhydrazine (1 ml) and acetic acid (1.2 ml) in 50% ethanol (10 ml) under reflux for 6 hours. A highly swollen gel was obtained, centrifuged off, washed thoroughly with 50% ethanol, and then heated under reflux in this solvent for 5 hours with benzaldehyde (1 ml) and benzoic acid (0.2 g) (10). The pale yellow flocculus was centrifuged off, washed thoroughly with ethanol and ether, and dried *in vacuo* (wt., 0.10 g).

(*b*) Periodate-oxidized I (0.30 g) was added with vigorous stirring to sodium borohydride (0.15 g) in water (10 ml). After 6 hours, acetic acid (50 ml) was added, the precipitate was centrifuged off, washed with 50% ethanol, and suspended in 0.1 *N* sulphuric acid (5). After 18 hours, the precipitate was washed with water and lyophilized (wt., 0.16 g).

Prepared by procedure (*a*) or (*b*), degraded polymer III was found to consume only trace quantities of sodium metaperiodate. Both preparations, suspended in water at 45° C, were degraded by the *exo*-laminarinase (6), yielding glucose, and by *Rhizopus arrhizus* QM 1032 *endo*-laminarinase (6), yielding glucose and laminaribiose (paper chromatographic evidence).

Methylation of I

To a solution of glucan I (0.20 g) in 10% potassium hydroxide (20 ml) dimethyl sulphate (2 ml) was added slowly with good stirring. After 18 hours the solution was neutralized with sulphuric acid, concentrated to a slurry, 20 ml of the alkali was again added, and a second methylation carried out. The slurry obtained from this reaction mixture was dialyzed to remove salts, and a precipitate which formed in the dialysis sac was centrifuged off, and lyophilized. Dimethylformamide (20 ml) (11)was added to the methylation product, together with methyl iodide (10 ml) and silver oxide (4 g), and the mixture was shaken for 18 hours. The suspension was filtered, the solids were extracted several times with hot acetone, and the combined extracts and filtrate were concentrated. Yield, 0.14 g. After a second methylation with methyl iodide, the filtrate contained only a few milligrams of material, and the acetone extract, 60 mg of product (A). Therefore, the solids were suspended in sodium cyanide solution and dialyzed against water, more sodium cyanide being added periodically until no more silver oxide appeared to remain. The final, neutral, suspension contained in the dialysis membrane was lyophilized. Yield, 50 mg (B).

Methanolysis and Hydrolysis Products of Methylated I

Methylation products A and B were treated with 1% methanolic hydrogen chloride in sealed tubes on the steam bath for 18 hours. The methanolysates were neutralized with ethereal diazomethane, concentrated, and the syrupy residues examined by gas–liquid phase chromatography. Both products showed the presence of six components, the relative emergence times of which corresponded to those reported (12) for α- and β-anomers of a tetra-, a tri-, and a di-*O*-methyl methyl hexoside. Triangulation of the peaks obtained gave the following percentage compositions (anomeric percentages in parentheses).

	Fraction A	Fraction B
Tetra-	17.1 (4.4, 12.7)	16.8 (4.9, 11.9)
Tri-	64.6 (18.4, 46.2)	59.2 (15.8, 43.4)
Di-	18.3 (5.6, 12.7)	23.9 (7.4, 16.5)

The glycoside mixtures were hydrolyzed with 1 *N* sulphuric acid, and examination of the neutral hydrolyzates by paper chromatography indicated that each contained a tetra-, a tri-, and a di-*O*-methyl ether constituent, together with a trace proportion of a monomethyl component.

The hydrolyzates of A and B were combined and the sugar mixture was chromatographed on Whatman 3 MM paper (solvent B). Extraction of the trimethyl component from the paper afforded a solid product

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

which, after recrystallization from ether, had m.p. 119–121° C, undepressed by admixture with 2,4,6-tri-*O*-methyl-D-glucose.

The dimethyl component was a syrup. It did not react readily with lead tetraacetate in acetic acid, showing that position 2 was substituted (13). After reduction with sodium borohydride, formaldehyde was produced when the product was oxidized with lead tetraacetate – potassium acetate in 90% acetic acid, and chromatographic examination of the oxidation mixture indicated the presence of a material having characteristics consistent with those of a di-*O*-methyl pentose. These properties tentatively identify the D-glucose ether as the 2,4-di-*O*-methyl derivative.

Enzymic Degradation of Glucan I

Glucan I (0.20 g) was suspended in water (20 ml) at 35° C, and *Basidiomycete* QM 866 *exo*-laminarinase preparation (50 mg) (6) was added with stirring. In 1 hour most of the polysaccharide appeared to have been brought into solution, the digest was then stored at 40° C for 18 hours, and finally it was heated on the steam bath for 1 hour. Paper chromatographic examination of the digest showed the presence of glucose (strong), a disaccharide (strong), and probably a trisaccharide (trace). The solution was concentrated to a volume of 3–4 ml, several volumes of ethanol were added, and precipitated material was recovered (wt., 60 mg). A concentrate of the supernatant solution was chromatographed on Whatman 3 MM paper (solvent A). Elution of the appropriate zones yielded: (*a*) α-D-Glucose [95 mg); crystallized from water–methanol–ethanol, m.p. 144–146° C; $[\alpha]_D$ 52.0° (*c*, 1.8 in water, equilibrium value). (*b*) α-Gentiobiose (64 mg); crystallized from aqueous methanol, m.p. 90–92° C; $[\alpha]_D$ 8.9° (*c*, 1.4 in water, equilibrium value); the X-ray powder diagram was indistinguishable from that of an authentic specimen containing methanol of crystallization. Calculated for $C_{12}H_{22}O_{11}.2CH_3OH$: C, 41.38%; H, 7.44%. Found: C, 41.67%; H, 7.53%.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the generosity of Dr. E. T. Reese, who provided preparations of laminarinase-type enzymes. They also thank D. Mansfield and Miss M. Gates for valuable technical assistance and L. Hoffman for carrying out gas–liquid phase chromatographic analyses. Microanalyses were performed by M. Mazurek.

ABSTRACT

The self-absorption of the β^--radiation from S^{35} and P^{32} has been studied in various compounds. The function derived by Gora and Hickey has been shown to fit the data. The back-scattering of the β^--radiation from P^{32} by various elements and compounds has been examined and a semiempirical treatment used to suggest an effective atomic number for back-scattering by compounds.

INTRODUCTION

There have been many experimental studies dealing with the phenomenon of scattering and absorption of β^--radiation in counters of various geometrical efficiencies. These have been made to try to describe these processes adequately and to use the data obtained to transform measured counting rates into accurately known disintegration rates.

The theoretical description of scattering and absorption of β^--radiation is difficult because of the continuous distribution of β^--particle energies and the complexity of the scattering process. It is known that, when β^--particles interact with matter, they are scattered by elastic collision with atomic nuclei and lose energy by inelastic collision with atomic electrons. Absorption is due to the combined effects of scattering and energy loss.

In this paper we have studied the problems of self-absorption and back-scattering with counters of geometrical efficiencies of 2π steradians and less.

(a) Self-absorption

Self-absorption, the absorption of radiation in the material of the source itself, is the limiting factor in accurate disintegration-rate determinations where the sample is mounted in solid form. The absorption of β^--radiation is described approximately by the exponential law

$$A = A_0 e^{-\mu x}, \quad [1]$$

where A is the activity observed when radiation from a source of activity A_0 has passed through material of thickness x cm. The absorption coefficient, μ, in cm^{-1}, can be related to the density, d, in mg cm^{-3}, of the absorber and the end-point energy E_0 of the β^--emitter by equations of which the following (1) is typical:

$$\mu = 0.022 d E_0^{-1.33}. \quad [2]$$

Many self-absorption relations have been based on the approximate exponential

[1]*This work received financial assistance from the National Research Council of Canada.*

absorption as shown in equation [1]. The general approach has been to consider the absorption of radiation emitted from a point in the source, then to sum up the contribution from all possible points. Early self-absorption studies (2–6) were made with counters of very low geometrical efficiency. The electrons were assumed to travel normal to the source and the problem was reduced to a one-dimensional type. Equation [1] was integrated over the sample thickness from $x = 0$ to $x = a$ and the following relation obtained:

$$A = \frac{A_0}{\mu a}(1-e^{-\mu a}). \qquad [3]$$

It was pointed out (6, 7) that, for thin samples of superficial density less than 1 mg/cm^2, self-scattering is a very important factor. In subsequent publications (8–10) equations were derived which took this effect into account.

Objections to the simple self-absorption relation expressed in equation [3] were also raised as self-absorption was studied with counters subtending larger solid angles. Elliot and co-workers (11–14) showed that, from very thin layers, radiation is emitted isotropically, while from thicker layers the intensity observed at an angle θ to the normal approaches a cos θ relationship.

According to these results, the activity observed at an angle θ is written

$$A_\theta = \frac{A_0 \cos\theta}{\mu a}(1-e^{-\mu a/\cos\theta}),$$

which reduces to the experimental cosine distribution at large values of a.

Gora and Hickey (15) measured self-absorption in a flow-type counter. They assumed isotropic distribution and integrated both over sample thickness from $x = 0$ to $x = a$ and over the angles from $\theta = 0$ to $\theta = \pi/2$ to obtain

$$\frac{A}{A_0} = \tfrac{1}{2}\left[\frac{1-e^{-\mu a}}{\mu a} + e^{-\mu a} + \mu a Ei(-\mu a)\right]. \qquad [4]$$

$Ei(-\mu a)$ is the exponential integral of $(-\mu a)$. Gora and Hickey found that the simple relation described by equation [3] held only if the value of μ was varied with the geometrical efficiency of the counter.

Roalsvig and Haslam (16) later derived a similar equation. They irradiated disks of Cu, Zn, Ni, Mo, and polystyrene of thicknesses ranging from ten to several hundred milligrams per square centimetre. They found that equation [4] fitted their experimental results very well for $\mu/d = 0.0119E_0^{-1.83}$.

Hendler (17) studied the self-absorption of C^{14} and found that a hyperbolic function described the situation over the range of investigation. Katz (18) then showed that the hyperbolic function did not fit his data and Massini (19) pointed out that possibly the effect of the counting arrangement used by Hendler led to the hyperbolic function.

Self-absorption in counters of geometrical efficiencies of 2π steradians and less still poses many problems. (The problem of self-absorption in a 4π counting geometry has been intensively investigated by Yaffe and co-workers (20, 21) and Campion and co-workers (22–25).) Most experimental work has concerned itself with the study of self-absorption of a particular β^--emitting nuclide in source material of a particular composition. In the present work the composition of the source, the energy of the β^--emitter, and the geometrical efficiency of the counter have all been varied.

(b) Back-scattering

The main features of back-scattering observed in counters of less than 2π geometry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

have been well examined (26, 27) so that the effects of varying the energy of the β^--emitter, the atomic number, and mass thickness of the back-scatterer are known.

An important experimental fact about back-scattering is that the extent of back-scattering increases with the thickness of the backing material to a fixed value. The fixed value defines a condition termed 'saturation back-scattering'. For elements, the saturation back-scattering is a function of atomic number. For compounds, it has been suggested that the saturation back-scattering value obtained might characterize an 'effective' atomic number.

Various experimenters have defined an 'atomic number' for compounds purely empirically to suit their particular experimental data.

Glendenin and Solomon (28) proposed an average atomic number $\bar{Z}$ to explain their back-scattering results:

$$\bar{Z} = \frac{N_1Z_1+N_2Z_2+\ldots N_nZ_n}{N_1+N_2+\ldots N_n},$$

where $Z_1 \ldots Z_n$ are the atomic numbers of the various elements in the compound and $N_1 \ldots N_n$ are the numbers of atoms of each in the formula.

Perlman and Friedlander (29) used another definition of an average atomic number for their self-absorption studies:

$$\bar{Z}^{\frac{1}{2}} = \frac{N_1A_1Z_1^{\frac{1}{2}}+N_2A_2Z_2^{\frac{1}{2}}+\ldots}{N_1A_1+N_2A_2+\ldots} = \frac{\sum_i N_iA_iZ_i^{\frac{1}{2}}}{\sum_i N_iA_i},$$

where A_i is the atomic weight of the element defined by atomic number Z_i. This is the form these authors use, although it is referred to as $\bar{Z}^{\frac{1}{2}}$ in their paper.

Saldick and Allen (30), in studying the oxidation of ferrous sulphate in acid solution by high-energy cathode rays, suggested an effective atomic number, $\bar{Z}_E$:

[5] $$\bar{Z}_E = \sum_i [(\text{electron density})_i Z_i].$$

Their formula is a special case of the more general formula of Henriksen and Baarli (31):

[6] $$\bar{Z}_{E_1} = \sum_i [(\text{electron density})_i Z_i^x]^{1/x}.$$

Müller (32) defined an empirical effective atomic number, $\bar{Z}_{E_2}$, to explain his data for the back-scattering of β^--radiation by compounds:

[7] $$\bar{Z}_{E_2} = \sum_i [(\text{weight fraction})_i Z_i] = \frac{\sum_i N_iA_iZ_i}{\sum_i N_iA_i},$$

where the effective atomic number is the sum of each atomic number multiplied by the weight fraction of that atom present in the compound.

Danguy and Quivy (33) studied the back-scattering of electrons by solutions and alloys and found that their results could be fitted by Müller's effective atomic number.

Gray *et al.* (34) calculated effective atomic numbers according to equations [5], [6], and [7], and correlation was completed with observed back-scatter intensities. Müller's effective atomic number (equation [7]) showed the poorest correlation, with marked

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

scatter on the points. The results using equation [5] were much better. The best results were obtained using equation [6] for effective atomic number with a value of $x = 0.93$.

In this paper the back-scattering due to compounds has been investigated in order to check the various formulations with regard to effective atomic number.

EXPERIMENTAL

(a) Self-absorption

Two β^--emitters were studied, S^{35} ($E_0 = 0.167$ Mev) and P^{32} (1.71 Mev). The self-absorption of the β^--radiation was measured by varying the composition of the sources and varying the solid angle subtended by the counter at the sources.

Sources containing P^{32} were prepared by precipitating the orthophosphates of Ca, Cu, Ba, and Pb from a stock solution of orthophosphoric acid containing a fixed ratio of the active P^{32} to the inactive P^{31} isotope. Similarly, sources containing S^{35} were prepared by precipitating the sulphates of Ba, Sr, and Pb from a stock solution of sulphuric acid containing a fixed ratio of S^{35} to inactive sulphur isotopes. Aliquots of varying size of the precipitated salts (orthophosphate or sulphate) in slurry form were transferred to aluminum planchettes of standard dimensions. To ensure uniform distribution over the area of the planchette, the slurry was stirred before evaporation to dryness. Acetone was found to be a convenient slurrying agent for the unhydrated salts, while water was used for the hydrated salts.

Sources of varying thicknesses and constant area were thus prepared and weighed. The superficial density of the sources ranged from 0.05 to 35.0 mg/cm^2. The activity of the sources was measured with a 2π proportional counter and in two positions below an end-window gas-flow proportional counter. This gave results in geometrical efficiencies of 4%, 20%, and 50%. The aluminum planchettes, used as source mounts, were of sufficient thickness to ensure saturation back-scattering from the aluminum for all sources.

(b) Back-scattering

Inorganic compounds were used as backing material in powder form. The powder, finely ground, was contained in cylindrical metal boxes of sufficient depth to ensure saturation back-scattering.

Elements were also used as backing material to provide a standard curve of back-scattering vs. atomic number. The elements were in either foil or powder form.

The high-energy β^--emitter, P^{32}, was used as source material. To obtain a point source, 100 microliters of P^{32} solution of high specific activity was pipetted on to VYNS film and allowed to evaporate. The VYNS film, of superficial density 10 μg/cm^2, was then placed over the circular hole of an aluminum tray designed to fit as a shelf in the end-window counter. The backing material was cemented into position closely behind the source. Care was taken in all cases to keep the distance from the source to the backing constant. The activity of the samples was measured by the end-window counter in a geometrical efficiency of 20%.

RESULTS

(a) Self-absorption

Experimental self-absorption curves were obtained in the conventional manner by plotting the logarithm of the 'apparent' specific activity (measured activity per milligram of compound) versus the superficial density (mg/cm^2). The results of measurements in geometrical efficiencies of 50%, 20%, and 4% were normalized to the 50% position and were found to be superimposable.

In Fig. 1 is shown the self-absorption results for the phosphate sources. The points represent the experimental data. The difference in the self-absorption of the betas of P^{32} in phosphates of various densities is clearly shown. In Fig. 2 the self-absorption data for the sulphate sources are shown. Again the effect of density is clearly evident for the various sulphate sources.

The data have been fitted to the Gora and Hickey (15) function for a value of $\mu a = 0.022 d a E_0^{-1.33}$ (equation [2]). In Figs. 1 and 2 the solid lines represent the curves thus calculated. The agreement between the experimental and calculated results is very good for all the data. The error in each experimental point is estimated to be $\pm 5\%$. This includes non-uniformity of samples, statistical fluctuations in activity measurements, and weighing of samples. No correction has been made for the back-scattered radiation. The back-scatterer was the same for all sources, and the effect due to it was treated as a constant.

A further test of this function has been made by Meghir (35),* who studied the self-absorption of C^{11} in barium carbonate in a 4π counter which is essentially two 2π counters. The results are shown in Fig. 3. The triangles represent the self-absorption data for C^{11} in

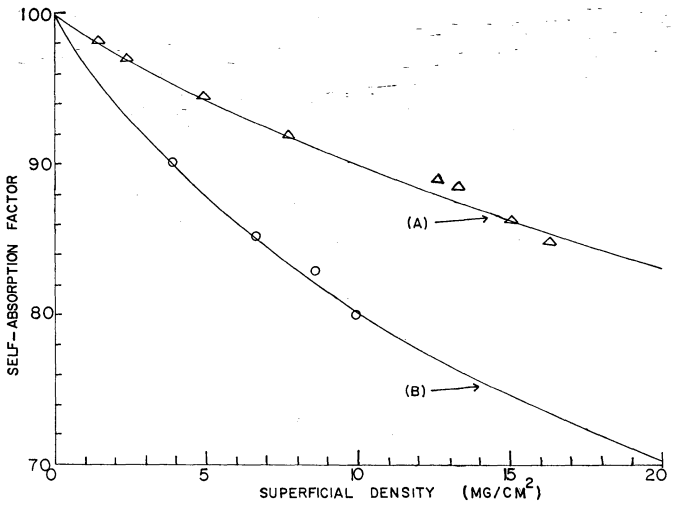

FIG. 3. Test of Gora and Hickey function: △ C^{11} in $BaCO_3$. The triangles represent the data obtained by Meghir (35). The solid line represents the curve obtained from the self-absorption expression. ○ Self-absorption of C^{11} in polystyrene (36). The solid curve was obtained by Meghir using the appropriate density corrections.

We are grateful to Dr. S. Meghir of this laboratory for kindly allowing us to use his results.

barium carbonate. The solid curve (A) is again obtained from the Gora and Hickey function. Crandall *et al.* (36) studied the self-absorption of C^{11} in polystyrene. Their data are shown by open circles, and Meghir obtained the curve (B) shown by use of the above function with the appropriate density correction.

Back-scattering

The effective atomic number, $\bar{Z}_{E_1}$, of each compound used was calculated from equation [6] with $x = 1$. The empirical effective atomic number, $\bar{Z}_{E_2}$, of Müller (equation [7]) was also calculated. The materials used as back-scatterers and their 'atomic numbers' are given in Table I. It is seen that the two formulae for effective Z give virtually the same

TABLE I

Effective atomic number of elements and compounds used as back-scatterers

Back-scatterer	$\bar{Z}_{E_1}$	$\bar{Z}_{E_2}$	Back-scatterer	$\bar{Z}_{E_1}$	$\bar{Z}_{E_2}$
C	6.00	6.00	Ni	28.00	28.00
BeO	6.67	6.56	Cu	29.00	29.00

ZnO	25.37	25.67			

result for low 'atomic numbers'. However, at high 'atomic numbers' there is a significant difference.

In Fig. 4 saturation back-scattering is plotted versus $\bar{Z}_{E_1}$. It is seen that a smooth curve may be drawn through all the points representing both elements and compounds. In Fig. 5 saturation back-scattering is plotted versus Müller's $\bar{Z}_{E_2}$. A smooth curve may be drawn through the points representing elements and the points representing compounds of low 'atomic number'. The points representing compounds of high 'atomic number' fall below the curve.

We were not able to reproduce the points of inflection found by Müller corresponding to atomic numbers of the rare gas configurations. Indeed, it seemed possible to redraw the Müller data without these points of inflection, especially since the rare gases were not used as back-scatterers in his experiments.

It is possible from a crude one-dimensional model* to suggest an 'effective atomic number' for back-scattering by compounds. This is shown in Fig. 6. The β-source is located at $x = 0$ on the x-axis. The activity of the source is $2a_0$. It is assumed that the shape of the β-spectrum and the angular distribution pattern of the β-radiation are virtually unchanged by passage through and absorption in the source. The absorption is assumed to be nearly exponential.

In Fig. 6(A), when there is no reflector, the measured activity is a_0, as only the activity in the negative direction reaches the counter. When there is a reflector, as in Fig. 6(B), the measured activity is the sum of the activity emitted in the negative direction plus the activity reflected back from the positive direction, i.e. a_0+b_0. The reflector is imagined to be infinite in length in order to describe the case of saturation back-scattering.

R, the reflection coefficient, is equal to the product of the number of scatterers and the cross section for back-scattering. For elements of low atomic number the screening of the

**A somewhat similar treatment has been given by G. L. Brownell (Preliminary Report No. 8, Nuclear Science Series, National Research Council, Washington, 1950), but to the authors' knowledge never published elsewhere.*

and the number moving in the negative direction is

$$b(x) = b_0 e^{-\mu x}.$$

To determine $b(x)$ in terms of $a(x)$, one considers the number of beta particles moving in the positive direction at a distance dx from x. Then $a(x+dx)$ will be the sum of the number transmitted from x and the number reflected from x.

$$a(x+dx) = a(x)-(R+\epsilon)a(x)dx+Rb(x)dx$$

$$\frac{da}{dx} = -(R+\epsilon)a(x)+Rb(x)$$

$$-\mu a_0 e^{-\mu x} = -(R+\epsilon)a_0 e^{-\mu x}+Rb(x)$$

and

$$b(x) = \left\{\frac{(R+\epsilon)-\mu}{R}\right\}a_0 e^{-\mu x}.$$

To find μ in terms of R and ϵ, one considers the number of beta particles moving in the negative direction at $x-dx$.

$$b(x-dx) = b(x)-(R+\epsilon)b(x)dx+Ra(x)dx$$

$$-\frac{db}{dx} = -(R+\epsilon)b(x)+Ra(x).$$

Then

$$\mu\left\{\frac{(R+\epsilon)-\mu}{R}\right\}a_0 e^{-\mu x} = -(R+\epsilon)\left\{\frac{(R+\epsilon)-\mu}{R}\right\}a_0 e^{-\mu x} + Ra_0 e^{-\mu x}$$

and

$$\mu = \sqrt{[(R+\epsilon)^2-R^2]}.$$

Hence $b(x)$ may be expressed

$$b(x) = \left\{\frac{(R+\epsilon)-\sqrt{[(R+\epsilon)^2-R^2]}}{R}\right\}a_0 e^{-\mu x}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

At $x = 0$

$$b(x) = b_0 = \left\{\frac{(R+\epsilon)-\sqrt{[(R+\epsilon)^2-R^2]}}{R}\right\}a_0.$$

The efficiency of reflection, η, is then

$$\eta = \frac{b_0}{a_0} = 1 + \frac{\epsilon}{R} - \sqrt{\left[\left(1 + \frac{\epsilon}{R}\right)^2 - 1\right]}.$$

The percentage back-scattering is given by the efficiency

$$\left\{\left(a_0 + \frac{b_0}{a_0}\right) - a_0\right\} \times 100$$

$$= \frac{b_0}{a_0} \times 100.$$

Therefore back-scattering depends on the ratio ϵ/R. This suggests an effective Z for compounds. For a compound, the reflection coefficient is given by

$$R \propto N_1Z_1^2 + N_2Z_2^2 + \ldots N_nZ_n^2,$$

where $N_1 \ldots N_n$ represent the particle densities and $Z_1 \ldots Z_n$ the atomic numbers of elements $1 \ldots n$.

The loss coefficient is given by

$$\epsilon \propto N_1Z_1 + \ldots N_nZ_n.$$

Therefore

$$\frac{\epsilon}{R} \propto \frac{N_1Z_1 + \ldots N_nZ_n}{N_1Z_1^2 + \ldots N_nZ_n^2}.$$

This indicates an effective Z as given in equation [6]:

$$\frac{N_1Z_1^2 + N_2Z_2^2 + \ldots N_nZ_n^2}{N_1Z_1 + \ldots N_nZ_n} = \bar{Z}_{E1}.$$

The reflection coefficient may be written

$$\eta = 1 + \frac{\gamma}{\bar{Z}_{E1}} - \sqrt{\left[\left(1 + \frac{\gamma}{\bar{Z}_{E1}}\right)^2 - 1\right]},$$

where γ is some constant of proportionality. Let $S = 1 + \gamma/\bar{Z}_{E1}$, then

$$\eta = S - \sqrt{[S^2 - 1]}.$$

Therefore $S = (1+\eta^2)/2\eta$ and

$$\frac{\gamma}{\bar{Z}_{E1}} = \frac{(1-\eta)^2}{2\eta}$$

$$\bar{Z}_{E1} = 2\gamma\frac{\eta}{(1-\eta)^2}.$$

The plot of $\bar{Z}_{E1}$ should yield a straight line.

In Fig. 7, curve (A) shows a plot of $\eta/(1-\eta)^2$ vs. $\bar{Z}_{E1}$. However, for $\bar{Z}_{E1} > 60$, the results are anomalously high. For high values of Z the inner shells will screen the nucleus and

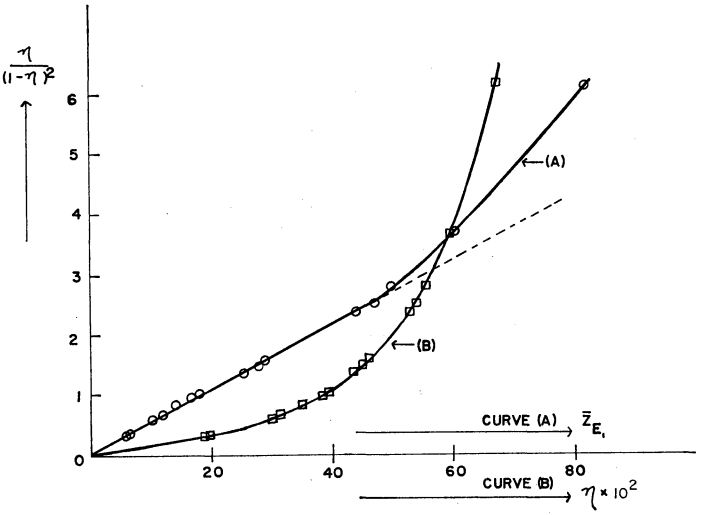

FIG. 7. (A) Plot of $\eta/(1-\eta)^2$ vs. $\bar{Z}_{E_1}$. (B) Plot of $\eta/(1-\eta)^2$ vs. η.

reduce the effective value of Z^2 in R. Only the loosely bound electrons will contribute to ϵ and hence the value of Z in ϵ is reduced as well. The first effect will tend to reduce the reflection coefficient, the second to increase it. In curve (B) of Fig. 7 it is seen that the ratio $\eta/(1-\eta)^2$ increases for high η, indicating that the second effect is the more important.

HETEROCYCLIC STEROIDS

II. PREPARATION AND N.M.R. SPECTRA OF 17,17-DIALKYL-13(14)-UNSATURATED STEROIDS[1]

E. CASPI[2] AND D. M. PIATAK
Worcester Foundation for Experimental Biology, Shrewsbury, Massachusetts, U.S.A.

Received May 6, 1963

ABSTRACT

A series of 17,17-dialkyl-13(14)-unsaturated steroids was prepared via the Wagner–Meerwein rearrangement. Some of the steroids were synthesized with an isoxazole ring or a pyrazole ring attached to ring A. The n.m.r. spectra of the compounds prepared are discussed.

During investigations on steroidal isoxazoles (1) 17β-acetoxyandrost-4-eno[2,3*d*]isoxazole (I) and 17,17-dimethyl-18-norandrosta-4,13(14)-dieno[2,3*d*]isoxazole (III) were found to have tumor-inhibiting properties when assayed by the method of Abe *et al.* (2). Further biological data disclosed that the 17β-acetoxyisoxazole I had 1/5 of the androgenic activity of testosterone, while the 17,17-dimethylisoxazole III was devoid of accompanying activity. In order to explore these observations, several steroidal analogues were prepared. In addition, the n.m.r. spectra of the compounds are discussed.

Preparation of 17,17-dimethyl-18-norandrosta-4,13(14)-dien-3-one (VI), 2α,17,17-trimethyl-18-nor-5α-androst-13(14)-en-3-one (IX), 17β-methyl-17α-ethyl-18-norestra-4,13-(14)-dien-3-one (VII), and 17,17-dimethyl-9α-fluoro-11β-hydroxy-18-norandrosta-4,13-(14)-dien-3-one (VIII) involved simple Wagner–Meerwein rearrangement of the

corresponding 17β-hydroxy-17α-alkylandrostanes. Structural assignments were based primarily on elemental analysis and n.m.r. spectroscopy.

Confirmation of the α orientation of the 2-methyl group of IX was established by its optical rotary dispersion curve, which was identical in shape with that of 17β-hydroxy-2α-methyl-5α-androstan-3-one; their magnitudes of molar rotation were also the same. Stereochemistry of the migrating methyls was rationalized on mechanistic grounds as being β, since Wagner–Meerwein rearrangements are known to proceed with "retention" of configuration (3).

The steroidal pyrazole 17,17-dimethyl-18-norandrosta-4,13(14)-dieno[3,2*c*]pyrazole (X) was conveniently prepared by refluxing hydrazine hydrate with 2-hydroxymethylene-17,17-dimethyl-18-norandrosta-4,13(14)-dien-3-one in ethanol according to the procedure of Clinton *et al.* (4). The compound gave the correct analysis, a λ_{max}^{MeOH} 260 mμ, and characteristic infrared bands at 1675, 1630, and 1560 cm^{-1} (4).

The isoxazoles were obtained as described previously (1) by refluxing the corresponding 2-hydroxymethylene steroids in glacial acetic acid with hydroxylamine hydrochloride. The 17β-methyl-17α-ethyl-18-norestra-4,13(14)-dieno[2,3*d*]isoxazole (IV) was prepared from 17β-methyl-17α-ethyl-18-norestra-4,13(14)-dien-3-one (VII); the fluoroisoxazole V, from 11β,17β-dihydroxy-9α-fluoro-17α-methylandrost-4-en-3-one (4); and the 17β-methoxy isoxazole II, from 17β-methoxyandrost-4-en-3-one (5). Concomitant Wagner–Meerwein rearrangement occurred with isoxazole formation in the preparation of V. Identification of the isoxazoles was made by elemental analyses and ultraviolet, infrared, and n.m.r. spectroscopy.

Certain pertinent n.m.r. bands are listed in Table I. In compounds with a 17,17-dialkyl group, i.e. III to X, the methyl at 17 (or 17-*gem*-dimethyl) is observed at τ = 9.00–9.05, quite significantly shifted upfield from the tertiary 17α-methyl in 17β-hydroxy-17α-alkyl compounds, XI, XII, and XVI. This shift (+0.3 p.p.m.) is consistent with the expected downfield shift (7) of tertiary alkyl moieties when an oxygen function is added to the

carbon bearing the alkyl moiety. The *secondary methyl* of the ethyl moiety in the *gem*-dialkyl compounds IV and VII shows an analogous upfield shift. The structure of compounds containing the 17,17-dialkyl-13(14)-ene moiety was deduced from this upfield shift, the disappearance of an 18-methyl band, and the absence of a band ($\tau \approx 4$) attributable to a vinyl proton at other than C-4.

Of interest is the variation in chemical shift for the C-19 methyl group brought about by substitution of a hydroxymethylene at C-2 or a hydroxy function at C-11. An upfield shift of ca. +0.2 p.p.m. is seen in the instance where the C-2 position is substituted by hydroxymethylene, e.g. XII to XVI. This upfield shift of +0.2 p.p.m. is also evident when an isoxazole or pyrazole ring is formed at the C-2, C-3 positions, e.g. XIII to I, VI to III, VIII to V, and VI to X. The 11β-hydroxyl causes the known downfield shift (8) of the 19-methyl (−0.3 p.p.m.) as evidenced in the shift from $\tau = 8.8$ to $\tau = 8.5$ for XIV to XII and for VI to VIII and in the shift from $\tau = 9.0$ to $\tau = 8.7$ for III to V. The 9α-fluorine does not appear to have a pronounced influence on the 19-methyl. These chemical shifts are additive as illustrated with the value for the 19-methyl of VI ($\tau = 8.83$). By adding the upfield shift of +0.2 p.p.m. for substitution at C-2 and the downfield shift of −0.3 p.p.m. for substitution at C-11, the figure arrived at ($\tau = 8.73$) is in fair agreement with the value for V ($\tau = 8.68$).

The chemical shift of the vinylic proton at C-4 varies significantly with substitution

					1,560								

at C-2 and C-3, while little effect is observed by substitution at C-9 and C-11. A pronounced downfield shift of −0.4 p.p.m. is brought about by the formation of an isoxazole or pyrazole ring at the C-2, C-3 positions, as seen by comparing VI to VIII and XVI with I to II and III to V.

In the case of the attached heterocyclic rings the proton on the carbon at the 3′-position of the isoxazole ring or at the 5′-position of the pyrazole ring exhibits a value of τ = 1.9–2.0. These chemical shifts seem to be characteristic for the —N=CH—C= grouping.

Preliminary biological evaluation indicated that there was no consistent enhancement of antitumor activity for the compounds prepared. A full report will be published in a later communication.

EXPERIMENTAL*

Preparation of 17,17-Dialkyl-3-ketones VI, VII, VIII, and IX

To a solution of the 17β-hydroxy-17α-alkylsteroid (1.00 g) in glacial acetic acid (15 ml) was added glacial acetic acid saturated with hydrogen chloride (1.0 ml). The solution was then heated at reflux for 10 minutes. The solution was cooled, water added, and most of the acetic acid removed *in vacuo*. The steroids were recovered with ether, washed with saturated sodium bicarbonate solution, then water, dried, and concentrated *in vacuo*. The compounds crystallized readily upon trituration with methanol. (See Table II for analytical results.)

17,17-Dimethyl-18-norandrosta-4,13(14)-dieno[3,2c]pyrazole (X)

The 2-hydroxymethylene derivative of I was prepared via the sodium hydride procedure of Weisenborn *et al.* (6).

A solution of the obtained 2-hydroxymethylene compound (4.42 g) and hydrazine hydrate (85%; 1.7 g) in 100 ml ethanol was heated at reflux for 4 hours. The solvent was removed *in vacuo*. Chromatography of the reaction mixture on silica followed by recrystallization from acetone gave pure 17,17-dimethyl-18-norandrosta-4,13(14)-dieno[3,2*c*]pyrazole. (See Table II for analytical results.)

Preparation of Isoxazoles

The isoxazole steroids were prepared from 2-hydroxymethylene derivatives and hydroxylamine hydrochloride in glacial acetic acid, exactly as described in our previous communication (1).

ACKNOWLEDGMENT

The steroids used in this study were provided by Cancer Chemotherapy National Service Center, National Cancer Institute, U.S. Public Health Service.

Suffield Experimental Station, Ralston, Alberta
Received March 8, 1963

ABSTRACT

In 1957, a new method for the synthesis of methylphosphonous dichloride, in high yield, by the reduction of the aluminum chloride – phosphorus trichloride – methyl chloride complex in diethyl phthalate solution by finely powdered antimony, was developed. That this is a general method for the synthesis of the more volatile alkylphosphonous dichlorides was demonstrated by the preparation, in good yield, of a series of compounds from the aluminum chloride – phosphorus trichloride complexes formed from ethyl chloride, *n*-propyl chloride, *i*-propyl chloride, *n*-butyl chloride, and *s*-butyl chloride. As expected, isomerization occurred in the case of the normal alkyl chlorides.

In the period 1956–1957, a requirement arose for the synthesis of P^{32}-labelled organophosphorus compounds, of high specific activity, from methylphosphonous dichloride. A literature survey at this time revealed no simple methods for the preparation which were suitable and 'safe' for use in a radioactive synthesis involving multicurie sources of P^{32}.

A new method for the preparation of methylphosphonous dichloride was developed, therefore, which appears to have general application for the synthesis of alkylphosphonous dichloride (1), although the present discussion is restricted to those more volatile than antimony trichloride because of the recovery techniques employed.

In 1958, Komkov *et al.* (2) reported a similar synthesis. Their method appeared not to be as suitable for use in the radioactive synthesis of methylphosphonous dichloride as the method described herein, because the reduction reaction proceeded violently at times, even with close control, the manipulative techniques were more complex, and the yields somewhat lower.

The synthesis of 'sarin', isopropyl methylphosphonofluoridate, labelled P^{32}, has been described (3). Methylphosphonic dichloride, the basic intermediate in this synthesis, was prepared from the aluminum chloride – phosphorus trichloride – methyl chloride complex by solution in diethyl phthalate followed by treatment with gaseous sulphur dioxide.

$$[CH_3PCl_3]^+[AlCl_4]^- \xrightarrow[\text{phthalate}]{\text{diethyl}} CH_3PCl_4 + [DEP][AlCl_3]$$
$$\downarrow SO_2$$
$$CH_3POCl_2 + SOCl_2$$

While methylphosphonic tetrachloride was never isolated from the reaction mixture, its presence is clearly demonstrated by the subsequent reaction with sulphur dioxide, since neither the complex itself, nor its solution in solvents which do not form a complex with aluminum chloride, reacts with sulphur dioxide. It appeared likely, therefore, that

[1]*Issued as Suffield Technical Paper No. 189, D.R.B. Project No. D52-20-20-27. Permission to publish this work is gratefully acknowledged.*

reduction of methylphosphonic tetrachloride might be a route to methylphosphonous dichloride.

$$[CH_3PCl_3]^+[AlCl_4]^- \xrightarrow[\text{phthalate}]{\text{diethyl}} CH_3PCl_4 + [DEP][AlCl_3]$$

$$CH_3PCl_4 \xrightarrow{\text{reduction}} CH_3PCl_2$$

In the synthesis of sarin, labelled P^{32}, granular antimony is used in the first step, to reduce phosphorus pentachloride to phosphorus trichloride. The addition of finely powdered antimony (250 mesh) to an efficiently stirred solution of the aluminum chloride – phosphorus trichloride – methyl chloride complex in diethyl phthalate results in a smooth, strongly exothermic reaction, which, on completion, gives a 90% yield of redistilled methylphosphonous dichloride (yield based on phosphorus trichloride).

That this is a general method for the synthesis of alkylphosphonous dichlorides was demonstrated by the preparation of the compounds listed in Table I from the aluminum

TABLE I

Products obtained by antimony reduction of aluminum chloride – phosphorus trichloride – alkyl chloride complexes in diethyl phthalate solution

RCl in complex	Product	Crude yield (%)	Redistilled yield (%)	Redistilled product

chloride – phosphorus trichloride complexes formed with ethyl chloride, *n*-propyl chloride, *i*-propyl chloride, *n*-butyl chloride, and *s*-butyl chloride.

The identities of the products from the methyl and ethyl chloride complexes were confirmed by addition of sulphur to give methylphosphonothionic dichloride and ethylphosphonothionic dichloride respectively.

It will be noted that the products obtained from the complexes formed from *n*-propyl and *i*-propyl chlorides have the same boiling point, refractive index, and, it was found, identical infrared spectra, i.e., they are the same compound. The product was confirmed to be isopropylphosphonous dichloride by oxidation to isopropylphosphonic dichloride. It is of interest to note that unlike methylphosphonous dichloride and ethylphosphonous dichloride, isopropylphosphonous dichloride does not add sulphur even on being heated to 100° C with anhydrous aluminum chloride as a catalyst.

Products obtained from the complexes formed from *n*-butyl and *s*-butyl chlorides are also identical. The nature of the product was confirmed as *s*-butylphosphonous dichloride by its conversion to the *s*-butylphosphonic dichloride.

The results obtained are to be expected since, under the reaction conditions, the *n*-alkyl chlorides will be isomerized to the *s*-alkyl chlorides (4, 5). The results also parallel those of Kinnear and Perren (6), who showed that the complexes from the *n*-alkyl and *s*-alkyl chlorides gave only *s*-alkylphosphonic dichloride on treatment with water.

In our investigation, the products have been recovered by direct distillation from the reaction mixture. Thus, while the reaction described would appear to have a fairly general application, other separation techniques would have to be employed for those compounds less volatile than antimony trichloride and/or diethyl phthalate.

EXPERIMENTAL

The reduction reactions are very exothermic and cooling is required to keep the temperature below 75° C. At higher temperatures the reaction mixture slowly decomposes to give ethyl chloride from the diethyl phthalate, which reduces the yield of desired product. Good yields are also dependent on the complete formation of the aluminum chloride – phosphorus trichloride – alkyl chloride complex.

The apparatus used was similar to that described (3) for the synthesis of P^{32}-labelled methylphosphonic dichloride from the complex. It differed in that no hot-air jacket was required on the inlet tube to the crude product receiver and the column was fitted with a Whitmore-Lux type, total reflux, variable takeoff head.

Methylphosphonous Dichloride

The complex from aluminum chloride (200 g, 1.5 mole), phosphorus trichloride (137.5 g, 1 mole), and methyl chloride (50.5 g, 1 mole) was prepared by the method previously described (3). This complex was dissolved with external cooling in diethyl phthalate (600 ml) and the solution thoroughly degassed at 2 mm and at a temperature of 75° C. The solution was rapidly cooled to 30° C, efficiently stirred, and finely powdered antimony (250 mesh, 81.2 g, 0.667 mole) added. The temperature rose slowly at first and then more rapidly; external cooling was used at this stage to maintain the temperature at approximately 55° C. The reaction appeared to be complete in 35 minutes, when most of the antimony had disappeared and a fine white precipitate had formed (presumed to be antimony trichloride). The product was flashed from the mixture at 10 mm pressure and a temperature of 75° C into the crude product receiver, cooled in dry ice – acetone. The product was then distilled to give methylphosphonous dichloride (109 g, 93%; b.p. 77–79° C at 700 mm) and fractionated to give a very small forerun and methylphosphonous dichloride (105.5 g, 90%; b.p. 78–79° C at 700 mm).

Methylphosphonothionic Dichloride

Methylphosphonous dichloride (196.4 g, 1.68 mole), prepared in the manner described above, and anhydrous aluminum chloride (1.5 g) were introduced into a three-necked reaction flask, fitted with a condenser, thermometer, and magnetic stirring bar, under an atmosphere of dry nitrogen. Dried granular sulphur (53.8 g, 1.68 mole) was added in small portions with external water cooling, in amounts sufficient to keep the reaction temperature at 60–65° C. Addition took 50 minutes, the cooling bath was removed, and the reaction mixture heated to 85° C for 5 minutes. The product, methylphosphonothionic dichloride, was recovered by fractional distillation under reduced pressure (244.5 g, 98%; b.p. 68–69° C at 35 mm; n_D^{27} 1.5468). Physical constants (7): b.p. 40° C at 5 mm; n_D^{25} 1.5473.

Ethylphosphonous Dichloride

Ethyl chloride (74.2 g, 1.15 mole), aluminum chloride (133.3 g, 1.0 mole), and phosphorus trichloride (137.5 g, 1.0 mole) were shaken in a sealed pressure bottle at room temperature. After 2 hours the reaction mixture had liquefied and then solidified. Reaction was completed by heating the mixture to 100° C for 1 hour. The product was powdered in a dry box under an atmosphere of dry nitrogen, added to the 'complex' reaction flask, and dissolved in diethyl phthalate (600 ml) with external cooling (temperature rose to 35° C). The solution was degassed at 2 mm and a temperature of 55° C and then cooled to room temperature. Finely powdered antimony (250 mesh, 81.2 g, 0.667 mole) was then added to the efficiently stirred mixture. The temperature began to rise immediately and when it had reached 65° C (5 minutes) the reaction flask was externally cooled with an ice–water mixture. The temperature rose to 75° C and then slowly fell. Reaction appeared complete in 30 minutes and the crude product was flashed from the mixture at 75° C and 10 mm into the crude product receiver, cooled in dry ice – acetone. The crude product was fractionated to give ethylphosphonous dichloride (108.6 g, 83%; b.p. 64° C at 150 mm).

Ethylphosphonothionic Dichloride

Dried granular sulphur (26.1 g, 0.815 mole) was added to ethylphosphonous dichloride (107 g, 0.815 mole), prepared above, in a similar manner to the preparation of methylphosphonothionic dichloride. The sulphur addition reaction was slower but proceeded smoothly at a temperature of 90° C. Cooling was used to keep the temperature between 90 and 110° C and the reaction was finally heated to 110° C for 30 minutes, after all the sulphur had been added to the reaction mixture. The product was recovered by fractional distillation under reduced pressure to give 116.5 g, 87.6%; b.p. 52° C at 6 mm; $n_D^{27.5}$ 1.5390. Physical constants (7): b.p. 47–48° C at 3 mm; n_D^{25} 1.5406. The infrared spectrum agreed with that of a reference sample.

Isopropylphosphonous Dichloride

(a) From Isopropyl Chloride

Isopropyl chloride (78.5 g, 1 mole) was added dropwise to an efficiently stirred mixture of anhydrous aluminum chloride (133.3 g, 1 mole) and phosphorus trichloride (137.5 g, 1 mole) in the complex reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

flask. The reaction was strongly exothermic and required external cooling in dry ice – acetone to keep the temperature at 35° C. After addition of approximately two thirds of the isopropyl chloride the reaction mixture solidified. After methylene chloride (100 ml) was added, the remainder of the isopropyl chloride was added dropwise to the stirred reaction mixture which was then heated to reflux for 1 hour. Diethyl phthalate (600 ml) was added very slowly, with external cooling, to the stirred reaction mixture, the solution degassed at 75° C and 2 mm and cooled to room temperature. Finely powdered antimony (250 mesh, 81.2 g, 0.667 mole) was added to the well-stirred solution, using external water cooling. Rapid reaction took place and the temperature reached 68° C. The reaction mixture was finally heated to 75° C for 15 minutes and the crude product recovered in the normal way. Distillation gave the product (124.3 g, 85.8%; b.p. 63° C at 76 mm, 69° C at 80 mm). This product was carefully fractionated through a Todd column to give isopropylphosphonous dichloride (97. 8 g, 67.4%; b.p. 88° C at 202 mm; $n_D^{25.4}$ 1.4870).

(b) From n-Propyl Chloride

By the same procedure as used in (*a*) above, *n*-propyl chloride (78.5 g, 1.0 mole) gave the same product (123 g, 85%; b.p. 58° C at 64 mm, 62.5° C at 80 mm). Careful fractionation through a Todd column gave 88.7 g, 61.2%; b.p. 88–88.5° C at 199–203 mm; n_D^{25} 1.4868. The infrared spectra of the products from (*a*) and (*b*) were identical.

Isopropylphosphonic Dichloride

Isopropylphosphonous dichloride (from (*b*) above) (68.4 g, 0.47 mole) was weighted into a 200-ml three-necked flask fitted with a condenser, thermometer, gas inlet tube, and magnetic stirring bar. A slow stream of dry oxygen was passed through the stirred liquid and external water cooling used to maintain the temperature at 35° C in the early stages. Oxygenation was continued for 8 hours, by which time the temperature of the reaction mixture had dropped to room temperature. The reaction product was fractionated through a Todd column to give isopropylphosphonic dichloride (45.5 g, 60%; b.p. 37° C at 1.5 mm, 60° C at 5.6 mm, 85° C at 28 mm; n_D^{25} 1.4647). Physical constants: b.p. 35.3° C at 1.5 mm (6); b.p. 60° C at 6 mm (7).

s-Butylphosphonous Dichloride

The same method as for the preparation of isopropylphosphonous dichloride was used. *s*-Butyl chloride (92.5 g, 1 mole) gave *s*-butylphosphonous dichloride (89 g, 56%; b.p. 68° C at 37 mm). Fractionation through a Vigreux column gave 63.7 g, 40%; b.p. 62–62.5° C at 28 mm; n_D^{25} 1.4908. A repeat reaction gave 123.5 g, 77.6%; b.p. 68° C at 37 mm. *n*-Butyl chloride (92.5 g, 1 mole) gave the same product (149.2 g, 93.7%; b.p. 72–73° C at 45 mm). Fractionation through a Vigreux column gave 135 g, 85%; b.p. 70° C at 40 mm; n_D^{25} 1.4909. The infrared spectra of the products from *n*-butyl and *s*-butyl chlorides were identical.

s-Butylphosphonic Dichloride

The same method as for the preparation of isopropylphosphonic dichloride was used. Starting with 25.0 g, 0.16 mole of *s*-butylphosphonous dichloride, a yield of 16.9 g (62%) of *s*-butylphosphonic dichloride was obtained (b.p. 56° C at 2 mm; n_D^{25} 1.4700). Physical constant (6): b.p. 57° C at 2 mm.

THE FORCES OPERATIVE IN HOMONUCLEAR DIATOMIC MOLECULES

RICHARD F. W. BADER[1]
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received May 24, 1963

ABSTRACT

The electron densities obtained from the S.C.F. wave functions determined by Ransil for some first-row homonuclear diatomic molecules are tested through a calculation of the forces acting on the nuclei. None of the density functions (for Li_2, Be_2, C_2, N_2, and F_2) give the required condition of electrostatic equilibrium, the departure from a nonzero force increasing with increasing nuclear charge. Adverse atomic polarizations are shown to be primarily responsible for these results, and in particular for the surprising result that the density in the $3\sigma_g$ orbital of N_2 and F_2 actually exerts a force tending to separate the molecule into atoms.

I. INTRODUCTION

The forces exerted on the nuclei in a number of first-row diatomic molecules are calculated from the wave functions determined by Ransil (1). Our reasons for doing this are as follows. The wave functions obtained by Ransil employ only a minimal basis set and represent one of the simplest approximations to the Hartree-Fock solutions for these molecules. While the dissociation energies predicted by these functions are disappointingly low it is important to test these same wave functions against other observable properties in order to determine their overall reliability. For example, it is conceivable that the distribution of the electron density as obtained from these wave functions may not be too far removed from a satisfactory one even though the energy eigenvalue is incorrect. This is possible due to the differing sensitivity of various properties to the radial and angular characteristics of the wave function. A sensitive test of the overall density distribution is provided by a calculation of the forces operative on a nucleus in a molecule. The electronic forces are determined by a one-electron operator $\langle P_1/r_i^2 \rangle$ and hence by the one-electron density distribution (2). Hall (3) has shown that wave functions determined by the self-consistent field procedure (such as the ones considered in this paper) are "stable" to one-electron operators, and in particular, that these wave functions will satisfy the exact Hellmann–Feynman theorem for the calculation of the electronic forces. In addition, a discussion of the orbital contributions to the forces gives an insight into the nature of the binding in these molecules and, it is hoped, may also indicate the manner in which the original basis set is most seriously lacking.

II. CALCULATIONS AND RESULTS

The forces were calculated for the wave functions termed the "best limited L.C.A.O.–M.O." set (1). These are sets of molecular orbitals, constructed from the inner shell and valence atomic orbitals only, in which the orbital exponents have been optimized with respect to the molecular energy by a variational procedure. The electron density ρ is given by

$$\rho = 2 \sum_i \phi_i \phi_i^*,$$

where the ϕ_i are doubly occupied orthonormal molecular orbitals, (orbitals of π symmetry are considered as two doubly occupied ones). The electronic force on nucleus α

[1]*Present address: Department of Chemistry, McMaster University, Hamilton, Ontario.*

along the bond axis is given by

$$F_{\alpha e} = Z_\alpha \int (\cos\theta_i/r_i^2)\rho\, d\tau,$$

where Z_α is the nuclear charge of atom α. Since the density is given by a sum of orbital contributions, the total electronic force may be broken up in a similar manner as follows. Both the nuclear and electronic forces involve a common factor of Z_α/R^2, where R is the internuclear distance. Thus the total force on nucleus α can be conveniently written (4) as

$$F_\alpha = \frac{Z_\alpha}{R^2} \sum_i (f_i - 1), \qquad [1]$$

where the f_i are the electronic forces due to each doubly occupied molecular orbital with the factor Z_α/R^2 removed. For closed-shell homonuclear diatomic molecules within the single determinantal approximation the number of such doubly occupied orbitals is equal to Z_α (counting each completely filled π orbital twice) and thus summing over i in equation [1] gives simply

$$F_\alpha = \frac{Z_\alpha}{R^2} \sum_i f_i - \frac{Z_\alpha^2}{R^2} = F_{\alpha e} + F_{\alpha n}.$$

When R refers to the equilibrium bond length $F_{\alpha e} = -F_{\alpha n}$ and the resultant force must equal zero. At this point of electrostatic equilibrium $\sum_i f_i = Z_\alpha$.* Formulation [1] brings out clearly the physical interpretation to be given to the electronic forces due to each of the molecular orbitals (4). At infinite internuclear separations each electron will shield one unit of nuclear charge and thus in the limit of large values for R, each f_i value will approach unity and the total force between the two atoms will be zero. A pair of electrons which are tightly bound in an inner shell orbital will continue to shield one unit of charge on each nucleus as R decreases and also give an f_i value of unity, i.e., even on molecule formation the inner shell electrons are not effectively penetrated by the approaching nucleus and their f_i value remains constant from $R = \infty$ to $R = R_e$. The resultant force $f_i - 1$ due to the presence of such electrons is zero and the orbital is termed a *nonbinding*† orbital. The f_i value of a bonding orbital exceeds unity as R decreases due to the accumulation of charge in the binding region between the nuclei. Such an orbital thus has an $f_i - 1$ value greater than zero, indicating that its density is distributed so as to exert a binding force on the nuclei in excess of the associated nuclear repulsive force. Such an orbital is termed a *net-binding* orbital. An antibonding combination of atomic orbitals leads to a decrease in the f_i value as R decreases and thus to an $f_i - 1$ value which is negative. Orbitals possessing such negative values are termed net *antibinding* as they lead to a net force of repulsion on the nuclei, tending to separate the molecule into atoms. Thus the value of f_i relative to unity indicates immediately whether or not the electrons in the corresponding orbital are distributed in such a way as to simply shield an equivalent number of nuclear charges, whether they contribute to the binding by exerting a force pulling the two nuclei together, or whether their presence leads to a net force of repulsion tending to separate the molecule into atoms.

The f_i values and the total resultant forces for the lowest $^1\Sigma_g^+$ states of the molecules

*This is another reason why the force provides a good observable by which to test the electron density function. A knowledge of the equilibrium bond length which is often accurately known allows one to determine the "experimental" value for $F_{\alpha e}$ with greater accuracy than is possible for many other molecular properties.

†In accordance with a suggestion made by T. Berlin, J. Chem. Phys., **19**, 214 (1951), we use the term binding when referring to forces and reserve the term bonding for the usual interpretation in terms of energy.

Li_2, Be_2, C_2, N_2, and F_2 at their equilibrium internuclear separations are given in Table I.

In no case do the densities calculated by Ransil for these molecules lead to a zero resultant force on the nuclei. For Li_2 the electronic force is too large, and in the remaining cases the electronic force is not large enough to counterbalance the nuclear force of repulsion. The error in the resultant force is seen to increase as the nuclear charge increases. This result is to be expected as the forces possess a $1/r_i^2$ radial dependence which causes their value to be sensitive to the nature of the wave function in regions close to the nucleus. This sensitivity increases, due to the contraction of the charge density, as Z_α increases. The results for the forces on the Be, C, N, and F nuclei parallel those found for the heavy nuclei in HF (5), H_2O (6), and NH_3 (7) as calculated from S.C.F. wave functions. In these three hydride molecules the force on hydrogen was close to zero but the resultant force on the heavy nucleus was in each case close to the entire nuclear force of repulsion. While the errors in the present results are much smaller in magnitude than the total nuclear forces of repulsion, the two sets of values are nevertheless very similar. The forces on the F and N nuclei in HF and NH_3 (and hence the resultant electric fields at the F and N nuclei) were found to be of the same order of magnitude as those found in F_2 and N_2, the values of the forces being -2.94 and -2.05 a.u. respectively. The results indicate that the S.C.F. densities, particuarlly for the C_2, N_2, and F_2 molecules, are only fair approximations to the distributions required for electrostatic equilibrium. The reasons for these nonzero resultant forces are best determined through a consideration of the orbital contributions to the forces. In order to facilitate this discussion and that of the binding in these molecules in terms of the atomic orbital contributions to the electron density, we give in Table II a more detailed breakdown of the orbital forces in the N_2 molecule.

The atomic, penetration, and overlap forces arise from the three possible types of atomic and overlap population densities.* *Atomic force*: the force exerted on a nucleus due to the polarization (e.g., $2s$–$2p$ hybridization) of the atomic charge density situated on that nucleus. *Penetration force*: the force exerted on a nucleus by the atomic charge density situated entirely on another nucleus. It is a measure of the electronic shielding of one nucleus from the other and the amount of this shielding is determined by the extent to which one nucleus penetrates the charge density surrounding the second nucleus. *Overlap force*: the force on a nucleus due to the density resulting from the overlap of atomic orbitals situated on two different nuclei. This force term is a sensitive measure of the binding power of a molecular orbital. The binding is not simply proportional to the magnitude of the overlap which determines the amount of density transferred on molecule formation. Of equal importance is where the density is placed and this is quantitatively measured by the overlap force.

In all five cases the f_i values for the $1\sigma_g$ and $1\sigma_u$ orbitals (which are primarily comprised of the $1s$ orbitals) are very close to unity. These orbitals are, therefore, nonbinding as their density simply shields an equivalent number of nuclear charges. This shielding is evident from the results for these two orbitals in N_2 in Table II where the penetration forces are seen to be close to unity and the atomic and overlap forces are very small.

The $2\sigma_g$ orbital exerts a strong binding force on the nuclei, the net force $(f(2\sigma_g)-1)$ being actually greater than unity in all cases except that of Li_2. The overriding contribution to $f(2\sigma_g)$ in all the cases but that of F_2 is from the overlap density, a result which

*For a fuller discussion of the force contributions and a similar force analysis of the S.C.F. results for hydrogen fluoride see reference 5.

*A negative force is one in the same direction as the force of nuclear repulsion. The resultant force F_α is in atomic units (e^2/a_0^2). To change an f_i value into atomic units multiply the value by Z_α/R^2.

†These values are for a two-electron density. They must be doubled to obtain the total electronic force.

‡For comparison, the forces on the Li and N nuclei when the internuclear separations in the Li_2 and N_2 molecules are increased by 0.1 Å are 0.0031 and 0.28 a.u. respectively.

TABLE II

Force contributions from the atomic and overlap densities in N_2

Molecular orbital	$1\sigma_g$	$1\sigma_u$	$2\sigma_g$	$2\sigma_u$	$1\pi_u$	$3\sigma_g$
Atomic force	0.0540	0.1514	0.1902	−1.2406	0.0000	−1.6916
Penetration force	0.9987	1.0052	0.8187	0.8445	0.5613	0.6492
Overlap force	0.0140	−0.0309	1.6238	−0.2521	0.3937	0.7702
Total orbital force (f_i)	1.0667	1.1256	2.6327	−0.6482	0.9550	−0.2722
Orbital energy in a.u. (1)	−15.647	−15.644	− 1.421	−0.7137	−0.5454	−0.5555

indicates that this orbital is the one primarily responsible for the binding in these molecules. The detailed results for N_2 in Table II show that a great deal of charge is transferred to the binding region between the nuclei in the formation of this molecular orbital. Unlike the $2\sigma_u$ and $3\sigma_g$ orbitals, the atomic force contribution is relatively small for $2\sigma_g$.

The $2\sigma_u$ orbital is not only net antibinding but is actually antibinding (i.e., $f(2\sigma_u)$ is itself negative). The main reason for the strongly antibinding nature of this orbital is the unfavorable direction of the atomic polarization on each nucleus arising from the $2s$–$2p$ hybridization. This hybridization removes charge from the binding region and concentrates it behind each nucleus. The density which is transferred in the formation of this molecular orbital is also concentrated primarily in the antibinding regions as the overlap force contribution is negative. It seems somewhat surprising that the $2\sigma_u$ orbital should be so strongly antibinding, although it is interesting to note that in the N_2 and F_2 molecules where the $2\sigma_g$ and $2\sigma_u$ orbitals are not the uppermost ones, the sum of their f_i values is approximately two. This indicates that when considered together the 2σ orbitals are quite similar to the 1σ pair in that they simply shield two units of nuclear charge, the strong net binding of $2\sigma_g$ just cancelling the net antibinding of $2\sigma_u$.

The most surprising result is the strongly antibinding character of the $3\sigma_g$ orbital which is occupied in both the N_2 and F_2 molecules. Since it is an orbital of σ_g symmetry it is assumed to be a bonding one (its orbital energy is negative) but the force analysis indicates that the density is so disposed as to pull the nuclei away from one another. In both N_2 and F_2 the force due to the overlap density in this orbital is binding, as one would expect for a σ_g orbital. Indeed in F_2 the overlap force contribution is larger for this orbital than for any other in the molecule. However, there is a large negative atomic force term due to the unfavorable $2s$–$2p$ hybridization which negates the overlap force. The net result is that the density in the $3\sigma_g$ orbital exerts a large force tending to separate the two nuclei. The unfavorable $2s$–$2p$ hybridization undoubtedly is of the kind termed "forced hybridization" by Mulliken (8), i.e., hybridization necessary to retain orthogonality to the $1\sigma_g$ and $2\sigma_g$ orbitals. A more flexible basis set of orbitals should be capable of yielding a $3\sigma_g$ orbital which concentrates charge in the binding region without the necessity of introducing unfavorable atomic polarizations to maintain the necessary orthogonalities. For example, it would be of interest to examine the "double-zeta" wave function for the nitrogen molecule (9) in a similar fashion and see if one of the major changes is as suggested here, i.e., a large overlap force but with a smaller amount of $2s$–$2p$ hybridization.

Table I indicates that the density in the $1\pi_u$ orbital in C_2, N_2, and F_2 can be roughly described as nonbinding. The density approximately shields its share of the nuclear charge. The overlap between π atomic orbitals can be appreciable (of the same order of magnitude as the $2s$ atomic orbital overlap) but the density which is transferred because of this overlap is placed above and below the internuclear axis where it is not as effective at binding the nuclei. (Compare the overlap force contributions in Table II for the $2\sigma_g$ orbital, which is principally $2s$, with the corresponding contribution from the $1\pi_u$ orbital.) In addition, the π atomic orbitals offer poor shielding of the nuclei (compare the penetration contributions to $2\sigma_g$ and $1\pi_u$ in Table II). The combination of these two effects leads to very small net-binding or net-antibinding forces for these orbitals. Any polarization of the π orbitals, say d_π–p_π, can increase the amount of density in the binding region and increase the binding of these orbitals.

All but one of the integrals required to calculate the forces were determined by machine computation (I.B.M. 650) from programs derived from the analytical expressions for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

these integrals (10, 11). The integral determining the force on atom α due to the overlap of a $2p$ atomic orbital on α with a $2s$ orbital on another atom (with a different orbital exponent) was evaluated by the method of Barnett and Coulson (12).

ACKNOWLEDGMENTS

We are very indebted to Miss O. Boshko for writing the programs for the force integrals and obtaining their numerical values and also to the Computing Centre at the University of Ottawa for machine time. We are grateful to Dr. G. A. Jones for helpful discussions and to Mrs. P. Bader and Mrs. H. Weinberg for checking the numerical results.

A REINVESTIGATION OF THE RANGE OF Na^{24} IONS OF KEV ENERGIES IN ALUMINUM[1]

M. McCargo,[2] F. Brown, and J. A. Davies
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received May 3, 1963

ABSTRACT

The range of Na^{24} in aluminum has been reinvestigated in the energy region 1.0–100 kev, using an isotopically separated beam of Na^{24}. Below 10 kev, the results differ significantly from our earlier data in which a much larger integrated flux of alkali metal ions (Na^{23} + Na^{24}) was required. Above 10 kev the discrepancy between the two sets of data disappears. The recent theoretical treatment of Oen, Holmes, and Robinson is found to be in quite reasonable agreement with the median ranges ($\overrightarrow{R_m}$) obtained in the present work, particularly if an allowance for the electronic stopping contribution at the higher energies is included.

INTRODUCTION

The range of radioactive alkali metal ions of kev energies in aluminum has previously been investigated at these laboratories (1, 2). The ions were produced by a linear accelerator without a mass-separation stage and hence a rather large integrated beam current was needed in order to inject into the target a sufficient number of radioactive atoms for subsequent analysis.

Recent work (3) has shown that, unless the integrated flux is extremely small, the penetration depth of the incident beam can decrease significantly during the bombardment. For example, in the case of 30 kev Xe ions, an integrated flux of $\sim 10^{16}$ ions/cm^2 was found to reduce the penetration depth of the incident beam by almost a factor of 2. A similar effect was observed also with Ar^{41} ions in aluminum. The existence of such a marked "saturation effect" for inert gas ions in aluminum suggests that some of our earlier measurements of alkali metal ions be reinvestigated to determine whether or not the observed data had been influenced significantly by the rather large integrated currents used. In this earlier work, the integrated beam current striking the target was about 5 microcoulombs (3×10^{13} ions) for Cs^+ bombardments, and as much as 100 microcoulombs (6×10^{14} ions) for Na^+. The actual bombarded area in each run was not recorded, but autoradiography of several targets suggested an approximate value of 0.1 cm^2. The corresponding integrated fluxes, therefore, must have been approximately 3×10^{14} Cs^+/cm^2 and 6×10^{15} Na^+/cm^2. The latter value is large enough to have exerted a possibly significant effect on the range distribution at the lower energies.

Consequently, the range of Na^{24} ions in aluminum has been reinvestigated over the energy region 1.0–100 kev. An electromagnetic isotope separator has been used to provide a beam of monoenergetic, isotopically separated Na^{24} ions, thereby enabling the integrated flux to be reduced to a negligibly small level ($\sim 10^{11}$ atoms/cm^2).

EXPERIMENTAL

In brief, the experimental technique consists of three stages: (i) bombardment of a highly polished aluminum target with a beam of radioactive ions of chosen energy; (ii) removal of successive thin layers of aluminum by a two-step process of anodic oxidation and stripping; and (iii) measurement of the residual radioactivity in the target after each layer is removed.

The anodizing, stripping, and counting procedures have been described fully in an earlier paper (4), as has also the bombardment technique (5).

The radioactive isotope Na^{24} was prepared by neutron irradiation of Na_2CO_3 in the NRU reactor.

RESULTS AND DISCUSSION

Integral range distribution curves at each of the incident ion energies studied are illustrated in Fig. 1. Two distribution curves obtained in the earlier work (2) have been

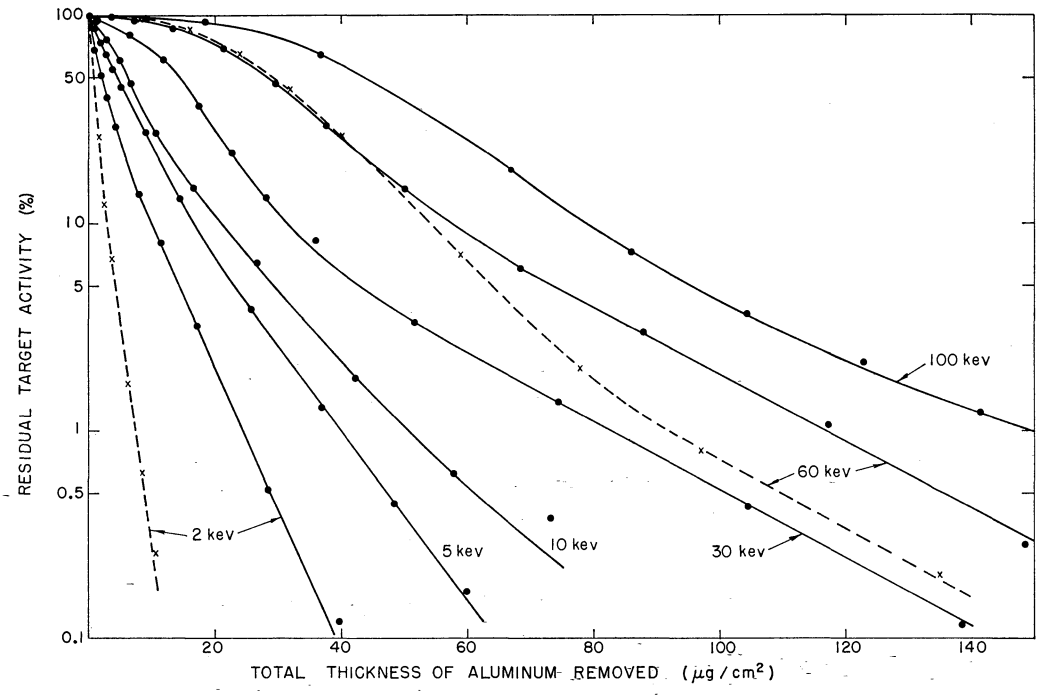

FIG. 1. Integral range distributions of Na^{24} ions in aluminum: ● new data, using trace bombardments; × previous work (2).

included for comparison. Again, as in the previous experiments, we observe a point of inflection followed by an approximately exponential tail. The significance of this tail has been discussed recently by Robinson and Oen (6). In general, the qualitative features of the distribution are the same as those observed with the larger integrated flux, except that at the lower energies the range distribution for trace bombardments is shifted significantly to larger penetration depths. This shift can be seen more clearly in Table I.

The symbol (→) signifies that the measured value is the projected range perpendicular to the target surface (i.e. the penetration depth), and *not* the total distance travelled by the projectile. It is evident that below about 10 kev the integrated flux used in the earlier work was sufficiently large to reduce significantly the measured penetration depth. At higher energies, as one might expect, the flux effect becomes smaller; and above 10 kev the two sets of data agree within the experimental reproducibility of ±6%.

COMPARISON WITH THEORY

Recently, Oen, Robinson, and Holmes (7) have developed a Monte Carlo technique for calculating the range of atomic projectiles in solids, based on an exponentially screened

NOTE: (a) Previous work (2)—using a mixture of Na^{23} and Na^{24}. (b) Present data—using a trace bombardment of Na^{24}. Except where otherwise stated, the estimated experimental error is ±10% for $\overrightarrow{R_p}$, and ±6% for $\overrightarrow{R_m}$, $\overrightarrow{R}$, and $X_{1/2}$.

coulomb, or "Bohr", potential for the atomic scattering process, and ignoring any contribution from electronic stopping. Using this treatment, they have computed the range of Na^{24} in Al as a function of energy, and have compared their predicted curve with our previous experimental values (ref. 7, Fig. 11).

In Fig. 2, we have extended their comparison to include the more accurate experimental

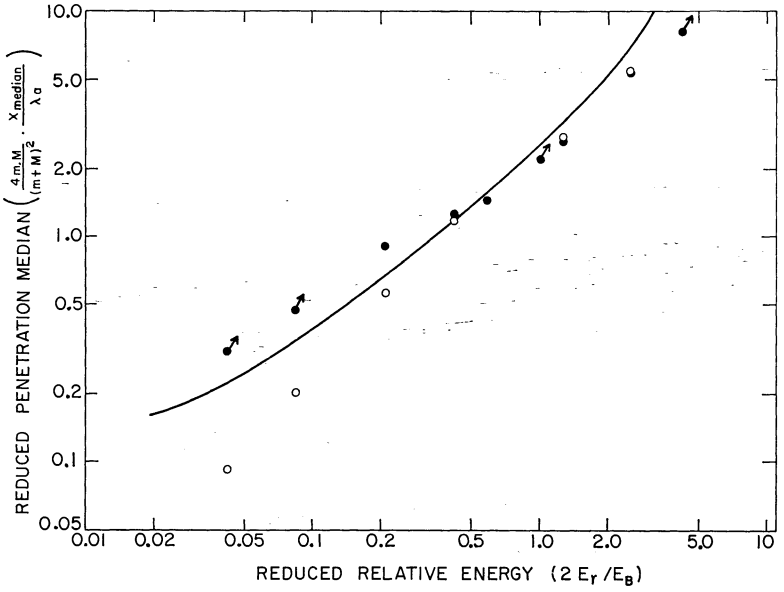

FIG. 2. Comparison of experimental data for Na^{24} in aluminum with the theoretical curve of Oen *et al.* (see ref. 7, Fig. 11): ● new data, using trace bombardments; ○ previous work (2).

data obtained in the present work. The screening distance a_B used by Oen *et al.* is not necessarily the Bohr value, but includes a factor k which is introduced by them as an adjustable parameter to permit a closer fit of the experimental results to the theoretical curve. The points in Fig. 2 have been calculated from the experimental data, using the Bohr value of the screening distance (i.e. $k = 1.0$). The effect of using a "screening length" 10% greater than the Bohr value (i.e. $k = 1.1$) is illustrated by an arrow on some of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

points. The matching between theory and experiment for $k = 1.0$ is quite good, particularly at the lower energies. Above 30 kev, the experimental points fall somewhat below the predicted curve, a fact which can reasonably be attributed to the increased importance of electronic stopping. It can be seen that the appreciable discrepancy noted previously (7) at low energy was due mainly to the large integrated flux used in the earlier experimental work. There is no significant improvement in using $k = 1.1$, and we conclude that for Na in Al the Bohr screening distance is a reasonable approximation.

An alternative theoretical treatment of the atomic stopping process, based on a Thomas–Fermi potential, has been developed by Lindhard and Scharff (8), who obtain by analytical methods a range-energy expression in the form of a universal curve relating a reduced range parameter ρ and a reduced energy parameter ϵ. In a more recent communication, Lindhard (9) has modified his treatment to take account of the important contribution of electronic stopping at higher energies. The range predicted by the Lindhard theory is the total path length, not the experimentally measured projected range ($\rightarrow$) perpendicular to the target surface. Lindhard therefore has derived a suitable formula (ref. 8, eqn. 5) for converting projected ranges into total path lengths, thereby enabling comparison between experiment and theory.

The results of such a comparison for Na^{24} in Al are illustrated in Fig. 3. The experi-

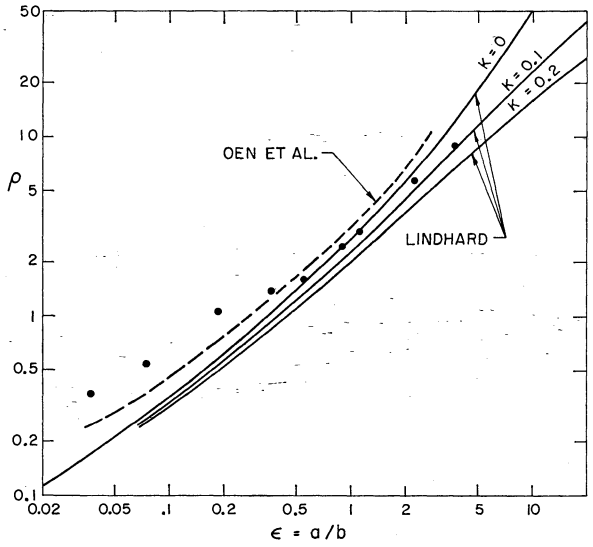

FIG. 3. Comparison of the new experimental data, using trace bombardments, with various theoretical curves. For the definition of ρ and ϵ, see reference 8. The appropriate value of Lindhard's electronic stopping parameter K, for Na^{24} in aluminum, is 0.15.

mental points were obtained from the $\overrightarrow{R_m}$ values in Table I, multiplied by the appropriate path length conversion factor 1.38. The $K = 0$ curve is the universal range-energy expression derived by Lindhard and Scharff for nuclear stopping alone. When electronic stopping is included, a series of theoretical curves is obtained, each one characterized by an electronic stopping parameter K. At low energies, these curves all approach the $K = 0$ curve. For Na^{24} in Al, the appropriate K value is 0.15.* The theoretical curve of Oen *et al.* (see Fig. 2) has also been included for comparison.

**The expression for K, given by Lindhard (9), is*

$$K = \xi_e \cdot \frac{0.0793 Z_1^{1/2} Z_2^{1/2}}{(Z_1^{2/3}+Z_2^{2/3})^{3/4}} \cdot \frac{(A_1+A_2)^{3/2}}{A_1^{3/2} A_2^{1/2}}$$

where A and Z are the mass and atomic numbers, the subscripts 1 and 2 refer to the projectile and target atom, and $\xi_e \simeq Z_1^{1/6}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Both theoretical treatments are in quite reasonable accord with the experimental data obtained in the present work. Oen's treatment gives somewhat better agreement than Lindhard's at lower energies where electronic stopping is negligible; at higher energies, however, the Lindhard treatment accounts quite satisfactorily for the increasing importance of electronic stopping. A similar agreement with the Lindhard theory has been observed recently with various inert gas ions in aluminum (5, 10) and in other solids (11).

In the above comparisons with theory, $\vec{R}_m$ values have been used in preference to $\vec{R}$ in order to minimize the contribution of the penetrating "tail" in the range distribution. Robinson and Oen (6) suggest that the "tail" is caused by a channeling effect in the crystal lattice, an explanation which has recently been verified experimentally in these laboratories (12). Since the theoretical treatments are based on a random distribution of atoms in the solid, they are evidently applicable only to that portion of the beam which has not become channeled. Consequently, $\vec{R}_m$ is a more appropriate quantity than $\vec{R}$ for comparison with theory.

With the newly discovered importance (12) of crystal-lattice effects on the range of atomic projectiles, it is obvious that future experimental work should be carried out either in amorphous solids or in single crystals of known orientation.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the invaluable help of G. A. Sims in all this experimental work, and the assistance of J. C. Tole and R. L. Cushing in carrying out the ion bombardments.

NEUTRAL EXTRACELLULAR GLUCAN OF PULLULARIA PULLULANS (DE BARY) BERKHOUT[1]

W. SOWA,[2] A. C. BLACKWOOD,[3] AND G. A. ADAMS
Division of Applied Biology, National Research Council, Ottawa, Canada
Received May 9, 1963

ABSTRACT

A neutral extracellular glucan ($[\alpha]_D^{23}$ +189°) was produced in 12% yield by *Pullularia pullulans* (de Bary) Berkhout grown on a glucose substrate. A single symmetrical peak on free-boundary electrophoresis in borate and acetate buffers was evidence of homogeneity. Infrared spectroscopy showed that the predominant glucoside linkages were $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ with a small proportion of $\alpha(1 \rightarrow 3)$. Graded acid hydrolysis under conditions of minimum reversion yields glucose, maltose, isomaltose, nigerose, panose, and isomaltotriose. In addition, a trisaccharide, *O*-α-D-glucopyranosyl-$(1 \rightarrow 4)$-*O*-α-D-glucopyranosyl-$(1 \rightarrow 6)$-D-glucopyranose, was isolated. Another trisaccharide was isolated and tentatively identified as *O*-α-D-glucopyranosyl-$(1 \rightarrow 4)$-*O*-[α-D-glucopyranosyl-$(1 \rightarrow 6)$]-D-glucose and hence a small degree of branching may occur in the molecule. The present study has confirmed previous observations that the main linkages are $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ and has provided unequivocal proof of the presence of $\alpha(1 \rightarrow 3)$ linkages. Periodate oxidation studies confirmed the foregoing structural features and showed that the glucan was linked $\alpha(1 \rightarrow 4)$, 65%; $\alpha(1 \rightarrow 6)$, 29%; and $\alpha(1 \rightarrow 3)$, 6%.

The yeast-like fungus *Pullularia pullulans* produces a mixture of glucose-containing extracellular polysaccharides (1). It has been shown (2, 3) that one of the polysaccharides formed by the fungus from glucose as the carbon source is a linear glucan ("pullulan") having $[\alpha]_D$ +192° and composed of approximately 300 α-D-glucopyranose units linked $(1 \rightarrow 4)$ and $(1 \rightarrow 6)$ in the ratio 3:2. Bouveng *et al.* (4) have examined the polysaccharides produced by *Pullularia pullulans* from various sugar substrates, and have found that a sucrose medium yielded a linear glucan having $[\alpha]_D$ +190° and consisting of more than 250 units linked $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ in the ratio 2:1. A small amount (1–2%) of glucose remaining after periodate oxidation of the polysaccharide suggested that $(1 \rightarrow 3)$ linkages might be present, although this was not supported by methylation data. No evidence for the presence of $(1 \rightarrow 3)$ linkages in the polysaccharide produced from glucose was reported in earlier work (2, 3).

The present publication reports the results obtained from partial acid hydrolysis and from periodate oxidation of the glucan produced by *Pullularia pullulans* grown on glucose.

The growth conditions of the organism and the method of recovery used for the preparation of the polysaccharide in the present work favored isolation of the water-soluble glucan to the exclusion of the more insoluble jelly-like polysaccharide which adheres to the mycelium (1). The polysaccharide showed a single symmetrical peak on electrophoresis in borate and acetate buffers, gave no precipitate with Cetavlon, and showed no carboxyl absorption in its infrared spectrum. This evidence showed that the polysaccharide was homogeneous and contained no acid groups. Bouveng *et al.* (4) found that yields of polysaccharide were increased and that formation of uronic acid and other hexose units was diminished when the organism was grown on glucose rather than other sugar substrate (except for sucrose).

Infrared spectroscopy of the polysaccharide showed strong absorption at 850 cm^{-1},

[1]*Issued as N.R.C. No. 7490.*

[3]*Professor of Agricultural Bacteriology, MacDonald College, Montreal, Que.*

characteristic of α-D-glucopyranose units (5). Absorption at 755 cm^{-1} and from 915 cm^{-1} to 930 cm^{-1} indicated that the predominant linkages were $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$. The presence of $\alpha(1 \rightarrow 3)$ linkages was indicated by a small amount of absorption at 790 cm^{-1}; glucopyranose units linked in this manner absorb at 793 ± 3 cm^{-1} (5). Glucose was the only sugar detectable in acid hydrolyzates of the polysaccharide by both paper and gas–liquid partition chromatographic techniques.

The polysaccharide was partially hydrolyzed under conditions which, in studies of amylopectin (6) and glycogen (7), have been shown to produce minimum reversion. The sugars so obtained were separated by paper chromatography and paper electrophoresis. The results are shown in Table I.

TABLE I

Products from partial hydrolysis of glucan

Sugar	Yield (wt% based on glucan)
D-Glucose	20.2
Maltose (4-*O*-(α-D-glucopyranosyl)-D-glucopyranose)	4.4
Isomaltose (6-*O*-(α-D-glucopyranosyl)-D-glucopyranose)	11.2
Nigerose (3-*O*-(α-D-glucopyranosyl)-D-glucopyranose)	1.4
Isomaltotriose (*O*-α-D-glucopyranosyl-(1 → 6)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucopyranose)	3.3
Panose (*O*-α-D-glucopyranosyl-(1 → 6)-*O*-α-D-glucopyranosyl-(1 → 4)-D-glucopyranose)	4.3
Oligosaccharide A (*O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucopyranose)	2.5
Oligosaccharide B (*O*-α-D-glucopyranosyl-(1 → 4)-*O*-[α-D-glucopyranosyl-(1 → 6)]-D-glucose)	0.9

Glucose, maltose, isomaltose, nigerose, and panose were obtained in crystalline form or were characterized by the preparation of crystalline derivatives. Isomaltotriose was identified on the basis of its chromatographic properties, specific optical rotation, and products of partial hydrolysis. Oligosaccharide A was a trisaccharide having a high M_G value in borate buffer, indicative of a reducing end group linked through positions 3 or 6 (8). Infrared spectroscopy showed that it contained both $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ linkages. The products of partial hydrolysis of the reduced trisaccharide were isomaltitol, maltose, glucose, and sorbitol. The absence of maltitol on paper chromatography or paper electrophoresis showed that the C_4 of the reducing end group was not substituted. On the basis of this evidence the oligosaccharide was identified as *O*-α-D-glucopyranosyl-(1 → 4)-*O*-α-D-glucopyranosyl-(1 → 6)-D-glucopyranose. Oligosaccharide B was obtained in small yield (0.9%), and from its R_G value (Table II) appeared to be a trisaccharide. Its infrared spectrum showed that it contained both $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ linkages, although it was not obtained completely free of glucose, isomaltose, and a trace of panose. Since it was not maltotriose, isomaltotriose, panose, or oligosaccharide A it was tentatively identified as *O*-α-D-glucopyranosyl-(1 → 4)-*O*-[α-D-glucopyranosyl-1(1 → 6)]-D-glucose, which would result from branching in the polysaccharide. The M_G value (0.50) was higher than expected for an oligosaccharide substituted at position 4 of the reducing unit (8). There is

TABLE II

Chromatography of glucose trisaccharides

Trisaccharide	$R_{Glucose}$ in solvent system			
	A (26 hr)	B (48 hr)	C (65 hr)	E (65 hr)
Panose	0.41	0.27	0.21	0.27
Isomaltotriose	0.38	0.22	0.21	0.28
Oligosaccharide A	0.28	0.16	0.17	0.22
Oligosaccharide B	0.42	0.24	0.27	0.32
Maltotriose	0.50		0.27	

some evidence for branching in the glucan from the work of Wallenfels *et al.* (3), who detected 2,3-di-*O*-methyl-D-glucose after methylation and hydrolysis of "pullulan".

The polysaccharide consumed 1.23 moles of periodate and released 0.29 mole of formic acid per anhydroglucose unit. These results indicate that 29% of the linkages were (1 → 6), 65% were (1 → 4), and 6% were (1 → 3). The 29% of (1 → 6) linkages is based on the assumption that the molecule has only a small amount of branching (as indicated by the small proportion of oligosaccharide B) and that there are few end groups in the molecule.

The periodate-oxidized glucan yielded glucose after reduction and hydrolysis, indicating that some units in the polysaccharide were substituted through C_3 or doubly substituted at positions 2 and 4. The formation of glycerol and erythritol during these reactions provided additional evidence for (1 → 4) and (1 → 6) linkages in the polysaccharide.

The present study has confirmed previous observations that the main linkages are $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$, the former predominating (2–4). Previous conclusions were based on methylation and paper chromatographic data while in the present investigation isomaltose and panose have been isolated and identified. Maltotriose was not recoverable due to the lability of the $\alpha(1 \rightarrow 4)$ linkages under the hydrolytic conditions used.

The glucan produced by *Pullularia pullulans* from glucose under the present experimental conditions differs from "pullulan" by having $\alpha(1 \rightarrow 3)$ linkages and also by having a ratio of (1 → 4) to (1 → 6) linkages of 2.2 to 1 instead of 3 to 2. In this latter respect it resembles more closely the glucan produced from a sucrose substrate and having a linkage ratio of 2 to 1 (4).

Unequivocal evidence for the presence of $\alpha(1 \rightarrow 3)$ linkages in the glucan has been provided by the isolation of the crystalline acetate of nigerose. Hydrolytic conditions were such as to preclude its formation by reversion in the amounts isolated. Additional supporting evidence for the existence of $\alpha(1 \rightarrow 3)$ linkages in the polysaccharide was provided by infrared examination and also by the finding of intact glucose residues after prolonged periodate oxidation. Although Bouveng *et al.* (4) suggested that (1 → 3) linkages might be present in the *Pullularia* glucan, they were unable to find supporting evidence in methylation studies. Bender *et al.* (2) and Wallenfels *et al.* (3) found evidence for only $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ linkages in their polysaccharide from *Pullularia pullulans*.

EXPERIMENTAL

Paper chromatograms were run by the descending method at room temperature on Whatman No. 1 paper using the following solvent systems (v/v): (A) butan-1-ol, pyridine, water—6:4:3; (B) ethyl acetate, pyridine, water—10:4:3; (C) propan-1-ol, ethyl acetate, water—7:1:2; (D) butan-1-ol, ethanol, water—3:1:1; (E) ethyl acetate, acetic acid, formic acid, water—18:3:1:4.

Paper electrophoresis was carried out on Whatman 3 MM paper in 0.1 *M* sodium tetraborate buffer at 550 v and 50 ma for 3–4 hours.

Sugars on the chromatograms were detected by *p*-anisidine hydrochloride (9), silver nitrate – sodium hydroxide (10), or benzidine – trichloroacetic acid (11) reagents.

Evaporations were carried out under reduced pressure at a bath temperature of 40° or less. Solutions were deionized with Amberlite IR 120 (H^+) and Duolite A 4 (OH^-) resins.

Preparation of Pullularia pullulans Polysaccharide

The microorganism was grown in a medium having the following composition per liter of distilled water: 20 g glucose, 0.1 g yeast extract, 1.0 g asparagine, 1.0 g K_2HPO_4, 0.5 g $MgSO_4$, 10 γ thiamine. In addition the medium for the inoculum contained 0.5% cystein. The cultures were grown at 25° C with continuous shaking in 2-liter flasks each containing 750 ml of medium. After 5 days' growth the cultures were centrifuged and the polysaccharide was isolated from the supernatant liquid by precipitation with acetone in a Waring blendor. The crude polysaccharide was purified by reprecipitation from aqueous solution once with acetone and once with ethanol. The purified product was recovered in 12% yield (based on the glucose in the medium) by freeze-drying.

General Properties of the Polysaccharide

The purified polysaccharide had $[\alpha]_D^{23}$ +189° (*c* 0.91 in water), ash 0.46%, nitrogen nil, phosphate nil.

Examination of the polysaccharide by moving-boundary electrophoresis in 0.05 *M* sodium tetraborate buffer using a Spinco Model H Tiselius-type apparatus showed a single moving peak and also a non-moving peak due to borate. In acetate buffer, pH 5 and ionic strength 0.1, there was a single, large, stationary peak along with a barely visible trace of a moving peak. The moving peak later disappeared due to diffusion.

When an aqueous solution of "Cetavlon" (cetyl trimethyl ammonium bromide) (10%, w/v) was added to twice its volume of a solution of the polysaccharide in water (1%, w/v), no precipitate was formed.

The polysaccharide (10 mg) was hydrolyzed in *N* sulphuric acid (2 ml) at 100° C for 7 hours. The cooled solution was deionized, concentrated to a sirup, and examined by paper chromatography in solvent systems (A), (D), and (E). Only glucose was detectable with the *p*-anisidine hydrochloride and the silver nitrate – sodium hydroxide reagents respectively. The syrup (10.7 mg) was acetylated in pyridine (0.1 ml) and acetic anhydride (0.1 ml) at room temperature for 18 hours. The reaction mixture (12) was examined by gas–liquid partition chromatography using an F and M chromatograph with an 8-ft column of DC QF-1 (13% by weight, Dow Corning fluorosilicone) on Chromosorb W, 100–120 mesh, at 225° C. The helium flow rate was ca. 80 ml/min. Only two peaks corresponding to α- and β-glucopyranose pentaacetates were observed.

The infrared spectrum of the polysaccharide in potassium bromide disks showed strong absorption at 850 cm^{-1}, 755 cm^{-1}, and from 915 cm^{-1} to 930 cm^{-1}. There was also a very small amount of absorption at 790 cm^{-1}.

Partial Hydrolysis of the Polysaccharide

The glucan (10.0 g) was added to refluxing hydrochloric acid (0.1 *N*, 2.5 l.) (7). After 2 hours, the hydrolysis was stopped by pouring the solution into ice and water and the hydrolyzate was deionized and concentrated to a syrup (10.2 g). A preliminary experiment had established that under these conditions of hydrolysis the specific optical rotation changed from $[\alpha]_D^{27}$ +190° (*c* 0.4 in 0.1 *N* hydrochloric acid) after 1/2 hour to $[\alpha]_D^{27}$ +56° (*c* 0.4 in 0.1 *N* hydrochloric acid) after 8 hours. The maximum amount of oligosaccharides (chromatographic examination) was formed after 2–4 hours ($[\alpha]_D^{26}$ ca. +125° (*c* 0.4 in 0.1 *N* hydrochloric acid)).

Initial fractionation of an aliquot of the hydrolyzate (4.8 g) was obtained by chromatography on sheets of Whatman 3 MM paper using solvent system (A). The following fractions were obtained: glucose (958 mg), maltose (208 mg), isomaltose (529 mg), and a trisaccharide fraction (402 mg). Paper electrophoresis of the latter fraction showed that it was composed of two major trisaccharide components and a third very minor component (oligosaccharide B). The two major trisaccharides, panose (74 mg) and isomaltotriose (58 mg), were obtained by extraction of the appropriate areas of the electrophoretograms with water. The aqueous solutions were deionized and then distilled repeatedly with methanol to remove borate. By paper chromatography of the remainder of the acid hydrolyzate (5.1 g) on sheets of Whatman 3 MM paper in solvent system (C), three additional oligosaccharides were obtained, nigerose (70 mg), oligosaccharide A (126 mg), and oligosaccharide B (46 mg).

Characterization of the Sugars

D-*Glucose*

The sugar having the same R_G as glucose was crystallized from methanol. After recrystallization from methanol, it melted at 140–146° C, undepressed by admixture with α-D-glucopyranose and had $[\alpha]_D^{21}$ +94° → +51° (*c* 2.3 in water).

Maltose

The sugar corresponding to maltose on chromatograms crystallized from a syrup. It had m.p. 118–120° C and $[\alpha]_D^{19}$ +115° → +128° (*c* 0.97 in water). Paper chromatographic examination of the crystalline maltose showed that traces of other oligosaccharides were present. A portion of the syrup (25 mg) was acetylated with acetic anhydride (1 ml) containing sodium acetate (15 mg) by refluxing the mixture for 1 hour. The

cooled solution was poured into ice water (50 ml) and extracted with chloroform (3×20 ml). The chloroform extract was washed with saturated sodium bicarbonate solution, dried with anhydrous sodium sulphate, and evaporated to a syrup. The β-maltose octaacetate was crystallized twice from ethanol, m.p. and mixed m.p. 157–158° C.

Isomaltose

The isolated sugar which was chromatographically indistinguishable from isomaltose was acetylated with sodium acetate and acetic anhydride. The acetate, after isolation, crystallized from ethanol. After two recrystallizations from ethanol, the crystals had $[\alpha]_D^{23}$ +97.7 (*c* 1.8 in chloroform) and m.p. 143–144° C. The mixed melting point with β-isomaltose octaacetate was undepressed.

Panose

An oligosaccharide having M_G 0.33 in borate buffer was obtained from the trisaccharide fraction. It crystallized from ethanol–water after seeding the solution with authentic panose. After recrystallization from methanol–water, it had m.p. and mixed m.p. 220° (decomp.) and $[\alpha]_D^{23}$ +160° → +150° (*c* 3.3 in water).

Isomaltotriose

The oligosaccharide isolated from the trisaccharide fraction by electrophoresis and having M_G 0.65 in borate buffer had $[\alpha]_D^{23}$ +137° (*c* 2.55 in water). Reported values for isomaltotriose range from +128° to +145° (7, 13–16). In solvent (A), the oligosaccharide had $R_{Glucose}$ 0.37–0.39; Myrbäck and Willstaedt record $R_{Glucose}$ 0.368 for isomaltotriose (17). An aliquot of the syrup (3–5 mg) was partially hydrolyzed with 0.5 *N* hydrochloric acid (1 ml) in a sealed tube at 100° for 45 minutes. The solution was deionized and concentrated to a syrup. The only products of hydrolysis detectable with silver nitrate – sodium hydroxide after paper chromatography in solvent (A) were isomaltose and glucose.

Nigerose

A small amount of sugar having M_G 0.71 in borate buffer and $R_{Maltose}$ 1.28 in solvent (C) was recovered from the hydrolyzate. Ough reports $R_{Maltose}$ 1.27 for nigerose in this solvent system (18). A portion of the syrup (30 mg) was acetylated with sodium acetate and acetic anhydride as described earlier. The β-nigerose octaacetate, which did not crystallize from ethanol, was freed from a small amount of β-glucose pentaacetate by thin-layer chromatography of the syrup on silica gel G (19). A solution of the mixture in chloroform was applied to two plates (20 cm×20 cm) which were run (2×45 minutes) in benzene containing methanol (4%, v/v). The disaccharide was made visible by spraying the plates with water. The powder obtained from the appropriate areas of the plates was eluted with methanol–chloroform (1:1) to yield β-nigerose octaacetate. After two crystallizations from ethanol, it had $[\alpha]_D^{25}$ +79° (*c* 0.19 in chloroform) and m.p. 150–152°. The mixed melting point with an authentic sample was undepressed.

Oligosaccharide A

Oligosaccharide A (amorphous) had $[\alpha]_D$ +128° (*c* 2.92 in water). Its molecular weight, determined in methanol by vapor pressure osmometry,* was 500 and its degree of polymerization, determined by the method of Peat, Whelan, and Roberts (20), was 2.8. It was different from panose, isomaltotriose, and maltotriose on paper chromatography in several solvent systems (Table II). In borate buffer, M_G 0.64 was indicative of a 1 → 3 or 1 → 6 linkage at the reducing end. The infrared absorption in potassium bromide at 915 cm^{-1}, 845 cm^{-1}, and 763 cm^{-1} was consistent with the presence of both α(1 → 4) and α(1 → 6) linkages. Oligosaccharide A (8 mg) was reduced with sodium borohydride (8 mg) in water (2 ml) for 3½ hours at room temperature. The solution was made slightly acidic with dilute acetic acid, deionized, and distilled to dryness with methanol several times to yield the reduced trisaccharide (6 mg). This was partially hydrolyzed in refluxing hydrochloric acid (0.1 *N*, 1.5 ml) for 15 minutes. The solution was passed through Duolite A4 resin and concentrated to a syrup. Paper chromatography in solvent systems (B) and (E) and detection with the silver nitrate reagent showed that the products were unhydrolyzed reduced trisaccharide, maltose, isomaltitol, glucose, and sorbitol. After electrophoresis in sodium molybdate buffer at pH 5 (21) and detection with the silver nitrate reagent, four spots were observed having $M_{Sorbitol} < 0.1$ (maltose), 0.6 (unhydrolyzed reduced A), 0.7 (isomaltitol), and 1.0 (sorbitol).

Oligosaccharide B

Oligosaccharide B was obtained as a syrup which contained small amounts of glucose, isomaltose, and a trace of panose as impurities. Its R_G in several solvent systems (Table II) was similar to that of a glucose trisaccharide. In borate buffer it had M_G 0.50. Infrared spectra of the oligosaccharide in potassium bromide and in Nujol were very similar to the spectra of amorphous panose, indicating the presence of α(1 → 4) and α(1 → 6) linkages. The oligosaccharide was converted to its β-acetate but this could not be obtained crystalline. On thin-layer chromatograms (19) the acetate travelled more slowly than β-maltotriose hendecaacetate.

Oxidation of the Polysaccharide with Periodate

The polysaccharide (0.5003 g) was oxidized in 0.018 *M* sodium periodate solution in a volumetric flask (500 ml) which was kept in the dark at room temperature (25–27° C). Aliquots (5 ml) were removed at

**Mechrolab Vapour Pressure Osmometer, model 301A, Fisher Scientific Company.*

intervals for estimation of periodate and formic acid. The periodate consumption was determined by adding an aliquot to a solution of potassium iodide (10% w/v, 5 ml) and phosphate buffer (pH 6.98, 50 ml) (22). The iodine which was liberated was titrated with 0.0101 *N* sodium thiosulphate solution using starch as indicator. The formic acid produced by oxidation was determined by titration with standard alkali. An aliquot was added to ethylene glycol (0.5 ml) to destroy unreacted periodate and after 30 minutes, the formic acid was titrated with 0.0100 *N* sodium hydroxide solution using methyl red as indicator. Periodate consumed and formic acid produced are shown in Table III. Extrapolation of a plot of these results to

TABLE III

Periodate oxidation of polysaccharide

Time (hr)	8	28	73	121	168
Moles IO_4/AGU	1.046	1.152	1.236	1.274	1.303
Moles HCO_2H/AGU	0.183	0.258	0.288	0.326	0.340

zero time showed that 1.23 moles of periodate was consumed and 0.29 mole of formic acid was released per anhydroglucose unit.

After 168 hours of oxidation, 300 ml was withdrawn from the reaction mixture and iodate and periodate were precipitated by the addition of lead acetate (0.2 *M*). After filtration and deionization of the solution the polyaldehyde was recovered by freeze-drying. This product was reduced in water (40 ml) with sodium borohydride (300 mg) for 3 hours at room temperature. The solution was then acidified with dilute acetic acid, deionized, and distilled several times with methanol. The polyalcohol (158 mg) was recovered by freeze-drying.

A sample of the polyalcohol (16 mg) was hydrolyzed in *N* sulphuric acid (2 ml) at 100° C for 7 hours. The solution was deionized, concentrated, and examined by paper chromatography in solvent system (D). The silver nitrate – sodium hydroxide reagent showed the presence of glycerol, erythritol, and a trace of glucose.

STERIC EFFECTS IN AROMATIC CARBONYL COMPOUNDS

I. BASICITIES AND ULTRAVIOLET SPECTRA

KEITH YATES AND BRIAN F. SCOTT
Department of Chemistry, University of Toronto, Toronto, Ontario

Received April 1, 1963

ABSTRACT

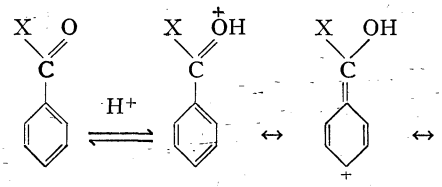
The basicities of eight *o*-methyl and *o*-dimethyl carbonyl compounds have been determined by spectrophotometric methods in aqueous sulphuric acid. The basicities of a further 19 compounds of the same class have been recalculated from literature data using a recently determined H_0 scale of acidity. The effects of ortho substitution on the base strength have been found to increase with the steric requirements of the group attached to the carbonyl carbon.

The ultraviolet intensities of 18 of the above compounds have either been freshly determined or carefully redetermined. The mean interplanar angle θ between carbonyl and phenyl groups has been obtained for both base and conjugate acid forms using the relationship $\epsilon/\epsilon_{planar} \simeq \cos^2\theta$.

For the conjugate acids of the *o*-methyl derivatives a linear relation exists between $\epsilon/\epsilon_{planar}$ and the steric effect on basicity. This is discussed in terms of inhibition of resonance in the cations. No similar relation exists for the *o*-dimethyl derivatives. Steric effects on basicity in the latter are discussed in terms of steric inhibition of solvation of the cations.

INTRODUCTION

The failure of the Hammett equation to correlate the reactivities of ortho-substituted aromatic compounds is well known, and is due to steric interactions between reacting group and ortho substituent (1). The ionization of aromatic carbonyl compounds in strong acids illustrates this. Although the basicities of meta- and para-substituted compounds of this class (where X = H, CH_3, OH, NH_2) have been shown (2–5) to obey



I II

linear free-energy relationships of the Hammett type, the *basicities* of ortho-substituted benzoic acids, for example, do not (6). Although modified forms of the Hammett equation (7) have been used with success for some of the reactions of ortho-substituted benzene derivatives, this particular class of ionization is not amenable to this type of treatment (6), due to the greater possibilities for resonance stabilization in II than in I. This is presumably even more true for diortho-substituted bases. The bulk of the *o*-methyl groups forces the protonated carbonyl group out of the plane of the aromatic ring and hence raises the energy of the cation with respect to the neutral molecule, in which resonance effects are of much less importance.

In addition to this steric inhibition of resonance by ortho groups, there are to be considered steric inhibition of solvation (which will also be more important in the cation than in the neutral molecule), the electronic effect of the substituents, and the possibility of specific interactions such as hydrogen bonding.

We have attempted to study only the first two of the above effects on the ionization of this type of base. For this purpose we have investigated the base strengths and ultraviolet spectra of a series of *o*-methyl- and *o*-dimethyl-substituted benzaldehydes, benzoic acids, acetophenones, benzamides, and benzophenones. For the basicity determinations we have used modified forms of the general Hammett technique in aqueous sulphuric acid (3), using recently determined H_0 values based on a uniform set of indicators (8), and have recalculated previous data (2, 3, 4, 9) where necessary. *o*-Methyl substituents were chosen since their interactions approximate closely to bulk steric effects. Specific interactions should be small for these groups, and their electronic effects can reasonably be assessed from the effects of *p*-methyl substituents.

We have also estimated the steric inhibition of coplanarity (and hence of π-orbital overlap) between the carbonyl group and phenyl ring from ultraviolet spectral data. This approach has also been used by Wepster to estimate inhibition of resonance in *p*-nitroaniline type bases (10).

EXPERIMENTAL

Reagents

Commercially available benzaldehydes were purified by vacuum distillation using a small positive pressure of nitrogen. Commercially available acetophenones, benzoic acids, and benzamides were purified by recrystallization or vacuum distillation. Diazotization of 2,6-dimethylaniline, followed by the standard Sandmeyer procedure with cuprous cyanide, gave the nitrile, which was then hydrolyzed in hot 85% H_2SO_4 to give 2,6-dimethylbenzamide. M.p. 139–139.5° C, lit. m.p. 139° C (11). Several attempts to hydrolyze this amide further failed to give 2,6-dimethylbenzoic acid. 2-Methylbenzophenone was prepared from *o*-toluyl chloride and benzene by the standard Friedel–Crafts method. B.p. 89° C at 0.6 mm, lit. b.p. 168° C at 12 mm (12). Calc. for $C_{14}H_{12}O$: C, 85.6; H, 6.12. Found: C, 84.9; H, 6.20.

Sulphuric acid solutions ranging from 0.001 *N* to 98% by weight were prepared from Fisher C.P. Reagent grade sulphuric acid (95% min.) and Fisher Reagent Fuming (30%) sulphuric acid. Concentrations were determined by titrating weighed samples with standard base. The H_0 values of these acids were obtained by interpolation from a composite curve constructed using the values given by Paul and Long (13) for the range 0–60% acid, and the values recently determined by Jorgenson and Hartter (8) for the range 60–98% acid.

Measurement of Ultraviolet Spectra

All spectra were measured on a Bausch and Lomb Spectronic 505 Recording Spectrophotometer, using 1-cm quartz cells and a thermostatically controlled cell-block at 25±0.05° C. Solutions of the bases in the various sulphuric acids were prepared essentially as described previously (3) using a Hamilton syringe and Chaney adaptor to measure out stock solutions of organic compounds. All spectra in strongly acid solutions were repeated with time to check for possible decomposition. In the case of 2,4,6-trimethylacetophenone it was necessary to record spectra as rapidly as possible after mixing (about 2 minutes) and repeat the measurements at intervals. Spectra were then obtained by extrapolation back to zero time. In all other cases, spectra were measured as rapidly as possible after mixing with acid.

Determination of pK_{BH^+} Values

These were obtained by the spectrophotometric method essentially as described previously (3). In cases of low solubility of the organic compound in the more dilute sulphuric acids, a modification similar to that described by Stewart and Granger (6) was used. To test for possible acylium ion formation, solutions of 2,6-dimethyl- and 2,4,6-trimethyl-benzamide in 95% acid were poured into ice water several minutes after mixing. The original amides were recovered almost quantitatively from these solutions, showing that these compounds ionize in the region studied by simple proton addition, as do the other carbonyl bases.

Calculation of pK_{BH^+}

The basicity constants of all compounds except the benzamides were obtained from the spectral data by the "linear" modification of the method of Davis and Geissman (14) previously described by Stewart and Granger (6). If the bases are behaving as typical Hammett indicators, plots of $\log\{(D_{BH^+}-D)/(D-D_B)\}$ (Stewart's notation (6)) against H_0 should be linear with unit slope and intercepts equal to pK_{BH^+}. Since in all cases good linear plots were obtained with slopes in the range 0.90–1.05 it was felt that Stewart's method of correcting for medium effects was adequate and that the ionizations of these compounds were following the H_0 function sufficiently closely for the purposes of the present investigation. (Also this method is considerably less laborious than the one applied to the benzamides.)

For personal use only.

The treatment of the data for 2,4,6-trimethylacetophenone was somewhat different to the above. In addition to the fact that this compound decomposes fairly rapidly in sulphuric acid (15), the neutral base absorbs only weakly ($\epsilon_B < 2000$). Therefore the above "linear" method was applied to data obtained at one wavelength only, the wavelength of maximum absorption of the conjugate acid, 320 mμ. The function $\log\{(\epsilon_{BH^+} - \epsilon)/(\epsilon - \epsilon_B)\}$ was plotted against H_0, where ϵ_{BH^+} refers to the measured extinction in 95% acid, ϵ_B to the value in 46% acid, and ϵ to values obtained in intermediate acids. The spectrum in each of 16 different sulphuric acids was recorded and extrapolated as described. This was repeated on two fresh samples of ketone in each acid, and an average of three extrapolated values taken. Although the points on the log plot showed scattering, especially in the more concentrated acids where decomposition is rapid, a least mean squares treatment gave a correlation coefficient of 0.97, with a slope of 0.93 and intercept −7.4. It is felt that this pK_{BH^+} is as accurate as can reasonably be expected, and is more reliable than the earlier estimate of −8.4 (−7.9 on the old H_0 scale) made by Schubert and Latourette (15) on the basis of measurements in only three different sulphuric acid concentrations.

It has recently been shown that the H_0 function is not strictly applicable to the ionization of benzamides (16), but that these bases are probably following some related acidity function. A method was described for estimating pK_{BH^+} for these bases, using the modified equation

$$H_0 = pK_{BH^+} - n \log \frac{BH^+}{B},$$

where n is not unity as in the Hammett relation (13). This method has been used exclusively to obtain pK_{BH^+} for the benzamides. A typical fit of experimental data to a line calculated using the above equation with $n = 1.59$ and $pK_{BH^+} = -2.10$ is shown for mesitamide in Fig. 1. The corresponding change of extinction

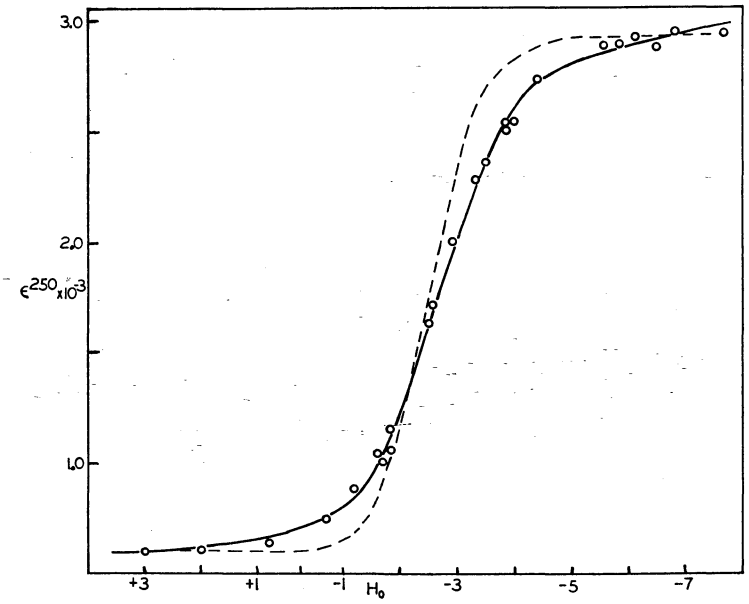

FIG. 1. Mesitamide: change in ϵ at 250 mμ with H_0. Circles are experimental points. Solid line calculated from $H_0 = pK_{BH^+} - 1.59 \log [BH^+]/[B]$ as in ref. 16. Broken line calculated for a Hammett base with pK_{BH^+} obtained as in ref. 6.

with acidity expected for a Hammett base ($n = 1$) is shown for comparison. It is felt that this method gives more accurate relative pK_{BH^+} values for the amides, although the absolute values may be subject to uncertainty because the bases do not follow H_0 precisely.

Recalculation of Previously Reported pK_{BH^+} Values

In order to compare the above pK_{BH^+} values with previously reported results it was necessary to convert the latter to the acidity scale used to define pK_{BH^+} in the present work. The reason for choosing the new values of H_0 obtained by Jorgenson and Hartter in the region 60–98% was that this scale was established with a uniform set of structurally similar indicators, using modern spectrophotometric techniques. Further it was shown by the above authors (8) that plots of $\log [BH]^+/[B]$ against percentage of H_2SO_4 were more closely parallel for successive indicators than those obtained with the original Hammett indicators (13, 17).

The procedure used to convert the old pK_{BH^+} values was simply to take the reported sulphuric acid

For personal use only.

concentration corresponding to 50% ionization, based on the old scale (13), and read the corresponding value directly off a plot of the new H_0 values against concentration.

To test the validity of this procedure, the spectra of benzoic acid, whose ionization range approximately covers the region of divergence of the two scales, were freshly determined in 50–95% H_2SO_4. Treatment of this data using the new H_0 values resulted in a pK_{BH^+} of −7.60, compared with −7. 58 obtained by converting the reported value of −7.18 (6) by the interpolation method.

RESULTS AND DISCUSSION

Steric Effects on Base Strength

The experimental pK_{BH^+} values for the *o*-methyl- and *o*-dimethyl-substituted carbonyl bases are listed in Table I, together with data for the unsubstituted and *p*-methyl

derivatives ($pK_{BH^+} = H_0 + \log [BH^+]/[B]$). The calculated pK_{BH^+} values listed for those bases with methyl groups in ortho positions are values to be expected for these compounds in the absence of steric effects. These have been obtained by assuming that the total electronic effect of a methyl group in the ortho position is the same as that in the para position, and that substituent effects are additive (18).

The difference $(pK^{exptl}_{BH^+}-pK^{calc}_{BH^+})$ has then been taken as a measure of the steric effect on the basicity. It can be seen that in every case the steric effect of one ortho group is positive, i.e. base weakening, and increases with the size of the group X in the order $H < OH < NH_2 < CH_3 < C_6H_5$, qualitatively as expected. In order to compare these

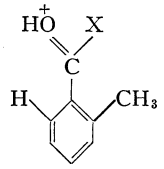
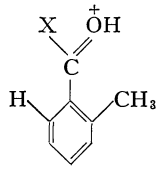
For personal use only.

effects on a more quantitative basis, allowance should be made for the fact that the ionization behavior of each type of base has a different sensitivity to total electronic effects. This will be discussed later. In two cases, the *o*-methyl derivative is actually weaker than the unsubstituted base, despite the base-strengthening electronic effect of a methyl group. These effects on basicity arise in part from steric inhibition of coplanarity between the carbonyl group and ring, the resulting loss of resonance stabilization energy being more serious in the conjugate acid than in the free base. Two possible preferred planar conformations can be written for these conjugate acids:

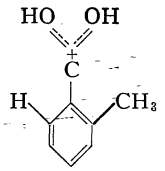


III



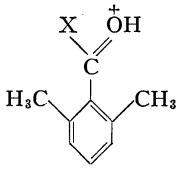
IV

Contributing structures showing charge delocalization have been omitted since the possibilities for π-orbital overlap are somewhat different in each type of base. Structure III is presumably the preferred conformation only in the case of *o*-tolualdehyde (X = H), where the steric interactions are between ortho methyl and aldehyde hydrogen, and between ortho hydrogen and the hydroxyl group. Since neither of these should be large it is not surprising that the magnitude of the steric effect is not much greater than the experimental uncertainty in pK_{BH^+}. In all other cases, structure IV will be preferred. In this case the *o*-methyl–hydroxyl repulsion will be common to all four bases, *differences* in steric effects arising mainly from the repulsion of X by the ortho hydrogen. The effect of the first of these repulsions can be estimated roughly from the steric effect for *o*-toluic acid, where the protonated carboxyl group is symmetrical, and hence III and IV are



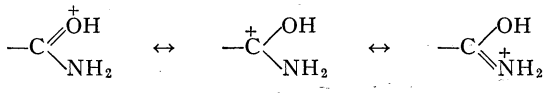
equivalent. The total steric effects in *o*-methylacetophenone, 2,4,5-trimethylacetophenone, and *o*-toluamide are larger, as would be expected. The reason the decrease in basicity is not much larger than these in *o*-methylbenzophenone, where X is a bulky phenyl group, is due to the fact that at least one of the aromatic rings can easily adopt a coplanar arrangement with the protonated carbonyl group, and thus provide resonance stabilization of the cation. There is evidence that the predominant effect of single ortho groups in carbonyl type bases is steric inhibition of resonance in the conjugate acid (6). It will be noted that these effects are not large, ranging from 0.18–0.63 pK units.

If we consider now the steric effects of two *o*-methyl groups, then all five types of base have the same "planar" conformation as given below. Therefore differences in steric



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

effects are again largely determined by the interaction of the group X with an ortho substituent. Since the latter is now the more bulky methyl group, changes in base strength are more pronounced. This is shown by the data in Table I, the effects again being qualitatively in agreement with the size of X, except for X = C_6H_5, where the effect is not expected to be very large, for the reasons discussed earlier. The effects are not large where X = H or OH, but are particularly striking where X = CH_3 or NH_2. The base 2,4,6-trimethylacetophenone is several thousand times weaker than would be predicted if only the base-strengthening electronic effects of the three methyl groups were considered, and is actually weaker than acetophenone itself by a factor of 10. (This has been pointed out before (2) but the earlier quantitative estimate of the steric effect was based on a pK_{BH^+} value for 2,4,6-trimethylacetophenone which we believe to be less reliable than the present one.) Where X = NH_2, the steric effects are also large, resulting in basicities more than 10 times lower than expected on the basis of substituent electronic effects alone, two independent estimates of the effect agreeing to 0.13 unit. Although steric effects are apparently more pronounced in the ketones than the amides it must be remembered that the latter are less sensitive to the effects of overlap with the π-orbitals of the ring. This is due to the appreciable resonance stabilization within the protonated carboxamide group itself as shown by the very high basicity of amides compared to other types of carbonyl base (5). A study of molecular models shows that if all atoms in the carboxamide group are to be essentially coplanar in order to achieve this internal resonance stabilization, the coplanarity of phenyl and side chain is more difficult to achieve in the amide than in the ketone. In the latter, the ketone methyl group can be rotated to minimize repulsions with the *o*-methyl group whereas in the amides rotation about the C—N bond is appreciably restricted (19), resulting in a tendency to twist the whole group out of the plane of the benzene ring.



Ultraviolet Spectra and Interplanar Angles

The spectral data for the neutral and protonated forms of the carbonyl bases discussed above are listed in Table II. The values of λ_{max} and ϵ_{max} are mainly those determined in the present work, since it was felt that for purposes of calculation these would be more self-consistent than a collection of data from various sources, obtained by different experimental techniques and in non-standard sulphuric acid concentrations. (In the cases of two *o*-dimethyl derivatives, however, values of ϵ_B and ϵ_{BH^+} have been taken from the literature and used to calculate further data.) The values of λ_{max} for both B and BH^+ are in close agreement with literature values, where available, but the values of ϵ_B and ϵ_{BH^+} are in several cases appreciably different from previously reported values. The ϵ values reported herein are the mean values of up to six independent determinations, with a *maximum* deviation from the means of $\pm 2\%$.

The above extinction coefficient data were used to calculate mean interplanar angles between the carbonyl group and benzene ring in both the free bases and their conjugate acids. This was done using the approximate relation $\epsilon/\epsilon_{planar} \approx \cos^2\theta$ (20), where ϵ_{planar} is the extinction coefficient to be expected in a system which can easily adopt a uniplanar arrangement and θ is the mean angle of twist between the carbonyl group and aromatic ring in a sterically hindered compound having an extinction coefficient ϵ. This method has been described by Braude (20) and has been used with success both by Braude and

co-workers (21), who obtained results in good agreement with angles of twist calculated from dipole moment measurements, and by Wepster (10), who investigated steric effects in aniline type bases. We have taken ϵ for the *p*-methyl isomers to be ϵ_{planar} and thus calculated θ values for the *o*-methyl isomers. This is reasonable since the cross-sectional areas of the two molecules are the same and the electronic effects of *o*- and *p*-methyl groups are approximately equal. The angles θ_B and θ_{BH^+} for the two forms of each base are also listed in Table II. Strictly speaking, the oscillator strength f, and not ϵ, should be used to estimate angle of twist (10) but difficulties arise in estimating f for these compounds since the type of electronic transition studied, $\pi \rightarrow \pi^*$, is overlapped to some extent by the weaker $n \rightarrow \pi^*$ band, and in some cases by the more intense bands occurring in the 200 mμ region. This is not too serious in the more dilute acid solutions and an approximate separation of the three bands can be achieved. This was done for the spectra in 46% H_2SO_4 and oscillator strengths obtained from the relation $f = 4.32 \times 10^9 \int \epsilon d\nu$. These are given in Table II. The six values which could be obtained are linearly related to the corresponding ϵ values; therefore ϵ values, which are easier to obtain, were used throughout to calculate angles of twist.

Turning to the spectra of the 2,6-dimethyl and 2,4,6-trimethyl derivatives, values of θ can only be calculated if the assumption is made that each ortho or para substituent causes an equal increment in ϵ for the parent compound. In this way ϵ_{planar} can be estimated from ϵ values for the unsubstituted and para-substituted derivatives. That this assumption is not strictly valid is shown by the fact that ϵ_{planar} calculated for 2,4,6-trimethylbenzaldehyde is actually *lower* than the observed ϵ value in any given solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In this case θ was assumed to be effectively zero. This is supported by the results of dipole moment studies (20). In view of these considerations, the estimates of $\epsilon/\epsilon_{planar}$ and hence θ for the *o*-dimethyl-substituted compounds are somewhat less quantitative than those for the *o*-methyl compounds, where the assumptions involved are more reasonable.

It can be seen from Table II that the calculated mean interplanar angle between carbonyl and aromatic ring increases with size of the group X attached to the carbonyl carbon, and also with the number of *o*-methyl groups, as would be expected. This is true of both the B and BH^+ forms, although in general the conjugate acids have lower values of θ than their corresponding bases, presumably due to the extra stabilization to be gained from delocalization of charge into the ring.

A study of molecular models and projection diagrams shows that Braude's explanation of the decrease in θ in terms of reduced possibilities for coplanarity is a reasonable one (20). In the case of 2,4,6-trimethylacetophenone, for example, a molecular model shows that coplanarity must be very difficult to achieve, resulting in a very low population of uniplanar molecules. This is reflected in the ϵ value of 1700, which is extremely low for the allowed benzoyl $\pi \rightarrow \pi^*$ transition which normally has $\epsilon > 10^4$.

Relationship of Base Strength and Ultraviolet Intensities

If the major effect of ortho substitution on base strength is steric inhibition of resonance between the protonated carbonyl group and benzene ring, as suggested by Stewart and Granger (6), there should be a correlation between ΔpK_{BH^+} ($= pK^{calc}_{BH^+} - pK^{exptl}_{BH^+}$) and ϵ_{BH^+}. Such a correlation has been found by Wepster (10) between the basicities and ultraviolet intensities of *p*-nitroanilines. This was attributed to steric inhibition of resonance of the nitro group with the ring.

In the present case, where different classes of carbonyl base are being considered, each series has a different sensitivity to overall electronic effects, as measured by the Hammett ρ value. Therefore in order to compare the magnitudes of steric effects on a more nearly equal basis, the ΔpK_{BH^+} values should be divided by ρ. The pK_{BH^+} values for benzaldehydes (2), acetophenones (3), and benzoic acids (4) have previously been found to obey the modified Hammett equation $\log (K_{BH^+}/K^0_{BH^+}) = \rho\sigma^+$ (22) with a high degree of precision. Thus ρ values based on σ^+ rather than σ have been recalculated in accordance with the H_0 scale used in the present paper and are given in Table III. The pK_{BH^+} values

TABLE III

Hammett rho values for the ionizations of carbonyl bases

Benzophenones		4	~2	9

of the benzamides have previously been reported to follow σ more closely than σ^+, and this was proposed as evidence for N-protonation of the carboxamide group (5). However, it now seems certain that amides protonate on oxygen (23), and in fact more recent determinations of pK_{BH^+} for substituted benzamides (16) show that pK_{BH^+} correlates reasonably well with σ^+ ($r = 0.914$) as compared to σ ($r = 0.911$). While it is now generally recognized that the σ^+ scale of substituent effects is not necessarily applicable to all systems in which a positively charged group is conjugated with a benzene ring, all compounds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

studied in the present work do protonate predominantly on oxygen and hence direct conjugation with the ring is possible in each case. For this reason ρ for the benzamides has been estimated from a plot of pK_{BH^+} versus pK_{BH^+} for the acetophenones. Thus all ρ values in Table III are essentially values relative to ρ for the acetophenones, and are based on the same solvent system and the same experimental approach. In this way the steric effects as measured by $\Delta pK_{BH^+}/\rho$ should be accurate relative to each other, even if their absolute values are subject to some uncertainty.

The plot of $\Delta pK_{BH^+}/\rho$ for the *o*-methyl-substituted derivatives against $\epsilon/\epsilon_{planar}$ for the corresponding conjugate acids in Fig. 2 shows a good linear relationship. Since $\epsilon/\epsilon_{planar}$

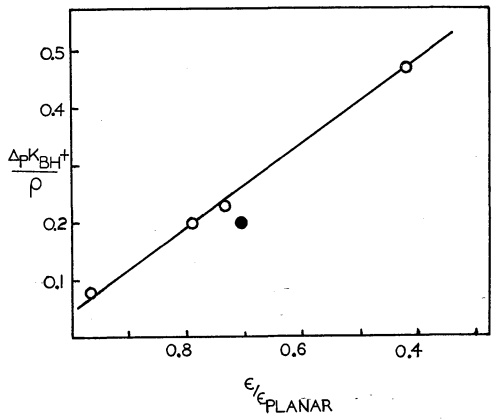

FIG. 2. Relation between steric effect on base strength and on ultraviolet intensity. Open circles, 2-methyl derivatives. Solid circle, 2,4,5-trimethylacetophenone.

$\approx \cos^2\theta$, and the overlap between the two π-electron systems is reduced by an amount proportional to $\cos^2\theta$ (24), this linear relationship is evidence that steric inhibition of resonance in the conjugate acid is the predominant steric effect when one *o*-methyl group is present, and supports the conclusion reached earlier by Stewart and Granger (6).

However, no such simple relationship exists for the *o*-dimethyl-substituted compounds. All the $\Delta pK_{BH^+}/\rho$ values in Table IV are greater than would be predicted by the simple

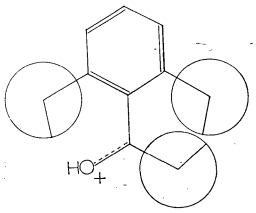
relationship shown in Fig. 2; therefore some other base-weakening steric effect must be operating in addition to steric inhibition of resonance. The magnitude of this effect is small in the case of 2,4,6-trimethylbenzyldehyde and mesitoic acid, although in the latter case the interpretation of $\epsilon/\epsilon_{planar}$ in terms of interplanar angles is complicated by appreciable mesitoylium ion formation (25). In the 2,6- and 2,4,6-substituted acetophenones and benzamides, however, the effect is much larger. If the line in Fig. 2 is extrapolated and used to estimate steric effects based on $\epsilon/\epsilon_{planar}$ for these compounds, the values obtained are much smaller than those observed, as shown in Table IV. This additional steric effect can reasonably be explained by steric inhibition of solvation of the conjugate acid forms in the following way. With only one *o*-methyl substituent present, the carbonyl group is twisted out of plane by about 30° or less, so that some charge delocalization by resonance is still possible. Thus the effective size of the cation is large and one *o*-methyl group cannot effectively hinder the approach of solvent molecules. In this case steric inhibition of resonance is the predominant base-weakening effect. Where two *o*-methyl substituents are present, the angle of twist is larger, especially where the group X is CH_3 or NH_2 (θ = 50–60° in the ketones and 70° in the amides). Thus overlap and resultant charge delocalization into the ring are drastically reduced, and the effective size of the cation is smaller. Therefore solvent stabilization is more important. In addition there are now two *o*-methyl groups to block the approach of solvent molecules. This is illustrated by the projection diagram for 2,6-dimethylacetophenone where the positive charge is shown residing effectively on the carbonyl group. Thus for large angles of twist there is a cumula-



tive effect. As steric inhibition of resonance is increased, steric inhibition of solvation becomes more serious as the charge is more localized, and is comparable to if not greater in magnitude than inhibition of resonance where the group attached to the carbonyl is NH_2 or CH_3. It can be estimated roughly that this additional loss of stabilization amounts to about 3 kcal in the ketone, and 1 kcal in the amide, conjugate acids. The reason this is smaller in the amides is presumably due to the fact that appreciable charge delocalization within the protonated carboxamide group results in a larger effective cation size, in which solvation effects are of less importance and which is also more difficult for the methyl groups to block.

The benzophenones have not been included in the above discussion. In similarly substituted ArCOX molecules where the group X is also phenyl, the values of ϵ cannot be as simply interpreted in terms of angle of twist since the unsubstituted phenyl ring X can easily assume coplanarity with the carbonyl group, resulting in a high absorption intensity.

Received April 29, 1963

ABSTRACT

The n.m.r. spectra of 1α-methoxy-2β-hydroxy-3α-aminocyclohexane, 1α-methoxy-2α-hydroxy-3β-aminocyclohexane, their N-acetyl and O,N-diacetyl derivatives, ethoxy analogues, and 3α-amino-1α,2β-cyclohexanediol and 3β-amino-1α,2α-cyclohexanediol triacetates were measured in chloroform solution. From the chemical shifts of the O- and/or N-acetyl methyl protons it was possible to assign conformations to all the substituted derivatives and in most cases the assignments thus made were confirmed by first-order analysis of the multiplet pattern from the methine protons. In all cases, the conformations found were those predicted on simple conformational grounds and no evidence for a conformational equilibrium at room temperature was obtained from the coupling constants. In general, the coupling constants for the methine protons followed the pattern predicted by the Karplus equation. Acetylation of the 1α-alkoxy-2α-hydroxy-3β-aminocyclohexanes with acetic anhydride gave both the O,N-diacetyl derivative and the O,N,N-triacetyl derivative.

In an earlier paper (1) a chemical proof of structure for the 3-amino-1,2-cyclohexanediols I and II was given, from which the structures of the corresponding 1-alkoxy-2-hydroxy-3-aminocyclohexanes III and IV (R = CH_3 or C_2H_5) and 1-alkoxy-2,3-epoxy-

cyclohexanes V and VI (R = CH_3 or C_2H_5) used as intermediates in their synthesis were deduced. Although the stereochemical configurations of compounds I–IV were thus established, their conformations were not, and it was of interest to verify that the conformations were in fact those predicted on the basis of simple conformational principles (2, 3); i.e.

[1]*Issued as D.R.C.L. Report No. 415.*

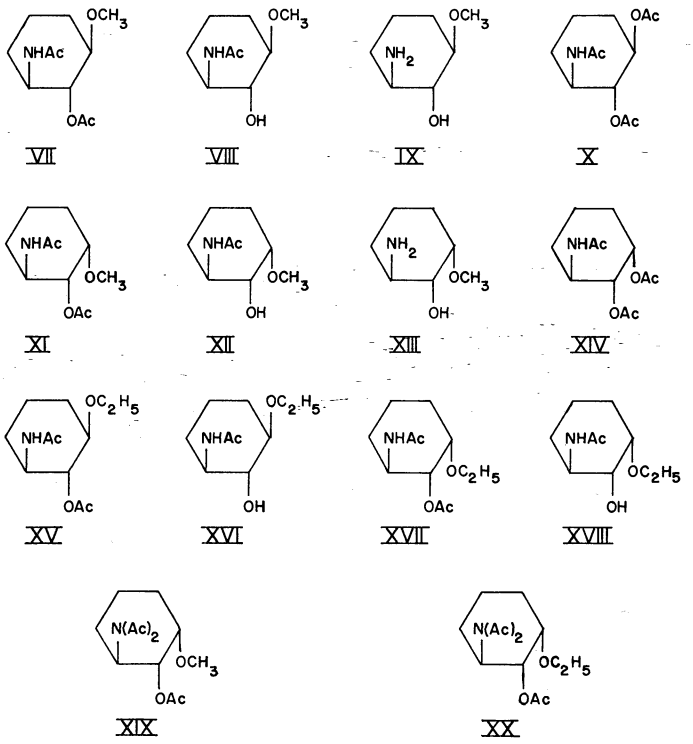
e,e,e for I and III and a,e,e, for II and IV (cf. ref. 9). The usefulness of n.m.r. spectroscopy for elucidation of the configuration and conformation of cyclohexane compounds was first demonstrated by Lemieux, Kullnig, and Moir (4) using the 1,3-dimethoxy-2-acetoxycyclohexanes which were obtained from the oxides V and VI (R = CH_3) by methanolysis followed by acetylation. The method was subsequently extended by Lemieux and coworkers (5) to the determination of the structures of other compounds containing six-membered rings, notably penta- and hexa-pyranose carbohydrate derivatives, and has gained widespread use in recent years for the solution of such structural problems (6–9). Recently, Richardson and McLaughlan (9) assigned structures to some 3-amino-3,6-dideoxyhexapyranose derivatives on the basis of their n.m.r. spectra, and observed chemical shifts for the protons of acetoxyl, acetamido, and methoxyl groups which were apparently characteristic of their conformations. It therefore seemed of interest to examine the n.m.r. spectra of similar derivatives of compounds I to IV to demonstrate whether the chemical shifts referred to above apply to the cyclohexane series with equal facility. The structures of the compounds examined in this connection are given in Chart I.

CHART I



Interpretation of the spectra was generally straightforward and was facilitated, in cases in which the compounds contained unsubstituted hydroxyl or amino hydrogens, by equilibration with deuterium oxide. Since the unsubstituted aminoalcohols are basic, a single sharp peak was observed for the NH_2/OH protons. In no case was it possible to analyze the complex pattern due to the methylene ring hydrogens, but the downfield shift of the methine ring hydrogens caused by the adjacent substituents made it possible for the signals

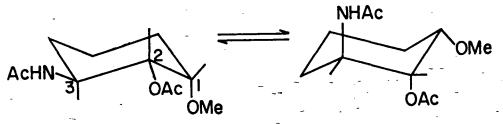
following discussion reference will be made only to the methoxy derivatives and the 3-amino-1,2-cyclohexanediol triacetates, since the ethoxy compounds gave essentially the same results and hence served only to confirm the conclusions reached for the methoxy series. The only noteworthy point observed in the ethoxy series was the increased multiplicity of the signal of the methylene protons of the ethoxy group, which is to be expected because of the molecular asymmetry (10).

Inspection of the chemical shifts observed for the acetoxy and acetamido methyl protons indicated in all cases that the substituents had the expected conformations. Thus, 1α-methoxy-2α-acetoxy-3β-acetamidocyclohexane (XI) showed an acetoxy methyl resonance at τ 7.90 and an acetamido methyl resonance at τ 8.08. Since both values are consistent with those found by Richardson and McLaughlan (9) for equatorially oriented substituents, compound XI probably has the conformation XI*a*. Comparison of the τ-values



XIa XIb

for the methoxy methyl protons showed that there is little difference between axial (6.64$\pm$0.01) and equatorial (6.60$\pm$0.01) values, so that these resonances are not indicative of conformation in these derivatives.

In several compounds (VII, XI, XIII, XIV, XV, XVII, XIX, and XX) the methine ring hydrogens (H_1, H_2, and H_3) gave separate multiplets from which the first-order coupling constants were obtained. A complete analysis of these spectra was not necessary because of the large chemical shift of the methine protons from the methylene protons and accordingly, the three methine ring hydrogens were analyzed as an ABC-system.* The coupling constants thus obtained were virtually identical with those obtained from the splittings of the H_2 multiplet. Attempts to remove the coupling between the methine and methylene protons by field sweep double irradiation were unsuccessful presumably due to the rather large spread of the methylene resonance. The coupling constants from the acetylated compounds clearly establish the correctness of the conformations assigned on the basis of substituent resonances. Furthermore, the values observed for the unsubstituted compound XIII showed for the first time that it also has the expected conformation.

It is, however, difficult to rationalize the precise values found for the coupling constants

**Using an I.B.M. Model 650 computer and a program devised by Dr. R. R. Fraser and Miss O. Boshko.*

or indeed to explain why such a wide range of values should be obtained for axial:axial and axial:equatorial couplings. Karplus (11) derived by quantum mechanical analysis an equation for the relationship between the coupling constant (J) of two hydrogens and their dihedral angle (ϕ),

$$J = J_0 \cos^2 \phi - C,$$

where J_0 and C are constants. When this equation was derived there was sufficient experimental evidence (12) to show that the coupling constants varied slightly with the electronegativity of the substituents and recent work has shown that although the $\cos^2 \phi$ term adequately describes the relationship (13) it is necessary to modify either the J_0 (13, 14) or the C term (15). If it is assumed that the largest coupling constants observed correspond to protons on adjacent carbon atoms which are truly diaxial (i.e. the dihedral angle between them is 180°) it still remains to explain the smaller values observed for other compounds which should possess identical conformations. The smaller coupling constants could arise because of an equilibrium between two conformations, because the dihedral angle between axially oriented protons on adjacent carbon atoms is less than 180°, or because of some hitherto unrecognized effect of the substituent at C_1 on the axially unsymmetrical acetoxyl and acetamido groups which is reflected in a modification of the coupling constant in question.

If there were an equilibrium between conformers XI*a* and XI*b* and the rate of interconversion was rapid, the observed coupling constants would be the weighted mean of the couplings from each conformer and would thus have a smaller value than expected. Although such a conformational inversion would be energetically unfavorable, it might be stabilized by the occurrence of hydrogen bonding. Some suggestive evidence for this comes from the fact that in this series of compounds the small a:a coupling constants are observed in two out of three cases (compounds VII and XV) when the C_1 substituent is cis with respect to the acetamido function. When these groups are trans, however, the a:a coupling $J_{2,3}$ is with one exception (compound XIII) 10.5±0.1 c.p.s. Accordingly, the spectrum of compound VII was measured in acetic acid, which would probably prevent intramolecular hydrogen bonding between the 1,3-substituents. The a:a coupling constant $J_{2,3}$ was increased thereby only from 9.1 to 9.4 c.p.s., which is hardly significant. It is therefore concluded that conformational inversion at room temperature is an improbable explanation for the low $J_{2,3}$ values observed.

Although some slight distortion of the ring might result from a change in configuration of the substituent at C_1 with a consequent small distortion of the dihedral angle between the axially oriented protons at C_2 and C_3, the magnitude of the effect on $J_{2,3}$ seems too large to be caused by such a mechanism. Hence, it is tentatively suggested that the variations in a:a coupling constants reported here and elsewhere (8, 16) owe their origin in part to modification of the orientation of the axially unsymmetrical substituents attached to the carbon atoms bearing the protons in question, by a change in configuration of another unsymmetrical substituent located on an adjacent carbon atom. In view of the few examples available, however, it is not possible to decide unequivocally at present whether such a substituent effect is responsible for the low a:a coupling constants and further work to elaborate this point is planned.

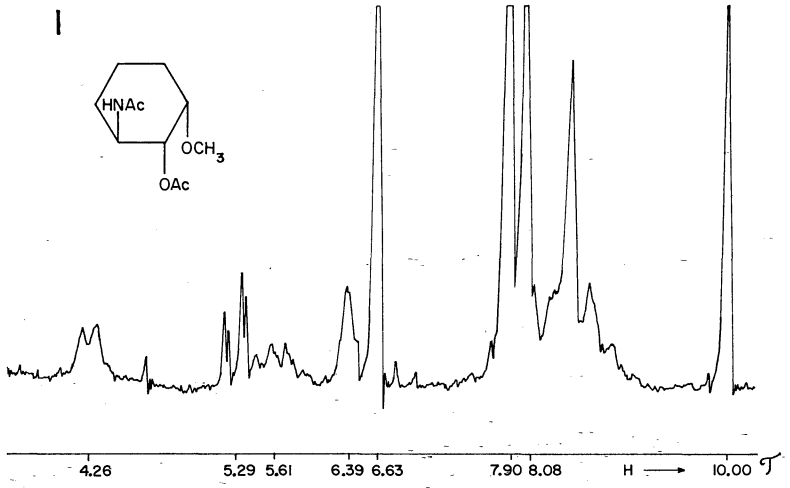
Comparison of the different chemical shifts for H_1, H_2, and H_3 enables a limited number of substituent effects to be assigned. Thus, the equatorial H_1 shows a downfield shift of ca. 0.4 p.p.m. compared with the axial H_1, which agrees well with values recorded elsewhere (17, p. 116). Acetylation of the hydroxy substituent at C_2 causes H_2 to shift to low field by 1.5 p.p.m., which is slightly more than usual (ref. 17, p. 55). Acetylation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

primary amino function at C_3 shifts H_3 downfield by 1.2 p.p.m. Acetylation of the hydroxyl group also causes shifts in the resonance of the N-Ac (+0.06 p.p.m.), NH (+0.4 p.p.m.), and H_3 (−0.33 p.p.m.) protons which must be due to the diamagnetic anisotropy of the acetoxy carbonyl function.

Acetylation of IX and III (R = C_2H_5) with acetic anhydride under reflux gave the O,N-diacetyl derivatives VII and XV in 74% and 70% yield respectively. Acetylation of the N-acetyl derivative XII or the aminoalcohol IV (R = C_2H_5), however, under identical conditions, furnished the crystalline O,N-diacetyl derivatives XI and XVII in yields of only 50% and 48% respectively, but gave in addition the corresponding liquid O,N,N-triacetyl derivatives XIX and XX in 48% and 37% yield respectively.

The structures of the latter compounds were deduced from their elemental analyses and their n.m.r. and infrared spectra. The main points of difference between the n.m.r. spectra of the O,N,N-triacetyl and O,N-diacetyl derivatives are shown in Figs. 1 and 2



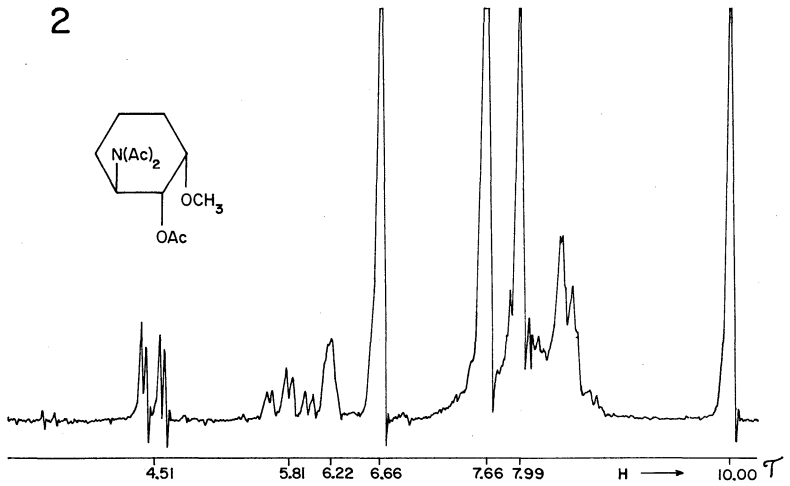


FIG. 1. The n.m.r. spectrum of 1α-methoxy-2α-acetoxy-3β-acetylaminocyclohexane (XI).
FIG. 2. The n.m.r. spectrum of 1α-methoxy-2α-acetoxy-3β-diacetylaminocyclohexane (XIX).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

for the methoxy compounds XIX and XI. The doublet at τ 4.20 in the spectrum of the O,N-diacetyl derivative XI which had been assigned to the NH proton was not observed in compound XIX. Furthermore, no signal corresponding to N-acetyl protons at τ 8.08 was observed for the latter, which instead showed a resonance at τ 7.66 equivalent to two methyl groups which was assigned to a di-N-acetyl function. On these grounds XIX was assigned the O,N,N-triacetyl structure. The n.m.r. spectra of the corresponding ethoxy derivatives XVII and XX were entirely analogous.

The structural assignment made on the basis of the n.m.r. spectra of compounds XI and XIX was confirmed by measurement of their infrared spectra in carbon tetrachloride solution. Compound XI showed prominent bands at 3410 cm^{-1} (N—H, non-bonded), 3320 cm^{-1} (N—H, bonded), 1722 cm^{-1} (C=O, ester), 1683 cm^{-1} (C=O, amide I), 1233 cm^{-1} (C—O, acetate), and 1500 cm^{-1} (amide II) (18). The ester carbonyl and amide I absorptions were of equal intensity. Compound XIX, on the other hand, showed no N—H or amide II absorption but gave prominent bands at 1743 cm^{-1} (C=O, ester), 1700 cm^{-1} (C=O, amide I), and 1225 cm^{-1} (C—O, acetate). The intensity of the amide I absorption was considerably greater than that of the ester carbonyl and the observed shift in frequency of the amide I band from 1683 cm^{-1} in XI to 1700 cm^{-1} in XIX is in agreement with the tertiary amide structure, since Richards and Thompson observed that substitution of an amide nitrogen with an electrophilic group produces a shift to higher frequency (19). The infrared spectra of XVII and XX were analogous to those of XI and XIX respectively.

EXPERIMENTAL* †

The proton magnetic resonance spectra were measured on a Varian V-4302 spectrometer operating at 60 Mc/sec, using a Varian V-4352 integrator for base-line stabilization. All solutions were 10% w/v in chloroform and were calibrated with reference to internal tetramethylsilane by the usual side-band technique.

Infrared spectra were measured in carbon tetrachloride (0.05 *M*) using a Perkin–Elmer Model 21 double-beam recording spectrometer.

The preparation of all the compounds used herein except VII, XI, XV, XVII, XIX, and XX was described previously by Bannard and Hawkins (1).

1α-Methoxy-2β-acetoxy-3α-acetylaminocyclohexane (VII)

1α-Methoxy-2β-hydroxy-3α-aminocyclohexane (IX) (1) (0.290 g, 0.002 mole) was heated under reflux for 1 hour with acetic anhydride (5 ml) in an apparatus protected from entry of moisture. The excess acetic anhydride was removed from the cooled solution by distillation *in vacuo* (0.001 mm) at room temperature. The crystalline residue was recrystallized from acetone, yielding 340 mg (74.2%) of colorless needles, m.p. 168–169°. Calc. for $C_{11}H_{19}O_4N$: C, 57.62; H, 8.35; N, 6.11%. Found: C, 57.89; H, 8.36; N, 6.30%.

1α-Methoxy-2α-acetoxy-3β-acetylaminocyclohexane (XI) and 1α-Methoxy-2α-acetoxy-3β-diacetylaminocyclohexane (XIX)

1α-Methoxy-2α-hydroxy-3β-acetylaminocyclohexane (XII) (1) (0.374 g, 0.002 mole) was acetylated under the conditions described above. Removal of the excess anhydride *in vacuo* left a pale brown oil which did not crystallize on standing. The material was transferred to a four-bulb Späth tube and heated in an air bath at 79–84° at 0.03 mm pressure. A colorless distillate collected in the second bulb, leaving a viscous brown oil in the first bulb. The latter material crystallized on standing overnight. The distillation process was repeated from bulb 2 to bulb 3 at an air bath temperature of 79–81° and finally from bulb 3 to bulb 4 at 74–76°. The crops of crystals remaining in bulbs 1 to 3 were collected and recrystallized from anhydrous ether, yielding 230 mg (50.2%) of 1α-methoxy-2α-acetoxy-3β-acetylaminocyclohexane (XI) as colorless feathery needles, m.p. 138–140°. Calc. for $C_{11}H_{19}O_4N$: C, 57.62; H, 8.35; N, 6.11%. Found: C, 57.60; H, 8.37; N, 5.95%. This compound sublimed slowly under the conditions used for final distillation of the oil fraction, 258 mg (47.6%), which proved to be pure 1α-methoxy-2α-acetoxy-3β-diacetylaminocyclohexane (XIX). Calc. for $C_{13}H_{21}O_5N$: N, 5.16; acetyl, 46.50%. Found: N, 5.17; acetyl, 46.45%.

1α-Ethoxy-2β-acetoxy-3α-acetylaminocyclohexane (XV)

1α-Ethoxy-2β-hydroxy-3α-aminocyclohexane (III, R = C_2H_5) (0.318 g, 0.002 mole) on acetylation under the conditions described for the preparation of VII yielded 336 mg (69.1%) of 1α-ethoxy-2β-acetoxy-3α-acetylaminocyclohexane (XV) as colorless needles, m.p. 167–169°, after recrystallization from 95% ethanol. Calc. for $C_{12}H_{21}O_4N$: C, 59.24; H, 8.70; N, 5.76%. Found: C, 59.41; H, 8.83; N, 5.78%.

**All melting points are uncorrected.*

For personal use only.

1α-Ethoxy-2α-acetoxy-3β-acetylaminocyclohexane (XVII) and 1α-Ethoxy-2α-acetoxy-3β-diacetylaminocyclohexane (XX)

Acetylation of 1α-ethoxy-2α-hydroxy-3β-aminocyclohexane (IV, R = C_2H_5) (0.335 g, 0.0021 mole) under the same conditions as described for the preparation of XI and XIX gave 244 mg (47.6%) of 1α-ethoxy-2α-acetoxy-3β-acetylaminocyclohexane (XVII) as colorless needles, m.p. 113.5–114.5° after recrystallization from anhydrous ether. Calc. for $C_{12}H_{21}O_4N$: C, 59.24; H, 8.70; N, 5.76%. Found: C, 59.16; H, 8.78; N, 5.86%. The oil fraction, 1α-ethoxy-2α-acetoxy-3β-diacetylaminocyclohexane (XX), 223 mg (37.2%), was recovered in the same manner as its lower homologue. Calc. for $C_{14}H_{23}O_5N$: N, 4.91; acetyl, 45.25%. Found: N, 4.76; acetyl, 44.93%.

ACKNOWLEDGMENTS

The authors are indebted to Dr. R. N. Jones and Mr. R. Lauzon, Division of Pure Chemistry, National Research Council, Ottawa, for recording the infrared spectra. One of us (R. A. B. B.) wishes to thank the Defence Research Board of Canada for granting him leave of absence to participate in this work.

RING-PROTON CHEMICAL SHIFTS OF SOME SUBSTITUTED ANILINES IN CARBON TETRACHLORIDE AND TRIFLUOROACETIC ACID

W. F. Reynolds and T. Schaefer
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received April 26, 1963

ABSTRACT

The chemical shifts of the ring-proton spectra of a series of substituted anilines are reported relative to internal benzene in the solvents carbon tetrachloride and trifluoroacetic acid. The substituent parameters in cyclohexane derived by Martin can be used together with our parameters for the para-fluoro and -ammonio (NH_3^+) groups to demonstrate additivity of the substituent effects in both carbon tetrachloride and trifluoroacetic acid. The somewhat puzzling ring-proton shifts in the latter solvent are attributed to counterion effects arising from a juxtaposition of the two centers of charge. Steric hindrance to π-overlap of the amino group with the ring is demonstrated in certain cases and a parallel behavior is found between the ring-proton shifts and the electronic spectra of these molecules.

INTRODUCTION

Differences in shielding between ring protons in substituted benzenes have been discussed in terms of additive substituent effects (1–3); Hammett sigma constants (1–6); electric field effects due to substituents (2, 3, 4, 6, 7); magnetic anisotropy of the substituents (3, 4); and of special solvent effects (8).

In the course of a study of the exchange of amino protons in substituted anilines we have measured the ring-proton shifts in a number of ring- and N-substituted anilines in CCl_4 and trifluoroacetic acid (TFA). We establish the minimum amount of alkyl substitution in the ortho position necessary for the observation of steric effects on the chemical shifts of the ring protons in anilines. We give a qualitative interpretation of the ring-proton shifts in TFA and establish additivity relationships in this solvent.

EXPERIMENTAL

The ring-proton resonance spectra of 5 mole% solutions of the anilines in CCl_4 and TFA were measured at 60 Mc/s on a Varian DP-60 spectrometer. The internal reference was benzene and peak separations were measured by standard techniques. A small amount of the anhydride was added to the TFA solutions to react with any water present. The compounds were mostly reagent grade chemicals but a few others were used as well.

RESULTS

In Carbon Tetrachloride

In Table I the shifts for the ring protons of various anilines are given in p.p.m. relative to internal benzene. For aniline and its N-substituted derivatives the shifts in CCl_4 result from an approximate analysis. The spectra were actually of the type A_2B_2C (9). However, at 60 Mc/s the relative shifts were fairly large and we estimate that the shifts are accurate to 0.05 p.p.m. For aniline and N,N-dimethylaniline a comparison with the definitive deuteration experiments of Spiesecke and Schneider confirms this estimate (4). In those cases in Table I where shifts are given to three significant figures they were arrived at by an exact analysis. Because methyl groups couple to ortho protons (10, 11) and because methyl groups shift the resonances by small amounts (see below), the asymmetrically methyl-substituted anilines gave spectra which could be analyzed with some confidence. We feel their shifts are accurate to 0.05 p.p.m.

*The ring protons are labelled relative to the amino group.

The amino protons had broad resonance peaks at 3 to 4 p.p.m. from benzene, indicating proton exchange between nitrogen atoms (12) or quadrupole relaxation of the nitrogen nuclei at a rate rapid enough to broaden the hydrogen peaks (13).

In Trifluoroacetic Acid

The collapse of the ring-proton spectrum of aniline in acetic acid was first observed by Isobe *et al.* (14) and by Schneider (15). The collapse is not quite complete for N-substituted anilines when the substituents are larger than methyl. For ring-substituted anilines the relative shifts between ring protons are dominated by the substituents other than the ammonio (NH_3^+) group. (The very broad ammonio-proton resonances occurred at 1 to 1.5 p.p.m. to low field from benzene.) The anilines are protonated* in TFA since the N-alkyl groups always showed coupling of 5.2 to 5.6 c/s with an extra proton as expected for the proper anilinium ion. For example, N-methylaniline gave a methylt riplet peak with a measured splitting of 5.5 ± 0.1 c/s. This agrees with the structure $C_6H_5NH_2^+(CH_3)$. Hence, at 5 mole%, the lifetime of the ion at room temperatures exceeds 0.03 second. The exchange rate is a function of both temperature and concentration and is the subject of investigation in our laboratory.

DISCUSSION

The Para-substituted Anilines

The very careful work of Martin (3) on the ring-proton shifts of para-substituted benzenes at infinite dilution in cyclohexane shows that deviations from additivity of the substituent effects amount to 0.1 p.p.m. Using Martin's shielding parameters we can reproduce our observed shifts in CCl_4 with a mean deviation of 0.05 p.p.m. Part of this deviation is no doubt due to our use of 5 mole% solutions. We do not give the tabular values here since they only serve to establish the relative accuracy of our measurements. Martin's shielding parameters agree well with the chemical shifts of monosubstituted benzenes found by Spiesecke and Schneider (4). The substituent effects appear to be the result of several superimposed effects, presumably dominated by the polarization of the benzene π-electron system. We do not discuss them further here since they are fully discussed in a forthcoming paper by Martin (16).

We can account for the ring proton shifts in TFA by assigning a shielding parameter to the ammonio group of -0.30 p.p.m. for both the meta and ortho positions. This is the shift to low field from benzene of the broad peak of aniline in TFA (compound 18 in Table I).† Table II compares the predicted and observed shifts using Martin's substituent parameters in cyclohexane and $\delta_{m,p}(NH_3^+) = -0.30$ p.p.m. (see footnote in Table II). The mean deviation is less than 0.05 p.p.m.

Proton Shifts of Aniline in Trifluoroacetic Acid

It is not obvious why the ring-proton resonance of aniline in TFA should be a single broad peak, indicating a shielding difference of not more than about 0.1 p.p.m. Given that π-overlap with the ring is destroyed by protonation, an isolated anilinium ion should still show differences in shielding at the various ring positions of many c/s. This follows from a simple calculation involving the field due to a monopole. The use of Buckingham's equation (7) predicts shifts of -1.11 p.p.m., -0.49 p.p.m., and -0.38 p.p.m. relative to benzene for the ortho, meta, and para protons respectively. These predicted shifts would

Even anilines with strongly electron-withdrawing substituents are protonated at low concentrations in TFA, although, of course, the exchange rate will be higher.

†*The width of the peak would allow a shift between protons of as much as 0.1 p.p.m. if the usual magnitudes of ring-proton coupling constants are assumed.*

*Martin's substituent parameters are used together with $\delta_o^F = 0.280$ p.p.m., $\delta_m^F = 0.000$ p.p.m., and $\delta_o^{NH_3^+} = -0.30$ p.p.m.
†Ring protons are labelled relative to the amino group.

be modified somewhat by reaction field effects in solution (7). The fact that Martin's substituent parameters, derived from measurements in cyclohexane, could be used in Table II also indicates some other explanation for the observed effects of the ammonio group.

In this connection the studies of Fraenkel appear to resolve the dilemma (17). By means of n.m.r. techniques he has shown that anilinium salts in various solvents exist as intimate ion pairs *with the two centers of charge juxtaposed.* The anion–cation exchange is fast on an n.m.r. time scale. At the high solute concentrations used here such a result is to be expected. It thus appears that the effect of the ammonio group at the different ring positions is counteracted by the trifluoroacetate anion. If the ortho and meta positions were in a symmetrical environment with respect to the anion there would be no coalescence effect such as we observe in aniline.* There is still a net shift to low field of 0.3 p.p.m. which can probably be put down to an incomplete neutralization of the effect of theNH_3^+ group by the anion.

Methyl-substituted Anilines

Using Martin's substituent parameters for the methyl group the observed shifts in CCl_4 (compounds 10–17 in Table I) can be predicted to within a mean deviation of 0.07 p.p.m. Our measured shifts are little more reliable than this. However, the effect of a methyl group is also only about three times this deviation and the actual shifts are therefore dominated by the amino group.

In TFA the mean deviation between observed and predicted shifts in Table III is 0.04 p.p.m. We have assumed the substituent parameter to be −0.30 p.p.m. for the ammonio group at all positions. The agreement is certainly within experimental error at all three positions.

Steric Effects

It is natural to assume that the shifts of the ring protons of aniline itself in CCl_4 approximately reflect the overlap of the amino group with the π-orbitals of the ring. Spiesecke

It is only a coincidence that the n.m.r. spectra and electronic spectra of both benzene and the anilinium ions are very similar. In the case of electronic spectra the inductive effect of a substituent shifts the ground and excited states about equally and in the same direction (18). Therefore the inductive effect produces little change in the position or intensity of the benzene bands. Anilinium salts have electronic spectra virtually superimposable on the benzene spectrum (19, p. 248), a strong argument for no conjugation or *hyperconjugation of the* NH_3^+ *group with the ring. In this connection see a recent calculation by Bishop and Craig (20).*

*Ring protons are labelled relative to the ammonio group.

and Schneider (4) found a good correlation of the para shifts with the appropriate Hammett sigma constants in a series of monosubstituted benzenes. At other positions such a correlation was poor, presumably mainly due to magnetic anisotropy effects of the substituents. (Our shifts also show a poor correlation at meta and ortho positions with the sigma constants, although we do not give the graphs here.)

Although the shifts for compounds 19–22 in Table I are not known very accurately it is clear that a noticeable steric effect arises only when a methyl group is substituted ortho to the N,N-dimethyl group. When substituted ortho to the N-methyl group a methyl group does not appear to have a noticeable effect. Fraser has found a steric effect on the shifts when two methyl groups are substituted ortho to the N-methyl group (5).

In unsubstituted N,N-dimethylaniline, the nitrogen valences are probably nearly planar at about 120° to each other (19, p. 409). Steric effects twist the dimethylamino group out of the plane of the ring and the nitrogen valences become increasingly more pyramidal: the lone-pair electrons gain *s* character. When the angle of twist is 90° the nitrogen valences are pyramidal. Appreciable deviation from planarity is required before the interaction with the ring is reduced significantly since the overlap follows a $\cos^2\theta$ law.

The behavior found in the shifts closely parallels that of the electronic spectra (19, pp. 410–413; 20). The parent aniline has only a small alteration of its electronic spectrum due to ortho substituents, the spectrum of N-methylaniline is slightly affected, while the spectrum of N,N-dimethylaniline is strongly affected by ortho-methyl groups. The angle of twist inferred from the data is 50° for 2-methyl-N,N-dimethylaniline and 68° for 2,6-dimethyl-N,N-dimethylaniline if the intensities of the *C*-band are used, assuming planarity for the unsubstituted compound. Subtraction of the substituent parameters for the methyl groups from the observed shifts for the two compounds (compound 22 in Table I and reference 5) leaves 0.5 p.p.m. as the decrease in the para shift in both cases due to steric hindrance. On a $\cos^2\theta$ basis this would mean an angle of twist of $\cos^2\theta = 0.2/0.7 =$ (observed shift/expected shift in the absence of hindrance). This gives $\theta = 57°$ in both cases.* It is doubtful whether this number is to be taken seriously but investigation of a series of likely compounds is perhaps indicated.

**We have assumed that the para shift caused by the amino group is entirely mesomeric, an assumption which receives support from other work (4).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In N-phenylaniline (compound 28 in Table I) the lone pair now overlaps with two rings and, naively, one might expect a twofold decrease in shielding, as is roughly true. The addition of a methyl group to the nitrogen (compound 29) causes crowding and, we conclude from the shift, decreases overlap almost to zero or to an sp^3 configuration at the nitrogen.

NOTE ADDED IN PROOF

A further calculation of the effect of the ammonio group on chemical shift has yielded results more consistent with experimental measurements. It was assumed that the charge on the group (4.8×10^{-10} e.s.u.) was distributed equally on the three protons. The field due to this charge was calculated for two possible positions of the ammonio group: (*a*) with one proton in the plane of the ring, adjacent to the ortho and meta protons under consideration; (*b*) with one proton in the plane of the ring opposite to the ortho and meta protons. The two positions have an equivalent effect on the para proton. The net result of this calculation is the consideration of the effect of a charge averaged over six possible positions. This should represent a close approximation to integration over all possible positions.

The components of the field along the bond axes of the different protons were precisely calculated. However, the complete calculation of the resultant of the total field acting at the proton was only carried out for the ortho protons since it is complex and tedious. The total field acting at the meta and para positions was approximated by assuming that the total charge was concentrated at the center of the circle circumscribed by the ammonio protons. Since the meta and para protons are relatively far removed from the ammonio group, this assumption should introduce only a very slight error.

The results of the calculation are given in Table IV. If Buckingham's equation (7) is

TABLE IV

Calculation of the field effect due to the ammonio group

Position	$10^{-5}E_z$ (e.s.u.)	$10^{-11}E^2$ (e.s.u.^{2})	$-2\times10^{-12}E_z-10^{-18}E^2$ (p.p.m.)	$-2\times10^{-12}E_z-0.25\times10^{-18}E^2$ (p.p.m.)
Ortho	1.15	2.77	−0.51	−0.30
Meta	1.44	0.35	−0.32	−0.30
Para	1.39	0.20	−0.29	−0.28

used in unmodified form, agreement with experiment is better than for the calculation outlined in the previous text, but still not particularly good. It is interesting to note that the estimated effect of E_z is now least at the ortho position. This suggests that if the coefficient of E^2 in Buckingham's equation is too high, then a lower value of the coefficient may give much better agreement. As seen in column 5 of Table IV, predicted shifts agree, within experimental error, with those determined experimentally if one assumes a value of 0.25×10^{-18} for the coefficient of the E^2 term.

ACKNOWLEDGMENTS

ABSTRACT

The chlorite holocellulose of mesta fiber (*Hibiscus cannabinus*) was extracted with alkaline solutions of successively increasing concentration and finally with alkaline borate solution. Hemicellulose fractions (I–IV) were thus obtained. Analytical data are recorded for each fraction.

Partial acid hydrolysis of the mesta hemicellulose gave 2-O-(4-O-methyl-α-D-glucopyranosyl uronic acid)-D-xylopyranose. Methanolysis and hydrolysis of the fully methylated hemicellulose (fraction II) gave a mixture of 3-O-methyl-D-xylose, 2,3-di-O-methyl-D-xylose, 2,3,4-tri-O-methyl-D-xylose, and 2-O-(2,3,4-tri-O-methyl-α-D-glucopyranosyl uronic acid)-3-O-methyl-D-xylopyranose in the approximate molar ratio of 1.6:34:1:6.4. The number-average molecular weight of the methylated polysaccharide was 18,400±500 (degree of polymerization, 110±3). The number-average molecular weight of the original hemicellulose (fraction II) was found to be 23,000±500 (degree of polymerization, 164±3). On the basis of this and other evidences it is suggested that the polysaccharide is composed of chains of 144 (1 → 4)-linked β-D-xylopyranose residues having approximately every seventh residue carrying a terminal 4-O-methyl-α-D-glucuronic acid residue linked through position 2. A small degree of branching in the backbone of D-xylose is indicated.

Mesta is a bast fiber which grows extensively in India and also in some parts of Eastern Asia. It is used as a substitute for jute.

In the present investigation an attempt has been made to fractionate the total carbohydrate constituents of mesta fiber. The chemical constitution of the main hemicellulose fraction has been studied in some detail.

Defatted mesta fiber was delignified by treatment with dilute sodium chlorite solution (1). The resulting holocellulose was extracted successively with 2% sodium carbonate solution, 4% sodium hydroxide solution, 10% sodium hydroxide solution, and finally with 16% sodium hydroxide solution containing 4% boric acid (2). This led to the isolation of four hemicellulose fractions (I–IV). Fraction II was purified further with Fehling's solution (3) to give fraction IIA.

Partial acid hydrolysis of mesta hemicellulose gave xylose and a main acidic component, identified as 2-O-(4-O-methyl-α-D-glucopyranosyluronic acid)-D-xylopyranose.

The hemicellulose (fraction II) was converted into its fully methylated derivative, which on hydrolysis gave 2,3,4-tri-O-methyl-D-xylose, 2,3-di-O-methyl-D-xylose, 3-O-methyl-D-xylose, and partially methylated aldobiouronic acid in the approximate molar ratio of 1.0:34.0:1.6:6.4. The methyl ester methyl glycoside of the partially methylated aldobiouronic acid was reduced with lithium aluminum hydride (4). Hydrolysis of the reduced product yielded 2,3,4-tri-O-methyl-D-glucose, identified as its aniline derivative, and 3-O-methyl-D-xylose, characterized by ionophoresis and also as its aniline derivative.

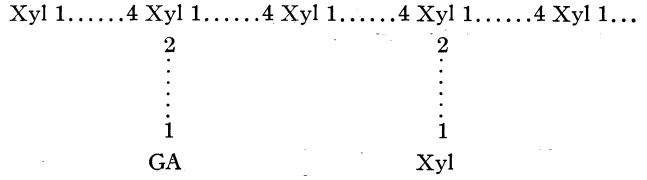
DISCUSSION

The large quantity of 2,3-di-O-methyl-D-xylose obtained, in conjunction with the negative rotations of the original and methylated hemicellulose indicated that the xylose residues in the backbone of the hemicellulose molecule were linked together by β-(1 → 4)-glycosidic bonds. The fact that the partly methylated aldobiouronic acid was unsubstituted

at C_4 of the xylose moiety together with the absence of any 3,4-di-O-methyl-D-xylose in the neutral portion of the hydrolyzate of the methylated hemicellulose showed that the xylose residues were attached directly to the (1 → 4)-linked xylan framework. The constitution of the aldobiouronic acid showed that the side chains were composed of (1 → 2)-linked 4-O-methyl-α-D-glucuronic acid residues. The data from methylation study of the mesta hemicellulose showed the presence of approximately seven xylose residues for each 4-O-methyl glucuronic acid residue. This has been corroborated by the equivalent weight and uronic anhydride content of the fraction IIA hemicellulose.

The number-average molecular weight of the methylated polysaccharide, as determined by osmometry, was found to be 18,400±500 (D.P., 110±3). Since methylation indicated the presence of two non-reducing xylose end groups for a molecule of this size, there was on the average one branch in the main chain of xylose residues. For the original polysaccharide there would be two such branch points. The amount of formic acid liberated by periodate oxidation of the polysaccharide suggested a few branches in the molecule. The presence of mainly 3-O-methyl xylose in the hydrolysis product of the methylated polysaccharide indicated that the branch points involve (1 → 2)-linkages. The slightly higher proportion of 3-O-methyl xylose probably arises from partial hydrolysis of the partially methylated aldobiouronic acid or incomplete methylation of hemicellulose or demethylation during hydrolysis.

On the basis of these results the annexed partial structure for the hemicellulose from mesta fiber indicates the main features of the molecule.



Xyl = D-xylopyranose, GA = 4-O-methyl-α-D-glucuronic acid

Consumption of 6.6 moles of periodate per 7 sugar residues of the polymer is in fair agreement with the above simplified structure.

The structure of the main fraction of the mesta hemicellulose thus appears to be identical with that of jute (5) or roselle hemicelluloses (6); it is also similar to that of flax hemicellulose (7).

EXPERIMENTAL

All specific rotations are equilibrium values unless otherwise stated. Evaporations were carried out under diminished pressure at 40–45° C (bath temperature).

Paper chromatograms were run by the descending method using the following solvent systems (v/v): (A) butan-1-ol – ethanol – water (40:11:19); (B) butan-1-ol – pyridine – water (10:3:3); (C) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (D) ethyl acetate – acetic acid – water (9:2:2); (E) butan-2-one, two-thirds saturated with water containing 1% of ammonia; and (F) benzene–ethanol–water (169:47:15; upper layer). A saturated solution of aniline oxalate (8) in water was used as the spray reagent. Paper ionophoresis was in borate buffer at pH 10.

Composition of the Fiber

The composition of the mesta fiber, analyzed by standard methods (9), was: alpha-cellulose 60.04, xylan 14.82, lignin (after Schwalbe) 10.11, uronic anhydride 3.87, acetyl 4.82, nitrogen 0.19, fat and wax 0.62, ash 0.69, residues of galactose 0.65, glucose 64.31, mannose 0.70, arabinose 1.24, xylose 12.35, and rhamnose 0.79%.

Isolation and Purification of the Hemicellulose Fractions

The mesta fiber was cut into small pieces and exhaustively extracted with an azeotropic mixture of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

ethanol–benzene (1:2; w/w). The defatted fiber was delignified by the sodium chlorite method (1) to give holocellulose (yield 90.38; lignin (Schwalbe's) 3.65 and acetyl 4.13%).

Holocellulose (437.6 g) was extracted successively with 10 parts of 2% sodium carbonate solution, 4% sodium hydroxide solution, 10% sodium hydroxide solution, and finally with 16% sodium hydroxide solution containing 4% boric acid for 48, 2, 2, and 72 hours respectively. Hemicellulose fractions (I–IV) were isolated from the extracts as described in the case of jute hemicellulose (10). Hemicellulose fraction I was light brown in color due to the presence of lignin, which was removed by treatment with sodium chlorite in hot methanol (11). Hemicellulose fraction II (5 g) was purified by three precipitations with Fehling's solution according to the method of Chanda *et al.* (3) to give hemicellulose fraction IIA (3.95 g). The analytical data on the hemicellulose fractions are given in Table I. Samples of hemicellulose fractions, alpha-cellulose (prepared

Isolation and Identification of Aldobiouronic Acid

Aldobiouronic acid was isolated by partial acid hydrolysis of the hemicellulose (mixtures of fraction II and III. 50 g) as described for jute hemicellulose (5). Chromatography of the product in solvent C showed the presence of a main component with R_{xyl} 0.85. A portion of the acidic syrup (5.43 g) was separated on a cellulose column (72×4.5 cm) (14) using solvent D into a main portion of aldobiouronic acid and a trace of xylose, which was removed by chromatographic separation on filter sheets with solvent B. The pure aldobiouronic acid was extracted from the appropriate strips with water, treated with Amberlite IR-120 (H), concentrated, and dried to a powder (1.52 g). It had $[\alpha]_D^{32}$ +96.56° (*c*, 1.07 in water). Anal. Calc. for $C_{12}H_{20}O_{11}$: equiv. wt., 340; OMe, 9.1%. Found: equiv. wt., 337.5; OMe, 9.25%. The acetate derivative (15) had m.p. 201° C, $[\alpha]_D^{25}$ +99.6° (*c*, 0.6 in chloroform). Anal. Calc. for $C_{22}H_{32}O_{15}$: OMe, 17.3%. Found: OMe, 17.02%. A portion of the aldobiouronic acid (480 mg) was converted to the methyl ester methyl glycoside, which on reduction with lithium aluminum hydride in dry tetrahydrofuran (4) followed by hydrolysis and chromatographic separation on filter sheets yielded D-xylose having m.p. and mixed m.p. 144° C, $[\alpha]_D^{30}$ +18° (*c*, 1.5 in water), and 4-O-methyl-D-glucose having $[\alpha]_D^{27}$ +60.5° (*c*, 1.1 in water). The xylose dibenzylidine dimethyl acetal derivative (16) had m.p. and mixed m.p. 210° C and $[\alpha]_D^{27}$ −11.7° (*c*, 1.5 in chloroform). The derived 4-O-methyl-D-glucosazone had m.p. and mixed m.p. 159–160° C. Anal. Calc. for $C_{19}H_{24}O_4N_4$: OMe, 8.3%; N, 15.0%. Found: OMe, 8.6%; N, 15.4%.

Another portion of the aldobiouronic acid (762 mg) was converted to the fully methylated disaccharide (497 mg) by the usual method. Hydrolysis of the fully methylated disaccharide (432 mg) yielded a syrup which was separated by paper chromatography using solvent A into fractions *a* and *b*. Fraction *a* (156 mg) was 2,3,4,6-tetra-O-methyl-D-glucose having m.p. and mixed m.p. 86–88° C, $[\alpha]_D^{32}$ +83.6° (*c*, 1.6 in water).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Anal. Calc. for $C_{10}H_{20}O_6$: OMe, 52.5%. Found: OMe, 52.1%. The anilide of 2,3,4,6-tetra-O-methyl-D-glucose had m.p. and mixed m.p. 126–127° C, $[\alpha]_D^{27}$ +210° (*c*, 0.5 in acetone). Anal. Calc. for $C_{16}H_{25}O_5N$: OMe, 39.87%; N, 4.5%. Found: OMe, 39.4%; N, 4.1%. Fraction *b* (81.8 mg) was obtained as a syrup. Chromatography with solvent F and ionophoresis showed only 3,4-di-O-methyl-D-xylose, $[\alpha]_D^{32}$ +23.22° (*c*, 0.81 in water). Anal. Calc. for $C_7H_{14}O_5$: OMe, 34.8%. Found: OMe, 34.5%. The derived anilide had m.p. and mixed m.p. 113–114° C.

Methylation of the Hemicellulose

Hemicellulose (fraction II, 19.2 g) was methylated by successive addition of dimethyl sulphate and sodium hydroxide and finally with methyl iodide and silver oxide to yield a fully methylated derivative (19.8 g), $[\alpha]_D^{30}$ −42.4° (*c*, 1.1 in chloroform) (found: OMe, 39.1%). The infrared spectrum of the product indicated complete substitution. The methylated hemicellulose (10.8 g) was fractionated by treatment with a mixture of boiling chloroform – light petroleum ether (b.p. 60–65° C) to yield a main fraction (10.1 g) soluble in chloroform – petroleum ether (3:7). It had $[\alpha]_D^{31}$ −40.9° (*c*, 0.95 in chloroform) (found: OMe, 38.91%).

Hydrolysis of the Methylated Hemicellulose and Separation of Methylated Sugars

The methylated hemicellulose (5.19 g) was hydrolyzed with methanolic hydrochloric acid and then with aqueous hydrochloric acid in the usual way. Evaporation after neutralization with silver carbonate yielded a syrup (5.41 g) which was treated (in aqueous solution) with barium carbonate. The mixture of methylated sugars was fractionated on a column (90×4.5 cm) of powdered cellulose with solvent E to give three fractions, and elution of the column with water afterwards yielded a fourth fraction which was treated with Amberlite resin IR-120 (H) to remove barium ion.

Fraction I.—Chromatography of the sugar (111.9 mg) in solvent A showed that it corresponded to an authentic sample of 2,3,4-tri-O-methyl-D-xylose. The syrup crystallized partially on standing. Recrystallization from diethyl ether containing a small amount of petroleum ether yielded crystals of 2,3,4-tri-O-methyl-D-xylose having m.p. and mixed m.p. 89–90° C, $[\alpha]_D^{30}$ +19.8° (*c*, 0.54 in water). Anal. Calc. for $C_8H_{16}O_5$: OMe, 48.4%. Found: OMe, 48.1%.

Fraction II.—The syrup (3.528 g) crystallized when seeded with 2,3-di-O-methyl-D-xylose. Recrystallization from diethyl ether yielded crystals having m.p. and mixed m.p. 91–92° C, $[\alpha]_D^{24}$ −12.86° (6 minutes) → +23.6° (53 minutes constant) (*c*, 1.86 in water). Anal. Calc. for $C_7H_{14}O_5$: OMe, 34.8%. Found: OMe, 34.3%. The crystalline aniline derivative, recrystallized twice from ethyl acetate, had m.p. and mixed m.p. 123–124° C, $[\alpha]_D^{24}$ +181.6° (*c*, 0.4 in ethyl acetate). Anal. Calc. for $C_{13}H_{19}O_4N$: OMe, 24.5%; N, 5.5%. Found: OMe, 24.3%; N, 5.7%.

Fraction III.—The syrup (153 mg), $[\alpha]_D^{24}$ +16.1° (*c*, 0.9 in water), could not be crystallized. Paper ionophoresis of the syrup showed the presence of 3-O-methyl-D-xylose together with a trace of 2-O-methyl-D-xylose. Anal. Calc. for $C_6H_{12}O_5$: OMe, 18.9%. Found: OMe, 18.4%.

Fraction IV.—The syrup (1.425 g) was found to be a partially methylated aldobiouronic acid. Reduction and hydrolysis of the methyl ester methyl glycoside followed by chromatography on filter sheets with solvent A gave two fractions, *a* and *b*. Fraction *a*, obtained as a syrup (128.8 mg), was identified as 3-O-methyl-D-xylose by paper electrophoresis. It had $[\alpha]_D^{31}$ +16.3° (*c*, 1.28 in water). Anal. Calc. for $C_6H_{12}O_5$: OMe, 18.9%. Found: OMe, 18.5%. The aniline derivative had m.p. 135° C, $[\alpha]_D^{30}$ +81.28° (*c*, 0.54 in ethyl acetate). Anal. Calc. for $C_{12}H_{17}O_4N$: OMe, 12.97%; N, 5.86%. Found: OMe, 12.5%; N, 5.57%. Fraction *b* (143 mg), identified as 2,3,4-tri-O-methyl-D-glucose, had $[\alpha]_D^{32}$ +67.8° (*c*, 1.43 in water). Anal. Calc. for $C_9H_{18}O_6$: OMe, 41.9%. Found: OMe, 41.6%. The aniline derivative had m.p. and mixed m.p. 144–145° C. Anal. Calc. for $C_{15}H_{23}O_5N$: OMe, 31.3%. Found: OMe, 31.7%.

Quantitative Estimation of O-Methyl Xyloses

The mixture of neutral O-methyl xyloses from the hydrolysis product of methylated hemicellulose was separated by filter paper chromatography using solvent A. The appropriate strips were eluted with water and component sugars were estimated by alkaline hypoiodite method (3) using sodium hydroxide – phosphate buffer (pH 11.4). The molar ratio between mono-, di-, and tri-O-methyl-D-xyloses from duplicate experiments was 1.5:33.8:1.

Periodate Oxidation of the Hemicelluloses

Hemicellulose fractions II and III (0.99 g) in water (59.9 ml) were oxidized by 0.3 *M* sodium metaperiodate solution (29.3 ml) in the dark at 10–15° C. Analyses for periodate consumption according to the arsenite method of Fleury and Lange (17) were made at 24-hour intervals. The oxidation was essentially complete after 289 hours with the consumption of 0.81 mole of periodate per mole of anhydropentose unit in both the cases.

The sodium salts of hemicellulose fractions II and III (0.89 g), in water (60 ml) containing potassium chloride (5 g), were oxidized with 0.3 *M* sodium metaperiodate (30 ml) in the dark at 10–12° C. The formic acid released was estimated by the procedure of Halsall, Hirst, and Jones (18), which showed that 1 mole of formic acid was produced from 3800 g of the hemicellulose in both the cases.

Determination of the Molecular Weights

The number-average molecular weight of hemicellulose fraction II was determined by measuring the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

osmotic pressure of a solution of its sodium salt in 0.4 *M* sodium chloride. The measurements were made by the static method at 35±0.02° with the Hellfritz osmometer (19). The membrane was du Pont's Gel cellophane 600 P.T. The molecular weight of the methylated hemicellulose was determined in butyl acetate solution using "Ultrazellafilteraller feinst" membrane supplied by Membranfiltergesellschaft, Göttingen. The osmotic height was measured for different concentrations of the polysaccharide and the values $\Delta h/C$, the reduced osmotic pressure, were linearly extrapolated to zero concentrations. The results are summarized in Table III.

TABLE III

Osmometry data

DIBENZOYLSILANES AND SUBSTITUTED BENZOYLSILANES

A. G. Brook and G. J. D. Peddle[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received April 23, 1963

ABSTRACT

A number of silicon-substituted benzoylsilanes have been prepared. These all showed identical carbonyl infrared stretching wavelengths, and were all yellow, having essentially identical ultraviolet absorption spectra. Hence it is concluded that the spectral properties of benzoylsilanes are insensitive to the nature of the groups attached to silicon, even when these could provide d_π–p_π bonding.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

It has previously been reported that benzoylsilanes (α-silylketones) have anomalous infrared and ultraviolet spectra, compared with their carbon analogues. Not only is the carbonyl-stretching vibration at considerably longer wavelength (6.18 μ, 1618 cm^{-1}) than in usual carbonyl compounds, but the long wavelength (carbonyl) ultraviolet absorption band falls in the visible region at about 403–417 mμ, so that all benzoylsilanes are yellow, regardless of whether phenyl or methyl groups are attached to silicon.

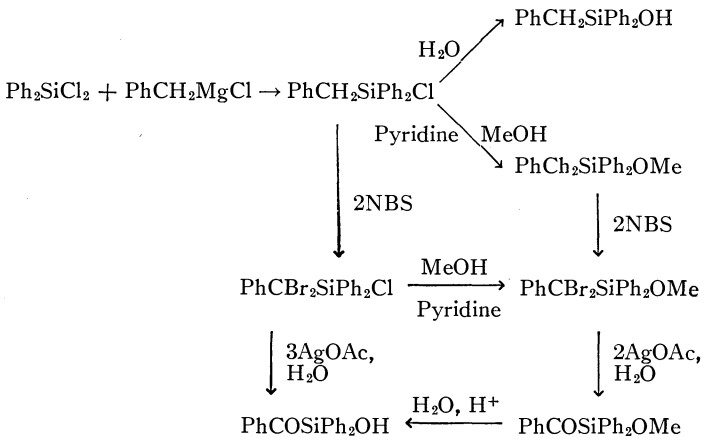
It seems reasonable to assume that the available *d* orbitals of silicon play some role in these spectral phenomena. West (2) has observed that d_π–p_π bonding can occur between silicon and adjacent atoms possessing unshared electrons such as halogen and oxygen, and that as the number of groups available for such bonding increases, the strength of the d_π–p_π bonds decreases. If d_π–p_π bonding with the carbonyl group is associated with the spectral behavior of the acylsilanes, then if alternative and perhaps stronger d_π–p_π bonding with some other group becomes possible, it might be anticipated that the spectral behavior of the ketone would revert toward that of a normal ketone. In order to see if this concept was valid attempts have been made to synthesize a number of substituted benzoylsilanes. These were of three main types: (*a*) hydroxy- and methoxy-benzoylsilanes, I; (*b*) halogenobenzylbenzoylsilanes, II; (*c*) dibenzoylsilanes, III.

$PhCOSiPh_2(OR)$	$PhCOSiPh_2CXYPh$	$PhCOSiR_2COPh$
I	II	III
(*a*) R = H	(*a*) X = H, Y = Cl	(*a*) R = Ph
(*b*) R = Me	(*b*) X = H, Y = Br	(*b*) R = Me
	(*c*) X = Cl, Y = Br	
	(*d*) X = Y = Br	

The synthesis of these compounds followed, in general, previously reported routes (1, 3). However, acylsilanes, with the possible exception of benzoyltriphenylsilane, are not particularly stable, hydrolyzing rapidly on exposure to air, benzaldehyde being formed. Most of the benzoylsilanes reported herein were exceptionally unstable.

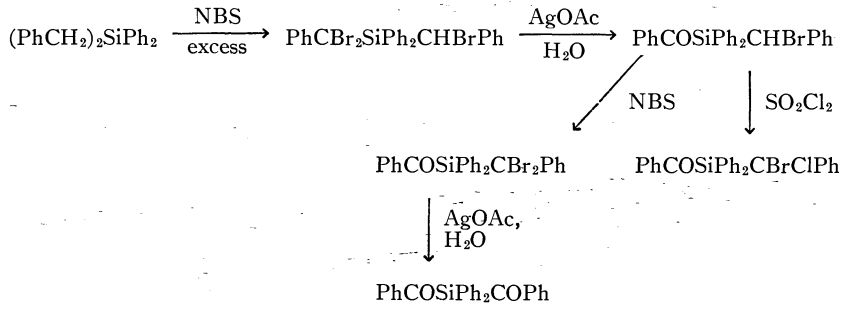
The hydroxy- and methoxy-benzoylsilanes were synthesized as indicated by the following sequence of reactions:

[1]*Woodrow Wilson Fellow*, 1959–1960.



All of these reactions occurred readily and in good yield with the exception of the hydrolysis of dibromobenzyldiphenylmethoxysilane. Under all conditions used the methoxy group also hydrolyzed readily, giving the hydroxysilane or a mixture of the hydroxy- and methoxy-silanes, which were separated only with difficulty.

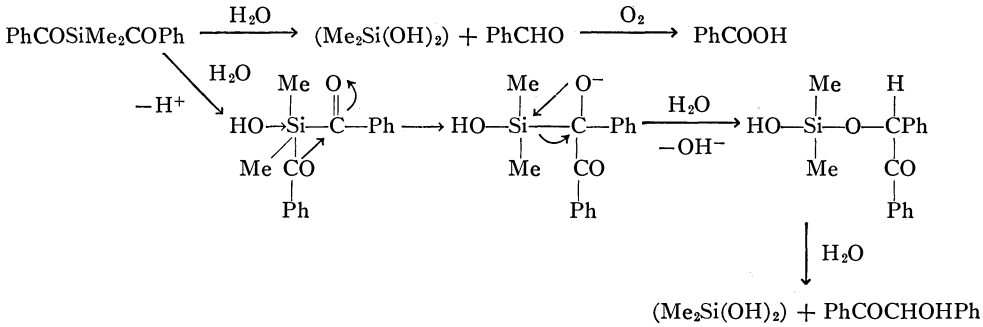
The synthesis of the dibenzoylsilanes caused particular difficulty, largely due to their instability. They and the various halobenzylbenzoylsilanes were prepared by the following routes:



Dibenzyldiphenylsilane resisted tetrabromination with N-bromosuccinimide even in refluxing tetrachlorethylene, probably because of steric hindrance, and only a tribromo derivative could be isolated. Hence hydrolysis of the tribromide to a bromoketone, followed by further halogenation, toward which the ketone was not very stable, had to be employed. Hydrolysis of this dibromoketone gave very low yields of an extremely unstable compound, which appeared to be dibenzoyldiphenylsilane (see below).

Attempts to prepare the related dibenzoyldimethylsilane were made by an analogous route, except that tetrabromination with N-bromosuccinimide was successful. Hydrolysis with silver acetate – water gave a yellow oil which, however, decomposed to colorless products during attempted distillation, or during chromatography on silica gel or silicic acid columns. The major decomposition products isolated were benzaldehyde and/or benzoic acid, formed by hydrolysis and oxidation, and benzoin. The formation of this latter product may be explained as arising from rearrangement of the dibenzoyl compound, by a route analogous to that found for monobenzoylsilanes (4, 5), as illustrated below:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



The ultraviolet spectra and carbonyl-stretching region of the infrared spectra for the new benzoylsilanes are reported in Table I together with the data for benzoylmethyldiphenylsilane (1) as reference compound. It is evident that in these compounds the carbonyl-stretching vibration is insensitive to the substituents attached to silicon, as was

NOTE: (s) = shoulder.
[a]Unresolved shoulder at about 405 mμ.
[b]Extinction coefficient not determined since compound contaminated with small amount of benzoyldiphenylsilanol, as shown by infrared spectrum.

observed previously (1). The ultraviolet spectra also conform closely to those found earlier for methyl- or phenyl-benzoylsilanes, with no significant change occurring in position for either the π–π^* or for the long wavelength (carbonyl) band. These results indicate that if d_π–p_π bonding is occurring between silicon and the adjacent oxygen or halogen atoms in these molecules, it has little effect on the silicon–carbonyl interaction which causes the anomalous spectral behavior.

The spectra of dibenzoyldiphenylsilane are worthy of comment. Since the compound was too unstable to be analyzed it is necessary to establish that impurities are not responsible for any of the prominent absorption bands. The most probable impurities, based on our experience, are benzaldehyde, benzoic acid, benzoin, and silanols. That these were not present in significant concentrations is evident from the absence of absorption bands at 2.8–3.0 μ (OH) or in the 3.7 μ (CHO) region.

The intensity of the π–π^* band of the compound (ϵ 24,100) relative to benzoyldiphenylmethylsilane (ϵ 13,900) indicates the presence of two benzoyl groups, although the long wavelength (carbonyl) band has an extinction coefficient little greater than that of the monobenzoylsilane. At the same time, the infrared shows two strong carbonyl bands at 5.97 and 6.18 μ. These may be due to two non-equivalent carbonyl groups, due to differences in the interaction with silicon or to conformational effects (6). Alternatively the two

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

carbonyl bands may be due to equivalent carbonyl groups undergoing vibrational coupling with each other to produce two bands, as has been observed with other dicarbonyl compounds (7). It does not seem possible at this time to decide whether both carbonyl groups of dibenzoyldiphenylsilane interact identically with the silicon atom, or whether one is a typical α-silyl ketone and the other acts as a "normal" ketone type of carbonyl group.

EXPERIMENTAL

All reactions involving organometallics were carried out under a dry oxygen-free nitrogen atmosphere. Infrared spectra were taken in CCl_4 on a Beckman IR5 instrument calibrated against polystyrene; ultraviolet spectra were taken in ethanol.

A. Benzyldiphenylchlorosilane and its Derivatives

Benzyldiphenylchlorosilane

To 104 g (0.41 mole) of diphenyldichlorosilane in 250 ml of ether was added dropwise 0.41 mole of 1.65 *N* benzylmagnesium chloride. After the mixture had been stirred overnight a negative Gilman color test I (8) was obtained. To the suspension was added 1 l. of petroleum ether (b.p. 60–70°) and the mixture was filtered. After removal of the solvents the material was distilled at 190–194° at 0.6 mm to give 85 g (67%) of benzyldiphenylchlorosilane, n_D^{25} 1.6078 Anal. Calc. for $C_{19}H_{17}SiCl$: Si, 9.07. Found: Si, 9.12.

α,α-Dibromobenzyldiphenylchlorosilane

To 20.0 g (0.65 mole) of benzyldiphenylchlorosilane in 150 ml of carbon tetrachloride was added 25.0 g (0.14 mole) of N-bromosuccinimide and a few small lumps of benzoyl peroxide. The mixture was refluxed for 16 hours, cooled, and the succinimide filtered off. Evaporation of the filtrate to dryness gave a yellow oil which was crystallized twice from hexane to give 15.75 g (52%) of α,α-dibromobenzyldiphenylchlorosilane, m.p. 79–81°. Anal. Calc. for $C_{19}H_{15}SiClBr_2$: C, 48.8; H, 3.22. Found: C, 48.8; H, 3.29.

Benzoyldiphenylsilanol

To 5.0 g (0.0107 mole) of dibromobenzyldiphenylchlorosilane in 50 ml acetone and 7 ml of water was added at 0° (ice-water bath) 7.1 g (0.032 mole) of silver trifluoroacetate in 110 ml of benzene. A pale yellow color and grey precipitate formed immediately. The ice bath was removed once addition was complete and the mixture was stirred for 2 hours. The silver bromide was filtered off, about 1 l. of water was added, and the mixture was extracted with benzene. The benzene layers were back-extracted with water, dilute sodium bicarbonate, and then water. After the benzene layer was dried over sodium sulphate the solvents were removed under reduced pressure to yield a yellow oil, which was recrystallized from hexane–cyclohexane to give 2.13 g (65%) of bright yellow benzoyldiphenylsilanol, m.p. 97–99°. Anal. Calc. for $C_{19}H_{16}SiO_2$: C, 75.0; H, 5.28. Found: C, 74.5; H, 5.22. The solid became a sticky mass in a few days with a strong odor of benzaldehyde.

Benzyldiphenylmethoxysilane

To 15 g (0.048 mole) of benzyldiphenylchlorosilane in 80 ml of methanol was added 5 ml of pyridine. The reaction mixture became hot. After 15 minutes the reaction mixture was drowned in water and extracted with benzene. The dried benzene layer on distillation gave 10 g (70%) of benzyldiphenylmethoxysilane, b.p. 159–161° at 0.28 mm, n_D^{25} 1.5932.

Benzyldiphenylsilanol

To 1 l. of ice and water containing 5 ml of conc. ammonium hydroxide was added slowly with vigorous stirring 10 g (0.032 mole) of benzyldiphenylchlorosilane in 100 ml of ether. After 0.5 hour the ether layer was removed, dried over sodium sulphate, and the solvent removed under reduced pressure to give 9.4 g of a white solid, m.p. 46–49°. Recrystallization from petroleum ether (b.p. 60–70°) gave 7.2 g (77%) of benzyldiphenylsilanol, m.p. 51.5–53°. Anal. Calc. for $C_{19}H_{18}SiO$: C, 78.5; H, 6.23. Found: C, 78.4; H, 6.22.

α,α-Dibromobenzyldiphenylmethoxysilane

(a) From dibromobenzyldiphenylchlorosilane.—To 5.0 g (0.011 mole) of the dibromobenzyl compound in 15 ml of methanol and 25 ml of benzene was added 0.9 ml (0.012 mole) of pyridine. After 18 hours the reaction was drowned in water and ether-extracted. The combined organic layers were dried with sodium sulphate, and removal of the solvents under reduced pressure gave 4.02 g (81%) of α,α-dibromobenzyldiphenylmethoxysilane, m.p. 79–82°, which on recrystallization from hexane had m.p. 80–82°. Anal. Calc. for $C_{20}H_{18}SiOBr_2$: C, 52.0; H, 3.91. Found: C, 52.7; H, 3.91.

(b) From Benzyldiphenylmethoxysilane.—A solution of 3.0 g (0.01 mole) of benzyldiphenylmethoxysilane in 50 ml of carbon tetrachloride was refluxed 5.5 hours with 3.56 g (0.02 mole) of N-bromosuccinimide and a few small lumps of benzoyl peroxide. On cooling and filtering of the succinimide, the filtrate was evaporated to dryness to yield a viscous oil. Crystallization from hexane gave 3.48 g (72%) of α,α-dibromobenzyldiphenylmethoxysilane, m.p. 79–81°, identified by mixed melting point with the material described above. Their infrared spectra were identical.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Attempted Preparation of Benzoyldiphenylmethoxysilane

To 4.62 g (0.01 mole) of α,α-dibromobenzyldiphenylmethoxysilane in 100 ml of acetone and 50 ml of benzene was added 3.4 g (0.02 mole) of silver acetate and 5 ml of water. The mixture was stirred overnight in the dark. The yellow solution was filtered from the silver bromide, drowned in water, and extracted into ether. Removal of the ether gave an oily yellow solid whose infrared spectrum showed the presence of strong Si—OMe absorption at 9.2 μ and only very weak OH absorption in the 2.7–2.8 μ region. The carbonyl absorption occurred at 6.19 μ. Attempts to purify the material by crystallization from hexane or by chromatography on alumina failed, and the odor of benzaldehyde soon became apparent. Subsequent repetitions of this experiment, with changes in solvent or of time of hydrolysis, failed to yield pure benzoyldiphenylmethoxysilane. When the silver acetate was replaced by silver trifluoroacetate, the major product was benzoyldiphenylsilanol, m.p. 97–99°, identified by mixed melting point.

B. Dibenzyldiphenylsilane and its Derivatives.

The polyhalogenated derivatives of this compound, most of which served as precursors for the preparations of ketones through hydrolysis with silver acetate, were prepared by conventional methods such as are described in Section A. Hence only a few typical preparations will be described in detail—the properties of the various additional compounds are summarized in Table II.

α,α,α'-Tribromodibenzyldiphenylsilane

Dibenzyldiphenylsilane was prepared from diphenyldichlorosilane and benzylmagnesium chloride in 61% yield, m.p. 60.5–61°, reported (9) 61°. A mixture of 36.4 g (0.1 mole) of dibenzyldiphenylsilane and 80 g (0.45 mole) of N-bromosuccinimide in 300 ml of carbon tetrachloride was refluxed for 44 hours with occasional small additions of benzoyl peroxide. After cooling and removal of 51.8 g (91%) of succinimide, the filtrate was concentrated under vacuum. Addition of petroleum ether gave 47 g (79%) of α,α,α'-tribromobenzyldiphenylsilane, m.p. 129–130°, which after several recrystallizations melted at 145–149°.

Attempts to further brominate the tribromide with N-bromosuccinimide in carbon tetrachloride, in tetrachloroethylene, or in a mixture of these solvents, over various time intervals, gave mainly recovered tribromide, and no tetrabromide could be isolated.

Benzoyl-α-bromobenzyldiphenylsilane

A mixture of 15 g (0.025 mole) of α,α,α'-tribromodibenzyldiphenylsilane and 14.9 g (0.089 mole) of silver acetate in 150 ml of ethanol, 120 ml of acetone, and 60 ml of water was stirred in the dark for 41 hours. The silver bromide was filtered off, water was added to the filtrate, and the material was extracted with ether several times. The ether layers, after being dried over sodium sulphate, were concentrated under reduced pressure, and the resulting yellow oil was crystallized from ethanol – ethyl acetate to give 5.1 g (64%) of yellow benzoyl-α-bromobenzyldiphenylsilane, m.p. 90–92°. Anal. Calc. for $C_{26}H_{21}SiOBr$: C, 68.4; H, 4.60. Found: 68.4, H, 4.67.

α,α,α'-Tribromo-α'-chlorodibenzyldiphenylsilane

A solution of 6.18 g (0.011 mole) of α,α,α'-tribromodibenzyldiphenylsilane and 1.62 g (0.012 mole) of sulphuryl chloride in 50 ml of chlorobenzene was refluxed for 2.5 hours with a trace of added benzoyl peroxide. Red fumes, presumably bromine, were evolved during the reaction. The solvent was removed under reduced pressure and the resulting oil was crystallized from ethyl acetate – ethanol to give 4.17 g (58%) of α,α,α'-tribromo-α'-chlorodibenzyldiphenylsilane, m.p. 125–140°, which on recrystallization melted at 125–127°. The crystals turned orange-brown on standing. Anal. Calc. for $C_{26}H_{20}SiBr_3Cl$: Si, 4.42. Found: Si, 4.47, 4.59.

α,α-Dibromobenzylbenzoyldiphenylsilane

A solution of 0.68 g (0.0015 mole) of α-bromobenzylbenzoyldiphenylsilane in 10 ml of carbon tetrachloride and 0.23 g (0.0013 mole) of N-bromosuccinimide was refluxed for 1 hour with a trace of benzoyl peroxide. After removal of the succinimide and the solvent the yellow oil was chromatographed on a 6-in. silica gel column, and eluted with benzene. The yellow eluate, after removal of the solvent and crystallization from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ethyl acetate – ethanol – petroleum ether (b.p. 40–60°), gave 0.35 g (44%) of yellow α,α-dibromobenzylbenzoyldiphenylsilane, m.p. 107–109°. After 5 days marked decomposition had occurred, although the product was stored in sealed containers. Similar runs on a larger scale gave yields from 0–45%—in general better yields were obtained from smaller runs. Anal. Calc. for $C_{26}H_{20}SiBr_2O$: C, 58.2; H, 3.76. Found: C, 59.6; H, 3.95.

Dibenzoyldiphenylsilane

A solution of 0.3 g (0.0005 mole) of dibromobenzylbenzoyldiphenylsilane in 3 ml of acetone, 12 ml of ethanol, 5 ml of benzene, and 0.2 ml of water was stirred in the dark for 7 hours with 0.3 g (0.0018 mole) of silver acetate. The silver salts were filtered off and the yellow filtrate was added to ether, washed with water, and dried with sodium sulphate; the ether was then removed under vacuum and the yellow oil was chromatographed on an 8-in. silica gel column, using benzene as eluant. Two yellow bands appeared on the column, the first eluted giving a positive test for halogen. This was isolated and shown to be recovered dibromobenzylbenzoyldiphenylsilane, 0.25 g (83%) after crystallization from petroleum ether (b.p. 60–70°), m.p. 107–109°. The second yellow fraction eluted was an oil which failed to crystallize when treated with a variety of solvents. It gave a negative test for halogen, and identification as dibenzoyldiphenylsilane, 0.02 g (9%), is based on the infrared and ultraviolet spectra (see discussion section). The compound decomposed rapidly on standing, even in a nitrogen atmosphere, liberating the odor of benzaldehyde.

Runs similar to the above, but without the use of acetone during the "hydrolysis", gave after chromatography on silicic acid dibenzoyldiphenylsilane in yields up to 40%.

Dibenzyldimethylsilane

To a solution of 26.4 g (0.20 mole) of dimethyldichlorosilane in 400 ml of toluene was added 0.41 mole of benzylmagnesium chloride in 300 ml of ether. The ether was distilled off and the mixture was refluxed at 100° for 21 hours. After filtration of the magnesium salts the solvents were removed under reduced pressure and the resulting oil was crystallized from ethanol to give 47 g (96%) of dibenzyldimethylsilane, m.p. 56–58°. Anal. Calc. for $C_{16}H_{20}Si$: C, 79.93; H, 8.39. Found: C, 80.21; H, 8.23.

$\alpha,\alpha,\alpha',\alpha'$-Tetrabromodibenzyldimethylsilane

Bromination of 10 g (0.042 mole) of dibenzyldimethylsilane in 150 ml of carbon tetrachloride with 30 g (0.17 mole) of N-bromosuccinimide at reflux with an added trace of benzoyl peroxide over 6 hours gave, after removal of the succinimide and solvents, and crystallization from ethyl acetate, 21.8 g (94%) of $\alpha,\alpha,\alpha',\alpha'$-tetrabromodibenzyldimethylsilane, m.p. 122–125°. Anal. Calc. for $C_{16}H_{16}SiBr_4$: C, 34.54; H, 2.90. Found: C, 34.90; H, 3.16.

Hydrolysis of Tetrabromodibenzyldimethylsilane

A solution of 5.0 g (0.009 mole) of the above tetrabromide in 20 ml ethanol, 30 ml of benzene, and 1 ml of water was treated with 6.01 g (0.036 mole) of silver acetate. An immediate exothermic reaction occurred, a dark precipitate formed, and the solution became yellow. The mixture was stirred for 3 hours in the dark. The silver salts, 6.6 g (98%), were filtered off, ether was added, and the ether layer was washed with water and dried over sodium sulphate; the ether was removed to give 2.8 g of yellow oil.

Attempts to crystallize the oil, which smelt strongly of benzaldehyde, from a variety of solvents failed. Attempted distillation at 0.06 mm failed when the material decomposed, turning black at 125°. If the oil was left in contact with air, it decomposed, turning black and forming solid from which benzoin, m.p. 134–136°, identified by mixed melting point, could be isolated in 25% yield.

Attempts to purify the oil by chromatography on silica gel, silicic acid, or alumina also failed. While two yellow bands were separated on the column, only one yellow band (benzoyldibromobenzyldimethylsilane?), which contained halogen and smelled strongly of benzaldehyde, could be eluted; the second faded to colorless on the column before it could be eluted.

Attempted hydrolysis using silver nitrate instead of silver acetate gave essentially quantitative yields of silver bromide, but only pale yellow oils, together with up to 70% yields of benzoic acid, m.p. 120–121°, could be obtained, indicating that considerable hydrolysis and oxidation had occurred.

STRUCTURAL RELATIONSHIPS OF EXTRACELLULAR POLYSACCHARIDES FROM PHYTOPATHOGENIC XANTHOMONAS SPP.

PART II. X. HYACINTHI, X. TRANSLUCENS, AND X. MACULOFOLIIGARDENIAE[1]

P. A. J. GORIN AND J. F. T. SPENCER
National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received May 6, 1963

ABSTRACT

The extracellular polysaccharide formed from *Xanthomonas hyacinthi* is shown to be a branched polymer containing glucuronic acid, mannose, and glucose. Acid and enzymic hydrolysis show the presence of β-D-Glp 1 → 4 D-Man and the 4-unit sequence β-D-GlpA 1 → 2 D-Manp 1 → 3 β-D-Glp 1 → 4 D-Gl. Examination by the methylation technique showed the presence of a considerable proportion of 2-linked mannopyranose units. The spectrum of methyl glycosides formed from this polysaccharide and those from *Xanthomonas maculofoliigardeniae* and *Xanthomonas translucens* are similar, and in terms of sugar linkages differentiate them from that of *Xanthomonas stewartii*, which contains glucuronic acid, glucose, and galactose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The extracellular polysaccharides from phytopathogenic *Xanthomonas* spp. appear to have several structural features in common. In general they contain glucuronic acid, glucose, and mannose (1–4), and in the species so far examined 4,6-carboxyethylidene groups (5). These properties distinguish the organisms from *Xanthomonas stewartii*, which yields a polysaccharide containing glucuronic acid, glucose, and galactose (3). In this paper the *Xanthomonas hyacinthi* polysaccharide is examined in detail. Two other polysaccharides produced by *Xanthomonas translucens* and *Xanthomonas maculofoliigardeniae* were examined by the methylation technique in order to find whether there are any basic differences in fine structure.

The polysaccharide from *X. hyacinthi* was examined for structural details using chemical and enzymic hydrolysis techniques. The polysaccharide contained 1 acidic function for every 7 sugar units. Hydrolysis with aqueous acid yielded a series of acidic oligosaccharides, the number of units in a sequence being assumed from their paper chromatographic behavior rather than their neutral equivalents, which were too high for accurate measurement. These appeared to be a di-, tri-, and tetra-saccharide and were isolated chromatographically and characterized. The disaccharide was shown to be 2-*O*-β-D-glucuronopyranosyl-D-mannose, identified by its hydrolysis products, lead tetraacetate oxidation characteristics, and by its crystalline hepta-*O*-methyl methyl ester. The trisaccharide, which consisted of glucuronic acid, mannose, and glucose, appeared to be closely related to that isolated from the polysaccharides of *Xanthomonas campestris* (6) and *Xanthomonas oryzae* (4). On treatment with lead tetraacetate, nearly one mole of oxidant was consumed per mole of trisaccharide, which resulted in oxidation of the glucose unit. The product, on hydrolysis, yielded arabinose, or arabitol when the oxidation product was first reduced with sodium borohydride. Since the trisaccharide gave 2-*O*-β-D-glucuronopyranosyl-D-mannose on hydrolysis the mannose unit must be attached to the 3-position of glucose (7) (structure I). Methylation followed by hydrolysis gave a little tetra-*O*-methylhexose and no dimethylhexose, indicating the presence of some hexopyranosyl-2-*O*-β-D-glucuronopyranosyl-D-mannose also. The tetrasaccharide which gave the aldobiouronic acid

[1]*Issued as N.R.C. No. 7482.*

and glucose on acid hydrolysis offered further information on the polysaccharide structure. Under milder acidic conditions it yielded a little material which chromatographed with the aldotriouronic acid. Lead tetraacetate oxidation characteristics indicated a 1,4 reducing end-unit (7), suggesting it had structure II.

Partial degradation of the polysaccharide with acid followed by enzymolysis of the fragments with an enzyme preparation, S157B, containing cellulase, kindly supplied by Dr. E. Reese, gave in low yield cellobiose, characterized as its β-octaacetate and glucose, thus indicating that some glucose units linked 1,4-β are present in the polysaccharide. Information on the source of the liberated cellobiose and glucose was obtained by enzymolysis of the aldotetraouronic acid. This material yielded glucose and the aldobiouronic acid, thus indicating that the enzyme had a wide range of enzymic attack. Evidently it can attack the 1,4-β glucose-to-glucose unit at the reducing end and the 1,3 mannose-to-glucose unit (Fig. 1). Possibly, the absence of cellobiose is due to the presence of a β-glucosidase in the enzyme preparation. Acetolysis of the acetate of *X. hyacinthi* polysaccharide gave material which, after deacetylation and chromatography, was shown to

β-D-GlpA 1 → 2 D-Manp 1 → 3 D-Gl (I)
↓ acid or enzyme S157B
β-D-GlpA 1 → 2 D-Man + Glucose
↑ enzyme S157B
β-D-GlpA 1 → D-Manp 1 → 3 β-D-Glp 1 → 4 D-Gl (II)

FIG. 1.

contain 4-*O*-β-D-glucopyranosyl-D-mannose, characterized by its lead tetraacetate oxidation characteristics and acid hydrolysis products before and after sodium borohydride reduction.

Periodate oxidation of the *X. hyacinthi* polysaccharide followed by sodium borohydride reduction and then acid hydrolysis gave glucose, glycerol, and erythritol. A similar result was also obtained using the *X. maculofoliigardeniae* and *X. translucens* polysaccharides. These results are consistent with the finding that 1,4-linked and 1,3-linked glucose and 1,2-linked mannose units are present in the oligosaccharides formed on partial hydrolysis.

The ratios of glucose to mannose and the specific rotations of the three polysaccharides showed variation and are recorded in Table I. A greater degree of structural difference

TABLE I

Neutral sugar components formed on acid hydrolysis of polysaccharides

Polysaccharide source	Glucose	Mannose	Specific rotation of polysaccharides
X. hyacinthi	1	0.78	−5°
X. translucens	1	0.90	−12°
X. maculofoliigardeniae	1	0.95	−35°

was found when the linkage sites on the majority of the neutral sugars units were determined by methylation, followed by methanolysis of the methylated products. The fragments, thus formed, were compared quantitatively by gas phase chromatography. Although complications were possible due to the presence of carboxyethylidene groups, the gas chromatograms gave a characteristic spectrum of products in which only the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

proportions showed variation. The presence of methyl tetra-*O*-methyl-glycosides showed that the polysaccharides are non-linear. The relative amounts of methyl tetra-*O*-methyl-glucoside and -mannoside showed great variation from one polysaccharide to another. However, whether these differences are due to the presence of 4,6-carboxyethylidene groups is not clear at this stage. Less information could be obtained on the identity of the methyl tri-*O*-methyl glycosidic fragments since in this region many different glycosides co-chromatograph. The presence of methyl 3,4,6-tri-*O*-methyl-D-mannose and methyl 2,3,6-tri-*O*-methyl-D-glucose was assumed by reference to the periodate oxidation results and the partial hydrolytic studies. In the di-*O*-methyl series the presence of methyl 2,6-di-*O*-methyl-D-glucoside was also assumed. The ratios of these glycosides by peak area were not reproducible from one column packing to another. The packing used with the greatest response for methyl tri-*O*-methyl- compared with methyl tetra-*O*-methyl-hexosides was the fully methylated hydroxyethyl cellulose WP-09 of Kircher (8). Comparison in terms of peak areas of the proportions of *O*-methyl glycosidic fragments is made in Table II.

TABLE II

Neutral glycosides formed on methanolysis of methylated polysaccharides in terms of gas chromatographic peak areas

Methyl glycoside	Source of methylated polysaccharide		
	X. hyacinthi	*X. translucens*	*X. maculofoliigardeniae*
2,3,4,6-Tetra-*O*-methyl-D-mannose	3.8	4.6	2.3
2,3,4,6-Tetra-*O*-methyl-D-glucose	2.1	7.9	3.8
3,4,6-Tri-*O*-methyl-D-mannose*	10 (10)	10 (10)	10 (10)

Unknown	1.1	2.8	2.8
2,6-Di-*O*-methyl-D-glucose	3.1	2.7	4.4

*The figures in parentheses are the molar ratios of the methyl glycosides after a calibration correction has been made.

EXPERIMENTAL

Evaporations were carried out under reduced pressure and specific rotations measured at 25° C. The organisms used were *X. hyacinthi* (ATCC 12612), *X. maculofoliigardeniae* (ATCC 10201), and *X. translucens* (ATCC 10722). These were grown on media identical with that used for *Corynebacterium* spp. (9).

Estimation of Hexoses in Xanthomonas Spp. Polysaccharides

The polysaccharides (1.0 g samples) were heated overnight at 100° C in 2 *N* sulphuric acid (20 ml). The solutions were neutralized ($BaCO_3$), filtered, and evaporated to sirups. The neutral components with the exception of traces of rhamnose, which was also present, were estimated colorimetrically with the benzidine reagent after strip separation on paper chromatograms (10). The mannose–glucose ratios are recorded in Table I. In addition the neutral equivalent of *X. hyacinthi* polysaccharide was shown to be 1050.

Partial Acid Hydrolysis of X. hyacinthi Polysaccharide

The polysaccharide (35 g) was heated on a steam bath for 6 hours in *N* sulphuric acid. The solution was neutralized ($BaCO_3$), filtered, and treated with Amberlite IR 120. Acidic material was removed with Dowex-1 (bicarbonate form), which was filtered off. Treatment with 5% aqueous formic acid (2 liters) eluted the uronic acids and evaporation of the solution yielded 11.6 g of solids. The material was fractionated on a cellulose column using ethyl acetate – acetic acid – water (9:4:4 v/v) as solvent. The aldobiouronic acid (1.7 g) was isolated and hydrolyzed overnight with 6 *N* sulphuric acid at 100° C to yield glucuronic acid and mannose. The material was resistant to lead tetraacetate oxidation and was therefore linked 1,2 (7). A portion (0.22 g) was methylated by the dimethyl sulphate – sodium hydroxide method. Extraction of the acidified solution yielded partly methylated material (0.17 g). This was refluxed in methyl iodide (10 ml) and three daily additions of silver oxide (0.50 g) were made. The solution was filtered and evaporated to a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

crust (0.16 g). Extraction with hot hexane followed by evaporation to a small volume allowed crystals to separate on cooling. Recrystallization from ether–hexane yielded methyl 2-*O*-[methyl(2,3,4-tri-*O*-methyl-β-D-glucuronosyl]-3,4,6-tri-*O*-methyl-D-mannoside with m.p. 141° C (11). Calculated for $C_{20}H_{36}O_{12}$: C, 51.3%; H, 7.75%. Found: C, 51.15%; H, 7.8%.

(i) Characterization of the Aldotriouronic Acid

The aldotriouronic acid (0.46 g), $[\alpha]_D$ +15° (*c*, 1.0, H_2O), was eluted next and on hydrolysis with *N* sulphuric acid at 100° C overnight gave the above aldobiouronic acid, glucose, and a trace of mannose. A few milligrams in water (0.1 ml) was treated with sodium borohydride (5 mg) for 18 hours. Acetic acid was then added, followed by Amberlite IR 120. Filtration and evaporation gave a solid which was dissolved in methanol, which was then evaporated. Two more evaporations gave the reduced aldotriouronic acid. Hydrolysis with *N* sulphuric acid on a steam bath overnight yielded the aldobiouronic acid, and only traces of mannose and glucose, thus indicating that the aldotriouronic acid has a glucose reducing end-unit. Lead tetraacetate oxidation of the aldotriouronic acid resulted in 0.7, 0.8, and 0.9 mole of oxidant being consumed after 3, 10, and 20 minutes, respectively, suggesting mainly a 3-linked glucose reducing end-unit. The 3-linkage was confirmed since hydrolysis of the oxidized sugar with aqueous oxalic acid resulted in the production of arabinose. Sodium borohydride reduction of the oxidized sugar followed by acid hydrolysis yielded arabitol, with only traces of other polyols.

Methylation of the aldotriouronic acid by means of the same procedure as used for the aldobiouronic acid gave a fully methylated product. On hydrolysis with *N* sulphuric acid at 100° C overnight it yielded, in addition to acidic material and tri-*O*-methylhexose, a trace of tetra-*O*-methylhexose. No di-*O*-methylhexose was formed.

(ii) Characterization of Aldotetraouronic Acid

The next material eluted from the cellulose column appeared to be an aldotetraouronic acid with $[\alpha]_D$ +17° (*c*, 0.5, H_2O). Acid hydrolysis with *N* sulphuric acid at 100° C overnight gave an aldobiouronic acid, a trace of mannose, and a greater proportion of glucose than that formed on hydrolysis of the aldotriouronic acid. Hydrolysis for 2 hours under the same conditions yielded a trace of material which co-chromatographed with the aldotriouronic acid. Sodium borohydride reduction followed by acidic hydrolysis of the aldotetraouronic acid showed that the non-reducing end-group was glucose. On treatment with lead tetraacetate 0.7, 1.1, and 1.5 moles were consumed after 3, 10, and 25 minutes respectively, thus indicating mainly a 1,4-linked reducing group.

Enzymic Hydrolysis of Partially Degraded X. hyacinthi Polysaccharide

The polysaccharide (20 g) was heated on a steam bath in 0.1 *N* sulphuric acid (500 ml) for 3 days. The solution was no longer viscous and was neutralized ($BaCO_3$), filtered, and evaporated to a small volume. This procedure gave free mannose with only traces of glucose. Acidic material was then precipitated by addition of the aqueous solution to methanol. A portion (2.3 g) of the isolated solid (9.5 g) was dissolved in water and treated with Amberlite IR 120. After filtration and partial evaporation to 20 ml the pH was brought to 6 with sodium bicarbonate. Enzyme preparation S157B (100 mg) was added and the solution kept at 45° C for 16 hours. Cellobiose (31 mg) and glucose (21 mg) were liberated and isolated on Whatman No. 3 paper sheets using ethyl acetate – pyridine – water (10:4:3 v/v) as solvent and the disaccharide was converted to β-octaacetyl cellobiose by the hot acetic anhydride – sodium acetate method. Two recrystallizations of the product from ethanol gave crystals with m.p. 194–195° C that gave an X-ray diffraction pattern identical with that of authentic material.

Enzymic hydrolysis of the aldotrio- and aldotetrao-uronic acids under identical conditions gave 2-*O*-β-D-glucuronopyranosyl-D-mannose and -glucose, identified chromatographically.

Acetolysis of X. hyacinthi Polysaccharide

The acetate of the polysaccharide was formed by the action of dimethylformamide – pyridine – acetic anhydride, and isolated by precipitation from excess water. The acetate (10 g) was dissolved in acetic anhydride (100 ml) containing sulphuric acid (9 ml) and the solution kept at 35° C for 24 hours. It was then added to ice water and after destruction of acetic anhydride was complete the solution was extracted with chloroform, which was evaporated. The residue was redissolved in chloroform (200 ml), and methanol (100 ml) containing sodium (0.50 g) was added. After 30 hours the solution was extracted with water, which was evaporated to give a sirup. This was shown to consist mainly of mannose and an aldobiouronic acid on paper chromatograms in the ethyl acetate – acetic acid – water (9:2:2 v/v) solvent. In addition a disaccharide slightly faster than the acid could be detected with the *p*-anisidine hydrochloride spray (12). This (230 mg) was isolated by chromatography on a cellulose column using acetone–water (5:1 v/v) as solvent. Hydrolysis with *N* sulphuric acid overnight showed it consisted of glucose and mannose. The reducing end was shown to be mannose since only glucose remained on sodium borohydride reduction followed by acid hydrolysis. The disaccharide consumed 0.74, 1.14, and 1.57 moles of lead tetraacetate after 3, 10, and 30 minutes, respectively and was therefore linked 1,4. Its specific rotation, +15° (*c*, 0.6, H_2O), agrees with that (+12°) noted by Bergmann and Schotte (13) for 4-*O*-β-D-glucopyranosyl-D-mannose.

For personal use only.

Periodate Oxidation of Polysaccharides

This was carried out by shaking the polysaccharide (1%) in a 5 *M* excess of periodic acid in water. After a week the acid was neutralized with barium carbonate, the solution was filtered, and sodium borohydride was added. Excess reagent was destroyed after a day and borate was removed. Hydrolysis of the modified polysaccharide was carried out with *N* sulphuric acid at 100° C overnight. The hydrolysis products were identified on paper chromatograms as glucose, erythritol, and glycerol.

Methylation and Methanolysis of Polysaccharides

The polysaccharides were methylated as in Part I of this series (3), first with the dimethyl sulphate – sodium hydroxide reagent. After three methylations the partly methylated polysaccharides became insoluble in water and these were isolated and fully methylated by the Kuhn procedure (14). The products were first partially methanolyzed with 5% methanolic hydrogen chloride overnight and then neutralized (Ag_2CO_3), filtered, and evaporated. The products were hydrolyzed to the free sugars in *N* H_2SO_4, heated at 100° C for 18 hours. The hydrolyzates were then neutralized ($BaCO_3$), filtered, and evaporated. Conversion to the methyl glycosides was carried out by refluxing in 5% methanolic hydrogen chloride for 18 hours. The samples obtained after neutralization (Ag_2CO_3) and evaporation were then analyzed by gas phase chromatography.

Gas Phase Chromatography of Methyl Glycosidic Fragments

Gas phase chromatography was carried out at 210° C using a 6-ft phthalate – ethylene glycol on Celite (1:4.5) column (15) in order to obtain good resolution of trimethyl and tetramethyl glycosides. For comparison of di-, tri-, and tetra-*O*-methyl glycosides a 4-ft column consisting of 30% fully methylated hydroxyethyl cellulose WP-09 (Union Carbide Chemicals Co.) on Gas-Chrom P (60–80 mesh) was used at 190° C and 220° C (8). The detectors used were of the hot-wire type and helium was the carrier gas.

In order to make calculations of the relative amounts the following equilibrium ratios of methyl glucosidic anomers were used, the former figures corresponding to the material with the greater retention time: methyl 2,3,4,6-tetra-*O*-methyl- (66:34); methyl 2,3,6-tri-*O*-methyl- (71:29); and methyl 2,6-di-*O*-methyl-glucoside (70:30). Methyl 3,4,6-tri-*O*-methyl- and methyl 2,3,4,6-tetra-*O*-methyl-mannoside gave single peaks on chromatography.

The methyl glycosidic standards used in comparisons of retention times in the glucose series were 2,3,4,6-, 2,3,4-, 2,3,6-, 2,4,6-, 3,4,6-, and 2,6-. In the mannose series 2,3,4,6-, 3,4,6-, 2,3,4-, 2,3,6-, 2,4,6-, and 3,4- were used. The gas chromatograms had peak areas as recorded in Table II.

ACKNOWLEDGMENTS

The authors wish to thank Mrs. S. F. Hector and Mr. N. Gardner for technical assistance and Mr. M. Mazurek for carrying out elemental analysis. Our thanks are due to Dr. E. Reese for supplying a sample of enzyme preparation S157B.

EXTRACTIVES FROM POPULUS TREMULOIDES HEARTWOOD

THE TRITERPENE ALCOHOLS[1]

R. A. ABRAMOVITCH AND R. G. MICETICH
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received May 3, 1963

ABSTRACT

The 'unsaturated alcohol fraction' from *P. tremuloides* heartwood (R. A. Abramovitch, R. G. Micetich, and S. J. Smith, Tappi, **46**, 37 (1963)) has been found to contain α- and β-amyrin, butyrospermol, 24-methylenecycloartanol, lupeol, and α-amyrenonol. Some aspects of the infrared and n.m.r. spectra of these compounds are discussed and the suggestion is made that the tritisterols and orysterols may actually be $C_{31}H_{52}O$ triterpenes containing a cyclopropane ring.

The extractives from aspen poplar (*Populus tremuloides*) heartwood have been investigated systematically and separated into a number of fractions (1). The structure of a crystalline steroidal ketone, tremulone, has been established and confirmed by a partial synthesis (2). The present paper is concerned with the resolution and the characterization of the individual components of the 'unsaturated alcohol fraction' (1).

The 'unsaturated alcohol fraction' was obtained as a yellow waxy solid (20% by weight of the unsaponifiable fraction which, in turn, constitutes 0.4% by weight of the dry wood) of indefinite melting point, which could not be resolved into its components by chromatography. Resolution into at least eight components was finally achieved by acetylation followed by alumina column chromatography and fractional crystallization of the mixture of acetates. Table I summarizes the results obtained.

TABLE I

Column chromatography of the 'unsaturated alcohol' acetates

Fraction No.	Eluant	Product	Wt% of total acetates
1*	Light petroleum (b.p. 60–65°)	Acetates IIA, IIB, III	45
2	Benzene – light petroleum (1:9)	Acetate IV	7
3	Benzene – light petroleum (1:4)	Acetate I	19
4	Ether – light petroleum (1:1)	Ketoacetate I	12
5	Ether	Ketoacetate II	15
6	Ether–methanol (1:1)	Alcohol ketoacetate	2

*Fraction No. 1 was resolved into its three component acetates by fractional crystallization from ethanol.

Acetate IIA

This was the least soluble of the three fractions and had m.p. 238–240°, $[\alpha]_D^{22}$ +85.5° (chloroform). It analyzed for $C_{32}H_{52}O_2$. Deacetylation gave the alcohol, m.p. 200–201°, $[\alpha]_D^{22}$ +102° (chloroform). These values are in good agreement with those reported for β-amyrin acetate and β-amyrin, respectively (3, 4). The n.m.r. spectrum of the acetate also agreed with this formulation: a triplet centered at 4.72 τ (C_{12} olefinic proton), a triplet centered at 5.46 τ (J 7.5 c.p.s.) (axial C_3 proton), a strong band at 8.0 τ (acetate C—CH_3), and three strong signals, characteristic of the amyrins (5), were observed at 8.87, 9.01, and 9.12 τ. A direct comparison with an authentic sample of β-amyrin acetate finally confirmed the assignment.

dihydro acetate (16). Taking all these results into consideration led to the assumption that acetate I was probably the acetate of 24-methylenecycloartanol (I). This triterpenoid ($C_{31}H_{52}O$) has been isolated from rice bran oil (17), and more recently from the wood of *Tristania conferta* R. Br and *Angophora subvelutina* F. Muell (18). The proposed structure of acetate I was confirmed by its ozonolysis. Apart from formaldehyde, a ketone was obtained which, on Wolff–Kishner reduction followed by acetylation, gave cycloartanyl acetate, indistinguishable from an authentic sample obtained by the catalytic reduction of cycloartenyl acetate. At that time, samples of 24-methylenecycloartanyl acetate and the alcohol became available through the courtesy of Dr. G. Ohta, and proved to be identical with acetate I and the corresponding alcohol, respectively.

A comparison of the optical rotations and melting points of the known monohydroxy triterpenoids containing a cyclopropane ring and their acetates with those reported for the tritisterols and orysterols (Table II) is of interest. These "sterols" of reported composition $C_{30}H_{50}O$ were isolated from wheat germ oil and rice germ oil, and are supposed

TABLE II

Physical constants of the tritisterols and orysterols (19) and triterpenes containing a cyclopropane ring

Compound	Alcohol		Acetate	
	M.p. (°C)	$[\alpha]_D$ (deg)	M.p. (°C)	$[\alpha]_D$ (deg)
α-Tritisterol	114–115	+54.3	107–108	+70.4
β-Tritisterol	70–97	+49.2	—	+55.5
α-Orysterol	121–122	+49	—	—
β-Orysterol	113–114	+51.3	104	—
γ-Orysterol	119–120	+51.9	111.5	+59.4
Cycloartenol (20)	99	+48–54	119–120	+59
Cycloeucalenol (21)	138–139	+45	110	+63
Cyclolaudenol (22)	125	+46	120–121	+55
24-Methylenecycloartanol (17)	121–122	+43	116–117	+54

to be related to the tetracyclic triterpenes. It would seem likely, however, that they are, in fact, $C_{31}H_{52}O$ triterpenoids with cyclopropane rings and may well be impure samples of known compounds of this series.

Ketoacetate I

This compound, $C_{32}H_{50}O_3$, had m.p. 280° (decomp.), and $[\alpha]_D^{22}$ +94° (chloroform). It exhibited bands at 1745 cm^{-1} (acetate) and 1668 cm^{-1} (α,β-unsaturated ketone) in the infrared. Hydrolysis gave a ketoalcohol, $C_{30}H_{48}O_2$, m.p. 206°, $[\alpha]_D^{22}$ +98.6° (chloroform), λ_{max}^{EtOH} 250 mμ, which, on chromic acid oxidation, gave a diketone (bands at 1710 and 1665 cm^{-1}), m.p. 197–198°, $[\alpha]_D^{22}$ +136° (chloroform). This indicates that the alcohol group must be present either in a six-membered ring or in a side chain. The above data are consistent with ketoacetate I being α-amyrenonyl acetate and the corresponding alcohol α-amyrenonol (II) (23). The n.m.r. spectrum of ketoacetate I would support such a formulation. A sharp single-proton peak at 4.58 τ is assigned to the C_{12} olefinic proton, a triplet centered at 5.57 τ (J 13 c.p.s.) to the axial C_3 proton,* and a strong signal at 8.04 τ to the acetate C—CH_3. There are also three signals of increasing strength

**For other triterpenes the splitting constant for the axial C_3 proton is about 7 c.p.s. (β-amyrin, J = 7.5 c.p.s.; butyrospermyl acetate, J = 6.5 c.p.s.). The larger splitting constant observed here might be a reflection of the slight ring distortion caused by the presence of a carbonyl function at C_{11}.*

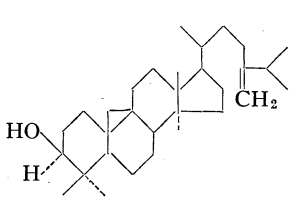
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

at 8.72, 8.88, and 9.17 τ, respectively, which seems to be characteristic of triterpenes of the amyrane and lupane series. That the alcohol was indeed α-amyrenonol was established by its catalytic reduction over platinum oxide in acetic acid, followed by acetylation to give α-amyrin acetate (24).

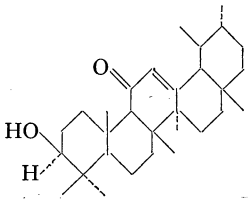
The question arises, as in the case of tremulone (2), as to whether α-amyrenonol is present in the plant as such, or whether it is an artifact resulting from the oxidation of α-amyrin. This cannot be answered at this time. It may be significant that the keto group in both cases arises through the oxidation of the methylene group adjacent to the double bond.

Fractions 5 and 6

The infrared spectrum of fraction 5 indicated the presence of an unsaturated ketoacetate while fraction 6 gave, in addition, bands characteristic of a hydroxyl group. The latter may arise by partial deacetylation on the column, or may be due to a tertiary hydroxyl group. These fractions were obtained as waxes which could not be recrystallized and were not examined further at this time.



I



II

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured on a Perkin–Elmer Model 21 spectrometer on potassium bromide disks of the compounds. Nuclear magnetic resonance spectra were recorded on a Varian A60 instrument using carbon tetrachloride solutions of the compounds and tetramethylsilane as internal standard, and with an oscillator frequency of 60 Mc/sec. Chromatographic alumina Type H was used. The light petroleum used had b.p. 60–65° and was free of unsaturation.

Resolution of the Unsaturated Alcohol Acetates

The crude unsaturated alcohol fraction (1) (0.617 g) was boiled under reflux with acetic anhydride (10 ml) and pyridine (5 ml) for 3 hours, and the solution evaporated to dryness under vacuum to give a brown wax (0.620 g). This was dissolved in the minimum amount of light petroleum and chromatographed on a column of alumina (ca. 50–80 times the weight of the acetates) and developed as outlined in Table I. Fractions of 250 ml each were collected and the progress of the chromatography followed by the weight, appearance, and infrared spectrum of each fraction. Fraction 1 was a sandy white solid whose infrared spectrum did not show any strong bands at 885 cm^{-1}. Fraction 2 was a solid and exhibited an intense band at 885 cm^{-1}. Fraction 3 was a wax whose infrared spectrum differed appreciably from that of fraction 2, but which also exhibited a strong band at 885 cm^{-1}. Fraction 4 was a light yellow wax with bands at 1745 and 1668 cm^{-1} in the infrared, but no strong band at 885 cm^{-1}. Fraction 5 was a red wax, while fraction 6 showed strong hydroxyl absorption in the infrared.

Fraction 1, m.p. ca. 200°, was fractionally crystallized from 95% ethanol. The least soluble fraction was acetate IIA, the next acetate IIB, the most soluble acetate III.

Acetate IIA—β-Amyrin Acetate

After repeated recrystallization from 95% ethanol, it had m.p. 238–240°, $[\alpha]_D^{22}$ +85.5° (chloroform). Its melting point and infrared and n.m.r. spectra were identical with those of an authentic sample of β-amyrin acetate; the melting point of this compound was undepressed on admixture with the authentic sample. (Calc. for $C_{32}H_{52}O_2$: C, 81.99; H, 11.18. Found: C, 82.04; H, 11.07.)

Acetate IIA (0.100 g) was boiled under reflux with 4% ethanolic potassium hydroxide (10 ml) for 3 hours, the cooled mixture filtered through a short column of alumina, and the solvent evaporated. The residue was recrystallized from light petroleum to give β-amyrin, m.p. 200–201°, $[\alpha]_D^{22}$ +102° (chloroform). The reported (3) constants for β-amyrin are: m.p. 199–200°, $[\alpha]_D$ +99.8° (benzene).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Acetate IIB—α-Amyrin Acetate

This crystallized from 95% ethanol in needles, m.p. 223°, $[\alpha]_D^{22}$ +79° (chloroform), identical (mixed melting point and infrared spectrum) with authentic α-amyrin acetate.

Acetate III—Butyrospermyl Acetate

This crystallized from 95% ethanol in needles, m.p. 143–144°, $[\alpha]_D^{22}$ +3.5° (chloroform). (Calc. for $C_{32}H_{50}O_2$: C, 81.99; H, 11.18. Found: C, 81.54; H, 11.33.) Heilbron, Jones, and Robins (25) give m.p. 146.5–147.5°, $[\alpha]_D^{20}$ +11±2° for butyrospermyl acetate.

Butyrospermyl Benzoate

Acetate III (0.050 g) was boiled under reflux with 3% methanolic potassium hydroxide (5 ml) for 3 hours. The cooled solution was filtered through a short column of alumina and the methanol removed on a steam bath. The residual wax (0.038 g) was heated with benzoyl chloride (1 ml) and pyridine (1 ml) on a steam bath for 3 hours and then kept at room temperature overnight. Water was added, the mixture extracted with chloroform, the chloroform layer washed in succession with dilute sulphuric acid, water, dilute sodium hydroxide, and water, and dried ($MgSO_4$). The chloroform was evaporated and the residue recrystallized from a chloroform–methanol mixture to give butyrospermyl benzoate (0.010 g), m.p. 128°, undepressed on admixture with an authentic sample.

Acetate IV—Lupeol Acetate

Repeated recrystallization of fraction 2 from methanol gave lupeol acetate, m.p. 218–219°, $[\alpha]_D^{22}$ +47.8° (chloroform), identical in all respects with an authentic sample.

Acetate I—24-Methylenecycloartanyl Acetate

Repeated recrystallization of fraction 3 from ethanol gave the pure acetate, m.p. 114–115°, $[\alpha]_D^{22}$ +53.4° (chloroform), identical with an authentic sample. (Calc. for $C_{33}H_{54}O_2$: C, 82.09; H, 11.27; mol. wt., 483. Found: C, 81.90, 82.35; H, 11.26, 11.13; mol. wt. (osmometer), 493.)

24-Methylenecycloartanol

Acetate I (0.100 g) was boiled under reflux with 3% methanolic potassium hydroxide (10 ml) for 3 hours, water (10 ml) was added, and the methanol removed in a stream of warm air. Crystals which separated from the cooled solution were recrystallized from aqueous methanol and were obtained as flakes (0.070 g), m.p. 120–121°, $[\alpha]_D^{22}$ +43.1° (chloroform), identical with authentic 24-methylenecycloartanol. (Calc. for $C_{31}H_{52}O$: C, 84.48; H, 11.89; mol. wt., 441. Found: C, 84.17; H, 11.72; mol. wt. (osmometer), 448.)

24-Methylcycloartanyl Acetate

This (m.p. 122°, $[\alpha]_D^{22}$ +54.8° (chloroform)) was obtained by the reduction of acetate I in ethanol over 10% palladium–charcoal. Ohta (17) gives m.p. 123–124°, $[\alpha]_D$ +54.5° for this compound.

Cycloartanyl Acetate

Acetate I (0.125 g) in ethyl acetate (20 ml) was ozonized at −78°, Adams' catalyst (0.060 g) was added, and the reaction product hydrogenated at 0°. Formaldehyde was detected with chromotropic acid. The filtered solution was evaporated and the residual 24-ketocycloartanyl acetate (0.070 g) recrystallized from ethanol. It had m.p. 119°. Ohta (17) gives m.p. 121–123° for this ketone. The ketone was subjected to a Wolff–Kishner reduction using the procedure outlined previously (2) and the product acetylated to give cycloartanyl acetate (0.025 g), m.p. 132–133°, identical with an authentic sample. The latter was obtained by the catalytic reduction of cycloartenyl acetate.

Ketoacetate I—α-Amyrenonyl Acetate

Repeated recrystallization of fraction 4 from an ether–methanol mixture gave the acetate, m.p. 280° (decomp.), $[\alpha]_D^{22}$ +94° (chloroform). (Calc. for $C_{32}H_{50}O_3$: C, 79.62; H, 10.44. Found: C, 79.61, 79.65; H, 10.54, 10.37.) Spring and Vickerstaff (23) give m.p. 278° for α-amyrenonyl acetate. Deacetylation as described above for 24-methylenecycloartanyl acetate gave α-amyrenonol, m.p. 206°, $[\alpha]_D^{22}$ +98.6° (chloroform), λ_{max}^{EtOH} 250 mμ. (Calc. for $C_{30}H_{48}O_2$: C, 81.76; H, 10.98; mol. wt., 441. Found: C, 81.67; H, 10.85; mol. wt. (osmometer), 430.) Spring and Vickerstaff (23) give m.p. 208°, $[\alpha]_D^{20}$ +108.6° (benzene), λ_{max}^{EtOH} 250 mμ for α-amyrenonol. α-Amyrenonol (0.065 g) in glacial acetic acid (2 ml) was hydrogenated at atmospheric pressure and room temperature. Uptake of hydrogen was very slow. The filtered solution was diluted with water and extracted with chloroform. The chloroform layer was washed with water, dried ($MgSO_4$), and the solvent evaporated. The residue was acetylated and the product recrystallized from ethanol to give α-amyrin acetate (0.030 g), m.p. 225°, identical with an authentic sample.

α-Amyrendione

The alcohol (0.050 g) obtained by the deacetylation of ketoacetate I was dissolved in glacial acetic acid (5 ml) and a solution of chromic anhydride (0.020 g) in acetic acid (5 ml) and water (0.5 ml) was added slowly with stirring. The mixture was kept overnight at room temperature, diluted with water, and extracted with benzene. The benzene extract was washed with water, filtered through a short column of alumina, and the benzene evaporated. The residue was recrystallized from aqueous methanol and was obtained as

REARRANGEMENT STUDIES WITH C^{14}

XV. ETHYL-2-C^{14} IODIDE FROM THE IRRADIATION OF ETHYL-1-C^{14} IODIDE WITH COBALT-60 GAMMA RAYS

I. S. BHARDWAJ[1] AND C. C. LEE

Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received March 20, 1963

ABSTRACT

Irradiation of ethyl-1-C^{14} iodide gave ethyl-2-C^{14} iodide with G_r of 0.27–0.28 for samples that were either deaerated or not deaerated. Addition of 1% by weight of iodine before irradiation decreased the extent of rearrangement to nearly zero. The occurrence of 1,2-hydrogen shifts in ethyl radicals outside of the spurs, which may be susceptible to scavenger action, is suggested as a possible path which would lead to the ethyl-2-C^{14} iodide.

The irradiation of 2% aqueous solutions of ethanol-1-C^{14} with Co^{60} γ-rays was found to give ethanol-2-C^{14} with a G value of about 0.04 (1). A similar study on the irradiation of liquid 2-phenylethyl-1-C^{14} iodide gave 2-phenylethyl-2-C^{14} iodide with a G value of about 0.5 (2). A possible explanation for these isotope position rearrangements may be the occurrence of 1,2-shifts in the free radicals produced during irradiation. Adloff and Ricq (3) have also reported that following Co^{60} γ-irradiation of an aqueous solution of benzoic acid-1-C^{14}, rearrangement of the C^{14} to the aromatic ring was observed with a G value of 0.01. The possible involvement of an intermediate cycloheptatrienyl radical or tropylium ion was suggested. On the other hand, irradiation of toluene-α-C^{14} with a 3-Mev electron beam gave bibenzyl with essentially no activity in the rings, indicating that benzyl radical formation did not proceed through a symmetrical tropylium ion (4). The present paper deals with another application of C^{14} as label in the study of isotope position rearrangements induced by γ-irradiation.

RESULTS AND DISCUSSION

Two-milliliter samples of ethyl-1-C^{14} iodide,* either not deaerated, or deaerated by several cycles of freezing, evacuating, and thawing, were sealed in Pyrex tubes and irradiated at room temperature in fixed positions near a 50-c Co^{60} source. Two of the deaerated samples also contained 1% by weight of added iodine. Radiation dosages were measured in roentgens by a Farmer–Baldwin "substandard" X-ray dosimeter, model Mk II.† Using a conversion factor of 1 r equals 0.975 rad for water (5) and correcting for the difference in electron density between ethyl iodide and water, the dose rates were about 55,000 rads/hr for ethyl iodide. Allowance was also made for the decay of Co^{60} in calculating the total absorbed dosage. After irradiation for various periods up to a maximum of about 4.5 months (175 million rads or 10.9×10^{21} ev/g), the samples were worked up for rearrangement to ethyl-2-C^{14} iodide.

The ethyl iodide was converted to the corresponding Grignard reagent and then treated with oxygen to give ethanol which, in turn, was reacted with iodine and sodium hydroxide to give iodoform. The activity of the iodoform thus gave a measure of the C^{14} content in the C-2 position. Such a degradation on freshly obtained ethyl-1-C^{14} iodide

or on ethyl-1-C^{14} iodide that had been stored for several months without γ-irradiation resulted in essentially inactive iodoform. After sufficient extents of irradiation, active iodoform was obtained. The results are summarized in Table I. As basis for calculation,

†Propionanilide derived from ethyl-1-C^{14} iodide before irradiation.

the activity of the ethyl-1-C^{14} iodide before irradiation was measured as the anilide derivative, prepared from reaction of ethyl-1-C^{14}-magnesium iodide with phenylisocyanate (6). From the activities of the iodoform and the anilide, the percentage rearrangement to ethyl-2-C^{14} iodide and values for G_r, the number of molecules rearranged per 100 ev absorbed, were calculated and included in Table I.

It can be seen from Table I that the extent of rearrangement increases with increasing radiation dosage. The rearrangement yield, expressed as G_r, is remarkably constant at 0.27–0.28 for both the deaerated and not deaerated samples. The absence of observable effects of dissolved air on rearrangement yields possibly may be explained by assuming that during the prolonged irradiation of the samples, all dissolved oxygen would have been used up in the initial stages of irradiation before the occurrence of measurable extents of rearrangement. Addition of 1% iodine to the samples before irradiation, however, decreased the extent of rearrangement to a very low level. Rearrangements of less than 0.1% may be considered to have only marginal significance since under the conditions of the C^{14} assays an observed activity of only twice that of background for a 20-mg iodoform sample would be equivalent to about 0.1% rearrangement. The observed activities of the iodoform derived from the iodine-containing samples were of the order of background. The fact that, of the two iodine-containing samples, the more highly irradiated one even gave slightly less active iodoform would suggest that the 0.04–0.05% rearrangement calculated for these samples may not be of great significance. It may, therefore, be concluded that the presence of 1% iodine, added before irradiation, could cut the rearrangement down to nearly zero.

The radiolysis of liquid ethyl iodide has been extensively investigated. More recent studies (7–10) have summarized the earlier work and have paid special attention to the possible mechanistic pathways of the radiolysis. The chief products from γ-irradiation of liquid ethyl iodide have been shown to be iodine, ethylene, and ethane, with smaller amounts of hydrogen iodide and *n*-butane, and with acetylene, methane, and hydrogen as minor products (10). The presence of thermalized ethyl radicals was demonstrated by exchange with I^{131} during irradiation (7, 8, 11). However, since iodine, either added before irradiation or produced during irradiation, did not completely scavenge all free radicals,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

parts of the products of radiolysis of liquid ethyl iodide must arise from reactions between "hot" radicals within the spurs (7–10). A comprehensive diffusion-controlled mechanism has recently been suggested by Gilles, Williams, and Hamill (10).

Since ethylene and hydrogen iodide are among the products of radiolysis, one might argue that the formation of ethyl-2-C^{14} iodide from irradiation of ethyl-1-C^{14} iodide arose from addition of hydrogen iodide to C^{14}-labeled ethylene. However, the amounts of ethylene and hydrogen iodide produced were not greatly decreased when ethyl iodide was irradiated in the presence of added iodine (10). The present finding that iodine added before irradiation practically eliminated the rearrangement to ethyl-2-C^{14} iodide suggests, therefore, that reaction between hydrogen iodide and C^{14}-labeled ethylene, both of which would be present among the products, may not be the most probable route of the rearrangement. On the other hand, reaction between ethylene and hydrogen iodide might proceed in steps similar to those postulated by McCauley, Hamill, and Williams (12) in explaining the formation of isopropyl iodide during photolysis of *n*-propyl iodide:

$$C_2H_4 + I\cdot \rightarrow C_2H_4I\cdot$$
$$C_2H_4I\cdot + HI \rightarrow C_2H_5I + I\cdot$$

It could then be argued that added iodine would interfere with the second step, giving rise to ethylene iodide instead of ethyl iodide. Thus an overall addition of hydrogen iodide to labeled ethylene to give ethyl-1-C^{14} and -2-C^{14} iodide cannot be excluded absolutely. However, it should be pointed out that in the analogous study on γ-induced rearrangement of 2-phenylethyl-1-C^{14} iodide to 2-phenylethyl-2-C^{14} iodide (2), addition of hydrogen iodide to labeled styrene cannot be the reaction path since such an addition would lead to either unchanged 2-phenylethyl-1-C^{14} iodide or structurally rearranged 1-phenylethyl-2-C^{14} iodide, but not to the isotopically rearranged 2-phenylethyl-2-C^{14} iodide.

The occurrence of 1,2-hydrogen shifts remains as a possible explanation for the observed rearrangement. Again, since added iodine effectively reduced the extent of rearrangement to nearly zero, and since hot radicals or the first binary encounters within the spurs may be immune to interference by added scavenger (7, 10), the observed rearrangement likely involved thermalized ethyl radicals outside of the spurs. Recombination of the rearranged radical with iodine would give ethyl-2-C^{14} iodide:

$$CH_3C^{14}H_2\cdot \rightarrow \cdot CH_2C^{14}H_3$$
$$C^{14}H_3CH_2\cdot + I_2 \rightarrow C^{14}H_3CH_2I + I\cdot$$

With iodine added before irradiation, thermal radicals may be scavenged before hydrogen shifts can take place. The fact that G_r for this rearrangement is greater than that for the corresponding irradiation of aqueous ethanol-1-C^{14} (1) is reasonable as ethyl radicals would be more readily formed from ethyl iodide. The G value for the rearrangement to 2-phenylethyl-2-C^{14} iodide from irradiation of 2-phenylethyl-1-C^{14} iodide (2) is greater than that of the present system. This may be regarded as indicative of more facile 1,2-phenyl shifts than 1,2-hydrogen shifts as have been observed in carbonium ion reactions (13–15).

EXPERIMENTAL

Propionanilide

Ethyl-1-C^{14} iodide (1.0 ml) was converted to the Grignard reagent and then treated with phenylisocyanate according to an established procedure (6) to give propionanilide, m.p. 103–104° C (lit. (6) m.p. 104–104.5° C). It was repeatedly crystallized until its specific activity was essentially constant.

For personal use only.

Degradation of Ethyl Iodide

Before or after irradiation, the active ethyl iodide was converted to ethylmagnesium iodide in anhydrous ether. The solution was cooled in an ice bath and oxygen was bubbled through for 12 hours. The resulting complex was decomposed by dilute sulphuric acid and the solution was then fractionated through a helix-packed column. After removal of most of the ether, the distillate, boiling above 60° C, and containing both ethanol and water, was used directly for conversion to iodoform.

Preliminary trials showed that the weight of iodoform obtainable from the haloform reaction with ethanol was rather low. High yields of iodoform were reported in the literature only when a rather elaborate electrochemical oxidation procedure was used (16). However, the following method, worked out by D. G. Lee (1, 17), gave sufficiently high yields (about 25%) for the present purpose.

In a 500-ml three-necked flask fitted with magnetic stirrer, reflux condenser, and two dropping funnels were placed the aqueous ethanol distillate and a buffer solution consisting of 3.25 g boric acid, 2.94 g potassium hydroxide, and 105 ml distilled water (16). With the temperature maintained at about 50° C by a heating mantle and with constant stirring, 50 ml of 10% sodium hydroxide solution was added dropwise through one funnel and a solution of iodine and potassium iodide (50 g iodine, 100 g potassium iodide in 400 ml water) was added through the second funnel. About 3 hours was required for the addition of the sodium hydroxide. The addition of the iodine – potassium iodide solution was carried out more slowly and continued until the dark iodine color remained undischarged. This required up to 48 hours, during which time up to 150 ml of the iodine – potassium iodide solution was consumed. The iodoform precipitated during the course of the reaction was collected and recrystallized about six times to give a sample with essentially constant specific activity, melting at 118–118.5° C (lit. (18) m.p. 119° C).

ACKNOWLEDGMENT

We wish to thank Mr. John Dyck of the Prairie Regional Laboratory, National Research Council of Canada, for carrying out the C^{14} assays. The financial support given by the National Research Council of Canada is also gratefully acknowledged.

THE OXIDATION OF FERROUS SULPHATE BY Co^{60} γ-RADIATION[1]

E. ONAT,[2] R. L. HAINES, AND I. H. S. HENDERSON
Defence Research Chemical Laboratories, Ottawa, Ontario

Received May 10, 1963

ABSTRACT

An investigation of the Co^{60} γ-oxidation of ferrous sulphate in the range 0.015 to 0.15 *M* in 1.0 *N*, 5.0 *N*, and 10.0 *N* sulphuric acid solutions shows that although the yields obtained were invariably higher than those predicted from the concentration ratios of ferrous ion to dissolved oxygen, no evidence was obtained to confirm the very high yields reported by Proskurnin and co-workers. The increase in yield observed has been attributed to interference with the "primary" hydrogen yield by a mechanism involving electron or hydrogen atom capture by a ferrous ion – oxygen complex.

INTRODUCTION

The oxidation of millimolar ferrous ion in 0.8 *N* sulphuric acid has been investigated extensively and the yields of ferric ion well established as 15.6 ferric ions per 100 ev absorbed in air-saturated solution (1) and as 8.2 ferric ions per 100 ev absorbed in oxygen-free solution (2, 3). Proskurnin, Orekhov, and Chernova (4), investigating this reaction at higher concentrations of ferrous ion, sulphuric acid, and oxygen, reported yields up to 60 ferric ions per 100 ev absorbed.

Miller (5), Johnson (6), and Le Bail *et al.* (7) attempted to verify the work of Proskurnin but found no increase in yield at the higher concentrations. Le Bail (7), however, found that the yield was enhanced in the presence of traces of benzene, metallic platinum, and stainless steel. Chernova, Orekhov, and Proskurnin (8) reported later that the reason the above workers did not find evidence of an enhanced yield was because, under high oxygen pressure, a compound of iron was formed that was not determined either at a wavelength of 304 mμ as ferric ion or by titration as ferrous ion. These authors ascribed the appearance of an unidentified absorption band at 250 mμ to such a compound.

The work reported here was undertaken as part of an investigation of the feasibility of the conversion of radiation energy into electrical energy through an electrochemical system, in which it is obviously desirable to utilize the maximum fraction of radiation energy to yield electrochemically active products. Attempts were made to confirm and extend Proskurnin's work, with a view to determining whether conditions could be found under which there would be a substantial increase in the yield of oxidation products.

EXPERIMENTAL

All irradiations were carried out using Co^{60} γ-radiation at dose rates of 2.5×10^{17}, 6.2×10^{17}, or 8.4×10^{18} ev/ml hr from sources of approximately 400 and 1200 c, or from a well source of approximately 200 c. Dose rates were determined by means of the Fricke dosimeter with millimolar ferrous sulphate and sodium chloride in 0.8 *N* sulphuric acid, using the value 15.6 ferric ions produced per 100 ev absorbed. All irradiations were carried out in borosilicate glass containers which had been preirradiated in contact with sulphuric acid solutions in order to remove traces of organic impurities. At the two lower dose rates, solutions were irradiated in open test tubes containing approximately 75 ml of sample. Irradiations under water using the well source at the highest dose rates employed were carried out in sealed ampoules containing 4.0 ml of sample or in a sealed annular cell containing 30.0 ml of sample.

Irradiations were carried out under air and under 1 and 5 atm of oxygen. The initial ferrous ion concentration was varied from 0.015 to 0.15 g-ions/liter in 1.0 *N*, 5.0 *N*, and 10.0 *N* sulphuric acid. Total dose

was varied from 1.0×10^{17} ev/ml to 2.5×10^{18} ev/ml. In experiments carried out under 1 atm oxygen, the solutions were kept saturated by bubbling oxygen through the solution at flow rates of 60–300 ml/min. For experiments at 5.0 atm, the glass irradiation vessels were placed in a thin-walled (0.030 in.) steel bomb which could be maintained at the desired pressure for some time prior to and during irradiation. Solutions were prepared using triply distilled water and reagent grade sulphuric acid. For solutions of ferrous ion less than 2.0×10^{-2} *M*, Merck Reagent Grade salts were employed without purification. In order to reduce the blank from ferric ion in solutions of ferrous ion greater than 2.0×10^{-2} *M*, it was found necessary to subject the stock solutions to a preliminary electrolysis under argon between platinum electrodes at a current of a few milliamperes for at least 2 weeks, with frequent replacement of anolyte by siphoning partially purified solution through the salt bridge. In general, the ratio of ferric ion to ferrous ion concentration was maintained at a value less than 1.0×10^{-4}. The reduced ferrous sulphate stock solution was stored in the dark under argon.

Ferric ion was determined using a Cary recording spectrophotometer model 14 PM, at a wavelength of 304 mμ (9). Before analysis, the irradiated solutions were brought to the temperature of the cell compartment in a constant-temperature bath. Calibration curves were plotted for ferric ion absorption at 304 mμ in 1.0 *N*, 5.0 *N*, and 10.0 *N* solutions of sulphuric acid. Values of extinction coefficients relative to those obtained with 0.8 *N* H_2SO_4 were 0.98, 1.015, and 1.297 at 1.0 *N*, 5.0 *N*, and 10.0 *N* sulphuric acid, in excellent agreement with those reported by Boyle and Mahlman (10). The data of Scharf and Lee (11) were used to evaluate the extinction coefficient in 0.8 *N* H_2SO_4 at 24.2°, the temperature at which the cell compartment was thermostated.

In some experiments the radiolytically produced ferric ion was determined indirectly by titration of the ferrous ion solutions with 2×10^{-3} *N* potassium permanganate before and after irradiation as well as by the direct spectrophotometric method. Titrimetric end points were determined potentiometrically using the procedure outlined by Kolthoff and Sandell (12). Although the precision of the method was inherently low because of the low percentage conversion, it was used to check the suggestion of Chernova *et al.* (8) that total iron was not accounted for as the sum of ferrous ion determined by titration and ferric ion determined spectrophotometrically.

Oxidation of Ferrous Ion By Molecular Oxygen

Preliminary investigations indicated that ferrous ion was oxidized rapidly by molecular oxygen, particularly at the higher concentrations of ferrous ion employed. The results obtained here followed the kinetic dependence reported by Lamb and Elder (13) for oxygen oxidation of solutions of ferrous ion in sulphuric acid solution, and by George (14) for the oxidation reaction in perchloric acid solution, namely,

$$\frac{d[Fe^{2+}]}{dt} = -k[Fe^{2+}]^2[O_2].$$

The data for the ferric ion yield in 5 *N* sulphuric acid saturated with oxygen at 1 atm are shown plotted against the square of ferrous ion concentration in Fig. 1. The yield was independent of oxygen flow rate in

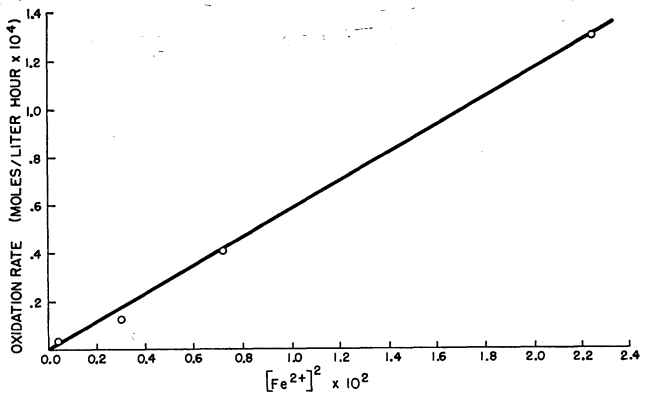

FIG. 1. Rate of oxidation of ferric ion by molecular oxygen at 25° C in 5.0 *N* H_2SO_4 under 1.0 atm O_2 vs. square of initial concentration of ferrous ion.

the range 60 ml/min to 300 ml/min. The experiments at pressures of 5 atm oxygen showed less consistency because of the time required for the solutions to equilibrate with the gas, and the difficulty of maintaining a standard temperature. However, the observed ratio of the rate of ferric ion production under 5 atm and 1 atm pressure was approximately 5:1. The oxidation rate increased with increasing acid concentration in the

range 1–10 N H_2SO_4. The rate of production of ferric ion from 0.1 M ferrous ion in 5.0 N sulphuric acid at 1 atm oxygen was found to be 5.8×10^{-5} mole Fe^{3+} per liter per hour at 24° C.

Blank corrections for ferric ion produced as a result of "dark" reaction between ferrous ion and molecular oxygen were made by using, as reference solutions in the spectrophotometer, solutions which had been subjected to the same oxygen pressures for the same time as the irradiated solutions. As noted above, this procedure was not entirely satisfactory for experiments at an oxygen pressure of 5.0 atm, but the results obtained under these conditions were consistent within experimental scatter with the other data reported here. In the absence of confirmation of the very high yields reported by Proskurnin *et al.* (4, 8) the experiments were not repeated.

EXPERIMENTAL RESULTS

In general it was found that the concentration of ferric ion increased linearly with dose up to a total dose of at least 2.0×10^{18} ev/ml. However, in air-saturated solutions of 5.0 N and 10.0 N sulphuric acid, in which the oxygen solubility was appreciably less than that in 1.0 N sulphuric acid, a falloff in yield was sometimes observed for doses in excess of 1.2×10^{18} ev/ml. Ferric ion yields reported below were evaluated either from the initial slopes of ferric ion vs. dose curves, or, when preliminary experiment had established linearity of yield with dose, from the equation

$$G_{Fe^{3+}} = \frac{15.6(\text{O.D.})_s\,\epsilon_f\,t_f\,(\text{e.d.})_f}{(\text{O.D.})_f\,\epsilon_s\,t_s\,(\text{e.d.})_s},$$

where $(\text{O.D.})_s$ was the observed 304 mμ optical density for the sample after an irradiation time t_s, $(\text{O.D.})_f$ the optical density for the Fricke solution after irradiation time t_f at the same position, ϵ_f/ϵ_s the ratio of the 304 mμ extinction coefficients and $(\text{e.d.})_f/(\text{e.d.})_s$ the ratio of calculated electron densities for the two solutions.

The data for experiments carried out under air are shown in Fig. 2 as number of ferric

ions produced per 100 ev absorbed ($G_{Fe^{3+}}$) plotted against initial ferrous ion concentration for the three acid concentrations employed. The dose rate for this series of experiments was approximately 6.2×10^{17} ev/ml hr. Figure 3 shows similar plots for solutions saturated with oxygen at 1.0 atm pressure at dose rates of approximately 6.2×10^{17} ev/ml hr and 7.4×10^{18} ev/ml hr. Since no dependence of yield on dose rate was observed, no identification of dose rates is shown on the curves. In one series of experiments with 0.02 M

ferrous ion in 5.0 N sulphuric acid, parallel determinations of ferric ion were made spectrophotometrically and indirectly by determination of ferrous ion consumed by potentiometric titration, since it had been reported that yields determined from ferrous consumption were approximately four times as high as spectrophotometric values (8). The results of individual experiments are given in Table I. Because the titration method required

the determination of the difference between two relatively large numbers, much less reliance could be placed on this analysis than the spectrophotometric method. However, the agreement observed is such as to preclude the possibility of a difference as great as that reported previously (8).

At the higher concentrations of ferrous ion employed, the initial concentration of ferric ion approached 10^{-4} M or higher, particularly in experiments carried out under an oxygen pressure of 5.0 atm. Therefore it was desirable to determine the influence of initial ferric ion concentration on the yield to permit an estimate of the relative importance of ferric ion reduction by hydrogen atoms. In this experiment, the initial ferric ion concentration was varied from 0.3% to 11.9% of the total iron concentration of 0.0227 M in 5.0 N sulphuric acid. The solutions were saturated with oxygen at 1.0 atm. The results, given in Table II, showed no dependence of yield on initial ferric ion concentration. Several

obtained under these conditions. In these runs the analytical error was increased because the blank correction for ferric ion produced by dark reaction was large, in some instances substantially larger than the radiation yield.

DISCUSSION

Examination of the experimental data of the present work indicates that there were two opposing effects which modified the yield. The first of these, which tends to increase the yield to values in excess of 15.6 ferric ions per 100 ev absorbed, is revealed most clearly in the data obtained at an oxygen pressure of 1.0 atm in 1.0 and 5.0 N sulphuric acid with ferrous ion concentrations 0.015 M and greater and in the data obtained at 5.0 atm oxygen pressure. As noted below, there is evidence that this effect was present in all ferrous ion solutions greater than 0.015 M in the present work, but that its influence was masked in part by the second effect, namely the dependence of yield on the ferrous ion/oxygen concentration ratio. This dependence was investigated in detail by Allen and Rothschild (3) for solutions of ferrous ion up to 0.002 M in 0.8 N sulphuric acid at a variety of oxygen partial pressures in which excellent agreement was observed with the equation

$$G_{Fe^{3+}} = 8.2 + \frac{7.35}{1 + \dfrac{K_5[Fe^{2+}]}{K_3[O_2]}}. \qquad [a]$$

The k's are rate constants for reactions in the sequence below, which very satisfactorily describes the radiolytic ferrous ion oxidation for solute concentrations in the ranges indicated:

$$H_2O_2 + 2Fe^{2+} = 2Fe^{3+} + 2OH^- \qquad [1]$$

$$OH + Fe^{2+} = Fe^{3+} + OH^- \qquad [2]$$

$$H + O_2 = HO_2 \qquad [3]$$

$$HO_2 + H^+ + Fe^{2+} = Fe^{3+} + H_2O_2 \qquad [4]$$

$$H + H^+ + Fe^{2+} = H_2 + Fe^{3+} \qquad [5]$$

$$Fe^{3+} + H = Fe^{2+} + H^+. \qquad [6]$$

Modifying equation [a] to include variation of hydrogen ion activity in order to permit a test of the applicability of the equations to the present results, we obtain

$$G_{Fe^{3+}} = 8.2 + \frac{7.35}{1 + \dfrac{k_5[Fe^{2+}][H_3O^+]_c}{k_3[O_2][H_3O^+]_{0.8}}}, \qquad [b]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where $[H_3O^+]_c/[H_3O^+]_{0.8}$ is the ratio of hydrogen ion concentrations in sulphuric acid of concentrations c and 0.8 N, respectively, while the value of k_5/k_3 was taken as 1/1200 in 0.8 N sulphuric acid (3). The results showing lack of dependence of yield on initial ferric ion concentration in the present concentration range (Table II) indicated the validity of neglecting equation [6] in this derivation. Oxygen concentrations in 1.0 N, 5.0 N, and 10.0 N sulphuric acid at 25° C relative to that in 0.8 N sulphuric acid were calculated from the data presented by Seidell (15) to be 0.89, 0.63, and 0.48 respectively. (As noted below, the possibility of complexing between oxygen and ferrous ion could modify the oxygen solubility, particularly at the higher ferrous ion concentrations, but in the absence of experimental confirmation, the above values were assumed.) Estimates of hydrogen ion concentrations in the sulphuric acid solutions employed were made from the Raman spectral data of Young *et al.* (16) using the equation $C_{H^+} = C_{HSO_4^-} + 2C_{SO_4^{2-}}$. The concentration ratios obtained were 1.00:1.25:6.51:12.89 for 0.8 N, 1.0 N, 5.0 N, and 10.0 N solutions, respectively.

Calculated values of $G_{Fe^{3+}}$ using equation [*b*] are compared with interpolated values from the curves of Figs. 2 and 3 in Table IV for two ferrous ion concentrations in each

sulphuric acid concentration and oxygen pressure employed, and compared graphically for 10.0 N sulphuric acid solutions in Figs. 2 and 3. For each concentration, equation [*b*] leads to lower $G_{Fe^{3+}}$ values than those determined experimentally.

That the experimental yields are higher than those calculated from equation [*b*] coupled with the observation of yields as high as 17.6 ions per 100 ev in 1.0 N and 5.0 N sulphuric acid saturated with oxygen at 1.0 atm, with comparable results at 5.0 atm, suggests the occurrence here of reactions not significant at concentrations of ferrous ion less than 0.01 M. It is suggested that there is a sufficiently high concentration of a complex such as FeO_2^{2+} at the higher concentrations of ferrous ion to interfere with intratrack formation of molecular hydrogen by atom combination or by neutralization of a hydrogen-molecule ion by a free electron. The overall reaction,

$$FeO_2^{2+} + e^- + 2H^+ \rightarrow Fe^{3+} + H_2O_2, \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

would lead to a maximum enhancement of the ferric ion yield of $6G_{H_2}$ where G_{H_2} is the "primary" hydrogen yield in millimolar ferrous ion in 0.8 N sulphuric acid, that is to approximately 2.5+15.6 or 18.1. Evidence for the existence of a complex such as FeO_2^{2+} has been inferred from the kinetics of ferrous ion oxidation by molecular oxygen (14). Chernova, Orekhov, and Proskurnin (8) suggested that the appearance of a band at about 250 mμ was due to such a complex. In order to check this latter possibility, a spectrum was recorded from 210 mμ to 330 mμ on a solution of 0.052 M ferrous ion in 5.0 N sulphuric acid solution having a ferric ion concentration less than 1.0×10^{-6} M and this was compared with spectra obtained on samples of the same solution (*a*) after exposure to oxygen at 5.0 atm for 19 hours and (*b*) after addition of sufficient 30% hydrogen peroxide to produce as much ferric ion as had been produced in the sample exposed to oxygen (4.40×10^{-4} M Fe^{3+}). No evidence was obtained for a band attributable to a complex between ferrous ion and oxygen in the region of 250 mμ, the major band being that due to ferric ion at 220 mμ (11). These results do not, however, preclude the possibility of complexing between ferrous ion and oxygen.*

CONCLUSIONS

The results of the present work confirm those of other workers, (5–7) who have attempted to reproduce the very high ferric ion yields reported by Proskurnin, Orekhov, and Chernova (4, 8). The sources of the discrepancy have not been determined, but may be associated with experimental details not duplicated in the present work. The suggestion offered to explain the occurrence of these high yields (G = 60 ferric ions/100 ev absorbed), namely that there exists a discrepancy between titrimetric and spectrophotometric determination of ferric ion (8), was also not confirmed in the present work.

When the ferrous ion concentration was increased to values in excess of 0.015 M, two opposing effects were noted. The first of these, a decrease in the ferric ion yield with increasing ratio of ferrous ion to oxygen concentration, was in qualitative agreement with the data of Allen and Rothschild (3). The second effect, which tended to increase the yield, has been tentatively attributed to electron capture by a ferrous ion – oxygen complex, thus decreasing the formation of "primary" molecular hydrogen, leading to an enhancement of the ferric yield by a maximum of $6G_{H_2\ prim} = 2.5$.

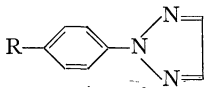
NOTES

REACTIONS OF PHENYL-SUBSTITUTED HETEROCYCLIC COMPOUNDS
IV. BROMINATION OF 2-PHENYL-1,2,3,2H-TRIAZOLE

BRIAN M. LYNCH

Addition of silver sulphate to a solution of bromine in concentrated sulphuric acid produces a highly reactive electrophilic brominating species, which is probably $AgBr_2^+$ (cf. Arotsky and Symons (1)). In previous work (2), we have used this combination of reagents to effect selective para bromination of 1-phenylpyrazole (which probably reacts in the form of its conjugate acid under the reaction conditions).

The present note reports the application of this bromination technique to 2-phenyl-1,2,3,2H-triazole (I), where 2-*p*-bromophenyl-1,2,3,2H-triazole (II), m.p. 113°, is obtained. Apparently, the highly reactive "positive bromine" overcomes the deactivating influence of the electron-attracting triazole ring (cf. ref. 3), even under circumstances where this influence may be enhanced as a result of protonation in the strongly acidic reaction medium.



I: R = H
II: R = Br
III: R = NO_2

The proton magnetic resonance spectrum of the bromination product of I offered a particularly simple proof of structure II: it showed a typical A_2B_2 pattern centered at a τ value of 2.25 for the four protons of the *p*-bromophenyl group, and a single line at τ 2.25 for the two equivalent protons of the triazole ring. Analysis of the A_2B_2 pattern assuming that $J_{AB}' = 0$ and $J_A = J_B$ (cf. Richards and Schaefer (4)) gave $J_{AB} = 9.4$ c/s, and an A–B chemical shift separation of 0.39 τ. Since the triazolyl group in derivatives of I is known to be strongly electron attracting (3), it is presumed that the protons ortho to the triazole ring would have the lower τ values in the absence of spin–spin coupling, and on this basis it is possible to deduce τ 2.05_5 for the protons ortho to the triazole ring, and τ 2.44_5 for the protons ortho to the bromine atom. If we assume, following Pople, Schneider, and Bernstein (5), that the chemical shift of a proton in a 1-X, 4-Y benzene will be X_o+Y_m at the 2-position, and X_m+Y_o at the 3-position (X_o, X_m and Y_o, Y_m are the chemical shifts of the ortho and meta protons in the monosubstituted benzenes C_6H_5X and C_6H_5Y), and also that the chemical shifts of the protons influenced by the triazolyl group are similar to those under the corresponding influence of a nitro group (supporting evidence for this assumption is presented below), these τ values appear reasonable.

The τ value 2.25, observed for the protons of the triazole ring in II, is consistent with the positions noted for the proton resonances in other five-membered nitrogen heterocyclic compounds. Thus, Reddy, Hobgood, and Goldstein (6) found τ 2.30 and 2.86 for the 2- and 4(5)-protons of imidazole, while Moore and Whittaker (7) found τ 1.77 for the ring proton of 2-ethyltetrazole.

The product II was found to be identical with a sample of the bromophenyl-1,2,3,2H-triazole, m.p. 113–114°, prepared previously (8) by treatment of glyoxal bisphenylhydrazone with bromine in aqueous suspension. This reaction presumably involves initial para bromination of the bisphenylhydrazone, followed by oxidative cyclization, since bromine in aqueous suspension has no effect on I; although the structure of the product obtained previously (8) was not proved by an unambiguous synthesis, it could be subject to little doubt in view of the demonstrated generality of the initial para bromination of the bisarylhydrazones of glucose and glyoxal before their oxidative cyclization to triazoles (cf. ref. 8).

The product II was also obtained via a Sandmeyer reaction from 2-*p*-nitrophenyl-1,2,3,2H-triazole (III). The structure III was assigned recently (9) to the mononitration product of I, and the correlation of the bromo- and nitro-phenyl-1,2,3,2H-triazoles confirms the assignment of structure III.

More direct confirmation of the structure III for the mononitration product of I was provided by its proton magnetic resonance spectrum. Two signals, at τ 1.70 (four protons) and 2.10 (two protons), were observed. The higher-field absorption is assigned to the triazole ring protons, deshielded from the value noted for the compound II by the electron-attracting *p*-nitrophenyl group, while the four-proton signal is assigned to the protons of the nitrophenyl group. It is suggested that the chemical shifts induced by the nitro and triazolyl substituents are of closely similar magnitudes, thus leading to virtual equivalance of all four protons in the nitrophenyl group of III (the four-proton signal showed barely resolvable fine structure, revealed as an asymmetric triplet (separation, ca. 1 c/s) by adjustment of sweep width).

It is evident that measurements of proton magnetic resonance spectra offer simple and convenient alternatives to classical syntheses in proving the structures of derivatives of phenyl-substituted heterocyclic compounds.

EXPERIMENTAL

Melting points are uncorrected. The microanalysis was by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A.

2-p-Bromophenyl-1,2,3,2H-triazole (II)

(a) By Direct Bromination

2-Phenyl-1,2,3,2H-triazole (I) (3 g) was dissolved in sulphuric acid (*d* 1.84, 45 ml), and bromine (1 ml) was added dropwise. Finely powdered silver sulphate (8 g) was added, and the mixture was stirred vigorously for 3 hours. Silver bromide was filtered off and the filtrate was poured onto ice. The resulting precipitate was extracted with hot benzene, and the benzene extract deposited large plates, m.p. 112°, on slow evaporation. Crystallization of this crude material from methanol yielded needles of 2-*p*-bromophenyl-1,2,3,2H-triazole (II) (3.1 g), m.p. 113°, identical (mixed m.p.) with a sample prepared by the action of bromine on glyoxal bisphenylhydrazone (cf. ref. 8). Anal. Calc. for $C_8H_6BrN_3$: C, 42.88; H, 2.70%. Found: C, 43.06; H, 2.72%.

(b) Via a Sandmeyer Reaction

2-*p*-Aminophenyl-1,2,3,2H-triazole hydrochloride (1.6 g) (from reduction of 2-*p*-nitrophenyl-1,2,3,2H-triazole (III) with tin and hydrochloric acid) was dissolved in 6 *N* sulphuric acid (9 ml) and cooled to 0°, diazotized with sodium nitrite (0.7 g) in water (2 ml), and kept at 5° for 30 minutes. The solution of the diazonium salt was added to a boiling solution of cuprous bromide (8 g) in hydrobromic acid (48%, 60 ml). Steam distillation afforded 2-*p*-bromophenyl-1,2,3,2H-triazole, which was collected and crystallized from methanol, yielding needles (0.5 g), m.p. 113°, identical (mixed m.p.) with the product obtained in (*a*) above.

Proton Magnetic Resonance Spectra

The spectra were measured on a Varian A-60 Analytical n.m.r. spectrometer operating at 60 Mc/s. The samples were examined as solutions in deuterochloroform with tetramethylsilane as internal reference. Copies of the spectra are available on request.

ACKNOWLEDGMENTS

I thank the National Research Council of Canada for a grant in support of this work, Dr. A. G. McInnes and Mr. D. G. Smith (Atlantic Regional Laboratory, National Research Council, Halifax) for the measurements of proton magnetic resonance spectra, Dr. H. El Khadem (University of Alexandria) for his courtesy in carrying out a mixed melting point determination, and Miss Y. Hung for technical assistance.

THE SYNTHESIS OF 5-O-β-D-GLUCOPYRANOSYL-D-XYLOSE AND 3,5-DI-O-β-D-GLUCOPYRANOSYL-D-XYLOSE

J. K. N. Jones and P. E. Reid

In continuation of a program (1) of synthesizing oligosaccharides which may occur as components of polysaccharides we have investigated the products of the condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (4.18 moles) with 1,2-*O*-isopropylidene-D-xylofuranose (1 mole) under standard Koenigs–Knorr conditions (2). This condensation would be expected to yield a mixture of 5-*O*-β-D-glucopyranosyl-D-xylose, 3-*O*-β-D-glucopyranosyl-D-xylose, and 3,5-di-*O*-β-D-glucopyranosyl-D-xylose. After removal of the blocking groups the mixture of monosaccharides and oligosaccharides was fractionated by chromatography on a charcoal column followed by chromatography on an ion exchange resin (3) and where necessary on sheets of Whatman 3 mm paper. These techniques yielded two chromatographically pure oligosaccharide fractions.

Fraction I (5-O-β-D-Glucopyranosyl-D-xylose)

This fraction was obtained as a crisp, white, hygroscopic glass. Chromatographic examination of the hydrolyzate of the fraction indicated the presence of glucose and xylose only. Hydrolysis of the methyl ether of the fraction and fractionation of the resulting mixture of methylated sugars yielded 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-D-xylose. Thus fraction I is either 5-*O*-β-D-glucopyranosyl-D-xylose or 4-*O*-β-D-glucopyranosyl-D-xylose but is not 3-*O*-β-D-glucopyranosyl-D-xylose.

The disaccharide and the reduced disaccharide obtained by reduction with sodium borohydride were oxidized with sodium metaperiodate at 23±2° under unbuffered conditions. The results obtained were plotted graphically and the flattened portions of the curves were extrapolated to zero time. The values obtained indicate that the disaccharide consumed 4.2 moles of sodium metaperiodate and released 3.0 moles of formic

THE SYNTHESIS OF 5-O-β-D-GLUCOPYRANOSYL-D-XYLOSE AND 3,5-DI-O-β-D-GLUCOPYRANOSYL-D-XYLOSE

J. K. N. Jones and P. E. Reid

In continuation of a program (1) of synthesizing oligosaccharides which may occur as components of polysaccharides we have investigated the products of the condensation of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (4.18 moles) with 1,2-*O*-isopropylidene-D-xylofuranose (1 mole) under standard Koenigs–Knorr conditions (2). This condensation would be expected to yield a mixture of 5-*O*-β-D-glucopyranosyl-D-xylose, 3-*O*-β-D-glucopyranosyl-D-xylose, and 3,5-di-*O*-β-D-glucopyranosyl-D-xylose. After removal of the blocking groups the mixture of monosaccharides and oligosaccharides was fractionated by chromatography on a charcoal column followed by chromatography on an ion exchange resin (3) and where necessary on sheets of Whatman 3 mm paper. These techniques yielded two chromatographically pure oligosaccharide fractions.

Fraction I (5-O-β-D-Glucopyranosyl-D-xylose)

This fraction was obtained as a crisp, white, hygroscopic glass. Chromatographic examination of the hydrolyzate of the fraction indicated the presence of glucose and xylose only. Hydrolysis of the methyl ether of the fraction and fractionation of the resulting mixture of methylated sugars yielded 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-D-xylose. Thus fraction I is either 5-*O*-β-D-glucopyranosyl-D-xylose or 4-*O*-β-D-glucopyranosyl-D-xylose but is not 3-*O*-β-D-glucopyranosyl-D-xylose.

The disaccharide and the reduced disaccharide obtained by reduction with sodium borohydride were oxidized with sodium metaperiodate at 23±2° under unbuffered conditions. The results obtained were plotted graphically and the flattened portions of the curves were extrapolated to zero time. The values obtained indicate that the disaccharide consumed 4.2 moles of sodium metaperiodate and released 3.0 moles of formic

acid per mole of disaccharide and the reduced disaccharide consumed 4.9 moles of sodium metaperiodate and released 2.78 moles of formic acid per mole of reduced disaccharide. In both cases overoxidation was negligible.

The results obtained from the reduced disaccharide are consistent with those expected theoretically from reduced 5-*O*-β-D-glucopyranosyl-D-xylose (1) but would not be expected to result from the periodate oxidation of reduced 4-*O*-β-D-glucopyranosyl-D-xylose or 3-*O*-β-D-glucopyranosyl-D-xylose.

The periodate oxidation of 5-*O*-β-D-glucopyranosyl-D-xylose (1) would be expected to result in a rapid consumption of 4 moles of sodium metaperiodate and a release of 2 moles of formic acid per mole of disaccharide followed by a slow consumption of 1 mole of periodate and a release of 2 moles of formic acid, this latter depending on the rate of hydrolysis of the intermediate formyl ester. The periodate oxidation of 4-*O*-β-D-glucopyranosyl-D-xylose (1) would be expected to result in an uptake of 4 moles of sodium metaperiodate and a release of 2 moles of formic acid per mole of disaccharide followed by a slow release of 1 mole of formic acid due to the hydrolysis of a formyl ester and the formation of an intermediate stable to further oxidation.

The results obtained are difficult to interpret. The curve for periodate consumption followed that expected for 5-*O*-β-D-glucopyranosyl-D-xylose but the curve for formic acid release did not show a break at the expected point. The periodate oxidation of the disaccharide thus rules out the possibility of a $1 \rightarrow 4$ linkage and also a $1 \rightarrow 3$ linkage but does not unequivocally prove the presence of a $1 \rightarrow 5$ linkage. In view of this uncertainty the disaccharide phenylosazone was subjected to oxidation with sodium metaperiodate. Hough, Powell, and Woods (4) have shown that pentose disaccharides containing $1 \rightarrow 5$, $1 \rightarrow 4$, and $1 \rightarrow 3$ linkages may be distinguished by the periodate oxidation of their phenylosazones. Thus, on the basis of the results of Hough, Powell, and Wood (4) it would be expected that 5-*O*-β-D-glucopyranosyl-D-xylose phenylosazone on periodate oxidation would yield mesoxaldehyde bis-1,2-phenylhydrazone whilst the phenylosazone of 4-*O*-β-D- or 3-*O*-β-D-glucopyranosyl-D-xylose would not.

Periodate oxidation of the disaccharide phenylosazone yielded mesoxaldehyde bis-1,2-phenylhydrazone, indicating a $1 \rightarrow 5$ linkage. On the basis of the evidence discussed above fraction I was identified as 5-*O*-β-D-glucopyranosyl-D-xylose.

Fraction II (3,5-Di-O-β-D-glucopyranosyl-D-xylose)

Fraction II was obtained as a crisp, white, hygroscopic glass. Chromatographic examination of the partial hydrolyzate of the fraction indicated the presence of components chromatographically identical with glucose, xylose, and 5-*O*- and 3-*O*-β-D-glucopyranosyl-D-xylose.

The reducing oligosaccharide and the reduced oligosaccharide obtained after reduction with sodium borohydride were oxidized with sodium metaperiodate at $23 \pm 2°$ under unbuffered conditions. The results obtained (calculated for a trisaccharide) were plotted graphically and the flattened portions of the curves were extrapolated to zero time. The reducing oligosaccharide consumed 4.85 moles of sodium metaperiodate per mole oligosaccharide and released 1.85 moles of formic acid per mole oligosaccharide followed by a slow release of formic acid. The reduced trisaccharide consumed 4.7 moles of sodium metaperiodate and released 1.85 moles of formic acid per mole of oligosaccharide.

The theoretical results expected from the periodate oxidation of a trisaccharide composed of 2 moles of glucose attached glycosidically to a single xylose residue which has a free C_1 position are shown in Table I. The theoretical results expected from the periodate

For personal use only.

oxidation of a trisaccharide composed of two molecules of glucose attached glycosidically to a single xylose residue which has been reduced to a pentitol are shown in Table II. Comparison of the results of the periodate oxidation of fraction II with the theoretical results shown in Tables I and II, coupled with the results of the partial hydrolysis of fraction II, indicates that the compound is probably *3,5-di-O-β-*D*-glucopyranosyl-*D*-xylose.*

TABLE I

Periodate oxidation of reducing trisaccharide (unbuffered conditions)

Linkage	Moles of periodate consumed/mole trisaccharide	Moles of formic acid released/mole trisaccharide	Moles of formic acid/mole trisaccharide as formyl ester	Overoxidation expected
1 → 2 1 → 3 pyranose	4	2	0	No
1 → 2 1 → 4	4	2	0	No
1 → 2 1 → 5	4	2	0	No
1 → 3 1 → 4	5	2	1	No
1 → 3 1 → 5	5	2	1	No

TABLE II

Periodate oxidation of reduced trisaccharide (unbuffered conditions)

Linkage	Moles of periodate consumed/mole of reduced trisaccharide	Moles of formic acid released/mole of reduced trisaccharide	Overoxidation expected
1 → 2 1 → 5	5	2	No
1 → 2 1 → 3	5	2	No
1 → 2 1 → 4	4	2	No
1 → 3 1 → 4	5	2	No
1 → 3 1 → 5	5	2	No

EXPERIMENTAL

Optical rotations were measured at 23±2°. Solutions were concentrated under reduced pressure at 50° or less. The following solvent systems were used to separate sugars on paper chromatograms: (*a*) ethyl acetate, acetic acid, water (9:2:2); (*b*) ethyl acetate, acetic acid, formic acid, water (18:3:1:4); (*c*) butan-1-ol, ethanol, water, (3:1:1); (*d*) butan-1-ol, pyridine, water (5:3:2) (all v/v). Reducing sugars were detected with the *p*-anisidine spray (5) and non-reducing sugars were detected by the alkaline silver nitrate spray (6). Rates of movement of sugars on paper chromatograms are quoted relative to the rate of movement of D-galactose (R_{gal}).

Periodate Oxidation

The periodate oxidations of the di- and tri-saccharides and of their non-reducing derivatives obtained after sodium borohydride reduction were carried out on accurately weighed samples (ca. 20 mg) with 0.3 *M* sodium metaperiodate (2 ml) made up to 50 ml with distilled water. The reactions were carried out in the dark at room temperature. Aliquots (2 ml) were withdrawn for analysis. The periodate consumption was estimated by the method of Neumuller and Vasseur (7) and the formic acid that was released by the method of Andrews *et al.* (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Fraction B.—Chromatographic examination in solvent (*b*) indicated the presence of 2,3,4,6-tetra-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-D-xylose plus traces of other components.

Fraction C.—This was chromatographically identical with 2,3-di-*O*-methyl-D-xylose in solvents (*b*) and (*c*) and was definitely separated from 2,4-di-*O*-methyl-D-xylose. It yielded *N*-phenyl 2,3-di-*O*-methyl-D-xylosylamine, m.p. and mixed m.p. 118–123°, $[\alpha]_D$ +189° (*c*, 0.65 in ethyl acetate).

Reduction of Disaccharide

The disaccharide (0.39 g) in water (11 ml) was treated with sodium borohydride (0.116 g) for 18 hours, sodium borohydride (0.162 g) was added, and the solution was allowed to stand for 24 hours. A large excess of acetone was added (ca. 10 ml) and after 3 hours the solution was diluted with water, passed through a small bed of Amberlite IR120 (H form) ion exchange resin, concentrated to a syrup, and codistilled with methanol three times. The syrup ran as a single component in solvent (*b*). It gave a positive reaction with the silver nitrate spray but not with the *p*-anisidine spray reagent. It had $[\alpha]_D$ −19° (*c*, 2.7 in water).

Periodate Oxidation of Disaccharide

The results are quoted as moles of periodate consumed and moles of formic acid produced per mole at stated time intervals at room temperature: 1.92, 1.40 (10 minutes); 2.08, 1.44 (20 minutes); 2.38, 1.84 (60 minutes); 3.13, 2.24 (120 minutes); 3.42, 2.5 (180 minutes); 3.68, 2.75 (240 minutes); 4.1, 3.12 (420 minutes); 4.32, 3.32 (720 minutes); 4.42, 3.73 (1740 minutes).

Periodate Oxidation of Reduced Disaccharide

The results are quoted as moles of periodate consumed and formic acid released at time intervals stated at room temperature: 2.45, 1.67 (10 minutes); 2.6, 1.78 (20 minutes); 2.98, 1.89 (60 minutes); 3.28, 2.03 (120 minutes); 3.52, 2.18 (180 minutes); 3.82, 2.28 (240 minutes); 4.1, 2.46 (360 minutes); 4.4, 2.5 (630 minutes); 4.95, 2.78 (1440 minutes); 5.05, 2.78 (2880 minutes).

Periodate Oxidation of Disaccharide Phenylosazone

The disaccharide phenylosazone (0.1 g) in 50% aqueous ethanol was oxidized with sodium metaperiodate as described by Hough, Powell, and Woods (4). After 10 minutes a yellow precipitate separated and was removed by filtration. The precipitate was washed well with water and recrystallized twice from aqueous ethanol to give orange needles, m.p. and mixed m.p. with authentic mesoxaldehyde bis-1,2-phenylhydrazone (prepared from glucosazone) 198–200°. The compound had absorption spectra in the ultraviolet and visible ranges identical with those of authentic mesoxaldehyde bis-1,2-phenylhydrazone.

Fraction II (3,5-Di-O-β-D-glucopyranosyl-D-xylose)

The compound was a crisp, white, hygroscopic glass easily soluble in methanol and water; R_{gal} 0.16, solvent (*b*); R_{gal} 0.070, solvent (*c*); $[\alpha]_D$ −30° (*c*, 0.1 in water).

Partial Hydrolysis of Fraction II

A small sample of the fraction was heated with 0.1 *N* hydrochloric acid at 100° and samples were taken at intervals. Chromatographic examination in solvent (*d*) indicated the presence of components chromatographically identical with D-glucose, D-xylose, 5-*O*-β-D-glucopyranosyl-D-xylose, and 3-*O*-β-D-glucopyranosyl-D-xylose.

Reduction of Fraction II

The fraction was reduced with sodium borohydride as described for the disaccharide. The product was a crisp, white glass, $[\alpha]_D$ −17.4° (*c*, 0.54 in water).

Periodate Oxidation of Fraction II

The results are quoted as moles of periodate consumed and moles of formic acid released per mole (calculated for trisaccharide) at stated time intervals at room temperature: 2.08, 0.59 (15 minutes); 2.64, 0.82 (45 minutes); 3.5, 1.17 (90 minutes); 3.9, 1.63 (180 minutes); 4.42, 1.87 (300 minutes); 4.67, 1.98 (410 minutes); 4.87, 2.1 (680 minutes); 4.95, 2.5 (1500 minutes).

Periodate Oxidation of Reduced Fraction II

The results are quoted as moles of periodate and formic acid released per mole (calculated for reduced trisaccharide) at stated time intervals at room temperature: 1.93, 0.81 (15 minutes); 3.12, 1.26 (45 minutes); 3.6, 1.45 (90 minutes); 4.07, 1.72 (180 minutes); 4.33, 1.89 (300 minutes); 4.7, 1.89 (420 minutes); 4.94, 1.99 (1680 minutes).

The periodate oxidation of the disaccharide osazone was carried out in 50% aqueous ethanol (v/v) by the method of Hough, Powell, and Woods (4) and an oxidation of glucosazone was carried out concurrently by the same method.

Condensation of 1,2-O-Isopropylidene-D-xylofuranose and 2,3,4,6-Tetra-O-acetyl-α-D-glucopyranosyl Bromide

1,2-*O*-Isopropylidene-D-xylofuranose (14.9 g) (prepared by the method of Levene and Raymond (9)) was dissolved in ethanol-free dry chloroform (200 ml) and was shaken in the dark with argentous oxide (102 g), drierite (100 g), iodine (2 g), and glass beads (3-mm diameter, 100 g) for ½ hour. 2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (145 g) (prepared by the method of Barzai-Martos and Korosy (10)) in ethanol-free dry chloroform (400 ml) was added and the mixture was shaken for 7 days. The solution was filtered, the residue washed with chloroform, and the filtrate and washings were concentrated to a syrup. The syrup was dissolved in chloroform and deacetylated by the addition of sodium methoxide at 0° C. The solution was concentrated to a syrup, dissolved in water, passed through a small bed of Amberlite IRA-400 (OH form) ion exchange resin, and concentrated to a syrup (70.4 g).

The syrup was dissolved in water (150 ml), an aliquot (14 ml) was taken and diluted to 28 ml, and barium hydroxide (1 g) was added. The solution was heated at 80–90° for 2 hours, barium hydroxide (1 g) was added, and heating continued for 1 hour. The solution was neutralized with solid carbon dioxide, filtered and the filtrate was passed through beds of Amberlite IR120 (H form) and IRA-400 (OH form) ion exchange resins. The eluate was concentrated to a syrup (2.76 g) and heated at 100° with 0.1 *N* sulphuric acid for 1½ hours. The solution was neutralized with barium carbonate, filtered, passed through a small bed of Amberlite IR120 (H form) resin, and concentrated to a syrup (2.21 g). Chromatographic examination in solvent (*a*) indicated the presence of glucose, xylose, and at least two oligosaccharides. The remainder of the solution was treated with barium hydroxide (30 g) for 6 hours at 70° and was recovered as described above. The process was repeated using barium hydroxide (10 g). The syrup so obtained (36 g) was treated with 0.1 *N* sulphuric acid as described above (yield 23.1 g).

The resultant syrupy product was dissolved in water and fractionated on a column of charcoal (Darco-G-60). The column was eluted with water and then with increasing concentrations of aqueous ethanol up to 10% v/v. Fractions containing oligosaccharides were fractionated on a column of Dowex 50WX2 200–400 mesh, Li^+ salt ion exchange resin (95×1.8 cm) (3) and where necessary the fractions obtained were refractionated on sheets of Whatman 3 mm paper by development in solvent (*a*) or (*b*). By these means two chromatographically pure fractions were obtained.

Fraction I (5-O-β-D-Glucopyranosyl-D-xylose)

The compound was obtained as a crisp, white, hygroscopic glass easily soluble in water and methanol. R_{gal} 0.74, solvent (*b*); R_{gal} 0.5, solvent (*c*). $[\alpha]_D$ −2.6° (*c*, 2.82 in water). Calc. for $C_{11}H_{20}O_{10}$: C, 42.3%; H, 6.4%. Found: C, 42.4%, 42.3%; H, 6.6%, 6.5%.

Hydrolysis of Disaccharide

The disaccharide was hydrolyzed with sulphuric acid (*N*) for 9 hours at 100°. The hydrolyzate was neutralized with barium carbonate, filtered and the filtrate was concentrated to a syrup. Chromatographic examination of the syrup in solvent (*b*) indicated the presence of glucose and xylose only.

Preparation of Disaccharide Phenylosazone

Disaccharide (0.2 g), sodium acetate (0.115 g), acetic acid (0.15 g), freshly distilled phenylhydrazine (0.24 g), and water (4 ml) were heated in a boiling-water bath for 30 minutes and allowed to cool. The precipitate was recovered by centrifugation, washed three times with ice-cold dilute acetic acid and three times with ice water. After recrystallization from aqueous methanol it had m.p. 211–213° (decomp.), mixed m.p. glucosazone 188–203 (decomp.). Calc. for $C_{23}H_{30}N_4O_8$: C, 56.3%; H, 6.19%; N, 11.4%. Found: C, 56.6%; H, 6.4%; N, 11.2%.

Methylation of Disaccharide

The disaccharide (0.39 g) was methylated with dimethyl sulphate and sodium hydroxide. The syrup obtained partially crystallized. The crystals were recrystallized from ether and then ether/light petroleum (b.p. 40–60°) to give white needles, m.p. 104–105°, $[\alpha]_D$ +56.6° (*c*, 0.5 in methanol). Calc. for $C_{18}H_{34}O_{10}$: C, 52.6%; H, 8.3%; OCH_3, 52.9%. Found: C, 52.2%; H, 8.2%; OCH_3, 51.9%. Hydrolysis of a small portion of the crystalline material with 85% formic acid for 9 hours at 100° and chromatography of the syrup (in solvent (*c*)) obtained after removal of the formic acid by distillation indicated the presence of 2,3-di-*O*-methyl-D-xylose and 2,3,4,6-tetra-*O*-methyl-D-glucose.

The disaccharide methyl ether (0.3 g, mixture of crystals and syrup) was hydrolyzed with 50% formic acid for 5 hours at 80° and with 70% formic acid at 100° for 8 hours. The solution was concentrated to a syrup and codistilled with water three times. The syrup was dissolved in water, deionized by passage through small beds of Amberlite IR120 (H form) and Dowex-A4 (OH form) ion exchange resins and concentrated to a syrup. The syrup was dissolved in butanol/light petroleum (b.p. 100–120°) and fractionated on a cellulose column (120×0.5 cm).

Fraction A.—This fraction was chromatographically identical with 2,3,4,6-tetra-*O*-methyl-D-glucose in solvent (*c*). It crystallized spontaneously, m.p. and mixed m.p. with authentic 2,3,4,6-tetra-*O*-methyl-D-glucose 83–85°, $[\alpha]_D$ +70° (25 minutes) → +78° (equilibrium) (*c*, 0.9 in water).

THE STRUCTURE OF HYDRANGIN

K. H. PALMER

An extract of the roots and rhizomes of the small tree *Hydrangea arborescens* Linn. indigenous to the Eastern United States was used by the Cherokee Indians as a cure for urinary calculi and cystitis (1). Although early workers (1, 2) reported the isolation of an alkaloid, Bondurat (3) and later Schroeter (4) isolated a crystalline "glucoside", m.p. 236°, named hydrangin.

A methanolic extract of the milled roots and rhizomes yielded on concentration 3% of crude hydrangin (m.p. 225–228°), which on recrystallization or, better, vacuum sublimation (200°, 0.01 mm), gave pure hydrangin, m.p. 229°. Only sublimed samples of the material gave consistent analytical results and analyzed for $C_9H_6O_3$. A saturated chloroform solution had an infrared spectrum consistent with aromatic ring (1593 cm^{-1}), unsaturated carbonyl group (1709 cm^{-1} and 1688 cm^{-1}), and a strongly bonded hydroxyl group (envelope 3300 cm^{-1}). The ultraviolet absorption maxima (2033, 3290, 3784 Å; log ϵ, 4.42, 3.98, 3.79) showed in alkaline solution a bathochromic shift and intensity changes (2110, 2325, 3816 Å; log ϵ, 4.68, 4.31, 4.66) characteristic of phenolic compounds (5). Hydrangin failed to show the bathochromic shift in a buffered boric acid solution characteristic of *o*-diphenols (6). The formation of a monoacetylhydrangin m.p. 142° (ν_{max} 1777 cm^{-1}) confirmed the presence of a single phenolic group.

All the above data were consistent with either a monohydroxychromone or hydroxycoumarin. The latter alternative was preferred since all simple coumarins have an ultraviolet absorption minimum from 2600 to 2650 Å, whilst chromones show appreciable absorption in this region (7). The insolubility of hydrangin precluded the characteristic frequency shifts in the infrared maxima, observed in polar and non-polar solvents, of lactone systems (8). Simple model coumarins in acetonitrile solution showed an absorption maximum at 1739 ± 5 cm^{-1}; both hydrangin and acetylhydrangin have a maximum at 1739 cm^{-1}. The bathochromic shift in the ultraviolet absorption maxima and the absence of a maximal absorbance between 2800 and 3250 Å (7) of hydrangin suggested that the hydroxyl group was present on the aromatic ring. A negative Gibb's test (9), given by phenols with a free para position, indicated that hydrangin was either a 6- or 7-hydroxycoumarin. Umbelliferone (7-hydroxycoumarin) was synthesized (10) and found to be identical in all respects with hydrangin. Further processing of the mother liquors yielded an additional 1% of umbelliferone.

EXPERIMENTAL

Ultraviolet spectra were determined in 95% ethanol (log ϵ_{max} in parentheses) using a Unicam SP700 spectrophotometer; the infrared spectra were obtained using a Perkin–Elmer DB21 instrument. Melting points are corrected and were determined on a Kofler micro hot stage.

The Extraction of Hydrangea arborescens

A 1-kg quantity of roots and rhizomes of *H. arborescens* Linn., obtained from the S. B. Penick Co., was finely ground and extracted by the cold percolation method—first by heptane then by methanol. The methanol extract was concentrated *in vacuo*, when 30 g of a brown crystalline solid (I), m.p. 225–228°, separated and was collected by filtration. On further evaporation of the mother liquors, an additional 10 g of deep brown crystalline material (II), m.p. 213–220°, was precipitated from the syrupy dark brown liquor. To the mother liquor was added 100 ml of 1 *N* sodium hydroxide solution. The resulting solution was extracted with chloroform; the aqueous liquors were made neutral and extracted with a chloroform/methanol (4:1) mixture.

The initial chloroform extract was evaporated to dryness *in vacuo* and to a portion of the resultant syrup dilute sulphuric acid was added; the acid extract failed to give a positive test for alkaloids with either Meyers or Dragendorff's reagent. An acetic acid extract of the syrup similarly gave a negative test for alkaloids.

The chloroform/methanol extract gave on evaporation a deep yellow syrup (3 g), which did not contain appreciable amounts of hydrangin. The crude hydrangin (I) was recrystallized from methanol, when faintly colored needles, m.p. 225–228°, were obtained (2.80 g). Sublimation of this material at 165–200° (at 0.01 mm Hg) gave colorless needles, m.p. 229°. λ_{max}: 2033 Å (4.42), 3290 Å (3.98), 3784 Å (3.79); λ_{min}: 2646 Å. In alkaline solution, λ_{max}: 2110 Å (4.68), 2325 Å (4.31), 3816 Å (4.66); λ_{min}: 2899 Å. ν_{max} (Nujol mull): 3300 cm^{-1} (bonded hydroxyl); 1709 cm^{-1}, 1688 cm^{-1} (carbonyl); 1593 cm^{-1}, 1515 cm^{-1}, 1485 cm^{-1} (aromatic ring); (CH_3CN solution): 3400 cm^{-1} (bonded hydroxyl); 1739 cm^{-1} (carbonyl); (saturated $CHCl_3$ solution): 3200 cm^{-1} (bonded hydroxyl); 1717 cm^{-1}, 1682 cm^{-1} (carbonyl). Calculated for $C_9H_6O_3$: C, 66.7; H, 3.7. Found: C, 66.7, 66.68; H, 3.65, 3.7. Gibb's test with 2,6-dibromoquinone chlorimide did not give the blue color which is indicative of a phenol with a free para position.

Acetylhydrangin

Hydrangin (0.500 g) was dissolved in 5 ml of pyridine, 1 ml of acetic anhydride added, the whole refluxed for 1 hour, the pyridine and excess acetic anhydride were removed *in vacuo*, and the resultant pale yellow syrup dissolved in chloroform and washed with saturated aqueous solution of sodium bicarbonate, followed by water. The dried chloroform solution was evaporated *in vacuo* to give a pale yellow froth (0.6104 g) which crystallized from methanol to give colorless needles, m.p. 142°; yield 0.55 g.

Calculated for $C_{11}H_8O_4$: C, 64.69; H, 3.95. Found: C, 64.70, 64.72; H, 4.00, 3.99. ν_{max} (Nujol mull): 1777 cm^{-1} (O-acetylaromatic); 1754 cm^{-1} (carbonyl); 1625 cm^{-1} (aromatic ring).

Model coumarin infrared spectra—only the ν_{max} for the 1800–1650 cm^{-1} range are reported in Table I. All the compounds listed were recrystallized from methanol to constant melting points.

SYNTHESIS OF DEUTERIATED METHYL BENZOATES AND DIMETHYL PHTHALATES[1]

R. PHILLIPS AND L. C. LEITCH

As part of an investigation (1) of the infrared spectra of carbonyl compounds, the deuteriated methyl benzoates and dimethyl phthalates shown below were synthesized:

$C_6H_5CO_2CD_3$	$C_6H_4(CO_2CD_3)_2$
$C_6D_5CO_2CH_3$	$C_6D_4(CO_2CH_3)_2$
$C_6D_5CO_2CD_3$	$C_6D_4(CO_2CD_3)_2$

For reasons stated in previous communications on deuterated esters (2, 3) the required compounds were prepared from the silver salts and methyl or trideuteriomethyl iodide rather than by esterification. Silver phthalate was more conveniently prepared from aqueous solutions of the ammonium salt and silver nitrate than from the acid and silver carbonate as described by Ekeley and Banta (4). The methyl esters were formed in moderate yield when a suspension of the silver salt was stirred in an ether solution of methyl iodide for a day. Deuterated benzoic and phthalic acids were prepared by the platinum-catalyzed exchange of potassium benzoate and phthalate in deuterium oxide (5). The deuterium content of the compounds was determined by the method of Jones and MacKenzie (6).

EXPERIMENTAL

Tetradeuteriophthalic Acid

Phthalic acid (8.3 g; 0.05 mole) was stirred in 100 ml of water and neutralized by the addition of 20% aqueous potassium carbonate. The neutral or slightly alkaline solution was evaporated to dryness under reduced pressure. The residue was dissolved in 40 ml of 99.5% deuterium oxide and the solution was poured into a tube which contained 0.1 g of platinum oxide, and which was constricted at the top near the joint. A stream of deuterium was bubbled through for a minute or two to reduce the oxide to platinum and then the tube was evacuated on the vacuum line, sealed, and heated for 72 hours in a rocking furnace at 130°. At the end of this period, the contents of the tube were poured into a flask for removal of the solvent under reduced pressure. The residue was heated with a second 40-ml portion of deuterium oxide as before. The residue from the second exchange was taken up in 100 ml of water and the solution was acidified with hydrochloric acid. It was filtered hot with the aid of carbon black. On cooling the filtrate, deuteriophthalic acid crystallized out. It was filtered off, washed with a little ice-cold water, and dried. Yield: 7.0 g.

Silver Phthalate

Phthalic acid (1.7 g; 0.01 mole) was mixed with 10 ml of water in a beaker and neutralized with ammonium hydroxide. The solution was heated on the steam bath until free of excess ammonia and diluted with water to about 75 ml. A solution of 4.0 g of silver nitrate in 25 ml of water was then added with stirring. The precipitate of monosilver salt which first formed redissolved. Further addition of silver nitrate solution precipitated the disilver salt, which was filtered off, washed once with water, then with acetone, and dried. The yield was nearly quantitative.

Silver Tetradeuteriophthalate

The deuterated silver phthalate was prepared in the same manner from tetradeuteriophthalic acid.

Further addition of silver nitrate solution precipitated the disilver salt, which was filtered off, washed once with water, then with acetone, and dried. The yield was nearly quantitative.

Silver Tetradeuteriophthalate

The deuterated silver phthalate was prepared in the same manner from tetradeuteriophthalic acid.

[1]*Issued as N.R.C. No. 7471.*

Di(trideuteriomethyl) Phthalate

Silver phthalate (3.78 g; 0.01 mole) was pulverized in a mortar and added to 50 ml of anhydrous ether in which had been dissolved 1.5 ml of trideuteriomethyl iodide. The mixture was stirred under a reflux condenser for 24 hours. The yellow precipitate of silver iodide was filtered off and washed with ether. The ether solution and washings were largely evaporated on the steam bath and the residue was purified by distillation from a Späth bulb in an air bath at 90–100° under 0.1 mm pressure. Yield: 1.5 g (72%), n_D^{20} 1.5122. For ordinary dimethyl phthalate, n_D^{20} is 1.5140. Calc. for $C_{10}H_4D_6O_4$: D, 6.00. Found: D, 6.06.

Dimethyl Tetradeuteriophthalate

This ester was prepared as described above for the methyl-labelled ester, n_D^{20} 1.5132. Calc. for $C_{10}H_6D_4O_4$: D, 4.00. Found: D, 3.99.

Di(trideuteriomethyl) Tetradeuteriophthalate

The totally deuterated ester was also prepared as described above, n_D^{20} 1.5119. Calc. for $C_{10}D_{10}O_4$: D, 10.00. Found: D, 10.24.

Pentadeuteriobenzoic Acid

Sodium benzoate (14.2 g, 0.1 mole) was exchanged as described by Brown and Garnett (5). The yield of deuterated benzoic acid was quantitative.

Methyl Pentadeuteriobenzoate

A suspension of 8.0 g (0.034 mole) of pulverized silver pentadeuteriobenzoate was stirred under reflux for 24 hours with 250 ml of absolute ether and 7.0 g of methyl iodide. The silver iodide was filtered off and washed with ether. The filtrate was evaporated on the steam bath and the residue of methyl pentadeuteriobenzoate was purified by distillation in a Späth bulb. Yield: 4.0 g (82%), n_D^{20} 1.5140. For normal methyl benzoate, n_D^{20} is 1.5160. Calc. for $C_8H_3D_5O_2$: D, 5.00. Found: D, 4.83.

Trideuteriomethyl Benzoate

This compound was prepared in the same manner as the above compound from trideuteriomethyl iodide and silver benzoate. The yield of product, n_D^{20} 1.5150, was 75%. Calc. for $C_8H_5D_3O_2$: D, 3.00. Found: D, 3.00.

Trideuteriomethyl Pentadeuteriobenzoate

The compound was similarly prepared from trideuteriomethyl iodide and silver pentadeuteriobenzoate. The yield of product, n_D^{20} 1.5142, was 75%. Calc. for $C_8D_8O_2$: D, 8.00. Found: D, 7.92.

ACKNOWLEDGMENT

The authors are indebted to Dr. R. N. Jones and Mrs. M. A. MacKenzie of these laboratories for the deuterium analyses.

SYNTHESES INVOLVING IMIDOGEN INTERMEDIATES: PHENANTHRIDINES AND BENZO[c]PHENANTHRIDINES[1]

R. A. Abramovitch, D. Newman, and G. Tertzakian

It has been suggested (1, 2) that the reaction of certain aromatic nitro compounds with ferrous oxalate involves the formation of imidogen intermediates[2] which could be either

[1]*Preliminary communication: ref. 1.*

[2]*These have also been called azene or nitrene intermediates. Both of these names are now considered unsuitable. Imidogen is used by Chemical Abstracts (Index). We wish to thank Drs. R. L. Shriner and R. S. Cahn for their advice on this matter.*

Yield: 1.5 g (72%), n_D^{20} 1.5122. For ordinary dimethyl phthalate, n_D^{20} is 1.5140. Calc. for $C_{10}H_4D_6O_4$: D, 6.00. Found: D, 6.06.

Dimethyl Tetradeuteriophthalate

This ester was prepared as described above for the methyl-labelled ester, n_D^{20} 1.5132. Calc. for $C_{10}H_6D_4O_4$: D, 4.00. Found: D, 3.99.

Di(trideuteriomethyl) Tetradeuteriophthalate

The totally deuterated ester was also prepared as described above, n_D^{20} 1.5119. Calc. for $C_{10}D_{10}O_4$: D, 10.00. Found: D, 10.24.

Pentadeuteriobenzoic Acid

Sodium benzoate (14.2 g, 0.1 mole) was exchanged as described by Brown and Garnett (5). The yield of deuterated benzoic acid was quantitative.

Methyl Pentadeuteriobenzoate

A suspension of 8.0 g (0.034 mole) of pulverized silver pentadeuteriobenzoate was stirred under reflux for 24 hours with 250 ml of absolute ether and 7.0 g of methyl iodide. The silver iodide was filtered off and washed with ether. The filtrate was evaporated on the steam bath and the residue of methyl pentadeuteriobenzoate was purified by distillation in a Späth bulb. Yield: 4.0 g (82%), n_D^{20} 1.5140. For normal methyl benzoate, n_D^{20} is 1.5160. Calc. for $C_8H_3D_5O_2$: D, 5.00. Found: D, 4.83.

Trideuteriomethyl Benzoate

This compound was prepared in the same manner as the above compound from trideuteriomethyl iodide and silver benzoate. The yield of product, n_D^{20} 1.5150, was 75%. Calc. for $C_8H_5D_3O_2$: D, 3.00. Found: D, 3.00.

Trideuteriomethyl Pentadeuteriobenzoate

The compound was similarly prepared from trideuteriomethyl iodide and silver pentadeuteriobenzoate. The yield of product, n_D^{20} 1.5142, was 75%. Calc. for $C_8D_8O_2$: D, 8.00. Found: D, 7.92.

ACKNOWLEDGMENT

The authors are indebted to Dr. R. N. Jones and Mrs. M. A. MacKenzie of these laboratories for the deuterium analyses.

SYNTHESES INVOLVING IMIDOGEN INTERMEDIATES: PHENANTHRIDINES AND BENZO[c]PHENANTHRIDINES[1]

R. A. Abramovitch, D. Newman, and G. Tertzakian

It has been suggested (1, 2) that the reaction of certain aromatic nitro compounds with ferrous oxalate involves the formation of imidogen intermediates[2] which could be either

[1]*Preliminary communication: ref. 1.*

[2]*These have also been called azene or nitrene intermediates. Both of these names are now considered unsuitable. Imidogen is used by Chemical Abstracts (Index). We wish to thank Drs. R. L. Shriner and R. S. Cahn for their advice on this matter.*

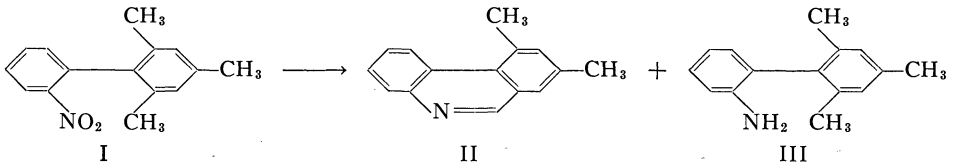
For personal use only.

in the triplet or singlet state: these intermediates then undergo further reactions leading to the observed products. Arguments in favor of the triplet state for imidogen intermediates obtained by the thermal decomposition of azides have been put forward by Smolinsky (3) and by Walker and Waters (4). Support for the mechanism of the ferrous oxalate reaction has come from studies on the deoxygenation of aromatic *C*-nitroso compounds by triethyl phosphite (5).

From the thermal decomposition of 2′-azido-2,4,6-trimethylbiphenyl in hexadecane solution Smolinsky (6) obtained 8,10-dimethylphenanthridine (II) as the major product, some amine (III) (arising from hydrogen abstraction from the solvent and the dihydrophenanthridine formed initially), and a small amount of 2,4,9-trimethylcarbazole. The action of ferrous oxalate dihydrate on 2′-nitro-2,4,6-trimethylbiphenyl (I) at 300° in the absence of solvent has now been studied. The amine (III) (27.4%) and phenanthridine (II) (22.6%) were isolated, but no carbazole. The amine cannot, therefore, arise exclusively from the dihydrophenanthridine formed initially by insertion of the imidogen intermediate



into an adjacent side-chain methyl group. The unlikely possibility that III could have arisen by hydrogen abstraction from the water of hydration of the oxalate by the imidogen intermediate was eliminated by the use of anhydrous ferrous oxalate: the proportion of II to III was practically unchanged. Hydrogen abstraction by the imidogen intermediate must, therefore, have taken place from methyl groups *in another molecule* (much intractable tar was formed in these reactions and yields of products were low) somewhat more readily than intramolecularly. This can be rationalized if it is assumed that (i) the reaction is taking place at the surface of the ferrous oxalate (or its decomposition products e.g. FeO), and (ii) that the molecules, the two rings of which are non-coplanar, tend to orient themselves at the oxalate surface such that the nitro group of one molecule may be close in space to the methyl group of another. Some supporting evidence for the first assumption was obtained as follows: anhydrous ferrous oxalate was boiled under reflux with hexadecane (internal temperature 290°), when very little decomposition occurred, even after prolonged heating. On the other hand, when I was added brisk decomposition of the oxalate occurred at about 250°. It therefore seems as though the decomposition of the ferrous oxalate is assisted by the nitro compound adsorbed on its surface and in turn this causes the imino intermediate to be formed. When a solution of I in hexadecane was heated with ferrous oxalate the amine (III) (42.1%) and phenanthridine (II) (14.8%) were obtained. In this case, hydrogen abstraction from the solvent is also possible.

It was attractive to attempt to extend this synthesis of the phenanthridine ring system to the formation of the interesting benzo[*c*]phenanthridine nucleus, found in nature in a number of alkaloids (7). A new synthetic route to this type of compound, which involves an internuclear cyclization of the Pschorr type (8), suffers from the disadvantage that it involves a relatively large number of steps and that the overall yield of product is low. The required 2-mesityl-1-nitronaphthalene (V) was readily obtained by a Gomberg–Hey reaction of 1-nitronaphthalene-2-diazonium sulphate (IV) with mesitylene. The use of the diazonium chloride led to complications (9) and did not result in the formation of the required product. When the nitro compound (V) was heated with triethyl phosphite (10) no cyclized product could be isolated and only starting material was recovered. The nitro

compound was heated with ferrous oxalate at 300°, and the ether-soluble products chromatographed on a column of alumina to give 8,10-dimethylbenzo[*c*]phenanthridine (VI) (20%) and 1-amino-2-mesitylnaphthalene (VII) (10%). The structure of VI was established by its elementary analysis and the fact that its ultraviolet absorption spectrum was very similar to that of benzo[*c*]phenanthridine (8) (Fig. 1). Reduction of 2-mesityl-1-nitronaphthalene with hydrazine hydrate in the presence of palladium–charcoal yielded the

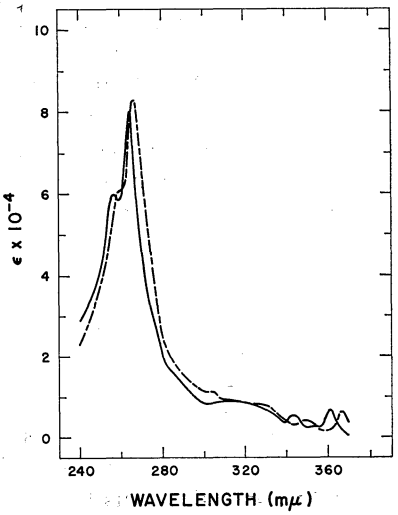

FIG. 1. Ultraviolet absorption spectrum of benzo[*c*]phenanthridine (—) and 8,10-dimethylbenzo[*c*]-phenanthridine (- — -).

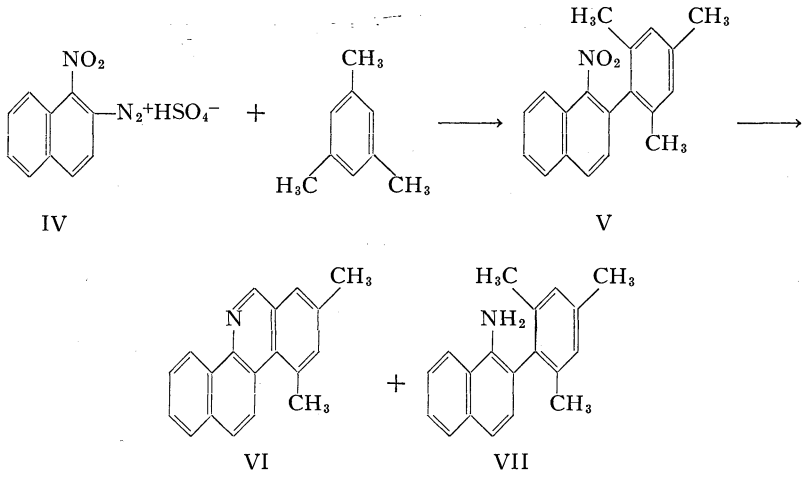
primary amine whose infrared spectrum was identical with that of the amine isolated from the ferrous oxalate reaction. The method seems to be a promising one, but might be limited by the availability of the required substituted nitro compounds.



EXPERIMENTAL

Melting points are uncorrected. Ultraviolet spectra were measured on a Cary Model 14 spectrometer, and infrared spectra on a Perkin–Elmer Model 21 instrument using sodium chloride optics. The alumina used in the column chromatographies was Peter Spence, Type H (100–200 mesh).

Reaction of 2′-Nitro-2,4,6-trimethylbiphenyl with Ferrous Oxalate

(a) Using Anhydrous Ferrous Oxalate

2′-Nitro-2,4,6-trimethylbiphenyl (11) (1.5 g), anhydrous ferrous oxalate (2.5 g; prepared by heating the dihydrate in mineral oil (12)), and granulated lead (12 g) were heated under air condenser in a metal bath at 240° (internal temperature), when a reaction set in. The temperature was slowly raised to 300°, the mixture then cooled and extracted with ether, and the dried ($MgSO_4$) ether extract evaporated to give a brown oil (0.723 g). This was chromatographed on a column of alumina. Elution with light petroleum (b.p. 60–80°) gave first 2′-amino-2,4,6-trimethylbiphenyl (0.362 g) whose infrared spectrum was identical with that of an authentic sample (prepared by the reduction of the nitro compound with hydrazine hydrate and Raney nickel). Further elution with light petroleum gave 8,10-dimethylphenanthridine (0.298 g), m.p. 149–150°, undepressed on admixture with an authentic sample (kindly supplied by Dr. G. Smolinsky). The infrared spectra of both samples were identical. Similar results were obtained using hydrated ferrous oxalate.

(b) In n-Hexadecane Solution using Anhydrous Ferrous Oxalate

In a preliminary experiment it was shown that heating anhydrous ferrous oxalate with *n*-hexadecane at 290° led to almost no decomposition of the oxalate. Even at 340° most of the oxalate had not begun to decompose despite the fact that it turned darker.

The nitro compound (1.4 g) and anhydrous ferrous oxalate (3 g) in *n*-hexadecane (10 ml) were stirred and heated under air condenser. At about 250° a vigorous reaction occurred, the temperature was slowly raised to 300° and maintained there for 20 minutes. The mixture was cooled and extracted with ether, the solvent evaporated, and the residue chromatographed on a column of alumina (70 g). Elution with light petroleum gave first *n*-hexadecane, followed by 2′-amino-2,4,6-trimethylbiphenyl (0.510 g) and then 8,10-dimethylphenanthridine (0.170 g), which were identified as before.

2-Mesityl-1-nitronaphthalene

2-Amino-1-nitronaphthalene (1.88 g) in concentrated sulphuric acid (2.5 ml) and water (30 ml) was heated on a steam bath for 15 minutes, the suspension of the sulphate cooled to 0–5°, and a solution of sodium nitrite (2 g) in water (5 ml) slowly added with stirring. At the completion of the diazotization mesitylene (25 ml) was added followed by 20% aqueous sodium hydroxide. The strongly basic mixture was stirred vigorously at 0–5° for 2 hours, at room temperature for 19 hours, and finally at 80° for 1 hour. The organic layer was separated, the aqueous layer extracted with two small portions of mesitylene and the combined mesitylene layers dried (Na_2SO_4) and the solvent distilled under vacuum. The residual dark brown oil was distilled under reduced pressure and a fraction (0.81 g), b.p. 182–192° at 0.6 mm, collected and chromatographed on a column of alumina (60 g). Elution with light petroleum (b.p. 36–48°) gave *2-mesityl-1-nitronaphthalene* (0.416 g) as pale yellow crystals, m.p. 127.5–128°. Several recrystallizations from light petroleum (b.p. 60–70°) raised the melting point to 130–130.5°. (Calc. for $C_{19}H_{17}NO_2$: C, 78.33; H, 5.88. Found: C, 78.62; H, 6.11.) Infrared spectrum (KBr disk): 1623 (m), 1535 (s), 1380 (s), 1340 (s), 820 (m), and 742 cm^{-1} (s).

1-Amino-2-mesitylnaphthalene

A solution of 2-mesityl-1-nitronaphthalene (0.100 g) in ethanol (10 ml) was boiled under reflux for 20 minutes in the presence of hydrazine hydrate (98–100%, 1 ml) and 10% palladium–charcoal (0.050 g). The resulting solution was filtered and evaporated to yield *1-amino-2-mesitylnaphthalene* (0.087 g) as an almost colorless wax which could not be recrystallized. Infrared spectrum (liquid film): 3460 (s) (br), 1596 (m), 1400 (m), 790 (s), and 752 cm^{-1} (s). Schotten–Baumann benzoylation of the amine followed by chloroform extraction of the product gave a brown gum (0.055 g) which was chromatographed on alumina (8 g). Elution with benzene gave the *N-benzoyl derivative* (0.030 g) which, on recrystallization from light petroleum (60–80°), had m.p. 179–180°. (Calc. for $C_{26}H_{23}NO$: C, 85.45; H, 6.34. Found: C, 85.58; H, 6.32.) Infrared spectrum (Nujol mull): 3310 (m), 1645 (s), 1512 (s), 1277 (m), 815 (w), and 740 cm^{-1} (m).

Reaction of 2-Mesityl-1-nitronaphthalene with Ferrous Oxalate

2-Mesityl-1-nitronaphthalene (0.60 g) was thoroughly mixed with ferrous oxalate dihydrate (0.80 g) and finely granulated lead (8 g) and heated under air condenser at 340° (bath temperature) for 15 minutes. The cooled product was extracted with ether, the solvent removed, and the brown gum (0.240 g) thus obtained chromatographed on a column of alumina (17 g). Elution with light petroleum (b.p. 36–48°) gave *8,10-dimethyl-benzo[c]phenanthridine* (0.102 g) which, on recrystallization from absolute ethanol, had m.p. 130°. (Calc. for $C_{19}H_{15}N$: C, 88.68; H, 5.88. Found: C, 88.56; H, 6.18.) Infrared spectrum (Nujol mull): 1615 (s), 1403 (s), 1278 (m), 850 (w), 800 (s), and 735 cm^{-1} (m). Elution with light petroleum – benzene (3:1 v/v) gave 1-amino-2-mesitylnaphthalene (0.050 g) as a colorless oil, the infrared spectrum of which was identical with that of the authentic specimen prepared above.

ACKNOWLEDGMENTS

This work was carried out during the tenure (by G. T.) of a C.I.L. Fellowship and with the financial support of the National Research Council. The authors are also grateful to Dr. G. Smolinsky for a sample of 8,10-dimethylphenanthridine.

THE STRUCTURAL SIGNIFICANCE OF GLYCERALDEHYDE AND GLYCOLLIC ALDEHYDE IN POLYSACCHARIDE DEGRADATIONS AND THEIR RECOVERY AND IDENTIFICATION AS THE REDUCED ANALOGUES[1]

A. M. UNRAU

In the early application of periodate oxidation (1) of sugars, the so-called dialdehydes were converted to the corresponding dicarboxylic acids (2) because of the relative instability of the aldehyde. A much more convenient approach involved the reduction of the dialdehyde with sodium borohydride (3, 4, 5), and the acetal system thus generated could easily be hydrolyzed with acid to yield its characteristic components. This procedure has been extensively used by Smith *et al.* in their investigations on the nature of the trihydric alcohols resulting from degradations of disaccharides (6) and degradations of a variety of polysaccharides. In recent years the same school (7) has developed an improved degradative scheme which has been subsequently used to great advantage in structural investigations of very complex synthetic polysaccharides (8) and natural polysaccharides (9). Application of a sequence of this newer procedure has indicated that polysaccharides such as mesquite gum (10) and a galactan from *Centrosema* (11) have an internal matrix the structure of which is more complex than was first anticipated.

In these investigations, usually little attention is paid to the glycollic aldehyde which is invariably formed in the reaction sequence. This is due chiefly to the lability of this compound and not because of its insignificance as a structural entity. Another possible product which may be encountered is glyceraldehyde which could arise from a 1,2-linkage. This fragment will be lost in the usual procedure due to its lability and thermal instability. Both of these compounds can, however, be easily recovered as the reduced derivatives, namely glycerol and ethylene glycol, by the incorporation of a few additional reactions in the general sequence.

In the event that 1,2-linkages are suspected in a polysaccharide, the glyceraldehyde released after the mild acid cleavage of the acetal systems can be readily transformed to the corresponding glyceric acid by bromine oxidation. Glycollic aldehyde present would also be transformed to the corresponding acid and both could be removed from the neutral

THE STRUCTURAL SIGNIFICANCE OF GLYCERALDEHYDE AND GLYCOLLIC ALDEHYDE IN POLYSACCHARIDE DEGRADATIONS AND THEIR RECOVERY AND IDENTIFICATION AS THE REDUCED ANALOGUES[1]

A. M. UNRAU

In the early application of periodate oxidation (1) of sugars, the so-called dialdehydes were converted to the corresponding dicarboxylic acids (2) because of the relative instability of the aldehyde. A much more convenient approach involved the reduction of the dialdehyde with sodium borohydride (3, 4, 5), and the acetal system thus generated could easily be hydrolyzed with acid to yield its characteristic components. This procedure has been extensively used by Smith *et al.* in their investigations on the nature of the trihydric alcohols resulting from degradations of disaccharides (6) and degradations of a variety of polysaccharides. In recent years the same school (7) has developed an improved degradative scheme which has been subsequently used to great advantage in structural investigations of very complex synthetic polysaccharides (8) and natural polysaccharides (9). Application of a sequence of this newer procedure has indicated that polysaccharides such as mesquite gum (10) and a galactan from *Centrosema* (11) have an internal matrix the structure of which is more complex than was first anticipated.

In these investigations, usually little attention is paid to the glycollic aldehyde which is invariably formed in the reaction sequence. This is due chiefly to the lability of this compound and not because of its insignificance as a structural entity. Another possible product which may be encountered is glyceraldehyde which could arise from a 1,2-linkage. This fragment will be lost in the usual procedure due to its lability and thermal instability. Both of these compounds can, however, be easily recovered as the reduced derivatives, namely glycerol and ethylene glycol, by the incorporation of a few additional reactions in the general sequence.

In the event that 1,2-linkages are suspected in a polysaccharide, the glyceraldehyde released after the mild acid cleavage of the acetal systems can be readily transformed to the corresponding glyceric acid by bromine oxidation. Glycollic aldehyde present would also be transformed to the corresponding acid and both could be removed from the neutral

[1]*Contribution No. 76 from the Department of Plant Science, University of Manitoba, Winnipeg 19, Manitoba.*

components through the use of anion exchange resin. The acids can then be eluted with base, the free acid regenerated through the use of cation exchange resin, and the acids heated under high vacuum to yield a mixture of dimeric lactones. Reduction of the lactones (12) with potassium borohydride yields the corresponding alcohols, which can easily be separated and identified as characteristic crystalline derivatives. This approach has in part been used to some advantage in structural studies on mesquite gum (10), acidic xylans (9), and a synthetic xylan.

An alternative procedure involves the second introduction of reducing agent after the mild acid cleavage of the acetal systems. In this way, glycollic aldehyde will be reduced directly to ethylene glycol, and any glyceraldehyde or free sugars will be transformed to the corresponding alcohols.

The suggested reaction sequences were easily tested using model systems. For an example of a 1,2-linkage, 1,2-monoacetone-D-galactose and D-mannose 1,2-orthoacetate were chosen. These compounds were readily prepared following published (13, 14, 15) procedures. Periodate oxidation, in which one mole of oxidant was consumed per mole of each hexose derivative, gave the dialdehydes, which were reduced to the corresponding alcohols with sodium borohydride. To prevent the possible loss of the substituents on C_1 and C_2 during the oxidation, the solutions were buffered to pH 7.2–7.5. Acid hydrolysis of the alcohols released glycerol (from C_4, C_5, and C_6) and D-glyceraldehyde from the D-galactose derivative and L-glyceraldehyde from D-mannose 1,2-orthoacetate. Addition of bromine oxidized the aldehydes to the respective glyceric acids. Chromatographic examination of the mixtures indicated the presence of glycerol and an acidic substance corresponding to glyceric acid. These compounds were present in a 1:1 molar ratio as determined by the periodate – chromotropic acid procedure (17, 18). The carboxylic acids were separated from glycerol by use of ion exchange resins. The glyceric acids were again regenerated and then converted to the dimeric lactones in the usual manner; reduction with potassium borohydride gave glycerol, which was identified chromatographically and as the crystalline *p*-nitrobenzoate.

Glycollic aldehyde arises upon periodate oxidation followed by reduction (BH_4) from pentose and hexose units in which the C_2- and C_3-hydroxyls are not substituted. This two-carbon fragment was easily recovered as the reduced analogue, ethylene glycol, by two routes using starch as a model substrate. Starch was degraded according to the Smith procedure (7). After the mild acid hydrolysis of the polyalcohol, the solution was neutralized and reducing agent (KBH_4) added to reduce glycollic aldehyde to ethylene glycol. The reaction mixture was worked up in the usual manner and erythritol, glycerol, and ethylene glycol identified as the crystalline *p*-nitrobenzoates. The ratio of erythritol and glycerol to ethylene glycol was 1:1 as theoretically required.

In the event that 1,2-linkages are suspected and bromine is introduced into the reaction mixture after the mild acid hydrolysis step, glycollic acid thus generated can be adsorbed on anion exchange resin. This reaction sequence was carried out using starch as the model substrate. Upon elution of the acid from the anion exchange resin with alkali and regeneration of the free acid with cation exchange resin, the residue was heated at 80–90° C under high vacuum to effect lactonization. The product was reduced with borohydride, and ethylene glycol was eventually recovered and characterized as the crystalline *p*-nitrobenzoate.

EXPERIMENTAL

Paper chromatographic separations were carried out using the descending technique. For routine qualitative and quantitative procedures, Whatman No. 1 paper sheets were used while Whatman No. 3 MM was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

employed for resolution of larger quantities of mixtures. The following three solvent systems were used: A, ethyl acetate – acetic acid – water (8:2:2); B, ethyl acetate – pyridine – water (9:2:1); and C, *n*-butanol – acetic acid – water (12:5:3). Tollens solution and *p*-anisidine–trichloroacetate solution were used for detection of non-reducing and reducing components, respectively.

Specific rotations quoted are equilibrium values. Melting points quoted are uncorrected. Unless otherwise stated, evaporations were carried out under reduced pressure at a bath temperature of 38–45° C.

*Preparation of 1,2-Isopropylidene-*D*-galactose*

This compound was prepared according to the procedures outlined by Levene and Meyer (13) and Svanberg and Sjoberg (14) with only slight modifications. The syrupy product which presumably already contained some monoacetone-galactose was dissolved in ethyl acetate containing concentrated nitric acid (16) and the solution heated for a short interval (just to boiling). The solution was cooled and upon addition of petroleum ether, 1,2-monoacetone-D-galactose crystallized which after recrystallization had m.p. 156–157° C, $[\alpha]_D^{25}$ −10.8° in ethanol (*c*, 3.0).

*Periodate Oxidation of 1,2-Monoacetone-*D*-galactose*

To a quantity (4.1 g) of the compound in alkaline (pH 7.5) phosphate buffer (200 ml), $[\alpha]_D^{25}$ −9.9°, was added a 50% molar excess of sodium periodate. A slightly alkaline buffer was used to prevent any hydrolysis of the 1,2-isopropylidene group. After the observed rotation became constant ($[\alpha]_D^{20}$ −2.9° of the dialdehyde) periodate and iodate were precipitated by addition of barium chloride. To the filtrate was added potassium borohydride and the solution kept at room temperature for 24 hours. The specific rotation changed to a constant value of 3.1°. The acetal was hydrolyzed in dilute acid to yield glycerol from C_4, C_5, and C_6 and D-glyceraldehyde from C_1, C_2, and C_3. The change in rotation ($[\alpha]_D^{25}$ 0.12° → 0.21°) indicated the liberation of D-glyceraldehyde, $[\alpha]_D^{25}$ 14° (*c*, 1.5 in water).

Bromine Oxidation

To the above mixture was added bromine at 1-hour intervals, in the presence of barium carbonate, to transform D-glyceraldehyde to the corresponding carboxylic acid. The completion of this reaction was assumed from the change in the specific rotation to that approximating D-glyceric acid (barium salt), $[\alpha]_D^{25}$ 21.3° (*c*, 1.5 in water). Upon acidification, the specific rotation changed to 14°. The solution was evaporated, the mixture of glycerol and D-glyceric acid extracted with alcohol (95%), and the molar ratio as determined chromatographically using the periodate – chromotropic acid procedure (7, 18) found to be 1:1 as theoretically expected. The two components were separated by means of ion exchange resin columns. The neutral eluate was evaporated to a syrupy residue which when chromatographed was found to contain glycerol. Treatment of the dry residue with *p*-nitrobenzoyl chloride (10% molar excess) in pyridine (4 ml) in the usual manner gave tri-*p*-nitrobenzoylglycerol, m.p. and mixed m.p. 194–195° C.

Reduction of D*-Glyceric Acid to Glycerol*

Glyceric acid was eluted from the anion exchange resin with 1 *N* NaOH, and the free acid regenerated by treatment of the alkaline solution with cation exchange resin. The solution was evaporated to near dryness and chromatographic examination revealed one component corresponding to glyceric acid. Water was removed by drying under high vacuum. The residue was heated for 2 hours at 70° C under vacuum to effect lactone formation (presumably the dimeric lactone forms since this is more likely, from stereochemical considerations, than a beta-lactone) and the product dissolved in water containing potassium borohydride. After 24 hours, the solution was evaporated to dryness, methanolic hydrogen chloride added, which upon evaporation removes borate. An aqueous solution of the residue was deionized and the final syrupy product chromatographed. Only glycerol was detected. The dry residue upon treatment with *p*-nitrobenzoyl chloride gave glycerol tri-*p*-nitrobenzoate, m.p. and mixed m.p. 194–195° C.

Periodate Degradation of D*-Mannose 1,2-(Methyl orthoacetate)*

This compound was prepared according to the general procedure described by Isbell (16). A quantity (3.2 g) of the 1,2-orthoacetate was obtained by alkaline deacetylation of 3,4,6-triacetyl-D-mannose 1,2-orthoacetate. The orthoacetate was treated with sodium periodate in an alkaline medium (pH 7.4–7.6) to prevent loss of the orthoacetate substituent. After the consumption of one molecular equivalent of periodate, the dialdehyde was reduced with sodium borohydride in the usual manner. The product was hydrolyzed with mineral acid to yield glycerol (from C_4, C_5, and C_6) and L-glyceraldehyde (from C_1, C_2, and C_3). The specific rotation, considering only the optically active component, was −13.2°, indicating a good yield of the aldehyde. The mixture was treated with bromine and barium carbonate as described previously to yield barium L-glycerate, $[\alpha]_D^{25}$ −19.8° (*c*, 2.1 in water). Acidification gave the free acid, $[\alpha]_D^{25}$ −13.6° (*c*, 1.9 in water). Glycerol and L-glyceric acid were found to be present in a 1:1 molar ratio as deduced by paper chromatography and appropriate application of the periodate – chromotropic acid reagent. The two components were quantitatively separated as described before. Glycerol was identified as the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 194–195° C. Lactonization of the acid and reduction of the lactone with borohydride gave glycerol, which was identified as the solid *p*-nitrobenzoate.

Isolation of Glycollic Acid from Periodate-degraded Starch

Soluble starch, 2.0 g, in water (100 ml) was oxidized with periodic acid in the usual manner. After no further periodate was consumed, the solution was neutralized with barium carbonate and filtered. The polyaldehyde was reduced with potassium borohydride followed by mild acid hydrolysis. The mixture was further treated with bromine to oxidize glycollic aldehyde to the corresponding carboxylic acid. The solution was finally neutralized ($PbCO_3$), evaporated to dryness, borate removed, and an aqueous solution of the residue deionized. The neutral effluent was shown to contain erythritol, glycerol, and a trace of glucosyl-erythritol as deduced from hydrolysis of this component and the resulting equimolar ratio of glucose and erythritol. Glycollic acid was eluted from the anion exchange resin with dilute alkali and the free acid regenerated. The solution was evaporated and the residue heated (80° C) under high vacuum. Because of the possible volatility of the lactonized product, a cold finger apparatus was used. The product was reduced with potassium borohydride and the reaction mixture worked up in the usual manner. Ethylene glycol was identified chromatographically and as the di-*p*-nitrobenzoate, m.p. and mixed m.p. 145–146° C. As theoretically required, the molecular proportion of ethylene glycol was approximately equivalent to the combined molecular proportions of glycerol and erythritol.

Borohydride Reduction of Starch Polyalcohol Hydrolyzate

A quantity of starch (2 g) which had been treated with periodate, borohydride, and hydrolyzed with weak acid (7) in that order was re-treated with potassium borohydride to reduce glycollic aldehyde to ethylene glycol. Jayme and Satre (19) used a similar but somewhat less satisfactory procedure to characterize glycollic aldehyde. The mixture was worked up in the usual manner. The oily residue was chromatographed and found to contain erythritol, glycerol, and ethylene glycol. The relative molar quantity of each was determined by the periodate – chromotropic acid procedure (17, 18) and the combined molar quantity of glycerol and erythritol was equivalent to the molar quantity of ethylene glycol as theoretically required. The components were separated by paper chromatography and each compound further identified as the solid *p*-nitrobenzoate: ethylene glycol *p*-nitrobenzoate had m.p. and mixed m.p. 144–145° C, glycerol *p*-nitrobenzoate had m.p. and mixed m.p. 194–196° C, and erythritol *p*-nitrobenzoate had m.p. and mixed m.p. 249–252° C.

THE DIMER OF BROMOTRIFLUOROETHYLENE

W. R. Cullen and Pritam Singh

Park, Holler, and Lacher (1) have briefly reported that dimerization of bromotrifluoroethylene takes place at 210° in the presence of the polymerization inhibitor Terpene-B.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

They suggested that the dimer is 1,2-dibromohexafluorocyclobutane since debromination gives hexafluorocyclobutene. They also suggested that their product was an approximately 50:50 mixture of the cis and trans forms. During the course of a study of the reactions of bromotrifluoroethylene with compounds containing As—As and P—P bonds (2) a product of molecular formula $C_4F_6Br_2$ was often obtained; therefore, it was decided to investigate further the preparation and structure of this compound.

It has now been found that dimerization of bromotrifluoroethylene occurs under quite mild conditions, giving a product which can be debrominated to give hexafluorocyclobutene. The infrared spectrum of this product is very similar to that of the product obtained by the bromination of hexafluorocyclobutene. However, extra bands are present in the spectrum of the dimer. Both these spectra are similar to that of the cyclic dimer of chlorotrifluoroethylene. The retention times of the dimer and the bromination product are identical on a dinonylphthalate column at 100°.

The ^{19}F n.m.r. spectrum of the bromination product (Fig. 1(*a*)) shows an AB quartet

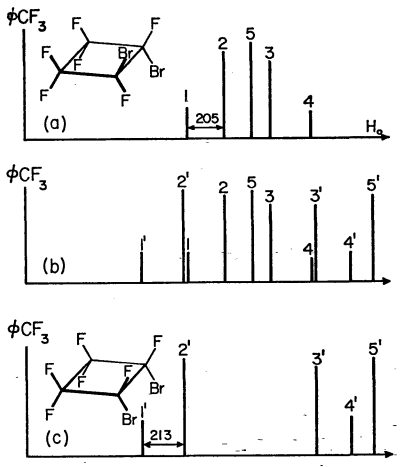

FIG. 1.

(lines 1–4) and an absorption due to one other nonequivalent fluorine (line 5). This pattern would be expected from a pure isomer of 1,2-dibromohexafluorocyclobutane, the two adjacent equivalent CF_2 groups giving rise to the AB pattern and the other absorption being due to the two equivalent fluorines on the two adjacent CFBr groups (3). The coupling constant for the AB system, 205 cycles/sec, is of the same order as that found for similarly fluorinated cyclobutanes (3). The ^{19}F n.m.r. spectrum of the dimer is shown in Fig. 1(*b*), and if the bands corresponding to those in Fig. 1(*a*) are removed then the spectrum of Fig. 1(*c*) remains. This last spectrum is again what would be expected from a pure isomer of 1,2-dibromohexafluorocyclobutane, consisting of an AB pattern (lines 1′, 2′, 3′, 4′) (coupling constant 213 cycles/sec) and one other line (line 5′).

Bromination of hexafluorocyclobutene would be expected to give predominantly the trans isomer and since only one isomer appears to be present this must be the trans form. Consequently the spectrum of Fig. 1(*c*) is that of the cis isomer.

These results strongly indicate that the dimer of bromotrifluoroethylene is a mixture of *cis*- and *trans*-1,2-dibromohexafluorocyclobutane. The relative amounts of the isomers are given by the relative intensities of lines 5 and 5′ (Fig. 1(*b*)). The proportion is therefore approximately 60% cis and 40% trans.

EXPERIMENTAL

Volatile reagents and products were manipulated in a vacuum system. Infrared spectra were recorded on a Perkin–Elmer model 421 instrument. Nuclear magnetic resonance spectra were determined on neat liquids using a Varian spectrometer operating at 40 Mc/sec.

Dimerization of Bromotrifluoroethylene

In a typical experiment 17.4 g of bromotrifluoroethylene was heated in a sealed tube (50 ml) for 6 days at 100°. Unchanged monomer (12.5 g) was recovered. The reaction products were an involatile polymer (0.90 g), which remained in the tube, and 3.8 g of a volatile fraction, which condensed in a trap cooled to −78°. This fraction was purified by v.p.c. (dinonylphthalate on firebrick at 100°) and found to contain ca. 70% of the expected dimer (found: mol. wt., 323; calc.: mol. wt., 322). The infrared spectrum showed the following absorption bands (vapor): 1375 (s), 1278 (s), 1230 (vs), 1172 (vw), 1072 (vw), 1047 (vw), 1016 (w), 996 (w), 963 (w), 941 (w), 866 (s), 836 (s), 797 (w), 759 (w), 724 (w) cm^{-1}. The ^{19}F n.m.r. spectrum (Fig. 1(*b*)) had absorption at 1667, 1872, 1880, 2082, 2199, 2249, 2460, 2487, 2703, 2855 cycles/sec to the high-field side of an internal benzotrifluoride reference.

In further experiments it was found that irradiation of the monomer for 5 hours in thick-walled Pyrex tubes using a 100-w ultraviolet lamp produced very little polymer (3%) and no dimer. Dimerization by heating at 100° was slow, e.g. 2% dimer and 1% polymer after 18 hours, but at higher temperatures the rate was faster, e.g. 45% dimer and 40% polymer after 48 hours at 150°.

Debromination of the Dimer

When the dimer (2.338 g), benzonitrile (5 ml), and zinc dust (2.0 g) were shaken at 20° for 4 hours, hexafluorocyclobutene (0.788 g; 67% yield) was obtained which was identified by its molecular weight of 163 (calc.: mol. wt., 162) and by its infrared spectrum.

Bromination of Hexafluorocyclobutene

The butene (16.6 g) and bromine (16.6 g) in a sealed tube were irradiated with a 100-w ultraviolet lamp for 8 hours (4). The crude 1,2-dibromohexafluorocyclobutane so obtained distilled at 96–97° (760 mm) (lit. value, 96–97° (4)) and was purified by v.p.c. The major component of the distillate (ca. 90%) had the same retention time on the dinonylphthalate column (100°) as did the dimer. The infrared spectrum of the bromination product showed the following absorption bands (vapor): 1375 (s), 1276 (s), 1230 (vs), 1193 (w), 1171 (w), 1071 (vw), 1046 (w), 996 (s), 946 (w), 846 (w), 840 (s), 759 (s), 636 (w) cm^{-1}. The ^{19}F n.m.r. spectrum (Fig. 1(*a*)) had absorption at 1877, 2082, 2199, 2249, 2460 cycles/sec to the high-field side of an internal benzotrifluoride reference.

THE PREPARATION OF 3-BROMOINDOLE

K. Piers, C. Meimaroglou, R. V. Jardine, and R. K. Brown

The few reports in the literature describing attempts at the direct halogenation of indole in the pyrrole ring, with bromine, chlorine, or iodine (1–3), indicate that a vigorous reaction does indeed occur. However, only in the case of iodination, and then only in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dilute aqueous solution, has the isolation of a monohaloindole (3-iodoindole) been successful (1, 2). The reaction of chlorine and bromine with indole is reported to yield "a mixture of higher substitution products" (3) which apparently could not be resolved.

A more successful route to 3-bromo- and 3-chloro-indole, devised by Weissgerber (3), involved the action of halogens on N-benzoylindole. Sulphuryl chloride has been reported to convert indole to 3-chloroindole or to 2,3-dichloroindole depending upon the amount of halogenating agent used (4). Buu-Hoï (5) found that the reaction of N-bromosuccinimide with N-benzoylindole gave a reasonably good yield of 3-bromo-N-benzoylindole which could readily be hydrolyzed to 3-bromoindole (3). More recently Yanovskaya (6) reported that in dioxane solution at 0° the action of dioxane dibromide on indole gave a 60% yield of 3-bromoindole.

Certain work in progress in this laboratory required a considerable quantity of 3-bromoindole. Although Weissgerber's procedure gave reasonably good results and produced 3-bromoindole from indole in an overall yield of about 45% (3), this route is time consuming. Accordingly, the preparation of the haloindole was attempted following the procedure reported by Yanovskaya (6). However, in our hands, the reaction in purified dioxane solvent (7, p. 284) gave only a very small amount of material, which spontaneously decomposed on attempts at its purification, in the manner characteristic of 3-bromoindole. The temperature of the reaction solvent could not be reduced to 0°, as reported, since the solvent and contents solidified below 8°. Hence we carried out the bromination at 8–10°, but otherwise as described (6). The same procedure, modified by the addition of a small amount of diethyl ether as diluent for the dioxane to permit attainment of 0° reaction temperature gave the same "tarry" material as before and little or no 3-bromoindole.

In the above reactions it was noted that hydrogen bromide evolved from the solution, especially near the end of the bromination reaction. Since Weissgerber found that 3-bromoindole decomposed readily when impure, or when in the presence of strong mineral acids, it was felt that some means of neutralizing or removing the acid would improve the reaction. The solvent pyridine proved to be the answer to the problem. When the halogenation was carried out using pyridine as solvent, indole could be converted to 3-bromoindole with dioxane dibromide in 48% yield. Use of pyridinium bromide perbromide as halogenating agent and pyridine as solvent and carrying the reaction out at 0–2° increased the yield of pure 3-bromoindole to at least 64%.

EXPERIMENTAL

To a solution of 4.0 g (0.034 mole) of indole in 40 ml of reagent pyridine cooled to 0–2°, was added slowly 10.8 g (0.034 mole) of pyridinium bromide perbromide (7, p. 65) dissolved in 30 ml of pyridine. The rate of addition was such that the temperature of the reaction mixture did not rise above 2°. When addition was complete, the solution was poured into cold ether and the resulting mixture freed from insoluble material by filtration. The cold ether solution was washed several times with cold dilute aqueous hydrochloric acid to remove the pyridine. The residual ether solution of the haloindole was then washed first with cold dilute aqueous sodium hydroxide, then with water. The dried ether solution ($MgSO_4$) was freed from ether and the residue crystallized from *n*-heptane and decolorized with charcoal if necessary. Yield, 4.3 g (64%) of pure 3-bromoindole melting at 65–66° (decomp.).

When dioxane dibromide was used as brominating agent in pyridine solution the same procedure gave 3-bromoindole in 48% yield.

In the recrystallization procedure, it is important not to heat the solution above 60° since 3-bromoindole, which deposits in the flask, begins to decompose at 65°. 3-Bromoindole may be kept satisfactorily if placed under a solvent such as pentane and stored at −20°. Otherwise even very pure material undergoes slow decomposition.

BORATE COMPLEXING BY FIVE-MEMBERED-RING *vic*-DIOLS

VAPOR PRESSURE EQUILIBRIUM AND N.M.R. SPECTRAL OBSERVATIONS[1]

M. MAZUREK AND A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

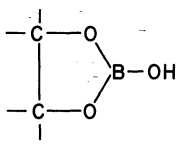
Received May 27, 1963

ABSTRACT

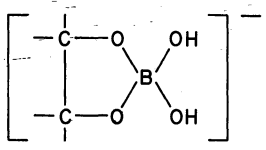
Thermometric measurement of vapor pressure equilibria in reaction mixtures containing borate ion and *cis*-3,4-dihydroxytetrahydrofuran (I) or D-glucose 5,6-carbonate (II) indicate that complexing involves at least three different equilibria. Borate complexing by I is characterized by a gross change in n.m.r. spectral characteristics, most striking being a strong overall decoupling effect. Alterations in the spectrum of II and of 5-*O*-methyl D-glucose in the presence of borate, when compared with those of D-glucose, suggest that complex formation by the latter sugar proceeds with a pyranose-to-furanose interconversion. The O—C—C—O dihedral angle, within the range 0° to about 40°, does not appear to be a factor determining the stability of borate complexes. Crystalline spirane-type complexes of I, II, and of D-threose have been prepared, illustrating the usefulness of borate complexing for the isolation of some furanose sugars and derivatives.

Solutions of alkali tetraborates are found by thermometric vapor pressure measurements to behave as equimolecular mixtures of alkali borate and boric acid.

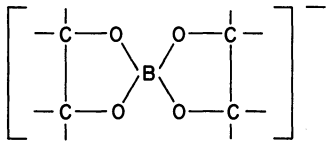
The reaction of boric acid and borate salts with diols has for long provided a highly useful means for examining stereochemical and structural problems (1–3). Borate–polyol systems frequently involve complicated equilibria between several types of compounds (1, 4–6), i.e., cyclic esters (I) and ionized, strongly acidic complexes in which one boron



I



II



III

atom is associated with one (II) or two (III) molecules of a diol. A different kind of complex, also strongly acidic, is the "tridentate" type formed by cyclitols that contain a

[1]*Issued as N.R.C. No. 7487.*

For personal use only.

cis-cis-1,3,5-triol grouping, in which the hydroxyl groups are axially-oriented by bonding to the central tetrahedral boron atom (3). Several methods have been used for examining borate-complexing reactions: conductivity, pH, and cryoscopic measurements and, especially with carbohydrates, polarimetry (6) and ionophoresis (2, 3). In the current study, some new data have been obtained by thermometric measurement of vapor pressure equilibria* (7) in borate–diol systems and by proton magnetic resonance (n.m.r.) spectroscopy, attention being centered on 5-membered-ring compounds containing a *cis*-1,2-glycol group.

Cryoscopic data indicate that alkali tetraborates in water dissociate to form borate ion and boric acid in equimolecular proportion (8, 9). Thermometric values for solutions of potassium or sodium tetraborate (Experimental, Fig. 5) accord with this view in that at high dilution approximately six particles per mole appear to be present,† corresponding to:

$$K_2B_4O_7 + H_2O = 2K^+ + 2BO_2^- + 2HBO_2. \qquad [1]$$

In concentrated solutions the apparent molarity decreases, possibly due to the existence of $B_4O_7^{--}$ under these conditions (9). The behavior of tetraborate solutions on addition of acid or alkali agrees with that expected from equation [1]. Acid results in the formation of more boric acid, the vapor pressure properties of which are those of a monomeric, undissociated molecule, and the overall number of particles is decreased proportionately (equation [2]). On addition of alkali, water is formed (but is not detected in the presence of the solvent), again with a decrease in total particles (equation [3]).

$$\underset{(4\text{ particles})}{K^+BO_2^- + H^+Cl^-} = \underset{(3\text{ particles})}{K^+Cl^- + HBO_2} \qquad [2]$$

$$\underset{(3\text{ particles})}{HBO_2 + Na^+OH^-} = \underset{(2\text{ particles})}{Na^+BO_2^- + H_2O} \qquad [3]$$

Thermometric measurements of reactions between boric acid and several polyols are characterized by negligibly small values of $\Delta\Delta R$, whereas alkali borates give large $\Delta\Delta R$ values with the same polyols (10). According to the considerations of the previous paragraph, therefore, the thermometric estimation of complexing between a diol and tetraborate can be related to the two borate ions present rather than to the total number of species containing boron. This molar relationship has been adopted as a basis for cryoscopic (11) and polarimetric measurements (6) on sugar–tetraborate reactions and appears to be valid also for the present purposes.

When erythritan (*cis*-3,4-dihydroxytetrahydrofuran (IV)) is treated with increasing proportions of potassium tetraborate there is a sharp initial rise in $\Delta\Delta R$. Equilibrium then appears to be maintained at a maximum level over a broad range, and finally a moderate decrease in $\Delta\Delta R$ is observed (Fig. 1). Such characteristics correspond closely to those expected from theoretical considerations. As has been pointed out (4, 6) a low proportion of borate favors formation of a spirane complex (III), whereas with additional borate present the equilibrium should be shifted towards formation of a type II complex and, in lesser amount, of an ester (I). Hence, the extensive complexing observed at the outset is consistent with formation of III (equation [4]; D = diol) since the maximum $\Delta\Delta R$ value

$$2D + K^+B^- = K^+[DBD]^- \text{ (III)} \qquad [4]$$

is reached when the proportion of diol to borate ion is 2:1 (diol:tetraborate = 0.1 M:0.025

**The vapor pressure difference (heat of vaporization) between the aqueous solution and water is measured thermometrically as a function of electrical resistance (ΔR). The deviation from the sum of individual ΔR values for diol and borate when the two components are admixed is $\Delta\Delta R$; i.e., $\Delta\Delta R = (\Delta R_{diol} + \Delta R_{borate}) - \Delta R_{diol+borate}$.*

†For simplicity, the hydration of metaboric acid or metaborate ion is not considered in these equations.

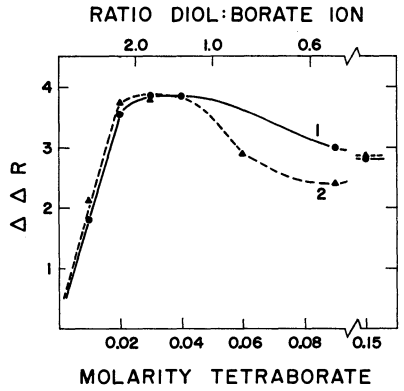

FIG. 1. Thermometric measurement of vapor pressure equilibria in solutions containing potassium tetraborate and (1) *cis*-3,4-dihydroxytetrahydrofuran, (2) D-glucose 5,6-carbonate. $\Delta\Delta R$ values for the latter derivative at tetraborate concentrations greater than 0.05 *M* decrease with time, possibly due to instability of the carbonate group at high pH.

M). At this point the apparent degree of complexing is 70% of that expected for quantitative formation of III but, due to the attendant drop in pH (to 7.8), the $\Delta\Delta R$ value probably should be about 10% greater (the $\Delta\Delta R$ value for the potassium tetraborate solution is lowered by about this amount when the pH is adjusted to 7.8).* Since the interconversion of III to a 1:1 complex (equation [5]) involves no overall change in the total number of

$$K^+[DBD]^- \text{ (III)} + K^+B^- = 2K^+[BD]^- \text{ (II)} \qquad [5]$$

particles present, it could account for the levelling-off effect (Fig. 1) as the diol:borate ion ratio approaches 1:1. Formation of an unionized species (I) then could lead to decreasing $\Delta\Delta R$ values (or a low overall $\Delta\Delta R$ value) since this reaction would be accompanied by an increase in the number of effective particles, but without change in the amounts of complexed borate and diol (equation [6]). Alternatively, the complexes may be less stable at

$$K^+[BD]^- \text{ (II)} = BD \text{ (I)} + K^+OH^- \qquad [6]$$

the relatively high pH of the more concentrated borate solutions, making for the observed decrease in $\Delta\Delta R$. In any event, the increased alkalinity has a bearing on these relationships, as shown by the fact that the addition of potassium hydroxide instead of more potassium tetraborate to a solution in which the diol:borate ratio is 1:1 causes a drop in $\Delta\Delta R$.

A crystalline erythritan–borate complex (V) of the spirane type has been prepared using conditions recommended by Vermaas (4), but derivatives corresponding to I and II have not been isolated from the reaction mixtures. The potassium salt of V was not entirely suitable for combustion analysis but the ammonium salt proved more satisfactory for this purpose. These salts were found thermometrically to be dissociated completely in water and partially in ethanol. The n.m.r. spectrum for V (Fig. 2B) is markedly different from that of erythritan itself (Fig. 2A) and shows a moderate paramagnetic shift for the 3- and 4-protons, associated with esterification of the hydroxyl groups in α-position (12, 13). Most striking in the spectrum of the complex is the fact that signals for the 2,2′- (and 5,5′-) protons constitute essentially an AB pattern, whereas these protons in the parent

**Erythritan and boric acid together (molar ratio of 2:1) show no significant change in $\Delta\Delta R$, but on addition of 1 mole of potassium hydroxide the same value for $\Delta\Delta R$ is obtained as above, when the diol–tetraborate molar ratio is 0.1:0.025. Hence the boric acid component of tetraborate does not influence the stoichiometry of the thermometric measurement.*

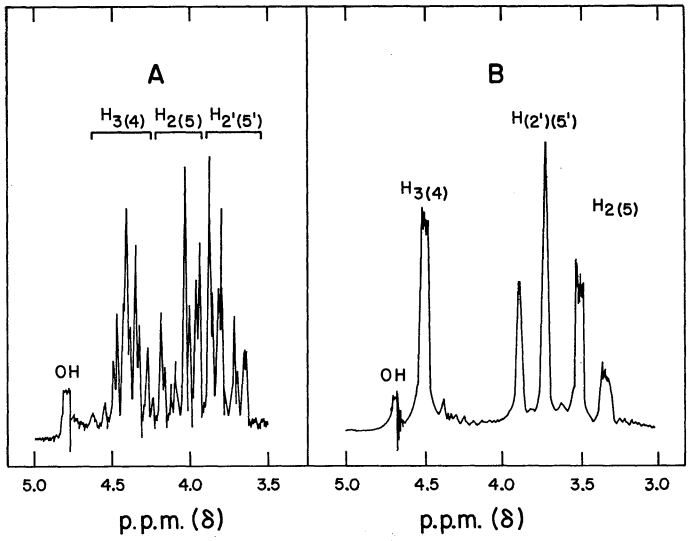

FIG. 2. Proton magnetic resonance spectrum of (A) *cis*-3,4-dihydroxytetrahydrofuran in deuterium oxide; (B) ammonium salt of *cis*-3,4-dihydroxytetrahydrofuran – borate spirane complex (V) in deuterium oxide (the potassium salt of V gives the same spectrum).

compound are coupled with protons 3 and 4 as the AB part of an ABX spectrum.* Also, it is probable that the relative chemical shifts for the AB protons are reversed by complex formation. Thus, of the two quartets comprising the four-proton signal at about 4.0 p.p.m. (Fig. 2A) that at lower field (4.1 p.p.m.) shows stronger splitting due to coupling with $H_{3(4)}$ and is ascribed to $H_{2(5)}$ (14). In Fig. 2B, however, the signal for $H_{2(5)}$ appears to be at relatively higher field since only the doublet at 3.4 p.p.m. shows evidence for coupling with $H_{3(4)}$. The large change in spin coupling constants J_{AX} and J_{BX} produced by complexing presumably can be ascribed chiefly to introduction of the anisotropic boron atom, but might be enhanced by conformational changes in the erythritan moiety.

The plot for complex formation between tetraborate and D-glucose 5,6-carbonate (VI), an example of a furanose sugar, is closely similar to that for erythritan (Fig. 1), and hence the same equilibrium relationships must apply. Complexing by this sugar appears feasible only at the 1,2-hydroxy-hemiacetal group of the α-anomer, which is made more clearly evident by changes in the n.m.r. spectrum of VI when borate is introduced (Fig. 3). Signals attributable to the α- and β-anomeric protons (which show an anomeric ratio at equilibrium of approximately 1:1) are found to be replaced as complexing occurs by the one-proton signal at lower field, the large coupling constant for the latter being consistent with a 1,2-*cis*-configuration for the complex (15). A crystalline ammonium salt of a borate complex of VI has been prepared and also found to contain 2 moles of the sugar per mole of borate. Incidentally, this spirane complex is unusual in that it contains a remarkably large number (six) of 5-membered heterocyclic rings.

The chemical shift for the anomeric proton of the D-glucose–carbonate complex (5.85 p.p.m.), and its coupling constant (3.8 c.p.s.) are close to those recorded for the anomeric proton of D-glucose in borax solution (13). The overall complexing behavior of D-glucose (Fig. 4) differs from that of the 5,6-carbonate derivative but, by analogy with acetonide

**As kindly pointed out by Dr. H. J. Bernstein, the erythritan spectrum should be classified more strictly as of the ABX–XBA type.*

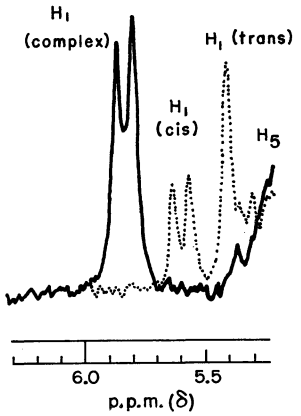

FIG. 3. Partial proton magnetic resonance spectrum of D-glucose 5,6-carbonate (dotted line) in deuterium oxide (cis and trans refer to the α- and β-(1,2-*cis* and -*trans*)-anomers, respectively), and of the ammonium salt of D-glucose 5,6-carbonate – borate spirane complex (solid line) in deuterium oxide.

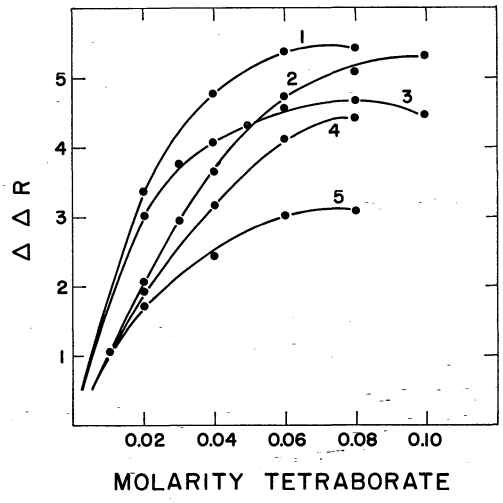

FIG. 4. Thermometric measurement of vapor pressure equilibria in solutions containing potassium tetraborate and (1) L-sorbose, (2) D-glucose, (3) D-fructose, (4) D-arabinose, and (5) D-mannose.

formation, it is possible that D-glucopyranose yields an α-D-furanose form of the 1,2-cyclic borate. Strong support for this surmise is found in the close similarities observed between the n.m.r. spectra for D-glucose and 5-*O*-methyl D-glucofuranose in tetraborate solution. Thus, the chemical shifts for H_1, H_2, and H_3 are at 5.9, 4.5, and 4.3 p.p.m., respectively, in both spectra, and the same values are found in both for J_{12} (3.8 c.p.s.) and J_{23} (<0.5 c.p.s.). By contrast, 4-substituted D-glucose derivatives—cellobiose and 4,6-*O*-ethylidene-D-glucopyranose—exhibit small and different kinds of spectral changes in the presence of borate, most noticeable being the absence of any effect on their anomeric proton signals. These pyranose derivatives also have relatively low electrophoretic mobility in borax (2) and give $\Delta\Delta R$ values only 20–25% of those for D-glucose and its 5-*O*-methyl, 3,5-di-*O*-methyl, and 5,6-carbonate derivatives. Hence the present data point to the likelihood that a furanose form is involved in the reaction of D-glucose with borate ions, while providing no support for the assumption (13) that the pyranose structure is retained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in the complex. Also, they support the conclusion of Boeseken (1) that D-glucofuranose contributes importantly to the conductivity of D-glucose – boric acid solutions.

A decrease in ring size during complex formation may well take place with other sugars. Thus the effect of borate on the n.m.r. spectrum of D-xylose (13) and on the vapor pressure equilibrium of D-arabinose (Fig. 4) is strikingly similar to its effect on the corresponding properties of D-glucose. The thermometric plot for D-fructose– and L-sorbose–borate (Fig. 4) closely duplicate that for the 5-membered-ring diols at the outset, consistent with formation initially of a furanose–spirane complex. With all of these sugars, in contrast to erythritan and D-glucose carbonate, the $\Delta\Delta R$ values do not go through a maximum at a $\Delta\Delta R$ of about 4, but this difference is due likely to additional reaction by borate with other free diol groupings present in the 1,2-complexes (see refs. 2 and 6). A somewhat different type of behavior is shown by D-mannose (Fig. 4) in that there is no marked change in the region characteristic of a 2:1 complex, but a constant $\Delta\Delta R$ value is obtained at a sugar: borate ratio of 1:1. The low degree of complexing observed for mannose is in accord with its relatively small electrophoretic mobility in borax (2).

Crystalline borate complexes of several diols have been prepared (4, 5) although, aside from those of the ester type, few have been reported in the sugar series (6). As shown with erythritan and D-glucose carbonate, complexes of the spirane type are easily obtained and might prove useful in the isolation and purification of furanose sugars and their derivatives. This possibility is illustrated further in the preparation of an ammonium borate complex of D-threose. Since the tetrose itself is not crystalline the borate salt offers the advantage of a derivative from which the free sugar can be regenerated under mild conditions, e.g., by use of ion-exchange resins. The n.m.r. spectral changes in signals for the anomeric proton observed during formation of this complex are virtually the same as shown in Fig. 4, the anomeric mixture being apparently converted entirely to the 1,2-*cis*-form. The spin-coupling constant J_{12} for the crystalline product is the same as that for the glucofuranose derivative and, as observed with erythritan, complexing markedly decreases splitting of the signals for the methylene protons.

The preferred conformation of 1,2-cyclic acetals and ketals appears to be one in which puckering of the ring makes for a dihedral angle of 35–45° between the two C—O bonds (15, 16). Chelates formed by the tetrahedral borate ion and *vic*-diols would be expected to adopt a similar type of energetically favorable conformation. It may be noted, therefore, that the spin-coupling constant J_{12} (3.8 c.p.s.) for the complex of D-glucofuranose 5,6-carbonate or of 5-*O*-methyl D-glucofuranose is the same as that reported for 1,2-*O*-isopropylidene-D-glucofuranose (15). Since, however, the relationship between coupling constant and dihedral angle (17) is influenced by the chemical nature of a compound (16), the actual size of the angle could be somewhat different in these two types of derivatives. A value of 45° given by the Karplus curve (17) probably is close to the true angle for the acetonide (15, 16) but may be slightly high for the borate, since 1,2-*cis*-cyclohexanediol reacts only weakly with borax (2, 3) yet its C—O bonds define an angle of 50° without the introduction of noticeable strain (18). A dihedral angle substantially smaller than that of the O—C_1—C_2—O grouping in the D-glucose products characterizes the complex formed between methyl β-D-erythroside and potassium tetraborate, as shown by a relatively large spin-coupling constant for J_{23} of 6.2 c.p.s. Since there is no reason to expect that the fused 5-membered rings of this latter complex are planar, the observed value of J probably represents a dihedral angle not too far removed from the 30° value given by the Karplus curve. However, complexing also can take place readily with a diol in which the hydroxyl groups are virtually eclipsed: camphane-2-*exo*,3-*exo*-diol, in which the two C—O bonds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

define an angle close to 0° (19, 20), gives approximately the same $\Delta\Delta R$ value (3.8 at a diol:borate ratio 2:1) as do methyl β-D-erythroside and D-glucose 5,6-carbonate. Hence the dihedral angle of the O—C—C—O grouping, within the range 0° to about 40°, does not appear to be a factor determining the stability of borate complexes.

The adverse influence of steric factors such as non-bonded interaction with groups close to the diol group is seen in the lower degree of complexing by methyl α-D-erythrofuranoside, as compared with that reported above for the β-(1,2-*trans*)-anomer ($\Delta\Delta R$ 2.87 vs. 3.93). This greater instability, associated with the larger number of 1,2-*cis*-interactions in the α-D-glycoside, is reflected more markedly in the behavior of D-erythrose and of 5-*O*-methyl D-mannofuranose (21). In these compounds there appears to be the possibility for complexing at the 1,2-position of the *cis*-anomer and also with the 2,3-*cis*-diol group. The n.m.r. spectrum of each sugar indicates that the 1,2-*trans*-anomer greatly predominates in solution. Displacement of the equilibrium towards formation of a 1,2-*cis*-complex, as found with D-threose and the D-glucofuranose derivatives, involves more unfavorable interactions than when the 2,3-complex is formed. Changes produced by borate on the n.m.r. spectra of these sugars show, accordingly, that although considerable complexing must occur, little can involve the C_1-hydroxyl since signals for the anomeric protons are not shifted to lower field.

EXPERIMENTAL

Proton magnetic resonance spectra were prepared with a Varian A-60 high-resolution spectrometer. Deuterium oxide was used as solvent and tetramethylsilane as external standard.

Measurement of Vapor Pressure Equilibrium

A thermoelectric "osmometer" (Mechrolab Inc., Mountain View, California) was used. Measurements were made with an aqueous probe at 37° C, the procedure being that used for determination of molecular weight. The solution was stored in a syringe mounted in the chamber, a drop of it was applied to the appropriate thermistor bead, and a drop of water to the other bead. Changes in resistance (ΔR) were noted at 3 minutes' equilibration time, the molarity was then obtained by reference to a plot of ΔR vs. molarity, prepared under the same conditions with standard solutions.

A typical estimate of the degree of borate complexing is given by the following data for erythritan and potassium tetraborate:

	ΔR		ΔR
0.1 *M* erythritan	5.37	0.1 *M* erythritan	5.37
0.02 *M* borate	6.42	0.04 *M* borate	11.83
Calc. for 1:1 mixture	11.79		17.20
Found	8.23		13.36
$\Delta\Delta R$ =	3.56		3.84

The calculated value for complete complexing is ΔR 5.37, i.e., the found ΔR value for a 0.1 *M* solution of an undissociated compound.

Some Properties of Potassium Tetraborate Solutions

The apparent molarity of potassium tetraborate solutions of varying concentration is given in Fig. 5.

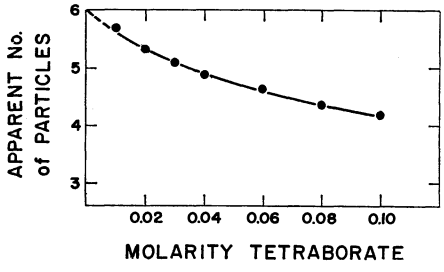

FIG. 5. Thermometric measurement of vapor pressure equilibria in solutions of potassium tetraborate.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

A change in ΔR equivalent to an overall decrease of approximately one particle in solution is found on addition of hydrochloric acid or sodium hydroxide to potassium tetraborate solution (the ΔR values for solutions of the acid and base themselves are approximately twice those for equimolar solutions of un-ionized compounds):

ΔR of 1:1 mixture with the borate solution

	ΔR	Calc.	Found	$\Delta\Delta R$
0.02 *M* borate	6.06			
0.01 *M* HCl	1.05	7.11	6.58	0.53
0.02 *M* HCl	2.09	8.15	7.22	0.93
0.01 *M* NaOH	1.03	7.09	6.57	0.52
0.02 *M* NaOH	2.06	8.12	7.09	1.03

Erythritan – Potassium Borate Complex (V)

Erythritan (660 mg; freshly distilled) and potassium tetraborate tetrahydrate (493 mg) were dissolved in water (1 ml), ethanol (3 ml) was added, and the solution stored at 3° C. After 18 hours the solid product was collected and washed twice each with ethanol and ether and dried *in vacuo*. Yield, 250 mg; highly birefringent needles. Calculated for $C_8H_{12}O_6KB$: C, 37.18%; H, 4.76%; K, 15.39%; mol. wt., 254 (unionized), 127 (ionized). Found: C, 34.17%; H, 4.75%; K, 15.29%; mol. wt. (osmometric), 118 in water.

Erythritan – Ammonium Borate Complex

Prepared as above for V from erythritan (528 mg) and ammonium tetraborate tetrahydrate (340 mg). Yield, 215 mg. Calculated for $C_8H_{16}NB.H_2O$: C, 38.27%; H, 7.23%; N, 5.58%. Found: C, 38.32%; H, 6.94%; N, 5.75%. A dihydrate was formed when the sample was equilibrated to atmospheric moisture for 3 hours. Calculated for $C_8H_{16}O_6NB.2H_2O$: C, 35.71%; H, 7.49%; N, 5.21%; mol. wt., 269 (unionized), 135 (ionized). Found: C, 35.34%; H, 7.35%; N, 5.02%; mol. wt., 126 in water (171 in ethanol).

D-*Glucose 5,6-Carbonate – Ammonium Borate Complex*

Prepared as for V from D-glucose 5,6-carbonate (1.13 g) and ammonium tetraborate tetrahydrate, $[\alpha]_D$ −10.0° (*c*, 2 water). Yield, 570 mg. Calculated for $C_{14}H_{20}O_{14}NB.3H_2O$: C, 34.23%; H, 5.34%; N, 2.85%; mol. wt., 491 (unionized), 246 (ionized). Found: C, 34.39%; H, 5.35%; N, 2.75%; mol. wt., 239 in water (450 in ethanol).

D-*Threose – Ammonium Borate Complex*

To a solution of D-threose (1.8 ml containing about 1.0 g of the sugar) was added ammonium tetraborate tetrahydrate. Ethanol (6 ml) was added and the solution was stored at 3° C, affording crystalline material (0.52 g); $[\alpha]_D$ −49.5° (*c*, 2 water). Calculated for $C_8H_{16}O_8NB.\frac{1}{2}H_2O$: C, 35.05%; H, 6.25%; N, 5.11%. Found: C, 34.86%; H, 6.16%; N, 5.04%.

The D-threose starting material, prepared via lead tetraacetate oxidation of D-galactose, contains several percent of D-lyxose (22). Treatment of the isolated complex with Amberlite-IR 120 followed by paper chromatographic examination showed that all but a trace of the pentose component had been removed.

ACKNOWLEDGMENT

Nuclear magnetic resonance spectra were measured at the University of Saskatchewan, through the kind cooperation of Professor K. J. McCallum.

FREE RADICALS BY MASS SPECTROMETRY

XXXI. H-ATOM AND D-ATOM REMOVAL IN THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF ISOBUTANE AND DEUTEROISOBUTANES[1]

T. F. PALMER[2] AND F. P. LOSSING
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received May 2, 1963

ABSTRACT

In the reaction of isobutane with Hg^3P_1 atoms, cleavage of the tertiary C—H bond is about seven times as frequent as cleavage of a primary C—H bond. This ratio is greatly changed by deuterium substitution in the tertiary position. Cleavage of the tertiary C—D bond in $(CH_3)_3CD$ occurs only about 0.6 times as frequently as cleavage of a primary C—H bond. In $(CD_3)_3CH$, no cleavage of a primary C—D bond could be detected, and only the tertiary H-atom is removed.

INTRODUCTION

The reaction of Hg^3P_1 atoms with isobutane has been the subject of a number of investigations, both as to the quenching cross section (1, 2) and the nature of the primary dissociation step (3, 4). This work, and its relation to the general question of the mercury-photosensitized reactions of other paraffins has recently been reviewed (5) and will not be discussed here in any detail. As for other paraffins, the primary dissociation in isobutane appears to involve only C—H bonds, but it is not clear whether the H-atom removed in this reaction is uniquely the tertiary H-atom, or whether removal of a primary H-atom occurs concurrently. Recent work on the quenching cross sections of deuterated propanes shows that the primary interactions of Hg^3P_1 with propane occurs mainly at the secondary C—H bonds (2), but the actual bond cleavage may occur at either position in a ratio not far from unity (6, 7). Taking account of the number of primary and secondary hydrogens available, it appears that secondary bond rupture is favored by a significant factor. In the present work an attempt has been made to determine the relative frequencies of bond rupture in isobutane, which contains only primary and tertiary C—H bonds.

In the course of this work, some experiments were carried out on deuteroisobutane. In agreement with recent findings of other workers (6, 7) substitution of D for H is found to have a large effect on the frequency of bond rupture.

EXPERIMENTAL

The Hg^3P_1-photosensitized reactions were carried out in a flow system coupled to a mass spectrometer, using the techniques previously described (8, 9). Although butyl radicals could be detected in the reaction when low-energy ionizing electrons were used, no identification of these as *t*-butyl or isobutyl could be made. Analysis of the ratio of *t*-butyl radicals to isobutyl radicals by means of the relative amounts of the three possible dimerization products proved not to be feasible. Owing to the small amount of radicals formed initially and to an appreciable loss of these by secondary reactions with excited mercury atoms or, more probably, with H-atoms (6), the quantity of octanes was extremely small. The mass spectra of the three possible octanes, moreover, in the region free from interference by isobutane (i.e. above mass 58) consists of peaks of low intensity. Above mass 57, for example, the spectra of 2,2,4-trimethylpentane and 2,2,3,3-tetramethylbutane have no peaks with intensities greater than 6% of the base (most intense) peak. The solution to this analytical problem therefore rested on the "trapping" of the butyl radicals with an excess of CD_3 radicals produced from the Hg-photosensitized decomposition of $Hg(CD_3)_2$ added to the reaction

stream (9). With such an excess, the reactions of the butyl radicals were reduced to the four combination and disproportionation reactions

$$(CH_3)_3C + CD_3 \xrightarrow{k_1} (CH_3)_3CCD_3 \quad [1]$$

$$\xrightarrow{k_2} CD_3H + \text{isobutene} \quad [2]$$

$$(CH_3)_2CHCH_2 + CD_3 \xrightarrow{k_3} (CH_3)_2CHCH_2CD_3 \quad [3]$$

$$\xrightarrow{k_4} CD_3H + \text{isobutene}. \quad [4]$$

Assuming all other reactions of butyl radicals to be swamped by these reactions, the quantities of *t*-butyl and isobutyl radicals can be estimated from the yields of neopentane-d_3 and isopentane-d_3, and the disproportionation to combination ratios k_2/k_1 and k_4/k_3. The analysis of the pentanes was carried out using the mass-60 peak ($(CH_3)_2{}^+CCD_3$) for neopentane-d_3 and the mass-75 peak (parent ion) for isopentane-d_3. The mass spectral sensitivity coefficient for neopentane-d_3 was measured using a sample of the pure compound. No standard sample of isopentane-d_3 was available, so the sensitivity coefficient was taken to be the same as that of undeuterated isopentane. Since the comparison involves only parent ions, this assumption introduces little error.

Samples of the deuterated species, isobutane-d_1, isobutane-d_9, neopentane-d_3, and $Hg(CD_3)_2$ were obtained from Merck and Co., Montreal. A sample of neopentane-d_9 was prepared by the Grignard reaction from $(CD_3)_3Cl$ (97%, Merck and Company), followed by purification by VPC on a squalane–celite column at 45° C. The neopentane-d_9 was found to have an isotopic purity of 96%.

The sample of isobutane-d_9 contained about 5% of isobutene-d_8. This was removed by passing it through the squalane column at room temperature.

RESULTS AND DISCUSSION

The results obtained by the addition of increasing amounts of $Hg(CD_3)_2$ to the reaction stream carrying a partial pressure of 7 μ of isobutane are shown in Fig. 1. The yield of

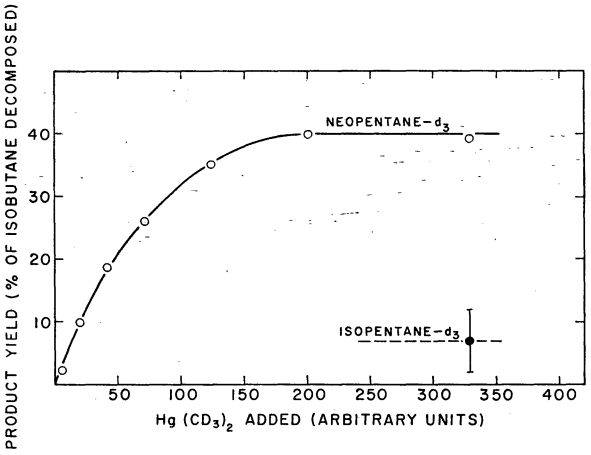

FIG. 1. Limiting yields of neopentane and isopentane formed by adding an excess of CD_3 radicals to the reaction stream containing Hg^3P_1 atoms and $(CH_3)_3CH$.

neopentane-d_3 (per isobutane decomposed) increased rapidly with added $Hg(CD_3)_2$ and levelled off at about 40%. The limiting yield of isopentane-d_3 was extremely small, amounting to about 7% with an estimated accuracy of ±5%. This yield is shown as a single point in Fig. 1 at the highest pressure of $Hg(CD_3)_2$. With lower amounts of $Hg(CD_3)_2$ the mass-75 peak was barely detectable. Taking $k_2/k_1 = 0.9$ (10, 11), the maximum yield of neopentane-d_3, 40%, corresponds to a 76% yield of *t*-butyl radicals. The disproportionation-to-combination ratio k_4/k_3 is not known, but by comparison with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ratios for $CH_3 + n\text{-}C_4H_7$ and $CH_3 + t\text{-}C_4H_7$, a value of 0.5 seems reasonable. Taking $k_4/k_3 = 0.5$, the yield of isopentane-d_3 ($7\pm5\%$) corresponds to a yield of 11% for isobutyl radicals, with a rather large uncertainty. These values give an overall yield of $87\pm10\%$. On the assumption that the missing $13\pm10\%$ is distributed proportionately between *t*-butyl and isobutyl radicals, these results show that in the primary dissociation tertiary C—H bond cleavage accounts for about 87% of the total reaction, and is therefore about seven times as frequent as cleavage of a primary C—H bond. Owing to the uncertainties in the isopentane-d_3 yield and in the ratio k_4/k_3, the ratio of tertiary/primary cleavage could be as low as 4 or as high as 10.

Deuteroisobutanes

A possibility not considered in the foregoing discussion is that of an isomerization of isobutyl radicals to *t*-butyl radicals. This point was investigated using isobutane-d_1, $(CH_3)_3CD$. If an isobutyl radical formed from this species isomerizes to *t*-butyl and combines with CD_3, the neopentane formed would be -d_4. No neopentane-d_4 was detected in this experiment, and the possibility of a significant amount of isomerization in this system at 55° C can be ruled out.

The introduction of a D-atom in the tertiary position, however, caused a large change in the ratio of initial bond rupture, as can be seen from Fig. 2. The major combination

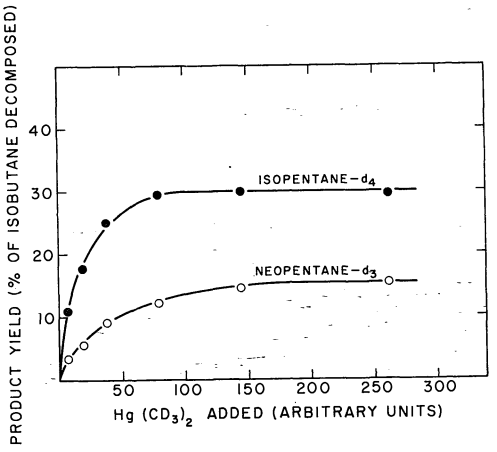

FIG. 2. Limiting yields of neopentane and isopentane formed by adding an excess of CD_3 radicals to the reaction stream containing Hg^3P_1 atoms and $(CH_3)_3CD$.

product on the addition of CD_3 is isopentane, rather than neopentane as in Fig. 1. For $(CH_3)_3CD$, the two dissociation reactions are

$$(CH_3)_3CD + Hg^* \rightarrow (CH_3)_3C + D + Hg \quad [5]$$

$$\rightarrow (CH_3)_2CDCH_2 + H + Hg. \quad [6]$$

Addition of CD_3 radicals to the stream gives the combination and disproportionation reactions [1] and [2] for *t*-butyl as before, and reactions [7] and [8] for isobutyl

$$(CH_3)_2CDCH_2 + CD_3 \xrightarrow{k_7} (CH_3)_2CDCH_2CD_3 \quad [7]$$

$$\xrightarrow{k_8} CD_4 + \text{isobutene}. \quad [8]$$

Taking $k_2/k_1 = 0.9$, the limiting yield of 15% of neopentane-d_3 corresponds to a yield of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

29% for *t*-butyl radical formation. Assuming $k_8/k_7 = k_4/k_3 \approx 0.5$, the limiting yield of isopentane (30%) corresponds to a yield of 45% for isobutyl radicals. The total yield in this case is about 74%. The ratio of tertiary to primary bond rupture for $(CH_3)_3CD$ is therefore about 0.6, as compared to about 7 for $(CH_3)_3CH$.

With such a large factor favoring C—H bond cleavage over C—D bond cleavage, one might expect that the decomposition of isobutane-d_9 $(CD_3)_3CH$ would be almost entirely by a tertiary C—H rupture. Figure 3 shows the yield of neopentane-d_9 obtained by

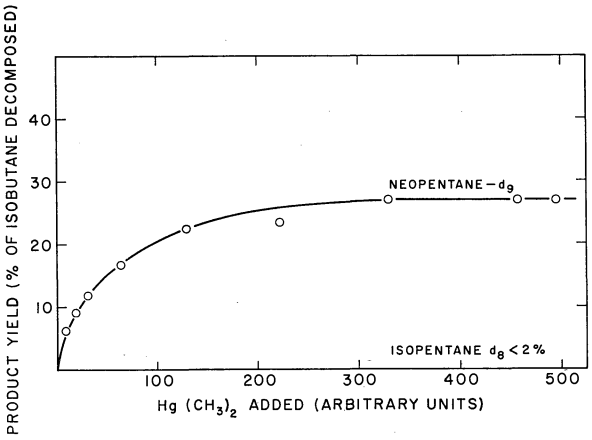

FIG. 3. Limiting yields of neopentane and isopentane formed by adding an excess of CH_3 radicals to the reaction stream containing Hg^3P_1 atoms and $(CD_3)_3CH$.

reacting $(CD_3)_3CH$ with Hg* in the presence of increasing amounts of $Hg(CH_3)_2$. Any isopentane-d_8 that may have been formed was below the limit of detection, i.e., less than 2%. The yield of neopentane-d_9 rose with increasing $Hg(CH_3)_2$, and levelled off at 27%. This is much less than the limiting yield of neopentane-d_3 from $(CH_3)_3CH$ (Fig. 1), even though no evidence for isobutyl radical formation could be found. Unless the total yield in this case is much lower for some unknown reason, it would appear that the disproportionation-to-combination ratio for $CH_3 + (CD_3)_3C$ must be much greater than for $CD_3 + (CH_3)_3C$. Owing to this uncertainty, a reliable upper limit for the yield of isobutyl radicals from $(CD_3)_3CH$ cannot be obtained from these results. However, since the isopentane yield was less than 2% it can be estimated that the ratio of tertiary to primary cleavage is probably greater than 20.

The large effect of deuterium substitution on the frequency of bond rupture in isobutane is similar to that reported recently for propane (6, 7). The ratios of secondary to primary bond cleavage in $(CH_3)_2CH_2$ and $(CH_3)_2CD_2$ were 1.2 and 0.2 (6) (1.38 and 0.3 (7)). In the present work the ratios for tertiary to primary bond cleavage in $(CH_3)_3CH$ and $(CH_3)_3CD$, 7 and 0.6, exhibit a change which is about the same or possibly a little larger. The overall effect on the secondary C—H bond in propane has been defined by Gunning *et al.* (7) as

$$[k_i(\mathrm{H})/k_i(\mathrm{D})] = [\sigma_Q^2(\mathrm{H})/\sigma_Q^2(\mathrm{D})] \times [\%(i\text{-pr})_H/\%(i\text{-pr})_D].$$

For $(CH_3)_2CH_2$ and $(CH_3)_2CD_2$, the secondary bond effect was found to be 18. Defining a tertiary bond effect in the same way

$$[k_t(\mathrm{H})/k_t(\mathrm{D})] = [\sigma_Q^2(\mathrm{H})/\sigma_Q^2(\mathrm{D})] \times [\%(t\text{-bu})_H/\%(t\text{-bu})_D]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and using the quenching cross sections measured by Gunning *et al.* (7), the ratios for t-C—H and t-C—D bond rupture found in this work give $k_t(H)/k_t(D)$ for isobutane to be $[4.8/0.44]\times[87/39] = 24$.

REPLACEMENT REACTIONS IN THE QUINIC ACID SERIES[1,2]

P. A. J. GORIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received March 8, 1963

ABSTRACT

The action on D-quinic acid of hot 95% acetic acid containing mineral acid gave, after complete acetylation, 1,4,5-tri-*O*-acetyl-epi-quinide consisting of approximately equal portions of the (−)- and (±)-isomers, and tetra-*O*-acetyl-scyllo-quinic acid. The stereochemistry of the products and their derived free polyols were determined by nuclear magnetic resonance (n.m.r.) spectroscopy and synthesis.

Elimination of the tosyloxy group in 5-tosyl-epi-quinicol was shown to take place readily in aqueous acetic acid with participation of the primary carbinol group to give an anhydro quinicol derivative and epi-quinicol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It has been shown (1) that certain inositols can be converted to partly acetylated stereoisomers by refluxing with 95% acetic acid – mineral acid. Inversion takes place most readily when one hydroxyl group in a six-membered ring has an adjacent *cis*-hydroxyl on one side and a *trans*-hydroxyl on the other. Such an arrangement is common in the more readily available inositols, *O*-methylinositols, quercitols, and cyclohexanetetrols. Reactions involving these materials have been evaluated, both from a preparative point of view and as a means of calculating non-bonded interaction energies in six-membered rings (2).

D-Quinic acid, by virtue of the orientation of its hydroxyl groups, should also undergo modification to yield partly acetylated derivatives of its optically active stereoisomer. Accordingly, quinic acid was treated for several days in refluxing 95% acetic acid containing 1.5% sulphuric acid. Gas phase chromatographic examination of the product after complete acetylation followed by treatment with diazomethane indicated that at least five materials were present. The reaction when followed by this method showed that equilibrium was not reached in 93 hours at which time carbonization in the medium was considerable. Because of this consideration and the complexity of the mixture the system does not lend itself to the calculation of non-bonded interaction energies, but only to the preparation of new isomeric quinic acid derivatives.

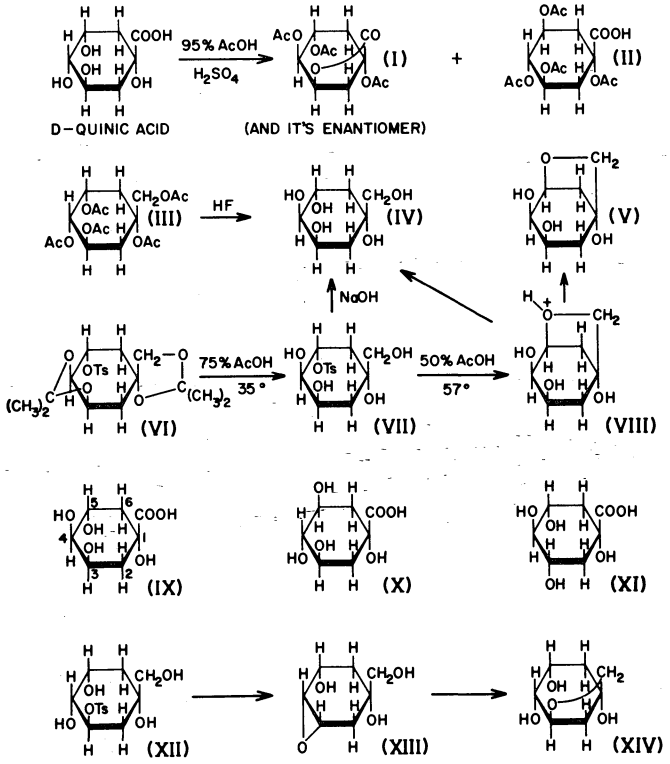
The reaction product obtained after 100 hours was acetylated with acetic anhydride to give a mixture containing 45% lactone and 55% free acid. Two chemically distinguishable compounds were isolated by fractional crystallization. One of these, obtained in 5% yield, was an optically inactive stereoisomer of tetra-*O*-acetyl-D-quinic acid, indicating that the reaction was not as stereospecific as with hexasubstituted cyclitols. The other product was isolated in 17% yield and shown to be an optically active γ-lactone triacetate with an empirical formula of $C_{13}H_{16}O_8$ (I). On fractional crystallization this product ($[\alpha]_D$ −61°) gave two materials, chemically the same, as indicated by their identical n.m.r. spectra, but having different specific rotations (−119° and 0°). The rotation of the optically active substance differed markedly from the D-quinic acid analogue (3) and although there are several structures possible for the active lactone only one (I) arising by inversion of the substituent at C-4 is possible. All other active lactones would be racemized in the equilibrium mixture on re-formation from the corresponding acid.

[1]*Issued as N.R.C. No. 7501.*

[2]*This work was carried out in part in the Department of Organic Chemistry, University of New South Wales, Sydney, Australia.*

Fletcher and Hedgeley (4) have shown that an acetate group bounded by *cis*- and *trans*-acetoxy neighbors in inositols can be inverted, with concomitant deacetylation, by the action of liquid hydrogen fluoride. In the present investigation this reagent, however, did not yield the lactone triacetate (I) readily from quinic acid. Starting with tetra-*O*-acetyl-D-quinic acid, a mixture of γ-lactones was obtained. Acetylation of this with acetic anhydride in pyridine yielded the highly crystalline optically active lactone triacetate, but only in 1% yield.

The lactone triacetate (I) prepared by the 95% acetic acid – sulphuric acid method could be reduced to a polyol using sodium borohydride. This polyol (IV) could be prepared definitively by treating the polyol pentaacetate (5) (III), derived from D-quinic acid, with liquid hydrogen fluoride. Chromatography yielded the required material which was characterized as its di-*O*-isopropylidene derivative. A similar type of reaction could be effected by treating the polyol with the 95% acetic acid reagent. However, the yield of desired product was poor probably due to simultaneous oxidation.



It should be noted that stereoisomers of quinic acid have not been previously obtained and named. Maquenne's nomenclature systems for cyclitols (6) is available and this can be modified in order to cover systematically the quinic acids and their derived alcohols. On the other hand, it is proposed that the three new quinic acids, described presently, be called epi-(−)-quinic acid (XI), epi-(±)-quinic acid, and scyllo-quinic acid (X). Although there are many types of compounds having somewhat similar names, it should not be confusing to call the corresponding alcohols epi-quinicol and scyllo-quinicol, respectively. The acids are numbered in the same way as in quinic acid (as depicted in IX) and the derived alcohols too, except that the hydroxymethyl carbon atom is called C-2′.

As mentioned previously one crystalline product obtained from quinic acid was an optically inactive isomer of tetra-*O*-acetyl-D-quinic acid which is believed to be tetra-*O*-acetyl-scyllo-quinic acid (II). This material, on examination by n.m.r. spectroscopy, gave two acetoxy proton signals, the greater at 2.06 p.p.m. and the other, one third in magnitude, at 2.22 p.p.m. Tetra-*O*-acetyl-D-quinic acid gave three signals at 2.07, 2.11, and 2.18 p.p.m. in the ratio of 2:1:1, respectively. The signal at 2.07 p.p.m. clearly corresponds to the equatorial acetoxy protons at C-4 and C-5 (7). It seems likely that the signal at 2.11 p.p.m. is from the C-3 acetoxy protons and the one at 2.18 p.p.m. arises from the C-1 acetoxy protons.* By analogy the signals in tetra-*O*-acetyl-scyllo-quinic acid would correspond to equatorial acetoxy protons at C-3, C-4, and C-5 (2.06 p.p.m.) and C-1 acetoxy protons (2.22 p.p.m.). Lithium aluminum hydride reduction of tetra-*O*-acetyl-scyllo-quinic acid methyl ester gave scyllo-quinicol and this was readily converted to its 2′,3,4,5-tetraacetate, the tertiary hydroxyl group remaining unacetylated. The n.m.r. spectrum of this material was in accord with that assigned to its acidic precursor since signals at 2.05 p.p.m. and 2.11 p.p.m. were obtained in the ratio 3:1. These should correspond to the protons of the equatorial 3-, 4-, and 5-acetoxyls and those of the primary acetoxyl respectively.

Synthesis of scyllo-quinicol was possible by two methods. It was isolated, in 3% yield, from the sodium borohydride reduction of crude quinide, that is, material obtained by lactonizing D-quinic acid at 210° C. These lactonizing conditions are milder than those of Hesse (8), who used 220–250° C and produced 'inactive quinide', as it was named by later workers. Evidently isomerization of the quinic acid or its derived lactone took place under these conditions and it would not be surprising if further examination of the crude mixture showed that other materials in the quinic series were present.

Attempts to improve the low yield were made by hydrogenolyzing D-quinicol at 165° C with copper chromite. This procedure, which can cause isomerization (9, 10) to yield all-*trans* methyl β-glucopyranoside starting from isomeric methyl β-hexopyranosides (11), gave scyllo-quinicol in only 2% yield. Increasing the temperature to 180° C gave mainly tetrols instead of quinicols and from the mixture one unidentified tetrol was isolated in a crystalline state.

Since a more definitive synthesis of scyllo-quinicol was required an alternative route was attempted. Reduction of crude 1,4,5-tri-*O*-acetyl-epi-quinide ($[\alpha]_D$ −61°) with sodium borohydride yielded epi-quinicol (IV), which was converted to its di-*O*-isopropylidene derivative with acetone – sulphuric acid. Tosylation gave 5-tosyl-2′,1:3,4-di-*O*-isopropylidene-epi-quinicol (VI) which proved to be racemic, and could be hydrolyzed to 5-tosyl-epi-quinicol (VII) with 75% acetic acid at 35° C. However, treatment of this substance with hot aqueous alkali gave mainly epi-quinicol (IV) and only a trace of material corresponding with scyllo-quinicol on a paper chromatogram.

The above n.m.r. and synthetic data therefore suggest that scyllo-quinic acid has either structure X or XI, with a preference for the former. Although the action of 95% acetic acid – mineral acid on D-quinic acid does not bring about equilibrium, the kinetic data obtained shows that, on extrapolation, it is unlikely that partly acetylated D-quinic acid or its racemate would ever predominate over the scyllo isomer. The formation of XI rather than X in such proportions would therefore not be likely in view of the higher free energy of the former.

At 57° C in 50% acetic acid further reaction of 5-tosyl-epi-quinicol took place, the

**Examination of tetra-O-acetyl-epi-quinic acid gave one signal only at 2.17 p.p.m., presumably due to time averaging.*

tosyloxy group being eliminated by rearward attack of the C-2′-hydroxymethyl group to yield a 2′,5-anhydro quinicol (V). From this a monoisopropylidene derivative and a triacetate could be prepared. The remainder of the product consisted of epi-quinicol (IV). This reaction appears to involve an oxonium ion intermediate (VIII) which can decompose via two separate routes. The participation of a hydroxyl group is rare, one of the very few unequivocal examples being the ring closure of tetramethylene chlorhydrin to yield tetrahydrofuran in water at 70° C (12).

The participation of the primary hydroxyl group of compounds in this series in alkaline elimination reactions can also be demonstrated. Treatment of 3-tosyl-D-quinicol (XII) with sodium methoxide and following of the reaction chromatographically showed the presence of an intermediate 1,2-epoxide (XIII) which rearranged to give 2′,3-anhydro-D-quinicol (XIV), a more rapid conversion occurring when aqueous alkali was used. These reactions bear a resemblance to the conversion of 4,1′6′-tri-*O*-tosylsucrose pentaacetate to 3,6-anhydro-α-D-galactopyranosyl-1,4:3,6-dianhydro-β-D-fructose using sodium ethoxide (13). In this case, an epoxide migration took place prior to formation of the 3,6-anhydro ring in the pyranose moiety.

EXPERIMENTAL

Solutions were evaporated under reduced pressure and specific rotations measured at 25° C.

Reaction of D-Quinic Acid with 95% Acetic Acid – Sulphuric Acid

A 1% solution of quinic acid in 95% acetic acid containing sulphuric acid (1.5% by volume) was refluxed. At appropriate intervals aliquots were withdrawn and added to excess pyridine – acetic anhydride (1:1). After a day at 40° C the solutions were added to excess dilute sulphuric acid and left until destruction of acetic anhydride was complete. Extraction with chloroform followed by evaporation yielded the acetate mixtures, which were treated in methanol with ethereal diazomethane. Gas chromatographic examination was carried out at 210° C on a 4-ft column of 2% LAC-IR-296 on Chromosorb W 80/100 mesh (14) using helium as carrier gas. The results (in %) are listed below:

Emergence order of acetates	Time (hr)					
	1	2.25	10.25	30	60	93
1 (Unknown)			2	4	8	14
2 (Tetra-*O*-acetyl-scyllo-quinic acid methyl ester)	6	10	17	31	32	25
3 (1,4,5-Tri-*O*-acetyl-D-quinide and tetra-*O*-acetyl-epi-quinic acid methyl ester)	16	25	34	20	16	16
4 (Tetra-*O*-acetyl-D-quinic acid methyl ester)	68	50	23	19	16	15
5 (1,4,5-Tri-*O*-acetyl-epi-quinide)	12	16	22	25	28	29

Preparation of Isomeric Quinic Acid Derivatives

In a typical run, D-quinic acid (10 g) was refluxed in 95% acetic acid (500 ml) containing sulphuric acid (7.5 ml) for 100 hours. After the mixture was cooled, acetic anhydride (500 ml) was added, the temperature not being allowed to rise above 50° C, and after 18 hours the acetylation mixture was added to excess ice water. The mixture was extracted twice with chloroform, washed once with water, dried ($MgSO_4$), filtered, and evaporated to a syrup which crystallized.

Crystallization was completed by addition of a little ether to yield a substance which was recrystallized twice from ethyl acetate – ether. It (2.72 g) had m.p. 176–178° C and $[\alpha]_D$ −61° (*c*, 2,2, $CHCl_3$). In the infrared there were two absorption bands at 1750 cm^{-1} corresponding to acetate carbonyls and a single peak at 1795 cm^{-1} due to a γ-lactone carbonyl of a quinic acid isomer (1,4,5-tri-*O*-acetyl-epi-quinide (I)). Calculated for $C_{13}H_{16}O_8$: C, 52.0%; H, 5.3%. Found: C, 51.65%; H, 5.0%.

Fractional crystallizations from chloroform – ethyl acetate yielded the (−)-isomer with m.p. 209–210° C and $[\alpha]_D$ −119° (*c*, 1.0, $CHCl_3$). The mother liquors contained the racemic isomer with m.p. 182–183° C. The n.m.r. spectra of these substances were identical.

After removal of the above lactone derivatives the mother liquors yielded more crystals from ether. Two further recrystallizations from ether yielded optically inactive tetra-*O*-acetyl-scyllo-quinic acid (II)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(0.92 g) with m.p. 198–200° C. It absorbed in the infrared at 1750 cm^{-1} (acetate carbonyl) and 1720 cm^{-1} (carboxyl carbonyl). Nuclear magnetic resonance spectroscopy in chloroform showed two proton signals, one at 2.22 p.p.m. corresponding to one acetate and the other at 2.06 p.p.m. to three acetate groups. Calculated for $C_{15}H_{20}O_{10}$: C, 50.0%; H, 5.6%. Found: C, 50.0%; H, 5.6%. Authentic tetra-*O*-acetyl-D-quinic acid gave three signals at 2.07, 2.11, and 2.18 p.p.m. in the ratio 2:1:1 respectively.

The crude mixture obtained above from D-quinic acid was fractionated on a silicic acid column. Lactones were eluted with chloroform and free acids with acetone. By a gravimetric estimation the mixture consisted of 45% lactone triacetates and 55% acid tetraacetates.

1,4,5-Tri-O-acetyl-epi-(−)-quinide (I) from Tetra-O-acetyl-D-quinic Acid using Hydrogen Fluoride

Liquid hydrogen fluoride (20 ml) was added to an ice-cooled polythene vessel containing tetra-*O*-acetyl-D-quinic acid (7.5 g). After the mixture had been left at 25° C overnight it was added to pyridine (100 ml) containing acetic anhydride (50 ml) and kept at 50° C for 6 hours. The acetylated products were isolated by addition to ice-cold 5% sulphuric acid (2 liters) and extraction with chloroform. The acetates, consisting entirely of γ-lactones with infrared absorption at 1800 cm^{-1}, were dissolved in ether (50 ml) and kept in the refrigerator for a week. The crystals which formed were recrystallized from ethyl acetate. The triacetyl-epi-quinide (80 mg) had m.p. and mixed m.p. 208° C and $[\alpha]_D$ −112° (*c*, 1.0, $CHCl_3$). Calculated for $C_{13}H_{16}O_8$: C, 52.0%; H, 5.3%. Found: C, 52.1%; H, 5.3%.

epi-(−)-Quinicol (IV) from Penta-O-acetyl-D-quinicol (III) using Hydrogen Fluoride

By a procedure similar to that described above, penta-*O*-acetyl-D-quinicol (2.00 g) was converted with hydrogen fluoride to a mixture of isomeric quinicol acetates (1.80 g). These were deacetylated in 0.1 *N* sodium methoxide (25 ml) and the resulting mixture of polyols was partially resolved by cellulose column chromatography using *n*-butanol one quarter saturated with water as solvent. The first compound eluted was epi-(−)-quinicol (211 mg) with $[\alpha]_D$ −3° (*c*, 4.1, MeOH). It was characterized by refluxing a 100-mg sample in acetone (15 ml) containing sulphuric acid (0.1 ml) for 3 hours. After neutralization (Na_2CO_3), filtration, and evaporation 2′,1:3,4-di-*O*-isopropylidene-epi-(−)-quinicol was obtained and recrystallized twice from hexane. It (37 mg) had m.p. and mixed m.p. 119–120° C and was identical with authentic material obtained from 1,4,5-tri-*O*-acetyl-epi-(−)-quinide by the method described later in this section. Calculated for $C_{13}H_{22}O_5$: C, 60.4%; H, 8.6%. Found: C, 60.3%; H, 8.5%.

scyllo-Quinicol and Derivatives from Tetra-O-acetyl-scyllo-quinic Acid (II)

Tetra-*O*-acetyl-scyllo-quinic acid was treated in methanol with an excess of ethereal diazomethane. On evaporation the methyl ester crystallized and after two recrystallizations from methanol had m.p. 145–148° C. Calculated for $C_{16}H_{22}O_{10}$: C, 51.3%; H, 5.9%. Found: C, 51.2%; H, 5.9%.

Crude methyl ester obtained from the free acid (1.3 g) was added in ether (25 ml) to refluxing ether (50 mg) which contained lithium aluminum hydride (1.5 g). After 1 hour ethyl acetate was added, followed by acetic acid, and the solution evaporated to dryness. Aqueous sodium hydroxide was added and the mixture heated at 100° C for 1 hour and the resulting suspension was treated with mixed-bed resin and filtered. Evaporation yielded a syrup (0.72 g), from which scyllo-quinicol could be isolated by crystallization. Two recrystallizations from methanol–ethanol gave 176 mg with m.p. 184–186° C. Calculated for $C_7H_{14}O_5$: C, 47.2%; H, 7.9%. Found: C, 47.0%; H, 7.8%.

The polyol (50 mg) was added to acetic anhydride – pyridine (1 ml:1 ml) which was heated at 100° C for 1 hour and the solvent then evaporated. Two recrystallizations from ether–hexane gave 2′,3,4,5-tetra-*O*-acetyl-scyllo-quinicol with m.p. 113–114° C. Calculated for $C_{15}H_{22}O_9$: C, 52.2%; H, 6.4%. Found: C, 52.0%; H, 6.3%. Examination of the acetate protons by n.m.r. spectroscopy in chloroform showed three protons at 2.11 p.p.m. and nine protons at 2.05 p.p.m.

Isolation of scyllo-Quinicol by Reduction of Crude D-Quinide

In a separate experiment quinic acid (10 g) was converted to a mixture containing mainly D-quinicol by the method used for the preparation of 3-tosyl-D-quinicol which is described later. Fractionation of the polyols on a cellulose column using *n*-butanol one quarter saturated with water as solvent gave D-quinicol (4.22 g) and scyllo-quinicol (0.31 g). The latter was recrystallized twice from ethanol to give a product with m.p. and mixed m.p. 185–186° C. Calculated for $C_7H_{14}O_5$: C, 47.2%; H, 7.9%. Found: C, 47.6%; H, 7.9%.

scyllo-Quinicol Formed by Hydrogenolysis of D-Quinicol

D-Quinicol (0.95 g) was dissolved in dioxane (50 ml) containing copper chromite (0.47 g) and hydrogenated for 6 hours at 165° C under 1000 p.s.i. of hydrogen. After filtration and evaporation a portion of the product was fractionated on a cellulose column as above to yield D-quinicol (437 mg) and scyllo-quinicol (45 mg). Two crystallizations of the latter from ethanol gave material with m.p. and mixed m.p. 184–185° C. Calculated for $C_7H_{14}O_5$: C, 47.2%; H, 7.9%. Found: C, 47.2%; H, 7.95%.

Repetition of the hydrogenolysis at 180° C with 2.0 g of D-quinicol gave a complex mixture, consisting mainly of tetrols. Only one of these was isolated crystalline by cellulose chromatography using benzene–ethanol–water (200:50:1) as solvent. Two recrystallizations from ethanol gave 55 mg of material with m.p. 151–152° C. Calculated for $C_7H_{14}O_4$: C, 51.8%; H, 8.7%. Found: C, 52.0%; H, 8.7%. No further characterization studies were carried out.

epi-Quinicol (IV) and its Di-O-isopropylidene Derivative from 1,4,5-Tri-O-acetyl-epi-quinide (I)

Crude 1,4,5-tri-*O*-acetyl-epi-quinide (8.0 g) consisting of a mixture of (−)- and (±)-isomers, was deacetylated by addition of 0.1 equivalent of 0.1 *N* sodium methoxide in methanol and the solution evaporated to dryness.

The de-esterified product was dissolved in methanol (100 ml) at 0° C, sodium borohydride (3.0 g) added and the solution left in the refrigerator overnight. The polyol was isolated by the procedure described previously for the preparation of D-quinicol.

The di-*O*-isopropylidene derivative was obtained by heating the polyol under reflux for 10 minutes in acetone (50 ml) containing sulphuric acid (0.5 ml). The solution was neutralized (Na_2CO_3) and then added to a chloroform–water mixture. After shaking the mixture, the chloroform layer was washed once with water and evaporated to a syrup. This crystallized and one crystallization from *n*-hexane yielded 2′,1:3,4-di-*O*-isopropylidene-epi-quinicol (3.0 g). A further crystallization gave material with m.p. 121–122° C and $[\alpha]_D$ 0° (*c*, 1.0, $CHCl_3$). Calculated for $C_{13}H_{22}O_5$: C, 60.4%; H, 8.6%. Found: C, 60.3%; H, 8.6%.

2′,1:3,4-Di-O-isopropylidene-5-tosyl-epi-(±)-quinicol (V)

The diacetone polyol (2.01 g) was treated overnight in pyridine (4 ml) containing tosyl chloride (2.0 g). After work-up of the product the tosylate was crystallized twice from ether and had m.p. 115–116° C and $[\alpha]_D$ 0° (*c*, 2.0, $CHCl_3$). Yield, 2.74 g. Calculated for $C_{20}H_{28}O_7S$: C, 58.6%; H, 7.1%. Found: C, 58.2%; H, 6.8%.

Alkaline Hydrolysis of 5-Tosyl-epi-quinicol (VII)

The tosyl derivative (0.10 g) was dissolved in 75% acetic acid (2 ml) and the solution kept at 35° C for 3 hours. Evaporation yielded a syrup which was dissolved in 0.1 *N* sodium hydroxide (10 ml) and then heated on a steam bath for 2 hours. Deionization of the solution and evaporation gave a product which contained mainly epi-quinicol and only a trace of a substance corresponding to scyllo-quinicol on a paper chromatogram (solvent: *n*-butanol–ethanol–water, 40:11:19; spray: ammoniacal silver nitrate (15)).

Elimination of Tosyloxy Group of 5-Tosyl-epi-quinicol in 50% Acetic Acid

The tosylate (2.7 g) was heated at 57° C in 50% acetic acid (250 ml) for 6 hours. Liberated toluenesulphonic acid was removed by addition of Dowex-1, and the solution evaporated to a syrup. A portion was acetylated and examined by gas phase chromatography using 1½% LAC-IR-296 on a celite column. Peaks corresponding to epi-quinicol (18%) and anhydro quinicol (87%) derivatives were detected. Fractionation on a cellulose column using *n*-butanol one half saturated with water as solvent gave the anhydro quinicol (1.09 g) and a little epi-quinicol (0.14 g; characterized as its di-*O*-isopropylidene derivative).

The anhydro fraction gave 520 mg of crystals (V) with an indeterminate melting point greater than 165° C after two crystallizations from ethanol and $[\alpha]_D$ 0° (*c*, 1.0, H_2O). Calculated for $C_7H_{12}O_4$: C, 52.5%; H, 7.55%. Found: C, 52.2%; H, 7.45%. It was converted to its triacetate by being heated in pyridine–acetic anhydride at 100° C for an hour. The product was crystallized twice from ether–hexane and had m.p. 151–153° C. Calculated for $C_{13}H_{18}O_7$: C, 54.5%; H, 6.3%. Found: C, 54.7%; H, 6.2%.

The anhydro compound (40 mg) was dissolved in acetone (20 ml) containing 2 drops of sulphuric acid and Drierite (5 g). After 3 hours the product was isolated after neutralization with sodium carbonate and extraction with chloroform from water. Crystallization from ether–hexane gave the isopropylidene compound with m.p. 98–99° C. Calculated for $C_{10}H_{16}O_4$: C, 60.0%; H, 8.05%. Found: C, 60.1%; H, 8.2%.

Starting from 1,4,5-tri-*O*-acetyl-epi-(−)-quinide the following derivatives were prepared and their specific rotations recorded: sodium epi-(−)-quinate, $[\alpha]_D$ −27° (*c*, 1.1, dil. NaOH); epi-(−)-quinic acid, $[\alpha]_D$ −18° (*c*, 1.0, H_2O); epi-(−)-quinicol, $[\alpha]_D$ −10° (*c*, 6.6, H_2O); 2′,1:3,4-di-*O*-isopropylidene-epi(−)-quinicol, $[\alpha]_D$ −9° (*c*, 10.0, $CHCl_3$), its 5-tosyl derivative, $[\alpha]_D$ −90° (*c*, 10.0, $CHCl_3$); and the derived anhydro compound, $[\alpha]_D$ −41° (*c*, 0.8, H_2O).

2′,1:4,5-Di-O-isopropylidene-3-tosyl-D-quinicol

The product obtained by heating D-quinic acid (10 g) at 210° C for 3 hours was dissolved in methanol (100 ml) which was made alkaline with sodium methoxide, and sodium borohydride (3.0 g) added. After 18 hours the solution was acidified with acetic acid and evaporated to dryness, the residue dissolved in water and treated with Amberlite-IR 120. Boric acid was removed by repeated evaporations in methanol. The product was refluxed for 10 hours in acetone (500 ml) containing sulphuric acid (2 ml). Excess sodium carbonate was added and when neutral the solution was evaporated to a solid which was partitioned between chloroform and water. The diisopropylidene polyol obtained by evaporation of the chloroform layer gave only gummy crystals and was therefore converted directly to its more crystalline tosyl derivative.

The syrup was dissolved in pyridine (20 ml) and tosyl chloride (5.0 g) added. After 18 hours the solution was cooled and excess reagent destroyed with a little water. Addition of excess water precipitated the tosylate, which was recrystallized from ethanol and had $[\alpha]_D$ −63° (*c*, 1.0, $CHCl_3$) and m.p. 149–152° C. Calculated for $C_{20}H_{28}O_7S$: C, 58.2%; H, 6.9%. Found: C, 58.3%; H, 6.8%.

3-Tosyl-D-quinicol (XII)

The di-*O*-isopropylidene tosyl quinicol (1.63 g) was hydrolyzed by being warmed for 6 hours at 60° C in 50% acetic acid (80 ml). The solution was evaporated and two recrystallizations of the residue from ethanol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

gave 3-tosyl-D-quinicol (0.81 g) with m.p. 136–138° C and $[\alpha]_D$ −51° (*c*, 1.6, MeOH). Calculated for $C_{14}H_{20}O_7S$: C, 50.6%; H, 6.1%. Found: C, 50.9%, 50.9%; H, 6.1%, 6.2%.

2′,3-Anhydro-D-quinicol (XIV) from Alkaline Elimination of 3-Tosyl-D-quinicol

3-Tosyl-D-quinicol (200 mg) was dissolved in methanol (3 ml) containing sodium (16 mg). After 3 hours at 5° C all starting material had disappeared and two new spots appeared on a paper chromatogram. On leaving the mixture overnight at room temperature the slower moving material disappeared and the solution was evaporated and deionized with mixed-bed resin. Filtration and evaporation yielded crystals which were recrystallized twice from ether containing a trace of ethanol. The 2′,3-anhydro-D-quinicol had a vague melting point greater than 160° C and $[\alpha]_D$ −20° (*c*, 1.0, H_2O). Calculated for $C_7H_{12}O_4$: C, 52.5%; H, 7.55%. Found: C, 52.5%; H, 7.6%. The above reaction was observed to take place more readily with aqueous sodium hydroxide.

ACKNOWLEDGMENTS

The author would like to thank Professor S. J. Angyal for his interest in this work. Thanks are due to Mr. M. Mazurek for carbon and hydrogen estimations and Mr. W. C. Haid for carrying out n.m.r. spectroscopic determinations.

PERFLUOROALKYL ARSENICALS

PART VIII. REACTION OF ARSENIC SULPHIDES WITH PERFLUOROALKYL IODIDES

W. R. CULLEN

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received May 10, 1963

ABSTRACT

$(CH_3)_2AsSC_2H_5$, prepared from $(CH_3)_2AsCl$ and $Pb(SC_2H_5)_2$, and $((CH_3)_2As)_2S_2$ react with R_fI at 100° to give the compounds $(CH_3)_2AsR_f$ ($R_f = CF_3$, C_3F_7). The compounds As_2S_x ($x = 2, 3$) do not react with CF_3I at 100°. $((CF_3)_2As)_2S$, prepared from $(CF_3)_2AsI$ and Ag_2S or from $(CF_3)_2AsH$ and S, reacts with Hg to give $((CF_3)_2As)_2$, decomposes at 175° to give $(CF_3)_3As$, and reacts with CF_3I at 125° to give mainly $(CF_3)_3As$. Some $(CF_3)_2AsI$ and $CF_3SAs(CF_3)_2$ is also produced from this last reaction.

Abel has reported (1) that the Si—S bond in *n*-butylthiotrimethylsilane is cleaved by *n*-butyl iodide to give iodotrimethylsilane and di-*n*-butyl sulphide:

$$(CH_3)_3SiSC_4H_9 + C_4H_9I \rightarrow (CH_3)_3SiI + (C_4H_9)_2S.$$

It was therefore of interest to determine if the reversed polarity of perfluoroalkyl iodides (2) would result in similar reactions taking place to give perfluoroalkyl silicon compounds, and preliminary studies in this laboratory indicate that this is so. However, in order to test the idea that this reaction might apply to systems other than those containing Si—S bonds a study of the reactions of some compounds containing As—S bonds has been made.

Ethylthiodimethylarsine, b.p. 150°, prepared from chlorodimethylarsine and lead mercaptide, reacts with trifluoroiodomethane and heptafluoroiodopropane at 100° to give dimethyltrifluoromethyl- and heptafluoropropyldimethyl-arsine respectively in moderate yield. In both reactions diethyl disulphide is formed so that addition of the perfluoroalkyl iodide to the As—S bond appears to take place to a considerable extent according to the following reactions:

$$(CH_3)_2AsSC_2H_5 + R_fI \rightarrow (CH_3)_2AsR_f + ISC_2H_5 \qquad (R_f = CF_3 \text{ or } C_3F_7)$$

$$2ISC_2H_5 \rightarrow C_2H_5S—SC_2H_5 + I_2.$$

Although other unidentified products are produced it is worth noting that iododimethylarsine is not formed in either reaction and that ethyltrifluoromethyl sulphide is not present in the reaction products obtained from the thioarsine and trifluoroiodomethane.

Dimethyltrifluoromethylarsine is also obtained in moderate yield from the reaction, at 100°, of trifluoroiodomethane with the compound formulated by Bunsen as cacodyl disulphide, $((CH_3)_2As)_2S_2$ (3). This compound is now known to have the structure $(CH_3)_2As(S)—S—As(CH_3)_2$ (4), thus only one As—S bond would be expected to be easily attacked by trifluoroiodomethane. An unusual feature of this reaction was the slow deposition of a colorless solid from the volatile reaction products. This solid which decomposed above 200° is provisionally identified as dimethyltrifluoromethylarsenic sulphide. The qualification arises because not enough material was available to fully characterize the compound.

Although trialkylarsines and tetramethyldiarsine react fairly readily with perfluoroalkyl iodides (5 and references cited therein, 6) arsines of the type R_2AsX (R = CH_3;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

X = halogen or C_6H_5) require temperatures in excess of 100° for reaction to occur (5 and references cited therein) and it is thought that these higher-temperature reactions involve attack by perfluoroalkyl radicals. The reactivity of compounds containing $(CH_3)_2As—S$ units therefore appears to be a function of the As—S bond, and the direction of addition of the perfluoroalkyl iodide to this bond appears to be a function of the polarity of this bond.

However, not all compounds containing As—S bonds react in this way since bistrifluoromethylarsenious sulphide reacts with trifluoroiodomethane at 125° to give low yields of iodobistrifluoromethylarsine and bistrifluoromethyl(trifluoromethylthio)arsine:

$$(CF_3)_2As—S—As(CF_3)_2 + CF_3I \rightarrow (CF_3)_2AsI + CF_3SAs(CF_3)_2.$$

The major volatile product is tristrifluoromethylarsine. The sulphide itself undergoes very slow decomposition when heated to 125° but when heated to 175° tristrifluoromethylarsine and arsenic disulphide are produced. Therefore, the reaction with trifluoroiodomethane at 125° seems to take place by two different paths, the minor one being the cleavage reaction described above, and the major one being the thermal decomposition reaction to produce tristrifluoromethylarsine. This arsine could also be formed by cleavage reactions of the sort

$$(CF_3)_2As—S—As(CF_3)_2 + CF_3I \rightarrow (CF_3)_2AsCF_3 + ISAs(CF_3)_2,$$

but this would use up much more trifluoroiodomethane than is found experimentally. The thermal decomposition reaction is faster in the presence of trifluoroiodomethane, suggesting that it is being catalyzed either by the trifluoroiodomethane or the products of the cleavage reaction. The direction of the cleavage reaction may be significant since the presence of two strongly electronegative groups on the arsenic could reverse the polarity of the As—S bond.

Neither arsenic trisulphide nor disulphide react with trifluoroiodomethane at 100°. The disulphide in particular could be expected to react easily with perfluoroalkyl iodides since it appears to contain both As—S and As—As bonds (7). However, recent molecular-orbital calculations on As_4S_4 and the related molecule S_4N_4 (8) indicate that in those compounds the bonding electrons are considerably delocalized so that the reactivity of the bonds may be considerably diminished.

Bistrifluoromethylarsenious sulphide, a colorless liquid, b.p. 86° (153 mm), is prepared from iodobistrifluoromethylarsine and silver sulphide at 20°:

$$2(CF_3)_2AsI + Ag_2S \rightarrow ((CF_3)_2As)_2S + 2AgI.$$

The sulphide is stable to water at 20° but reacts quantitatively with mercury to give tetrakistrifluoromethyldiarsine:

$$((CF_3)_2As)_2S + Hg \rightarrow ((CF_3)_2As)_2 + HgS.$$

A similar reaction is known for dimethylarsenious sulphide (9). Bistrifluoromethylarsenious sulphide is also produced when bistrifluoromethylarsine and sulphur are heated to 100°. There is no reaction between the two at 20°:

$$2(CF_3)_2AsH + 2S \rightarrow ((CF_3)_2As)_2S + H_2S.$$

Dimethylarsine has been reported to react with sulphur at 20° according to the following reactions (10):

$$2(CH_3)_2AsH + 2S \rightarrow ((CH_3)_2As)_2S + H_2S$$
$$2(CH_3)_2AsH + 3S \rightarrow ((CH_3)_2As)_2S_2 + H_2S.$$

In the present investigation the second of these reactions has been repeated. The yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of hydrogen sulphide is quantitative after 1 month and cacodyl disulphide is amongst the solid products. Cacodyl sulphide is reported to react with sulphur to give cacodyl disulphide (3) and therefore it is suggested that in both reactions of dimethylarsine with sulphur, cacodyl sulphide is first produced which, when excess sulphur is present, reacts further to give cacodyl disulphide:

$$(CH_3)_2As—S—As(CH_3)_2 + S \rightarrow (CH_3)_2As(S)—S—As(CH_3)_2.$$

On this basis the failure of bistrifluoromethylarsine to react with excess sulphur to give a disulphide would not be unexpected since disulphide formation to give a compound analogous to cacodyl disulphide would involve oxidation of one of the arsenic atoms by sulphur and the presence of the electronegative trifluoromethyl group would make this much more difficult. Thus, although trimethylarsine is easily oxidized by sulphur, tristrifluoromethylarsine does not react at 20° (11) and it has now been found that dimethyltrifluoromethylarsine does not react with sulphur at 100°.

EXPERIMENTAL

The apparatus and techniques used in this investigation were the same as have been described in previous papers in this series.

Preparation of Ethylmercaptodimethylarsine

Lead mercaptide was prepared and purified as described by Abel (1). The mercaptide (80 g) and chlorodimethylarsine (40 g) were refluxed in a nitrogen atmosphere for 4 hours. The volatile contents of the reaction flask were removed under vacuum and distilled at atmospheric pressure to give *ethylmercaptodimethylarsine*, b.p. 150° (75% yield). Anal. Found: C, 28.9; H, 6.62%, $C_4H_{11}AsS$ requires: C, 29.5; H, 6.44%. The compound was unstable to air, a white solid being slowly formed. The infrared spectrum showed the following absorption bands (liquid film): 2940 (s), 2900 (s), 2850 (sh,m), 2795 (sh,w), 1805 (vw), 1448 (s), 1425 (s), 1415 (s), 1370 (m), 1305 (vw), 1257 (s), 1050 (w), 967 (m), 895 (s), 837 (s), 825 (sh,w), 760 (m), 730 (w) cm^{-1}.

Reactions of Ethylmercaptodimethylarsine

(*a*) *With trifluoroiodomethane.*—The arsine (5.7 g) and trifluoroiodomethane (12 g) were heated to 100° for 6 days. Volatile products were taken into the vacuum system, leaving an orange liquid (0.5 g) in the tube. The infrared spectrum of this liquid showed the absence of any C—F bands. The liquid in an attempted distillation was heated to 250° in an atmosphere of nitrogen (760 mm) without decomposition. The liquid had a boiling point of 180–184° at 136 mm. Analysis gave C, 8.6; H, 1.92; As, 22.2; S, 6.30%, results which do not seem to fit any reasonable reaction product. The volatile products were separated by trap-to-trap distillation into unreacted trifluoroiodomethane, a fraction which condensed at −98° and which was identified by its infrared spectrum as dimethyltrifluoromethylarsine (3.6 g, 60% yield), and a fraction which condensed at −64°. The last fraction was distilled in a nitrogen atmosphere (760 mm) to give a few drops refluxing at 56–60° (probably dimethyltrifluoromethylarsine), otherwise it all distilled at 145–155°. This fraction, an orange liquid (1.5 g), was separated into two components by v.p.c. (dinonyl phthalate column at 140°). One component, ca. 15% of the mixture, on the evidence of its infrared spectrum contained C—F bonds, but the amount recovered did not allow characterization; the other component was identified as diethyl disulphide by means of its infrared spectrum.

(*b*) *With n-heptafluoroiodopropane.*—The arsine (6.9 g) and heptafluoroiodopropane (19.0 g) were heated to 100° for 9 days. The volatile contents of the reaction tube were taken into the vacuum system, leaving an orange oil similar to that obtained in the preceding experiment. The volatile fraction was carefully distilled at 760 mm in an atmosphere of nitrogen to give 5.8 g (51% yield) of heptafluoropropyldimethylarsine, b.p. 90–95° (lit. value 92° (6)), identified by its infrared spectrum, and a small fraction which distilled in the range 100–150°. Vapor phase chromatography (dinonyl phthalate columns at 140°) showed that this contained two main components; one of these was identified as unreacted ethylmercaptodimethylarsine by comparison of retention times, the other was identified as diethyl disulphide by its infrared spectrum and by analysis. Found: C, 39.3; H, 7.9%. Calc. for $C_4H_{10}S_2$: C, 40.2; H, 8.2%. The weight of the disulphide collected was 0.6 g.

Reaction of Cacodyl Disulphide with Trifluoroiodomethane

The sulphide was prepared by passing hydrogen sulphide through an alcoholic solution of dimethylarsinic acid (3). The sulphide (2.3 g) and trifluoroiodomethane (17.5 g) were heated to 100° for 5 days. Trifluoroiodomethane (14.3 g) was recovered. The only reaction products which were investigated were those which on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

preliminary separation passed through a trap cooled to −46°. This fraction slowly deposited a small amount of a colorless solid and was set aside until this deposition had stopped. The remaining liquid on trap-to-trap distillation gave 0.9 g of dimethyltrifluoromethylarsine which was identified by its molecular weight of 168 (calc.: M, 174) and by its infrared spectrum. The white solid decomposed at temperatures above 200° and showed polymorphic changes on heating. Analysis indicated that the solid was *dimethyltrifluoromethylarsenic sulphide*. Found: C, 17.4; H, 4.9; As, 35.8; S, 15.1%. $C_3H_6AsF_3S$ requires: C, 17.5; H, 2.92; As, 36.4; S, 15.5%.

Reaction of Arsenic Sulphides with Trifluoroiodomethane

Trifluoroiodomethane (10.0 g) and arsenic disulphide (10.0 g) were heated to 100° for 7 days. No fraction less volatile than trifluoroiodomethane (9.9 g) was isolated. A similar result was obtained when trifluoroiodomethane and arsenic trisulphide were heated to 100° for 4 days.

Preparation of Bistrifluoromethylarsenious Sulphide

Iodobistrifluoromethylarsine (5 g) and freshly prepared silver sulphide (17 g) were left for 12 days at 20°. A colorless liquid (3.5 g) was obtained which condensed as a solid in a trap cooled to −46°. This fraction distilled at 86° (153 mm) in a nitrogen atmosphere and was identified as *bistrifluoromethylarsenious sulphide*. Anal. Found: C, 10.6; H, 0.0; As, 32.5; F, 50.1; S, 6.79%; M, 455 (Rast). $C_4As_2F_{12}S$ requires: C, 10.5; H, 0.0; As, 32.8; F, 49.6; S, 6.99%; M, 458. The infrared spectrum showed the following absorption bands (vapor): 2320 (vw), 1257 (vw), 1187 (vw), 1159 (vs), 1130 (vs), 1105 (vs), 1060 (sh,w), 1045 (sh,w), 730 (s) cm^{-1}.

Reactions of Bistrifluoromethylarsenious Sulphide

(*a*) *With water.*—The sulphide (0.304 g) and water (3 ml) were immiscible and did not react at 20° (20 days).

(*b*) *With mercury.*—When the sulphide (0.514 g) and mercury (60 g) were shaken at 20° for 21 days tetrakistrifluoromethyldiarsine was produced (0.476 g, 100% yield). The diarsine was identified by its infrared spectrum and its molecular weight of 430 (calc.: M, 426).

(*c*) *Pyrolysis.*—The sulphide (0.410 g) was heated to 125° for 14 days. No involatile product was formed and the infrared spectrum of the recovered sample was essentially the same as that of the starting material. When the sulphide (0.152 g) was heated to 175° for 3 days tristrifluoromethylarsine (0.084 g; found: M, 279; calc.: M, 282), of known infrared spectrum, was produced. A red-yellow crystalline solid had formed on the tube walls and an X-ray powder photograph of this solid showed the presence of arsenic disulphide. Unchanged bistrifluoromethylarsenious sulphide (0.025 g) was recovered.

(*d*) *With trifluoroiodomethane.*—Trifluoroiodomethane (6.8 g) and the sulphide (0.786 g) were heated to 125° for 8 days. A red-yellow film slowly formed on the tube walls. Trifluoroiodomethane (6.6 g) was recovered and the volatile products were identified as tristrifluoromethylarsine (0.452 g; M, 281) and an orange-yellow mixture of iodobistrifluoromethylarsine and bistrifluoromethyl(trifluoromethylthio)arsine. The iodoarsine was identified by its infrared spectrum and by its reaction with mercury to give tetrakistrifluoromethyldiarsine. The mixture of the diarsine and the thioarsine weighed 0.116 g and the components could be separated well enough by trap-to-trap distillation to enable positive identification of their infrared spectra.

Reaction of Bistrifluoromethylarsine with Sulphur

There was no reaction when the arsine (0.591 g) and sulphur (0.6 g) were left for 20 days at 20°. When the same reactants were heated to 100° for 3 days hydrogen sulphide (0.0076 g; found: M, 34.0. calc.: M, 34.0) and bistrifluoromethylarsenious sulphide (0.328 g) were isolated. Bistrifluoromethylarsine (0.260 g) was recovered. All fractions were of known infrared spectrum.

Reaction of Dimethylarsine with Sulphur

The arsine (1.928 g) and sulphur (1.2 g) were left for 1 month at 20°. Large white crystals slowly formed and hydrogen sulphide (0.300 g, 100% yield; M, 34.1) was isolated. The solid was extracted with warm alcohol and the alcohol was removed *in vacuo*. The remaining white vile smelling solid was recrystallized from ether and was identified as slightly impure cacodyl disulphide by means of its X-ray powder photograph.

Reaction of Dimethyltrifluoromethylarsine with Sulphur

The arsine (2.701 g) and sulphur (1.0 g) did not react after 3 days at 115°. Recovery of the arsine was nearly quantitative (2.665 g).

PROTON MAGNETIC RESONANCE SPECTRUM OF 1-PHENYLCYCLOPROPYLCARBOXYLIC ACID: A_2B_2 SPECTRA OF CYCLOPROPANES

H. M. HUTTON[1] AND T. SCHAEFER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received May 21, 1963

ABSTRACT

A_2B_2 spectra of 1,1-disubstituted cyclopropanes have been calculated over a range of values of the spectral parameters. The sign of the geminal coupling is opposite to that of the vicinal couplings. Since this is also the case with other saturated ring systems the theoretical spectra should be useful in studies of other saturated ring systems.

The shifts and coupling constants are given for the protons in 1-phenylcyclopropylcarboxylic acid in solution in carbon disulphide, chloroform, and benzene as an example of the A_2B_2 analysis. The ring protons in 1-phenylcyclopropylcarbinol were found to be equivalent in different solvents, with insignificant coupling to the protons in the methylene and phenyl groups. A qualitative discussion of the shifts of the various protons in various solvents is given.

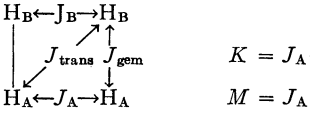
INTRODUCTION

The analysis of A_2B_2 spectra has been discussed in some detail (1, 2, 3), especially in regard to unsaturated ring systems (2, 3). Here we propose to discuss and illustrate with an example the probable A_2B_2 proton spectra for 1,1-disubstituted cyclopropanes. This discussion is applicable also to A_2B_2 arrangements in other fixed saturated ring systems (4, 5). From the collection of proton coupling constants in cyclopropanes (6 and references cited therein) and from spin decoupling experiments (7 and references cited therein) we know that the probable range of values is -4 to -8 c.p.s. for J_{gem}, 4 to 8 c.p.s. for J_{trans}, and 7 to 11 c.p.s. for J_{cis}, depending on the substituents. We use an approach similar to that which Martin and Dailey (2) applied to disubstituted benzenes except that we express our parameters in units of Δ, the chemical shift.

Computation of the A_2B_2 Spectra

For our systems there are four coupling constants as in I. J_A and J_B are the two cis couplings and the parameters K, L, M, N, and Δ are also defined.

I



$$\Delta = \eta H_0(\sigma_B - \sigma_A)$$

$$K = J_A + J_B \qquad N = J_{gem} + J_{trans}$$

$$M = J_A - J_B \qquad L = J_{gem} - J_{trans}$$

The secular equation for this system has been repeatedly tabulated (1, 2, 3). We refer the reader to page 2595 of reference 2 for the notation and give an abbreviated set of transitions in Table I to which we will refer later. The substitution of $-L$ for L does not alter the secular equation and that of $-M$ for M merely interchanges the labeling of certain transitions, so that the signs of L and M cannot be obtained from the spectrum. The spectrum is, however, sensitive to the relative signs of K and N (3). We here define K, the sum of the two cis coupling constants, to be positive (8 and references cited therein). N may then be negative or positive and, for the spectra under consideration, we have $N < 0$ for $|J_{gem}| > |J_{trans}|$ and $N > 0$ for $|J_{gem}| < |J_{trans}|$. It is almost certain that $J_{gem} < 0$ and that $J_{trans} > 0$ (6, 7, 8) and hence we have $L < 0$, which makes it possible

TABLE I

Computation of A_2B_2 spectra

Explicitly defined parameters			Solution of the 4×4 determinant
$2C_N = (\Delta^2+N^2)^{1/2}$	$\tan 2\phi = N/\Delta$		$p_m = E(mS_0^1) - H_{mm}(S_0)$ (E is the energy value and $H_{mm}(S_0)$ is the diagonal element in the representation used)
$2C_{LM\pm} = [(\Delta\pm M)^2+L^2]^{1/2}$	$\tan 2\theta_a = L/K$		
$2L_M = (L^2+M^2)^{1/2}$	$\tan 2\psi_\pm = L/(\Delta\pm M)$		

The coefficients C_{mn} of the diagonal representation are given by:
$(mS_0^1) = C_{m1}(1S_0)+C_{m2}(2S_0)+C_{m3}(3S_0)+C_{m4}(4S_0)$

Transitions in the high-field half-spectrum

Transition in c.p.s. from center of spectrum	Relative intensity	
1. $C_N+1/2N$		$1 - \sin 2\phi$
2. $\Delta+1/2N-C_N-p_1$	$[(C_{11}+C_{14})$	$\cos\phi - (C_{12}+C_{14})\sin\phi]^2$
3. $C_N-1/2N$		$1 + \sin 2\phi$
4. $\Delta-1/2N-C_N+p_2$	$[(C_{22}+C_{24})$	$\cos\phi + (C_{21}+C_{24})\sin\phi]^2$
5. C_N+K-p_3	$[(C_{32}+C_{31})$	$\cos\phi + (C_{31}+C_{34})\sin\phi]^2$
6. C_N+p_4	$[(C_{41}+C_{44})$	$\cos\phi - (C_{42}+C_{44})\sin\phi]^2$
7. C_N-p_4	$[(C_{42}+C_{44})$	$\cos\phi + (C_{41}+C_{44})\sin\phi]^2$
8. C_N-K+p_3	$[(C_{31}+C_{34})$	$\cos\phi - (C_{32}+C_{34})\sin\phi]^2$
9. $C_{LM+}+L_M$		$\sin^2(\theta_a-\psi_+)$
10. $C_{LM-}+L_M$		$\cos^2(\theta_a+\psi_-)$
11. $C_{LM+}-L_M$		$\cos^2(\theta_a-\psi_+)$
12. $C_{LM-}-L_M$		$\sin^2(\theta_a+\psi_-)$

to assign values to J_{gem} and J_{trans} from the spectrum. J_A and J_B will differ by hardly more than 1 c.p.s. in these systems (6). We therefore have no specific information as to the relative signs of L and M and we cannot distinguish between J_A and J_B from the spectra.

The eigenvalues and eigenvectors of the 4×4 determinant of the secular equation were computed on an IBM 1620. The theoretical spectra were obtained for all combinations of the parameters in units of the shift Δ:

$$K = 0.4, 0.6, 0.8, 1.0, 1.2, 1.5 \qquad M = 0, 0.01, 0.02, 0.04$$
$$L = 0.3, 0.4, 0.5, 0.6 \qquad N = -0.1, 0, 0.1, 0.2$$

These values correspond to the most probable values of the coupling constants (4, 5, 6) together with the values of Δ which would give rise to intelligible spectra. Some of the computed spectra are presented in Figs. 1 to 9. Since the spectra are symmetric about the centers, only the high-field halves are shown. Parentheses around transition 8 indicate that it now comes from the low-field proton transitions.

The Effect of the Parameters K, L, M, N

The effect of the relative signs of the coupling constants and the magnitudes and signs of the parameters K, L, M, N upon the A_2B_2 spectra has been discussed in detail by Grant *et al.* (3). The changes which occur specifically for 1,1-disubstituted cyclopropanes will be outlined.

(a) Parameter K

The K parameter does not change the positions of lines 1 and 3 nor those of the antisymmetric set of transitions 9, 10, 11, 12. It does, however, change the position of the symmetric set of transitions 5, 6, 7, 8, of line 2, and of line 4 to a small extent. Line 2, at a position of $\Delta+\frac{1}{2}N-C_N-p_1$, moves toward the outer portion of the B spectrum as K

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

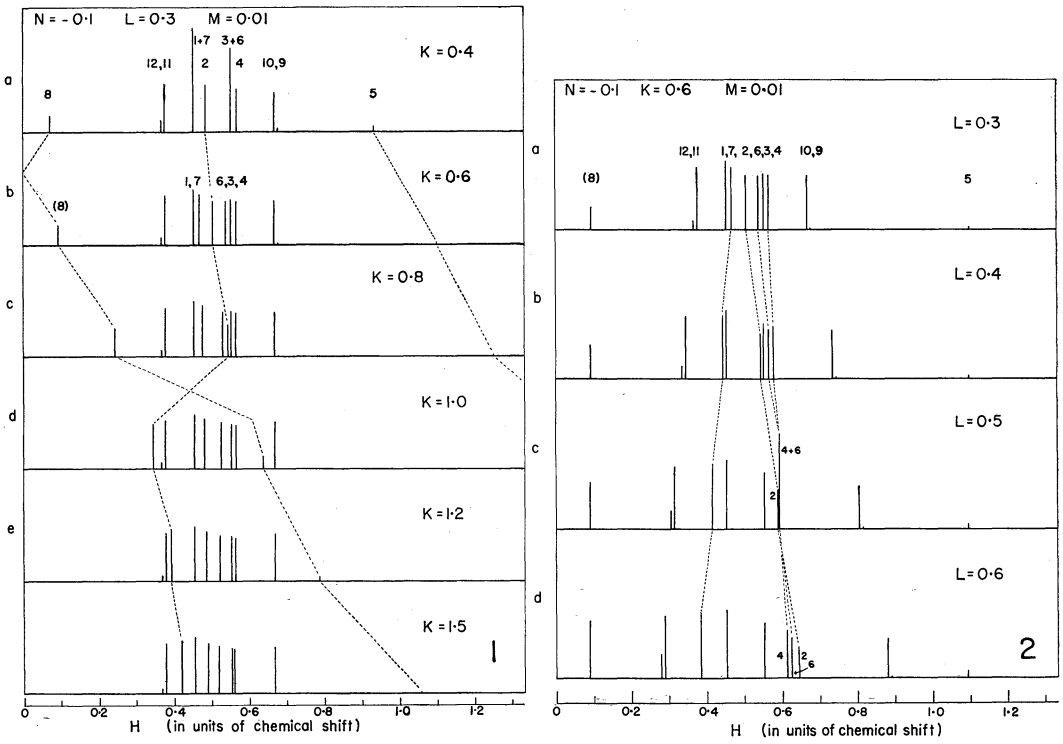

FIG. 1. The variation of the spectrum with a change in the parameter K is presented for $N = -0.1\Delta$, $L = 0.3\Delta$, and $M = 0.01\Delta$. The high-field B transitions of the symmetrical A_2B_2 spectrum are illustrated with the magnetic field in units of the chemical shift from the center of the spectrum. The parentheses around transition 8 indicate in this and all succeeding diagrams that it is an A transition overlapping the B spectrum. The intensities of transitions 5 and 9 have been doubled relative to the intensities of the other transitions. The parameters K, L, N, M are given in units of the chemical shift Δ.

FIG. 2. Starting with the spectrum presented in Fig. 1(*b*), the spectral changes due to the parameter L are shown for $N = -0.1\Delta$, $K = 0.6\Delta$, and $M = 0.01\Delta$. The changes in the spectrum when varying L from 0.3Δ to 0.6Δ for the other values of the parameter K in Fig. 1 are the same as that given here for the case of $K = 0.6\Delta$.

increases until $|K| > |-\Delta-\frac{1}{2}N|$. At this point the valve of p_1 reverses sign, bringing line 2 back into the interior of the spectrum. These changes in the spectrum can be seen in Figs. 1, 3, 5, and 7 for $L = 0.3\Delta$, $N = -0.1\Delta$, 0, 0.1Δ, 0.2Δ.

The parameter K may be approximated from the spectra as the differences $\nu_8-\nu_7 = \nu_6-\nu_5$.

(b) Parameter L

The change in the spectrum with an increase in the value of L from 0.3Δ to 0.6Δ can be seen in Figs. 2, 4, 6, and 8. Both the antisymmetrical transitions 9 through 12 and the symmetrical transitions 5 through 8 are affected by an increase in L. As L increases the difference $\nu_8-\nu_7 = \nu_6-\nu_5$ becomes less and less a reasonable approximation to the value of K. Transitions 2 and 4 also shift with an increase in L, but 1 and 3 are unaffected. When $|L| \gg |M|$, L may be obtained almost exactly from the spectrum as the difference between lines 9, 11 or 10, 12. This is very likely the case for 1,1-disubstituted cyclopropanes.

(c) Parameter N

Lines 1 to 4 are most affected by a change of N. As N decreases to zero lines 1, 3 coalesce at the chemical shift position and reverse their relative positions when N becomes negative.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

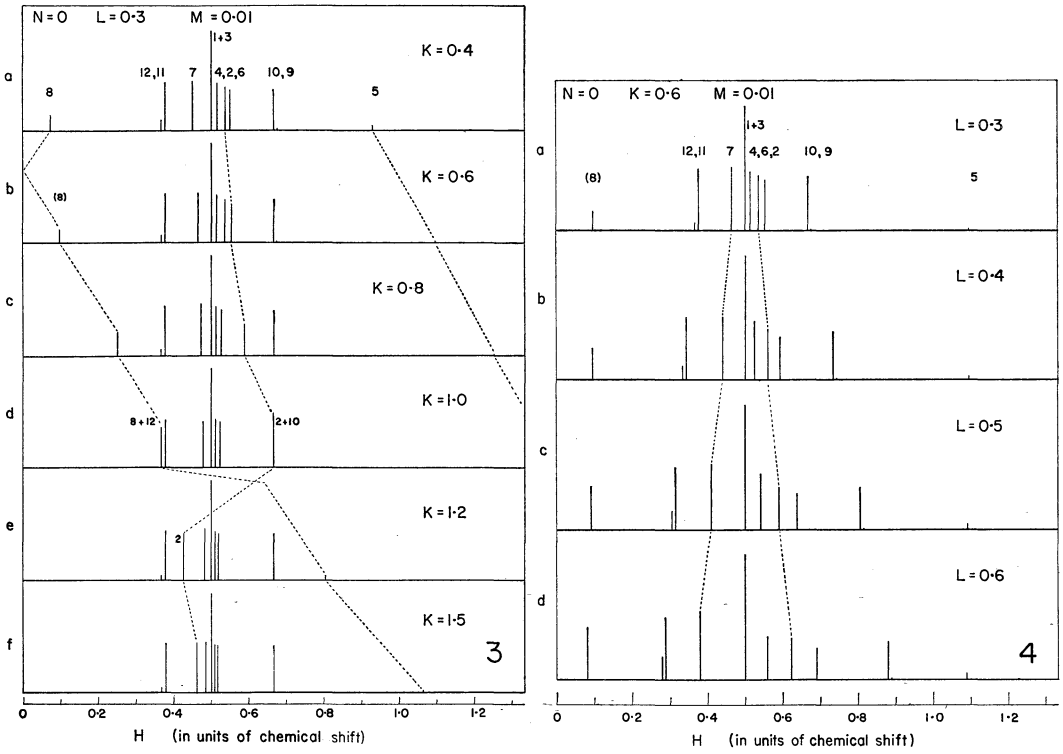

FIG. 3. The variation of the spectrum with a change in the parameter K is presented for $N = 0$, $L = 0.3\Delta$, and $M = 0.01\Delta$.

FIG. 4. Starting with the spectrum presented in Fig. 3(*b*) the spectral changes due to the parameter L are shown for $N = 0$, $K = 0.6\Delta$, and $M = 0.01\Delta$. The changes in the spectrum when varying L from 0.3Δ to 0.6Δ for the other values of the parameter K in Fig. 3 are the same as that given here for the case of $K = 0.6\Delta$.

Lines 1 and 3 are always separated by the algebraic value of N. The most important change as N goes from a positive to a negative value is that of lines 2 and 4. These two lines reverse their relative positions so that the sign of N can be distinguished from the appearance of the spectrum as shown in Figs. 1 and 5, 2 and 6. This indicates the relative signs of J_{gem} and J_{trans} in substituted cyclopropanes. The antisymmetrical transitions 9 to 12 are unaffected by a change of N. The symmetrical quartet 5 to 8 is also not significantly changed over the small range over which N has been varied.

(d) Parameter M

The M parameter affects only the positions of the antisymmetrical set 9 to 12 for any given value of L. As a first approximation the value of M may be taken as the difference between lines 9 and 10 or 11 and 12. As M increases from zero lines 11, 12, and 9, 10 separate, as Fig. 9 indicates. Since $M = J_A - J_B$ is of the order of 1 c.p.s. or less (6) the spectra presented have all been calculated assuming a small, and rather arbitrary, value of $M = 0.01\Delta$.

Analysis of Spectra

The A_2B_2 spectra for cyclopropane derivatives can be conveniently analyzed using the transition frequencies of Martin and Dailey (2) given in Table I. The use of symmetry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

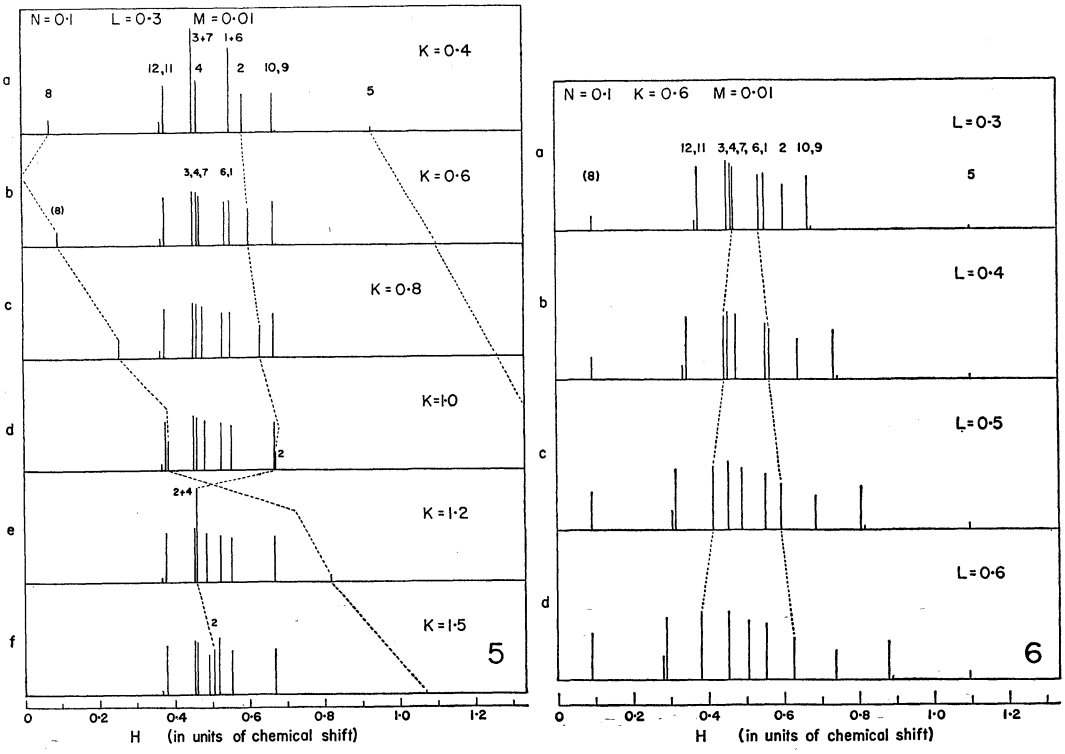

FIG. 5. The variation of the spectrum with a change in the parameter K is presented for $N = 0.1\Delta$, $L = 0.3\Delta$, and $M = 0.01\Delta$. A comparison of corresponding spectra in this diagram and Fig. 1 illustrates the spectral change for N negative $|J_{gem}| > |J_{trans}|$ and N positive $|J_{gem}| < |J_{trans}|$.

FIG. 6. Starting with the spectrum presented in Fig. 5(*b*), the spectral changes due to the parameter L are shown for $N = 0.1\Delta$, $K = 0.6\Delta$, and $M = 0.01\Delta$. Here also, a comparison with the corresponding spectra in Fig. 2 illustrates the difference for a negative and positive value of N. The changes in the spectrum when varying L from 0.3Δ to 0.6Δ for the other values of the parameter K in Fig. 5 are the same as that given here for the case of $K = 0.6\Delta$.

and of the spin operator leaves only one 4×4 determinant which cannot be solved explicitly. The transitions which arise from this subdeterminant are lines 2, 4, 5, 6, 7, 8. These lines involve the quantities p_m and C_{mn} which must be obtained from the numerical solution of the 4×4.

Since the frequencies and intensities of the remaining transitions are given explicitly in terms of the molecular parameters Δ, L, N, and M, the main problem is the identification of these lines. The value of N may be obtained from the difference of lines 1 and 3 and the chemical shift Δ from the position of either 1 or 3 with respect to the center of the spectrum. L and M may be calculated from lines 9, 10, 11, 12. When $|L| \gg |M|$, as will normally be true for these spectra, the parameter L may be obtained from $\nu_9 - \nu_{11} = \nu_{10} - \nu_{12}$. M will be approximately $\nu_9 - \nu_{10} = \nu_{11} - \nu_{12}$. These two parameters can then be adjusted to fit the experimental and theoretical spectra to within the accuracy desired.

One parameter, K, remains to be evaluated. The values obtained for Δ, N, and L are used to solve the 4×4 numerically with the method of successive approximations to find the value of K. The lines which vary the most with a change of K, lines 2 and 8, are a good means of identifying the correct value of K. If a fit between the experimental and theoretical transitions cannot be obtained using N as a positive quantity, then the calculations should be repeated for N negative.

For personal use only.

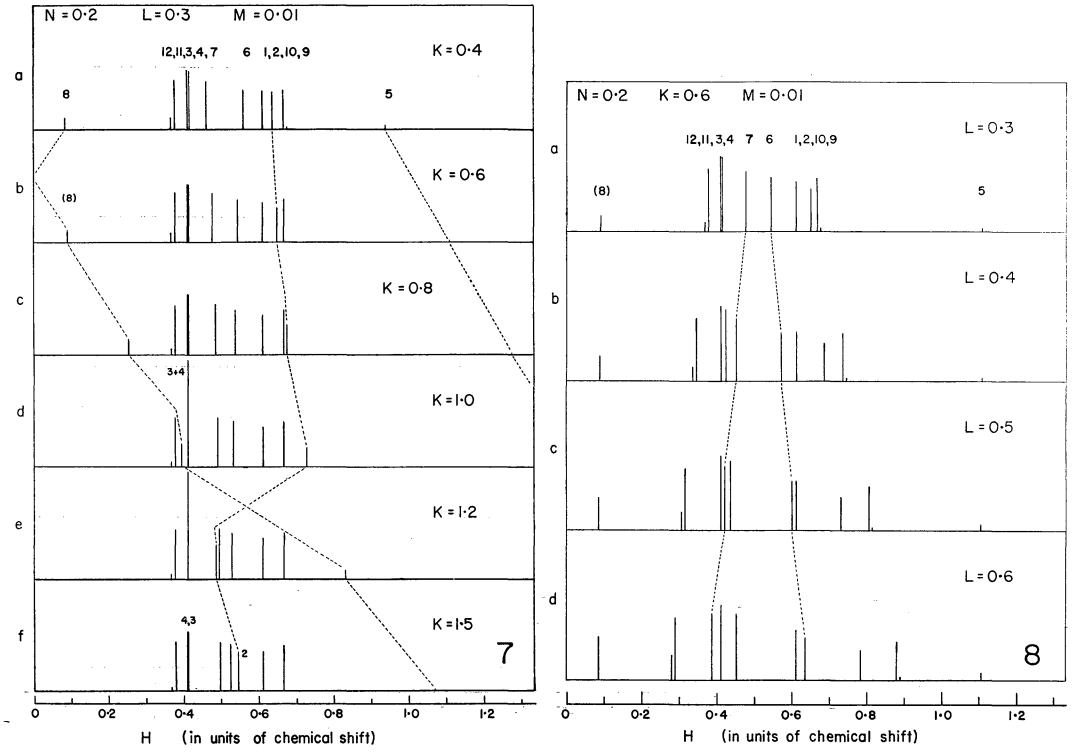

FIG. 7. The variation of the spectrum with a change in parameter K is presented for $N = 0.2\Delta$, $L = 0.3\Delta$, and $M = 0.01\Delta$.

FIG. 8. Starting with the spectrum presented in Fig. 7(*b*) the spectral changes due to the parameter L are shown for $N = 0.2\Delta$, $K = 0.6\Delta$, and $M = 0.01\Delta$. The changes in the spectrum when varying L from 0.3Δ to 0.6Δ for the other values of the parameter K in Fig. 7 are the same as that given here for the case of $K = 0.6\Delta$.

Application to 1-Phenylcyclopropylcarboxylic Acid

The values obtained for the chemical shifts with respect to internal TMS and the coupling constants for 1-phenylcyclopropylcarboxylic acid are given in Table II. Figure 10 shows the proton resonance spectrum with the calculated spectrum below. The phenyl

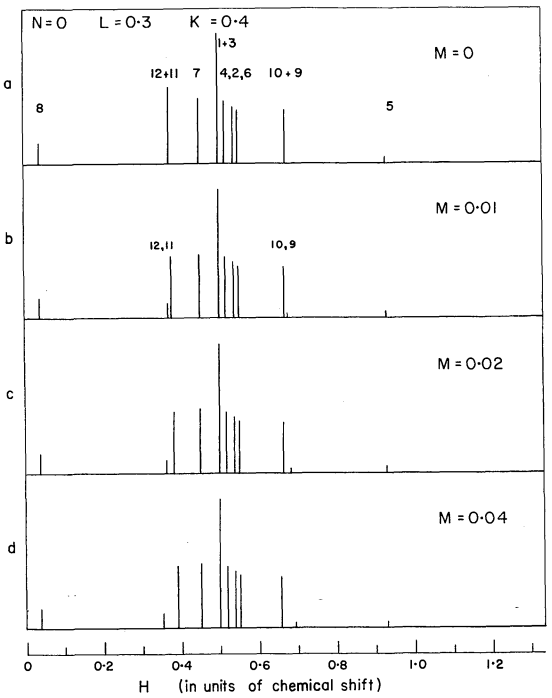

FIG. 9. The effect of the M parameter on the A_2B_2 spectrum is illustrated. The spectrum in Fig. 3(*a*) corresponds to that in (*b*) above. Since the parameter M for 1,1-disubstituted cyclopropanes appears to be small, all the spectra in Figs. 1 to 8 were calculated for $M = 0.01\Delta$. For other values of M only transitions 9, 10, 11, 12 in the preceding figures would change as illustrated above.

and carboxyl protons were approximately 440 c.p.s. and 740 c.p.s. to low field of TMS. They will not be discussed further.

The parameters give a fit of the theoretical and experimental lines to within ± 0.1 c.p.s., which is as good as the uncertainty in the measurements. The parameter M could not be evaluated since no splitting of lines 11, 12 and 9, 10 was observed. This does not necessarily indicate that $M = 0$ since there appears to be sufficient coupling of the cyclopropyl protons with the phenyl substituent to broaden the lines slightly. This could mask any splitting of up to 0.4 c.p.s. The spectrum in Fig. 10 was calculated assuming $M = 0.2$ c.p.s. Line 5 was not observed in the spectrum due to its low intensity and the broadening by the phenyl group.

The designation of protons H_A and H_B in Fig. 10 is assigned arbitrarily and could be reversed. J_A cannot be distinguished from J_B, especially since their values are very similar. From the spectrum alone J_{gem} and J_{trans} cannot be distinguished. However, we know that J_{gem} is almost certainly negative and J_{trans} positive (6, 7, 8). A satisfactory fit to the observed spectrum could only be obtained with opposite signs for J_{trans} and J_{gem}.

The Proton Spectrum of 1-Phenylcyclopropylcarbinol

This compound was expected to have an A_2B_2 spectrum but in the four solutions mentioned in Table III the ring protons were isochronous. They were not sufficiently coupled to either substituent to give an observable splitting of the single resonance peak.*

**If there were a small coupling to the ortho protons of the phenyl ring this would be obscured by an averaging effect over the other phenyl protons. This is so because the phenyl ring protons are isochronous and the coupling to the meta and para protons would be expected to be very nearly zero (10).*

*In c.p.s. at 60 Mc/s to low field from internal TMS.
†Phenyl resonance hidden by solvent peak.

No coupling was observed between the methylene and hydroxyl protons, indicating exchange of the hydroxyl protons at a rate sufficient to obscure the expected splitting of about 5 c.p.s. (9). The shifts of all protons relative to internal TMS are given in Table III.

The chemical shifts in the various solutions merit some discussion. The phenyl proton shifts are almost solvent independent. This is also nearly the case for the protons on the cyclopropyl ring. By way of contrast, the similarly placed protons in bis(2,2-dichlorocyclopropyl) ether show a difference of about 0.5 p.p.m. in carbon disulphide and benzene solutions (11). Relative to internal TMS the shift is to high field in benzene. In the latter case we have shown that the shift is markedly temperature dependent, indicating association effects (11). Association effects in the present case must be very small. In fact, there is a small shift to *low* field when the solvent is changed from carbon disulphide to benzene. This is also so for the methylene protons. The dielectric constants of benzene and carbon disulphide are nearly the same and reaction field effect differences must therefore be very small (16). We suggest that these very odd shifts must be a result of a peculiar packing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

arrangement in solution which cannot, however, be more closely specified at present. The unexpected shifts in benzene solution are further emphasized by the almost identical shifts at the same concentration in chloroform. Further studies of the concentration and temperature dependence of these shifts are indicated.

The hydroxyl proton shifts in the two carbon disulphide solutions are reasonable since dilution would be expected to break up hydrogen bonding to other hydroxyl groups, thus causing a high-field shift (12). Again, hydrogen bonding to benzene solvent molecules is indicated since this would cause a shift to high field (13).

Ring Proton Shifts of the Acid

In Table II it can be seen that the H_B protons shift more to high field than do the H_A protons when the solvent is changed from carbon disulphide to benzene. If it could be decided which side of the cyclopropane ring is avoided by the benzene solvent molecule, a definite assignment of H_A and H_B could be made. From previous experience with benzene as a solvent (7, 14, 15) we suggest that the carboxyl group will cause a closer packing of the benzene molecules about the protons trans to it. The H_B protons as given in Table II would then be trans to the carboxyl group. A series of studies to establish preferences of this type are indicated.

Because of the magnetic anisotropy of *both* the C=O bond and the benzene ring, coupled with the possibility of rapid rotation on an n.m.r. time scale of both groups about the bonds to the cyclopropyl ring, we hesitate to speculate further on the relative shifts of the H_A and H_B protons in carbon disulphide itself. However, from Tables II and III it is clear that substitution of a carboxyl group for the hydroxymethyl group causes a large low-field shift for both H_A and H_B. *If* we attribute this to the anisotropy of the C=O bond, it may be reasonable that the protons cis to it (H_A) should be most affected. This assignment would then agree with that suggested above from benzene solvent effects.

In chloroform both protons shift to low field and since the carboxyl group may be expected to introduce a considerable dipole moment, we suggest that this is a reaction field effect (16).

EXPERIMENTAL

1-Phenylcyclopropylcarboxylic acid was studied as a 6 mole% solution in carbon disulphide, 7 mole% solution in chloroform, and as an 8 mole% solution in benzene. 1-Phenylcyclopropylcarbinol was investigated as a 20 mole% solution in benzene and chloroform and 10 mole% and 15 mole% solution in carbon disulphide. Tetramethylsilane (TMS) was used as an internal standard. Small quantities of these compounds were a gift from Dr. James W. Wilt. Their physical properties are given in his paper (17). No impurities were observable in the proton spectra.

The spectra were obtained on a Varian Associates high-resolution DP60 spectrometer. The results represent an average of 10 spectra run forward and reverse. Corresponding A and B transitions were found to be symmetrical with respect to the center of the spectrum to within ±.05 c.p.s. The possible error in each line position is not more than ±0.1 c.p.s.

ACKNOWLEDGMENTS

We are grateful to Dr. J. W. Wilt for the gift of the compounds. H. M. H. thanks Canadian Industries Limited for fellowship support. The financial assistance of the National Research Council is deeply appreciated.

THE CONSTITUTION OF A SYNTHETIC GLUCAN

II. METHYLATION STUDIES[1]

G. G. S. DUTTON AND A. M. UNRAU[2]

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received April 16, 1963

ABSTRACT

After repeated and vigorous treatments, a fully methylated glucan was obtained. Hydrolysis of the methylated glucan with sulphuric acid gave tetra-, tri-, di-, and mono-*O*-methyl-D-glucoses in a 5:5:3:1 ratio. Both the furanose and pyranose tetramethyl isomers were identified. Nearly all of the possible pyranose and furanose cyclic trimethylglucoses were positively identified. An attempted resolution of the dimethylglucoses was relatively unsuccessful. The monomethylglucoses were identified by electrophoresis.

An earlier paper (1) has reported the general structural features of a synthetic glucan prepared by Mora (2). The present paper describes an investigation of the fully methylated glucan which was obtained after successive Haworth, Kuhn (3), and Purdie methylations. Several extended treatments of the partially methylated glucan (96 hours) with Purdie's reagents were required to obtain a product which had 45.35% methoxyl and showed no hydroxyl band in its infrared spectrum. The methylated glucan was soluble in petroleum ether (30–60°) containing 5% chloroform. A small quantity of insoluble material was obtained when the chloroform concentration was 3% by volume. A methylated synthetic xylan showed similar properties (4).

Hydrolysis of the methylated glucan with sulphuric acid under conditions shown to minimize demethylation (5) gave tetra-, tri-, di-, and mono-methylglucose fractions in a 4.9:5.0:2.9:1 ratio. A small quantity of glucose was present. Since the sulphuric acid hydrolysis technique (5) was used, the presence of glucose may have some structural significance.

By chromatography on a cellulose-hydrocellulose column using butanone–water azeotrope (17) the mixture of methylated sugars was resolved into four main fractions containing tetra-, tri-, di-, and mono-*O*-methyl ethers. The components within each fraction were then split into two parts by reaction with 1% methanolic hydrogen chloride at room temperature. Under these conditions all the methyl ethers carrying a free hydroxyl group on C_4 should form furanosides (designated by F) and by column chromatography should be separable from the pyranose forms of the free sugars (designated by P). It is of course to be expected that such a separation will not be clear-cut and that a portion of the sugars with free hydroxyls on C_4 may appear in the P-fractions. In the case of the tri- and di-*O*-methyl ethers a further subdivision may be achieved by taking advantage of the fact that trityl chloride will react selectively with a free C_6-hydroxyl group. Thus the trimethyl components designated 3F were separated into those which formed a trityl derivative (3FTr) and those in which the C_6-position was methylated (3F6, and similarly for the other fractions). An attempt was then made to separate chromatographically the components of each subfraction either directly or after periodate oxidation. In certain cases some insight into the composition of a subfraction was obtained by estimating the periodate

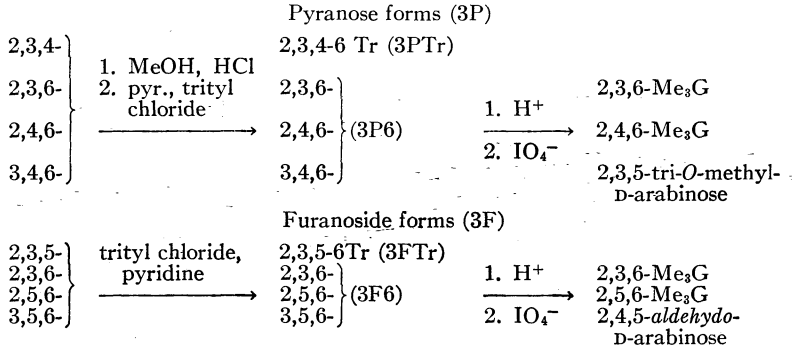
[1]*Presented at the 44th Chemical Institute of Canada Meeting in Montreal, August, 1961.*

[2]*Present address: Department of Plant Sciences, University of Manitoba, Winnipeg, Manitoba.*

consumption and formaldehyde production from a portion of the derived glucitols prepared by reduction with sodium borohydride. It is obvious that such manipulations cannot give a strictly quantitative picture but they do serve to indicate some of the main structural features of the polysaccharide. Careful attempts were made to characterize each component by crystalline derivatives but this did not prove successful in all cases. It may be mentioned that a sample of the glucoside mixture from this polysaccharide (and also from the polyxylose (4)) was subjected to vapor phase chromatography but gave a pattern that was too complex to resolve. Despite the excellent pioneer work which has been carried out on the separation of methylated methyl glycosides there is still a paucity of data on methyl furanosides. A description of the results obtained in the chemical separation of this mixture of methylated glucoses is given below.

The tetramethylglucose fraction was shown by its rotation to contain about 20% 2,3,5,6-tetra-*O*-methyl-D-glucose, the rest being the 2,3,4,6-isomer. Both isomers were identified by separation of the furanose component as the methyl glycoside from the pyranose sugar, on a cellulose column. The pyranose sugar gave the crystalline *p*-nitrobenzoate while the furanose sugar was transformed, after hydrolysis, to the corresponding gluconamide.

Part of the slowest-moving tri-*O*-methyl fraction was obtained crystalline and identified as the 2,4,6-isomer from the physical constants of the sugar and by conversion to the *N*-phenylglycosylamine. The remainder of the tri-*O*-methyl fraction was treated with methanolic hydrogen chloride at room temperature and the furanosides thus formed separated from the pyranose sugars on the column, giving two fractions designated 3F and 3P. The two fractions were then separately resolved as follows:



The pyranose sugars were converted to the glycosides and the mixture treated with trityl chloride, which readily gave methyl 2,3,4-tri-*O*-methyl-6-*O*-trityl-D-glucoside. The 2,3,4-tri-*O*-methyl-D-glucose was further identified by (*a*) conversion to the *N*-(*p*-nitrophenyl)-glycosylamine and (*b*) reduction ($NaBH_4$), periodate oxidation, and preparation of the 1-*p*-nitrobenzoate of the resulting 2,3,4-tri-*O*-methyl-L-xylose. The 3P6 mixture of pyranosides was hydrolyzed and oxidized with periodate to give a trimethylpentose and two unchanged trimethylglucoses. The mixture was resolved by cellulose column chromatography and the 2,3,6-tri-*O*-methyl-D-glucose converted to the crystalline 1,4-di-*p*-nitrobenzoate. The other tri-*O*-methyl-D-glucose had a rotation corresponding to that of the 2,4,6-isomer and was chromatographically identical with it. The pentose, presumed to be 2,3,5-tri-*O*-methyl-D-arabinose, was oxidized (Br_2) to the acid. The amide gave a negative Weerman test (6) and the lactone and amide had optical rotations very similar to those expected from the respective L-compounds. The amide did not crystallize, however.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

From the furanoside (3F) mixture, a water-insoluble trityl derivative was obtained which was presumed to be the 6-*O*-trityl ether of methyl 2,3,5-tri-*O*-methyl-D-glucoside. The trityl group was removed and the free sugar oxidized (Br_2). The derived amide gave a negative Weerman test (6), showing that the hydroxyl on C_2 was substituted. Treatment of the lactone with phenylhydrazine gave the solid phenylhydrazide of 2,3,5-tri-*O*-methyl-D-gluconic acid. The mixture of water-soluble furanosides (2,5,6-, 2,3,6- and 3,5,6-trimethyl ethers) was hydrolyzed and treated with periodate. Three components were obtained, one presumably being 2,4,5-tri-*O*-methyl-*aldehydo*-D-arabinose and two unchanged tri-*O*-methylglucoses. The mixture was resolved by cellulose chromatography and the compounds identified as follows: 2,3,6-tri-*O*-methyl-D-glucose gave the crystalline 1,4-di-*p*-nitrobenzoate; 2,5,6-tri-*O*-methyl-D-glucose was oxidized (Br_2) and converted to the lactone. The latter gave a negative Weerman test and formed a solid phenylhydrazide; 2,4,5-tri-*O*-methyl-*aldehdyo*-D-arabinose gave a positive Schiff test. The amide of the corresponding acid gave a negative Weerman test.

An attempt was made to resolve the dimethylglucose mixture by a technique similar to that outlined for the tri-*O*-methylglucose mixture. The furanoside (2F) and pyranose (2P) mixture was separated by column chromatography as before. The components were then treated as follows:

Pyranose forms (2P)

2,4-, 3,4-, 4,6- —(1. MeOH, HCl; 2. trityl chloride, pyr.)→ 2,4-6Tr, 3,4-6Tr (2PTr), 4,6-(2P6)

2PTr —(1. H^+; 2. IO_4^-)→ 2,4-di-*O*-methyl-D-glucose; 2,3-di-*O*-methyl-D-arabinose

Furanoside forms (2F)

2,3-, 2,5-, 2,6-, 3,5-, 3,6-, 5,6- —(trityl chloride, pyridine)→ 2,6-, 3,6-, 5,6- (2F6)

2F6 —(1. H^+; 2. IO_4^-)→ 1-*O*-methylglyceraldehyde; 2,5-di-*O*-methyl-D-arabinose; 3,4-di-*O*-methyl-D-erythrose

2,3-6Tr, 2,5-6Tr, 3,5-6Tr (2FTr) —(1. H^+; 2. IO_4^-)→ 2,3-di-*O*-methyl-D-glucose; 2,5-di-*O*-methyl-D-glucose; 2,4-di-*O*-methyl-D-glucose

Considering the pyranose sugars (2P) first, component 2P6, which should have been 4,6-di-*O*-methyl-D-glucose, failed to crystallize. Electrophoresis demonstrated that the syrup was composed of two compounds in approximately equal quantities and a third substance in minor quantities. The periodate oxidation of component 2PTr showed that part of the mixture was not attacked by periodate and the R_f and M_g values suggested that this sugar was 2,4-di-*O*-methyl-D-glucose. 2,3-Di-*O*-methyl-D-arabinose was apparently present as indicated by the R_f and M_g values. Two components with R_f values of about 0.79 and 0.85, whose identities are unknown, were also present. These compounds gave a peculiar purple color when paper chromatograms were sprayed with *p*-anisidine.

Periodate oxidation of component 2F6 gave a complex mixture of products. A considerable amount of dimethyl sugar was not attacked by periodate whereas, according to the reaction scheme, none of the dimethylglucoses should have escaped periodate attack. The unchanged dimethyl fraction was shown by electrophoresis to be composed of at least three sugars. Chromatographic evidence was obtained for a faster-migrating dimethylpentose, presumably 2,5-di-*O*-methyl-D-arabinose. Several components with R_f greater than 0.75 were observed. The presence of 1-*O*-methylglyceraldehyde was shown as follows: The distillate from the periodate reaction mixture was bubbled through a solution of sodium borohydride. Chromatographic examination of the distillate gave a small amount

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of Tollens-positive material. On the assumption that this material was 1-*O*-methylglycerol it consumed approximately 1 mole of periodate and gave 1 mole of formaldehyde. Demethylation gave glycerol. These results establish the identity of 1-*O*-methylglycerol, and of the possible dimethylglucoses this can only be formed by 2,6-di-*O*-methyl-D-glucose. In a similar manner, a component with R_f 0.81 gave results which corresponded to 3,4-di-*O*-methylerythritol. Of the dimethylglucoses only 5,6-di-*O*-methyl-D-glucose can furnish the corresponding 3,4-di-*O*-methyl-D-erythrose.

Whereas the general procedure outlined served quite well in the resolution of the tri-*O*-methylglucose mixture, very little success was experienced when it was applied to the di-*O*-methylglucose mixture. It is suspected that all the possible di-*O*-methylglucoses were present and a more rigorous scheme must be evolved to resolve this complex mixture satisfactorily.

The identity and ratio of the mono-*O*-methylglucoses was established by electrophoresis and paper chromatography. By the latter, no appreciable 5-*O*-methyl isomer appeared to be present. The remaining four monomethylglucoses, the 2-, 3-, 4-, and 6-*O*-methyl isomers, were present in a 3:5:1:2 ratio. A small quantity of glucose was obtained crystalline and transformed to the phenylosazone.
