GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART VII. THE DEHYDRATION OF *p*-MENTHAN-8-OL[1,2,3]

E. VON RUDLOFF

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received July 11, 1962

ABSTRACT

Mixtures of *cis*- and *trans*-*p*-menthan-8-ol were prepared by hydrogenation of α-terpineol over platinum or palladium catalysts and the isomer ratios obtained were determined by gas–liquid chromatography. The dehydration of a 1:1 mixture, as well as of the pure stereoisomers, was studied with a number of reagents. Aqueous oxalic and acetic acids, fused potassium hydrogen sulphate, anhydrous oxalic, silicic, and boric acids, and "Florisil" promoted the typical acid-catalyzed dehydration, with *p*-menth-4(8)-ene and smaller amounts of isomeric *p*-menth-8-enes as the primary products, and *p*-menth-3-ene the final product owing to isomerization. With anhydrous silicic acid the latter was obtained in better than 80% yield. With non-acidic alumina, or thionyl chloride in excess pyridine, the main product was *p*-menth-8-ene (up to 90%); no isomerization to *p*-menth-3-ene was obtained. The possible reaction mechanisms are discussed.

INTRODUCTION

Dehydration of suitable terpene alcohols provides a simple means for synthesizing unsaturated terpenes required as reference compounds in gas–liquid chromatography (GLC). In Part II of this series (1) the analysis of the mixture of *p*-menthadienes and oxides obtained in the acid-catalyzed dehydration of α-terpineol (*p*-menth-1-ene-8-ol) was described. More recently (2), the author has reported results obtained in the dehydration of a number of terpene alcohols, including α-terpineol and *p*-menthan-8-ol (dihydro-α-terpineol), with a simple non-acidic reagent, viz., base-modified alumina. The dehydration of *p*-menthan-8-ol by acidic and non-acidic dehydrating agents has now been studied in detail and optimum conditions for the preparation of *p*-menth-3-, -4(8)-, and -8-ene by this means have been determined. Since cis or trans elimination of the elements of water can proceed equally well with *p*-menthan-8-ol, it was hoped that such a study would also provide data on the relative ease of the formation of exocyclic double bonds in cyclohexane derivatives.

In 1910, Béhal (3) hydrogenated α-terpineol over nickel catalyst by the Sabatier–Senderson method and obtained what was then thought to be *cis*-*p*-menthan-8-ol. Shortly afterwards Wallach (4) obtained the solid trans isomer (m.p. 35° C) using colloidal palladium catalyst. Both authors reported that dehydration with acetic acid containing sulphuric acid gave *p*-menth-4(8)-ene. Perkin and Pickles (5) dehydrated *p*-menthan-8-ol

(m.p. 35° C) with fused potassium hydrogen sulphate and reported the isolation of *p*-menth-8-ene. However, Kötz and Busch (6) obtained 87% of theory of *p*-menth-3-ene when this reaction was carried out in a copper autoclave at 200° C for 24 hours. Zeitschel and Schmidt (7) isolated *trans*-p-menthan-8-ol from American pine oil and claim to have obtained the pure cis and trans isomers by fractional distillation. However, their cis isomer was a liquid and gave a phenylurethane, m.p. 90–92° C. Keats (8), on the other hand, obtained solid *cis-p*-menthan-8-ol, m.p. 25° C (phenylurethane m.p. 114° C), and attempted to correlate the stereochemistry of both isomers by conversion, via the chloride, to *cis*- and *trans-p*-menth-8-ene. The above discrepancies were resolved when in 1960 Eastman and Quinn (9) succeeded in obtaining both isomeric alcohols pure (m.p. 35° and 47° C) by fractional distillation through a highly efficient distillation column, and showed that both the pure isomers gave phenylurethanes of m.p. 115–117° C, whereas mixture of these gave phenylurethanes of m.p. 91–97° C. In this study small aliquots of α-terpineol were hydrogenated over either platinum oxide or palladium-on-charcoal and the total product was analyzed by GLC to determine the yield of hydrogenation products and the isomer ratio. The most favorable conditions were then used for preparing a 1:1 mixture of *cis*- and *trans-p*-menthan-8-ol and smaller amounts of the pure isomers. These were then used in the dehydration studies.

EXPERIMENTAL

The gas chromatographic equipment and techniques have been described previously (1, 2, 10). All columns were made up with the stationary phase on Chromosorb W (60–80 mesh) in the weight ratio of 1:6. Retention times were measured from the time of injection to the initial emergence of the peaks (1, 10). The percentage compositions of terpene mixtures were determined by measuring the area under the curves (triangulation method), the error being ±1 to ±5% depending on peak size (see also ref. 11) and degree of separation. Terpene hydrocarbons were analyzed at 65° C (2 m×0.6 mm O.D. columns) or 80° C (4-m columns), and the *p*-menthan-8-ol isomers and unreacted α-terpineol at 100–110° C. The retention times of *p*-menthenes, *p*-cymene, α-terpineol, and the *p*-menthan-8-ols have been described previously (1, 2, 10, 12). The relative rentention times (RRT) of *trans*- and *cis-p*-menthane with respect to limonene (=1.00) were 0.29 and 0.355 on the adipate polyester column (at 65° C) and 0.30 and 0.35 on the polyethylene glycol 1540 column (at 65° C) respectively. Good separation of the hydrocarbons was also obtained on an ethylene glycol bis-(propionitrile)-ether column. With this column *p*-menth-3-ene and camphene were completely separated (RRT 0.33 and 0.42 respectively). Recently, Wilcox *et al.* (13) have shown that in the dehydration of α-terpineol with ethanolic sulphuric acid peak 1 was in fact *p*-menth-3-ene, and not camphene as previously reported (1). This was confirmed by means of this column.

Individual components were isolated by injecting 10- to 50-μl amounts onto the analytical columns and collecting individual peaks, or center cuts thereof, in glass traps which were cooled in an acetone – solid carbon dioxide bath. In preparative runs the detector current was reduced from 250 ma to 100 ma to prevent thermal decomposition (14). The identity of individual components was determined by comparison of infrared spectra and retention data with those of authentic samples. No isomerization of the *p*-menthenes during GLC analysis was encountered. The infrared spectra obtained for *p*-menth-8-, -4(8)-, and -3-ene agreed with those reported by Frank and Berry (15) in all respects. Infrared spectra were recorded as liquid films between sodium chloride plates on a Perkin–Elmer Model 21 double-beam spectrophotometer.

Hydrogenation of α-Terpineol

Commercial α-terpineol (Fisher Scientific Co.), having n_D^{20} 1.4829, $[\alpha]_D^{20}$ +15.1°, was used in all experiments. Small-scale hydrogenation was carried out in a micro hydrogenation apparatus, α-terpineol (10 mg) in solvent (0.5 ml) being reduced in the presence of reduced catalyst (1–5 mg) at room temperature. With platinum oxide (Adam's) catalyst and either methanol or methanol – acetic acid (4:1, v/v) as solvent, the product was found to contain 50–52% *trans*-, 46–48% *cis-p*-menthan-8-ol, and 2% unreacted α-terpineol. Using palladium-on-charcoal catalyst and methanol, the uptake of hydrogen was slower and the product after 48 hours contained 50% unreacted α-terpineol, 35% *trans*-, and 15% *cis-p*-menthan-8-ol. The rate of hydrogenation could be increased by carrying out the reaction at 50–60° C or by adding acetic acid to the solvent, but the product after 48 hours still contained 25% and 10% unreacted α-terpineol respectively. Repeated preparative runs (10-mg scale) on the polyester or polyethylene glycol GLC column gave pure *cis*- and *trans-p*-menthan-8-ol in small amounts. Both crystallized on keeping at 0–2° C, m.p. 33–34° and

42–44° C respectively (lit. m.p. 34.5–35° and 46.7–47° C respectively (9)). No significant optical rotation was recorded.

α-Terpineol (50 g) was added to reduced platinum oxide catalyst (1 g, commercial) in methanol (80 ml) and acetic acid (20 ml). Hydrogenation was continued for 4 days, when the uptake of hydrogen ceased. The mixture was filtered, ether (200 ml) and water (200 ml) were added, and the ether layer was washed repeatedly with a saturated aqueous sodium bicarbonate solution to remove the acetic acid. The neutral ethereal solution was washed with water and the ether was evaporated. The residue (50 g) was shaken with powdered potassium permanganate to remove unreacted α-terpineol. The product was taken up in ether (100 ml), washed with water, and dried over anhydrous sodium sulphate. After evaporation of the ether, the residue (49 g) was distilled at 90 mm pressure to give pure *p*-menthan-8-ol with a ratio of trans to cis isomer of 51:49 (GLC analysis); n_D^{25} 1.4640. The derived phenylurethane had m.p. 90–96° C (lit. 91–91° C (9)).

In another experiment, α-terpineol (100 g) was similarly hydrogenated over reduced palladium-on-charcoal (5 g, 5% commercial). The product (98 g) after neutralization, washing, drying, and removal of solvents was fractionally distilled through a spinning band column (Podbielniak, 8 mm×1 m) at 50 mm pressure and a high reflux ratio. The fraction b.p. 116–118° C (32 g) was redistilled under the same conditions to give practically pure (98%, GLC) *trans-p*-menthan-8-ol (15 g), m.p. 34–35° C, n_D^{25} 1.4622. The derived phenylurethane had m.p. 115–117° C after recrystallization from petrol (b.p. 60–70° C) (lit. m.p. 117° C (9)). Found: C, 73.93; H, 9.06; N, 5.16%. Calculated for $C_{17}H_{25}O_2N$: C, 74.14; H, 9.15; N, 5.09%. By repeated fractional distillation of fractions which contained a high percentage of the cis isomer, the latter was obtained 97% pure (GLC), m.p. 24–28° C, n_D^{25} 1.4658, phenylurethane m.p. 114–116° C (lit. 116° C (9)).

Dehydration Experiments

(1) Aqueous Reagents

p-Menthan-8-ol (1.00 g), oxalic acid dihydrate (3 g), and water (6 ml) were heated under reflux for the desired length of time. The mixture was then steam-distilled for 0.5 hours and the product was extracted with ether (2×5 ml). The ethereal solution was washed with aqueous bicarbonate solution (1 ml), water (2×1 ml), and was dried over anhydrous sodium sulphate. The filtered solution was evaporated to dryness on a steam bath in a flask having a long neck (1). The residue was weighed and analyzed by GLC for the content of hydrocarbons and unreacted starting material. The results obtained are shown in Table I. In the "0" hour experiment the mixture was steam-distilled at once.

dehydration products in the reaction with anhydrous sodium sulphate the reaction was also carried out with five times the amount of reagent. With "Florisil" and alumina the reaction was also carried out for 3 and 5 hours, with heating under reflux, to determine the degree of isomerization and hydrogen transfer.

(3) Dehydration with Thionyl Chloride – Pyridine Reagent (16)

The alcohol (1.00 g) was dissolved in dry pyridine (40 ml) and the solution was cooled to about 5° C. Thionyl chloride (5.0 g) was added dropwise with shaking during 10 minutes. After standing 5 minutes,

sodium carbonate (3 g) in water (15 ml) was added slowly. The mixture was extracted thrice with ether and the ether layer was washed with saturated tartaric acid solution until all pyridine had been removed. After washing with water the ethereal solution was worked up and analyzed as above (see Table II).

RESULTS AND DISCUSSION

The results obtained in the hydrogenation experiments show that with platinum catalyst at atmospheric pressure α-terpineol is reduced to an approximately 1:1 mixture of *cis*- and *trans*-menthan-8-ol. With palladium catalyst this ratio changes to about 7:2 in favor of the more stable trans isomer. These findings are in accord with those reported for substituted cyclohexenes by Siegel and Smith (17) and also by Sauvage *et al.* (18). Eastman and Quinn (9) report a higher yield of the trans isomer using platinum catalyst, but these authors employed high pressures. Siegel and Smith have shown that the ratio of isomers formed is a function of pressure, as well as of catalyst. The quantitative separation of the two isomers was readily achieved on a milligram scale by GLC on 2-m polyester or polyethylene glycol columns. For larger quantities the less efficient separation by fractional distillation (see ref. 9) was used. However, once preparative GLC in gram amounts has been achieved with the same degree of efficiency as analytical GLC, the preparation and characterization of pure stereoisomeric terpene alcohols of this type should present no more difficulty. Preliminary results in this laboratory indicate that repeated small-scale runs on analytical columns offer a more promising means of achieving this than the use of larger diameter columns (1- to 5-cm diameter) and larger samples (0.1–2 g).

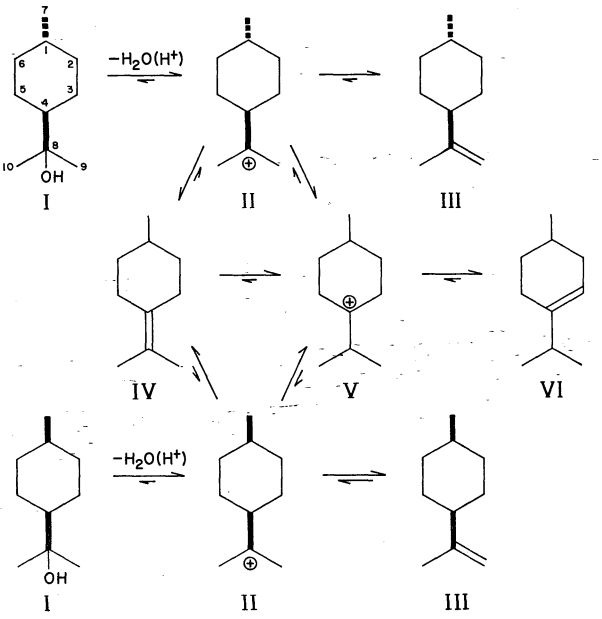
The results of the dehydration of *p*-menthan-8-ol with either aqueous oxalic or acetic acid were similar to those obtained previously with α-terpineol (1), except that with this fully saturated alcohol no side reactions, such as oxide formation, occurred. With aqueous oxalic acid the dehydration was complete in about 3 hours' reaction time, *p*-menth-4(8)- and -3-ene being the major reaction products and the isomeric *p*-menth-8-enes the minor ones (see Table I*a*). As expected, more *trans-p*-menth-8-ene than the cis isomer was formed throughout the reaction. When the reaction was carried out with pure *trans-p*-menthan-8-ol (Table I*b*), no *cis-p*-menth-8-ene was detected, showing that no isomerization from trans to cis isomers occurred during dehydration. Similarly, no isomerization from cis to trans isomer was detected (Table I*c*). With increased reaction time the overall yield of terpenes remained almost constant, but the yield of *p*-menth-3-ene increased at the expense of the other isomers. This is in accord with the findings of Frank and Berry (15), who studied the isomerization of *p*-menth-8-ene. When a mixture of *trans*- and *cis-p*-menth-8-ene (88%) and *p*-menth-4(8)-ene was heated with excess aqueous oxalic acid isomerization to *p*-menth-3-ene proceeded somewhat faster than in the dehydration reaction.

With 50% aqueous acetic acid as dehydrating agent, the reaction not only proceeded very much slower (see Fig. 1) but isomerization was very much reduced. This resulted in an increased yield of *p*-menth-4(8)-ene, e.g. almost 60% in the reaction with *cis-p*-menthan-8-ol. Also, the greater stability of the trans isomers is clearly evident from the slower rate of dehydration of *trans-p*-menthan-8-ol and the higher yield of *trans-p*-menth-8-ene. Both Béhal (3) and Wallach (4) reported that dehydration of *p*-menthan-8-ol with acetic acid containing sulphuric acid gives *p*-menth-4(8)-ene. In the present study, when the alcohol was heated under reflux with glacial acetic acid containing 5% sulphuric acid for 1 hour, the yield of steam-volatile products was low (60%) and polymerization extensive. Since *p*-menth-3-ene was the major hydrocarbon formed (59%) and the 4(8)-isomer was obtained in minor amounts only (6%), this reaction was not investigated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

further. With glacial acetic acid alone the reaction proceeded very slowly (about 50% dehydration in 12 hours) and the product obtained was similar to that formed in the reaction with aqueous acetic acid.

The results obtained with the aqueous acidic reagents can be readily explained by assuming that the dehydration proceeds via carbonium-ion intermediates (E_1 elimination). Protonation of *p*-menthan-8-ol (I) and subsequent loss of the elements of water would lead to carbonium ion II. Loss of a proton can then result in the formation of either *p*-menth-8-ene (III) or the 4(8)-isomer (IV). Rearrangement of the carbonium ion II to one with the charge at carbon 4 (V) followed by loss of a proton could then result in the formation of either *p*-menth-3-ene (VI) or -4(8)-ene (IV). Since these steps are reversible, reprotonation of III, IV, and VI may be assumed to take place. This would account for the isomerization of *p*-menth-8- and -4(8)-ene to *p*-menth-3-ene. Thus, in the initial steps formation of an exocyclic double bond is the preferred reaction route, and only in the subsequent isomerization is the more stable *p*-menth-3-ene formed. This is clearly borne out in the experiments with 50% aqueous acetic acid, where the acid strength has been reduced to such an extent that isomerization proceeds only very slowly (see Fig. 1).



With solid anhydrous acids the reaction proceeds similarly (see Table II*a*) but much faster (especially isomerization), presumably due to the higher temperature of reaction. Fused potassium hydrogen sulphate gave a mixture of hydrocarbons very similar to that obtained with aqueous oxalic acid, confirming in part the findings of Kötz and Busch (6). Semmler and Rimpel (19) have pointed out that this reagent does not give a single product. With boric acid the relative yield of *p*-menth-3-ene was much lower and that of the *p*-menth-8-enes considerably higher, as would be expected for a weak acid. Anhydrous oxalic acid, "Florisil" (a commercial silica containing about 15% MgO, see also ref. 20), and especially anhydrous silica gave high yields of *p*-menth-3-ene. Increased reaction times did not increase the relative yields of this isomer, but caused overall losses due to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

resinification. With "Florisil" a new side reaction occurred, *trans*- and *cis*-*p*-menthane and *p*-cymene being formed in increasing amounts with increasing reaction times. Thus, this reagent not only catalyzes dehydration but causes hydrogen transfer between the monoolefins to give the saturated and aromatic analoges. *p*-Menthadienes were not found in the reaction product. Recently, Wilcox *et al.* (13) have shown that dehydration of α-terpineol with ethanolic sulphuric acid gave, amongst others, *p*-menth-3-ene, and not camphene as previously reported (1) (see also Experimental). The formation of *p*-menth-3-ene in conjunction with *p*-cymene shows that hydrogen transfer can take place readily with acidic reagents.

With the non-acidic reagents the ratio of *p*-menthene isomers obtained is significantly different (see Table II*b*). These reagents give *p*-menth-8-ene as the main reaction product, smaller amounts of the 4(8)-isomer, but no *p*-menth-3-ene. Thus this dehydration proceeds in an anti-Saytzeff (Hofmann) orientation and without isomerization of the resulting olefins. The reaction is similar to the homogeneous elimination with thionyl chloride in excess pyridine (see Table II*b*) and forms an excellent complement to the acid-catalyzed dehydration.

Since pyridine-modified alumina dehydrates *l*-menthol mainly to *p*-menth-2-ene (*trans*) and less *p*-menth-3-ene (2), the reaction does not involve pyrolytic cis elimination of the elements of water (21). Pines and co-workers (22, 23) have proposed for the gas-phase dehydration of alcohols with ammonia-modified alumina a concerted mechanism involving both acidic and basic sites. These authors suggest that isomerization is suppressed by neutralization of the strong acid sites by the weak base. Beranek *et al.* (24) have shown that in gas-phase dehydrations over pyridine-modified alumina the active centers responsible for dehydration differ from those causing isomerization of olefinic double bonds. Since in the present study the dehydration with base-modified alumina was carried out at the boiling point of the alcohol, it is possible that the reaction proceeds by the same mechanism as in gas-phase dehydration. However, even though it seems probable that a concerted E_2 elimination takes place, this in itself does not account for an anti-Saytzeff oriented loss of the elements of water. Anti-Saytzeff orientation in E_2 eliminations is thought by Hughes and Ingold (25, 26) to be due to inductive control. Brown *et al.* (27, 28), on the other hand, propose that steric influences are the deciding factors in determining the direction of elimination. However, these authors have based their proposals on elimination reactions of substituted alcohols (ammonium, sulphonium, and sulphoxonium compounds) and the results obtained in this study with alumina catalyst on the free alcohol could not be correlated with these proposals.

Brown's view (29, 30) that introduction of a trigonal atom is resisted in cyclohexanes would favor the formation of *p*-menth-8-ene. Whereas this view is supported by the results obtained in the dehydration with alumina or thionyl chloride in excess pyridine, it does not hold for the acid-catalyzed reaction. In the latter type of reaction both *p*-menthan-8-ol and α-terpineol (1) give the exocyclic derivative as the primary dehydration product. Thus, there appears to be an inherent contradiction in Brown's proposal. The dehydration of other terpene alcohols is being studied in the hope of obtaining further insight into the reaction mechanism.

The present study has shown that dehydration of *p*-menthan-8-ol with solid reagents is useful for the preparation of either *p*-menth-8-ene or -3-ene. It should be pointed out that the use of solid reagents simplifies experimental procedure since, after reflux, the resulting hydrocarbons may be simply distilled off and used as reference compounds as such. Although *p*-menth-4(8)-ene was formed in every instance, its yield was usually

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

low and rose above 50% yield only when aqueous acetic acid was used. For reference purposes in GLC studies it is often quite advantageous to have more than one isomer present in the test mixture, and the product obtained with, for example, boric acid can serve to establish the relative retention times of the four *p*-menthene isomers under discussion.

ACKNOWLEDGMENTS

The helpful discussions with Dr. A. S. Perlin are gratefully acknowledged. Thanks are also due to Mr. M. Granat for technical assistance and Mr. W. C. Haid for recording the infrared spectra.

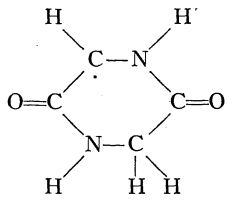
ABSTRACT

The electron spin resonance of an X-ray irradiated single crystal of diketopiperazine has been measured at 9 Gc/sec for various orientations of the crystal in the static magnetic field. From an analysis of the hyperfine structure observed we have been able to calculate the components of the hyperfine interaction tensor for the radical produced by the irradiation. The principal values for the hyperfine interaction tensor are similar to those found for the radical produced by the X-ray or γ-ray irradiation of glycylglycine and N-acetylglycine and is therefore attributed to a radical with a C—H fragment. The fine details of the spectrum indicate that the radical responsible for the electron resonance observed probably has the structure



which is formed from diketopiperazine by the loss of a hydrogen atom from one of the CH_2 groups in that molecule.

INTRODUCTION

The study of the electron spin resonance spectra of the long-lived radicals produced in organic crystalline compounds by X-ray and γ-ray irradiation has led to much valuable information on the structures of the various paramagnetic species. In many cases the identity of the radical produced has been unequivocally established and in others the probable nature of the radical has been clearly indicated. Amongst the many examples known mention may perhaps be made of the studies on the radicals produced in single crystals of malonic acid (1), succinic acid (2), glycollic acid (3), glutaric acid (4), glycine (5, 6), *dl*-alanine (7–9), and glutamic acid HCl (10). The e.s.r. spectra of γ-irradiated single crystals of more complex compounds derived from amino acids have been studied by Gordy and his co-workers and several other groups. These works have led to an understanding of the nature of the radicals produced in N-acetylglycine (11), glycylglycine (12–14), and urea oxalate (15). In many of these latter cases it appeared that the radical was formed by the loss of a hydrogen atom during the irradiation process. The resulting radical gave an electron resonance largely dominated by the hyperfine splitting splitting from a CH group. It was, therefore, of interest to study the radical resulting from the X-ray irradiation of diketopiperazine, the anhydride of glycine, and this paper describes the results of our experiments which led to the identification of the radical responsible for the observed electron spin resonance. We have also determined the principal values of the components for the hyperfine interaction tensor and their direction cosines.

EXPERIMENTAL

The single crystals of diketopiperazine grown from aqueous solution by slow evaporation were monoclinic prisms with the 010 face dominant. The cell constants as determined by Bernal (16) and Corey (17) are: space group $P2_1/a$, $a = 5.19$ Å, $b = 11.50$ Å, $c = 3.96$ Å, $\beta = 97°$. There are two molecules per unit cell. Carefully chosen crystals were irradiated at room temperature with 50 kv X rays for several hours. The irradiated crystals were studied at 9 Gc/sec in our e.s.r. spectrometer using 10 kc/sec modulation and a cavity operating on the TE_{012} mode. A 6-inch Varian magnet with pole shims supplied the magnetic field. The angular rotation of the crystals could be measured to about $\pm 2°$, and the hyperfine splitting constants are probably correct to about ± 0.5 gauss.

A diagram of the crystal and its axes is given in Fig. 1, which also shows the reference set of axes a', b', and c' chosen for our studies. With the chosen orthogonal set of axes the alignment of the crystal could be made more accurately than with any other choice.

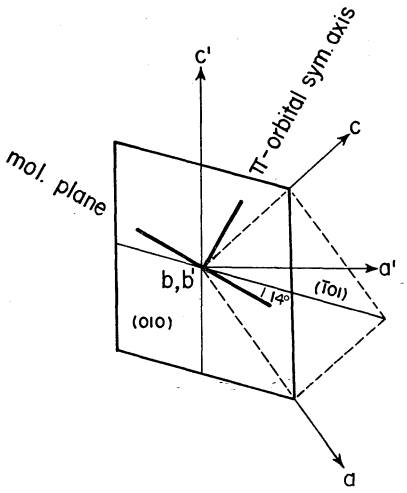


FIG. 1. Relation between crystal axes a, b, c and reference axes a', b', c'. The dotted outline shows the unit cell. The orientation of the radical is also indicated in the figure by the heavy lines. The direction of the CH bond is not indicated in the figure but it is perpendicular to the (010) plane.

RESULTS AND DISCUSSION

The energy levels for an oriented radical in a single crystal in an external magnetic field can be calculated from the spin Hamiltonian

$$[1] \qquad \mathcal{H} = \beta \mathbf{H} \cdot \mathbf{g} \cdot \mathbf{S} + \mathbf{S} \cdot \mathbf{A} \cdot \mathbf{I} - g_n \beta_n \mathbf{H} \cdot \mathbf{I}.$$

Our data can be interpreted in terms of these levels. For most orientations the observed spectra can be regarded as consisting of a main doublet which is split further into triplets of intensity ratio 1:2:1. Figures 2, 3, and 4 show three main types of spectra observed,

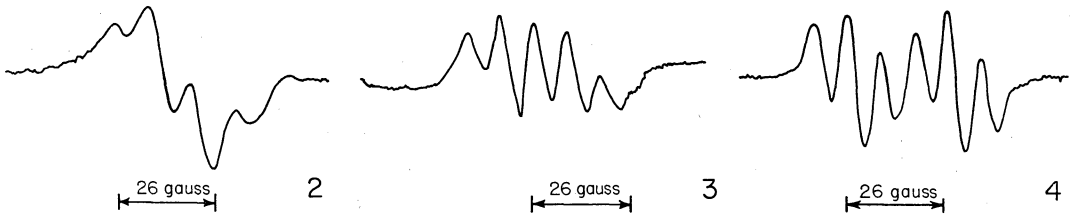

FIG. 2. Electron spin resonance spectrum of an X-ray irradiated single crystal of diketopiperazine (H_0 direction cosines: 0,1,0).

FIG. 3. Electron spin resonance spectrum of an X-ray irradiated single crystal of diketopiperazine (H_0 direction cosines: 0.766,0.643,0).

FIG. 4. Electron spin resonance spectrum of an X-ray irradiated single crystal of diketopiperazine (H_0 direction cosines: 3/2,0,1/2).

For personal use only.

which correspond to four, five, and six lines with intensity ratios 1:3:3:1, 1:2:2:2:1, and 1:2:1:1:2:1 respectively. The splitting of the main doublet is anisotropic and varies between 7 and 27 gauss but the triplet splitting is almost isotropic and approximately 9 gauss in extent. Experimental values of the observed hyperfine interactions at different orientations enabled the hyperfine interaction tensor to be evaluated with respect to the a', b', c' system of axes. The principal values of the hyperfine interaction tensor and the respective direction cosines are given in Table I.

TABLE I

Direction cosines of principal values of the interaction tensor **A** of 1,4-diketopiperazine radical with respect to the a', b', c' system of axes

Principal values (gauss)	Direction cosines		
	l	m	n
7.4	0	1	0
15.9	1/2	0	3/2
26.5	3/2	0	−1/2
Isotropic component = 16.6 gauss			

The theory of the π-electron–σ-proton hyperfine interaction is well known (1, 2). The isotropic portion of the coupling constant is given by $A_H = Q\rho$, where ρ is the π-electron density at the adjacent carbon atom. Using the value of $Q \simeq 23$, it follows from the data in Table I that the π-electron density on the carbon atom of the interacting CH group is approximately 0.72. The principal axis corresponding to the smallest principal value (7.4 gauss) lies parallel to the direction of the σ-CH bond. The intermediate principal value is parallel to the π-orbital symmetry axis, i.e. normal to the 'molecular' plane. These results are similar to those found for the radicals formed in single crystals of N-acetylglycine, glycylglycine, and urea oxalate. The orientation of the radical may now be calculated. It is indicated in Fig. 1 by the heavy lines. This calculated orientation agrees well with the molecular orientation deduced from Corey's (17) results. These indicate that the diagonal joining the two CH_2 groups is approximately parallel to the b-axis and that the molecule is parallel to the $\bar{1}01$ plane, which is also shown in Fig. 1. There is a difference of 14° between the radical plane, as calculated, and the molecular plane, which is taken to be the $\bar{1}01$ plane. There might thus be a slight reorientation of the molecule as the result of X-ray bombardment to form the free radical. It is to be noted that the molecules in this crystal are not extensively hydrogen bonded.

In the crystals of diketopiperazine the molecules are approximately planar hexagonal and possess a center of symmetry. Although the unit cell contains two molecules which are differently orientated, the planes of the two molecules are nearly parallel. The positions of the CH_2 groups are such that the CH bonds of two adjacent radicals would be nearly parallel, and for monoclinic crystals both would be almost parallel to the b-axis. For these reasons only one pair of doublets is observed for all orientations of the crystal. Thus the structure of the free radical formed by the X-ray irradiation of diketopiperazine is that shown in Fig. 5.

The small, almost isotropic triplet splitting observed is attributed to the hyperfine interaction between the odd π-electron and the two protons of the undamaged methylene group. This is the so-called π-electron–π-proton interaction (2) whch is found in various radicals, such as those formed by irradiation of succinic acid (2, 3), glutaric acid (4),

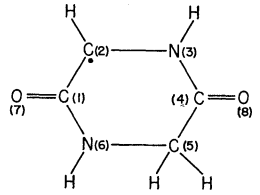

FIG. 5.

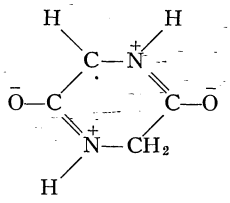
glutamic acid HCl (5), etc. Heller and McConnell (2) have proposed that the isotropic interaction b_N due to a π-proton is directly proportional to the spin density ρ_N on the neighboring unsaturated carbon atom, i.e.

$$[2] \qquad b_N = \rho_N B \cos^2 \theta,$$

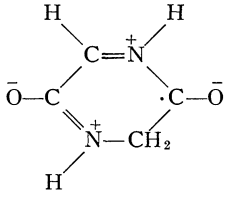
where B is a constant = 40 gauss (for the $(CH_3)_2COH$ radical), and θ is the angle between the π-orbital and the projection of the π-proton C—H bond along the C—C bond onto the orbital, i.e. $\theta = 0$ when the π-proton CH bond is parallel to the π-orbital symmetry axis. In the present case $\theta = 30°$ and therefore $B \cos^2 \theta = 30$ gauss. The observed triplet splitting of 9 gauss corresponds to an odd π-electron density of 0.3 at the carbon atom adjacent to the methylene group. Of course the odd π-electron density could also be at the adjacent nitrogen atom but then the magnitude would be different as presumably the values of ρ and B would not be the same as for the carbon atom. Nevertheless it seems unlikely that the odd electron density is ever very high at the nitrogen atoms; otherwise a large nitrogen hyperfine interaction would surely have been observed.

The occurrence of an appreciable spin density at carbon atom C(4) can be understood from the following considerations. A possible valence bond structure for the radical is shown below:

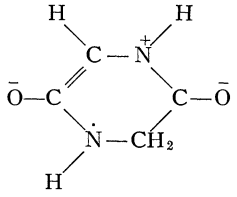


(I)

from which the following structures, II and III, are easily formed:



(II)



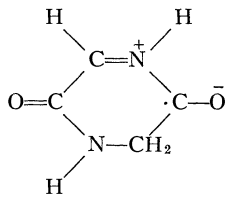
(III)

In these structures it is evident that an appreciable spin density is possible at carbon atom C(4) and nitrogen atom N(6).

It is, of course, also possible to account for a high spin density on carbon atom C(4) on the molecular orbital basis. In this case it is assumed that a delocalized π-orbital is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

formed involving atoms C(2), N(3), C(4), and O(8). Electron spin resonance studies on various amino quinones (18), amine cations (19), and diazine anions (20) have shown that such conjugation systems are common in heterocyclic free radicals. From this molecular orbital viewpoint the radical can be regarded as forming a structure like IV,



(IV)

which gives a high spin density at carbon atom C(4) because of the assumed π-orbital involving the above-mentioned four atoms, i.e. C(2), N(3), C(4), and O(8).

In both structures II and III it is possible for interaction to occur between the unpaired π-electron and the two methylene protons by the mechanism of hyperconjugation. This type of interaction is known to be almost isotropic and if the two protons are placed symmetrically with respect to the π-orbital symmetry plane (as is the case in the radical from diketopiperazine) the two coupling constants would be equal and a triplet structure with a 1:2:1 intensity ratio would be expected. This is in accord with our experimental observations. Furthermore, as has already been pointed out, it is unlikely that there is an appreciable spin density at the nitrogen atom N(6) and so we must conclude that valence bond structure III predominates in the radical along with structure I.

ACKNOWLEDGMENTS

We are indebted to the Defense Research Board and the National Research Council for generous support of this research work. Professor I. Miyagawa, Institute of Solid State Physics, University of Tokyo, has also studied the e.s.r. spectra of X-ray irradiated single crystals of diketopiperazine and obtained similar results. We are indebted to Professor Miyagawa for sending us a copy of his report in advance of publication.

STEREOCHEMISTRY OF ARSENIC

PART VI. TRI-*p*-TOLYLARSINE

J. TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received August 7, 1962

ABSTRACT

Crystals of tri-*p*-tolylarsine are rhombohedral, with cell dimensions $a = 9.84$ Å, $\alpha = 80° 2'$, and space group $R\bar{3}$. There are two molecules in the unit cell, and hence the molecule has symmetry C_3. The structure has been determined from a projection along the rhombohedral cell axis, and the bond lengths and valency angles are given. In comparison with an ideal model having maximum interaction between the arsenic lone pair and the aromatic π-electrons, each ring is rotated about its As—C bond by 36°, the three rotations being in the same sense. These displacements increase overcrowded distances in the ideal model to about the normal van der Waals separations, the closest intramolecular contacts between *p*-tolyl groups being C···C = 3.4 Å and H···H = 2.8 Å. All the intermolecular contacts correspond to van der Waals interactions.

INTRODUCTION

The crystal structure of tri-*p*-tolylarsine has been examined as part of a series of investigations of arsenic derivatives. The chief points of interest in this molecule are the values of the C—As—C angles and the rotations of the aromatic rings from the positions which they would occupy in an "ideal" structure (1).

EXPERIMENTAL

Crystals of tri-*p*-tolylarsine are colorless rhombs with {100} forms developed. The density was measured by flotation in aqueous potassium iodide, and the unit cell dimensions and space group were determined from precession films (Mo $K\alpha$ radiation, $\lambda = 0.7107$ Å).

Crystal Data

Tri-*p*-tolylarsine, $C_{21}H_{21}As$; $M = 348.3$; m.p. = 148–149° C

Rhombohedral, $a = 9.84$ Å, $\alpha = 80° 2'$

Volume of the unit cell = 914 Å^3

D_{calc} (with $Z = 2$) = 1.258, D_{meas} = 1.25 g cm^{-3}

Absorption coefficient for X rays, $\lambda = 0.7107$ Å, $\mu = 19.4$ cm^{-1}

$F(000) = 360$

The Laue group is $\bar{3}$ and there are no systematically absent reflections; therefore the space group is $R3$ or $R\bar{3}$.

The intensities of the $hk0$ reflections were recorded on precession films, estimated visually, and the structure amplitudes derived as usual. No absorption corrections were applied, and the absolute scale was established later by correlation with the calculated structure factors.

Structure Analysis

Since there are only two molecules in the cell, they must have symmetry C_3, with their threefold axes coincident with the space group symmetry axis. The arsenic atoms occupy the special positions xxx, $\bar{x}\bar{x}\bar{x}$ (even if the true space group is the one of lower symmetry, the origin can be chosen midway between the arsenic atoms). The arsenic positions were determined from the Patterson line $P(xx0)$, and an electron-density projection along the principal cell axis was computed with signs based on the As contributions only. This map was necessarily centrosymmetric, and it could be interpreted in terms of space group $R\bar{3}$. Carbon atom coordinates —x, y, and z— were derived and refinement proceeded by several cycles of F_o synthesis, the final electron-density projection being shown in Fig. 1. Although the resolution is rather poor, as a result of the trigonal symmetry of the structure the projection is quite sensitive to small changes in orientation of the *p*-tolyl groups. It was possible therefore to determine the carbon atom positions more precisely than the general appearance of Fig. 1 would suggest.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

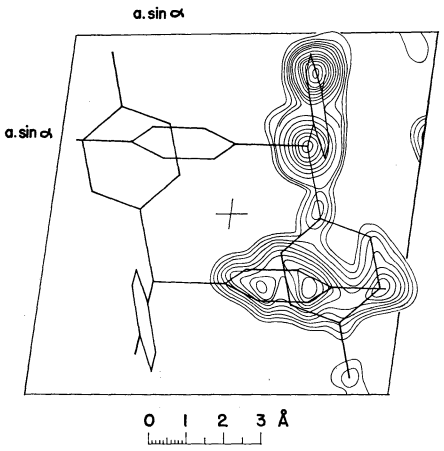

FIG. 1. Electron-density projection along the rhombohedral cell axis; contours at intervals of 1 e Å^{-2} (lowest contour 2 e Å^{-2}) except at the arsenic atom where contours are at 5 e Å^{-2}.

An (F_o—F_c) synthesis was then computed; since many of the atoms were close together in projection, this map was not very useful, but it was possible to make a few small adjustments in the carbon atom positions. The final measured and calculated structure factors are available from the author on request, the discrepancy factor, for the 95 observed reflections, being 0.15. The scattering factors used were those listed by Sagel (2), with $B = 6.5$ Å^2 for all the atoms.

Coordinates and Molecular Dimensions

The final positional parameters of the atoms are listed in Table I, x, y, z being fractional coordinates referred to the rhombohedral crystal axes, and X, Y, Z coordinates in Å with respect to orthohexagonal

TABLE I

Final positional parameters

Atom	x	y	z	X	Y	Z
As	0.1867	0.1867	0.1867	0	0	3.692
C_1	0.251	−0.014	0.192	1.677	−0.537	2.828
C_2	0.392	−0.065	0.151	2.898	0.088	3.144
C_3	0.439	−0.207	0.156	4.094	−0.296	2.551
C_4	0.343	−0.301	0.201	4.075	−1.315	1.602
C_5	0.201	−0.251	0.244	2.853	−1.961	1.285
C_6	0.155	−0.108	0.238	1.664	−1.567	1.879
C_7	0.393	−0.454	0.208	5.359	−1.742	0.969

axes a, b, and c. The standard deviations were calculated from Cruickshank's (3) formulae, the mean values being $\sigma(x) = \sigma(y) = \sigma(z) = 0.007$ Å for As and 0.05 Å for C. These formulae are not strictly applicable in the present case where there is considerable overlap in projection. This factor, however, is probably cancelled out by the fact that each coordinate has effectively been measured twice.

The best plane through the p-tolyl group given in Table I has the equation

$$+0.1546X - 0.6692Y + 0.7268Z = 2.6835$$

and all the atoms listed in Table I, including the As atom, were found to lie within ±0.01 Å from this plane. The other p-tolyl groups are of course related by the trigonal symmetry.

The bond lengths and valency angles in the molecule, calculated from the coordinates of Table I, are shown in Fig. 2. The closest intramolecular contacts between the p-tolyl groups are C_2—C_6' = 3.43 Å and H_2—H_6' = 2.81 Å (assuming that the hydrogen atoms lie on the ring diagonals with C—H = 1.08 Å).

DISCUSSION

Differences between chemically equivalent bond lengths and valency angles are not significant, the mean values, with standard deviations, being:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

As—C	=	1.96±0.05 Å
C_{ar}—C_{ar}	=	1.40±0.03 Å
C_{ar}—CH_3	=	1.49±0.07 Å
∠ C—As—C	=	102.0±2°
∠ As—C—C	=	120±3°
∠ C—C—C	=	120±2°

These dimensions are very similar to those of other arsenic derivatives (4–6).

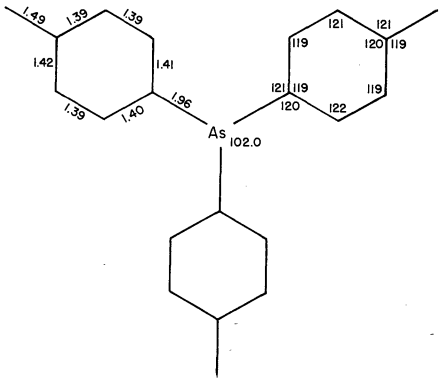

FIG. 2. Measured bond lengths (Å) and valency angles (degrees).

The *p*-tolyl groups are planar, and the arsenic atom lies on the plane of each of the three groups. In the absence of any intramolecular steric interferences between the groups we might expect that the most stable molecular configuration would be that in which there is maximum overlap between the arsenic lone pair and the π-electrons of each of the three *p*-tolyl groups. The arsenic lone pair is directed along the rhombohedral [111] axis and makes an angle of 116° with each of the As—C bonds. An "ideal" model was constructed in which the substituent groups were oriented so that the normals to the aromatic rings lay in the planes defined by the lone pair and the As—C bonds. This model exhibited overcrowding between the *ortho* carbon atoms and between the hydrogen atoms bonded to these carbons.

In comparison with this ideal model the true structure has each ring rotated, in the same sense, about its As—C bond by 36°, the minimum C···C and H···H approaches between adjacent *p*-tolyl groups thereby being increased to 3.4 Å and 2.8 Å respectively, that is to about the normal van der Waals separations. The deviations from the "ideal" model appear to be such as to make the interactions between the lone pair and the aromatic rings as large as possible while increasing the non-bonded intramolecular contacts to the van der Waals distances. The symmetrical deviations may be contrasted with the markedly unsymmetrical displacements in the halogenodiphenylarsines (5, 6).

The intermolecular distances correspond to normal van der Waals interactions.

The author is indebted to the National Research Council and to the President's Research Fund, University of British Columbia, for financial support, to Dr. W. R. Cullen for the crystal sample and for helpful discussion, to Dr. F. R. Ahmed for kindly making available his IBM 1620 programs, and to the staff of the University of British Columbia Computing Centre for assistance with the operation of the computer.

SODIUM CHELATES OF ETHYLENEDIAMINETETRAACETIC ACID

VLADIMIR PALATY*
Department of Anatomy, University of British Columbia, Vancouver, British Columbia
Received August 10, 1962

ABSTRACT

The stability constant of the sodium chelate of EDTA was determined by means of a sodium-sensitive glass electrode. It appears that a hydrogen chelate of the formula $NaHY^{2-}$ is formed in the neutral solution of EDTA, but is very unstable. The stability constants, $pK_{NaY} = -2.61$ and $pK_{NaHY} = 0.03$, are comparable to the value obtained by Schwarzenbach and Ackermann under different experimental conditions by a less sensitive method.

INTRODUCTION

Sodium-sensitive glass electrodes, developed by Eisenman and his co-workers (1) in 1957, have been widely employed for the determination of sodium cation activity. This entity is of basic importance in biological studies of sodium metabolism. To test the suitability of the electrode for the determination of stability constants of sodium chelates, an attempt was made to determine this constant for the sodium chelate of ethylenediaminetetraacetic acid. Its value was determined by Schwarzenbach and Ackermann (2) from the shift of the titration curve of EDTA (ethylenediaminetetraacetic acid, usually shortened as EDTA or H_4Y), caused by the addition of sodium chloride. For the reaction (I),

$$Na^{1+} + Y^{4-} = [NaY]^{3-}, \qquad (I)$$

they found $\log_{10} K = 1.66$. They did not observe any formation of a hydrogen chelate.

The sodium-sensitive glass electrode is sluggish at sodium ion activities lower than 5×10^{-3} *M*, and because the most suitable molar ratio is 1 mole EDTA per mole of sodium, experimental conditions different from those of Schwarzenbach and Ackermann (2) had to be used. The activities and the activity coefficients were calculated by means of the Debye–Hückel equation. The ionic strength of the solutions was always less than 0.1 *M* and therefore the use of this equation was justifiable. Because the sodium-sensitive glass electrode exhibits some response to the ions of potassium as well as to those of sodium, tetramethylammonium hydroxide was employed as the titrant.

EXPERIMENTAL

Reagents

The reagents used were 10^{-2} *M* ethylenediaminetetraacetic acid, di(tetramethyl)ammonium salt; 10^{-2} *M* sodium chloride in 10^{-2} *M* di(tetramethyl)ammonium salt of EDTA; and 1 *M* tetramethylammonium hydroxide, standardized by potassium hydrogen phthalate. The usual precautions were taken to guard against contamination by carbon dioxide.

Instruments

The activity of the sodium ion was measured with a bulb-type sodium-sensitive glass electrode, prepared from NAS_{11-18} glass (1). The electrode was filled with 0.1 *M* sodium chloride. A silver – silver chloride electrode served as the internal reference. Standardization of the sodium electrode was made with standard sodium chloride solutions over the whole pH_s range used in the measurements.

For measuring the pH_s value a Beckman Type G glass electrode was employed. It was standardized with NBS standards.

A Cary Electrometer Model 31, equipped with a high-impedance switch, was used for measuring the E.M.F. of both cells. Saturated calomel electrodes were used as reference.

RESULTS

For the determination of the last two dissociation constants of EDTA, titrations of 10^{-2} *M* EDTA solution were performed. A correction for the small change of volume was made. The following values were used in the calculations: $-\log K_w = 14.167$; $a_{H^+} = 9$ A; $a_{EDTA} = 6$ A (for all ionic forms of EDTA), and $a_{Na^+} = 4.5$ A. The observed and calculated values for the dissociation constants are given in Table I, where pK_c, pK_f, pK_Y, and pK_{HY} were calculated as follows:

$$pK_c = -\log_{10} \frac{c_{H^{1+}} \times c_{H_nY^{-4+n}}}{c_{H_{n+1}Y^{-4+n+1}}} \qquad pK_f = -\log_{10} \frac{f_{H^{1+}} \times f_{H_nY^{4+n}}}{f_{H_{n+1}Y^{4+n+1}}}$$

$$pK_Y = -\log_{10} \frac{a_{H^{1+}} \times a_{Y^{4-}}}{a_{HY^{3-}}} \qquad pK_{HY} = -\log_{10} \frac{a_{H^{1+}} \times a_{HY^{3-}}}{a_{H_2Y^{2-}}}$$

TABLE I

Dissociation constant for the reaction $H_2Y^{2-} = H^{1+} + HY^{3-}$										
$[(CH_3)_4N] \times 100$	2.21	2.32	2.42	2.52	2.63	2.74	2.84

The titrations of EDTA in the presence of 10^{-2} *M* sodium chloride were performed similarly. For two reasons it was assumed that a hydrogen chelate of formula $[NaHY]^{2-}$ was formed. First, the observed activity of the sodium ion was significantly less than the theoretical value in the region where almost no Y^{-4} was present in the solution (pH_s 6.50–8.50) and, besides, it was dependent on the pH_s value. Second, the stability constant K_{NaY}, calculated under the assumption that only $[NaY]^{3-}$ had been formed, fell steeply to a constant value with the disappearance of the HY^{3-} from the solution. When a new calculation was performed, assuming the formation of the hydrogen chelate, the value of K_{NaY} appeared to be constant through the whole pH region. The observed and calculated values are given in Table II. The observed activities of the sodium ion are illustrated in Fig. 1.

TABLE II

Stability constant for the reaction $Na^{1+} + Y^{4-} = [NaY]^{3-}$								
pH_s	9.20	9.55	9.95	10.10	10.25	10.55	10.75	11.30

NOTE: pK_{NaHY}, pK_{NaY}, pK_f, and pK_c have the meaning analogous to those symbols in Table I.

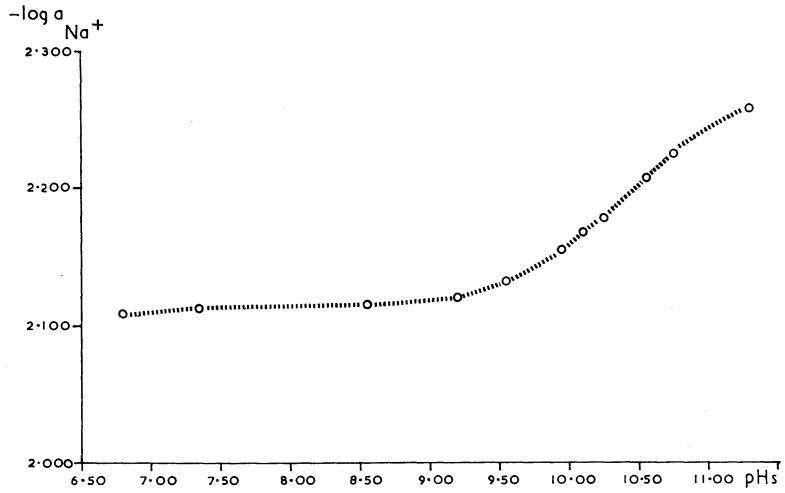

FIG. 1. The sodium cation activity in the presence of an equimolar concentration EDTA ($10^{-2}M$) as the function of pH_s.

DISCUSSION

The results presented here indicate that the sodium-sensitive glass electrode (1) is very suitable and precise for the determination of stability constants of sodium chelates. This method is much more sensitive than the pH shift method, as described in reference 2, but attention must be paid to the properties of the electrode, especially to the low sensitivity and sluggishness at sodium activities lower than 5×10^{-3} M. Apparently, the assumption that only the normal chelate $[NaY]^{3-}$ is formed by EDTA is not correct, as there is evidence for formation of a hydrogen chelate, $[NaHY]^{2-}$, an analogue to those of calcium and magnesium. The most important evidence is considered to be the dependence of the stability constant value on pH, when calculated according to the assumption that only the $[NaY]^{3-}$ chelate is formed. This was not observed by Schwarzenbach and Ackermann (2), because the pH shift method is very insensitive in the case of weak chelates. The stability constants $pK_{NaY} = -2.61$ and $pK_{NaHY} = 0.03$ are comparable to the value given in reference 2, if different experimental conditions are considered.

NEW APPROACHES TO THE STUDY OF ELECTROCHEMICAL DECARBOXYLATION AND THE KOLBE REACTION

PART I. THE MODEL REACTION WITH FORMATE

B. E. Conway and M. Dzieciuch
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received June 29, 1962

ABSTRACT

The kinetics of electrochemical decarboxylation of formate ions has been studied in detail for the first time as a model reaction for examination of the decarboxylation and radical coupling that occurs with higher aliphatic acids. Current–potential curves have been obtained which show a sharp transition region, not diffusion controlled, which is characteristic of passivation phenomena. The behavior is observed with gold, palladium, platinum, and gold–palladium alloys. Tafel slopes and exchange currents have been evaluated for the reaction and possible reaction mechanisms are examined in relation to the experimental results.

Galvanostatic charging, reverse pulse discharging, and open-circuit decay transients have been obtained which indicate formation of films of adsorbed intermediates on the surface. The transition regions in the current–potential curves are associated with formation of this ad-layer. The galvanostatic results enable distinctions to be made between some of the possible reaction mechanisms proposed and estimates to be made of the extent of film formation by adsorbed intermediates formed in the reaction.

GENERAL INTRODUCTION

The following introduction is intended to cover material presented in this paper and in Parts II and III.

Despite the discovery by Kolbe many years ago (1) of a coupling reaction at the anodic electrode during electrolysis of aliphatic carboxylic acids R.COOH to give derivatives R_2 and some oxidation by-products (Hofer–Moest reaction), rather little is known of the mechanism of this reaction from a fundamental electrochemical point of view, e.g. with regard to the primary anodic step (see ref. 2, p. 398). The reaction has been the subject of organic chemical studies for many years, including uses for chain extension of semi-esters of dicarboxylic acids, dimerization of certain compounds, and other modifications of the reaction which have been adequately reviewed (2) in the literature of organic chemistry.

In this present series of papers (Parts I–III), it is the aim to examine the basic electrochemical behavior of reactions involving anodic decarboxylation by choosing, initially, two systems in which side reactions are minimized, so that the electrochemical kinetics of a single reaction can be studied. In the first case we examine the mechanism of the apparently simplest anodic decarboxylation that can occur, viz., that of formic acid or the formate ion. No other papers have evidently been published previously on the electrochemical kinetics of this reaction, and other work (e.g. ref. 3) has been concerned only with the problem of coulombic yields of CO_2 at the anode, the absence of hydrogen as an anodic product, and the production of hydrogen at the cathode. This reaction is ideally suited for electrochemical study since (*a*) the reaction pathway is very largely the simple decarboxylation to give hydrogen ions and carbon dioxide, and (*b*) the reaction is an essential model reaction for studies on the Kolbe reaction itself. It is also of interest in relation to the fuel-cell oxidation of methanol, where formic acid is the limiting product under certain conditions and diminishes cell efficiency.

In the second case (Part II), we examine a true coupling reaction but one which is virtually free from complications caused by the formation of side products.* Such a reaction is that occurring in the electrolysis of trifluoroacetates, where C_2F_6, and the stoichiometric quantity of carbon dioxide, are almost exclusively the reaction products. Since the C-atom at the trifluoromethyl function is in a high state of oxidation, oxidative side reactions, such as occur in the acetate case, are absent and the electrochemical mechanism can be examined under ideal conditions.

The approaches made have been as follows: evaluation of the Tafel parameters determining the current–potential relationship and examination, where possible, of the significance of these parameters in terms of rate-controlling steps; examination of the role of adsorbed intermediates by galvanostatic charging† and open-circuit decay measurements (18) with evaluation of electrode capacitance (19) and surface charge; examination of the role of anodic barrier layer films in the reaction as in the case of the oxygen evolution reaction (20); comparison between the kinetics of the model reactions in non-aqueous solvents (where oxygen evolution or production of oxide intermediates is eliminated) and in water.

Previous proposals regarding the mechanism of the Kolbe reaction are summarized below; none is entirely satisfactory and, as we shall show, most previous theories are based on an inadequate recognition of basic factors governing the kinetics of electrochemical and, in particular, anodic reactions.

In earlier theories by Schall (4) and Fichter (5) it was postulated that an acyl peroxide intermediate was involved which was formed by oxidation of carboxylate ions by electrochemically generated nascent oxygen simultaneously formed. This theory is now untenable since the Kolbe reaction proceeds, in fact, more efficiently in non-aqueous solutions, where no direct oxygen evolution is possible, than in aqueous solutions, where some simultaneous oxygen evolution from the solvent usually occurs; also no evidence for peroxide intermediates can be cited, although their steady-state concentration in an heterogeneous reaction might, of course, be small.

An alternative theory, proposed by Glasstone and Hickling (6), involves the assumption that hydroxyl radicals or hydrogen peroxide generated at the anode initiates the decomposition of the carboxylate ion. The peroxide or OH radical is assumed to produce an acyl-peroxide intermediate which then decomposes to either CO_2 and the Kolbe hydrocarbon or other oxidation products, e.g. alcohols, which are commonly formed as side products. This theory is subject to the same objections as mentioned above for the acyl peroxide theory (and is, in fact, a variant of it) and no hydrogen peroxide or peracids can be detected in the Kolbe reaction. In general, oxidizing intermediates, e.g., OH, which may be formed during the aqueous Kolbe reaction are only incidental to the reaction and in fact complicate it by forming side oxidation products and other species on the electrode surface (see Part II).

The most satisfactory general theory of the reaction is undoubtedly the discharged ion or adsorbed free radical mechanism originally discussed by Crum-Brown and Walker (8) and supported by Walker and co-workers (9, 10) and others in the field (11–14). In this theory, the carboxylate ion is regarded as being discharged onto the electrode surface,

*The literature on the Kolbe reaction is, in fact, almost as much concerned with the chemistry of the side reactions as with the coupling reaction itself. The side reactions are not necessary steps for the coupling process and arise only from choice of system and conditions in the earlier work.

†Recently a similar original approach to the aqueous acetate Kolbe reaction was made by Dickenson and Wynne-Jones (14). However, our preliminary description (16) of the application of this method to anodic decarboxylation was, in fact, published prior to the submission of their papers and described earlier (21). These approaches were evidently made independently and at about the same time.

For personal use only.

where it subsequently decomposes* to give the Kolbe products (and any other side products); the reaction is thus essentially

$$2R.COO^- \rightarrow 2RCOO\cdot(M) + 2e$$
$$2RCOO\cdot(M) \rightarrow 2R\cdot(M) + 2CO_2$$
$$R\cdot(M) + R\cdot(M) \rightarrow R_2,$$

where M signifies a metal site at which the radical is adsorbed. In this scheme, no mention has previously been made concerning which step is rate determining. In the present work we present some conclusions concerning the identity of the rate-determining step and report information on surface coverage (Part III) and anode film formation by adsorbed intermediates. The corresponding sequence for formate discharge is different from the above and must involve steps such as

$$H.COO^- \rightarrow HCOO\cdot(M) + e$$
$$H.COO\cdot(M) \rightarrow H\cdot(M) + CO_2 \text{ or } H.COO\cdot(M) \rightarrow CO_2 + H^+ + e.$$

Normally, in the formate reaction, no coupling is possible to form the "Kolbe" product H_2 since the $H\cdot$ can ionize very rapidly to give H^+ ions in solution at the high anodic potentials required for carboxylate ion discharge to occur at significant rates.

The origin of side products such as CH_4, alcohols, and esters in the acetate case has been examined (11, 12) by deuteration techniques and discussed in terms of carbonium ion intermediates (15) and H-atom abstraction steps (11, 12).

Since the present work was commenced and our preliminary results on determination of the extent of coverage with intermediates by galvanostatic and decay techniques was published (16, 17), Dickenson and Wynne-Jones (14) have published anodic polarization and charging curves for acetate solutions in water. Their results serve to demonstrate the complicated nature of the reaction in aqueous media when oxide film formation and oxygen evolution are concomitant processes in the Kolbe reaction.

In most work, it has been recognized that a critical potential (6, 7), or a critical current density (14), is required for significant Kolbe yields in aqueous solutions. The significance of this potential will be further elucidated in the present work, developing our earlier observations (17), and it will be shown that this potential is apparently not unique to aqueous alkyl carboxylate systems but applies in non-aqueous solutions and also to the simple decarboxylation of formate.

EXPERIMENTAL

(a) General

General techniques for electrochemical kinetic measurements under high purity conditions were used, as previously described (22, 23). The cell, equipped with solution-sealed stopcocks and joints, was similar to that used previously (20, 23) and could be thermostated by circulation of coolant through glass coils sealed into the cell. Provision was made for runs on five or six electrodes in a given purified solution by the usual technique (20, 22, 23). Most of the experimental details described below also apply to the work reported in Parts II and III, except where otherwise stated.

(b) Solutions

Formic acid (98–100%) was first dried over anhydrous cupric sulphate for 3 days and then distilled under vacuum at room temperature. Only the middle fraction was retained. Final traces of water were removed by allowing the acid to remain in contact with boric anhydride for at least 1 week with continuous stirring. Purity of the acid was checked by the freezing point method (observed 8.2(3)° C; literature (24) 8.2(5)° C).

Reagent grade potassium formate was purified by dissolving the salt in hot conductivity water and filtering through decolorizing charcoal. The salt was then recrystallized twice from conductivity water at 0° C,

**Such a reaction is also consistent with the known behavior of carboxyl radicals in the gas phase, e.g., in the decomposition of organic acid peroxides.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

washed with ethanol, and dried at 120° C under vacuum. Solutions of potassium formate in formic acid were prepared by adding formic acid, freshly vacuum distilled from the boric anhydride, to a known weight of the purified salt.

In all experimental measurements, pre-electrolysis of the solutions (22) was carried out on a sacrificial anode for a minimum of 24 hours at a current density of 10^{-2} amp cm^{-2}.

(c) Gases

Hydrogen used for the reference electrodes was purified as previously described (23).

Medical grade carbon dioxide free from hydrogen sulphide, carbon monoxide, and sulphur dioxide was used to saturate all solutions and was further purified by passing the gas through a purification train. The use of the train was discontinued when experimental results showed no significant differences when the highly purified gas was substituted by that passed through a molecular sieve material only (Union Carbide, type 13X).

Nitrogen gas, used for bubbling through the solutions during pre-electrolysis, was purified by passing the gas through a deoxygenation train, as described previously (20, 23).

(d) Electrodes

Satisfactory reproducibility of measurements was obtained by adopting a standardized method of electrode preparation. The electrodes used for kinetic runs were prepared from spectroscopically pure wires of gold, palladium, and platinum, 0.5-mm diameter, which were first cleaned in alcoholic potassium hydroxide, washed in conductivity water, and dried with redistilled acetone. Electrodes were then sealed under oxygen-free nitrogen in glass bulbs following our previous procedures (25). Electrodes of larger area required for low current density coulombic efficiency determinations were cut from sheets of the metal foil and spot-welded to a wire of the same type of metal; subsequent purification was as described above, except for sealing in the bulbs.

Hydrogen reference electrodes were used in all the work both in non-aqueous and aqueous solutions (see Part II), and were prepared without addition agents. Electrodes were always used in pairs and their potentials were checked frequently. Reversibility of hydrogen electrodes in pure aliphatic acids has been demonstrated previously (26).

(e) Coulombic Efficiency Measurements

Coulombic efficiency studies were carried out in a cell consisting of two compartments separated by a solution-sealed stopcock. The cathode compartment was vented directly to the atmosphere while the anode compartment could be vented either to the atmosphere or to a gas collecting system. Provision was also made to allow gas to be bubbled through each compartment to presaturate the solutions, e.g. with CO_2.

The number of coulombs passed during electrolysis was evaluated by means of a copper coulometer, using well-known procedures.

Solutions and electrodes were prepared as described above. The cell was filled with solution, saturated with carbon dioxide, and allowed to come to thermal equilibrium at 5° C. The flow of gas through the solution was then stopped, and the solution electrolyzed for approximately 30 minutes at the required current density, the gas evolved being vented to the atmosphere. This procedure ensured that the system was saturated with the anticipated product gas. Measurements were then made by placing the copper coulometer in the electrolysis circuit and connecting the cell to a previously evacuated gas collecting burette, where the gas was then collected by displacement of mercury at constant pressure and temperature in an air thermostat at 30±0.2° C. At the commencement of electrolysis, the evolved gas was allowed to accumulate so that the solution was not sucked into the evacuated gas collecting system when the stopcock to the burette was opened. When a sufficient volume of gas had been collected and the electrolysis terminated, the pressure was adjusted in the system and the total volume of evolved gas recorded, and corrected to s.t.p. after making allowance for the partial pressure of solvent vapor.

(f) Gas Analysis

Carbon dioxide was determined in an Orsat absorption pipette by absorption in 40% aq. KOH. Remaining gases were then transferred to a sampling bulb and analyzed by gas phase chromatography (Perkin–Elmer Model 154) using a silica gel column. The fractograms of the unknown mixture were compared against calibration curves for H_2, O_2, CF_4,* C_2F_6,* and the quantity of unknown gases determined by comparing either peak heights or half widths.

(g) Electrical Measurements

Currents were measured by means of a Sensitive Research milliammeter (Model S) with ranges from 0.01 to 1000 ma full scale. The accuracy of the instrument was certified by the manufacturer as 0.5% of full scale deflection.

Potential measurements were made by one of the following procedures: (i) Potentials were read directly from a recording potentiometer (Philips model PR2210A) with a high input impedance ($\sim 10^{14}$ ohms)

See Part II.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

electrometer (Keithly model 610A) between the recorder and test electrode. (ii) Alternatively, potential measurements were made by means of a manual high-impedance potentiometer (Radiometer model PHM-4b or a Doran pH–mV meter).

(h) Polarization Measurements

Potential measurements vs. the hydrogen electrode in the same solution were conducted over the current density range of 5×10^{-7} to 10^{-2} amp cm^{-2} at 5° C.* This temperature was chosen in order to eliminate slight attack of the metal which otherwise occurs at room and elevated temperatures. Successive measurements were made with the five other electrodes in the same solution. Potentials were either recorded on a recording potentiometer using the Keithly electrometer as an impedance converter or obtained on the high-impedance Doran pH–mV meter.

Potential measurements were conducted by either the rapid method (22), in which the potential was measured as quickly as possible (beyond the short period of double-layer charging) after setting the current to successive desired values, or by waiting until the potential had reached a steady value. The latter procedure was used in the film-forming or transition region of the Tafel lines observed (see below).

(i) Galvanostatic Measurements

General conditions were as described above. When pre-electrolysis was terminated, overpotential measurements were carried out on one electrode over the current density range of 10^{-7}–10^{-2} amp cm^{-2}. If the potential measurements were unsatisfactory, galvanostatic measurements were not carried out, and pre-electrolysis was continued for a further period or a fresh solution was prepared until satisfactory current–potential relations were obtained.

Potential–time relationships, for the anodic charging process, open-circuit decay, and forced cathodic decay were then obtained at each remaining electrode.

Galvanostatic charging curves were obtained by previously setting the current at the desired value, and impressing it on the test electrode by activating a mercury-wetted vacuum relay having an extremely short switching time. Details of the circuit are given in Part III. The resulting transient was then recorded photographically on the oscilloscope, the input to which was circuited through the Keithly high-impedance electrometer.

Potential–time relationships for the open-circuit decay process were obtained by either polarizing the test electrode at the desired current density until a steady potential was reached or by polarizing the electrode successively for several controlled increments of time (1–300 seconds) with decay transients taken after each period of time, the current being terminated by activating the relay; the resulting open-circuit decay transient was recorded.

Galvanostatic forced decay studies were carried out by anodically polarizing the test electrode at the desired current density for controlled intervals of time (1–300 seconds), reversing the current at the same numerical value by activating the vacuum relay, and recording the resulting transient on a calibrated oscilloscope (see Part III).

In all runs, the electrode was allowed to return to within 5–10 mv of its original rest potential before further transients were taken.

RESULTS

(a) Current–Potential Curves

Current density (i) – potential (V) curves in the form of Tafel lines over a current density range of five to six powers of 10 are shown in Fig. 1(a, b, c) for the system potassium formate (0.1, 1.0, 5.0 M) – 100% formic acid at Pt, Au, and Pd electrodes. From previous work (20), we had available some Pd–Au alloys and as a matter of interest, in relation to the electronic configuration of the alloys (23), runs were also carried out on these materials. The results are shown in Fig. 2(a, b, c). In all these experiments, the data presented are based on runs on at least 12 electrodes studied in at least two separately prepared solutions. A typical assembly of points is shown for one series of runs in Fig. 1(b) but in the other figures referred to above, the data are shown as the best straight lines drawn over the linear regions of the $V - \log [i]$ plots. In most cases very satisfactory reproducibility was observed and it was unnecessary to make statistical calculations of the lines of best fit.

In all cases, the $V - \log [i]$ plots showed a sharp inflection at a critical current density. At first it was suspected that this might have been due to presence of traces of anodic

**That is, below the freezing point of the pure solvent. No trouble was encountered in the non-aqueous solution with freezing of the solution as the presence of electrolyte lowers the freezing point.*

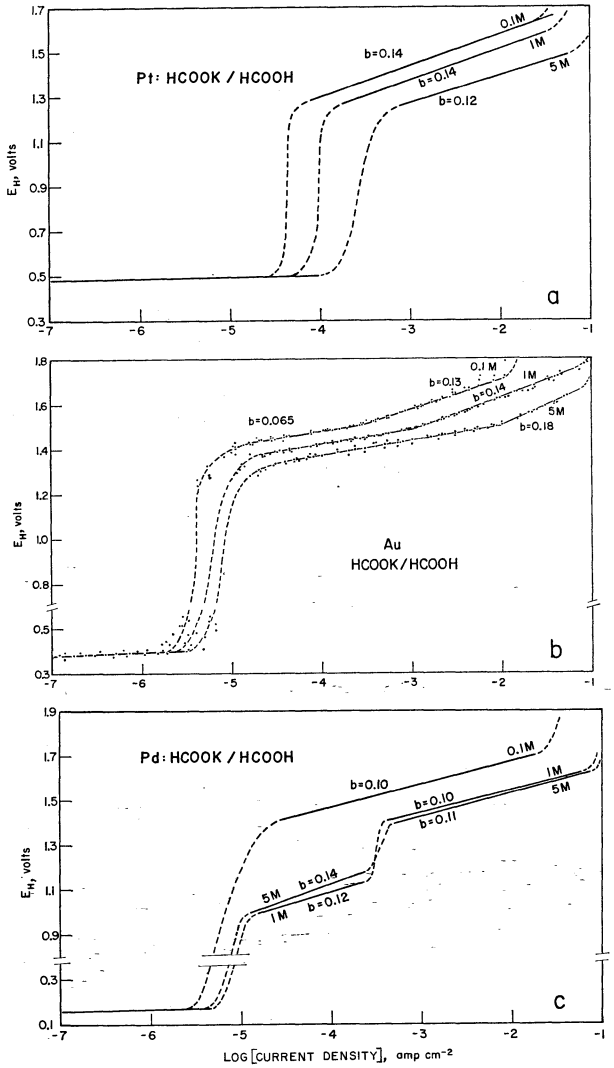

FIG. 1. Current–potential curves for anodic decarboxylation at platinum, gold, and palladium in solutions of HCOOK in 100% HCOOH (5° C).

depolarizers, e.g. formaldehyde, so that the critical current was simply a diffusion-controlled oxidation current. Rigorous purification of the solutions did not modify the effect. Addition of formaldehyde and other likely impurities had the effect of lowering the critical current rather than raising it. The effect is hence due to a general activation-controlled process and is also found in the aqueous solutions (Part II) and in the case of trifluoroacetate decarboxylation (Part II). Its significance will be further discussed below. The critical currents are generally increased with increasing formate concentration; analogous effects were also observed first in potentiostatic work on the aqueous acetate Kolbe reaction (27) and reported again subsequently (14) for steady-state current-potential curves. In these measurements (14, 27), however, the critical currents increased with *decreasing* carboxylate concentration. The critical currents observed in the acetate

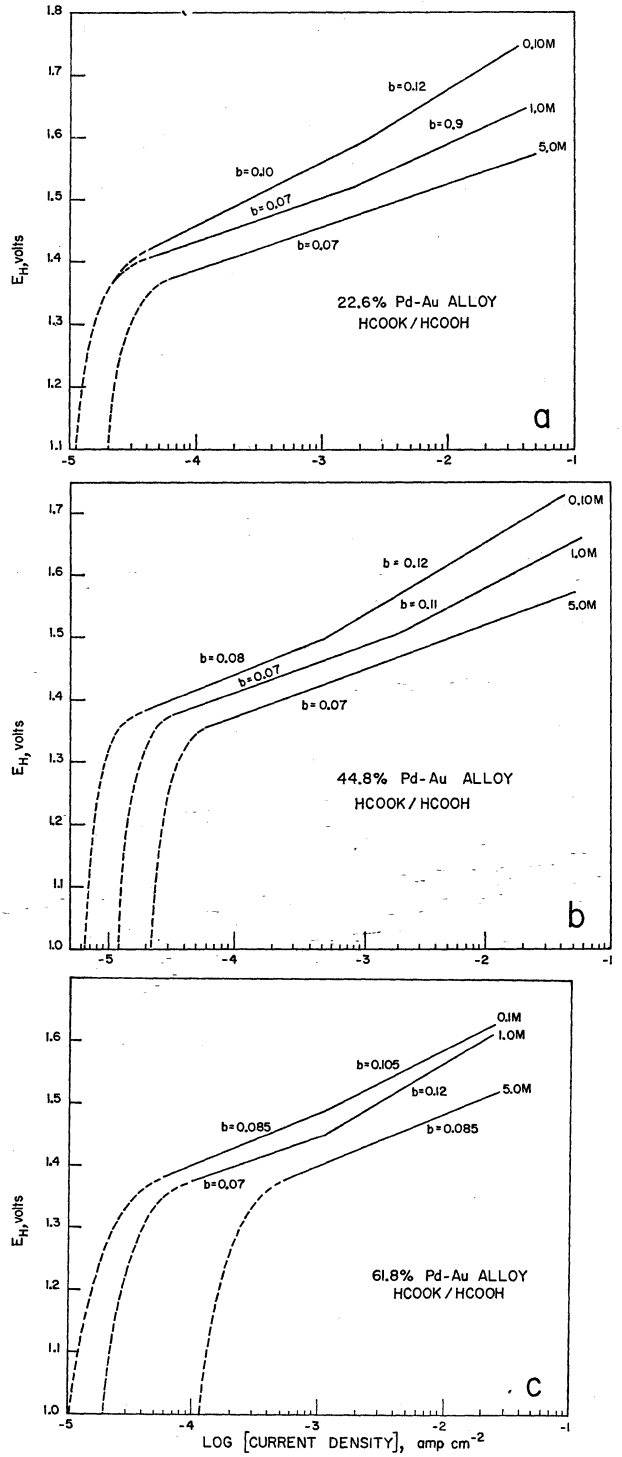

Fig. 2. Current–potential curves for anodic decarboxylation at Pd–Au alloys in solutions of HCOOK in 100% formic acid (5° C). (*a*) 22.6 wt% Pd–Au; (*b*) 44.8 wt% Pd–Au; (*c*) 61.8 wt% Pd–Au.

work may correspond to a process different from that leading to the critical behavior in the formate system, since already in the acetate work the anodic potentials are very high (viz. $E_H \doteqdot 2$ v). We suspect, in relation to the present results and those for trifluoroacetate in aqueous solution (Part II), that another critical region may exist at current densities lower than those used in the acetate work and would correspond to our critical behavior, which occurs at 10^{-5}–10^{-4} amp cm^{-2}. In the Russian work (27), the data appear to be expressed in current rather than current densities, so quantitative comparison of their results with other data is not possible.

At palladium and platinum, the Tafel slopes approach $2.3(2RT/F)$ in the upper region. In the lower region at Pt and Pd, the current density is, at first, almost independent of potential. At gold, in the upper region, two Tafel regions are observed with slopes of about 0.065 (ca. $2.3RT/F$) and 0.13 to 0.18 ($>2.3(2RT/F)$) depending on the concentration of the electrolyte. Two Tafel slopes are also observed in the upper region for the Pd–Au alloys and the lower slopes have varying values dependent upon the alloy composition.

(b) Galvanostatic Transients and Decay Behavior

The sharp transitions from a lower to an upper region in the current–potential curves described above suggested that a phenomenon similar to passivation with anodic film formation was occurring in the decarboxylation reaction. This was supported by the observation of: (*a*) periodic fluctuations of potential at constant current, near the critical current for transition in the current–potential plot (such periodic phenomena are characteristic of changes of an anode from an active to a passive, back to an active state, etc., and are well known in anodic oxidation of metals (28)) and (*b*) "overshoot" and "undershoot" transients in the potential when the current was either being raised or lowered, respectively, near the critical current; the latter effects were observed particularly in the aqueous solution reaction.

Further information was sought on the nature of the transition behavior in the current–voltage curves, in the light of the above observations, by examining charging, discharging, and open-circuit decay behavior of the anodes in formic acid containing potassium formate. Typical curves obtained galvanostatically for anodic charging and reverse cathodic discharging after polarization are shown in Figs. 3 and 4, which are copies of oscilloscope photos; (related open-circuit decay curves will be discussed in Part III; e.g. see Figs. 6, 10, 11, Part III). For the three metals studied in the present work, gold, palladium, and platinum, there is clear evidence of an arrest in the transients corresponding to the charge associated with a film of adsorbed intermediates produced in the anodic reaction. The arrests only appear after moderate and high anodic polarizations and confirm that the transition behavior in the current–potential plot is associated with a critical condition for formation of an anodic product (an anodic passive film) on the electrode surface, which can be removed either by a self-discharge process (18, 29) on open-circuit or by a reverse cathodic pulse, as with adsorbed O or H (30). Following our initial observations in a preliminary paper (16, 17), we believe this is the first direct proof of the role of an adsorbed layer of intermediates in electrochemical decarboxylation reactions. Similar layers are formed in the case of the Kolbe reaction itself (with CF_3COO^-) and will be discussed in Part II.

The arrest behavior in the formic acid/formate system is characteristic not only of the current density of the initial anodic polarization, but also depends on the *time* of prior anodic polarization at this current density, as shown in Fig. 5 for cathodic discharge. Similar behavior on open-circuit decay at Pd will be seen in Fig. 6, Part III. The time

effects increase in the order Pd > Pt > Au and are associated with buildup of thicker, or more extensive, layers of the anodic product with time as will be discussed quantitatively in Part III.

(c) Coulombic Efficiency in the Anodic Decarboxylation

Results of the coulombic efficiency runs are shown in Table I. Provided the solution is presaturated with CO_2, the coulombic yield approaches 1 mole of CO_2 per 2 Faradays at

TABLE I

Current efficiencies for CO_2 production in anodic decarboxylation in formic acid
(1 *M* HCOOK/HCOOH, 5° C)

Electrode	Current density, amp cm^{-2}	Products	Efficiency, %
Pt	1×10^{-2}	CO_2	86
	2.5×10^{-3}	CO_2	79
	5×10^{-4}	CO_2	65
Pd	1×10^{-2}	CO_2	84
	1.2×10^{-3}	CO_2	75
	5×10^{-4}	CO_2	56
Au	1×10^{-2}	CO_2	86
	1×10^{-3}	CO_2	62
	5×10^{-4}	CO_2	55

high current densities. The actual values vary from about 86% to 55% of the theoretically expected yields based on the reaction

$$HCOO^- \rightarrow CO_2 + H^+ + 2e. \qquad [I]$$

This discrepancy from 100% is due to some attack on the metal, which is visible as a colloidal suspension after prolonged coulombic-yield electrolyses. It is minimized by operating at low temperatures (5° C in the present work). The low yields at low current densities where there is little visible bubble formation may be due to supersaturation of the solution by CO_2. No other gases, including oxygen, can be detected from the formate decarboxylation and, in particular, no hydrogen (the "Kolbe analogue") is present and peroxides were shown to be absent. The above coulombic yields justify interpretation of the observed electrochemical behavior largely in terms of steps which may be involved in the overall anodic reaction [I], particularly at the higher current densities.

DISCUSSION

(a) Kinetic Parameters

The parameters i_0 (the exchange current) and b, the Tafel slope, which characterize the kinetics of the rate-determining step, can be obtained from the current–potential relations of Figs. 1 and 2. Evaluation of i_0 values requires calculation of the reversible potential for reaction [I] on the hydrogen scale, since the reaction itself is not practically reversible. The half-cell reactions involving the hydrogen electrode are

$$CO_2 + 2H^+ + 2e \rightarrow HCOOH$$

and

$$H_2 \rightarrow 2H^+ + 2e,$$

i.e.

$$HCOOH \rightarrow CO_{2(g)} + H_{2(g)}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The equilibrium constant is

$$K = f_{CO_2} f_{H_2} / a_{HCOOH}$$

in terms of the fugacities of the gases and the activity of formic acid. The free energy change is

$$\Delta G = \Delta G^0 + RT \ln f_{CO_2} f_{H_2} - RT \ln a_{HCOOH}$$

and the e.m.f. of the hydrogen – formic acid cell is hence, at unit fugacity (pressure) of the gases (the standard state),

$$E = E^0 - (RT/2F) \ln a_{HCOOH}.$$

The ΔG^0 value for the above reaction is obtained from the standard free energies of formation of HCOOH (liq.) and CO_2 (g) as 10.622 kcal mole^{-1} (31) for a standard state of unit mole fraction of HCOOH and unit fugacity (in atm) of CO_2 (here unit pressure is actually taken). The value of E^0 is hence -0.230 (European convention) on the hydrogen scale in pure formic acid. The observed log current–potential behavior can hence be extrapolated to the theoretical reversible potential and the log $[i_0]$ evaluated or log $[i_0]$ can be calculated from the observed overpotential and Tafel slope. Values of log $[i_0]$ and b are summarized in Table II. The formic acid decarboxylation is seen to be highly irreversible

and this can offer a kinetic explanation of the difficulty of obtaining useful rapid oxidation beyond the formate stage to CO_2, encountered in the fuel cell oxidation of methanol.

(b) Reaction Mechanism

No previous studies of the mechanism of the reaction have been made although the production of $HCOO^{\cdot}$ radicals as intermediates has been recognized (3). The following steps corresponding to the overall reaction [I] can be envisaged (equivalent steps involving the molecule HCOOH can, of course, be written but involve the same intermediates):

$$M + HCOO^- \rightarrow HCOO^{\cdot}(M) + e \qquad [II]$$
$$HCOO^{\cdot}(M) \rightarrow CO_2 + H^{\cdot}(M) \qquad [III]$$
$$H^{\cdot}(M) \rightarrow H^+ + e \qquad [IV]$$
$$[H^+ + HCOO^- \rightleftarrows HCOOH],$$

scheme A

where (M) indicates a site on the metal surface to which the ad-species is bound; or

$$M + HCOO^- \rightarrow HCOO^{\cdot}(M) + e \qquad [II]$$
$$HCOO^{\cdot}(M) \rightarrow CO_2 + H^+ + e \qquad [V]$$

scheme B

or

$$M + HCOO^- \rightarrow M + CO_2 + H^+ + 2e, \qquad [VI]$$

scheme C

i.e. the overall reaction in one step involving two electrons.

A pathway involving

$$HCOO^{\cdot}(M) \rightarrow CO_2 + H(M) \qquad [III]$$

followed by

$$2H(M) \rightarrow H_2 \text{ (Kolbe analogue product)}$$

or

$$H(M) + HCOO^- \rightarrow H_2 + CO_2 + e$$

is not observed presumably since if [III] occurs, the desorption ionization [IV] will tend to be very rapid at the high anodic potentials involved, and steady-state coverage by H(M) will be very small.

Radical–ion desorption steps (cf. the case of the hydrogen evolution reaction) such as

$$HCOO^{\cdot}(M) + HCOO^- \rightarrow (HCOO)_2 + e,$$

or recombination of the $HCOO^{\cdot}$ radicals, could lead to diformyl peroxide. Experimentally peroxides are not detectable.

Step [VI] (the scheme C) or a radical desorption step such as

$$HCOO^{\cdot}(M) + HCOO^- \rightarrow 2H^+ + 2CO_2 + 3e$$

is unlikely since they involve more than one electron in a single rate-determining step. Similarly, such a step as

$$HCOO^- + H(M) \rightarrow 2H^+ + CO_2 + 3e$$

is kinetically improbable as a single electrochemical step. Schemes A and B are hence the likely pathways in CO_2 evolution and are examples of the "discharged ion" theory of decarboxylation.

The Tafel slopes for Langmuir conditions (i.e. at limitingly low or limitingly high surface coverage by intermediates; cf. refs. 18, 32) are readily apparent for various rate-determining steps in the above schemes and have been derived by now well-known

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

principles of analysis of consecutive electrochemical reactions (33, 29). The following limiting values are obtained.

Scheme A	
(*a*) Ion discharge [II]	$2.3(2RT/F)$
(*b*) First-order decomposition of HCOO·(M), [III], with [II] in quasi-equilibrium and surface coverage of HCOO·(M) potential dependent	$2.3RT/F$
(*c*) HCOO·(M) approaching full coverage and its surface concentration potential independent	Limiting current
(*d*) H(M) ionization [IV] (steps [II] and [III] in quasi-equilibrium)—unlikely to be rate controlling at high anodic potentials	$2.3(2RT/3F)$
H·(M) ionization at full coverage by H·—unlikely to be rate controlling at high anodic potentials	$2.3(2RT/F)$
Scheme B	
(*a*) Ion discharge [II] (as in scheme A)	$2.3(2RT/F)$
(*b*) HCOO·(M) ionization and decomposition	
(i) Full coverage by HCOO·	$2.3(2RT/F)$
(ii) Potential-dependent coverage with [II] in quasi-equilibrium	$2.3(2RT/3F)$

In order to make as complete an analysis as possible of the theoretically predictable results, we now examine cases where effects of coverage by the intermediates on their respective heats of adsorption are significant and introduce these effects in the free energies of activation of the various steps, as in previous papers (34, 19); this treatment is necessary since we show here and in Part III that the electrode surface is appreciably covered by the adsorbed intermediates. We obtain for scheme A

$$v_2 = k_2(1-\theta_F)a_{F^-}\exp -[\Delta G_2^{\ddagger}-\beta VF+\beta r_1\theta]/RT, \quad [1]$$

where subscripts F^- and F represent the formate ion and adsorbed radical, respectively, the latter at a total coverage θ; r_1 is a term similar* to that used previously (34) to allow for the variation of heat of adsorption of F with coverage, and β is the usual symmetry factor (19). Similarly

$$v_{-2} = k_{-2}\theta_F \exp -[\Delta G_{-2}^{\ddagger}+(1-\beta)VF-(1-\beta)r_1\theta]/RT \quad [2]$$

$$v_3 = k_3\theta_F(1-\theta_H) \exp -[\Delta G_3^{\ddagger}-\beta r_1\theta+(1-\beta)r_2\theta]/RT \quad [3]$$

$$v_{-3} = k_{-3}\theta_H(1-\theta_F) \exp -[\Delta G_{-3}^{\ddagger}-\beta r_2\theta+(1-\beta)r_1\theta]/RT, \quad [4]$$

**This term arises (cf. ref. 34) in the expression for the variation of heat of adsorption ΔH of the intermediate with coverage θ in the equation*

$$\Delta H_F = \Delta H_F^0 - r_1\theta.$$

An equation of this form originates if there is heterogeneity of adsorption sites or if there are surface induction effects (37) associated with change of the work function of the metal with coverage. Two-dimensional interaction effects will not generally give rise to a linear equation for ΔH as a function of θ and the magnitude of the r values for such a model are usually too small to account for the observed fall of heat of adsorption with coverage, e.g. of O, N, *and* H *from the gas phase at various metals (37, 38). The general case for the simultaneous adsorption of several species at comparable coverages has been worked out elsewhere (19).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where r_2 is a term similar to r_1, but referring to the variation of heat of adsorption of H with coverage. The velocity of [IV] is

$$v_4 = k_4\theta_H \exp -[\Delta G_4^{\neq} - \beta VF - \beta r_2\theta]/RT. \quad [5]$$

We now examine limiting cases assuming, with Thomas (34), that at coverages sufficient to influence the exponential terms ("Temkin" conditions) the pre-exponential terms are of the order of magnitude of unity and will not be very potential dependent (cf. ref. 34). If [II] were rate determining we obtain the same result as in the Langmuir case, namely $dV/d \ln i_2 = 2RT/F$.

When [III] is rate determining, and [II] in quasi-equilibrium, so that

$$VF = r_1\theta + \text{constants}, \quad [6]$$

and θ_H is small (since [IV] will tend to be fast under these conditions and particularly at the high anodic potentials involved here), we obtain

$$v_3 = k'\theta_F \exp -\left[\Delta G_3^{\neq} + \frac{r_2 - r_1}{2r_1} VF\right]/RT, \quad [7]$$

and the Tafel slope as

$$dV/d \ln i_3 = \frac{2RT}{F}\left(\frac{r_1}{r_1 - r_2}\right)(\beta \rightarrow \tfrac{1}{2}). \quad [8]$$

As in previous calculations (19, 36), we are faced with the problem of assignment of values to r_1 and r_2; it is clear that we actually only require the ratio r_2/r_1. Since [IV] will tend to be fast at the high anodic potentials, $\theta_H \rightarrow 0$ so that $\theta \rightarrow \theta_F$. In the case of the radicals "F" and H, we note that their areas are quite different and from space-filling models it may be calculated that the area of "F" is about 14.2 Å^2 and that of H (e.g. for one atom of H per surface hexagonal hole or per surface metal atom) about 6 Å^2. For purely steric reasons the effective value of r_1 will be some 2.5 times larger than that of r_2 and we may anticipate that if r_1 and r_2 are also associated with some two-dimensional dipole-layer induction effects (37) in the interphase, r_1 will be greater than r_2 owing to greater surface dipole moment, since presumably the adsorbed H.COO$^-$ will be appreciably more polar than the adsorbed H. The steric effect in the ratio of effective r_1 and r_2 values arises since, if reaction [III] were allowed to proceed for a unit surface fully covered with "F" to produce the equivalent coverage by H (assuming no further antecedant reactions), the latter species would, in fact, only cover approximately 1/2.5 of the surface. Thus, when any "F" radical decomposes it effectively locally creates for the resulting H a relatively uncovered region of the surface.

We may hence anticipate values of r_1 about 3 to 4 times r_2; $dV/d \ln v_3$ will hence be in the range $3RT/F$ to $2.7RT/F$; when $r_1 \gg r_2$, $dV/d \ln v_3 \rightarrow 2RT/F$ as a *minimum* value. The observed slopes lower than $2RT/F$ cannot be explained by taking, for example, $r_1 < r_2$ since negative values of $dV/d \ln v_3$ then result, which have no physical significance. The lower slopes (ca. RT/F) at Au and the Pd–Au alloys hence cannot be explained in terms of reaction [III] proceeding at appreciable coverages under "Temkin" conditions.

Finally, for the unlikely case of [IV] being rate determining at potentials substantially anodic to the hydrogen electrode potential, and with [II] (and [III]) in resulting quasi-equilibrium, the limiting result is

$$v_4 = k_4' \exp -\left[\Delta G_4^{\neq} - \beta VF - \beta\left(\frac{r_2}{r_1}\right) VF\right]/RT \quad [9]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

or

$$= k_4' \exp -\left[\Delta G_4^{\neq} - \beta VF\left(1 + \frac{r_2}{r_1}\right)\right]/RT \qquad [10]$$

and

$$dV/d \ln i_4 = \frac{2RT}{F}\left(\frac{r_1}{r_1+r_2}\right). \qquad [11]$$

In scheme B, the result for [II] is the same as above and for [V], rate determining

$$v_5 = k_5\theta_F \exp -[\Delta G_5^{\neq} - \beta VF - \beta r_1\theta]/RT. \qquad [12]$$

If [II] is in quasi-equilibrium and equation [6] applies,

$$dV/d \ln i_5 = RT/F \ (\beta \doteqdot 1/2) \qquad [13]$$

except for limitingly full coverage by HCOO· when the Langmuir result applies ($dV/d \ln i_5 = 2RT/F$) in any case.

Barrier layer film effects, which are important in some anodic reactions (20, 35), are evidently not significant in the present reaction since the maximum Tafel slopes observed are not abnormally high. There is some possibility, however, of the role of such effects in the Kolbe reaction itself and in aqueous solutions (see Parts II and III).

The polarization behavior at all three electrodes at low current densities (below the critical current) is associated with an unusually low slope. This is characteristic of a process occurring at a current less than or close to its exchange current. The apparent overpotential referred to the hypothetical standard formate reversible potential is quite appreciable at these low current densities, so it is not the formate decomposition reaction itself which determines this behavior. Since the current efficiency for CO_2 production at the lowest current densities is only about 55–60%, and metal dissolution visibly occurs (by formation of colloidal metal in prolonged low current density polarization) we suggest that this low-slope region is associated with the "active" attack of the metal which occurs simultaneously with reactions [II] and [III] at low coverage. This is consistent with the subsequent "passive" behavior at the critical current, at higher current densities. Such low slopes are not observed in the aqueous solutions (Part II).

(c) Galvanostatic Results

Some possibility for distinction between the various reaction mechanisms envisaged above is afforded by the galvanostatic charging results. It is seen that at appreciable current densities (Figs. 3 and 4) there is a significant arrest amounting to 200–250 μcoulombs/cm^2 at Pt or Au and up to 1770 μcoulombs/cm^2 both on the charging and forced discharge transients (and implicit in the open-circuit decay curves) at appreciable anodic current densities (16, 17). The charging arrest cannot be a diffusion-controlled transient since: (*a*) at the current density used, the transition time for $HCOO^-$ oxidation is some 10^3 to 10^4 times larger than that observed; (*b*) the arrest is also seen both on the reverse transient and on open-circuit decay. The magnitude of the arrests at platinum and gold correspond to an initial coverage of about one monolayer by some more or less reversibly removable ad-species, presumably produced in the discharge step. This calculation is based on an assumed area of the HCOO· radical of 14.2 Å^2 (from Courtauld models). It is reasonable to assume this ad-species is the HCOO· radical discussed above; it is unlikely to be H· since any adsorbed H would tend to be removed at a very high rate (ca. $10^{10}\theta_H$ amp cm^{-2}) at the high anodic potentials (ca. 1–1.5 v) used so that its steady-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

state coverage in an *anodic* reaction could hardly be significant and certainly not experimentally measurable in a slow transient such as observed here. The charging results therefore indicate an appreciable coverage presumably by HCOO· radicals; it may hence be concluded that, at least for the upper potential region (Figs. 1 and 2), discharge from or to which gives the arrest in the transients, a radical desorption step is the rate-controlling process, i.e. either process [III] (scheme A) or [V] (scheme B) is involved. Reaction [III] gives $dV/d \ln i = RT/F$ under "Langmuir" conditions or $(2RT/F)\cdot(r_1/r_1-r_2)$ under "Temkin" conditions while V gives $2RT/F$ for full coverage, or for potential-dependent coverage conditions, $2RT/3F$ ("Langmuir") or RT/F ("Temkin" conditions). The slope $2RT/3F$ is *not* observed under any of the conditions examined, but slopes of approximately RT/F and $2RT/F$ are found for Au and the Au–Pd alloys while slopes of about $2RT/F$ are found for Pt and Pd. At gold, the change of slope from a low to a higher value with increasing current density is explicable formally in terms either of a transition from one rate-determining step to another in a *consecutive* reaction sequence, or in terms of a transition from "Langmuir" to "Temkin" conditions (e.g. for reactions [III] or [V]); the corresponding change for reaction [V] is from $2RT/3F$ (Langmuir) to RT/F (Temkin) to $2RT/F$ (full coverage). The first transition is not observed. We believe the latter type of transition may be applicable in the present case, since a second *consecutive* step (e.g. [IV]) is not plausible in this scheme. Alternatively [III] (Langmuir) followed by [V] (at full coverage)—which is really a related path involving the same initial state—is also consistent with the results for gold and some of the alloys. For Pt or Pd, the results are consistent with [III] (Temkin) or [V] (full coverage) over the whole current density range in the upper region. We have outlined plausible reaction mechanisms here consistent with the experimental behavior but it is premature to propose any further final conclusions at the present stage. The behavior of possible intermediates,-e.g. the HCOO· is further discussed in Part III in terms of the e.m.f. decay behavior.

(d) The Transition Behavior

The transition behavior observed in the present system is quite analogous to that observed in oxygen evolution (20) and, in general, in anodic passivation. In the present work, no oxygen evolution or oxide film formation is possible and we must presume that the passivation behavior is associated with formation of a film of "formate" or formate radicals on the metal surface. This is supported by the form of the observed galvanostatic transients and by the open-circuit decay behavior (Fig. 5). Under certain conditions, visible decomposition of the film at Pd occurs on open circuit when it has been formed to an appreciable thickness (16); the metal then returns to an "active" condition and the film layer can be repeatedly re-formed by anodic polarization. Periodic phenomena commonly associated with critical conditions for passivation were also observed in the present work. The critical potentials previously referred to (6, 7, 14) in work on the Kolbe reaction are probably related to this condition of passivation and formation of a carboxylate film (HCOO·(M) in the present case). Further evidence that the transition region corresponds to completion of an ad-layer is afforded by the quantitative analysis of the e.m.f. decay transients in terms of surface charge and adsorption pseudocapacity to be discussed in Part III.

Time Dependence of Electrode Potential

In the present non-aqueous system, very little time variation of potential was noted except near the critical current in the transition region where, under rather critical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

conditions of current adjustment, periodic oscillations of the potential occurred of the kind well known near the critical condition for passivation. In the upper potential region, steady potential values were attained within 10–20 seconds. Extended logarithmic time dependence of the overpotential of the kind reported in Part III for the aqueous solutions of potassium formate was not observed for the reaction in the 100% formic acid solutions.

Dependence of Kinetic Parameters on the Metal

In Table II are shown the Tafel slopes and exchange currents for the various metals used. Basically, the same type of transition behavior is observed at all three metals and the highest Tafel slopes are all of the order of $2.3(2RT/F)$. Gold and the gold-rich Au–Pd alloys, however, differ from platinum and palladium in that a slope of about $2.3RT/F$ is observed in the upper potential region followed by the slope of $2.3(2RT/F)$. As we have discussed on p. 35, this could arise from a change of coverage conditions, since at the top of the transition region, the pseudocapacity data indicate coverage by $HCOO^{\cdot}$ to only about 0.5 monolayer. As in the case of the oxygen evolution reaction at alloys (20), no direct relationships to metal *d*-band configuration are observed since the anodic reactions are proceeding, at the higher current densities, on a film of an anodic intermediate, so that the kinetic parameters will not necessarily be expected to reflect properties of the metal itself.

ACKNOWLEDGMENT

Grateful acknowledgment is made to the National Research Council for support of this work.

NEW APPROACHES TO THE STUDY OF ELECTROCHEMICAL DECARBOXYLATION AND THE KOLBE REACTION

PART II. THE MODEL REACTION WITH TRIFLUOROACETATE AND COMPARISONS WITH AQUEOUS SOLUTION BEHAVIOR

B. E. CONWAY AND M. DZIECIUCH

ABSTRACT

Electrochemical kinetic studies on the Kolbe reaction have been carried out in the trifluoroacetate – 100% trifluoroacetic acid system, where the reaction can be examined from an electrochemical viewpoint with minimum complication by oxidative side reactions. High yields of the Kolbe products C_2F_6 and CO_2 are obtained and current–potential curves exhibiting transition behavior and linear Tafel regions are found. Tafel slopes are deduced for "Langmuir" and "Temkin" conditions of surface coverage by intermediates and compared with the experimental observations. Plausible reaction mechanisms are proposed, which are supported by galvanostatic discharge transients; the latter indicate that the coverage by adsorbed intermediates in the trifluoroacetate reaction approaches a monolayer. In the aqueous formate systems, multilayer formation is indicated, including deposition of layers of different species corresponding to different arrest regions in the galvanostatic discharge transients. It is suggested that these layers may consist of oxide and the discharged carboxylate and that the transition behavior and critical potentials in the Kolbe reaction correspond to conditions for passivation of the metal by oxide and carboxylate species.

INTRODUCTION

A general introduction to the problem has been given in Part I (1), where the model decarboxylation reaction involving formate in formic acid was examined. In the present paper, studies of the kinetics of the Kolbe decarboxylation and coupling reaction with the trifluoroacetate ion in 100% trifluoroacetic acid are reported. Comparisons are made with the kinetics of this reaction and of the formate decarboxylation in aqueous media. The system has been chosen as one giving minimal side reactions owing to the difficulty of further oxidation of the trifluoromethyl function and also since complications due to oxygen evolution or anodic oxide formation (cf. ref. 2) are absent under non-aqueous conditions. The system can hence be studied from a fundamental electrochemical viewpoint with minimum ambiguity. The results demonstrate that in aqueous media the decarboxylations are more complex than in non-aqueous media and probably involve surface films both of oxide and carboxylate species.

EXPERIMENTAL

(a) General

General methods of approach through current–potential studies, galvanostatic charging and discharging experiments, and coulombic yield determinations have been described in Part I (1) and were applied to the present system.

(b) Solutions

Trifluoroacetic acid (b.p. 70–72° C) was first gently* refluxed over phosphorus pentoxide for 1 hour, and distilled (3). A second distillation from fresh phosphorus pentoxide was then carried out and only the fraction distilling at 71.1° C was kept for preparation of the experimental solutions. The acid was stored in glass-stoppered vessels until required. Prior to use, the acid was again distilled from fresh phosphorus pentoxide in order to eliminate water completely and thus avoid the consequent possibility of direct oxygen evolution.

**The formation of the anhydride is minimized by keeping the temperature of the mixture as low as possible. In any case it is readily separated in the subsequent distillation.*

Potassium trifluoroacetate was prepared by neutralizing previously purified trifluoroacetic acid with potassium hydroxide. The salt was then recrystallized twice from conductivity water, washed with ethanol, and exhaustively dried under vacuum at 100° C for 24 hours.

Solutions of potassium trifluoroacetate in the 100% trifluoroacetic acid were prepared from the freshly dried salt by redistilling (see above) the purified trifluoroacetic acid directly from the desiccant under vacuum near room temperature. Pre-electrolysis was for 24 hours at 10^{-2} amp cm^{-2} on a sacrificial electrode.

(c) Electrical Measurements

These were as described in Part I. The details of the galvanostatic circuit are given in Part III. Hydrogen reference electrodes were used as in the pure formic acid solutions and were satisfactorily reversible.

(d) Current Efficiency for CO_2 and C_2F_6 Production

The expected gases were CO_2 and C_2F_6 (CF_4 was also found in traces). The CO_2 was determined as described in Part I and C_2F_6 by gas chromatography using standard records obtained with known samples of Matheson C_2F_6. Gas collection and total charge passed were determined as in Part I.

(e) Measurements in Aqueous Solutions

In order to compare the kinetic behavior of the trifluoroacetate and formate decarboxylations under aqueous and non-aqueous conditions, a number of runs were performed in 1 *M* aqueous solutions of the potassium salts of the two acids and in solutions also containing 1 *M* KOH. The latter was used to stabilize the pH and also possibly to facilitate simultaneous oxygen evolution or oxide film formation in the aqueous systems. All other conditions were as described above and in Part I; the water used was conductivity water which had been redistilled in purified nitrogen. During the runs, the solutions were saturated with pure carbon dioxide. All runs were carried out at 5° C.

RESULTS

(a) Current–Potential Curves

The Tafel lines for Pt, Pd, and Au in 1 *M* CF_3COOK in 100% CF_3COOH are shown in Fig. 1(*a*, *b*, *c*). The lines are already in a high-potential region (>2.0 v) at 10^{-5} amp cm^{-2} and the transition behavior previously observed in the formate system occurs between 10^{-6} and 10^{-5} amp cm^{-2} in the trifluoroacetate system (see Fig. 2 for comparison). It is also observed on the open-circuit decay and the cathodic galvanostatic discharge. The Tafel lines in the upper region at all three metals are striking on account of their high slopes of $4RT/F$ to about $6RT/F$, depending on metal and current density. These high slopes are not impurity controlled and are maintained with the most carefully purified solutions and electrodes. Similar high slopes are known for the oxygen evolution reaction when oxide films are present (4) and, in some cases, are associated with barrier layer charge transfer processes (5). Comparison between the current–potential behavior in the trifluoroacetate and formate decarboxylation reactions is shown in Fig. 2.

Comparative runs were carried out in aqueous solutions and are shown in Fig. 3(*a*, *b*, *c*). The current–potential behavior is again complex but Tafel slopes only exceed $2RT/F$ for Pt, except in the transition regions, which cover a range of potential of about 1.5 v. At high current densities the slopes at Pd and Au are about 0.08 v, i.e. much lower than in the non-aqueous solutions. In general, the Tafel regions are well defined and remarkably reproducible, e.g. the data for Pt and Pd, except near the transition region, where presumably film formation is either not complete or has not reached a steady state. At Pt, two transition regions are observed: a main one at $10^{-5.5}$ amp cm^{-2}, analogous to that observed at Pd and Au and in the formate system, and a smaller one at $10^{-2.9}$ amp cm^{-2} with hysteresis between the upper and lower regions. The significance of the Tafel lines will be discussed after the coulombic yields have been reported in the following section.

The time variation of electrode potential in the aqueous Kolbe reaction is relatively small except at low current densities ($< 10^{-5}$ amp cm^{-2}), where the potential increases initially in an approximately logarithmic manner with time, as also shown in Part III, and becomes constant after about 10–20 minutes. At higher current densities beyond the

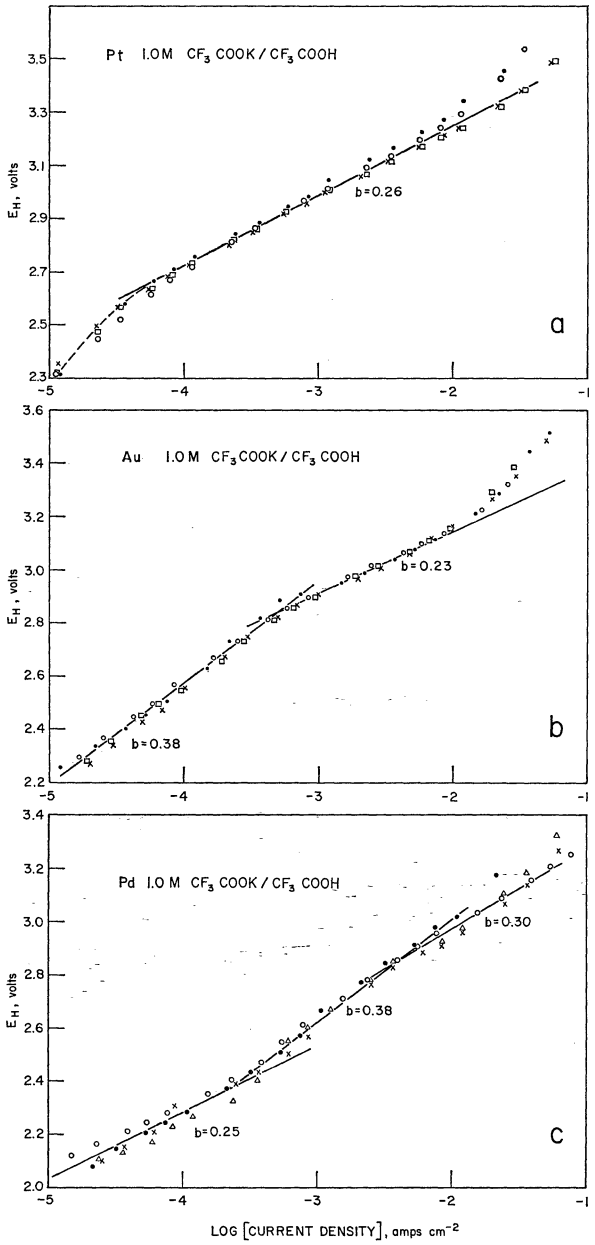

FIG. 1. Current–potential curves at 5° C for the trifluoroacetate Kolbe reaction in 100% trifluoroacetic acid.

limiting current, the time variation is small and sensibly constant electrode potentials are reached in about 2 minutes in the direction of both increasing and decreasing current densities.

In order to compare the behavior observed with trifluoroacetate in water with that for formate under the same conditions, a number of current–potential curves were obtained for the system 1 *M* H.COOK in water. The results were more difficult to reproduce than

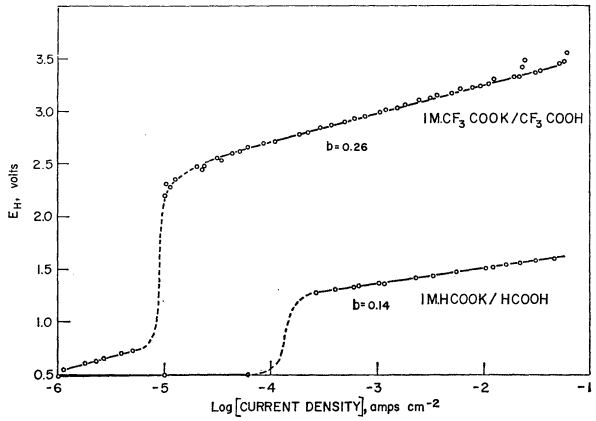

FIG. 2. Comparison between the current–potential curves for trifluoroacetate and formate decarboxylation in the respective pure acids (1 *M* potassium salts; 5° C).

those obtained in the 100% formic acid, particularly at Pd. By carrying out the reactions in the presence of 1 *M* (and 5 *M*) KOH, reproducibility was much improved. The current–potential curves are shown in Fig. 4 for aqueous formate and aqueous formate plus KOH at 5° C.

(b) Coulombic Yields

Coulombic yields in the 100% trifluoroacetic acid are very satisfactory and amount to 96% of the theoretical yields based on the reaction

$$2CF_3COO^- \rightarrow C_2F_6 + 2CO_2 + 2e. \qquad [I]$$

Also, the correct ratio of C_2F_6 (except for small traces (less than 2%) of CF_4 at low current densities) to CO_2 for 2 Faradays is observed in CO_2-saturated solutions. The yields are better than those in the formate system owing, probably, to a smaller attack on the metal. The coulombic yields are recorded in Table I. It is this observation of high coulombic yields that allows the kinetics in the pure trifluoroacetic acid to be discussed almost

TABLE I

Coulombic efficiencies for gas evolution in the trifluoroacetate Kolbe reaction (100% trifluoroacetic acid, 5° C)

Metal	Current density, amp cm^{-2}	Coulombic efficiencies, %	
		CO_2	C_2F_6
Pt	1×10^{-2}	94	96
	2.5×10^{-3}	93	92
	5×10^{-4}	93	85

	3.1×10^{-3}	22	38

calculated for CO_2 and O_2 assuming that 2 F per mole CO_2 and 4 F per mole O_2 are involved in the evolution of the gas mixture. From the measured volumes of each of the two gases evolved and the total number of coulombs passed as determined in the copper coulometer, the coulombic percentage yields may be calculated. The coulombic percentage yields do not necessarily add up to 100%, since the reactions leading to gas evolution are themselves not necessarily 100% coulombically efficient with respect to volumes of the gases evolved. Thus, visible surface films are formed at gold and palladium in the aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

formate system but not under non-aqueous (100% formic acid) conditions. The films may hence be surface oxides (see below).

The anodic reaction at Pd and Au in aqueous potassium trifluoroacetate, which was studied for comparative purposes only and in less detail than the corresponding non-aqueous reaction gives 87–96% O_2 and only 5–10% CO_2 with very little C_2F_6. The results are striking in so far as at Au and Pd, the decarboxylation reaction is almost completely inhibited by the oxygen evolution process which proceeds with quite high coulombic efficiency (and visible oxide films can be seen at Au), and the Tafel plots in Fig. 3(*b*, *c*) are hence principally for O_2 evolution from the trifluoroacetate solution. At Pt the Kolbe coupling reaction to give C_2F_6 still occurs but only at a moderate efficiency of ca. 25% with oxygen evolution. This disparity of behavior is probably connected with the stability and extent of growth of oxide films at Au and Pd in comparison with that at Pt. This result can also offer an explanation of why oxidation products are more predominant in the acetate Kolbe reaction at Au than at Pt.

(c) Galvanostatic Transients

The qualitative features of the transients (Fig. 5) were similar to those observed in the formate – formic acid system except that the arrests were generally shorter at a given current density, indicating a rather smaller surface concentration of ad-species. However, in the aqueous formate system, anodic films of appreciable thickness are indicated, as shown below (Fig. 6). Considerable complexity in the transients was observed in the aqueous systems, indicating formation of several electrochemically distinct species on the surface. These transients are discussed in more detail below.

(d) Exchange Currents

Exchange current densities, i_0, could not be evaluated for the trifluoroacetate reaction owing to lack of the appropriate thermodynamic data and to the low coulombic yields in the aqueous media. However, for the aqueous formate decarboxylation, i_0 values can be evaluated, since the standard reversible potential can be calculated (9); values are recorded in Table III for the various aqueous solutions used. The i_0 values are based on the reversible potentials given in Table IV.

DISCUSSION

(a) Reaction Mechanisms

By analogy with the reaction with formate, we may envisage the following steps in the overall reaction [I]:

$$CF_3COO^- \rightarrow CF_3COO^{\cdot}(M) + e \qquad [II]$$

$$CF_3COO^{\cdot}(M) \rightarrow CF_3^{\cdot}(M) + CO_2 \qquad [III]$$

$$2CF_3^{\cdot} \rightarrow C_2F_6. \qquad [IV]$$

Side reactions could lead to the production of the peroxide $(CF_3.COO)_2$ or the ester $CF_3.COOCF_3$; the coulombic yields indicate that these pathways are insignificant, although *adsorbed* peroxide could be an intermediate which quantitatively decomposes to C_2F_6 and CO_2. A reaction involving two ions, decarboxylation, coupling, and two-electron transfer in one step is unlikely. The above scheme is hence believed to be the most reasonable pathway on which to base a more definitive treatment of reaction mechanism. At full coverage by $CF_3COO^{\cdot}$ in [III], potential-dependent radical–ion desorption paths such as

$$CF_3^{\cdot} + CF_3COO^- \rightarrow C_2F_6 + CO_2 + e \qquad [V]$$

or

$$CF_3COO^{\cdot} + CF_3COO^- \rightarrow C_2F_6 + 2CO_2 + e \qquad [VI]$$

TABLE III

Mean Tafel parameters for the aqueous formate decarboxylation reaction (5° C)
(minimum of 10 electrodes in two solutions)

Electrode	Concentration	$b(\pm 1\%)$, v	$i_0(\pm 40\%)$ amp cm^{-2}	Current density range, amp cm^{-2}
Pt	1 *M* HCOOK/H_2O	0.13 (lower)	1×10^{-10}	6×10^{-6}–1×10^{-2}
		0.12 (upper)	1.7×10^{-21}	2×10^{-4}–5×10^{-2}
Au	"	0.12 (lower)	3.9×10^{-11}	5×10^{-6}–1×10^{-3}
		0.16 (upper)	3.9×10^{-17}	1.5×10^{-4}–5×10^{-2}
Pt	1 *M* HCOOK + 1 *M* KOH/H_2O	0.06 (lower)	4×10^{-30}	9×10^{-6}–2×10^{-3}
		0.17 (upper)	3.2×10^{-17}	1.5×10^{-3}–1.1×10^{-1}
Pd	"	0.06 (lower)	4×10^{-29}	1.5×10^{-6}–5×10^{-3}
		0.12 (above hysteresis)	1.3×10^{-20}	1.5×10^{-2}–5×10^{-1}
		0.10 (in hysteresis region)	4×10^{-24}	2.5×10^{-4}–1.5×10^{-2}
Au	"	0.06 (lower)	8×10^{-26}	1.5×10^{-6}–2.5×10^{-3}
		0.13 (above hysteresis region)	4×10^{-19}	5×10^{-3}–1.1×10^{-1}
		0.09 (in hysteresis region)	6×10^{-26}	5×10^{-5}–5×10^{-3}
Pt	1 *M* HCOOK + 5 *M* KOH/H_2O	0.06 (lower)	5×10^{-31}	7×10^{-6}–3×10^{-3}
		0.16 (upper)	2×10^{-18}	5×10^{-3}–2×10^{-1}
Pd	"	0.06 (lower)	1×10^{-29}	2×10^{-6}–4×10^{-4}
		0.11 (upper)	2×10^{-22}	8×10^{-5}–2.5×10^{-2}
Au	"	0.06 (lower)	2×10^{-28}	5×10^{-6}–9×10^{-4}
		0.12 (upper)	1×10^{-19}	6×10^{-5}–5×10^{-2}

NOTE: Exchange currents are calculated with respect to the reversible potential estimated from the thermodynamic free energy for 25° C; see Table IV.

The apparent i_0 values for Au are based on the overall current. The values given are hence correct to within about a third of an order of magnitude, taking into account the observed current efficiencies. The uncertainty is not seriously different from that involved in the extrapolation to the reversible potential. At Pt and Pd the errors are correspondingly less.

TABLE IV

Reversible potentials for the reaction
$HCOOH \rightleftarrows 2H^+ + CO_2 + 2e$ on the hydrogen scale
in the same solution indicated

Solution	E_H, v
1 *M* aq. HCOOK	−0.047
1 *M* aq. HCOOK + 1 *M* aq. KOH	+0.105
1 *M* aq. HCOOK + 5 *M* aq. KOH	+0.125

NOTE: Data are calculated from thermodynamic data for 25° C. Standard state HCOOH = unit activity, 1 atm pressure of CO_2 and H_2. The reversible potential of the reaction shown depends on KOH concentration since the extent of hydrolysis of the potassium formate by $H_2O + HCOO^- \rightarrow HCOOH + OH^-$ depends on KOH activity. The reversible potentials calculated for 5° C will differ from the above values by approximately 17 mv since the standard entropy change for the reaction HCOOH (aq.) $\rightleftarrows CO_2 + H_2$ is approximately 43 e.u.

may also be envisaged analogous to the reaction $H^{\cdot} + H^+ + e \rightarrow H_2$ in the hydrogen evolution reaction. However, reaction [VI] is probably not exclusively the desorption path since, in the acetate case, methylations as well as acetoxylations of suitable substrates can be achieved (15, 16), indicating that steps such as [III] must be involved. The pathway [II], [VI] would, of course, not involve any alkyl radicals.

By analogy with the treatment given in Part I for the formate decarboxylation and with that for the hydrogen and oxygen evolution reactions, the limiting Tafel slopes for the above steps under Langmuir conditions (6, 7) are obviously $dV/d \ln i_2 = 2RT/F$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

($\beta = 0.5$); $dV/d \ln i_3 = RT/F$ or a limiting current as the coverage by $CF_3COO^{\cdot}$ tends to unity; $dV/d \ln i_4 = RT/2F$ or a recombination controlled limiting current as the coverage by $CF_3^{\cdot}$ tends to unity. For reaction [V], when $\theta_{CF_3COO\cdot}$ is potential independent at full coverage, the Tafel slope would be $dV/d \ln i_5 = 2RT/F$. Similarly for reaction [VI], the Langmuir slopes are $2RT/3F$ or $2RT/F$ and the slopes at intermediate coverage will be $2RT/3F$ or RT/F as in the analogous hydrogen evolution case (6).

The step corresponding to reaction [IV] in Part I, viz. ionization of H and decarboxylation in one stage, is unlikely here since this would lead to the formation of the carbonium ion CF_3^+, which presumably will give $CF_3.COOCF_3$ (or CF_3OH in water) as a final product. This pathway is insignificant. The corresponding slopes under conditions (cf. refs. 6, 7) where coverage-dependent activation energies must be considered are

$$dV/d \ln i_2 = 2RT/F; \; dV/d \ln i_3 = \frac{2RT}{F} \cdot \frac{r_1}{r_1 - r_2},$$

as in the corresponding formate reaction, where r_1 now refers to changes of adsorption energy of $CF_3.COO^{\cdot}$ with coverage and r_2 to corresponding changes for $CF_3^{\cdot}$ (see Part I). The same limitations apply to the values of the Tafel slope *under these conditions* as have been discussed for the unimolecular formate decomposition; the minimum value of this slope for reaction [III] is $2RT/F$.

At low coverage by $CF_3^{\cdot}$, step [IV] will be associated with a slope of $RT/2F$ while at high coverage by $CF_3^{\cdot}$ or $CF_3COO^{\cdot}$, where activated adsorption of $CF_3^{\cdot}$ from C_2F_6 might consequently arise (cf. the hydrogen case (6, 7)), the recombination slope would be RT/F. The Tafel slopes ($dV/d \ln i$) deduced are summarized below:

Reaction	"Langmuir" conditions	Intermediate coverage ("Temkin" conditions)
[II]	$2RT/F$	$2RT/F$
[III]	RT/F or limiting current as $\theta_{CF_3COO\cdot} \rightarrow 1$	$\frac{r_1}{r_1 - r_2} \cdot \frac{2RT}{F}$
[IV]	$RT/2F$ or limiting current as $\theta_{CF_3\cdot} \rightarrow 1$	$r_1RT/2Fr_2$ or r_1RT/Fr_2 for activated adsorption of C_2F_6 as $2CF_3^{\cdot}$
[V]	$2RT/F$ (at full coverage by $CF_3COO^{\cdot}$)	$\frac{2RT}{F} \cdot \frac{r_1}{r_1+2r_2}$ or $\frac{2RT}{F} \frac{r_1}{r_1+r_2}$ for activated adsorption
[VI]	$2RT/F$ ($\theta_{CF_3COO\cdot} \rightarrow 1$) or $2RT/3F$ (low coverage)	$2RT/3F$ or RT/F for activated adsorption

FOOTNOTE ADDED IN PROOF: In a forthcoming publication, we deduce the Tafel slopes for these reactions under conditions where the variation of free energy of adsorption of intermediates with coverage originates from induced heterogeneity (ref. 37, Part I) rather than intrinsic heterogeneity effects. For such a case, Tafel slopes are derived which are related to those given in the above table but not specifically involving the two r parameters.

The observed slopes (for non-aqueous conditions; Fig. 1(*a*, *b*, *c*)) above the transition region are consistently above $2RT/F$ and approach values between 0.24 and 0.38 v (i.e. between about $4RT/F$ or $6RT/F$ respectively for the Naperian Tafel slopes). Slopes higher than $2RT/F$ can, in principle, be explained in terms of barrier layer films as discussed previously for processes at anodic oxide films (4, 5); under such conditions, the slope is proportional to the thickness of the film and the transfer coefficient for a single-electron charge-transfer step becomes δ/D where δ is the half-jump distance or barrier half-width

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and D is the thickness of the film. The observed slopes thus would correspond, as in the oxygen evolution reaction at gold and gold–palladium alloys (4), to film thicknesses of the order of two to three monolayers.

The galvanostatic cathodic discharge curves (Fig. 5) indicate arrests of about 30–100 μcoulombs cm^{-2} which, with an area of the species $CF_3COO^{\cdot}$ taken as 25 Å^2 from Courtauld models, correspond to apparent fractional coverages of about 0.36–1.7; with a real to apparent area factor (cf. ref. 8) of about 3, these coverages would all become *less* than a monolayer. This conclusion will be seen subsequently to be of importance in the discussion of the kinetics. The detailed data are shown in Table V. Extended polarization prior to discharge increases the coverage and pseudocapacity somewhat as seen from the table; the capacity and coverage also depend on current density (or potential), as expected.

NOTES: 1. θ values are based on an area of 25 Å^2 for the $CF_3COO^{\cdot}$ radical assuming no free area between groups. The corresponding effective molecular area for a square lattice arrangement will be $4/\pi$ times larger and value of the charge for $\theta = 1$ will be $4/\pi$ times smaller. 2. The values quoted in this table are all calculated for the *apparent* electrode area. 3. θ and C values are calculated from the arrest region in the transients. 4. The derived data recorded in this table were calculated from measurements on 10× enlargements of the oscilloscope photographs.

The appreciable coverages observed are inconsistent with reaction [II] being rate determining and indicate a relatively slow desorption step. The recombination slopes $RT/2F$ (or RT/F) for [IV] are not observed under any conditions, so that it can be stated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

fairly unambiguously that the radical coupling reaction [IV] cannot be rate determining. The nature of the products does not indicate a carbonium ion desorption mechanism, so that [III] or [V] are probably the only rate-determining steps which can be formulated in accordance with all the experimental data. The coverage results indicate appreciable values of θ so that the kinetic treatment for appreciable coverages ($\theta \doteqdot 0.5$) must probably be preferred. For [III], this predicts Tafel slopes of $r_1/(r_1-r_2)\times 2RT/F$. All observed slopes (see Fig. 1(*a*, *b*, *c*)) are much greater than $2RT/F$ (with $\beta = 1/2$) and could in principle (but see below) be explained with values of r_1 which are about 1.5–2 times r_2; thus for $r_2 = (1/2)r_1$ the Tafel slope is $4RT/F$ and with $r_2 = (2/3)r_1$ the slope is $6RT/F$. As in the formate case, it is reasonable to suppose that r_1 for the adsorption of the bulky polar $CF_3COO^{\cdot}$ group is greater than that for the smaller $CF_3^{\cdot}$ group. As we have mentioned above, it should be noted that high anodic slopes could, in principle, be explained on the basis of charge transfer across barrier layer films (4, 5) as in the formation of anodic oxide layers in oxygen evolution. However, for the present reaction, with the observed real fractional coverages of less than unity in most cases, this explanation is inconsistent with the experimental data as it implies a barrier film thickness D of at least four to six times the half-jump distance δ ($\beta \doteqdot \delta/D$). It will be noted that the high slopes always occur *above* the transition region, that is, where the surface, as in the formate case, is probably filled by the carboxylate radicals (see Parts I and III). In such a case, the "Temkin" slope deduced for reaction [III] is actually inapplicable since the coverage by $CF_3COO^{\cdot}$ is either high (Langmuir conditions) or unity and hence independent of potential. A potential-dependent desorption step such as [V] proceeding on the more or less completely covered surface appears therefore to be indicated as the likely mechanism in the upper Tafel region. The metal–solution interface can then be represented electrically as a complex double layer with a potential difference across the layer of $CF_3COO^{\cdot}$ plus $CF_3^{\cdot}$ radicals and a further potential difference across an ionic double layer. The potential profile will hence be as qualitatively shown in Fig. 7, i.e. with a surface dipole double layer and an ionic double layer beyond its limit at the interface with the solution. The effective symmetry factor is then appreciably less than 0.5 if the activated state ($\ddagger$) in the charge transfer desorption reaction [V] falls within the ionic double layer and an appreciable fraction of the total metal–solution potential difference falls across the dipole double layer.* The same effects need *not* arise in the formate reaction, where the rate of decomposition of the adsorbed radical layer itself can be potential dependent at high coverage by the reaction

$$HCOO^{\cdot} \rightarrow CO_2 + H^+ + e, \qquad [VI]$$

as discussed in Part I. This is consistent with the normal (ca. $2RT/F$) slopes observed in the upper Tafel region in the formate decomposition.

(b) Reactions in Aqueous Solution

Much of the earlier work on the Kolbe reaction has been carried out in aqueous media. Several experiments were hence performed in aqueous solutions of potassium trifluoroacetate in order to compare the kinetic behavior under the idealized conditions in the wholly non-aqueous trifluoroacetate system with that in the aqueous solutions. The current potential curves are shown in Fig. 3(*a*, *b*, *c*). Comparisons were also made with the behavior of 1 *M* formate in aqueous and aqueous 1 *M* KOH solutions (Fig. 4).

**This model is actually a variant of the barrier layer model except that no separate process of potential-dependent activated transport of charge carriers within a film of significant thickness is involved.*

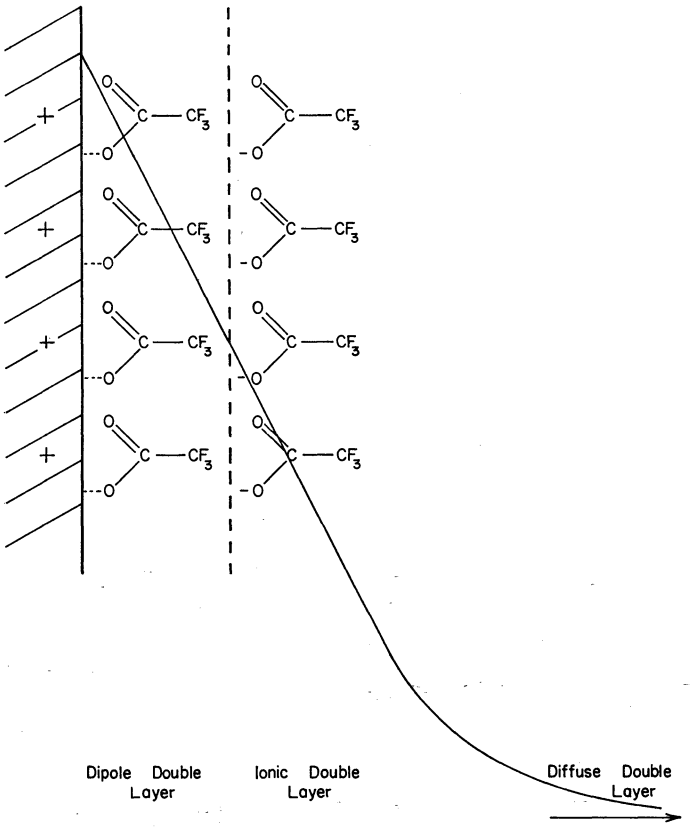

FIG. 7. Schematic representation of surface layer at electrode with adsorbed trifluoroacetate radicals.

The runs in aqueous CF_3COOK exhibit slopes greater than $2.3(2RT/F)$ (0.25–0.30 v) in the upper region only at platinum electrodes, while at gold or palladium the slopes are between 0.12 and 0.08 v. There is usually hysteresis, near the transition region, between the results obtained for increasing polarizing currents and decreasing currents, suggesting irreversibility in the film-forming process. At platinum, there appears to be a small second transition region at a current density of 2×10^{-3} amp cm^{-2} possibly corresponding to that mentioned for the acetate case by Dickenson and Wynne-Jones (2). This is not observed at palladium or gold. At platinum and gold, the Tafel regions are well defined and extend over two or three decades of current density.

The coulombic yields observed (see p. 46) indicate that under aqueous conditions the trifluoroacetate Kolbe reaction only proceeds with appreciable efficiency at Pt, and the current–potential curves shown in Fig. 3 for Au and Pd are therefore essentially those for oxygen evolution from the trifluoroacetate solution. This difference of behavior between Pt, and Au and Pd on the other hand, is consistent with the observed Tafel slopes which are only greater than $2.3(2RT/F)$ in the Pt case and are comparable with those observed in the non-aqueous trifluoroacetic acid at Pt. At Au and Pd in the aqueous case, the reaction is largely oxygen evolution so that the Tafel parameters will not be expected to be comparable with those in the non-aqueous solutions where the Kolbe reaction proceeds with high efficiency at these metals (Table I). It must be supposed that for chemical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reasons the oxide films are more stable and thicker at Au and Pd than at Pt and cause the inhibition of the trifluoroacetate discharge. Such oxide films cannot, of course, be formed in the pure trifluoroacetic acid.

The runs in aqueous formate and aqueous KOH – formate solutions (Fig. 4) all demonstrate well-defined transition regions, and the lower-slope region is well developed since the limiting transition current density is higher here than in the formate – 100% formic acid system (Part I). At palladium, gold, and platinum, the lower Tafel region consistently has a slope of $0.06(2.3RT/F)$ and the upper regions* have slopes of about 0.12 $[2.3(2RT/F)]$ or somewhat larger. In Part III we show that the transition region in most cases corresponds to the filling up of the surface with adsorbed radicals, so that the lower-slope region probably corresponds to the rate-determining step

$$HCOO^{\cdot} \rightarrow H^{\cdot} + CO_2$$

associated with the unimolecular decomposition slope of $2.3RT/F$ (see Part I). The upper region then probably corresponds to discharge of the formate radicals (reaction [VI]) at high coverage, or discharge of further formate ions onto the layer or film of adsorbed formate, e.g. in a way analogous to the oxygen evolution reaction which often occurs on an oxide layer. Typical transition region behavior (i.e. oscillation) is observed in the aqueous system as in the non-aqueous one.

It is of interest that addition of KOH in the aqueous formate decarboxylation reaction diminishes the "height" of the transition region. Inspection of the curves (Fig. 4), indicates that this is mainly due to a shift of the lower Tafel line to higher overpotentials† (or lower exchange currents; see Table III) in the presence of KOH. This effect, which is very marked, is seemingly general, since it is observed at Pt, Au, and also Pd, although the reproducibility of the results in pure aqueous formate solutions is bad at the latter metal. We suggest that this striking effect arising upon addition of the KOH is due either to adsorption of OH^- ions competitive with that of $HCOO^{\cdot}$ radicals or to facilitation of formation of an oxide film‡ in the lower Tafel region; the overall process in this region is not oxygen evolution and the Tafel parameters for this region, if they were calculated for oxygen evolution with respect to the reversible oxygen potential, are not at all comparable with those we have reported elsewhere for oxygen evolution at gold or palladium (4) in pure 1 *M* KOH solutions, or which are available (13) for platinum. The process in the lower-slope region is hence not simply oxygen evolution or oxide film formation, as is also apparent from the significant evolution of CO_2 (in the absence of KOH). The data of MacDonald and Conway (4) for oxygen evolution at Au and Pd in 1 *M* aq. KOH are shown in Fig. 4(*c*, *h*) for comparison. It is evident from these figures that the formate decarboxylation at Au in the presence of 1 *M* KOH proceeds over most of the current density range at potentials less than those for the oxygen evolution reaction in 1 *M* KOH in the absence of formate. In the case of Pd, which shows no transition region in the oxygen evolution Tafel line, it will be noted that a transition region is developed (as in the non-aqueous solutions) in the formate/KOH system. This transition region, and probably that at Au in the formate solution, is hence not specifically connected with the oxygen evolution process. In considering the role of simultaneous reactions of formate decomposition and

**The Tafel lines shown for the aqueous formate reaction are based on the observed total current. Corrections for the O_2 evolution co-current do not seriously affect the shape of the Tafel lines or the slopes except at gold, where the current efficiencies are lowest (Table II).*

†This result will be of interest in connection with the fuel-cell oxidation of methanol, where formate oxidation is the last step. In alkaline solution, this step is obviously kinetically much more difficult than in neutral (or acid) solutions.

‡The galvanostatic results, shown below, indicate, for example, complex film formation in the aqueous formate decarboxylation reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

oxygen evolution, it must be borne in mind that formation of formate radicals at the surface will almost certainly modify the oxygen evolution kinetics, and the present results show that formation of oxygen-containing species substantially inhibits the formate kinetics and no simple relationship between the kinetics of the two reactions, when they can occur together, can be proposed. At intermediate current densities, e.g. in the case of gold (Table II), oxygen evolution is appreciable and occurs simultaneously with CO_2 evolution.

(c) Galvanostatic Transients and Reaction Mechanism

The reversed pulse cathodic transients for the trifluoroacetate and aqueous formate systems have been shown in Figs. 5 and 6. The results for the anhydrous trifluoroacetate system at the three metals Pt, Pd, and Au consistently indicate fairly short arrest regions (Fig. 5) not exceeding about 100 μcoulombs cm^{-2} of apparent electrode area (a monolayer of $CF_3COO^{\cdot}$ (25 Å^2) corresponds to about 66 μcoulombs cm^{-2} of real area). By contrast, the formate reaction in aqueous solutions and in alkaline aqueous solutions (1 *M* KOH) evidently proceeds at anodic films of appreciable thickness (5–20 monolayers), as indicated by the transients shown in Fig. 6. In general, at the three metals, the film thickness increases with current density (as also at Pd in 100% HCOOH; see Part I). With all three metals, and particularly with Pd, the arrest behavior in the aqueous and aqueous KOH media is more complex than in the pure formic acid system. At Pd, three arrest regions are developed at high current densities which suggest relatively thick (20–30 monolayers) anodic films in various valence states of the metal, or possibly both oxide and formate film formation over different potential ranges. Some evidence for this is seen in the current–potential curve (Fig. 4) for Pt, where at the highest current densities the behavior of the current with decreasing potential is quite different from that found for decreasing current if the polarization has not reached the highest values. The critical potentials referred to in the work on the Kolbe reaction (e.g. refs. 2, 10; cf. 11) are, we believe, associated with the upper potentials (or related critical currents for film formation) in the film-forming region of the transients. Both in the aqueous and non-aqueous solutions a critical film-forming region occurs at a certain limiting current and it is evidently this film formation or "passivation" which has been regarded as necessary for occurrence of the Kolbe reaction at appreciable efficiencies. Actually, under non-aqueous conditions (in the CF_3COOH system), this film formation is actually not a prerequisite since we have found that the coupling reaction also occurs at currents less than the critical current, i.e. in the lower Tafel region. However, in aqueous solutions, it is usually found (12, 2) that some oxygen evolution precedes Kolbe coupling, so it appears that the electrode requires to be "passivated" by a carboxylate film (possibly on top of an oxide film, e.g. see Fig. 6(*b*, *c*) for the formate case) before significant coupling can occur. Presumably so long as a film of reactive oxygen-containing species (e.g. $OH^{\cdot}$ or $O^{\cdot}$) is present at the interface, some oxidative degradation of discharged alkyl carboxylate radicals tends to occur, leading to "Hofer-Moest" products; we suggest that only when this film is superseded by a complete carboxylate film does the coupling reaction occur efficiently. In the 100% trifluoroacetic or formic acid systems, no oxide film formation can occur (for example, no double arrests are seen in the transients) and the decarboxylation reaction occurs only on a simple film of the adsorbed carboxylate at high current density, and on a partially covered metal surface (see Part III) at current densities below the critical current.

The results of the present comparisons between the behavior in aqueous and non-aqueous solutions and our conclusions on the role of adsorbed intermediates serve, we believe, to clarify some of the points which were actively under discussion by various contributors in 1947 (14).

NEW APPROACHES TO THE STUDY OF ELECTROCHEMICAL DECARBOXYLATION AND THE KOLBE REACTION

PART III. QUANTITATIVE ANALYSIS OF DECAY AND DISCHARGE TRANSIENTS AND THE ROLE OF ADSORBED INTERMEDIATES

ABSTRACT

Galvanostatic cathodic discharge and open-circuit decay transients have been obtained for the decarboxylation of formate in formic acid and interpreted quantitatively in terms of the adsorption of intermediates in the reaction. These intermediates are identified with $HCOO^{\cdot}$ radicals. Extended anodic polarization at platinum and particularly at palladium leads to the formation of films of an anodic product which are considerably thicker than a monolayer. After relatively long times (>100 seconds) of anodic polarization, the film growth obeys the inverse logarithmic rate law deduced by Mott and Cabrera. The thick films which are formed at palladium are believed to be responsible, upon autocatalytic decomposition, for the delayed gas evolution phenomenon observed at this metal.

A new method for deduction of adsorption pseudocapacitance and charge associated with the ad-layer from open-circuit decay curves and Tafel parameters is used to obtain the pseudocapacitance and charge associated with the transition region in the current–potential curves for the formate decarboxylation. It is shown that this region corresponds to filling of the surface with adsorbed intermediates formed in the reaction. These observations are shown to support the reaction mechanism proposed in Part I.

INTRODUCTION

The mechanisms of consecutive reactions can always be elucidated more definitively if knowledge of the behavior and concentrations of intermediates is available. Steady-state current–potential curves for electrochemical reactions can lead to an understanding of the reaction mechanism only to a limited extent, through evaluation of Tafel slopes; non-steady-state measurements by means of analysis of transients can lead, in favorable cases, to important complementary information on: (*a*) the coverage of the electrode by reaction intermediates as a function of potential and (*b*) the associated adsorption pseudocapacitance (1); interpretation of the potential dependence of the latter (2) can then lead to information on the adsorption behavior (e.g. the type of isotherm applying) of the intermediates at the surface. In the case of anodic film formation, the extent of film growth can be examined as a function of time and current density, if the film can be formed and removed (cathodically) in a more or less reversible manner.

In the present paper, we examine the behavior of the adsorbed intermediates formed in the formate decarboxylation by a quantitative analysis of the discharge and e.m.f. decay transients.

EXPERIMENTAL

(1) General Conditions

Experimental conditions, methods of preparation of solutions and electrodes, etc. were identical with those described in Parts I and II.

(2) Electrical Circuits

A general circuit was devised whereby anodic d-c. charging, reversed pulse cathodic discharging following steady anodic polarization, and open-circuit e.m.f. decay could be followed with the same apparatus. High-speed mercury-wetted vacuum relays were used and activated by a microswitch. A bank of accumulators provided the polarizing current. The arrangement of resistors to provide various constant currents to the

cell is shown in Fig. 1 and the galvanostatic relay circuit is illustrated in Fig. 2 with the appropriate connections shown for anodic charging, cathodic discharging, and open-circuit decay. Potential measurements were made with respect to two hydrogen electrodes in the same solution, provided with a Luggin capillary to the anode compartment of the cell. The potential difference between the transiently polarized anode and the reference electrodes was fed to a calibrated Hewlett–Packard oscilloscope through a Keithley

electrometer (input impedance up to 10^{14} ohm). Transients were recorded on a Polaroid film by means of a Polaroid Land Camera and subsequently enlarged some 8 to 10 times for quantitative analysis of the potential–time traces.

RESULTS AND DISCUSSION

Three types of derived information were required:

(i) Film thickness or associated charge, as a function of current density and time of anodic polarization in the anhydrous formic acid system, where remarkable delayed gas evolution effects (at Pd) had previously indicated (3) extensive formation of an unstable anodic film which decomposed after a delay time related to the duration of prior anodic film formation, and hence probably to its thickness.

(ii) Initial capacity at the polarization potential at the commencement of an e.m.f. decay transient.

(iii) The variation of pseudocapacity (probably associated with adsorbed $HCOO^{\cdot}$) with potential over the range of potentials examined in the steady-state current–potential studies, and the total charge corresponding to formation of the ad-layer associated with the region of significant[1] pseudocapacity (2).

(i) Anodic Film Formation

Following the observation (3) of a delayed gas evolution (CO_2) in the e.m.f. decay at a palladium electrode, and which was dependent on the time of previous anodic polarization, a number of experiments were carried out to evaluate, by cathodic galvanostatic discharge, the extent of film formation in the anodic decomposition of formate in 100% formic acid as a function of the time and current density of previous polarization. The results for palladium, gold, and platinum are shown in Fig. 3 in terms of the delay time in the arrest region of the galvanostatic cathodic discharge transients as a function of the logarithm of the time of previous anodic polarization. In Figs. 4 and 5 the corresponding charges associated with the arrest region are plotted reciprocally in terms of the log at the previous anodic polarization time and in Fig. 6 are shown the arrests on open circuits after anodic polarization of Pd for various times. Choice of the logarithmic plot was suggested by theories of film growth (4) in which, under high-field conditions (i.e. with thin films as in the present case), with metal ion transfer from the metal into the anodic film the rate-controlling process in film growth, a reciprocal relation should exist between film thickness and the logarithm of time of growth. In the present case, the thickness is assumed to be proportional to the charge associated with the film. In the formate case, this charge amounts to about 120 μcoulombs cm^{-2} per monolayer of $HCOO^{\cdot}$ (area 14.2 $Å^2$). The parabolic growth law (4) in which the film thickness should vary with the square root of time of growth for low-field conditions, when metal ion diffusion in the film is rate controlling for film growth, does not fit the present results so well as the reciprocal log plot.

At palladium, the charge associated with the arrest region increases with time of anodic polarization and reaches about 4000 μcoulombs cm^{-2} or about 35 layers in thickness. If this were a layer of a palladium formate which decomposed on open circuit, about 0.01 ml of CO_2 would be liberated at a 10 cm^2 electrode. This is presumably the gas[2] which is observed in the delayed gas evolution (3). The film growth rate cannot be

[1]*That is, where the adsorption pseudocapacity is appreciably greater than the anticipated anodic ion double layer capacity of about 40–80 $\mu F\ cm^{-2}$.*

[2]*We have previously reported (3) that the gas produced in periodically interrupted electrolysis, in which an appreciable volume of the total gas evolved arises from delayed evolution, is chemically indistinguishable from that evolved continuously. We have hence concluded that the gas evolved after delay is also* CO_2.

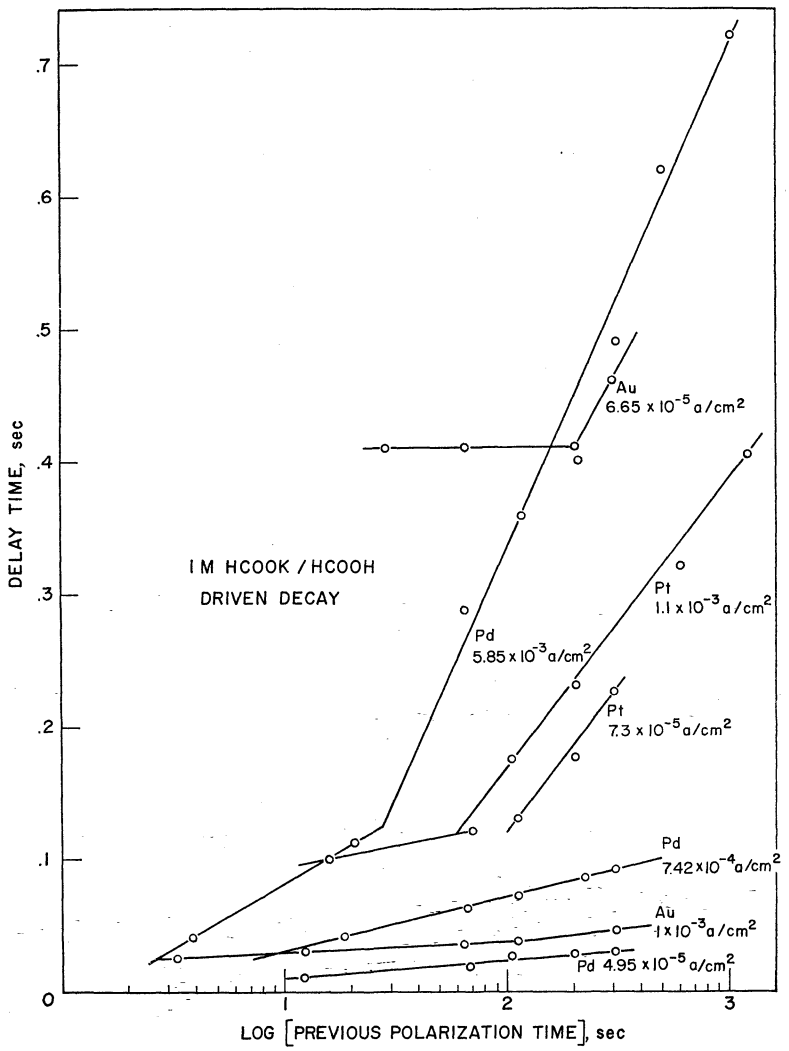

FIG. 3. Delay times in the arrest region as a function of the log of the time of previous polarization at Au, Pt, and Pd (1 *M* HCOOK/HCOOH, 5° C).

directly related to the current passing, since most of the current is associated with the overall Faradaic process of CO_2 evolution in the formate electrolysis; only a small fraction of the total current is evidently involved in increasing the anode film thickness with time. The maximum charge of about 4000 μcoulombs cm^{-2} at the palladium electrode is just sufficient to produce a visible gas evolution if the layer is a formate of palladium[3] which decomposes to give CO_2[4] autocatalytically after a delay period or, equivalently, after the electrode potential has fallen to a critical value (3). No delayed gas evolution is seen at platinum or gold or in the Kolbe reaction itself and this is consistent with the 10 times smaller film thickness (or charge) observed at the platinum electrode (Fig. 5) in the same formate/formic acid system.

[3]*No stable palladium formate compounds appear to exist and this is consistent with the present observations that such a compound, if formed under strongly oxidizing conditions, decomposes as soon as the potential has fallen to lower anodic values.*

[4]*See footnote 2 of previous page.*

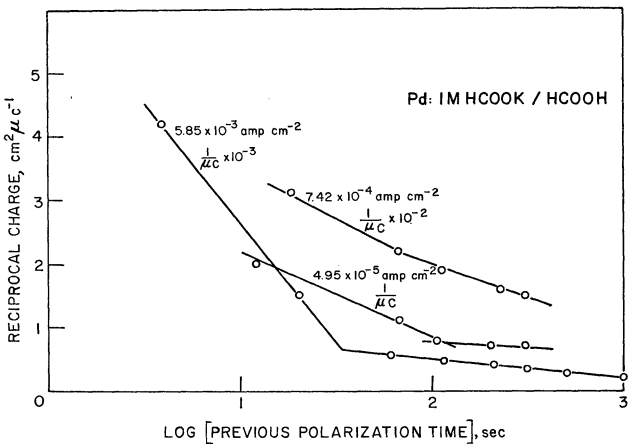

FIG. 4. Reciprocal charge associated with the arrest region at palladium as a function of the log of the time of previous anodic polarization (1 *M* HCOOK/HCOOH, 5° C; from galvanostatic discharge).

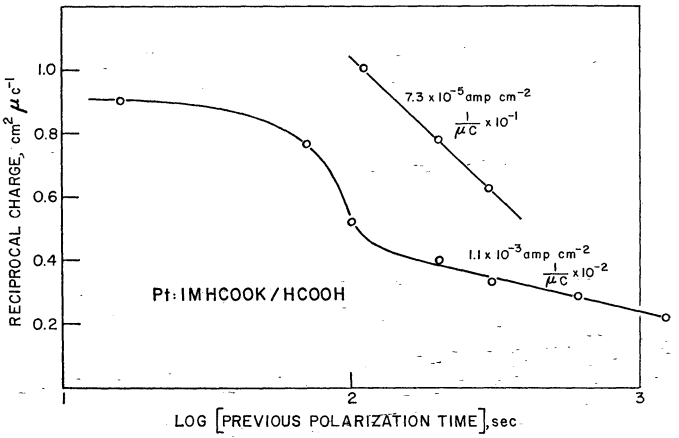

FIG. 5. Reciprocal charge associated with the arrest region at platinum as a function of the log of the time of previous polarization (1 *M* HCOOK/HCOOH, 5° C; from galvanostatic discharge).

In the trifluoroacetic acid Kolbe reaction, a similar buildup of an adsorbed layer with time is observed (Fig. 7) but this does not exceed 50–80 μcoulombs cm^{-2}—the limit for a monolayer. This is further confirmation (see Part II) that for the trifluoroacetate reaction in anhydrous trifluoroacetic acid, the process occurs on a more or less completely filled surface at current densities above that for the transition behavior, or passivation, and barrier layer films of appreciable thickness are not involved.

(ii) Anodic Film Formation in Aqueous Solutions

The anodic film formation in the *aqueous* formate reaction is also quite extensive, as previously shown in Part II. Arrests in the galvanostatic transient up to 2000 μcoulombs cm^{-2} were measured, indicating films of about 20 monolayers per apparent cm^2. In the polarization measurements made in obtaining the current–potential curve, it was noticed that near the transition region there was considerable time variation of electrode potential, which was not observed at lower or higher current densities. As the current was either increased or decreased the potential would "overshoot" or "undershoot", respectively,

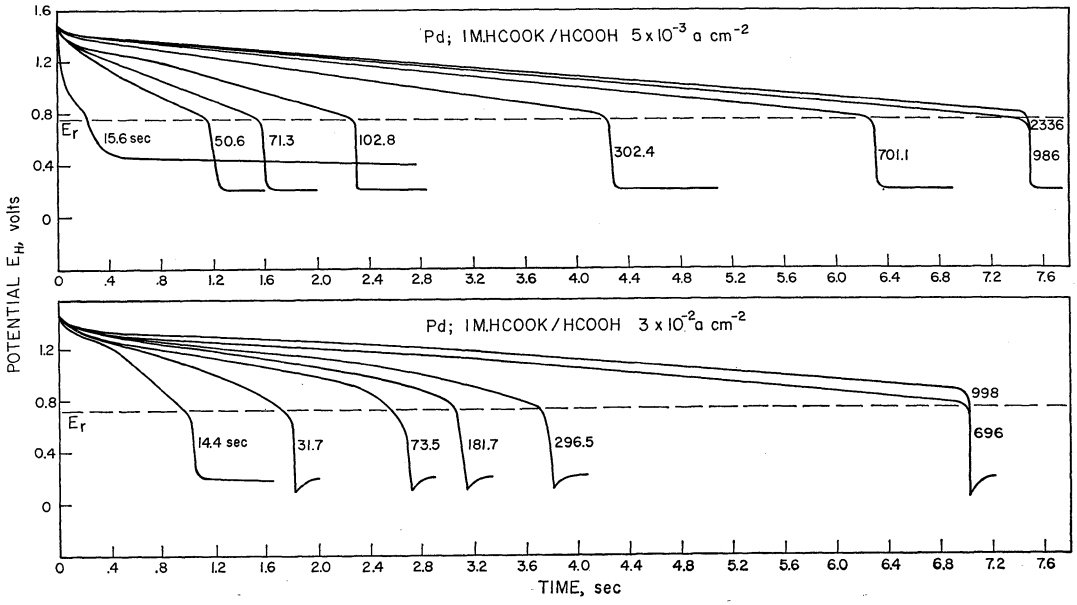

FIG. 6. Open-circuit e.m.f. decay curves for the anodic polarization of Pd (1 *M* HCOOK in 100% HCOOH, 5° C) for various times.

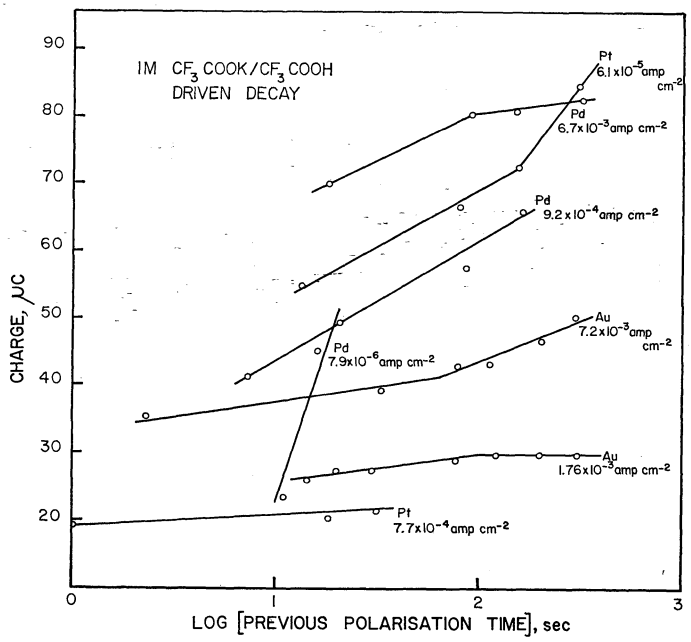

FIG. 7. The surface charge associated with the arrest region in the trifluoroacetic acid Kolbe reaction (1 *M* potassium trifluoroacetate, 5° C) as a function of time of previous anodic polarization.

and then return to a steady value. Similar behavior has been observed previously in the oxygen evolution reaction (5) and at barrier layer film electrodes (6). The phenomenon is characteristic of slow readjustment of space charge in a barrier layer film when the field is changed. Some typical plots of the logarithmic change of potential with time near the transition region and of e.m.f. recovery after "undershoot" are shown in Figs. 8 and 9.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

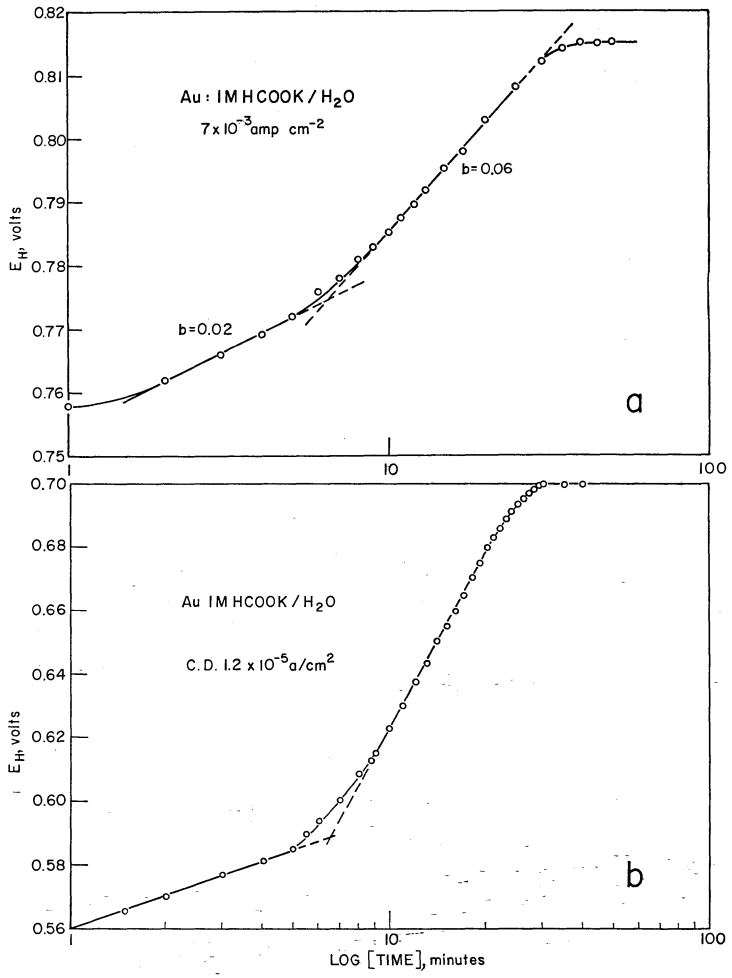

FIG. 8. Typical buildup curves plotted logarithmically in time for the aqueous formate reaction: (*a*) Au, 1 *M* HCOOK/H_2O; 7×10^{-3} amp cm^{-2} (near the transition region); (*b*) Au, 1 *M* HCOOK/H_2O; 1.2×10^{-5} amp cm^{-2} (below the transition region).

The buildup curves are similar to those found in the anodic evolution of oxygen at platinum and are probably associated with the same type of process (7), viz. deactivation of sites on the metal surface by adsorption of a product (probably $HCOO^{\cdot}$ in the present case) of one of the steps in the reaction. The logarithmic recovery after "overshoot" or "undershoot", also observed in the oxygen evolution reaction (5) at palladium, is probably associated with a first-order readjustment of space charge (6) in the multilayer film following a sudden change of field as the potential (or current density) is changed.

(iii) The Charge and Pseudocapacity Associated with Adsorbed Intermediates Calculated from Open-circuit Decay Transients

Here we examine the case of the formate decomposition only in 100% formic acid near the transition region. The behavior in aqueous solution is probably too complex (see Part II) for the simple non-steady-state analysis described below to be applicable.

It is well known (8, 9) that the capacitance of an electrode can be deduced from the *initial* rate of fall of potential at the potential V_1 (assumed free of ohmic or concentration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

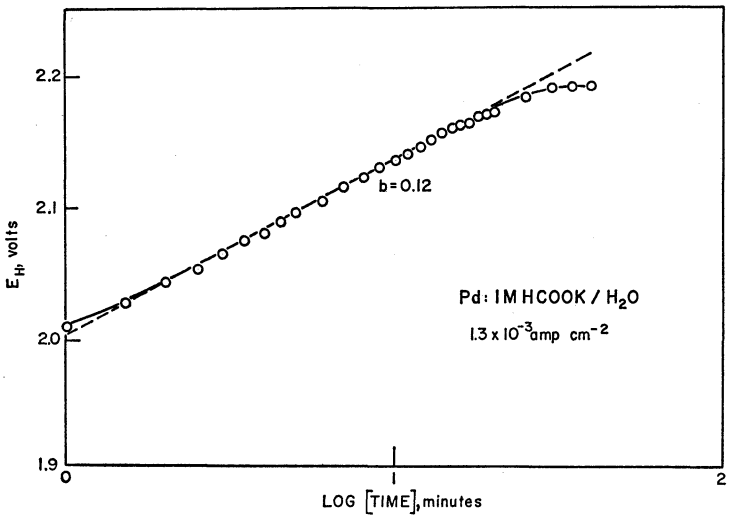

FIG. 9. Recovery from "undershoot" in the aqueous formate reaction. Pd, 1 *M* HCOOK/H_2O; 1.3×10^{-4} amp cm^{-2}.

polarization effects) corresponding to the moment of commencement of decay. The current passing is then, momentarily, the initial polarizing current i_1 and

$$[1] \qquad i_1 = -C_{V_1}(dV/dt)_1,$$

so that the *initial* capacitance can be calculated. The capacitance as a function of potential V could then in principle (cf. ref. 9) be evaluated as a function of potential by using various initial polarizing currents as we have suggested previously (12).

The kinetics of e.m.f. decay are normally expressed (8, 11, 12) by an equation,

$$[2] \qquad i_V = -C_V(dV/dt) = i_0e^{V/b},$$

at any potential (where b is the Naperian Tafel slope), and $i_0e^{V/b}$ is, in fact, the self-discharge current passing at the potential V; it is clear then (as we show elsewhere (10)) that C_V can be obtained at any potential in the decay curve if the corresponding Tafel expression is known over the same range of potentials, since the Tafel equation defines the term $i_0e^{V/b}$ at any potential. In this discussion, it is assumed, as usual (8, 11, 12), that on open circuit the same process as that during steady polarization is the rate-determining one. The charge associated with the capacity C_V is hence obviously

$$[3] \qquad \Delta q = \int_{V_1}^{V_2} \frac{-i_0e^{V/b}}{dV/dt}\cdot dV,$$

where we keep the term dV/dt in the denominator for convenience in order to evaluate $i_0 \exp [V/b]/dV/dt$ experimentally and integrate the result over a range of values of V. The value of Δq obtained is obviously that corresponding to the change of q over the potential range V_1 to V_2. If C_V corresponds to a pseudocapacity associated with the adsorption of reaction intermediates (1, 2, 13), it will usually be large (12, 13) compared with the double-layer capacity when the coverage θ by intermediates is $0.2 < \theta < 0.9$, so that integration, in equation [3], over the potential region of appreciable values of C_V will give, approximately, the actual value of q associated with the adsorbed intermediates,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and hence θ the extent of coverage, if we assume that one electron is required for Faradaic discharge to produce each adsorbed group ($HCOO^{\cdot}$ in the present case) and also assume an effective molecular area for the adsorbed species, as discussed previously (Parts I and II).

The above treatment has been applied to the evaluation of the pseudocapacity and coverage associated with the adsorbed species in the formate decarboxylation, particularly near the critical current or transition region where we suspect that formation of a passivating layer is occurring. Values of dV/dt have been obtained from the decay curves and values of $i_0 e^{V/b}$ from the actual current–potential relationships (see Part I).

The decay curves are shown in Fig. 10 for gold, platinum, and palladium taken from potentials above the transition region, and in Fig. 11 for palladium taken in a separate experiment from a potential corresponding to a lower current density. The arrests in the decay curves in Fig. 10 are related to the arrests obtained on galvanostatic forced discharge mentioned in Part I, and correspond to an appreciable pseudocapacity. The data for platinum and palladium are taken for a current density and time below that for which multilayer formation sets in (see Fig. 4).

The capacity curves (calculated from equation [2]) over the transition regions are shown in Fig. 12 as a function of the overpotential for the reaction (see Part I) and the integral charges associated with this region are shown in Fig. 13 for Pt and Pd.

The capacity curve for the higher current density arrest region at Pd has almost the correct *shape* (2, 13) for the case of Langmuir adsorption of the intermediates. Its maximum value is, however, too low (particularly bearing in mind that the real to apparent area factor for the metal surface must be greater than 1), since for the adsorption of formate radicals, the maximum theoretically expected "Langmuir" value is $kF/4RT$, where k is the charge associated with $\theta = 1$, i.e. 120 μcoulombs cm^{-2} in the present case for a molecular area of 14.2 Å^2 for $HCOO^{\cdot}$; C_{max} is hence 1200 μF cm^{-2} for the present system. The actual observed capacity behavior as a function of potential fits the general equation

$$\frac{k}{C} = \frac{dV}{d\theta} = \frac{RT}{F}\frac{d \ln [\theta/1-\theta]}{d\theta} + r_1/F,$$

deduced previously (2) taking into account variation of heat of adsorption of $HCOO^{\cdot}$ with coverage (14, 15) through the term r_1 (defined in Part I). The observed capacity curve (Fig. 12(*b*)) and the charge as a function of potential are consistent with $r_1 \doteqdot 3$ kcal $mole^{-1}$ for Pd.

At palladium, two transition regions are observed in the current–potential plots (Fig. 1 in Part I) for 1 *M* and 5 *M* potassium formate solutions in formic acid. Correspondingly, two pseudocapacity regions are observed as shown in Fig. 12(*a*,*b*). The lower-region capacity exhibits a wider region of potential dependence than the upper one, which approaches (but is not identical with) ideal Langmuir behavior (cf. Fig. 13). This behavior suggests that an anodic film is first formed at the lower current density and then suffers an oxidation at higher potentials. A surface redox step can, of course, formally exhibit the same type of pseudocapacity as a direct adsorption process since, if a Nernst type of relation applies to the potential associated with this layer as a function of activity of "oxidized" and "reduced" species, an appreciable pseudocapacity will arise over the potential region where the ratio of the activities of "oxidized" and "reduced" forms varies from about 0.1 to 10. Similar considerations have been discussed previously for the surface phase at the nickel oxide electrode (12).

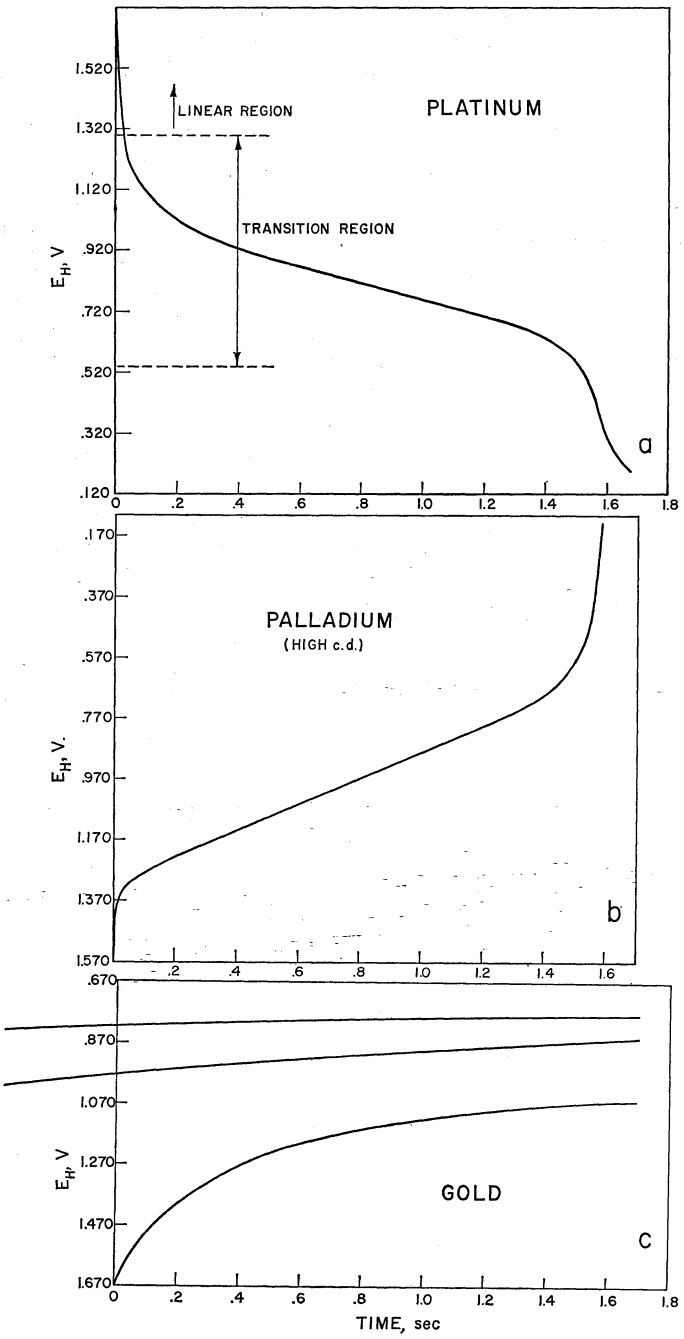

FIG. 10. E.m.f. decay curves taken from potentials above the transition region for formate decarboxylation (1 *M* HCOOK/100% HCOOH, 5° C): (*a*) platinum; (*b*) palladium; (*c*) gold.

The corresponding data for platinum indicate a larger value of r_1 (viz. 7 kcal mole^{-1}) since C and q (or θ) depend on potential over a wider range of potentials than for the case of Pd on the ideal Langmuir case. Since in both of these cases, the θ values vary from

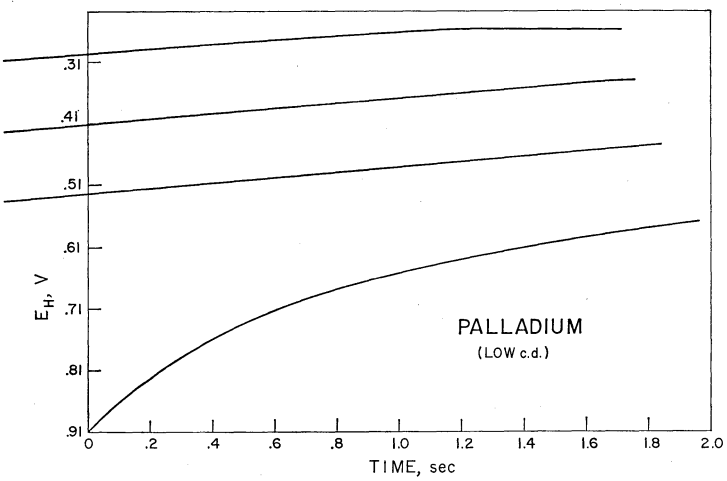

FIG. 11. E.m.f. decay curve at Pd at a lower current density than that used for Fig. 10(*b*).

ca. 0.1 to 1, but different r_1 values are found for the *same* reaction (and hence presumably for the same intermediates), we conclude that r_1 may be predominantly determined by heterogeneity of energies of adsorption at various sites rather than by two-dimensional interaction effects within the ad-layer. It is recognized, however, that different orientations of the adsorbed species at Pt and Pd could also lead to different two-dimensional interactions and hence to different r_1 values. The linear variation of heat of adsorption with coverage assumed in this treatment and elsewhere (14, 15) is actually best accounted for (2) in terms of the model discussed by Boudart (16) and based on induced heterogeneity effects through the surface potential arising from the ad-layer and its effect on the electronic work function of the metal.

Significance of the Transition Region

The above results give rather direct evidence regarding the behavior of the adsorbed intermediates, which we must presume to be $HCOO^{\cdot}$ radicals. It is clear that the transition from lower current density behavior to that at high current density, associated with a sharp change of potential, must be ascribed to filling up of the surface by the adsorbed species. This suggests that the primary discharge of formate ions is not the rate-controlling step, as was also deduced in Parts I and II. Beyond a certain critical current, decomposition of the radicals can no longer support the current and a limiting current is observed. This suggests that the rate-controlling reaction at low current densities is

$$HCOO^{\cdot} \rightarrow H + CO_2,$$

which gives a limiting current, rather than

$$HCOO^{\cdot} \rightarrow H^+ + CO_2 + e,$$

which is always potential dependent. Once the transition region is completed, further potential-dependent reactions can continue by

$$HCOO^{\cdot}{}_{\theta \rightarrow 1} \rightarrow H^+ + CO_2 + e$$

at the higher current densities. The transition behavior, which shows all the characteristics of a "passivation" phenomenon, may thus be directly ascribed to formation of a monolayer of adsorbed reaction intermediates. The corresponding "active" region is that

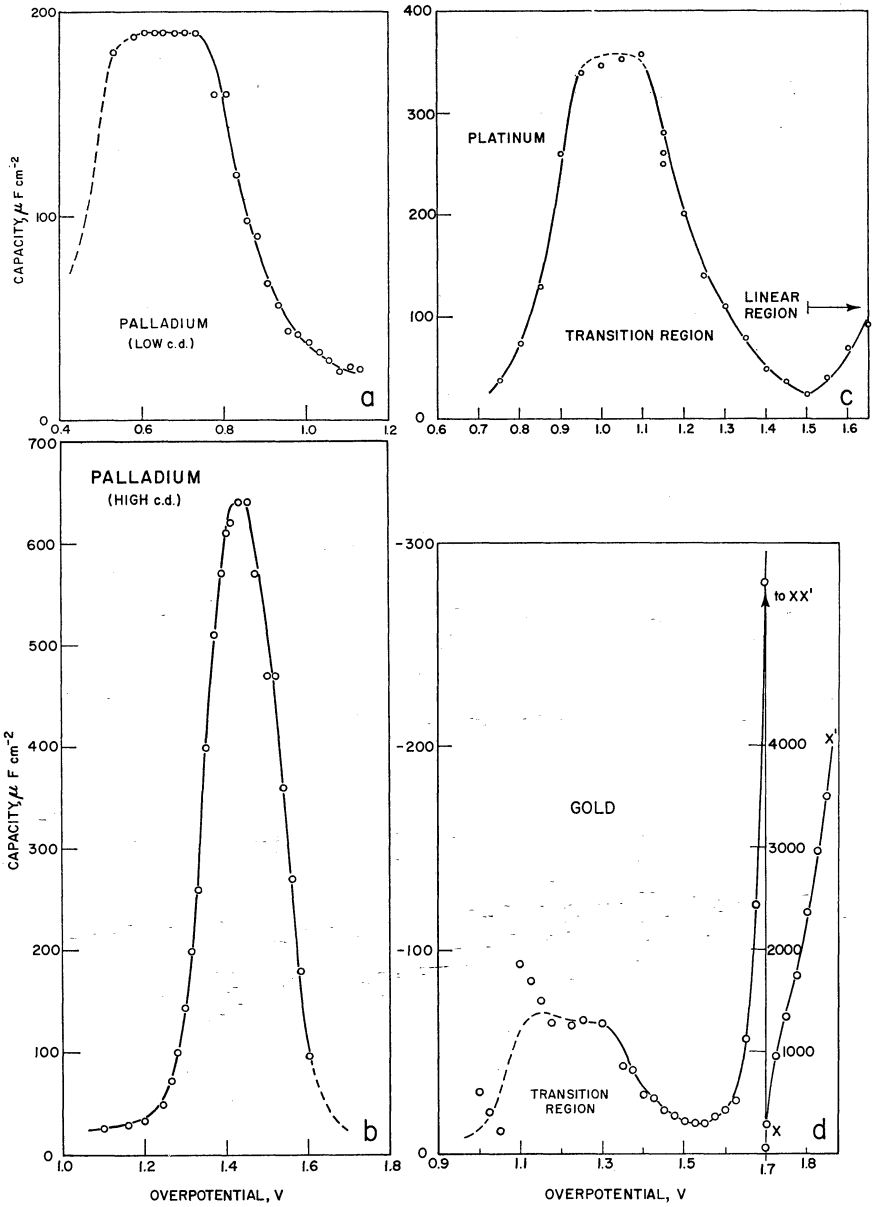

FIG. 12. Capacity curves for the formate decarboxylation in the transition region as a function of overpotential (1 *M* HCOOK/100% HCOOH, 5° C; from open-circuit decay and Tafel-line parameters): (*a*) palladium, low current density; (*b*) palladium, high current density; (*c*) platinum; (*d*) gold.

at low current densities, i.e., less than the transition current densities, where we have shown (Part I) that some attack of the electrode occurs and the coulombic yields of CO_2 are appreciably less than those expected for the quantitative occurrence of the formate decarboxylation.

Beyond the transition region at higher current densities, the pseudocapacity again increases with increasing current density (or potential, see Fig. 12(*d*)) and time owing to formation of thicker films as discussed above and shown in Figs. 4 and 5.

HYDROGEN CHEMISORPTION ON NICKEL–MAGNESIA CATALYSTS

N. RAMASUBRAMANIAN[1] AND L. M. YEDDANAPALLI
Chemistry Department, Loyola College, Madras, India
Received July 16, 1962

ABSTRACT

The hydrogen adsorption activities, per gram of nickel, of two nickel–magnesia catalysts are compared and explained on the basis of different types of nickel being present. The application of the Elovich equation to interpret the kinetic data shows the possibility of the presence of three kinetic stages in the temperature and pressure range studied. A study of the effect, on the hydrogen adsorption, of deliberate oxygen addition to and re-reduction of the catalyst surface shows that the nature of the oxygen contamination in the catalyst is different from that of the added oxygen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

It is evident from the work of Schuit and de Boer (1) that an imperfect reduction of the catalyst affects the fast and slow chemisorption of hydrogen on nickel. Taylor *et al.* (2) observed breaks in the Elovich plots of the data obtained on the aged nickel – Kieselguhr catalyst but not on the freshly prepared catalyst and it was suggested that oxygen contamination might be the cause of the occurrence of multiple kinetic stages. In the case of hydrogen chemisorption on nickel–magnesia catalysts the presence of more than a single stage of adsorption is shown by the Elovich plots (3). Nickel being the active adsorbent for hydrogen chemisorption in nickel–magnesia catalysts, it is felt that the nature of the sites, reduced and unreduced, can be better understood from a comparison of the chemisorptive capacity of nickel in catalysts of varying nickel content. Two catalysts of nickel content 79% and 18% were studied and the Elovich equation was applied to interpret the kinetic data. The results were analyzed to find out how the amounts of fast and slow adsorption and the rates of slow adsorption, calculated per gram of nickel in the catalysts, vary.

On the nickel–magnesia catalysts it was observed (3) that breaks on the Elovich plots appeared in either direction depending on the temperature and pressure conditions. Low (4) from his work on rhodium and palladium catalysts reported that the time of appearance and temporal range of existence of the individual kinetic stages are affected by initial pressure and by temperature. Therefore, the chemisorption on catalyst II was studied more extensively at different temperatures and initial pressures. In an attempt to determine the role of oxygen contamination, a study of the influence of oxygen introduced deliberately and re-reduction of the catalyst surface on the adsorption process was made on catalyst II.

EXPERIMENTAL

The method employed, preparation, and analysis of the catalysts, etc., have been described elsewhere (3). The catalyst II was prepared from 18 g of nickel nitrate and 50 g of magnesium nitrate and the precipitated, dried hydroxides were reduced in a stream of pure hydrogen at 390±5° C for 60 hours. Eight grams of nickel nitrate and 70 g of magnesium nitrate were used for preparing catalyst III and the drying and reduction conditions were the same as those for catalyst II. The nickel content of the catalysts II and III were 79.06% and 18.02%, respectively.

RESULTS

The algebraic method of Sarmousakis and Low (5) was used to evaluate the Elovich parameters. The q vs. log t plots were linear and showed discontinuities. The data obtained

[1]*Present address: Division of Applied Chemistry, National Research Council, Ottawa, Canada.*

on the two catalysts are presented in Table I, where q_1 stands for the amount adsorbed in the first minute (the fast adsorption); $q_{100}-q_1$, the difference in the amounts adsorbed

at the 100th and 1st minutes (the slow adsorption); and α_1 and α_2 the α values of the observed adsorption stages, respectively. A distinct difference in behavior with increasing temperature is readily seen from a comparison of the results on the two catalysts. The fast adsorption is higher on catalyst II and at lower temperatures the difference is more marked. On the other hand, the slow adsorption becomes considerably higher on catalyst III with increasing temperature. These observations point out that relative to one another, on the two catalysts II and III, respectively, sites active for high-temperature slow adsorption and lower-temperature fast adsorption are less. The difference in the activity of the chemisorption sites available on the catalysts could be seen from the α values also. When a α is very large, i.e. the q vs. log t plot is linear, the constant α in the Elovich equation becomes inversely proportional to the rate of adsorption at a time t. In contrast to catalyst II, on catalyst III the ratio α_2/α_1 is less than unity at and below 240° C and at higher temperatures both the α values are low. On catalyst III a higher degree of dispersion of nickel in magnesia and hence a higher activity is expected. It is interesting to note that it is less active than catalyst II towards total adsorption.

It is seen from Table I that at lower temperatures $\alpha_2 > \alpha_1$, whereas at higher temperature $\alpha_2 < \alpha_1$. It was pointed out by Low (4) that comparison of the kinetic stages on the basis of their temporal order of appearance resulted in misleading conclusions and, in general, low initial gas pressure and high temperature favor the early appearance of any one stage. The Elovich plot is a straight line for the adsorption carried out on catalyst II at 55 cm Hg and 240° C for about 3 hours; above or below this temperature α_2 is less or greater than α_1 (Table I). Therefore the temperatures 280 and 200° C were chosen to study the initial pressure effect. The variation of the α values with initial pressure at these two temperatures is shown in Fig. 1. At the higher temperature of 280° C there is a change in the value of α_2 relative to α_1, around 15 cm Hg. Then, according to Low's (4) generalization, this means that in the pressure range studied at 280° C the stages observed below 15 cm Hg are the first and second $\alpha_1 < \alpha_2$ and above this pressure are the second and third $\alpha_2 < \alpha_1$. At 200° C the stages observed are the first and second throughout the pressure range studied.

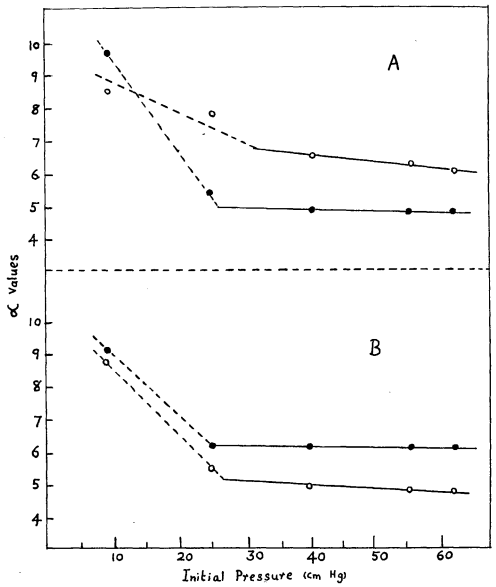

FIG. 1. Variation with initial pressure of α values; hydrogen adsorption at (A) 280 and (B) 200° C on catalyst II; ○, α_1 and ●, α_2.

It was then of interest to study the chemisorption at the lower pressure of 10 cm Hg at the other temperatures too. In Fig. 2 are shown the plots of the α values against

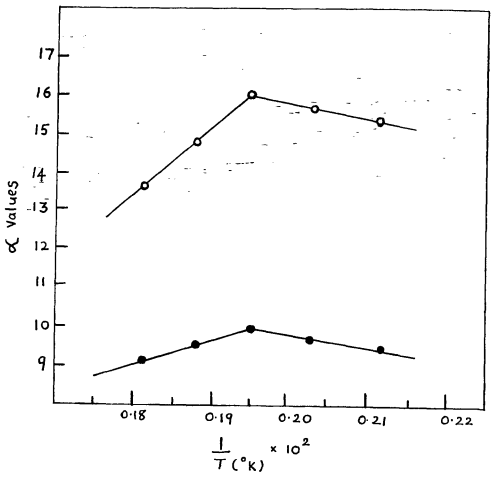

FIG. 2. Variation with temperature of α_1, ●, and α_2, ○; hydrogen adsorption at 10 cm Hg on catalyst II.

temperature and it is readily seen that first and second stages show up. As pointed out earlier, at 240° C the Elovich plot is a straight line for the data obtained at 55 cm Hg and the observed kinetic stage has to be the second. On the basis of more than two kinetic stages being present, though mostly only two of these are observed depending on the temperature and pressure conditions, a comparison points out that the temperature range of appearance of the kinetic stages is different on the two catalysts.

It is suspected that oxygen contamination might be the cause of the occurrence of multiple kinetic stages (2). To find out how the two stages of adsorption were affected by oxygen, introduced deliberately, the catalyst II was evacuated as usual for 8 hours at 380±5° C and cooled to room temperature. A small quantity of pure oxygen (0.3 cc at NTP) was sent into the catalyst vessel and the temperature raised gradually to 380° C over a period of 2 hours. The mercury levels on the manometer became equal, which indicated that the oxygen was taken up almost completely. The catalyst was evacuated for ½ hour at 380° C and a few experiments were carried out under conditions similar to those of an experiment on the usual starting surface S_I. The Elovich plots of the kinetic data are shown in Fig. 3, where A represents the run on the surface S_I and B, C, D, E,

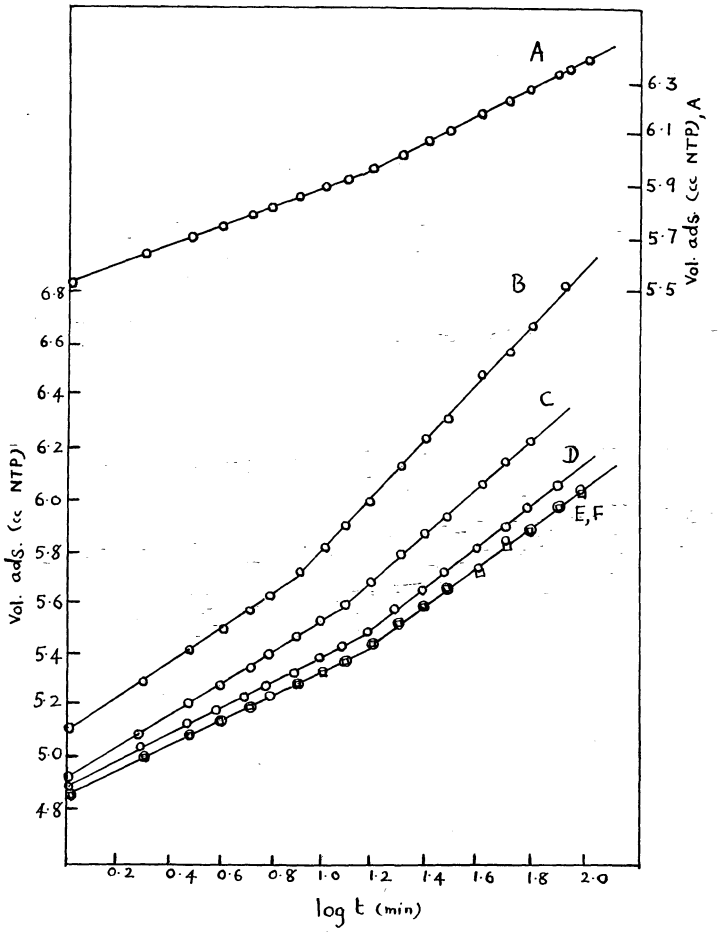

FIG. 3. The effect of oxygen contamination; hydrogen adsorption on catalyst II at 55 cm Hg and 280° C; A, normal run 81; B, C, D, E, and F, the successive runs 92 to 96 subsequent to oxygen contamination.

and F the successive experiments after oxygen addition. The values of the Elovich parameters, the fast adsorption q_1, and the slow adsorption $q_{100}-q_1$ are given in Table II. The oxygen contamination is seen to result in an increased slow adsorption, as is evidenced by the decreased α values, at the expense of the fast adsorption, a behavior similar to

that observed by Schuit and de Boer (1) on nickel–silica catalysts. The increase in the slow adsorption is nearly twice the decrease in the fast adsorption and is to a higher extent on the observed second kinetic stage. It is seen that after three repeated experiments reproducible results are obtained and the catalyst surface will be referred to as S_{II} to distinguish it from S_I. The break in the Elovich plot occurs earlier subsequent to oxygen addition but in the succeeding experiments there is a gradual shift towards and to the time of occurrence of break obtained on surface S_I. During the course of the repeated experiments at 280° C the slow adsorption decreases and the fast adsorption remains nearly constant at the decreased value.

The catalyst was re-reduced by heating at 410° C in hydrogen at atmospheric pressure for 12 hours. It was subsequently evacuated for 8 hours at 410° C and this procedure of heating in hydrogen and evacuation was repeated twice. After a couple of adsorption measurements at 280° C and 55 cm Hg reproducible results were obtained. This surface will be referred to as S_{III}. The results of a set of experiments on the surfaces S_{II} and S_{III} are compared with those on S_I in Table II. Compared to S_I, the α_1 and α_2 values on S_{II} show a slight decrease or $(q_{100}-q_1)$ a slight increase. It is evident from the results on S_{III} that on re-reduction at a higher temperature the fast adsorption has increased and the values of q_1, α_1, and α_2 are closer to those on S_I. On all the three surfaces the trend in the variation of the two α values with temperature is the same.

DISCUSSION

Of the two catalysts, the room-temperature fast adsorption is much less, the high-temperature slow adsorption is greater, and the total adsorption is less on the higher magnesia content catalyst III than on catalyst II. If unreduced nickel in the catalyst was mainly responsible for the activated or high-temperature slow adsorption of hydrogen (1) then the observation that the high-temperature slow adsorption is greater on catalyst III would mean that there is more nickel in the unreduced state in catalyst III than in catalyst II. A higher adsorptive capacity due to a higher degree of dispersion of nickel in magnesia is expected on the former catalyst. The fact that it is less active indicates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the possibility of some of the nickel becoming unavailable for chemisorption purposes with increase in magnesia content. Thus there seems to be a similarity to nickel–silica catalysts, the hydrogen adsorptive capacity of which was explained by the proposal of the presence of different types of nickel, viz., pure or relatively pure, unreduced, and unavailable nickel made by Schuit (6). The analysis of the kinetic data using the Elovich equation brings out the characteristics of the catalyst, seen from the study, on catalyst II, of the variation of α with temperature and pressure, which shows that there is every likelihood of at least three kinetic stages being present and that the temperature range of existence of the stages is different on the two catalysts.

The fact that oxygen contamination has a marked influence on the rates of adsorption and on the occurrence of kinetic stages is readily seen from the immediate effect of added oxygen. However, it is observed that this effect is not lasting; during the repeated adsorption measurements at 280° C there is a steady approach to the previous usual behavior, and hydrogen treatment at 410° C restores it. This would mean that there is the possibility that the added oxygen is being removed by hydrogen at a decreasing rate, a process faster and complete at the higher temperature. Then, the reproducibility obtained at 280° C only shows the drastic lowering of the reduction rate. The results on S_I and S_{II} show that the added oxygen, whatever amount that was left, has changed the fast and slow adsorption rates considerably but not the time of occurrence of the break and the general trend in the variation of the α values with temperature. Thus it appears that, though the catalyst has been heated in oxygen over the reduction temperature range employed in its preparation and the added oxygen affects the occurrence of the kinetic stages and to a greater extent the rates of adsorption, compared to the oxygen contamination in the catalyst, the added oxygen behaves differently in the sense that it can be relatively easily removed by hydrogen reduction.

ABSTRACT

Xanthomegnin, a pigment isolated from *Trichophyton megnini*, was shown to be (−) 3,3′-bis-[2-methoxy-5-hydroxy-7-(2-hydroxypropyl)-8-carboxy-1,4-naphthoquinone lactone]. Application of the Hudson–Klyne lactone rule (C. S. Hudson, J. Am. Chem. Soc., **32**, 338 (1910); W. Klyne, Chem. Ind. (London), 1198 (1954)) gave results which supported the proposed stereochemistry.

Xanthomegnin, a yellow pigment, is one of the metabolites we have isolated[1] from the mycelium of *Trichophyton megnini*. The isolation of the compound was effected by deionization of the crude extract, followed by subsequent Soxhlet extraction, column chromatography, and fractional crystallization procedures. Xanthomegnin represented about 0.10% of the dried mycelium.

The pigment crystallized from a chloroform–benzene solution as orange platelets which did not melt but cindered at 264°. It was insoluble in hydroxylic solvents, only slightly soluble in acetone, ethyl acetate, or benzene, and moderately soluble in chloroform.

The empirical formula of xanthomegnin was originally established as $C_{15}H_{12}O_6$ based on the elemental analysis. However, the proton count by n.m.r. showed only 11 hydrogen atoms in the pigment, and the odd number persisted for the derivatives. On further investigation it was shown that the formula was actually $(C_{15}H_{11}O_6)_2$, where the molecule consisted of two identical halves joined into a dimeric structure. Zeisel, Kuhn–Roth, and active hydrogen determinations indicated one methoxyl, one methyl, and one hydroxyl group respectively per monomeric unit.

The infrared spectrum[7] showed a broad absorption at 3389 cm^{-1} ($CHCl_3$) for a bonded hydroxyl, and two carbonyl peaks, one at 1716 cm^{-1} and one at 1680 cm^{-1}. There was an additional band at 1622 cm^{-1} and a strong aromatic absorption at 1600 cm^{-1}.

The n.m.r. showed peaks at the following τ values:[8] −2.55, bonded hydroxyl; 2.83,

aryl hydrogen; 5.53, $\diagdown$C—H, multiplet; 6.03, methoxyl; 7.08, Ar—CH_2—, doublet; and 8.51, methyl, doublet. The respective splitting of the alkyl constituents and the chemical shift of the methine suggested the moiety Ar—CH_2—CH(O$\diagup$)—CH_3.

The ultraviolet spectrum of the compound in dioxane exhibited a maximum at 228 mμ (ε 24,500), an inflection at 289 mμ (ε 7,900), and a peak at 389 mμ (ε 4,500).

Xanthomegnin formed a diacetate, and the single infrared absorption peak at 1775 cm^{-1} indicated that both esters were vinyl acetates. The aromatic maximum, poorly resolved in the pigment itself, appeared as a well-defined absorption at 262.5 mμ (ε 21,300) in the acetylated compound. Acetylation produced a hypsochromic shift of the chromophore from 389 to 344 mμ.

When the diacetate was subjected to catalytic hydrogenation in ethyl acetate with Adam's catalyst 2 mole-equiv of hydrogen were absorbed rapidly. In the infrared spectrum of the product, the 1680 cm^{-1} peak was no longer present and the 1716 cm^{-1} carbonyl band was shifted to 1658 cm^{-1}. Reacetylation returned the carbonyl absorption to 1716 cm^{-1}, thus indicating the hydrogen-bonded character of the quinol hydroxyl to the carbonyl. The bonded hydroxyl appeared at -2.64 τ and a free hydroxyl at 3.91 τ in the n.m.r. spectrum. The hydrogenated compound, upon acetylation, produced the same hexaacetate obtained by reductive acetylation of the pigment.

The quinone nature of the chromophore was therefore established, and comparison of the ultraviolet spectrum of xanthomegnin diacetate with that of 1,4-naphthoquinone and 2-methoxy-1,4-naphthoquinone showed marked similarities.

The pigment underwent reversible color changes at various pH's, being yellow in acidic and neutral media, and violet in basic solutions. This behavior is typical of certain hydroxy quinones.

The results of color tests conducted on the pigment with alkali solutions, methanolic lead acetate, and sulphuric acid suggested the 5-hydroxynaphthoquinone structure for xanthomegnin (2).

The position and the phenolic nature of the hydroxyl in the monomer could be postulated from the following information: (i) acetylation gave a vinyl acetate; (ii) the hydroxyl was bonded to the quinone as shown by absorption at 3389 and 1622 cm^{-1}, and -2.55 τ; (iii) hypsochromic shifts upon acetylation is a behavior of *peri*-hydroxy quinones (3); and (iv) the color reactions were consistent with those of 5-hydroxynaphthoquinones.

At this point we endeavored to establish the nature of the 1716 cm^{-1} carbonyl. In order to satisfy the double-bond equivalents of the formula of the pigment, a naphthoquinone derivative would have to have an additional ring. Since n.m.r. suggested the Ar—CH_2—CH(O$\diagup$)—CH_3 grouping, it seemed fitting that this structure was incorporated

into a δ-lactone ring. In order to test whether or not the carbonyl was a lactone, a sample of xanthomegnin was dissolved in aqueous alkali and the barium salt precipitated by the addition of barium chloride. The infrared spectrum of the barium salt showed the disappearance of the 1716 cm^{-1} band and the appearance of the carboxylate bands at 1410 and 1550 cm^{-1}.

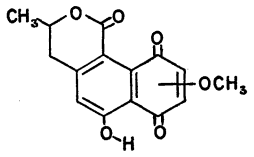
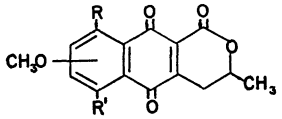
Since the lactone was hydrogen bonded to a quinol hydroxyl in the reduced product, there were only three possible orientations (A, B, C) for the lactone ring attached to a



A.

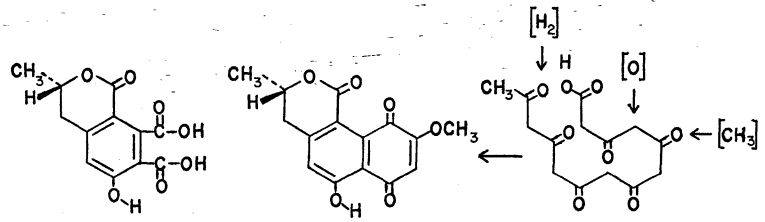


B. R = OH; R' = H
C. R = H; R' = OH

naphthoquinone structure. The problem remained to establish whether the methoxyl or the lactone was on the quinone ring of the naphthoquinone.

Oxidative cleavage of the quinone nucleus in xanthomegnin with alkaline peroxide gave a $C_{12}H_{10}O_7$ acid, m.p. 194–195°, $[\alpha]_D^{23}$ −76.7, −78.0 (*c* 0.34, 0.29 in acetonitrile), λ_{max}^{EtOH} 254, 337 mμ (ε 7,300, 5,500). The n.m.r. spectrum (in trideuteroacetic acid) showed the presence of the Ar—CH_2—CH—CH_3 group but no peak for the OCH_3 substituent.

The infrared absorption (acetonitrile solution) showed what appeared to be two carbonyl bands overlapping at 1725 cm^{-1} and a single carbonyl peak at 1680 cm^{-1}. These data were consistent for the structure of 4-hydroxy-6-(2′-hydroxypropyl)-hemimellitic acid δ-lactone (I). The carboxyl group flanked by another carboxyl and the lactone structure is apparently twisted out of planarity with the aromatic ring. It thus exhibited an infrared absorption like a non-aryl acid which placed its band high enough to overlap with the δ-lactone absorption peak. The other carboxyl, ortho to the phenol, behaved like salicyclic acid.



I II III

Sublimation of acid I resulted in dehydration and formation of a $C_{12}H_8O_6$ compound which had the spectral characteristics of a phthalic anhydride. Hydrolysis of the anhydride regenerated the original $C_{12}H_{10}O_7$ acid.

With I as the structure of the phthalic acid, II could then be drawn as the structure of the parent naphthoquinone. The 2-position for the methoxyl was chosen in accordance with the acetate hypothesis (see III) for natural products (3) and has not been established on chemical evidence.

A small amount of crotonic acid was isolated from the oxidation reaction. This apparently arose from the oxidative cleavage of the phenolic ring to produce β-hydroxybutyric acid, which readily dehydrates to crotonic acid.

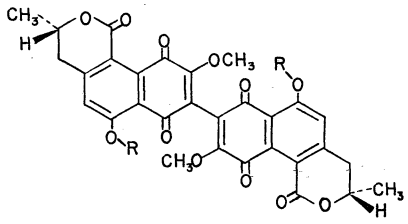
One problem which remained to be solved was the odd number of protons in the n.m.r. spectra. In the spectra of xanthomegnin, the diacetate, and the hexaacetate, the apparent number of protons was 11, 13, and 19, respectively. In no instance was there evidence of the hydrogen atom in the 3-position of the naphthoquinone structure.

When the molecular weight determination was conducted on xanthomegnin diacetate using the ebullioscopic method with chloroform as the solvent, a value of 655 was obtained. An alternate determination[9] by measurements of the vapor pressure lowering of benzene solutions at 38° gave an average value of 877. Since the calculated molecular weight of the monomeric structure would be 330, the data would indicate the dimeric nature of the pigment.

Considering the remarkable insolubility of xanthomegnin in organic solvents, its failure to melt, and its inability to sublime *in vacuo* at elevated temperatures, it was apparent that the physical properties of the pigment were inconsistent with the monomeric structure. The absence of the hydrogen at the 3-position together with the molecular weight findings leads us to propose the following dimeric structures for xanthomegnin and the diacetate as the only ones which satisfy all the spectroscopic and analytical data:



IV. XANTHOMEGNIN, R = H

V. XANTHOMEGNIN DIACETATE, R = AC

The final question to be settled was the absolute configuration of the asymmetric center in the δ-lactone. Klyne (1) has shown that the Hudson lactone rule can be applied to determine the absolute stereochemistry of the asymmetric center of the potential alcohol of the 5- and 6-membered-ring lactones. The direction of rotation induced by the formation of the lactone ring from the hydroxy acid is determined by the stereochemistry of the carbon atom bearing the hydroxyl group.

When acid I was dissolved in aqueous potassium hydroxide (*c* 2.05), the initial specific rotation was −98°. After 30 minutes it had risen to a constant value of −35°. Acidification of the solution resulted in a return of the rotation to −81°. The rotational increment passing from the acid to the lactone is hence −63°, establishing the absolute stereochemistry as depicted in I, and subsequently, IV and V.

No reference could be found in the literature to compounds where the double bond in the α,β-position had been studied in relation to the lactone rule. It is felt that the conclusion is most probably valid, although for this reason, the proposed configuration is advocated with reservation until verification is made of the fact that the lactone rule also applies to dihydroisocoumarins.

EXPERIMENTAL

All melting points were observed on a Kofler microscope hot-stage and are corrected. Rotations were measured with a Hilger Standard Polarimeter or a Zeiss Automatic Polarimeter using a 0.5-dm tube. The

[9]*Performed by Dr. A. F. Siriani, National Research Council, Ottawa, Canada.*

ultraviolet spectra were obtained in absolute ethanol or dioxane on the Beckman DK-1 recording spectrophotometer. The infrared spectra were recorded on a Perkin–Elmer model 21 using a potassium bromide pellet unless noted to the contrary. All n.m.r. spectra were taken at 60 Mc in deuterated chloroform with tetramethylsilane (0 c.p.s., $\tau = 10$) as an internal standard with the single exception when trideuteroacetic acid was used as the solvent. All analyses were carried out by Dr. C. Daesslé, Montreal, Que., and Dr. A. Bernhardt, Mülheim, Germany.

The Isolation of Xanthomegnin

A yellow matabolite, xanthomegnin, was isolated from the crude pigment extract of the mycelium of *Trichophyton megnini* by a sequence of deionization, Soxhlet extraction, column chromatography, and fractional crystallization procedures. The isolation has been reported separately.[1] The compound crystallized from a chloroform–benzene solution as orange platelets which did not melt but cindered at 264°.

Anal. Calc. for $(C_{15}H_{11}O_6)_2$: C, 62.72; H, 3.86; O, 33.42; methoxyl, 10.80 (2); methyl, 5.23 (2); active hydrogen, 0.35 (2). Found: C, 62.50; H, 3.92; average of four concordant analyses; O, 32.52; methoxyl, 10.87, 12.40; methyl, 3.01; active hydrogen, 0.75, 0.55.

Xanthomegnin Diacetate (V)

A mixture of 100 mg of xanthomegnin, 2 ml of acetic anhydride, and 10 drops of pyridine was allowed to stand at room temperature for 18 hours in the dark. The solution was poured onto ice to hydrolyze the excess anhydride, and the yellow flocculent solid was collected and recrystallized twice from ethanol–chloroform, m.p. 227–228°; ν 1775 cm^{-1} (vinyl acetate); λ_{max}^{diox} 262.5, 344 mμ (ϵ 21,300, 4,700); 7.40 τ, 3 protons per acetate.

Anal. Calc. for $(C_{17}H_{13}O_7)_2$: C, 62.01; H, 3.98. Found: C, 61.50; H, 3.97.

Tetrahydroxanthomegnin Diacetate

An ethyl acetate solution of 10.1 mg of xanthomegnin diacetate (V) absorbed 0.630 ml (1.84 mole-equiv, 2 mole-equiv = 0.685 ml), of hydrogen at room temperature and atmospheric pressure in the presence of 12 mg of prereduced platinum oxide.

Reduction was then carried out on a larger scale by stirring a solution of 89 mg of the acetate under hydrogen with 20 mg of platinum oxide until the uptake of hydrogen was complete. After the removal of the catalyst by filtration, the ether-soluble fraction of the product was crystallized from carbon tetrachloride, yielding 63 mg of bead-like crystals, m.p. 192–193°. The infrared spectrum showed no carbonyl absorption at 1716 and 1680 cm^{-1} but exhibited a new band at 1658 cm^{-1}. The n.m.r. spectrum showed a bonded hydroxyl at -2.64 τ and a free hydroxyl at 3.91 τ.

Anal. Calc. for $(C_{17}H_{15}O_7)_2$: C, 61.63; H, 4.56. Found: C, 60.52; H, 4.40. It proved to be very difficult to free the compound of water and solvents.

Tetrahydroxanthomegnin Hexaacetate

The 94 mg of hydrogenated xanthomegnin diacetate from the combined fractions was acetylated by dissolving the material in 2 ml of acetic anhydride, adding 10 drops of pyridine, and then allowing the solution to stand overnight in the dark. The reaction mixture was poured onto ice and after 1 hour the precipitate was collected by filtration and air dried. This product was chromatographed on silica gel, yielding 59 mg of nearly colorless solid from the benzene–ether (1:1 v/v) eluate. Recrystallization from isopropyl alcohol gave a pale yellow, amorphous precipitate, m.p. 191–192°; $[\alpha]_D^{23}$ -86.4, -82.2 (c, 0.72, 0.51 in chloroform); ν 1716 cm^{-1}; λ_{max}^{diox} 262 mμ (ϵ 37,000).

Anal. Calc. for $(C_{22}H_{19}O_9)_2$: C, 60.72; H, 4.61. Found: C, 60.55; H, 4.64.

Reductive Acetylation of Xanthomegnin Diacetate

Upon stirring a mixture of 27 mg of xanthomegnin diacetate (V), 27 mg of zinc dust, 2 ml of acetic anhydride, and two drops of pyridine for 10 minutes, the initially yellow solution became colorless. The reaction mixture was stirred vigorously for an additional 60 minutes and then allowed to stand overnight. Solid materials were filtered off and the filtrate was poured onto ice. After 2 hours the pale yellow precipitate was collected and recrystallized from isopropyl alcohol, m.p. 191–193°. Admixture of the product with tetrahydroxanthomegnin hexaacetate did not result in a lowering of the melting point, and the infrared spectra of the two compounds were superimposable.

Anal. Calc. for $(C_{21}H_{19}O_9)_2$: C, 60.72; H, 4.61. Found: C, 60.95; H, 4.64.

4-Hydroxy-6-(2′-hydroxypropyl)-hemimellitic acid δ-Lactone (I)

An alkaline peroxide oxidation of 500 mg of xanthomegnin was carried out in 50 ml of 10% aqueous sodium hydroxide. Ten milliliters of 30% hydrogen peroxide was added dropwise to the stirred solution while the reaction temperature was maintained below 10° with an ice bath. After ½ hour, an additional 2 ml of peroxide was added, the ice bath was removed, and the reaction mixture was allowed to stand at room temperature for 2 hours.

The solution was acidified to pH 4 with concentrated hydrochloric acid (approx. 10.5 ml). A slight excess of sodium bicarbonate was then added and the solution extracted twice with chloroform; only 2 mg of unreacted pigment was recovered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The solution was reacidified and extracted for 2 days with ether in a liquid–liquid extractor. Part of the material thus obtained was an easily sublimable product, which was separated by collecting it on a cold finger adjusted into the flask. By leaving the flask in a water bath at 45° for 20 hours, 32 mg of white sublimate was collected at atmospheric pressure. On further investigation this sublimate, m.p. 58–60°, proved to be predominantly crotonic acid (reported (4) m.p. 72°). Comparison of the R_f values of the sublimate with pure samples on Whatman No. 1 paper with ethanol – ammonium hydroxide – water (16:1:3 v/v) and bromocresol purple as developer confirmed the presence of crotonic and oxalic acids.

The main product was dissolved in ethyl acetate and washed six times with water, each wash being re-extracted five times with ethyl acetate. The small amount of water-soluble material was chiefly oxalic acid, as shown by a paper chromatogram using *n*-propanol – eucalyptol – formic acid (5:5:2 v/v), with water added to persistent cloudiness and using an ammoniacal silver nitrate developer.

The residue recovered upon evaporation of the ethyl acetate was recrystallized from acetone–benzene, yielding 163 mg of slightly colored, stubby needles (I), m.p. 194–195°. Two additional recrystallizations did not raise the melting point.

Anal. Calc. for $C_{12}H_{10}O_7$: C, 54.14; H, 3.79. Found: C, 54.49, 54.45; H, 4.07, 3.97.

3-Carboxy-6-hydroxy-4-(2′-hydroxypropyl)-phthalic anhydride Lactone

Sublimation of 40 mg of acid I at 165° and 2 mm gave 29 mg of pale yellow, stout needles of the anhydride, m.p. 227–229°; ν 1780 and 1855 cm^{-1} (phthalic anhydride); λ_{max}^{diox} 270, 352 mμ (ϵ 5,050, 7,760).

Anal. Calc. for $C_{12}H_8O_6$: C, 58.07; H, 3.25. Found: C, 58.16; H, 3.30.

Five milligrams of the anhydride was dissolved in 10 drops of acetic acid. The solution was diluted by approximately 20% with water, one drop of concentrated hydrochloric acid was added, and the mixture was allowed to stand overnight. Water was then added to force precipitation of the hydrolyzed product. The white solid was collected by filtration and dried, m.p. 196–197°. Admixture of this product and a sample of acid I gave no depression of the melting point. The infrared spectra were superimposable.

Rotation Studies on Acid I to Determine the Δ Value of the Lactone

The initial rotation of the acid was determined in 5% potassium hydroxide solution and was found to be $[\alpha]_D^{20}$ −98° (*c* 0.20). The rotation then decreased until it reached a constant value of −35°, after ½ hour and at room temperature; Δ value, −63°. Upon the addition of hydrochloric acid the rotation returned to −81° (*c* 0.14).

The rotation of the acid was determined again in 5% potassium hydroxide solution, giving −94° (*c* 0.20), changing to the constant value −29°; Δ value, −65°.

ACKNOWLEDGMENTS

The authors are indebted to Dr. R. Fraser of the University of Ottawa and to Mr. J. Nicholson of the National Research Council for obtaining the n.m.r. spectra and for valuable consultations concerning the interpretations thereof.

THE ACIDITY FUNCTION, H_0, IN AQUEOUS CONCENTRATED ACID AND SALT SOLUTIONS

DONALD ROSENTHAL* AND JAMES S. DWYER
Department of Chemistry, The University of Chicago, Chicago, Ill., U.S.A.

Received August 17, 1962

ABSTRACT

Some H_0 measurements in concentrated LiCl solutions are reported. It is shown that the H_0 values in 1–9 *M* LiCl, 1–9 *M* $HClO_4$, and 1–11 *M* HCl solutions can be calculated using the equation

$$H_0 = pCH + n \log a_w - BC,$$

where a_w is the activity of water, C is either the molar or molal concentration, and n and B are least-squares constants. Values of $n = 2$ (molar equation) and $n = 1$ (molal equation) fit the experimental data better than does $n = 4$. With the molar equation a non-integral value of n for $HClO_4$ is required to give reasonable H_0 values. The adequacy and significance of integral and non-integral values of n are considered. The nature of the constant B is also discussed. A more general equation is developed which under certain conditions reduces to the simpler equation. The more general equation is based upon a model which assumes the existence of more than one hydrated form of the indicator base, its conjugate acid, and H_3O^+. Some of the implications of this more general equation are considered.

INTRODUCTION

H_0 is defined as

$$H_0 \equiv pK_{BH^+} - \log (C_{BH^+}/C_B) \quad [1]$$

for the reaction $BH^+ \rightleftarrows B + H^+$, where B is a suitable uncharged indicator base (usually a substituted aniline) (1, 2). It is implicitly assumed that the proton and perhaps also B and BH^+ are solvated by water molecules in aqueous solutions. If, as seems reasonable, the number of water molecules required to solvate BH^+ is not equal to the number of water molecules required to solvate B and H^+, the above chemical equation can be more adequately represented as

$$BH^+ + nH_2O \rightleftarrows B + H^+.$$

Indeed, Bascombe and Bell (3) have indicated they could account for the H_0 values of less than 8 *M* strong acid solutions by assuming $n = 4$ and therefore that

$$H_0 = -\log [H^+](f_{H^+}f_B/f_{BH^+}a_w^4) = pMH + 4 \log a_w - \log (f_{H^+}f_B/f_{BH^+}). \quad [2]$$

Values of H_0 can be evaluated by assuming that

$$\log (f_{H^+} f_B/f_{BH^+}) = BM, \quad [3]$$

where B is a constant whose value depends upon the nature of the acid or salt and M is the molar concentration of electrolyte (acid or salt). That value of B which best fits the data is selected. Equation [3] is not unreasonable, since $\log f_B = B'M$ is valid for most non-electrolytes over a rather extended range of concentrations (4, 5), and $\log f_{H^+}/f_{BH^+}$ is relatively small in magnitude and for the present purposes can be adequately represented by $B''M$, so that $B = B' + B''$ (4, 6).

**Present address: Department of Chemistry, Clarkson College, Potsdam, N.Y.*

The present study was initiated to examine the adequacy of various equations in the calculation of H_0 values, and to consider what is the detailed nature of the acid–base equilibrium which defines H_0. In addition to published data on H_0 in hydrochloric and perchloric acid solutions, the results of some H_0 measurements we have made on slightly acidified lithium chloride solutions were used.

EXPERIMENTAL DETAILS OF LiCl H_0 MEASUREMENTS

Reagents

Baker Analyzed Reagent grade LiCl and reagent grade HCl were used. The indicators used were Eastman Kodak Co. white label brand compounds recrystallized twice from alcohol and once from water. The following melting points were obtained after the above purification: for *p*-nitroaniline 147–148° C, for *o*-nitroaniline 71.5–71.7° C, for 4-chloro-2-nitroaniline 116–117° C.

Solutions

Lithium chloride solution was made up roughly to 10.5 *M* and allowed to stand from 4 to 7 days until the insoluble impurities settled out. The clear supernatant was then siphoned off or filtered and standardized with a silver nitrate solution. The titer was adjusted to within one part per thousand of 10.00 *M*. Stock solutions (4×10^{-4} *M*) of the indicators and HCl solutions (0.1000 *M* and 1.000 *M*) were prepared.

All solutions used in the spectrophotometric measurements were prepared from the LiCl, HCl, and indicator stock solutions using calibrated volumetric glassware and diluting to 100 ml in a calibrated volumetric flask. The temperature of the solutions and glassware was maintained at 25±0.5° C.

Spectrophotometric Measurements

Measurements were made using a Beckman DU Quartz Spectrophotometer with 10-cm fused silica cells. The solutions and cells were maintained at 25±0.5° C. In each instance the reference solution was identical in composition with the corresponding indicator solution except for the absence of the indictor. The molar absorptivity of the indicators in the basic form was obtained with indicator solutions of concentration sufficient (ca. 10^{-5} *M*) that the absorbance was about one at the absorption maximum. To make sure the indicators were completely in the basic form, each solution was 0.001 *M* in NaOH. The wavelength of maximum absorbance and the molar absorptivity of the basic form of the indicators were different for water and the various LiCl solutions, and so were determined for each salt concentration used. The absorption maximum and molar absorptivity of the basic form changed as follows in going from water to the most concentrated LiCl solution: *p*-nitroaniline–water (0.001 *M* NaOH), 382 mμ, 1.30×10^4 liters $mole^{-1}cm^{-1}$; 8 *M* LiCl, 386 mμ, 1.264×10^4; *o*-nitroaniline–water (0.001 *M* NaOH), 412 mμ, 4.46×10^3; 9 *M* LiCl, 420 mμ, 4.23×10^3; 10 *M* LiCl, 423 mμ, 4.21×10^3; 4-chloro-2-nitroaniline–water (NaOH), 425 mμ, 4.52×10^3; 9 *M* LiCl, 431 mμ, 4.35×10^3. In general, the change in the wavelength maximum and molar absorptivity was not a linear function of concentration, but for *p*-nitroaniline the error made in assuming a linear function is negligible. Measurements made in aqueous solutions revealed the indicators conform to Beer's law in the concentration range employed in these studies. The results obtained in the LiCl solutions are consistent with the assumption that the indicators conform to Beer's law in these solutions.

The absorbance was zero in aqueous solutions in which the indicators were in their acid forms. It was assumed the molar absorptivity of the acid forms of the indicators was zero in all the LiCl solutions.

A series of absorbance measurements was made in 4 *M* LiCl using *p*-nitroaniline and *o*-nitroaniline, and in 8 *M* LiCl using *o*-nitroaniline and 4-chloro-2-nitroaniline. Hydrochloric acid concentrations varied from 5×10^{-3} *M* to 8×10^{-2} *M* and C_{BH^+}/C_B (equation [1]) varied from 0.5 to 3. The total indicator concentration was such that the absorbance of the solutions was between 0.3 and 1.6. H_0 was calculated from the absorbance measurements and the appropriate molar absorptivities using equation [1] and Paul and Long's pK_{BH^+} values for the indicators (2).

$H_0-pM\mathrm{H}$ was found to be a constant (1.054, $n = 5$, $S.D_{\bar{x}} = 0.012$) in the 4 *M* LiCl, and equal to 2.488 ($n = 7$, $S.D_{\bar{x}} = 0.004$) in the 8 *M* LiCl solutions (7). Having demonstrated the existence of *an* acidity function, H_0, in 4 and 8 *M* LiCl solutions, measurements were made with *p*-nitroaniline in 1–7 *M* LiCl solutions which were 5×10^{-3} *M* in HCl, and with *o*-nitroaniline in 9 *M* LiCl solutions. These H_0 results are summarized in Table III.

DISCUSSION

Least-squares H_0 Calculations

Using the expression

$$H_0 = pM\mathrm{H}+n\log a_w-BM, \qquad [4]$$

where $n = 4$, least-squares values of B were obtained for HCl, $HClO_4$, and LiCl from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

H_0 data for 1–11 M HCl, 1–9 M $HClO_4$, and 1–9 M LiCl solutions (the range of concentrations for which there are both H_0 values and activity of water data). Columns 5 and 6 of Tables I, II, and III contain values of H_0 calculated from equation [4] using the least-squares B values. Where an attempt is made to fit all the data (column 6), many of the calculated H_0 values are significantly different from the corresponding experimental values. Where only the 1–6 M data is fitted (column 5), the differences between the calculated and experimental values are comparable in magnitude to the errors in the H_0 measurements (2). Extrapolation of the least-squares straight line to concentrations greater than 6 M (data in parentheses column 5) leads to systematic deviations between calculated and experimental H_0 values. These deviations might be explained in terms of a competition between the hydrogen or lithium ion, chloride or perchlorate ion, indicator base and conjugate acid for water of solvation in these more concentrated acid or salt solutions, which results in a value of n less than four. (In some instances there is insufficient water to provide the "normal hydration numbers" for all species which are present.) In addition, there may be systematic deviations from equation [3] in very concentrated solutions (5).

In using and interpreting a value of $n = 4$ in equation [4], Bascombe and Bell assumed (3) that B and BH^+ were either unhydrated or hydrated to the same extent. There is evidence that both B (8, 9) and BH^+ (8, 10, 11, 12) are hydrated in aqueous solution and further that they are not hydrated to the same extent.

Instead of assigning a value to n, least-squares values of n and B were obtained using equation [4], and the H_0 values given in columns 7 and 8 of Tables I, II, and III were calculated. With an additional adjustable parameter it is not surprising that a better fit to the experimental data is obtained. However, the remarkable thing is that the deviation, between the experimental and calculated H_0 values (column 8), is in every case less than the magnitude of the experimental error expected for such measurements. If equation [4] is to be regarded as anything more than an empirical expression, the values of B and n obtained as a result of the least-squares calculations (column 8) need to be interpreted. The magnitude and sign of the values of B are not inconsistent with equation [3] and the previous relevant discussion (13). The non-integral values of n obtained for $HClO_4$ and LiCl, and the magnitude and the difference in n values for HCl and $HClO_4$ are not so readily explained.

Integral Values of n

Perhaps as reasonable as the assumption that n equals four (3) is the assumption that, at least where there is excess water available, there are three water molecules in the primary hydration shells of BH^+ and H_3O^+ and one (or no) water molecules in the primary hydration shell of B (8–12). (This model of the H_0 determining reaction assumes that B is a primary amine. This is true of many of the indicators used in establishing the H_0 values for HCl and $HClO_4$, and all the indicators in the LiCl measurements. Errors due to the fact that the n (and B) values of the indicators may differ are partially compensated for by the procedure by which pK_{BH^+} values are assigned and by the fact that any one indicator is only used over a small range of acid (or salt) concentration and thus a small range of activity of water. However, some of the deviation between calculated and experimental H_0 values may be attributed to this source of error.) This would give a value for n of two (or one). Such values are in better agreement with the n values from the least-squares calculations. The H_0 values calculated using equation [4] with $n = 2$ are given in columns 9 and 10 of Tables I–III. Considering just the 1–6 M data (column 9),

‡Calculated using the least-squares value of B (and n in column 7) obtained for the 1–6 M LiCl data.
§(H_0−pMH) was shown to be constant for a particular LiCl solution over a wide range of dilute HCl concentration (see Experimental Details). H_0 equals pMH plus the value listed in the column.

the results obtained for HCl and LiCl with $n = 2$ were in better agreement with the experimental H_0 values than the results obtained with $n = 4$. For $HClO_4$ the results obtained with $n = 2$ were no better than those obtained with $n = 4$. Where all the data given in Tables I–III are considered (column 10), the deviations between the calculated and experimental H_0 values are less than the uncertainties in the H_0 values for HCl and LiCl. The $HClO_4$ deviations can probably not be explained merely in terms of the errors in the experimental H_0 values. For HCl, LiCl, and $HClO_4$ deviations were less with $n = 2$ (column 10) than with $n = 4$ (column 6). The value of n is significantly closer to two than to one for HCl, LiCl, and $HClO_4$. (However, see Discussion in final section.)

The large deviations which occur for $HClO_4$ (column 10, Table II) and some of the other deviations (columns 7–10, Tables I–III) might be explained in terms of an effective change in n in going from dilute to more concentrated solutions. It may be unreasonable to attempt to use a model in which n has a constant value for all acid (or salt) concentrations. However, there is no convincing evidence that n equals four even in the more dilute solutions. Table IV contains the values of the least-squares constants for equation [4] when only portions of the concentration–H_0 values in Tables I–III are used (see also

TABLE IV

Results of least-squares calculations for portions of the H_0 data

*Values in parentheses are standard deviations.

columns 7 and 8, Tables I–III). H_0 is not a very sensitive function of n at low concentrations where the logarithm of the activity of water is very small, and errors in the experimental H_0 values can be 0.05 or greater. This explains the negative n value for HCl in the 1–3 M range and the large $S.D_n$ values at these low concentrations. In general n values are closer to two than four, but not always significantly so. There is no case in which n is significantly closer to four than to two.

Non-integral and Variable Values of n

In sufficiently concentrated salt solutions there is insufficient water to satisfy the "normal hydration numbers" of all the species present. This means that in addition to species like $H_3O^+.3H_2O$ (3), $B.H_2O$, and $BH^+.3H_2O$, species like $H_3O^+.2H_2O$, $H_3O^+.H_2O$, H_3O^+, B, $BH^+.2H_2O$, $BH^+.H_2O$, and BH^+ must also be present (14). A series of chemical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

equations and equilibrium constant expressions of the following general form can then be written:

$$H_3O^+.mH_2O \rightleftarrows H_3O^+.(m-1)H_2O + H_2O$$

$$K_{Hmw} = \frac{[H_3O^+.(m-1)H_2O]a_w}{[H_3O^+.mH_2O]} \frac{f_{H(m-1)w}}{f_{Hmw}}; \quad [5]$$

$$BH^+.pH_2O \rightleftarrows BH^+.(p-1)H_2O + H_2O$$

$$K_{BHpw} = \frac{[BH^+.(p-1)H_2O]a_w}{[BH^+.pH_2O]} \frac{f_{BH(p-1)w}}{f_{BHpw}}; \quad [6]$$

$$B.qH_2O \rightleftarrows B.(q-1)H_2O + H_2O$$

$$K_{Bqw} = \frac{[B.(q-1)H_2O]a_w}{[B.qH_2O]} \frac{f_{B(q-1)w}}{f_{Bqw}}; \quad [7]$$

and

$$nH_2O + BH^+.dH_2O \rightleftarrows B.(n+d-b)H_2O + H_3O^+.bH_2O$$

$$K^i_{BH^+} = \frac{[B.(n+d-b)H_2O][H_3O^+.bH_2O]}{[BH^+.dH_2O]a_w^n} \frac{f_{B(n+d-b)w}f_{Hbw}}{f_{BHdw}}. \quad [8]$$

In the above, the subscript w refers to water. Where H appears as the first subscript it refers to H_3O^+, and the subscript of f identifies the species to which the molar activity coefficient refers. Only one particular $K^i_{BH^+}$, K'_{BH^+} corresponding to particular n, d, and b values need be explicitly defined. All other equilibrium constants of form [8] can be expressed as a function of K'_{BH^+}, equilibrium constants of form [5]–[7], a_w, and activity coefficients quotients.

It is assumed that operationally

$$H_0 = pK_{BH^+} - \log \frac{([BH^+]+[BH^+.H_2O]+[BH^+.2H_2O]+\ldots)}{([B]+[B.H_2O]+\ldots\ldots\ldots\ldots)}, \quad [9]$$

where the numerator and denominator of the log term are each equivalent to an absorbance divided by a molar absorptivity. (This assumption is probably correct for the LiCl H_0 measurements, because the molar absorptivities were determined in each of the salt solutions. In HCl and $HClO_4$ solutions this assumption implies the further assumption that the molar absorptivities of each of the solvated species in the numerator are equivalent, and similarly for the denominator.) For convenience, it is further assumed that only those species indicated at the beginning of this section need be considered, i.e., m = 1–3 in equation [5], p = 1–3 in equation [6], and q = 1 in equation [7]. The treatment could be made more general by postulating additional solvated species, but this would only make the resulting equations more cumbersome without changing the essential form of the result. There may be differences in the secondary hydration shells of each of the species postulated. These differences, if important, are assumed to be adequately incorporated into the activity coefficients. Finally, this model does not specifically consider the consequences of solvation of Li^+ or the anions by B, the sharing of a water molecule by the ions, the structure of these solutions (15), and the decrease in the static dielectric constant with increasing salt (or acid) concentration, etc. (7, 16).

Having made the above indicated assumptions, the concentration of each of the four species in the numerator of the log term of equation [9] can be expressed as a function of the $BH^+.3H_2O$ concentration by using the equation [6] type equilibrium constants. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

two terms in the denominator can be expressed as a function of $B.H_2O$ concentration (equation [7]). The equilibrium constant K'_{BH^+} (equation [8]) for the reaction in which $n = 2$, $d = 3$, and $b = 3$ is then used to express $[BH^+.3H_2O]/[B.H_2O]$ as a function of a_w and $[H_3O^+.3H_2O]$. Finally $[H_3O^+.3H_2O]$ is expressed as a function of total acid concentration using equation [5]. This leads to

$$H_0 = (pK_{BH^+} - pK'_{BH^+}) + pMH - \log \frac{1}{a_w^2} \frac{f_{Bw} f_{H3w}}{f_{BH3w}} \times \underset{A}{\frac{\left[1 + \frac{K_{BH3w} f_{BH3w}}{a_w f_{BH2w}} + \frac{K_{BH2w} K_{BH3w} f_{BH3w}}{a_w^2 f_{BHw}} + \frac{K_{BHw} K_{BH2w} K_{BH3w} f_{BH3w}}{a_w^3 f_{BH}}\right]}{\left[1 + \frac{K_{H3w} f_{H3w}}{a_w f_{H2w}} + \frac{K_{H2w} K_{H3w} f_{H3w}}{a_w^2 f_{Hw}} + \frac{K_{Hw} K_{H2w} K_{H3w} f_{H3w}}{a_w^3 f_H}\right]\left[1 + \frac{K_{Bw} f_{Bw}}{a_w f_B}\right]}}_{B \qquad C} \quad [10]$$

This equation is more general than the previous expressions [2] and [4] and gives additional insight into possible H_0 functionality. Equation [10] will reduce to equation [4] whenever only one equilibrium K''_{BH^+} (equation [8]) is important over the concentration range of interest, i.e., when one term in each of the sums of terms in A, B, and C (square brackets, equation [10]) is large compared to all the other terms, and provided equation [3] is valid. To obtain equation [4] it must also be assumed that $pK_{BH^+} = pK''_{BH^+}$. Because of the way pK_{BH^+} is evaluated (2) this assumption may not always be true. Where two or more terms in A, B, or C (equation [10]) are comparable in magnitude over any portion of the acid (or salt) concentration range, *in general*, equation [4] will not adequately describe H_0 as a function of concentration over an extended range of concentrations and different values of n will be obtained over different, more limited ranges.

It has already been shown that the H_0 data for HCl, $HClO_4$, and LiCl can be calculated using equation [4]. However, a non-integral value of n must be used to satisfactorily fit the $HClO_4$ data. This could be interpreted as evidence for the necessity of using a more general form of equation [10], since integral values of n are to be expected. Presumably equation [4] appears adequate with non-integral values of n because the experimental H_0 values are inherently rather inaccurate (2), H_0 is relatively insensitive to n values at low acid concentrations, the activity of water changes by less than an order of magnitude for the data, and there are two adjustable parameters in equation [4]. Even for HCl and LiCl, where integral values of n ($n = 2$) are adequate, it seems probable that two or more terms in A, B, or C (equation [10]) are important (see discussion at the beginning of this section). Depending upon which terms in A, B, or C are important, the apparent value of n in equation [4] might increase, decrease, or change very little, when calculations over a limited range at low concentrations are compared with the results at higher concentrations. For example, there are some indications (8) that B is rather weakly solvated. If $B.H_2O$ were the predominant species in the less concentrated solutions and B the predominant species in concentrated solutions, the last term in C would become important in more concentrated solutions and n would change from two towards one. At higher concentrations where H_3O^+ and BH^+ are competing for water the second term in A ($BH^+.2H_2O$) might be more important than the second term in B ($H_3O^+.2H_2O$), in which case n would then increase. If the second term in A were comparable to the second term in B, there would be little or no change in n. It is difficult to draw any general conclusions from the data.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The fact that equation [4] best fits the HCl data (smallest a_w range) and seems least adequate for the $HClO_4$ data (largest a_w range) is at least consistent with what would be expected if equation [10] applies.

For the reduction of equation [10] to equation [4] it was necessary to assume the validity of equation [3]. In the earlier discussion equation [3] was shown to be reasonable. The experimental justification of equation [3] is that equation [4] is adequate for the explanation of the H_0 values of HCl and LiCl, and gives reasonable n and B values. The inadequacy of equation [4] in explaining $HClO_4$ H_0 values has been interpreted as evidence for the necessity of using a more general form of equation [10]. Alternatively, the $HClO_4$ results, at least in part, might be interpreted as evidence for the inadequacy of equation [3]. If

$$\log f_B f_{H^+}/f_{BH^+} = BM+g \log a_w, \quad [11]$$

the values of n obtained by equation [4] are theoretically interpretable in terms of equation [10] only if the empirical constant g is small. The possibility that g is large can not entirely be ruled out (see next section).

Related Expressions for H_0

The following modified versions of equation [4] were used to obtain least-squares values of B and n:

$$H_0 = pMH+n \log a_w-Bm \quad [12]$$

$$H_0 = pmH+n \log a_w-Bm \quad [13]$$

$$H_0 = pmH+n \log a_w-BM, \quad [14]$$

where m refers to molal concentrations. (Differences between H_0 on the molal and molar scales are negligible.) The results are summarized in Table V. In each instance the calculated value of H_0 obtained utilizing the least-squares values of B and n was not significantly different from the experimental value. The utilization of pmH rather than pMH did not lead to significantly different values of n (compare the results for equations [4] with [14], and [12] with [13]), but the utilization of molality rather than molarity in expressing the total electrolyte concentration (salt or acid) did lead to different values of n (compare the results for equations [4] with [12], and [13] with [14]).

$n = 1$ were less than the error in the experimental H_0 values. A value of $n = 2$ in equation [12] or [13] yielded reasonable H_0 values for LiCl, but not for HCl and $HClO_4$. A value of $n = 2$ in equation [14] (and equation [4]) yielded reasonable H_0 values for HCl and LiCl, but not for $HClO_4$.

If it is assumed that

$$\log f_B f_{H^+}/f_{BH^+} = Bm \qquad [15]$$

in equations [12] and [13], then the n values could be interpreted in a manner similar to that employed in the discussion of equation [4], i.e., in terms of equations [8] and [10]. When the activity coefficients in equation [15] are on the molal scale (as in equation [13]), equation [15] can be justified by arguments similar to those employed to justify equation [3] (17). (Most of the reservations expressed in the discussion of the interpretation of equations [3] and [4] (preceding section) are also applicable to equations [12] and [13].)

The interpretation of integral values of n for equations [13] and [4] in terms of equation [8] leads to the expectation that the same n values will be obtained using these two equations. However, the H_0 data can be fitted with $n = 1$ for equation [13] or [12] but not for equation [4] or [14]. A value of $n = 2$ is satisfactory for LiCl and HCl H_0 calculations with equation [4] or [14], but is not satisfactory for HCl or $HClO_4$ calculations using equation [12] or [13]. This anomaly can only be resolved if equations [4] and [14], and/or equations [12] and [13], are regarded as empirical in nature. One reason for this might be that equations [3] and/or [15] are not valid. There is no compelling reason for preferring either equation (4, 17). Another possible explanation is that a form of equation [10] more general than equation [4], [12], [13], or [14] should really be employed. Consistent with the latter interpretation is the fact that the values of n given in Table V are, at least in some instances, significantly different from integers.

PAPER CHROMATOGRAPHY OF ETHYLENEDIAMINE DIHYDROCHLORIDE AND DIACETATE IN ACIDIC SOLVENT SYSTEMS[1]

R. A. B. BANNARD AND A. A. CASSELMAN
Defence Research Chemical Laboratories, Ottawa, Ontario
Received August 2, 1962

ABSTRACT

Quantitative chromatography of ethylenediamine dihydrochloride on *unwashed* Whatman No. 17 paper in *t*-butanol:acetic acid:water (2:1:1) resulted in a 1% conversion to ethylenediamine diacetate (R_F 0.51) and a 98% recovery of the dihydrochloride (R_F 0.28). The cause of the multiple zoning, which was not observed on acid-washed papers, was traced to minor quantities of alkaline earth metals which are present as impurities in *unwashed* papers. Ion exchange mechanisms are suggested to account for the observed conversion. Quantitative chromatography of ethylenediamine diacetate on *unwashed* or acid-washed Whatman No. 17 paper in *t*-butanol:0.5% hydrochloric acid (3:1) resulted in quantitative recovery of the dihydrochloride due to displacement of the weak acid in the substrate by the strong acid in the solvent system.

In an earlier communication (1) we reported that paper chromatography of clam poison dihydrochloride on *unwashed* Whatman No. 1 paper in the solvent system *t*-butanol: acetic acid:water (2:1:1) gave two Weber-positive components, R_F 0.32 and 0.53. Repetition of the experiments using Whatman No. 1 paper which had been washed with hydrochloric or acetic acid or specially pretreated (1) for removal of extractable impurities gave only one Weber-positive component, R_F 0.32, which was identified as clam poison dihydrochloride. The faster-moving component observed on *unwashed* paper (substance X) was not identified but was concluded to differ from clam poison diacetate (R_F 0.53 on *unwashed* Whatman No. 1 paper in the same solvent system). It was also concluded that substance X is not a different ionic species or a tautomer of clam poison. Since our supply of clam poison was limited, it seemed worthwhile to examine the behavior of another diacid base during paper chromatography in the same solvent system to determine whether multizoning would occur and disappear under similar conditions and, if possible, to establish the cause of these phenomena. Results obtained during chromatography of ethylenediamine dihydrochloride and diacetate are reported herein.

Qualitative chromatograms were performed on *unwashed* Whatman No. 1 and No. 17 papers and on the same papers which had been pretreated by chromatographic washing with 0.01 *N* hydrochloric acid, 0.6 *N* acetic acid, 0.01 *N* sulphuric acid, or by the method described earlier for removal of extractable impurities (1). Two solvent systems were used, namely, *t*-butanol:acetic acid:water (2:1:1) and *t*-butanol:0.5% hydrochloric acid (3:1). Amines were detected by spraying with ninhydrin. Chloride ion was revealed by spraying with 5% silver nitrate followed by washing with water and ultraviolet irradiation. Acetate ion was detectable as deep blue spots by dipping chromatograms performed on Whatman No. 1 paper in an alcoholic lanthanum nitrate – iodine solution, followed by dipping in 5 *N* ammonium hydroxide. Incomplete removal of solvent during drying masked the test for acetate ion when Whatman No. 17 paper was used.

Results of the experiments in *t*-butanol:acetic acid:water (2:1:1) are summarized in Table I, from which it is evident that multizoning similar to that previously observed

TABLE I

Paper chromatography of ethylenediamine dihydrochloride and diacetate on Whatman No. 1 and No. 17 papers in *t*-butanol:acetic acid:water (2:1:1)

Compound	Whatman No. 1						Whatman No. 17			
	Unwashed			Acid washed¶			Unwashed		Acid washed¶	
Ethylenediamine dihydrochloride	0.24 (f)*	0.31 (s)*†	0.37 (f)*†	0.44 (f)*	0.54 (s)*‡‖	0.34 (s)*†	0.30 (s)*†	0.50 (s)*‖	0.28 (s)*†	
Ethylenediamine diacetate	0.24 (f)*			0.44 (f)*	0.57 (s)*‡	0.55 (s)*‡§		0.52 (s)*		0.57 (s)*§

NOTE: s = strong; f = faint.
*Ninhydrin positive.
†Positive for chloride ion.
‡Positive for acetate ion.
§Spot exhibits strong tailing to R_F 0.35.
‖Spot exhibits faint ninhydrin-positive shadow to R_F 0.37.
¶See experimental section for details.

with clam poison dihydrochloride occurs when ethylenediamine dihydrochloride is chromatographed on the *unwashed* papers. The two principal ninhydrin-positive spots at R_F 0.30–0.31 and 0.50–0.54 were observed on all chromatograms of the dihydrochloride on *unwashed* papers but frequently the very faint spots at R_F 0.24, 0.35, and 0.44 on Whatman No. 1 paper were not discernible. These spots were never observed on Whatman No. 17 paper. Since chloride ion was coincident with the strong ninhydrin-positive spot at R_F 0.30–0.31 and there was no marked tailing or bearding of the spot with either chromogen it was tentatively concluded that this substance was an ethylenediamine mono- or di-hydrochloride. Similarly, since acetate ion was coincident with the strong ninhydrin-positive material at R_F 0.54 (Whatman No. 1) it was tentatively concluded that this substance was an ethylenediamine mono- or di-acetate. It is noteworthy that the latter material was followed by a very faint and diffuse ninhydrin-positive shadow extending back to R_F 0.37. The principal ninhydrin-positive spot obtained by chromatography of ethylenediamine diacetate under similar conditions on Whatman No. 1 paper (and this was the only material ever observed on the heavier paper) was at R_F 0.57 and was coincident with acetate ion. This material was obtained as a somewhat elongated dense spot which did not exhibit strong tailing or diffuse shadowing. It was tentatively concluded that this material was probably identical with the substance of R_F 0.50–0.54 resulting from chromatography of the dihydrochloride under similar conditions.

Chromatography of the dihydrochloride on the acid-washed papers gave only one compact ninhydrin- and chloride-positive spot, R_F 0.28–0.34. Under identical conditions, the diacetate gave one ninhydrin- and acetate-positive spot, R_F 0.55 on Whatman No. 1 paper, and one ninhydrin-positive spot, R_F 0.57 on Whatman No. 17 paper. Both of these spots exhibited strong tailing back to R_F 0.35.

Chromatography of both salts in *t*-butanol:0.5% hydrochloric acid (3:1) gave only one compact ninhydrin- and chloride-positive spot, R_F 0.12–0.14, on both papers regardless of whether the paper was acid washed or *unwashed*. This material was considered to be ethylenediamine mono- or di-hydrochloride.

The similarity of the forementioned R_F values suggested that some conversion of ethylenediamine hydrochloride to acetate occurs when the dihydrochloride is chromatographed on *unwashed* Whatman No. 1 or No. 17 papers using *t*-butanol:acetic acid:water (2:1:1) as developer, and that total conversion to hydrochloride results when ethylenediamine diacetate is chromatographed on *unwashed* or pretreated Whatman No. 1 or No. 17 papers when *t*-butanol:0.5% hydrochloric acid (3:1) is used as developer.

To demonstrate the validity of these tentative conclusions, quantitative chromatography of ethylenediamine dihydrochloride and diacetate was studied using *unwashed* Whatman No. 17 paper. Whatman No. 1 paper was judged unsuitable for this purpose since it could not be loaded sufficiently heavily and because of the multiplicity of ninhydrin-positive spots which it sometimes produced (see Table I).

Ethylenediamine dihydrochloride (3 g) was chromatographed on six sheets of *unwashed* Whatman No. 17 paper using *t*-butanol:acetic acid:water (2:1:1) as developer. The two bands, R_F 0.28 and 0.51, which were located on the air-dried chromatograms by ultraviolet irradiation were recovered by aqueous elution, yielding 3.45 g and 0.4 g respectively of crude products which occupied total areas of 402 and 393 sq. in. respectively on the chromatograms. Vacuum sublimation of the slower-moving band followed by recrystallization of the sublimate gave 2.94 g (98.0%) of ethylenediamine dihydrochloride, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was identified by its infrared spectrum and elemental analysis. Vacuum sublimation of the faster-moving band, followed by recrystallization of the sublimate from ethanol, gave 40 mg (1.0%) of ethylenediamine diacetate, which was identified by its infrared spectrum and its melting point in admixture with an authentic specimen. It is therefore evident that the ninhydrin-positive material appearing at R_F 0.28 during quantitative chromatography of ethylenediamine dihydrochloride on *unwashed* Whatman No. 17 paper in *t*-butanol:acetic acid:water (2:1:1) is unchanged dihydrochloride, i.e. the substance applied to the chromatogram moves as an ion pair. The latter conclusion agrees with that reported by Waldron-Edward (2) following qualitative chromatography of ethylenediamine dihydrochloride and sulphate in butanol:acetic acid:water (4:1:5) on *unwashed* Whatman No. 1 paper, during which multiple spotting was also observed. It is clear that the substance which appears at R_F 0.51 on the quantitative chromatogram referred to above is ethylenediamine diacetate which has been formed from the dihydrochloride during chromatography. The amount of dihydrochloride thus converted cannot exceed 2%. This result was unanticipated because the areas covered by the two bands were almost identical. Furthermore, although there was a difference in intensity of the two bands (as revealed by ultraviolet irradiation or spraying with ninhydrin) the difference was not proportional to the quantities of substances present. Thus, when multiple spots are observed on paper chromatograms it is unsafe to conclude either that impurities in the starting material are responsible or that extensive conversion of the latter to another substance is involved without careful quantitative investigation. Possible explanations for this multizoning effect are considered below.

Ethylenediamine diacetate (400 mg) was chromatographed on four sheets of *unwashed* No. 17 paper using *t*-butanol:0.5% hydrochloric acid (3:1) as developer. Ultraviolet irradiation of the air-dried chromatograms revealed only one band, R_F 0.13. This material was recovered by aqueous elution and purified by sublimation *in vacuo*, yielding 284 mg (96.0%) of ethylenediamine dihydrochloride as colorless needles, which was identified by its infrared spectrum. Clearly, based on the R_F values observed in this experiment, the diacetate has been converted quantitatively to the dihydrochloride during chromatography by the action of the stronger acid in the developing solvent.

The occurrence of multiple zones or spots during chromatography of pure substances is now a frequently observed phenomenon. In a recent review article on the subject Keller and Giddings (3) list the following possible causes: (i) chemical reaction of the substrate prior to or during chromatography, (ii) impurities in the solution chromatographed, (iii) discontinuities in the immobile phases, (iv) discontinuities in the mobile phase, (v) charged species and complexes, and (vi) equilibrium between two species. It is frequently difficult, however, to demonstrate which of these causes is responsible for a particular case of multiple spotting. From the purity of the dihydrochloride used and the nature of the solvent system employed, it seemed unlikely that causes other than (i), (v), or (vi) could be responsible for formation of ethylenediamine diacetate from the dihydrochloride during chromatography. Since the phenomenon was observed only on *unwashed* paper it appeared probable that a complexing (3, 4) or ion exchange (3, 5) mechanism involving impurities in the paper was responsible. Some support for this view resulted from the observation that ethylenediamine diacetate exhibits strong tailing during chromatography on the acid-washed papers but *not* on the *unwashed* papers. It was previously reported (4–6) that acid washing removes trace quantities of calcium and magnesium ions which otherwise remain bound to the paper. The presence of these

ions can lead to troublesome tailing during chromatography of phosphate esters in basic solvent systems (4) and their absence can lead to equally troublesome tailing during chromatography of aminoacids and peptides (6). We observed the latter phenomenon during chromatography of clam poison dihydrochloride on acid-washed paper and for this reason subsequent washing with calcium acetate and water was used to restore a small amount of calcium ion to the paper and eliminate the tailing (cf. Connell, Dixon, and Hanes (6)).

Acid-washed Whatman No. 17 paper was washed chromatographically with 0.1 *N* calcium acetate for 2 days, then with water for 2 days, followed by air drying. Ethylenediamine dihydrochloride and diacetate were then chromatographed on these papers using *t*-butanol:acetic acid:water (2:1:1) as developer. For the diacetate, results were identical with those observed on *unwashed* paper, i.e. tailing was eliminated. From the dihydrochloride under the same conditions, however, two ninhydrin-positive spots, R_F 0.32 and 0.54, were obtained. The latter spot exhibited a faint ninhydrin-positive shadow back to R_F 0.37, i.e. *the results obtained were identical with those observed on unwashed papers.* Thus, restoration of calcium ion to the paper regenerated the multiple-spot phenomenon in acid-washed paper. Similar results were also obtained on acid-washed No. 17 papers to which a small amount of magnesium ion had been restored by washing with 0.1 *N* magnesium acetate and water. It is therefore concluded that alkaline earth metals present in small amounts in *unwashed* paper are responsible for the observed effect.

Formation of diacetate from dihydrochloride could readily result from an ion exchange process. It is known that alkaline earth metals present in paper are bound as salts of residual carboxylic acid groups in cellulose (7). Several years ago Schute (5) suggested a cation exchange mechanism involving trace amounts of metallic ions such as Na^+, K^+, Ca^{++}, and Mg^{++} bound to carboxyl groups in the paper to explain absorption of alkaloids by paper when acidic solvent systems are employed. A simple extension of this mechanism could account for the hydrochloride-to-acetate conversion observed in the present investigation. A carboxylate salt of type II could be formed by partial acetolysis of the dicarboxylate salt I (where M^{++} is an alkaline earth metal cation) under the influence of the solvent

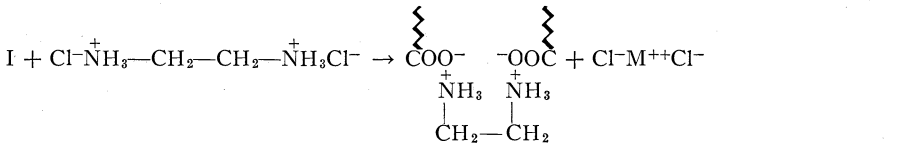
$$\underset{\text{I}}{\text{COO}^-\text{M}^{++}\,^-\text{OOC}} + \text{HOAc} \rightarrow \underset{\text{II}}{\text{COO}^-\text{M}^{++}\text{AcO}^-} + \text{HOOC}$$

system used (7). Sites of type II in the paper could then readily effect conversion of the dihydrochloride to the diacetate by anion exchange. Clearly, the extent to which such a mechanism could operate is governed by the number of carboxylate groups and alkaline earth metal cations present in the paper, both of which are small (7), and also by the rapidity with which complete acetolysis of the salt II leads to restriction of the phenomenon to an early stage in development of the chromatogram by destroying the anion exchange sites. Were it not for the latter factor, intervention of the suggested mechanism would be expected to lead to pronounced bearding of the dihydrochloride band as it moves down the paper. Such an effect is not observed. However, generation of a small amount of acetate during a very early stage in the development of the chromatogram, before all the active sites for ion exchange are eliminated by the acid in the solvent system, could account for the diffuse band of diacetate recovered in the quantitative experiment in which conversion was observed.

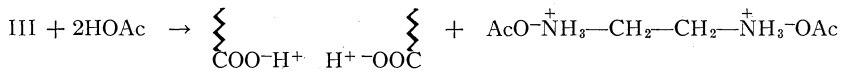
An alternative mechanism which would accomplish conversion of dihydrochloride to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

diacetate involves ion exchange between the alkaline earth metal cation in the dicarboxylate salt I and the ethylenediammonium ion present in the dihydrochloride, with formation of III. By this means a small amount of chloride ion from the salt would be removed when the dihydrochloride is first applied to the paper. Development with the acid solvent system would then release the ethylenediammonium cation, forming a small quantity of ethylenediamine diacetate. Again by this mechanism the effect would be limited to an early stage in development of the chromatogram since alkaline earth metals would be removed from active sites of type I by the acid in the solvent system.



III



Both ion exchange mechanisms mentioned above are in agreement with the experimental observations but it is not possible on the basis of the data currently available to distinguish between them. The possibility also exists that the observed conversion of dihydrochloride to diacetate occurs via intervention of a chelated metal complex, since it is well known that ethylenediamine has a great tendency toward formation of such complexes (8, p. 519). If complex formation is responsible it appears probable that an alkaline earth metal rather than a transition metal is involved, since washing the papers with acid does not remove the latter (4) yet causes the multizoning to disappear. However, formation of complexes between ethylenediamine and alkaline earth metals has not been reported (8, p. 184; 9; 10). There would thus appear to be no basis for assuming intervention of a complexing mechanism at present.

It is suggested that the formation of 1% of ethylenediamine diacetate during chromatography of ethylenediamine dihydrochloride on *unwashed* Whatman No. 17 paper in *t*-butanol:acetic acid:water (2:1:1) results from chemical reaction of the dihydrochloride via an ion exchange mechanism with traces of alkaline earth metals present in the paper as impurities. It is not clear whether the ion exchange occurs directly on application of the substrate to the paper, during an early stage in development of the chromatogram, or at both these times. On the other hand, complete conversion of ethylenediamine diacetate to the dihydrochloride during chromatography of the former on *unwashed* or pretreated Whatman No. 17 paper in *t*-butanol:0.5% hydrochloric acid (3:1) is ascribed to displacement of the weaker acid from the salt by the stronger acid in the solvent system.

The similarity in chromatographic behavior of clam poison dihydrochloride and ethylenediamine dihydrochloride in *t*-butanol:acetic acid:water (2:1:1) on *unwashed* papers, together with the positive identification of ethylenediamine diacetate as the minor component produced during chromatography of ethylenediamine dihydrochloride under such conditions, indicates the desirability of careful re-examination of the minor component from chromatography of clam poison dihydrochloride (1) to determine whether or not it is the diacetate salt.

EXPERIMENTAL[2,3]

Ethylenediamine Dihydrochloride

Ethylenediamine (6.01 g, 0.100 mole) was placed in a 250-ml round-bottom flask, ether (15 ml) was added, and the resultant solution was mechanically stirred in an ice bath while a solution of hydrochloric acid (37%, 33 ml, 0.4 mole) in ether (50 ml) was added dropwise over a period of 30 minutes. The resultant colorless precipitate was collected, washed with anhydrous ether (5×10 ml), and recrystallized from water–methanol (4:1), yielding 12.6 g (94.7%) of ethylenediamine dihydrochloride as colorless needles, which sublimed without melting. Calc. for $C_2H_{10}N_2Cl_2$: C, 18.06; H, 7.58; N, 21.06; Cl, 53.31%. Found: C, 18.28; H, 7.53; N, 20.96; Cl, 53.44%.

Ethylenediamine Diacetate

The procedure was identical with that used for preparation of the dihydrochloride except that acetic acid (23.1 ml, 99.7%, 0.4 mole) was employed instead of hydrochloric acid. The resultant solid was recrystallized from absolute ethanol, yielding 16.0 g (88.8%) of ethylenediamine diacetate as colorless needles, m.p. 117–118°. Calc. for $C_6H_{16}N_4O_4$: C, 39.99; H, 8.95; N, 15.55%. Found: C, 39.80; H, 8.79; N, 15.64%.

Qualitative Paper Chromatography

(1) Using Whatman No. 1 Paper

Strips of Whatman No. 1 paper (6.25×22.5 in.) were pretreated by chromatographic washing (*a*) with 0.01 *N* hydrochloric acid (3 days) and water (3 days), (*b*) with 0.6 *N* acetic acid (3 days) and water (3 days), (*c*) with 0.01 *N* sulphuric acid (3 days) and water (3 days), and (*d*) by the method described previously for elimination of extractable impurities from papers employed for quantitative paper chromatography of clam poison (1). To a strip of each of these pretreated papers, together with untreated Whatman No. 1 paper, 7.5 λ (150 γ), spots of 2% aqueous solutions of ethylenediamine dihydrochloride and ethylenediamine diacetate were applied. The chromatograms were developed in *t*-butanol:acetic acid:water (2:1:1) and in *t*-butanol:0.5% hydrochloric acid (3:1). After drying in a forced air oven at 60° to remove as much solvent as possible, the chromatograms were treated with reagents for detection of amine (ninhydrin), chloride ion (5% silver nitrate followed by ultraviolet irradiation), and acetate ion (lanthanum nitrate – ammonia).

(2) Using Whatman No. 17 Paper

The experiments described above were repeated using untreated and pretreated Whatman No. 17 paper employing 200 γ of the ethylenediamine salts per spot.

Lanthanum Nitrate Test for Acetate Ion

This test is a modification of the spot test for acetate reported by Feigl (11). Resublimed iodine (0.2 g) was dissolved in ethanol (75 ml), lanthanum nitrate (5 g) was added, and the solution made up to 100 ml with water. The chromatogram or test strip was dipped into the lanthanum nitrate solution and allowed to stand 1.5 to 2 minutes at room temperature before being dipped into a 5 *N* ammonium hydroxide developer. Acetate ion was revealed by the appearance of deep blue spots in 2–5 minutes. The minimum quantity of ethylenediamine diacetate detectable by this method was 5 γ (1 γ of ethylenediamine diacetate was detectable by dipping chromatograms in a 0.4% solution of ninhydrin in water-saturated *n*-butanol).

Quantitative Paper Chromatography

(a) Chromatography of Ethylenediamine Dihydrochloride in t-Butanol:Acetic Acid:Water (2:1:1)

Ethylenediamine dihydrochloride (500 mg) was applied as a streak from 25% aqueous solution to each of six sheets of *unwashed* Whatman No. 17 paper ($18\frac{1}{4}\times22\frac{1}{2}$ in.). The chromatograms were suspended by the stirrup method (12) in a Model A 300 Chromatocab (Research Equipment Corp., Oakland, Calif.) and developed simultaneously by the descending method in *t*-butanol:acetic acid:water (2:1:1) for 38 hours, using a single wick of Whatman No. 3 paper as solvent feed. After air drying, ultraviolet irradiation revealed the presence of two bands, R_F 0.28 and 0.51, which, after elution with water (40 ml each), combination of corresponding eluates, filtration through a fine-porosity fritted-glass funnel, concentration, and drying *in vacuo*, gave 3.45 g and 0.4 g respectively of crude product, which occupied areas of 402 and 393 sq. in. respectively on the chromatograms.

Sublimation of the slower-moving band at 185° at 10^{-3} mm pressure gave 3.1 g of colorless solid which, after recrystallization from water–methanol (4:1), yielded 2.94 g (98.0%) of colorless needles with an infrared spectrum (KBr pellet) identical with that of an authentic sample of ethylenediamine dihydrochloride and possessing the following analytical data: C, 18.32; H, 7.64; N, 20.84; Cl, 53.05%.

The dried material from the faster-moving band was washed with boiling absolute ethanol (3×5 ml). Sublimation of the dried ethanol-soluble fraction at 120° at 10^{-3} mm pressure gave 50 mg of colorless solid, recrystallization of which from ethanol gave 40 mg (1.0%) of colorless needles, m.p. 116.5–117.5° alone and in admixture with an authentic sample of ethylenediamine diacetate. The infrared spectra (KBr pellet) of the two samples were also identical.

(b) Chromatography of Ethylenediamine Diacetate in t-Butanol:0.5% Hydrochloric Acid (3:1)

Ethylenediamine diacetate (100 mg) was applied as a streak from 10% aqueous solution to each of four sheets of *unwashed* Whatman No. 17 paper ($18\frac{1}{4}\times22\frac{1}{2}$ in.) and developed as described above except that *t*-butanol:0.5% hydrochloric acid (3:1) was used as developer (48 hours). Each chromatogram exhibited one band at R_F 0.13 under ultraviolet irradiation. The total area covered by the combined bands was 251 sq. in. The bands were recovered as described above, yielding 0.528 g of crude product, recrystallization of which from water–methanol (4:1) yielded 0.284 g (96.0%) of colorless needles, the infrared spectrum of which (KBr pellet) was identical with that of an authentic sample of ethylenediamine dihydrochloride.

PHOTOCHEMICAL SYNTHESES

5. SULPHENES AS PHOTOCHEMICAL INTERMEDIATES[1]

J. F. KING, P. DE MAYO, E. MORKVED,[2] A. B. M. A. SATTAR, AND A. STOESSL[3]
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 23, 1962

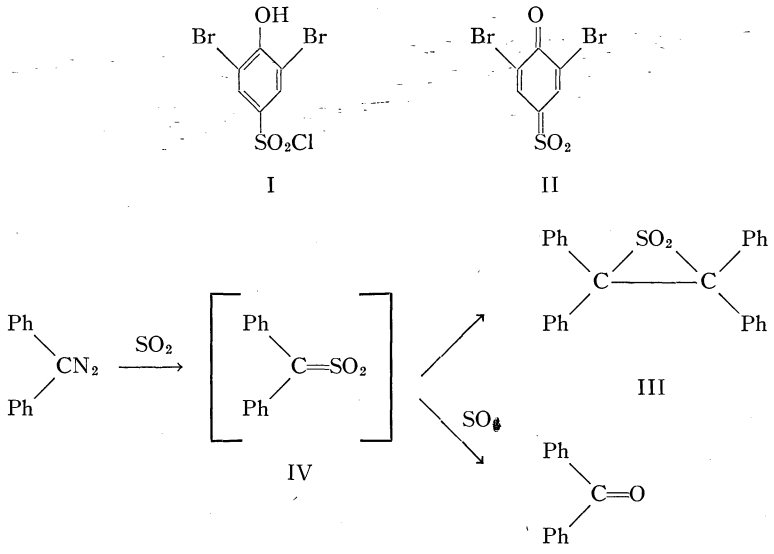
ABSTRACT

The present status of sulphenes ($R'R''C{:}SO_2$) as stable entities or chemical intermediates is discussed. The early report by Locher and Fierz (Helv. Chim. Acta, **10**, 642 (1927)) of the preparation of a stable crystalline sulphene has been investigated; it is concluded that their claim is unfounded.

The irradiation of unsaturated sultones in the presence of methanol is shown to give sulphonic esters: the corresponding thermal reaction of sultones is known to lead to sulphonic acid derivatives. It is proposed that the irradiation of unsaturated sultones yields sulphenes, which then react with the medium.

The preparation and properties of ketenes have been studied over many years, but investigations directed towards a similar study of the sulphonyl analogue, the sulphene, $R'R''C = SO_2$, have been but sporadic and inconclusive.

Zincke and Brune reported in 1908 (2) that treatment of I with sodium acetate in acetone gave a yellow color, formulated as II, which rapidly faded with deposition of polymer. Not long after, Wedekind and Schenk (3) found that treatment of benzylsulphonyl chloride with triethylamine yielded stilbene together with triethylamine hydrochloride. They proposed the following mechanism to account for the formation of stilbene: (*a*) abstraction of hydrogen chloride from the sulphonyl chloride forming the "sulphene" (the term was first proposed by these authors in this connection), (*b*) decomposition of



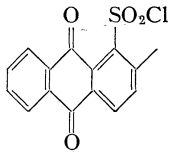
[1]*Part of the material here reported has been described in a preliminary communication (1).*
[2]*Nee E. Henmo.*
[3]*Present address: Research Institute, Canada Department of Agriculture, London, Ontario.*

the phenylsulphene to phenylcarbene and sulphur dioxide, and (*c*) coupling of two phenylcarbene molecules to form stilbene. Subsequent studies by Wedekind and co-workers (4, 5) and much more recent work in this laboratory (6) with these and analogous materials have yielded sulphur-containing compounds readily derivable from sulphene intermediates.

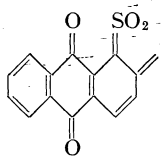
Recently (7, 8) it has been found that enamines react with methanesulphonyl and benzylsulphonyl chlorides in the presence of base to give four-membered ring aminosulphones. It has been suggested that the sulphene, formed as in the Wedekind reaction, might be an intermediate.

A process akin to Wedekind's step (*b*) was first reported by Staudinger and Pfenninger (9), who observed that diphenyldiazomethane in an inert solvent readily reacts with sulphur dioxide, giving tetraphenylethylene sulphone (III), or when the sulphur dioxide is in excess, benzophenone. The mechanism put forward by these authors involved, in both cases, initial formation of diphenylsulphene (IV) followed in the former case by reaction with a second molecule of diphenyldiazomethane with subsequent loss of nitrogen, and in the latter case by addition of sulphur dioxide to the sulphene followed by loss of "S_2O_3". When the reaction was carried out in hydroxylic solvents the products were those derivable by direct addition of solvent to the sulphene in the manner of ketenes: in water, the sulphonic acid; in methanol, the methyl ester; and in ethanol, the ethyl ester of the sulphonic acid. More recently the reaction of diphenyldiazomethane and sulphur dioxide in the presence of an amine has been shown (10) to yield the sulphonamide. The reaction of other diazo compounds with sulphur dioxide shows the generality of the Staudinger and Pfenninger process. Stilbestrol and a number of analogues have been synthesized by pyrolysis of the sulphone initially formed by reacting the phenylethyldiazomethane with sulphur dioxide (12), and ethylene sulphone—previously unknown—has been prepared (11) from diazomethane and sulphur dioxide.

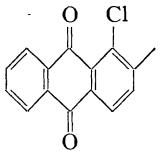
The only record of the preparation of a stable crystalline sulphene is that of substance V by Locher and Fierz (13), who report that it is formed in poor yield on heating the



VI



V



VII

acid chloride (VI) in chlorobenzene. Because of the intrinsically unlikely nature of this transformation (though it is not entirely without some chemical analogy (15)), we have reinvestigated their claim.

Exact replication of their experiments was difficult because these authors did not present adequate evidence for their conclusions as to the character of either the sulphonic acid, its acid chloride, nor the so-called anilide said to be derived from the "sulphene". Further, they did not specify quantities or reaction times for the alleged sulphene-forming reaction. We have prepared the sulphonic acid by the method of Locher and Fierz and find that it may exist in both hydrated and anhydrous forms, which are interconvertible; the anhydrous form melts at 220–221°. Significantly, Locher and Fierz report that the sulphene melts at 221–222° (they report no melting point for the acid).

The acid chloride can be prepared from the acid using phosphorus oxychloride and phosphorus pentachloride as described by Locher and Fierz, but is made much more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

cleanly using thionyl chloride. They reported a melting point of "ca. 165°" for this material and asserted that the compound was difficult to crystallize owing to instability; they reported no analyses. We find the compound to be readily purified, providing normal precautions are taken to exclude moisture. It melts at 181–183° in an evacuated capillary; heating on a Kofler block in the air leads to hydrolysis and when only small samples are used the melting point obtained is that of the anhydrous sulphonic acid. On heating in chlorobenzene for short periods (e.g. 2 hours or less) little reaction takes place. On refluxing for longer periods (14 hours or more) there is both hydrolysis and loss of sulphur dioxide with formation of 1-chloro-2-methylanthraquinone (VII); the latter transformation has precedent in simpler systems in which sulphene formation is impossible (14 and work referred to, especially, F. Ullmann and P. Kertesz, Ber., **52**, 546 (1919)). To ascertain whether the sulphonic acid produced might be formed by rapid addition of water to the sulphene during isolation, the reaction product—immediately after refluxing for 14 hours—was treated with D_2O. Quantitative examination of the infrared spectrum in the methyl symmetrical deformation region (1375 cm^{-1}) showed the absence of significant $—CH_2D$ formation in the deuterated material.

Locher and Fierz report that the "sulphene" on treatment with aniline yields the sulphanilide as small yellow needles melting at 132–133°.[4] We have attempted to make the anilide by heating the sulphonyl chloride with aniline in chlorobenzene as described briefly by these authors but have isolated only aniline hydrochloride by this method. Attempts to prepare the anilide by heating the sulphonyl chloride with aniline followed by pouring into dilute hydrochloric acid gave, surprisingly, only the anilinium salt of the sulphonic acid.[5] The latter compound is prepared more cleanly directly from the sulphonic acid and aniline; it is obtained from chlorobenzene solution as small yellow needles melting around 235° with decomposition.

In view of the above results, and the similarity between the alleged sulphene and the anhydrous sulphonic acid, the claim of Locher and Fierz to have prepared a stable sulphene cannot be credited.

Although sulphenes may well be intermediates in some of the reactions discussed, alternative rationalizations are possible. If the sulphene can have but an ephemeral existence, it seemed that in order to prove it to be an intermediate in a reaction, one would have to generate it under mild, and possibly specific, conditions, so as to reduce the chance of producing the final product by other routes. From another area of work (16) there was available in these laboratories the cyclic unsaturated sultone VIII. This contains the cyclic homannular dienic system, known, in a number of cases, to open to the acyclic triene on irradiation (for a review see ref. 17). The present case contained the so far unique feature of two heteroatoms situated where the bond fission would be expected to occur.

Irradiation of VIII in methanol gave the expected ester (IX), which structure followed by analogy with the following simpler instance, XI → XIII, and which was confirmed by alkaline cleavage to benzoic acid (1 mole) and the known sodium sulphonate (X) (16).

In view of the apparent success of the photochemical transformation, the sultone XI (18) was prepared and irradiated in methanol. The product (XII) was an unstable oil

[4]*In view of the high melting points of all other compounds in this series, this is an unlikely melting point for the most stable crystal form of either a sulphonamide or a salt derived from this sulphonic acid. Though not established, it is attractive and reasonable, nonetheless, to suggest that the material which Locher and Fierz actually had in hand was the anilinium salt and that the reported melting point is either a misprint or—less likely—that the melting point is that of a low-melting crystal form or solvate (see Experimental).*

[5]*The ease of hydrolysis of the acid chloride and the failure to form the anilide under these conditions suggest that both of these reactions may involve attack on the sulphur atom by the oxygen of the adjacent carbonyl group. We plan further study of this point.*

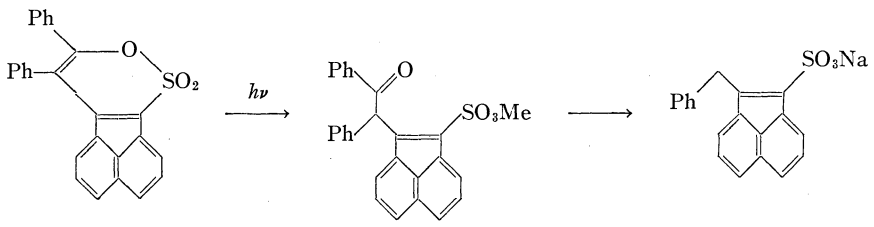
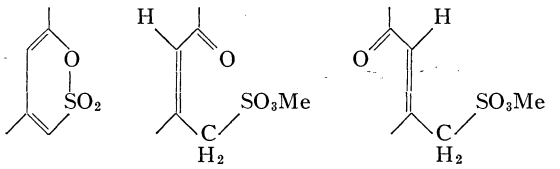
For personal use only.

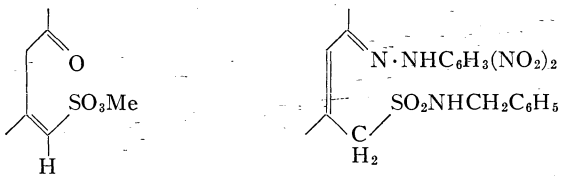


VIII IX X

which had, however, the expected spectroscopic properties. It showed λ_{max} 234 mμ (ϵ 8500) in the ultraviolet for the unsaturated ketone, and had a band at 1696 cm^{-1} ($CHCl_3$) in the infrared[6] to be attributed to the conjugated carbonyl. The n.m.r. spectrum showed a singlet (3 H) at τ 7.8 for the methyl ketone and a closely spaced doublet at τ 7.9 for the allylic methyl group, the vinyl proton appearing at τ 3.68. A singlet (3 H) at τ 6.14 is attributed to the methoxyl group whilst another singlet (2 H) at τ 5.44 is due to the methylene group. All peaks and all protons are thereby accounted for. The isomeric structure XIV is excluded by ultraviolet and infrared spectral evidence, but XIII and XII are not distinguished. The oily methyl ester was characterized as the 2,4-dinitrophenylhydrazone. This showed bands in the n.m.r. spectrum (apart from the aromatic



XI XII XIII



XIV XV

hydrogens) at τ 4.2 (1 H), 5.4 (2 H, singlet), 6.25 (3 H, singlet), and a close doublet and singlet (6 H) at τ 7.75, in agreement with the expected structure.

Irradiation of the sultone XI in ether containing two equivalents of benzylamine gave an oil which was converted to the 2,4-dinitrophenylhydrazone. Chromatography on bentonite–Celite gave the sulphonamide (XV). This showed λ_{max} 375 mμ (ϵ 25,000), appropriate for a conjugated ketone derivative, and showed peaks in the n.m.r. spectrum at τ 7.8 (3 H, singlet, CH_3CO—), 7.66 (3 H, close doublet, CH_3—C(H)=C—), 4.0 (1 H, unresolved, —C(H)=C—), 6.17 (2 H, singlet, —CH_2—SO_2—), 5.61 (2 H, apparent doublet, benzyl CH_2), and ca. 5.16 (1 H, unresolved, NH).

[6]*Mesityl oxide has* λ_{max} *238 m*μ *(*ϵ *11,300),* ν_{max} *1685 cm*$^{-1}$ *(*$CHCl_3$*).*

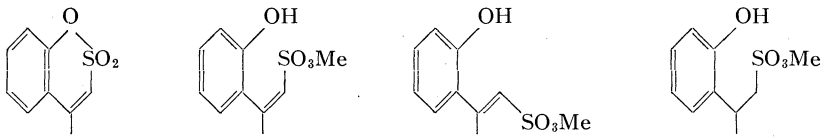
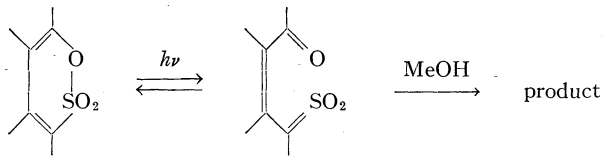
For personal use only.

Finally, irradiation of the sultone XVI (19) in methanol gave the corresponding ester of the phenol (XVII). The n.m.r. spectrum indicated that it was a mixture of the geometrical isomers XVII*a* and XVII*b*, and the mixture was hydrogenated to the homogeneous dihydro compound XVIII.



XVI XVII*a* XVII*b* XVIII

Appropriate controls clearly established that all these transformations were photochemically induced. Furthermore, although slow reaction with the solvent occurred in the absence of light, the products were in that case entirely acidic and no trace of the sulphonic esters could be detected. It would thus appear that these photolyses, like those in related systems (17), proceed by bond rearrangement, that is, in the present instance, through the sulphene XIX. In the absence of any suitable base, recyclization to the



XIX

sultone would be expected, as occurs with the equivalent ketene system (20). By analogy with the experiments of Wedekind it was thought possible that competitive thermal dissociation of the sulphene might be induced. In the event, irradiation in dry diglyme with warming gave up to 25% sulphur dioxide, in agreement with the present view.

EXPERIMENTAL

Unless otherwise stated melting points were determined on a Kofler hot stage. The light source for the irradiation experiments was a Hanovia CH-3 lamp (80 watts). If not otherwise indicated infrared spectra refer to Nujol mulls, ultraviolet spectra to solutions in 95% ethanol, and n.m.r. spectra (determined on a Varian HR 60 spectrometer) to solutions in deuterochloroform using tetramethylsilane as internal standard. Petroleum ether refers to the fraction of boiling range 30–60°. The quartz immersion apparatus used in some of the irradiation experiments is that previously described (21).

Irradiation of Sultone VIII

Irradiations were carried out for periods varying from 30 to 100 minutes in methanol solution contained in a stoppered Pyrex flask cooled by a stream of air. The reaction mixture was worked up by pouring into excess water and extracting with chloroform; the extracts were washed successively with dilute sodium bicarbonate solution and water, and dried over sodium sulphate. Evaporation of the solvent left a brown semicrystalline residue from which most of the color was removed by washing with a small amount of ether. In a typical experiment, irradiation of 474 mg of the sultone (VIII) in 700 ml of methanol for 40 minutes, in two equal lots, yielded 348 mg (73%) of the crude sulphonic ester (IX).

The analytical specimen was prepared by chromatography of the crude ester on silica gel followed by four recrystallizations from chloroform–ether; m.p. 162–179°. Calc. for $C_{27}H_{20}O_4S$: C, 73.63%; H, 4.58%; S, 7.27%; OCH_3, 7.05%. Found: C, 73.87%; H, 4.59%; S, 7.53%; OCH_3, 6.56%.

Alkaline Hydrolysis of the Sulphonic Ester IX

(*a*) Sulphonic ester IX (150 mg) was added to a solution of sodium hydroxide (4 g) in a mixture of water (30 ml) and 95% ethanol (90 ml), and the solution refluxed under nitrogen for 2 hours. The mixture was cooled and acidified, and the crude sodium salt isolated as previously described (16). This was washed successively with small amounts of ether and ethyl acetate and recrystallized from ethanol, giving yellow crystals identified as X by the infrared and ultraviolet spectra.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(*b*) In another experiment the sulphonic ester (IX) (17.7 mg, 0.040 mmole) was refluxed for ½ hour under nitrogen with a solution of potassium hydroxide (0.45 g) in water (3 ml) and ethanol (9 ml). The solution was cooled and made acid to Congo red with 6 *N* sulphuric acid. The acidic solution was then slowly distilled, constant volume being maintained by addition of water. The distillate was titrated with *N*/100 sodium hydroxide using phenolphthalein as indicator. The titer consumed by the first 55 ml of distillate (after correction for the blank) corresponded to 0.041 mmole of acid. Continued distillation yielded no more acid. In a separate experiment the acidic material of the distillate was identified as benzoic acid by melting point, mixed melting point, and infrared spectrum.

Irradiation of Sultone XI in Anhydrous Methanol

A solution of XI (3.50 g) in methanol dried by the magnesium methoxide procedure (182 ml) was irradiated in the quartz immersion apparatus for 3½ hours. The product was poured into dilute sodium chloride solution (800 ml) and extracted with carbon tetrachloride. The extract was washed with sodium bicarbonate solution and with water, dried with sodium sulphate, and evaporated. The crude product was distilled *in vacuo*, yielding a yellow oil which deposited crystals on cooling. Calc. for $C_7H_{12}O_4S$: C, 43.75%; H, 6.29%; O, 33.31%; S, 16.65%; OCH_3, 16.13%. Found: C, 44.70%; H, 6.06%; O, 32.90%; S, 16.25%; OCH_3, 14.91%.

A solution of the distilled product (169 mg) in methanol (2 ml) was added to a solution of 2,4-dinitrophenylhydrazine (212 mg) in methanol (12 ml) containing hydrochloric acid. After standing at room temperature for 20 minutes the solution was poured into water and extracted with chloroform as usual. The crude product was dissolved in benzene and poured onto a column of bentonite (8 g) mixed with three times its volume of Celite. The crystalline dinitrophenylhydrazone was eluted slowly with benzene. The fractions were combined and recrystallized twice from chloroform – ethyl acetate; m.p. 143–145°. Calc. for $C_{13}H_{16}O_7N_4S$: C, 41.92%; H, 4.33%; O, 30.07%; N, 15.04%; OCH_3, 8.33%. Found: C, 42.37%; H, 4.42%; O, 30.08%; N, 15.00%; OCH_3, 8.64%.

Irradiation of Sultone XI in Ether containing Benzylamine

A solution of XI (320 mg) in ether (160 ml) containing benzylamine (0.43 ml) was irradiated in the quartz immersion apparatus under nitrogen for 140 minutes. The ether solution was washed respectively with *N* hydrochloric acid, water, saturated sodium bicarbonate solution, and water, and then evaporated. The gummy product (347 mg) was dissolved in methanol (4 ml) and water (1 ml), and added to a solution of 2,4-dinitrophenylhydrazine (490 mg) in methanol (15 ml) containing concentrated hydrochloric acid. The mixture was poured into water, giving a precipitate which was filtered off and washed with water, and taken up in methanol, which was then evaporated. The orange-red gummy product (543 mg) was dissolved in benzene and placed on a column consisting of bentonite (20 g) mixed with three times its volume of Celite. The material eluted with chloroform and 10% ethanol in chloroform was recrystallized four times from chloroform – petroleum ether; m.p. 157–158°. Calc. for $C_{19}H_{21}O_6N_5S$: C, 51.00%; H, 4.73%; N, 15.65%; S, 7.15%. Found: C, 51.04%; H, 4.76%; N, 15.39%; S, 6.74%.

Elimination of Sulphur Dioxide during Irradiation of Sultone XI

A sample of the sultone (XI) was dissolved in diethyleneglycol dimethyl ether ("diglyme", previously distilled over sodium) contained in a 50-ml round-bottomed quartz flask placed approximately 2.5 cm from the light source. During the irradiation the temperature rose rapidly to the temperature recorded. A slow stream of nitrogen was passed through the solution and led into a trap containing a solution of iodine in aqueous potassium iodide. After an interval the irradiation was stopped and the loss of iodine in the trap determined by titration with *N*/10 sodium thiosulphate. In each case a blank experiment was run with approximately the same weight of sultone and with other conditions identical except that the solution was heated in an oil bath without irradiation to the same temperature as that of the irradiation experiment.

Wt. of sultone irradiated (mg)	Wt. of sultone in blank (mg)	Vol. diglyme (ml)	Temp. (0° C)	Time (hr)	Loss of I_2; irradiation (mmole)	Loss of I_2; blank* (mmole)	Net mole% sulphur dioxide
197	209	15	80	11	0.36	0.08	23
144	166	15	130	9.5	0.24	0.06	20
622	582	20	110	5.5	0.585	0.075	13

*In a blank experiment carried out by heating the solvent for 12 hours at 120° without the sultone, the loss of iodine was 0.03 mmole.

Irradiation of Sultone XVI

A solution of XVI (1.18 g) in methanol (160 ml) was irradiated in the immersion apparatus for 7¼ hours. The product was worked up by evaporating the methanol to a small volume, pouring into water, and extracting with chloroform. The chloroform extract was washed with water and then extracted with 1% sodium hydroxide solution, which in turn was washed with chloroform, acidified with hydrochloric acid, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

extracted with chloroform. The chloroform extract was washed with water and evaporated, yielding 485 mg of acidic product, which was chromatographed on silica gel. The major fractions (300 mg) showed sharp bands in the n.m.r. at τ 7.77, 7.51, 6.30, and 6.11, consistent with the presence of the geometrical isomers XVII*a* and XVII*b*.

Some (138 mg) of this material was dissolved in ethyl acetate and hydrogenated in the presence of palladium on charcoal catalyst until approximately 1 mole of hydrogen was taken up. Evaporation of the solvent left a colorless oil which was distilled *in vacuo* at 100–110° C. Calc. for $C_{10}H_{14}SO_4$: C, 52.17%; H, 6.13%; OCH_3, 13.48%. Found: C, 51.80%; H, 6.13%; OCH_3, 13.06%. $\lambda\lambda_{max}$ 273 mμ (ϵ 2280) and 278 mμ (ϵ 2090); singlet τ 6.27, doublet τ 8.49 (J = 6 cycles/sec), unresolved bands at ca. τ 3.0 (aromatic H), τ 4.4 (benzylic H), and τ 6.5 (doublet due to CH_2).

2-Methylanthraquinone-1-sulphonic Acid

This compound was prepared from the barium salt followed by recrystallization from concentrated hydrochloric acid, as described by Locher and Fierz (13), who concluded that this material is a dihydrate. On drying *in vacuo* at 70–80°, recrystallization from benzene, or heating to 200° in air, the hydrated acid loses water, giving the anhydrous acid as yellow crystals (parallelogram-shaped plates from benzene) which rapidly turn a dirty greenish color on exposure to light; m.p. 220–221° (Kofler or vacuum capillary). Considerable sublimation was observed on the Kofler block, especially above 200°; the sublimate has a highly characteristic "shingled" appearance which is particularly striking when viewed with polarized light. On cooling below 160°, the melted sample solidified, and on heating, it melted again at 215–220°. A sample was recrystallized twice from benzene. Calc. for $C_{15}H_{10}O_5S$: C, 59.61%; H, 3.34%; S, 10.58%. Found: C, 59.75%; H, 3.43%; S, 10.15%.

The infrared spectra of the hydrated and anhydrous forms of the acid are distinctly different and serve as a ready means of identifying the compounds. On standing for a few hours in an open test tube enclosed in a flask containing a few drops of water and filled with nitrogen (or simply on standing for a day in the air), the anhydrous acid is converted to the hydrated form. When a few drops of D_2O are placed in the flask instead of H_2O, a material is obtained which has the same infrared spectrum as the hydrated acid except that the broad band at 3600 cm^{-1} is diminished and a new broad band at 2500 cm^{-1} is present. A sample of twice-recrystallized anhydrous acid was allowed to equilibrate for 3 days in the air of the laboratory. Calc. for $C_{15}H_{10}O_5S.1\frac{1}{2}H_2O$: C, 54.71%; H, 3.98%; S, 9.72%; H_2O, 8.21%. Found: C, 54.07%; H, 3.89%; S, 9.34%; loss on drying, 8.2%.

2-Methylanthraquinone-1-sulphonyl Chloride (VI)

2-Methylanthraquinone-1-sulphonic acid (hydrate, 540 mg) was dissolved in freshly distilled thionyl chloride (10 ml) and the solution refluxed for 1 hour. The excess thionyl chloride was evaporated under reduced pressure, leaving a brownish crystalline residue which readily recrystallized from methylene chloride – petroleum ether, giving well-formed pale yellow blades melting at 181–183° (vacuum capillary). Calc. for $C_{15}H_9SO_4Cl$: C, 56.17%; H, 2.83%; S, 10.00%; Cl, 11.06%. Found: C, 55.76%; H, 2.96%; S, 9.54%; Cl, 10.63%.

Action of Heat on 2-Methylanthraquinone-1-sulphonyl Chloride

(a) In Dry Chlorobenzene

A solution of the sulphonyl chloride (VI) (131 mg) in thrice-distilled chlorobenzene (6 ml) was refluxed for 18 hours in a dry 10-ml round-bottomed flask fitted with an air condenser bearing a drying tube containing Drierite. The solvent was then removed *in vacuo*, leaving a yellow crystalline solid. Methylene chloride (ca. 2 ml) dissolved all but 23 mg of this material; the infrared spectrum of the undissolved material showed it to be the sulphonic acid (hydrate). The infrared spectrum of the solution was similar to that of 1-chloro-2-methylanthraquinone except for a band at 1185 cm^{-1} characteristic of the anhydrous sulphonic acid (in CH_2Cl_2). The methylene chloride solution was washed with water and both phases evaporated separately. The aqueous phase yielded 32 mg of a pale yellow solid whose infrared spectrum ($CHCl_3$) was identical with that of the sulphonic acid. The methylene chloride phase gave 45 mg of pale yellow crystals which, after two recrystallizations from glacial acetic acid, melted at 169–170°; melting point on admixture with an authentic sample of 1-chloro-2-methylanthraquinone, 169–171°; its infrared spectrum (CH_2Cl_2) was identical with that of 1-chloro-2-methylanthraquinone.

Another solution of the sulphonyl chloride (178 mg) in chlorobenzene (6 ml) was heated just below reflux temperature (bath temperature 132°) for 2 hours and the solvent evaporated as above. The infrared spectrum (CH_2Cl_2) of the product (163 mg) indicated it to be substantially unchanged starting material; all differences from the spectrum of pure starting material were readily ascribable to the presence of approximately equal amounts of the sulphonic acid and 1-chloro-2-methylanthraquinone.

In a third experiment a solution of the sulphonyl chloride (119 mg) in dry chlorobenzene (5 ml) was refluxed for 14 hours as before. It was allowed to cool for 5 minutes, D_2O (0.5 ml) was then added, the mixture shaken for 5 minutes and allowed to stand for 20 minutes. It was then poured into methylene chloride and extracted with water. Evaporation of the methylene chloride phase yielded 64 mg of a yellow crystalline solid whose infrared spectrum (CH_2Cl_2) showed it to be impure 1-chloro-2-methylanthraquinone. The

For personal use only.

aqueous phase gave 44 mg of a pale yellow crystalline solid, which was recrystallized from benzene. The infrared spectrum (KBr) was virtually identical with that of an authentic sample of the sulphonic acid run at the same time; in particular, the band at 1385 cm^{-1} showed precisely the same intensity relative to the other bands in both spectra.

(b) On Kofler Block (in Air)

About 3 or 4 mg of the sulphonyl chloride was placed on a microscope slide (without cover glass) and set on the Kofler block at 125°, and the temperature increased gradually. At ca. 145° the transparent blades became opaque. Heating was continued until the temperature reached 200°; no melting had taken place. The infrared spectrum was identical with that of the anhydrous acid.

When one or two crystals of the sulphonyl chloride were placed on a microscope slide (with cover glass) and placed on the Kofler block at <130°, the same crystal change at ca. 140° was observed followed by sublimation gradually around 150° and rapidly above 200°; the sublimate was identical in appearance with the characteristic sublimate formed on heating the sulphonic acid. The material melted sharply at 218–220°, yielding a transparent yellow melt. On cooling below 160° the melt crystallized; on heating again it showed the characteristic sublimation above 200° and melted around 210–219°.

Reaction of the Sulphonyl Chloride VI with Aniline

The sulphonyl chloride (VI) (106 mg) was heated at 135° with aniline (2 ml) for 100 minutes. The mixture was allowed to cool and then poured into excess dilute hydrochloric acid. The reddish precipitate was filtered off, washed with dilute hydrochloric acid, dried, and recrystallized from toluene, giving a brownish crystalline solid whose infrared spectrum was identical with that of the anilinium salt.

Anilinium 2-Methylanthraquinone-1-sulphonate

Aniline (0.1 ml) was added to a solution of the sulphonic acid (90 mg) in water (2 ml). A yellowish crystalline precipitate formed within 20 seconds. This was filtered off and recrystallized three times from water, giving pale yellow blades which on heating on the Kofler block changed crystal form with partial melting around 148–150°, apparently changed crystal form again at 200–210°, and finally melted around 230–238° with decomposition. Calc. for $C_{21}H_{17}O_5NS.H_2O$: C, 61.01%; H, 4.63%; N, 3.39%. Found: C, 61.06%; H, 4.63%; N, 3.49%.

Adding aniline to a hot solution of the sulphonic acid in chlorobenzene gave fine yellow needles which (after recrystallization from chlorobenzene) apparently changed crystal form below 160°, then around 200°, and finally melted at 235–238° with decomposition. The infrared spectrum was identical with that of the material obtained from aqueous solution.

ACKNOWLEDGMENTS

The authors would like to thank Mr. R. E. Klinck for the determination of the n.m.r. spectra. They are indebted for financial support to the U.S.A.F. under Grant No. AF-AFOSR-61-6.

OXIDATION STATES OF MANGANESE IN FUSED ALKALI NITRATES

RUTH M. BENNETT* AND OWEN G. HOLMES

University of Saskatchewan, Regina Campus, Regina, Saskatchewan

Received August 7, 1962

ABSTRACT

When dissolved in fused alkali nitrate, manganese (II) is oxidized to MnO_2. In the same solvent MnO_4^- decomposes to MnO_2. Peroxide ion arrests the decomposition at MnO_4^{2-}, while the presence of hydroxide ion results in the formation of MnO_4^{3-}. The spectra of MnO_4^{2-} and MnO_4^{3-} in molten nitrate show great similarity to their spectra in alkaline aqueous solution.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Fused nitrate salts form useful and interesting solvents due to the variety of reactions which they undergo with different solutes. The nitrate ion is capable of participating in oxidation–reduction processes and acid–base reactions. Duke (1) has interpreted the latter on the basis of the dissociation of nitrate ion in the melt into nitronium ion and oxide ion, analogous in many respects to the ionic dissociation of water.

In this report we present some observations on the chemistry of manganese when its compounds are dissolved in molten alkali nitrates. Spectrophotometric methods were used for identification and analysis of species of different oxidation states which occurred under various experimental conditions.

EXPERIMENTAL

In the experiments reported here, a eutectic mixture of $NaNO_3$–KNO_3, 45.5 mole% $NaNO_3$, melting point 218° C, was used as solvent. The nitrate melts were maintained at 260±15° C both during the periods of chemical reaction with solutes and during the periods of spectrophotometric examination.

Manganese was introduced into the nitrate melt either as anhydrous manganese (II) sulphate or as potassium permanganate. The manganese was approximately 4×10^{-4} *M* in all cases reported.

Anhydrous sodium peroxide, 96.0% Na_2O_2, was used as a source of peroxide ions, while hydroxide ions were added in the form of sodium hydroxide which assayed at 99.0% NaOH.

The compounds $NaNO_3$, KNO_3, $MnSO_4$, $KMnO_4$, Na_2O_2, and NaOH used in these experiments were Fisher Reagent grade.

Aqueous solutions of manganate ion were prepared for spectrophotometric analysis by dissolving potassium permanganate in 4 *M* sodium hydroxide and heating for several minutes until no further color changes were observed.

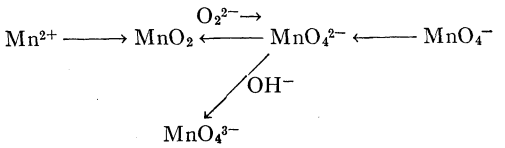
Absorption spectra of liquid solutions were measured with a Beckman DU spectrophotometer. For the fused salt solutions, the 1-cm pyrex absorption cells were housed and heated in a small electrical furnace through which an optical path had been cleared. This assembly was placed between the source and the optical system of the instrument rather than behind the dispersing unit as in the conventional Beckman DU arrangement.

Reflectance spectra were measured with a reflectance accessory attached to the spectrophotometer. For reference, instead of the usual $MgSO_4$ block, a quenched eutectic $NaNO_3$–KNO_3 mixture was used. Both quenched pure solvent and solution were powdered by a mechanically driven mortar and pestle prior to reflectance measurement.

RESULTS AND DISCUSSION

The chemistry of manganese in fused $NaNO_3$–KNO_3 can be summarized as follows:

**Holder of a Bursary from the National Research Council.*



Each of the indicated reactions is discussed separately below.

(1) Oxidation of Mn^{2+}

Manganese (II) is rapidly oxidized to MnO_2, which precipitates from the molten nitrate solution. Simultaneously NO_2 is expelled. These observations can be accounted for by:

$$Mn^{2+} + 2NO_3^- \rightarrow MnO_2 + 2NO_2. \quad [1]$$

In the presence of excess O_2^{2-}, MnO_2 is further oxidized to manganate ion:

$$MnO_2 + O_2^{2-} \rightleftharpoons MnO_4^{2-}. \quad [2]$$

(2) Decomposition of MnO_4^-

In fused $NaNO_3$–KNO_3 at 260° C, permanganate ion slowly decomposes ultimately to MnO_2 and O_2. However, green manganate ion is an intermediate of several minutes' duration. Figure 1 shows the reflectance spectrum of the cooled and powdered solid obtained

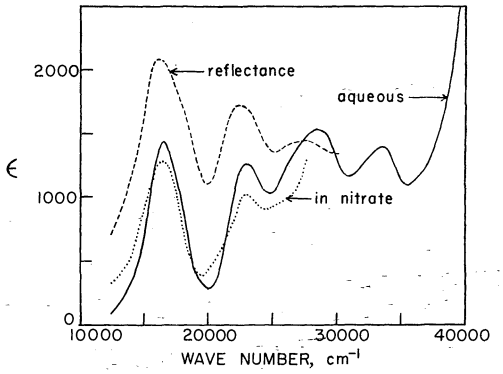


FIG. 1. Spectra of MnO_4^{2-}.

on filtering a solution of MnO_4^{2-} containing MnO_2 through glass wool. The absorption scale for this reflectance spectrum is only relative. Equations [3]–[6] are suggested for the reduction of MnO_4^- to MnO_2 in this system.

$$4MnO_4^- + 2NO_3^- \rightarrow 4MnO_4^{2-} + 2NO_2^+ + O_2 \quad [3]$$

$$2MnO_4^{2-} \rightarrow 2MnO_2 + 2O^{2-} + O_2 \quad [4]$$

$$MnO_4^{2-} \rightleftharpoons MnO_2 + O_2^{2-} \quad [5]$$

$$2MnO_4^{2-} + 2NO_2^+ \rightarrow 2MnO_2 + 2NO_3^- + O_2 \quad [6]$$

Equation [3] shows the decomposition in nitrate melt of MnO_4^- into MnO_4^{2-} and O_2, a process in which the NO_3^- acts as a base to provide the necessary oxides. The pyrolysis of $KMnO_4$ above 200° C yields a mixture of K_2MnO_4 and MnO_2 (2), as there is not enough oxygen content to allow K_2MnO_4 alone.

Equations [4], [5], and [6] present alternatives for the decomposition of MnO_4^{2-}. In [4] the decomposition is direct, yielding oxide ions; in [5], peroxide ions. Equation [6]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

suggests that nitronium ion could play an acidic role in this decomposition by accepting the oxides released when MnO_4^{2-} is converted into MnO_2.

(3) Stabilization of MnO_4^{2-} by O_2^{2-}

Peroxide ion present in the melt in excess of the MnO_4^{2-} concentration prevents further decomposition to MnO_2. This observation is consistent with that summarized in equation [2]. Peroxide ion would destroy the NO_2^+ necessary for the process in equation [6] by neutralization:

$$2NO_2^+ + 2O_2^{2-} \rightarrow 2NO_3^- + O_2. \qquad [7]$$

The absorption spectrum of MnO_4^{2-} preserved in molten nitrate solution by O_2^{2-} is shown in Fig. 1. The ultraviolet spectrum was inacccessible due to interference of the nitrate ion (3).

(4) MnO_4^{3-} in Fused Nitrate

The addition of NaOH to manganate ion in fused nitrate causes a rapid change in color from green to blue. The spectrum of the blue solution is shown in Fig. 2, along with

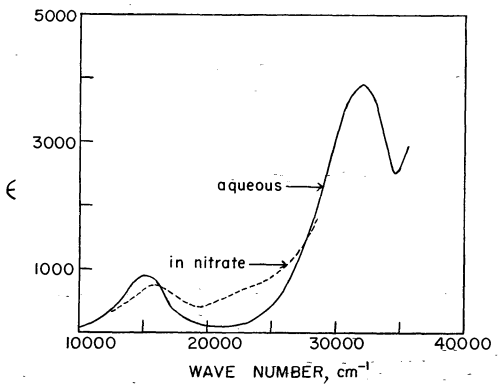

FIG. 2. Spectra of MnO_4^{3-}.

the spectrum of MnO_4^{3-} reported by Carrington and Symons (4). Although attempts to chemically identify the blue species were unsuccessful, its spectrum and a previous report (5) of the production of $Na_3MnO_4.10H_2O$ by oxidation of manganese (II) with alkaline nitrate indicate that it is hypomanganate, MnO_4^{3-}. In the spectrum of MnO_4^{3-} in nitrate solution shown in Fig. 2, the absorption in the region 20,000–25,000 cm^{-1} was probably due to residual MnO_4^{2-}.

The introduction of OH^- raises a number of possibilities for the stabilization of MnO_4^{3-}. Further experimental evidence is required before the role of OH^- in the chemistry of molten nitrate solutions can be understood.

(5) Spectra of MnO_4^{2-} and MnO_4^{3-} in Fused Nitrate

In Table I a summary is given of the band maxima and molar extinction coefficients for MnO_4^{2-} and MnO_4^{3-}.

It is apparent that the aqueous and nitrate spectra are remarkably similar, as is generally observed for solutes in these solvents (3, 6).

The formulas given here, MnO_4^{2-} and MnO_4^{3-}, are those suggested by Carrington and Symons (4), who give arguments in support of them.

LIQUID–LIQUID EXTRACTION OF BERYLLIUM

II. STUDIES OF BERYLLIUM–THIOCYANATE EXTRACTION

WENDELL J. BIERMANN AND ROBERT MCCORKELL
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received April 9, 1962

ABSTRACT

The partition of beryllium and aluminum between aqueous thiocyanate solutions and several organic solvents was determined under a variety of experimental conditions. From these batch studies it was concluded that a two-solvent countercurrent extraction of beryllium from a thiocyanate solution should give good recovery of beryllium with effective separation from aluminum and, by inference, other inert gas configuration cations.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In the first paper of this series (1), it was shown that the thiocyanate ion was particularly useful as a ligand for forming an extractable complex with beryllium, showing considerable selectivity with inert gas configuration ions, as represented by Al^{+3}. It also appeared that the organic solvent played an active role in forming the extractable species, methyl isobutyl ketone, isoamyl acetate, 2-octanol, and 1-hexanol being among the inexpensive and efficient solvents.

There being no indication that quantitative separation of beryllium from other metals could be achieved except through a series of extractions, it was evident that studies of the beryllium–thiocyanate extraction would ultimately require a continuous-extraction technique. Because of the relative simplicity of batch extraction studies on a separatory funnel scale, it seemed desirable to first study the effects of the several variables concerned on the efficiency of extraction and separation in this manner. Such information would then considerably facilitate later continuous-extraction studies.

This paper, therefore, concerns itself with the determination of distribution coefficients, in the convenient guise of percentages extracted, of systems whose behavior will be relevant to a continuous countercurrent extraction based on the beryllium–thiocyanate–solvent complex and associated stripping and reagent-recovery steps. As in the previous work, separation from aluminum is used as the criterion of specificity, since generally this is the most common and difficult separation involving beryllium.

EXPERIMENTAL

The percentages of metal ion extracted were determined by shaking the mixtures in separatory funnels, equal volumes of organic and aqueous phases being used. Metal concentrations were determined as previously described and thiocyanate was determined by titration with standardized mercury (II) nitrate solutions, neither beryllium nor aluminum causing any interference. pH measurements were made with a conventional glass electrode – calomel pH meter and hydrogen ion concentrations have been approximated as $[H^+]$ = antilog $(-pH)$.

The organic solvents were obtained by fractional distillation of commercial grade materials, the fractions being retained were: methyl isobutyl ketone, 114.5–115.5° C; 1-hexanol, 155–157° C; and 2-octanol, 176–179° C.

EXPERIMENTAL RESULTS

As would be anticipated, the percentage of beryllium extracted at constant ammonium thiocyanate concentration shows a maximum as the pH is varied. These results, collected in Table I, show a maximum extraction in the interval pH 2 to pH 3 regardless of the solvent, indicating that the solvent is not involved in the pH-sensitive process.

TABLE I

The extraction of beryllium from aqueous ammonium thiocyanate solutions as a function of pH before extraction

pH	Percent beryllium extracted by: 1-Hexanol	Methyl isobutyl ketone	Isoamyl acetate
0.5	20.4	11.6	6.8
1.0	39.7	34.5	21.7
2.0	55.3	45.4	29.9
3.0	54.2	42.3	30.8
4.0	26.3	30.7	11.3
5.0	11.0	1.8	1.1

NOTE: The concentration of ammonium thiocyanate was initially 2.0 *M* and the beryllium concentration 0.10 *M* in all the above.

Schwartzenback (2, p. 2) reports that the p*K* for the process $Be^{++} + H_2O = BeOH^+ + H^+$ is -3.63, from which it can be shown that the hydroxy complex becomes the predominate species between pH 3 and pH 4, in agreement with our postulate that hydroxylation is the cause of the falloff of extraction above pH 3.

The falloff of extraction below pH 2 is not so simply explained. Schwartzenback (2, p. 37) reports the p*K* for thiocyanic acid to be -0.85, from which the thiocyanate ion concentration is calculated to be 1.8 *M* at pH 2.0 and 1.2 *M* at pH 1.0 in these solutions. In all three solvents, the falloff of extraction between these two pH values is in the same ratio as the thiocyanate ion concentration, suggesting that only one thiocyanate ion is coordinated per beryllium ion, making it difficult to envision the nature of the extracted species. If the species extracted were $(NH_4)_2Be(CNS)_4$, analogous to transitional metal thiocyanates extracted by Bock and Watkins or Welt and Diamond (3), or $Be(CNS)_2$·$(solvent)_2$, which we had anticipated, extraction should fall off much more rapidly with pH. As all our other data indicate a ligand number of about 2 for the thiocyanate bound to beryllium, it is probable that either the p*K* value for thiocyanic acid is not reliable, or that some other effect is operating simultaneously, for example, an enhanced solubility of the solvents at lower pH.

pH variation is of little use in the separation of beryllium and aluminum, as the formation constant of the first hydroxy aluminum complex is very close to that for beryllium. Results not included here confirm this to be the situation.

The effect of thiocyanate ion concentration on the extraction of beryllium and aluminum is shown in Table II, the extraction generally showing a decrease with lower thiocyanate concentration, the pH being held constant.

The percentage extraction of beryllium should be proportional to the activity of the extracted species $Be(CNS)_n^{2-n}$ in the aqueous phase, which should, in turn, be proportional to the activity product $a_{Be^{++}}a^n_{CNS^-}$. An approximate value of n can be derived by making two simplifying assumptions: (1) that the activity coefficient ratio $\gamma_{Be(CNS)_n^{2-n}}/\gamma_{Be^{++}}\gamma^n_{CNS^-}$ remains constant in both phases over the range of concentrations used, and (2) that the formation constant of the thiocyanato beryllium complex is sufficiently small that the concentration of free beryllium ion can be approximated as the concentration of unextracted beryllium. It was found that the product $[Be^{++}][CNS^-]^2$ varies linearly with the percentage extraction up to 4 *M* ammonium thiocyanate within an average deviation of $\pm 5\%$ for 1-hexanol and 2-octanol and $\pm 10\%$ for methyl isobutyl ketone. Extraction with the last-named solvent increases more rapidly than the concentration function, which is indicative of an average ligand number slightly greater than 2.

TABLE II

Extraction of beryllium and aluminum as a function of ammonium thiocyanate concentration

[NH_4CNS], moles/liter	Percentage metal extracted using:					
	Methyl isobutyl ketone		1-Hexanol		2-Octanol	
	Be	Al	Be	Al	Be	Al
0.5	2.9	0.2	8.0	0.0	2.3	0.0
1.0	14.4	1.1	23.6	0.1	10.9	0.0
1.5	29.4	1.6	41.8	9.0	21.9	1.0
2.0	43.2	3.7	52.3	19.3	34.1	1.5
2.5	59.3	7.0	64.8	30.8	43.9	4.7
3.0	71.0	12.7	72.1	41.2	56.1	10.3
4.0	78.8		83.0			
5.0	83.1		88.7			
6.0	85.1		91.5			
7.0	86.6		94.5			

NOTE: The above were determined by using an aqueous solution initially 0.100 *M* in the metal, the pH adjusted to 3.00 by sulphuric acid. Equal volumes of aqueous and organic phases were used.

Aluminum extraction tends to fall off more rapidly than beryllium as the thiocyanate concentration is lowered, being proportional to the third power of the thiocyanate concentration.

Tables IIIA and IIIB are a summary of experiments measuring the extraction of thiocyanate ion at different concentrations of thiocyanate, metal, and hydronium ions.

These were done to determine whether any appreciable extraction of uncoordinated thiocyanate took place, an important consideration if multistage extraction is used, and also to establish the feasibility of stripping excess thiocyanate from the raffinate.

Where the water phase contained metal ions, the amount of uncomplexed thiocyanate extracted was computed from the data of Table II, on the assumption that each mole of beryllium ion extracted had complexed 2 moles of thiocyanate ion and aluminum, 3. In view of the contributing experimental errors and approximations, the data are consistent with the conclusion that about 2% of the excess ammonium thiocyanate would be removed by methyl isobutyl ketone per stage of extraction at pH 3 and somewhat less for the alcohols, based on their relative behavior at pH 2.

The rapid rise of extraction of thiocyanate at lower pH values would permit stripping excess thiocyanate from raffinates by any of the three solvents with little contamination by excess aluminum, the extraction of which becomes small when both the pH and thiocyanate concentrations are low.

For convenience, the initial beryllium ion concentration had been kept at 0.100 *M* in all the preceding work. Where the chemistry of the extraction process is only partially understood, it is not justifiable to assume that the partition will not be affected by concentration. In Table IV is shown the dependence of beryllium extraction on initial

TABLE IV

Effect of beryllium concentration on the extraction from ammonium thiocyanate at pH 3.00 with methyl isobutyl ketone

3.00	0.10	71	2.86	—
3.00	0.20	70	2.72	—
3.00	0.40	58	2.54	59
3.00	0.80	50	2.20	49
3.00	1.00	45	2.10	46

beryllium concentration, at constant pH and initial ammonium thiocyanate concentration. As the thiocyanate concentration is appreciably reduced when larger amounts of beryllium are extracted, the equilibrium concentration of thiocyanate in the aqueous layer was calculated on the basis of two thiocyanate ions extracted with each beryllium ion, and the percentage beryllium extraction predicted at each of these equilibrium concentrations was obtained by linear interpolation of Table II. The close agreement shows that the distribution coefficient is independent of concentration over a wide range and, incidentally, confirms a ligand number of 2 for the coordination of thiocyanate by beryllium in the extracted species.

As a matter of interest, it was decided to examine the effect of changing the cation associated with the thiocyanate ion, leading to the information of Table V. It is evident that small radii considerably enhance extraction; this is probably a "salting-out" effect, but could indicate that the tendency of formation of complexes containing beryllium in anionic forms, which was noted in the discussion of Table II, is enhanced by the presence of high-field ions. No practical import is associated with this effect as economic considerations indicate the use of ammonia as the associated cation.

Stripping of beryllium from the organic phase does not seem to offer any difficulty. A single extraction with dilute ammonia water quantitatively removes the beryllium, and

	NH_4CNS	KCNS	NaCNS	LiCNS
Methyl isobutyl ketone	28.3	30.6	34.3	47.8
1-Hexanol	38.7	40.1	48.0	56.4
2-Octanol	21.3	21.5	28.4	33.6
Isoamyl acetate	15.2	18.4	21.3	33.0

NOTE: Initial beryllium concentration 0.100 *M*, pH 3.00.

either water or dilute sulphuric acid could be used for stripping in a column, as both remove about 30%, per extraction stage, of the beryllium in the organic phase with a solvent ratio of 1.

DISCUSSION

In order to obtain high purity of beryllium in the extract and at the same time have only small losses in the raffinate, a two-solvent countercurrent extraction process is indicated as neither single solvent countercurrent nor crosscurrent extractions are particularly suited to this system (4). The extraction solvent might be any one of those which was found suitable in the exploratory work described earlier and the wash solvent would be a suitable ammonium thiocyanate solution, such as 2 *M* adjusted to pH 3 by sulphuric acid.

Based on a column having eight stages with feed at the center, using the above wash solvent and methyl isobutyl ketone as the extraction solvent, and postulating the feed to contain equimolecular amounts of beryllium and aluminum, and a solvent ratio of 4, an approximation based on the Kremser equation predicts a raffinate containing only about 1% of the beryllium in the feed, and the beryllium in the extract from the wash section would contain less than 0.01 mole% aluminum.

Studies of such a continuous-extraction system are presently underway in this laboratory, as are studies designed to give a more adequate description of the extracted species and the equilibria involved in its formation.

THE ORIGIN OF CARBON ATOMS 2, 3, AND 7 OF RICININE[1]

P. F. JUBY[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received September 14, 1962

ABSTRACT

The isolation of carbon atoms 2 and 3 of the α-pyridone nucleus of ricinine is described. Evidence is provided to support the suggestion that succinic acid or a closely related four-carbon dicarboxylic acid provides carbon atoms 2, 3, and 7 in the biosynthesis of the ricinine molecule.

In a preliminary communication (1) evidence was presented to support proposals (2, 3) that in the higher plants the pyridine ring and related α-pyridone ring of such compounds as nicotine and ricinine (I) (see Fig. 1) may be synthesized directly from simple metabolic intermediates related to acetate, succinate, glycerol, and propionate. From the percentage activities found at the nitrile group of ricinine isolated from *Ricinus communis* L. plants that had been fed various simple labelled substances, it was suggested that succinic acid, or a closely related four-carbon dicarboxylic acid found in the Krebs tricarboxylic acid cycle, provided carbon atoms 2, 3, and 7 of ricinine. If such be the case, the four-carbon acid would be incorporated in such a way that one of the carboxyl groups (C-1) would provide the carbon for the nitrile group of ricinine (C-7), and the 2- and 3-carbon atoms would give rise to carbons 3 and 2 respectively of the pyridone ring. The other carboxyl group would be lost by decarboxylation either before or after incorporation into the pyridone ring or its precursor.

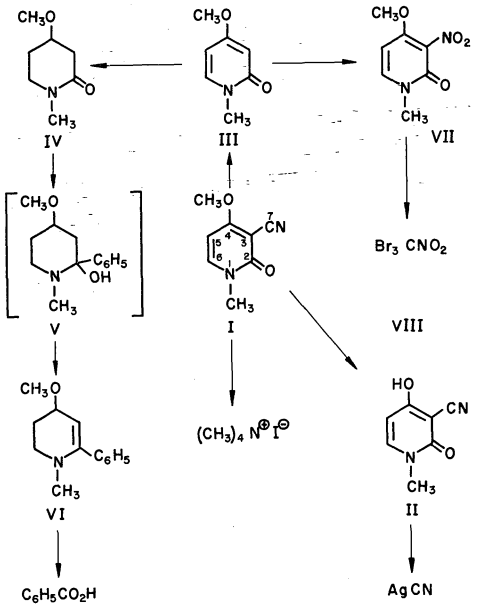

FIG. 1. Degradation schemes for ricinine.

In order to test this suggestion it is therefore necessary to isolate carbons 2 and 3 from the remaining carbons in ricinine. Carbon atom 2 was isolated in the form of the carboxyl group of benzoic acid. Removal of the nitrile group from ricinine (I) by hydrolysis followed by decarboxylation gave rise to 4-methoxy-1-methyl-2-pyridone (III), which was reduced easily to the corresponding piperidone (IV) with hydrogen and Adams' catalyst. The action of phenyl magnesium bromide on the piperidone (IV) gave the carbinol (V), which lost the elements of water spontaneously and produced the unstable 4-methoxy-1-methyl-2-phenyl-2-piperideine (VI). The product (VI) was treated immediately with potassium permanganate, and the benzoic acid containing carbon 2 of ricinine as its carboxyl group was isolated and burnt in a combustion train. The carbon dioxide was collected as barium carbonate.

The observation (4) that nitrophenols react with calcium hypobromite to yield tribromonitromethane (bromopicrin) in which the carbon atom is the one that carried the nitro group prompted the application of this degradative procedure to the ricinine molecule. Nitration of 4-methoxy-1-methyl-2-pyridone (III) gave a mononitroderivative, the nuclear magnetic resonance spectrum of which contained two doublets centered at τ values of 3.90 and 2.55 p.p.m. with a coupling constant of 8.0 c.p.s. The product, therefore, must contain a proton on each of two adjacent carbon atoms. Accordingly, the nitro group must be located on carbon 3 and the product is 4-methoxy-1-methyl-3-nitro-2-pyridone (VII). Treatment of VII with calcium hypobromite liberated carbon 3 of ricinine as bromopicrin (VIII), which was purified by gas–liquid chromatography. The pure bromopicrin was converted by combustion to carbon dioxide, which was collected as barium carbonate.

To determine the activity of the nitrile group, the methoxy group of ricinine was first hydrolyzed and the resulting ricinic acid (II) oxidized as previously described by Böttcher (5). The liberated hydrogen cyanide was precipitated as silver cyanide and its activity measured.[3]

The methyl groups attached to oxygen and to nitrogen were each isolated as tetramethylammonium iodide.

These methods of determination were applied to two samples of ricinine obtained from plants of *R. communis* L. that had been fed succinic acid-2,3-^{14}C and sodium acetate-2-^{14}C. Quantities of the radioactive ricinine to be used for the determinations were diluted initially with varying quantities of inactive ricinine. The results obtained are recorded in Table I, which gives the activity at each carbon atom in terms of a percentage of the total activity of ricinine.

TABLE I

Location of radioactivity in ricinine

Position		Percentage of activity of ricinine from plants fed succinic acid-2,3-^{14}C	Percentage of activity of ricinine from plants fed sodium acetate-2-^{14}C
OCH_3	(as $(CH_3)_4NI$)	0.55	0.66
NCH_3	(as $(CH_3)_4NI$)	0.58	0.65
7	(as AgCN)	19.1	20.8
2	(as $BaCO_3$ from $C_6H_5CO_2H$)	38.6	38.9
3	(as $BaCO_3$ from Br_3CNO_2)	36.9	38.3
	Total	95.7	99.3

[3]*The method of determination of the activity of the nitrile group by difference gave erratic results and was abandoned.*

The results given in Table I for ricinine obtained from plants fed succinic acid-2,3-^{14}C show that the sum of the activities of carbon atoms 2, 3, and 7 (nitrile) and the carbon atoms of the two methyl groups represents 95.7% of the total activity of the ricinine molecule. Thus, within experimental error, all the activity of the ricinine is accounted for when the plants are fed succinic acid-2,3-^{14}C. Moreover, both carbon atoms 2 and 3 are approximately equally labelled as would be expected if they were derived from carbons 3 and 2 respectively of succinic acid-2,3-^{14}C. The nitrile carbon of ricinine is derived from carbon 1 of succinic acid. This carbon becomes labelled as a result of randomization of activity in the Krebs cycle.

Feeding of sodium acetate-2-^{14}C to *Ricinus* plants gave rise to ricinine labelled similarly to that obtained from succinic acid-2,3-^{14}C. The results (see Table I) may be explained by assuming that the acetate-2-^{14}C enters the Krebs cycle with the subsequent formation of succinic acid-2,3-^{14}C. Strong experimental evidence is thus provided to support the proposal that succinic acid or a closely related four-carbon dicarboxylic acid found in the Krebs cycle is an intermediate in the biosynthesis of ricinine.

Recently, Waller and Henderson (6) have reported that most of the activity in ricinine obtained from young *Ricinus* plants fed succinate-1,4-^{14}C was located on the nitrile carbon. This is in agreement with the present observations, since the activity of carboxyl-labelled succinate will not be randomized amongst carbon atoms 2 and 3 (of succinate) as a result of the operation of the Krebs cycle.

The high extent of incorporation of such compounds as nicotinic acid and nicotinamide (7) into ricinine suggests that these compounds are closer to ricinine than succinic acid in the biosynthetic pathway. The results obtained with ricinine may well be applicable to the pyridine ring of such compounds as nicotine and the related tobacco alkaloid anabasine, since nicotinic acid has been shown (8) to be an important intermediate in the biosynthesis of nicotine. Ricinine (1) and nicotine (9, 10) isolated from the plants after feeding acetate-1-^{14}C as well as acetate-2-^{14}C to *Ricinus* and *Nicotiana* plants, respectively, show labelling patterns which are compatible with the conclusion that succinic acid (or a closely related four-carbon dicarboxylic acid) is a common precursor of the intermediate nicotinic acid.

EXPERIMENTAL

Melting points were determined on a Kofler block and are corrected. Radioactive samples were counted as thin layers on aluminum planchets in either a Radiation Counter Laboratories Inc. internal sample proportional counter or a Baird-Atomic, Inc. end window proportional counter, as indicated in the text. Appropriate corrections were made for background count and sample self-absorption. Succinic acid-2,3-^{14}C and sodium acetate-2-^{14}C were supplied by Merck and Company Ltd., Montreal.

Growth of Ricinus Plants and Administration of the Tracers

Seeds of *R. communis* L., after removal of the outer shells, were planted just beneath the surface of moist sand contained in glass trays placed in a dark cabinet in a greenhouse kept at 20–25°. The sand was kept moist with distilled water. After 12 days the trays were brought out into the light for about 16 hours each day, and the sand kept moist with an inorganic nutrient solution containing $MgSO_4.7H_2O$ (0.85 g), KH_2PO_4 (0.14 g), $NH_4H_2PO_4$ (0.071 g), KNO_3 (0.072 g), $Ca(NO_3)_2.4H_2O$ (0.21 g), $Fe(NH_4)_2(SO_4)_2.6H_2O$ (0.036 g) per liter of distilled water. On the 22nd day of growth, when the plants had reached a height of 15–20 cm, and when the primary leaves were just emerging, an aqueous solution (total 1.0 ml) of succinic acid-2,3-^{14}C (0.85 mg) was introduced into 56 plants by means of glass capillary tubes (partly filled with the solution by capillary rise) inserted into the base of each plant stem. Uptake of the solution by each plant was usually complete within a few minutes. The succinic acid-2,3-^{14}C fed had a total activity of 9.1×10^7 d.p.m. measured on the Radiation Counter Laboratories instrument.

In a like manner an aqueous solution (0.7 ml) of sodium acetate-2-^{14}C (6.05 mg) was fed to 42 *Ricinus* plants grown under conditions similar to those described for the succinic acid feeding experiment. The acetate-2-^{14}C fed had a total activity of 3.58×10^8 d.p.m. (Radiation Counter Laboratories instrument).

Isolation of Ricinine

The tubes were left in the stems until the plants were harvested 72 hours after insertion. The wet stems and leaves were powdered by grinding in the presence of liquid nitrogen. After evaporation of the nitrogen, the ground material was extracted with absolute ethanol in a Soxhlet extractor for 12 hours. The extract was evaporated, the residue suspended in water and washed with petroleum ether (30–60°), and the aqueous solution extracted continuously for 12 hours with chloroform.

Removal of the solvent from this last extract yielded crystalline ricinine, which was purified to constant count by alternate crystallization from methanol and by sublimation at 180° and 5×10^{-4} mm.

Ricinine (415 mg), m.p. 202° (11), with radioactivity of 8000 d.p.m./mg (Radiation Counter Laboratories instrument, previously reported (1) in c.p.m./mg) was obtained from plants fed succinic acid-2,3-^{14}C, which represents an incorporation of 3.6%.

The plants fed acetate-2-^{14}C gave ricinine (353 mg), m.p. 202°, with activity of 65,000 d.p.m./mg (Radiation Counter Laboratories instrument, previously reported (1) in c.p.m./mg), which represents an incorporation of 6.6%.

Degradations of Ricinine from the Succinic Acid-2,3-^{14}C Feeding Experiment

Activities of the OMe and NMe Groups

Active ricinine (52.28 mg) from the succinic acid-2,3-^{14}C feeding experiment (8000 d.p.m./mg) was diluted with pure inactive ricinine (28.1 mg) obtained from *Ricinus* plants not fed any radioactive precursor. The two methyl groups were successively removed by a modification of the Herzig–Meyer method (12). The liberated methyl iodide in each case was trapped in 15% methanolic solutions of trimethylamine and the precipitated tetramethylammonium iodide was crystallized from methanol to constant activity. The tetramethylammonium iodide from the OMe group had an activity of 23.5 d.p.m./mg, and that from the NMe group, 24.8 d.p.m./mg, both measured on the Radiation Counter Laboratories instrument.

Determination of the Activity of the Nitrile Group

Ricinine (5.75 mg) from the feeding experiment was diluted with pure inactive ricinine (ca. 95 mg). The mixture was recrystallized from methanol. A small sample of this diluted ricinine was subjected to combustion and the resulting carbon dioxide collected in a barium hydroxide solution. The barium carbonate thus produced had an activity of 34.2 d.p.m./mg, measured on the Baird-Atomic instrument.

The remainder of the diluted active ricinine was hydrolyzed with dilute aqueous potassium hydroxide to the corresponding hydroxy compound, ricinic acid (II), which was oxidized with chromic acid according to the procedure described by Böttcher (5). The liberated hydrogen cyanide was collected in a solution of silver nitrate acidified with nitric acid. The precipitated silver cyanide (35 mg) had an activity of 77.0 d.p.m./mg (Baird-Atomic instrument).

Dilution of Active Ricinine

All the following experiments were carried out with active ricinine from the succinic acid-2,3-^{14}C feeding which was diluted with pure, inactive ricinine by a factor of approximately 11. The active ricinine was co-crystallized with the inactive sample. A small sample of the diluted ricinine was converted by combustion to carbon dioxide, which was converted to barium carbonate as usual. The barium carbonate, counted on the Baird-Atomic instrument, had an activity of 56.0 d.p.m./mg.

Removal of the Nitrile Group from Ricinine

The diluted ricinine (550 mg) was hydrolyzed and decarboxylated (13) with 57% sulphuric acid solution to 4-methoxy-1-methyl-2-pyridone (350 mg) (III). The product was purified by sublimation at 80° and 5×10^{-4} mm and had m.p. 114–116°.

Reduction of 4-Methoxy-1-methyl-2-pyridone to the Corresponding Piperidone (IV)

A solution of the pyridone (III) (195 mg) in methanol (25 ml) was shaken in an atmosphere of hydrogen with Adams' catalyst at room temperature and under pressure of a small head of mercury, until no further uptake of hydrogen was observed. The 4-methoxy-1-methyl-2-piperidone (IV) was worked up in the usual manner and distilled, b.p. 60–64° at 1 mm. In the ultraviolet the oily product showed end absorption only. Found: C, 58.83; H, 9.29; N, 9.63. Calc. for $C_7H_{13}O_2N$: C, 58.72; H, 9.15; N, 9.78%.

4-Methoxy-1-methyl-2-phenyl-2-piperideine (VI)

Phenyl magnesium bromide was prepared in dry ether (25 ml) in the usual manner using magnesium (400 mg) and bromobenzene (2.62 g). A portion (5 ml) of the ethereal solution of the Grignard reagent was added to 4-methoxy-1-methyl-2-piperidone (170 mg) dissolved in dry ether (6 ml) and the reaction mixture was heated under reflux for 16 hours. The complex was decomposed with dilute hydrochloric acid, the aqueous layer saturated with sodium carbonate, and the mixture shaken. The ether layer was removed and the aqueous layer re-extracted exhaustively with chloroform. The ether and chloroform extracts were combined, the solvents removed, and the residue subjected to a short-path distillation at 12 mm. The fraction distilling at 80–120° (air-bath temperature) was collected. It consisted of a colorless oil that rapidly turned red-brown on exposure to air. The product showed a maximum at 247 mμ (ϵ = 4000) in its ultraviolet absorption spectrum. An infrared spectrum (liquid film) of the product showed no O—H stretching absorption, but contained strong absorption in the 1580–1640 cm^{-1} region, indicative of unsaturation, together with strong C—H deformation bands in the 700–800 cm^{-1} region. The product failed to form either a crystalline hydro-

For personal use only.

chloride or a satisfactory picrate. It was not further characterized, but used immediately in the next step.

Oxidation of the Piperideine (VI) to Benzoic Acid

The distilled piperideine was heated under reflux with potassium permanganate (2.0 g) in water (40 ml) for 2 hours. Ethanol was added to the cooled mixture to destroy the excess permanganate, and the filtered solution was acidified with concentrated hydrochloric acid. Extraction with ether gave an extract which on evaporation left a solid residue (80 mg). This residue was purified to constant count by crystallization from water and sublimation, after which it consisted of a colorless crystalline product, m.p. 121–122°, either alone or in admixture with an authentic specimen of benzoic acid. Comparison of infrared spectra confirmed the identity. A sample of the active benzoic acid was converted by combustion to carbon dioxide, which by collection in a barium hydroxide solution was obtained as barium carbonate, with an activity of 24.7 d.p.m./mg (Baird-Atomic instrument).

Nitration of 4-Methoxy-1-methyl-2-pyridone

The pyridone (III) (140 mg) was dissolved in concentrated sulphuric acid (1.0 ml) and the solution cooled in an ice-water bath. A solution of fuming nitric acid (0.2 ml) in concentrated sulphuric acid (2.0 ml) was added to the pyridone solution and the mixture allowed to stand at room temperature for 20 minutes. It was neutralized with aqueous sodium hydroxide and extracted several times with chloroform. The 4-methoxy-1-methyl-3-nitro-2-pyridone (VII) produced was purified by recrystallization from benzene, m.p. 172–173°. Found: C, 45.75; H, 4.35; N, 15.39. Calc. for $C_7H_8O_4N_2$: C, 45.65; H, 4.38; N, 15.21%. A nuclear magnetic resonance spectrum (60 Mc) of the product (VII) in $CDCl_3$ using tetramethylsilane as an internal reference showed signals at τ values of 6.48 and 6.08 p.p.m. and two doublets centered at 3.90 and 2.55 p.p.m. with $J = 8.0$ c.p.s. The nitropyridone gradually decomposed when exposed to light.

Preparation of Tribromonitromethane (VIII) from 4-Methoxy-1-methyl-3-nitro-2-pyridone

A paste was prepared from calcium hydroxide (10 g), water (40 ml), both at 0°, and bromine (3.3 ml). The nitropyridone (VII) (150 mg) was well mixed with the paste. The mixture was gently warmed for several minutes, then strongly heated until about 6.0 ml of distillate had been collected. The crude tribromonitromethane (bromopicrin) (200 mg) was separated by centrifuging, washed with distilled water, and distilled over a short path at 12 mm and an air-bath temperature of 60–70°. The distilled product was purified in two batches by gas–liquid chromatography. A 2 m long, 0.635 cm diameter silicone grease column was used at 80°, with the helium carrier gas at a pressure of 25 p.s.i., giving a flow rate of approximately 150-cc/min. A retention time (peak maximum) of about 36 minutes was observed for the bromopicrin. The bromopicrin (70 mg) was collected in a small U-tube cooled with an ice–water mixture. An infrared spectrum of the purified bromopicrin showed absorption in good agreement with reported absorption maxima (14). The spectrum was also superimposable upon a spectrum obtained from bromopicrin prepared from picric acid by a similar procedure (15). Gas–liquid chromatography of a small sample of the purified bromopicrin showed only one component with a retention time almost identical with that obtained for authentic bromopicrin. The pure bromopicrin was converted by combustion to carbon dixoide, which was collected in a barium hydroxide solution as barium carbonate. The barium carbonate had an activity of 165.5 d.p.m./mg (Baird-Atomic instrument).

Degradations of Ricinine Obtained from the Acetate-2-^{14}C Feeding Experiment

Activities of the OMe and NMe Groups

The O-methyl and N-methyl groups were isolated as described for ricinine from the succinic acid-2,3-^{14}C feeding experiment. The active ricinine (30.4 mg) was first diluted with pure inactive ricinine (48.6 mg). The tetramethylammonium iodide from the OMe group had an activity of 135.0 d.p.m./mg and that from the NMe group, 132.5 d.p.m./mg, both measured on the Radiation Counter Laboratories instrument.

Determination of the Activity of the Nitrile Group

Ricinine (29.2 mg) from the feeding experiment was diluted with pure inactive ricinine (83.5 mg). The nitrile group was isolated as silver cyanide as before. The silver cyanide had an activity of 4300.0 d.p.m./mg (Radiation Counter Laboratories instrument).

Degradations to Isolate Carbon Atoms 2 and 3

Active ricinine was diluted approximately 20 times by the usual method. A small sample of the diluted ricinine was converted by combustion to carbon dioxide and collected as barium carbonate, which had an activity of 229.0 d.p.m./mg (Baird-Atomic Instrument).

By methods outlined in Fig. 1 and described above, carbon atoms 2 and 3 were isolated as the carboxyl group of benzoic acid and as bromopicrin respectively. Both derivatives were converted by combustion to carbon dioxide, which was collected in a barium hydroxide solution as barium carbonate. The barium carbonate from C-2 had an activity of 71.7 d.p.m./mg, and that from C-3, 701.0 d.p.m./mg (Baird-Atomic instrument).

ACKNOWLEDGMENTS

The authors thank Mr. M. Lesage for running the gas–liquid chromatograms and Mr. H. Seguin for the microanalyses and sample combustions.

THE S^{32} (n,p) P^{32} REACTION AS A FAST-NEUTRON FLUX MONITOR[1]

D. C. SANTRY AND J. P. BUTLER
Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario
Received August 24, 1962

ABSTRACT

An extensive study is made of the use of sulphur as a monitor for neutrons with energies from 2 to 20 Mev. Irradiated disks of pressed sulphur are burnt before counting to increase the efficiency and reproducibility of determining the P^{32} activity. It was established that on burning irradiated sulphur 95.5±0.5% of the P^{32} activity is retained with a reproducibility of ±1.0%. Measurements of relative cross sections for the S^{32} (n,p) P^{32} reaction have been extended to 20.3 Mev using the T (d,n) He^4 and D (d,n) He^3 reactions to produce monoenergetic neutrons. Neutron production using Zr–T targets is examined as is the effect of extraneous neutrons from the D (d,np) D process on the S^{32} (n,p) reaction.

INTRODUCTION

By counting the 1.71 Mev beta particles from P^{32} (half-life 14.22 days) the S^{32} (n,p) P^{32} reaction may be used as a standard to monitor a high-energy neutron flux. It is suitable for the measurement of either a continuous neutron spectrum, as in a nuclear reactor, or for the measurement of a monoenergetic-neutron flux. Reactor cross-section values for the sulphur reaction have been summarized by Mellish (1). He has used the reaction to normalize and compare other fast-reactor cross sections which had been measured by different investigators. Allen *et al.* (2) have measured the cross section for the S^{32} (n,p) reaction as a function of neutron energy from 1.59 to 9.56 Mev and from 13.38 to 14.95 Mev. In addition to having its cross section well established, various techniques have been developed by Reinhardt and Davis (3), Fujita *et al.* (4), and Parker (5) for using the sulphur reaction for fast-neutron dosimetry.

We have been using sulphur as a monitor in measuring excitation curves for fast-neutron reactions (6), and in this paper describe a study of this convenient method for fast-neutron monitoring. The procedures for sample preparation and activity measurements are given. In addition, we have extended the measurements of the S^{32} (n,p) cross section to 20.3 Mev.

EXPERIMENTAL AND RESULTS

A. Monitor Material

For the monitor we have chosen elemental sulphur in the form "flowers of sulphur". It is readily available, inexpensive, and relatively pure. Any impurities which may be present appear to have low activation cross sections. Powdered sulphur has been pressed into disks of known and reproducible area with diameters of 3/16 in. to 1 1/8 in. using a briquetting[2] or disk[3] press. Disks of a desired thickness can be rapidly produced by packing powdered sulphur into a short hollow tube of a predetermined volume, then tapping it out into the press. Under pressure sulphur packs into firm disks and requires no extraneous binding agent. Disks thicker than 0.015 in. do not powder or crack under normal handling and irradiation conditions. We use a pressure of 25 tons/in^2 and produce 0.040-in. disks 3/16 in. in diameter, which weigh about 34 mg. The relatively small size of the disks enables one to determine a flux more accurately in a position where flux gradients exist.

B. Irradiations

Sulphur was irradiated with neutrons produced with an accelerator using the (D + D) and (D + T) reactions. The spread in energy of neutrons produced in this manner depends on the angle the sample subtends at the neutron source. By using samples with a small diameter and irradiating at a distance, the angle

subtended can be made small. Consequently, the sulphur was irradiated with essentially a monoenergetic flux of fast neutrons of known energy.

Irradiations were also carried out in the Chalk River NRX reactor in positions which had a fast-neutron contribution.

In all irradiations thin aluminum foil served to protect the sulphur disks from contamination during irradiations. For reactor irradiations several samples were also enclosed in 0.030-in. cadmium foil to reduce the effect of thermal neutrons.

C. Counting and Calibration

Using a technique suggested by Reinhardt and Davis (3), the sulphur disks, after an irradiation, were weighed and placed on suitable aluminum counting trays. The trays were then placed on a hot plate heated to 370° C. The sulphur melts, self-ignites, and burns off, leaving the P^{32} activity behind on the tray as a weightless source. This burning method has several desirable features: (i) it increases the counting efficiency of P^{32}, (ii) it removes any S^{35} which may have formed as a contaminating activity by the (n,γ) reaction on sulphur, (iii) it eliminates discrepancies which might arise from variations in the thickness and surface texture of the samples, and (iv) by producing a thin source, it permits an easy standardization of a counting system for the absolute counting of the P^{32} activity produced.

In our work an end-window beta proportional counter was used with an aluminum window of 1 1/2-in. diameter and 0.00075-in. thickness. Samples were positioned very near the counter window. Under these conditions the efficiency for counting a weightless source of P^{32} was 51.5%. This was measured by counting high specific activity P^{32} which had been standardized by 4π-absolute beta counting.

D. Examination of the Method

1. It was necessary to determine if any P^{32} activity was lost in the burning of sulphur. Samples which had been irradiated in a uniform flux were weighed and counted as disks. After burning, the samples were recounted as thin sources. The ratio of [residual activity after burning] to [activity of disks] is plotted against the [weight of disk] as curve A in Fig. 1. An extrapolation of this linear curve to zero weight indicates that 93% of the P^{32} activity remains after burning. This is in agreement with measurements made by other investigators (3, 5) who used much thicker samples. Curve B in Fig. 1 shows the same measurements made

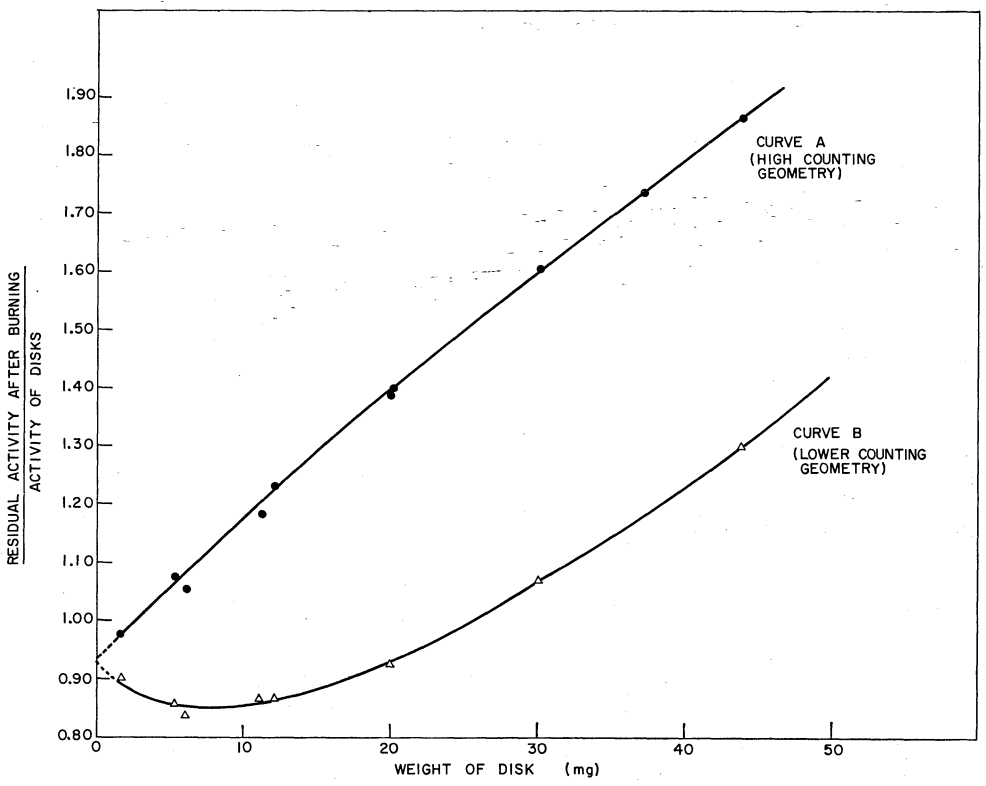

FIG. 1. Variation in the ratio of observed P^{32} activity in burnt and unburnt samples with sample weight (3/16 in. diam. sulphur disks).

For personal use only.

at lower counting geometry. The curve is not linear at low sample weight. The initial increase in counting efficiency of a disk with increasing weight, which reduces the ratio, is due to self-scattering effects (7). For thin wide sources there is an enhanced scattering of beta particles out of the sample plane and into the counter. At greater thicknesses self-absorption predominates and the standard absorption curve is observed. Although self-scattering is more noticeable at low counting geometry with a window-type detector, it may also exist at higher geometry. Because of this, the extrapolation over the region where thin disks cannot be prepared may not be exact. A further check on the retention of P^{32} on burning was made by irradiating simultaneously disks of sulphur and Li_2SO_4 in a uniform flux. The Li_2SO_4 was dissolved in 0.05 N nitric acid containing phosphate carrier. The P^{32} activity was determined by 4π-absolute beta counting. This activity when compared with the P^{32} activity from the burnt sulphur disks indicated a value of $95.5\pm0.5\%$ retention (the average of four separate determinations). On the basis of this value and the unburnt activity measurements, an efficiency curve is drawn in Fig. 2 for counting P^{32} in sulphur disks. Included in the

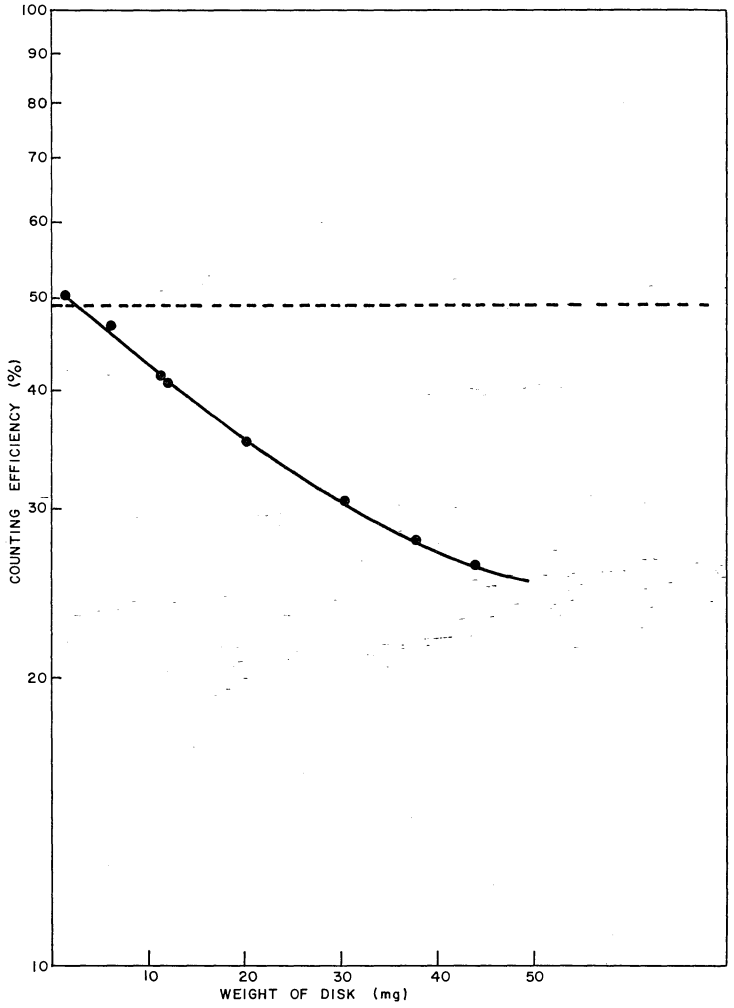

FIG. 2. Counting efficiency of P^{32} for irradiated sulphur disks 3/16-in. diam. —— disks, - - - burnt samples.

graph is the efficiency curve for counting burnt samples, i.e. $(51.5\times0.955)\%$. The difference between the two curves represents the gain in counting efficiency using the burning technique.

2. To test the reproducibility of the burning process samples of different diameters and thicknesses were irradiated in a uniform flux, burnt, and counted. After 2 minutes of heating, burning was complete. Further heating had no effect on the remaining activity. The counting rate per mg of sulphur irradiated was constant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

to within a standard deviation of ±1.0%. A thin dark residue which remains after the sulphur is burnt does not interfere with the P^{32} determination. To check this a thin P^{32} source was deposited on an aluminum tray and counted. Then a sulphur disk was placed over the source and burnt. No change in activity of the sample was observed. Larger sulphur samples when burnt and reweighed indicated that an average source was less than 2 $\mu g/cm^2$, i.e., essentially weightless.

3. Since elemental sulphur melts at about 110° C it cannot be used in a high-temperature region of a nuclear reactor. For such positions we have irradiated pressed disks of $Li_2SO_4.H_2O$ encased in cadmium. The hydrate appeared to press better than the anhydrous salt. Since there may be partial conversion of the hydrate at reactor temperatures it was necessary to complete the conversion by heating the disks after an irradiation to 150° C for at least 1 hour. The samples were then weighed to determine the amount of sulphate irradiated. As mentioned previously, the disks were dissolved in a known amount of dilute acid and a suitable aliquot deposited on a counting tray as a weightless source. The reduced counting efficiency of this sulphur compound is partially offset by the higher fast-neutron flux associated with a high-temperature position in a reactor. Lithium sulphate when pressed into disks is not as robust as are elemental sulphur disks.

4. Irradiated sulphur was analyzed for impurities by following its radioactive decay. Samples counted immediately after an irradiation show some short-lived impurities, the most important of which is the 2.62-hour Si^{31} formed by the S^{34} (n,α) Si^{31} reaction. Allowing the samples to decay for at least 1 day eliminates these activities. Irradiated samples when counted as disks or burnt samples decay with a half-life of 14.2 days, indicating that only P^{32} activity is present. However, when sulphur is irradiated in the presence of a high thermal-neutron flux (not encased in cadmium), 87-day S^{35} is observed. It constitutes a small percentage of the net activity in a sulphur disk at the end of an irradiation. From decay analysis it is possible to apply the small correction for this impurity. The burning of the sulphur sample before counting effectively removes this contaminant. Due to the low isotopic abundance of S^{33} and its low counting efficiency, 25-day P^{33} is not observed.

E. Cross-Section Measurements

To use the S^{32} (n,p) P^{32} reaction as a flux monitor, it is desirable to have a complete curve of cross section vs. neutron energy. However, from 9.56 to 13.38 Mev and above 14.95 Mev neutron energies there are no cross-section data available.

By using the differential cross-section data for the D (d,n) He^3 and T (d,n) He^4 reactions we were able to complete the S^{32} (n,p) cross-section curve up to 20.3 Mev.

The energy and intensity of neutrons produced with an accelerator depend on the angle at which the neutrons are emitted relative to the incident deuteron beam. Consequently, the saturation activity S_1 produced in a sulphur monitor irradiated at a given angle, i.e. at an energy En_1, is given by

$$S_1 = N_1\phi_1\sigma_1.$$

Another monitor S_2 irradiated at a different angle, i.e. at an energy En_2, is given by

$$S_2 = N_2\phi_2\sigma_2.$$

N_1 and N_2 are the number of S^{32} atoms irradiated at each angle, ϕ_1 and ϕ_2 are the neutron fluxes, σ_1 and σ_2 are the cross-section values for the sulphur (n,p) reaction at the neutron energies En_1 and En_2 respectively. By irradiating the sulphur monitors simultaneously at two different angles, we can combine the above equations. Thus,

$$\sigma_2 = \frac{S_2N_1}{S_1N_2}\frac{\phi_1}{\phi_2}\sigma_1.$$

That is, the cross section at one energy can be expressed relative to a previously measured cross section at another energy.

Cross sections were measured at 10.40, 11.00, and 11.60 Mev using the D (d,n) He^3 reaction. The irradiation conditions were similar to those described previously (6). A gas target 1.6 cm in diameter and 1.27 cm in length was filled to a pressure of 225 cm of Hg with deuterium gas (>99.5% D_2). The deuteron beam from a Tandem Van de Graaff Accelerator enters the gas cell through a 0.00025-in. tantalum window and after traversing the cell is stopped in a gold end plate. Sulphur disks of 1/2-in. diameter and 0.060-in. thickness were irradiated at 0° and 55° on both sides of the axis of the deuteron beam. The disks were accurately positioned 12.2 cm from the end of the gas cell and subtended a half angle of 2.9° at the point of origin of neutrons. The deuteron energy was chosen to produce neutrons in the forward direction at an energy where the sulphur (n,p) cross section was not known. At 55° the corresponding neutrons were produced at energies where the cross section had been measured previously (2). The energies involved are listed in Table I together with the values of the relative neutron intensities as listed by Brolley and Fowler (8). Corrections were applied to the P^{32} activities for the presence of extraneous neutrons (see Table II). Background neutrons at both angles were determined by counting the P^{32} activity obtained in irradiations with the gas cell evacuated. The effect of breakup neutrons produced by the D (d,np) D reaction was calculated from the cross-section and angular distribution measurements of Cranberg *et al.* (9) and Anderson *et al.* (10). detailed discussion of these corrections is included in Section G of this paper. Irradiations were performed away from the floor and walls so that the effect of scattered neutrons on the sulphur could be considered small.

For cross-section measurements above 12 Mev, neutrons were produced using the T (d,n) He^4 reaction. This irradiation assembly was also described in a previous paper (6). Zirconium–tritium targets (1.2 cm^3/cm^2 of tritium at NTP) were bombarded with 125 kev deuterons from a Texas Nuclear Neutron Generator, and with 4.00 Mev deuterons from the tandem accelerator. Sulphur disks of 3/16-in. diameter and 0.040-in. thickness were irradiated at angles of 25°, 50°, 75°, 105°, and 140° on both sides of the axis of the deuteron beam and at 0°. The sulphur disks were 1.4 cm from the target and subtended a half angle of 9°. Monoenergetic neutrons from 13.58 to 14.76 Mev were obtained using 125 kev deuterons. The energies and relative neutron intensity values used (11, 12) are listed in Table III. These irradiations were normalized

at 14.50 Mev to the cross-section value for the sulphur (n,p) reaction as measured by Allen *et al.* (2). No corrections for background or breakup neutrons were required.

Monoenergetic neutrons of energies from 12.53 to 20.3 Mev (Table III) were produced using the T (d,n) He^4 reaction and a 4.00 Mev deuteron beam. Again the data were normalized at 14.50 Mev to the sulphur cross-section data. Sulphur samples were irradiated using Zr targets containing no tritium to measure the background contribution at various angles (see Table II). Corrections for breakup neutrons were negligible.

The results for the cross sections measured and the values to which they were normalized are listed in Table IV. The cross-section values are plotted in Fig. 3 together with the data of Allen *et al.* (2). Our measure-

ments from 13.58 to 14.76 Mev have not been included in Fig. 3. They confirm the shape of the cross-section curve in this region as that given by Allen. The values we measured at 10.4, 11.0, and 11.6 Mev do not fall on a smooth curve. The measurements were reproducible and may indicate either discontinuities in the excitation curve similar to that observed at 4.5 Mev or incorrect angular distribution data upon which the determinations were based. The values at the three energies were averaged together and the curve drawn through an average value in this region.

The errors in the cross-section values include:

(*a*) standard deviation in the observed counting rates (1 to 3%);
(*b*) corrections for activity produced by extraneous neutrons (up to 5%);
(*c*) burning of sulphur disks (1.4%);
(*d*) irradiation geometry (2%);
(*e*) relative flux intensity values (1% for 125 kev deuteron irradiations and 3.5 to 5% for the others).

The error in the cross-section values listed in Table IV is the root-mean-square deviation and does not include any error in the sulphur cross-section value to which the data were normalized. The neutron energies given are average values and the spread in energy represents the error in energy as seen by the sulphur samples.

F. An Examination of Neutron Production Using Zr–T Targets

Since the energies of neutrons emitted and the relative neutron intensity values depend on the effective deuteron bombarding energy, it is important to know the thickness of the Zr–T layer. The targets supplied[4] were listed as having about 9 mg/cm² of zirconium metal. While this thickness can be measured optically, as described below, it cannot be assumed that the tritium is distributed uniformly throughout the zirconium. As a check on the calculated value of the effective deuteron energy for these Zr–T targets, neutron spectra were measured as a function of angle for targets irradiated with 4.00 Mev deuterons. A 1-in.×1-in. plastic scintillator of polyvinyltoluene was used as a neutron detector. This technique has been described by Swartz and Owen (13) and Cross (14). The energy of recoiling protons produced in the scintillator by neutrons was analyzed on a 100-channel pulse-height analyzer. From the pulse-height spectra measured at various angles, relative neutron energies were obtained. The neutron energy scale was normalized at 14.42 Mev by viewing neutrons emitted at an angle of 105° to the incident deuteron beam. At this angle the neutron energy is insensitive to the energy of the bombarding deuterons over the energy range expected, as seen in Table V.

TABLE V

Deuteron energy (Mev)	Neutron energy at 105° (Mev)
3.00	14.26
3.50	14.38
4.00	14.50

Values for the relative neutron intensities were also determined from the spectra. The results are given in Tables VI and VII for two Zr–T targets. The calculated neutron energies were from the tables of Fowler

*An effective angle of 1.8° was used.

calculated and observed neutron energies and intensities for target A are in excellent agreement, but not so for target B. In the last column of Tables VI and VII are the values calculated for target B if the average deuteron energy was 2.75 Mev. The agreement here implies that the deuteron beam was striking a section of the target which was about four times thicker than expected. Such a thick source gives a greater spread in energy of the deuterons, and hence a greater spread in the neutron energy at a particular angle, with the exception of the back angles 105° and 140°. Photomicrographs of traverse sections cut through the center of several sources showed many to have unevenly deposited zirconium. Source B discussed above did appear to be three times thicker than source A when measured optically. In all sources there appeared to have occurred an interaction between the zirconium layer and the tungsten substrate. This has the effect of altering the rate of energy loss of deuterons in the target material. Variations in thickness and composition of these Zr–T targets have little effect on neutron production for very low energy (<300 kev) deuteron irradiations, but for higher deuteron energies, where one must calculate the effective deuteron energy producing neutrons, caution should be exercised. At present we still use these sources since they have the highest tritium content of any solid targets on the market and do not involve the health hazard associated with using tritium gas under pressure in a cell.

G. Corrections for the D (d,np) D Reaction

A source of monoenergetic neutrons for energies greater than 2.5 Mev is the D (*d,n*) He^3 reaction. However, for neutrons above 7.7 Mev there is associated with the monoenergetic group a continuum of neutrons produced by the D (*d,np*) D or breakup reaction. Sulphur used to monitor neutrons produced by the D + D process will also be activated by the presence of these breakup neutrons. Since there is no other source of monoenergetic neutrons with energies in the region of 8.0 to 12.5 Mev, calculations have been made for a breakup correction required when using the S^{32} (*n,p*) P^{32} reaction as a neutron monitor.

The data of Cranberg *et al.* (9) and Anderson *et al.* (10) were used to calculate the relative amounts of P^{32} activity produced at a given deuteron energy from the D (*d,n*) He^3 and D (*d,np*) D reactions. For both reactions the activity produced is proportional to the product of the sulphur (*n,p*) cross section and the neutron intensity. Since the neutron intensity is proportional to the cross section for neutron production, an effective cross section, $\hat{\sigma}_{S(n,p)}$, for the reaction of breakup neutrons on sulphur can be calculated from the following equation

$$\hat{\sigma}_{S(n,p)} = \frac{\int_{0.95\ \mathrm{Mev}}^{E_{max}} \sigma_{S(n,p)}\sigma_{D(d,np)}dE}{\int_{0.95\ \mathrm{Mev}}^{E_{max}} \sigma_{D(d,np)}dE},$$

where $\sigma_{S(n,p)}$ is the cross section for the sulphur (*n,p*) reaction and $\sigma_{D(d,np)}$ is the cross section for producing breakup neutrons of a given energy *E*. Both of these cross sections are energy dependent. The integral extends from the calculated maximum neutron energy in the spectrum down to 0.95 Mev, where $\sigma_{S(n,p)}$ is zero. Values for $\hat{\sigma}_{S(n,p)}$ and the various quantities used in the equation are given in Table VIII. Also listed in the last column of the same table are values for

$$\frac{\hat{\sigma}_{S(n,p)} \int \sigma_{D(d,np)}dE \times 100}{\hat{\sigma}_{S(n,p)} \int \sigma_{D(d,np)}dE + \sigma_{S(n,p)}\sigma_{D(d,n)}}.$$

This is the percentage correction that must be applied to the observed P^{32} activity to account for breakup neutrons when using sulphur to monitor neutrons from the D + D reaction. The term $\int \sigma_{D(d,np)}dE$ is the denominator of the preceding equation and expresses the total number of neutrons of all energies in the spectrum, and $\sigma_{D(d,n)}$ is the cross section for monoenergetic neutron production. The percentage corrections are plotted against deuteron energy in Fig. 4 and have an estimated error of ±5%.

To test the calculated corrections, the Al^{27} (*n,α*) Na^{24} cross section was measured at 13.6 Mev with sulphur as a flux monitor (16). Neutrons of this energy were produced in two different ways. In one case, the

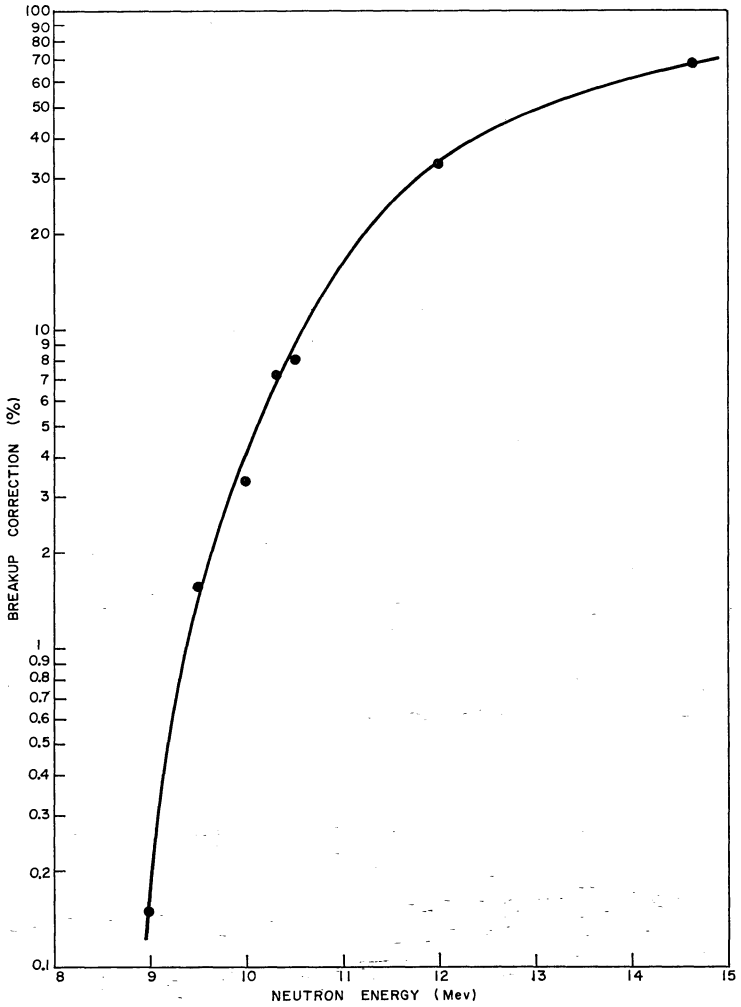

FIG. 4. Breakup correction applied to the P^{32} activity when using sulphur to monitor D + D neutrons emitted at zero degrees.

D (d,n) He^3 reaction was used with samples placed at 0° to a 10.6-Mev deuteron beam. Calculated corrections applied to the observed activities in sulphur and aluminum samples to account for breakup neutrons were 57% and 0.9% respectively. The measured Al^{27} (n,α) Na^{24} cross section was 123 ± 9 millibarns. In the other case, 125 kev deuterons and the T (d,n) He^4 reaction were used with samples placed at 140°. No breakup corrections were required. This time a measured cross section for the Al^{27} (n,α) reaction was 127 ± 5 millibarns.[5] The confirmation of the breakup correction at this energy gives one confidence in applying the correction at lower energies where sulphur was used as a monitor.

DISCUSSION

The use of sulphur for monitoring high-energy neutrons appears to be satisfactory. The ease with which the irradiated material can be converted to a form which can be counted efficiently without involving chemical separations and purification make it ideal for routine monitoring. The half-life of the product is a good compromise. It is long enough that counting immediately after an irradiation is not necessary and short enough that sufficient activity is produced even with a relatively low neutron flux.

[5] *A recent value of 131±6 millibarns was measured at this energy by Bayhurst and Prestwood (17).*

The difficulty of determining an absolute cross section makes it necessary to use a monitor and give a measured cross section relative to that of the monitor. Mellish (1) suggested using the sulphur reaction for such a monitor in measuring fast-reactor cross sections and establishing its effective cross-section value as 60 millibarns. We would like to suggest that the sulphur reaction be also used as a standard for comparison when monitoring monoenergetic fast neutrons. For the present, cross-section values taken from a smooth curve through Allen's data and ours could be used. The S^{32} (n,p) cross-section data appear to be reliable since excitation curves for other fast-neutron reactions determined by us, using sulphur as a monitor, are in agreement with measurements monitored in other ways (16).

METALLO-ORGANIC COMPOUNDS CONTAINING METAL–NITROGEN BONDS

PART IV. SOME BIS-(PRIMARY AMINO)-TITANIUM COMPOUNDS[1]

D. C. Bradley and E. G. Torrible[2]
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 8, 1962

ABSTRACT

The aminolysis reactions involving primary amines with either $Ti(NMe_2)_4$ or $Ti(NEt_2)_4$ have been studied. The primary amines behave as bifunctional reactants, forming colored, insoluble, non-volatile bis-(primary amino)-titanium compounds $Ti(NR)_2$ which (except for $R = C_6H_5$) are highly reactive towards water or alcohols. With *n*-butylamine some soluble polymers of the general formula $Ti_x(NBu^n)_{2x-2}(NEt_2)_4$ were isolated. With *tert*-butylamine the dimers $Ti_2(NBu^t)_2(NMe_2)_4$ and $Ti_2(NBu^t)_2(NHBu^t)_2(NMe_2)_2$ were obtained. The structures of these polymeric metal–nitrogen compounds are discussed.

INTRODUCTION

In a previous communication the preparation of a number of dialkylamino derivatives of titanium and zirconium was reported (1). The titanium compounds $(TiNR_2)_4$ were monomeric and could be distilled *in vacuo*. The monomeric nature of these compounds was significant in view of the tendency of titanium to expand its coordination number and the presence of donor nitrogen atoms in the dialkylamino groups. The absence of coordination–polymerization in these compounds and the limitation of aminolysis (e.g. $Ti(NMe_2)_4 + 3HNEt_2 \rightarrow Ti(NMe_2)(NEt_2)_3 + 3HNMe_2$) were ascribed to steric hindrance.

Since the steric effects of primary amines RNH_2 must be considerably less than those of secondary amines R_2NH it was considered worthwhile to investigate the aminolysis of dialkylamino-titanium compounds with primary amines:

$$Ti(NR_2)_4 + 2RNH_2 \rightarrow Ti(NR)_2 + 4HNR_2. \qquad [1]$$

Moreover, the primary amino derivatives were expected to be polymeric since the primary nitrogen is potentially bifunctional and could lead to the formation of a metal–nitrogen chain,  . There was also the additional possibility that in the primary amino derivatives the titanium might be able to achieve a coordination number of six as a result of coordination–polymerization. We now report the results of the reactions of several primary amines with tetrakis-(dialkylamino)-titanium compounds.

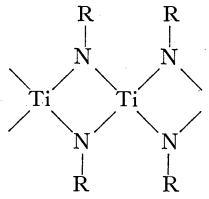
RESULTS AND DISCUSSION

When either $Ti(NMe_2)_4$ or $Ti(NEt_2)_4$ was treated with an excess of the primary amine RNH_2, where R = Pr^n, Pr^i, Bu^i, Bu^s, cyclohexyl, or phenyl, the deeply colored insoluble bis-(monoalkylamino)-titanium compound $Ti(NR)_2$ was obtained (viz. equation [1]), with the primary amines being bifunctional. With the exception of the anilino derivative, which was black and relatively stable towards hydrolysis, the new compounds were red and extremely vigorously hydrolyzed. The difference in chemical

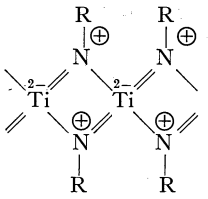
[1]*Part III, D. C. Bradley and I. M. Thomas, Can. J. Chem.*, **40**, *1355 (1962).*
[2]*Present address: Department of Chemistry, Queen's University, Kingston, Ontario.*

reactivity between the anilino derivative and the cyclohexylamino derivative was remarkable and in view of the similarity in size of the ligands suggests that electronic factors must be of predominant importance. The most likely factor to favor resistance to hydrolysis would be covalency expansion by the titanium involving donation of the lone pair of electrons from nitrogen. This could occur either by σ-bonding, which would cause coordination–polymerization, or by π-bonding, and in either case the increased electron density on the titanium would lower its susceptibility to nucleophilic attack by water. However, covalency expansion by σ-coordination should be assisted by electron release by the alkyl or aryl group attached to nitrogen and this would be greater for the cyclohexylamino derivative than for the anilino derivative. Covalency expansion by π-bonding (II) would be enhanced in the anilino derivative because of interaction with the ring π-orbitals and we are inclined to favor this as an explanation for the striking difference in behavior of cyclohexylamino and anilino derivatives. It is hoped to gain further information on this point as a result of infrared and n.m.r. studies now in progress on metallo-organic compounds containing metal–nitrogen bonds.

The insolubility and non-volatility of the bis-(monoalkylamino)-titanium compounds suggest that they are high polymers and it is evident that an infinite linear polymer (I) is feasible in which each unit of the polymer is joined by a double nitrogen bridge.



I



II

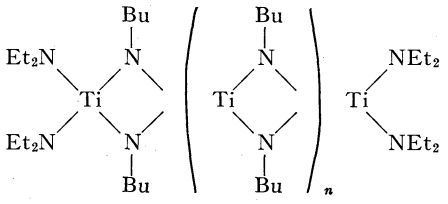
A notable feature of I is that the titanium atoms are 4-coordinated and that covalency expansion by σ-coordination would produce a 3-dimensional polymer.

Experiments in which *n*-butylamine was added to tetrakis-(diethylamino)-titanium showed that soluble polymers containing both diethylamino and *n*-butylamino groups could be obtained. An attempt to prepare the dimer $Ti_2(NBu^n)(NEt_2)_6$ by means of the reaction depicted in equation [2] gave a dark red liquid containing some solid. Heating

$$2Ti(NEt_2)_4 + Bu^nNH_2 \rightarrow Ti_2(NBu^n)(NEt_2)_6 + 2Et_2NH \qquad [2]$$

this inhomogeneous product caused disproportionation and $Ti(NEt_2)_4$ distilled over at 110–120° at 0.1 mm, leaving a non-volatile dark red solid whose analysis was near to the requirements of $Ti(NBu^n)_2$ but which still contained a small proportion of diethylamino groups. Further experiments in which $Ti(NEt_2)_4$ was treated with an excess of *n*-butylamine gave products having the general formula $Ti_x(NBu^n)_{2x-2}(NEt_2)_4$ (x = 6–14). These compounds were soluble in boiling cyclohexane and molecular weights were determined ebulliometrically in this solvent. The more polymeric compounds were noticeably less soluble in cyclohexane at room temperature and although quite soluble when hot they would not crystallize on cooling but gave gels instead. Surprisingly these compounds appeared to be insoluble in such "donor" solvents as pyridine, dioxane, or acetonitrile. All of the butylamino-titanium polymers contained residual diethylamino groups which resisted disproportionation at 130° at 0.1 mm and the molecular weights in boiling cyclohexane were in reasonable agreement with the structural formula III.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



III

According to this model the polymers contain the repeating unit I with the double metal–nitrogen bridge but finite polymers are produced because the diethylamino groups act as chain stoppers. Assuming that the titaniums are tetrahedrally bonded to nitrogen then a rigid linear polymer results. We have explored the possibility that 6-coordinated titanium might be involved in these polymers but it appears to be impossible to formulate such low polymers in terms of octahedrally coordinated titanium. It is possible that the metal–nitrogen bridges shown in formula III are reinforced by π-bonding due to intramolecular covalency expansion by titanium as shown in II.

An attempt was made to study the formation of polymers by the addition of primary amine to a solution of $Ti(NEt_2)_4$ in boiling diethylamine:

$$x\mathrm{RNH_2} + \mathrm{Ti(NEt_2)_4} \rightarrow \frac{1}{n}[\mathrm{Ti(NR)}_x(\mathrm{NEt_2})_{4-2x}]_n + 2x\mathrm{Et_2NH}. \qquad [3]$$

Experiments showed that $Ti(NEt_2)_4$ is monomeric in boiling diethylamine; hence the degree of polymerization n of the polymer produced in reaction [3] could in principle be determined ebulliometrically. However, the addition of either cyclohexylamine, isobutylamine, or *n*-butylamine to the $Ti(NEt_2)_4$ in boiling diethylamine gave no evidence of immediate reaction. After about 3 hours a slight red coloration had developed but it was concluded that reaction [3] must be reversible and in the presence of excess of diethylamine is forced to the left-hand side. To test the reversibility of equation [3] some bis-(isopropylamino)-titanium was refluxed with diethylamine and with di-*n*-propylamine but the replacement of isopropylamino groups was very slow. It appears that once the solid infinite polymer $[Ti(NR)_2]_\infty$ is formed it is resistant to aminolysis by secondary amines. Nevertheless, treatment of $Ti(NPr^i)_2$ with excess of *n*-butylamine caused slow replacement of isopropylamino by *n*-butylamino groups and a soluble *n*-butylamino-titanium polymer was formed.

Finally, we report some interesting results from the treatment of tetrakis-(dimethylamino)-titanium with excess boiling *tert*-butylamine. After about 2 hours of reaction the volatile materials were evaporated off *in vacuo* and a dark red solid (IV) remained. Analysis of IV and a molecular weight determination suggested that it was $Ti_2(NBu^t)_2(NMe_2)_4$, for which the bridged structure IV is proposed. Prolonged treatment of $Ti_2(NBu^t)_2(NMe_2)_4$ with excess boiling *tert*-butylamine gave another dimer, $Ti_2(NBu^t)_2(HNBu^t)_2(NMe_2)_2$ (V), which sublimed readily at 140–160° at 0.1 mm as a dark red

solid. The results suggest that the development of the double metal–nitrogen bridged linear polymer I is prevented in the case of *tert*-butylamino groups by the strong steric hindrance of the *tert*-butyl groups. It does not seem to be possible by the aminolysis reaction to arrange four Bu^tN-groups around each titanium, as required in I.

EXPERIMENTAL

Special precautions were taken to exclude water from the apparatus and chemicals and all reactions were conducted in an atmosphere of oxygen-free nitrogen. The amines and solvents were dried over sodium and distilled immediately before use.

Analysis

(a) For titanium.—The alkylamino derivative was weighed into a platinum crucible, hydrolyzed cautiously, and the hydrated oxide dried under an infrared lamp and then ignited to TiO_2.

(b) For nitrogen.—In the case of derivatives of the low-boiling amines the sample was hydrolyzed in alkali, the amine steam distilled and titrated with standard acid. For the less volatile amines the nitrogen was determined by the Kjeldahl method.

Molecular Weight Determinations

Measurements were carried out in boiling cyclohexane in the previously described (2) all-glass ebulliometer employing a differential water thermometer using the method of internal calibration (3) with fluorene.

Preparation of Bis-(alkylamino)-titanium Compounds

The preparation of bis-(isopropylamino)-titanium is described to illustrate the general technique, and the essential details of the other preparations carried out similarly are summarized in Table I.

TABLE I

Preparation of bis-(primary alkylamino)-titaniums

Compound	Color	Reaction time (hr)	Found (%)		Calc. (%)

*From $Ti(NMe_2)_4$.
†From $Ti(NEt_2)_4$.

An excess of isopropylamine (ca. 20 ml) added to tetrakis-(dimethylamino)-titanium (4.4 g prepared by Bradley and Thomas' method (1)) caused a deep red coloration with deposition of some red solid. The mixture was refluxed for 1 hour and allowed to cool overnight. Evaporation of the amines *in vacuo* followed by drying at 140° left a red solid which was vigorously hydrolyzed and reacted with alcohols to form titanium alkoxides. Found: Ti, 29.2; N, 16.5. $Ti(NPr^i)_2$ requires: Ti, 29.6; N, 16.9%. Gas chromatographic analysis of the volatile product of *n*-propanolysis showed the presence of isopropylamine but no dimethylamine. In some of the other preparations a small amount of $Ti(NMe_2)_4$ or $Ti(NEt_2)_4$ was distilled out of the product during drying *in vacuo* at 100–140° but dialkylamino groups were not detected in the final product.

Preparation of n-Butylamino-titanium Diethylamide Polymers

Addition of excess *n*-butylamine (15.0 g) to tetrakis-(diethylamino)-titanium (6.15 g prepared by Bradley and Thomas' method (1)) caused precipitation of an orange solid which dissolved when heated, giving a red solution. After refluxing for 4 hours the solution was allowed to cool but nothing crystallized. After evaporating off the amines the product was dried at 130° at 0.1 mm, and a small amount (ca. 0.2 g) of $Ti(NEt_2)_4$ distilled over at 110–120°. The final product was a dark red solid (3.25 g) which was shown by gas chromatographic analysis of the volatile products of *n*-butanolysis to contain both *n*-butylamino and diethylamino groups. In some cases the polymeric product was treated further with boiling *n*-butylamine to displace more diethylamino groups. The results are summarized in Table II.

Reaction Between Bis-(isopropylamino)-titanium and n-Butylamine

Excess of *n*-butylamine was added to bis-(isopropylamino)-titanium (3.0 g) and the scarlet solid became orange colored and slowly dissolved during 44 hours of heating at 100°. Evaporation of the amines followed

TABLE II

Polymeric *n*-butylamino-titanium diethylamides

Compound	Found			Calc.		
	Ti	N	M.W.	Ti	N	M.W.
$Ti_6(NBu^n)_{10}(NEt_2)_4$	22.9	15.4	1,280	22.4	15.25	1,286
$Ti_{14}(NBu^n)_{26}(NEt_2)_4$	24.0	15.1	2,770	23.9	15.0	2,806
$Ti_{16}(NBu^n)_{30}(NEt_2)_4$	24.1	15.1	3,120	24.05	14.9	3,188
$Ti_{100}(NBu^n)_{198}(NEt_2)_4$	25.0	14.8	3,920	25.0	14.8	19,136

by drying at 140° at 0.1 mm left a brown solid (3.75 g). Found: Ti, 24.8; N, 15.0. $Ti(NBu)_2$ requires: Ti, 25.2; N, 14.7%. Gas chromatographic analysis of the volatile product of *n*-butanolysis revealed only the presence of *n*-butylamine. The product was soluble in *n*-butylamine.

Reaction Between Tetrakis-(dimethylamino)-titanium and tert-Butylamine

Addition of excess *tert*-butylamine to $Ti(NMe_2)_4$ (10.3 g) caused a moderate reaction, with liberation of dimethylamine. After approximately 2 hours' fractional distillation to remove more dimethylamine, slowly formed during continued heating, during which time some solid was precipitated and the solution became dark red, the amines were evaporated off *in vacuo*. Final drying *in vacuo* at 120° gave no $Ti(NMe_2)_4$ and left a dark red solid (9.2 g). Found: Ti, 23.3; N, 20.3; M.W., 365. $Ti_2(NBu^t)_2(NMe_2)_4$ requires: Ti, 23.2; N, 20.3%; M.W., 414. The compound reacted vigorously on ethanolysis, liberating both *tert*-butylamine and dimethylamine.

The foregoing product (7.9 g) was treated with excess boiling *tert*-butylamine under a fractionating column for 3 hours and then the solution was evaporated to dryness *in vacuo*. On heating the product to 140–160° at 0.1 mm a dark red sublimate (4.2 g) was obtained. Found: Ti, 20.5; N, 17.2; M.W., 540. $Ti_2(NBu^t)_2(NHBu^t)_2(NMe_2)_2$ requires: Ti, 20.4; N, 17.9%; M.W., 470.

In another experiment in which $Ti(NMe_2)_4$ (8.9 g) was treated with excess *tert*-butylamine as before the residue (8.6 g) remaining after removal of amines and drying at 115° *in vacuo* was close in analysis to the composition of the sublimate obtained in the previous experiment. Found: Ti, 20.9; N, 17.9%; M.W., 530. A good yield of sublimate (6.0 g from 7.6 g) was obtained at 140–150° at 0.1 mm. Found: Ti, 20.8; N, 18.0%; M.W., 510.

THE CHEMISTRY OF THE AMINOCHROMES

PART V. REARRANGEMENTS IN THE PRESENCE OF SODIUM HYDROXIDE AND ZINC ACETATE[1, 2, 3]

R. A. HEACOCK AND G. L. MATTOK
The Psychiatric Research Unit, University Hospital, Saskatoon, Saskatchewan

Received September 10, 1962

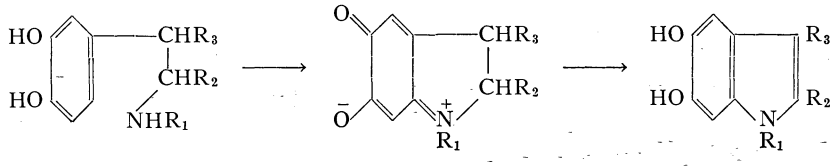
ABSTRACT

The rates of rearrangement of several aminochromes have been measured in: (1) water, (2) aqueous sodium hydroxide, and (3) aqueous zinc acetate. The rates were found to be first order with respect to aminochrome concentration in each reaction medium, and to zinc acetate concentration. However, no simple kinetic relationship between the rate of rearrangement and alkali concentration was detected. The rate increased very rapidly with increasing alkali concentration.

Mechanisms for these rearrangements are suggested, based on the influence of substituents in the 1-, 2-, and 3-positions of the aminochrome molecule on the kinetic and thermodynamic features of the reaction.

INTRODUCTION

The ease with which the red solutions obtained on oxidation of the catecholamines could be decolorized was recognized long before the structures of the compounds involved were established (see ref. 1 for references). As a result of studies on the oxidation of 3,4-dihydroxyphenylalanine (DOPA) carried out over 30 years ago, Raper proposed what was essentially the correct explanation of the changes that occurred, namely that the oxidation of DOPA (I: $R_1 = R_3 = H$; $R_2 = COOH$) resulted in the initial formation



I II III

of an aminochrome,* i.e. a 2,3-dihydroindole-5,6-quinone derivative (II: $R_1 = R_3 = H$; $R_2 = COOH$),† which subsequently underwent a spontaneous internal oxidation–reduction process, forming the colorless 5,6-dihydroxyindole (III: $R_1 = R_2 = R_3 = H$). The rate of decolorization of the intermediate pigment could be increased by the action of either base or acid. In the latter case, however, the rearrangement product was not 5,6-dihydroxyindole, but 5,6-dihydroxyindole-2-carboxylic acid (III; $R_1 = R_3 = H$; $R_2 = COOH$) (3). This general picture has subsequently been confirmed spectroscopically, manometrically, and paper chromatographically (4–6).

Solutions of adrenaline (I: $R_1 = CH_3$; $R_2 = H$; $R_3 = OH$) and certain related catecholamines with a hydroxyl group in the β-position that have undergone oxidation in

[1]*This investigation was supported by grants from the Government of Saskatchewan (Department of Public Health) and the Department of National Health and Welfare (Ottawa).*

[2]*Presented in part at the 45th Annual Conference of the Chemical Institute of Canada, Edmonton, Alberta, May, 1962.*

[3]*Part IV: Can. J. Chem.* **38**, *516 (1960).*

**The term "aminochrome" as a general name for the highly colored cyclic oxidation products of the catecholamines was not introduced until 1951 by Sobotka and Austin (2).*

†*The chemical and physical properties of these compounds suggest that the zwitterionic form of the molecule, as shown above, makes the major contribution to the aminochrome structure (cf. ref. 1).*

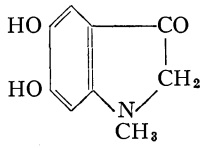
For personal use only.

alkaline media exhibited a transient but intense yellow-green fluorescence (see ref. 1 for references). The fluorescent derivative of adrenaline was, in fact, 5,6-dihydroxy-*N*-methylindoxyl* (i.e. adrenolutin; IV), first isolated and characterized by Lund in 1949



IV

(7, 8) and obtained by the alkaline rearrangement of the initially formed aminochrome (i.e. adrenochrome; II: $R_1 = CH_3$; $R_2 = H$; $R_3 = OH$). Rearrangement of aminochromes to 5,6-dihydroxyindole or 5,6-dihydroxyindoxyl derivatives is catalyzed by certain metallic ions, particularly Zn^{2+} and Al^{3+} (9, 10).

Although speculative mechanisms, notably those of Trautner and Bradley (11), Sobotka, Barsel, and Chanley (12), and Bu'Lock and Harley-Mason (13), have been advanced to explain certain aspects of the manner by which the rearrangement of the aminochromes to 5,6-dihydroxy-indole or -indoxyl derivatives occurs, none is based on a systematic physico-organic chemical investigation.

A number of reports of an essentially qualitative nature dealing with the stability of adrenochrome solutions has appeared in the literature, and these have been summarized previously (1). Zambotti and Moret studied the effects of pH and temperature on the stability of adrenochrome solutions in phosphate buffer polarographically and manometrically and reported that, in the relatively limited range studied, the decomposition of adrenochrome follows first-order kinetics and that the rate of disappearance of aminochrome varied linearly with the pH at 37° and exponentially with temperature at pH = 7.38 (14–16).

It appeared to the authors that a systematic study of the kinetic and thermodynamic features of the rearrangement of a number of different aminochromes would enable a more satisfactory explanation of the mechanisms of these reactions to be formulated.

EXPERIMENTAL

Aminochromes

Adrenochrome (17), *N*-isopropylnoradrenochrome (18), and adrenochrome methyl and ethyl ethers (18) were prepared as pure crystalline solids by the methods described in the literature. However, in the cases of epinochrome, 2-methyladrenochrome, *N*-ethyl-2-methylnoradrenochrome, and noradrenochrome, where it was either not possible to isolate a pure sample of the aminochrome or where only limited quantities of the relevant catecholamines were available, the aminochrome was prepared in aqueous solution by oxidation of the appropriate catecholamine hydrochloride (25 mg in 3 ml water) with freshly prepared silver oxide (2×0.2 g) (finally filtering the oxidation mixture through a small Dowex-1 (Cl^-) (200/400 mesh) resin bed to ensure complete removal of colloidal and ionic silver (cf. ref. 17). The rates of rearrangement obtained for adrenochrome prepared in this way showed satisfactory agreement with those determined using crystalline adrenochrome. Solutions of noradrenochrome prepared in this manner were not entirely satisfactory, since the visible absorption spectra of these solutions frequently showed a shift in λ_{max} accompanied by an increase in the intensity of absorption at this wavelength. This phenomenon is possibly due to the relatively slow cyclization of the initially formed "noradrenaline quinone" (i.e. 1-(α-hydroxy-β-aminoethyl)-3,4-benzoquinone) to noradrenochrome (cf. refs. 19, 20). However, it is not unreasonable to assume that the rates obtained represent the relative order of reactivity of this compound.

Kinetic Measurements

The rearrangements of the various aminochromes were studied in three reaction media: (*a*) water, (*b*) aqueous sodium hydroxide, (*c*) aqueous zinc acetate. The reactions were followed by measuring the decrease in absorbance at λ_{max} (ca. 480–495 mμ) with time using a Beckmann DK-2 spectrophotometer equipped with

**Often formulated in the enolic form, i.e. as 3,5,6-trihydroxy-N-methylindole.*

of the reagents were preheated to the reaction temperature in the cell holder. The reaction mixtures were prepared by the admixture of 2 ml of the aminochrome solution with 1 ml of the catalyst solution, care being taken to ensure rapid and complete mixing of the reagents.

There was a good linear relationship between the aminochrome concentration and the absorbance at λ_{max}.

The Reaction of Adrenochrome Methyl Ether with Zinc Acetate

A saturated solution of zinc acetate (1.5 ml) was added to a solution of adrenochrome methyl ether (73 mg) in water (2.2 ml). The reaction mixture was left to stand for 1 hour and the dark blue precipitate which formed was filtered off, washed with water and ether, and dried in air. The weight of the dry precipitate was 60.2 mg. The aqueous filtrate, which was initially yellow but which quickly became blue-green in color, gave, after standing for an hour, on the addition of more zinc acetate solution (3 ml) a blue precipitate, which was filtered, washed with water and ether, and dried in air. The weight of this dry residue was 29.8 mg.

The aqueous filtrate (30 ml) was extracted with ether (3×10 ml). Concentration of the dried (Na_2SO_4) ether extract afforded a white crystalline residue (5.5 mg). A paper chromatographic examination of this residue indicated that it was probably 5,6-dihydroxy-*N*-methylindole (i.e. III: $R_1 = CH_3$; $R_2 = R_3 = H$ (cf. ref. 21)). Assuming that this was in fact the product, the expected yield of a complex composed of one zinc atom and one aminochrome unit would be 90.4 mg, and that for 1:2 complex, 78.9 mg. The total weight of complex obtained was 85.7 mg.

Analyses of several different samples of these products for carbon, hydrogen, nitrogen, and zinc were inconclusive. (Found: C, 47.57, 47.38, 43.20, 43.19, 42.52, 49.53, 51.06; H, 5.32, 4.08, 4.07, 3.83, 4.15, 4.61, 4.70; N, 5.96, 5.90, 4.07, 5.63; Zn, 12.57, 12.57%.) The calculated composition of 1:1 zinc/aminochrome complex would be C, 46.41; H, 4.29; N, 5.42; Zn, 25.28%; and that for a 1:2 zinc/aminochrome complex would be C, 53.16; H, 4.91; N, 6.20; Zn, 14.47%. It is therefore difficult to say whether the experimentally determined percentage composition of the complex supports a 1:1 or a 1:2 complex.

It is interesting to note that the averages of the experimental values (i.e. C, 46.35; H, 4.69; N, 5.39; Zn, 12.57%) fit the calculated composition of a hydrated 1:2 complex (4 molecules of water) (i.e. $C_{20}H_{26}N_2O_{10}Zn$ requires C, 46.21; H, 5.04; N, 5.39; Zn, 12.58%).

Since these products are insoluble in the usual reagents, it was not possible to purify them further by recrystallization.

In view of the formation of insoluble precipitates in this case, the reaction was not followed spectroscopically beyond approximately 10% reaction, since clouding of the cell walls that resulted would have given anomalous results.

RESULTS

The rearrangements of adrenochrome and its methyl ether were first order with respect to aminochrome concentration in all three reaction media (see Figs. 1, 2, 3, and 4). In the

presence of zinc acetate the rearrangements also obeyed first-order kinetics with respect to zinc acetate. Rearrangements in the presence of sodium hydroxide, whilst being first order with respect to aminochrome concentration, did not show any simple dependency on

alkali concentration (see Fig. 5). The rate of rearrangement in the presence of sodium hydroxide increased rapidly with alkali concentration.

With the exception of experiments which were carried out to determine the order of the reaction, they were all performed with standardized zinc acetate and sodium hydroxide concentrations. The first-order rate constants were calculated by the method of initial slopes to avoid errors due to any secondary reactions.

The rates of rearrangement, at 35°, of some aminochromes are given in Table II. When the substituent on carbon atom 3 only is varied the sequence of reactivity is: H > OH > OCH_3 > OC_2H_5. Further, when the substituent on the nitrogen atom only is varied the sequence of reactivity is *i*-C_3H_7 > CH_3 > H. Variation of the substituent on C_2 from H to CH_3 had little effect on the rate of reaction (see Table II). These generalizations are true for rearrangements in water, alkali, and zinc acetate solution. An incidental observation is that OH^- is about 10 times better a catalyst for the rearrangement than Zn^{2+} (on a molar basis). It is also of interest to note that solutions of noradrenochrome are not as unstable as they are generally considered to be.

The effect of temperature in the range 30–50° on the rates of some of these reactions was also investigated, and the thermodynamic functions (at 35°) for these rearrangements are given in Table III. In each of the three reaction media, the activation energy decreases as the rate of rearrangement increases. In general, the entropy term is fairly constant. However, with epinochrome, which carries two hydrogen atoms on C_3, the entropy term is consistently more favorable than for adrenochrome. Although this difference is small, it is probably significant.

DISCUSSION

Rearrangements in Water and Alkali

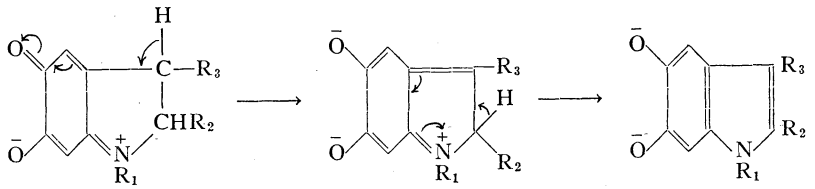
The overall reaction consists of removal of protons from the 2- and 3-positions in the five-membered ring of the aminochrome molecule (II) and the addition of a proton to each of the C_5- and C_6-carbonyl oxygen atoms on the *o*-benzoquinone ring. The primary reaction center must therefore be either C_2 or C_3. The following lines of evidence suggest that the primary reaction center is, in fact, C_3: (i) In the cases investigated, substituents in the 3-position had a marked effect on the reaction rates, whilst those in the 2-position had little effect; (ii) the entropy term for epinochrome (II: $R_1 = CH_3$; $R_2 = R_3 = H$) is slightly more favorable for rearrangement than for the other aminochromes. This would be expected if the rate-determining process is removal of a proton from carbon 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The reaction in water is first order with respect to aminochrome concentration. (This is the case for at least 40% reaction.) In aqueous alkali, the rearrangement is also first order with respect to aminochrome; however, the order with respect to sodium hydroxide concentration is not simple, indicating that alkali probably plays a multiple role in the reaction.

The rate-controlling process would then be the loss of a proton from the three position, resulting in a transition state involving one aminochrome molecule.

The two carbonyl groups in *o*-quinonoid structures tend to promote electromeric changes in opposite directions, resulting in the high reactivity associated with these structures, which have a tendency to revert to structures in which the tension of the opposed electromeric effects has been relieved (22). The tendency of the C_5-carbonyl group to polarize effectively lowers the electron density on C_3, by the series of electromeric changes as shown below, thus facilitating the removal of the proton from the 3-position. Electron-attracting substituents at C_3 will diminish the supply of electrons available for the



electromeric shifts, resulting in the polarization of the C_5-carbonyl group. The rate of rearrangement will therefore decrease with an increase in electron-attracting capacity of the C_3-substituent (R_3), and this is, in fact, observed for the following series of compounds: epinochrome (R_3 = H) > adrenochrome (R_3 = OH) > adrenochrome methyl ether (R_3 = OCH_3) > adrenochrome ethyl ether (R_3 = OC_2H_5).

The rate-determining stage is then followed by a second series of electronic shifts in the pyrrole moiety of the molecule, resulting in the loss of a proton from C_2 and the formation of a fully aromatic structure.

Electron-donating groups on the nitrogen atom will promote further polarization of the C_6-carbonyl group, resulting in an increase in the already high contribution of the zwitterionic form of the aminochrome molecule to the ground-state resonance hybrid. This results in a raising of the ground-state free energy of the molecule. The observed sequence of reactivity for the *N*-substituted aminochromes is: *N*-*i*-C_3H_7 > *N*-CH_3 > *N*-H. This would be expected on the basis of the inductive effects of these groups. This effect is also probably associated with the observed shift towards longer wavelengths of the main absorption peak (see Table I) of the *N*-substituted aminochromes with increasing electron-donating capacity of the *N*-substituent.

The rapid increase in the rate of rearrangement of the aminochromes with increasing alkali concentration indicates that the catalyst does not play a single role in the reaction, but presumably assists several processes simultaneously. The hydroxyl ions will act as proton scavengers, and the presence of alkali will also tend to stabilize the enolate anion of the transition state. Furthermore, interaction of the hydroxyl ions with the quaternary nitrogen center will localize the positive charge of the zwitterionic system and thus destabilize the molecule by limiting the possibilities for resonance.

Rearrangements in the Presence of Zinc Acetate

Several of the observed kinetic features of these rearrangements are similar to those in the alkali-catalyzed and uncatalyzed rearrangements. The same sequence of reactivity for substituents in the 1-, 2-, and 3-positions is observed. The thermodynamic aspects of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the rearrangements are similar. However, there are some important differences. Firstly, there is a good first-order dependency with respect to the zinc acetate concentration, whilst there is no simple relationship to alkali concentration. Secondly, rearrangement of the various aminochromes in the presence of sodium hydroxide leads to analogous products in every case. However, when zinc acetate is the catalyst, rearrangement of the aminochromes with R_3 = H or OH leads to the formation of the same products as with alkali, whereas when R_3 = *O*-alkyl (i.e. the aminochrome ethers) these aminochromes react with zinc acetate solution to form an insoluble dark blue precipitate (cf. ref. 21), which forms relatively slowly. The composition of these precipitates is uncertain. Analysis of the product derived from adrenochrome methyl ether did not confirm either a 1:1 or 1:2 zinc/aminochrome composition but suggested a hydrated 1:2 complex. It was impossible to obtain a pure sample of this material, since it is probable that the product is contaminated with insoluble melanitic materials which are formed at the same time as the complex. Insoluble precipitates were never obtained initially in the cases where R_3 = H or OH.

Bu'Lock and Harley-Mason have suggested, by analogy with the products formed during the oxidation of catechol in the presence of zinc acetate, that the rearrangement of aminochromes in the presence of zinc acetate proceeds via an intermediate composed of one zinc unit and two aminochrome units (13). Our results do not rule out the formation of such a complex as the final product with the aminochrome ethers, but, the transition state for the zinc ion catalyzed rearrangement must, from the kinetic data, involve only one zinc ion and one aminochrome molecule.

The bimolecular process required to form a 1:1 complex is more likely than the three-body collision necessary for the formation of the 1:2 complex proposed by Bu'Lock and Harley-Mason. Further, it is difficult to rationalize the pronounced effect of the C_3-substituent, in the case of the aminochrome ethers, on the solubility and stability of this complex.

From the kinetic data, there will be a primary interaction between one Zn^{2+} ion and one aminochrome molecule. Presumably, the zinc ion approaches the dicarbonyl function of the benzoquinone moiety. The polarization of the C_6-carbonyl group will assist this approach. The proximity of the Zn^{2+} ion to the C_5-carbonyl will induce polarization in this group, thus providing the driving force for the same electromeric shifts, resulting in the removal of the C_3-proton, as proposed for the hydroxyl ion catalyzed rearrangement. The C_2-proton is removed by the second series of shifts as described previously.

The mechanisms of rearrangement of the aminochromes in the presence of alkali or zinc acetate therefore differ mainly in the method by which the two catalysts bring about the same electronic changes in the aminochrome molecule. This is in accord with the fact that, apart from catalytic aspects, the same general kinetic features are observed for the two types of rearrangement.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Burrough-Wellcome and Co. (Canada) Ltd., for a generous gift of epinine hydrochloride and to Mrs. B. D. Scott for the preparation of samples of 3,4-dihydroxyephedrine hydrochloride and *N*-ethyl-3,4-dihydroxynorephedrine hydrochloride.

A NUCLEAR MAGNETIC RESONANCE INVESTIGATION OF THE PROTONATION OF AMIDES IN FLUOROSULPHURIC ACID

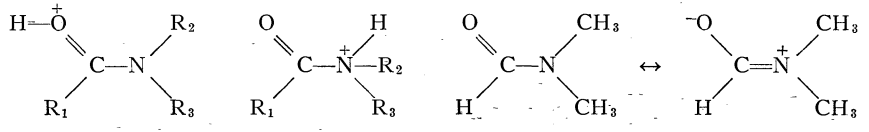
R. J. GILLESPIE AND T. BIRCHALL
Department of Chemistry, McMaster University, Hamilton, Ontario
Received August 30, 1962

ABSTRACT

The proton resonance spectra of solutions of acetamide, *N,N*-dimethylacetamide, formamide, and *N,N*-dimethylformamide in fluorosulphuric acid have been studied at temperatures between 25° and −98°. At low temperatures a new peak appears in the spectra of solutions of all four compounds which is not present at room temperatures and which, from peak areas and other considerations, may be assigned with certainty to the $\rangle C{=}\overset{+}{O}H$ group. It is thereby unambiguously established that these amides protonate on the carbonyl oxygen and not on the nitrogen atom.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

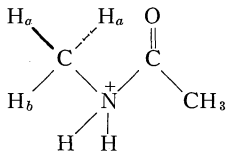
The structure of the ion formed when amides are protonated has been the subject of discussion since Hantzsch (1) first presented evidence for *O*-protonation of benzamide in concentrated sulphuric acid from ultraviolet absorption spectra studies. A variety of other evidence has since been put forward by other workers in support of *O*-protonation but much evidence has also been adduced in favor of *N*-protonation (II). All this previous work has been summarized by Katritzky and Jones (2), who conclude that the evidence as a whole strongly indicates that amides are predominantly protonated at the oxygen atom.



I II III

Perhaps the strongest evidence for *O*-protonation has come from proton magnetic resonance studies. For example, the spectrum of pure liquid dimethylformamide shows two peaks of equal area for the *N*-methyl groups (3, 4). It is concluded that the two methyl groups have different environments because of restricted rotation about the OC—NMe_2 bond, due to its partial double-bond character (III). Fraenkel and Niemann (5) have shown that these two peaks remain unchanged in solution in aqueous strong acids and in 100% H_2SO_4 and D_2SO_4. They assume that in the *O*-protonated form (I) rotation around the OC—NMe_2 bond would still be restricted, while in the *N*-protonated form (II) the $NHMe_2^+$ group should be free to rotate; thus they concluded that the *O*-protonated form predominates in these strong acid solutions. For *N*-methylformamide the signal from the *N*-methyl protons is a doublet attributed to spin–spin coupling with the single hydrogen attached directly to nitrogen. This doublet collapses to a single peak in basic or weakly acidic solutions but reappears again as a doublet, and not a triplet, in strongly acidic media, which rules out the possibility of an NH_2Me^+ group. Similar results have been obtained for *N*-methylacetamide (6). A solution of acetamide in 100% sulphuric acid gives a spectrum consisting of two signals of relative areas 3:2 which have been interpreted as being due to the CH_3 and NH_2 peaks of an *O*-protonated cation (7).

Spinner, who obtained infrared evidence for *N*-protonation (8),* has suggested, however, that the n.m.r. results can also be explained on this basis (9). For example, he attributes the doublet *N*-methyl group signal observed in the spectrum of protonated *N*-methylacetamide to the non-equivalent hydrogen atoms H_a and H_b resulting from restricted rotation about the C—N bond in the *N*-protonated form (IV). However, this



IV

would give components of the methyl group signal of relative areas 1:2 and not the equal areas observed. It must also be assumed that the expected spin–spin coupling between the *N*-methyl group and the two hydrogens directly attached to nitrogen is too weak to be observed. Spinner does, however, make the important point that all the n.m.r. evidence is rather indirect as in no case has a signal been observed in the spectrum from the proton supposedly captured by the oxygen atom in the *O*-protonated form. This has been attributed by other workers to rapid exchange of this proton with the solvent.

It is evident that the site of protonation could be determined unambiguously if the rate of exchange of the captured proton with the solvent could be slowed down sufficiently so that a separate signal for this proton could be observed in the spectrum. Earlier n.m.r. studies of the protonation of amides have been carried out at room temperature in aqueous acid solutions or in 100% sulphuric acid. In the present work we have studied solutions of formamide, acetamide, and their *N*,*N*-dimethyl derivatives in anhydrous fluorosulphuric acid. Fluorosulphuric acid is a stronger acid and a weaker base than 100% sulphuric acid (10) and has the added important advantage of a low freezing point of −89.0° (11). By recording the spectra of the fluorosulphuric acid solutions of these amides at sufficiently low temperatures it has been possible to observe for the first time the signal from the captured proton and thus to determine unambiguously the site of protonation.

EXPERIMENTAL

Materials

The amides were commercial samples which in the case of the solids were recrystallized. The n.m.r. spectra run at high gain showed no peaks that could be attributed to impurities. Fluorosulphuric acid was distilled twice in a dry atmosphere before use. The solutions of the amides in fluorosulphuric acid were approximately 6 mole%.

The n.m.r. spectra were recorded with a Varian H.R. 60 spectrometer equipped with a variable temperature probe and an integrator. Chemical shifts were measured from an external reference of tetramethylsilane using the audio side-band technique. No correction was made for differences in the bulk diamagnetic susceptibilities of the solution and the reference compound.

RESULTS AND DISCUSSION

Table I summarizes the chemical shifts and spin–spin coupling constants for the protonated forms of all four of the compounds studied.

Acetamide

The proton magnetic resonance spectrum of a 6 mole% solution of acetamide in fluorosulphuric acid at 25° consists of two peaks of relative areas 3.00:2.04 in addition to the

**Recent work (15) has shown, however, that Spinner's interpretation of the infrared data is probably not correct.*

and for a solution in 100% sulphuric acid (7), and the peaks have been assigned to the CH_3 and NH_2 groups. The NH_2 peak B is approximately 70–80 cycles/sec wide, due to quadrupole relaxation of the N^{14} nucleus. As the temperature is lowered the NH_2 peak becomes sharper and eventually splits into a doublet. At −80° another peak, A, becomes visible on the high-field side of the large solvent peak (Fig. 1*b*) and shifts to higher field as the temperature is further decreased until at −92° it was recorded as a separate well-resolved peak (Fig. 1*c*). This new peak can only be assigned to a proton on the carbonyl oxygen, and in agreement with this conclusion the relative areas of the three peaks were found to be A:B:C::1.07:2.10:3.00, confirming their assignment to the OH, NH_2 and CH_3 groups respectively. Protonation on nitrogen with no exchange would give a spectrum consisting of two peaks of equal area.

The splitting of the NH_2 resonance may be attributed to non-equivalence of the two hydrogens as a consequence of restricted rotation about the C—N bond due to its partial double-bond character. The loss of resolution in the NH_2 doublet at −92° can probably be attributed to the increased viscosity of the solution, which is very close to the freezing point or possibly slightly supercooled. Even at −90° the OH peak has a width of 23.2 cycles/sec and although some of this broadening is perhaps due to the increased viscosity of the solutions much of it can probably be attributed to the fact that at this temperature slow OH-solvent proton exchange is still occurring.

N,N-Dimethylacetamide

The spectrum of a solution of dimethylacetamide in fluorosulphuric acid at 25° contains only two signals, B and C, due to the $N(CH_3)_2$ and $C{:}CH_3$ groups respectively (Fig. 2*a*).

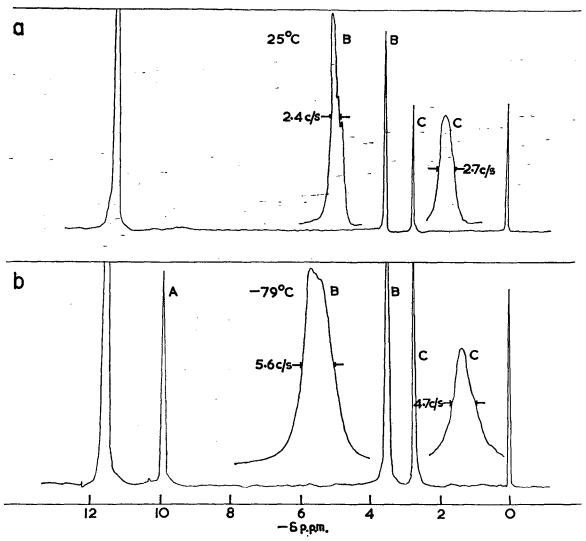

FIG. 2. Nuclear magnetic resonance spectra of a solution of *N,N*-dimethylacetamide in fluorosulphuric acid.

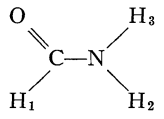
On decreasing the temperature a new peak, A, appears with a chemical shift of approximately −10 p.p.m. which is at first broad and then gradually narrows until it has a width of only 2.8 cycles/sec at −79° (Fig. 2*b*). This peak may be assigned to the protonated oxygen atom by comparison with the similar peak which occurs in the spectrum of acetamide at low temperatures. No further change in the spectrum occurs below −79°,

indicating that exchange of the captured proton with the solvent has become very slow. The relative areas of the three peaks at −79° were found to be A:B:C::0.96:5.91:3.00 and they are assigned to the OH, $N(CH_3)_2$, and $C.CH_3$ groups respectively. We may note that if *N*-protonation occurred three peaks of relative area 1:6:3 would be expected as for *O*-protonation. However, the new peak due to the captured proton has a chemical shift of −9.80 p.p.m., which is close to the chemical shift of −10.40 p.p.m. for the analogous peak in the acetamide spectrum which can be unambiguously assigned to the $=\overset{+}{O}H$ group. Moreover, A is a single sharp line showing no evidence of any fine structure, although if *N*-protonation occurred spin–spin coupling between the NH and $N(CH_3)_2$ protons would be expected since in a neutral aqueous solution of *N*-methylacetamide $J_{NH.NCH_3} = 3.8$ cycles/sec (5). At all temperatures the $N(CH_3)_3$ signal is essentially a single peak, although its width (2.4 cycles/sec at 25° and 5.6 cycles/sec at −79°), its unsymmetrical shape, and the presence of several ill-defined shoulders strongly indicate that it has an unresolved fine structure. This can presumably be attributed to a very small chemical shift between the two methyl groups, their non-equivalence being due to restricted rotation about the central C—N bond, and mutual spin–spin coupling. There is possibly also some coupling with the OH and $C.CH_3$ protons. The greater width of the $N(CH_3)_2$ signal at −79° can perhaps be attributed to a small increase in the chemical shift between the two methyl groups with decreasing temperature. In the pure liquid and in solution in various organic solvents the signals from the two *N*-methyl groups are clearly separated at room temperature (12). However, in 100% sulphuric acid Fraenkel and Franconi (7) were unable to resolve the two separate methyl groups. They attributed this to the broadening of the peaks caused by the high viscosity of sulphuric acid. However, as the viscosity of fluorosulphuric acid is only 1/10 that of sulphuric acid (11), this cannot be the only factor involved. Presumably the chemical shift between the *N*-methyl groups is smaller in the protonated than in the neutral amide. It is interesting to note that a recent study of the spectra of solutions of dimethylacetamide in a variety of organic solvents has shown that the chemical shift between the two methyl groups is solvent and concentration dependent and can become zero or even change sign in suitable solvents (12).

Formamide

The spectrum of pure liquid formamide at room temperature is shown in Fig. 3*a*. The broad peak C can be attributed to the NH_2 protons and the peak B to the formyl proton H_1 split by coupling with the H_3 proton (V) (13). The chemical shifts between the three



V

protons are relatively small and they will not therefore give rise to a simple first-order spectrum, which is the reason for the unsymmetrical nature of the formyl-proton doublet. In solution in fluorosulphuric acid the spectrum changes to that shown in Fig. 3*b*. It seems clear that the broad NH_2 peak has now split into the triplet expected for N^{14}—H coupling and that the middle peak of this triplet lies beneath the sharper doublet that can be attributed to H_1. Unresolved splitting due to coupling with H_2 in addition to H_3 is evident in the form of shoulders on the center peak. The observed separation of the outer components of the NH_2 triplet gives $J_{NH} = 62 \pm 5$ cycles/sec, which is in good

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

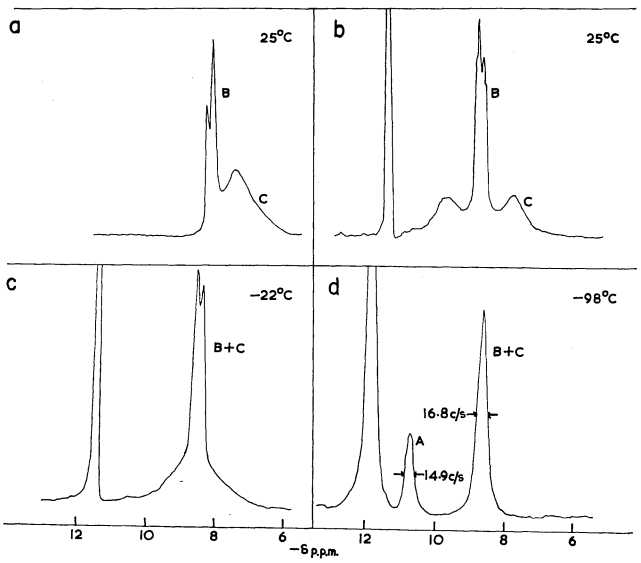


FIG. 3. Nuclear magnetic resonance spectra of (*a*) liquid formamide and (*b*, *c*, *d*) a solution of formamide in fluorosulphuric acid.

agreement with the value of 60±4 cycles/sec obtained by Roberts (14) for pure liquid formamide at temperatures above 50°. An integrated spectrum gave relative areas for the three peaks of 0.74:1.55:0.71, which is in reasonable agreement with the expected values of 0.67:1.66:0.67 in view of the extensive overlap of the broad peaks.

With decreasing temperature the NH_2 signal collapses to a single peak that is coincident with the peak due to the formyl proton (Fig. 3*c*). At −80° a new peak, A, appears at low field which may be attributed to the $C{=}\overset{+}{O}H$ group. At −98° the A peak has a chemical shift of −10.69 p.p.m. and integration of the spectrum gave relative peak areas A:B+C::1.00:3.03, in agreement with their assignment to the $C{=}\overset{+}{O}H$ and NH_2 plus CH groups respectively. The width of the $C{=}\overset{+}{O}H$ peak (14.9 cycles/sec) presumably indicates that exchange of this proton with the solvent is still occurring at −98°, although some of the broadening could be due to the increased viscosity of the solvent at this temperature.

N,N-Dimethylformamide

The spectrum of a solution of dimethylformamide in fluorosulphuric acid at 25° consists of the peak B, due to the formyl proton, and the doublet C, due to the two *N*-methyl groups (Fig. 4). For the pure liquid dimethyformamide and for solutions in a large number of organic solvents it has been found that two peaks are obtained for the *N*-methyl groups and it has been shown that this is because they are non-equivalent as a consequence of hindered rotation about the OC—N bond (3, 4, 12). The peak at higher field is split into a doublet of separation 1.1 cycles/sec and the lower field peak is split into a doublet of separation 0.7 cycle/sec. These splittings are almost exactly twice as large as those found by Hatton and Richards (12) for the pure liquid (0.65 and 0.3 cycle/sec respectively). The splitting is attributed to coupling of the *N*-methyl groups with the formyl proton, and the high-field peak has been assigned to the $CH_3{}^a$ group trans to the formyl hydrogen and the low-field peak to the $CH_3{}^b$ group cis to the formyl proton (VI). The greater

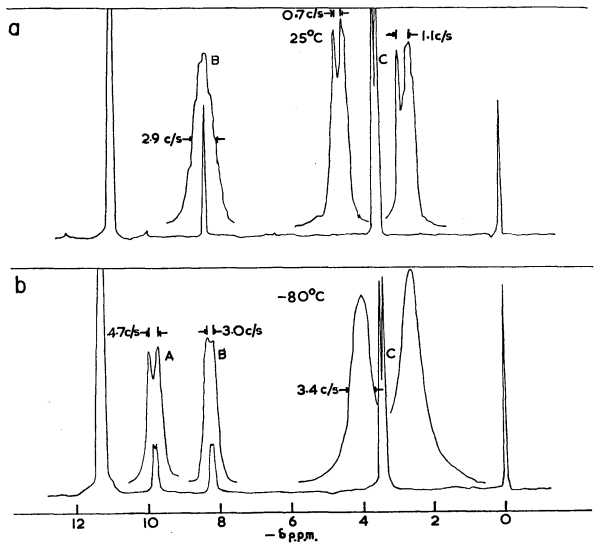

FIG. 4. Nuclear magnetic resonance spectra of a solution of *N*,*N*-dimethylformamide in fluorosulphuric acid.

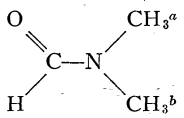

VI

coupling between the formyl proton and the *N*-methyl groups in the protonated form than in the neutral amide may reasonably be associated with a greater double-bond character of the central C—N bond in the protonated form. In solutions of dimethylformamide in 100% H_2SO_4 Fraenkel and Franconi (7) found rather larger splittings of the *N*-methyl resonances of 1.2 and 1.7 cycles/sec respectively. The reason for the difference between their results and ours is not clear. The resonance of the formyl proton is somewhat broad (2.9 cycles/sec) and a number of shoulders on the line strongly indicate unresolved fine structure. This must arise from spin–spin coupling between the formyl proton and the *N*-methyl groups. At low temperatures a new peak, A, appears in the spectrum at low field (−9.98 p.p.m.) which can evidently be attributed to the OH group of the *O*-protonated form. At −80° the relative areas of the peaks were found to be A:B:C::1.04:0.96:6.00, in agreement with the suggested assignment. The OH and CH peaks are both doublets due to mutual spin–spin coupling, $J_{CH,OH} = 4.7$ cycles/sec. That the resolution of the CH doublet is poorer than that of the OH doublet is presumably due to weak spin–spin coupling of the CH proton with the two *N*-methyl groups. The reason for the loss of fine structure in the doublet C due to the *N*-methyl groups is, however, not clear.

Benzamide and N-Methylbenzamide

A preliminary investigation of these amides in fluorosulphuric acid has been carried out and it has been found that proton exchange is sufficiently slow at low temperatures to allow the observation of a separate peak due to the captured proton. The *N*-methyl resonance in *N*-methylbenzamide is a doublet due to coupling with the single NH proton, $J \approx 5$ cycles/sec, but the position of the resonance due to the NH protons is uncertain and work on these and other amides is continuing.

Quadrupole Relaxation

The signal from protons bonded to N^{14} may be a broad single line or have a triplet structure (14). A sharp triplet is obtained when the electronic configuration around the nitrogen nucleus is symmetrical as in NH_4^+. This arises from spin–spin coupling of the protons with the N^{14} nucleus, which has a spin of unity. Rapid relaxation of the N^{14} nucleus occurs, however, when its quadrupole moment interacts sufficiently strongly with fluctuating electric-field gradients and the triplet structure of the proton resonance then collapses to a single peak. Roberts (14) has found in a number of cases that the fluctuating field-gradients become less effective as the temperature is increased, i.e. with increase in the rate of molecular motions, and the relaxation rate correspondingly decreases and the broad single proton resonance tends to become a triplet. Conversely as the temperature is lowered the relaxation rate increases, leading to collapse of the triplet structure to a single peak. This was observed in the present work in the case of a formamide solution in fluorosulphuric acid. The triplet structure observed for the NH_2 proton resonance at room temperature collapses to a single peak on lowering the temperature. It is interesting to note also that the NH_2 signal changes from a broad single peak in pure formamide (13) to a triplet in a dilute solution in fluorosulphuric acid. Evidently quadrupole relaxation is less effective in the latter solution but the reason for this is not clear. Indeed, protonation on oxygen must, surely, increase the C—N double-bond character and thereby increase the electrical asymmetry around the nitrogen nucleus, which would be expected to lead to more effective rather than less effective quadrupole relaxation.

The broad NH_2 peak of acetamide also narrows as the temperature is lowered, the relaxation of the N^{14} nucleus eventually becoming sufficiently great that it is effectively decoupled from the protons. The proton signal then becomes relatively sharp, allowing the observation of separate signals from the two non-equivalent NH protons.

ABSTRACT

The preparation of 16β-carboxy-(5α)-17α-pregnane-3β-ol-20-one and 16β-carbomethoxy-3β-fluoro-17α-Δ5-pregnene-20-one, as well as several of their derivatives, is described. The stereochemistry of these compounds is deduced from their optical rotatory dispersion curves.

Il a été montré précédemment (1) que, douée d'une réactivité particulière, la liaison éthylénique 16,17 du 3β-hydroxy 20-oxo pregna-5,16-diène (I)‡ se prête aisément aux réactions d'addition. C'est ainsi que le 3β-hydroxy 16α-cyano 20-oxo pregna-5-ène (IX), produit de la réaction du cyanure de potassium sur la diènone (I), a ouvert la voie à de larges possibiltés de synthèses (1). Dans un mémoire précédent (2), on a décrit la préparation et discuté la stéréochimie des dérivés du pregna-5-ène et 17-iso-pregna-5-ène substitués en C-16 présentant les différentes configurations possibles aux positions 16 et 17. La présente note a pour objet, d'une part, de généraliser certaines observations faites dans la série du 17-iso-pregna-5-ène (2) par des résultats identiques obtenus avec l'iso-pregnane substitué en C-16; et de signaler, d'autre part, la synthèse du 16β-méthoxycarbonyl 3β-fluoro 20-oxo (17α)pregna-5-ène (XVI*a*).

Le 3β-acétoxy 20-oxo 16:17α-époxy pregna-5-ène (II), d'accès aisé (3), a été choisi comme composé de départ pour la synthèse du 16β-carboxy 3β-hydroxy 20-oxo (5α,17α)-pregnane (VIII*a*). On s'est adressé à cet époxyde car, tout en rappellant la diènone (I), la double liaison réactive 16–17 s'y trouve protégée d'une manière adéquate (II). La réduction catalytique sur charbon palladié de la liaison éthylénique 5,6 du composé (II) conduit au 3β-acétoxy 20-oxo 16:17α-époxy (5α)pregnane (III), dont les constantes physiques sont en accord avec celles du composé décrit antérieurement (4).

L'étape suivante consiste à régénérer la liaison éthylénique 16,17. Tandis que différentes méthodes permettent de réduire une fonction époxyde du type (III) en énone correspondante (IV), c'est la technique au chlorure de chromyle§ qui a donné les résultats les plus satisfaisants. L'époxyde (III), soumis à ce procédé, fournit un mélange réactionnel qui a été séparé par chromatographie en quatre constituants différents. Le premier composé, élué à l'hexane et obtenu avec un rendement d'environ 3%, répond à la structure de la dièneone (VI). Ce composé résulte vraisemblablement de la déshydratation de la fonction hydroxyle en position 3 de l'alcool (IV*a*), identifié également parmi les produits secondaires de cette réaction (*vide infra*). Le second composé, produit principal de la réaction, obtenu avec environ 80% de rendement et élué au mélange hexane–benzène, est le 3β-acétoxy 20-oxo (5α)pregna-16-ène (IV*b*) attendu. Une élution ultérieure de la

colonne de chromatographie par un mélange benzène–chloroforme permet d'isoler, avec 5%, le 16α-hydroxy 3β-acétoxy 20-oxo (5α)pregnane (V*b*). Ce composé est l'acétate en position 3 du 3β,16α-dihydroxy 20-oxo (5α)pregnane (V*a*), facteur d'excrétion du sodium du cortex surrénal (6). Le même mélange, benzène–chloroforme, élue finalement 2% environ de 3β-hydroxy 20-oxo (5α)pregna-16-ène (IV*a*). L'hydrolyse alcaline d'un échantillon de l'acétate (IV*b*) obtenu ci-dessus conduit à un composé identique, confirmant la structure (IV*a*) assignée à la substance isolée du mélange réactionnel.

L'addition de Michael des éléments de l'acide cyanhydrique sur la double liaison 16,17 de l'acétate (IV*b*) fournit quantitativement le 3β-hydroxy 16α-cyano 20-oxo (5α)pregnane (VII*a*). La configuration β assignée à la chaîne latérale en position 17 résulte de l'effet Cotton positif présenté par la courbe de dispersion rotatoire de ce composé (VII*a*) et de son dérivé acétylé (VII*b*) (7), comme l'indique la Fig. 1. Par analogie avec d'autres additions sur cette liaison éthylénique 16,17 (8), on assigne la configuration α au groupement cyano de ce dérivé d'addition (VII*a*). L'attaque de l'anion CN^-, qui s'effectue par la face α stériquement la moins encombrée, justifie cette attribution de configuration qui s'est trouvé confirmée par l'examen du spectre de résonance magnétique nucléaire du cyano-acétate (VII*b*).* Cette conclusion est en accord avec la configuration assignée à cette fonction dans le composé (IX) obtenu dans la série du pregna-5-ène (2).

**Une étude détaillé des spectres de résonance magnétique nucléaire des composés obtenus dans ces séries (2) est actuellement en préparation (9).*

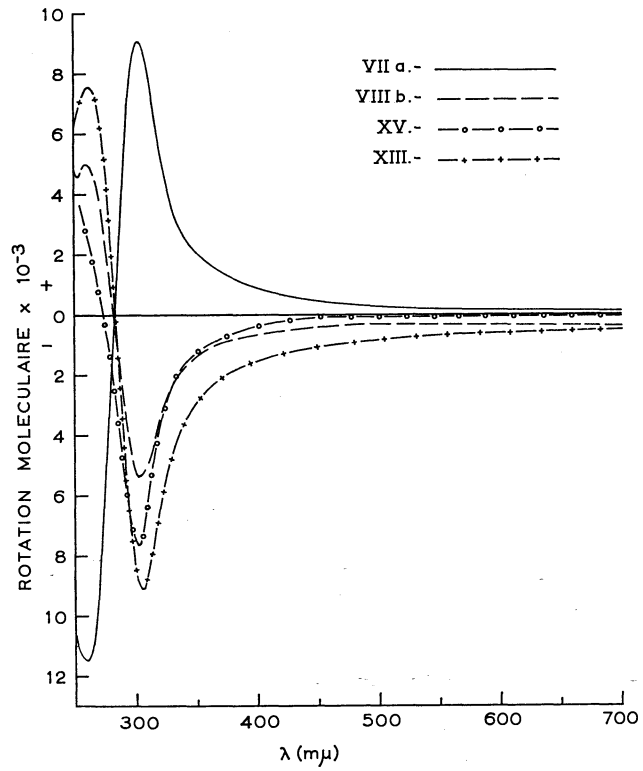

FIG. 1. Courbes de dispersion rotatoire du 3β-hydroxy 16α-cyano 20-oxo (5α)pregnane (VII*a*), 16β-carboxy 3β-acétoxy 20-oxo (5α,17α)pregnane (VIII*b*), 16α-méthoxycarbonyl 3β-acétoxy 20-oxo (5α,17α)-pregnane (XIII) et 16β-méthoxycarbonyl 6,20-dioxo 3α:5-cyclo (5α,17α)pregnane (XV).

Le groupement cyano de ce composé d'addition (VII*a*) est ensuite hydrolysé en milieu fortement alcalin (1, 2) en acide correspondant (VIII*a*). Lorsque l'acide (VIII*a*) est acétylé à température ordinaire, l'acétate correspondant (VIII*b*) est obtenu, qui, traité successivement par le chlorure de thionyle puis par l'ammoniac, conduit au 16β-carbamoyl 3β-acétoxy 20-oxo (5α,17α)pregnane (VIII*c*). Comme dans la série du pregna-5-ène, l'hydrolyse de (VII*a*) en (VIII*a*) est accompagnée d'une double inversion de configuration en C-16 et C-17 (1(*c*), 2). Ceci se déduit aisément de l'examen des courbes de dispersion rotatoire de l'acétoxy-acide (VIII*b*) et de l'acétoxy-amide (VIII*c*). L'effet Cotton négatif présenté par la courbe de dispersion rotatoire de l'acétoxy-acide (VIII*b*) (Fig. 1) conduit à assigner la configuration β à la chaîne carboxylée en position 16. En effet, les courbes de dispersion rotatoire des composés de la série (VIII) sont superposables à celles des composés correspondants obtenus dans la série de l'iso-pregna-5-ène (X) (7). En outre, comme l'indique la Fig. 1, l'intensité du creux qui caractérise l'acétate-acide (VIII*b*) est moins négative que celle associée au creux de la courbe de dispersion rotatoire de l'ester (XIII), appartenant à la série 16α,17α, dont la préparation est signalée ci-dessous. L'acide (VIII*a*) présente par conséquent la stéréochimie du 16β-carboxy (17α)pregnane, en accord avec les observations faites dans la série du pregna-5-ène (2).

Il a été montré antérieurement (2, 10) que le traitement de l'acide (X*a*) dans des conditions particulières conduit à la lactone d'énol (XI). En outre, lorsque cette lactone (XI)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

est portée à reflux dans le méthanol en présence de bicarbonate de potassium, le 16α-méthoxycarbonyl 3β-acétoxy 20-oxo (17α)pregna-5-ène (XII) est obtenu (2). L'hydrogénation sélective sur platine de la double liaison 5,6 fournit le (5α,17α)pregnane correspondant (XIII). La courbe de dispersion rotatoire de l'ester (XIII), dont l'effet Cotton négatif intense est caractéristique de la substitution 16α-carboxy 17α-acétyle du noyau stéroïde (7), est l'image spéculaire (Fig. 1) de la courbe de dispersion rotatoire du composé d'addition (VII*a*).

Par suite de l'importante activité progestative présentée par le 3β-fluoro 20-oxo pregna-5-ène (11), il semblait intéressant de préparer l'homologue correspondant dans la série du 16β-carboxy iso-pregna-5-ène. Le 16β-carbamoyl 3β-fluoro 20-oxo (17α)pregna-5-ène (XVI*c*) a été préparé par l'intermédaire du 6β-hydroxy cyclo-stéroïde (XIV). Le composé de départ utilisé pour cette synthèse est le 16β-méthoxycarbonyl 3β-hydroxy 20-oxo (17α)pregna-5-ène (X*b*), obtenu par la suite de réactions I $\rightarrow$ IX $\rightarrow$ X*a* $\rightarrow$ X*b*, décrite antérieurement (1, 2). Le traitement de l'alcool (X*b*) par le chlorure de l'acide *p*-toluène sulfonique dans la pyridine fournit le tosylate correspondant (X*c*). La solvolyse de ce tosylate (X*c*) dans l'acétone en présence d'acétate de potassium conduit par le jeu d'un réarrangement classique (12) au cyclo-stéroïde (XIV).

La preuve de la structure de ce 16β-méthoxycarbonyl 6β-hydroxy 20-oxo 3α:5-cyclo (5α,17α)pregnane (XIV) résulte de l'oxydation de ce composé, par l'acide chromique dans l'acétone en présence d'acide sulfurique (13), en 6,20-dicétone correspondante (XV). Ce composé (XV) ne présente aucune absorption en ultraviolet dans la région de 240 mμ, même après traitement alcalin. En outre, sa courbe de dispersion rotatoire, illustrée sur la Fig. 1, confirme la structure et la stéréochimie représentée en (XV). L'allure générale de cette courbe est caractérisée par l'absence d'effets Cotton multiple associés à un système Δ^4-3-cétonique. Par ailleurs, l'effet Cotton fortement négatif présenté par cette dicétone résulte de la combinaison (14) de l'amplitude du pouvoir rotatoire moléculaire

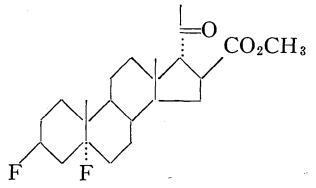
XVII



XVIII

Le traitement du 6β-hydroxy cyclo-stéroïde (XIV) par l'acide fluorhydrique conduit à un mélange qui, séparé par chromatographie, a permis d'identifier trois contituants. Le produit principal de la réaction, obtenu avec un rendement de 65%, est élué en premier lieu et répond aux propriétés du 16β-méthoxycarbonyl 3β-fluoro 20-oxo (17α)pregna-5-ène (XVI*a*). Ce dérivé fluoré (XVI*a*) résulte d'une attaque nucléophile en position 3 du composé (XIV) par l'ion F^- (17). L'analyse élémentaire du second constituant du mélange (11%), légèrement plus polaire sur la colonne que le composé principal de la réaction (XVI*a*), répond à la formule empirique $C_{23}H_{34}O_3F_2$. Par analogie avec la remarquable addition d'acide fluorhydrique sur la liaison éthylénique 5,6 de l'acétate de pregnénolone (XVII), observée dans des conditions expérimentales identiques (18), la structure (XVIII) est proposée pour ce composé difluoré. Ce 3β,5α-difluoro-stéroïde (XVIII) résulte vraisemblablement de l'addition d'acide fluorhydrique sur la liaison éthylénique 5,6 du fluoro-ester (XVI*a*), grâce à la présence du tétrahydrofuranne, qui, jouant le rôle d'accepteur de protons, augmente ainsi la concentration en ions fluorures dans le milieu réactionnel (19). Enfin, le troisième produit de cette réaction (isolé avec 8%) répond aux propriétés du 3β-hydroxy-ester (X*b*), produit probable de l'hydrolyse du 3β-fluoro-ester (XVI*a*) dans les conditions de l'expérience.

A partir de l'ester (XVI*a*), la fluoro-amide (XVI*c*) est préparée par hydrolyse alcaline, traitement de l'acide libre (XVI*b*) au chlorure de thionyle, suivi de réaction avec l'ammoniac. La configuration assignée aux dérivés fluorés (XVI*a*), (XVI*c*) et (XVIII) résulte également de l'examen de leurs courbes de dispersion rotatoire. Celles-ci, caractérisées par un effet Cotton négatif, sont superposables aux courbes des composés correspondants de la série oxygénée en position 3 (X) (7). Dès lors, la stéréochimie 16β-carboxy 17α-acétyle est attribuée à ces dérivés fluorés (XVI*a*), (XVI*c*) et (XVIII).

PARTIE EXPÉRIMENTALE

Les microanalyses ont été effectuées par le Dr. A. Bernhardt, Max Planck Institut, Mühlheim (Allemagne), et par les Laboratoires Midwest, Forest Lane, Indianapolis (Etats Unis).

Les pouvoirs rotatoires sont mesurés à 16–22° avec un tube de 1 dm pour la raie jaune du sodium (589 mμ).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Les courbes de dispersion rotatoire ont été prises avec un spectropolarimètre enregistreur Rudolph. Les pouvoirs rotatoires reportés sur la Fig. 1 et dans cette section sont exprimés en pouvoirs rotatoires moléculaires [Φ] (15).

Les points de fusion ont été mesurés en tubes capillaires à l'aide d'un appareil "Mel-temp"; ils ne sont pas corrigés.

Les spectres infra-rouges ont été obtenus avec un spectrophotomètre Perkin–Elmer, modèle 21, prisme NaCl.

Les spectres ultraviolets ont été déterminés avec un spectrophotomètre Beckman, modèle DU; EtOH: alcool éthylique à 95%.

Nous remercions M. J. C. Matthews pour les déterminations spectroscopiques et les pouvoirs rotatoires.

3β-Acétoxy 20-oxo 16:17α-époxy (5α)pregnane (III)

On dissout 1 g de l'époxy-pregnène (II) (3) dans 10 ml d'acétate d'éthyle et cette solution est hydrogénée en présence de 400 mg de palladium sur charbon (à 5%), jusqu'à absorption d'une molécule d'hydrogène. Après filtration du catalyseur, lavage au chloroforme et évaporation des solvents sous vide, on obtient 1.040 mg de (III), p.f. 178–181°. On recristallise par dissolution dans l'acétone, dilution avec l'hexane et évaporation de l'acétone; p.f. 183–185°; $[\alpha]_D$ +48° (*c*, 0.2; $CHCl_3$). Spectre UV: λ_{max}^{EtOH} 295 mμ (log ε: 1.56). Spectre IR: ν_{max}^{KBr} 1739 et 1242 cm^{-1} (acetate), 1706 cm^{-1} (20-cétone). (Plattner *et al.* (4(*b*)): p.f. 186–187°; $[\alpha]_D$ +52° (*c*, 1.2; $CHCl_3$).)

Traitement de l'époxyde (III) par le chlorure de chromyle

On dissout 1 g de l'époxyde (III) dans 20 ml d'acétone, ajoute 20 ml d'acide acétique glacial et agite cette solution durant 10 minutes à température ambiante. A ce mélange homogène, on additionne lentement une solution de chlorure de chromyle préparée comme suit (5): on mélange 15 g de zinc, 20 ml d'eau, 1.2 g de chlorure mercurique et 1 ml d'acide chlorhydrique concentré et agite ce mélange jusqu'à obtention d'une solution claire, qui est décantée; l'amalgame est ensuite lavé à l'eau. On ajoute alors à cet amalgame 25 ml d'eau, puis 6 ml d'acide chlorhydrique concentré. On fait ensuite passer un lent courant d'anhydride carbonique à travers cette solution. Le chlorure chromique (8 g) est ajouté par petites portions, tandis que le mélange réactionnel est agité vigoureusement jusqu'au virage de la coloration verte au bleu. Après addition de cette solution à la solution contenant le stéroïde, le mélange réactionnel est agité vigoureusement durant 30 minutes. On ajoute alors de l'eau et de la glace et extrait plusieurs fois le composé organique au chloroforme. La phase organique est concentrée sous vide, 100 ml d'acétone sont ajoutés, puis 1 ml d'acide chlorhydrique concentré. Après 2 heures de chauffage à reflux, le mélange réactionnel est repris par l'eau et le composé organique est extrait plusieurs fois au chloroforme. On lave à l'eau à neutralité, sèche sur sulfate de sodium anhydre et évapore les solvants sous vide.

Le produit brut obtenu (95%) est chromatographié sur 50 g d'alumine neutre. L'élution de la colonne par l'hexane fournit 35 mg de *20-oxo (5α)pregna-2,16-diène* (VI), qui, recristallisé dans un mélange acétone–hexane, présente les constantes physiques: p.f. 148–151°; $[\alpha]_D$ +48° (*c*, 0.2; $CHCl_3$). Spectre UV: λ_{max}^{EtOH} 240 mμ (log ε: 3.94), 318 mμ (log ε: 1.77). Spectre IR: ν_{max}^{KBr} 1656 et 1582 cm^{-1} (Δ^{16}-20-cétone). Anal. Calc. pour $C_{21}H_{30}O,1/2CH_3COCH_3$: C, 82.51; H, 10.16. Trouvé: C, 82.46; H, 10.53.

L'élution par un mélange hexane–benzène (98:2) conduit à 780 mg du composé (IV*b*), qui, recristallisé dans un mélange de chlorure de méthylène et hexane, fournit l'échantillon analytique de *3β-acétoxy 20-oxo (5α)pregna-16-ène* (IV*b*); p.f. 164–165°; $[\alpha]_D$ +43° (*c*, 1; $CHCl_3$). Spectre UV: λ_{max}^{EtOH} 240 mμ (log ε: 4.0), 318 mμ (log ε: 1.76). Spectre IR: ν_{max}^{KBr} 1730 et 1248 cm^{-1} (acétate), 1656 et 1587 cm^{-1} (Δ^{16}-20-cétone). (Plattner *et al.* (4(*b*)): p.f. 166–167°; $[\alpha]_D$ +42° (*c*, 1.2; $CHCl_3$).) Anal. Calc. pour $C_{23}H_{34}O_3$: C, 77.16; H, 9.57; O, 13.41. Trouvé: C, 76.81; H, 9.33; O, 13.42.

L'élution ultérieure de la colonne de chromatographie par un mélange benzène–chloroforme (3:1) conduit ensuite à 50 mg de *16α-hydroxy 3β-acétoxy 20-oxo (5α)pregnane* (V*b*), dont l'échantillon analytique, obtenu par recristallisation dans un mélange acétone–hexane, présente les constantes suivantes: p.f. = 185–187°; $[\alpha]_D$ +48° (*c*, 0.8; $CHCl_3$). Spectre UV: λ_{max}^{EtOH} 280 mμ (log ε: 1.77). Spectre IR: ν_{max}^{KBr} 3333 cm^{-1} (OH), 1730 et 1248 cm^{-1} (acétate), 1701 cm^{-1} (20-cétone). (Neher *et al.* (6): p.f. 184–186°.) Anal. Calc. pour $C_{23}H_{36}O_4$: C, 73,36; H, 9.64. Trouvé: C, 72.79; H, 9.48.

Enfin, le dernier composé, de polarité très voisine de celle de (V*b*), est élué peu après celui-ci par le même mélange benzène–chloroforme (3:1). On obtient ainsi 15 mg de l'hydroxy-ènone (IV*a*); p.f. 182–185°. Ce composé s'est avéré identique au *3β-hydroxy 20-oxo (5α)pregna-16-ène* (IV*a*) obtenu ci-dessous par hydrolyse alcaline de l'acétate (IV*b*) (pas de dépression du point de fusion, et les spectres infra-rouges sont superposables).

Hydrolyse alcaline de l'acétate (IVb)

On abandonne 20 heures à la température ambiante la solution de 200 mg de (IV*b*) (p.f. 143–145°) et 200 mg d'hydroxyde de potassium dans 10 ml de méthanol. On dilue à l'eau, extrait à l'acétate d'ethyle, lave à neutralité, sèche et évapore à sec pour obtenir 160 mg; p.f. 183–186°. Après recristallisation dans un mélange acétone–hexane, on obtient le *3β-hydroxy 20-oxo (5α)pregna-16-ène* (IV*a*); p.f. 187–190°; $[\alpha]_D$ +36° (*c*, 0.4; $CHCl_3$). Spectre UV: λ_{max}^{EtOH} 240 mμ (log ε: 3.92), 320 mμ (log ε: 1.73). Spectre IR: ν_{max}^{KBr} 3413 cm^{-1} (OH), 1658 et 1590 cm^{-1} (Δ^{16}-20-cétone). Anal. Calc. pour $C_{21}H_{32}O_2$: C, 79.70; H, 10.19. Trouvé: C, 79.72; H, 9.83.

3β-Hydroxy 16α-cyano 20-oxo (5α)pregnane (VIIa)

Un mélange de 1 g de (IV*b*) dans 20 ml de méthanol contenant 1 g de cyanure de potassium et 2 ml d'eau est chauffé à reflux durant 2 heures. Le mélange réactionnel est repris par l'eau et le précipité qui se forme est filtré, lavé à l'eau et sèché. On récolte 1.1 g de (VII*a*), p.f. 195–202°, qui est recristallisé dans un mélange chlorure de méthylène et méthanol; p.f. 226–227°; $[\alpha]_D$ +75° (*c*, 2; $CHCl_3$). DR: méthanol (*c*, 0.023): $[\Phi]_{700}$ +135°; $[\Phi]_{589}$ +165°; $[\Phi]_{302.5}$ +9060°; $[\Phi]_{262.5}$ −11,500°; $[\Phi]_{250}$ −10,650°. Spectre UV: λ_{max}^{EtOH} 272 mμ (log ε: 1.61). Spectre IR: ν_{max}^{KBr} 3436 cm^{-1} (OH), 2222 cm^{-1} (cyano), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{22}H_{33}O_2N$: C, 76.92; H, 9.68; O, 9.32; N, 4.08. Trouvé: C, 77.03; H, 9.69; O, 9.20; N, 4.07.

3β-Acétoxy 16α-cyano 20-oxo (5α)pregnane (VIIb)

Une solution de 500 mg de (VII*a*) dans 2 ml de pyridine anhydre et 1 ml d'anhydride acétique est abandonnée 16 heures à 22°. On dilue à l'eau, filtre le précipité que s'est formé, lave plusieurs fois avec une solution diluée d'acide chlorhydrique (5%), puis à l'eau et sèche ensuite sur sulfate de sodium anhydre. On obtient ainsi 550 mg de l'acétate (VII*b*), p.f. 166–169°. Une recristallisation dans un mélange chloroforme–méthanol donne de longs cristaux soyeux; p.f. 172–174°; $[\alpha]_D$ +62° (*c*, 1; $CHCl_3$). DR: méthanol (*c*, 0.060): $[\Phi]_{700}$ +182°; $[\Phi]_{589}$ +231°; $[\Phi]_{305}$ +9250°; $[\Phi]_{260}$ −1610°. Spectre UV: λ_{max}^{EtOH} 281 mμ (log ε: 1.68). Spectre IR: ν_{max}^{KBr} 2217 cm^{-1} (cyano), 1727 et 1250 cm^{-1} (acétate), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{24}H_{35}O_3N$: C, 74.76; H, 9.15; O, 12.45; N, 3.63. Trouvé: C, 74.68; H, 9.18; O, 12.66; N, 3.67.

16β-Carboxy 3β-hydroxy 20-oxo (5α,17α)pregnane (VIIIa)

On porte à reflux durant 1 heure, une solution contenant 1 g du dérivé cyané (VII*a*) dans 60 ml d'alcool éthylique, 4 g d'hydroxyde de potassium et 15 ml d'eau. Le mélange réactionnel est repris par l'eau, et extrait à l'acétate d'éthyle afin d'éliminer le composé de départ (VII*a*) (120 mg). La phase aqueuse est neutralisée à l'aide d'une solution diluée d'acide chlorhydrique (10%) et le précipité que se forme est filtré, lavé à pH neutre et sèché; p.f. 218–221° (695 mg). Après recristallisation dans le méthanol contenant quelques gouttes d'eau, on obtient l'échantillon analytique de l'acide (VIII*a*), p.f. 219–222°, $[\alpha]_D$ −38° (*c*, 0.4; CH_3OH). Spectre UV: λ_{max}^{EtOH} 281 mμ (log ε: 1.60). Spectre IR: $\nu_{max}^{CHCl_3}$ 3333 cm^{-1} (OH), 1720–1705 cm^{-1} (bande large et intense: 16-carboxy et 20-cétone). Anal. Calc. pour $C_{22}H_{34}O_4$: C, 72.89; H, 9.45; O, 17.66. Trouvé: C, 72.73; H, 9.49; O, 17.95.

16β-Carboxy 3β-acétoxy 20-oxo (5α,17α)pregnane (VIIIb)

On abandonne 18 heures à la température ambiante la solution de 500 mg de l'hydroxy-acide (VIII*a*) dans 1 ml de pyridine anhydre et 0.5 ml d'anhydride acétique. On dilue à l'eau, filtre le composé cristallin qui précipite, lave et sèche. Après recristallisation dans un mélange de chlorure de méthylène et hexane, l'acétate (VIII*b*) présente les caractéristiques physiques suivantes: p.f. 195–198°; $[\alpha]_D$ −51° (*c*, 1; $CHCl_3$). DR: méthanol (*c*, 0.060): $[\Phi]_{700}$ −348°; $[\Phi]_{589}$ −384°; $[\Phi]_{302.5}$ −5370°; $[\Phi]_{260}$ +4950°; $[\Phi]_{252.5}$ +4580°; $[\Phi]_{250}$ +4860°. Spectre IR: ν_{max}^{KBr} 3344 cm^{-1} (OH), 1733 et 1241 cm^{-1} (acétate), 1704 cm^{-1} (16-carboxyle et 20-cétone). Anal. Calc. pour $C_{24}H_{36}O_5$: C, 71.25; H, 8.97; O, 19.78. Trouvé: C, 71.03; H, 8.89; O, 19.82.

16β-Carbamoyl 3β-acétoxy 20-oxo (5α,17α)pregnane (VIIIc)

On dissout 1 g de l'acétoxy-acide (VIII*b*) dans 30 ml de benzène anhydre, puis distille lentement 10 ml de benzène pour éliminer toute trace d'humidité. Cette solution est ensuite refroidie dans la glace et 0.9 ml de chlorure de thionyle fraîchement distillé est ajouté lentement. Après 2 heures de chauffage à reflux, le mélange réactionnel est évaporé à sec, sous vide. On ajoute ensuite 30 ml de tétrahydrofuranne anhydre à ce chlorure de l'acide (VIII*b*). La solution est laissée au repos durant 15 minutes à 0°, puis on ajoute 25 ml d'hydroxyde d'ammonium. On conserve le mélange réactionnel, agité magnétiquement, 16 heures à la température ambiante. On dilue ensuite à l'eau, extrait à l'acétate d'éthyle, lave à neutralité, sèche et évapore à sec pour obtenir, après deux cristallisations dans un mélange de chlorure de méthylène et méthanol, 210 mg de l'amide (VIII*c*); p.f. 207–209°; $[\alpha]_D$ −57° (*c*, 1; $CHCl_3$). DR: méthanol (*c*, 0.060): $[\Phi]_{700}$ −230°; $[\Phi]_{589}$ −262°; $[\Phi]_{302.5}$ −5480°; $[\Phi]_{257.5}$ +5560°; $[\Phi]_{252.5}$ +5250°. Spectre IR: ν_{max}^{KBr} 3344 cm^{-1} (NH_2), 1656 et 1618 cm^{-1} (amide), 1730 et 1252 cm^{-1} (acétate), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{24}H_{37}O_4N$: C, 71.43; H, 9.24; O, 15.86; N, 3.47. Trouvé: C, 71.68; H, 9.23; O, 15.60; N, 3.36.

16α-Méthoxycarbonyl 3β-acétoxy 20-oxo (5α,17α)pregnane (XIII)

L'acétate-ester (XII) (200 mg) (2) dans 30 ml de méthanol est hydrogéné en présence de 50 mg d'oxyde de platine, préalablement réduit dans 10 ml de méthanol. En 2 heures on a fixé la quantité théorique d'hydrogène. Après filtration et lavage du catalyseur, le solvant est évaporé. On récolte 170 mg de (XIII), p.f. 197–200°. Pour analyse, on recristallise dans un mélange de chlorure de méthylène et hexane; p.f. 203–205°; $[\alpha]_D$ −79° (*c*, 0.6; $CHCl_3$). DR: Méthanol (*c*, 0.027): $[\Phi]_{700}$ −528°; $[\Phi]_{589}$ −587°; $[\Phi]_{305}$ −9100°; $[\Phi]_{262.5}$ +7530°; $[\Phi]_{250}$ +6190°. Spectre UV: λ_{max}^{EtOH} 283 mμ (log ε: 1.79). Spectre IR: ν_{max}^{KBr} 1739 et 1250 cm^{-1} (acétate), 1730 cm^{-1} (16-méthoxycarbonyl), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{25}H_{38}O_5$: C, 71.74; H, 9.15; O, 19.11. Trouvé: C, 71.68; H, 9.24; O, 19.15.

16β-Méthoxycarbonyl 3β-p-toluènesulfonate 20-oxo (17α)pregna-5-ène (Xc) (avec H. Barrera)

On laisse reposer 92 heures à la température ambiante la solution de 1.8 g de l'ester (X*b*) (p.f. 198–199°), préparé à partir de l'énone (I) suivant la séquence I → IX → X*a* → X*b*, décrite précédemment (1, 2),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

et 4.12 g de chlorure de l'acide *p*-toluènesulfonique recristallisé, dans 70 ml de pyridine anhydre. Après réaction, on dilue à l'eau, extrait à l'acétate d'éthyle, lave à neutralité, sèche sur sulfate de sodium anhydre et concentre le solvant sous vide, pour obtenir 1.55 g du tosylate (X*c*), p.f. 145–148°. Après recristallisation dans un mélange de chlorure de méthylène et hexane, on obtient l'échantillon analytique; p.f. 148–149°; $[\alpha]_D$ −86° (*c*, 0.9; $CHCl_3$). Spectre UV: λ_{max}^{EtOH} 224 mμ (log ε: 4.09), 256 mμ (log ε: 2.65), 262 mμ (log ε: 2.74), 267 mμ (log ε: 2.69), 274 mμ (log ε: 2.57). Spectre IR: ν_{max}^{KBr} 1733 cm^{-1} (16-ester), 1709 cm^{-1} (20-cétone), 1603, 1351 et 1174 cm^{-1} (tosylate). Anal. Calc. pour $C_{30}H_{40}O_6S$: C, 68.14; H, 7.63; O, 18.16; S, 6.07. Trouvé: C, 68.09; H, 7.58; O, 18.46; S, 5.92.

16β-Méthoxycarbonyl 6β-hydroxy 20-oxo 3α:5-cyclo (5α,17α)pregnane (XIV) (avec H. Barrera)

Une solution contenant 822 mg de tosylate (X*c*) et 910 mg d'acétate de potassium dans 31 ml d'acétone aqueux (50%) est maintenue à reflux durant 24 heures. Ensuite, l'acétone est évaporé sous vide, et le précipité qui se forme est collecté sur filtre et séché. Le produit brut ainsi obtenu est chromatographié sur 50 g d'alumine neutre. Le benzène élue 465 mg de (XIV), p.f. 187–189°, qu'on recristallise dans un mélange de chlorure de méthylène et hexane; p.f. 191–192°; $[\alpha]_D$ −36° (*c*, 1; $CHCl_3$). DR: méthanol (*c*, 0.030): $[\Phi]_{700}$ −64°; $[\Phi]_{589}$ −157°; $[\Phi]_{300}$ −5400°; $[\Phi]_{255}$ +7740°; $[\Phi]_{250}$ +7510°. Spectre IR: ν_{max}^{KBr} 3509 cm^{-1} (OH), 1733 cm^{-1} (16-ester), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{23}H_{34}O_4$: C, 73.76; H, 9.15; O, 17.09. Trouvé: C, 73.84; H, 9.10; O, 17.16.

16β-Méthoxycarbonyl 6,20-dioxo 3α:5-cyclo (5α,17α)pregnane (XV) (avec H. Barrera)

On ajoute goutte à goutte 0.35 ml de solution 8 *N* d'acide chromique dans l'acide sulfurique dilué (13) à 374 mg de l'alcool (XIV) dans 15 ml d'acétone (distillé sur permanganate), le mélange étant maintenu à 0°. On agite à l'aide d'un barreau magnétique 5 minutes à 0°. On verse dans l'eau, ajoute une solution diluée de bicarbonate de sodium (10%), extrait le précipité à l'acétate d'éthyle, lave à neutralité, sèche et évapore. Ce composé brut, passé sur 5 g d'alumine neutre, est élué par un mélange hexane–benzène (4:1). L'échantillon analytique de la dicétone (XV) est obtenu par recristallisation dans un mélange de chlorure de méthylène et hexane; p.f. 154–155°; $[\alpha]_D$ −25° (*c*, 1; $CHCl_3$). DR: méthanol (*c*, 0.063): $[\Phi]_{700}$ −18°; $[\Phi]_{589}$ −54°; $[\Phi]_{302.5}$ −7620°; $[\Phi]_{255}$ +3640°. Spectre UV: λ_{max}^{EtOH} 282 mμ (log ε: 1.92) (identique en milieu alcalin). Spectre IR: ν_{max}^{KBr} 1739 cm^{-1} (16-ester), 1712 cm^{-1} (6-cétone), 1698 cm^{-1} (20 cétone). Anal. Calc. pour $C_{23}H_{32}O_4$: C, 74.16; H, 8.66; O, 17.18. Trouvé: C, 74.48; H, 8.46; O, 17.30.

16β-Méthoxycarbonyl 3β-fluoro (17α)pregna-5-ène (XVIa) et 16β-méthoxycarbonyl 3β,5α-difluoro (17α)-pregnane (XVIII)

Dans un récipient en polyéthylène, muni d'un barreau magnétique, et contenant un mélange d'un gramme de l'alcool (XIV) dans 50 ml de chlorure de méthylène anhydre et maintenu à −70°, on ajoute goutte à goutte, avec agitation, une solution refroidie à −70° de 4 g d'acide fluorhydrique dans 30 ml de tétrahydrofuranne anhydre. Le mélange réactionnel est ensuite laissé 24 heures à 0°. On verse alors prudemment cette solution dans un large excès de carbonate de sodium (solution à 10%) et extrait au chloroforme. Après traitement habituel on obtient 880 mg d'un mélange, p.f. 138–150°. Ce mélange est chromatographié sur 30 g d'alumine neutre. L'hexane élue 90% tandis que les derniers 10% sont élués au benzène–chloroforme (9:1); p.f. 201–203°; $[\alpha]_D$ −110° (*c*, 0.7; $CHCl_3$). Le point de fusion de mélange avec un échantillon du 16β-méthoxycarbonyl 3β-hydroxy (17α)pregna-5-ène (X*b*)(2) ne donne pas de dépression et les spectres infra-rouges sont superposables.

Le produit cristallisé obtenu par élution à l'hexane présente: p.f. 142–158°; $[\alpha]_D$ −71° (*c*, 0.8; $CHCl_3$). Une rechromatographie minutieuse de 200 mg de ce mélange sur 25 g d'alumine a permis une meilleure séparation des deux constituants. L'hexane élue 165 mg d'un composé, p.f. 141–145°, $[\alpha]_D$ −83° (*c*, 0.7; $CHCl_3$), qui, recristallisé dans un mélange de chlorure de méthylène et hexane, fournit l'échantillon analytique du composé fluoré (XVI*a*): cristaux primatiques; p.f. 146–146.5°; $[\alpha]_D$ −116° (*c*, 0.8; $CHCl_3$). DR: méthanol (*c*, 0.065): $[\Phi]_{700}$ −128°; $[\Phi]_{589}$ −271°; $[\Phi]_{302.5}$ −6330°; $[\Phi]_{260}$ +3140°. Spectre IR: ν_{max}^{KBr} 1735 cm^{-1} (16-ester), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{23}H_{33}O_3F$: C, 73.36; H, 8.84; F, 5.05. Trouvé: C, 73.35; H, 8.71; F, 5.57.

L'élution ultérieure de la colonne de chromatographie par un mélange hexane–benzène (9:1) conduit à environ 25 mg d'un composé; p.f. 181–189°; $[\alpha]_D$ −59° (*c*, 0.2; $CHCl_3$). Par recristallisation de cette substance dans un mélange de chlorure de méthylène et hexane, on obtient le composé difluoré (XVIII), p.f. 192–194°; $[\alpha]_D$ −59° (*c*, 0.4; $CHCl_3$). DR: méthanol (*c*, 0.065): $[\Phi]_{700}$ −187°; $[\Phi]_{589}$ −285°; $[\Phi]_{302.5}$ −6605°; $[\Phi]_{265}$ +3780°. Spectre IR: ν_{max}^{KBr} 1734 cm^{-1} (16-ester), 1701 cm^{-1} (20-cétone). Anal. Calc. pour $C_{23}H_{34}O_3F_2$: C, 69.74; H, 8.60; F, 9.63. Trouvé: C, 70.00; H, 8.56; F, 9.94.

16β-Carbamoyl 3β-fluoro 20-oxo (17α)pregna-5-ène (XVIc)

On porte à reflux durant 2 heures une solution contenant 1 g du fluoro-ester (XVI*a*), 8 g d'hydroxyde de potassium dans 5 ml d'eau et 160 ml de méthanol. Le mélange réactionnel est repris par l'eau, acidifié par une solution d'acide chlorhydrique (10%), extrait, lavé et séché. Le spectre infra-rouge du produit brut présente une large bande carboxyle dans la région de 1720 cm^{-1}, correspondant à l'acide (XVI*b*). Cet acide n'est pas isolé mais immédiatement traité, 2 heures à reflux dans 30 ml de benzène anhydre, par 0.9 ml de chlorure de thionyle fraîchement distillé. On évapore ensuite, sous vide poussé, le benzène et le chlorure de thionyle en excès. Le chlorure d'acide sec, ainsi obtenu, est additioné de 20 ml de tétrahydrofuranne anhydre,

THE STRUCTURE OF PULCHERRIMINIC ACID[1]

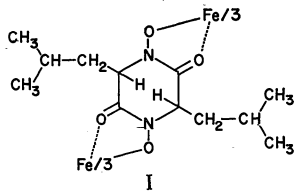
J. C. MacDonald
The National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan
Received August 7, 1962

ABSTRACT

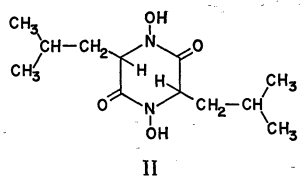
The red pigment pulcherrimin was isolated from three strains of *Candida pulcherrima* and converted to pulcherriminic acid. The properties of derivatives of this acid and the products obtained from its reduction indicate that it differs from pulcherriminic acid isolated by other workers. A probable structure for the new pulcherriminic acid is 2,5-diisobutyl-3,6-dihydroxypyrazine-1,4-dioxide. The structures of the compounds obtained from its reduction were also investigated.

INTRODUCTION

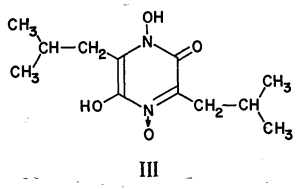
Pulcherrimin, the red pigment of *Candida pulcherrima*, was first isolated by Kluyver *et al.* (1), who proposed structure I for the compound. Early work by Cook and Slater (2) supported this structure, and it was shown that pulcherrimin could be converted to a dibasic acid, pulcherriminic acid, which gave L-leucine anhydride (2,5-diisobutyl-3,6-dioxopiperazine) on reduction with zinc and acetic acid, which in turn gave L-leucine on hydrolysis. Structure II was proposed for pulcherriminic acid, but when the same workers later prepared synthetic (racemic) 2,5-diisobutyl-1,4-dihydroxy-3,6-dioxopiperazine (3)



I



II



III

and found that it was not identical with natural pulcherriminic acid, further investigations were carried out which led to the proposal of structure III for pulcherriminic acid (4). In this structure the isobutyl substituents are attached to carbons-2 and -5 of the ring, and these carbon atoms should become carbon-2 of leucine on degradation by zinc – acetic acid reduction followed by hydrolysis. One would not expect optically active leucine from this degradation if structure III were correct, and the present work was undertaken to try and resolve this discrepancy. However, it was not possible to do this, because the pulcherriminic acid obtained in the present work appeared to differ in its properties and in its reactions from that described by Cook and Slater. The pulcherriminic acid, and especially its morpholinium and cyclohexylammonium salts, had lower solubilities than the corresponding compounds described by Cook and Slater (2). The latter salts could not be recrystallized from butanol–morpholine or butanol–cyclohexylamine, respectively, as described by these workers. The cyclohexylammonium salt of pulcherriminic acid obtained in this study was more soluble in water than in organic solvents, whereas Cook and Slater found that their salt was sparingly soluble in water, but soluble in common organic solvents. In an attempt to obtain pulcherriminic acid with the properties described by these workers, two strains of *C. pulcherrima*, other than the one

[1]*Issued as N.R.C. No. 7053.*

For personal use only.

supplied by Dr. A. H. Cook, were used to produce pulcherrimin. However, the pulcherriminic acid isolated from all three strains had the same melting point and infrared spectra (Fig. 1), and the morpholinium and cyclohexylammonium salts showed the same

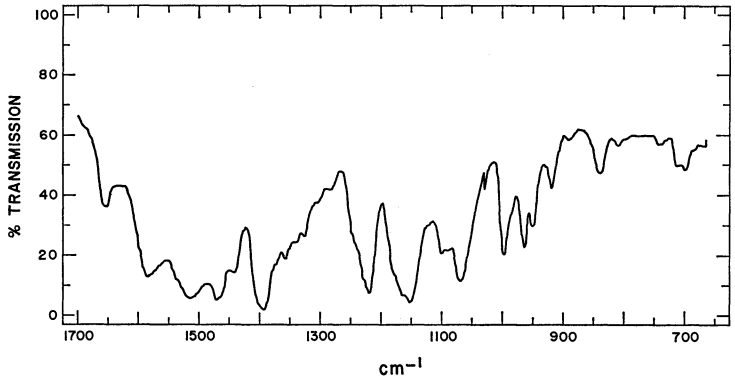

FIG. 1. Infrared spectrum of pulcherriminic acid. Solid in KBr.

low solubility in organic solvents. Therefore the work described below is concerned primarily with the properties and reactions of this new pulcherriminic acid.

The yield of purified pulcherriminic acid from pulcherrimin was quite good. For example, 81.7 mg of pulcherriminic acid, purified through its morpholinium salt, was obtained from 145 mg of pulcherrimin isolated from *C. pulcherrima*. This yield, together with the finding that crude pulcherrimin and the ferric salt made from the isolated pulcherriminic acid had identical infrared spectra (Fig. 2), indicates that the pulcherriminic acid isolated

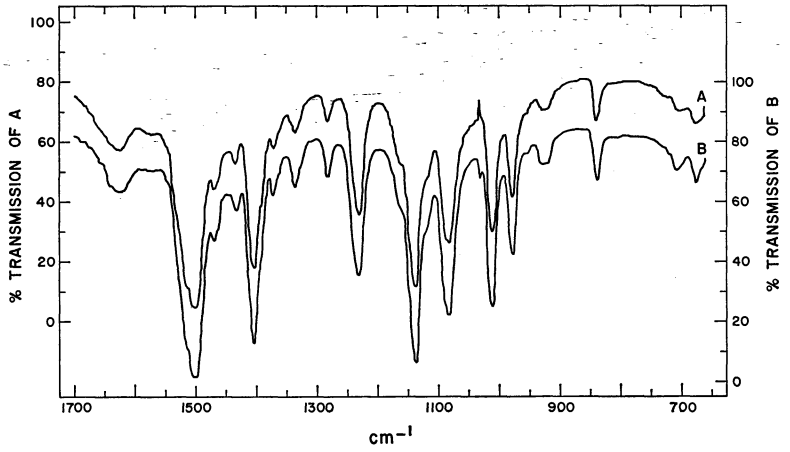

FIG. 2. Infrared spectrum of pulcherrimin (A) and the ferric salt of pulcherriminic acid (B). Solid in KBr. The absorption at 1625 cm^{-1} is due to an impurity in the KBr.

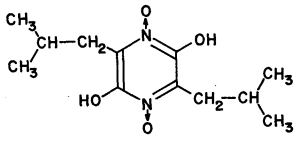
was the free acid whose ferric salt is pulcherrimin, and was not merely a minor constituent of the natural pigment pulcherrimin. Values for the percentage of iron in the ferric salt of pulcherriminic acid were, in general, too high, until a modification of a procedure used by Kluyver *et al.* (1) to prepare material of constant analysis from crude pulcherrimin

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was adopted. The procedure presumably removed coprecipitated ferric ions and consisted of heating the freshly precipitated ferric salt with acidic ethanol, while Kluyver *et al.* used strong acid and longer periods of heating.

The pulcherriminic acid isolated here had the empirical formula $C_{12}H_{20}N_2O_4$, and was dibasic, as shown by the titration of its morpholinium salt, and the elemental analysis of its morpholinium and cyclohexylammonium salts. The percentage of carbon found by analysis of these salts differs somewhat from that expected; this difference may be due to their instability and may indicate that it is difficult to obtain them absolutely pure. The pulcherriminic acid probably contains no asymmetric carbon atoms, because it was reduced to DL-leucine anhydride with zinc and acetic acid. The proton magnetic resonance spectra of pulcherriminic acid (Table I) indicated that the acid has two isobutyl side chains, and no ring hydrogen atoms. This evidence indicates that the pulcherriminic acid has structure IV or possibly a tautomer of this structure, III.



IV

TABLE I

Analysis of functional groups by proton magnetic resonance spectrometry

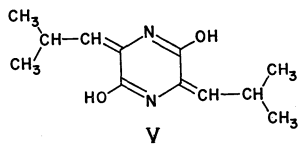
Compound*	Number of protons in functional groups†					
		Isobutyl group	Isobutylidene group			
	CH_3	$CH + CH_2$	CH	=CH	Ring H	NH
Pulcherriminic acid	12 (9.37, 9.26)	6.1 (CH multiplet 8.0; CH_2 7.35, 7.22)	0	0	0	0
Pulcherriminic acid sodium salt in D_2O	12 (9.14, 9.03)	6.3 (CH multiplet 7.8; CH_2 7.27, 7.16)	0	0	0	0
Compound A	12 (9.28, 9.17)	0	1.8 (multiplet 7.6)	1.8 (4.08, 3.90)	0	0
Compound B	12 (9.40, 9.32, 9.28, 9.17)	3.3 (8.53, 8.46)	1.3 (multiplet 7.6)	1.1 (4.07, 3.91)	1.1 (5.92)	1.2 (1.75)
DL-Leucine anhydride	12 (9.37, 9.30)	6.4 (8.50, 8.43)	0	0	1.8 (5.97)	1.9 (1.98, 1.80)

*The solvent was trifluoroacetic acid unless otherwise stated.
†This was calculated from the integral curve or from the areas under the peaks, setting the value for CH_3 protons equal to 12. Figures in parentheses represent the τ values (9) of the major peaks. Data were obtained with a Varian model A-60 n.m.r. spectrometer with tetramethylsilane as an external reference.

The reduction of pulcherriminic acid by phosphorus and iodine in acetic acid yielded at least three products, one of which was leucine anhydride. While pulcherriminic acid itself has no exocyclic double bonds, the other two products, compounds A and B, did have such bonds (see below). This indicates that there is a migration of double bonds during the reduction and that the structure of these derivatives could lead to a misinterpretation of the structure of the parent compound.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

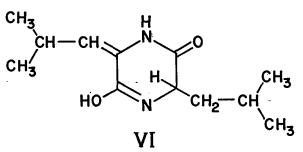
Compound A resembled a compound which Kluyver *et al.* (1) obtained from the pyrolysis of pulcherrimin in the presence of zinc dust. Both the compound obtained here and that obtained by Kluyver *et al.* had the empirical formula $C_{12}H_{18}N_2O_2$ and their ultraviolet spectra showed a single absorption maximum near 280 mμ (Fig. 3). The proton magnetic resonance spectrum of compound A (Table I) indicated that it has two isobutylidene substituents on the ring and no NH groups, which is consistent with structure V.



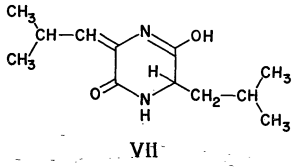
V

The results of degradation of compound A are also compatible with this structure. On hydrolysis, α-keto isocaproic acid (1.7 moles of derivative per mole of A) was formed, undoubtedly by decomposition of dehydroleucine released on hydrolysis (5). Ozonolysis of compound A yielded isobutyraldehyde, and reduction, leucine anhydride. Compound A was obtained in much higher yield from the reduction of pulcherriminic acid with phosphorus and iodine when acetic anhydride was added to the reaction mixture.

The proton magnetic resonance spectrum of compound B (Table I) indicates that it has an isobutyl side chain, an isobutylidene side chain, one ring hydrogen atom, and one NH group. This, together with its empirical formula $C_{12}H_{20}N_2O_2$ and the fact that it gave leucine anhydride on hydrogenation, indicates that its structure is either VI or VII.



VI



VII

Compound B yielded, on hydrolysis, DL-leucine (0.9 mole per mole of B) and α-keto isocaproic acid (0.7 mole of crude derivative per mole of B), and on ozonolysis isobutyraldehyde. These results are compatible with either structure.

The structure proposed here for pulcherriminic acid (IV, 2,5-diisobutyl-3,6-dihydroxypyrazine-1,4-dioxide) is well supported by the proton magnetic resonance spectra and the fact that DL-leucine anhydride is formed by zinc – acetic acid reduction. However, since the pulcherriminic acid isolated by Cook and Slater (2) gave L-leucine anhydride on reduction, it probably had a structure similar to II, with optically active centers of L-configuration at positions 2 and 5 of the ring. The empirical formula for their compound (4) would require that either the 2- or 5-substituent contained a double bond, which might lead to the formulation of their product as either 2-isobutyl-5-(2-methyl-1-propenyl)-1,4-dihydroxy-3,6-dioxopiperazine or 2-isobutyl-5-(2-methyl-2-propenyl)-1,4-dihydroxy-3,6-dioxopiperazine. It is possible that the pigment pulcherrimin is not necessarily a single compound but that its structure might vary slightly depending on the strain and the growth conditions used. However, only the one compound could be isolated in the experiments done here, and no further attempts to obtain a different compound are contemplated. The infrared spectra of pulcherrimin and pulcherriminic acid (Figs. 1 and 2) may prove of value to other workers in establishing whether the pulcherrimin isolated from other strains is the same as that described in this paper.

EXPERIMENTAL

Origin and Maintenance of Cultures

Candida pulcherrima PRL 2019 was a strain kindly supplied by Dr. A. H. Cook, Brewing Industry Research Foundation, Nutfield, Surrey, England. *C. pulcherrima* PRL 1933 was a red-pigmented mutant isolated from *C. pulcherrima* ATCC 7696. *C. pulcherrima* PRL 2007 was obtained from the Centraalbureau voor Schimmelcultures, C.B.S. number 1901, and was the strain used by Kluyver *et al.* (1) for the production of pulcherrimin. All cultures were maintained on slants of the agar medium described by Kluyver *et al.* (1), except that 1 g of Difco yeast extract replaced 1 ml of yeast autolyzate, and distilled water replaced tap water.

Production of the Pigment

C. pulcherrima PRL 1933 was grown 1 week at 28° C in Petri dishes containing Difco potato dextrose agar plus 0.21% ferric ammonium citrate. *C. pulcherrima* PRL 2007 was grown 4 days at 28° C in Petri dishes containing the agar medium used for the maintenance of cultures. Pulcherrimin was isolated from agar cultures as described by Cook and Slater (2). *C. pulcherrima* PRL 2019 was grown on the liquid medium described by Cook and Slater (2), except that Difco yeast extract replaced yeastrel, 60% sodium lactate replaced 50% potassium lactate, 0.1 mg calcium chloride was used instead of a 'trace', and distilled water replaced tap water. The organism was grown in 500-ml Erlenmeyer flasks each containing 100 ml of medium for 2 to 5 days at 28° C on a rotary shaker operating at 240 r.p.m. with a radius of motion of 1 in. Larger amounts of cells were produced by using 300 ml of culture grown on the liquid medium to inoculate 20 liters of medium contained in a stainless steel fermentor, which was a larger version of that described by Roxburgh *et al.* (6). This fermentor was operated at 28° C for 5 days with constant stirring at 300 r.p.m. and aeration at the rate of 6 liters per minute. The cells (1660 g) were collected with a Sharples centrifuge, suspended in 1.5 liters of methanol and centrifuged, prior to extraction with methanolic potash and isolation of pulcherrimin (yield 8.1 g) by the method of Cook and Slater (2).

Morpholinium Salt of Pulcherriminic Acid

Pulcherrimin (217 mg) was triturated with 5 ml of 2 *M* sodium hydroxide, the ferric hydroxide centrifuged off, and the supernatant liquid filtered. The ferric hydroxide was resuspended in 5 ml of sodium hydroxide and the process repeated. The combined filtrates were acidified with hydrochloric acid to precipitate crude pulcherriminic acid (buff or rust color), which was filtered and washed with water. The wet solid was dissolved in 2 ml of 2 *M* ammonium hydroxide, 4 ml of morpholine added, and the solution cooled at −8° C overnight. The morpholinium salt was filtered off, washed with cold *n*-butanol, and transferred to a centrifuge tube. The salt was suspended in an equal volume of butanol, heated in a steam bath for 1 minute, cooled in an ice bath for approximately 5 minutes, centrifuged, and the reddish supernatant liquid discarded. This procedure was repeated until the supernatant liquid had no reddish tinge and the morpholinium salt was a bright yellow color. The salt was suspended in ether and centrifuged, the ether discarded, and this ether washing repeated. Ether was removed from the salt by a stream of nitrogen, and then by evaporation *in vacuo*. The product (226 mg, m.p. 119–121° C) contained: C, 56.6%; H, 8.8%; N, 13.0%. $C_{20}H_{38}N_4O_6$ requires: C, 55.8%; H, 8.9%; N, 13.0%. The salt dissolved in water was titrated with standard hydrochloric acid to a pH of 3.80. The molecular weight, assuming the salt was dibasic, was 436. $C_{20}H_{38}N_4O_6$ requires 430.

The salt decomposed slowly when stored at room temperature, with lowering of the melting point and change to an oily liquid within 2 weeks of its preparation. The salt was soluble in water but insoluble in ether and in butanol–morpholine, 1:1, from which it could not be recrystallized. It could be recrystallized from butanol alone, but the yield was poor and the product had the same melting point and infrared spectrum as the product from the procedure described above.

Pulcherriminic Acid

The morpholinium salt of pulcherriminic acid (151 mg) was dissolved in approximately 10 ml of water and then acidified with hydrochloric acid. The flocculent precipitate was centrifuged down, the supernatant liquid discarded, the precipitate resuspended in water, and centrifuged down again. The washing with water was repeated in this manner until the supernatant liquid was no longer acidic, and then the pulcherriminic acid was collected by filtration and dried over sulphuric acid *in vacuo*. The product (81.7 mg) was a cream-colored or pale yellow solid, m.p. 162–164° C (decomposes). Analysis: C, 56.0%; H, 7.7%; N, 11.0%. $C_{12}H_{20}N_2O_4$ requires: C, 56.2%; H, 7.9%; N, 10.9%.

Ferric Salt of Pulcherriminic Acid

A solution of 30 mg of ferric chloride in 2 ml of trifluoroacetic acid was added to 50.2 mg of pulcherriminic acid dissolved in 1 ml of trifluoroacetic acid, mixed well, and then 3 ml of water added. The precipitate was collected by filtration, washed with water, and then heated for about 1 hour at 70° C with several milliliters of ethanol – 2 *M* hydrochloric acid (1:1). The solid was collected by centrifuging, and the heating with ethanol–acid repeated. The solid was finally washed with ethanol and dried *in vacuo*. The yield of the ferric salt was 51.2 mg, which contained: C, 49.3%; H, 6.2%; N, 9.7%; Fe, 12.8%. $C_{12}H_{18}N_2O_4 \cdot 2/3Fe$ requires: C, 49.4%; H, 6.2%; N, 9.6%; Fe, 12.8%. The infrared spectrum of the salt was identical with that of crude pulcherrimin (Fig. 2).

Cyclohexylammonium Salt of Pulcherriminic Acid

Pulcherriminic acid (53.8 mg) was dissolved in 2 ml of 2 *M* ammonium hydroxide, and 0.2 ml of cyclohexylamine added. A yellow precipitate formed immediately. About 4 ml of acetone was added to the suspension, which was then centrifuged, and the clear supernatant discarded. Such acetone washings were repeated until the supernatant liquid was no longer basic. The precipitate was then dried *in vacuo*. Yield 92.0 mg, m.p. 161–161.5° C (decomposition). Analysis: C, 62.9%; C, 62.7%; H, 10.2%; H, 10.3%; N, 12.5%. $C_{24}H_{46}N_4O_4$ requires: C, 63.4%; H, 10.2%; N, 12.3%.

The solubility of the salt was tested by shaking weighed samples with varying amounts of solvent overnight at room temperature (approximately 25° C). The solubility in water was between 1 and 2 mg/ml, in ethanol between 0.4 and 0.7 mg/ml, and in benzene or acetone less than 0.1 mg/ml.

The melting point of various freshly prepared samples differed, although the individual samples melted with decomposition sharply within a range of 1° C. Preparations were obtained melting as low as 157° C and as high as 171° C, although the infrared spectrum of all samples was the same. The salt decomposed on storage at room temperature and within a week had become a semiplastic solid with no definite melting point.

Reduction of Pulcherriminic Acid with Zinc and Acetic Acid

Pulcherriminic acid (215 mg) was reduced as described by Cook and Slater (2). After treatment with hydrogen sulphide and filtration, the solution was evaporated to dryness and the solid sublimed at 150° C and 0.02 mm to give 115 mg of leucine anhydride (60% yield), identified by its infrared spectrum. The product had no appreciable optical rotation (*c*, 0.52, ethanol, 4-decimeter tube). A sample from a similar experiment was recrystallized from ethanol for analysis. Found: C, 63.6%; H, 9.6%; N, 12.1%. $C_{12}H_{22}N_2O_2$ requires: C, 63.7%; H, 9.8%; N, 12.4%.

A yellow insoluble solid was obtained along with unreacted zinc from the reduction. This solid had the same infrared spectrum as pulcherrimin and was assumed to be the zinc salt of pulcherriminic acid. It was dissolved in 1.0 *M* sodium hydroxide, a solution of sodium sulphide added, and the precipitate of zinc sulphide filtered off. The filtrate was acidified and the solid which precipitated filtered off and washed with water. The solid was dissolved in 2.0 *M* ammonium hydroxide, reprecipitated by acidifying the solution with hydrochloric acid, washed with water, and dried *in vacuo*. The product (57 mg) had an infrared spectrum identical with that of pulcherriminic acid.

Leucine anhydride (105 mg) from the above reduction was hydrolyzed with 10 ml of 42% hydrobromic acid in a sealed tube for 16 hours at 100° C. After evaporation of the hydrobromic acid *in vacuo*, the amino acid was desalted, and sublimed (7). The product (114 mg or 96% of theory) had no measurable optical rotation (*c*, 0.54, 6 *M* hydrochloric acid, 4-decimeter tube), and had an infrared spectrum identical with that of DL-leucine.

Reduction of Pulcherriminic Acid with Phosphorus and Iodine in Acetic Acid

Pulcherriminic acid (1.50 g) was added to a flask containing 900 mg red phosphorus, 300 mg iodine, and 30 ml glacial acetic acid. The flask, fitted with a reflux condenser, was heated in a 150° C oil bath for $2\frac{1}{4}$ hours. The contents were filtered while hot into a cold solution of 3 g sodium metabisulphite in 240 ml water, whereon a flesh-colored precipitate formed. This precipitate was filtered off, and more material recovered from the filtrate by extraction several times with chloroform, and evaporation of the chloroform. To remove traces of acetic acid and colored material, the combined solids were suspended in water, sufficient sodium hydroxide solution added to make the suspension alkaline, and the material extracted by shaking with several portions of chloroform. The product (705 mg) obtained after evaporation of the chloroform was chromatographed on an alumina column (Merck chromatographic grade) 41 cm long and 6.5 cm in diameter. Chloroform was used in packing the column and dissolving the sample. The column was first eluted with approximately 3 liters of 1% ethanol in chloroform and 20-ml fractions collected. Portions of various fractions were evaporated, the residue dissolved in ethanol, and the ultraviolet spectrum of the solution determined with a Beckman DK2 spectrophotometer. The spectra of the three compounds obtained, compounds A, B, and C (Fig. 3), had been determined from previous experiments on a smaller scale and were used as a guide to the purity of the collected fractions. Fractions containing compound A were eluted first, followed by fractions containing compounds A and B. The column was then eluted with 4 liters of 2% ethanol in chloroform and compound B obtained in these fractions. The column was then eluted with chloroform and increasing amounts of ethanol to give first fractions containing compounds B and C, and then fractions containing compound C. Fractions containing only compounds A, B, or C were evaporated to dryness while fractions containing a mixture of two of these compounds were discarded.

Compound A was purified by sublimation at 140° C and 0.02 mm, followed by recrystallization from ethanol. The product (66.5 mg) contained: C, 64.7%; H, 8.1%; N, 12.7%. $C_{12}H_{18}N_2O_2$ requires: C, 64.8%; H, 8.2%; N, 12.6%. The compound was insoluble in water and very slightly soluble in organic solvents at room temperature. Decomposition point (sealed capillary) was 301–303° C. The ultraviolet spectrum in ethanol had a single peak at 278 mμ, ϵ = 24,400 (Fig. 3).

Compound B was purified in the same manner as compound A. The product (223 mg) contained C, 64.4%; H, 9.0%; N, 12.6%. $C_{12}H_{20}N_2O_2$ requires: C, 64.3%; H, 9.0%; N, 12.6%. Decomposition point

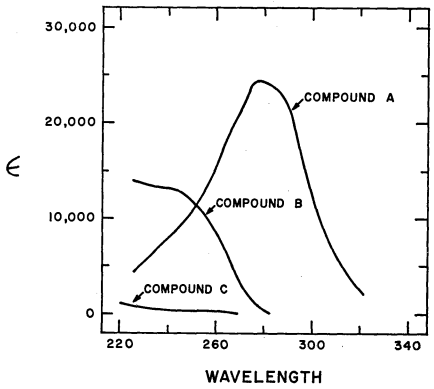

FIG. 3. Ultraviolet spectra for compounds A, B, and C. Solvent, absolute ethanol.

(sealed capillary) was 263–266° C. The ultraviolet spectrum in ethanol showed no single absorption peak but $\epsilon = 13{,}200$ at 240 mμ (Fig. 3).

Compound C was purified in the same manner as compound A. The product (76 mg) had an infrared spectrum identical with that of leucine anhydride, and a decomposition point of 266–267° C (sealed capillary).

Reduction of Pulcherriminic Acid with Phosphorus and Iodine in Acetic Acid Containing Acetic Anhydride

A mixture containing 1.00 g of pulcherriminic acid, 600 mg red phosphorus, 200 mg iodine, 6 ml acetic anhydride, and 54 ml glacial acetic acid was refluxed on a 155° C oil bath for 2¼ hours, and then filtered into a cold solution of 2 g of sodium metabisulphite in 160 ml of cold water, whereon a precipitate formed. After the solution had been allowed to stand overnight at −8° C, the suspension was filtered and the precipitate recrystallized from ethanol. The product (305 mg) had infrared and ultraviolet spectra identical with that of compound A. No compound A, B, or C could be found in chloroform extracts of the aqueous filtrate, which gave only gummy material on evaporation of the chloroform.

Reactions of Compound A

Hydrolysis.—A suspension of 30.9 mg of compound A in 3 ml of 6 *M* hydrochloric acid was heated in a sealed tube at 100° C for approximately 40 hours. The small amount of solid left was filtered off and 30 ml of 2,4-dinitrophenylhydrazine solution (concentration 1 mg/ml of 2 *M* hydrochloric acid) added to the filtrate. A yellow precipitate formed, and after the suspension had been kept at −8° C overnight, it was filtered off, washed with a little 0.1 *M* hydrochloric acid, and dried *in vacuo*. Yield 45.8 mg, m.p. 156–158.5° C. To the filtrate 30 ml more of the 2,4-dinitrophenylhydrazine solution was added to obtain 26.9 mg more of the compound, m.p. 153–156° C. The compound was soluble in 0.1 *M* sodium carbonate and its melting point was not depressed by mixture with the 2,4-dinitrophenylhydrazone of α-keto isocaproic acid, m.p. 156–157° C. Analysis: C, 46.7%; H, 4.7%. $C_{12}H_{14}N_4O_6$ requires: C, 46.5%; H, 4.6%.

Reduction.—Compound A (12.0 mg) was added to a mixture of 30 mg red phosphorus, 11 mg iodine, and 3 ml of glacial acetic acid and refluxed for 40 minutes. The reaction mixture was filtered into 24 ml of water containing 300 mg sodium metabisulphite. No precipitate formed until the solution was made alkaline by the addition of sodium carbonate. The suspension was then extracted three times with an equal volume of chloroform, the chloroform extracts evaporated to dryness, and the product sublimed at 140° C and 0.02 mm. Yield 11.4 mg (93% of theory) of leucine anhydride, identified by its infrared spectrum.

Ozonolysis.—Compound A (29.9 mg) and 36 ml dichloromethane were cooled in a dry ice – ethanol bath and ozone passed through until a faint blue solution was obtained. The solution was warmed slightly and 60 ml of 2,4-dinitrophenylhydrazine solution added. The flask was warmed to room temperature and shaken vigorously. The dichloromethane layer was removed and the aqueous layer extracted with 30 ml dichloromethane. The combined dichloromethane extracts were evaporated to dryness, the solid suspended in 60 ml 2 *M* hydrochloric acid and extracted six times with 30 ml petroleum ether (b.p. 60–80° C). The petroleum ether extracts were evaporated to dryness and the solid chromatographed on a silicic acid – celite column (8). The first colored band, eluted from the column with 2% ether in petroleum ether, was collected, the solvent evaporated off, and the solid recrystallized twice from petroleum ether. Yield 10.2 mg of isobutyraldehyde dinitrophenylhydrazone, m.p. 177–180° C. Analysis: C, 47.9%; H, 4.9%. $C_{10}H_{12}N_4O_4$ requires: C, 47.6%; H, 4.8%.

Reactions of Compound B

Hydrolysis.—Compound B (30.7 mg) and 3 ml 42% hydrobromic acid were heated in a sealed tube for 16 hours at 100° C. Dinitrophenylhydrazine solution (15 ml) was added and the solution cooled at −8° C

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

overnight. The precipitate was collected as mentioned for the hydrolysis of compound A. Yield 22.0 mg, m.p. 155–158° C. Analysis: C, 46.7%; H, 4.9%. $C_{12}H_{14}N_4O_6$ requires: C, 46.5%; H, 4.6%. The melting point was not significantly changed by mixing with the 2,4-dinitrophenylhydrazone of α-keto isocaproic acid. A second crop (8.3 mg) of this derivative was obtained by adding more dinitrophenylhydrazine solution to the filtrate, but it was discarded since its melting point (151–155° C) was low.

The filtrate, after the removal of the dinitrophenylhydrazone, was extracted several times with ether, and the aqueous layer, which contained leucine as shown by circular paper chromatography (solvent, *sec*-butanol – 3% ammonium hydroxide, 3:1), evaporated to dryness. The solid was extracted with water, the aqueous solution desalted (7), and the leucine purified by sublimation at 130° C and 0.02 mm. The product, 16.9 mg, had an infrared spectrum identical with that of DL-leucine and no measurable optical rotation (*c*, 0.52, 6 *M* hydrochloric acid, 2-decimeter tube).

Reduction.—Compound B (12.1 mg) was reduced for 100 minutes and the product isolated by the same methods as were used for the reduction of compound A. Yield 11.8 mg of leucine anhydride, identified by its infrared spectrum.

Ozonolysis.—Compound B (29.1 mg) was subjected to ozonolysis and isobutyraldehyde isolated as its 2,4-dinitrophenylhydrazone derivative by the same methods as were used for the ozonolysis of compound A. Yield 13.0 mg., m.p. 177–180.5° C. Analysis: C, 47.5%; H, 4.9%. $C_{10}H_{12}N_4O_4$ requires: C, 47.6%; H, 4.8%. The product had the same R_f (approximately 0.3) as authentic isobutyraldehyde dinitrophenylhydrazone when subjected to thin layer chromatography on silica gel G (E. Merck, Darmstadt, Germany) with benzene as the developing solvent.

Melting points were done with a Fisher-John's hot stage except for compounds which sublimed readily, in which case a sealed capillary and a metal heating block were used. Melting points were corrected by calibrating the melting point apparatus with appropriate reference compounds of known melting point.

ACKNOWLEDGMENTS

The author is grateful to Dr. R. U. Lemieux, Department of Chemistry, University of Alberta, for proton magnetic resonance spectra. Cultures for the isolation of pulcherrimin were grown by Dr. R. H. Haskins and Dr. J. F. T. Spencer of this laboratory. Analyses were done by Mr. M. Mazurek and infrared spectra by Mr. W. C. Haid. The author is also indebted to Mr. D. M. Tenaschuk for technical assistance and to Dr. L. C. Vining for valuable advice.

CHARACTERISTIC VIBRATIONAL FREQUENCIES OF OXYGEN COMPOUNDS OF PHOSPHORUS AND CHLORINE: CORRELATION OF SYMMETRIC AND ASYMMETRIC STRETCHING FREQUENCIES OF PO AND ClO BONDS

E. A. ROBINSON
Department of Chemistry, University of Toronto, Toronto, Ontario
Received August 28, 1962

ABSTRACT

Linear relationships have been established between the symmetric and asymmetric stretching frequencies of PO_2 and ClO_2 groups that are useful in the assignment of the characteristic vibrational frequencies of these groups in the Raman and infrared spectra of phosphorus and chlorine compounds containing two or more oxygen ligands. The values of the frequencies depend, in a systematic manner, on the electronegativities of the groups attached to the central atom.

INTRODUCTION

For a variety of inorganic and organic compounds containing the sulphuryl group, it was shown originally by Bellamy and Williams (1), and more recently by the present author (2), that any change in the symmetric stretching frequency is accompanied by a proportional change in the asymmetric stretching frequency. The latter work extended the relationship to include ionic species such as the anions of sulphuric acid and substituted sulphuric acids, and more recently we have shown that it is also applicable to the $S(OH)_2$ group (3). Such a relationship is reasonable since the SO_2 stretching frequencies are expected to be relatively free from mass and coupling effects. Recently a similar correlation has been obtained between the symmetric and asymmetric stretching frequencies of the UO_2 group in uranyl complexes (4).

Because of the rather similar chemical nature of oxygen compounds of phosphorus, sulphur, and chlorine it might be expected that similar relationships would apply also to compounds containing PO_2 and ClO_2 groups, as indeed is shown to be the case in the present paper. In the case of phosphorus compounds the correlation is restricted to species containing groups such as PO_2^-, since neutral compounds containing two double bonds between phosphorus and oxygen (e.g. PO_2X) are not known. In the same way that the previous correlation was shown to apply not only to simple sulphuryl compounds $XYSO_2$ but also to ions such as XSO_3^- and SO_4^{2-}, the present correlations include species such as $XYPO_2^-$, XPO_3^{2-}, and PO_4^{3-}, and $XYClO_2$, $XClO_3$, ClO_2^-, ClO_3^-, and ClO_4^-, that is, any species with two or more oxygen ligands attached to the central phosphorus or chlorine atom. The relationship also applies to compounds containing $P(OH)_2$ groups.

ClO STRETCHING FREQUENCIES

Data collected from the literature for ClO stretching frequencies of several oxychlorine compounds and ions are shown in Table I and plotted in Fig. 1.

In tetrahedral molecules of the type $XClO_3$ there should be one symmetric ClO_3 stretch and two asymmetric stretches which are degenerate. In the case of perchloric acid two asymmetric stretches have been observed and this is attributed to loss of tetrahedral symmetry in the molecule (5), but for fluorine perchlorate (6) and perchloryl fluoride (7) only one band has been observed in the asymmetric stretching region of the infrared

*Present assignment.

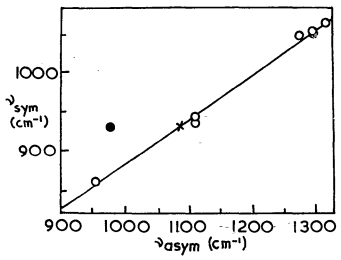

FIG. 1. Correlation of symmetric and asymmetric Cl—O stretching frequencies.

spectrum. In the case of perchloric acid the mean of the asymmetric stretching frequencies is taken as the frequency this vibration would have in the absence of resonance splitting. Recently, by comparison with the spectrum of the chlorosulphate ion (8), we cast doubt on the previous assignment of the frequency at 1315 cm^{-1} in the spectrum of perchloryl fluoride to the asymmetric ClO stretch (7). In view of the present correlation this doubt appears to be unfounded.

In the case of the chlorate ion the symmetric and asymmetric stretches have been assigned by several workers (e.g. see refs. 9, 10) near 930 and 975 cm^{-1}, respectively. These values, however, do not fit the correlation (the point marked ● in Fig. 1). However, if the line at 1082 cm^{-1} observed in the infrared spectrum of potassium chlorate by Ramdas (9) is assigned as the ClO asymmetric stretch, rather than 975 cm^{-1}, then the fit is good (the point marked × in Fig. 1). The line at 975 cm^{-1} can then be reinterpreted as an overtone of the bend at 486 cm^{-1} ($2\times486 = 972$ cm^{-1}). This view appears to be supported by the work of Rocchicciaoli (10), who observed a splitting of the low-frequency bend into two lines in the spectra of several solid chlorates, which was accompanied by a similar splitting of the line near 975 cm^{-1}. In all cases the two lines near 975 cm^{-1} can be interpreted as combination or overtone bands of the doublet in the region of the bending mode.

As can be seen from Fig. 1, when the symmetric stretch is plotted against the asymmetric stretch a good straight line results which can be represented by the equation

$$\nu_{sym} = 0.56\nu_{asym} + 322. \quad [1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In the case of the previous correlation of the symmetric and asymmetric stretches (2) of the SO_2 group, the straight-line equation was not given. It is now given for comparison:

[2] $$\nu_{sym} = 0.62\nu_{asym} + 329,$$

and is very similar in form to equation [1]. As in the previous correlation the exact positions of ν_{sym} and ν_{asym} depend on the electronegativities of the attached ligands, the highest frequencies being observed for the ligand of highest electronegativity, i.e. fluorine.

P—O STRETCHING FREQUENCIES

Unfortunately, very few reliable or complete measurements of the spectra or complete assignments of spectral frequencies to normal modes of vibration of such ions have been made. However, a small amount of reliable data is available. The ions $H_2PO_2^-$, HPO_3^{2-}, and $CH_3OPO_3^-$ have been examined by Tsuboi (11) and P—O symmetric and asymmetric stretches assigned; a complete assignment of the spectrum of the $P_2O_6^{4-}$ ion has recently been made by Palmer (12), and the symmetric and asymmetric stretches in the phosphate ion are also known (13). The data for the above ions is shown in Table II and the symmetric and asymmetric stretches are plotted in Fig. 2. As can be seen a good straight-line cor-

TABLE II

Well-established P—O stretching frequencies in phosphorus oxyanions

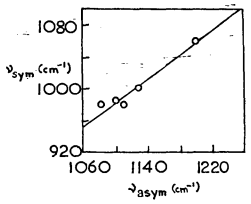

FIG. 2. Correlation of well-established P—O stretching frequencies.

relation is suggested on the basis of this rather limited amount of data, although the information is not sufficient to establish a definite general correlation.

It is of interest to note that the P—O stretching frequencies of $H_2PO_2^-$ are at higher frequency than those of HPO_3^{2-}, $CH_3OPO_3^{2-}$, and $[O_3P—PO_3]^{4-}$, which are in turn at higher frequencies than the stretching frequencies of the PO_4^{3-} ion. This is consistent with reduced double-bond character in the P—O bonds as the charge per phosphorus atom increases.

Having established a possible straight-line correlation between the P—O stretching frequencies for these oxyanions it was of interest to see if supporting evidence could be obtained from some of the published spectra for which complete assignments have not been given.

For personal use only.

Fluorophosphates

Corbridge and Lowe (14) measured the infrared spectra of the sodium, potassium, barium, and silver salts. Two bands were observed in each case in the PO stretching region and the lower frequency of each pair can be assigned as the symmetric stretch and the higher as the asymmetric stretch. Pustinger and co-workers (15) examined the spectra of the sodium, potassium, and silver salts and assignments very similar to those made above are possible. The frequencies so assigned agree well with the linear correlation between symmetric and asymmetric stretches.

Difluorophosphates

The only measurement of the spectrum of the difluorophosphate ion appears to be that of the ammonium salt by Corbridge and Lowe (14). Three bands were observed in the P—O stretching region at 1005 cm^{-1} (weak), 1125 cm^{-1} (strong), and 1262 cm^{-1} (strong). It seems reasonable to assign the latter two to the symmetric and asymmetric PO stretches, respectively.

Dimethylphosphonates

Only the sodium salt was examined. By assigning 1028 cm^{-1} as the frequency of the symmetric stretch and 1168 cm^{-1} as the frequency of the asymmetric stretch a good correlation with the straight line in Fig. 2 is obtained.

Dihydrogenphosphates

From the infrared spectra of the ammonium, sodium, potassium, and calcium salts, the mean frequencies of 1076 and 1271 cm^{-1} may be assigned as the symmetric and asymmetric stretches respectively. It is also possible to assign frequencies at 870 and 963 cm^{-1} in the spectrum of the sodium salt to the symmetric and asymmetric $P(OH)_2$ stretching frequencies. Similarly 877 and 935 cm^{-1} for the calcium salt and 890 and 963 cm^{-1} for the hydrated calcium salt may be assigned as the frequencies of these vibrations. All these assignments are consistent with the original correlation.

Phosphites

Infrared bands were observed at 1006, 1022, 1082, and 1130 cm^{-1} in the spectrum of the barium salt. If we assume that the first pair of frequencies can be assigned to the symmetric PO stretch and the latter pair to the asymmetric stretch, both frequencies being split by crystal forces, and take the mean value of each pair as the symmetric and asymmetric stretches, respectively, in the absence of crystal splitting, then the pair of frequencies so obtained (1014 and 1106 cm^{-1}) is in reasonable agreement with the relationship.

Peroxydiphosphates

Corbridge and Lowe (14) have also examined the infrared spectrum of lithium peroxydiphosphate. Lines in their spectrum at 998 and 1115 cm^{-1} may be assigned as the symmetric and asymmetric PO stretches, respectively, and these frequencies fit the straight-line correlation well. Theoretically the symmetric and asymmetric stretches of the $P_2O_8^{4-}$ ion should occur as a maximum of six lines in the spectrum. We asume, as only two lines are observed, that the three symmetric stretches and three assymmetric stretches are degenerate.

Phosphoramidates

Corbridge and Lowe report bands at 994 and 1158, 993 and 1162, and 994 and 1143 cm^{-1} in the infrared spectra of sodium, potassium, and ammonium phosphoramidates, respectively. The infrared spectrum of $NH_4.PO_3NH_3$ is also reported by Steger (16), who

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

assigns the P—O symmetric stretch at 993 cm^{-1} and the asymmetric stretch at 1170 cm^{-1}. However, in his published spectrum there is a distinct shoulder at approximately 1130 cm^{-1} which could possibly be reassigned as the asymmetric stretch. The pair of frequencies 993 and 1130 cm^{-1} fits the correlation well.

Other values for the symmetric and asymmetric P—O stretches in oxyanions of phosphorus which also support the present correlation can be deduced from spectra reported by other workers. Steger (16) gives lines at 1000 and 1125 cm^{-1} in the spectrum of $BaPO_3NH_2$ and at 1023 and 1183 cm^{-1} in the spectrum of the magnesium salt. Several workers report the spectrum of diphosphates. In the $P_2O_7^{4-}$ ion a maximum of three symmetric and three asymmetric P—O stretches are theoretically expected, and in the $H_2P_2O_7^{2-}$ ion two symmetric and two asymmetric stretches. Hanwick and Hoffmann (17) report lines at 1018 and 1128 cm^{-1} in the Raman spectrum of $K_4P_2O_7$, at 1018 and 1138 cm^{-1} in the spectrum of $K_2Na_2P_2O_7$, at 1087 and 1253 cm^{-1} in the spectrum of $K_2H_2P_2O_7$, and at 1105 and 1244 cm^{-1} in the spectrum of $Na_2H_2P_2O_7$. If the former of these pairs is taken as the frequency of P—O symmetric stretches (assumed degenerate), and the latter as that of the asymmetric stretches (assumed degenerate) correlation with the straight line of Fig. 2 is good. MacArthur and Beevers (18) give 987 and 1030 cm^{-1} as the symmetric P—O stretches and 1121 and 1152 cm^{-1} as the asymmetric P—O stretches of the $P_2O_7^{4-}$ ion. The mean symmetric stretch (1008 cm^{-1}) and mean asymmetric stretch (1137 cm^{-1}) are in good agreement with the frequencies of the single lines reported by Hanwick and Hoffmann. It is significant that the pair of stretches in the $H_2P_2O_7^{2-}$ ion come at relatively higher frequencies than the pair of frequencies in the $P_2O_7^{4-}$ ion, which is consistent with greater double-bond character of the P—O bonds in the former ion than in the latter.

Daasch and Smith (19) have measured the infrared spectra of several compounds containing the $P(OH)_2$ group. They do not give the exact frequencies of the bands in the spectra but approximate frequencies may be estimated from their published spectra. In the spectrum of benzenephosphonic acid ($C_6H_5.P(O)(OH)_2$) there are lines at approximately 920 and 1000 cm^{-1}, which can be assigned as the symmetric and asymmetric P—OH stretches and are in good agreement with the straight-line correlation. Pairs of lines which can be assigned as symmetric and asymmetric P—OH stretching frequencies were also observed in the spectrum of *p*-chlorobenzenephosphonic acid (at 925 and 1005 cm^{-1}). In the spectrum of dideuterobenzenephosphonic acid lines were observed at 925, 945, and 1030 cm^{-1}. If it is assumed that the lines at 925 and 945 cm^{-1} are the symmetric P—OD stretch split in the spectrum and the mean frequency of 935 cm^{-1} is taken as the value of the P—OD symmetric stretch and 1030 cm^{-1} as the frequency of the asymmetric stretch, then another pair of frequencies is obtained which fits the correlation.

The symmetric and asymmetric P—O stretches discussed above are plotted against each other in Fig. 3, which also shows the frequencies used in the preliminary correlation. The data is collected in Table III. The straight-line correlation is given by the equation

$$[3] \qquad \nu_{sym} = 0.65\nu_{asym} + 270.$$

It is interesting to note that anions containing highly electronegative ligands attached to the central phosphorus atom, e.g. $PO_2F_2^-$, have higher stretching frequencies than those containing less electronegative ligands, e.g. $PO_2(OH)_2^-$, carrying the same formal charge. P—OH stretching frequencies occur at even lower frequencies than the P—O stretches in the ions. These trends are consistent with increasing double-bond character of the P—O bonds as the electronegativity of the central phosphorus atom increases.

The correlation appears to be relatively well established but it is clear that more work is required to establish the assignment of P—O stretching frequencies definitely in some of the species discussed. However, the present correlation should prove useful in such a task.

The slopes of the straight-line relationship for symmetric and asymmetric P—O, S—O, and Cl—O stretching frequencies are 0.65, 0.62, and 0.56, respectively, and the intercepts are quite similar in magnitude (270, 322, and 329, respectively). The small decrease in the slopes in the series PO_2, SO_2, ClO_2 is probably due to a decrease in the double-bond character, which results in a decrease in the coupling between the symmetric and asymmetric stretches.

ACKNOWLEDGMENTS

STRUCTURE OF PYROLYZED POLYVINYLIDENE CHLORIDE

J. R. Dacey and R. G. Barradas
Department of Chemistry, Royal Military College of Canada, Kingston, Ontario
Received July 23, 1962

ABSTRACT

Systematic infrared analyses, using the standard KBr pellet technique, of samples ranging from the pure polymer (Saran) to the fully carbonized charcoal have been examined in an attempt to clarify the structural changes and mechanism of decomposition of the polymer on pyrolysis. A complementary technique has been investigated for obtaining homogeneous samples of the carbon and of the partially pyrolyzed polymer which will transmit infrared radiation without the use of any halide dispersal medium. The significance, possible applications, and limitations of these spectral studies are discussed. Pore volumes have been examined by means of a modified helium displacement densitometer and also through the adsorption of argon in a McBain–Bakr balance. Porosity measurements based on the adsorption of argon at its saturation vapor pressure are more satisfactory and they contribute towards a better understanding of the microstructure of Saran charcoal and of its partially carbonized antecedents. The influence of pelletizing pressure has been found to play an important role in the determination of pore volumes.

INTRODUCTION

Carbons derived from synthetic organic polymers are often porous; however, they may not always inherit a uniform pore size from the regular structure of the polymer predecessors because few valence angles and distances survive thermal decomposition unchanged during the course of their preparation by pyrolysis. Their porosities have been established as owing to capillaries ranging from a few angstroms to several microns.

The presence of ultrafine capillaries of the order of molecular size are of interest to surface chemists since these pores are responsible for the behavior of many such solids as partial molecular sieves, namely materials through which small molecules can penetrate more readily than larger ones.

Adsorption and kinetic studies on "Saran charcoal", a carbon produced by the complete pyrolytic decomposition of polyvinylidene chloride, have been extensively studied in our laboratory (1–5) and elsewhere (6–8). Less attention has been focused on the correlation of adsorption with the structure and mechanism of formation of the charcoal. One can tacitly assume that any variation in physical properties will depend upon fundamental structural parameters which are generally characteristic of composition, molecular geometry, and nature of the porosity.

In the present work we have carried out systematic infrared analyses, by means of the standard potassium bromide technique, of a large number of samples ranging from pure polymer to the fully carbonized charcoal in an attempt to clarify the structural changes of the polymer on pyrolysis. A technique has been concurrently established for obtaining homogeneous samples of Saran charcoal and of the partially pyrolyzed polymer in the form of thin wafers which will transmit infrared radiation without the use of potassium bromide or any other customary dispersal medium. The applications and limitations of these wafers in adsorption studies will be discussed.

Porosity measurements based on the adsorption of argon in a McBain–Bakr balance are compared with similar determinations utilizing a helium dilatometric technique.

EXPERIMENTAL

Method of Preparation of Samples

(a) Circular Wafer Samples

Pure polyvinylidene chloride (Dow Chemical Co.) was pressed into the form of a thin wafer in a stainless

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

steel die (2-cm diameter) under a pressure of 15,000 lb/in² by means of a Carver hydraulic press. In general, the weight of the polymer used for the production of the wafers was 58±1 mg. The compressed wafers were 0.13±0.01 mm in thickness. The fully decomposed wafer (calculated on the basis of $(CH_2CCl_2)_n = 2nC + 2n$HCl, representing 75.3% weight loss) was 14 mm in diameter and 0.09±0.01 mm in thickness. The stoichiometric weight loss of hydrogen chloride in relation to the carbon percentage composition during the course of pyrolysis is conveniently demonstrated in Fig. 1.

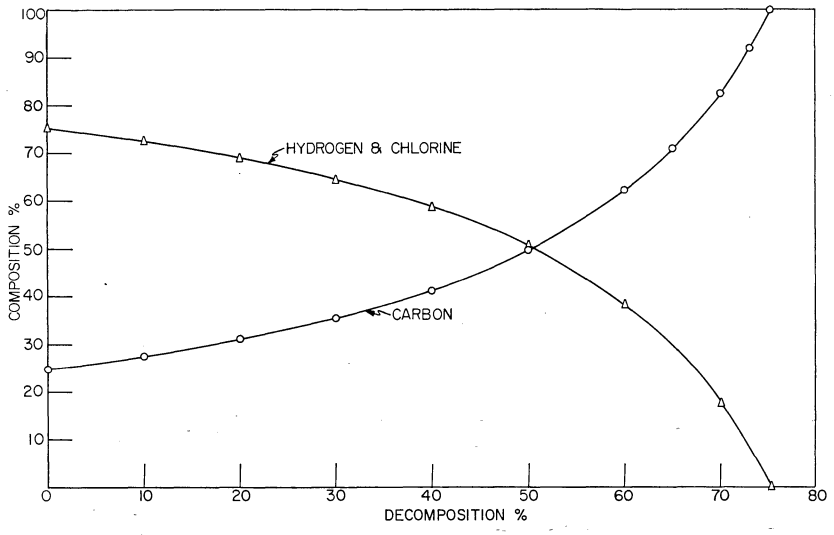

FIG. 1. Composition of polyvinylidene chloride during the course of pyrolysis.

(b) Samples Used in the McBain–Bakr Balance and Helium Densitometer

Disks prepared within the range of 0 to 75.3% decomposition were used in the sorption balance; their weights were approximately 100 to 150 mg. Larger disks of approximately 500-mg weight were prepared in a similar manner for use in the helium densitometer. All disks were compressed under a pressure of 10,000 lb/in².

(c) Pyrolysis

The disks and wafers were placed between flat porous plates and heated gradually to 195° C in a vacuum oven over a period of several days. Slow heating ensures the formation of a uniform composition, a regular surface, and an even pore structure. Rapid heating results in fast evolution of hydrogen chloride, which tends to give samples of uneven shape and texture, and an additional disadvantage is the formation of visible large-scale cracks.

To obtain a uniform sample of the partially decomposed polymer it is necessary to heat the pure polymer at the appropriate temperature for a considerable time; the degree of decomposition achieved is a function of the temperature. By using the data previously obtained by Dacey and Cadenhead (9) it is possible to produce uniform samples of any desired decomposition. The oven was set for various temperatures and pre-determined periods of heating using an Intermatic timing device (International Register Co.). After each heating period and temperature setting, the oven was automatically switched off and allowed to cool to room temperature, when one or more wafers and disks were removed. The percentage decomposition of the samples was determined by weighing.

For temperatures up to 195° C a conventional vacuum oven was used and for higher temperatures the samples were heated under vacuum in a quartz tube in an electric furnace capable of attaining temperatures in excess of 800° C. The hydrogen chloride liberated during pyrolysis was condensed in liquid air traps and removed periodically. Fully carbonized samples were obtained at a temperature of 700° C, since no significant weight loss occurred through heating the samples for another few hours at 725° C.

(d) Potassium Bromide Pellets

A range of samples of carbonized Saran prepared as described above was intimately ground together with dry potassium bromide (Analar Reagent grade). Mixtures containing 1% and in some cases 0.1% of the polymer were compressed into pellets of 170-mg weight and 0.5-mm thickness through application of 20,000 lb/in² pressure in a Carver press.

(e) Instrumentation and Apparatus

In general the spectra were recorded on a Perkin–Elmer 137B spectrophotometer, and where necessary the precise location of wave bands were checked by use of a Perkin–Elmer Model 21 instrument.

For personal use only.

The true density and degree of porosity were measured in a modified Franklin (11) volumetric adsorption apparatus through displacement of helium (Air Reduction (Canada) Ltd.) by the carbonized sample. A known weight of the carbon was outgassed and then exposed to helium in a conventional manner. By simple application of the gas laws, the volume of helium in the dead space was calculated. The true volume occupied by the carbon was thus obtained, and hence the actual density of the carbon. From a known apparent volume of the carbon disk (measured accurately by means of a vernier caliper) the percentage porosity was computed. The degree of porosity or pore volume was also obtained by the adsorption of argon (British Oxygen (Canada) Ltd.) at its saturation vapor pressure at $-195°$ C using a sensitive helical quartz spiral (12).

RESULTS

Spectra of Pyrolyzed Saran Dispersed in Potassium Bromide

The spectrum of a compressed compact wafer of the pure polymer agrees reasonably well with that reported by Krimm and Liang (13) for thin solid films, although in our case transmissions at wavelengths below 670 cm^{-1} could not be examined because of the limitations of the spectrophotometers available.

On partial carbonization the most apparent changes are in the diminution of the intensity of the CCl_2 stretching frequency at 750 cm^{-1} and also of the 1045 and 1070 cm^{-1} doublet attributed to the combination of an overtone of a CCl_2 stretching mode at 531 cm^{-1} ($2\times531 = 1061$ cm^{-1}) in resonance with the chain skeletal vibration at about 1070 cm^{-1}. This is quite consistent with the progressive removal of hydrogen chloride on pyrolysis.

Other striking observations include the formation of new bands at 1460 cm^{-1}, a doublet at 1570 and 1620 cm^{-1}, and one at 1710 cm^{-1}. The doublet and the band at 1710 cm^{-1} persist up to 42% weight loss (see Fig. 2), and at higher carbon percentage composition only two sharp bands, at 1570 and 1710 cm^{-1}, appear to dominate with medium intensities within this region of the spectrum.

The 1460 cm^{-1} band has been reported as one of four characteristic frequencies for C—H vibrations of extinite and vitrinite coals (21, 22). It is noteworthy to point out that although this band appears at an early stage of carbonization in our work, its intensity decreases as the other bands become stronger, and this is again consistent with the progressive elimination of hydrogen as hydrogen chloride.

It was noticed that even at a carbon composition of 83.1% the two bands at 1570 and 1710 cm^{-1} were clearly evident, although their intensities have apparently reduced considerably. This is not unreasonable as it is to be expected that at higher carbon percentage the amount of infrared radiation lost by scattering will have increased. This is more obviously manifested in the fully carbonized sample where the scattering is so great that only the stronger band at 1570 cm^{-1} appeared to be feebly perceptible. A reduction of the charcoal content of the KBr pellets and the use of fluorolube served to emphasize the distinct presence of the 1570 cm^{-1} band in the fully carbonized samples without equivocation (see Fig. 3). The spectral data obtained in this work for decomposed polymers of high carbon content show many features of similarity with those reported for coals of varying carbon composition (20–23).

Spectra of Pyrolyzed Saran Wafers in the Absence of a Dispersion Medium

Using thin wafers a similar set of spectra have been recorded (see Fig. 4). Here the pattern of spectral behavior is almost identical with those of the above series except that the losses of radiation through scattering have been increased at least twofold. In order to obtain any reasonable spectra, the reference beam intensity of the spectrophotometer was reduced by approximately a half through the use of a fine wire screen. It was later found that with considerable care and improvement in technique thinner wafers of pyrolyzed Saran could be obtained without sacrificing too much in structural texture and

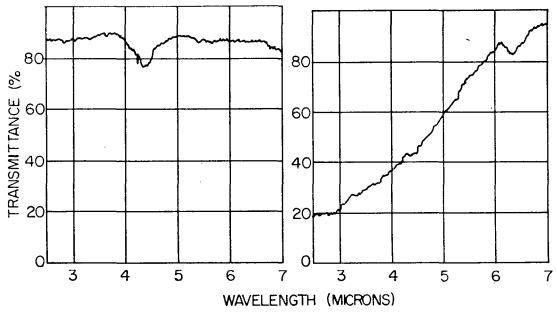

FIG. 3. Left: Infrared spectrum of fluorolube. Right: Infrared spectrum of a fully carbonized Saran charcoal coated with fluorolube.

rigidity. These new samples were approximately one third less in weight and thickness than those reported above and slightly better spectra could be obtained, and in some cases (carbon composition of less than 80%) even by dispensing with the reduction of the intensity of the reference beam in the spectrophotometer. However, it was noted that the reduction in thickness of the wafers was not proportional to the increase in optical transmittance, e.g., a diminution of an extra 10% in thickness for a sample already reduced by 20% in thickness did not show any noticeable gain in transmittance.

Determination of Pore Volumes

(a) Porosity Measurements by Means of Argon Adsorption

The following values of x/m (the ratio of the weight of adsorbate to adsorbent) were determined for Sarans of varying percentage decomposition. Using the density of liquid argon $\rho_A = 1.4$ at $-186°$ C, we can calculate the pore volumes as listed on the last column of Table I. Samples ranging from 0.1 to 0.12 g in weight were used in these experiments. A plot of porosity versus percentage decomposition is illustrated in Fig. 5.

TABLE I

Porosity values by argon adsorption

Percentage decomposition	x/m (g/g)	Pore volume (cc/g)
75.3	0.570	0.410
73.1	0.507	0.362
72.3	0.500	0.357
67.0	0.384	0.275
59.3	0.183	0.131
50.0	0.000	—
40.0	0.000	—

(b) Porosity Measurements by Means of Helium Displacement

Disks of approximately 0.5 g were used in this series of determinations. In view of their considerably increased size as compared with those used in the argon adsorption experiments their apparent volumes could be estimated with good accuracy by means of a vernier caliper. A plot of the experimentally evaluated pore volumes versus percentage decomposition determined at room temperature by the helium dilatometric technique is also shown in Fig. 5.

(c) Regular Reduction of Volume of the Samples on Pyrolysis

An interesting observation is the regular diminution of volume of the disks with

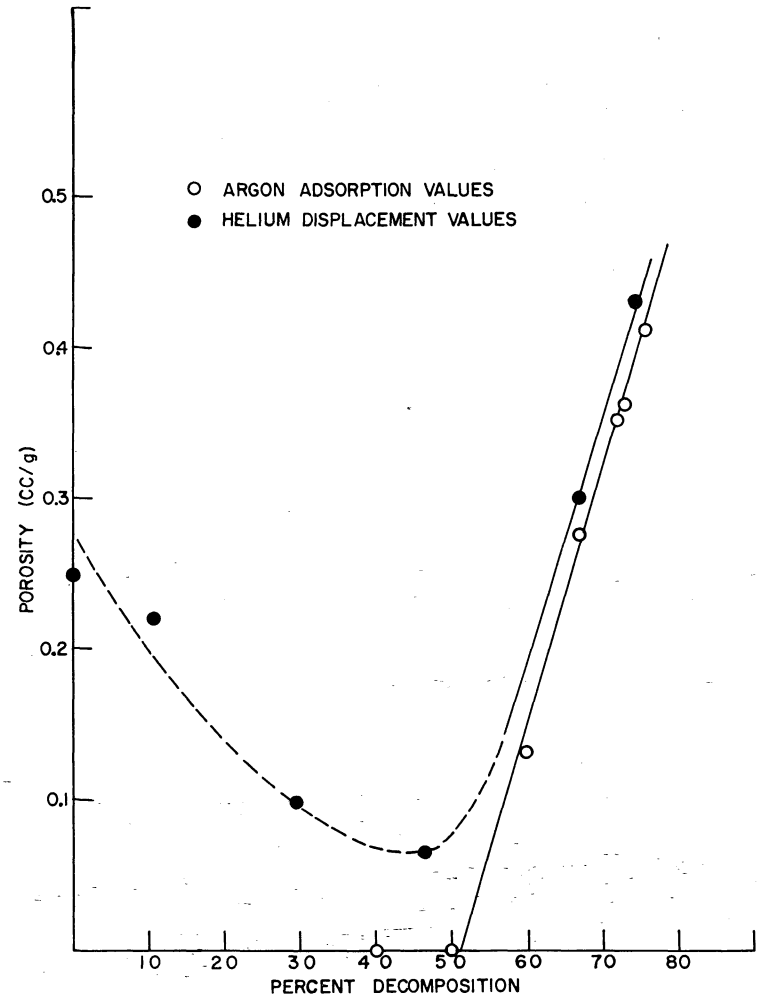

FIG. 5. Porosity values versus percentage decomposition: O argon adsorption values, ● helium displacement values.

progressive pyrolysis. This is shown in Fig. 6, where the total volume exhibits a linear decrease with increasing percentage decomposition.

DISCUSSION

Origin and Nature of Pore Structure

Saran charcoal falls into the category of Franklin's definition (14) as a "non-graphitising" carbon; it does not show any trace of homogeneous development of the three-dimensional graphitic structure even when heated up to temperatures of about 3000° C. Non-graphitizing carbons have been shown by X-ray studies to possess a characteristic open structure and a strongly cross-linked system of randomly orientated crystallites. Such an architecture of carbon atoms naturally favors the existence of large porosity and internal surface area.

The importance of cross-linking in the structure of the porous carbons is also revealed by their physical properties. Saran charcoal is hard and strong. The greater hardness of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

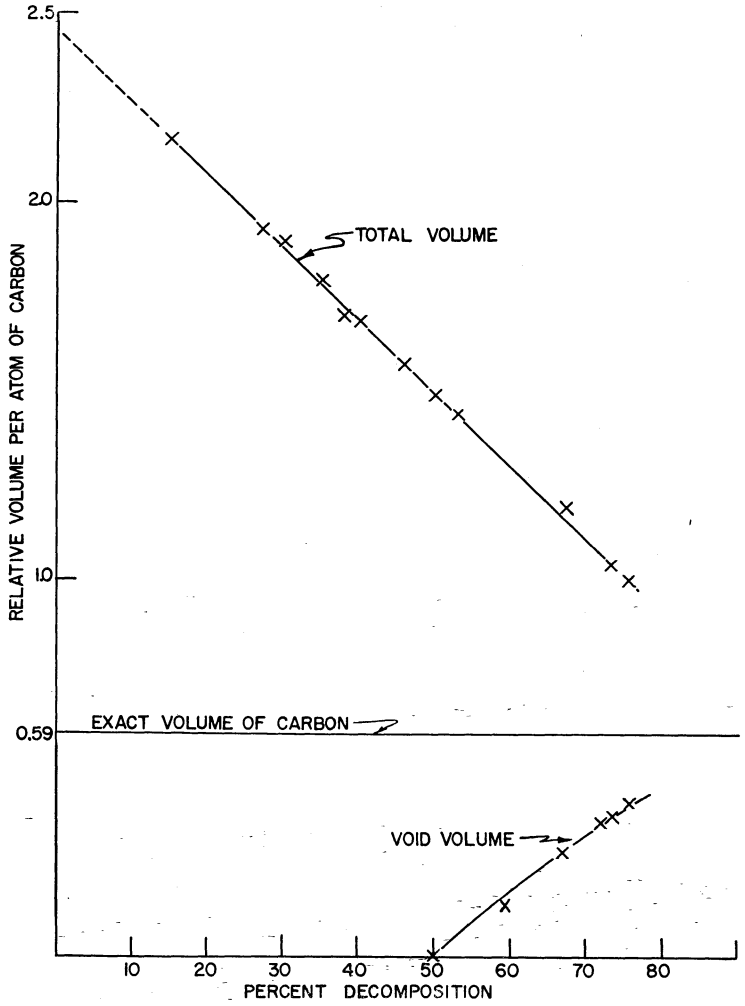

FIG. 6. Relative volume per atom of carbon versus percentage decomposition. Void volume values refer to those obtained by argon adsorption.

the non-graphitizing as compared with the graphitizing carbons must be attributed to greater regularity and strength of the bonding between neighboring crystallites.

Correlation Between Spectral Data, Structure, and Mechanism of Carbonization

The 1710 cm^{-1} band is the weaker of the two which persist up to 70% decomposition (83.1% carbon) but it is coincident with the carbonyl stretching frequency encountered in cyclohexanone and other six-membered ketonic ring compounds (cf. ref. 16, p. 142 *et seq.*). Standard precautions were taken to avoid entry of oxygen during the formation of the wafers and disks, but this does not guarantee the *total* exclusion of oxygen. In the event of trace contamination due to oxygen one could accept the possibility that certain aromatic quinonoid compounds may be formed. The 1710 cm^{-1} band could not be detected at full carbonization (75.3% decomposition) but this cannot be construed as proof of its absence in view of the intense scattering effect associated with the spectra. It should be emphasized that extreme care must be taken to avoid chemisorbed oxygen in the preparation of any pyrolytic carbon sample before reliance can be placed on its use in other experimental measurements.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The persistence of the lone band at 1570 cm^{-1} may hence be interpreted as being due to the C=C stretching vibrations commonly found in aromatic conjugated rings. Thus the spectral evidence would tend to support earlier speculations (10(*a*), 10(*b*)) that the polymer decomposed according to a Diels–Alder mechanism as depicted in Fig. 7, whereby

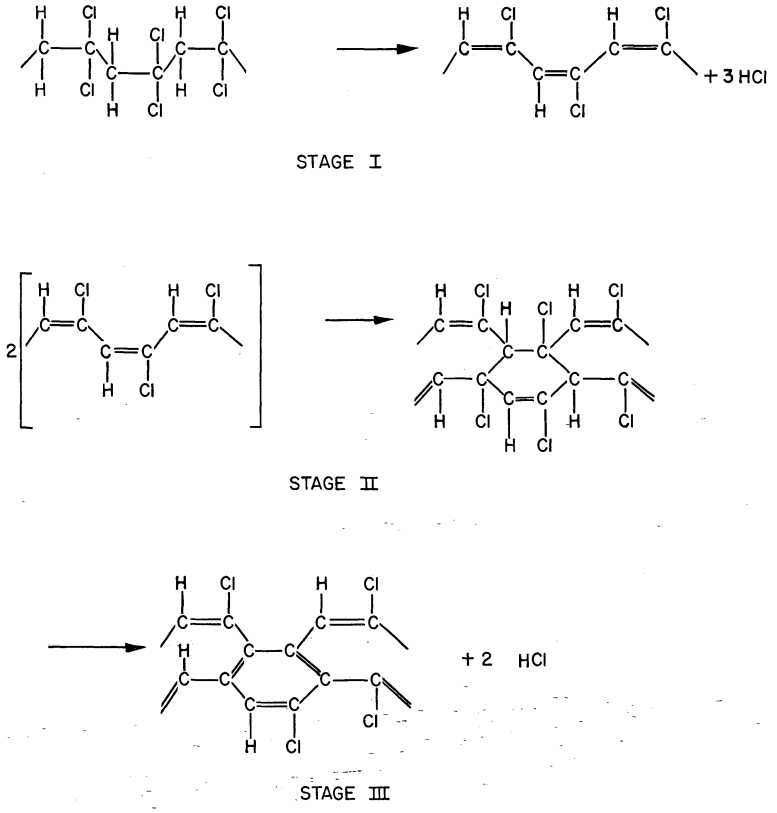

FIG. 7. Suggested Diels–Alder mechanism for the decomposition of polyvinylidene chloride.

a linear polyacetylene is first produced with successive release of adjacent HCl groups along the polymer chain, followed by a possible cyclization of adjacent polyene chains ending with the growth of fused rings. The presence of unpaired electrons in Saran charcoal has been demonstrated by microwave adsorption experiments (17), and in particular Franklin's evidence from X-ray diffraction patterns (14) is concordant with the above decomposition hypothesis.

The rate of HCl evolution also lends support to the suggested mechanism of carbonization. For temperatures between 150° C and 200° C hydrogen chloride is released at a very rapid rate up to about two-fifth decomposition by weight of the polymer. For temperatures in excess of 200° C the rate slows down progressively when adjacent hydrogen and chloride atoms may then be more than one or two carbon-to-carbon distances apart (Fig. 7, stage III). The internal surface ruptures and high temperatures of the final carbonization may provide conducive circumstances for distantly separated individual hydrogen and chlorine atoms to "hop" from carbon atom to carbon atom before reaching favorable sites for mutual interaction. During the last stages of pyrolysis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

one can visualize that HCl molecules may then escape through established pore channels or slowly created new ones.

It must be accepted that obvious hazards are inherent in any mechanistic interpretation of the pyrolysis based on classical organic chemistry, but on the evidence reviewed (including the present work) it would appear that there are strong grounds for accepting the Diels–Alder mechanism. Moreover, it is equally plausible that the fully carbonized polymer may well comprise of a compact homogeneous network of aromatic cross-links.

Interpretation of Porosity Data

Figure 5 relates Saran at various percentage decompositions with the porosities obtained by argon adsorption and helium displacement. No argon was observed to be adsorbed with samples of less than 50% decomposition whereas the values obtained from the helium displacement experiments indicate the presence of fine pores at all compositions. This is not an entirely surprising result, since it has been previously found (1, 5) that Saran charcoal (100% carbon) consists of a series of fine pores accessible to a wide range of small and relatively flat molecules but not to such bulky molecules as α-pinene, sulphur hexafluoride, and tetraethylmethane, which do not enter the pore too readily. Inspection of Table II in terms of the molecular geometry of the adsorbates

TABLE II

Argon	0.41		

*Non-equilibrium value after 6 days.

listed will confirm the view that the pores are fine and probably slot-like in cross section, and between 12 and 15 Å in width in their narrowest dimension. It would appear that with samples of the polymer below 50% decomposition, there may be pores which are so small that they deny penetration of argon but will allow the passage of helium.

The porosity values obtained with helium for samples above 66% decomposition are comparable although slightly higher than the argon adsorption values. With samples below 50% decomposition a marked divergence was clearly evident from Fig. 5, and there may be at least two possible sources of explanation:

(i) The apparently anomalous helium values may be due to "natural" pores existing in the pure polymer disks prior to pyrolysis. Helium pore volume values were later found to vary according to the pressure applied in the preparation of the disks (see Table III). The preliminary results in Table III introduce an additional parameter for consideration in the calculation of pore volumes of partially pyrolyzed samples. The effect of the compactness of the disks is being further pursued and will be reported in more detail elsewhere. It suffices for the present to point out that helium porosity values at low polymer decompositions are variable:

(ii) An additional complicating factor which would invalidate the helium values is the assumption that adsorption of helium is always negligible when the gas is used as a

dilatometric fluid (18). Once again our preliminary investigations (19) of this problem with Saran charcoal have revealed that appreciable adsorption of helium occurs even at room temperatures. This work is presently being carried out in a more thorough manner and will be reported later.

ACKNOWLEDGMENTS

Grateful thanks are due to the Department of Chemistry, Queen's University, Kingston, for permission to use their Perkin–Elmer Model 21 infrared spectrophotometer and also to Canadian Industries Limited, Ammonia Works, Millhaven, Ontario, for a gift of liquid nitrogen. Finally, we wish to thank the Defence Research Board for their generous financial support through DRB Grant No. 8220/12.

NOTES

STEREOCHEMISTRY OF ARSENIC
PART VII. IODODIPHENYLARSINE

J. TROTTER

Crystals of iododiphenylarsine are isomorphous with those of the bromo and chloro derivatives (1); the molecular configurations of the three compounds are very similar, and this study of the iodo compound has been confined to a measurement of the As—I bond distance.

The unit cell dimensions and space group were determined from precession films (Mo $K\alpha$, $\lambda = 0.7107$ Å). The crystal data are: Iododiphenylarsine, $C_{12}H_{10}AsI$; M, 356; m.p. 37–39°. Monoclinic, $a = 11.01 \pm 0.04$, $b = 8.82 \pm 0.03$, $c = 12.34 \pm 0.04$ Å, $\beta = 91°$ $37' \pm 5'$. Volume of the unit cell = 1198 Å^3. D_c (with $Z = 4$) = 1.962, $D_m \sim 1.9$ g cm^{-3}. Absorption coefficient for X rays, $\lambda = 0.7107$ Å, $\mu = 57$ cm^{-1}. Total number of electrons per unit cell = $F(000) = 672$. Absent spectra: $h0l$ when h is odd, $0k0$ when k is odd. Space group is $P2_1/a$.

Intensity data for the $h0l$ and $0kl$ reflections were recorded on precession films, estimated visually, and the structure amplitudes derived from the usual formulae, no absorption corrections being applied. The signs of the structure factors were derived by the isomorphous replacement method, and Fourier series then summed; the coordinates of the arsenic and iodine atoms, derived from the resulting electron-density maps, are given in Table I, expressed as fractions of the unit cell edges. The As—I bond length calculated

TABLE I
Positional parameters

Atom	x	y	z
As	−0.0173	0.1789	0.2755
I	0.0837	−0.4120	0.2000

from these parameters is 2.53 Å, which is, of course, longer than the distances As—Cl = 2.26 Å and As—Br = 2.40 Å in the chloro and bromo derivatives, but very similar to the As—I bond lengths in AsI_3 (2.52 Å) and $(CH_3)_2AsI$ (2.54 Å) (2). The other features of the molecular geometry do not differ significantly from those of the other halogen derivatives (3).

Structure factor data are not listed, but are available from the author.

The author thanks Dr. W. R. Cullen for the crystal sample and for helpful discussion, and the National Research Council of Canada and the President's Research Fund, University of British Columbia, for financial support.

POLAROGRAPHIC REDUCTION OF ORTHO ALKYL NITROBENZENES

OWEN H. WHEELER

Nitrobenzenes are reduced at the dropping mercury electrode in neutral or alkaline solution to phenylhydroxylamines or anilines (1). It has been shown (2) that methyl substitution ortho to the nitro group results in an increase in half-wave reduction potential ($E_{1/2}$ more negative) at pH 7.2 (in 80% water–dioxane). Alkyl groups larger than methyl were not investigated. This paper reports polarographic data (see Table I) for *ortho*-methyl-, -ethyl-, -isopropyl-, and -*t*-butyl-nitrobenzenes and the corresponding para

substituent where the effect of the substituent can only be electronic. These ortho alkyl nitrobenzenes show marked decreases in intensity and hypsochromic displacements of the wavelengths of ultraviolet absorption (3, 4) (see Table II) attributable to steric inhibition of resonance between the nitro group and the aromatic ring.

The values at pH 7.2 in 80% water–dioxane (Table I) for the ortho-substituted compounds are higher than those of the para isomers (increases of 0.07, 0.03, 0.02, and 0.03 v for Me, Et, *i*-Pr, and *t*-Bu), the increase for *o*,*o*-dimethylnitrobenzene being particularly large (0.014 v compared to *p*-nitrotoluene) and of the same order as that found for nitro-

For personal use only.

mesitylene and nitrodurene (0.13 v in both cases (2)). The potential increases, however, do not increase with increasing size of the substituent as might be expected. The diffusion current constants ($i_d/cm^{2/3}t^{1/6}$) were all smaller for the substituted nitrobenzenes and were generally less for the ortho than the para compounds.

The overall differences found were rather small and the results probably do not warrant a detailed analysis. However, the inductive and hyperconjugative effects of alkyl groups, by increasing the negative charge on the nitro group, will cause a higher reduction potential. The fact that these electronic effects increase and decrease, respectively, in the series methyl, ethyl, isopropyl, and *t*-butyl probably accounts for the increase in the reduction potential of *p*-*t*-butylnitrobenzene. In the case of ortho substitution these effects will be more directly felt by the nitro group. However, electronic effects cannot entirely explain the observed results, and steric hindrance must play a large role.

Steric hindrance has been shown to increase the reduction potential of aliphatic nitro compounds (5) and of aromatic aldehydes, ketones, and nitro compounds (6). Steric hindrance may arise from steric inhibition of resonance between the aromatic ring and the nitro substituent (2) and by steric hindrance to adsorption of the nitro group on the charged mercury surface. Both these effects would be expected to increase the reduction potential, the first by increasing the effective charge on the nitro group (by inhibiting resonance charge sharing with the ring) and the second by increasing the energy barrier to addition of electronic charge to the nitro group. Prevost and co-workers (6) have suggested that the first effect is predominant, since the $E_{1/2}$ values are nearly independent of substituent size. However, the spectra (Table II) show a steady increase in steric hindrance with increasing substituent size, an effect that can only be due to steric inhibition of resonance. Recent work on the polarographic reduction of aliphatic halides (7) has shown the importance of the steric requirements of both the reducible group and the electrode surface.

It must be concluded from the present work that polarographic reduction potentials are not a sensitive indication of steric hindrance.

EXPERIMENTAL

Nitrobenzenes

Nitrobenzene, *o*- and *p*-nitrotoluene, and 2,6-dimethylnitrobenzene were Eastman-Kodak white label samples. *o*- and *p*-Nitroethylbenzene and *o*- and *p*-nitroisopropylbenzene were prepared by nitration of the corresponding hydrocarbons (7, 8) and were separated by fractional distillation. *o*- and *p*-Nitro-*t*-butylbenzene were supplied by Professor H. C. Brown (9). Their physical constants are given in Table III.

TABLE III

had a drop-time of 3.3 seconds (open circuit in 0.1 *N* potassium chloride solution) and a flow of 1.63 mg of mercury/sec. The solutions (ca. 2×10^{-4} *M*) contained several drops of 0.1% gelatin in 80% water–dioxane and were deoxygenated by passing nitrogen, previously saturated with the same solvent, for 20 minutes. Voltages were measured against a Beckman calomel electrode (with capillary collar) dipping into the solution. No correction was necessary for the voltage drop in the cell since at this low internal resistance and low concentration the error was <0.005 v. The polarograms were run three or four times and the average values are reported in Table I.

2,3-DIPHENYLBUTANE-2,3-DIOL. SOLVENT EFFECTS

H. AGAHIGIAN, J. F. MORAVECK, AND H. GAUTHIER

The effect of concentration on the chemical shift of the hydroxyl resonance of alcohols has been reported (1(*a*); 1(*b*) and references cited therein) and the position of the hydroxyl proton is an estimate of the extent and nature of the hydrogen bonding. The use of different solvents may lend some insight into the nature of the hydrogen bonding, as has been suggested by Jardetsky (2).

The n.m.r. studies on the butanes have been quite comprehensive (3, 4) in an effort to establish the rotamer population as well as the coupling constants of the protons in possible rotamer configuration; however, butanediols, in particular the meso- and the *dl*-2,3-diphenylbutane-2,3-diols, have not been investigated with respect to solvent effects. Various diastereomeric alcohols have been studied (5) and the hydroxyl resonances have been determined and evidence was given to show the extent hydrogen bonding is dependent on the stereochemistry.

The meso- and *dl*-2,3-diphenylbutane-2,3-diol isomers were characterized (6) by their infrared spectra. An interesting feature of the infrared spectrum of the *dl*-2,3-diphenylbutane-2,3-diol was the broad hydroxyl band. Molecular models indicate that the intramolecular hydrogen bonding is enhanced in the *dl* form whereas in the meso form the intramolecular hydrogen bonding is not sterically favored.

The proton n.m.r. spectra of the *dl*- and meso-2,3-diphenylbutane-2,3-diol in benzene,

had a drop-time of 3.3 seconds (open circuit in 0.1 *N* potassium chloride solution) and a flow of 1.63 mg of mercury/sec. 2,3-DIPHENYLBUTANE-2,3-DIOL. SOLVENT EFFECTS

H. AGAHIGIAN, J. F. MORAVECK, AND H. GAUTHIER

The effect of concentration on the chemical shift of the hydroxyl resonance of alcohols has been reported (1(*a*); 1(*b*) and references cited therein) and the position of the hydroxyl proton is an estimate of the extent and nature of the hydrogen bonding. The use of different solvents may lend some insight into the nature of the hydrogen bonding, as has been suggested by Jardetsky (2).

The n.m.r. studies on the butanes have been quite comprehensive (3, 4) in an effort to establish the rotamer population as well as the coupling constants of the protons in possible rotamer configuration; however, butanediols, in particular the meso- and the *dl*-2,3-diphenylbutane-2,3-diols, have not been investigated with respect to solvent effects. Various diastereomeric alcohols have been studied (5) and the hydroxyl resonances have been determined and evidence was given to show the extent hydrogen bonding is dependent on the stereochemistry.

The meso- and *dl*-2,3-diphenylbutane-2,3-diol isomers were characterized (6) by their infrared spectra. An interesting feature of the infrared spectrum of the *dl*-2,3-diphenylbutane-2,3-diol was the broad hydroxyl band. Molecular models indicate that the intramolecular hydrogen bonding is enhanced in the *dl* form whereas in the meso form the intramolecular hydrogen bonding is not sterically favored.

The proton n.m.r. spectra of the *dl*- and meso-2,3-diphenylbutane-2,3-diol in benzene,

deuterochloroform, and acetone were studied. The meso compound in deuterochloroform had a methyl resonance at 8.45 τ, hydroxyl resonance at 7.70 τ, and an aromatic peak at 2.83 τ while the *dl* mixture in deuterochloroform had resonances at 8.55 τ (methyl), 7.32 τ (hydroxyl), and 2.83 τ (aromatic). The slight high-field resonance of the methyl in the *dl* mixture may be due to the anisotropy associated with the phenyl ring in the preferred rotamer orientation.

The hydroxyl resonance of the *dl* isomer is at lower field than the meso, which is consistent with the infrared data. A twofold dilution of the deuterochloroform solutions of both the *dl* and meso isomers caused the hydroxyl resonance to be shifted to high field by 3 c.p.s. and the methyl resonance by 2.4 c.p.s. In benzene solution the methyl resonances of the meso and *dl* isomers are the same and the expected shift to high field occurred (8.62 τ). The hydroxyl resonances were 7.94 and 7.55 τ for the meso and *dl* isomers respectively.

In acetone solution the spectrum of the meso compound exhibited an interesting effect. In addition to the low-field shift of the hydroxyl due to hydrogen bonding (6.10 τ), the phenyl resonance was split into two multiplets in a ratio of 2:3, 2.63 and 2.85 τ respectively. From the molecular models, it appears that the ortho protons are deshielded because of the steric interaction (7) of the phenyl rings in the preferred configuration due to the hydrogen bonding of the diol with the acetone. There appears to be formation of a solute–solvent "dimer" which is forcing the diol into a geometry where there is steric hindrance. Although the possibility that hydrogen bonding of the aromatic protons with acetone may cause this effect, it is unlikely. The exchange of the hydroxyl proton with deuterium to obtain the deuterated diol and a subsequent proton spectrum in acetone under identical conditions indicated the same splitting of the aromatic protons. There appears to be no isotope effect or at least the changes in bond length due to isotopic substitution had little or no effect on the geometry of the phenyl groups of the meso isomer.

The proton spectrum of the *dl* isomer in acetone (50 mg in 0.5 ml of acetone) was studied and the hydroxyl resonance was 5.87 τ; however, dilution to 1 ml and successive dilution in 0.5-ml increments showed no change in the resonance position of the hydroxyl proton. In a solution of the *dl* isomer in acetone (100 mg in 0.5 ml) the hydroxyl resonance is 5.83 τ.

An identical series using deuterochloroform demonstrated a high-field shift of the hydroxyl upon successive dilutions. This indicates that the intermolecular hydrogen bonding present in the acetone–diol dimer is large compared to the intramolecular hydrogen bonding. Because of the steric interaction of the phenyl groups in the meso diol in acetone one would expect the chemical shift of the hydroxyl resonance to be slightly higher than that of the *dl* isomer in the same solvent, the steric requirements favoring hydrogen bonding of the *dl* isomer. The *dl* isomer resonance is 5.83 τ and that of the meso isomer 6.10 τ, the steric repulsion accounting for the high shift of the meso compound.

Preparations of 2,3-diphenylbutane-2,3-diol have been described (8, 9, 10). In addition to these, there are many others too numerous to mention. Generally, the methods involved the reaction of acetophenone and ethyl benzoate in sodium dispersion; the reaction of acetophenone in alcohol and benzene in the presence of aluminum foil and mercuric chloride; or the reaction of acetophenone in isopropanol in the presence of sunlight for several months. However, when a quartz cell in the presence of ultraviolet light was used good yields of the meso and *dl* isomers of 2,3-diphenylbutane-2,3-diol were obtained in 5 days.

EXPERIMENTAL

In a typical run 2,3-diphenylbutane-2,3-diol was prepared by the reaction of 160 g (1.33 mole) of acetophenone, which was dried with calcium hydride and freshly distilled in 850 ml of isopropanol, and a drop of acetic acid in the presence of ultraviolet light (100 watt Hanovia Ultraviolet Lamp) for 20 days with stirring. The solvent was removed and a 95% yield of the isomer mixture was obtained, m.p. 92–117° C. The *dl* isomer was obtained pure by repeated crystallizations from petroleum ether – benzene, m.p. 125° C. The meso-2,3-diphenylbutane-2,3-diol was isolated by elution from an alumina column with benzene. By using the quartz cell the time of irradiation was limited to 5 days, with the yield of the isomers being approximately the same as those in the experiment in which a pyrex reaction vessel was used.

The n.m.r. spectra were obtained using the Varian A-60 spectrometer. The chemical shifts are reported in "τ" values. Tetramethylsilane was used as the internal standard. The concentrations were identical for the pure *dl* and meso measurements. In addition, known concentrations of synthetic mixtures gave essentially the same chemical shifts as those exhibited by the meso or the *dl* isomers at that concentration.

The infrared spectra were obtained as fluorolube–nujol mulls as well as KBr pellets.

ACKNOWLEDGMENTS

The authors wish to thank Mr. Warren Harple for the infrared spectral data and Mr. George D. Vickers for his assistance in this work.

N-β-D-GLUCOPYRANOSYLTHIOUREA

M. H. Benn

Recently, on the basis of a successful nucleoside synthesis in which D-glucosylthiourea was converted into 1-N-β-D-glucopyranosylthymine and by analogy with glucosylurea (1, 2), Naito and Sano (3) have assigned glucosylthiourea the N-β-D-pyranosyl structure.[1] As an extension of earlier studies of the glycosylureas (1) we are re-examining the chemistry of the glycosylthioureas and in view of the lingering controversy (1, 4, 5, 6) as to whether this type of compound has a Schiff's base or N-glycosidic structure, we wish to present our own independent observations, which support the conclusions of the Japanese workers.

[1]*The reported conversion of the pentabenzoate of glucosylthiourea into the pentabenzoate of glycosylurea, by the action of mercuric oxide (4), is additional evidence supporting this assignment.*

EXPERIMENTAL

In a typical run 2,3-diphenylbutane-2,3-diol was prepared by the reaction of 160 g (1.33 mole) of acetophenone, which was dried with calcium hydride and freshly distilled in 850 ml of isopropanol, and a drop of acetic acid in the presence of ultraviolet light (100 watt Hanovia Ultraviolet Lamp) for 20 days with stirring. The solvent was removed and a 95% yield of the isomer mixture was obtained, m.p. 92–117° C. The *dl* isomer was obtained pure by repeated crystallizations from petroleum ether – benzene, m.p. 125° C. The meso-2,3-diphenylbutane-2,3-diol was isolated by elution from an alumina column with benzene. By using the quartz cell the time of irradiation was limited to 5 days, with the yield of the isomers being approximately the same as those in the experiment in which a pyrex reaction vessel was used.

The n.m.r. spectra were obtained using the Varian A-60 spectrometer. The chemical shifts are reported in "τ" values. Tetramethylsilane was used as the internal standard. The concentrations were identical for the pure *dl* and meso measurements. In addition, known concentrations of synthetic mixtures gave essentially the same chemical shifts as those exhibited by the meso or the *dl* isomers at that concentration.

The infrared spectra were obtained as fluorolube–nujol mulls as well as KBr pellets.

N-β-D-GLUCOPYRANOSYLTHIOUREA

M. H. Benn

Recently, on the basis of a successful nucleoside synthesis in which D-glucosylthiourea was converted into 1-N-β-D-glucopyranosylthymine and by analogy with glucosylurea (1, 2), Naito and Sano (3) have assigned glucosylthiourea the N-β-D-pyranosyl structure.[1] As an extension of earlier studies of the glycosylureas (1) we are re-examining the chemistry of the glycosylthioureas and in view of the lingering controversy (1, 4, 5, 6) as to whether this type of compound has a Schiff's base or N-glycosidic structure, we wish to present our own independent observations, which support the conclusions of the Japanese workers.

[1]*The reported conversion of the pentabenzoate of glucosylthiourea into the pentabenzoate of glycosylurea, by the action of mercuric oxide (4), is additional evidence supporting this assignment.*

D-Glucosylthiourea was best prepared from 2:3:4:6-tetra-O-acetyl-D-glucosylisothiocyanate (7). The product was homogeneous when examined by paper chromatography.[2] The direct, acid-catalyzed condensation of glucose with thiourea (8) gave poor yields of glucosylthiourea, which is difficult to obtain pure.

In unbuffered solution, pH 3–4, in the dark, at 4°, glucosylthiourea rapidly consumed 2 moles mole^{-1} of periodate (within 4 hours), after which slow "overoxidation" (1, 6) took place (2.6 moles mole^{-1} periodate were consumed in 24 hours).

This rules out the Schiff's base structure and establishes the pyranosyl configuration of the sugar moiety.

The β-configuration at the anomeric center was inferred from the following, mainly spectral evidence. The infrared spectrum of glucosylthiourea, in a potassium bromide disk, shows strong absorption at 900 cm^{-1}, weak absorption at 775 cm^{-1}, and absence of absorption at 844 cm^{-1}, features considered as characteristic of glucosides possessing the β-configuration (6, 9).

Proton magnetic resonance spectroscopy of glucosylthiourea itself was inconclusive, but the tetra-O-acetyl glucosylisothiocyanate precursor gave a spectrum at 60 Mc/s in chloroform, practically identical with that of tetra-O-acetyl-β-D-glucopyranosyl chloride (10), in which the signal for the anomeric hydrogen was submerged in the signal due to the secondary hydrogens at τ 4.84. The chemical shift of protons adjacent to an isothiocyanate group is very close to that produced by an adjacent chlorine atom (11) and tetra-O-acetyl-α-D-glucopyranosyl chloride shows a clearly resolved signal for the anomeric hydrogen, τ 3.75 (10). It was therefore concluded that the tetra-O-acetyl glucosyl isothiocyanate has the β-D-pyranosyl configuration—as would be expected from its mode of preparation from tetra-O-acetyl-α-D-glucopyranosyl bromide. The preparation of glucosylthiourea from the isothiocyanate was performed under conditions unlikely to result in inversion of configuration.

N-β-D-Glucopyranosylthiourea does not mutarotate. In aqueous solution it shows intense ultraviolet light absorption at 242 mμ, log ϵ 4.19. Thiourea itself exhibits similar intense absorption at 254 mμ, log ϵ 4.2 (12).

HYDROGEN BONDING IN HALOFORM SOLUTIONS[1]

W. G. PATERSON AND D. M. CAMERON

Although it has not been possible to demonstrate a quantitative correlation of n.m.r. intermolecular hydrogen-bond shifts with hydrogen-bond strength and other physical properties, the trend of recent results has been encouraging (1). In this note some n.m.r. and infrared measurements are reported on chloroform–ether and chloroform–ketone solutions, which in the former case follow a simple qualitative correlation pattern, but which in the latter case apparently do not. Additional n.m.r. measurements on bromoform and iodoform solutions are also reported.

EXPERIMENTAL

The n.m.r. spectra were obtained at approximately 40° C on a Varian A-60 Analytical n.m.r. spectrometer operating at 60 Mc/s. Line positions were measured by the customary side-band technique (2), using a Hewlett–Packard Model 200AB audio-oscillator and a Hewlett–Packard Model 521C frequency counter. Tetramethylsilane (<0.5% by weight) was used as an internal reference and was accounted for in the mole fraction calculation. The precision in measurement of line position was approximately 0.2 c.p.s.

The infrared spectra were recorded on a Perkin–Elmer Model 421 infrared spectrophotometer. At the low concentrations which were used, only the hydrogen-bonded species was visible in the infrared spectrum. The instrument was calibrated using carbon monoxide. The infrared half-band-width measurements were considered to be accurate to less than 2 cm^{-1}. All materials were reagent grade or better and were used without further purification.

RESULTS AND DISCUSSION

The experimental results are summarized in Table I. In the n.m.r. measurements, the CHX_3 (X = Cl, Br) proton shifts in solutions of different concentration were extrapolated to infinite dilution. The CHX_3 hydrogen-bond shift δ_H was taken as the difference between the CHX_3 proton shift in cyclohexane, extrapolated to infinite dilution, and the

corresponding shift in the solvent under investigation (3). A plot of the n.m.r. hydrogen-bond shifts of $CHCl_3$ against those of $CHBr_3$, in a variety of solvents (Fig. 1), indicates

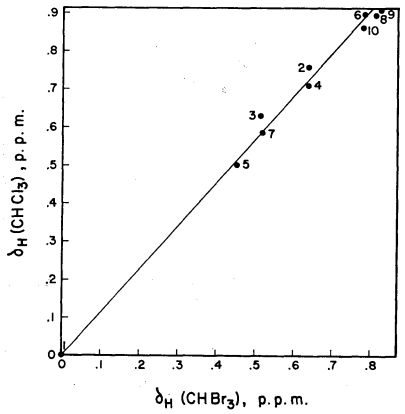

FIG. 1. Comparison of $CHCl_3$ hydrogen-bond shifts with $CHBr_3$ hydrogen-bond shifts in various solvents, relative to CHX_3 proton signal in cyclohexane. The numbering of points corresponds with the list of solvents in Table I.

that the solute–solvent interaction is essentially the same in all cases. The lack of gross deviation from linearity suggests the absence of significant steric hindrance to intermolecular association.

Although fairly well-defined correlations between n.m.r. hydrogen-bond shifts and the corresponding infrared frequency shifts have recently been demonstrated (11–15), sometimes the correlation has been poor or even nonexistent (3, 4; see also Table I). It was claimed by Huggins and Pimentel (4) that a better indication of hydrogen-bond strength, in their case for chloroform solutions, was the infrared band intensity, approximated by the half-band width. This is supported in part by the more quantitative treatment of Reid (16), who predicted enhancement in infrared band intensities for *weak* hydrogen bonds, such as those reported in this note.

Although $CHCl_3$ cannot be used for the infrared measurements because of solvent interference, the comparison of $CDCl_3$ infrared data with $CHCl_3$ n.m.r. data is probably justifiable (3–5). The relationship between the $CHCl_3$ n.m.r. hydrogen-bond shift and the $CDCl_3$ infrared half-band width in a variety of ethers and ketones is shown in Fig. 2. A crude correlation seems evident for the cyclohexane and monobasic ether solutions but not for the other solutions. It is possible that variable anisotropic effects in the carbonyl group of the ketones give rise to anomalous n.m.r. hydrogen-bond shifts (6).

A measure of the hydrogen-bond strength in CHX_3–ether systems should be given by the proton-acceptor or base strength of the ether. A comparison of observed n.m.r. hydrogen-bond shifts with recently measured (10) base strengths of monobasic ethers, given by the appropriate pK_a, is shown in Fig. 3. An approximate correlation is apparent, and the graph also indicates that increasing base strength is accompanied by an increased n.m.r. hydrogen-bond shift. This relationship is being examined currently in greater detail.

Finally it may be noted that the n.m.r. hydrogen-bond shift of $CHCl_3$ is always greater than that of $CHBr_3$. A few measurements on dilute solutions of CHI_3 showed that the magnitude of n.m.r. hydrogen-bond shifts was always in the order $CHCl_3 > CHBr_3 > CHI_3$. This is the anticipated result on the simple basis of electronegativity differences among the halogens.

THE PREPARATION OF ALKALI DITHIONATES

D. W. LARSON, R. W. O'DONNELL, A. B. VANCLEAVE, AND R. L. EAGER

The dithionates of lithium, sodium, potassium, rubidium, cesium, and ammonium have been prepared using an ion exchange technique. Barium dithionate was first prepared by the method given by Blitz (1). Sulphur dioxide was passed through an aqueous suspension of manganese dioxide to form manganese dithionate. Repeated attempts to use the procedure outlined by Blitz always resulted in very unsatisfactory yields and much of the manganese dioxide remained unreacted even after a number of hours. However, when the aqueous suspension was cooled in an ice-water bath and agitated with a magnetic stirrer, the manganese dioxide dissolved completely in a few hours and very satisfactory yields were obtained.

The final procedure adopted for the preparation of barium dithionate was as follows: Sulphur dioxide gas was passed through a cooled, continuously agitated suspension of 50 g of powdered manganese dioxide (Merck, precipitated reagent) in 250 ml of water until the powder had all dissolved (2 to 5 hours). The resulting solution was diluted to 1500 ml with distilled water and boiled to remove excess sulphur dioxide. Solid barium hydroxide (200 g) was added to the boiling solution and the precipitated manganese (II) hydroxide was removed by filtration. The absence of manganese (II) ion in the solution was confirmed with ammonium sulphide. Carbon dioxide gas was bubbled through the filtrate to remove the excess of barium hydroxide, the barium carbonate precipitate being removed by filtration. The solution was then evaporated to about 400 ml, more carbon dioxide was bubbled through the solution, which was then filtered and allowed to cool slowly while crystallization of barium dithionate occurred. Further evaporation of the decantate to about 200 ml yielded another crop of crystalline product. The barium dithionate product was further recrystallized twice from aqueous solution. The final yield of crystalline $BaS_2O_6.2H_2O$, was 106 g. Calculated on the basis of the MnO_2 used, the yield was 55% of the theoretical value. It would, of course, be possible to recover more product from the mother liquor.

Pure alkali dithionates were prepared from the recrystallized barium dithionate by an ion exchange technique. An ion exchange column was assembled with Amberlite 1R-120 cation exchange resin (16–50 mesh, styrene base, nuclear sulphonic acid type) in a glass column 6 mm in inside diameter and 70 cm in length. The resin, originally in the acid form, was eluted with 200 ml of distilled water to remove any free acid prior to loading the column with the desired alkali chloride. A saturated solution of the appropriate alkali chloride (analytical reagent grade) was passed slowly through the column until the effluent was of the same pH as the entering chloride solution. Complete loading of the column was necessary since the presence of any hydrogen ions on the resin would lead to the production of unstable dithionic acid and contamination in the final product. After flushing the loaded resin with distilled water to remove free salt, a saturated solution of barium dithionate was passed into the column. Liquid flow was restricted to 20 drops per minute, the effluent being collected in small samples. The effluent was frequently checked for the presence of barium ion using sulphuric acid as a test reagent; collection of effluent was stopped at the first detection of barium ion. After appropriate effluent samples were combined, the solution was carefully concentrated by evaporation and allowed to stand until a suitable crop of crystals of alkali dithionate had formed. Some

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

difficulty was encountered in crystallizing lithium dithionate, but this was circumvented by using vacuum desiccation. All of the alkali dithionates were obtained as well-formed colorless crystals; ammonium dithionate always occurred as a mass of finely textured material. None of the dithionates prepared by the above method gave any indication of the presence of sulphate on the addition of barium ion to their aqueous solutions.

Yields of dithionate varied from 12 to 19%, based on the amount of the corresponding chloride required to load the column. However, much of the alkali chloride used could be recovered by evaporating to dryness the acidic effluent collected as the column was being loaded, and heating the salt to 500° C to remove hydrochloric acid. About 50% of the rubidium and cesium chlorides used were recovered in this manner. Taking this fact into account, the dithionate yields could be said to vary from 24 to 38%, based on the amount of alkali chloride on the loaded resin. Since no recrystallization is necessary to get a product of high purity by this method, these yields are quite satisfactory. The main advantage of this method of preparation lies in the ease with which a product of high purity is obtained.

Infrared spectra of the dithionates showed a broad absorption band between 1200 and 1280 cm^{-1} and a fairly narrow band at 1000 cm^{-1}. The former band was often split into two peaks. These spectra compare well with the spectra for dithionates given by Golding (2), who lists five strong bands and one medium band between 1196 and 1266 cm^{-1}, and a strong band and a very strong band at 1035 cm^{-1} and 1015 cm^{-1} respectively. Differences appear to lie in the degree of resolution.

Refractive indices of the salts were measured by the Becke method, using calibrated refractive index oils. In all cases, the observed values were in excellent agreement with those quoted by Mellor (3). Table I shows the comparison between observed and literature values for refractive indices.

THE SYSTEM LITHIUM SULPHATE – ZINC SULPHATE – WATER AT 30° C

G. ARAVAMUDAN[1]

INTRODUCTION

Solubility and phase relationships were investigated in this system in continuation of the lithium sulphate – magnesium sulphate – water system, the results of which were reported recently (1). The binary (anhydrous) system Li_2SO_4–$ZnSO_4$ is of the simple eutectic type and is without the formation of either definite compounds or solid solutions in any part of the polytherm, according to Evseeva and Bergman (2).

EXPERIMENTAL

The mode of prepartion of the 'complexes' and their after-treatment during the present study were exactly similar to the pattern followed for the earlier system (1) except that the respective isomorphous zinc salts were used in place of the several forms of magnesium sulphate taken in the previous work. The saturated solutions were separated from the wet residues after equilibrium was attained, which generally took less than 24 hours. Chemical analysis of the two parts involved the determination of water by evaporation and drying at 400° to constant weight and the determination of zinc by the oxine method. The composition of the saturating phases was found from the analytical data using the algebraic variation of the Schreinemaker method.

RESULTS AND DISCUSSION

The results of the study are recorded in Table I. $ZnSO_4.7H_2O$ and $Li_2SO_4.H_2O$ are the stable phases at 30°, whereas $ZnSO_4.6H_2O$ appears in the isotherm, as can be seen in Fig. 1, as a metastable phase in the entire region of its existence. It was noticed that addition of $Li_2SO_4.H_2O$ crystals to supersaturated solutions of zinc sulphate brings about

Microscopic examination of crystals that separated on controlled evaporation, in the range 0–45° C, of solutions containing different proportions of lithium sulphate and zinc sulphate did not reveal any new solid phases.

CONFORMATIONAL EQUILIBRIUM IN ESTERS OF CYCLOHEXANOL BY PROTON MAGNETIC RESONANCE

V. ADJACENT DEUTERATION

E. A. ALLAN, E. PREMUZIC, AND L. W. REEVES

Low-temperature proton resonance studies of some cyclohexyl ethers in the second paper of this series (1) were unsuccessful in distinguishing the axial and equatorially

oriented ether groupings. The halides (1, 2) and various other compounds of the saturated six-membered-ring type (3, 4) have been successfully studied from the point of view of conformational equilibrium and in one case (3), of the kinetics of interconversion, from low-temperature n.m.r. spectra. In this communication the study of 2,6-tetradeuterocyclohexyl esters has shown that compounds with oxygen attached to the cyclohexane ring have an adjacent proton which has a much smaller axial-to-equatorial chemical shift difference than that observed in the halides. It is therefore necessary to deuterate these compounds in the 2 and 6 position in order to resolve separate resonances at low temperature and 40 Mc/s for the axial and equatorial —CH— proton at the point of substitution.

There are now many other studies of conformational processes in the six-membered-ring series at low temperature in the literature (5–11). Deuteration of the six-membered-ring series to simplify the complex spectra obtained was first achieved by Calvin and co-workers (12), followed recently by Anet (13) and Premuzic and Reeves (4).

The 2,6-tetradeuterated cyclohexyl esters were obtained by exchange of the α hydrogen atoms of cyclohexanone in basic D_2O solutions, followed by reduction with lithium aluminum hydride in ether. The formate, acetate, trifluoroacetate, and nitrate were prepared from 2,6-tetradeuterocyclohexanol. These compounds were dissolved in carbon disulphide (2) and a small amount of tetramethylsilane added to serve as an internal reference peak. Proton resonance studies at 40 Mc/s were performed in the temperature region −100° C to +25° C and special attention has been paid to the adjacent —CH—O— resonance peak. The substitution of deuterium for hydrogen in the 2 and 6 positions reduces the value of the vicinal coupling constants by approximately 1/6 but increases the number of theoretical first-order splittings. The —CHO— peak at 25° C appears as a relatively narrow line 4 c.p.s. in half width with no resolvable splittings and symmetrical in shape. The position of this peak can be determined with a maximum error of 0.15 c.p.s. by repeated bracketing between side bands generated from audio modulations on the tetramethylsilane resonance. Concentrations of the acetate, trifluoroacetate, nitrate, and formate in CS_2 were 30, 15, 16, and 15 mole% respectively. The data is presented in tabular form (Table I). Careful chemical shift measurements

a single broad line, i.e. the coalescence temperature, is noted in the table. The percentage of equatorial acetate group in this particular ester agrees well with the value obtained by Anet in the same solvent (13). The formate has a detectably smaller proportion of the compound in the equatorial form, presumably because of smaller steric repulsions involving the free rotations of the ester grouping in the axial position. The dominant steric repulsions must involve the oxygen adjacent to the ring and the 3,5-axial protons, with the ester group axially oriented. The chloro- and bromo-cyclohexanes are 77% and 82% axial under the same conditions (2).

THE EFFECT OF AGITATION ON THE RATE OF NATTA TYPE PROPYLENE POLYMERIZATION*

T. Keii,† M. Taira, and T. Takagi

According to Natta *et al.* (1), the stationary rate of propylene polymerization in the presence of titanium trichloride and triethyl aluminum is expressed by

$$r_\infty = AGP \exp(-10 \text{ kcal}/RT),$$

where A is the frequency factor, G the weight of titanium trichloride, and P the pressure of propylene. The value of the activation energy, 10 kcal/mole, suggests that the rate-determining step of the reaction is not physical but chemical in nature. On the basis that the reaction is observed to be second order, the rate-determining step may be further supposed as a surface reaction which is either of the Twigg–Rideal type (between a propylene molecule in the solution and the titanium trichloride surface covered completely

with triethyl aluminum) or the Langmuir–Hinshelwood type (between the triethyl aluminum adsorbed strongly and a propylene molecule adsorbed weakly). Accordingly, the rate of this reaction can be considered as independent of physical factors, such as degree of agitation.

However, we have found the existence of an effect of agitation on the rate of this polymerization. Using an apparatus with a stroboscope (Fig. 1), we carried out the

polymerization of propylene in the system $TiCl_3$ (ARA of Stauffer Co. Ltd.) – $(C_2H_5)_3Al$ (obtained from Stauffer Co. Ltd. and redistilled) – *n*-heptane (Philips Co. Ltd.). The observed rate of propylene absorption in our system changed exponentially with reaction time from the large initial value to the stationary one, as reported by Natta *et al.* (1). Figure 2, shows the result obtained from the experiment with reaction conditions 44° C,

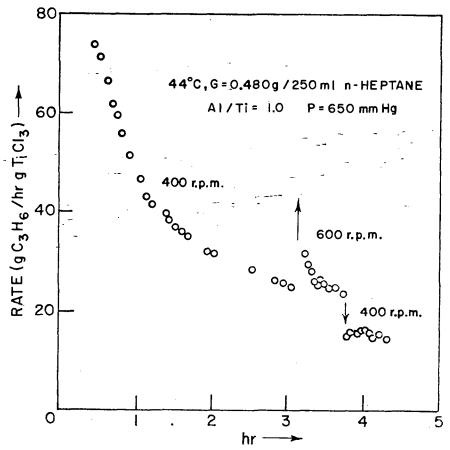

FIG. 2. The dependence of the rate on the rotational speed of the stirrer.

G = 0.48 g/250 ml *n*-heptane, Al/Ti = 1.0, P = 650 mm Hg. In order to examine the behavior in detail, the experiment was repeated, changing randomly the rotational speed of the stirrer within the range 300–600 r.p.m. Figure 3 shows the results obtained at 44° C and 27° C. The variation of the rate with the change of the rotational speed was found to be reproducible, giving an abrupt increase (decrease) followed by a gradual decrease (increase) in rate as the rotational speed is instantly changed to a higher (lower) one. The latter gradual decrease or increase always approaches the rate curve (smooth curve in Fig. 3), which is observed with a constant speed of rotation. It can be seen from the

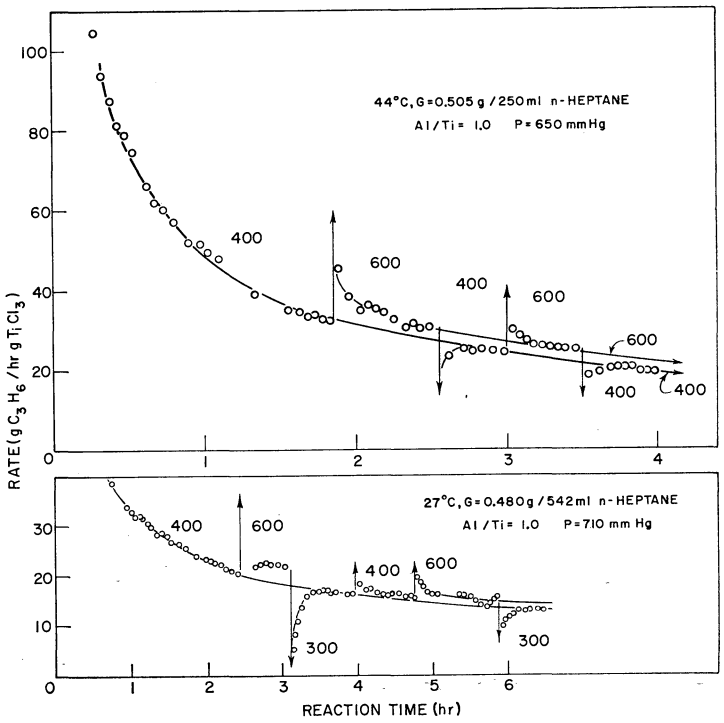

FIG. 3. The dependence of the rate on the rotational speed of the stirrer.

curves in Fig. 3 that the stationary rate of this propylene polymerization is a function of the rotational speed of the stirrer as well as the rate of the initial stage of polymerization. The dependence of the former rate is clearly smaller than the usual one of physical absorption of a gas by a liquid, rate $\propto$ (r.p.m.)^3. Therefore, the other step of mass transfer, i.e., that between liquid phase and solid phase, must be taken into account for the rate-determining step.

Further experiments are being carried out on the chemico-engineering aspects of the reaction.

The authors wish to thank Drs. R. J. Cvetanović, S. Bywater, S. Affrossman, and Y. Amenomiya for their kind discussions. T. K. thanks Dr. I. E. Puddington, Director, for the splendid hospitality afforded him by the Division of Applied Chemistry.

KINETICS AND MECHANISM OF THE PERSULPHATE OXIDATION OF 2-PROPANOL AND 2-BUTANOL

L. S. Levitt and Barbara W. Levitt

INTRODUCTION

Edwards *et al.* (1) have reported that the disodium salt of ethylenediaminetetraacetic acid (EDTA) decreases the first-order rate constant for the oxidation of 2-propanol by potassium persulphate to a value equal to or lower than that observed when $K_2S_2O_8$ is allowed to decompose in water or buffer solution, in the absence of organic compounds. This fact was interpreted as evidence for the chelating agent (EDTA) having removed traces of Cu^{++} which might be present as an impurity in analytical grade persulphate and might conceivably function as a catalyst in persulphate oxidations.

This questionable conclusion, unsupported by any direct evidence for the presence of Cu^{++}, led Edwards to believe that all previous investigations in the kinetics and mechanisms of persulphate oxidations of both inorganic and organic substrates were grossly in error due to the previously unsuspected presence of Cu^{++}.

It was also concluded by Edwards *et al.* that O_2 affects the rate of persulphate oxidations in two different ways: usually, as an inhibitor of a radical-chain process, but in the presence of EDTA, as a catalytic accelerator. The mechanism presented by these authors for the case where O_2 is excluded from the reaction environment[1] is given by the following sequence:

$$S_2O_8^{=} \xrightarrow{k_1} 2SO_4^{-}$$

$$SO_4^{-} + R_2CHOH \xrightarrow{k_2} HSO_4^{-} + R_2\dot{C}OH$$

$$R_2\dot{C}OH + S_2O_8^{=} \xrightarrow{k_3} R_2CO + HSO_4^{-} + SO_4^{-}$$

$$R_2\dot{C}OH + SO_4^{-} \xrightarrow{k_4} R_2CO + HSO_4^{-}$$

From the above series of reactions, the derived rate law (1) is $v = (k_1k_2k_3/k_4)^{1/2}[S_2O_8^{=}] \times [ROH]^{1/2}$, which implies kinetics first order with respect to persulphate and half order with respect to alcohol, or overall 3/2 order.

Wiberg (2) has reported that allyl acetate decreases the first-order rate constant for the oxidation of 2-propanol (0.02 *M*) by potassium persulphate (0.02 *M*) from the value 0.84 hr^{-1} at 60° and pH 5 to the value observed in the absence of 2-propanol (0.014 hr^{-1}). This fact was likewise interpreted as an "inhibition" by allyl acetate of a radical-chain process, and the oxidation mechanism was represented by the following sequence of five irreversible free-radical reactions, from which was derived the final rate law, $v = (2k_1k_2k_4/k_5)^{1/2}[S_2O_8^{=}]$:

$$S_2O_8^{=} \xrightarrow{k_1} 2SO_4^{-}$$

$$SO_4^{-} + H_2O \xrightarrow{k_2} HO\cdot + HSO_4^{-}$$

$$HO\cdot + R_2CHOH \xrightarrow{k_3} H_2O + R_2\dot{C}OH$$

[1]*It is impossible to rigorously exclude oxygen since oxygen is constantly being produced during the course of the reaction by means of the slow oxidation of water.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

$$R_2\dot{C}OH + S_2O_8^{=} \xrightarrow{k_4} R_2C{=}O + HSO_4^{-} + SO_4^{-}$$

$$R_2\dot{C}OH + SO_4^{-} \xrightarrow{k_5} R_2C{=}O + HSO_4^{-}$$

When we compare the Wiberg mechanism with that proposed by Edwards we note that whereas Edwards invokes a direct attack of SO_4^{-} radicals on an alcohol molecule, Wiberg shows the intermediate formation of HO· radicals and their subsequent reaction with the alcohol molecules.

Edwards' purpose in adding the chelating agent (EDTA) was to attempt to demonstrate that the observed decrease in the rate constant could be attributed to the removal of trace amounts of Cu^{++} which might be present and possibly function as a catalyst in persulphate oxidations. Wiberg's purpose in adding the "radical trap", allyl acetate, to the reaction mixture was to attempt to demonstrate the radical nature of the reaction.

Both of these attempted demonstrations of mechanism are invalidated, however, by the fact that the phenomenon of retardation in the rate of persulphate oxidations can be brought about by the addition to the alcohol–persulphate solution of any one of hundreds of organic compounds which are in no way either chelating agents or radical traps, but simply compounds which are themselves oxidized at a relatively slow rate by persulphate under the same conditions (3).

EXPERIMENTAL RESULTS

We have carried out kinetic experiments[2] in which various organic compounds, notably 2-butanol, allyl acetate, and thiodiglycol sulphoxide, were separately added to the persulphate and isopropyl alcohol in buffered aqueous solution. In each case, the overall disappearance of $S_2O_8^{=}$, measured by iodometric titration, was considerably slower than the oxidation of 2-propanol itself. The rate constants, which always remained strictly first order with respect to persulphate,[3] were nearly identical with those observed when the added compound was oxidized in the buffer solution in the absence of 2-propanol.

Our results strongly suggest that the oxidation mechanisms of both Wiberg and Edwards are incorrect, for the following reasons. First of all, it is not true that allyl acetate, as stated by Wiberg, reduces the first-order rate constant to that observed in the buffer solution alone. We have found that 0.04 *M* allyl acetate reduces the rate constant only to approximately the value (0.063 hr^{-1}) observed when it itself reacts with 0.02 *M* persulphate at pH 7 and 60°. This is 4.5 times the rate of disappearance of persulphate in the buffer alone. The results of Kolthoff, Meehan, and Carr (4) also show that the reaction with allyl acetate is significantly faster (by about 40% at the half-time) than that with the buffer alone.

What is more significant, however, is the fact that 2-butanol (which hardly can be considered a "radical trap") produces the same type of result. Thus 0.02 *M* 2-butanol gives $k = 0.22$ hr^{-1} when alone in the buffer solution, and 0.02 *M* 2-propanol alone gives 0.84 hr^{-1}, but the two together in the same solution give 0.30 hr^{-1}. We have obtained similar results when various sulphoxides (3) or other alcohols are mixed with the 2-propanol, or with one another. We find, in general, that the more slowly the added compound is oxidized by persulphate, the more effective it is in diminishing the overall rate of disappearance of persulphate in solutions of mixed substrates.

[2]*The experimental procedure was identical with that previously described (11). It should be noted that we encountered no difficulty in obtaining reproducible data, though such difficulty was reported by Edwards et al. (1).*

[3]*It is seen from the first-order plots in Fig. 1 that the lines are perfectly straight, with no evidence of the sigmoid character reported in reference 1.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

When 0.020 *M* 2-propanol is oxidized and, at the half-time of this oxidation, a quantity of 2-butanol required to make the solution 0.01 *M* with respect to the latter is injected into the reaction flask, the first-order rate plot (Fig. 1D) changes immediately from its

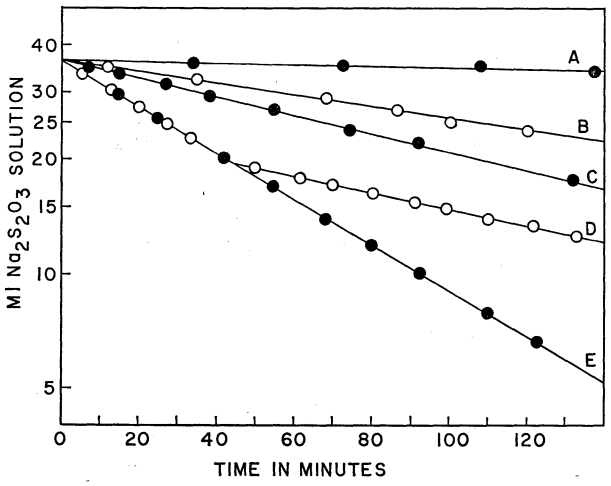

FIG. 1. First-order plot of persulphate (0.02 *M*) oxidations in buffer solution (pH 8.0) at 60°: A, buffer alone; B, 0.02 *M* 2-butanol; C, 0.02 *M* 2-butanol + 0.02 *M* 2-propanol; D, 0.02 *M* 2-propanol with 0.01 *M* 2-butanol added at the half-time; E, 0.02 *M* 2-propanol alone.

previous slope corresponding to $k = 0.84\ hr^{-1}$ to that corresponding to the much smaller value $k = 0.29\ hr^{-1}$. In the reverse situation, however, when 0.02 *M* 2-butanol is oxidized and 0.01 *M* 2-propanol is injected at the half-time, the first-order rate plot increases only slightly in slope ($k = 0.22\ hr^{-1} \rightarrow k = 0.26\ hr^{-1}$). These data are summarized in Table I and some of them plotted in Fig. 1.

TABLE I

First-order rate constants for the disappearance of 0.02 *M* $K_2S_2O_8$ in buffered aqueous solutions of various organic compounds at 60° and pH 8.0

Substrate	k (hr^{-1})
Buffer solution alone	0.018
2-Propanol (0.02 *M*)	0.84
Allyl acetate (0.04 *M*) (pH 7.0)	0.060
Allyl acetate (0.04 *M*) + 2-propanol (0.02 *M*) (pH 7.0)	0.063
2-Butanol (0.02 *M*)	0.22
2-Butanol (0.02 *M*) + 2-propanol (0.02 *M*)	0.30
2-Butanol (0.02 *M*) + 2-propanol (0.01 *M*) injected at the half-time	0.22 (→ 0.26)
2-Propanol (0.02 *M*) + 2-butanol (0.01 *M*) injected at the half-time	0.84 (→ 0.29)

DISCUSSION

It is apparent from the above results that the diminution in the rate, when a compound which is more slowly oxidized[4] by persulphate is added to the isopropyl alcohol – persulphate solution, is due to the formation, by the competing substrate, of a stronger intermediate complex with the active oxidizing species (possibly sulphur tetroxide, $^{+}\ddot{O}{:}SO_3^{-}$)

[4]*It was, indeed, found that persulphate slowly oxidized the sequestering agent (1).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

(5) than that which isopropyl alcohol forms with the oxidant. The mechanism appears, then, to involve an equilibrium of the type (3, 6)

$$R_2CHOH + S_2O_8^{=} \rightleftharpoons \text{complex} \rightarrow R_2CO + 2HSO_4^{-}$$

The complex is very likely one of the possible persulphate esters, formed as unstable intermediates analogous to the formation of chromate esters in the chromic acid oxidation of alcohols (7). One alcohol apparently can displace another from this complex, as demonstrated by the present results: when 2-butanol is added to the 2-propanol solution, the k immediately decreases from 0.84 to 0.29 hr^{-1}; on the other hand, 2-propanol is not able to displace 2-butanol since the k increases only slightly from 0.22 to 0.26 hr^{-1} when 2-propanol is added to the 2-butanol solution. We may be dealing here with a type of ester interchange, which can be represented as:

$$R'OH + \text{R-ester} \rightleftharpoons ROH + \text{R}'\text{-ester},$$

and which is entirely analogous to the ester interchange postulated by Westheimer (7) in the chromic acid oxidation of 2-propanol in the presence of *t*-butyl alcohol, where the latter compound was observed to retard the rate markedly (8). In persulphate oxidations, the esters[5] are probably of the structure $RO—SO_2—O—O—SO_3^{-}$ (an alkyl peroxidisulphate) or $RO—O—SO_3^{-}$ (an alkyl peroxymonosulphate). The latter might be formed by the displacement of $SO_4^{=}$ from $S_2O_8^{=}$ by the alcohol molecule (6). It is interesting to note that chloride ion (9) also effects a marked retardation in the rate of persulphate oxidations, and this may be due to displacement of $SO_4^{=}$ from $S_2O_8^{=}$ by Cl^{-} to give $ClOSO_3^{-}$. This, too, is analogous to the effect of Cl^{-} on chromic acid oxidations, due to formation of $ClCrO_3^{-}$ (10).

In view of these experimental observations it would seem that the "inhibition" of the persulphate oxidation of alcohols by EDTA, reported by Edwards (1), has no more to do with the elimination of trace metal catalysis than the "inhibition"[6] by allyl acetate, reported by Wiberg (2), has to do with removal of SO_4^{-} or $HO\cdot$ radicals. Further evidence against a radical-chain mechanism for the persulphate oxidation of organic compounds is the relatively high activation energy (11, 12) of approximately 26 kcal/mole for these reactions, and the fact that molecular oxygen has no effect on the rate of the persulphate oxidation of sulphides (11), sulphoxides (11), or toluene (13); even in the Ag^{+}-catalyzed persulphate cleavage of glycols strong evidence has been presented by Greenspan and Woodburn (14) for the absence of free-radical intermediates.[7]

The original proposal of a free-radical chain mechanism for persulphate oxidation of alcohols was made by Bartlett (15, 16). The first step in the oxidation of thiols was considered by Eager and Winkler (17) to be the reversible dissociation of persulphate into sulphate ion radicals:

$$S_2O_8^{=} \rightleftharpoons 2SO_4^{-}$$

The mechanisms proposed by Wiberg and by Edwards, however, consider this first step as an *irreversible* process because rate equations of the form required by these authors cannot be derived without this assumption. Now, it is well known that persulphate is

[5]*We assume that* $S_2O_8^{=}$ *and* SO_4 *and their derivatives in the solution all titrate iodometrically as equivalent oxidizing agents, in the same fashion as do t-Bu-hypochlorite and the chromate esters.*

[6]*The competing organic compound is erroneously referred to as the "inhibitor" in Wiberg's paper (2).*

[7]*It is noteworthy that these authors found that* Cu^{++} *failed to catalyze the persulphate cleavage of glycols.*

prepared by the anodic oxidation of aqueous bisulphate solutions, where the mechanism is, of necessity, either

$$HSO_4^- - e^- \rightarrow SO_4^- + H^+$$
$$2SO_4^- \rightarrow S_2O_8^=$$

or (5)

$$HSO_4^- - 2e^- \rightarrow SO_4 + H^+$$
$$SO_4 + SO_4^= \rightarrow S_2O_8^=$$

It is therefore clear that if SO_4^- is formed by dissociation of $S_2O_8^=$ as shown in the Wiberg or Edwards mechanism, it is quite impossible for such dissociation to be irreversible. Thus the mechanisms in question are also quite impossible, since the introduction of the $SO_4^- \cdot$ recombination step into the kinetic scheme leads to a completely altered rate expression which is not in accord with experiment.[8]

Turning now to Wiberg's rate expression for these oxidations, we note that this equation does not involve the constant k_3, which represents the rate of direct attack of the $HO \cdot$ radical on the alcohol molecule. Since this reaction is depicted as the only one in which an intact alcohol molecule participates, one might expect little or no variation of the rate when secondary alcohols other than 2-propanol are oxidized under the same conditions by persulphate.[9] This is not what is observed experimentally, however, since the structure of the alcohol has a marked effect on the rate (18, 19), as shown by the above-mentioned rate constants for 2-propanol and 2-butanol.

Returning finally to Edwards' kinetic scheme for the case where oxygen is excluded from the reaction, we noted above that the rate equation predicts an overall 3/2-order reaction. Therefore, when the initial concentrations of persulphate and alcohol are equal, a given kinetic run should plot as a 3/2-order reaction with respect to the disappearance of persulphate. However, as is well known, this is certainly not the case, for the reactions are strictly first order with respect to persulphate regardless of the initial concentrations.

In any case, the proposed radical-chain mechanisms do not in any way lead to the remarkable dependence of the initial first-order rate constant on the initial concentrations of alcohol and persulphate, which we have shown (6) to be of the form

$$k = k_{max}[ROH]_0[S_2O_8^=]_0/(b+[ROH]_0)(c+[S_2O_8^=]_0),$$

where b and c are empirical constants. As already pointed out in a previous article (3, 6), there is a close, but not exact, analogy between this rate expression and that for enzyme kinetics, thus strongly suggesting the existence of at least one equilibrium step in the reaction sequence leading to a reactive intermediate complex (20, 12) which decomposes irreversibly to the observed oxidation products, as discussed above.

ACKNOWLEDGMENT

The authors are indebted to Mr. Henry J. Helble for obtaining some of the kinetic data, and for verifying the kinetic constants for some of the runs.

[8]*Wiberg's own data on the induced exchange of radioactive sulphate with persulphate in the presence of 2-propanol confirm those of others (R. L. Eager and K. J. McCallum. Can. J. Chem.* **32**, *692 (1954); P. C. Riesebos and A. H. W. Aten, Jr. J. Am. Chem. Soc.* **74**, *2440 (1952)) that a significant, though small, exchange does occur, strongly suggesting that at least one of the two steps of Wiberg's postulated reaction sequence which directly involve* $S_2O_8^=$ *should be reversible, unless the exchange is to be attributed to a possible side reaction.*

[9]*It is true that the rate constants* k_4 *and* k_5 *do appear in Wiberg's rate equation and these represent reactions of radicals formed by abstraction of a hydrogen atom from the carbinol carbon of the secondary alcohol. However, the bond dissociation energies of all these secondary alcohol radical species, and hence their reactivities, are nearly identical.*

DEGRADATION OF D-RIBONO-1 → 4-LACTONE TO D-ERYTHRONO-1 → 4-LACTONE

D. L. MITCHELL

D-Erythrono-1 → 4-lactone (I) can be readily prepared by the alkaline bromine oxidation of D-erythrose. A convenient source of the D-erythro-alcohol grouping occurs at carbons 4 and 5 of D-glucose, and various procedures which employ glycol cleaving reagents have been described for the selective degradation of D-glucose (1), 4,6-*O*-ethylidene-D-glucose (2), and starch (3) to D-erythrose. An analogous degradation of L-rhamnose to L-erythrono-1 → 4-lactone has also been described (4). Most other preparations which have been described are manipulatively more difficult and give less satisfactory yields (see refs. 1 and 5 for a summary of methods).

Sodium 2,3-*O*-isopropylidene-D-ribonate (II), conveniently obtained from 2,3-*O*-isopropylidene-D-ribono-1 → 4-lactone (6), was selectively cleaved between carbons 4 and 5, by sodium metaperiodate, to form sodium 2,3-*O*-isopropylidene-L-erythruronate (III) *in situ*. After selective sodium borohydride reduction of the newly formed aldehyde group at carbon 4, D-erythrono-1 → 4-lactone was obtained in 76% yield with loss of the *O*-isopropylidene group occurring during the lactonization. In this sequence of reactions, the four carbon atoms of D-erythrono-1 → 4-lactone have originated from carbons 1 to 4 of D-ribono-1 → 4-lactone, and, therefore, subsequently from carbons 1 to 4 of D-ribose. Application of this reaction to C^{14}-labelled D-ribose could be useful in obtaining a partial degradation of this pentose.

D-Erythrono-1 → 4-lactone readily forms the derived 2,3-*O*-isopropylidene-D-erythrono-1 → 4-lactone with the reaction being easily followed polarimetrically. The molecular

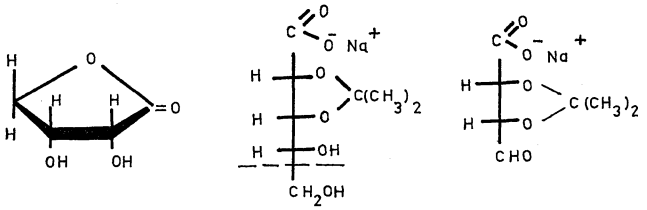
DEGRADATION OF D-RIBONO-1 → 4-LACTONE TO D-ERYTHRONO-1 → 4-LACTONE

D. L. MITCHELL

D-Erythrono-1 → 4-lactone (I) can be readily prepared by the alkaline bromine oxidation of D-erythrose. A convenient source of the D-erythro-alcohol grouping occurs at carbons 4 and 5 of D-glucose, and various procedures which employ glycol cleaving reagents have been described for the selective degradation of D-glucose (1), 4,6-*O*-ethylidene-D-glucose (2), and starch (3) to D-erythrose. An analogous degradation of L-rhamnose to L-erythrono-1 → 4-lactone has also been described (4). Most other preparations which have been described are manipulatively more difficult and give less satisfactory yields (see refs. 1 and 5 for a summary of methods).

Sodium 2,3-*O*-isopropylidene-D-ribonate (II), conveniently obtained from 2,3-*O*-isopropylidene-D-ribono-1 → 4-lactone (6), was selectively cleaved between carbons 4 and 5, by sodium metaperiodate, to form sodium 2,3-*O*-isopropylidene-L-erythruronate (III) *in situ*. After selective sodium borohydride reduction of the newly formed aldehyde group at carbon 4, D-erythrono-1 → 4-lactone was obtained in 76% yield with loss of the *O*-isopropylidene group occurring during the lactonization. In this sequence of reactions, the four carbon atoms of D-erythrono-1 → 4-lactone have originated from carbons 1 to 4 of D-ribono-1 → 4-lactone, and, therefore, subsequently from carbons 1 to 4 of D-ribose. Application of this reaction to C^{14}-labelled D-ribose could be useful in obtaining a partial degradation of this pentose.

D-Erythrono-1 → 4-lactone readily forms the derived 2,3-*O*-isopropylidene-D-erythrono-1 → 4-lactone with the reaction being easily followed polarimetrically. The molecular



I II III

rotational difference between the product and the reactant is large ($[\Delta M]_D$ ca. 100). This observation is in agreement with the optical rotational differences previously recorded between 2,3-*O*-isopropylidene-D-ribono-1 → 4-lactone and D-ribono-1 → 4-lactone (6) and for other 2,3-*O*-isopropylidene-1 → 4-lactones prepared in this laboratory (7).

The following new derivatives were also prepared: (i) 2,3-*O*-isopropylidene-D-ribonamide, (ii) 2,3-*O*-isopropylidene-D-erythronamide, (iii) a mono-*O*-toluene-*p*-sulphonyl-D-erythrono-1 → 4-lactone, and (iv) a di-*O*-toluene-*p*-sulphonyl-D-ribono-1 → 4-lactone.

EXPERIMENTAL

Solutions were concentrated under reduced pressure (ca. 15 mm). Melting points were uncorrected and optical rotations were determined in water, unless otherwise stated. Paper chromatography was carried out by the descending method on Whatman No. 1 filter paper using the solvent system (v:v) ethyl acetate – acetic acid – formic acid – water (18:3:1:4). Unsubstituted 1 → 4-lactones were detected on paper chromatograms with an alkaline silver nitrate spray reagent (8).

Conversion of D-*Ribono-1 → 4-lactone to* D-*Erythrono-1 → 4-lactone*

2,3-*O*-Isopropylidene-D-ribono-1 → 4-lactone (5.20 g, 0.028 mole) was hydrolyzed with 1 molar equivalent of 0.1 *N* sodium hydroxide at room temperature. The optical rotation, $[\alpha]_D^{20}$ 56°, did not change appreciably over a period of 15 hours. The solution was adjusted to pH 7 with acetic acid, diluted to 2 liters with water, and finely powdered potassium metaperiodate (7.01 g, 0.029 mole) was added and the solution was stored in the dark for 2 hours.* A solution of lead acetate (15.3 g) in water (100 ml) was added with stirring and the insoluble lead salts were separated by filtration and washed thoroughly with cold water (50 ml). The combined filtrates were added dropwise, with stirring, to an excess of sodium borohydride (3 g). The solution was filtered free from a small deposit of metallic lead, and the filtrate was acidified with dilute acetic acid and passed down a column of Amberlite IR-120 (H) resin. The eluate was concentrated to dryness and the syrupy acid was lactonized by repeated additions of acetic acid and ethanol and reconcentration to dryness. The residue was extracted with boiling acetone and the solution concentrated to a crystalline mass (3.28 g, 76%) of m.p. 102° (from ethanol), ν_{max} 1753 cm^{-1} (nujol) and $[\alpha]_D^{20}$ −74° (*c*, 1.1). Lit. m.p. 103° C and $[\alpha]_D^{20}$ −73.3° (H_2O) (9). The rates of movement on paper chromatograms for D-erythrono-1 → 4-lactone and D-ribono-1 → 4-lactone were R_{Rh} 1.7 and R_{Rh} 1.4 respectively. Anal. Calc. for $C_4H_6O_4$: C, 40.7; H, 5.1. Found: C, 40.9; H, 5.2.

*2,3-O-Isopropylidene-*D-*erythrono-1 → 4-lactone*

A solution of D-erythrono-1 → 4-lactone (0.105 g) in acetone (5 ml) containing concentrated hydrochloric acid (3 drops) was observed polarimetrically (Table I). After 4 hours, the neutralized solution (silver carbonate) was filtered from inorganic salts and the filtrate was concentrated. The product spontaneously crystallized and was purified twice by sublimation (1–3 mm, 55–60° C) to yield a product (0.105 g, 74%) of m.p. 68–68.5° C, $[\alpha]_D^{20}$ −112° (*c*, 1.5) (Table I) and ν_{max} 1740 cm^{-1} (nujol). Lit. m.p. 65–67.5° C and $[\alpha]_D^{22}$ −116° (10). No hydroxyl absorption was detected. Anal. Calc. for $C_7H_{10}O_4$: C, 53.2; H, 6.4. Found: C, 53.4; H, 6.4.

*2,3-O-Isopropylidene-*D-*erythronamide*

A solution of 2,3-*O*-isopropylidene-D-erythrono-1 → 4-lactone (0.031 g) in liquid ammonia (2 ml) was stored in a sealed ampoule at room temperature for 48 hours (11). After the ampoule was chilled to −80° C, it was opened and stored in a desiccator over evaporating dishes containing concentrated sulphuric acid and solid sodium hydroxide. The solid had m.p. 107–109° C and ν_{max} 3300, 3250, 3150, 1670, and 1630 cm^{-1} (nujol). No lactone carbonyl absorption was detected. Anal. Calc. for $C_7H_{13}NO_4$: C, 48.0; H, 7.5; N, 8.0. Found: C, 47.8; H, 7.6; N, 8.2.

**Sodium metaperiodate was used for some preparations.*

*Acidified acetone (*c*, 2.1).
†Water (*c*, 1.5).

2,3-O-Isopropylidene-D-ribonamide

2,3-*O*-Isopropylidene-D-ribono-1 → 4-lactone (0.26 g) was dissolved in liquid ammonia and stored at room temperature in a sealed ampoule for 3 days. The ammonia-free syrup solidified on trituration with ethanol and was recrystallized from acetone–ether, m.p. 108–110° C. $[\alpha]_D^{21}$ 58° (*c*, 0.5, ethanol), ν_{max} 3250, 3150 (broad peak), 1650, and 1630 cm^{-1} (nujol). No lactone carbonyl absorption was detected. Anal. Calc. for $C_8H_{15}NO_5$: C, 46.8; H, 7.4; N, 6.8. Found: C, 47.1; H, 7.5; N, 6.6.

Periodate oxidation (unbuffered) indicated a periodate uptake of 0.54 mole/mole (5 minutes) and 0.70 mole/mole (8 hours). The solution after 8 hours' oxidation gave a positive test for formaldehyde with the chromotropic acid reagent.

Mono-O-toluene-p-sulphonyl-D-erythrono-1 → 4-lactone

Solid toluene-*p*-sulphonyl chloride (0.650 g) was added in one portion to a cold (0° C) solution of D-erythrono-1 → 4-lactone (0.095 g) in dry pyridine. After storage for 0.5 hour, excess sulphonyl chloride was decomposed by the addition of water (0.3 ml), and the solution poured into a slurry of chipped ice and water (75 ml). The solid was collected, dried (0.105 g, 85%), and recrystallized from methanol (4 ml) to yield fine needles first melting at 172–173° C, then solidifying at ca. 178° C in strongly birefringent prismatic flakes, and remelting at 183–184° C. ν_{max} 3300 cm^{-1} and ν_{max} 1760 cm^{-1} (nujol). Anal. Calc. for $C_{11}H_{12}SO_6$: C, 48.2; H, 4.4; S, 11.8. Found: C, 48.6; H, 4.5; S, 11.7. Attempts to prepare the di-*O*-toluene-*p*-sulphonyl derivative were unsuccessful.

Di-O-toluene-p-sulphonyl-D-ribono-1 → 4-lactone

D-Ribono-1 → 4-lactone (2.53 g) and toluene-*p*-sulphonyl chloride (16.6 g) in pyridine (20 ml) were stored in the refrigerator for 1.5 hours. Water (0.5 ml) was added to the solution to decompose the excess sulphonyl chloride, and after standing for 0.5 hours, the dark red solution was poured into a slurry of chipped ice and water (1.5 liters). The precipitated gum was extracted with chloroform and the chloroform extracts were washed successively with dilute mineral acid, dilute sodium bicarbonate solution, and finally with water. The crude tarry product was dissolved in methanol, warmed, treated with charcoal and the solution filtered through a pad of cellulose. The filtrate, upon dilution with a small volume of light petroleum, deposited crystals (3.36 g, 43%). A specimen, which was recrystallized from methanol – light petroleum (b.p. 60–80° C), melted at 123–125° C and had $[\alpha]_D^{25}$ 9° (*c*, 2.1, ethanol). ν_{max} 3350 cm^{-1} and ν_{max} 1780 cm^{-1} (nujol). Anal. Calc. for $C_{19}H_{20}O_9S_2$: C, 50.0; H, 4.4; S, 14.1. Found: C, 50.2; H, 4.5; S, 14.3.

A sample (61 mg) was dissolved in acetone (10 ml) and 0.01 *N* sodium hydroxide (50 ml). At intervals, aliquots (5 ml) were withdrawn and the remaining alkali was titrated with 0.01 *N* sulphuric acid using phenolphthalein as the indicator.

Time (minutes)	1	5	10	180	24 hr
Moles of alkali consumed/mole of compound	1.2	1.3	1.8	1.9	2.0

Attempts to prepare mono-*O*-toluene-*p*-sulphonyl-D-ribono-1 → 4-lactone by using equimolar quantities of reactants according to the method described above resulted in producing the di-*O*-toluene-*p*-sulphonyl derivative, m.p. 124–125° C, $[\alpha]_D^{25}$ 9° (*c*, 1.13, ethanol), in very low yield (9%). Found: C, 50.2; H, 4.6; S, 14.3.

Attempts to prepare the tri-*O*-toluene-*p*-sulphonyl-D-ribono-1 → 4-lactone by using a large excess of toluene-*p*-sulphonyl chloride and a warmer reaction temperature (one experiment at 37° C, a second experiment at room temperature) yielded a black tarry product that could not be crystallized.

X-RAY DIFFRACTION DATA FOR ALKALI DITHIONATES

D. W. LARSON[1] AND A. B. VANCLEAVE[2]

Departments of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 13, 1962

ABSTRACT

X-Ray powder diffraction patterns have been recorded for the alkali dithionates and for barium and ammonium dithionate. The patterns have been indexed and unit cell dimensions determined for lithium dithionate dihydrate, sodium dithionate (anhydrous), and rubidium dithionate. Previously determined cell dimensions have been confirmed in other cases.

INTRODUCTION

X-Ray crystal structure studies have previously been carried out on all the alkali dithionates (1–4) except lithium dithionate; however, the only ones for which X-ray powder diffraction patterns are available are sodium dithionate dihydrate (5) and cesium dithionate (4, 6). Also lacking are powder data for barium dithionate and ammonium dithionate.

EXPERIMENTAL

The dithionates of lithium, sodium, potassium, rubidium, cesium, and ammonium were prepared in a high state of purity from barium dithionate using an ion exchange technique (7). X-Ray powder diffraction patterns were obtained on a General Electric XRD-5 X-Ray Diffraction Unit, using a copper target tube operated at a potential of 50 kv and a tube current of 16 ma. A 0.0007-inch nickel foil filter was used to absorb Cu K_β radiation, and intensities of the diffraction maxima were determined by using a krypton-filled proportional counter. The spectra were recorded at 24° C. A 1° beam slit and a 0.02° detector slit were employed. A protractor speed of 0.2°/min was used in conjunction with a recorder speed of 30 in./hr at a time constant of 4. Instrumental errors were minimized by calibration with reference to sodium chloride (ASTM data card 5-0628). The 2θ angles were measured with an estimated accuracy of $\pm 0.02°$.

The crystalline salt samples were powdered to -325 mesh and carefully packed into $24 \times 19 \times 2$ mm cavities in flat lucite sample holders for the recording of spectra. Relative intensities were determined by determination of peak height above background, both by direct count and by estimation from chart recordings, and also by determination of integrated peak areas. Since good agreement between the different methods of estimating relative intensities was observed, only those values estimated from chart recordings are given. No large variation in relative intensity of spectral lines was observed when a flat sample spinner was employed.

Potassium, rubidium, and cesium dithionate ($K_2S_2O_6$, $Rb_2S_2O_6$, and $Cs_2S_2O_6$) form hexagonal crystals (2–4). Unit cell dimensions for potassium dithionate have been determined by Stanley (2) as $a = 9.785$ Å and $c = 6.295$ Å. For rubidium dithionate and cesium dithionate, unit cell dimensions have been determined by analysis of the powder patterns; these values are $a = 10.17$ Å and $c = 6.42$ Å, and $a = 6.35$ Å and $c = 11.55$ Å respectively. Hagg (4) has studied cesium dithionate and gives the unit cell dimensions as $a = 6.326$ Å and $c = 11.535$ Å; corrected to the present standards of X-ray wavelengths, Hagg's dimensions are $a = 6.338$ Å and $c = 11.558$ Å. The indexed powder patterns for the above three salts are given in Tables I–III.

The powder pattern for ammonium dithionate ($(NH_4)_2S_2O_6$) is presented in Table IV, indexed as that of an hexagonal crystal with unit cell dimensions $a = 10.22$ Å and $c = 6.47$ Å. This indexing must be

regarded as tentative, since optical observations indicate deviation from hexagonal symmetry; the optical interference figure is a black cross which appears to separate into two isogyres when the microscope stage is rotated. There seems to be no evidence for ammonium dithionate being a hemihydrate, as reported by Mellor (8). Infrared studies indicate no water of hydration, and there is no observable weight loss when the powder is heated at 100° C.

Barium, lithium, and sodium dithionate crystallize as dihydrates ($BaS_2O_6 \cdot 2H_2O$, $Li_2S_2O_6 \cdot 2H_2O$, and $Na_2S_2O_6 \cdot 2H_2O$), forming orthorhombic crystals (9, 8, 1). In Tables V, VI, and VII the powder data for these three salts are given. Unit cell dimensions for lithium dithionate dihydrate have been determined as $a = 10.15$ Å, $b = 10.43$ Å, and $c = 5.99$ Å; for sodium dithionate dihydrate, $a = 10.65$ Å, $b = 10.76$ Å, and $c = 6.41$ Å. The above values for the sodium salt compare well with those given by Martinez, Garcia-Blanco, and Rivoir (1). When the powders of these three dihydrates are heated at 90° C, loss of the two molecules of water of hydration occurs. With sodium dithionate dihydrate, efflorescence takes place even at room temperature when the crystals are ground to a powder. Loss of water was confirmed by weight loss measurements and infrared spectra on the powders before and after heating. Anhydrous sodium dithionate yielded a good powder spectrum; this has been indexed as that of an hexagonal crystal with unit cell dimensions $a = 9.08$ Å and $c = 5.91$ Å (refer to Table VIII). No significant maxima were observed in the diffraction spectrum of the dehydrated barium dithionate, and the pattern for anhydrous lithium dithionate (see Table IX) was too brief to be indexed.

PRESSURE-INDEPENDENT FLOW SYSTEM PYROLYSIS OF DIMETHYL MERCURY

M. KRECH AND S. J. PRICE
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received August 20, 1962

ABSTRACT

The pyrolysis of $HgMe_2$ has been investigated in a benzene carrier system using temperatures from 693° K to 800° K and pressures from 0.36 cm to 26.0 cm. High-pressure limiting rate constants were obtained above approximately 10 cm pressure. The high-pressure activation energy, E_0, of 53.7±0.5 kcal/mole is identified with D(MeHg—Me) within the limits $D < E_0 < D+RT$.

INTRODUCTION

Many investigations of the pyrolysis of dimethyl mercury have been made (1–10). Several of these have given estimates of D(MeHg—Me) and, by combination of kinetic and thermodynamic data, D(Me—Hg). Russel and Bernstein (8) have questioned all previous work in static systems because of complexities in the mechanism of the pyrolysis. They also reject previous estimates of D(MeHg—Me) from flow system work because of the low total pressures used. However, Russel and Bernstein's work has also been questioned (9) because of the accumulation of H_2 during their inhibited experiments. The present work has utilized the efficient energy transfer properties of benzene to extend flow system results to a high-pressure limit.

EXPERIMENTAL

Materials

(*a*) Dimethyl mercury was prepared by adding an ether solution of methyl magnesium iodide to an ether slurry of $HgCl_2$. The reverse Grignard removes the difficulty of adding a solid during the reaction and gives an excellent yield (75%). The excess Grignard was hydrolyzed, the organic layer separated and dried over $CaCl_2$, the bulk of the ether stripped, and the remaining solution fractionally distilled (b.p. 92° C at 750 mm).

(*b*) Spectro grade benzene was prepared for use by refluxing over sodium for 24 hours and then degassing twice by bulb-to-bulb distillation.

Apparatus and Procedure

The apparatus used was a modified Szwarc toluene carrier system designed to work at pressures up to 2 atm. Pressures were measured using a mercury manometer for pressures above 4 cm and a mercury – dioctyl phthalate differential manometer for pressures below 4 cm. Dimethyl mercury vapor was injected into the carrier stream through a capillary sealed to the barrel of the stopcock at the top of the alkyl reservoir. The alkyl and benzene vessels were weighed at the end of each run to determine the amounts used. In each experiment, a pre-run of 2–5 minutes during which benzene only was passed was used to stabilize flow conditions. A similar post-run was used to remove all products from the reaction zone while conditions were still stabilized. The quartz reaction zone had a volume of 171 cc. Contact times were controlled by a capillary sealed in at the outlet of the reaction vessel. A dry ice – acetone trap removed benzene, unreacted alkyl, and diphenyl. The remaining products were continuously transferred by a diffusion pump via a Le Roy still at −160° C and a Toepler pump to a gas burette. On completion of a run the gaseous products were measured and then transferred to a sampling vessel for analysis by gas chromatography on a 1-m silica gel column at 40° C using a flow rate of helium of approximately 20 cc/min.

RESULTS

The results are shown in Table I. Rate constants were calculated from the usual first-order equation assuming

$$\text{fraction decomposed} = \frac{1/2(\text{moles } CH_4) + \text{moles } C_2H_6}{\text{moles } HgMe_2}.$$

The times listed under alkyl represent the portion of the total run during which alkyl was passed. The analyses showed traces of C_2H_4 in most runs but no C_3 or C_4 hydrocarbons were observed. (The Le Roy still was warmed to $-100°$ C after several runs to allow any C_3 or C_4 hydrocarbons to be collected with the other gaseous products.)

The rate constant was studied as a function of pressure at four temperatures. From these studies it appears that when benzene is used as a carrier the first-order rate constant is independent of pressure above 10 cm at all temperatures used in the present work. Previous work (6) and preliminary investigations following the present work indicate that toluene is somewhat less than half as efficient as benzene in maintaining the rate of alkyl decomposition. However, benzene is a less efficient radical scavenger than toluene. To test for possible side reactions, runs were carried out under the unfavorable conditions of low benzene pressure and high temperature. When corrected for slight differences in total pressure, the first-order rate constants obtained at approximately 2.5 cm at 783° K using alkyl concentrations of 6.6×10^{-9} to 20.8×10^{-9} mole/cc show little variation.

Figure 1 shows the Arrhenius plots for the high-pressure limit and for 16 mm. The lines may be represented respectively by $\log k\ (\text{sec}^{-1}) = 14.8-53{,}700/2.303RT$ and $\log k\ (\text{sec}^{-1}) = 13.6-51{,}000/2.303RT$.

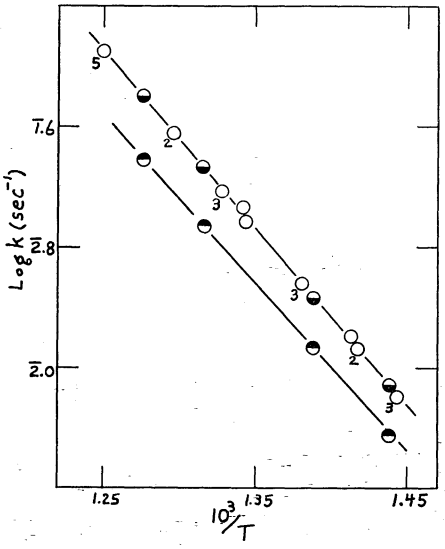

FIG. 1. Arrhenius plots for the decomposition of dimethyl mercury at the high-pressure limit (○, ◒) and at 16 mm (◓). Subscripts refer to number of experiments averaged to obtain a point. Half-filled circles are points taken from log k vs. log p curves.

DISCUSSION

The present results may be represented by a mechanism similar to that previously proposed for the decomposition of $HgMe_2$ in the presence of toluene (6):

$$Hg(CH_3)_2 \rightarrow HgCH_3 + CH_3 \quad [1]$$

$$HgCH_3 \rightarrow Hg + CH_3 \quad [2]$$

$$CH_3 + C_6H_6 \rightarrow CH_4 + C_6H_5 \quad [3]$$

$$2CH_3 \rightarrow C_2H_6 \quad [4]$$

$$2C_6H_5 \rightarrow C_{12}H_{10}. \quad [5]$$

The results at 783° K using low benzene concentrations apparently rule out any appreciable contribution from reaction [6] under the experimental conditions used. Since k_6 is

$$CH_3 + C_6H_5 \rightarrow C_6H_5{-}CH_3 \quad [6]$$

probably at least four times k_3, this result must be attributed to the removal of approximately 67% of the CH_3 by reaction [4] and to the 100- to 200-fold excess of benzene over the maximum C_6H_5 concentration.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Since reaction [2] is extremely fast in comparison to reaction [1], the observed high-pressure activation energy may be placed within the limits $D(\text{MeHg—Me}) < 53{,}700$ cal mole$^{-1} < D(\text{MeHg—Me}) + RT$ or, if $h\nu/kT$ is taken as approximately unity, $D(\text{MeHg—Me}) \approx 53{,}000$ cal mole^{-1}. This is in good agreement with an estimated value of 52,500 cal mole^{-1} obtained by applying Slater's theory to low-pressure flow system results, taking $n = 9$ (11). Taking $D(\text{CH}_3\text{—H}) = 102.5$ kcal mole^{-1} in conjunction with ΔHf^0_{298} ($HgMe_2$, g) = 22.4 kcal mole^{-1} (12, 13) yields 57.2 kcal mole^{-1} for the sum of the two metal–carbon bond dissociation energies in mercury dimethyl. To be consistent, this value should be corrected to 0° K, where it would have a value of approximately 56 kcal mole^{-1}, giving $D(\text{Me—Hg}) = 3.0 \pm 1.0$ kcal mole^{-1}.

In Table II the present results are compared with previous determinations of the Arrhenium parameters for the pyrolysis of dimethyl mercury. Since A and E tend to be

self-compensating, calculated values of the rate constants at 400° C have been included. The differences in total pressure and in the composition of the gaseous mixtures used make direct comparison difficult. However, when due allowance is made for the relative efficiencies of benzene, carbon dioxide, and toluene in energy transfer, good agreement is obtained between the three flow system studies. The static system work of Laurie and Long (4) is in fair agreement with the flow system data. Possible errors in the cyclopentane-inhibited studies have previously been discussed (9).

SYNTHESIS OF SOME PHENAZINE DERIVATIVES[1]

CHAIM STAMMER[2] AND ALFRED TAURINS
Department of Chemistry, McGill University, Montreal, Que.
Received August 15, 1962

ABSTRACT

Nitration of 2-amino-, 2-N-methylamino-, and 1-amino-phenazine resulted in the formation of 2-amino-1-nitro-, 2-N-methylamino-1-nitro-, and 1-amino-4-nitro-phenazine, respectively. Nitration of 2-aminophenazine was shown to proceed via the intermediate nitramine, which was isolated and identified. 2-Hydroxy-1-nitrophenazine was found to exist in the solid state exclusively in the hydroxy form, and 4-nitro-1(5H)-phenazinone was the only solid obtained on acidification of a 1-hydroxy-4-nitrophenazine salt solution.

DISCUSSION

In a continuation of the studies dealing with the structure and reactivity of aza-aromatic nitramines (1–3), an investigation of the behavior of phenazine nitramine derivatives was undertaken.

2-Aminophenazine (I) (4) was nitrated in concentrated sulphuric acid with 70% nitric acid at temperatures between −50° and −15°. This resulted in the formation of 2-nitraminophenazine, in an almost quantitative yield. The nitramine obtained in this way was found to be a mixture of the monohydrate (II) and anhydrous (III) forms, the former being the main component. On prolonged drying, II was gradually transformed into the anhydrous form (III). The pure monohydrate was prepared by slow crystallization from a dilute acidic solution of the mixture. When dried by benzene distillation at 50°, both the monohydrate and the mixture of the two forms yielded the anhydrous nitramine.

Both the monohydrate and the anhydrous nitramine decomposed rapidly when heated to 150–160°. No differences in the chemical behavior of the two forms were observed. They were weakly acidic, dissolved in dilute alkali, and could be reprecipitated from solution with dilute acids. When treated with concentrated sulphuric acid, the nitramines (II, III) were rearranged to 2-amino-1-nitrophenazine (IV).

The infrared spectra of the two forms were in agreement with the proposed structures. In the spectrum of the monohydrate (II), the broad band with maxima at 3540, 3400, and 3200 cm^{-1} indicated the presence of water of crystallization. Absorption which could be attributed to $\overset{+}{N}$—H stretching and to —NO_2 symmetrical vibrations were present in the spectra of the two forms, and the absorption patterns in the range 900–700 cm^{-1} were in agreement with a phenazine substituted in position 2. Distinguishing features between the spectra of II and III were the presence of peaks at 855 and 790 cm^{-1} in the spectrum of III which did not appear in that of II and the difference in the frequency and shape of the bands assigned to the $\overset{+}{N}$—H stretching vibrations (a broad weak band at 2700 cm^{-1} in the spectrum of II and a broad unresolved band between 3100 and 2700 cm^{-1} in that of III). The presence of an $\overset{+}{N}$—H absorption in the spectra of both forms and the

XIV XVI XVII

shift of the $-NO_2$ symmetric vibrations to higher frequencies suggested a nitriminophenazinium inner-salt structure for the nitramines (II, III). Such a structure had been proposed previously (5) for other aza-aromatic nitramines.

Rearrangement of 2-nitraminophenazine was carried out in concentrated sulphuric acid at 0°. After 3 hours, isomerization was complete and 2-amino-1-nitrophenazine (IV), the main rearrangement product, was obtained in a 55% yield. The aminonitro compound (IV) was basic, and dissolved readily in 5% hydrochloric or sulphuric acid. Direct nitration of 2-aminophenazine (I) performed under conditions similar to those of rearrangement resulted in the formation of IV in a slightly lower yield. Thus it would appear that in direct nitration, formation of IV occurred via rearrangement of the intermediate nitramine.

Proof for the structure of the aminonitro derivative (IV) was obtained in several ways. When IV was oxidized in an alkaline medium with potassium permanganate, the production of quinoxaline-2,3-dicarboxylic acid showed that only one carbocyclic ring in IV was substituted. Reduction of IV provided a diamine, of necessity 1,2-diaminophenazine (V). The aminonitro compound IV on being refluxed with concentrated hydrochloric acid or boiled with 1% aqueous sodium hydroxide was converted into 2-hydroxy-1-nitrophenazine (VI) (6, 7). In the infrared spectrum of IV there were bands at 3430, 3290, and 3170 cm^{-1} in the N—H stretching region, and peaks at 1520 and 1280 cm^{-1} which could be correlated with the asymmetric and symmetric vibrations of the nitro group. The lack of any bands between 900 and 850 cm^{-1} and the presence of a peak at 802 cm^{-1} were consistent with 1,2-substitution.

1,2-Diaminophenazine (V) was prepared both by zinc – acetic acid reduction and by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

catalytic reduction of 2-amino-1-nitrophenazine (IV). When a methanolic solution of IV was reduced with hydrogen in the presence of a platinum catalyst, the color of the liquid changed from brown, to deep red, to colorless. On exposure to air, the colorless liquid became deep red again, and a product, identical with the diamine (V) obtained by zinc – acetic acid reduction, was isolated. The colorless methanolic solution was considered to contain a product of further reduction, most probably 1,2-diamino-5,10-dihydrophenazine (VII).

Hydrolytic replacement of the amino group of 2-amino-1-nitrophenazine (IV) in acidic medium was very slow. On the other hand, the replacement reaction in alkaline medium proceeded in a straightforward fashion. It was complete within $1\frac{1}{2}$ hours, and a nearly quantitative yield of 2-hydroxy-1-nitrophenazine was obtained.

When *o*-nitroaniline and methylaniline hydrochloride were allowed to react in the presence of fused zinc chloride according to a modified Wohl–Lange procedure (4), a mixture consisting of approximately 15% 2-aminophenazine (1) and 85% 2-N-methylaminophenazine (VIII) was obtained. Separation of the amines was achieved by chromatography. Acetylation of VIII provided 2-N-acetyl-N-methylaminophenazine (IX). Nitration of the N-methylamine (VIII) in concentrated sulphuric acid with nitric acid (70% excess) at temperatures below −20° resulted in the immediate formation of 2-N-methylamino-1-nitrophenazine (X).

It has been established (8–11) that nitration of electron-deficient aza-aromatic amines proceeded mainly by an "indirect route", and that in cases in which the intermediate nitramine was not formed, the amine resisted nitration. Since the nitration of the N-methylamine (VIII) took place under such mild conditions, it was believed that 2-methylamino-1-nitrophenazine (X) was produced by the intramolecular rearrangement of an unstable intermediate nitramine. Had a direct nitration occurred, much more vigorous reaction conditions would have been necessary and different products would likely have been formed. The nitration of 2-aminophenazine (I) had been considered to proceed by the same reaction mechanism. In the case of the N-methylamine (VIII), however, nitration occurred at a much faster rate, and the reaction resulted in a higher yield of product, 65% versus 55%, being obtained. The increased rate of rearrangement was expected since 2-nitraminophenazine (II, III) had already rearranged readily, and because it had been demonstrated in the pyridine series that introduction of a methyl group into the amino function decreased the stability of the intermediate nitramine in the rearrangement reaction. The fact that the nitro groups in both instances, migrated to position 1 of the phenazine nucleus provided additional support for the assumption that the same mechanism was operative in each case.

The structure proposed for the methylaminonitro compound (X) was substantiated by the infrared spectrum, which had bands indicating the presence of an N—H group, a methyl group, a nitro group, and 1,2-substitution. Further evidence for the structure of X was obtained by its transformation to 2-hydroxy-1-nitrophenazine (VI) on treatment with a 1% sodium hydroxide solution.

1-Aminophenazine (XI) was prepared at first by the deamination of 1,3-diaminophenazine (XII) (12). The difficulties encountered in the deamination led to an investigation of alternative procedures for the synthesis of the amine. 1-Aminophenazine (XI) was reported (13) to have been obtained in a 50% yield by refluxing 2,2′-diaminodiphenylamine (XIII) with nitrobenzene. However, no details of procedure were given in the report and attempts to duplicate the published results failed. After considerable effort had been directed toward determining the exact reaction conditions for the oxidation,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

it was found that by heating the diamine (XIII) with nitrobenzene in a nitrogen atmosphere, and removing the water formed in the reaction by distillation, 1-aminophenazine (XI) was obtained in a 40% yield.

The main mononitration product of 1-aminophenazine in concentrated sulphuric acid was found to be 1-amino-4-nitrophenazine (XIV). Nitration with a 30% excess of nitric acid for 1 hour was complete, but a considerable amount of a substance soluble in ammonia was produced simultaneously with XIV. The former was assumed to be 1-nitramino-4-nitrophenazine on the basis of its solubility in ammonia, rapid decomposition at the melting temperature, relative stability with respect to dilute acids, and the infrared spectrum of the crude product. Complete nitration of 1-aminophenazine with no detectable formation of polynitro compounds soluble in ammonia was achieved when a 70% excess of nitric acid was used and the reaction was terminated after 2 minutes. The structure of the aminonitro compound XIV was demonstrated by oxidation and reduction reactions, by its infrared spectrum, and by replacement of the amino group with an hydroxyl function.

Oxidation of 1-amino-4-nitrophenazine (XIV) in alkaline medium with potassium permanganate provided quinoxaline-2,3-dicarboxylic acid. Reduction of a methanolic solution of the aminonitro compound (XIV) with hydrogen and using a platinum catalyst resulted in a change in the color of the solution from brown to blue to colorless. The colorless solution, on exposure to air, became blue then changed to brown, and a brown solid precipitated. It was assumed that the final reduction product, which gave the colorless solution, was 1,4-diamino-5,10-dihydrophenazine. The colorless solution was rapidly oxidized by air back to the blue solution containing 1,4-diaminophenazine (XV). This sequence of reactions excluded the possibility of 1,2-substitution for the amino nitrophenazine (XIV), since 1,2-diaminophenazine (V) had been identified previously, and of 1,3-substitution because a methanolic solution of 1,3-diaminophenazine (XII) was red. The behavior of the aminonitro compound (XIV) on reduction with zinc – acetic acid provided further confirmation of 1,4-substitution, insofar as the solution of the reduction product in acetic acid was violet while the solutions of the 1,2-diamine (V) and the 1,3-diamine (XII) were brown and green respectively. The 1,4-diaminophenazine (XV) was isolated from the acetic acid solution in the form of blue needles when the acidic solution was rendered alkaline with ammonia in a nitrogen atmosphere. The substance did not melt below 300°, and in solution on exposure to air formed a brown unidentified product.

Additional evidence in favor of the proposed structure was accumulated when, on boiling of 1-amino-4-nitrophenazine (XIV) with aqueous alkali, 1-hydroxy-4-nitrophenazine (XVI), as its alkali salt, was produced. By acidifying the aqueous solution of the alkali salt (XVI), 4-nitro-1(5H)-phenazinone (XVII) was obtained. The alkaline solution of 2-hydroxy-1-nitrophenazine (VI), when acidified, gave the phenazinol tautomer exclusively.

The formation of XVII as the only solid tautomer, and the sole existence of the hydroxy tautomer of 2-hydroxy-1-nitrophenazine (VI) in the solid state, were explained by a hydrogen-bonding effect and formation of a stable six-membered chelate ring. The stability of the hydroxy tautomer in VI required the nitro group to be located in position 1, likewise in the case of XVII the nitro group must be in position 4.

Confirmatory evidence for the structure proposed for the phenazinone (XVII) was based on the reversible transformation of the compound into the ammonium salt of 1-hydroxy-4-nitrophenazine (XVI), the infrared spectra of XVI and XVII, and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

ultraviolet spectrum of XVII in aqueous solution. The general absorption pattern in the 900–700 cm^{-1} region of the infrared spectrum of XVI was similar to that of 1-amino-4-nitrophenazine (XIV) and constituted a clear indication of analogous structures. The absorption pattern in the same region for the phenazinone (XVII), however, was completely different, the two very characteristic bands at 820 ± 10 and 750 ± 15 cm^{-1}, which appeared in all the other phenazines studied, being absent.

4-Nitro-1(5H)-phenazinone (XVII) was soluble in water at 25° to the extent of 0.5 mg/ml. The red solution, on 10-fold dilution, became yellow in color. When this yellow solution was evaporated, red crystals of XVII were recovered. In acidic medium (pH 2.0) the phenazinone (XVII) was much less soluble, and the solution was red. These observations could be explained by an equilibrium in water solution between the phenazinone (XVII) and the hydroxy tautomer in its anionic form (XVI), the phenazinone being red and the anion yellow in color. This equilibrium was studied by means of ultraviolet spectroscopy. The aqueous solution of phenazinone (XVII) (4.15×10^{-5} mole/liter) absorbed at 425 mμ with a molar extinction coefficient of 13,970; no absorption occurred at wavelengths above 530 mμ. An alkaline solution of XVII of an equivalent concentration gave the same absorption curve, and it was concluded that at the given concentration, the phenazinone was already fully converted to the anion. An acidic solution of XVII (2 drops of 3.7% hydrochloric acid per 4 ml of solution) of the same concentration displayed a maximum at 400 mμ and a molar extinction coefficient of 12,050. It also absorbed markedly at 530 mμ ($\epsilon = 3370$). Assuming that the compound in acidic solution existed completely in the phenazinone form, the absorption at 530 mμ could be used to measure the amount of phenazinone (XVII) present in equilibrium in water solutions of different concentrations. Because of the high absorbance exhibited by the solutions studied, the differential method of measurement was applied. The reference cells were filled with alkaline solutions of phenazinone (XVII) of the same concentration, and the differential absorbance shown at 530 mμ was attributed to the presence of phenazinone (XVII) in equilibrium. The approximate ratio of phenazinone (XVII) to anion (XVI) in a saturated aqueous solution of 4-nitro-1(5H)-phenazinone (XVII) was 7:93; on 5-fold dilution the ratio dropped to 2:98, and on 10-fold dilution no detectable amount of XVII was found.

In the nitrations of 2-amino-, 2-N-methylamino-, and 1-amino-phenazines, the nitro groups entered the α-positions of the ring. No β-substituted products were isolated, although in each case the β-position of the ring was available. These results were in agreement with those observed for other electrophilic reactions in the phenazine series such as chlorination (14) and direct nitration (15) in which only α-substituted products were obtained. Such behavior provided confirmatory evidence for the theoretical predictions which had been based on molecular orbital calculations (16, 17).

NOTE ADDED IN PROOF: A. Gray and F. G. Holliman (Tetrahedron, **18**, 1095 (1962)) have claimed the preparation of 1-amino-4-nitro-, 1-hydroxy-4-nitro-, and 1,4-diaminophenazine. On the basis of our present work we suggest that these compounds actually are: 1-amino-2-nitro-, 1-hydroxy-2-nitro-, and 1,2-diamino-phenazine, respectively.

EXPERIMENTAL

The melting points were determined in a Gallenkamp melting point apparatus and are uncorrected. The analyses were carried out in the C. Daesslé Laboratory, Montreal. Infrared spectra were determined on a Perkin–Elmer Model 21 double-beam instrument equipped with a sodium chloride prism. The ultraviolet absorption spectra were measured by means of a Beckman recording spectrophotometer Model DK1. Neutral, activity I Woelm aluminum oxide was used for chromatography unless otherwise noted.

2-Nitraminophenazine (II, III) (2-Nitrimino-(10H)phenazinium Betaine)

2-Aminophenazine (I) (200 mg; m.p. 279°) was powdered and dissolved in concentrated sulphuric acid (2 ml). The brown solution was cooled to −50° and formed a thick paste. Nitric acid (0.073 ml; sp. gr. 1.42; 70% nitric acid) was added at once, and the reaction mixture was stirred for 1–2 minutes until an orange liquid had formed. The temperature rose to about −20°. The solution was poured onto crushed ice (12.5 g) and was stirred until the ice had melted. The orange precipitate which formed was filtered, and the wet solid cake was suspended in water (100 ml). The addition of concentrated ammonia (16 drops) effected solution of the solid material and brought the pH of the solution to 8.0. The solution was filtered through a sintered-glass plate, then was heated to 50°. On addition of aqueous acetic acid (1:1; 20 drops) to the filtrate, fine yellow needles (243 mg) separated from solution. A portion of this material (100 mg) was dissolved in water (200 ml) and ammonia (6 drops) at 75°. The hot solution was acidified with aqueous acetic acid (1:2; 15 drops). On gradual cooling, gold needles deposited, and were isolated. A yield of 98 mg of 2-nitraminophenazine monohydrate (II), m.p. 150–160° (explodes), was obtained. $\bar{\nu}_{max}^{KBr}$ 3540, 3400, 3200, 2700, 1515, 1315, 1300, 880, 835, 820, 765, 755, 745 cm^{-1}. Anal. Calc. for $C_{12}H_8N_4O_2.H_2O$: C, 55.80; H, 3.95. Found: C, 55.22; H, 4.16%.

2-Nitraminophenazine monohydrate (II) (100 mg) was ground and suspended in dry benzene (50 ml). The suspension was heated to 50° for 2 hours with occasional swirling, then approximately 35 ml of the benzene was distilled off under reduced pressure at a temperature not exceeding 50°. The solid 2-nitraminophenazine (III) (60 mg) was separated by filtration, m.p. 150–160° (decomp.). $\bar{\nu}_{max}^{KBr}$ 3100–2700, 1510, 1320, 1295, 880, 855, 830, 820, 790, 765, 750, 740 cm^{-1}. Anal. Calc. for $C_{12}H_8N_4O_2$: C, 59.98; H, 3.36; N, 23.33. Found: C, 59.56; H, 3.40; N, 23.35%.

2-Amino-1-nitrophenazine (IV)

2-Nitraminophenazine (II, III) (0.5 g) was added gradually to concentrated sulphuric acid (5 ml) which had been cooled to −40°. The thick paste was stirred continuously. When all the substance had dissolved, the viscous brown liquid was kept in an ice-water bath for 3 hours. The reaction mixture was diluted with ice water (200 ml), and the precipitate (90 mg) which formed was filtered. The acidic filtrate was heated to 60°, then neutralized with ammonia, yielding 390 mg of a yellow-green substance. The crude material (400 mg) was dissolved in chloroform (500 ml), and the solution was chromatographed on alumina (90 g). Elution with methanol–chloroform (1:21) provided 2-amino-1-nitrophenazine (IV) (344 mg), yellow needles, m.p. 264–265°. $\bar{\nu}_{max}^{KBr}$ 3430, 3290, 3170, 1520, 1280, 845, 835, 802, 795, 770, 755, 740 cm^{-1}. Anal. Calc. for $C_{12}H_8O_2N_4$: C, 60.00; H, 3.40; N, 23.30. Found: C, 60.25; H, 3.43; N, 23.53%.

1,2-Diaminophenazine (V)

A suspension of 2-amino-1-nitrophenazine (IV) (50 mg) in glacial acetic acid (9 ml) was prepared by grinding the substance with acid in a mortar. The suspension was diluted with water (1.5 ml), and zinc powder (excess) was added in three small portions at 30°. The mixture was shaken vigorously; the yellow suspension became orange-brown and formed a clear solution. The excess zinc was filtered off and washed with water (8 ml). The filtrate was made alkaline by the gradual addition of concentrated ammonia (50 ml), whereupon the liquid became purple and brown lustrous needles were deposited from solution. The mixture was refrigerated for 3 hours, then the crystalline product (41 mg) was isolated. This material after two sublimations (1 mm at 130–135°) provided 1,2-diaminophenazine (V), purple needles, m.p. 189–191°. $\bar{\nu}_{max}^{KBr}$ 3390, 3300, 3170, 825, 785, 755 cm^{-1}. Anal. Calc. for $C_{12}H_{10}N_4$: N, 26.64. Found: N, 26.68%.

2-Amino-1-nitrophenazine (IV) (17 mg) was suspended in methanol (5 ml) and reduced with hydrogen in the presence of Adams' catalyst (14 mg PtO_2). The suspended particles dissolved and color changes from brown to purple to almost colorless were observed. The colorless solution on exposure to air became purple again and on evaporation of the solvent 13 mg of a brown solid was obtained. Sublimation of this material provided 1,2-diaminophenazine (V) in the form of purple needles.

2-Hydroxy-1-nitrophenazine (VI)

2-Amino-1-nitrophenazine (IV) (50 mg) was refluxed with 0.8% sodium hydroxide solution (25 ml). After 40 minutes, the solid dissolved, forming an orange solution. Refluxing was continued for 1 hour. The hot solution was filtered and treated dropwise with 3.7% hydrochloric acid at 60° until the pH was 2.0. Yellow crystals precipitated and, after standing overnight in a refrigerator, were filtered and washed with slightly acid water. The material was dissolved in hot water (20 ml) to which concentrated ammonia (4 drops) had been added. The orange solution was filtered hot and acidified to pH 2.0 by the dropwise addition of 3.7% hydrochloric acid at 80°. After standing overnight, the yellow needles which had precipitated were isolated. A yield of 46 mg of 2-hydroxy-1-nitrophenazine (VI), m.p. 238, was obtained. $\bar{\nu}_{max}^{KBr}$ 3040, 1550, 1530, 1250, 840, 802, 755 cm^{-1}. Anal. Calc. for $C_{12}H_7N_3O_3$: C, 59.75; H, 2.93; N, 17.42. Found: C, 59.67; H, 3.29; N, 17.49%.

2-Amino-1-nitrophenazine (IV) (22 mg) was dissolved in concentrated hydrochloric acid (15 ml). The solution was refluxed for 24 hours, during which time the liquid changed in color from red to orange to deep brown. It was filtered and ammonia was added to the hot filtrate until the pH was 3.0. The yellow needles (6 mg) which precipitated were isolated and identified as starting material (IV). After 2 days' standing at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

room temperature, an orange crystalline substance precipitated from solution. This material was isolated and identified by its infrared spectrum as 2-hydroxy-1-nitrophenazine (VI), m.p. 223°.

2-N-Methylaminophenazine (VIII)

Methylaniline hydrochloride (1.45 g) and *o*-nitroaniline (1.40 g) were heated together. The mixture melted at 80–90°; at 135° fused zinc chloride (4.5 g) was added and the temperature was raised to 170° during ½ hour. A vigorous reaction ensued, with vapors of water and *o*-nitroaniline being evolved. The reaction subsided after a few seconds but the mixture was stirred at 170° for 25 minutes longer. Hot water (20 ml) was added carefully and stirring was continued until the mixture had cooled to room temperature. The aqueous layer was decanted, and the tarry residue was washed twice with water (3 ml), then was ground with 2% hydrochloric acid (20 ml). The acidic extract was filtered and the residue on the filter was washed with 0.5% hydrochloric acid. The combined filtrates were cooled and made alkaline with 20% sodium hydroxide (20 ml). A voluminous brown precipitate formed, which, after standing overnight, was filtered and washed with water until the latter gave a neutral reaction. The brown powder (1.2 g) was sublimed. At a temperature up to 120° under reduced pressure, unchanged *o*-nitroaniline was obtained; *in vacuo* with the temperature being gradually raised to 160°, an orange sublimate (0.35 g) was collected. Several batches of the latter (1.2 g) were combined and resublimed. At 125–130°, a sublimate consisting of *o*-nitroaniline and an oily material was obtained, and at 150–160° a mixture of orange and deep red crystals (0.77 g) sublimed. The latter mixture (1.76 g) was taken up in chloroform (176 ml) and filtered, leaving a residue (0.16 g) of 2-aminophenazine (I). The filtrate was chromatographed on alumina (450 g). Elution with chloroform provided 1.43 g of orange needles. Purification of these by sublimation afforded 2-N-methylaminophenazine (VIII), m.p. 199–201°. $\bar{\nu}_{max}^{KBr}$ 3260, 855, 815, 805, 755, 750, 735 cm^{-1}. Anal. Calc. for $C_{13}H_{11}N_3$: C, 74.62; H, 5.30; N, 20.08. Found: C, 74.73; H, 5.64; N, 20.16%. On further elution, 2-aminophenazine (I) (90 mg) was recovered.

2-N-Acetyl-N-methylaminophenazine (IX)

2-N-Methylaminophenazine (VIII) (100 mg) was dissolved in glacial acetic acid (0.5 ml), and acetic anhydride (0.5 ml) was added. The solution was allowed to remain at room temperature for 24 hours, then was diluted with water (2 ml) and evaporated to dryness under reduced pressure. Recrystallization of the residue from aqueous ethanol provided 2-N-acetyl-N-methylaminophenazine (IX) (75 mg), m.p. 155°. $\bar{\nu}_{max}^{KBr}$ 2980, 2900, 1665, 860, 830, 765, 760, 745 cm^{-1}. Anal. Calc. for $C_{15}H_{13}N_3O$: N, 16.69. Found: N, 16.78%.

2-N-Methylamino-1-nitrophenazine (X)

2-N-Methylaminophenazine (VIII) (200 mg) was dissolved in concentrated sulphuric acid (2 ml). The brown solution was cooled to −50° and solidified to a paste. Nitric acid (0.11 ml; sp. gr. 1.42) was added at once, and the mixture was stirred until a red liquid was obtained (10–20 seconds). The liquid was poured onto crushed ice (12.5 g), and the brown solution which formed was filtered. The filtrate was treated with ammonia at 0° until the pH was 3.0–4.0. A brown mass precipitated; it was filtered and washed with water until the wash water gave a neutral reaction. The crude product (200 mg) was taken up in chloroform (45 ml) and chromatographed on alumina (80 g). Elution with methanol–chloroform (1:20) and recrystallization from chloroform gave 162 mg of 2-N-methylamino-1-nitrophenazine (X), m.p. 278–280°. The analytical sample was sublimed *in vacuo* at a temperature above 200°. $\bar{\nu}_{max}^{KBr}$ 3340, 2900, 1515, 1265, 830, 802, 800, 785, 760 cm^{-1}. Anal. Calc. for $C_{13}H_{10}N_4O_2$: N, 22.04. Found: N, 22.14%.

1-Aminophenazine (XI)

Crude 2,2′-diaminodiphenylamine (m.p. 85–90°) (20 g) was heated and stirred with nitrobenzene (200 ml). A stream of nitrogen (3 bubbles/sec) was passed through the reaction vessel during the process. The reaction was controlled in such a way that as the nitrobenzene slowly distilled off, it was replaced continuously by the addition of fresh nitrobenzene (Table I). When the reaction was complete after 5 hours, the product (150 ml) was diluted with benzene (850 ml) and shaken with 3.7% hydrochloric acid (500 ml). The emulsion which formed was filtered and the residue was washed with the same acid (200 ml). The blue acidic layer of the combined filtrates was separated from the brown benzene layer, and the latter was extracted twice with the acid (300 ml). The combined acidic extracts (1 l.) were filtered, diluted with water (1 l.), and boiled

TABLE I

Progress of the oxidation reaction of 2,2′-diaminodiphenylamine with nitrobenzene

Time, hr	Amount of nitrobenzene, distilled off, ml	Amount of fresh nitrobenzene added, ml	Appearance of distillate
1	40	40	Yellow, cloudy
2	55	40	Orange, cloudy
3	48	40	Orange, slightly turbid
4	55	40	Orange, clear
5	52	40	Orange, clear

until no odor of nitrobenzene could be detected. Then the liquid (1.2 l.) was cooled and filtered. The gradual addition of anhydrous sodium acetate (150 g), with stirring, at room temperature, resulted in the formation of a precipitate. After standing for 3 hours in the refrigerator, the solid product was isolated. The red crystalline material (9.7 g) was sublimed twice, providing 1-aminophenazine (XI) (7.76 g), red crystals, m.p. 181–182°. Reported m.p. 179–181° (18). $\bar{\nu}_{max}^{KBr}$ 3480, 3340, 820, 765, 735 cm^{-1}.

1-Amino-4-nitrophenazine (XIV)

1-Aminophenazine (XI) (600 mg; m.p. 181–182°) was ground and dissolved in concentrated sulphuric acid (6 ml). The solution was cooled to a paste (−50°) and nitric acid (0.324 ml; sp. gr. 1.42) was added with stirring. The mixture was placed in an ice-water bath and stirring was continued for approximately 2 minutes until a drop of the liquid nitration mixture when added to ice water dissolved to form a yellow solution. Then the nitration mixture was poured onto crushed ice (300 g). The yellow suspension obtained was extracted with four portions of chloroform, the temperature being maintained near 0°. The chloroform extracts were combined (400 ml) and allowed to pass through a column of alumina (500 g; activity IV). Elution with chloroform provided a brown solution (600 ml) from which, on evaporation, was obtained 320 mg of 1-amino-4-nitrophenazine (XIV), orange needles, m.p. 281–282° (sublimes). $\bar{\nu}_{max}^{KBr}$ 3430, 3290, 1520, 1285, 820, 802, 775, 770, 765 cm^{-1}. Anal. Calc. for $C_{12}H_8O_2N_4$: N, 23.30. Found: N, 23.11%. Concentration of the mother liquor provided an additional 17 mg of (XIV), m.p. 274–278°, and when the mother liquor from this material was rechromatographed on alumina a further 7 mg of (XIV), m.p. 278–281°, was collected. In the latter instance, evaporation of the mother liquor to dryness left 95 mg of a brown crystalline powder, m.p. 140–145° (decomp.), which was distinguished by a strong band at 2150 cm^{-1} in the infrared spectrum.

4-Nitro-1(5H)-phenazinone (XVII)

1-Amino-4-nitrophenazine (XIV) (200 mg; m.p. 281–282°) was refluxed with a 1% solution of sodium hydroxide (80 ml). The solid dissolved completely after 20 minutes and the brown solution which formed was refluxed for another hour, then was allowed to cool slowly for 2 hours. A yellow precipitate settled out of solution, then redissolved when the mixture was heated to 60°. The hot liquid was filtered and the filtrate was acidified at room temperature to pH 2.0 by the dropwise addition of 3.7% hydrochloric acid. After standing for 3 hours at room temperature, the red crystalline material (180 mg) which formed was isolated. The latter (75 mg) was heated to 40° with water (150 ml), cooled to room temperature, and filtered. The filtrate was acidified with 3.7% hydrochloric acid (15 ml) at room temperature, and allowed to stand; a red crystalline substance precipitated and was isolated. A yield of 60 mg of 4-nitro-1(5H)-phenazinone (XVII), m.p. 200° (decomp.), was obtained.

1-Hydroxy-4-nitrophenazine Ammonium Salt (XVI)

Crude 4-nitro-1(5H)-phenazinone (XVII) (50 mg) was dissolved in water (20 ml) and rendered alkaline with ammonia (3 drops). The solution was filtered and treated with concentrated ammonia (14 drops) at 60°. The mixture was allowed to stand overnight in the refrigerator. Isolation of the precipitate which formed afforded 1-hydroxy-4-nitrophenazine ammonium salt (XVI) (22 mg) as light yellow needles, which decomposed at 280°. $\bar{\nu}_{max}^{KBr}$ 3400, 3100, 1540, 1530, 1510, 1320, 1265, 820, 805, 765 cm^{-1}. Anal. Calc. for $C_{12}H_{10}N_4O_3$: N, 21.70. Found: N, 21.45%.

ACKNOWLEDGMENT

The authors are grateful to Dr. Barbara G. Ketcheson for the preparation of the manuscript.

CONCURRENT ION–MOLECULE REACTIONS IN ETHYLENE AND PROPYLENE

A. G. HARRISON
Department of Chemistry, University of Toronto, Toronto, Ontario
Received September 7, 1962

ABSTRACT

The ion–molecule reactions occurring in ethylene and in propylene at high pressures in the mass spectrometer ion source have been studied. It has been shown that two of the six secondary ions in ethylene and four of the nine secondary ions studied in propylene are products of more than one ion–molecule reaction. The cross sections for the separate reactions at 10 v/cm field strength are reported.

INTRODUCTION

The identification of the reactant ion in ion–molecule reactions by appearance potential measurements provides information on the reactant ion of lowest appearance potential. Due to the limited sensitivity of such determinations, particularly for ions of low abundance, concurrent reactions involving ions of higher appearance potential will frequently remain undetected. If such is the case the measured reaction cross sections will be in error.

Pobo and Hutchinson (1) have outlined a method whereby the contribution of concurrent ion–molecule reactions leading to the same product ion in binary systems may be estimated. A recent communication from this laboratory (2) has extended this method and has shown that four of the seven secondary ions studied in cyclopropane are the product of more than one ion–molecule reaction.

The principles of the method can be briefly reiterated. Consider the two ion–molecule reactions leading to the same product ion,

$$P_1^+ + M \rightarrow S^+ + N_1$$
$$P_2^+ + M \rightarrow S^+ + N_2.$$

The total secondary ion current, I_s, can be expressed as the sum of two independent contributions in the usual fashion:

$$[1] \qquad I_s = f_1Q_1d[M]I_{P_1} + f_2Q_2d[M]I_{P_2},$$

where [M] is the concentration of molecules, d is the distance from the electron beam to exit slit, f_x is the collision efficiency, and Q_x is the reaction cross section. Equation [1] on rearrangement gives two similar equations:

$$[2] \qquad \frac{I_s}{I_{P_1}} = f_1Q_1d[M] + f_2Q_2d[M]\frac{I_{P_2}}{I_{P_1}}$$

$$[3] \qquad \frac{I_s}{I_{P_2}} = f_1Q_1d[M]\frac{I_{P_1}}{I_{P_2}} + f_2Q_2d[M].$$

The plot of the ion current ratios indicated by equations [2] and [3] should lead to linear relations, the relevant cross sections being obtained from the slopes and intercepts. As pointed out previously (2) the variation of ion current ratios is achieved by varying the electron energy. The success of the method therefore depends on two assumptions, first, that the reaction cross sections do not change with electron energy, and, second, that the relative collection efficiencies for the primary and secondary ions do not change with electron energy. The present study of the ion–molecule reactions of ethylene and of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

propylene was undertaken in part to obtain further evidence concerning these assumptions.

The ion–molecule reactions in ethylene were studied briefly by Schissler and Stevenson (3, 4) and, in detail, by Field *et al.* (5) and Fuchs (6). Although general agreement has been obtained on the reactions occurring and their cross sections, the present work presents evidence that two of the secondary ions, $C_4H_2^+$ and $C_4H_5^+$, are produced in more than one ion–molecule reaction.

Two of the ion–molecule reactions in propylene were reported by Schissler and Stevenson (3, 4); a more detailed study has been made by Fuchs (6). Again the present results suggest that several of the secondary ions are the product of more than one reaction.

EXPERIMENTAL

The experimental work was carried out using an A.E.I. Ms-2 mass spectrometer. The instrument and general experimental procedure have been described previously (2). In the present work reaction cross sections have been measured at 50 v electron energy and at low electron energy near the appearance potential threshold for the reactant ion. The cross sections at 50 v were determined in the usual fashion by measurement of the ion current ratio I_s/I_P as a function of the source pressure [M]. At the source concentrations used in this work (maximum of less than 1×10^{13} molecules/cc) such a small fraction of the primary ions disappears by ion–molecule reactions, or by charge-transfer reactions such as reported by Field for ethylene (7), that corrections to the measured primary ion currents are negligible. In these measurements it was assumed that only one reaction was occurring. The reaction identification was taken from previous work (5, 6). At low electron energies the results for each secondary ion were treated in the manner of equations [2] and [3]. The choice of a first reactant ion was dictated by appearance potential measurements. The choice of a second possible reactant ion was dictated from thermochemical considerations, the assumption being made that endothermic reactions do not occur. In general, for ethylene no more than two reactions to form each secondary ion are thermochemically possible. For propylene several exothermic reactions can be postulated for most of the secondary ions. The choice of the second reactant ion was dictated, in part, by the results found for the similar system cyclopropane (2) and, in part, by the relative abundances of the primary ions at the low electron energies.

For secondary ions which are formed by only one reaction, equation [1] predicts a linear relation between secondary and primary ion currents at constant source concentration. Several studies (8, 9) have not found such a relation at low field strengths. Since the success of the method outlined above depends on a linear relation, this factor was investigated in some detail. Satisfactory linear plots were obtained at field strengths of 10 v/cm or greater, although deviations were observed at lower field strengths. Typical results are shown in Fig. 1, where the ratio I_s/I_P is plotted against I_P for the reaction

$$C_2H_4^+ + C_2H_4 \rightarrow C_3H_5^+ + CH_3.$$

It is probable that the deviations at lower field strengths are caused by changes in the ionic residence time due to varying space-charge effects as the electron energy is varied. All results in the present work were obtained at a field strength of 10 v/cm.

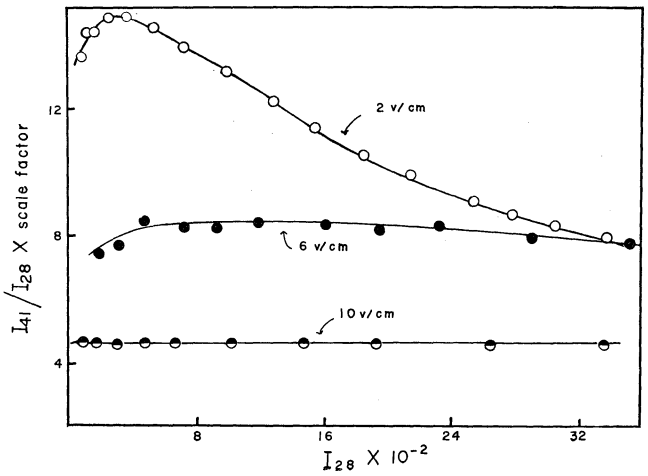

FIG. 1. I_{41}/I_{28} as a function of I_{28} in ethylene. Scale factors: ○ 10^{+2}, ● 10^{+3}, ◓ 10^{+3}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The ethylene and propylene were research grade chemicals of 99.9+% purity and were used without further purification.

RESULTS AND DISCUSSION

The results obtained for ethylene are summarized in Table I. The cross sections at 50 v electron energy and 10 v/cm field strength are in good agreement with previous

results (5) with the exception of reaction 4 leading to the $C_4H_2^+$ ion. This discrepancy will be discussed below.

At low electron energies both reactions 4 and 5 were found to contribute to the formation of $C_4H_2^+$ and both reactions 8 and 9 to the formation of $C_4H_5^+$. Figures 2 and 3

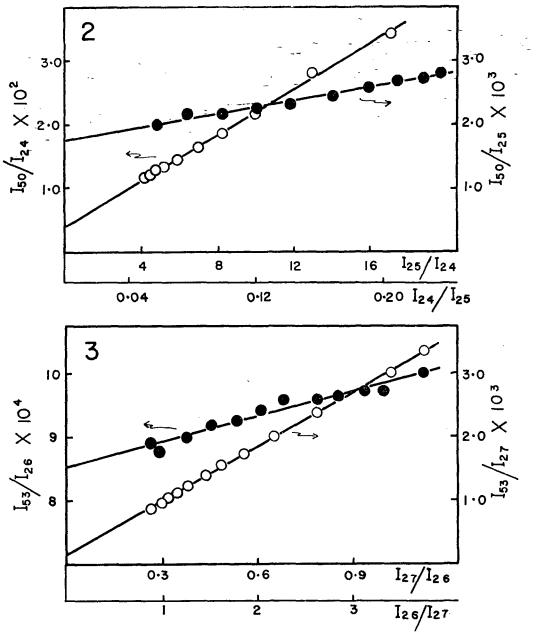

FIG. 2. Dependence of I_{50} ($C_4H_2^+$) on I_{24} (C_2^+) and I_{25} (C_2H^+). Ethylene [M] = 7.00×10^{12} molecules/cc.
FIG. 3. Dependence of I_{53} ($C_4H_5^+$) on I_{26} ($C_2H_2^+$) and I_{27} ($C_2H_3^+$). Ethylene [M] = 6.80×10^{12} molecules/cc.

show the experimental results for these two ions plotted in the manner of equations [2] and [3]. The non-zero intercepts and slopes clearly show that two reactions are involved in each case. The cross sections calculated from these data are given in Table I. The concurrent charge-transfer reaction

$$C_2H_2^+ + C_2H_4 \rightarrow C_2H_4^+ + C_2H_2,$$

reported by Field (7), cannot explain the variation of I_{53}/I_{26} since at constant source pressure this reaction would cause only a constant, if small, diminution in the measured $C_2H_2^+$ ion current.

Although both reactions 1 and 2 leading to the $C_3H_3^+$ ion are thermochemically permitted, no evidence could be found for the occurrence of reaction 2. An estimate of the sensitivity of the method suggests that if reaction 2 does occur the cross section must be less than 2×10^{-16} cm^2/molecule. The $C_4H_3^+$ ion can be formed by both reactions 6 and 7. No evidence could be found for reaction 7 and it is estimated that the cross section for this reaction must be less than 1×10^{-16} cm^2/molecule. The $C_3H_5^+$ and $C_4H_7^+$ ions can be formed by only one exothermic reaction.

The cross section obtained at 50 ev for reaction 4 (assuming that this is the only reaction resulting in $C_4H_2^+$) is considerably larger than previously obtained. The present result is in agreement with the results at low electron energy. Considering equation [1], a plot of I_{50}/I_{24} against [M], which is the usual method for obtaining cross sections, gives a slope,

$$f_4Q_4d+f_5Q_5d\frac{I_{25}}{I_{24}},$$

rather than the simple quantity f_4Q_4d. Using $I_{25}/I_{24} = 4.1_5$, determined experimentally at 50 ev, and the individual cross sections obtained at low energy (Table I) a cross section of 142×10^{-16} cm^2/molecule is calculated for reaction 4 at 50 ev. The cross section obtained for reaction 4 at higher electron energies will obviously be strongly dependent on the ion current ratio I_{25}/I_{24}, which may explain the discrepancy between the present result and earlier results. It is interesting to note that the rate constants for the ion–molecule reactions in ethylene calculated by Field *et al.* (5) were all reasonably constant with the exception of that for reaction 4, which was unexplainably high. This is undoubtedly due to the undetected contribution from reaction 5; the cross section obtained in the present work for reaction 4 alone brings all the rate constants into line.

The agreement between the cross sections at low electron energy and the cross sections obtained at 50 or 70 ev is within experimental error for all secondary ions which are formed by one reaction only. This result provides support for the assumptions that the cross sections and the relative ion collection efficiencies do not vary with electron energy.

The results obtained for propylene are summarized in Table II. In addition to the nine secondary ions reported in Table II secondary ions at m/e = 68 ($C_5H_8^+$), 77 ($C_6H_5^+$), 79 ($C_6H_7^+$), and 81 ($C_6H_9^+$) were reported by Fuchs (6) but were not investigated in the present work because of their low intensity. The secondary ion at m/e = 52 ($C_4H_4^+$) was not reported by Fuchs. The cross sections obtained at 50 ev are compared in Table II with the results obtained by Fuchs (6) at 70 ev and ~13 v/cm field strength. The cross sections obtained in the present work are somewhat higher, as would be expected. The reactions given in Table II do not comprise a comprehensive listing of possible exothermic reactions but only those for which positive evidence was found for their occurrence.

Four of the secondary ions, $C_4H_3^+$, $C_4H_4^+$, $C_4H_7^+$, and $C_6H_5^+$, were found by low-energy studies to be formed by two ion–molecule reactions each. The experimental results

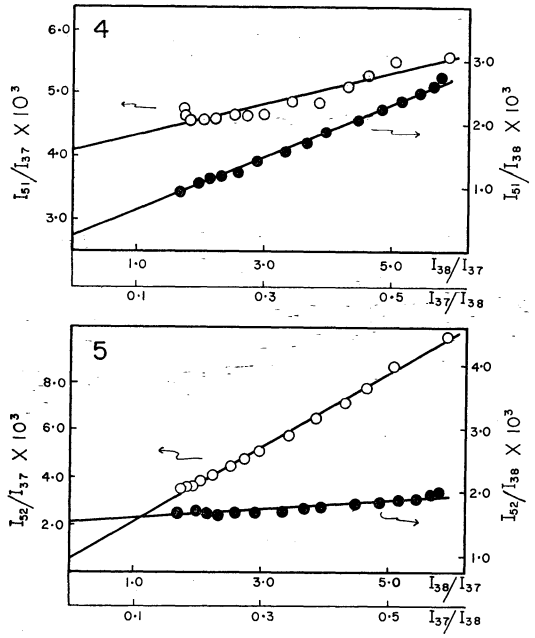

FIG. 4. Dependence of I_{51} ($C_4H_3^+$) on I_{37} (C_3H^+) and I_{38} ($C_3H_2^+$). Propylene [M] = 6.86×10^{12} molecules/cc.

FIG. 5. Dependence of I_{52} ($C_4H_4^+$) on I_{37} (C_3H^+) and I_{38} ($C_3H_2^+$). Propylene [M] = 6.86×10^{12} molecules/cc.

for these cases are shown in Figs. 4–7. The cross sections calculated from these figures are reported in Table II. Reactions 11 and 12 resulting in $C_4H_3^+$ are the same as found for cyclopropane (2); however, the cross section for reaction 12 is lower by a factor of 10 compared to cyclopropane. This is consistent with the considerably lower abundance of $C_4H_3^+$ in the high-pressure mass spectrum of propylene. The formation of $C_4H_4^+$ by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

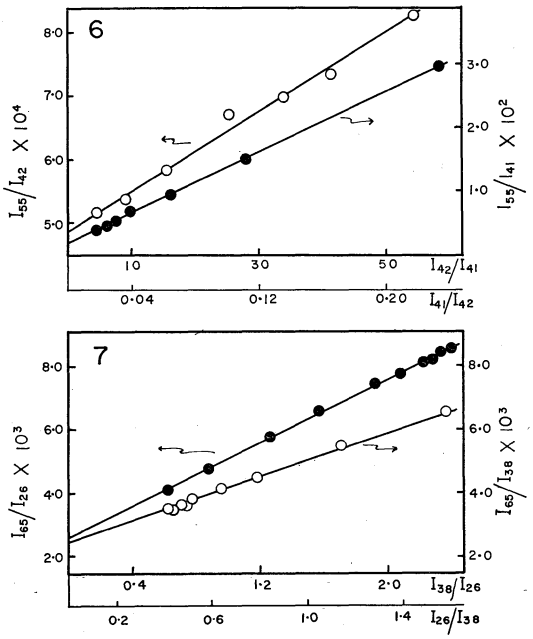

FIG. 6. Dependence of I_{55} ($C_4H_7^+$) on I_{42} ($C_3H_6^+$) and I_{41} ($C_3H_5^+$). Propylene [M] = 3.74×10^{12} molecules/cc.

FIG. 7. Dependence of I_{65} ($C_5H_5^+$) on I_{26} ($C_2H_2^+$) and I_{38} ($C_3H_2^+$). Propylene [M] = 6.12×10^{12} molecules/cc.

reaction 13 is in contrast to the results for cyclopropane (2), where the reaction

$$C_2H_2^+ + C_3H_6 \rightarrow C_4H_4^+ + CH_4$$

was found in addition to reaction 14. The results for propylene were not consistent with reaction of $C_2H_2^+$. Reactions 17 and 18 to form $C_4H_7^+$ are identical with the assignments made for cyclopropane, although the cross sections are considerably higher for propylene.

For the $C_4H_5^+$, $C_4H_6^+$, $C_4H_8^+$, $C_5H_7^+$, and $C_5H_9^+$ ions only one reaction leading to each ion was found. Reaction 16 leading to the $C_4H_6^+$ ion is in contrast to the reaction

$$C_3H_6^+ + C_3H_6 \rightarrow C_4H_6^+ + C_2H_6$$

proposed by Fuchs (6). No evidence could be found for this reaction in the present work. Reaction 16 has also been postulated for cyclopropane (2, 10). For these five reactions the cross sections obtained at low electron energies are in quite satisfactory agreement with the results obtained at higher energies. This agreement suggests again that the reaction cross sections and the relative collection efficiencies are not varying with electron energy and further that any contributions from undetected reactions must be quite small.

The 50 ev cross sections reported in Table II for reactions 11, 13, 18, and 20 are based on the erroneous assumption that these are the only reactions leading to the respective secondary ions. As discussed above for the $C_4H_2^+$ ion from ethylene these composite cross sections can be calculated from the individual cross sections obtained at low energy and the observed ion current ratios at 50 ev. The calculated and experimental cross sections are compared in Table III. In each case satisfactory agreement is obtained between the calculated and experimental results. This agreement again suggests that contributions from undetected reactions are small.

THERMOGRAVIMETRY OF THE DEHYDRATION OF $Mg(OH)_2$[1]

R. C. TURNER, I. HOFFMAN, AND D. CHEN
Research Branch, Canada Department of Agriculture, Ottawa, Ontario
Received August 3, 1962

ABSTRACT

The DTG curves for the dehydration of a number of preparations of $Mg(OH)_2$ were determined. Equations necessary to calculate energies of activation and rate constants from these curves were derived on the basis of a two-thirds-order process for dehydration. It was found that the energy of activation was about 5 kcal greater for naturally occurring than for precipitated $Mg(OH)_2$. This was interpreted to mean that there was a difference in the energy levels of the two preparations, and therefore a difference in their apparent solubility products. Differences obtained in the DTG curves for four different preparations of $Mg(OH)_2$ indicated the probability of a series of energy levels for $Mg(OH)_2$.

An investigation (1) of reactions responsible for certain characteristics of potentiometric titration curves of clays, saturated with Al^{3+} and then titrated with MgO, led to the suggestion that $Mg(OH)_2$ was precipitated at a pH below that expected if the solubility product were near $10^{-11.0}$ (2). Although more recent work (3) indicated that precipitation of a double hydroxide may account for the phenomenon, the possibility that $Mg(OH)_2$ can be formed with a solubility product considerably less than $10^{-11.0}$ was supported by the work of Quartaroli and Belofoiri (4). They observed that naturally occurring $Mg(OH)_2$ (brucite) had the same solubility as precipitated $Mg(OH)_2$, when it was first suspended in an aqueous solution. After the suspension was allowed to settle and the supernatant liquid replaced with fresh solution, however, the apparent solubility product decreased, and, with successive replacements of the supernate, it continued to decrease to a minimum significantly less than $10^{-11.0}$. When this procedure was tried in this laboratory, it was found that after a number of replacements of the supernate in a CO_2-free system the apparent solubility product of a sample of brucite was about $10^{-13.5}$.

Although the results in this laboratory agreed in general with the work of Quarteroli and Belofoiri, it was realized that with successive replacements of the supernatant liquid the smallest, more rapidly dissolved crystals might have been selectively removed, leaving only larger crystals requiring more than the time allowed in our experiment (8 days) to come to equilibrium with the solution. Consequently, other properties of the precipitated and naturally occurring $Mg(OH)_2$ were studied. This paper deals with the thermogravimetry of the two materials.

THEORETICAL

It was found that the kinetic treatment for a first-order reaction, which applied to the thermogravimetry of the decomposition of soil organic matter (5), could not be used for the dehydration of $Mg(OH)_2$. It was necessary to derive equations for the two-thirds-order process, which was the order reported by Gregg and Razouk (6).

The kinetics of a first-order reaction applied to thermogravimetry was developed from the basic equation

$$[1] \qquad -\frac{dw}{dT} = \frac{k_0}{b} e^{-A/T} w,$$

[1]*Contribution No. 65 and 34 from Soil Research Institute and Analytical Chemistry Research Service, respectively.*

where w is the weight remaining to be lost at temperature T, k_0 ($k_0 = ke^{A/T}$) is the frequency factor, b is the constant rate of heating, and A is E/R, where E and R are the energy of activation and gas constant respectively. The corresponding equation for a two-thirds reaction is

$$-\frac{dw}{dT} = \frac{k_0}{b} e^{-A/T} w^{2/3}. \qquad [2]$$

After integration, equation [2] can be put in the form

$$F = \left[-\epsilon \int_0^p e^{-1/p} dp + 1 \right]^3, \qquad [3]$$

where w/w_0, $(k_0 A)/(3bw_0^{1/3})$, and T/A are given the symbols F, ϵ, and p respectively. Differentiation of equation [3] gives

$$\frac{dF}{dp} = -3\epsilon e^{-1/p} \left[-\epsilon \int_0^p e^{-1/p} dp + 1 \right]^2. \qquad [4]$$

Using the expansion of Schlömilch (7) for $-E_i(-x)$, it can be shown that

$$\int_0^p e^{-1/p} dp = pe^{-1/p} \left(\frac{p}{(p+1)} - \frac{p^2}{(p+1)(p+2)} + \frac{2p^3}{(p+1)\ldots(p+3)} - \frac{4p^4}{(p+1)\ldots(p+4)} + \frac{14p^5}{(p+1)\ldots(p+5)} - \ldots \right). \qquad [5]$$

The expression enclosed in parentheses in equation [5] is an infinite series, but when p is small, all terms after a given one can be ignored without affecting the result materially. With p less than 0.04 (which applies in this work) ignoring all but the first two terms has no effect on the first three significant figures of the result and introduces an error less than 0.06%. With this approximation equation [5] becomes

$$\int_0^p e^{-1/p} dp = e^{-1/p} \frac{2p^2}{(p+1)(p+2)} \qquad [6]$$

and equations [3] and [4] can be written, respectively,

$$F = \left[-\epsilon e^{-1/p} \frac{2p^2}{(p+1)(p+2)} + 1 \right]^3 \qquad [7]$$

and

$$\frac{dF}{dp} = -3\epsilon e^{-1/p} \left[-\epsilon e^{-1/p} \frac{2p^2}{(p+1)(p+2)} + 1 \right]^2. \qquad [8]$$

It can be shown by a treatment similar to that used for a first-order reaction (5) that

$$\epsilon = \frac{e^{1/p_m} (p_m+1)(p_m+2)}{2p_m^2[(p_m+1)(p_m+2)+1]}, \qquad [9]$$

where the subscript m denotes maximum rate of reaction.

From equations [7], [8], and [9] it is possible to calculate dw/dT, w/w_0, w, and k_0 if T_m and A are known. T_m can usually be measured from experimental DTG curves but some other means of calculating A from experimental data is necessary. It was found graphically (5) that, for a first-order reaction, a fairly simple relation existed between A, T_m, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

δT,[2] where δT is the temperature required to reduce the rate of decomposition to half its value on either side of the maximum rate. For the two-thirds-order reaction the corresponding relation was

$$[10] \qquad \log A = \log T_m - \log \frac{\delta T}{T_m} + 0.2998 - \left[\frac{T_m}{A}\right]^{1.35}.$$

Table I shows the properties of equation [4] and therefore of equation [8] which were required to obtain equation [10] or are needed in the application of the equations to experimental results. The first three terms of the infinite series in equation [5] were used to calculate p_1 and p_2 to ensure sufficient significant figures.

TABLE I

*p_1 is the value of p at one half the maximum rate before the maximum is reached.
†p_2 is the value of p at one half the maximum rate after the maximum is passed.

EXPERIMENTAL

The brucite used in the experiments was a high-quality sample available in these laboratories. The only impurities that were detected in it were Mn (less than 0.02%) and Fe (0.05%). It was ground to pass a $\frac{1}{2}$-mm sieve. The precipitated $Mg(OH)_2$ was produced by adding NaOH to a solution of $MgCl_2$. The solid was separated from the solution, washed free from chlorides, and air dried.

The apparatus used was a Stanton Thermo-Recording Balance of 0.1 mg sensitivity, modified by the installation of a current chopper (purchased from the manufacturer) and the introduction of a rheostat to control the current entering the furnace. A linear rate of 5.4° C per minute was maintained over the entire temperature range by following a program of previously determined settings. Samples (100.0 mg) were weighed in platinum crucibles on an ordinary analytical balance. Automatic arresting of the thermobalance at 5-minute intervals recorded the time scale on the weight curve. The rate of weight change per 2.5-minute interval as obtained by simple difference was plotted vs. temperature to give differential thermogravimetric (DTG) curves. Prolonged heating at constant temperature was effected without the use of the current chopper by manual operation of the main furnace switch over short intervals.

RESULTS

The DTG curves from 600 to 770° K for the precipitated and naturally occurring $Mg(OH)_2$ (Fig. 1) indicated some loss in weight with both materials at all temperatures in this range. Near 373° K, the precipitated material also lost about 0.5 mg, presumably free or adsorbed H_2O. The natural material did not lose any weight until 600° K was reached. Both samples continued to lose weight until the temperature reached nearly 1273° K (6, 8). The maximum rate of weight loss occurred at 689° for the precipitated and at 745° K for the natural material.

The value for δT measured from the DTG curve for the precipitated material was 36°. When this value along with 689° for T_m were substituted into equation [10], A was found to be 25,860. With this value for A, dF/dp was calculated by means of equations [9] and [8] for a number of temperatures, including that at which the experimental was at a maximum. Since dw/dT is equal to $(w_0^{1/3}/A)(dF/dp)$, it was possible to calculate w_0 at the maximum rate of dehydration. With this value for w_0, dw/dT was calculated from

[2]*This was given the symbol ΔT in the previous publication (5).*

For personal use only.

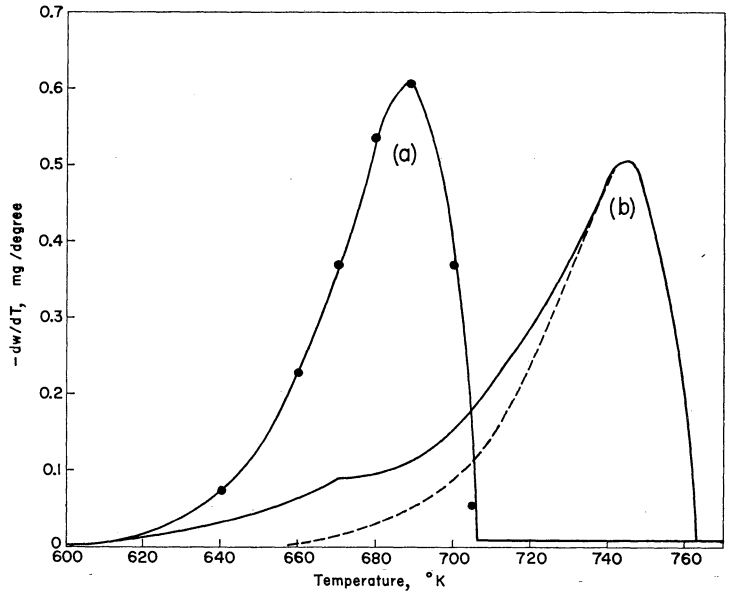

FIG. 1. DTG curves for (*a*) precipitated $Mg(OH)_2$ and (*b*) naturally occurring $Mg(OH)_2$.

the values for dF/dp for the other temperatures. These values, shown as filled circles in Fig. 1, agreed well with the experimental curve.

For the brucite, a value for δT was calculated by multiplying the fraction to the right of the maximum rate of dehydration by 1.85 (see Table I) to find the theoretical value to the left of the maximum; the sum of the two fractions was 38°. This value with 745° K for T_m gave a value of 28,660 for A when substituted into equation [10]. Values for dw/dT were then calculated as before and the theoretical DTG curve was constructed (broken line in Fig. 1). Comparison of the calculated with the experimental curve showed that there was considerable loss in weight between 600 and 730° K not accountable by the main reaction.

From the definitions in the theoretical part, E, k_0, and k for a number of temperatures were calculated from the theoretical DTG curves in Fig. 1. These results (Table II)

TABLE II

Summary of values calculated from the theoretical DTG curves

Material	E (kcal)	k_0 ($mg^{1/3}min^{-1}$)	Temperature (°K): 653	689	728	745
			k ($mg^{1/3}min^{-1}$)			
Precipitated	51.4	$10^{16.2378}$	0.11	0.87	6.46	14.6
Brucite	57.0	$10^{16.4531}$	0.0025	0.024	0.23	0.56

showed that the energy of activation for dehydration was 5.6 kcal higher for the natural than for the precipitated material. The values of k_0 for the two materials were very similar. The values for k, however, were much greater at a given temperature for the precipitated material than for brucite because of the difference in activation energy.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A number of independent experiments were made to check the validity of the kinetic treatment. Since the kinetic treatment was based on the assumption that dehydration of $Mg(OH)_2$ proceeds by a two-thirds-order process, the rate of the reaction was followed at constant temperature. The temperature of the precipitated material was raised from room temperature at the rate of 5.4° per minute until it reached 653° K. It was then held constant and the loss in weight followed as a function of time with the automatic recorder, until the rate of loss in weight was too small to measure. A plot of $(w/w_0)^{1/3}$, with w_0 equal to the total loss in weight during the isothermal treatment, against time was made. Since the two-thirds-order reaction can be represented by

$$[11] \qquad \left[\frac{w}{w_0}\right]^{1/3} = -\frac{kt}{3w_0^{1/3}} + 1,$$

the above plot should be a straight line with slope equal to $-(k/3w_0^{1/3})$. Figure 2 shows that the plot for the precipitated material (curve *a*) followed a straight line until well

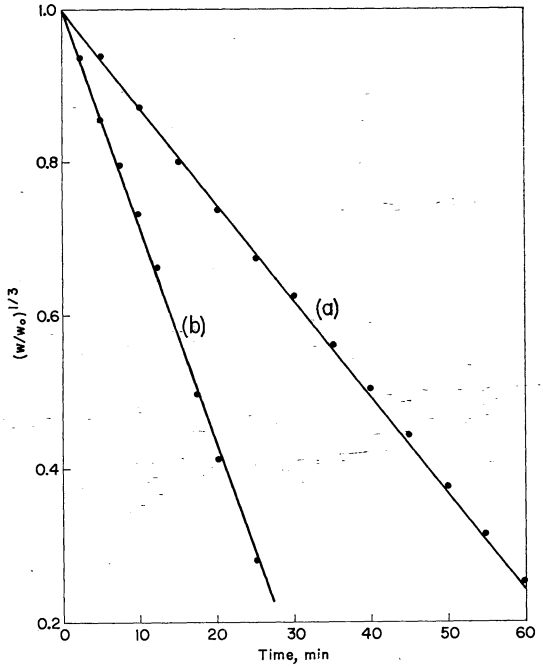

FIG. 2. Rates of dehydration of $Mg(OH)_2$: (*a*) precipitated $Mg(OH)_2$ at 653° K, (*b*) naturally occurring $Mg(OH)_2$ at 728° K.

over 95% of the reaction was completed. From the slope of the line, k was found to be 0.11 $mg^{1/3}min^{-1}$, the same as that calculated from the theoretical DTG curve (Table II).

The same procedure was followed with brucite except that the temperature was raised to 648° K and held at this temperature until the rate of weight loss was negligible, then raised to 668°, and again held constant until the rate of weight loss was very small. It was then raised to 728° K and the progress of the reaction followed, as before, at this temperature. The plot was also a straight line (curve *b*, Fig. 2); from the slope of the line, k was equal to 0.22 $mg^{1/3}min^{-1}$, which is in good agreement with the value in Table II.

There does not seem to be any doubt about the order of the reaction or the magnitude of the rate constants calculated from the theoretical DTG curves.

As pointed out above, it appeared from the theoretical and experimental DTG curves for brucite (Fig. 1) that much of the loss in weight between 600 and 730° K could not be ascribed to the main reaction. This was supported by results from the experiment described in the last paragraph concerning the rate of dehydration of brucite at constant temperature. When the temperature was held at 648° a considerable decrease in rate of weight loss with time, even more pronounced at 668° K, was observed (Fig. 3). Dehydration of an homogeneous material would have proceeded at rates essentially constant at

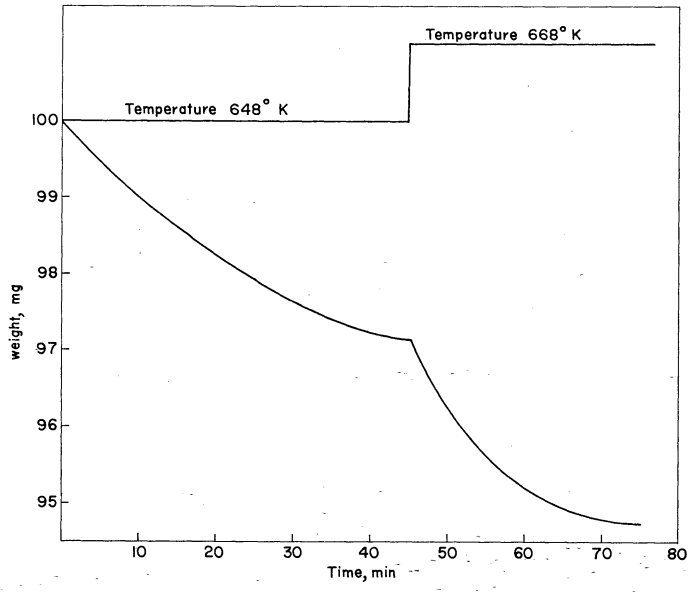

FIG. 3. Weight loss as a function of time at two temperatures for naturally occurring $Mg(OH)_2$.

each of these temperatures, since the difference between $w^{2/3}$ at the beginning and end of each interval was very small.

As a check on the validity of equation [8] for calculating A and thus the activation energy, an alternate method was used for its calculation from the experimental DTG curve for the precipitated material. Values of $(\log \Delta w/\Delta T)/w^{2/3}$, with $\Delta w/\Delta T$ calculated for each 2.5-minute interval and w the average weight remaining to be lost in the corresponding intervals, were plotted against $1/T$, with T the mean temperature in each interval. The plot, which should be a straight line in accordance with equation [2], is shown in Fig. 4. The slope of the line, equal to $-A/3.026$, was $-10{,}900$, which makes A equal to 2.51×10^4 and E about 50 kcal, a value in good agreement with the one given in Table II.

From the DTG curves in Fig. 1, it appeared that there were at least two forms of $Mg(OH)_2$. Further information on this point was gained by studying the thermogravimetry of $Mg(OH)_2$ prepared by two other methods. One preparation was obtained by reacting Mg metal with hot H_2O and the other was prepared by utilizing a KOH melt according to directions given by Mellor (9). The DTG curves for all four preparations are shown in Fig. 5. The Mg plus H_2O and Mellor preparations each showed two maximum

rates of dehydration but none of these, with the possible exception of the second for the Mellor preparation, corresponded with those for the precipitated or natural $Mg(OH)_2$. The higher temperature for the maximum rate for the Mellor preparation was not greatly different from that for brucite.

DISCUSSION

Since the results from the isothermal experiments agreed with those calculated from the equations derived in the theoretical section for DTG curves, interpretations based on this theoretical treatment were considered justified. For instance, the theoretical treatment shows a difference of about 5 kcal between the energies of activation for dehydration of precipitated and naturally occurring $Mg(OH)_2$. Admittedly, this is a small difference when considered in the light of the magnitude of the error usually involved in measuring activation energies at these relatively high temperatures. The fact, however, that the rate constants determined at constant temperature for the two materials agreed with those calculated from the DTG curves, calculations that depended almost entirely on this difference in activation energies for the differences in rate constants (Table II), is rather convincing evidence that there was a difference of the order of 5 kcal.

The total loss of H_2O per gram was the same for the two preparations and they both had the characteristic brucite X-ray diffraction pattern. Consequently, the difference in activation energy for dehydration was attributed to a difference in energy levels of materials with the same crystal form, rather than to two different ones. This difference could be caused by differences in surface energy and crystal lattice defects (10). With the reasonable assumption that the activated complex for dehydration was the same for the two preparations, it can be concluded that the difference in energy levels was about 5 kcal.

Apparent solubility products of $10^{-11.0}$ for the precipitated and $10^{-13.5}$ for naturally occurring $Mg(OH)_2$ were mentioned in the introduction. Since these are equilibrium constants for dissolving $Mg(OH)_2$ at 25° C (assuming that activities of the solids can be put equal to unity), the difference indicates a change in free energy of about 3.4 kcal in going from one to the other. This difference in free energy is in the same order of magnitude as the 5 kcal difference in energy levels mentioned above. The difference in energy levels also includes any difference in entropy between the two materials, so that the two differences, 5 and 3.4 kcal, are not strictly comparable. The fact that they are of the same order of magnitude, however, supports the conclusion of Quartaroli and Belofoiri (4) that the naturally occurring $Mg(OH)_2$ has a solubility product lower than $10^{-11.0}$, which is generally found for the precipitated material (2).

Furthermore, the DTG curves in Fig. 1 indicate why the natural material showed the same solubility as the precipitated material when it was equilibrated with water the first time. Presumably it contained some of the more soluble material, i.e. material that was dehydrated at the same temperature as precipitated $Mg(OH)_2$. When this material had been dissolved and removed, the lower solubility became apparent.

The DTG curves for the four different preparations of $Mg(OH)_2$ (Fig. 5) indicate that there is a series of energy levels and the possibility that different levels can be found for still other preparations cannot be excluded. A series of apparent solubility products would, therefore, be expected. According to the DTG curves, however, all preparations should show about the same solubility when equilibrated with H_2O for the first time, since all showed some decomposition at the temperature of maximum rate of decomposition of precipitated $Mg(OH)_2$.

HINDERED DIPHENYL ETHERS RELATED TO THE BISBENZYLISOQUINOLINE ALKALOIDS[1]

MARJORIE ALLEN[2] AND R. Y. MOIR
Department of Chemistry, Queen's University, Kingston, Ontario
Received in original form August 31, 1961; as revised August 28, 1962

ABSTRACT

Sixteen steps from vanillin led to syntheses of (*a*) dimethyl 3-(4′-carbomethoxyphenoxy)-4,5-dimethoxyphthalate (I*c*), a known degradation product of isochondrodendrine, and (*b*) the more hindered dimethyl 3-(4′-carbomethoxy-2′-methoxyphenoxy)-4,5-dimethoxyphthalate (I*a*), which has not been derived from any alkaloid, though the usual concepts of biosynthesis do not rule out the occurrence of alkaloids which could lead to it. Diphenyl ethers related to I*a* would be expected to show the effects of steric hindrance, but even with the most hindered member of the group, 7-(4′-carboxy-2′-iodophenoxy)metameconine (VA*e*), no evidence for an appreciable half-life of rotational isomers could be obtained. Attempts to make diphenyl ethers through the condensation of phenols with dicyclohexylcarbodiimide led to other products.

Diphenyl ethers of type I are of interest both because of their relationship to the bisbenzylisoquinoline alkaloids, and because of their place in the study of steric effects in diphenyl ethers. For example, the ester I*a* would be expected to arise from the hypothetical alkaloid II*a* in the same reactions that actually gave I*c* as the degradation product of the dimethyl ether of isochondrodendrine (II*b*) (1). Indeed, our whole study of diphenyl ethers arose from the efforts of Dr. J. A. McRae and his students to form the ester I*a*, the same biosynthetic argument[3] that had succeeded for the structure of isochondrodendrine leading them to suppose II*a* to be a probable structure for the alkaloid cularine (2, 3). The synthesis of I*a* proved unexpectedly difficult, and the challenge presented by the difficulty maintained our interest even when it became apparent many years ago that I*a* was not in fact closely related to cularine (III) (3).

The early efforts of Dr. McRae and his students to synthesize I*a* had several practical results. Prolonged attempts to use the Ullmann reaction directly led to the independent discovery of the transmethylation side reaction (5–7). Attempts to use the phthalide group as a guarded source of carboxyl groups led to two lines of attack continued in the present work: a study of the place of steric hindrance in the synthesis of diphenyl ethers (5, 9, 10, 13), and an extensive development of the chemistry of metameconine (IV*a*) (5, 8–12). Oxidation of the metameconines yielded phthalic acids. One of these (9) was related to pellotine (14) and to capaurine (15, 16), and another (11), an essential link in determining the structure of the bisbenzylisoquinoline alkaloids bebeerine and tubocurarine (17, 18), was synthesized by methods which added greatly to the security of its proof of structure.

[2]*Holder of a Scholarship from the National Research Council of Canada, 1960–61.*

[3]*To exclude structure II*a*, the argument based on accepted biosynthetic pathways must be supplemented by the observation that with one or two exceptions no bisbenzylisoquinoline alkaloid is known which bears, on a benzyl moiety, a methoxyl or hydroxyl meta to the methylene group (4). Groups so situated are a commonplace in the benzylisoquinoline alkaloids, and it is interesting that the extra meta groups in the known exceptions are at positions involving little steric interference about the diphenyl ether linkage.*

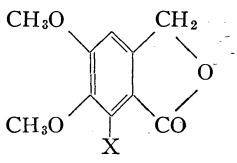
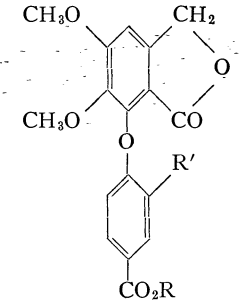
III

Synthesis of Ia

Success was made possible by the application of a method of synthesis discovered by Hems and his co-workers (19). Many years ago we took the decisive step for the preparation of I*a* in using the Hems synthesis to convert 7-hydroxymetameconine (IV*c*) into the diphenyl ether VA*a*, in which all the groups were correctly placed (9). The principal difficulty in completing the work lay in the (indirect) replacement of the nitro group of VB*a* by the methoxyl group of VA*d*. Once this was accomplished, the ester I*a* was fairly easily obtained by oxidation and methylation of the intermediate VA*d*.



IVa: X = H
IVb: X = I
IVc: X = OH



V

Substituent code

a: R′ = NO_2 A: R = H
b: R′ = NH_2 B: R = Me
c: R′ = H
d: R′ = OMe
e: R′ = I
f: R′ = OH

Replacement of the nitro group by the methoxyl group was made especially difficult by the fact that the first step of the conversion, reduction of the nitro group of VB*a* to the amino group of VB*b*, took place in low yields only. We were therefore restricted to the trial of only three methods of converting the amino acid group to methoxyl:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

(*a*) The obvious treatment of the diazotized amine with methanol led to the replacement of the diazonium group with hydrogen rather than with methoxyl. The resulting product VB*c* was itself of considerable interest since on oxidation it gave the acid I*b*; this acid and the methyl ester appeared to be identical with the compounds obtained by Faltis and Frauendorfer (1) from the dimethyl ether of isochondrodendrine (II*b*). They also synthesized the acid and the ester with the use of the Ullmann reaction, which succeeded because of the presence of only two groups ortho to the diphenyl ether linkage (1, 10).

(*b*) Attempts to proceed via the diazonium fluoborate and the acetoxy compound failed. No attempt was made to proceed via the phenol by hydrolysis of the diazonium derivative because of the uniformly negative results obtained with this reaction in the metameconine series.

(*c*) The method that finally succeeded had been previously used by us in the metameconine series (5, 9), and had also been recommended by Blair and Newbold (20). Diazotization of the amino ester VB*b*, followed by the treatment with potassium iodide and iodine over chloroform (21), gave the iodo ester VB*e*. After many trials, themselves interesting in outlining the capabilities of the Ullmann reaction in this series, the iodo group of VBe was converted to the free phenolic group of VA*f*. An easy methylation then completed the conversion of VA*f* to VA*d*, the desired methoxy acid from which I*a* was made by oxidation and methylation.

The 16 steps by which vanillin was converted to the final product I*a* included 7 reactions of substitution on the benzene ring. Five of these occurred in the synthesis of VB*a*, and were shown in our previous work to take place without rearrangement (5, 8–12). Of the two remaining substitution reactions, one (in the conversion of the amino group in VB*b* to the iodo group in VB*e*) has been used so often in synthetic and structural work that there seems no point in discussing the possibility of rearrangement in it. Some attention must be given to the possibility of rearrangement in the final substitution reaction, the Ullmann reaction in which the iodo compound VB*e* was converted to the phenolic acid VA*f*, since a restricted class of Ullmann reactions is known which involves some rearrangement. Such a possibility is no light matter, since the structures given for almost all the known bisbenzylisoquinoline alkaloids rest either on the tacit assumption of the lack of rearrangement in the Ullmann reaction (22), or upon a similar assumption in the degradation of diphenyl ethers with metals and amines, a reaction that has also been called into question (23).

However, the following considerations seem to show that the possibility of rearrangement is not of concern in the present work. The expected rearrangement reaction would occur through a benzyne intermediate, and would require (in the present series) the presence of a hydrogen atom ortho to the halogen undergoing displacement (24). In related reactions, 4-bromoveratrole reacted with ethylamine without rearrangement, though ortho protons were available (25), and the iodometameconines (e.g. IV*b*) reacted easily in Ullmann reactions with hydroxide, methoxide, or ethoxide ions, though no ortho protons were available (5, 9). A still closer experimental parallel is the rather high-temperature Ullmann reaction by which Lowenthal and Pepper (26) converted 5-bromosalicylic acid without rearrangement into 2,5-dihydroxybenzoic acid. From a wider point of view, the fact that although the rearrangement as a side reaction was discovered a long time ago (27), the known examples are confined to aryl halides bearing, at most, alkyl groups as other substituents suggests that there is a limitation to the rearranging mechanism. This conclusion is supported to some extent by the fact that no inconsis-

For personal use only.

tencies have arisen in the widespread and uncritical use of the Ullmann reaction in structural investigation of alkaloids. Perhaps most convincing is the consideration that the rearrangement reaction belongs to the class of benzyne reactions in which an ortho proton must be removed by a base (24). Ionization of the proton would be made very difficult by the presence on the ring of a negatively charged group, and in fact no example of a benzyne reaction has ever been observed with any aryl halide bearing a negatively charged group on the ring, even when bases much stronger than aqueous sodium hydroxide have been used (24). It is shown in the experimental part that the Ullmann reaction with VB*e* was preceded by saponification of the carbomethoxy group to give the negatively charged carboxyl ion. Bottini and Roberts (23) showed that the formation of cresols from hydroxide ion and halogenated toluenes gave a much lower ratio of "rearranging" to "non-rearranging" reaction at 250° than at 350°. The rearranging reaction could scarcely be predominant at the still lower temperature (175°) of our reaction in which the charge situation was less favorable to it.

*Attempted Resolution of the Triply Ortho-substituted Diphenyl Ether VA*e

Two characteristics made 7-(2′-iodo-4′-carboxyphenoxy)metameconine (VA*e*) an attractive compound for an attempt to demonstrate rotational isomerism in the series. First, it formed a well-characterized strychnine salt. Secondly, it possessed in the iodine atom a more promising blocking group than the nitro group previously used (10); as Trotter has shown in a series of papers (28), the nitro group is rather easily twisted out of coplanarity with the ring to which it is attached.

The behavior to be expected from such a salt depends on the half-life of the rotational isomers. With a half-life of the order of minutes or less, separation into diastereoisomers becomes too difficult, but a compensating factor appears. Usually one diastereoisomer is less soluble than the other, so that at equilibrium (now quickly reached because of the short half-life) the crystals deposited from the solution consist of one diastereoisomer only, and this diastereoisomer may be obtained pure in yields much greater than the maximum of 50% possible with stable isomers. The possibility of distinguishing a resolution of this type from a simple failure to resolve again depends on the half-life of the rotational isomers in solution. With half-lives of the order of several minutes, dissolution of the crystals is followed by an easily observable mutarotation; examples are known in the diphenyl series (29). However, half-lives much less than the time required for dissolution would give mutarotations observable only by the closest attention to experimental errors.

The properties of the strychnine salt of VA*e* showed it to be a single substance; the yield in which it was obtained was too large to allow it to be regarded as one of a pair of stable diastereoisomers. Failure to resolve would then have been due either to double-salt formation or to maintenance in the crystal of free rotation about the diphenyl ether linkage; with the bulky and irregular molecule of VA*e*, both possibilities seem sufficiently unlikely to make further discussion worthwhile. No mutarotation was observed on dissolution of the salt, and as shown in the experimental part, the necessary attention to the precision of the measurements ensured that the mutarotation, if it occurred, must have had a half-life much less than the 3 minutes required for dissolution and initial observation. As a check on the work, it may be noted that both a failure to resolve, or rapid racemization, should give solutions of specific rotations appropriate to the strychnine salt of an inactive acid. Such a check was obtained with the brucine salt of the previous work (10), but the strychnine salt of VA*e* had a specific rotation very different

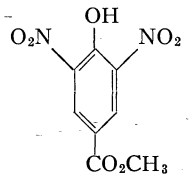
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from that expected. This anomalous result may be compared with the wide variation of rotations recorded for strychnine salts, as noted in the experimental part.

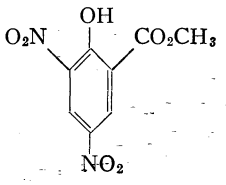
Further progress in attempts to demonstrate rotational isomerism in this series can only be made if the techniques of X-ray crystallography and nuclear magnetic resonance spectroscopy become available to us. The effects of the ortho substitution upon the infrared and ultraviolet spectra of the ethers of this series will be reported in another paper.

An Attempted New Synthesis of Diphenyl Ethers

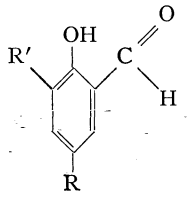
In accord with a suggestion of Dr. J. K. N. Jones, an attempt was made to condense phenols to diphenyl ethers by the action of dicyclohexylcarbodiimide. Highly activated phenols, such as VI, VII, and VIII, reacted readily with the reagent, but under the conditions used, the less acidic phenol salicylaldehyde did not react, nor could cross reaction with more reactive phenols be induced with it. Since there is general agreement (30) that the first step in such reactions is the formation of an isoureide, the proposed synthesis amounted to setting up a competition between external and internal nucleophilic attacks on the activated benzene ring of the isoureide: external attack by a phenol or phenoxide ion to give a diphenyl ether, and internal attack by a nitrogen atom of the isoureide to give an N-phenylurea. A similar competition occurs in the well-known reaction of carbodiimides with carboxylic acids; anhydrides are not formed if the intermediate acylisourea undergoes sufficiently rapid rearrangement to the acylurea (30). Busch, Blume, and Pungs (31) found that diphenylcarbodiimide and certain activated phenols (not those of the present work) gave rearranged triphenylureas. It was not surprising, then, that the highly activated phenols VI and VII with dicyclohexylcarbodiimide gave 1:1 addition products whose infrared spectra showed the bands expected for ester groups and for



VI



VII



VIII*a*: R = R′ = NO_2
VIII*b*: R = NO_2; R′ = H
VIII*c*: R = H; R′ = NO_2

amides of the type AcNHR. The absence of dicyclohexylurea in the reaction products confirmed the fact that no diphenyl ether had been formed, and when the addition product from VI was heated strongly with another mole of VI, it was recovered unchanged.

The reactions of the nitrosalicylaldehydes VIII*a*, VIII*b*, and VIII*c* were of special interest since, in our hands, the Hems synthesis has failed when applied to highly substituted salicylaldehydes. In fact, dicyclohexylurea was obtained in the reaction of dicyclohexylcarbodiimide with each of VIII*a*, VIII*b*, and VIII*c*, but the condensation so indicated was not that of diphenyl ether formation. With 3,5-dinitrosalicylaldehyde (VIII*a*), the initial crude product became warm when treated with methanol; recrystallized from methanol the product was shown by analysis to correspond to a 1:1 addition product which had undergone the loss of water and the addition of methanol.

No doubt the interpretation of these results is obvious, but since analysis and spectra showed that the reaction product from 5-nitrosalicylaldehyde (VIII*b*) was quite different in character from that with dinitrosalicylaldehyde (VIII*a*), we prefer to regard our results

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

as merely establishing the fact that the reaction cannot be expected to offer a route to diphenyl ethers. New observations on the nitration of salicylaldehyde are reported in the experimental part.

EXPERIMENTAL

Melting points and infrared spectra were determined as previously described (11) but the wavelength values quoted are uncorrected.

7-(4′-Carbomethoxy-2′-nitrophenoxy)metameconine (VBa)

This material was made in nine steps from vanillin as previously described (9, 10).

7-(2′-Amino-4′-carbomethoxyphenoxy)metameconine (VBb)

7-(4′-Carbomethoxy-2′-nitrophenoxy)metameconine (2.0 g) was kept at 60–70° for 30 minutes with iron powder (1.0 g) and glacial acetic acid (50 ml). A small amount of insoluble material was removed by filtration and washed with a little acetic acid; the combined filtrates were evaporated to a black sticky residue which gave a white precipitate when treated with water. The white precipitate was recovered and very thoroughly washed with water. As five recrystallizations did not give a pure product, the material was then extracted with dilute hydrochloric acid; the small amount of insoluble material was recovered as usual and identified as unchanged starting material by melting point and mixture melting point. The acid extract was carefully neutralized with sodium bicarbonate and the precipitated solid twice recrystallized from ethanol to give white fluffy needles which partially melted at 200°, resolidified, and melted again at 209–211°. Two more recrystallizations gave the analytical material with the same partial melting point at 200°, and final melting point of 210–212°. Found: C, 60.19, 60.22; H, 4.79, 4.87; N, 4.04, 3.97%. Calc. for $C_{18}H_{17}O_7N$: C, 60.17; H, 4.73; N, 3.90%.

In two similar experiments, the nitro compound (8.15 g) was reduced to give the amine having a final melting point of 210–211° in a yield of 3.03 g or 40%. In five further runs the relative amount of acetic acid was doubled and the temperature of reduction increased to 85–90°; the crude yield was 12.2 g, or 59% from 22.4 g of starting material, but purification of a portion of the amine showed that the overall yield of reasonably pure material was only 43%.

7-(2′-Amino-4′-carboxyphenoxy)metameconine (VAb)

7-(2′-Amino-4′-carbomethoxyphenoxy)metameconine (0.2 g) was heated on the steam bath for 30 minutes with aqueous sodium hydroxide (10 ml, 10%). The solution was cooled and acidified and the resulting precipitate recovered and twice recrystallized, once from aqueous methanol, and once from methanol, to give a product of m.p. 269.5–270.5°. The melting point reported previously (9) for material made in a different way was 268.4–268.8°.

7-(4′-Carbomethoxy-2′-iodophenoxy)metameconine (VBe)

(*a*) The method is that used by Chalmers, Dickson, Elks, and Hems (21) in the synthesis of a precursor of thyroxine. Sodium nitrite (0.5 g) was dissolved in concentrated sulphuric acid (10 ml) with gentle warming; the solution was then cooled to 0° and diluted with glacial acetic acid (10 ml). A second solution, prepared from 7-(2′-amino-4′-carbomethoxyphenoxy)metameconine (2.0 g, m.p. 210–211°), concentrated sulphuric acid (20 ml), and glacial acetic acid (20 ml), was cooled to 0° and then added over the course of 2 hours to the first solution while the reaction mixture was vigorously stirred and kept between −2° and 1°. Stirring was continued for 1 hour after the addition was complete, the diazonium solution was then poured, with vigorous stirring but without cooling, into a mixture of chloroform (50 ml), water (100 ml), potassium iodide (5.0 g), iodine (5.0 g), and urea (2.0 g); the temperature rose to 40°. Stirring was continued for an additional hour; the layers were then separated and the aqueous layer twice extracted with chloroform (100-ml portions). The chloroform solutions were combined, twice washed with water, and then covered with a solution of sodium sulphite (10 g) in water. Sulphur dioxide was bubbled into the mixture until the color due to the iodine had been discharged; the pale yellow chloroform layer was separated, twice washed with water, dried with magnesium sulphate, and evaporated. The dry residue was recrystallized from ethanol (150 ml) to give white needles, m.p. 208–209°, in a yield of 1.03 g or 39%. It was found (after the product had been recovered unchanged from a second attempt at diazotization) that the needles were insoluble in hydrochloric acid, contained halogen but not nitrogen, and that admixture with the starting material markedly depressed the melting point. Three more recrystallizations of the needles from ethanol gave the analytical sample of VB*e*, m.p. 206.5–207.5°. Found: C, 45.99, 46.10; H, 3.27, 3.19; I, 27.24, 27.34%. Calc. for $C_{18}H_{15}O_7I$: C, 45.97; H, 3.22; I, 26.99%.

In two other runs the crude amino compound (6.0 g, m.p. 196–200°) was converted to purified iodo compound (only one diazotization step being performed for each run!), m.p. 206–207°, in a yield of 3.96 g or 50%.

(*b*) The crude amino compound (2.0 g) was diazotized at 20° with butyl nitrite, hydrogen chloride, and acetic acid, and the mixture poured into a mixture of potassium iodide, water, iodine, and chloroform. Crude product, m.p. 201–209°, was isolated in a yield of only 0.51 g, but one recrystallization from ethanol gave the pure iodo compound VB*e*, m.p. 206–207°.

For personal use only.

(*c*) Attempts to proceed via the isolated diazonium fluoborate failed. In the first attempt, the amine failed to dissolve in a mixture of hydrochloric acid and aqueous sodium fluoborate, and eventually most of it was recovered unchanged. In the second attempt, modelled on a different preparation of Niemann and McCasland (32), the amine was first diazotized with butyl nitrite and hydrogen chloride in acetic acid solution; sodium fluoborate solution (33) and hydrochloric acid were then added but no precipitate formed even when the solution was held 60 hours below 0°. A diazonium compound still remained at the end of this time, since the solution gave a bright red precipitate with a solution of β-naphthol. It is not unusual for this method to fail with ortho-substituted amines (34).

Reaction of 7-(4′-Carbomethoxy-2′-iodophenoxy)metameconine with Bases

In this section, the increasing severity of the conditions demonstrates the relative reactivities of the iodo and carbomethoxy groups towards alkali. Saponification occurred in all the experiments, but the Ullmann reaction only under the most severe conditions used.

(*a*) 7-(4′-Carbomethoxy-2′-iodophenoxy)metameconine (2.0 g, m.p. 204–206°) and a trace of copper catalyst were heated under reflux with the solution made from potassium (1.0) and dry methanol (50 ml) for 12 hours, the preparation being protected from atmospheric moisture. A very long isolation procedure gave crude starting material (m.p. 200–206°, undepressed by admixture) and crude 7-(4′-carboxy-2′-iodophenoxy)metameconine (0.24 g, m.p. 249–252°), easily identified since, when treated with diazomethane in ether, it gave the starting material (after one recrystallization the m.p. being 206–208°, undepressed by admixture).

(*b*) 7-(4′-Carbomethoxy-2′-iodophenoxy)metameconine (0.95 g) was heated under reflux for 2 hours with acetone (10 ml) and aqueous potassium hydroxide (20 ml of 5%); the solution was then cooled and acidified, and the oily mixture extracted with ether. Evaporation of the ethereal extract and recrystallization of the residue from ethanol gave a product (0.56 g) of m.p. 256–258°. Two more recrystallizations yielded white crystals (0.3 g) of 7-(4′-carboxy-2′-iodophenoxy)metameconine which melted sharply at 260°.

(*c*) 7-(4′-Carbomethoxy-2′-iodophenoxy)metameconine (0.3 g), aqueous sodium hydroxide (5 ml of 10%), and a trace of copper catalyst (Kahlbaum's copper bronze #02219) were heated under reflux with stirring. After 1 hour, more sodium hydroxide (5 ml) was added, and after a second hour acetone (5 ml) and water (5 ml) were added to dissolve the insoluble material; heating and stirring were continued for an hour longer. The copper was then removed by filtration, and the filtrate acidified; it deposited a sticky precipitate which solidified when strongly cooled; after recrystallization from ethanol (10 ml) the precipitate weighed 0.2 g, m.p. 256–259°. A second recrystallization yielded crystals of two types; as one type did not depress the other's melting point on admixture, the two forms were reunited and recrystallized to give the analytical sample, m.p. 260.5–261.0°, of 7-(4′-carboxy-2′-iodophenoxy)metameconine (VA*e*). Found: C, 45.45, 45.28; H, 3.05, 2.85%. Calc. for $C_{17}H_{13}O_7I$: C, 44.76; H, 2.87%.

Methylation of a portion of the analytical sample with diazomethane gave a product which after one recrystallization from ethanol had m.p. 205–207°, undepressed by admixture with authentic 7-(4′-carbomethoxy-2′-iodophenoxy)metameconine, the starting material.

(*d*) 7-(4′-Carbomethoxy-2′-iodophenoxy)metameconine (0.5 g) was heated under reflux with aqueous sodium hydroxide (15 ml of 10%) until a clear solution was obtained (2 hours). The solution was transferred to a copper test tube, and copper catalyst (0.5 g) was added. The copper test tube was then placed, upright, inside a glass tube sealed at one end; the system was cooled strongly, evacuated, sealed, heated slowly to 120° (bath temp.), held at this temperature for 1 hour, cooled, and opened. The contents of the tube was filtered, the filtrate acidified, and the precipitate recrystallized from ethanol to give 0.28 g of a product whose melting point (251–257°) was not depressed by admixture with the 7-(4′-carboxy-2′-iodophenoxy)metameconine of (*c*) part.

(*e*) Conditions were the same as those in (*d*) part, except that the reaction temperature was 170–180°. In three runs 7-(4′-carbomethoxy-2′-iodophenoxy)metameconine (2.3 g) was converted into crude 7-(4′-carboxy-2′-hydroxyphenoxy)metameconine (1.42 g or 84%), m.p. near 255°, markedly depressed on admixture with the analytical sample of the iodo acid from (*c*) part. The product was interesting in being almost insoluble in either ethanol or water, though quite soluble in a mixture of the two. Two recrystallizations of a small portion of the crude material raised the melting point of the supposed 7-(4′-carboxy-2′-hydroxyphenoxy)metameconine (VA*f*) to 282–288°, but the recovery was very small. Because of this difficulty of purification, and because of the great scarcity of material, the substance was characterized and purified as its methyl ether methyl ester, as shown in the next section.

7-(4′-Carbomethoxy-2′-methoxyphenoxy)metameconine (VBd)

Supposed 7-(4′-carboxy-2′-hydroxphenoxy)metameconine (0.6 g, crude, from (*e*) part of the previous section) was suspended in methanol while a solution of diazomethane in ether was slowly added in excess. During the addition the crystals at first slowly dissolved; later, a precipitate formed. Next morning the precipitate was recovered (m.p. 190–192°; yield 0.25 g); two recrystallizations from aqueous methanol gave the analytical sample, m.p. 189.6–190.2°. Found: C, 61.24, 61.18; H, 5.10, 5.08%. Calc. for $C_{19}H_{18}O_8$: C, 60.96; H, 4.85%. In two more runs, 0.74 g starting material was converted to crude product, m.p. 185–188°, in a yield of 0.35 g or 44%.

Dimethyl 3-(4′-Carbomethoxy-2′-methoxyphenoxy)-4,5-dimethoxyphthalate (Ia)

(a) Oxidation

7-(4′-Carbomethoxy-2′-methoxyphenoxy)metameconine (0.10 g, m.p. 185–188°) was heated on the steam bath with aqueous potassium hydroxide (5 ml of 10%) until solution was obtained (1 hour). Potassium permanganate (0.30 g) in water (5 ml) was added and the heating continued for 30 minutes. Sulphur dioxide was then passed into the cooled reaction mixture until it was colorless; a few drops of concentrated sulphuric acid were added and a trace of solid removed by filtration. The filtrate was cooled in an ice bath; the crystals which separated were recovered (m.p. 241–246°) and recrystallized from water (5 ml) to give colorless plates (0.06 g) which first melted and then resolidified as fine needles at 208–210°, and then melted again at 264–265°, when observed between cover glasses on the hot stage of the microscope. A second oxidation of 0.25 g of starting material gave two crops of acid, final m.p. 264–265°, in a combined yield of 0.17 g, or 65%, of the supposed 3-(4′-carboxy-2′-methoxyphenoxy)-4,5-dimethoxyphthalic acid (I*d*). Because of the unsatisfactory nature of the free phthalic acids as derivatives, we followed the usual policy (11, 13) of characterizing the acid through its methyl ester.

(*b*) *Esterification*

Treatment of the acid product of the oxidation (0.14 g, as just above) with an excess of diazomethane gave a vigorous reaction. Next morning the solution was evaporated and the residue recrystallized from methanol to give small, diamond-shaped plates, m.p. 156.0–157.5°. One more recrystallization gave the first analytical sample, m.p. 157.0–157.2°. Found: C, 58.80, 58.50; H, 5.29, 5.24%. In a second experiment, the acid (0.09 g) was methylated in the same way; after four recrystallizations from methanol the second analytical sample had m.p. 157–158°. Found: 57.71, 57.71; H, 4.97, 5.23%. Calc. for $C_{21}H_{22}O_{10}$: C, 58.06; H, 5.11%.

7-(4′-Carbomethoxyphenoxy)metameconine (VBc)

The method was similar to the general method of Hodgson and Walker (35). Sodium nitrite (0.25 g) was dissolved in concentrated sulphuric acid (5 ml) with gentle warming. The solution was then cooled to 0° and glacial acetic acid (5 ml) was added with stirring and cooling. 7-(2′-Amino-4′-carbomethoxyphenoxy)metameconine (VB*b*) (1.0 g, m.p. 209.0–210.5°) was stirred with acetic acid (5 ml), and sufficient sulphuric acid (2 ml) was added to give a pale yellow, viscous solution; this second solution was cooled and added over a period of 90 minutes to the first solution with vigorous stirring. Stirring was then continued for another 90 minutes, the temperature being maintained at −2 to 0°. Methanol (50 ml) was then added; the temperature rose to 10°, and some frothing occurred. The mixture was gradually warmed and finally heated under reflux for 90 minutes. Some solvent (about 30 ml) was removed by distillation; the cooled residue was poured onto ice (100 g), the resulting orange precipitate recovered and recrystallized from ethanol to give short orange needles (0.38 g or 40%), m.p. 162–172°. Four more recrystallizations from ethanol gave the pale orange analytical sample, m.p. 194–195°. Found: 62.57, 62.54; H, 4.69, 4.70%. Calc. for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%. A second run using the same quantities and conditions gave 0.5 g of once-recrystallized material as remarkable lenticular plates, m.p. 191–193°; after another recrystallization the crystals (0.36 g, m.p. 194.0–195.5°) still had slightly curved edges.

Dimethyl 3-(4′-Carbomethoxyphenoxy)-4,5-dimethoxyphthalate (Ic)

(a) Oxidation

7-(4′-Carbomethoxyphenoxy)metameconine (0.36 g, m.p. 194.0–195.5°) was heated with water (10 ml) and aqueous potassium hydroxide (2 ml of 10%) for 1 hour, a clear red solution being obtained. Potassium bicarbonate (1 g) was added, and while the mixture was heated on the water bath, solid potassium permanganate (0.35 g) was added until a permanent pale purple color remained. Heating was continued for 45 minutes in all; the mixture was then cooled and filtered, and the precipitate washed with a little water. The combined filtrates were decolorized with sulphur dioxide and acidified with hydrochloric acid. A precipitate slowly settled out; it was recovered and recrystallized from water to give a product (crystals "A") which melted at 141–146°, resolidified, and melted again over the range 171–191°, yield 0.16 g or 42%. This product was purified as its ester (see below). The aqueous mother liquors from this experiment and from another experiment (in which 0.16 g of starting material had given no crystalline precipitate) were continuously extracted with ether; the ethereal extract was evaporated; the solid residue dissolved in potassium hydroxide solution, reprecipitated with acid, recovered, and twice recrystallized from water to give fine needles which on the hot stage of the microscope melted at 138–140° with effervescence, resolidified at 151–154°, and slowly melted again at 245–259°. The acid, 3-(4′-carboxyphenoxy)-4,5-dimethoxyphthalic acid (I*b*), has previously been reported to form a dihydrate (36), first m.p. 207°, second 245°; and a monohydrate (1), first m.p. 178° or 188°, second m.p. 245° (less stable form) and 254–255°, or sinters 247°, melts 250–253° (more stable form) (in a capillary). This interesting dependence on the rate of heating adds to the unsatisfactory properties of the free phthalic acid as a characteristic derivative; our main attention was accordingly given to the methyl ester.

(*b*) *Esterification*

The crystals "A" above (0.16 g) were almost dissolved in ether (5 ml) and an excess of an ethereal solution of diazomethane (20 ml) was slowly added, the mixture being cooled in ice. A vigorous reaction occurred;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

after 3 hours, the ether was removed, the residue crystallized by solution in methanol followed by evaporation, and then recrystallized from aqueous methanol. Long needles, m.p. 116.0–116.5°, were obtained in a yield of 0.14 g. A second recrystallization gave the analytical sample, m.p. 115.6–116.2°. Found: C, 59.78, 59.65; H, 4.92, 5.16%. Calc. for $C_{20}H_{20}O_9$: C, 59.40; H, 4.99%. Faltis and Frauendorfer (1) reported that the substance sintered at 111° and melted at 113–114°; King (36) did not obtain a crystalline ester.

Attempted Resolution of 7-(4′-Carboxy-2′-iodophenoxy)metameconine (VAe)

7-(4′-Carboxy-2′-iodophenoxy)metameconine (0.6 g, m.p. 257–258°) suspended in chloroform (100 ml) was dissolved by the addition of ethanol (10 ml). Strychnine (0.44 g, m.p. 279–282°, from the nitrate) in chloroform (20 ml) was added to the solution. After 24 hours, the solution was concentrated to 20 ml and diluted with petroleum ether to precipitate a colorless oil which gradually hardened; the precipitate was recovered and recrystallized from ethanol to give a white product, m.p. 174–178°, in a yield of 0.82 g or 79%; three more recrystallizations from ethanol gave white crystals (0.38 g), m.p. 178.5–179.5°, and a fifth recrystallization left the melting point unchanged. Found: C, 57.34, 57.63; H, 4.97, 5.03; N, 3.51, 3.42%. Calc. for $C_{38}H_{35}O_9N_2I$: C, 57.73; H, 4.46; N, 3.54%. The ethanol mother liquors from the first three recrystallizations were combined and concentrated; they deposited crystals (0.31 g, m.p. 161–166°, mixture m.p. with the anal. sample 177–181°) which after one recrystallization had m.p. 176–177°; thus a second diastereoisomer did not seem to be present.

The strychnine salt (analytical sample, 0.3023 g) was dissolved in chloroform to give a solution volume of 5 ml. At age 3 minutes for the solution, a single reading showed a rotation of −0.49°; the mean for 10 readings taken before age 10 minutes was −0.470°, while that for 10 readings at 20 hours was −0.471°; sets of 10 readings at ages 1 hour, 2.25 hours, and 5 hours showed no deviation of the mean from these larger than 0.006°. The zero point was 0.032°. From these readings $[M]_D = -650°$ (0.077 M in chloroform). The lack of mutarotation showed that dynamic interchange of the stereoisomers did not occur at an observable rate, but time did not permit us to investigate further the following anomaly in our results. Strychnine itself has $[M]_D^{18} = -465°$ (0.067 M in chloroform) (37, 38), but while our salt showed a molecular rotation apparently significantly more negative than this, known salts of strychnine have much less negative molecular rotations than does the free base. Thus aqueous solutions of the salts of mineral acids (39) and organic acids (40) show molecular rotations close to −110°, while solutions of organic salts of strychnine in organic solvents show numerically very small molecular rotations, which may be either positive or negative in sign (39, 41, 42).

Nitration of Salicylaldehyde

(a) Preparation of the Crude Mixture of 3- and 5-Nitrosalicylaldehydes (VIIIb and VIIIc)

The method of von Miller (43) was followed, but the yield obtained (58%) was much less than those (90–100%) reported by others (43–47).

(b) Separation of the Mononitro Derivatives

(i) Via the sodium salts.—Von Miller (43) reported an easy separation by fractional crystallization of the yellow sodium salt of the 5-nitro derivative from the red salt of the 3-derivative. The method has often been used without comment; there are two reports (44, 46) of easy and almost quantitative separations (though the reported proportions of the isomers differed very greatly!), and three (47–49) in which the method was difficult or inefficient. In our work fractions enriched in one or other of the components were obtained, but in very prolonged, careful, and repeated fractional crystallizations of the sodium salts, only two small crops of the pure yellow salt of the 5-isomer; the other fractions were all mixtures of the yellow and red salt. There seemed to be little difference in their solubilities, and the successes reported previously presumably were based on the maintenance of suitably supersaturated solutions.

(ii) Via the sodium bisulphite addition compounds.—Taege (50) found that 5-nitrosalicylaldehyde formed a stable crystalline addition compound, and that the derivative of 3-nitrosalicylaldehyde did not crystallize. Our results did not agree with this. In fact, when a mixture of the sodium salts, enriched in the 3-isomer, was treated with sodium bisulphite, a small amount of a crystalline precipitate was obtained which on treatment with aqueous acid gave directly almost pure 3-nitrosalicylaldehyde, m.p. 108.5–110.5°. The 5-isomer could also be obtained almost pure (see below).

(iii) By partial acidification.—One quarter of a mother liquor saturated in both salts was treated cautiously with dilute hydrochloric acid until the color just changed; the rest of the mother liquor was then added with shaking, and next morning the precipitate was recovered; its melting point of 103–109° showed that it was almost entirely 3-nitrosalicylaldehyde. But later crops were mixtures much less rich in the 3-isomer. Presumably the selective precipitation of the 3-isomer was a solubility effect, since the difference in their acidity constants is small and in the wrong direction (51).

(iv) By a combination of methods.—The most elementary theory suggests that separations of this type are best carried out with at least two methods having different separation coefficients. The following work demonstrated that the intractable mixture of salts could be broken by the use of this principle, though the separation was tedious. Salicylaldehyde (100 g) was nitrated in the usual way (43) and the mixed product was treated at 70° with water (300 ml) and sodium bisulphite (88.4 g); all but a few milligrams dissolved. Next morning, the light yellow crystals which had separated from the chilled solution were recovered (from mothor liquor A), washed with sodium bisulphite solution, resuspended in water, treated with hydrochloric

For personal use only.

acid and a stream of air, the crystals recovered, washed, and dried, yield 28.2 g (20% on salicylaldehyde) of almost pure 5-nitrosalicylaldehyde, m.p. 124.5–128.5°. The acid mother liquor B was subjected to an air stream for a long time, and four successive crops of mixed aldehydes were obtained. Thus the crystalline addition product must have been a mixture, and the recovery from it of 5-isomer was due at least as much to the faster decomposition in acid of the 5-derivative as to its lesser solubility in water. Mixed aldehydes were also recovered from mother liquor A; the mixed aldehydes from A and B were separately converted to their sodium salts and subjected to very long and careful fractional crystallizations from water. A gave two small crops of the pure yellow salt from which almost pure 5-nitrosalicylaldehyde was obtained directly by acidification; m.p. 126.5–127° and 126–126.5°, yield 7.8 g or 5.6% in all. All other fractions were mixtures; one of the mother liquors from B was used to establish the results in (iii) above (and therefore also confirmed the previous demonstration of the crystalline bisulphite addition product of the 3-isomer). The remaining salts and mother liquors from A and B were now united in one aqueous solution for the demonstration of the differential separation. The combined solution was treated as in (iii) with one quarter of the amount of hydrochloric acid required for neutralization, and the precipitate (B1) recovered. The filtrate was then concentrated until (as it was judged) enough water had been removed to bring it back to saturation, in the cold, in the 3-isomer; after being chilled, it deposited a salt (C1). The double separation was then repeated several times to obtain the "less soluble acids" B2, B3, and B4, and the "less soluble salts" C2 and C3. One recrystallization of C2 and C3 gave a pure yellow salt which on treatment with acid gave almost pure 5-nitrosalicylaldehyde, m.p. 125.5–125.8°, yield 3.2 g or 2.3%. The deep orange C1 gave mainly the 3-isomer. The fractions B1, B2, B3, and B4 were somewhat impure 3-isomer, yield 14.2 g or 10%. Two recrystallizations from aqueous acetic acid and one from ethanol of the united fractions of the crude 3-isomer, with charcoal, gave large, bright, sandy-yellow crystals, m.p. 108.5–109.5°, of pure 3-nitrosalicylaldehyde, yield 18.2 g or 13%. One recrystallization of its united fractions from aqueous acetic acid gave beautifully shaped, very light yellow crystals of pure 5-nitrosalicylaldehyde, m.p. 125.4–126.4°, yield 33.7 g or 24%. Mixed fractions (useful for further nitration) were also obtained in a yield of 15%.

(c) Dinitration

The crude mixture of mononitrosalicylaldehydes (43.4 g) obtained as in (*a*) part was treated according to the method of Lovett and Roberts (52) to give crude 3,5-dinitrosalicylaldehyde (VIII*a*) in a yield of 90%. Three recrystallizations from benzene and one from aqueous acetic acid gave 6.7 g of bright yellow crystals, m.p. 72.1–74.4°. A slightly better sample, m.p. 72.3–73.7°, was recovered from the mother liquors in a yield of 1.0 g. A second crop, 26.4 g, m.p. 72.9–73.4°, was obtained as a light yellow powder and a third crop, 0.78 g, m.p. 70.6–72.1°, as a darker powder. There was, therefore, little evidence of fractionation, supporting the correctness of our melting point, which was much higher than those recorded before, viz., 56° (53), 58–60° (52), and 62–63° (45).

Reactions of Dicyclohexylcarbodiimide

(a) With Methyl 2-Hydroxy-3,5-dinitrobenzoate (VII)

Dicyclohexylcarbodiimide (2.0 g) was added to a warm solution of methyl 2-hydroxy-3,5-dinitrobenzoate (54) (4.0 g, m.p. 124–125°) in dry ethyl acetate (40 ml). A precipitate began to form immediately. Next morning the precipitate was recovered and the solid residue from the evaporation of the mother liquor to dryness was added to it. One crystallization from methanol and two from benzene gave small bright yellow needles whose melting point of 205–207° was raised to 211–212° by two more recrystallizations from methanol and one from aqueous acetone. A final recrystallization from methanol gave the analytical sample of the 1:1 addition compound, m.p. 211.6–212.2°. Found: C, 56.08, 56.26; H, 6.21, 6.32; N, 12.46, 12.30%. Calc. for $C_{21}H_{28}O_7N_4$: C, 56.24; H, 6.29; N, 12.49%. Dicyclohexylurea could not be found in the mother liquors, though a little phenolic starting material was recovered.

(b) With Methyl 3,5-Dinitro-4-hydroxybenzoate (VI)

Methyl 3,5-dinitro-4-hydroxybenzoate (54) (10 g), dissolved in dry ethyl acetate (75 ml), was treated with dicyclohexylcarbodiimide (5 g). The mixture became warm and a precipitate began to form in a few minutes; after 2 days it was recovered and recrystallized from benzene to give a yellow product (6.89 g), m.p. 191–201°. Two more recrystallizations from benzene and one from methanol gave prisms which exhibited dimorphism at the melting point: the prisms partially melted at 190°, the melt resolidified as needles, the remaining prisms melted at 196–200°, and the needles sharply at 200°. Another recrystallization from methanol gave a mixture of needles (0.96 g) and prisms (0.34 g) which were separated by hand; the needles melted at 199–200° and the prisms behaved as before; in chloroform solution the infrared spectra of the two forms were identical. One more recrystallization from methanol gave a pure sample of the 1:1 addition compound, which separated originally as needles but which after 3 days had completely changed to prisms; they showed the same double melting point as before, and two more recrystallizations from methanol produced no change in the melting point. Found: C, 56.18, 56.26; H, 6.36, 6.20; N, 12.75, 12.69%. Calc. for $C_{21}H_{28}O_7N_4$: C, 56.24; H, 6.29; N, 12.49%. The reaction mixture filtrate and the mother liquors gave, after one recrystallization of the crude crystals from methanol, an excellent product showing the double melting point in the range 190–200°, in a yield of 8.39 g, as well as a fraction (m.p. 97–112°, 2.29 g) thought to be impure phenolic starting material since, when the reaction was repeated in dry benzene at the reflux temperature, 9.62 g of crude addition product, m.p. 195–198°, was obtained as well as 2.4 of

material, m.p. 107–111°, undepressed by admixture with methyl 3,5-dinitro-4-hydroxybenzoate. No dicyclohexylurea could be found in the mother liquor.

The addition product (2.25 g, m.p. 190–200°) was recovered unchanged in a yield of 1.85 g after it had been heated at 170° for 2 hours with methyl 3,5-dinitro-4-hydroxybenzoate and dimethylformamide, the mixture poured into water, and the precipitate recrystallized from methanol. No substituted diphenyl ether could be recovered.

(c) With Unactivated Phenols

When methyl 3,5-dinitro-4-hydroxybenzoate (2.4 g), dicyclohexylcarbodiimide (2.2 g), and methyl salicylate (20 ml) were heated 8 hours on the steam bath, the only insoluble compound produced was the same addition product observed in (*b*) just above, identified by melting point and infrared spectrum. Cyclohexylcarbodiimide failed to react on prolonged contact with methyl *p*-hydroxybenzoate in dry ethyl acetate.

(d) With 3,5-Dinitrosalicylaldehyde (VIIIa)

A solution of 3,5-dinitrosalicylaldehyde (8.4 g, m.p. 55–58°) and dicyclohexylcarbodiimide (4.4 g) in dry ethyl acetate (80 ml) was heated under reflux for 4 hours and then evaporated to dryness. Light-sensitive crystals, m.p. 186–206°, were obtained by recrystallization of the residue from benzene, yield 4.78 g. The benzene mother liquor was evaporated to dryness and the residual gum triturated with methanol; significantly, the mixture became quite warm. A solid (0.82 g, m.p. 171–186°) separated from the cooled methanol; it was added to the previous solid fraction, and efforts to purify these solids failed. The methanolic mother liquor, however, yielded prisms (2.47 g, m.p. 156–186°) which after two more recrystallizations from methanol and two from aqueous acetone gave the analytical sample, which seemed also to be dimorphic (m.p. 192.5–193.5° with a little previous melting and resolidification at 188°). Found: C, 58.46, 58.26; H, 6.59, 6.52; N, 12.98, 13.25%; mol. wt., 415. Calc. for $C_{21}H_{28}O_6N_4$: C, 58.32; H, 6.53; N, 12.96%; mol. wt., 432. In a second experiment, the methanolic mother liquors gave dicyclohexylurea as white crystals (0.7 g), separated by virtue of its low solubility in benzene; after one recrystallization it was pure. It was identified by its melting point (233.2–234.0°), mixture melting point, and infrared spectrum.

(e) With 5-Nitrosalicylaldehyde (VIIIb)

Two experiments very similar to those above, but using purified 5-nitrosalicylaldehyde as the phenolic component, were performed. From the first experiment, pure dicyclohexylurea (m.p. 233.0–233.4°, with an abrupt change of crystal form but no melting at 222°) was obtained. Found: C, 69.92; H, 10.64; N, 11.08%. $C_{13}H_{24}ON_2$ requires: C, 69.65; H, 10.72; N, 12.50%. In the second experiment, five recrystallizations of the entire solid reaction mixture from ethanol gave the analytical sample of the principal reaction product, m.p. 142–143°. Found: C, 62.94, 62.74; H, 6.54, 6.63; N, 11.12, 11.27%.

(f) With 3-Nitrosalicylaldehyde (VIIIc)

In two experiments using purified 3-nitrosalicylaldehyde as the phenolic component, small amounts of unchanged 3-nitrosalicylaldehyde were recovered and identified by mixture melting point. The only other pure product obtained was dicyclohexylurea (identified by m.p., mixture m.p., and infrared spectrum), which separated spontaneously from the dry ethyl acetate of the first experiment.

(g) Infrared Spectra

The values given are uncorrected. The addition products, A with methyl 2-hydroxy-3,5-dinitrobenzoate and B with methyl 4-hydroxy-3,5-dinitrobenzoate, showed bands at the same position (near 3320 cm^{-1}) as the N—H stretching band of dicyclohexylurea (C) in potassium bromide disks; in a chloroform solution of B, the band was weakened and raised to 3440 cm^{-1}. This band was completely absent in D, the condensation product with 3,5-dinitrosalicylaldehyde, and in E, the condensation product with 5-nitrosalicylaldehyde. A and B showed an ester carbonyl stretching band at 1730 and 1737 cm^{-1}, absent in the others; all the compounds showed bands in the "amide I" region; 1650 (A), 1640 (B), 1630 (C), 1682 (D), and 1660 cm^{-1} (E) in potassium bromide (aldehyde C—H stretching bands being absent in the spectra of D and E); in chloroform the band for B was *raised* to 1670 cm^{-1}, as would be expected for a band of this type. A, B, D, and E showed strong bands near 1620 cm^{-1}, extremely strong in the latter pair. The "amide II" region (near 1550 cm^{-1}) was occupied also by the nitro groups' frequency; in A and B the two sources overlapped to form a wide band, in potassium bromide disks, but in the spectrum of a chloroform solution of B the bands were resolved, one component moving to a lower frequency (as would be expected for a true "amide II" frequency). In agreement with the loss of the N—H stretching bands, the spectra of D and E both showed narrower bands (with potassium bromide disks) having the shape of the nitro groups' band alone. As expected, a strong, moderately broad band near 1290 cm^{-1} in the spectra of A and B was absent in that of D; the differences between D and E suggested by the elementary analysis were most clearly supported in the spectra by the presence in the spectrum of E, but not of D, of an extremely strong, broad band between 1330 and 1290 cm^{-1}, and by the presence in the spectrum of E of two moderately strong, very sharp, and well-resolved bands at 1480 and 1380 cm^{-1}, present at most as weak shoulders in the spectra of the other compounds.

ACKNOWLEDGMENTS

The present work was undertaken as a tribute to Professor J. A. McRae and to all the many research students at Queen's who have worked upon the problem. It is hard to have

to report that Dr. McRae died nearly a year before the completion of our own work. We wish to thank Dr. R. H. Manske for the suggestions which led to the beginning of this work nearly 25 years ago, for his advice as to the early concepts of the biosynthesis of cularine, and for his long continued interest in the problem. Miss Shelagh Courtney determined most of the infrared spectra, Miss Lorna Craig and Mr. Stephen Safe made our work possible by the production of very large amounts of the necessary intermediates, and Dr. C. A. Sankey gave us the large amounts of vanillin needed as starting material. The National Research Council of Canada supported the work by a research grant, and by the grant of a scholarship to one of us.

DIELECTRIC EVIDENCE FOR ACETONE HYDRATE[1]

G. J. WILSON[2] AND D. W. DAVIDSON
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received August 16, 1962

ABSTRACT

The phase diagram of the acetone–water system shows that acetone hydrate decomposes at an incongruent melting point. The existence of acetone hydrate is confirmed by a study of the low-frequency dielectric properties of this system. A dispersion region, related to the relaxation of water molecules in the clathrate structure, is characterized by a "static" dielectric constant and an activation energy about half as large as the corresponding values for ice, and by a limiting high-frequency dielectric constant of about 7 at 200° K. The magnitude of the latter is attributed to orientation of acetone molecules within the larger cavities of the hydrate structure.

It is now well-established that a cubic form of ice which is stable at low temperatures for long periods of time can be formed by condensation of water vapor on a sufficiently cold surface (1). Since 1896 several workers have reported that an isotropic form of ice could be formed by cooling aqueous solutions of a large number of organic substances, including acetone (for summary, see ref. 2). In particular, Cohen and van der Horst (3) suggested the formation of "ice VIII" in cooled concentrated solutions of acetone and other organic liquids. They inferred that acetone was found in their analyses of the crystals as a result of their inability to separate the crystals completely from the acetone-rich mother liquor. Recently an X-ray study by Quist and Frank (4) clearly suggested that the cubic solid obtained at high acetone concentrations was acetone hydrate rather than ice VIII. The diffraction patterns were identical with those reported by von Stackelberg and Müller (5) for "hydrates of structure II" like those of $CHCl_3$ and C_2H_5Cl. In these structures, first proposed by Claussen (6), the organic molecules (A) occupy the larger of two different-sized cavities formed by a lattice of hydrogen-bonded water molecules. Since there are eight large cavities to the 136 water molecules in the unit cell, the maximum A content is given by $A.17H_2O$. The oxygen atoms of the water molecules belong to space group O_h^7—$Fd3m$ and the side of the unit cell is 17.2 Å.

In view of the uncertainty of the conditions of existence of acetone hydrate and our interest in molecular motions in clathrate structures of this type, we have studied the acetone–water system at low temperatures by means of low-frequency dielectric measurements, as well as by thermal analysis.

EXPERIMENTAL METHODS

Dielectric measurements were made on solutions of four concentrations (15.5, 27.0, 27.5, and 97.7 wt%) of distilled Reagent Grade acetone (conductivity 1.2×10^{-7} ohm^{-1} cm^{-1}) in conductivity water. Temperatures were between −194 and −15° and frequencies between 0.050 and 500 kc/sec, with instrumentation as previously indicated (7, 8). The cell was a three-terminal type with vertical coaxial stainless steel electrodes. Samples of known composition slowly frozen in this type of cell were found in the course of preliminary work on other hydrates (9) to be as satisfactory as those frozen *ex situ* and compressed hydraulically into disks before insertion between the parallel plate electrodes of the usual type of cell for solids. To the inconvenience of pressing the sample at low temperatures in the second method must be added a considerable uncertainty in the proper value of the cell constant to be used at different temperatures. When, as for many of the present measurements, liquid and solid phases are both present, vertical electrodes are less subject to the trapping of air pockets and incomplete filling of the interelectrode region than horizontal ones. We believe

[2]*N.R.C. Postdoctoral Fellow, 1961–62.*

the effect of possible air gaps to be small, except below the eutectic temperature, in the method we have used. Temperatures were measured to within about ±0.2° with a copper–constantan thermocouple.

Ten-gram samples for thermal analyses were inserted in a glass tube fitted with a thermocouple and an evacuated jacket. Because of relatively fast heating and cooling rates (1 to 2° per minute) and inadequate stirring of the samples, temperatures of inflection points in the curves were possibly uncertain by 1 to 2°.

RESULTS

Phase Diagram

Figure 1 summarizes the results of the thermal analyses. The liquidus curve divides into two branches at concentrations greater than about 31% acetone: the lower branch

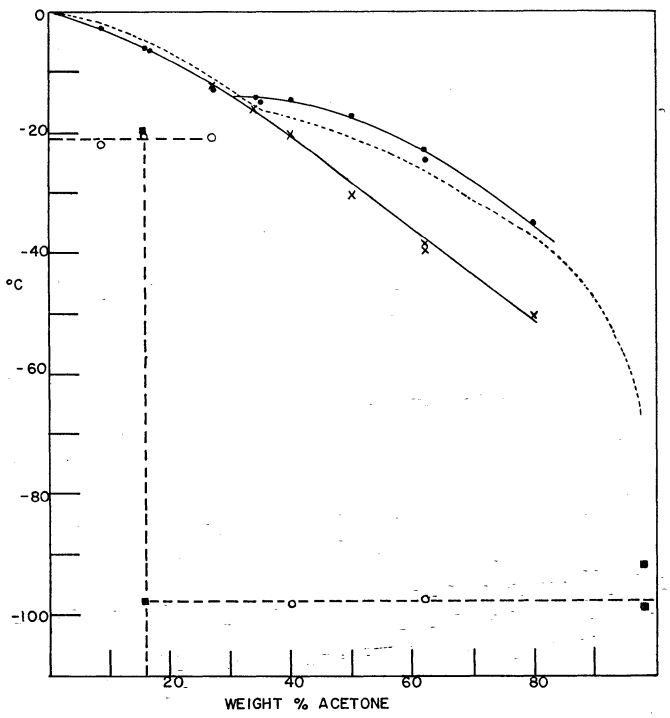

FIG. 1. Suggested phase diagram for the acetone–water system: × freezing points, ● melting points, ○ plateaus in heating and cooling curves, ■ discontinuities in dielectric heating curves.

marks the beginning of freezing, the upper the end of melting. The lower branch, continuous with the curve for lower concentrations, is assigned to the freezing of ice, the upper to the melting (and final decomposition) of acetone hydrate. Under our conditions practically all samples froze originally as ice but showed the later formation of acetone hydrate, during cooling to dry ice temperature and subsequent heating, either by a higher melting than freezing point (for large acetone concentrations) or by an inflection in the heating curve near −21° (for small concentrations). This latter temperature is some 6° lower than the intersection point of the ice and hydrate liquidus curves. Except for this feature, the behavior is that of a solid compound of acetone and water with an incongruent melting point. In fact, such a hydrate is a solid solution of guest molecules in a host lattice which can only exist when more than a critical fraction of the cavities are occupied (10). The composition of the hydrate will therefore depend on the activity of the acetone in the liquid phase present and may well depend also on the thermal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

history of the sample. The vertical line in Fig. 1 at 15.9% acetone refers to the ideal composition given when all the cavities are occupied.

Most of the earlier studies of the acetone–water system (11) appear to have made use of freezing point measurements alone and do not show the upper branch of Fig. 1. However, the results of Benjamin, although reported (11) as freezing temperatures, are qualitatively in agreement with our hydrate decomposition temperatures. They are shown as the broken curve in Fig. 1. Our eutectic temperature (−99°) is somewhat higher than Benjamin's (−105°).

Dielectric Behavior

The complex plane locus of Fig. 2 is typical of the dispersion and absorption behavior shown by acetone hydrate at audio and low radio frequencies. Superimposed on a region

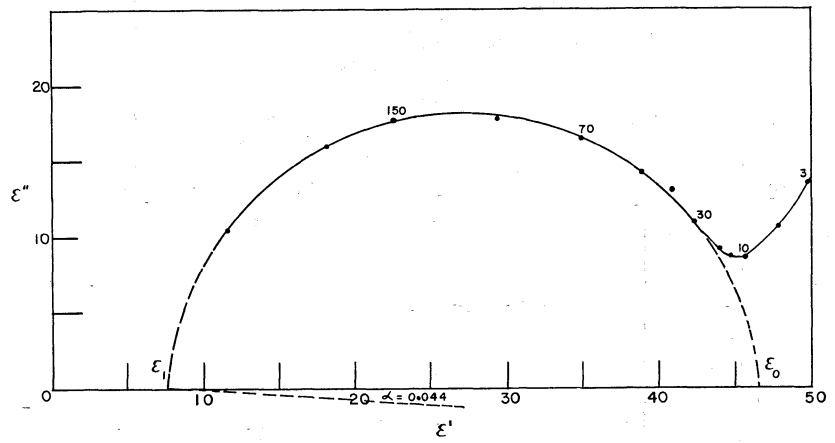

FIG. 2. Complex dielectric locus of 15.48 wt% acetone sample at −54.8°. Numbers beside points are frequencies in kc/sec.

usually marked by a well-defined absorption maximum is an additional absorption region at relatively low frequencies. Typically, the values of ϵ' and ϵ'' associated with this low-frequency absorption region continued to rise with decreasing frequency until the latter exceeded the range of the bridge. There is a similar effect in "slightly impure" ice (12).

As in ice (12), the low-frequency absorption was considerably reduced by application of a d-c. field, though in our case never completely eliminated. Figure 3 illustrates the effect on the sample of heating to −50°, followed by recooling in a field of some 1000 v/cm over a period of several hours. The absorption region occurring at higher frequencies is unaffected by the d-c. "fore-field". We attribute this latter region to orientational relaxation of the water molecules in the hydrate lattice.

Water Relaxation Region

It is difficult to define exactly the shape of the dispersion–absorption region associated with the rotational orientation of water molecules because of the low-frequency polarization mentioned above. It is slightly broader than would correspond to a single relaxation time. We have analyzed the results in terms of the time corresponding to the frequency of maximum absorption, as in a Cole–Cole type of representation (13), to which the data approximately conform. There is a definite tendency for the dispersion to become broader and for the Cole–Cole α to increase (cf. Fig. 2 with Fig. 3) as the temperature gets lower. In common with the hydrate of ethylene oxide (9), there is some indication that this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

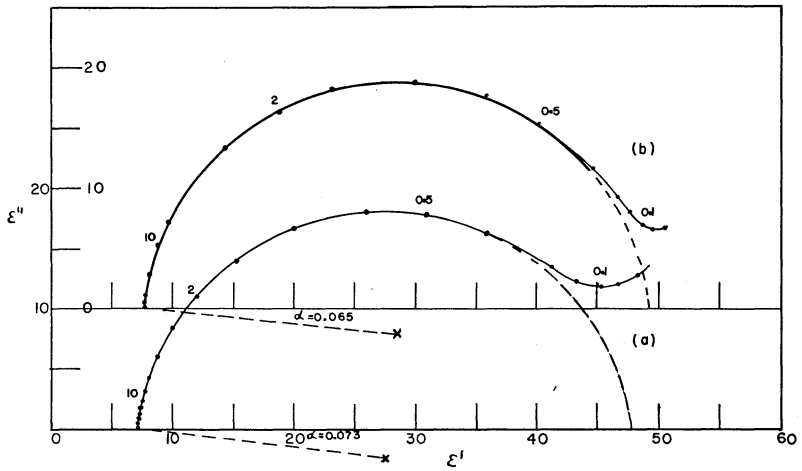

FIG. 3. Loci of same sample (27.45% acetone) (*a*) at −111.5° before and (*b*) at −107.0° after application of a d-c. field of 1000 v/cm.

dispersion region may be resolvable, particularly at low temperatures, into two or three single relaxation processes, but such a procedure is by no means unambiguous. For most samples the low-frequency polarization tends to overlap the water dispersion region more seriously as the temperature decreases, a relative temperature dependence which is the reverse of that found in ice.

The behavior of the real part ϵ' of the dielectric constant at a fixed frequency (100 kc/sec) is shown on the composite plot in Fig. 4. The points represent data obtained on samples in thermal equilibrium, the solid curves data on the 15.5% sample, which had been initially rapidly cooled and subsequently heated through the eutectic and acetone hydrate decomposition temperature ranges at a rate of ca. 0.5° per minute.

The ϵ' values at 100 kc/sec approximate to ϵ_1, the limiting high-frequency intercept, at low temperatures, increase rapidly with rising temperature through the dispersion region, and approach the static dielectric constant ϵ_0 near the hydrate-decomposition temperature. At this temperature, ϵ' falls, since the ice in the ice – aqueous acetone liquid mixture has an ϵ' value of not much more than 3 at this frequency (14).

Examination of a 97.7 wt% acetone solution above the eutectic temperature revealed no liquid phase dispersion to interfere with that attributed to acetone hydrate.

Limiting High-frequency Dielectric Constant: ϵ_1

The behavior of this quantity at different temperatures is illustrated for three samples in Fig. 5. Below the eutectic temperature the sample containing 15.5% acetone showed a lower value of ϵ_1 when rapidly cooled than when slowly cooled, which reflects either a "freezing-in" of some ice, a lower fraction of occupied cavities, or the presence of a larger air gap in the former. The ϵ_1 data for the slowly cooled case showed only a slight rise as the temperature rises through the eutectic point, followed by a fall at higher temperatures, which suggests very little liquid is in coexistence with the acetone hydrate for this composition. This roughly supports the stoichiometry provided by the X-ray formula, $A.17H_2O$, since the above composition represents 97% of the acetone content of the hydrate with fully occupied cavities. The samples of higher acetone content showed a rapid rise of ϵ_1 with increasing temperature above the eutectic point as more liquid phase was formed.

Upper points are estimated ϵ_0 values.

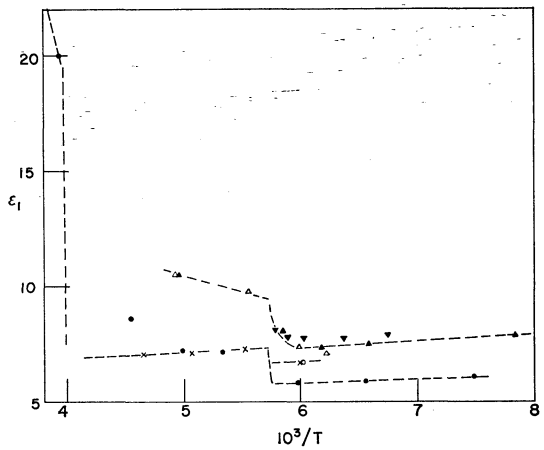

FIG. 5. Temperature dependence of ϵ_1. Points are identified in caption of Fig. 4.

These results suggest a true value of ϵ_1 somewhat in excess of 7 at temperatures near 200° K.

Limiting Low-frequency Dielectric Constant: ϵ_0

We have approximately evaluated the limiting low-frequency dielectric constant appropriate to the water relaxation by fitting a circular arc to the experimental points for

frequencies sufficiently high that the low-frequency polarization may be assumed to make only a minor contribution (cf. Figs. 2 and 3). This procedure is somewhat uncertain where there is serious overlap of the two polarization regions. Moreover, the presence of an air gap acting in series with the sample results in a measured ϵ_0 which is smaller than the true one, an effect which is greatest at low temperatures. Above the eutectic temperature the apparent value of ϵ_0 depends, in addition, upon the quantity, concentration, and distribution within the sample of the liquid phase. For samples of relatively high acetone content, ϵ_0 increases rapidly with rise of temperature.

Except for the samples with 27% acetone above the eutectic temperature, the experimental values of ϵ_0 tended to lie between 40 and 50 (see upper part of Fig. 4). We believe that the true static dielectric constant of acetone hydrate near its decomposition temperature is not likely to be greater than 60 and therefore no more than one-half the ϵ_0 value of ice at comparable temperatures (14).

Relaxation Times τ_0

These are plotted vs. $1/T$ in Fig. 6. They show no dependence upon sample composition to within the accuracy with which they have been derived (4 to 20%, depending upon sample and temperature). The activation energy derived from the straight line drawn in Fig. 6 is 6.3 kcal/mole, again about one-half of the corresponding figure for ice (14). As for ethylene oxide hydrate (9), there are signs that the dependence of τ_0 on $1/T$ may become less at low temperatures.

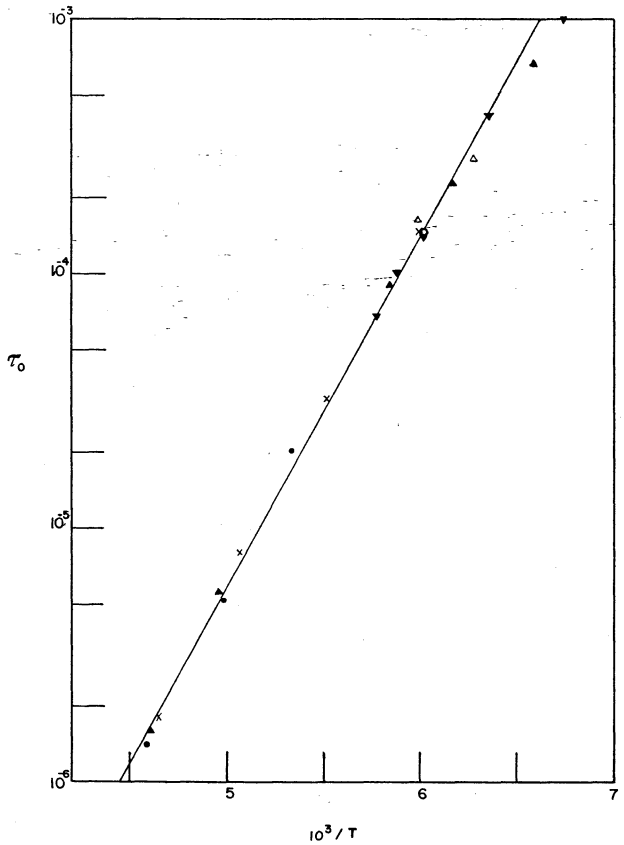

FIG. 6. Temperature dependence of τ_0. Points are identified in caption of Fig. 4.

Space-charge Polarization

In attributing the increasing values of ϵ'' and ϵ' at relatively low frequencies to space-charge polarization associated with the presence of impurity ions, we have been guided by the previous experience with ice and by the effect of application of a d-c. field. Since the ϵ'' values exceeded the range of the bridge at low frequencies we have tried to define qualitatively the amplitude of this dispersion by making photographic transient studies of the sample containing 15.5% acetone at temperatures corresponding to those of bridge measurements.

The results of one such measurement, along with the corresponding bridge results, are shown in Fig. 7. The transient curve represents the sample charging current, expressed

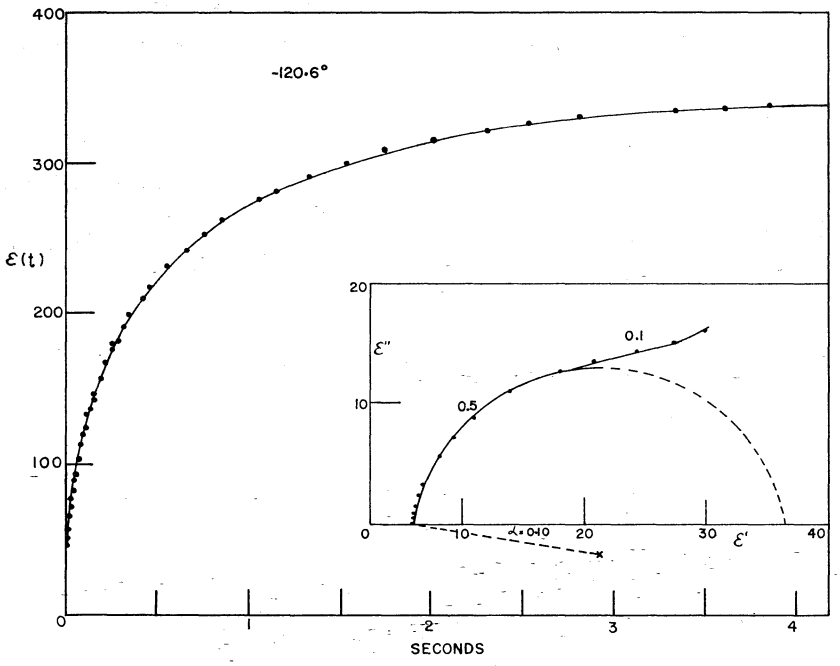

FIG. 7. Transient and bridge results for sample containing 15.48% acetone at −120.6°.

in units of capacitance equal to the cell constant, following application of a voltage rising linearly with time (15, 16). The linear contribution of a d-c. conductivity of 1.1×10^{-10} $ohm^{-1}cm^{-1}$ has been subtracted.

It is apparent that at times of the order of 5 seconds the polarization approaches a value equivalent to a dielectric constant some 10 times as great as that characteristic of the circular arc dispersion, for which τ_0 is of the order of 1 millisecond. The polarization curve rises somewhat more rapidly at the beginning, and less rapidly at the end, than the exponential, which rises to a fraction $(1-1/e)$ of its final value in the same time. In fact, the curve of Fig. 7 is fitted by $\epsilon(t) = 32+284t^{1/2}$ up to times of about 0.3 second, and by an exponential with a time constant of 0.81 second for times greater than 0.5 second. Such initial proportionality to $t^{1/2}$ and subsequent exponential behavior has been reported by Gränicher *et al.* (17) for the change of d-c. conductance of ice. Initial proportionality to $t^{1/2}$ was also found (12) for the rise in the low-frequency values of ϵ' and ϵ'' after removal of a d-c. fore-field. Extrapolation of relaxation data for higher temperatures (14) indicates that ordinary ice would have a relaxation time of the order of 4×10^3 seconds at this temperature.

DISCUSSION

The properties of the dielectric dispersion which we have attributed to the water molecules in acetone hydrate are qualitatively similar to those of other hydrates of the clathrate type that we have examined, in particular to those of ethylene oxide (9). These include values of ϵ_1 too large to be explained on the basis of induced polarization alone, values of ϵ_0 of the order of one-half those of ice, relaxation times intermediate between those of ice and liquid water, and an increase in breadth with decreasing temperature of a dispersion region which is slightly broader than the Debye type.

Calculation of ϵ_1

There seems little doubt that values of ϵ_1 considerably greater than 3 are related to the ability of the acetone molecules in the cavities to undergo orientation in the field. The magnitude of ϵ_1 to be expected on this basis may be estimated by a simple extension of the Onsager cavity method (18).

We consider a polar molecule at the center of a spherical cavity of radius a in a continuous medium of dielectric constant ϵ_∞. The reorientation rate of the molecule in the cavity is taken to be much greater than that of the water molecules in the surrounding medium, so that only polarizability effects in the latter contribute to ϵ_∞. The average component of the central molecule in the direction of the field is

$$\overline{\overline{m}}_E = \frac{3\epsilon_\infty}{2\epsilon_\infty+1}\frac{E}{1-f}\left[\alpha + \frac{\mu_0^2}{3kT(1-f)}\right],$$

in which E is the applied field, α and μ_0 the polarizability and dipole moment of the occluded molecule, and $f = 2(\epsilon_\infty-1)\alpha/(2\epsilon_\infty+1)a^3$. For the 16-faced cavities of von Stackelberg's structure II, a may be taken as 3.45 Å, one-half of the cavity diameter (5).

For acetone specifically, $\mu_0 = 2.88\times10^{-18}$ e.s.u. and, from the molar refraction, $\alpha = 6.4\times10^{-24}$ cm^3/molecule (19). With $\epsilon_\infty = 3$ one finds $f = 0.089$, $\overline{\overline{m}}_E = 1.64\times10^{-22}E$ e.s.u. at 200° K. The contribution to the Maxwell polarization arising from the permanent dipoles in the cavities is $P_2 = \nu y\overline{\overline{m}}_E$, where ν is the number of large cavities per cm^3 and y is the fraction of these cavities occupied by molecules. For eight cavities in a unit cube of side 17.16 Å (4) $\nu = 1.58\times10^{21}$ cavities per cm^3 and $P_2 = 0.260yE$. Under the further assumption that this polarization may simply be added to that of the continuum (i.e., to the polarizability contribution specified by ϵ_∞),

$$\epsilon_1 = 3+4\pi P_2/E = 3+3.3y,$$

which has a maximum value of 6.3 when all the cavities are occupied.

This value agrees well with the experimental value of about 7 at 200° K (Fig. 5). The calculated value of ϵ_1 is greatly dependent on the value assumed for ϵ_∞, which can only be determined experimentally at frequencies sufficiently high that rotations of the molecules in the cavities no longer contribute to the dielectric constant. In our frequency range, we have been unable to find the absorption region related to rotation of molecules in the cavities even at temperatures as low as −194°.

When y approaches unity there should be an approximately linear dependence of ϵ_1 on the square of the dipole moments of the occluded molecules. Such a dependence has been noted by Dryden (20) for some of the quinol clathrates, to which a similar model may be applied.

Values of ϵ_0

It is necessary to account for the relatively low values of ϵ_0, in comparison with those of ice or water, in terms of the structure built up in the hydrate by hydrogen bonding of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the water molecules. Detailed calculations of the type attempted by Powles (21) for ice, already laborious, are made more so by the presence of three types of water molecule with non-identical environments and of some angles which depart considerably from tetrahedral if all the distances between water molecules are taken as equal (5). Furthermore, even for the simplest Pauling model, computational difficulties due to the interdependence of legs leading out from a central molecule as the number of layers of neighbors grows, which appeared first on consideration of third-nearest neighbors in ice, appear now as soon as the group of molecules considered includes second-nearest neighbors (lying in the same pentagonal ring).

There are, however, a number of factors which should lead to values of ϵ_0 which are lower for the hydrates than for ice. The first of these is the presence of pentagonal rings which, in the hydrates of structure II, outnumber the hexagonal rings in a ratio of 9 to 1. A simple analysis of the probabilities of the occurrence of hydrogen atoms at different positions around the ring, subject to the conditions that the positions of the hydrogen atoms on one molecule be fixed and that there be one hydrogen atom in each bond, shows that the most likely arrangement is that in which the resultant moment of the OH bonds adds vectorially to zero. The next most likely configurations give rise only to small resultant moments. There is a similar but smaller tendency within hexagonal rings.

The second factor arises from the lower density of water molecules in the hydrates. The X-ray parameters of Quist and Frank (4) at ca. $-37°$ lead to a number of water molecules per cm^3 which is some 15% less than that for ice at a comparable temperature.

Finally, an important factor in determining the value of ϵ_0 is the quantity $(\epsilon_\infty+2)^2$, to which ϵ_0 is proportional (cf. equation 1.2 of reference 20). It is clear that if the refractive index of the hydrate were appreciably less than that of ice, a considerable reduction in ϵ_0 would occur.

It seems likely that the combined effect of the above factors is sufficient to reduce the static dielectric constant to roughly half its value in ice.

Relaxation of the Water Molecules

The faster relaxation rate and lower activation energy for water reorientation in acetone hydrate is consistent with a looser hydrogen-bonded structure than is found in ice. According to von Stackelberg and Müller (5) the distance between oxygen atoms in neighboring water molecules is 2.78 Å compared with 2.76 Å in ice, and some of the angles between hydrogen bonds are considerably distorted from tetrahedral values. If the water molecules were able to undergo reorientation independently of one another, one might expect three discrete dispersion regions characteristic of the three types of environment of the water molecules; the amplitudes of dispersion would be greatly different since the numbers of water molecules in the three environments are in the ratio 1:4:12. The more likely relaxation mechanism, the diffusion of rotational defects of the Bjerrum (22) type, should also lead to a broadening of the dispersion character, since presumably some diffusion paths through the hydrate are more likely than others.

The relaxation rate may also be affected by the degree of occupancy of adjacent cavities. It will be interesting to determine the effect on the relaxation of different types of occluded molecules.

Dielectric Evidence of the Existence of Acetone Hydrate

"High-frequency" dielectric constants of acetone–water mixtures which are greatly in excess of 3 below the eutectic temperature can only be accounted for by the presence of a hydrate structure containing cavities within which the acetone molecules are capable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of orientation at rates considerably faster than the measuring frequencies. Values no greater than 3 would be expected for mixtures of ice and solid acetone.

The relaxation properties of the dispersion region described above are greatly different from those of ice and are independent of concentration of acetone. They therefore must be attributed to the existence of a structure present at all appreciable acetone concentrations, rather than to an ice structure perturbed to an extent which depends upon the quantity of acetone present. These properties are qualitatively similar to those of the ethylene oxide hydrate, whose existence has been well established (cf. ref. 23 and references cited therein).

The dielectric behavior appears to be in accord with the suggested phase diagram in all respects.

REACTIONS OF PHENYL-SUBSTITUTED HETEROCYCLIC COMPOUNDS

I. NITRATION OF 2-PHENYL-1,2,3,2H-TRIAZOLE[1]

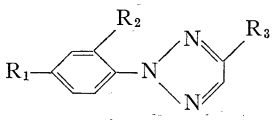
BRIAN M. LYNCH[2] AND TZE-LOCK CHAN[3]
Chemistry Department, Memorial University of Newfoundland, St. John's, Newfoundland

Received September 27, 1962

ABSTRACT

Structures have been assigned to the mono-, di-, and tri-nitration products of 2-phenyl-1,2,3,2H-triazole, on the basis, partly, of ultraviolet absorption spectra. The pattern of nitration closely resembles that of 1-phenylpyrazole. A compound previously described as 2-(*o*-nitrophenyl)-1,2,3,2H-triazole is actually 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole.

Riebsomer (1) investigated the nitration of 2-phenyl-1,2,3,2H-triazole (I) by mixed acids at 20°, and obtained two products, having m.p. 183° and 125°. He suggested that the higher-melting compound was 2-*p*-nitrophenyl-1,2,3,2H-triazole, and that the lower-melting compound was the ortho isomer. We required these substances as intermediates in the syntheses of 2-*p*-biphenylyl-1,2,3,2H-triazole (II) and 2-*o*-biphenylyl-1,2,3,2H-triazole (III), so Riebsomer's experiments were repeated.



I: $R_1 = R_2 = R_3 = H$

II: $R_1 = Ph$; $R_2 = R_3 = H$

III: $R_1 = R_3 = H$; $R_2 = Ph$

IV: $R_1 = R_3 = Ph$; $R_2 = H$

The higher-melting compound had the characteristics reported by Riebsomer, and its ultraviolet absorption was closely similar to that of 1-*p*-nitrophenylpyrazole (see Table I).

TABLE I

Ultraviolet absorption maxima of corresponding phenyltriazoles and phenylpyrazoles

1,2,3,2H-Triazole	λ_{max} (mμ)	log ε	Pyrazole	λ_{max} (mμ)	log ε
2-Phenyl	263	4.13	1-Phenyl	252	4.13
2-*p*-Nitrophenyl	306	4.09	1-*p*-Nitrophenyl*	312–314	4.24
4-Nitro-2-*p*-nitrophenyl	304	4.36	4-Nitro-1-*p*-nitrophenyl*	306	4.37
2-*p*-Biphenylyl	286	4.50	1-(2,4-Dinitrophenyl)	306	3.85
			1-*p*-Biphenylyl	280	4.50

*From DalMonte *et al.* (4).

Since the replacement of —CH: by —N: in heteroaromatic systems generally has little influence on ultraviolet absorption (2), correspondingly substituted 1-phenylpyrazoles and 2-phenyl-1,2,3,2H-triazoles should have similar electronic spectra, and assignments

[3]*Summer Research Assistant, 1962. Present address: Department of Chemistry, University of Kansas City, Kansas City, Missouri, U.S.A.*

of structure can be based on such similarities. Further, the infrared spectra of the higher-melting compound showed strong bands at 1345 and 1530 cm^{-1}, corresponding to the symmetric and asymmetric N—O stretching vibrations, closely similar in frequency to those noted for 1-*p*-nitrophenylpyrazole (1341 and 1527 cm^{-1}). Present work (3) indicates that these band positions are characteristic of a *p*-nitro substituent in N-phenylated pyrazoles and imidazoles, and it seems likely that the correlation extends to phenyltriazoles.

Additional evidence in support of Riebsomer's assignment for the compound of m.p. 183° was obtained after reduction to the corresponding amine, followed by diazotization of the amine and Gomberg arylation of benzene. This yielded a biphenylyltriazole with ultraviolet absorption closely resembling that of 1-*p*-biphenylylpyrazole (3; see Table I), and showing strong infrared absorption in the C—H out-of-plane deformation region at 700, 765–770 (phenyl group), 850 (para substitution), and 950–965 cm^{-1} (triazole ring), to which structure II is assigned.

The lower-melting compound mentioned by Riebsomer was also obtained in our nitrations, although the melting point was raised to 140° by adsorption chromatography and crystallization. The ultraviolet absorption of this product differed markedly from that of 1-*o*-nitrophenylpyrazole, thus excluding the structure suggested by Riebsomer. Furthermore, the analytical results reported previously (nitrogen analyses) (1) do not distinguish between a mono- and a di-nitrophenyltriazole. Our analytical figures show that the compound, m.p. 140°, is a dinitro-2-phenyl-1,2,3,2H-triazole. Ultraviolet absorption data do not distinguish unequivocally between the two most likely structures, i.e., 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole and 2-(2,4-dinitrophenyl)-1,2,3,2H-triazole, since the spectra of the correspondingly substituted pyrazoles are fairly similar to one another and to the spectra of the compound of m.p. 140° (see Table I).

However, 2-(2,4-dinitrophenyl)-1,2,3,2H-triazole should readily undergo nucleophilic fission of the inter-ring C—N bond (compare 1-(2,4-dinitrophenyl)pyrazole (5, 6)), and the dinitrophenyltriazole, m.p. 140°, was unaffected by boiling with methanolic sodium methoxide, thus leading to the conclusion that the compound of m.p. 140° is 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole. Reduction of 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole as for 2-*p*-nitrophenyl-1,2,3,2H-triazole, followed by tetrazotization and Gomberg arylation of benzene, yielded 2-*p*-biphenylyl-4-phenyl-1,2,3,2H-triazole (IV).

Further nitration of 2-*p*-nitrophenyl-1,2,3,2H-triazole at 25° was found to yield 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole (compare the behavior of 1-*p*-nitrophenylpyrazole (5)), while nitration of the mono- or di-nitro compounds at 80°, or of the dinitro compound at 25°, yielded 2-(2,4-dinitrophenyl)-4-nitro-1,2,3,2H-triazole. Proof of structure of the trinitro compound was obtained by fission with methanolic sodium methoxide to yield 2,4-dinitroanisole.

Exclusive mononitration of 2-phenyl-1,2,3,2H-triazole to the *p*-nitrophenyltriazole can be effected in good yield by nitric acid in acetic anhydride, a more selective attacking reagent than nitric acid – sulphuric acid.

The general conditions necessary for the stepwise nitration of 2-phenyl-1,2,3,2H-triazole thus show close correspondence with those for 1-phenylpyrazole (5), notwithstanding the presence of an additional electron-attracting nitrogen atom in the triazole.

EXPERIMENTAL

General

Analyses were by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A. Infrared spectra were recorded using a Unicam SP100 spectrophotometer (samples were examined using the potassium chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

disk technique) and ultraviolet spectra were measured in 95% ethanol using a Beckman DK-2A Ratio-Recording spectrophotometer; melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected.

2-Phenyl-1,2,3,2H-triazole (I)

This compound, b.p. 228°, was prepared by oxidation of glyoxal bisphenylhydrazone with copper (II) sulphate (Riebsomer (1)).

Nitrations

(a) Of the Phenyltriazole (I) by Mixed Acids at 20°

The conditions employed were essentially those reported previously (1). 2-Phenyl-1,2,3,2H-triazole (7 g) in sulphuric acid (*d* 1.84, 20 ml) was nitrated by addition of nitric acid (*d* 1.42, 10 ml) over 1 hour at 20°. The reaction mixture was poured onto crushed ice and the precipitate was collected and washed repeatedly with cold ethanol. Crystallization from ethanol gave light yellow needles (5.5 g) of 2-*p*-nitrophenyl-1,2,3,2H-triazole, m.p. 183°. Anal. Calc. for $C_8H_6N_4O_2$: C, 50.53; H, 3.18%. Found: C, 50.33; H, 2.90%. Ultraviolet absorption: see Table I.

The ethanol washings and the mother liquor from the crystallizations were combined and the solvent was removed under reduced pressure. The residue was dissolved in benzene and chromatographed on alumina. Removal of solvent from the eluate, followed by crystallization from ethanol, yielded light yellow needles, m.p. 140° (0.98 g), presumed to be 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole. Anal. Calc. for $C_8H_5N_5O_4$: C, 40.86; H, 2.14; N, 29.78%. Found: C, 41.01; H, 2.34; N, 29.85%. Ultraviolet absorption: see Table I.

(b) Of the Phenyltriazole (I) by Nitric Acid – Acetic Anhydride

To 2-phenyl-1,2,3,2H-triazole (5 g) in acetic anhydride (50 ml) was added nitric acid (*d* 1.52, 25 ml) in acetic anhydride (25 ml) at ca. 15°. Precipitation commenced almost immediately; after 1 hour, the mixture was poured onto ice, and the product was collected and crystallized from ethanol, giving 2-*p*-nitrophenyl-1,2,3,2H-triazole (5.3 g), m.p. 183°. No lower-melting nitration products were isolated.

(c) Of 2-Nitrophenyl-1,2,3,2H-triazole by Mixed Acids at 25°

2-*p*-Nitrophenyl-1,2,3,2H-triazole (1.4 g) was nitrated at 25° using the general conditions of part (*a*) above. Repeated crystallization of the reaction product from ethanol yielded 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole (1.3 g), m.p. 140°, identical in all respects with the lower-melting product from the nitration of I. Anal. Found: C, 41.14; H, 2.01; N, 29.60%.

(d) Of 2-p-Nitrophenyl-1,2,3,2H-triazole or 4-Nitro-2-p-nitrophenyl-1,2,3,2H-triazole at 80°, or of 4-Nitro-2-p-nitrophenyl-1,2,3,2H-triazole at 25°

These reactions were carried out using the conditions noted in part (*a*) above. Both the mono- and the di-nitro compounds (in sulphuric acid) gave a blue color on addition of nitric acid: completion of reaction was indicated by a color change to yellow. The products of all three reactions were needles, m.p. 104°, of 2-(2,4-dinitrophenyl)-4-nitro-1,2,3,2H-triazole. Anal. calc. for $C_8H_4N_6O_6$: C, 34.30; H, 1.44%. Found: C, 34.02; H, 1.52%. Ultraviolet absorption: λ_{max} 285 mμ, log ϵ 4.24. Yields were as follows: 2.4 g from 2.5 g mononitro compound at 80°, 0.65 g from 0.80 g dinitro compound at 80°, and 0.30 g from 1.0 g dinitro compound at 25°.

Proof of Structure of 2-(2,4-Dinitrophenyl)-1,2,3,2H-triazole

The trinitro compound (1.0 g) in methanol (25 ml) was heated under reflux with 0.6 *N* methanolic sodium methoxide (20 ml) for 10 minutes. The reaction mixture was poured onto ice, and the resulting precipitate was collected, dried, dissolved in benzene, and chromatographed on alumina. Evaporation of the eluate yielded 2,4-dinitroanisole (0.45 g), m.p. 87°, identical (m.p., mixed m.p., infrared and ultraviolet absorption) with an authentic sample.

2-p-Biphenylyl-1,2,3,2H-triazole (II)

2-*p*-Nitrophenyl-1,2,3,2H-triazole (2.0 g) was quantitatively reduced to the corresponding amine by tin and hydrochloric acid, and converted into the diazonium chloride by standard procedures. The diazo solution thus obtained was stirred vigorously with benzene at 5°, after buffering to pH 5 with sodium acetate. The mixture was allowed to reach room temperature with continuous stirring, and the benzene layer was chromatographed on alumina. Evaporation of the eluate, followed by crystallization from ethanol, yielded 2-*p*-biphenylyl-1,2,3,2H-triazole (0.5 g), m.p. 90°. Anal. Calc. for $C_{14}H_{11}N_3$: C, 76.00; H, 5.01%. Found: C, 75.80; H, 5.30%. Ultraviolet absorption: see Table I.

2-p-Biphenylyl-4-phenyl-1,2,3,2H-triazole (IV)

Similar reduction of 4-nitro-2-*p*-nitrophenyl-1,2,3,2H-triazole by tin and hydrochloric acid, followed by tetrazotization and reaction of the buffered tetrazonium salt solution with benzene, gave 2-*p*-biphenylyl-4-phenyl-1,2,3,2H-triazole, m.p. 124°, in poor yield. Anal. Calc. for $C_{20}H_{15}N_3$: C, 80.80; H, 5.08%. Found: C, 80.58; H, 5.69%. Ultraviolet absorption: λ_{max} 308 mμ, log ϵ 4.52.

APPLICATION OF QUASI-LATTICE THEORY TO ALCOHOL – CARBON TETRACHLORIDE SYSTEMS[1]

B. DACRE[2] AND G. C. BENSON
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received August 24, 1962

ABSTRACT

Values of heats of mixing are reported for methanol, *n*-butanol, and *n*-octanol with carbon tetrachloride at 25° C. The experimental results are combined with data from other sources and an analysis of the excess thermodynamic functions for carbon tetrachloride solutions of methanol, ethanol, *n*-propanol, *n*-butanol, and *n*-octanol in terms of Barker's theory of solutions is described. The behavior of these systems can be reproduced fairly well by the Barker model.

INTRODUCTION

A method for calculating the thermodynamic properties of solutions from a quasi-lattice model which allows for the effects of cooperative orientation has been described by Barker and co-workers (1, 2, 3). Application of the theory involves the assumption of certain volume and contact relations for the molecules and the adjustment of energy parameters to fit the experimental data. Despite these somewhat empirical aspects, the theory provides a useful approach to the study of associated solutions, and data for a number of binary systems have been analyzed by this approach. Quite recently Goates, Snow, and James (4) applied Barker's theory to the systems ethanol–cyclohexane, methanol–benzene, and ethanol–benzene and were able to find a set of contact interaction energies which were consistent with their enthalpy values.

The present paper reports the results of measurements of the heat of mixing of methanol, *n*-butanol, and *n*-octanol with carbon tetrachloride at 25° C. During an analysis of the results in terms of Barker's theory, values of the free energy, heat, and volume of mixing for a number of alcohol – carbon tetrachloride systems were published by Missen and co-workers (5, 6). These new data and information from other sources have been employed, together with the results obtained in the present work, in a comprehensive series of Barker calculations for mixtures of methanol, ethanol, *n*-propanol, *n*-butanol, and *n*-octanol with carbon tetrachloride (subsequently referred to as systems I, II, ···, V respectively). The object of the computations was to find a consistent set of interaction energies which would reproduce the thermodynamic mixing functions for the five systems. In the dilute concentration region where comparison could be made with values obtained from infrared and n.m.r. studies, alcohol monomer fractions were also calculated.

EXPERIMENTAL

The main features of the adiabatic calorimeter used for the heat of mixing determinations have been described previously (7). For the present work a pyrex mixing cell in which the two components were separated initially by mercury was supported inside the metal calorimeter vessel and the intervening space filled with water to improve the thermal contact.

Refractive indices and boiling points characterizing the pure components used to form the binary solutions are summarized in Table I. Spectrochemical grade methanol (Matheson, Coleman and Bell) and carbon tetrachloride (Eastman Organic Chemicals) were used directly. The *n*-butanol and *n*-octanol were reagent grade materials (British Drug Houses) which were distilled from sodium prior to use. A second distillation had a negligible effect on the values of the physical properties listed in Table I.

TABLE I

Physical properties of component liquids

Component	n_D^{20}	B.p. (760 mm)
Methanol	1.3287	—
n-Butanol	1.3992	117.6–117.8
n-Octanol	1.4292	194.6
Carbon tetrachloride	1.4600	—

An analysis of the precision of the various experimental quantities indicates that under the existing operating conditions the accuracy of the result depends mainly on the measurement of the changes in thermocouple e.m.f. during the mixing and calibration periods. A reasonable estimate of the error in these voltages is 0.15 μv, which corresponds to an error of about 0.5 cal mole^{-1} in the heat of mixing. The free vapor volumes in the mixing cell were quite small (0.1 to 0.2 cm^3) and no vapor space corrections were made since calculations showed that these were negligible compared to the estimated error of the results.

RESULTS

The experimental results for the heat of mixing at constant pressure H_p^E (stated in cal mole^{-1} of solution[3]) are given in Table II for the three alcohol – carbon tetrachloride

TABLE II

systems at 25° C. It was not possible to represent the concentration dependence of H_p^E properly by a Margules type of equation, as employed by Scatchard *et al.* (8), using powers of the mole fraction difference as high as 4. The inadequacy of the Margules form for alcohol systems presumably is due to the marked asymmetric character of the curves and has been noted by other workers (5, 6, 9). Otterstedt and Missen (10) have suggested a square root relation but this too failed to represent the data satisfactorily and graphical procedures were adopted. It was possible to draw, through large-scale plots of the results, acceptable smooth curves from which the standard deviations of the experimental points were 0.6, 0.8, and 0.7 cal mole^{-1} for systems I, IV, and V respectively. Values of H_p^E read from the curves at concentration intervals of 0.05 are collected in Table III. Heats of mixing for some of the same systems have been reported by several previous investigators (6, 8, 11, 12, 13). However, none of the measurements were made at 25° C and it

[3]*The defined thermochemical calorie, equal to 4.184 absolute joules, is used throughout this paper.*

TABLE III

Values of H_p^E at rounded concentrations for alcohol – carbon tetrachloride systems at 25° C

Mole fraction of alcohol	H_p^E (cal mole^{-1})		
	CH_3OH–CCl_4	C_4H_9OH–CCl_4	$C_8H_{17}OH$–CCl_4
0.05	67.7	82.5	89.1
0.10	78.4	107.0	108.0
0.15	81.9	116.2	120.3
0.20	81.6	120.0	126.5
0.25	78.6	121.2	127.8
0.30	74.1	120.2	126.6
0.35	68.9	115.3	123.0
0.40	62.4	108.0	117.7
0.45	54.4	96.3	111.4
0.50	45.4	83.3	104.2
0.55	37.0	70.5	95.9
0.60	29.4	57.2	86.2
0.65	22.6	44.0	75.3
0.70	16.0	32.0	63.5
0.75	10.0	22.0	52.2
0.80	4.0	13.8	41.8
0.85	−1.4	7.0	31.7
0.90	−5.6	2.6	21.0
0.95	−5.0	0.1	10.2

appears that a reliable interpolation can be made only in the case of the data of Otterstedt and Missen (6). Using the cubic form suggested by these authors, values of H_p^E at 25° C were calulated for systems I and V at the 19 concentrations given in Table III; the standard deviation from the values in Table III was 2.4 cal mole^{-1} for system I and 1.5 cal mole^{-1} for system V. This agreement is quite satisfactory since the standard deviations are of the same magnitude as those quoted in reference 6.

DATA FOR SYSTEMS I–V

Experimental results obtained at constant pressure must be corrected to constant volume before comparison with values calculated for a lattice model of the solution. Theoretically this means that the volume for each molecule should be constant for the mixing process (14, 15); however, it is common practice to evaluate the correction on the basis of constant volume for the system as a whole and this course was followed in the present work. The excess energy U_v^E (at constant volume) was calculated from values of the enthalpy H_p^E (at constant pressure) using the formula

$$U_v^E = H_p^E - T(\alpha/\beta)V^E \quad [1]$$

derived by Scatchard (16). In this equation V^E is the volume of mixing, T the absolute temperature, α the coefficient of thermal expansion for the solution, and β the isothermal compressibility.

Values of the excess entropy S_v^E were obtained from the relation

$$TS_v^E = U_v^E - G_p^E, \quad [2]$$

where G_p^E is the excess Gibbs free energy. This expression neglects the difference between the Gibbs and Helmholtz free energies since it depends on the square of V^E and is small for the systems considered.

A fit between theory and experiment can be attempted with most confidence at 25° C since the present enthalpy measurements for systems I, IV, and V were made at this temperature and values of V^E (for all five systems) are also available. Data for evaluating

For personal use only.

the ratio α/β at 25° C have been published for the pure components (17, 18) and estimates for solutions were made assuming additivity. The excess Gibbs free energies have not been determined at 25° for any of the systems but the temperature coefficient of the free energy is fairly small, particularly for the longer-chain alcohol systems. Values of G_p^E at 25° could therefore be estimated with reasonable accuracy from data at other temperatures.

The methods employed to obtain the "experimental" points, plotted in Figs. 1–5, are summarized in the following paragraphs. For clarity each of the five systems is considered individually.

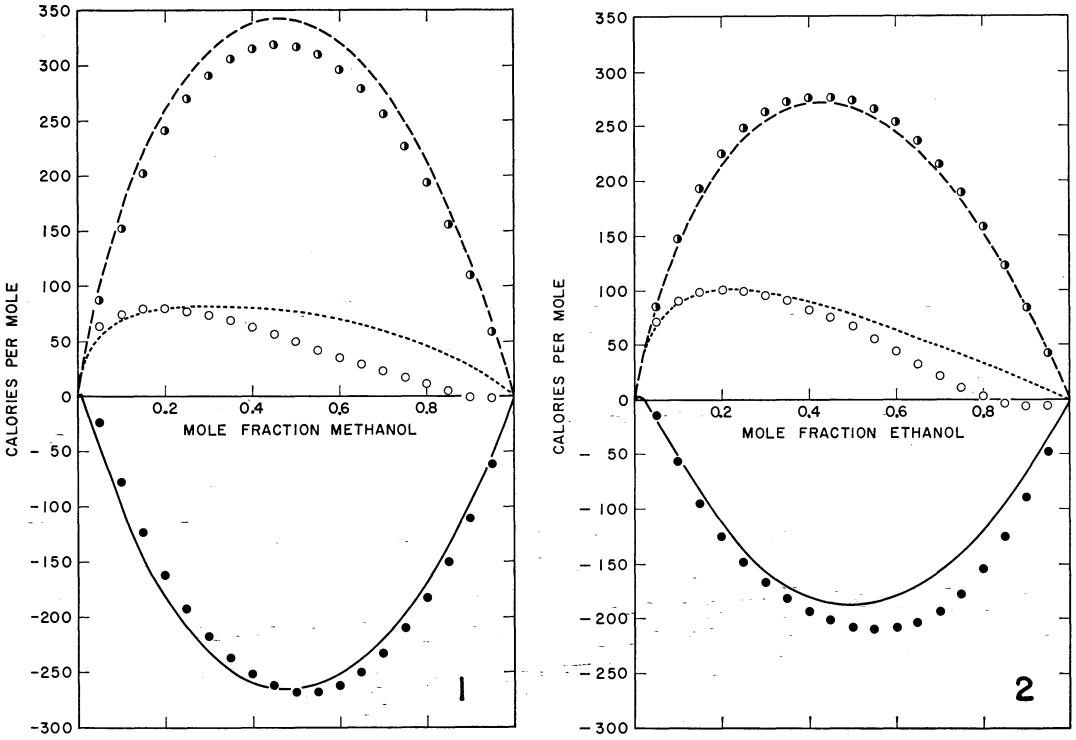

FIG. 1. Excess thermodynamic functions for methanol – carbon tetrachloride solutions at 25° C. Experimental points: ◑, G_p^E, ○, U_v^E, and ●, TS_v^E. Curves calculated from theory.

FIG. 2. Excess thermodynamic functions for ethanol – carbon tetrachloride solutions at 25° C. Experimental points: ◑, G_p^E, ○, U_v^E, and ●, TS_v^E. Curves calculated from theory.

(I) Methanol – Carbon Tetrachloride

G_p^E at 25° C was calculated from the equation given by Scatchard and Ticknor (19). More recent vapor pressure measurements (5, 12) are in fairly good agreement with these earlier data. Values of H_p^E were taken from the present work; data for V^E due to Paraskevopoulos and Missen (5), which are more extensive than the results given in reference 19, were used in making the correction to constant volume.

(II) Ethanol – Carbon Tetrachloride

The values of G_p^E at 45° and 65° C, reported by Barker, Brown, and Smith (2) were extrapolated to 25° assuming a linear variation with temperature. For H_p^E only the data of Otterstedt and Missen (6) at 35° C are available. In order to estimate values at 25° C it was assumed that the temperature variation at a given concentration was the mean of that for systems I and III at the same concentration. As a check on this method, values

of H_p^E estimated at 45° C were found to agree reasonably well with the experimental data of Brown and Fock (13) over the very limited concentration range studied by those authors. V^E was calculated from densities given in reference 2.

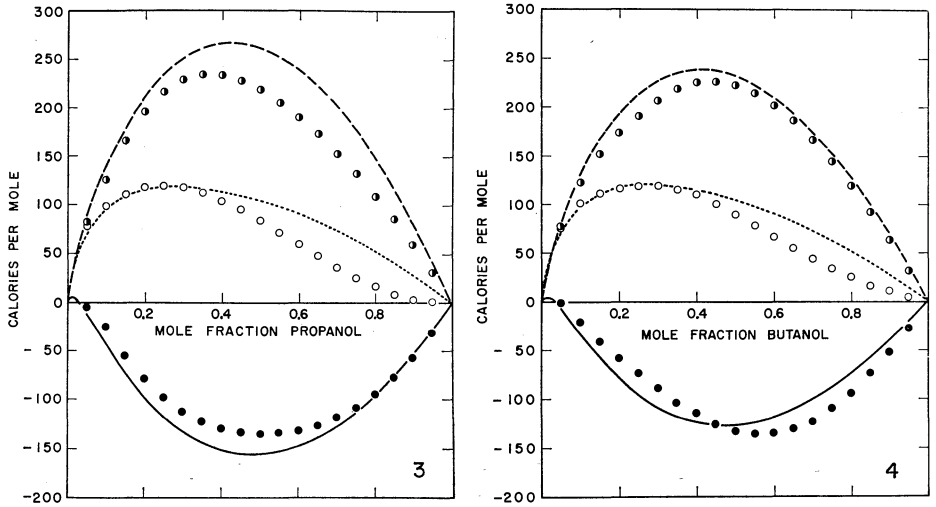

FIG. 3. Excess thermodynamic functions for propanol – carbon tetrachloride solutions at 25° C. Experimental points: ◑, G_p^E, ○, U_v^E, and ●, TS_v^E. Curves calculated from theory.

FIG. 4. Excess thermodynamic functions for butanol – carbon tetrachloride solutions at 25° C. Experimental points: ◑, G_p^E, ○, U_v^E, and ●, TS_v^E. Curves calculated from theory.

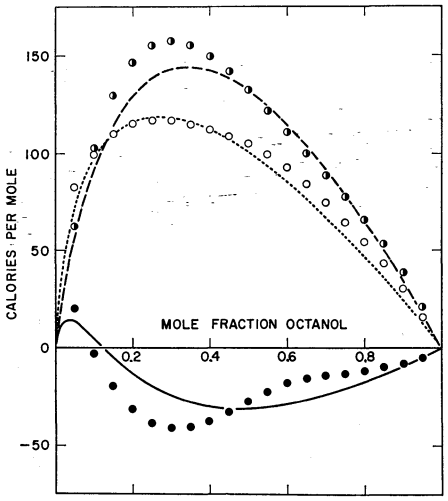

FIG. 5. Excess thermodynamic functions for octanol – carbon tetrachloride solutions at 25° C. Experimental points: ◑, G_p^E, ○, U_v^E, and ●, TS_v^E. Curves calculated from theory.

(III) n-Propanol – Carbon Tetrachloride

All the quantities G_p^E, H_p^E, and V^E were estimated at 25° C from the data of Missen and co-workers (5, 6).

(IV) n-Butanol – Carbon Tetrachloride

Values of G_p^E at 25° were calculated from data at 35° C (5) assuming a linear temperature dependence for H_p^E as determined from the present results at 25° and those of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reference 6 at 35° C. The excess enthalpies from the present work were corrected to constant volume with values of V^E given in reference 5.

(V) n-Octanol – Carbon Tetrachloride

The temperature dependence of H_p^E given by Missen and co-workers (6) was used to calculate G_p^E at 25° from data at 60° C (5). Values of H_p^E were taken from the present work and V^E data from reference 5.

THEORY

In applying Barker's theory (1) a quasi-lattice with coordination number $z = 4$ is assumed. Values used for the other geometric factors, i.e. r_μ, the number of sites occupied by a molecule of species μ, and Q_i, the number of contact points of type i, are summarized in Table IV. Alcohol molecules (component A) are assumed to have three kinds of contact

TABLE IV

Geometric characteristics of component molecules

Component	r_μ	Q_H	Q_O	Q_I	Q_S
CH_3OH	2	1	2	3	—
C_4H_9OH	5	1	2	9	—
$C_8H_{17}OH$	9	1	2	17	—
CCl_4	5	—	—	—	12

area; these are associated with the hydroxyl hydrogen, the oxygen atom, and the alkyl chain and are indicated by subscripts H, O, and I respectively. The carbon tetrachloride solvent (component B) has a single type of contact S. The interaction energy U_{i-j} is defined in such a way that $2U_{i-j}$ is the increase in energy when two $(i–j)$ contacts are formed from a pair of $(i–i)$ and $(j–j)$ contacts. Thus $U_{i-i} = U_{j-j} = 0$ and only six contact energies must be specified for each system. This number is further reduced by imposing the condition

$$U_{H-I} = U_{O-I} = U_{O-S} = U_{I-S}. \qquad [3]$$

In subsequent description it is convenient to write each of the above energies as U_3 and to denote U_{H-O} and U_{H-S} by U_1 and U_2 respectively. Use of equation [3] neglects differences between some of the contact energies on the assumption that they are relatively less significant than the H–O and H–S interactions.

The excess energy and Helmholtz free energy (at constant volume) are given by the formulae

$$U_v^E = -2RT\{[X_H X_O - xX_H' X_O']\eta_1 \ln \eta_1 + [X_I(X_H + X_O) - xX_I'(X_H' + X_O')]\eta_3 \ln \eta_2 + X_S[X_H\eta_2 \ln \eta_2 + (X_O + X_I)\eta_3 \ln \eta_3]\} \qquad [4]$$

$$A^E = RT\left\{x \ln x + (1-x)\ln(1-x) + Q_H \ln\left(\frac{X_H}{xX_H'}\right) + Q_O \ln\left(\frac{X_O}{xX_O'}\right) + Q_I \ln\left(\frac{X_I}{xX_I'}\right) + Q_S \ln\left(\frac{X_S}{(1-x)X_S'}\right) + r_B\left(\frac{z}{2} - 1\right)\ln\left(\frac{r_A x + r_B(1-x)}{r_B}\right)\right\}, \qquad [5]$$

Volume 41, 1963

Page 283. In the last term of the first line of equation [4] "η_2" should read "η_3".

where x is the mole fraction of alcohol and

$$[6] \qquad \eta_i = \exp(-U_i/RT).$$

The parameters X_H, X_O, X_I, and X_S are determined by solving the set of equations

$$[7] \qquad \begin{aligned} X_H(X_H+\eta_1X_O+\eta_3X_I+\eta_2X_S) &= xQ_H/2, \\ X_O(\eta_1X_H+X_O+\eta_3X_I+\eta_3X_S) &= xQ_O/2, \\ X_I(\eta_3X_H+\eta_3X_O+X_I+\eta_3X_S) &= xQ_I/2, \\ X_S(\eta_2X_H+\eta_3X_O+\eta_3X_I+X_S) &= (1-x)Q_S/2. \end{aligned}$$

The quantities X_H', X_O', and X_I' in equation [4] and X_S' in equation [5] are the solutions of the set [7] for the special cases $x = 1$ and $x = 0$ respectively.

Numerical calculations were carried out on an IBM 1620 computer; an iterative Newton–Raphson procedure was used to obtain values of X_H, X_O, X_I, and X_S from the set of equations [7] and these were subsequently employed in the evaluation of U_v^E, A_v^E, and TS_v^E. In the computations U_1 was identified with the hydrogen bond strength and a value, -5000 cal mole^{-1}, based on data for solutions of alcohols in carbon tetrachloride (20) was used. U_3 was put equal to zero in the preliminary calculations and U_2 was varied until an approximate fit could be obtained for the minimum of TS_v^E. Except in the case of the methanol system, the values of U_2 were very similar and an average (-1800 cal mole^{-1}) was adopted for systems II–V. Finally U_3 was adjusted until the maximum of U_v^E could be reproduced. The values of the energy parameters selected are given in Table V; these were used to construct the "theoretical" curves in Figs. 1–5.

TABLE V

Values of the contact energies

System	U_1 (cal mole^{-1})	U_2 (cal mole^{-1})	U_3 (cal mole^{-1})
CH_3OH–CCl_4	−5000	−1400	25
C_2H_5OH–CCl_4	−5000	−1800	0
C_3H_7OH–CCl_4	−5000	−1800	13
C_4H_9OH–CCl_4	−5000	−1800	11
$C_8H_{17}OH$–CCl_4	−5000	−1800	7

In certain instances a better fit of the "experimental" points could have been obtained by adjusting both U_2 and U_3. However, it seems preferable to attempt to reproduce the general features of the data with as small a number of parameters as possible. It is clear that the methanol system does not fit into the general scheme followed by the higher members of the homologous series.[4]

The fit of U_v^E at high alcohol concentrations is poor and the change of sign observed experimentally for the lower alcohols is not reproduced by the theory using the energy values of Table V.

For small alcohol mole fractions the theory predicts a region of positive values for TS_v^E which Barker (1) has attributed to the breaking of hydrogen bonds. This region extends to higher concentrations as the chain length of the alcohol is increased and is observed experimentally for the *n*-octanol system. In very dilute solutions the mole

[4] *After this manuscript was completed a paper by J. R. Goates, R. L. Snow, and J. B. Ott, J. Phys. Chem., **66**, 1301 (1962), appeared which presents an application of Barker's theory to a series of alcohol–benzene systems. It is interesting to note that these workers also had difficulty in fitting the methanol systems with the set of parameters used for the higher alcohols.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

fraction of alcohol present as polymer is given approximately by $2X_{H}X_{O}\eta_{1}$ and thus α, the monomer fraction, may be estimated from the formula

$$\alpha = 1-(2X_{H}X_{O}\eta_{1}/x). \quad [8]$$

Values of α calculated for systems II–V from the energies in Table V are very nearly the same for mole fractions below 0.1 and are shown as a single curve in Fig. 6. Similar

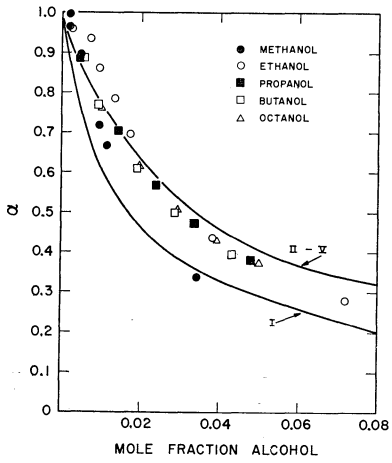

FIG. 6. Comparison of experimental results with theoretical curves for the monomer fraction in alcohol – carbon tetrachloride solutions.

calculations for the methanol system give somewhat lower results. An examination of Fig. 6 shows that there is fair agreement between the theoretical curves and the points which represent the results of infrared and n.m.r. studies (21, 22, 23).

CONCLUSION

In view of the number of interactions involved in the present set of systems (i.e. six) and considering the approximations made in the theoretical treatment, the agreement between experiment and theory is probably as good as can be expected. The numerous calculations that have been carried out in the course of the present work indicate that it is unlikely that any other set of three reasonably consistent energy parameters can improve the agreement and at this stage the introduction of additional parameters does not appear to be justified.

ACKNOWLEDGMENTS

The authors wish to thank Mr. P. D'Arcy for invaluable assistance in the calorimetric determinations. They are also indebted to the staff of the Computation Centre, N.R.C., for use of their facilities.

ABSTRACT

Cyclopentanone vapor, when excited by light of wavelength 3130 Å, gives rise to four different photoproducts and fluorescence. The photochemistry of the molecule has been investigated by Srinivasan (J. Am. Chem. Soc. **81**, 1546 (1959); **83**, 4344, 4348 (1961)). In the present work the fluorescence spectrum and fluorescence efficiency of cyclopentanone vapor are reported for the first time. The fluorescence spectrum is identical with that obtained from liquid solutions of cyclopentanone, with a maximum at 4100 Å. Time, temperature, oxygen, and inert gases do not affect the spectrum, which contains no component ascribable to phosphorescence, maximum 4450 Å. Beer's law is obeyed.

The fluorescence efficiency is also found to be independent of the variables temperature and pressure of inert gas, cyclopentanone, and oxygen. This is in marked contrast with the behavior of the photochemical yields (see work by Srinivasan). The yields of cyclobutane and ethylene tend to increase at high vibrational energy content of the excited molecule (low pressure, high temperature, short exciting wavelengths), while the yield of pentenal increases under conditions of decreasing vibrational energy content (high pressures, etc.). The fact that fluorescence stabilization does not occur in cyclopentanone can be related to the results of photolysis.

INTRODUCTION

The photodecomposition of cyclopentanone has been investigated extensively (1–3). Recently it was reinvestigated by Srinivasan (4(*a*)) and it was shown that, in addition to the two primary processes postulated by Benson and Kistiakowsky, a third primary process is quite important. The product 4-pentenal was isolated by Srinivasan, who suggested that it results from a rearrangement process, whereas the products carbon monoxide, ethylene, and cyclobutane are obtained as a result of molecular splitting. All three primary processes were postulated to be molecular since radical scavengers do not inhibit them. A detailed study of these three primary processes was published in a subsequent paper by Srinivasan (4(*b*)). The effect of inert gases on the decomposition of cyclopentanone was reported. The amount of cyclopentanone undergoing photolysis was not affected by inert gas addition whereas the ratio of pentenal to carbon monoxide changed sharply. On the other hand the ratio of ethylene to cyclobutane changed much less markedly. These experimental evidences led Srinivasan to postulate that the three primary processes are occurring from three different vibrational levels of the first excited singlet state and that the vibrational energy is being transferred during collisions at the rate of one or a few quanta per collision, which affects the products formed.

In view of the fact that fluoroscence and phosphorescence have been observed in condensed phases (5) and the quantum yield of the dissociation of cyclopentanone (gas phase) is less than unity, it is quite possible that part of the energy of the excited molecule is emitted in the gas phase as fluorescence and/or phosphorescence. Hence the study of cyclopentanone emission in the gas phase was undertaken to get a better understanding of the mechanism of photodecomposition.

In this article the fluorescence of cyclopentanone in the gas phase is reported. The effect of temperature, pressure, oxygen, and inert gas on the relative fluorescence yield

**Present address: National Research Council, Ottawa, Canada.*

has been studied and attempts are made to correlate the dissociation processes with the emission process of the cyclopentanone molecule.

EXPERIMENTAL

Materials

The cyclopentanone used in these experiments was an Eastman White Label chemical. Vapor phase chromatographic analysis showed the material to consist of only one component. In addition, it was distilled through a 1-m, well-packed column, and a middle fraction was taken. This fraction was further subjected to bulb-to-bulb distillation on the vacuum line, and stored behind a mercury cutoff at dry ice – acetone temperature. It is the same material used in our spectroscopic studies (5). The other materials used in these studies were Matheson's best quality gases, and were used directly from lecture bottles without further treatment.

Fluorescence Efficiency Measurements

The fluorescence cell was T-shaped and made of quartz. Its overall length was 14 cm, the end windows were 5 cm in diameter, while the T window was 2.5 cm in diameter. All windows were double in order to maintain a uniform temperature distribution. The cell was housed in an aluminum block oven, wound with nichrome wire and covered with layers of asbestos. Temperature was read from a copper–constantan thermocouple sunk into the aluminum block. Dead space existed between the cell and the first stopcock, where a condensation finger was located. The volume of the dead space was about 14 cc, but it was entirely wire wound and heated.

The light from a Hanovia high-pressure arc (No. 30600) was prefiltered by a Corning 7-54 filter and allowed to fall on the entrance slit (1 mm) of a Gaertner quartz prism monochromator. The monochromator was focused for the 3130 Å lines of the arc. These lines were collimated by two quartz lenses and allowed to pass through the cell. An air-cooled photomultiplier was placed behind the exit window of the cell in order to intercept and measure the intensity of the transmitted radiation. This photomultiplier was an RCA 1P28, powered by a Furst Electronics, constant voltage, d-c. power supply at 1000 v. The transmitted intensity (called I_t if cyclopentanone is present in the cell, or I_t^0 if it is absent) was reduced by the use of neutral density filters so that the I_t^0 photocurrent was no greater than 0.2 μa. An air-cooled 1P21 photomultiplier, similarly powered, was placed at the T window of the cell. The radiation passing through this window was filtered by a Corning 0-52 filter to remove scattered 3130 Å light. The amount of scattered light was small since the incident beam was well collimated and the cell walls partially blackened.

The fluorescent light was focused onto the 1P21 photomultiplier, which then gave the fluorescence intensity in the presence of cyclopentanone (I_f), and in its absence (I_f^0). Pressures of the ketone (of order 50 mm, 25° C) were used such that I_t was some five times greater than I_f^0. The actual magnitude of the I_f^0 photocurrent was 0.02 μa. The photocurrents were easily amplified and were recorded by a Leeds and Northrup Speedomax G, especially modified for use with photomultipliers.

There are four quantities to be measured in order to determine the fluorescence efficiency under a given set of conditions, I_f, I_f^0, I_t, and I_t^0. The zero quantities were measured either from the evacuated cell, or with the cell filled with an inert gas. Either method gave the same readings. Cyclopentanone was then passed in to fill the cell to its vapor pressure at room temperature, 10 mm. This amount of cyclopentanone in the cell was quantitatively transferred to another portion of the line and the procedure repeated. Five fillings followed by quantitative transfer back to the cell of all the material gave, in this case, a working concentration of 50 mm (25° C). The cell temperature was then brought up to 70–80° C and the quantities I_t and I_f were measured.

For addition of small amounts of inert gases the ketone was condensed into a side arm before the gas was added. After addition the ketone was evaporated by warming and the two gases were allowed to mix by diffusion for several hours. This method was found to be quite reliable because of the small dead space. However, for the addition of inert gases which greatly exceeded the pressure of cyclopentanone, a slow and careful leakage into the cell containing the uncondensed ketone gave very reliable results, with a minimum of diffusion time being necessary for complete mixing.

The fluorescence efficiency, Q, is taken as the fluorescence intensity ($I_f - I_f^0$) divided by the fraction of incident light absorbed, I_a. I_a is taken to be $(I_t^0 - I_t)/I_t^0$. Under the usually employed conditions, I_a was approximately one third of the incident intensity. The intensity of the incident light was found to vary by only a few percent over the period of a run. Such variations are accounted for by using the quantity I_a rather than merely $(I_t^0 - I_t)$. A detailed consideration of the possible sources of experimental error shows that any given value of Q can be in error by as much as 15%. However, the reproducibility of the experiments was much better than this. As a result we claim an accuracy for the relative yields, Q/Q_0, of about 5%.

Fluorescence Spectrum

The light from an Osram, 100 watt, high-pressure mercury arc was focused into the fluorescence cell by a quartz lens, after having been filtered by a Corning 7-54 filter and 5 cm of $NiSO_4$–$CoSO_4$ solution. This filter combination had an O.D. of about 0.7 at 3130 Å and was completely opaque (O.D. > 3) beyond 3600 Å. The cell contained about 100 mm of cyclopentanone at 130° C. Viewed at right angles to the exciting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

light the blue-violet fluorescence of cyclopentanone in the ultraviolet beam was quite evident to the unaided eye. A lens combination focused an image of the fluorescing beam onto the slit (0.1 mm wide) of a Hilger and Watts small quartz prism spectrograph, with a dispersion of about 110 Å/mm at 4000 Å. Kodak 103-F or 103-O plates were exposed for several hours, then the slit was partially masked and a mercury spectrum recorded for positive wavelength identification. The plates were developed for 4 minutes in D-19.

RESULTS AND DISCUSSION

Effect of Temperature, Vapor Pressure, Inert Gas Pressure, and Oxygen

Measurement of I_t/I_t^0 (λ_{ex}, 3130 Å) over the range of cyclopentanone concentrations 10 to 80 mm (25° C) at a vapor temperature of 100° C showed that the vapor obeyed Beer's law, at least under the conditions used in these studies.

The relative fluorescence yield, Q/Q_0, of a sample at 20 mm (25° C) of cyclopentanone was measured at eight temperatures over the range 54° to 134° C. The relative yield was constant, at 0.96 ± 0.05 over the entire range, where Q_0 is the fluorescence efficiency of the sample at 54° C. This indicates that the fluorescence efficiency is independent of the vapor temperature in the region of photochemical interest.

The fluorescence efficiency was found to be independent of cyclopentanone pressure. Indeed, the effect of pressure (cyclopentanone, inert gases, or oxygen) on the fluorescence efficiency was the same for all these gases, nil. We illustrate the situation in Fig. 1, where

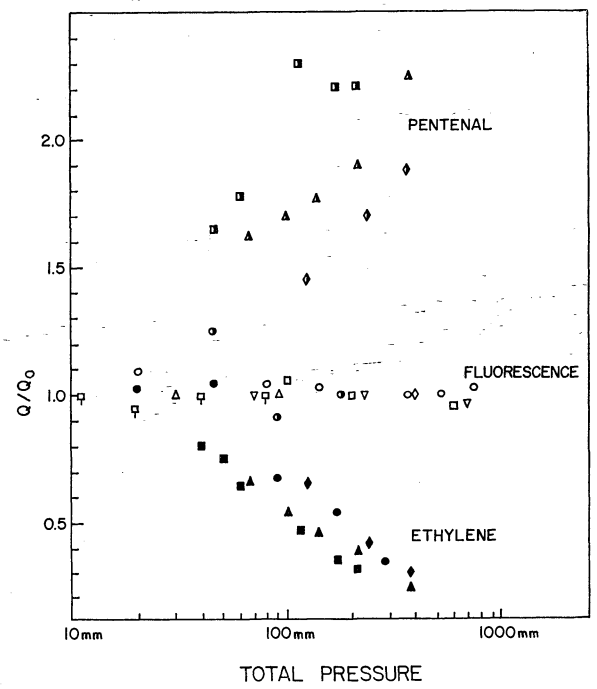

FIG. 1. Relative yields as defined in the text versus total pressure (inert gas plus cyclopentanone). Filled symbols are yields of ethylene, unfilled symbols are fluorescence yields, and half-filled symbols are the yields of pentenal. Symbol code is ⊓ cyclopentanone, ○ oxygen, □ methane, ▽ hydrogen, △ carbon dioxide, ◇ argon. Ethylene and pentenal yields are taken from the work of Srinivasan (4) (see text).

the relative fluorescence yields for all pressures up to 1 atm lie along the horizontal axis. The relative decomposition yields as a function of the pressure of the very same gases are included for the sake of comparison and discussion (4). For the yield as a function of cyclopentanone pressure, Q_0 is the efficiency at 10 mm (25° C) of cyclopentanone vapor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

at 100° C. For the other gases, including oxygen, Q_0 is usually the efficiency at 50 mm (25° C) and vapor temperature 70–80° C (for the low-pressure yields Q_0 refers to 10 mm of the ketone). In the case of the decomposition yields, Q_0 is the yield of ethylene in μmoles (filled symbols) or pentenal in μmoles (half-filled symbols), at room temperature and approximately 10 mm of cyclopentanone. Q is then the decomposition yield in μmoles under the same conditions but with added gas. Several of the decomposition yields at nearly the same total pressure have been averaged for the sake of clarity.

Fluorescence Spectrum of Cyclopentanone Vapor

As stated previously, in recording the fluorescence spectrum of cyclopentanone vapor the exciting lines were mainly 3130 Å of Hg. The fluorescence spectrum was photographed at different temperatures and in the presence of inert gas and oxygen. The results were always the same and as shown in the microdensitometer tracing Fig. 2. The spectrum is

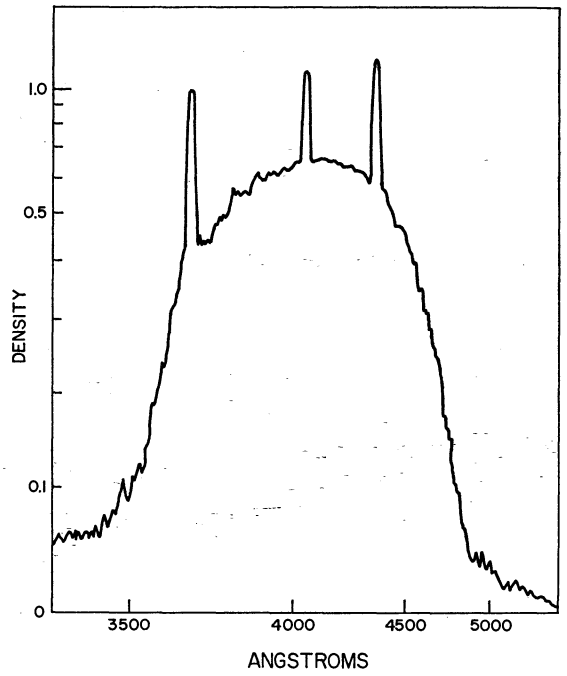

FIG. 2. Microdensitometer tracing of fluorescence of cyclopentanone vapor. Approximately 100 mm of cyclopentanone at 130° C recorded on a Kodak 103-O plate with 12 hours' exposure. The prominent peaks are the groups of mercury lines at 3660, 4047, and 4358 Å respectively.

in agreement with the fluorescence spectrum reported previously for solutions of cyclopentanone (5). The maximum is located at about 4100 Å. There is no evidence of phosphorescence emission from the vapor (maximum 4400–4500 Å) (5).

Connection with Photolysis

In spite of the variety and quantity of experimentation which have been performed on the photochemical and luminescence behavior of cyclopentanone it is not possible to unambiguously formulate a kinetic mechanism for these processes. Explicitly, the experiments to date leave undecided what role, if any, is played by the triplet state in the photoreactions of cyclopentanone. Although the existence of this state has been established (5),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the results of photolysis in the presence of oxygen 4(*b*)) have been interpreted as supporting the idea that the triplet state is not important in the photochemistry of this molecule. If this is the case one must assume that any ^3C formed by intersystem crossing does not lead to observable amounts of photoproduct. Then it is simple to extend the mechanism proposed by Srinivasan (4(*b*)). The new information which must be added is that, while fluorescence does occur, the fluorescence spectrum and fluorescence efficiency are independent of temperature and pressure. Since the fluorescence spectrum and efficiency do not change with time we assume that decomposition products do not contribute and fluorescence arises solely from the excited singlet state of cyclopentanone, ^1C. The steps needed are fluorescence, intersystem crossing, and some steps dealing with the final fate of ^3C:

$$1.\ C + h\nu \rightarrow {}^1C \qquad I_a$$

2. $^1C_n \rightarrow D_1$	k_{D1}	6. $^1C_m \rightarrow D_2$	k_{D2}
3. $^1C_n \rightarrow C + h\nu$	k_{F1}	7. $^1C_m \rightarrow C + h\nu$	k_{F2}
4. $M + {}^1C_n \rightarrow {}^1C_m + M$	k_{M1}	8. $M + {}^1C_m \rightarrow {}^1C_p + M$	k_{M2}
5. $^1C_n \rightarrow {}^3C$	k_{IS1}	9. $^1C_m \rightarrow {}^3C$	k_{IS2}

10. $^1C_p \rightarrow D_3$	k_{D3}
11. $^1C_p \rightarrow C + h\nu$	k_{F3}
12. $^1C_p \rightarrow {}^3C$	k_{IS3}
13. $^3C \rightarrow C$	
14. $^3C + Q \rightarrow C + Q$	

where subscripts n, m, and p denote decreasing vibrational levels of the excited state, M is an inert molecule, Q is a quencher.

On this basis, the fluorescence yield is found to be independent of pressure (independent of [M]) if the rate constants are the same for all vibrational levels of the excited state, that is, (1) $k_{D1} = k_{D2} = k_{D3}$, (2) $k_{F1} = k_{F2} = k_{F3}$, (3) $k_{IS1} = k_{IS2} = k_{IS3}$, (4) $k_{M1} = k_{M2}$. Then the fluorescence yield is

$$Q_F = \frac{k_F}{k_F + k_D + k_{IS}},$$

as for a much simpler model, one possessing only one vibrational level. From the viewpoint of our ignorance, conditions (2) to (4) are acceptable, but (1) seems rather stringent if not improbable.

Unlike some other photoexcited species, cyclopentanone does not undergo "fluorescence stabilization" in the presence of inert gas (6, 7). In fluorescence stabilization the excited molecule is vibrationally deactivated by collisions with inert molecules. By thus removing some of the excitation energy the probability of decomposition is decreased (the molecule is stabilized) and the molecule has more time to re-emit (fluorescence is enhanced). Fluorescence stabilization will *not* occur if fluorescence must compete with decomposition (at nearly the same rate) at every vibrational level, down to the very lowest vibrational level of the excited state. This is the situation implicit in the above mechanism, subject to the given conditions. In this case, the emission spectrum (being continuous in the present degree of resolution) need not necessarily suffer an observable change or shift with pressure of added gas. Fluorescence stabilization also will not occur if decomposition or intersystem crossing take place so rapidly upon absorption of light that collisional deactivation cannot compete even at high pressures. However, in this case the fluorescence spectrum, if observable, would be a resonance spectrum.

One cannot even begin to consider the numerous possibilities for intrusion of the triplet state more directly into the photodecomposition; such considerations would be mere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

speculation at the present time. However, in this regard it may be worth noting that while photolysis in the presence of oxygen affects the yield of ethylene and cyclobutane, as would the corresponding pressure of any inert gas, the yield of pentenal is not increased by addition of even 275 mm of oxygen (4(*b*)) (Fig. 1).

THE DETECTION AND ESTIMATION OF BRANCHING IN DEXTRAN BY PROTON MAGNETIC RESONANCE SPECTROSCOPY[1]

W. M. PASIKA AND L. H. CRAGG
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received September 20, 1962

ABSTRACT

The proton magnetic resonance spectrum of branched dextran contains a peak, not found in the spectrum of linear dextran, which is assigned to C_1 protons at non-1,6-linkages—linkages which in most branched dextrans form the branch points. A quantitative measure of the extent of branching—the ratio of 1,6-linkages to non-1,6-linkages—is obtained by taking the ratio of the areas of the peaks associated with these two types of linkages. The value so obtained agrees well with that obtained by periodate analysis.

For polysaccharides in which the non-1,6-linkages are known to be at branch points, n.m.r. spectroscopy thus affords a means of detecting and estimating branching which is more convenient than methods currently in use.

A. INTRODUCTION

Despite continuing research by many investigators, the methods available for the detection, characterization, and estimation of branching in polymers still leave much to be desired. In our investigation of the viscosity behavior of dextran and of polyelectrolytes derived from it we, like others before us, wished for a convenient physical method of detecting and measuring the degree of branching in these compounds. In the unsubstituted dextran, 1,3-branching can be detected by infrared spectroscopy (1) but in sulphated dextran the 1,3-branching peak is completely masked by a large broad peak attributed, by Orr (2), to sulphate. Even in the unsubstituted compound, the branching peak is not too pronounced (Fig. 1).

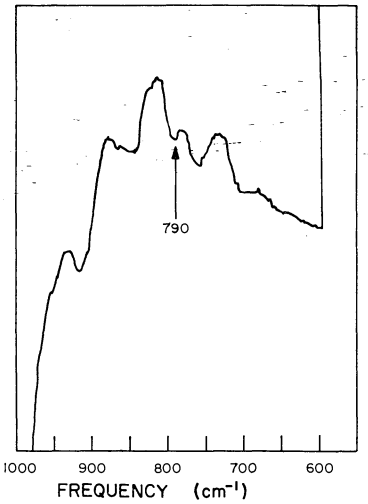

FIG. 1. Infrared adsorption at 790 cm^{-1} indicative of 1,3-branching in NRRL B-742. (Ordinate expansion 5×.)

The structures of linear and 1,3-branched dextran, which have been established on accumulated chemical evidence (3–7), are shown diagrammatically in Fig. 2. Examination

of these suggests that, because of differences in proton environments in the two compounds, proton magnetic resonance spectra might exhibit significant differences which could be related to branching. In this paper we present evidence that n.m.r. spectroscopy can indeed be used to detect branching, and to estimate its extent, in dextran. (Later we shall report extension of the method to dextran sulphate.)

B. RESULTS AND DISCUSSION

Isomaltotriose

Isomaltotriose was selected as a model compound to aid in peak assignments because of its close structural similarity to linear dextran (see Fig. 2). Its n.m.r. spectrum is reproduced in Fig. 3. Peak 4 at −4.80 p.p.m. is due to the proton of deuterium hydroxide,

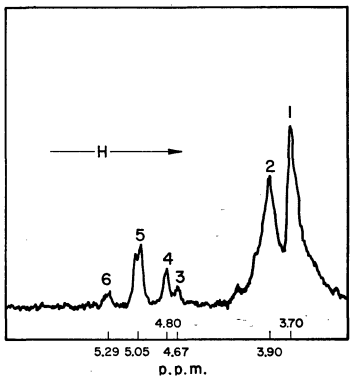

FIG. 3. The n.m.r. spectrum of isomaltotriose. (The external standard here, as in the succeeding n.m.r. spectra, was tetramethylsilane.)

DOH, which is present in small concentration in the solvent deuterium oxide. The relatively intense signals at 1 and 2 (−3.70 and −3.90 p.p.m.) may be attributed to the C_5 and C_6 protons and the C_2, C_3, and C_4 protons respectively. (The protons with the higher electron density environment would give the signal at the higher field.) The other signals, then, would be due to the anomeric C_1 protons, the signal at 5 (−5.05 p.p.m.) to the protons on the two C_1 carbons involved in the 1,6-linkages, and those at 3 and 6 (−4.67 and −5.29 p.p.m.) to the protons on the hemiacetal anomeric carbon. (Signals 3 and 6 can be assigned to the β and α configurations, respectively; cf. refs. 8 and 9.)

If these assignments are correct, the ratio of the sum of the areas of peaks 1 and 2 to the area of peak 5 should be 18/2 or 9, and the ratio of the area of peak 5 to the sum of the areas of 3 and 6 should be 2. The measured ratios, 9.0 and 2.2, are in satisfactory accord with these predictions. (The sides of the peaks were extrapolated to the base line and the areas so enclosed were measured with a planimeter.)

Linear Dextran

The spectrum of the linear dextran NRRL B-512 is reproduced in Fig. 4. In this high-polymeric polyglucose the contribution to the n.m.r. spectrum of the anomeric proton on the reducing end would be vanishingly small. We should expect, therefore, that peaks 3 and 6 would not appear. In fact, they do not. The three signals that are observed correspond to signals 1, 2, and 5 of the isomaltotriose spectrum, and are so labelled. Making an assignment analogous to that for isomaltotriose, one would predict that the ratio of the

For personal use only.

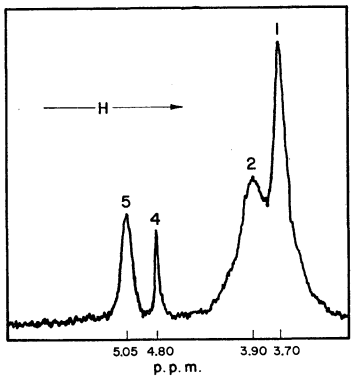

FIG. 4. The n.m.r. spectrum of NRRL B-512 "linear" dextran.

sum of the areas of peaks 1 and 2 to the area of peak 5 would be 6/1 or 6. The value obtained from area measurements was 5.9.

Branched Dextran

The n.m.r. spectrum for branched dextran NRRL B-742, reproduced in Fig. 5, contains peaks corresponding to those in Fig. 4, but, in addition, has a peak, 7, at −5.40 p.p.m.

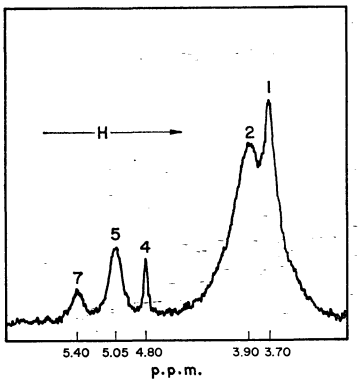

FIG. 5. The n.m.r. spectrum of NRRL B-742 branched dextran.

whose counterpart does not occur in the spectrum of isomaltotriose or linear dextran. (In the three spectra, corresponding peaks are labelled with the same number. That such peaks are indeed counterparts of one another is evident from the data of Table I. Differences in structure of the three compounds have affected very little, indeed, the chemical shift values.) This new peak can only be due to the one structural feature—non-1,6-linkages—known to be present in B-742 dextran (3, 4, 6, 10) but absent from isomaltotriose and present only to a very small extent (less than 5%) in B-512 dextran. (In Fig. 2, these "non-1,6-linkages" are represented by a 1,3-linkage.) The proton responsible for the signal at 7 must be either the one on the C_1, or else that on the C_3, of the 1,3-linkage (or the C_4 if the linkage is 1,4). Of the two alternatives, the first seems the more probable. The signal at 7 must arise at the expense of the signal at 5 (C_1 proton at the 1,6-linkage), which would mean a small shift from −5.05 to −5.40 p.p.m.; or else it is produced at the expense of the signal at 2 (C_2, C_3, C_4 protons), which would mean a much larger shift

B-742 dextran	4		−4.80	−4.80

*All of the shifts were to the left of the external standard (T.M.S.) and therefore are recorded as negative values. Values in the figures are to be read as negative values.

from −3.90 to −5.40 p.p.m. For neither the C_1 nor the C_3 proton would one expect a change in proton environment sufficient to produce a large shift. Tentatively, then, we assign the signal at 7 to the C_1 proton at the non-1,6-linkage.

If this assignment is correct, it should follow that, if comparisons are made at the same concentrations in grams per liter (i.e. with the same number of anhydroglucose units in a given volume of solution), (*a*) the combined intensities of signals 1 and 2 should be the same for the linear and branched dextrans and (*b*) the intensity of signal 5 for the linear dextran should equal the sum of the intensities of signals 5 and 7 for the branched dextran (anhydroglucose units that are joined by 1,3- or 1,4-linkages in the branched dextran would have been joined by 1,6-linkages had the dextran been linear).

To test these predictions, n.m.r. spectra for the B-512 and B-742 dextrans were obtained at several different concentrations under otherwise identical conditions. In Fig. 6 the sum of the areas of peaks 1 and 2 is plotted against concentration for both dextrans. In accordance with prediction (*a*) above, the points for the two dextrans fall on the same line. In Fig. 7 are plotted, against concentration: A, the area of peak 5 (1,6-linkage) for the linear dextran; B, the area of peak 5 for the branched dextran; and C, the area of peak 7 (the "branching peak") for branched dextran. Also plotted are the sums of the areas of 5 and 7 for branched dextran. These last points fall on the same line as do the points representing the peak 5 areas for linear dextran, in accordance with prediction (*b*) above. Thus the assignment of peak 7 to the C_1 proton of the non-1,6-linkage is confirmed.

Further confirmation is afforded by a comparison of peak areas in the branched dextran spectrum. From periodate oxidation and methylation studies (4), it is known that in this particular branched dextran the ratio of 1,6-linkages to non-1,6-linkages is 70/30 or 2.3 (10). Assignment of peak 5 to the protons on the C_1 carbons involved in 1,6-linkages and of peak 7 to the C_1 protons at the non-1,6-linkages would require, therefore, that the ratio of these signal intensities be 2.3. The ratio calculated as a ratio of the measured peak areas is 2.4.

It may be concluded then that n.m.r. spectra may be used not only to detect the branching in this dextran but also to make a reasonably good estimate of the extent of branching. (The ratio of 1,6-linkages to non-1,6-linkages calculated from the ratio of

For personal use only.

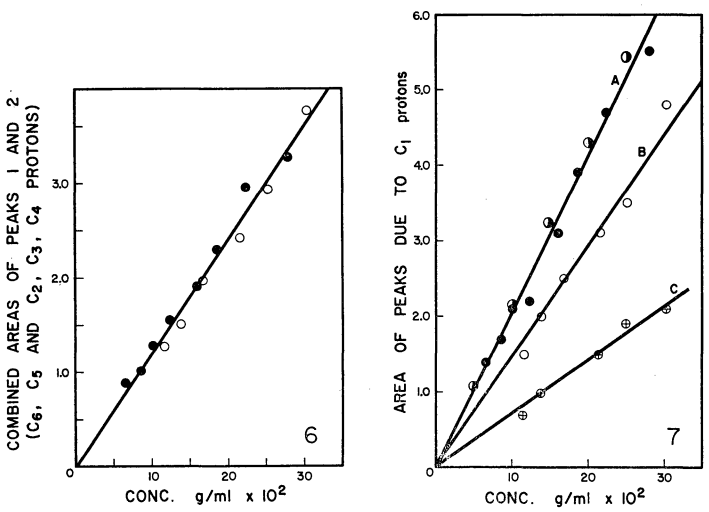

FIG. 6. Combined peak areas 1 and 2 for (●) linear (B-512) and (○) branched (B-742) dextran vs. concentrations.

FIG. 7. Areas of peaks due to C_1 protons of linear and branched dextrans: curve C (⊕) due to C_1 proton of non-1,6-linkage of B-742 dextran; curve B (○) due to C_1 proton of 1,6-linkage of B-742 dextran; curve A (●) due to C_1 proton of 1,6-linkage of B-512 dextran; curve A(◑) due to sum of curve C (⊕) and curve B (○).

peak areas, i.e. from the n.m.r. data, is 71:29 as compared to the 70:30 ratio obtained by other and much more tedious means.)

The method, as we have used it, does not distinguish between 1,2-, 1,3-, and 1,4-linkages, all of which occur at branch points in one form or another of branched dextran. As mentioned earlier, the proportions of 1,3-linkages can be detected, approximately, by infrared spectroscopy. Combining infrared and n.m.r. measurements would then give a convenient estimate of the extent of non-1,6-linkages other than 1,3-linkages (i.e. of 1,2 and 1,4 combined).

It is reasonable to predict that n.m.r. spectra may similarly be used to measure the extent of branching in other branched polysaccharides. It should perhaps be emphasized that what is detected is the existence of different kinds of linkage (in dextran, non-1,6- as compared to 1,6-linkages). These could be in the main chain (4) and, therefore, would not necessarily indicate branch points. But if it is known that in the family of compounds under study the different kinds of linkage occur only at branch points, the n.m.r. method would, as with our dextran, measure the extent of branching. Indeed, the method should in principle be applicable to polymers other than polysaccharides.

C. EXPERIMENTAL

Materials

The dextran samples have been described by Jeanes (10). Characterizing properties are as follows:

NRRL B-512 F: $\bar{M}_w$, 71,000; [η], 0.250 dl/g; % 1,6, 96; % 1,3, 4.
NRRL B-742: $\bar{M}_w$, 61,000; [η], 0.153 dl/g; % 1,6, 70; % 1,3, 18; % 1,4, 12.
Isomaltotriose was a purified sample prepared by Dr. D. H. Hutson.
Deuterium oxide (Merck, Sharp and Dohme of Canada): minimum isotopic purity 99.7 atom% D.

Methods

Spectra were obtained on a Varian A60 analytical proton nuclear magnetic resonance spectrophotometer which operated at 60 Mc/s. Tetramethylsilane (T.M.S.) was used throughout as the external standard.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Before introduction into the spectrometer, all samples were treated, to exchange labile protons of the hydroxyl groups with deuterons, by a thrice repeated process of dissolving in deuterium oxide and freeze-drying.

ACKNOWLEDGMENTS

We are grateful to Dr. R. U. Lemieux of the Department of Chemistry, University of Alberta, for helpful discussions, to Dr. D. H. Hutson, Royal Holloway College, University of London, for the sample of pure isomaltotriose, and to Dr. Allene Jeanes, Northern Utilization Research and Development Division, United States Department of Agriculture, Peoria, Illinois, for the samples of linear and branched dextran. We are grateful, too, for financial assistance, in the form of research grants, from the Defence Research Board of Canada.

OXYGEN-18 TRACER EVIDENCE FOR THE TERMINATION MECHANISM IN THE PHOTOCHEMICAL OXIDATION OF ACETALDEHYDE

C. A. McDowell and S. Sifniades

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received July 30, 1962

ABSTRACT

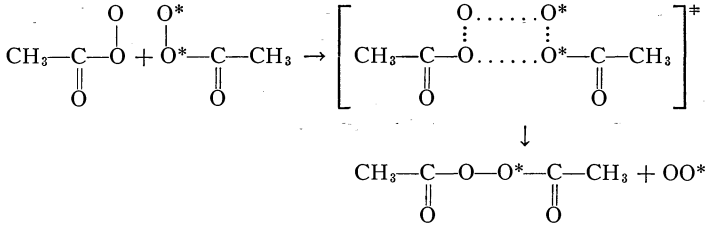
The chain-terminating step in the photochemical oxidation of acetaldehyde in the gas phase has earlier been established to be the reaction

$$2AcOO = AcOOAc + O_2.$$

Using oxygen-18 of 99.4% purity in the form of molecular oxygen we have made a careful study of the variation of the isotopic ratios of the various oxygens, by mass spectrometry, during the course of the photooxidation. The results show conclusively that the mechanism of the termination step is:

$$AcOO + AcO^*O^* = AcOO^*Ac + OO^*,$$

where O* represents O^{18}. Thus the recombination terminating reaction takes place with the elimination of one oxygen atom from each reacting peroxy AcOO radical. The mechanism of this elimination process is thought to be as follows:



INTRODUCTION

The thermal and photochemical oxidations of acetaldehyde in the gas phase both lead to the main product peracetic acid. It has also been established (1–4) that the terminating step in these oxidation reactions is the recombination of chain carrier and that the radical involved is the peroxyacetyl radical CH_3CO_3. In the case of the low temperature phase photooxidation of acetaldehyde the following kinetic mechanism (2–4) has been found to be in agreement with the experimental data for the processes leading to peroxide formation:

$$CH_3CHO \xrightarrow[3130\ Å]{h\nu} CH_3 + CHO \qquad [1a]$$

$$CH_3CHO \xrightarrow[3130\ Å]{h\nu} CH_3CHO' \qquad [1b]$$

$$\left.\begin{matrix} CH_3 + O_2 \\ CHO + O_2 \end{matrix}\right\} = R \qquad [1c]$$

$$\left.\begin{matrix} R + CH_3CHO = RH + CH_3CO \\ CH_3CHO' + O_2 = CH_3CO + HO_2 \end{matrix}\right\} \phi_2 I_a \qquad [1d]$$

$$CH_3CO + O_2 = CH_3CO_3 \qquad [2]$$

$$CH_3CO_3 + CH_3CHO = CH_3CO_3H + CH_3CO \qquad [3]$$

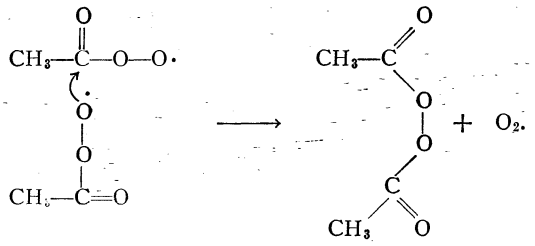
$$2CH_3CO = (CH_3CO)_2 \qquad [4]$$

$$CH_3CO + CH_3CO_3 = (CH_3CO)_2O_2 \quad [5]$$

$$2CH_3CO_3 = (CH_3CO)_2O_2 + O_2 \quad [6]$$

Since it has been shown (4) that the photochemical oxidation is proportional to $I_a^{1/2}$, where I_a is the number of quanta absorbed, and independent of the oxygen pressure, it is probable that reaction [2] is rather fast and it is also likely that at the oxygen pressures usually used in the experiments (greater than 5 mm HgO_2) reactions [4] and [5] are negligible compared with reaction [6]. Earlier work relied on simple titrations to detect the formation of the second peroxide other than peracetic acid. Paper chromatographic methods do confirm that diacetyl peroxide is a product of the oxidation (5). This observation has now been conclusively confirmed by gas chromatographic methods which will be described later in this paper. It is thus now clear that apart from the radical-initiation step, the important reactions leading to the production of the peroxides in the gas phase photooxidation of acetaldehyde at low temperatures are reactions [2], [3], and [6].

The determination of the absolute values for the recombination reactions of both the peroxyacetyl and the peroxypropionyl radicals showed that both processes are quite efficient (6). Why the processes represented by equation [6] should be so very efficient is not clear; but the experimental evidence (6) shows that in the case of the peroxyacetyl radical one collision in every two is effective and one collision in every four is effective in the case of the recombination of peroxypropionyl radicals. Nor is the chemistry of process [6] clear. There are obviously two possible mechanisms: (i) It could be that when the two peracetyl radicals interact, the oxygen molecule which is formed is produced by the elimination of an oxygen atom from each of the interacting radicals. (ii) The oxygen molecule formed in equation [6] could come exclusively from one of the interacting radicals by a radical displacement reaction which was previously suggested (6):



In the earlier work to which we have referred it was pointed out (see ref. 6, p. 277) that the use of isotopically enriched oxygen might enable the chemistry of process [6] to be elucidated. We shall now describe the results of such experiments using O^{18} as a tracer which do enable a decision to be made between the alternative mechanism outlined above. Here we should mention that similar studies using O^{18} as a tracer carried out by Traylor and Bartlett (7) have shown that in the liquid phase autooxidation of cumene, the termination step proceeds by mechanism (i), i.e.

$$ROO + RO^*O^* = ROO\cdots O^*O^*R = R—O—O^*—R \text{ (or } RO + RO^*) + OO^*,$$

where O^* represents an O^{18} atom.

EXPERIMENTAL

The acetaldehyde was purified gas chromatographically, using a 5 ft long column packed with dinonyl phthalate on firebrick. O^{18}, in the form of molecular oxygen, of 98.35% purity was obtained from the Isotope Department, Weismann Institute of Science, Rehovoth, Israel.

The experimental conditions were essentially the same as those described by McDowell and Sharples (4, 6). Somewhat higher light intensities were used to provide a short chain length so that the equilibration with oxygen-34 could be followed easily. In a typical experiment 60 mm Hg of gas composed of O_2^{32}, O_2^{36}, and argon in the ratio 106.4:6.13:5.00 were introduced into the 75-ml quartz reaction vessel, followed by 150 mm Hg of acetaldehyde. After the gases were allowed to mix for some 15 minutes, the vessel was illuminated with light from a G.E.C. AH6 high-pressure water-cooled mercury lamp. Light filters were used to permit the passage of radiation of wavelength 3130 Å. All the experiments were carried out at 25° C.

At the end of an experiment the products were separated into two portions, one of which was the materials condensable at 77° K. This condensable portion was analyzed by gas chromatography using a 2-ft column packed with dinonyl phthalate in firebrick at 0° C. This column separates hydroperoxides (8) and we found it gave a satisfactory separation of peracetic acid and diacetyl peroxide (see Fig. 1). The gaseous portion not

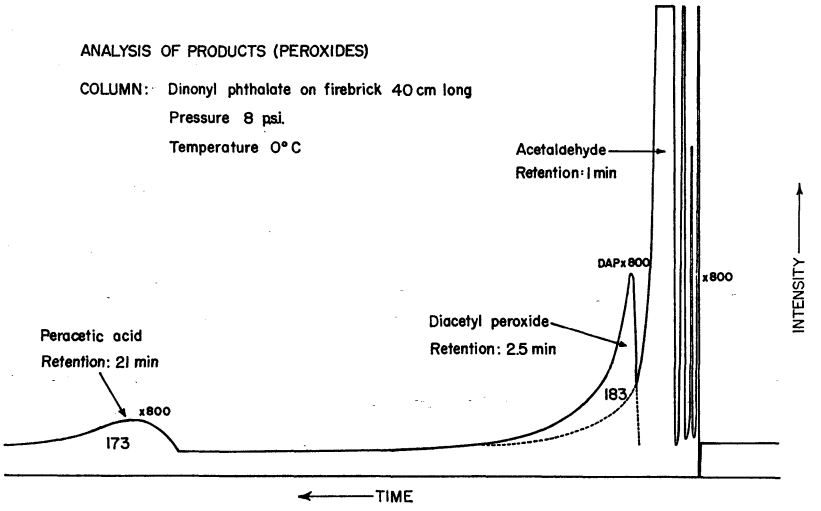

FIG. 1. Gas chromatogram for condensable products from photooxidation of acetaldehyde showing the presence of peracetic acid and diacetyl peroxide.

condensable at 77° K was analyzed mass spectrometrically and the intensities of the peaks at masses 32, 34, 36, and 40 recorded. The analyses beyond the first one were evaluated relative to the argon concentration, which was constant at 1.01×10^{-5} moles based on the original composition of the oxygen mixture at 25°. Two complete sets of experiments were run using the same concentrations of the reactants but at light intensities of 100 and 36.4 (arbitrary units). The results obtained are given in Tables I and II. It is to be

It will be convenient to express the two possible mechanisms for the production of oxygen in reaction [6] by the following scheme:

$$\begin{array}{c} AcO^{16}O^{18}Ac + O^{16}O^{18} \\ \uparrow \\ [AcO^{16}O^{16} \cdots O^{18}O^{18}Ac]^{\mp} \\ \Uparrow \qquad\qquad [6a] \\ AcO^{16}O^{16} + AcO^{18}O^{18} \\ \Downarrow \qquad\qquad [6b] \\ [AcO^{16}O^{16} \cdots AcO^{18}O^{18}]^{\mp} \text{ or } [AcO^{18}O^{18} \cdots AcO^{16}O^{16}]^{\mp} \\ \downarrow \qquad\qquad \downarrow \\ AcO^{16}O^{16}Ac + O^{18}O^{18} \text{ or } AcO^{18}O^{18}Ac + O^{16}O^{16} \end{array}$$

Mechanism [6a], involving a head-to-head approach of the two types of isotopically substituted peroxyacetyl radicals, must produce the asymmetrical oxygen-34, whereas mechanism [6b] will produce only oxygen-32 or oxygen-36 without any resulting equilibration with oxygen-34.

From Tables I and II it is evident that oxygen-34 appears during the course of the reaction. Since no equilibration among the species O_2^{32}, O_2^{34}, and O_2^{36} occurs (i) on long standing, (ii) during the photooxidation of rubene, (iii) from the thermal decomposition of rubene peroxide, or (iv) during the decomposition of unlabelled t-butylhydroperoxide (7), the appearance of oxygen-34 must be attributed to the formation of oxygen molecules by the mechanism indicated by [6a]. This interpretation is supported by a detailed kinetic analysis of the results given below.

Under the experimental conditions the chain length of the reaction is constant for each intensity of illumination. This is shown by the figures in the last column of Tables I and II. Moreover, the ratio of the means of the chain lengths is equal to the square root of the ratio of the light intensities used, which is in agreement with the generally accepted mechanism for the reaction (1, 4, 6). Assuming the mechanism outlined earlier, plus path [6a] for the chain-terminating reaction, we can derive equations which relate the chain length, C, and the change in the concentration of the isotopic oxygen during a reaction.

THEORETICAL

According to mechanism given by equations [2]–[6], for each mole of peracetic acid, CH_3CO_3H, produced, the equivalent of M_y moles of O_2^{34} are consumed (M_y = mole fraction of O_2^{34}; it is to be noted that $M_y = 1/2(M_{O_2}{}^{32}+M_{O_2}{}^{36})$, where $M_{O_2}{}^{32}$ and $M_{O_2}{}^{36}$ are the mole fractions of O_2^{32} and O_2^{36} consumed in the formation of peracetic acid. Note $M_{O_2}{}^{36}$ is later represented by M_z. For each mole of diacetyl peroxide produced via mechanism [6a], $2M_y$ moles of O_2^{34} are consumed and f_y moles of O_2^{34} are generated. f_y is the probability that a terminating collision will be between a labelled and an unlabelled peracetyl radical. In our terminology the peroxy radical $RO^{16}O^{18}$ is labelled.

We can write

$$y = y(P,D), \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where y is the total amount, in moles, of O_2^{34}, P = the amount of peracetic acid, and D = the diacetyl peroxide produced in the reaction.

Partial differentiation of equation [7] yields

$$dy = (\partial y/\partial P)_D dP + (\partial y/\partial D)_P dD. \quad [8]$$

But

$$(\partial y/\partial P)_D = -M_y \text{ and } (\partial y/\partial D)_P = -2M_y + f_y$$

and substitution of these in equation [8] leads to

$$dy = -M_y dP + (f_y - 2M_y) dD. \quad [9]$$

Under our experimental conditions P/D = the chain length, C, which is constant, so we may write $dP = CdD$. Substituting in equation [9] we get

$$dy = \{f_y - (C+2)M_y\} dD. \quad [10]$$

M_y is, however, equal to y/W, where W = total oxygen concentration. But $W = W_0 - (D+P)$ so we now have the following equation for M_y:

$$M_y = \frac{y}{W_0 - (C+1)D}. \quad [11]$$

Substituting this expression for M_y into equation [10] yields the result that

$$dy + \left\{\frac{(C+2)y}{W_0 - (C+1)D} - f_y\right\} dD = 0. \quad [12]$$

Equation [12] may be integrated to give the following expression in which the substitution $M_y = y/W$ has been made,

$$f_y - M_y = \{f_y - (M_y)_0\}\left(\frac{W}{W_0}\right)^{1/C+1}, \quad [13]$$

or taking logarithms this becomes

$$\ln (f_y - M_y) = \ln \{f_y - (M_y)_0\} + \frac{1}{C+1} \ln W/W_0. \quad [14]$$

A similar expression can be derived relating f_z and M_z, and C:

$$\ln (M_z - f_z) = \ln \{(M_z)_0 - f_y\} + \frac{1}{C+1} \ln W/W_0. \quad [15]$$

f_y is the probability that a terminating collision of two peracetyl radicals will be between a labelled and an unlabelled radical and can, if isotope effects are neglected, be taken as equal to $2\alpha(1-\alpha)$, where α is the atom-fraction of O^{18} in the total oxygen. Similarly, f_z is the probability that a terminating collision will take place between two labelled peracetyl radicals. Again neglecting isotope effects it is apparent that $f_z = \alpha^2$. M_z is the mole fraction of O_2^{36}.

DISCUSSION

The validity of the above theory and, *ipso facto*, the mechanism for the termination reactions, namely equation [6*a*], can be tested by applying equations [14] and [15] to our results. In Tables III and IV we outline the values for the various parameters in equations

There can therefore be no doubt but that the mechanism [6*a*] given for the terminating process is indeed the correct one. Furthermore, indirectly, the overall mechanism outlined for the production of peroxides in this photooxidation reaction is likewise confirmed.

It is also possible to show that both the isotopic and the peroxide analytic results are self-consistent and this again is further confirmation of the correctness of the mechanisms put forward. Perhaps the best way of showing the self-consistent nature of the results is that displayed in Table V.

Since we have now shown conclusively that the recombination of peroxyacetyl radicals takes place according to equation [6*a*] with the elimination of one oxygen atom from each reacting peroxyacetyl radical, it now remains for us to suggest a detailed mechanism for this process. A satisfactory reaction scheme is that shown below in Fig. 4 which involves a transition state, marked with the symbol ‡, in which a planar four-centered oxygen atomic system is the site of chemical reactivity.

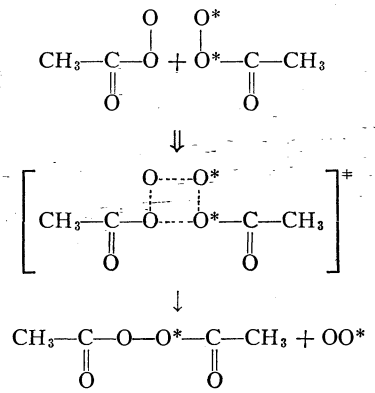

FIG. 4. Suggested mechanism for the recombination of peroxyacetyl radicals.

As the work of Traylor and Bartlett (7) and that now reported both show that the mechanism of the recombination of the peroxy radicals derived from cumene in the liquid phase is the same as that for the peroxy radicals from acetaldehyde in the gas phase, it may reasonably be assumed that this is a general mechanism for this type of reaction. If this is so, it is then of interest to compare the absolute values for the velocity constants from such reactions in both the gas and liquid phases. The absolute value for k_6 for the recombination of peroxyacetyl radicals is known to be $2.69(\pm 1.35)\times 10^{10}$ l. mole^{-1}sec^{-1} from the work of McDowell and Sharples (6). Unfortunately, no values are available for velocity constants for the recombination of these radicals in the liquid phase though there are data in the literature for the recombination of other peroxy

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

radicals in the liquid phase. These values for k_6 for various radicals in the liquid phase vary from 0.95×10^6 l. mole^{-1}sec^{-1} for the cyclohexylperoxy radicals (9) to 2.10×10^8 l. mole^{-1}sec^{-1} for the peroxy radical from benzaldehyde (10). This latter datum can be taken as approximating to within an order of magnitude to the value of k_6 expected for the recombination of peroxyacetyl radicals in solution. It would then be seen that k_6 for the gas phase recombination of peroxyacetyl radicals is between 10 and 100 times as great as the anticipated value for the liquid phase reaction. This difference seems to be what might reasonably be expected on theoretical grounds. Presumably the smaller value expected for k_6 for the liquid phase process would be due to entropy factors associated with possible solvation of the peroxy radical. Recombination of two solvated peroxy radicals would, of course, be expected to be a somewhat less rapid process than the gas phase recombination of the same peroxy radicals.

ACKNOWLEDGMENTS

We wish to thank the National Research Council of Canada for generous grants in aid of this research work. One of us (S. S.) is also indebted to that body for the award of a Studentship.

THE ABSOLUTE CONFIGURATION OF *dextro*-1-DEUTERIOETHANOL[1]

R. U. LEMIEUX[2] AND J. HOWARD[3]
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received August 31, 1962

ABSTRACT

Reduction of 1,2-*O*-isopropylidene-3-*O*-benzyl-5-oxo-α-D-xylofuranose with lithium aluminum deuteride followed by removal of the isopropylidene and benzyl groups provided 5-deuterio-D-xylose. Nuclear magnetic resonance examination of the 5-deuterio-β-D-xylopyranose tetraacetate showed the isomer with the 5-carbon in the R-configuration (deuterium equatorial) to be present in 30% excess. The substance was degraded to 1-deuterioethanol, which possessed a dextrorotation of the magnitude expected and which necessarily possessed the R-configuration. This result confirmed the prediction made by Brewster (Tetrahedron Letters, **20**, 23 (1959)).

Recently, Althouse, Ueda, and Mosher (1) have reported on the reduction of 1-deuteriotrimethylacetaldehyde by actively fermenting yeast and have reviewed the results of the investigations by Westheimer, Vennesland, and their respective co-workers on the alcohol dehydrogenase catalyzed reduction of both acetaldehyde by monodeuterio-reduced diphosphopyridine nucleotide (DPND) and of 1-deuterioacetaldehyde by unlabelled DPNH to form optically pure samples of 1-deuterioethanol. Furthermore, the various lines of conflicting reasoning applied by Vennesland, Streitweiser, Kaplan, Brewster, and their respective co-workers to predict the absolute configuration of optically active 1-deuterioethanol and other optically active primary alcohols rendered dissymmetric by monodeuteration of the 1-carbon are discussed. The speculations presented by Mosher and his collaborators (1) on the configurational relationship between the 1-deuterioneopentyl alcohol, obtained by reduction using actively fermenting yeast, and the 1-deuterioethanol prepared by the DPNH reduction of 1-deuterioacetaldehyde (2), overlook the fact that Lemieux and Giguere (3) found that, whereas the reduction of β-keto-*n*-caproic and β-keto-*n*-caprylic acids by actively fermenting yeast yielded the corresponding D-β-hydroxyacids, the similar reduction of β-ketobutyric acid gave L-β-hydroxybutyric acid. Evidently, at least two mechanisms for the reduction of a carbonyl group are present in actively fermenting yeast and the procedure does not provide a reliable means for the establishment of configurational relationships. The purpose of this communication is to report an unequivocal proof for the absolute configuration of *dextro*-1-deuterioethanol.

The 3-*O*-benzyl derivative (II) of 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (I) was subjected to simultaneous preferential hydrolysis of the 5,6-*O*-isopropylidene group and periodate oxidation of the resulting 5,6-glycol by treatment in 90% aqueous acetic acid with 0.08 *M* periodic acid at room temperature for 25 minutes. The 1,2-*O*-isopropylidene-3-*O*-benzyl-5-oxo-α-D-xylofuranose (III) thus obtained was purified by distillation and reduced at room temperature in ether by slow addition (over 1 hour) of lithium aluminum deuteride in ether. The product (IV) was subjected to catalytic hydrogenolysis to remove the benzyl group and form 1,2-*O*-isopropylidene-5-deuterio-α-D-xylofuranose (V). Acid

[1]*Presented at the XXIXth Congrès de l'Association Canadienne-Française pour l'Avancement des Sciences, Ottawa, 1961.*

hydrolysis of the latter compound gave 5-deuterio-D-xylose (VI), which was acetylated using sodium acetate and acetic anhydride to form 5-deuterio-β-D-xylopyranose tetraacetate (VII). The nuclear magnetic resonance signals produced by the hydrogen at the 5-carbon of this product, which is the mixture of diastereoisomers differing in the configuration of the 5-carbon depicted in Fig. 1B, are compared in Fig. 1 with those of the methylene group in undeuterated β-D-xylopyranose tetraacetate (Fig. 1A). Lemieux and his collaborators (4) have already made the assignment of the signals for the methylene

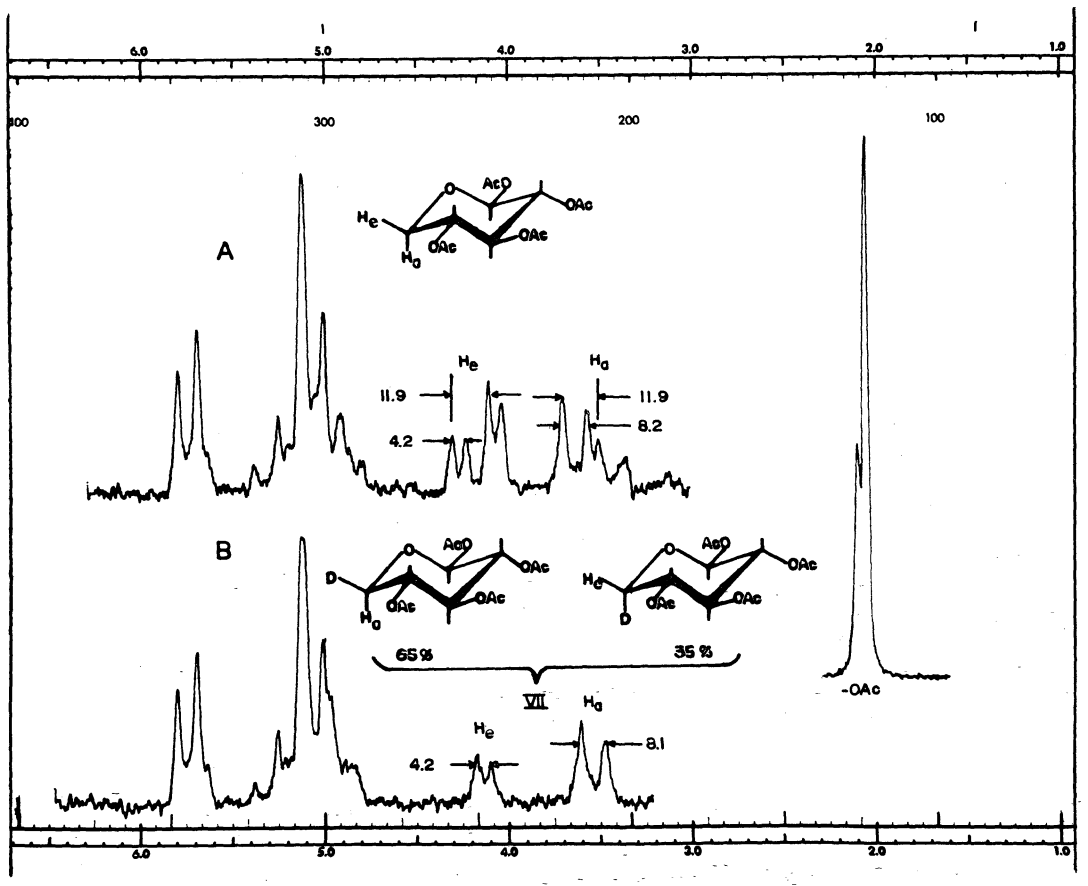

FIG. 1. Nuclear magnetic resonance spectra measured in chloroform. A. β-D-xylopyranose tetraacetate. B. Mixture of the diastereoisomeric tetraacetates (VII) of 5-deuterio-β-D-xylopyranose.

hydrogens in β-D-xylopyranose tetraacetate. In the case of the 5-deuterio derivatives (VII) the 5-hydrogen (either H_a or H_e) is coupled strongly only with the hydrogen at the 4-position. Therefore, the appearance of the two rough doublets (because of coupling with the deuterium atom) is in accord with expectation. Undoubtedly, the signal at low field, $\tau = 5.87$, with a spacing of 4.2 c.p.s. arose from the molecules in which the hydrogen is equatorial and the one at high field, $\tau = 6.46$, with a spacing of 8.1 c.p.s. arose from the molecules in which the hydrogen is axial (4). A comparison of the relative intensities of these two signals showed that the isomer which has the 5-hydrogen in axial orientation was 1.85 times more abundant than the other. Since the absolute configuration of β-D-xylopyranose tetraacetate is known to be that depicted in Fig. 1, the absolute configuration of the 5-carbon in the more abundant isomer of VII possesses, in terms of the Cahn–Ingold–Prelog designation (5), the R-configuration. Therefore, degradation of VII to 1-deuterioethanol by way of a sequence of reactions that does not disturb any of the four bonds of the 5-carbon would yield R-1-deuterioethanol (XVI) of about 30% optical purity. The degradation was accomplished as follows.

The tetraacetate (VII) was converted to tri-*O*-acetyl-5-deuterio-β-D-xylopyranosyl bromide (VIII) and this compound was reacted with *n*-butanol in the presence of silver

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

carbonate and anhydrous calcium sulphate to give *n*-butyl tri-*O*-acetyl-5-deuterio-β-D-xylopyranoside (IX) (6). Deacetylation provided *n*-butyl 5-deuterio-β-D-xylopyranoside (X), which was oxidized with sodium periodate at pH 5 to 6. The resulting dialdehyde (XI) was reduced with sodium borohydride at pH about 8 to afford the diol (XII). On subjecting the ditosylate (XIII) of the diol to a treatment with a refluxing solution of sodium iodide in dry acetone for 3 hours, the 2-tosyloxy-1-deuterioethyl group of XIII was transformed to the 2-iodo-1-deuterioethyl group of XIV. Hydrogenolysis of the iodo compound using palladium–hydrogen in methanol containing an excess of diethylamine gave the *n*-butyl 1-deuterioethyl mixed acetal of *O*-tosyl glycolaldehyde (XV). This substance was heated under conditions for distillation with dry *n*-butanol containing *p*-toluenesulphonic acid. The 1-deuterioethanol in the distillate was isolated by fractional distillation using the Podbielniak semimicro, spinning-band column. Four successive, about 0.35-ml fractions were collected in the boiling point range expected for ethanol. Examination of these fractions by gas–liquid partition chromatography and nuclear magnetic resonance spectroscopy showed the first three fractions, which distilled at the same temperature, to be virtually pure 1-deuterioethanol. Although the n.m.r. spectra of the fractions indicated the presence of water, the amount certainly was no more than is present in the ethanol–water azeotropic mixture. Levy, Loewus, and Vennesland (ref. 2, footnote 12) have shown that the drying of optically active 1-deuterioethanol does not change the sign of rotation. Consequently, the samples were not dried before measuring their rotations at the D-line of sodium. The fact that the samples were the expected 1-deuterioethanol is clear from the spectra shown in Fig. 2. Spectrum A is for a commercial grade of anhydrous ethanol and spectrum B is for a sample of ethanol–water azeotropic mixture. Spectrum C is of the combined fractions of 1-deuterioethanol after their individual rotations and n.m.r. spectra had been measured. The essentially doublet character of the signal for the methyl group clearly requires the deuterium to be at the 1-position of the ethanol.

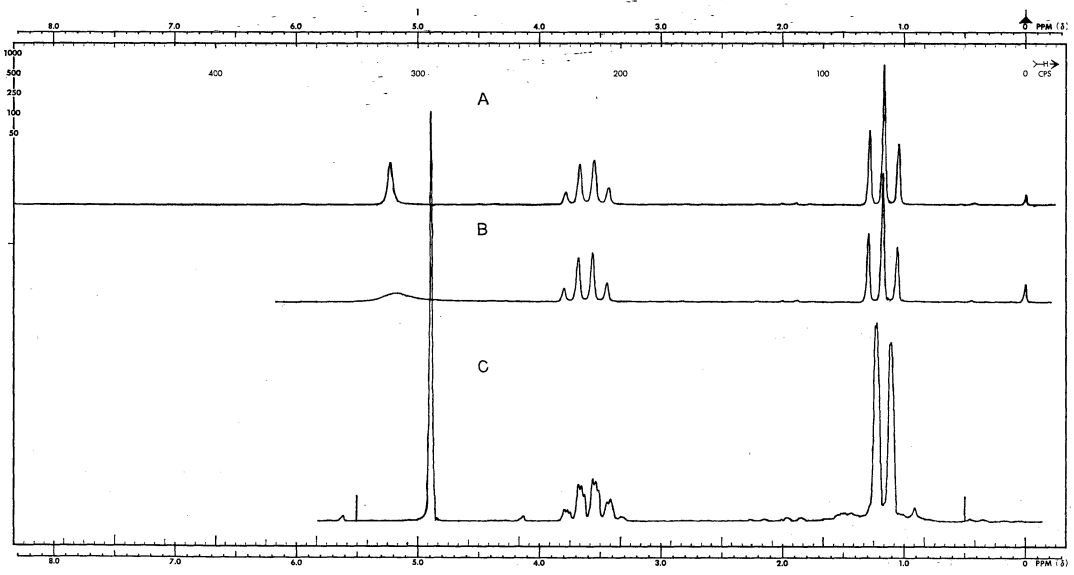

FIG. 2. Nuclear magnetic resonance spectra of ethanol (A), ethanol–water azeotrope (B), and the sample of *dextro*-1-deuterioethanol (C).

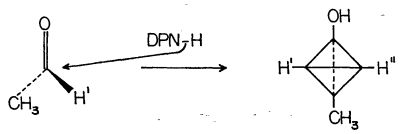
The optical rotations of the three fractions of 1-deuterioethanol were measured under conditions of replication whereby a solution which was expected to produce a rotation of $-0.052°$ different from the commercial alcohol used as a blank actually gave a rotation of $-0.057 \pm 0.02°$. The observed optical rotations of the first three 1-deuterioethanol fractions were found to be $+0.061°$, $+0.066°$, and $+0.069°$, respectively. From the known (2) rotation of an optically pure sample of 1-deuterioethanol, the expected magnitude for the rotation was $\pm 0.066°$. It is inconceivable that these fractions would contain an optically active compound other than the deuterioethanol. Nevertheless, should the distillate possess such a compound and it, rather than the deuterioethanol, was responsible for the optical rotation, the substance would have to be present in about the same trace quantity in each of the three fractions and be present in just sufficient quantity to produce the magnitude of rotation expected if all of the optical activity came from the deuterioethanol. This event is too unlikely to warrant consideration. It is therefore concluded that, as anticipated both by Brewster (7) and by van Eys and Kaplan (8), dextrorotatory 1-deuterioethanol has the R-configuration shown in XVI. Therefore, since the reduction of 1-deuterioacetaldehyde by DPNH leads to the formation of levorotatory S-1-deuterioethanol (2), it is now definite that the acetaldehyde accepts the hydride ion in the manner depicted in XVII.



XVII

Of the variety of reducing conditions studied for the reduction of the aldehyde (III) using a deuterated reducing agent, the conditions reported herein gave the largest extent of partial asymmetric synthesis. The effects of temperature and order of addition using lithium aluminum deuteride have already appeared in Table III of the paper recently published by Haubenstock and Eliel (9) and require no further comment. Of real interest is the fact that a solution of deuterated isobornylmagnesium bromide which rapidly (2 hours) reduced benzaldehyde (10) left the aldehyde III unchanged even after prolonged (3 days) reaction times. Other attempts to make the aldehyde enter into a Meerwein–Ponndorf–Verley type of reduction were unsuccessful. Most likely these results are due to ready enolization of the aldehyde and the consequent formation of an enolate which resists reduction. Schaffer and Isbell (11) have demonstrated that 1,2-*O*-isopropylidene-5-oxo-α-D-xylofuranose undergoes aldol condensation and we observed (paper chromatography) the formation of the *arabo*-configuration in the reduction of one of our preparations of the 3-*O*-benzyl derivative (III). Whatever the reason for the resistance to reduction by alkoxides, displayed by the aldehyde III, this property precluded our ability to prepare optically pure 1-deuterioethanol.

EXPERIMENTAL

The melting points were determined on a Leitz microstage and are uncorrected. Unless otherwise stated, the optical rotations were measured at room temperature to $0.01 \pm 0.01°$. The nuclear magnetic resonance spectra were measured on high-resolution Varian Associates spectrometers operating at 60 Mc/s.

1,2:5,6-Di-O-isopropylidene-α-D-glucofuranose (I)

The compound was prepared under the conditions described by Mehltretter and co-workers (12) except that the glucose was ground to pass through a 100-mesh sieve and no temperature control was used. A study of the progress of the reaction showed that the yield passed through a maximum after about 45 minutes' reaction time. At this time, only 3% of the glucose remained undissolved and the yield of product, melting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

at 93–104° and giving pure product after one recrystallization from 80–100° petroleum ether, was 80% based on the glucose which had reacted. Since these experiments were performed Recondo and Rinderknecht (13) reported the use of acetic acid to help solubilize the glucose and evolved a procedure which appears equivalent to the best conditions developed in this investigation.

1,2:5,6-Di-O-isopropylidene-3-O-benzyl-α-D-glucofuranose (II)

The procedure reported by Adams, Reeves, and Goebel (14) was followed and the product was distilled at 170–180° and 0.1 mm pressure. The yield was 95%.

1,2-O-Isopropylidene-3-O-benzyl-5-oxo-α-D-xylofuranose (III)

1,2:5,6-Di-*O*-isopropylidene-3-*O*-benzyl-α-D-glucofuranose, 30 g (0.086 *M*), was dissolved in 1 liter of glacial acetic acid. A solution of 21 g of periodic acid (H_5IO_6, 0.092 *M*) in 150 ml of water was added. After thorough mixing, the reaction was allowed to continue at 25°. After 25 minutes, the reaction was quenched by the addition of 60 g of sodium acetate dissolved in 2 liters of water. The aqueous solution was extracted using five 200-ml volumes of benzene, and the combined extracts were washed free of iodine with 0.1 *N* sodium thiosulphate solution. The yellowish oily residue, 20 g, which remained after the benzene was removed by distillation *in vacuo*, was dried by azeotropic distillation with benzene. The infrared spectrum showed weak carbonyl and very strong hydroxyl stretching vibrations and, consequently, the aldehyde was in the aldehydrol form. The oil was distilled in a high vacuum using a flask and condensing unit which had both been washed previously with concentrated nitric acid and distilled water to remove surface basicity in order to minimize the possibility for enolization. The faintly yellow viscous liquid, 16 g (67% yield), boiled at 140° at 0.15 mm pressure and its infrared spectrum showed no hydroxyl, but very strong carbonyl stretching vibrations. However, on exposure to moisture in the atmosphere the substance soon reverted to the aldehydrol form. The semicarbazone of the aldehyde was prepared, and melted at 170–173°. Anal. Calc. for $C_{16}H_{21}N_5O_3$: C, 57.29; H, 6.31%. Found: C, 57.71; H, 6.49%.

1,2-O-Isopropylidene-3-O-benzyl-5-deuterio-α-D-xylofuranose (IV)

Lithium aluminum deuteride (purchased from Metal Hydrides Inc., Beverly, Mass.), 0.923 g (0.022 *M*) (98% pure), was dissolved in 200 ml of ether (dried over lithium aluminum hydride) contained in a two-neck flask fitted with a condenser and calcium chloride tube, serum cap, and magnetic stirrer. As soon as the lithium aluminum deuteride had dissolved in the ether, 20-ml portions were slowly added, using a large hypodermic syringe, to 1,2-*O*-isopropylidene-3-*O*-benzyl-5-oxo-α-D-xylofuranose (III), 21.7 g (0.078 *M*), dissolved in 500 ml of dry ether contained in a liter flask fitted with a magnetic stirrer, serum cap, condenser, and calcium chloride tube. The time taken for the addition of all the deuteride was 60 minutes. After allowing the reaction mixture to stand for a further 15 minutes, a small portion of the solution was added to water. A moderate evolution of gas indicated that a slight excess of lithium aluminum deuteride had been added. Water, 5 ml, was then added with stirring. The precipitate was removed by filtration with the aid of Celite and the ether was removed *in vacuo*. The clear colorless oil, 21 g (96% yield), which remained was dried by azeotropic distillation with benzene. The infrared spectrum indicated strong hydroxyl and C—D stretching vibrations but no signal characteristic of the carbonyl group. No purification was achieved as could be judged by infrared spectroscopy on distilling the substance at 160° and 0.1 mm pressure. The material, $[\alpha]_D^{27} = -31.3°$ (*c*, 6 in ethanol), resisted crystallization as did the 2,4-dinitrobenzoate ester.

1,2-O-Isopropylidene-5-deuterio-α-D-xylofuranose (V)

Substance IV, 21 g (0.075 *M*), was dissolved in 150 ml of absolute alcohol and hydrogenolyzed at room temperature and 4 atm pressure using a 10% palladium on charcoal catalyst (purchased from Engelhard Industries Inc., Newark 2, N.J.). The uptake of hydrogen was complete after 9 hours. The catalyst was removed by filtration and the filtrate was evaporated to a thick colorless syrup, 13.5 g (95% yield). The infrared spectrum showed that removal of the benzyl group was complete. The compound was characterized through its hydrolysis to 5-deuterio-α-D-xylose (VI) as described below.

5-Deuterio-α-D-xylose (VI)

The deuterioisopropylidene xylose (V), 13.5 g (0.071 *M*), was dissolved in 100 ml of 0.1 *N* sulphuric acid and the solution was heated on a steam bath for 45 minutes. After this time, the optical rotation was constant. The hot solution was neutralized with aqueous 0.1 *N* barium hydroxide and, after cooling, the barium sulphate was removed by filtration with the aid of Celite. The filtrate was evaporated *in vacuo* and the residue was dried by azeotropic distillation with benzene and ethanol. The colorless clear syrup after seeding with a small amount of undeuterated D-xylose and treatment with a little absolute ethanol crystallized completely within an hour. The dried crystals, 10.4 g (97% yield), melted at 142–143°. Pure α-D-xylose melts at 145°. A sample was chromatographed on paper using an ethyl acetate – pyridine – benzene – water (5:3:1:3) solvent system. Only one spot for xylose ($R_f = 0.36$) was detected using aniline phthalate as the spray reagent.

Tetra-O-acetyl-5-deuterio-β-D-xylopyranose (VII) (15)

The deuterated xylose (VI), 10.4 g (0.069 *M*), and 12 g of fused sodium acetate were mixed and cautiously heated, with efficient stirring, with 50 ml of acetic anhydride. The temperature of the initial reaction was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

kept below 100° by cooling but after the initial strong liberation of heat had subsided, the mixture was kept at 100° for a period of 30 minutes, cooled, and poured into 200 ml of stirred water. Within a short time, the oil that separated began to crystallize and after 1 hour the mixture was cooled to 5° and the colorless product, 11 g (55% yield), melting at 122–125°, was collected by filtration. The filtrate was extracted with two 50-ml volumes of benzene and the combined extracts were washed with saturated sodium bicarbonate solution. Evaporation provided 8.4 g of a brown syrup which only partially crystallized. This material was retained and combined with the same syrups obtained in three subsequent acetylations of deuterated xylose. The mixture of α- and β-D-xylose tetraacetates, 26 g, was then deacetylated in 250 ml of anhydrous methanol made alkaline with a methanolic solution of potassium methoxide. The methanol was then evaporated to leave 14 g of syrupy deuterated xylose, which was immediately reacetylated using fused sodium acetate and acetic anhydride in the manner described above. The overall yield of tetra-*O*-acetyl-5-deuterio-β-D-xylopyranose (VII) was 78%.

The n.m.r. spectrum of the purified substance is shown in Fig. 1. Integration of the signals for the hydrogens on the 5-carbon, doublets centered at $\tau = 5.87$ (spacing 4.2 c.p.s.) and $\tau = 6.46$ (spacing 8.1 c.p.s.), showed the latter (high-field) signal to have an intensity 1.85 times that of the low-field signal.

Tri-O-acetyl-5-deuterio-α-D-xylopyranosyl Bromide (VIII)

The dry deuterated β-D-xylose tetraacetate (VII), 10.5 g (0.033 *M*), was dissolved in 100 ml of dry, ethanol-free chloroform. A 34-ml amount of 32% hydrobromic acid in acetic acid which contained 4 ml of acetic anhydride was then added to the chloroform solution at 10°. After 45 minutes, the optical rotation had become constant and the mixture was plunged into 300 ml of ice water contained in a separatory funnel. After thorough washing, first with ice water and then with saturated sodium bicarbonate solution at 0°, the chloroform solution was dried over sodium sulphate. The total time taken for washings was approximately 20 minutes. After filtration, the chloroform was evaporated *in vacuo* at a temperature not exceeding 50° to reduce the volume to 50 ml. This solution was used directly to prepare the butyl xyloside (IX) as described below. In a control experiment, removal of the chloroform gave a 91% yield of colorless crystalline product (VIII) melting in the range 95–100°. Pure tri-*O*-acetyl-α-D-xylopyranosyl bromide melts at 102° (16).

n-Butyl Tri-O-acetyl-5-deuterio-β-D-xylopyranoside (IX)

Hori (6) prepared this compound in 43% yield from the bromide VIII. The yield was improved to 53% by maintaining anhydrous conditions throughout the addition over a period of 4 hours of the bromide (VIII), dissolved in chloroform (see above), to a slurry of silver carbonate in *n*-butanol containing anhydrous calcium sulphate. The reaction and work-up conditions were otherwise similar to those reported by Hori (6). The yield was 9.5 g of a syrup which crystallized spontaneously and gave only a faint Fehling test. Recrystallization from 3 parts of methanol–water (2:1) gave 6 g of crystalline product (IX) melting at 95–99°. The overall yield from the tetraacetate (VII) was 53%.

Crystalline *n*-butyl 5-deuterio-β-D-xylopyranoside (X) was obtained in quantitative yield by deacetylation in dry methanol using sodium methoxide as catalyst in the usual manner. After one recrystallization from ethyl acetate and petroleum ether, the compound melted at 89–90°. Hori (6) reported the substance (X) to melt at 90–91°.

Periodate Oxidation of n-Butyl 5-Deuterio-β-D-xylopyranoside (X) to the Ditosylate XIII

The deuterated butyl xyloside (X), 10.3 g (0.0475 *M*), was dissolved in 210 ml of water containing 5 g of sodium acetate and 25.8 g of sodium metaperiodate (0.12 *M*) added over a 5-minute period to the stirred solution, kept at room temperature in a water bath. After approximately 15 minutes, the optical rotation was constant. The solution was filtered and extracted nine times using 50-ml portions of ethyl acetate. The combined extracts were dried over sodium sulphate and evaporated *in vacuo* to give 9.1 g of the syrupy hydrated dialdehyde XI. The infrared spectrum of the material showed strong absorptions in the hydroxyl, carbonyl, and C—D stretching regions.

The hydrated dialdehyde XI, 9.1 g, was dissolved in 100 ml of water, and 4 g of sodium borohydride in approximately 0.25-g portions was added over a period of 15 minutes to the stirred solution, which was kept at 0°. During the reduction the pH was kept at approximately 8.0 by the addition of glacial acetic acid. After 1 hour, the excess sodium borohydride was destroyed by the addition of glacial acetic acid to maintain a pH of 7. The solution was then extracted using six 60-ml portions of ethyl acetate and the combined extracts were dried over sodium sulphate. Filtration and solvent removal left 7.0 g of an oil which was distilled to give 5.4 g (64% yield) of clear colorless oil which boiled at 110° and 0.1 mm pressure. The n.m.r. spectrum of this compound in heavy water showed a triplet of 6 c.p.s. spacing at 5.25 τ. The spectrum showed two bands, one in the region 6.0 to 6.5 τ due to the hydrogens of the methylene groups attached to oxygen and the other in the region 8.2 to 9.3 τ due to the propyl group of the *n*-butyl group. The relative intensities of these bands was 1:1, as expected for the monodeuterio derivative. The specific rotation of the undeuterated compound was too small to measure in water but was $-11.7°$ in ethyl acetate ($c = 4$).

The deuterated diol XII, 5.3 g (0.03 *M*), was dissolved in 80 ml of dry pyridine. Tosyl chloride, 35 g (0.183 *M*), was dissolved in 80 ml of ethanol-free, dry chloroform. The two solutions were mixed at 0° and kept at this temperature for 1 hour. The reaction mixture was allowed to stand at room temperature for 3 hours and 8 ml of water was added with cooling. After 30 minutes, 200 ml of chloroform was added and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution was extracted successively using two 400-ml portions of ice-cold water, one 400-ml portion of 2 *N* hydrochloric acid at 0°, and one 50-ml portion of a saturated solution of sodium bicarbonate. The chloroform solution was then dried over magnesium sulphate, filtered, and evaporated *in vacuo* to a 14.5 g syrupy residue of the deuterated ditosylate XIII. The n.m.r. spectrum in carbon tetrachloride showed the presence of two tosyl groups per butyl group and a triplet of 5 c.p.s. spacing at 5.43 τ. The hydrogens of the methylene groups attached to oxygen produced their signals in a wide band ranging from 5.7 to 6.9 τ. The intensity of this band relative both to the signals for aromatic hydrogens and the signals of the hydrogens in the propyl group showed the deuterated compound (XIII) to possess one hydrogen less than the undeuterated normal substance prepared in the same way but from normal D-xylose. The compound (XIII) showed absorption in the region of the infrared, 2200 cm^{-1}, characteristic of the C—D bond stretch. The signal was not present in the absence of the deuteration.

The n-Butyl 1-Deuterioethyl Acetal of O-Tosylglycolaldehyde (XV)

The deuterated ditosylate (XIII), 14.4 g (0.02 *M*), was dissolved in a solution of 20 g of dry sodium iodide in 400 ml of dry acetone. On standing at room temperature overnight, 3.8 g of sodium *p*-toluenesulphonate precipitated. The filtrate was kept at a reflux temperature for 1½ hours and a further 2.2 g of the salt precipitated. The total amount, 6.0 g, corresponds to the replacement of 1.04 tosyloxy groups per mole of XIII. The reaction mixture was then filtered and evaporated at 35° *in vacuo* to a salt cake. Water, 100 ml, was added and the mixture was extracted with three 50-ml portions of ether. The combined ethereal extracts were washed first with a solution of sodium thiosulphate and then with water. After drying over magnesium sulphate, the solvent was removed *in vacuo* to leave 12.2 g of colorless product (XIV). The substance was dissolved in 50 ml of dry methanol which contained 5 ml of diethylamine and 1.5 g of 10% palladium on charcoal. The solution was hydrogenolyzed at an initial pressure of 3 atm. The hydrogen uptake (1 mole per mole of XIV) was complete after 30 minutes. The catalyst was removed by filtration and the filtrate was evaporated to a semisolid mass, which was dissolved in 100 ml of water, and the mixture was extracted with two 100-ml portions of ether. After drying over magnesium sulphate, the ether was removed *in vacuo* to leave 8.2 g of a colorless oil (XV). Although the n.m.r. spectrum of this product was not determined, that of the ethyl *n*-butyl acetal of *O*-tosylglycolaldehyde prepared in the same manner from D-xylose was in complete agreement with the structure expected for the compound.

dextro-1-Deuterioethanol (XVI)

The 1-deuterioethyl *n*-butyl acetal of *O*-tosylglycolaldehyde (XV), 8.0 g (0.025 *M*), and 1.36 g of *p*-toluenesulphonic acid were dissolved in 70 ml of pure dry *n*-butanol contained in a 100-ml flask which was fitted with a take-off condenser and a dropping funnel containing *n*-butanol. The *n*-butanol was dried by fractional distillation and was found to be devoid of optical activity when examined in a 2-dm tube. The flask was immersed in an oil bath which was maintained at 140°. Slow distillation resulted and 26 ml of distillate boiling in the range 100–114° was collected over a period of 5½ hours. Gas–liquid partition chromatography on an Apiezon column at 68° indicated that the distillate contained only ethanol and *n*-butanol. A second 4-ml fraction of distillate, which boiled over at 114°, was collected over a period of 1 hour. Analysis of this fraction showed only *n*-butanol to be present. The main fraction was then fractionally distilled using a Podbielniak, semimicro, spinning-band column under conditions which had previously been found to effect a sharp separation of ethanol from *n*-butanol. Three successive fractions were collected of 0.35-, 0.39-, and 0.36-ml volumes, respectively, boiling in the range 77–78° (uncorrected). A fourth fraction, 0.55 ml, boiled at 76–85° and was found by gas–liquid partition chromatography to contain a very small amount of *n*-butanol. However, the first three fractions appeared pure and represent a 74% yield.

The optical rotations of the above three fractions were measured separately in a 1-dm tube at the D-line of sodium. The fields were matched by one investigator and the readings were taken by someone else. This was done 10 times for each fraction, once with the tube pointing in one direction and once with the tube pointing in the opposite direction in order to be sure that there was no contribution to rotation arising from the glass windows. The investigators then changed positions and repeated the operation. The zero point was taken as the average reading obtained using the tube filled with pure synthetic ethanol. This reading coincided with the air blank. In this way, a minimum of 20 readings was made on each of the fractions and the blanks without the observer knowing the readings of the polarimeter. Thus, the results were kept as free as possible from subjective error. In no single reading (in over 100 readings) was the sign of rotation determined for a sample of 1-deuterioethanol not found to be positive relative to the blank. The averages of the rotations observed for the three fractions were +0.061°, +0.066°, and +0.069°, respectively. In taking these averages, the root mean square deviations were calculated in order to exclude some of the readings. The n.m.r. spectra of the fractions indicated that the samples contained less water than is present in the ethanol–water azeotrope. The three fractions were combined to obtain the n.m.r. spectrum of 1-deuterioethanol shown in Fig. 2. These spectra were taken with a Varian A60 spectrometer and show beyond doubt that the sample represents virtually pure 1-deuterioethanol. The only impurities evident in this sample are a trace of *n*-butanol and about 6% water. Most of the water present was undoubtedly introduced during several transfers of the 1-deuterioethanol which were made before the spectrum was taken. On the basis of the known observed rotation of optically pure 1-deuterioethanol (2), $\pm 0.22 \pm 0.02°$, and the fact that the sample prepared in this work could be expected to be 30% pure, the rotation of the sample should be $\pm 0.066°$. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

observed rotation of a 0.25% solution of β-D-xylopyranose tetraacetate in ethanol would be expected to be −0.052°. When the rotation was measured, using the procedure described above to measure the rotation of the samples of 1-deuterioethanol, a value of -0.057 ± 0.02 was obtained. Thus, there can be no doubt that *dextro*-1-deuterioethanol was prepared.

ACKNOWLEDGMENTS

This research was supported by the National Research Council of Canada through a grant-in-aid for research to R. U. L. The n.m.r. spectra were measured by Mrs. A. Westland (U. of O.) and R. Swindlehurst (U. of A.) and the microanalyses were made by Miss E. Busk.

ABSTRACT

Tristrifluoromethylarsine reacts with arsenic trichloride at 210° to give dichlorotrifluoromethylarsine. Attempts to prepare trifluoromethyl derivatives of mercury, boron, and aluminum by interaction of tristrifluoromethylarsine with halides of these elements have been unsuccessful. Tristrifluoromethylarsine is stable to phosphorus at 220° but reacts with nitric oxide at 70° to give nitrogen and low yields of trifluoronitroso- and trifluoronitro-methane. It probably forms a weak 1:2 complex with pyridine.

Dichlorotrifluoromethylarsine is easily reduced, at 20°, to trifluoromethylarsine by shaking with hydrogen chloride in the presence of mercury. Pyridine reacts with the chloroarsine at 20°.

DISCUSSION AND RESULTS

Walachewski reports (1) that tristrifluoromethylarsine reacts with arsenic triiodide at 220° to give iodotrifluoromethylarsines. It has now been found that chlorotrifluoromethylarsines are produced when tristrifluoromethylarsine interacts with arsenic trichloride at 210°, the major product being dichlorotrifluoromethylarsine:

$$2AsCl_3 + (CF_3)_3As \rightarrow 3CF_3AsCl_2.$$

This reaction provides a convenient source of the reactive chloroarsine, and is similar to that reported (2) for triphenylarsine:

$$(C_6H_5)_3As + AsCl_3 \rightarrow C_6H_5AsCl_2 + (C_6H_5)_2AsCl.$$

Furthermore, since there is evidence (3) that triphenylarsine will yield its phenyl groups in exchange for halogen atoms of several inorganic halides, attempts were made to prepare trifluoromethyl derivatives of boron, aluminum, and mercury by interacting their halides with tristrifluoromethylarsine.

Tristrifluoromethylarsine and boron triiodide at 130° give boron trifluoride, trifluoroiodomethane, iodobistrifluoromethylarsine, and arsenic triiodide. The products suggest that the boron triiodide mainly acts as a source of iodine since, apart from the boron trifluoride, the products are those obtained from tristrifluoromethylarsine and iodine at temperatures above 100° (1, 4). The formation of boron trifluoride could, however, indicate that some exchange of trifluoromethyl groups takes place since trifluoromethyl boron compounds are expected to be unstable with respect to the formation of boron trifluoride (5).

The slow reaction of tristrifluoromethylarsine with aluminum triiodide at 115° also produces trifluoroiodomethane and iodotrifluoromethylarsines. At 150°, however, the reaction is rapid and the tristrifluoromethylarsine is decomposed to carbon tetrafluoride, hexafluoroethane, arsenic trifluoride, and arsenic metal. The thermal decomposition of tristrifluoromethylarsine, which is reported (6) to take place at temperatures above 350°, can be represented by the equation

$$(CF_3)_3As \rightarrow As + 3/2C_2F_6,$$

only minor amounts of carbon tetrafluoride and arsenic trifluoride being produced. Therefore the decomposition of the arsine by aluminum triiodide at 150° is not simply a catalyzed thermal reaction. In producing carbon tetrafluoride and arsenic trifluoride the reaction bears a close resemblance to the fluorination of tristrifluoromethylarsine either by fluorine or cobalt trifluoride (4).

Tristrifluoromethylarsine and mercuric iodide do not react at 175°, although it is reported (7) that at this temperature bistrifluoromethylmercury reacts with mercuric iodide:

$$(CF_3)_2Hg + HgI_2 \rightarrow 2CF_3HgI.$$

Like tristrifluoromethylarsine, bistrifluoromethylmercury does not seem to take part in exchange reactions involving the trifluoromethyl group and the halogens of metals and metalloids (8, 9) even though reactions of this type are very common for alkyl and aryl mercury compounds.

These results support the view that fluoroalkyl groups readily exchange for halogen attached to other elements only when the group is attached to the more electropositive elements, for example (10)

$$(CH_3)_2SiCl_2 + 2C_3F_7Li \rightarrow (CH_3)_2Si(C_3F_7)_2 + 2LiCl.$$

A reaction which possibly involves exchange of a trifluoromethyl group for oxygen has recently been described by Griffiths and Burg (11). These authors report that tristrifluoromethylphosphine interacts with mercuric oxide at 100° to give bistrifluoromethylmercury:

$$2(CF_3)_3P + 2HgO \rightarrow (CF_3)_2Hg + \text{"}Hg[P(O)(CF_3)_2]_2\text{"}.$$

The exact nature of the other reaction product is not established. The corresponding reaction using tristrifluoromethylarsine has now been investigated. At 95° reaction occurs to only a very small extent and even at 165° recovery of the arsine is almost quantitative. At 95° a very low yield of bistrifluoromethylarsine oxide and trifluoronitrosomethane is obtained. The latter is also obtained from the reaction at 165°, though the arsine oxide, even if produced, would not be stable at this temperature (1). Griffiths and Burg could not isolate any of the diphosphorane, $(CF_3)_2POP(CF_3)_2$, from their reaction. The low yield and nature of the products obtained from the arsine reaction suggest that the reaction which occurred was with an impurity, probably mercuric nitrate, and not with the mercuric oxide.

The transfer of perfluoroalkyl groups from one metal or metalloid to another element has been described in two publications (12, 13):

$$(CH_3)_3SnCF_3 + BF_3 \rightarrow (CH_3)_3SnBF_3(CF_3)$$

$$(C_2F_5)_2Hg + 3S \rightarrow (C_2F_5)_2S_2 + HgS.$$

Bistrifluoromethylmercury on the other hand does not transfer its trifluoromethyl groups to metals such as zinc and magnesium (7). Since triphenylarsine reacts with phosphorus to give triphenylphosphine (14):

$$(C_6H_5)_3As + P \rightarrow (C_6H_5)_3P + As,$$

the reaction of tristrifluoromethylarsine with phosphorus was investigated. The arsine was found to be inert to phorphorus at temperatures up to 220°, the temperature at which both tristrifluoromethyl-arsine and -phosphine are formed from the appropriate element and trifluoroiodomethane (4). The transfer of phenyl groups from arsenic to phorphorus could be due to an increased stability of triphenylphosphine over that of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

triphenylarsine due to the greater possibility of overlap of the "lone pair" electron on the phorphorus with the π-orbitals on the phenyl groups. This sort of stabilization would of course not be operative in the trifluoromethyl derivatives of these elements.

The transfer of trifluoromethyl groups from arsenic to nitrogen has been achieved by Jander and Haszeldine (15). These authors found that tristrifluoromethylarsine and nitrosyl chloride react at 100° to give chloroarsines and a small amount of trifluoronitrosomethane, a reaction which is formally analogous to the exchange reactions discussed above. They also found that tristrifluoromethylarsine and nitric oxide react to give low yields (5%) of trifluoronitrosomethane when irradiated with ultraviolet light.

In the present investigation the thermal reaction between the arsine and nitric oxide has been investigated. Reaction occurs slowly at 70°, a white solid first forms which later disappears. Analysis of this solid shows a surprisingly low percentage of CF_3, a result which is confirmed in magnitude by the carbon analysis, and it is unlikely that any possible single product containing arsenic and trifluoromethyl could give such an analysis. The volatile reaction products are also complex: nitrogen is produced and small amounts of trifluoronitromethane and trifluoronitrosomethane can be isolated. The usual method for the preparation of trifluoronitrosomethane is by the reaction of nitric oxide with trifluoromethyl radicals (16). However, since the arsine is thermally stable at 70° (6) and since no hexafluoroethane is produced in the reaction of the arsine with nitric oxide at 70°, it seems improbable that a free-radical mechanism involving dissociation of the arsine to trifluoromethyl radicals is operating in this case to produce the trifluoronitrosomethane. The formation of trifluoronitromethane in this reaction is also unusual since trifluoronitrosomethane is stable at 70° (15, 16), a fact which suggests that the nitro compound is produced by interaction of the arsine with nitrogen dioxide. This would account for the formation of nitrogen and also for the observation that the gas in the reaction tube turns red before turning blue.

Arsenic trichloride seems to have the ability to act as an electron acceptor in forming 1:1 and 1:2 complexes with pyridine (17). Antimony trihalides are also electron acceptors and tristrifluoromethylstibine forms a moderately stable 1:1 pyridine adduct (18). Tristrifluoromethylarsine does not form a stable 1:1 adduct with pyridine, though Fig. 1 shows that possibly a weak 1:2 complex, $(CF_3)_2As,2C_5H_5N$, may exist.

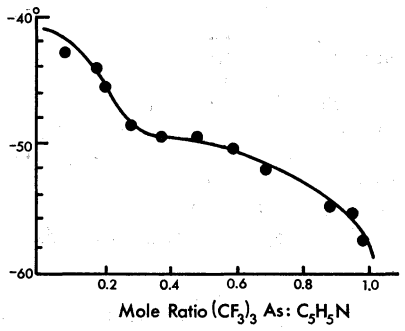

FIG. 1.

Dichlorotrifluoromethylarsine reacts with pyridine at 20°. Analysis of the solids produced indicates that the pyridine unit is decomposed.

Dichlorotrifluoromethylarsine reacts with hydrogen chloride in the presence of mercury to give trifluoromethylarsine in good yield:

$$CF_3AsCl_2 + Hg + 2HCl \rightarrow CF_3AsH_2 + HgCl_2.$$

For personal use only.

This reaction provides a more convenient source of the arsine than reduction of the diiodoarsine using a zinc–copper couple and hydrochloric acid (4). Bistrifluoromethylarsine has recently been obtained from chlorobistrifluoromethylarsine using the same method (19).

EXPERIMENTAL

The apparatus and techniques used in this investigation were the same as have been described in earlier papers in this series.

Reaction of Tristrifluoromethylarsine with Arsenic Trichloride

Tristrifluoromethylarsine (11.566 g) and arsenic trichloride (16 g) did not react after 9 hours at 165° and 14 hours at 195°. Reaction took place at 210° (20 hours). The contents of the reaction tube were distilled in a nitrogen atmosphere and gave tristrifluoromethylarsine (2.0 g, b.p. 33°, lit. value, 33.3° (4)), a small fraction, b.p. 33–70°, and 4.5 g of slightly impure dichlorotrifluoromethylarsine, b.p. 70–80° (lit. value, 71° (1)). Infrared examination of the last fraction showed the presence of chlorobistrifluoromethylarsine, which was removed by trap-to-trap distillation. All the volatile material except the dichlorotrifluoromethylarsine was shaken with excess mercury for 4 days at 20°. This produced 0.608 g of tetrakistrifluoromethyldiarsine (identified by its infrared spectrum) corresponding to the production of at least 0.85 g of chlorobistrifluoromethylarsine by the original reaction.

Reaction of Tristrifluoromethylarsine with Aluminum Triiodide

The arsine (3.535 g) and aluminum triiodide (1.5 g) were heated for 14 hours at 45° and quantitative recovery of the arsine was obtained. When the same reactants were heated to 115° for 14 hours reaction took place and the following fractions were isolated: −132° fraction, trifluoroiodomethane (0.201 g; found: M, 202; calc.: M, 196), which was shown by infrared examination to contain traces of tristrifluoromethylarsine and other unidentified impurities; −96° fraction, tristrifluoromethylarsine (3.272 g; found: M, 287; calc.: M, 282); −46° fraction, a pale green liquid (0.097 g) which hydrolyzed to give fluoroform (found: CF_3 (as CF_3H), 48%) and a hydrolyzate which contained arsenic but no aluminum.

The solid remaining in the reaction tube was heated with the recovered tristrifluoromethylarsine for 1 hour at 150°. Rapid reaction took place and the following fractions were isolated: −196° fraction (1.146 g; M, 98.2), shown by its infrared spectrum to be mainly carbon tetrafluoride together with traces of silicon tetrafluoride, hexafluoroethane, and other unidentified impurities; −160° fraction, shown by infrared examination to be mainly hexafluoroethane and silicon tetrafluoride (0.324 g; M, 125); −64° fraction, 0.598 g of arsenic trifluoride (found: M, 142; calc.: M, 142). The infrared spectrum of the last fraction showed very strong absorption in the region of 700 cm^{-1}, the As—F stretching region, and also indicated the presence of impurities. Alkaline hydrolysis yielded fluoride, arsenic (found: As, 55%; calc. for AsF_3: As, 57%), but no fluoroform. The solid residue in the original reaction tube was stable to alkaline hydrolysis at 20° (no fluoroform evolved) and an X-ray powder photograph showed the presence of arsenic metal and the absence of any unreacted aluminum triiodide.

Reaction of Tristrifluoromethylarsine with Boron Triiodide

When boron triiodide (1.6 g) and the arsine (3.062 g) were heated at 130° for 48 hours the most volatile fraction produced (0.137 g) was identified as being mainly boron trifluoride on the evidence of its infrared spectrum and molecular weight (found: M, 69.4; calc.: M, 67.0). The other volatile fractions isolated were trifluoroiodomethane (0.646 g; found: M, 198; calc.: M, 196), tristrifluoromethylarsine (2.225 g; found: M, 282; calc.: M, 282), and iodobistrifluoromethylarsine (0.259 g; found: M, 330; calc.: M, 340). The identity in each case was confirmed by the infrared spectrum. An X-ray powder photograph of the solid from the reaction tube showed the presence of arsenic triiodide. Alkaline hydrolysis of the most volatile fraction failed to produce any fluoroform though the hydrolyzate contained boron. The hydrolyzate of the least volatile fraction contained arsenic but not boron.

Reaction of Tristrifluoromethylarsine with Mercuric Iodide

The arsine (1.996 g) and mercuric iodide (19 g) did not react after 2 days at 105° and, in a separate experiment, 1 day at 175°.

Reaction of Tristrifluoromethylarsine with Mercuric Oxide

The arsine (2.156 g) and mercuric oxide (21.0 g) when heated to 95° for 17 hours gave 0.010 g of bistrifluoromethylarsine oxide, 2.126 g of tristrifluoromethylarsine (M, 282), and a trace of a blue gas, trifluoronitrosomethane. The identity of the fractions was confirmed by their infrared spectra. The recovered tristrifluoromethylarsine was heated with the mercuric oxide for 19 hours at 125°, and for 18 hours at 165°. In both cases trap-to-trap distillation showed that very little reaction had taken place. The weight of the tristrifluoromethylarsine finally recovered was 1.996 g (M, 282).

Reaction of Tristrifluoromethylarsine with Red Phosphorus

The arsine (1.050 g) failed to react with red phosphorus (2.01 g) when heated to 220° for 24 hours. Infrared examination of the volatile material recovered (100%) showed it to be only tristrifluoromethylarsine.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Reaction of Tristrifluoromethylarsine with Nitric Oxide

When 1.999 g of the arsine and 0.441 g of nitric oxide were heated to 70° for 4 days a white solid was produced and the gas in the tube became red and finally blue. The solid on the tube walls disappeared after the tube had been left for 5 days at 20°, and did not re-form on heating the tube to 70° for a further 24 hours. A non-condensable gas was produced which was identified as nitrogen by means of its infrared spectrum, its molecular weight of 29.9, and its inertness to alkaline pyrogallol. The remaining volatile contents of the tube on trap-to-trap distillation gave a most volatile fraction (ca. 60 cc of gas at S.T.P.) which consisted of a blue gas, trifluoronitrosomethane (ca. 30 cc of gas at S.T.P.), and at least one other unidentified colorless substance which sublimed in the vacuum system. The fraction which condensed at −130° was identified as slightly impure trifluoronitromethane (0.25 g) by means of its molecular weight (found: M, 112; calc.: M, 115) and its infrared spectrum. Tristrifluoromethylarsine (0.855 g; found: M, 277; calc.: M, 282) was recovered and a small unidentified least volatile fraction (0.13 g; M, 132) was also obtained. In a separate experiment the reaction was stopped after the white solid had formed. Analysis of this solid gave C, 4.58; H, 1.97; CF_3 (as CF_3H), 26.4%; arsenic was present in the hydrolyzate.

Reaction of Tristrifluoromethylarsine with Pyridine

A 1:1 mixture of pyridine (0.328 g) and the arsine (1.176 g) failed to react to give a solid phase on warming to 20°. Similarly a 2:1 mixture of the arsine and pyridine showed no evidence of stable complex formation. The melting point diagram, Fig. 1, was obtained by the direct method for the range indicated.

Reaction of Dichlorotrifluoromethylarsine with Pyridine

The arsine (0.630 g) and excess pyridine (5.0 g) were miscible at 20°, giving a yellow solution which became red after 24 hours. The volatile contents of the reaction tube were taken into the vacuum system, leaving a viscous red oil and a small amount of a white sublimable solid. The infrared spectrum of this solid showed the absence of any bands associated with a pyridine fragment. The remaining red oil was soluble in pyridine and when the solvent was removed it slowly solidified. Analysis of the solid gave C, 25.5; H, 2.16; N, 12.12%.

Reaction of Dichlorotrifluoromethylarsine with Hydrogen Chloride in the Presence of Mercury

The chloroarsine (0.614 g), mercury (100 g), and hydrogen chloride (0.850 g) were shaken at 20° for 48 hours. Trap-to-trap distillation showed that only hydrogen chloride and trifluoromethylarsine (0.330 g, 79% yield; found: M, 147; calc. for CF_3AsH_2: M, 146) were present. The identity of the arsine was confirmed by its infrared spectrum.

PERFLUOROALKYL ARSENICALS

PART VII. SOME REACTIONS OF CHLOROBISTRIFLUOROMETHYLARSINE AND RELATED COMPOUNDS[1]

W. R. CULLEN

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received August 31, 1962

ABSTRACT

Chlorobistrifluoromethylarsine reacts with mercury at 20° to give tetrakistrifluoromethyldiarsine. The diarsine is also the major product when this reaction is carried out using trifluoroiodomethane as solvent. Iodobistrifluoromethylarsine, mercury, and trifluoroiodomethane, however, give tristrifluoromethylarsine in good yield. Dichlorotrifluoromethylarsine reacts similarly to give the compounds $(CF_3)_3As$, $(CF_3)_2AsCl$, and $((CF_3)_2As)_2$. The mechanism of reactions of this type is discussed.

Chlorobistrifluoromethylarsine and bistrifluoromethylarsine react at 100° to give tetrakistrifluoromethyldiarsine. Chlorodimethylarsine and bistrifluoromethylarsine react similarly to give the unsymmetrical diarsine $(CF_3)_2As—As(CH_3)_2$. The same diarsine is produced in low yield from chlorobistrifluoromethylarsine and dimethylarsine though in this reaction bistrifluoromethylarsine and other compounds are formed. These results are interpreted in terms of a series of equilibria involving a non-random addition of hydrogen chloride across the unsymmetrical As—As bond.

Dimethylarsine and hydrogen chloride react at low temperatures to give dimethylarsonium chloride. The compound decomposes reversably on warming. The thermal stability of bistrifluoromethylarsine and tetrakistrifluoromethyldiarsine is described.

DISCUSSION AND RESULTS

The reaction of alkyl- and aryl-iodoarsines with trifluoroiodomethane in the presence of mercury at 20° gives alkyl- and aryl-trifluoromethylarsines in good yield (1, 2). It has now been found that iodobistrifluoromethylarsine reacts similarly to give tristrifluoromethylarsine (62% yield), the other product of reaction being tetrakistrifluoromethyldiarsine. The diarsine is probably produced by the direct reaction of iodobistrifluoromethylarsine with mercury (3):

$$(CF_3)_2AsI + Hg + CF_3I \rightarrow (CF_3)_3As + HgI_2$$

$$2(CF_3)_2AsI + Hg \rightarrow (CF_3)_2As—As(CF_3)_2 + HgI_2.$$

Iododimethylarsine also reacts easily with mercury at 20°. However, no volatile products are obtained if the reaction tube is pumped out at 20°. Small amounts of tetramethyldiarsine can be obtained only if the reaction products are strongly heated. Tetramethyldiarsine interacts completely with hexafluorobutyne-2 and bromotrifluoroethylene at 20°; yet the butyne and ethylene are recovered quantitatively after being shaken with iododimethylarsine and mercury (4). These results indicate that no free diarsine is produced in the reaction of the iodoarsine with mercury and suggest that a diarsine mercuric iodide complex, probably $(CH_3)_2As—As(CH_3)_2 \cdot HgI_2$, is formed which liberates the diarsine in strong heating:

$$2(CH_3)_2AsI + Hg \rightarrow (CH_3)_2As—As\ (CH_3)_2 \cdot HgI_2 \rightarrow (CH_3)_2As—As(CH_3)_2 + HgI_2.$$

After some diarsine has been obtained in this way part of the solid reaction residue is sublimable in a vacuum. Analysis of this yellow sublimate indicates that it is probably a mixture of the diarsine complex and its decomposition products. It has been found that

[1]*Presented at the Second International Symposium on Fluorine Chemistry, Estes Park, Colorado, July, 1962.*

other iododialkylarsines interact with mercury to give diarsine complexes (5). The diarsine melts at 0–0.5°. The previously recorded melting point was −6° (6).

Chlorobistrifluoromethylarsine, mercury, and trifluoroiodomethane give only traces of tristrifluoromethylarsine. The main product in this reaction is the diarsine, which has been found to be produced quantitatively from the reaction of chlorobistrifluoromethylarsine and mercury:

$$2(CF_3)_2AsCl + Hg \rightarrow (CF_3)_2As—As(CF_3)_2 + HgCl_2.$$

A similar difference in reactivities has been found for the compounds $(CH_3)_2AsX$ (X = Cl or I) (1). Dichlorotrifluoromethylarsine reacts with mercury and trifluoroiodomethane to give chlorobistrifluoromethylarsine (36%), tristrifluoromethylarsine (32%), and tetrakistrifluoromethyldiarsine (8%). This result suggests that the reaction can go by at least two paths, one resulting in the replacement of two chlorine atoms to give tristrifluoromethylarsine and the other resulting in the replacement of one chlorine atom and the production of chlorobistrifluoromethylarsine and ultimately the diarsine:

$$CF_3AsCl_2 + 2CF_3I + Hg \rightarrow CF_3As(CF_3)_2$$

$$CF_3AsCl_2 + CF_3I + Hg \rightarrow (CF_3)_2AsCl \xrightarrow{Hg} (CF_3)_2As—As(CF_3)_2.$$

The first step seems necessary because of the low yield of tristrifluoromethylarsine obtained from chlorobistrifluoromethylarsine, mercury, and trifluoroiodomethane. This result together with the result that a much higher yield of tristrifluoromethylarsine is obtained from iodobistrifluoromethylarsine, mercury, and trifluoroiodomethane suggests that the source of the tristrifluoromethylarsine in experiments of this sort is not the diarsine, a conclusion which is substantiated by the result that tetrakistrifluoromethyldiarsine, mercury, and trifluoroiodomethane give only minor amounts (2%) of tristrifluoromethylarsine at 20°. The diarsine is, however, readily cleaved by trifluoroiodomethane at 75° (1):

$$(CF_3)_2As—As(CF_3)_2 + CF_3I \rightarrow (CF_3)_3As + IAs(CF_3)_2.$$

Thus it seems likely that these reactions involving halotrifluoromethylarsines, mercury, and trifluoroiodomethane proceed through intermediates of the type $(CF_3)_2AsHgX$:

$$(CF_3)_2AsX + Hg \rightarrow (CF_3)_2AsHgX \begin{cases} \xrightarrow{CF_3I} (CF_3)_2AsCF_3 \\ \xrightarrow[XAs(CF_3)_2]{} (CF_3)_2As—As(CF_3)_2 \end{cases}$$

When X = I, the intermediate is reactive enough to interact with the CF_3I, which in these reactions is in large excess. However, when X = Cl the less active intermediate can react easily only with the very active halobistrifluoromethylarsine.

In the reaction of dichlorotrifluoromethylarsine with mercury and trifluoroiodomethane no unchanged chloroarsine was recovered. The reaction products account for only 75% reaction of the starting material and the remaining 25% probably reacts directly with the mercury to give polymers of the type $(CF_3As)_x$. Such polymers appear to be formed from the reaction of diiodotrifluoromethylarsine and mercury (7).

Bistrifluoromethylarsine is reported to be unstable at 220°, decomposing according to (8)

$$3(CF_3)_2AsH \rightarrow (CF_3)_3As + 2As + 3CF_3H.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In the present investigation a more detailed study of the thermal stability of this compound has been made. The arsine is stable up to 165°, and only slight decomposition is found after 20 hours at 200°; fluoroform is liberated but no volatile solid is produced. The thermal stability of tetrakistrifluoromethyldiarsine has also been investigated. In the gas phase at 210° decomposition gives tristrifluoromethylarsine and a brown solid. On the basis of the diarsine recovered and the tristrifluoromethylarsine produced, the reaction seems to be best represented by the equation

$$3(CF_3)_2As—As(CF_3)_2 \rightarrow 4(CF_3)_3As + 2As.$$

Another possible reaction route is the following:

$$x(CF_3)_2As—As(CF_3)_2 \rightarrow x(CF_3)_3As + (CF_3As),$$

which would probably be favored by small reaction volumes. When the diarsine is heated in a small tube such that liquid phase is always present no reaction is detected at 150° and only slight decomposition to tristrifluoromethylarsine and an involatile black solid occurs at 180°. Decomposition in the small tube is faster at 220°, though the rate is slower than when the diarsine is heated in the gas phase. Thus, in a closed system, the thermal decomposition of both bistrifluoromethylarsine and tetrakistrifluoromethyldiarsine failed to give volatile polymers of the type $(CF_3As)_x$. Mahler and Burg report (9) that thermal decomposition of the corresponding phosphorus compounds yields the volatile polymers $(CF_3P)_4$ and $(CF_3P)_5$.

Dehn and Wilcox (10) have reported that the reaction of chlorodimethylarsine with dimethylarsine at 100° produces tetramethyldiarsine and hydrogen chloride. In the present investigation when this reaction was first repeated it was found that the diarsine is produced in low yield (25%) after 3 days at 100°; hydrogen is also produced, but no hydrogen chloride could be isolated by trap-to-trap distillation. This result suggested that either the diarsine was formed by thermal decomposition of dimethylarsine with elimination of hydrogen, or that the hydrogen was formed by reaction of hydrogen chloride with dimethylarsine giving chlorodimethylarsine and hydrogen. On checking both of these possibilities negative results were obtained. However, in the reaction of dimethylarsine with hydrogen chloride it was found that at low temperatures a compound is formed between the two reactants which prohibits their separation by trap-to-trap distillation. This compound, which can be formulated as dimethylarsonium chloride, sublimes in the vacuum system, melts at −46°, exists as a liquid above this temperature, and is completely dissociated in the vapor phase at 20°. This behavior is in marked contrast with the

$$(CH_3)_2AsH + HCl \rightleftharpoons (CH_3)_2AsH_2Cl$$

reaction of dimethylarsine with hydrogen bromide and iodide, where the onium compound appears to be formed but then decomposes to hydrogen and the halodimethylarsine (10).

$$(CH_3)_2AsH + HX \rightarrow (CH_3)_2AsH_2X \rightarrow (CH_3)_2AsX + H_2 \qquad (X = Br, I)$$

In a second reaction hydrogen chloride was identified, by means of its mass spectrum, as a reaction product of dimethylarsine and chlorodimethylarsine, so the main reaction appears to be

$$(CH_3)_2AsH + ClAs(CH_3)_2 \rightleftharpoons (CH_3)_2As—As(CH_3)_2 + HCl.$$

The reaction must be represented as an equilibrium since the diarsine reacts with hydrogen chloride at 20° to give dimethylarsine. The mechanism of the production of hydrogen is still in doubt.

For personal use only.

Chlorobistrifluoromethylarsine and bistrifluoromethylarsine react at 100° to give tetrakistrifluoromethyldiarsine in good yield. Minor amounts of chlorotrifluoromethane are produced which could arise from disproportionation of the chloroarsine, a reaction well established for iodobistrifluoromethylarsine (11). Again the main reaction is best represented as an equilibrium,

$$(CF_3)_2AsCl + (CF_3)_2AsH \rightleftharpoons (CF_3)_2As—As(CF_3)_2 + HCl,$$

since the reaction of the diarsine with hydrogen chloride in the presence of mercury gives a high yield of bistrifluoromethylarsine at 20° (12). This last reaction is probably described by the following equations:

$$(CF_3)_2As—As(CF_3)_2 + HCl \rightleftharpoons (CF_3)_2AsH + ClAs(CF_3)_2$$
$$2(CF_3)_2AsCl + Hg \rightarrow (CF_3)_2As—As(CF_3)_2 + HgCl_2,$$

the only function of the mercury being to displace the equilibrium and so produce more starting material.

The experimental observation that bistrifluoromethylarsine and hydrogen chloride can be separated must mean that any onium compound formed from these two reactants is less stable than that formed from dimethylarsine and hydrogen chloride. This result would be qualitatively expected, in view of the strong electron-withdrawing power of the trifluoromethyl group. The relative reactivities are possibly quantitatively measured by the first ionization potential of 9.0 ev for dimethylarsine and 10.9 ev for bistrifluoromethylarsine (13).

Bistrifluoromethylarsine and chlorodimethylarsine react at 100° to give hydrogen chloride. The reaction again seems to be an equilibrium, since if the hydrogen chloride is removed more is produced by the remaining reactants. The bistrifluoromethylarsine recovered corresponds well with the hydrogen chloride produced according to the equation

$$(CF_3)_2AsH + ClAs(CH_3)_2 \rightleftharpoons (CF_3)_2As—As(CH_3)_2 + HCl.$$

Thus the reaction almost undoubtedly produces the new unsymmetrical diarsine 1,1-dimethyl-2,2-bis(trifluoromethyl)diarsine, though it has not yet been possible to isolate and characterize this compound. Neither dimethylarsine nor tetrakistrifluoromethyldiarsine is produced so that the addition of hydrogen chloride to the As—As bond in the unsymmetrical diarsine seems to be orientated by the overall polarity of the molecule. The same unsymmetrical diarsine is produced by the reaction of dimethylarsine with chlorobistrifluoromethylarsine at 100°; other reaction products are hydrogen, bistrifluoromethylarsine, chlorodimethylarsine, tetramethylarsine, and probably hydrogen chloride. Minor amounts of chlorotrifluoromethane and silicon tetrafluoride are also produced. The formation of the main reaction products can be accounted for by the following reactions:

$$(CH_3)_2AsH + ClAs(CF_3)_2 \rightarrow (CH_3)_2As—As(CF_3)_2 + HCl \quad [1]$$
$$(CH_3)_2As—As(CF_3)_2 + HCl \rightleftharpoons (CH_3)_2AsCl + HAs(CF_3)_2 \quad [2]$$
$$(CH_3)_2AsCl + HAs(CH_3)_2 \rightleftharpoons (CH_3)_2As—As(CH_3)_2 + HCl. \quad [3]$$

Reactions [1] and [2] involve the formation of the unsymmetrical diarsine, which because of the polarity effect reacts with hydrogen chloride to give bistrifluoromethylarsine. This accounts for the absence of chlorobistrifluoromethylarsine and consequently of tetrakistrifluoromethyldiarsine (by reaction [4]) from the equilibrium mixture. Reaction [3] simply

$$(CF_3)_2AsH + ClAs(CF_3)_2 \rightleftharpoons (CF_3)_2As—As(CF_3)_2 + HCl \quad [4]$$

accounts for the production of tetramethyldiarsine.

Recently Grant and Burg (14) have synthesised, at low temperature, the unsymmetrical diphosphine 1,1-dimethyl-2,2-bis(trifluoromethyl)diphosphine by the reaction

$$(CF_3)_2PCl + HP(CH_3)_2 \rightarrow (CF_3)_2P—P(CH_3)_2$$

and find that at higher temperatures this reaction gives $(CF_3)_2PH$. The unsymmetrical diphosphine is also cleaved by hydrogen chloride to give $(CF_3)_2PH$. These results are comparable to those described above, though Grant and Burg suggest that the production of bistrifluoromethylphosphine could be due to attack by the hydrogen chloride on the more basic phosphorus atom followed by a rearrangement of the products:

$$(CH_3)_2P—P(CF_3)_2 + HCl \rightarrow (CH_3)_2PH + ClP(CF_3)_2$$
$$(CH_3)_2PH + ClP(CF_3)_2 \rightarrow (CH_3)_2PCl + HP(CF_3)_2.$$

A similar explanation could be used to account for the results of the present investigation; however, the idea that the overall polarity of the molecular influences the direction of addition seems more attractive.

EXPERIMENTAL

Apparatus and Technique

The methods used in the present investigation have been described in earlier parts of this series. All starting materials were prepared by methods described in the literature.

Reaction of Chlorobistrifluoromethylarsine with Mercury

When chlorobistrifluoromethylarsine (1.855 g) was shaken with 30 g of mercury for 24 hours at 20°, 1.578 g (99% yield) of tetrakistrifluoromethyldiarsine was obtained (found: M, 417; calc.: M, 426). The identity of the diarsine was confirmed by infrared examination. A single distillation through a trap at −46° brought the molecular weight up to the theoretical value of 426.

Reaction of Iodobistrifluoromethylarsine with Trifluoroiodomethane in the Presence of Mercury

The iodoarsine (1.568 g), mercury (80 g), and trifluoroiodomethane (13.0 g) when shaken at 20° for 6 days gave trifluoroiodomethane (12.2 g), tristrifluoromethylarsine (0.831 g, 62% yield), and tetrakistrifluoromethyldiarsine (0.308 g, 32% yield). The fractions were separated by trap-to-trap distillation and identified by their infrared spectra.

Reaction of Chlorobistrifluoromethylarsine with Trifluoroiodomethane in the Presence of Mercury

The arsine (0.714 g), mercury (64 g), and trifluoroiodomethane (12.7 g) were shaken at 20° for 6 days. Trap-to-trap distillation gave tetrakistrifluoromethyldiarsine (0.455 g; 75% yield; M, 414) and a small fraction which condensed at −96°. This fraction (M, 257) on infrared examination was found to be largely unreacted chlorobistrifluoromethylarsine (calc.: M, 249) together with a trace of tristrifluoromethylarsine. The fraction was shaken with excess mercury for 2 days at 20° and only a trace of tristrifluoromethylarsine could be isolated from the tetrakistrifluoromethyldiarsine produced by reaction of the chloroarsine.

Reaction of Dichlorotrifluoromethylarsine with Trifluoroiodomethane in the Presence of Mercury

The arsine (0.942 g), trifluoroiodomethane (17.672 g), and mercury (60 g) were shaken at 20° for 4 days. The following fractions were obtained: 16.621 g of trifluoroiodomethane; 0.391 g (32% yield) of tristrifluoromethylarsine (found: M, 280; calc.: M, 282); chlorobistrifluoromethylarsine (0.396 g); and slightly impure tetrakistrifluoromethyldiarsine (0.079 g) identified by its low vapor pressure at 20° and its infrared spectrum. Because of the similarity of the boiling points of tristrifluoromethylarsine and chlorobistrifluoromethylarsine these were not separated by trap-to-trap distillation but were separated by reacting the fraction which condensed at −96° with excess mercury. This converted the chlorobistrifluoromethylarsine (whose presence in the −96° fraction was indicated by the infrared spectrum of that fraction) into tetrakistrifluoromethyldiarsine (0.352 g; M, 432), which was easily separated from the unchanged tristrifluoromethylarsine. The identity of these fractions was confirmed by their infrared spectra.

Reaction of Tetrakistrifluoromethyldiarsine with Trifluoroiodomethane in the Presence of Mercury

The diarsine (1.563 g), mercury (100 g), and trifluoroiodomethane (12.5 g) were shaken at 20° for 6 days. A small amount of mercuric iodide was produced. Trap-to-trap distillation and infrared examination of the fractions isolated showed that only 0.035 g of tristrifluoromethylarsine had been produced (2% yield); 1.506 g of the diarsine was recovered.

Reaction of Chlorobistrifluoromethylarsine with Bistrifluoromethylarsine

The chloroarsine (0.274 g) and bistrifluoromethylarsine (0.203 g) when heated to 100° for 16 hours gave

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

0.023 g of hydrogen chloride (M, 39.8), which on the evidence of its infrared spectrum contained a little chlorotrifluoromethane. Tetrakistrifluoromethyldiarsine (0.205 g, 51% yield) was also isolated and identified by its infrared spectrum and molecular weight (M, 426). Infrared examination of the fraction of intermediate volatility showed that this was mainly unchanged starting materials.

Thermal Stability of Tetrakistrifluoromethyldiarsine

The diarsine (0.597 g) was heated in the gas phase to 210° for 60 hours. After 12 hours at this temperature a brown film had formed on the walls of the reaction tube. Trap-to-trap distillation gave tristrifluoromethylarsine (0.451 g; M, 285), and the remaining liquid (0.065 g; M, 373) was identified as being mainly unreacted diarsine containing a little tristrifluoromethylarsine. In a second experiment the diarsine (0.564 g) was heated in a small tube (5 ml) for 4 days at 150°. The molecular weight and vapor pressure of the sample were unchanged after this treatment. After 48 hours at 180° a small amount of a black solid had formed and after a further 48 hours at this temperature 0.067 g of tristrifluoromethylarsine and 0.445 g of mainly unreacted diarsine (M, 380) were obtained. The diarsine fraction was heated to 220° for 48 hours. More black solid was formed and tristrifluoromethylarsine (0.174 g; M, 283) was isolated.

Thermal Stability of Bistrifluoromethylarsine

A sample of the arsine (0.210 g) showed no signs of decomposition after 3 months at 20° in a sealed tube. The arsine was not affected by heating at 100° for 3 weeks, or at 165° for 6 hours. After 20 hours at 200° slight decomposition with the formation of a trace of fluoroform was detected. The extent of reaction was checked in all cases by trap-to-trap distillation and infrared examination of the fractions isolated.

Reaction of Bistrifluoromethylarsine with Chlorodimethylarsine

When 0.782 g of bistrifluoromethylarsine and 0.512 g of chlorodimethylarsine were heated to 100° for 24 hours, 0.057 g of hydrogen chloride (M, 36.6) was produced. The hydrogen chloride was removed and when the rest of the reaction mixture was heated to 100° for 1 week a further 0.231 g of hydrogen chloride (M, 37.0) was formed. The infrared spectrum of this fraction showed the absence of any compounds containing C—F groups. The hydrogen chloride was again removed and the reaction mixture was heated to 100° for another week to give 0.011 g of hydrogen chloride. The total yield of hydrogen chloride was thus 69%. Trap-to-trap distillation recovered 0.210 g of bistrifluoromethylarsine (73% reaction), which did not condense at −78° and which was identified by its infrared spectrum. No other compounds were detected in this fraction. The remaining fraction, the least volatile one, on the evidence of its infrared spectrum contained chlorodimethylarsine and a trace of bistrifluoromethylarsine. No bands attributable to tetrakistrifluoromethyldiarsine were observed. The spectrum in the C—F stretching region included weak bands in the same positions as are reported below for the involatile product obtained from dimethylarsine and chlorobistrifluoromethylarsine. The fraction was rapidly oxidized by air.

Reaction of Dimethylarsine with Chlorobistrifluoromethylarsine

When dimethylarsine (1.442 g) and the chloroarsine (0.879 g) were heated at 100° for 3 days a small amount of hydrogen was produced which was identified by its mass spectrum. Trap-to-trap distillation together with infrared examination of the fractions isolated gave the following: −196° fraction, 0.146 g of a mixture of chlorotrifluoromethane and silicon tetrafluoride (M, 101); −23° fraction, 0.072 g of tetramethyldiarsine, m.p. −2–1°; and intermediate fractions which contained bistrifluoromethylarsine, chlorodimethylarsine, and a substance whose vapor phase infrared spectrum in the C—F region corresponded with that obtained from the involatile fraction isolated in the preceding experiment with bands at 1171, 1150, and 1100 cm^{-1}. No chlorobistrifluoromethylarsine was detected.

Reaction of Iododimethylarsine with Mercury

The iodoarsine (18 g) and mercury (200 g) were shaken for 5 days at 20°. A yellow solid was produced and on strong heating 1.374 g of a colorless involatile liquid was obtained. The bulk of the mercury was removed and the remaining solid was sublimed in a vacuum to give a yellow solid, insoluble in all common organic solvents. Anal. Found: C, 2.58; H, 0.55; As, 17.0%. Mercury and iodine were also present. The involatile liquid was identified as tetramethyldiarsine by its melting point of −1–0° (lit. value, −6° (6)) and by its reactions with excess iodomethane (7.75 g). This reaction gave pale yellow crystals at 0° and when the reaction tube was heated to 100° for 1 hour a black solid was obtained. The excess iodomethane was removed and the resulting solid was extracted with acetone, leaving 1.7 g of colorless crystals which were identified as tetramethylarsonium iodide, m.p. 325° (decomp.) (lit. value, 328° (15)), mercuriiodide, m.p. 183° (lit. value, 184° (16)). The acetone solution was evaporated *in vacuo* to give violet crystals of tetramethylarsonium triiodide, m.p. 133° (lit. value, 133° (15)). The yield of tetramethyldiarsine was 17%.

When the reaction was carried out in acetic acid as solvent the reaction followed substantially the same path. The acetic acid was recovered quantitatively, and tetramethyldiarsine was obtained (10% yield) only by strongly heating the reaction tube. The diarsine was identified as above.

Reaction of Chlorodimethylarsine with Dimethylarsine

Chlorodimethylarsine (0.679 g) and dimethylarsine (0.751 g) were heated to 100° for 3 days. Hydrogen was produced (identified by its mass spectrum) and trap-to-trap distillation failed to isolate any hydrogen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

chloride. The unreacted dimethylarsine was separated only with difficulty from the other fractions. Tetramethyldiarsine (0.3 g; 26% yield) was isolated as a fraction which condensed at −23° and was identified by its melting point of 0–0.5°. In a second experiment the chloroarsine (2.162) and excess dimethylarsine (3.154 g) were heated to 100° for 1 day. Hydrogen was again produced and tetramethyldiarsine (0.7 g; 22% yield; m.p., −1–0°) was isolated as above. The more volatile fractions were allowed to expand into a large volume and a mass spectrum of the vapor showed the presence of hydrogen chloride.

Reaction of Tetramethyldiarsine with Hydrogen Chloride

The diarsine (0.114 g) and hydrogen chloride (0.071 g) were left at 20° for 2 days. Trap-to-trap distillation followed by infrared examination of the fractions isolated showed the presence of dimethylarsine.

Thermal Stability of Dimethylarsine

The arsine (1.195 g) was unchanged after 2 days at 100°.

Reaction of Dimethylarsine with Hydrogen Chloride

The arsine (1.195 g) and hydrogen chloride (0.440 g) were heated to 104° for 2 days. No hydrogen was produced. Trap-to-trap distillation isolated only 0.005 g of hydrogen chloride. The remaining reaction products sublimed in the vacuum system and condensed at −130°. The molecular weight of this fraction was 68 at 20° (calc. for a 1:1 mixture of $(CH_3)_2AsH$ and HCl: M, 71). The vapor pressure of the solid was 0 mm at −130°, 1 mm at −96°, 3 mm at −78°. The solid melted at −46° under a pressure of 81 mm. The substance seemed to be stable as a liquid at temperatures above −46°. The vapor pressure values were reproducible on warming and cooling the sample.

THE ZINC CHLORIDE CATALYZED MIGRATION OF HALOGEN IN THE CLAISEN REARRANGEMENT[1]

E. PIERS AND R. K. BROWN
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received September 17, 1962

ABSTRACT

The zinc chloride catalyzed rearrangement of allyl 2,6-dichlorophenyl ether in nitrobenzene solution gave a good yield of 2-allyl-4,6-dichlorophenol along with some 2,6-dichlorophenol and 2-methyl-5,7-dichlorocoumaran. The coumaran increased at the expense of the 2-allyl-4,6-dichlorophenol. This is in contrast to the thermal rearrangement of this ether, which gave mainly 4-allyl-2,6-dichlorophenol along with smaller amounts of 2-allyl-6-chlorophenol and 2-allyl-4,6-dichlorophenol.

INTRODUCTION

In a paper published some time ago, Carlin and Fisher (1) pointed out the formal analogy between the mechanism proposed by Robinson and Robinson (2, 3) for the Fischer indole synthesis and that established to explain the Claisen rearrangement (4–8). Furthermore, Carlin and Fisher (1) found that five 2,6-dichlorophenylhydrazones, subjected to the conditions of the Fischer indole synthesis in the presence of zinc chloride, gave the corresponding 5,7-dichloroindoles, products which resulted from the migration of one of the chlorine atoms. The migration is believed to be due to the formation of a dienonimine intermediate which undergoes a zinc halide promoted allylic shift of the halogen atom (9, 10). These conversions appear to have no recorded analogy among the examples of the Claisen rearrangement, although Carlin and Fisher (1) suggested that they might indeed occur but to such a small extent as to have escaped detection.

It was felt that, since zinc chloride appeared to be necessary for the halogen shift in the indole synthesis (1, 9, 10), the application of this Lewis acid might catalyze the Claisen rearrangement as well as bring about a similar halogen migration. Accordingly experiments were performed to determine the effect of zinc chloride on the rearrangement of allyl 2,6-dichlorophenyl ether.

Examination of the literature has shown that a great deal of work has been published concerning the thermal rearrangement of allyl aryl ethers (4–8) but only a small number of investigations have been concerned with the effect of acidic reagents on this reaction. That the Claisen rearrangement might be catalyzed by acid was first shown by Tarbell and Kincaid. A kinetic study of the rearrangement of allyl 2,6-dimethylphenyl ether in diphenyl ether revealed that the addition of 1% and of 2% acetic acid increased the rate 28% and 42% respectively (11).

Later observations disclosed that the rearrangement of allyl aryl ethers occurred at a much lower temperature, when Lewis acids were present, than that required for thermal reaction. For example, treatment of the allyl ether of guaiacol with $BF_3.2CH_3CO_2H$ at 68° gave 38% of eugenol as well as some guaiacol, 6-allylguaiacol, and the allyl ether of allylguaiacol or eugenol (12). Also, allyl phenyl ether at −80° was converted by boron trichloride exclusively to *o*-allylphenol (13). Furthermore, a recent study (14) showed that boron trichloride effected the intramolecular rearrangement in high yields (90–98%)

[1]*Taken from the thesis of E. Piers to be submitted to the Graduate School of the University of Alberta in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

For personal use only.

of allyl phenyl ether to 2-allylphenol, allyl *p*-tolyl ether to 2-allyl-4-methylphenol, allyl 2,6-dimethylphenyl ether to a mixture of 2,6-dimethyl-3-allylphenol and 2,6-dimethyl-4-allylphenol, and also allyl mesityl ether to 3-allylmesitol.

RESULTS AND DISCUSSION

In the present work, heating a mixture of zinc chloride and allyl 2,6-dichlorophenyl ether (2:1) in nitrobenzene revealed that this Lewis acid also had a catalytic effect on the Claisen rearrangement since the reaction could be carried out to completion at 145° over a 24-hour period in the presence of zinc chloride whereas in its absence, under otherwise identical conditions, about 40% of the original ether was recovered (compare expt. 2, Table I, and expt. 5, Table II). Furthermore, as in the case of the Fisher cyclization of

TABLE I

The zinc chloride catalyzed rearrangement of allyl 2,6-dichlorophenyl ether in nitrobenzene

Expt. No.	Reaction conditions	Composition of reaction mixture* (%)

*No 2-allyl-6-chlorophenol was detected.

2,6-dichlorophenylhydrazones (1), halogen migration occurred here also since the zinc chloride catalyzed rearrangement of allyl 2,6-dichlorophenyl ether in nitrobenzene at 140–160° gave a mixture of 2,6-dichlorophenol (4–5%), 2-allyl-4,6-dichlorophenol (88–91%), and 2-methyl-5,7-dichlorocoumaran (4–8%). Lower temperatures required longer reaction times and gave, as well, unreacted starting material. Higher temperatures reduced the time necessary for complete reaction of the original ether but produced more of the cleavage product, 2,6-dichlorophenol, and of the coumaran (expts. 1–4, Table I). The coumaran increased at the expense of the 2-allyl-4,6-dichlorophenol as reaction time was extended, but the amount of cleavage product remained essentially enchanged (expt. 4, Table I).

Products were analyzed by V.P.C. and the retention times compared with those of authentic samples. Careful fractionation of the reaction mixture from experiment 4, Table I, permitted the isolation of all three products indicated. Elemental analysis and comparison of n.m.r. and infrared spectra proved the coumaran to be identical with the compound obtained by ring closure of 2-allyl-4,6-dichlorophenol according to Claisen's general method (15). Nuclear magnetic resonance analysis of this compound was in agreement with the structure designated as 2-methyl-5,7-dichlorocoumaran.

Repeated extraction of the phenolic products from an ethereal solution of the reaction mixture with Claisen's alkali (16), a procedure employed in a recent report concerning the Claisen rearrangement (17) although generally Claisen alkali extractions are made from hydrocarbon solvents (18), still left a considerable portion of the 2-allyl-4,6-dichloro-

†It took 3 hours under these conditions for all the original ether to disappear, whereas expt. 4, Table I, shows that with $ZnCl_2$ present, all the ether had disappeared in 1 hour.

phenol in the neutral fraction. In fact, synthetic mixtures of 2-allyl-4,6-dichlorophenol, diethyl ether, and diphenyl ether extracted three times with Claisen's alkali also gave incomplete separation of the phenol, although phenol extraction from this solvent was better than that from the nitrobenzene–ether solvent. Accordingly, in the present work, to avoid such loss of phenol, alkaline treatment was omitted and analyses were performed, quite satisfactorily, directly on samples of the total reaction mixture.

Thermal rearrangement of allyl 2,6-dichlorophenyl ether, either as the pure liquid or in nitrobenzene or diphenyl ether solution, yielded a mixture of products somewhat different from that obtained from the zinc chloride catalyzed reaction (Table II). The main product of the thermal reaction, 4-allyl-2,6-dichlorophenol, was accompanied by much smaller amounts of 2-allyl-6-chlorophenol and 2-allyl-4,6-dichlorophenol, but *none* of the 2,6-dichlorophenol or the coumaran (expts. 1 and 3, Table II). The formation of the monohalogenated phenol agrees with similar observations by previous workers (15, 19). For example, Tarbell and Wilson (19) have found that heating pure allyl 2,6-dichlorophenyl ether at 193–200° gave a mixture of 2-allyl-6-chlorophenol and 4-allyl-2,6-dichlorophenol. Our repetition of this experiment disclosed that, in addition, a small amount (2%) of 2-allyl-4,6-dichlorophenol was formed (expt. 1, Table II). In nitrobenzene solvent, the yield of both the 2-allyl-4,6-dichlorophenol and 2-allyl-6-chlorophenol increased. The addition of lithium chloride to the nitrobenzene solution further enhanced both the amount of halogen migration product and halogen elimination product, although no catalysis of the decomposition of the original ether appeared to occur. In the solvent

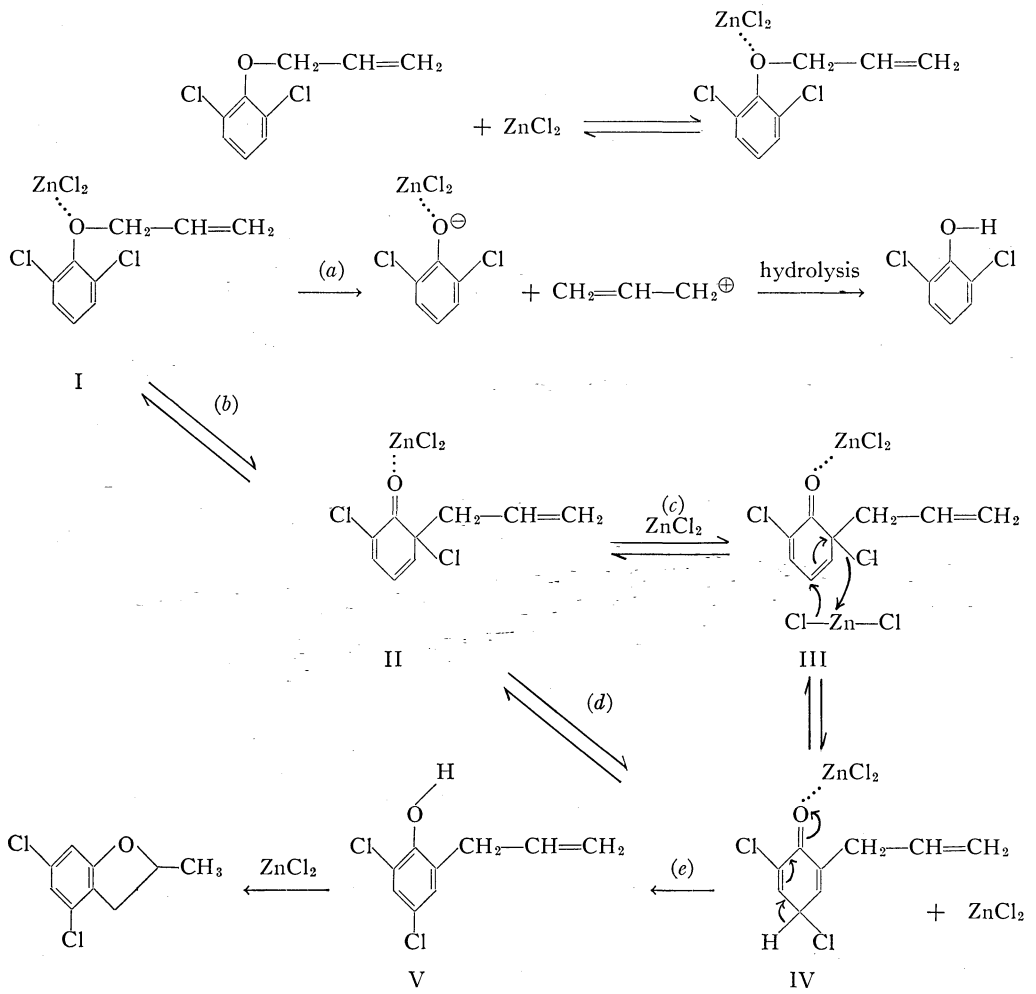
For personal use only.

diphenyl ether only half as much of the monochlorophenol was obtained and *none of the product of halogen migration* (expt. 2, Table II). When a naphthalene was employed as solvent results were very much similar to those found with diphenyl ether. However, in this case difficulty was experienced in obtaining clear separations by V.P.C. of the solvent naphthalene and 2-allyl-6-chlorophenol, hence the results are not recorded in Table II.

The above facts indicate that both halogen elimination and halogen migration are assisted by a polar reaction medium.

The formation of the products from the zinc chloride catalyzed reaction can be explained by the following scheme.



The zinc chloride – allyl 2,6-dichlorophenyl ether complex (I) cleaved in the usual manner via route *a* under the influence of the Lewis acid (20) to form 2,6-dichlorophenol. Simultaneously there occurred a preferential intramolecular rearrangement of I by route *b* to form the intermediate dienone II (7). The dienone then underwent a migration of halogen via an allylic shift, to a small extent by route *d*, but chiefly through the agency of a zinc chloride bridge, III (route *c*). Aromatization of IV gave the 2-allyl-4,6-dichloro-

halogen by a zinc chloride bridge is favored.

EXPERIMENTAL

Allyl 2,6-Dichlorophenyl Ether

To a solution of 0.5 mole of 2,6-dichlorophenol (21) in 200 ml of water containing 30 g of sodium hydroxide was added 300 ml of acetone. Allyl bromide (0.7 mole) was added and the solution was refluxed with stirring for 3 hours. The material was then poured into 700 ml of ice water, the resulting mixture extracted twice with ether, and the combined ether extracts dried over anhydrous magnesium sulphate. Removal of the ether afforded an oil which upon distillation under reduced pressure through a short Vigreux column gave 91 g (90%) of allyl 2,6-dichlorophenyl ether. B.p. 69–70° at 1 mm. Lit. b.p. 89–90° at 2 mm (19).

Zinc Chloride Catalyzed Rearrangement of Allyl 2,6-Dichlorophenyl Ether. General Procedure

Anhydrous powdered zinc chloride (41 g, 0.3 mole) was stirred into 150 ml of dry ether. While the mixture was gently heated to permit evaporation of the ether, redistilled nitrobenzene (123 g, 1 mole) was slowly added. After the resulting solution was heated to the desired temperature for the rearrangement, allyl 2,6-dichlorophenyl ether (30 g, 0.15 mole) was slowly added. The mixture was then stirred and heated under an atmosphere of purified, dry nitrogen for the specified time. The cooled material was then poured into a mixture of water and ether. After filtration, the ether layer was separated and washed several times with water, then dried ($MgSO_4$). Removal of the ether gave the mixture of reaction products, which was analyzed directly by V.P.C.

2-Methyl-5,7-dichlorocoumaran

The general procedure reported in the literature (15) was employed to obtain this compound. From 18.3 g (0.09 mole) of 2-allyl-4,6-dichlorophenol there was obtained 8.8 g (48%) of 2-methyl-5,7-dichlorocoumaran, b.p. 81° at 0.7 mm. Anal. Calc. for $C_9H_8Cl_2O$: C, 53.23; H, 3.97; Cl, 34.92%. Found: C, 52.91; H, 4.08; Cl, 35.20%.

Gas Chromatography

A Burrell Model K-2 Kromo-Tog, with helium as the carrier gas, was used for all analyses. A 2-m column, packed with 22% Apiezon L adsorbed on Gas Chrom P (60–80 mesh) afforded good separation of components into clearly resolved peaks. The paper areas of these peaks were measured by means of a planimeter. An analysis of carefully weighed authentic mixtures of the reaction products showed that these paper areas could be used as a direct measure of molar compositions of the reaction mixtures.

THE MERCURY-PHOTOSENSITIZED DECOMPOSITION OF PROPANE A MASS SPECTROMETRIC STUDY AT LOW PRESSURES

PART I

P. KEBARLE AND M. AVRAHAMI[1]
Chemistry Department, University of Alberta, Edmonton, Alberta
Received June 26, 1962

ABSTRACT

It is found that the primary decomposition involves the cleavage of a C—H bond. Both primary and secondary hydrogen atoms are lost. The relative rates of the two processes could not be determined accurately but are estimated to be approximately 1:1. It is found that at least 70% of the secondary reactions involves the interaction of hydrogen atom with a propyl radical. The main reaction is the re-formation of propane. An important disproportionation of hydrogen atoms with propyl radicals leading to propylene is shown to occur. The atomic cracking reaction $H + C_3H_7 \rightarrow C_3H_8^* \rightarrow C_2H_5 + CH_3$ is also observed. Using mixtures of C_3H_8 and C_3D_8 the relative cracking rate of *n*-propyl- to isopropyl-derived propane is determined to be equal to 5. This result is compared with theoretical predictions.

INTRODUCTION

The mercury-photosensitized decomposition of propane has been studied by several investigators (1–5). The results from previous work have established the main features of the reaction. The primary decomposition leads to isopropyl radicals and hydrogen atoms (1). At high propane pressures the secondary reactions are: abstraction of hydrogen from the unreacted propane by the hydrogen atom and recombination–disproportionation of the propyl radicals. This simple scheme leads to an expected quantum yield for hydrogen formation equal to 1. The experimentally observed values are considerably lower but it has been pointed out by Back (5) that hydrogen atoms are lost by addition to the propylene formed by the disproportionation of the propyl radicals.

When the mercury-photosensitized decomposition of propane is studied at low pressures a new secondary reaction is found to occur. If the recombination product of propyl + H is not stabilized by collisions it decomposes to ethyl and methyl free radicals (2). The recombinations of the radicals produced by this "atomic cracking" lead to butane, ethane, and methane.

The present mass spectrometric investigation developed from an interest in the atomic cracking reaction and its suppression by the addition of inert gas (He). In the course of this work, it was discovered that in addition to the known primary decomposition to isopropyl and H there occurs also an equally important split leading to *n*-propyl. The secondary reactions also involved some new features. These results together with some findings on the atomic cracking reaction are described in the first paper.

For the elucidation of some of the secondary reactions, it was convenient to use deuterated propanes. It was found that the primary decomposition of the various isotopic propanes showed some interesting and important differences. The results from these studies are described in the subsequent paper.

EXPERIMENTAL

The apparatus used is shown in Fig. 1. It consists of a flow reaction system coupled to a mass spectrometer. The original design of such a system is due to Lossing (6). The modifications incorporated in the

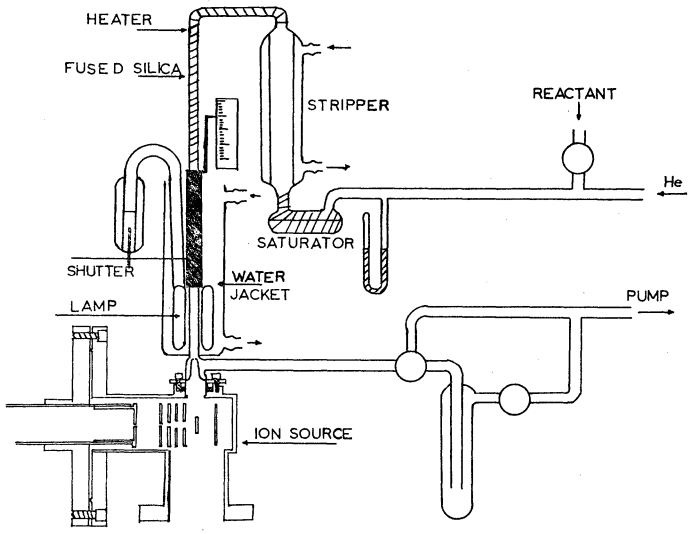

FIG. 1. Apparatus. Flow system for mercury-photosensitized decomposition attached to mass spectrometer.

present apparatus have been described elsewhere (7). For this reason, only the features pertinent to the work to be described will be mentioned. Propane is added to the carrier gas (He). The mixture is saturated with mercury vapor at 52° C in the saturator and stripper. The reaction zone is kept at 55° C. The length of the reaction zone, corresponding approximately to the length of the annular Hg resonance lamp, is close to 3.5 cm. For the flow velocity used, this results in a contact time of approximately 1.5 milliseconds. A sampling pinhole is located immediately below the reaction zone. A small portion of the reaction stream leaks through it into the mass spectrometer ion source. The predominant part of the reaction stream is either pumped out directly or passed through an efficient trap, where the condensables at liquid nitrogen temperature are collected for subsequent gas chromatographic separation. The pressure of the carrier gas was 10 mm Hg unless otherwise stated. The pressure of propane was 5 μ. The intensity of unreversed 2537 radiation has been estimated (6) in excess of 10^{-5} einsteins.

Analysis of the reaction mixture emerging from the reaction zone can be obtained directly by the mass spectrometer. With this method one may detect, in addition to the stable reaction products, the presence of free radicals. For positive detection, the radical concentration in the reaction stream should be more than 0.05 μ. The detection limit for the stable reaction products depends on the nature of the compound and the composition of the mixture. For an "average" compound the concentration should be not much less than one volume percent. For a substrate pressure of 5 μ this corresponds also to 0.05 μ. A much higher analytical sensitivity for the stable reaction products can be obtained through collection of the reaction products in the liquid nitrogen trap and subsequent gas chromatographic separation. The fractions separated by gas chromatography could be reintroduced into the mass spectrometer for analysis. In order to check the reliability of the freezing-out technique, control runs were made by using a synthetic mixture of composition similar to that of the reaction mixture. The analytical results showed that the recovery was in the average about 90%. The light reaction products ethane and ethylene were recovered with the even lower efficiency of 60–70%. The reason for this low recovery of the light products is specific to the reaction conditions of the system. Since one works at a very low propane pressure, the partial pressures of the products ethane and ethylene are of the same order or less than their saturation vapor pressures at the temperature of liquid nitrogen. Although appropriate corrections were applied to the results for ethane and ethylene, analytical results for these compounds cannot be considered very accurate.

Materials Used

The light propane (Philips research grade) was checked by gas chromatography for trace impurities. The heavy propane C_3D_8 (Merck and Dohme) was checked by mass spectrometry for completeness of deuterium substitution. It was found that it contained 6% of the lighter isotope C_3D_7H. Corrections to the analytical results for the presence of this isotope were made.

Mass Spectrometric Analysis of Deuteroisomers

Since spectral standards were not available for the deuteroisomers one had to rely mainly on the parent (molecular) peaks. This method of analysis can be employed if the parent peak is quite isolated, i.e. if there are no fragment peaks due to loss of one or a few hydrogen, correspondingly deuterium atoms, which would overlap with parent peaks of lighter deuteroisomers. This is the case with the *n*-pentane and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

three hexanes, and their analyses were obtained in this manner. The method depends very much on the purity of the samples, and for the hexanes and the *n*-pentane great care was taken with the gas chromatographic purification. Fragment peaks in the mass spectra were only checked for consistency with the composition predicted by the parent peaks and indication of impurities.

The propylenes and other olefins were analyzed at low electron energies where only the parent peaks appear. These analyses are the most accurate.

The analytical procedure did not give reproducible results for the *n*-butanes. Only some very tentative results could be obtained for the isobutane due to fragment peak interference.

RESULTS AND DISCUSSION

a. Specific Conditions of the Reaction System

The low pressure of the substance decomposed and the relatively high light intensity result in a radical to substrate ratio which is very much higher than that in conventional systems. Under these conditions radical–radical or excited mercury – radical reactions have been shown (6, 8, 9) to be the only important secondary processes inside the reactor. In the experiments where downstream collection was employed, downstream reactions must be considered. Evidence is given in the subsequent discussion that radical molecule reactions are unimportant also downstream. Disproportionation and recombination of the radicals emerging from the reactor should be the main reactions occurring before collection. A more detailed analysis of the situation (7) has shown that such downstream reactions cannot add more than several percent to the stable products emerging from the reactor. This is further verified by experiments described in Section *b* in which the lamp was moved with respect to the mass spectrometer sampling leak.

In view of this the discrepancy between the propylene measured with the mass spectrometer (5%) and the collection technique (3.5%) (Table I) should not be due to downstream reactions but probably to some deficiency in the analytical technique.

b. Primary and Secondary Reactions in the Decomposition of Propane

The products from the decomposition of propane are given in Table I. Only propylene, hydrogen, and methane were determined directly with the mass spectrometer. The remaining compounds were analyzed with the collection technique described in the experimental part. The propane decomposition which was measured directly with the mass spectrometer was approximately 100 per mille of the initial propane. Thus the concentrations given in Table I are in per mille of the initial propane and in percentage of the propane decomposed.

The minor products are shown in Table I in two different columns. The first group includes: ethane, *n*-butane and isobutane, *n*-pentane and isopentane, and the three hexanes 2,3-dimethylbutane, 2-methylpentane, and *n*-hexane. Considering the importance of radical–radical reactions mentioned in the preceding section we can interpret the formation of these products as due to the recombination reactions of methyl, ethyl, *n*-propyl, and isopropyl radicals. The mentioned products correspond exactly to the straight and cross recombination products of these radicals. The following reaction scheme may now be considered:

$$C_3H_8 + Hg^* \rightarrow n\text{-}C_3H_7 + H + Hg \qquad [1a]$$

$$\rightarrow \text{iso-}C_3H_7 + H + Hg \qquad [1b]$$

$$C_3H_7 + H \rightarrow C_3H_8^* \qquad [2]$$

$$C_3H_8^* + M \rightarrow C_3H_8 \qquad [3]$$

$$C_3H_8^* \rightarrow CH_3 + C_2H_5 \qquad [4]$$

$$C_2H_5 + H \rightarrow C_2H_6^* \rightarrow 2CH_3 \qquad [5]$$

$$H + CH_3 + C_2H_5 + C_3H_7 \rightarrow \text{recombination and disproportionation products.}$$

*From direct mass spectrometric determination.

The most direct confirmation for the reactions given in the reaction scheme comes from the results of the decomposition of mixtures of C_3H_8 and C_3D_8. In these runs mixtures of C_3H_8 and C_3D_8 in a concentration ratio 1:1 were decomposed. The reaction products after separation by gas chromatography were analyzed for isotopic composition with the mass spectrometer. The results from such runs are shown in Tables II–IV. The hexanes should result from recombination of propyl radicals originating from the primary decomposition. Therefore the hexanes should consist exclusively of the deuteroisomers $(C_3H_7)_2$, $C_3H_7 \cdot C_3D_7$, and $(C_3D_7)_2$. It can be seen in Table II that this is indeed the case. The

TABLE II

*The gas chromatographic separation of the two hexanes was not complete so that they were collected and analyzed together.

absence of deuteroisomers like $C_3H_6D \cdot C_3H_7$ shows that no significant part of the C_3H_7 radicals is formed by the addition of D (and by analogy, of H) to propylene, as is observed in the high-pressure decomposition of propane.[2] The ratio of the deuteroisomers $(C_3H_7)_2$:$C_3H_7C_3D_7$:$(C_3D_7)_2$ is not 1:2:1 as may have been expected on basis of an identical behavior of the C_3H_8 and C_3D_8. Instead the ratios are close to 4:4:1. Assuming equal behavior on recombination this means that the concentration ratio C_3H_7:C_3D_7 was close to 2. It will be shown in the succeeding paper, which deals specifically with the various propane deuteroisomers, that the difference of steady-state radical concentrations must be caused by different rates in the primary decomposition of the propane-H_8 and propane-D_8.

[2]*The absence of addition should also mean that there is no significant hydrogen abstraction from the propane since the addition competes successfully with the abstraction even at lower propylene to propane concentration ratios (5).*

For personal use only.

The ethyl and methyl radicals are produced by the "atomic cracking" reactions [4] and [5]. The isobutane should then result from the recombination of methyl with isopropyl radicals, the *n*-pentane and isopentane from the recombination of ethyl with *n*-propyl and isopropyl radicals. Since the ethyls and methyls result from a cracking reaction the C_3H_8–C_3D_8 mixture should produce the following ethyl and methyl radical isomers: C_2H_5, C_2H_4D, C_2D_4H, C_2D_5, and all four methyl isomers. These recombine with C_3H_7 and C_3D_7. It can be seen that the experimentally measured butanes and pentanes (Table III and IV) consist of the isomers required by the scheme. Moreover, since a ratio C_3H_7:C_3D_7 = 2.2 was found in the hexanes, essentially the same ratio should be found in corresponding isomers in the butanes and pentanes. The ratios given in the tables are in agreement with this requirement. The actual numerical results for the composition of the deuteropentanes will be used later, in Section *c*, in an attempt to obtain some details on the cracking reaction.

The products of the propane decomposition given in Table I include a group of unsaturated compounds: allene, butene-1, pentene-1, hexene-1, and 4-methylpentene-1. These products are present in relatively small amounts, and are set apart in Table I because they originate from the mercury-photosensitized decomposition of propylene—the major hydrocarbon product of the propane decomposition. The mercury-photosensitized decomposition of propylene at low pressures has been studied by the mass spectrometric method (6, 10). It has been shown that the primary decomposition leads to allyl radicals and hydrogen atoms and that a significant portion of the allyl radicals react further to give allene. The amount of allene found in the present results roughly corresponds to what might be expected considering the low concentration of propylene. The other products, butene-1, pentene-1, hexene-1, and 4-methylpentene-1, must be the recombination products of the allyl radical with the methyl, ethyl, *n*-propyl, and isopropyl radicals coming from the propane decomposition. This scheme is confirmed by the deuterium content of the products obtained from the decomposition of the C_3H_8–C_3D_8 mixture. For example, since the 1-hexene should be formed by the recombination of *n*-C_3H_7 and *n*-C_3D_7 with the allyl radical, the expected deuteroisomeric 1-hexenes should be $C_3H_7C_3H_5$, $C_3H_7C_3D_5$, $C_3D_7C_3H_5$, and $C_3D_7C_3D_5$. These are the major products found (Table IV). Moreover, since a ratio of *n*-C_3H_7:*n*-C_3D_7 = 2:1 was found in the *n*-hexane and *n*-pentane, a similar ratio should also be observed here. It can be seen that this is exactly the case.

The following alternate schemes can be considered responsible for the formation of the major products—propylene and hydrogen: the direct hydrogen elimination from propane in a primary reaction, [6]; the further decomposition of propyl radicals by collision with excited mercury, [7], followed by a recombination of hydrogen atoms, [8]; and finally the disproportionation of propyl radicals with hydrogen atoms, [9].

$$C_3H_8 + Hg^* \rightarrow C_3H_6 + H_2 + Hg \qquad [6]$$

$$C_3H_7 + Hg^* \rightarrow C_3H_6 + H + Hg \qquad [7]$$

$$H + H \rightarrow H_2 \qquad [8]$$

$$C_3H_7 + H \rightarrow C_3H_6 + H_2 \qquad [9a]$$

$$\rightarrow C_3H_8^* \rightarrow C_3H_6 + H_2 \qquad [9b]$$

The direct split [6] is unlikely but cannot be eliminated completely on the basis of information in the literature (5). In order to establish whether [6] occurs to any significant extent, runs with variable C_3H_8 and C_3D_8 concentrations were made and the hydrogen

formed was analyzed directly with the mass spectrometer. The results are given in Table V and Fig. 2. That [6] could not occur to any significant extent follows from Fig. 2. The plot of H_2:HD versus the initial propane ratio C_3H_8:C_3D_8 gives a straight line which

goes through the origin. Consider that a fraction of the hydrogen equal to f is formed by [6] and a fraction equal to g is formed by [8] or [9]. Then in the limit, as the ratio C_3H_8: C_3D_8 approaches zero, all hydrogen atoms reacting according to [8] or [9] will produce HD. Thus the intersection of the curve with the ordinate should give directly the ratio f:g. Since the curve goes through the origin, f must be equal to zero within the experimental error. A maximum possible intersection of the curve with the ordinate may be estimated at $H_2/HD = 0.05$ or 5% as a maximum for the contribution of [6] to the hydrogen-producing reactions.

The importance of the decomposition of free radicals by excited mercury as in [7] was suggested by Lossing (6, 8, 9, 11). If [7] were the major reaction forming propylene then the hydrogen atom recombination [8] should be the main source of the hydrogen. However, this recombination is third body restricted. To obtain information on the rate of H-atom recombination in the experimental system mixtures of H_2 and D_2 were mercury

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

photosensitized. The details of these experiments are given elsewhere (12). It was found that the H (and D) atoms recombine by a first-order reaction. Since the recombination is first order, it must be occurring on the wall (13). In these experiments it was also observed that when the lamp was in the position closest to the sampling leak only about 60% of the H atoms produced in the illuminated zone had recombined before reaching the leak. This percentage of recombination was found independent of the concentration of hydrogen. The hydrogen atoms were found almost completely recombined when the lamp was moved 12 cm upstream. If, in the propane decomposition, the hydrogen was formed predominantly by H-atom recombination then one may expect that the hydrogen detected when the lamp is in the bottom position should be only about 60% of the amount detected with the lamp in the upper position. Experiments were made in which the hydrogen and propylene were determined for both positions. It was found that the hydrogen was only about 6% less when the lamp was in the bottom position. Moreover the propylene was also found to be about 6% less, so that the hydrogen to propylene ratio was unchanged. This experiment shows that the majority of the hydrogen could not have been formed by H-atom recombination. The 6% difference for the two positions of the lamp most probably reflects slight differences in the transparency (cleanliness) of the silica reactor wall for the two positions and also some small amount of downsteam reactions.

The reaction that must be considered as the main source of the propylene and hydrogen formation is thus the disproportionation of H atoms with propyl radicals, reactions [9*a*] and [9*b*]. It was suggested that this reaction may be occurring in part as a "straight" disproportionation, [9*a*], and in part as a decomposition of excited propane formed by the recombination of H and propyl. A reaction closely related to these is of course the recombination leading, after stabilization, to propane. The extent of this reaction can be approximately determined by using C_3H_8–C_3D_8 mixtures of variable concentration and determining the amounts of cross recombination product C_3H_7D and C_3D_7H. Using this technique, it was found, in the succeeding paper, that about 40% of the primary decomposition ends up in recombination to propane. This means that the 100‰ observed decomposition given in Table I represents only the net decomposition, the actual primary decomposition is 100/0.6 = 166‰ and the recombination to propane 66‰ of the initial propane. The recombined propane is thus the major "product" followed by the hydrogen and propylene. In this light, the formation of the propylene by the disproportionation reactions [9*a*] and [9*b*] does not appear so unusual.

It is possible now to make a summary of the various reactions participating in the propane decomposition and their relative importance. The reactions are given below and are followed by the estimated number of molecules reacting per 100 molecules propane decomposed in the primary step.

$C_3H_8 + Hg^* \rightarrow n\text{-}C_3H_7 + H + Hg$		[1*a*]
$\rightarrow i\text{-}C_3H_7 + H + Hg$	100 [a+b]	[1*b*]
$C_3H_7 + H \rightarrow C_3H_8^*$		[2]
$C_3H_8^* + M \rightarrow C_3H_8$	40	[3]
$C_3H_8^* \rightarrow C_2H_5 + CH_3$	3.4	[4]
$C_3H_7 + Hg^* \rightarrow C_3H_6 + H + Hg$	30 mainly by [9]	[7]
$C_3H_7 + H \rightarrow C_3H_6 + H_2$		[9]
$C_3H_7 + \text{alkyl} \rightarrow C_3H_7\cdot\text{alkyl}$	5	
$H + H \rightarrow H_2$

For personal use only.

The relative extent of reactions [1*a*] and [1*b*] cannot be determined from the present results. It can be seen from the recombination products of the propyl radicals (Table I) that the steady-state concentration ratio of *n*-propyl:isopropyl was equal to 1. This ratio cannot be assumed to represent accurately the relative rates of the two primary steps. Thus about 30% of the C_3H_7 radicals react further to form propylene and the rates of this reaction will be at least somewhat different for the *n*-propyl and isopropyl radicals. Since all the remaining accounted reactions involving propyl are recombination reactions and thus not selective, we can estimate that the ratio of the two primary reactions should vary from about 1:1 to 1:2.[3]

c. Atomic Cracking of n-Propyl and Isopropyl Radicals

The excited propane decomposing by the atomic cracking reaction [4] may have been formed by the recombination of *n*-propyl or isopropyl radicals with hydrogen atoms. From the bond dissociation energies $D(n\text{-}C_3H_7\text{—}H) = 99$, $D(i\text{-}C_3H_7\text{—}H) = 94$, and $D(C_2H_5\text{—}CH_3) = 82$ kcal/mole (14), one calculates 17 and 12 kcal excess energy contained in the two recombination products. The recombination product of *n*-propyl should decompose more rapidly. An estimate of the relative decomposition rates of the two excited propanes is of considerable interest since data of this type are needed for the development of the theory of unimolecular reaction rates. The unimolecular decomposition of the excited isopropyl recombination product has been treated theoretically by Marcus (15). Extrapolating his data from an energy excess of 12 to 17 kcal one finds that the lifetime of the *n*-propyl recombination product should be about five times shorter than that of the isopropyl. It is shown in the subsequent text that an estimate of this ratio can be obtained from the isotopic composition of the pentanes formed in the decomposition of a 1:1 mixture of C_3H_8 and C_3D_8.

In the following reaction scheme, I stands for the *i*-propyl and N for the *n*-propyl radical.

$$H + I \rightarrow HI^* \rightarrow C_2H_5 + CH_3 \qquad [20, 20a]$$

$$\xrightarrow{M} HI \qquad [20b]$$

$$D + I \rightarrow DI^* \rightarrow C_2H_4D + CH_3 \qquad [21, 21a]$$

$$\xrightarrow{M} DI \qquad [21b]$$

$$H + N \rightarrow HN^* \rightarrow C_2H_5 + CH_3 \qquad [22, 22a]$$

$$\xrightarrow{M} HN \qquad [22b]$$

$$D + N \rightarrow DN^* \rightarrow \tfrac{1}{2}C_2H_5 + \tfrac{1}{2}CH_2D + \tfrac{1}{2}C_2H_4D + \tfrac{1}{2}CH_3 \qquad [23, 23a]$$

$$\xrightarrow{M} DN \qquad [23b]$$

Reaction [23*a*] expresses the fact that C—C bond cleavage can occur either α or β to the newly formed C—D bond. It is assumed that the two bond ruptures are equally probable.

Some of the ethyl radicals recombine with propyl to form pentanes, i.e.

$$C_2H_5 + \text{propyl} \rightarrow C_2H_5\cdot\text{propyl} \qquad [30]$$

$$C_2H_4D + \text{propyl} \rightarrow C_2H_4D\cdot\text{propyl}. \qquad [31]$$

Assuming that $k_{30} = k_{31}$ we have

$$\frac{R_{30}}{R_{31}} = \frac{(C_2H_5)}{(C_2H_4D)} = r = 4 \quad \text{(see Table III)}.$$

[3]*A more accurate estimate showing that the ratio is close to 1:1 is given in the succeeding paper.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Since the ethyl radicals disappear mainly by recombination reactions it is reasonable to assume that the steady-state concentration ratio r is equal to the ratio of the rates of formation of the two radicals, i.e.

$$r = \frac{k_{20a}(\mathrm{HI}^*)+k_{22a}(\mathrm{HN}^*)+\frac{1}{2}k_{23a}(\mathrm{DN}^*)}{k_{21a}(\mathrm{DI}^*)+\frac{1}{2}k_{23a}(\mathrm{DN}^*)}. \qquad [1]$$

With the usual steady-state assumption for (HI*), correspondingly (HN*), one obtains $(\mathrm{HI}^*) = k_{20}(\mathrm{H})(\mathrm{I})/k_{20a}+k_{20b}(\mathrm{M})$ and an analogous set involving [21], [22] etc. From the reaction scheme given in Section *b* it can be seen that the stabilization reaction [*b*] is very much more important than the cracking reaction [*a*]; thus we can write:

$$(\mathrm{HI}^*) = k_{20}(\mathrm{H})(\mathrm{I})/k_{20b}(\mathrm{M}) \qquad [20]$$

$$\vdots \qquad \vdots$$

$$(\mathrm{DI}^*) = k_{23}(\mathrm{D})(\mathrm{I})/k_{23b}(\mathrm{M}). \qquad [23]$$

The following further assumptions can be made:

The isopropyl should recombine equally fast with (H) or (D), but for the higher thermal velocity of H. Thus we can assume

$$k_{20} = \sqrt{2}k_{21} \text{ and analogously } k_{22} = \sqrt{2}k_{23}. \qquad [2]$$

The unimolecular decomposition of the excited protoisopropane should be nearly as fast as that of the deuteroisopropane. The bond energy difference C—D to C—H should be about 1.1 kcal/mole. Using the energy dependence of excited propane derived by Marcus one finds that this should cause a difference by a factor of 1.3 in the unimolecular rate constants, i.e.

$$k_{21a} = 1.3k_{20a} \text{ and analogously } k_{23a} = 1.3k_{22a}. \qquad [3]$$

It should be pointed out that the numerical factors in equations [2] and [3] happen to appear on opposing sides in the subsequent derivation and thus (approximately) cancel. The treatment is equivalent to assuming both these factors equal to unity.

Since the excitational energy in the propanes is nearly 100 kcal/mole the 5 kcal difference for the *n*-propyl- and isopropyl-derived propanes should make little difference in the quenching efficiency of the collisions with the third body. Thus one can assume:

$$k_{20b} = k_{21b} = k_{22b} = k_{23b}. \qquad [4]$$

In Section *b* it was found that:

$$(\mathrm{I}) = (\mathrm{N}). \qquad [5]$$

Substituting [2]–[5] and [20]–[23] into [1] one obtains after rearrangement:

$$x_{\mathrm{H}} = \frac{r-y}{y+0.5(1-r)}, \qquad [6]$$

where $y = (\mathrm{H})/(\mathrm{D})$ and $x_{\mathrm{H}} = k_{22}k_{22a}/k_{20}k_{20a}$. In an analogous manner a reaction set for the pair C_2D_4H and C_2D_5 can be written. Solving the resulting equations one obtains:

$$x_{\mathrm{D}} = \frac{y-r'}{r'+0.5y(r'-1)}, \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where x_D is analogous to x_H but involves the rate constants of the C_2D_4H and C_2D_5 radicals and $r' = (C_2D_4H)/(C_2D_5) = 0.63$ (Table III).

It is reasonable to assume that $x_H = x_D$.[4] Solving the two simultaneous equations [6] and [7] one obtains

$$y = (H)/(D) = 1.93 \text{ and } x_H = x_D = 4.8.$$

The rate constants for recombination of H with *n*-propyl or isopropyl, k_{22} and k_{20}, may not be the same but they should be quite similar. If they are assumed the same then $x_H = k_{22a}/k_{20a} \sim 5$ or the *n*-propyl-derived propane decomposes about five times faster. This result agrees well with the prediction based on the calculations by Marcus mentioned previously. Considering the many assumptions that had to be made, the very close agreement obtained has no significance.

The treatment just given is admittedly very speculative. In particular a number of assumptions concerning the equality of radical rate constants had to be made which, while reasonable, are of course not proved. It is therefore of interest to show that there is one independent check of the calculation.

A ratio for $y = (H)/(D)$ very close to the calculated one can be obtained from data in Section *b*. Figure 2 gives the relationship

$$R_{H_2}/R_{HD} = 1.3(C_3H_8)/(C_3D_8).$$

In our case $(C_3H_8) = (C_3D_8)$, so that $R_{H_2}/R_{HD} = 1.3$. It was also shown that the most likely reaction leading to the hydrogen formation was the disproportionation [9]. We can write:

$$R_{H_2}/R_{HD} = 1.3 = \frac{k(H)(C_3H_7)}{k'(H)(C_3D_7)+k''(D)(C_3H_7)}. \quad [50]$$

From Tables II and III it was found that

$$(C_3D_7) = (C_3H_7)/2.2. \quad [51]$$

The propylene ratio given in Table IV is $C_3H_6/C_3D_6 = 2.6$. This suggests that $k(C_3H_7)/k'(C_3D_7) = 2.6$ and using [51] one obtains:

$$k' = 2.2k/2.6. \quad [52]$$

Assuming

$$k = \sqrt{2}k'', \quad [53]$$

where the square root takes into account the higher thermal velocity of H, one obtains by combining [50]–[53]

$$(H)/(D) = 2.$$

A very similar estimate for this ratio can be obtained also if it is assumed that the hydrogen was formed by the direct recombination of hydrogen atoms.

THE MERCURY-SENSITIZED PRIMARY DECOMPOSITION OF DEUTERATED PROPANES
A MASS SPECTROMETRIC STUDY AT LOW PRESSURES
PART II

M. AVRAHAMI[1] AND P. KEBARLE
Chemistry Department, University of Alberta, Edmonton, Alberta
Received June 26, 1962

ABSTRACT

The primary decomposition of C_3H_8, $CD_3CH_2CD_3$, $CH_3CD_2CH_3$, and C_3D_8 was found equal to: 10, 8, 5.5, and 5%.

The primary reactions were

$$\text{propane} \rightarrow \text{isopropyl} + \text{hydrogen atom} \quad (a)$$
$$\rightarrow n\text{-propyl} + \text{hydrogen atom.} \quad (b)$$

The ratio a/b was strongly affected by deuterium substitution. The numerical values of the ratio for the compounds in the order given above are: 1.2, 6.8, 0.2, 0.9. Elucidation of the underlying reasons for this surprisingly large isotope effect might throw new light on the excited mercury – paraffin interaction.

INTRODUCTION

It is known that the interaction of Hg $^3P_1$ with molecules containing π electrons leads to the formation of excited molecules which may decompose, but which can also be deactivated by collisions with a third body. The clearest evidence for the formation of excited molecules is the decrease of primary quantum yield with increase of pressure. Excited mercury is quenched by such molecules already at appreciable distances. The situation with the paraffins is quite different. Their quenching cross sections are an order of magnitude smaller. The primary quantum yields of the higher paraffins are believed to be equal or close to unity and are not demonstrably affected by the increase of pressure. These facts suggest that a different type of process must be involved. A chemical interaction of the mercury with one or two of the hydrogen atoms surrounding the carbon skeleton may be suspected since all known Hg-sensitized decompositions of paraffins lead to C—H bond cleavage.

Some chance observations, made during the study of the decomposition of propane described in the preceding paper, led to an investigation of the primary decomposition of deuterium-substituted propanes. The results of these experiments pose some interesting questions and might provide a clue to a better understanding of the nature of the mercury–paraffin interaction.

EXPERIMENTAL

The apparatus, experimental techniques, and conditions are described in the preceding paper.

RESULTS AND DISCUSSION

Table I gives the percentage decomposition of the four deuteroisomers measured at identical experimental conditions. The secondary reactions do not consume any propane, but there is some recombination of H, correspondingly D, with propyl so that the

[1]*University of Alberta Postdoctoral Fellow 1960–62.*

*In % of initial propane. The initial propane pressure and all other experimental conditions were the same in all cases.

decomposition is less than the primary reaction. It is shown in the Appendix that the recombination is roughly proportional to the primary reaction. Therefore, the figures in Table I may be considered also as roughly proportional to the primary decomposition. The results exhibit a specific pattern. The compounds with deuterium in the secondary position decompose only half as much as the hydrogen-containing compounds. Deuterium substitution in the primary position also decreases the decomposition but the effect is very much smaller.

Even more interesting is the influence of deuterium on the relative importance of the primary splits to *n*-propyl or isopropyl radicals. The relative rates of these reactions can be traced by examining the recombination products of the propyl radicals. It was shown in the preceding paper that the propyl contained in the recombination products originated only from the primary reactions. This was also verified in the present experiments by determining the deuterium content in the hexanes. The relative amounts of the three hexanes are given in Table II. The isopropyl:*n*-propyl ratios calculated in

TABLE II

the table should relate to steady-state concentrations of the radicals. Very similar ratios could be obtained from the butanes and pentanes, which are also recombination products of the propyl radicals. These ratios will correspond to the primary rates of radical production only if the radical removal reactions are not specific to the nature of the *n*- or *i*-radical. The main removing reaction—the recombination to propane—should not be selective. The next most important reaction leading to propylene may be expected to be somewhat selective no matter what is the mechanism of propylene formation. Thus we may conclude that the propyl ratios from the hexanes, while not giving a quantitative measure, should at least indicate the trends of the primary reactions.

To obtain more conclusive information, a different experiment was made. Instead of allowing the hydrogen to recombine with the propyl radicals and lead to a "product" in which the nature of the *n*- or *i*-radical cannot be recognized, the propyls were forced

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

to recombine with an excess of methyl radicals (CD_3) produced by the simultaneous decomposition of mercury dimethyl-D_6. A sufficient methyl radical excess, by reducing the propyl radical concentration, should also suppress all other reactions of the propyl radical and lead almost exclusively to methyl–propyl recombination and disproportionation.[2] The results from such a methyl saturation experiment are shown in Fig. 1. Given

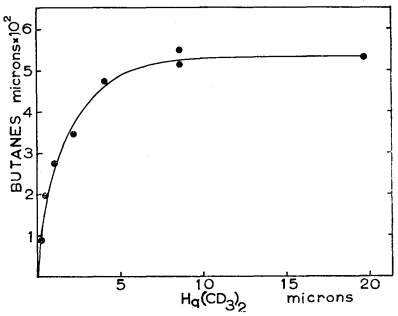

FIG. 1. Combined *n*-butane and isobutane resulting from the recombination of CD_3 with C_3H_7.

is the total recombination products *n*-butane and isobutane with gradually increasing pressure of initial $Hg(CD_3)_2$. It can be seen that the butane formation soon levels off to a constant value. This must correspond to essentially total removal of the propyl by methyl radicals. The position of the lamp in this experiment was 12 cm above the mass spectrometer leak.

The relative amounts of *n*-butane and isobutane could not be determined accurately by direct mass spectrometric analysis of the reaction stream. Therefore a set of runs was made with an initial mercury dimethyl concentration corresponding to saturation (mercury dimethyl pressure = 8 μ) and the products of the decomposition trapped out and analyzed by gas chromatography. The butanes and propylene obtained from these runs are given in Table III. Besides the butanes and the propylene, no other products due to the propane decomposition could be detected. The butanes, obtained from the light propane, were analyzed on the mass spectrometer and found to consist completely of the expected deuteroisomers $C_4H_9D_3$. The propylene, surprisingly, consisted not entirely of the expected C_3H_6 but contained 20% of the isomer C_3H_5D.

The only reasonable mechanism leading to the formation of propylene is the disproportionation of C_3H_7 with CD_3 radicals.[3] Initially it was believed that the C_3H_5D must have resulted from a deuterium exchange in the disproportionation reaction. In a later study, propylene (1 μ) and mercury dimethyl-D_6 (8 μ) were decomposed. The isolated propylene was found to contain about 10% C_3H_5D. The nature of the reaction leading to this product is still under investigation. Results up to the present suggest that such deuterium exchange may be occurring in reactions of excited triplet olefins (produced by mercury photosensitization) with the CD_3 radicals.

Since the butane ratios (Table III) were obtained from collection experiments, evidence

[2]*This technique has been developed by Lossing (1).*

[3]*The propylene to combined butanes ratio is equal to about 0.5 (Table III). This figure should express the disproportionation to recombination ratio of a mixture of the two propyls with methyl radicals. As is shown later from the experimental results one can conclude that the disproportionation ratio for isopropyl is quite similar to that for n-propyl. The disproportionation to recombination ratio of isopropyl with methyl measured by Heller (2) is 0.17. Thus the present results are out of line. However, the disproportionation in the present system may involve vibrationally excited propyl radicals. The excess energies should be initially around 13 and 18 kcal for n-propyl and isopropyl. Since this is equivalent to only a few vibrational quanta above the ground state, the spacing of the levels will be wide and the quenching by helium very inefficient. At the pressure of* CH_3 *1 μ and* He *10 mm the propyl radicals will have about 10,000 collisions with* He *before colliding with a methyl radical. These may not be sufficient for a complete vibrational deactivation (3).*

should be given that no complicating reactions occur downstream of the illuminated zone. One may argue that some of the butanes are formed by downstream hydrogen abstraction from propane by methyl radicals followed by methyl–propyl recombination. One can calculate that the downstream methyl radical decay due to recombination to ethane is too rapid to allow any significant abstraction to occur; however, the following experimental proofs are more direct. The experiment with variable mercury dimethyl concentration (Fig. 1) was done with the ultraviolet lamp 12 cm (~4 milliseconds) upstream of the mass spectrometer sampling leak. The methyl concentration should fall in 4 milliseconds to a small fraction of its original value. The absence of abstraction reactions is evidenced by the levelling off of the butane formation. In the propylene experiment mentioned above, the formation of *i*-pentane should have been observed if methyl radical addition followed by recombination occurred. No *i*-pentane was found in the trapped out reaction mixture.

The information obtained from the methyl addition experiments is in agreement with the results from the decomposition of the propanes alone. It provides also a more accurate estimate of the relative primary rates leading to isopropyl or *n*-propyl radicals. A ratio for these reactions can be obtained directly from the isobutane and *n*-butane products. These ratios are given in Table III. Since propylene is an appreciable product, amounting to about half of the combined butanes, the butane ratio still does not give a complete picture of the primary rates. One can correct the ratio by determining what fractions of the propylene originate from the *n*-propyl and isopropyl radicals. This can be done on the basis of a procedure which is outlined in the Appendix. The isopropyl to *n*-propyl ratios obtained by the calculation are given in the table. Comparing them with the direct isobutane to *n*-butane ratios one finds that the changes introduced by the correction are not very significant.

The experimental results may be briefly summarized as follows. Deuterium substitution affects the mercury-sensitized decomposition in two ways. First, it produces changes in the total primary decomposition. Second, it produces changes in the relative importance of the two primary processes leading to *n*-propyl or isopropyl radicals. The influence of the deuterium is to block bond cleavage in the position of substitution. The deuterium effects are very large.

The change in the primary decomposition can be due to changes of any of the following parameters: cross section for quenching of Hg $^3P_1$ to $^3P_0$, cross section for quenching of $^3P_1$ to ground state, primary quantum yield for reaction with $^3P_1$, primary quantum yield for reaction with $^3P_0$. Obviously a choice between these possibilities on the basis of the present experiments would be impossible. Information available in the literature is quite incomplete. The total quenching cross sections of only three deuterated species, D_2O, ND_3, and PD_3, have been measured (5, 6). The deuterated water and ammonia have cross sections which are only one half as large as those of the light compounds, while PD_3 has a cross section which is somewhat larger than that of PH_3. The differences resulting from deuteration have been explained on the basis of quenching to the metastable state. The energy change for this transition corresponds to 1767 cm^{-1}. In ammonia and water the closest vibrational frequencies (for resonance transfer) shift away from 1767 cm^{-1} with deuteration, while in the phosphine a shift towards this frequency occurs. Cross section measurements of deuterated paraffins are not available; however, measurements of the deuterated propanes are at present being made by Gunning and Rousseau.[4]

[4]*Gunning and Rousseau (7) have undertaken these measurements as an extension of the work quoted in reference 4. The preliminary results were kindly communicated by the authors.*

The preliminary results show that the total quenching cross sections follow the pattern of the total decomposition, observed in the present work, but are much more pronounced, i.e. $(C_3H_8) = 1.2$ Å^2, $(C_3D_6H_2) = 1.0$, $(C_3H_6D_2) = 0.17$, $(C_3D_8) = 0.09$. In analogy with the interpretations used for the deuterated ammonia, water, and phosphine, one might suppose that in this case also differences in quenching to the metastable state are the overriding factors. There are, however, reasons to argue against such an assumption. If one examines the available quenching cross sections of the paraffins (8), one is immediately impressed by their strong structural dependence. A significant increase of the cross section occurs when a secondary and then again when a tertiary hydrogen atom is introduced. At the same time, no specific correlation with normal modes of vibration in the region 1767 cm^{-1} can be made. It is therefore not unreasonable to suppose that the overriding process determining the total quenching cross section of the paraffins is the quenching of the $^3P_1$ excited atom to the ground state, which involves a chemical mercury–hydrogen atom interaction and followed by C—H bond cleavage in the paraffin. The findings of Cvetanović (9) on competitive quenching of nitrous oxide and *n*-butane are in essential support of such a picture. If this view were correct then deuterium should in some way hinder the process. It is difficult to conceive why deuterium should have such a large effect, since considerable excess energy for the final C—H break is available. However, essentially nothing is known about the nature of the mercury–paraffin activated complex and its energy requirements for decomposition. The strong shift of the decomposition from primary to secondary bond cleavage or the reverse, produced by deuterium substitution, also supports the view that the effects are not due to quenching to the metastable state but to a specific mercury–hydrogen, correspondingly deuterium, interaction.

Before being able to utilize the information contained in the deuterium effects, one would also require information on the primary quantum yields of the deuterium-substituted propanes. It is now known that the primary quantum yield for ethane, propane (10), and *n*-butane (9) is unity or close to unity. Since the structural changes from ethane to butane are drastic compared with the change from H to D in the propane, one might suppose that the primary quantum yields for the deuteropropanes should be also unity. If this does not happen to be the case, the operation of some specific effect, like quantum mechanical tunnelling of the hydrogen and deuterium atoms, might have to be invoked.

APPENDIX

a. Recombination Reaction Leading to Propane

Mixtures of C_3H_8 and C_3D_8 in which the mole fraction $X_{C_3H_8}$ was varied from 0 to 1 were decomposed and the disappearance of C_3H_8 and C_3D_8 and the formation of the

recombination products C_3H_7D and C_3D_7H measured with the mass spectrometer. The results are shown in Fig. 2. In Fig. 2A the percentage decomposition of C_3D_8 is shown.

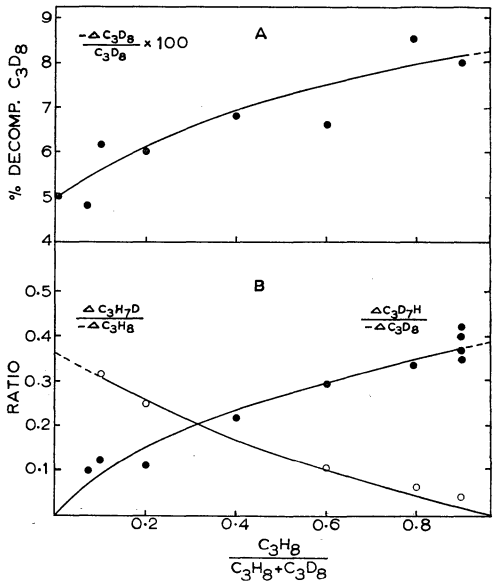

FIG. 2. A: Increase of C_3D_8 decomposition with $X_{C_3H_8}$ due to enhanced formation of recombination product C_3D_7H.
B: Cross recombination products to decomposition ratio as a function of $X_{C_3H_8}$.

The decomposition gradually increases as $X_{C_3H_8}$ is increased, since more and more of the recombination proceeds with H rather than D atoms. The decomposition extrapolated to $X_{C_3H_8} = 1$ is about 8.5% and should at this point correspond to the primary decomposition of C_3D_8. Unfortunately, the corresponding plot which would have given the primary decomposition of the C_3H_8 could not be obtained with any accuracy due to excessive mass interference at mass 44—the molecular mass of C_3H_8. However, the plots in Fig. 2B do provide at least a partial answer as to the extent of the primary decomposition in the two compounds. A plot is shown of $\Delta C_3D_7H/\Delta C_3D_8$ as a function of $X_{C_3H_8}$. In the limit of $X_{C_3H_8} = 1$ all C_3D_7 recombines with H and the intercept gives directly the fraction of the total decomposition ending in recombination. The curve extrapolates to a value of 40%, which agrees well with the predictions from Fig. 2A, where the primary minus the net decomposition was $8.5-5 = 3.5\%$, or the percentage recombination was $3.5\times100/8.5 = 41\%$. The corresponding plot $\Delta C_3H_7D/\Delta C_3H_8$ could be obtained in this case but involves a considerable error due to mass spectral interference. The shape of the curve is somewhat different from that of the deuterated propane. This is due to the fact that the primary decomposition of the C_3D_8 is slower. Thus, on a concentration basis the C_3D_8 is a less efficient provider of (D) atoms for the cross recombination product. The intercept for $X_{C_3H_8} = 0$ occurs at about 36% recombination. This is similar to the 40% obtained for the C_3D_8. The two values cannot be expected to agree. Thus, for example, the C_3D_7H extrapolation gives the recombination of C_3D_7 with H atoms at a concentration level determined by the mechanism of the C_3H_8 decomposition. What one may conclude from the experimental results is that the recombination to primary decomposition ratio in C_3H_8 and C_3D_8, when these substances are decomposed alone, is roughly the same.

b. Fraction of Propyl Radicals Forming Propylene

The constancy of the propylene to butanes ratio given in Table III shows that the reaction by which propyl is converted into propylene does not show any strong dependence on deuterium substitution. Making the assumption that in the first approximation the propylene-forming reaction depends only on whether the radical is *n*-propyl or isopropyl but not on the deuterium substitution, one can determine what proportion of the propylene originates from isopropyl or *n*-propyl radicals and in this way obtain also the original amounts of these radicals. A good fit of the data is obtained by assuming that 0.56 and 0.76 of the original isopropyl and *n*-propyl end up as isobutane and *n*-butane. A check of the procedure is obtained by comparing the calculated with the measured total propylene plus butanes. The calculated total is obtained by dividing the measured isobutane and *n*-butane by 0.56 and 0.76, respectively, and adding. Equally "good" agreement can be obtained with slightly different factors, so that the procedure is somewhat arbitrary.

A NEW TECHNIQUE FOR THE STUDY OF HIGH-POLYMER DEGRADATION REACTIONS*

H. H. G. JELLINEK AND J. E. CLARK
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received September 17, 1962

ABSTRACT

A quartz spoon gauge, recording pressures automatically, is described. The gauge, representing a closed reaction system, can be used for investigations of the degradation of polymers. It has been tested by degrading polymethylmethacrylate over a temperature range of 300 to 400° C. The important features of the gauge are as follows: (1) The pressure exerted by gases during degradation is continuously recorded at appropriate chart speeds via an electrical transducer (maximum displacement ±0.038 cm; spoon gauges used in this work had sensitivities in the region of 0.035 cm/atm). (2) Only small quantities of polymers are needed; 20 to 40 mg of polymer in the form of films was deposited on the walls of the reaction vessels; however, much smaller samples could be used, the limit being given by mechanical vibrations set up in the system. (3) Temperature equilibrium between the reaction vessels and a thermostated bath is reached within about 30 seconds.

Useful results for polymethylmethacrylate were obtained up to 400° C, which is a temperature about 100° higher than that reached by previous workers, not neglecting the initial parts of the reactions. The reproducibility of the results has been indicated by average curves obtained from several runs at any one particular temperature and their standard deviations.

The new technique for the study of polymer degradation reactions consists essentially of an automatic recording quartz spoon gauge, which can be used for thermal reactions or any other reactions such as photodegradation as long as volatiles are produced. The present paper deals with this technique as applied to thermal degradation processes. These reactions can be studied with this apparatus at higher temperatures than before because of the short time needed to reach temperature equilibrium between the reaction vessel and a thermostated bath. The method should in principle also be useful for the study of ceiling temperatures. Only small quantities of polymer are required; the smallest amount employed in this work was 20 mg but there is no reason why smaller quantities (ca. 1 mg) could not be used. The lower limit would essentially be given by mechanical vibrations set up in the system.

Thermal degradation of high polymers is quite well understood at relatively low temperatures where the rates of degradation are slow enough to be measured by instruments such as a thermobalance; but, once the rates become appreciable, different methods are needed. One attempt in this direction is reported in the present paper. There is scarcely any kinetic data in the literature for degradation reactions whose rates are high, although there is quite substantial information available from analytical experiments on the degradation of polymers at high temperatures (1).

The new apparatus described here has been evaluated using polymethylmethacrylate, which is known to degrade primarily into monomer. Useful rate measurements were obtained up to 400° C, which is about 100° C higher than the temperature used by other authors (2, 3, 4).

EXPERIMENTAL

(a) Apparatus and Procedure

The apparatus is shown in Fig. 1. The reaction vessel consists of a quartz spoon gauge (1) of about 15 cm^3 capacity. The top of the spoon's pointer has a sensitivity of about 0.035 cm/atm. This, of course, is only a

**Paper presented at the Eleventh Canadian High Polymer Forum, Windsor, Ontario, September 5–7, 1962.*

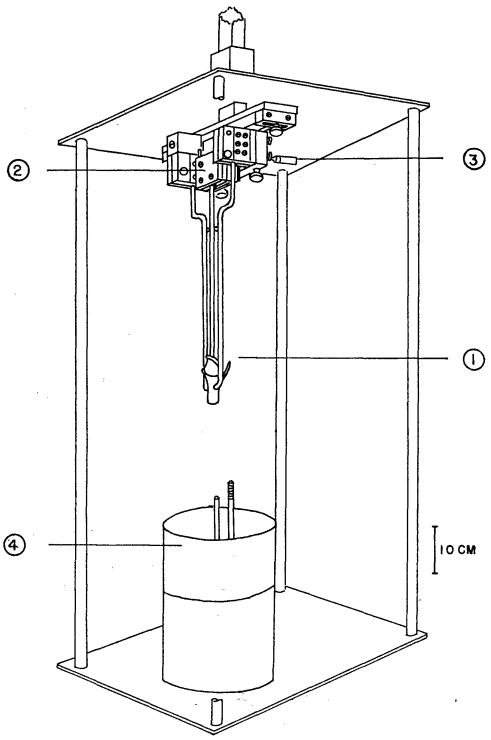

FIG. 1. Quartz spoon gauge apparatus: (1) quartz spoon gauge, (2) Statham transducer, (3) micrometer screw and holder, (4) furnace.

representative value; each individual spoon is calibrated by introducing air of known pressure. The sensitivity of spoons can vary within wide limits. The gauge is fixed in a clamping device (2) and, by means of a micrometer screw (3), contact can be made between the quartz pointer and the lever of a Statham transducer (strain gauge), Model G1OB-0.3-350. The transducer has a maximum displacement of ±0.038 cm and is connected to a two-channel Sanborn recorder, Model 150 (with carrier preamplifier, Model 150-1100, and a low-level preamplifier, Model 150-1500). Pressures, under conditions employed in this work, could be read within ±1 mm Hg; temperatures could be recorded simultaneously.

Polymer was deposited in the form of thin films (for 20-mg samples, the thickness was approximately 5×10^{-3} cm) on the walls of the reaction vessel. The films were formed by introducing into the reaction vessel the requisite volume of a 2% w/v solution of the polymer in acetone. The latter was evaporated slowly at slightly elevated temperatures (ca. 50° C) and the reaction vessel was eventually connected to a high-vacuum system (10^{-5} to 10^{-6} mm Hg). Finally, the film was baked out under high vacuum for at least 24 hours at 65±5° C. The spoon reaction vessel was then sealed off and inserted into the arrangement as shown in Fig. 1. Contact was made with the transducer and the whole assembly was rapidly lowered, so that the spoon reaction vessel was immersed in a thermostated 50:50 by weight lead–tin bath, which was regulated by a platinum resistance thermometer (Sunvic, Type PRT-4, in conjunction with a Sunvic resistance thermometer controller, Type RT-2) to within ±0.5° C at any one particular location of the bath. The temperature profile is given below:

Temperature (°C)	262	281	283	285	284	283
Location (in.)	At surface	−1	−2 to −4	−5 to −8	−9	−10

The reaction vessel was located approximately in the region 4 to 6 in. below the surface of the bath.

Figure 2 shows that it did not take longer than 30 seconds to reach temperature equilibrium between the reaction vessel and the bath. The chart of the Sanborn recorder could be run at various speeds (0.25, 0.5, 2.5, 5, 10, 25, 50, 100 mm/sec) to suit the rate of the reaction. Spoon reaction vessels of various sensitivities were employed; they were calibrated, as already indicated above, by introducing air of known pressures into the spoon gauge and recording by means of the Statham transducer. Characteristic calibration curves are

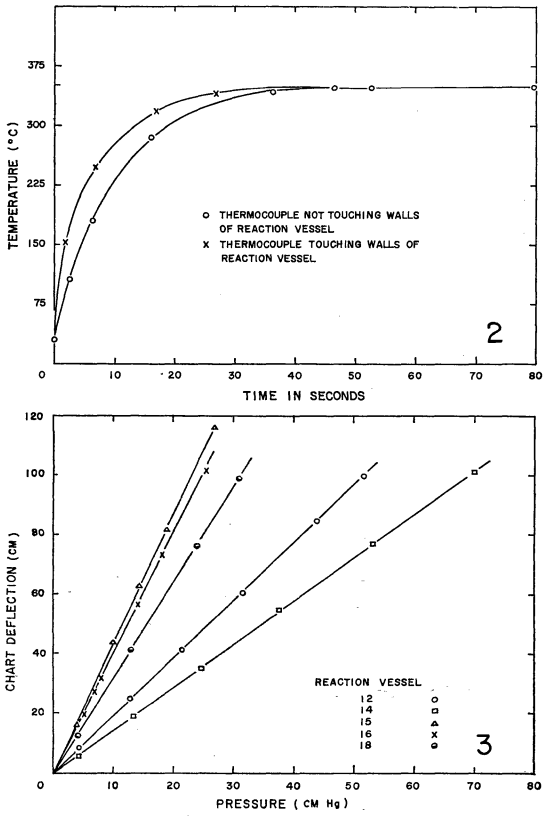

FIG. 2. Attainment of temperature equilibrium for the reaction vessel at 350° C.
FIG. 3. Calibration curves for various spoon gauges.

shown in Fig. 3. The calibration gave the same results whether it was carried out with the spoon in the bath at elevated temperatures or outside the bath at room temperature. The pressure versus chart divisions relationship is linear over the entire range employed.

(b) Materials

All solvents were of analytical reagent grade.

Methylmethacrylate (Rohm and Haas) containing 0.006% hydroquinone was treated as described in Riddle's book (5). Polymerization was carried out with 0.5% benzoylperoxide under vacuum for 30 minutes at 60° C (conversion approximately 5%). The reaction was stopped by pouring the polymer–monomer mixture into five times its volume of methanol. The polymer was filtered off, redissolved in acetone, and and precipitated by dropwise addition of methanol. It was eventually dried to constant weight in a vacuum desiccator. The intrinsic viscosity of the polymer in chloroform was found to be 2.01 dl g^{-1}.

A 2% w/v stock solution in acetone was prepared and aliquots of it were used in all subsequent experiments.

(c) Experimental Results

The experimental results are given in moles of gas produced as a function of time. The assumption that only monomer is produced is not quite correct since it was observed that especially at higher temperatures the remaining polymer showed a yellow to brown color and at 400° C small amounts of charred residue were also found. This may also explain the observation that usually somewhat more than the theoretical number of moles in terms of monomer was found on complete degradation. It is also possible that there is still some residual solvent in the polymer. The moles of gas produced were calculated by using the measured volume of the spoon reaction vessel and the ideal gas law.

Figure 4 shows curves representing average percentage values of a number of runs obtained with 20-mg and 40-mg films respectively at 300° C. Standard deviations are indicated. It is apparent that the degradation is slower for the larger polymer sample. Brockhaus and Jenckel (4) observed a pressure effect for the degradation, which also seems to be apparent in our results. Whether this effect is due only to a diffusion process or also to a chemical reaction remains to be seen.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

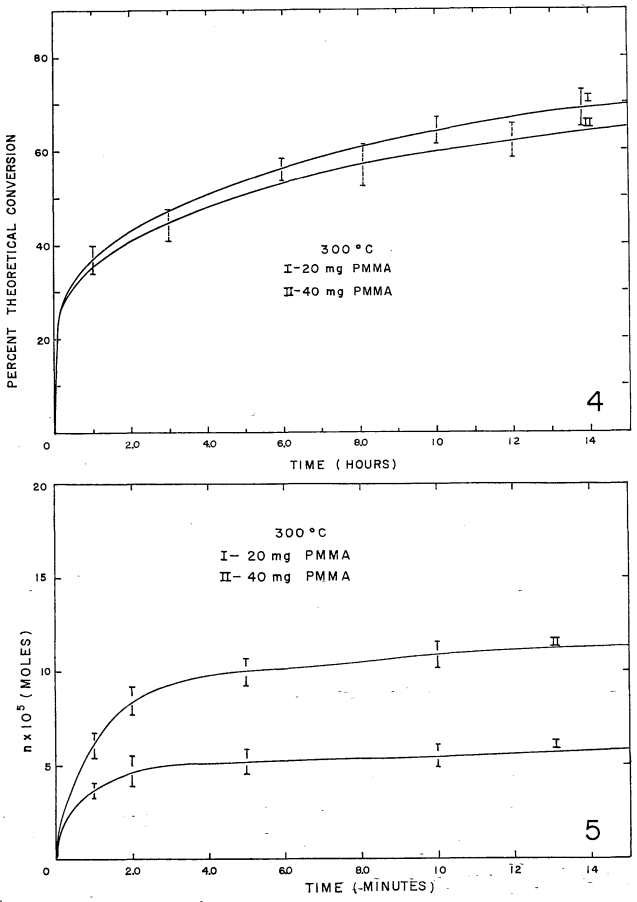

FIG. 4. Percentage conversion of PMMA at 300° C, average curves: I, 20 mg; II, 40 mg. Standard deviations are indicated.

FIG. 5. Degradation of PMMA at 300° C, initial parts only: I, 20 mg; II, 40 mg. Average curves, standard deviations are indicated.

A number of degradation experiments with 20-mg samples was carried out at various temperatures in addition to the runs at 300° C. These are shown in Figs. 5 to 9. The curves again represent average values of several runs. The vertical lines indicate standard deviations.

A number of average values and their standard deviations are given in Table I.

It is seen that satisfactory results are obtained with this apparatus.

There is some uncertainty in the recordings for the very initial parts of the process. Some vibrations are set up when the reaction vessel on being lowered comes into contact with the liquid, but these persist only for 1 or 2 seconds. Sometimes there is also a small jump in the recorded curves on immersion, making the actual pressure values somewhat uncertain. However, the main interest as far as a kinetic analysis is concerned lies in the rates of degradation (slopes) as a function of conversion and not in the actual pressure or mole values. Figure 10 shows plots of the rate of gas production as a function of the moles of gas produced at 300° C (20-mg samples). It is apparent that two different reactions take place.

DISCUSSION

The purpose of this paper is not to present a kinetic analysis but only to give an evaluation of the performance of the apparatus. The experiments show that satisfactory accuracy can be obtained. At higher temperatures, where the reaction is very fast, the

FIG. 7. Degradation of PMMA at 350° C. Average curve, standard deviations are indicated, 20 mg.

reproducibility decreases, as is to be expected. The heating period alone at such temperatures represents a large portion of the total reaction time. However, even for experiments at 400° C useful results can be obtained if a sufficiently large number of runs are carried out.

A few observations may be made relating to work on polymethylmethacrylate by other workers. Grassie and Melville (2) were the first to establish that a chain reaction, a depolymerization process, takes place. Jellinek (6), on the basis of their kinetic data, pointed out that two reactions occur simultaneously. Brockhaus and Jenckel (4) extended the work to higher temperatures and showed clearly that two reactions are involved. Madorsky (3) gave extensive analytical data on the products of the degradation. Bywater (7) studied the thermal degradation using mainly emulsion polymerizates.

Brockhaus and Jenckel (4) carried their experiments up to 350° C, but their minimum time for reaching temperature equilibrium was about 5 minutes; thus, about 60% of the polymer was degraded before the equilibrium was reached at 350° C. They give no indications as to the accuracy of their experiments. For our experiments, the heating

period was only 30 seconds and useful results could still be obtained at 400° C. These authors also ascertained, as already pointed out, that the rate of degradation is a function of monomer pressure in the system. Our experiments show a similar behavior.

As already mentioned, two degradation reactions take place simultaneously (see Fig. 10). Polymer, prepared under conditions as used in this work, consists of chains of which 50% have double bonds at the ends whereas the other 50% have only single bonds. Brockhaus and Jenckel (4) concluded from their experiments that one depolymerization process was operative which initiated at the double-bond chain ends and another slower one initiated at random in the chains. Gordon (8), however, fitted Brockhaus and Jenckel's results by assuming that both processes are initiated at chain ends, the double-bond chain ends having a rate constant of initiation greater than that for the initiation at the single-bond chain ends. Our results also clearly show that two reactions are operative.

Work concerning the kinetics of degradation of polymethylmethacrylate is in progress and will be published in due course.

ABSTRACT

The fundamental and first overtone NH_2 stretching bands in 55 ortho-, meta-, and para-substituted anilines, measured in dilute carbon tetrachloride solution, have been compared. For all ortho-substituted compounds (except *o*-alkyl, *o*-$COCH_3$, and *o*-$COOCH_2CH_3$) splitting of the symmetric band is observed in the first overtone region. On the basis of unusually low mechanical anharmonicity the high-frequency component is assigned to a vibration arising in an intramolecularly bonded NH_2 group. The mechanical anharmonicity of the "free" NH_2 group is found to be more dependent on the electronic nature of meta and para substituents for the symmetric mode than for the asymmetric mode, with minor changes on ortho substitution. The relative electrical anharmonicities for both modes have been estimated from changes in the ratio of the integrated intensity of the fundamental band to that of the first overtone band. For the asymmetric mode the electrical anharmonicity is independent of the electronic nature of the substituents, but depends on their ring position. For the symmetric mode the electrical anharmonicity decreases as charge separation increases in the molecule, with no significant difference for ortho-substituted compounds. These results are in qualitative agreement with a mechanism previously proposed for these vibrations.

INTRODUCTION

In several previous publications (1, 2) we have investigated the effect of ring substituents on the fundamental NH_2 stretching frequencies, half intensity band widths, and integrated absorption intensities in anilines, as measured in dilute carbon tetrachloride solution. Correlations with the Hammett (3) and Taft (4, pp. 618 ff.) substituent constants were established, and the systematic deviation of ortho-substituted anilines could be interpreted in terms of a vibrational mechanism taking into account the direction of the transition moment, the extent of nitrogen lone pair and aromatic π-electron participation, and the direct field effect of the ortho substituent for each of the two vibrational modes (5).

In an attempt to get a more complete understanding of the vibrational behavior of this group, its anharmonic nature has now been investigated. This paper reports a comparative study of the available data for the fundamental vibrations (5) and the measurements in the first overtone region recently published by Whetsel (6). Additional measurements in the overtone region on selected compounds are presented. Due to extensive overlapping of bands in the overtone region only the peak frequencies and the peak molar absorptivities instead of the integrated intensities can be obtained.

EXPERIMENTAL METHOD

The methods used to obtain the experimental data on the fundamental bands have already been described (5).

The additional overtone data required were obtained with a Beckman DK-1A spectrophotometer with a linear absorbance attachment, operating with a slit height of 13 mm, and at a scanning speed of 50 mμ/min. A pair of matched cylindrical 10-cm fused quartz cells were used to keep the amine concentrations down to below 0.07 *M*. Recent cryoscopic measurements by Rao and co-workers (7) show that theoretical molecular weights are obtained for aniline in carbon tetrachloride solution up to concentrations as high as 0.075 *M*, so that intermolecular hydrogen bonding can be neglected. Slit widths of about 5–8 cm^{-1} were obtained under the operating conditions.

Commercial carbon tetrachloride of spectroscopic quality was used, and all solutions were made up volumetrically and used immediately. The data reported represent averages obtained from at least two

solutions which were prepared independently, except for a few cases where the limited amount of material precluded this. Scale expansion was employed for the spectra of a few difficultly soluble amines. The amines were largely the same samples used in previous work in this laboratory.

Following the method of Whetsel (6), background corrections were applied to all spectra by drawing a line between the low absorbance levels at 1590 and 1415 mμ. Peak molar absorptivities in liter mole^{-1}cm^{-1} were calculated from the expression

$$\epsilon_{02} = a/cx,$$

where a is the corrected absorbance, c is the concentration in moles/liter, and x is the pathlength in cm.

The wavelength scale of the instrument was checked against mercury emission lines, and trial measurements of wavelength and absorbance on selected amines showed that good agreement with the results of Whetsel (6) could be obtained.

To obtain an estimate of the absorption intensity of the minor band component in those cases where band splitting occurred, the major component was reflected about an ordinate through the absorption maximum, and the image subtracted from the observed curve. Where the two components were of comparable intensity, the corrected peak absorbances were used directly to estimate the percentage of intramolecularly bonded molecules.

RESULTS AND DISCUSSION

Figure 1 shows some typical first overtone amine spectra in dilute carbon tetrachloride solution. The numerical data are summarized in Table I. As a first approximation the

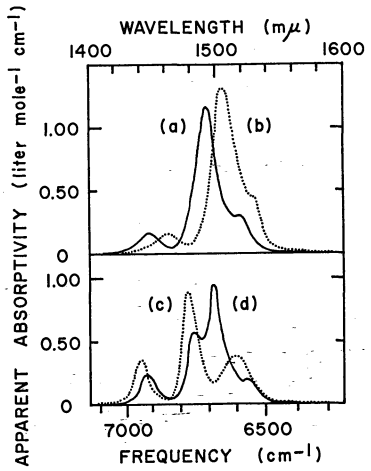

FIG. 1. Near-infrared spectra of some primary aromatic amines in dilute CCl_4 solution (~0.06 M) in 10-cm cells: (*a*) aniline, (*b*) N,N-dimethyl-*p*-phenylenediamine, (*c*) ethyl anthranilate, (*d*) *o*-iodoaniline.

substituent constant scale ($\sum\sigma$) was employed to relate the total electronic effect of the aromatic ring substituents on the NH_2 group (5).

The Band at 6580 cm^{-1}

All of the anilines examined have a relatively weak absorption band at about 6580±20 cm^{-1}, regardless of the substitution type. In *o*-trifluoromethylaniline this band was observed as high as 6645 cm^{-1}. This is probably a combination band.

Amino Group Stretching Frequencies

The overtone frequencies for both NH_2 stretching modes for meta- and para-substituted anilines increase smoothly as the electron-withdrawing character of the ring substituents increases, as shown in Figs. 2 and 3. The basis for these shifts has already been discussed in connection with the corresponding fundamental bands (5). The complex deviation of the frequency data for ortho-substituted compounds is a reflection of factors such as changes in the HNH bond angle, the effective charge on the N atom, and the mechanical anharmonicity on ortho substitution.

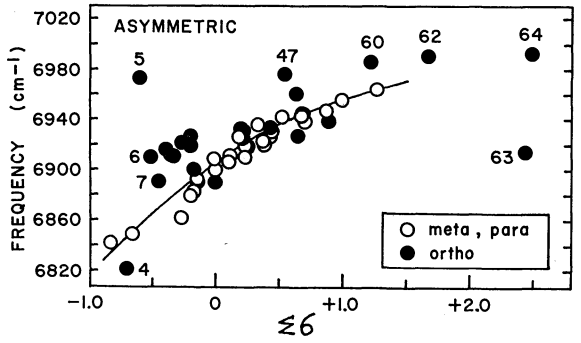

FIG. 2. The dependence of the first overtone asymmetric NH_2 stretching frequencies in anilines on the electronic nature of the substituents.

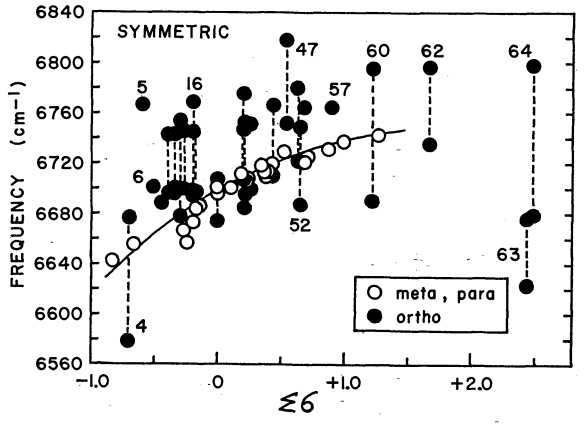

FIG. 3. The dependence of the first overtone symmetric NH_2 stretching frequencies in anilines on the electronic nature of the substituents. Vertical tie lines join the frequency of the intramolecularly bonded species (top point) to that of the free species (bottom point).

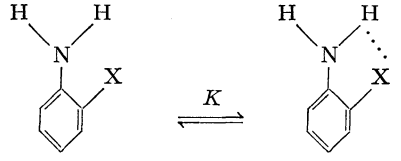
A further complication is introduced into the symmetric overtone frequencies by a splitting of the absorption band into two components, which appears to be quite general on ortho substitution. Exceptions are *o*-aminoacetophenone, ethyl anthranilate, and the *o*-alkyl anilines. Whetsel *et al.* (10) have previously pointed out such splitting for three ortho-substituted anilines, and assigned the high-frequency bands to free NH_2 groups and the low-frequency components to NH_2 groups bonded to ortho substitution. Both components of the symmetric band, joined by tie lines, are shown in Fig. 3 for those cases where the splitting permitted the evaluation of two frequencies. In some cases only distinct shoulders were observed on the high-frequency side of the main symmetric band, and graphical resolution was employed.

Mechanical anharmonicity calculations suggest that the *high*-frequency component of this symmetric doublet is due to bonded NH_2 groups, whereas the low-frequency component arises from free NH_2 groups in an equilibrium of the type



[1]

This concept rationalizes the anomalous overtone spectra of ortho-substituted anilines with respect to the meta- and para-substituted derivatives. It is supported by temperature studies, deuteration shifts, and the expected solvent dependence.*

The absence of splitting in the fundamental symmetric NH_2 band must mean that the hydrogen bonding interaction is too weak to be observed, except in the overtones. Sheppard (12) has concluded that the vibrational amplitude is an important factor in hydrogen bonded XH vibrations. Both the increase in the equilibrium NH bond lengths and in the vibrational amplitudes for the overtone vibrations would favor stronger interaction than for the fundamental vibrations. It is known that the overtones are in general more sensitive to interaction effects than the fundamental vibrations. Moritz (13) has shown that the asymmetric NH_2 stretching vibration is relatively insensitive to the effects of intramolecular hydrogen bonding involving only one proton, and the recent work of Wolff and Staschewski (14) shows that this is also true for intermolecular hydrogen bonding of primary amines.

Mechanical Anharmonicity

It is well known that the mechanical harmonic oscillator, characterized by a parabolic potential function, is only a useful approximation for very small displacements of the nuclei from the equilibrium position (r_e). As a better approximation cubic, quartic, and higher terms must be introduced (15, pp. 90–92) to give a potential function of the form

$$U = f(r-r_e)^2 - g(r-r_e)^3 + h(r-r_e)^4 + \ldots \quad [2]$$

where $h \ll g \ll f$. The vibrating motion, although still strictly periodic, will no longer have a pure sine form for any amplitude. For a diatomic anharmonic oscillator, the frequencies of the fundamental (ν_{01}) and the first overtone vibration (ν_{02}) lead directly to the mechanical anharmonicity (x_e) for the vibration if cubic and higher terms are neglected, from the expressions (15, pp. 94–96)

$$\nu_{01} = \omega_e(1-2x_e) \quad [3]$$

$$\nu_{02} = 2\omega_e(1-3x_e), \quad [4]$$

where ω_e is the mechanical frequency of the oscillator for very small displacements if anharmonicity could be neglected.

These expressions were applied directly to the experimental data to get the mechanical anharmonicity for the two complex NH_2 vibrational modes. The results are tabulated in Table I, and presented as a function of $\sum\sigma$ in Fig. 4. For ortho-substituted anilines with a split symmetric band, each of the ν_{02} frequencies was coupled with the corresponding ν_{01} band to get two x_e values. The mechanical anharmonicities were found to be normal for the low-frequency component, but unusually low for the high-frequency component. Pimentel and McClellan (16) have summarized the available information concerning the mechanical anharmonicity of XH stretching vibrations involved in hydrogen bonding, and conclude that it may be unusually low. On this basis the high-frequency component is assigned to a vibration arising in an intramolecularly bonded NH_2 group. For very strongly bonded systems negative x_e values have been reported (17). Our work agrees with this, since negative x_e values were found for the single sharp symmetric overtone peak observed for ethyl anthranilate and *o*-aminoacetophenone. Only bonded NH_2

**After this work was completed, Moritz (11) demonstrated that the spectra of monodeuterated ortho-substituted anilines can be interpreted in terms of cis–trans isomerism of the* NHD *group and the relative strengths of intramolecular hydrogen and deuterium bonds.*

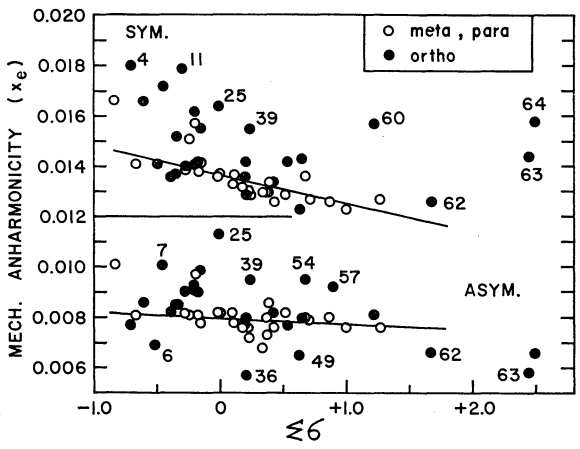

FIG. 4. The mechanical anharmonicity of the NH_2 stretching vibrations and the effect of substituents. The anharmonicities for the intramolecularly bonded species are not shown in this graph.

groups would be expected due to the favorable N—H · · · O distance, and the geometry of the six-membered chelate ring. A negative x_e value was also found for the high-frequency component of the doublet in 2,4-dinitroaniline.

The existence of a "free" form in equilibrium [1] probably implies a certain amount of torsional motion of the NH_2 group, this being one way in which the H atom can get away from the adjacent X group.

The mechanical anharmonicity for the symmetric mode of the "free" NH_2 group exceeds that for the asymmetric mode (average of approximately 0.014 as opposed to 0.008). The slight decrease of x_e with increasing electron-withdrawing power of substituent groups in meta- and para-substituted anilines is most pronounced for the symmetric mode. Ortho substitution introduces no systematic deviation of x_e for the asymmetric mode, but the corresponding values for the symmetric vibration of the "free" NH_2 group appear to be somewhat enhanced (Fig. 4).

Temperature Studies

The intensity ratio of the symmetric doublet was found to be temperature independent, within experimental error, over the range 0–60° C for *o*-nitroaniline, *o*-iodoaniline, and *o*-phenylenediamine, and no "free" band could be induced in ethyl anthranilate by raising the temperature to 60° C. We believe this does not contradict the intramolecular equilibrium proposed since the N · · · X distance is fixed. With the amino group oriented so that nitrogen lone pair – π electron overlap is favored, rotation of 180° about the C—N bond, if permissible in hydrogen-bonded systems like this, brings the other H atom into the interacting position. This is unlike the "free" trans $\rightleftharpoons$ "bonded" cis equilibrium observed in the infrared spectra of ortho-substituted phenols, where temperature dependence is observed (18).

Deuteration Shifts

Since the possibility of an accidental resonance between the overtone symmetric NH_2 vibration and some other vibration of the aniline molecule could not be overlooked, a sample of N,N-dideutero-*o*-nitroaniline, prepared by repeated equilibrium with methanol-*d*, was examined. The asymmetric band was found at 5263 cm^{-1}, and the symmetric doublet at 5072 cm^{-1} ("bonded") and 5039 cm^{-1} ("free"). The intensity ratio

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of the doublet was identical with that found in ordinary *o*-nitroaniline. The deuteration shifts (ν_H/ν_D) are 1.33, 1.34, and 1.33 respectively. These are in agreement with the corresponding shifts observed for OH/OD stretching vibrations in a large number of monomeric, dimeric, and polymeric hydroxylic compounds (16), where no systematic difference from the normal ν_H/ν_D value could be detected for bonded species.

Equilibrium Constants

By making the assumption that the symmetric molar extinction coefficient of an intramolecularly bonded NH_2 group is the same as that for a free NH_2 group,* the percentage of bonded NH_2 groups was estimated for all ortho-substituted compounds. These values are listed in Table I. They range from zero for ortho-alkyl anilines to 56% in *o*-nitroaniline to 100% in ethyl anthranilate and *o*-aminoacetophenone. The lower stability of five-membered chelate rings is readily apparent.

These results indicate that it is difficult for both H atoms of the NH_2 group to hydrogen-bond simultaneously to acceptor atoms (or groups) in the 2,6-positions. Thus in *o*-chloroaniline the percentage of bonded molecules (15%) is the same as it is in 2,4,6-trichloroaniline (15%), whereas in 2,6-dichloro-4-nitroaniline it is increased slightly (24%) due to the strongly electron-withdrawing character of the nitro group in the para position, which increases the HNH angle and brings the H atom closer to the adjacent substituent. In *o*-bromoaniline the percentage of bonded molecules (15%) is also the same as in 2,4,6-tribromoaniline (15%). Since the method used to obtain these values is relatively crude, even in *o*-nitroaniline and 2,6-dinitroaniline the percentage of bonded molecules must be considered to be approximately equal (56% and 43% respectively).

For ortho-halo anilines the order of increased bonding appears to be $F < Cl \approx Br < I$, which agrees with the order of increasing apparent HNH angle calculated for these compounds from the fundamental NH_2 stretching frequencies (5). The low bonding ability of fluorine, the most electronegative element, must be related to the fixed NH $\cdots$ X separation in the intramolecular hydrogen bond. For *o*-fluorophenol n.m.r. evidence (20) indicates that the proton–fluorine separation in the cis isomer is too great for hydrogen bond formation.

Using probable bond lengths and angles, the H$\cdots$X and N$\cdots$X distances can be estimated and compared with covalent atomic radii (Table II). The difference between the H$\cdots$X distance and the sum of the covalent radii for the H and X atoms decreases as the size of the halogen increases. The N$\cdots$X distance is considerably less than the limiting N—H$\cdots$N distance (3.5 Å) and the limiting N—H$\cdots$O distance (3.4 Å), where intermolecular hydrogen bonding has been estimated to vanish (16, pp. 285–293). The hydrogen atom is appreciably off the N$\cdots$X axis, but hydrogen bonding in non-linear systems is well known (16, pp. 304–305).

Frequency Shifts on H-Bond Interaction

The separation between the symmetric band doublet (in those cases where the presence of distinct bands could be established) ranges from 33 cm^{-1} in *o*-aminodiphenyl to 120 cm^{-1} in 2,4-dinitroaniline. Since it is not valid in this case to assume that this frequency displacement is a direct measure of the strength of the hydrogen bond because the NH$\cdots$X distance is fixed by the system, no direct correlation exists with the proportion of the bonded species present.

**This is not unreasonable, since it has been argued (19) that in relatively weak bent intramolecular hydrogen bonds involving five-membered rings the electrostatic interaction is most important, whereas the charge-transfer effects, which are responsible for large intensity increases, are only of secondary importance where the acceptor atom is halogen, oxygen, or nitrogen.*

TABLE II

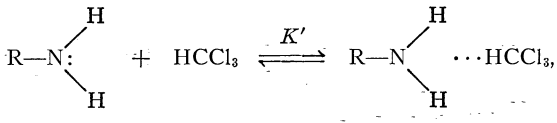
Estimated molecular geometry for *o*-haloanilines

Dimensions (Å)	F	Cl	Br	I
(*a*) H · · · X distance	2.46	2.53	2.57	2.63
(*b*) Sum of covalent radii for H and X	1.09	1.36	1.51	1.70
(*a*) − (*b*)	1.37	1.17	1.06	0.93
N · · · X distance	2.73	2.94	3.03	3.15
Data used in the above calculations:				
C—X distance	1.30	1.70	1.85	2.05
Covalent radius of X	0.72	0.99	1.14	1.33

Aromatic C—C distance: 1.395 Å
C—N distance: 1.43
N—H distance: 1.02
Covalent radius of H: 0.37
HNH angles were taken from Table I of ref. 5

Solvent Dependence

Whetsel (6) has observed that in *o*-nitroaniline and *o*-methylsulphonylaniline, where the symmetric band is split into two well-defined components, the high-frequency component falls at nearly the same position in both CCl_4 and $CHCl_3$, but the low-frequency component shifts toward higher frequencies by 10 to 25 cm^{-1} in $CHCl_3$. Our measurements confirm this for a large number of ortho-substituted anilines. Because the CH band of chloroform at 1409 mμ (7097 cm^{-1}) shifts to lower frequencies in the presence of amines Whetsel has interpreted the bonding to the solvent to be of the type



[5]

in agreement with our earlier suggestion based on other spectroscopic evidence (1). Equilibrium [5] appears to be important only in those aniline molecules in which one of the H atoms is not already bonded to an ortho substituent. The partial shift of lone-pair electrons away from the N atom when the amine becomes bonded to $CHCl_3$ increases the electronegativity of the N atom, and the hydrogen atoms of the amino group are bound more firmly, thus raising the overtone symmetric frequency (low-frequency component). In the intramolecularly bonded molecules the apparent HNH angle opening must be accompanied by charge delocalization from the N atom, decreasing the basicity and hindering complex formation with $CHCl_3$. This is not in agreement with the suggestion of Farmer and Thompson (21) that negative charge is induced on the N atom on hydrogen bond formation.

The results of Whetsel show further that for *o*-methylsulphonylaniline the percentage of intramolecularly bonded molecules decreases in $CHCl_3$. This can be understood in terms of the competition between equilibria [5] and [1].

For ethyl anthranilate, where all molecules are held to be intramolecularly bonded, no pronounced frequency shift for the symmetric singlet is expected on going from CCl_4 to $CHCl_3$. Experimentally a small increase in frequency (< 10 cm^{-1}) is observed, but part of this may be due to overlapping with the 6580 cm^{-1} band, which moves up to 6667 cm^{-1} in $CHCl_3$ and becomes very broad.

The o-tert-Butyl Group

Splitting of the symmetric band was observed for *o-tert*-butylaniline, 2,5-di-*tert*-butylaniline, but not for 2,4,6-tri-*tert*-butylaniline or for any of the other ortho-alkyl anilines examined. In previous work (5) enhanced HNH angles were found for all three of the above compounds. This can probably be ascribed to a steric interaction, the mechanism of which is not yet understood. It is interesting to note that Zanker and Wittwer (22) report a splitting of the asymmetric methyl CH stretching vibration in *o*-toluidine, but not in the meta and para analogues. They suggest hindered rotation of the CH_3 group as a possible cause.

Molar Absorptivities

The overtone molar absorptivities are shown in Figs. 5 and 6 as a function of $\sum\sigma$.

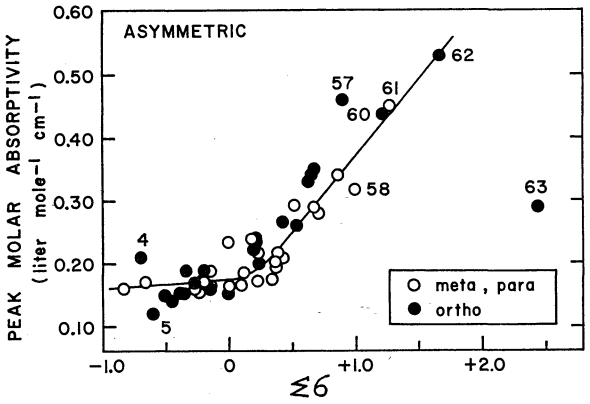

FIG. 5. The molar absorptivity of the first overtone asymmetric NH_2 stretching vibration in CCl_4 solution vs. substituent constants.

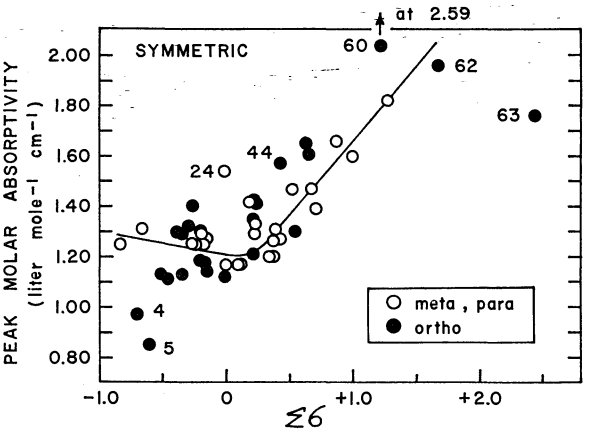

FIG. 6. The molar absorptivity of the first overtone symmetric NH_2 stretching vbiration in CCl_4 solution vs. substituent constants. The absorptivities for ortho-substituted compounds refer to the "free" NH_2 group.

Electron-withdrawing groups increase the intensities for both modes linearly for meta- and para-substituted anilines. As substituents become electron donating in character the asymmetric overtone absorptivity falls slightly, whereas the symmetric overtone absorptivity rises slightly.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

For the asymmetric mode the absorptivities found for ortho-substituted anilines are in good agreement with the results for meta- and para-anilines (Fig. 5). For the symmetric mode a reasonable correlation of all the results is obtained if the observed absorptivity of the low-frequency component is corrected for the estimated percentage in the bonded form now absorbing at a different frequency (Fig. 6). This can be considered as further evidence for the assignment of the low-frequency component to the free NH_2 group.

For ethyl anthranilate and *o*-aminoacetophenone (compounds 54 and 57), which are considered to be 100% bonded, it appears that the symmetric overtone intensity is reduced on intramolecular hydrogen bond formation. Such behavior in the overtones is not unknown (16).

The principal differences in the substituent dependence of the overtone molar absorptivities in relation to the fundamental integrated intensities are:

(*a*) As substituent groups become better electron donors the A_{01} values for both modes continue to fall, whereas ϵ_{02} for the symmetric mode appears to rise slightly.

(*b*) For electron-donating groups A_{01} (asym) > A_{01} (sym), whereas for electron-withdrawing groups this inequality is reversed. For the first overtones the symmetric absorptivities are always between 3 and 6 times as great as the corresponding asymmetric absorptivities.

(*c*) Ortho substitution introduces no general differences into the $\epsilon_{02}/\sum\sigma$ correlation for both modes, provided only the molecules with free NH_2 groups are considered for the overtone measurements. In most cases (except *o*-alkyl) ortho substitution enhances A_{01} for the asymmetric mode.

Electrical Anharmonicity

An approach to the partial interpretation of the above points in terms of the vibrational mechanism previously proposed (5) can be made through the electrical anharmonicity of the vibrations. The presence of electrical anharmonicity in a diatomic molecule implies that the variation of dipole moment M with internuclear distance r as the bond vibrates is not strictly linear, but that M must be replaced by the expression

$$M = M_0+M_1r+M_2r^2+M_3r^3+\ldots \qquad [6]$$

as has been described (15, pp. 94–96).

The fundamental/overtone intensity ratio is actually governed by both the electrical and the mechanical anharmonicity of the vibration. Neglecting terms higher than quadratic in [6], Russell and Thompson (23) have shown that for a diatomic oscillator approximation with $x_e \ll 1$, both the methods of Dunham (24) and of Heaps and Herzberg (25) lead to

$$(A_{02}/A_{01}) = x_e[1-(2B/ar_e)]^2, \qquad [7]$$

where $B = M_2/M_1$, and a is the constant in the Morse potential function

$$V = D_e\{1-\exp[-a(r-r_e)]\}^2 \qquad [8]$$

with vibrational energy levels given by

$$G(v) = (v+\tfrac{1}{2})\omega_e-(v+\tfrac{1}{2})^2x_e\omega_e. \qquad [9]$$

Figures 7 and 8 show that the A_{01}/ϵ_{02} ratio is a function of the electronic effect of the substituents, and that the nature of the dependence varies for the two vibrational modes. For the symmetric mode there is no dependence on the position of the substituent(s), whereas for the asymmetric mode ortho substitution appears to play a large additional

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

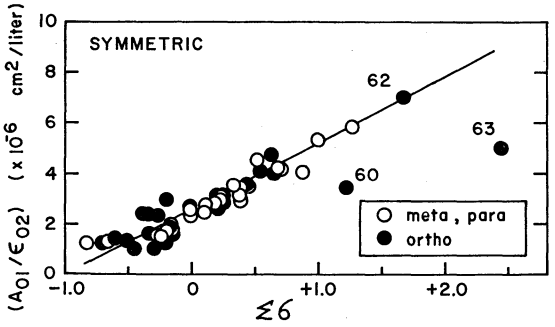

FIG. 7. The fundamental/first overtone symmetric intensity ratio for "free" NH_2 groups and its dependence on the electronic nature and position of ring substituents.

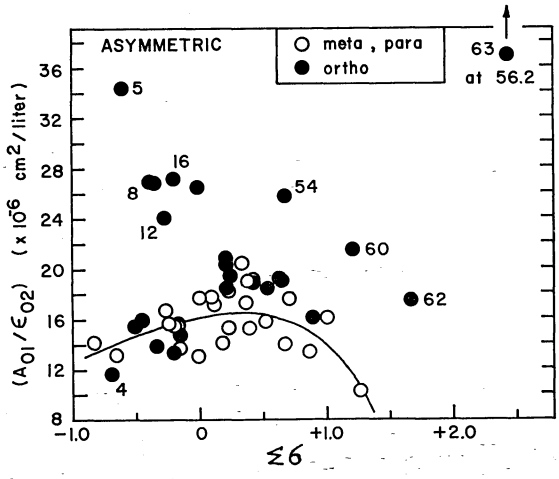

FIG. 8. The fundamental/first overtone asymmetric intensity ratio and its dependence on the electronic nature and position of ring substituents.

role in virtually all those cases where the ortho substituent(s) can accept or donate electrons through a resonance mechanism. Ortho-alkyl compounds (except 2,4,6-tri-*tert*-butyl) behave normally, as expected. The normal behavior of *o*-phenylenediamine suggests a relative orientation of the NH_2 groups so that the lone-pair orbitals would be on opposite sides of the aromatic ring. The positive deviation of the other ortho-anilines from the meta–para correlation in Fig. 8 increases approximately with the absolute value of the Taft σ_R values (4, pp. 594–597) for mono-ortho-substituted compounds. This may be connected with the reversal of sign of the dipole moment during one complete vibrational cycle in this mode.

For a series of secondary amines of widely differing type, Russell and Thompson (23) found a to be $\sim 2\times 10^8$ cm^{-1} and $r_e \sim 1$ Å. Assuming the same values for the aniline series, and letting the product ar_e be a constant as a first approximation, equation [7] becomes

$$B \approx 1-\sqrt{[(1/x_e)(A_{02}/A_{01})]}. \qquad [10]$$

By replacing (A_{02}/A_{01}) by (ϵ_{02}/A_{01}), relative values of the square root quantity were estimated from the experimental data. The results are shown graphically in Figs. 9 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

10. Since the (ϵ_{02}/A_{01}) ratios have relative significance only, a scale adjustment factor must be introduced before the square root quantity is subtracted from unity. If the same

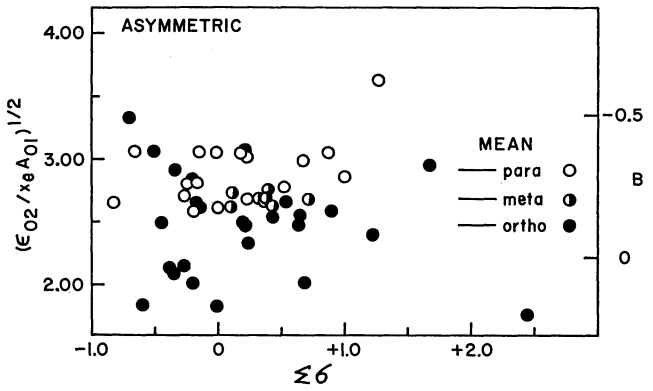

FIG. 9. The relative electrical anharmonicity for the asymmetric NH_2 stretching vibration in substituted anilines. The left-hand ordinate scale units are liter$^{1/2}$ cm^{-1} ($\times 10^3$).

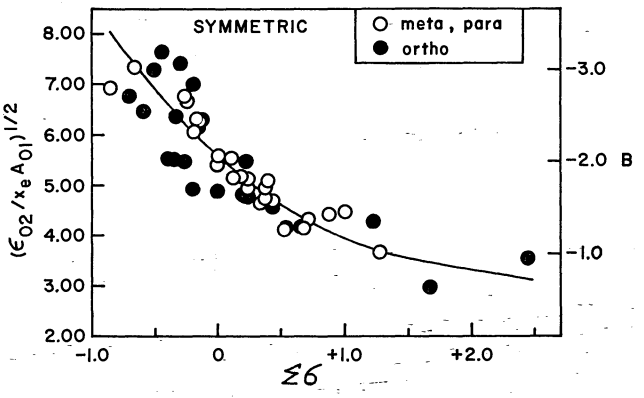

FIG. 10. The relative electrical anharmonicity for the symmetric NH_2 stretching vibration in substituted anilines. The data for ortho-substituted anilines refer to molecules with "free" NH_2 groups. The left-hand ordinate scale units are liter$^{1/2}$ cm^{-1} ($\times 10^3$).

band shape (such as a Lorentz shape) is assumed for both the fundamental and the overtone bands, the ratio

$$(A_{01}/A_{02}) \approx (\epsilon_{01}/\epsilon_{02})(\Delta\nu_{1/2}^{01}/\Delta\nu_{1/2}^{02}) \qquad [11]$$

or approximately 75 and 10 for the asymmetric and symmetric modes respectively.* This is equivalent to multiplying the left-hand ordinate scale in Fig. 9 by $\sqrt{[(15\times10^6)/75]} = 4.5\times10^2$, and the corresponding scale in Fig. 10 by $\sqrt{[(3.0\times10^6)/10]} = 5.5\times10^2$. The right-hand ordinate B scale established by this method in both diagrams is clearly a gross approximation, but the relative values should have significance.

For the asymmetric mode, B appears to be essentially independent of the nature of the substituent, but dependent on its ring position. If the positive square root is taken in [10], the mean ortho, meta, and para B values are -0.1, -0.2, and -0.3 respectively, suggesting that the quadratic term in the dipole moment expansion becomes less important

Both the symmetric and asymmetric first overtone bands have $\Delta\nu_{1/2}^{a}$ values of 80–90 cm^{-1}.

as the substituents move into a position closer to the direction of the transition moment.

For the symmetric mode a smooth correlation is found for ortho-, meta-, and para-anilines, with estimated B values ranging from -3.0 for strongly electron-donating substituents to -1.0 for strongly electron-withdrawing groups, suggesting that non-linearity in the dipole moment change arises primarily in the lone-pair orbital, decreasing as it becomes delocalized over the ring.

Calculations of dipole moment functions based on infrared intensities suffer from the disadvantage of multiple solutions, and decisions as to the most appropriate expression cannot always be made without recourse to some additional information about bond properties. For secondary amines, Russell and Thompson (23) found that the dipole moment expansion for the NH bond became more linear as the degree of ionic character of the bond increased. For a completely ionic bond B should be zero.

These calculations support the vibrational mechanism previously described (5). The contribution of nitrogen lone pair pulsations to the transition moment in the symmetric mode would be expected to lead to increased non-linearity in the dipole moment change, as is observed by comparing the experimental data in Figs. 9 and 10. However, as the lone-pair electrons become more extensively involved in conjugation with a very mobile π-electron system due to electron-withdrawing substituents, the molecules have greater charge separation in the ground state and in vibrationally excited states and hence the symmetric vibration becomes more "ionic". This is reflected in a decrease in $|B|$. Ortho substitution introduces no significant perturbation since the major contribution to the transition moment in this mode is due to the lone-pair component and the π-electron component.

In the asymmetric vibration the dipole moment function is determined primarily by movement of the charge centroids in the NH bonds as the equilibrium NH distances change. Because of their position with respect to the direction of the transition moment, and due to the reversal of sign of the dipole moment during the vibrational cycle, ortho substituents increase the "ionic character" of this vibration. The overall change in B is smaller than in the symmetric mode because of the relatively small amount of charge movement in the NH bonds themselves.

The Potential Energy Curve for the Hydrogen-Bonded Proton

Recent work by Barrow and his associates (26) has demonstrated experimentally the existence of energy level splitting resulting from a double minimum in the potential energy curve for the intermolecularly hydrogen-bonded proton in some systems. In order to account for the pair of solvent-dependent absorption bands in the first overtone OH stretching region for alcohols, the second minimum would have to lie in the region of the $v = 2$ vibrational level. No experimental evidence for such splitting in intramolecularly hydrogen-bonded systems appears to have been presented, and it is not clear how such a phenomenon would affect the symmetric and asymmetric vibrational modes of the NH_2 group. The experimental data and their interpretation presented here cannot, however, definitely rule out the double minimum explanation for these systems, and further work on the nature of the proton potential energy function is in progress.

ACKNOWLEDGMENTS

The author is indebted to Professor B. M. Wepster (Technische Hogeschool, Delft) and Professor L. R. C. Barclay (Mt. Allison University, Sackville, New Brunswick) for some samples of ortho-substituted amines. The overtone measurements were made by Mrs. G. D. Brown.

PROTON MAGNETIC RESONANCE ABSORPTION IN ETHYL STEARATE

R. F. GRANT[1]

AND
D. LLEWELYN WILLIAMS
Physics Department, University of British Columbia, Vancouver, British Columbia
Received August 8, 1962

ABSTRACT

The proton magnetic resonance absorption in ethyl stearate has been investigated at −77, 0, and 24° C in the solid β-phase and at 28° C in the solid α-phase. Spin-lattice proton magnetic resonance relaxation times were measured in the liquid up to 75° C and in the solid α-phase. The results suggest that the α-phase is composed partly of molecules in a liquid-like state and partly of molecules constrained to rotate about their longitudinal axes. The results also support the proposal that the dielectric dispersion observed in the β-phase is due to molecular motion in crystal defects.

INTRODUCTION

Ethyl stearate is dimorphic and may freeze into the translucent α-phase, in which the long hydrocarbon chains of the molecules are perpendicular to the plane formed by the end groups. The α-phase is unstable and changes irreversibly into the stable β-phase, in which the hydrocarbon chains are tilted with respect to the plane of the end groups (1).

Dielectric studies on ethyl stearate in the α-phase and β-phase have been interpreted in terms of molecular motion (2–4). In the β-phase this motion is generally thought to be associated with crystal defects, although there is some difference of opinion as to the kind of motion involved (3, 4).

Proton magnetic resonance absorption studies in some solid, long-chain hydrocarbons have revealed the presence of various kinds of molecular motion (5, 6). The following is a similar study of the molecular motion in ethyl stearate.

EXPERIMENTAL METHOD

The proton magnetic resonance absorption line shapes were measured with a spectrometer of conventional design employing a marginal oscillator (7). The magnetic field of 4000 gauss was supplied by a regulated Newport Type A electromagnet.

Spin-lattice relaxation times T_1 in the liquid and in the solid α-phase were measured by the Hahn method using two 90° pulses (8). The pulse spectrometer used for these measurements has been described previously (9).

The purified ethyl stearate used in this study was kindly supplied by Dr. D. W. Davidson of the National Research Council. In the β-phase, this ethyl stearate melted at 33.1° C. The sample used for T_1 measurements was degassed under vacuum by the freeze–pump–thaw method in order to remove the dissolved oxygen, which would otherwise affect the value of T_1; this procedure was carried out 15 times before the sample tube was sealed.

The sample was enclosed in a brass case and was maintained at −77° C by immersing the case in dry ice; an ice bath was used for 0° C. The temperatures above 20° C were held within ±0.1° C by circulating water from a large thermostated bath through copper tubing surrounding the sample case. Temperatures were measured by a copper–constantan thermocouple attached to the top of the sample tube.

RESULTS

The derivative curves of the proton magnetic resonance absorption in the β-phase of ethyl stearate observed at −77, 0, and 24° C, are shown in Fig. 1 These curves each

[1]*Present address: Canadian Services College, Royal Roads, Victoria, British Columbia.*

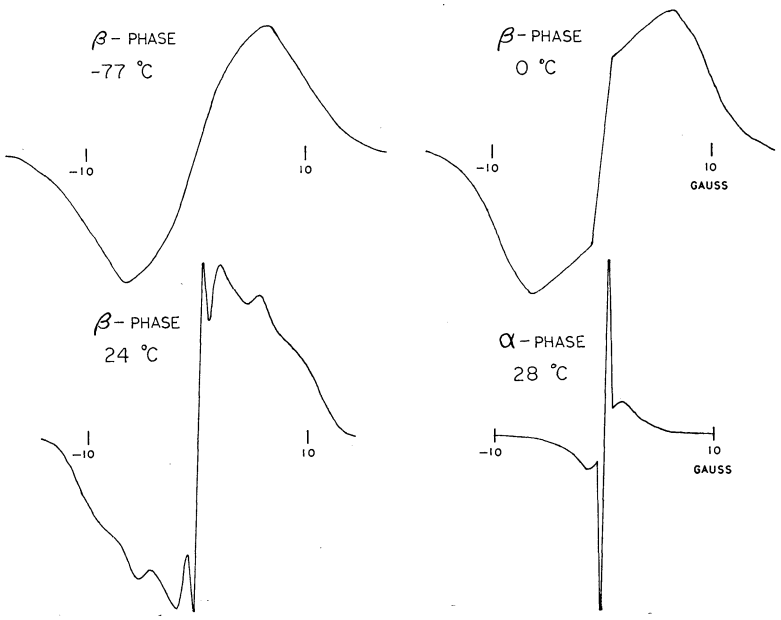

FIG. 1. Averaged derivative absorption curves from ethyl stearate in the α-phase and the β-phase.

represent the average of six traces. The second moments of the curves were calculated by a graphical method (10) and were corrected for the effects of modulation. The second moments are 25.8 gauss^2 at $-77°$ C, 24.3 gauss^2 at 0° C, and 21.0 gauss^2 at 24° C. The derivative of the resonance absorption in the α-phase of ethyl stearate observed at 28° C is also shown in Fig. 1; the second moment is 6.6 gauss^2.

The widths of the narrow peaks on the derivative curves found at 24° C in the β-phase and 28° C in the α-phase seem to be limited by the magnetic field inhomogeneity and modulation amplitude.

The spin-lattice relaxation times T_1 found in liquid ethyl stearate are shown in Fig. 2;

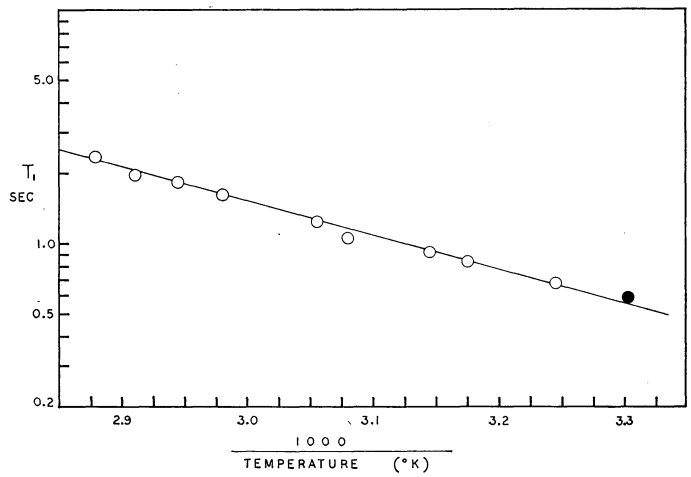

FIG. 2. Spin-lattice relaxation times for ethyl stearate as a function of inverse temperature. Open circles from liquid; filled circle from solid α-phase.

For personal use only.

they range from 2.34 sec at 74.4° C to 0.68 sec at 35.0° C. A T_1 of 0.59 sec was observed in the solid α-phase at 29.1° C, or about one degree below the α-phase freezing point. The same T_1 of 0.59 sec was found at 28.0° C and the normalized amplitude of the first pulse decay was observed to decrease with time. At 28.0° C the first pulse decay decreased to one half of its original intensity in 30 minutes and to one quarter in 50 minutes. Throughout this time there was no change in T_1. The sample was inspected before and after this experiment; it was definitely in the α-phase and it did not change in appearance.

DISCUSSION

The rigid lattice second moment, S, of the proton magnetic resonance for a polycrystalline sample can be calculated by a modification of Van Vleck's formula:

$$S = \frac{716}{N} \sum_{j>k} r_{jk}^{-6},$$

where N is the number of protons considered and r_{jk} is the distance between two protons j and k in angstrom units (11). The intramolecular proton distances in ethyl stearate were calculated by assuming that the dimensions of the molecule are the same as those obtained from electron diffraction studies of simple paraffin molecules (12). For convenience in calculation, the carboxyl group was treated as if it were part of the carbon skeleton of the paraffin chain. The intramolecular contribution to the second moment was found to be 18.5 gauss^2. The unit cell parameters for β-phase ethyl stearate suggested by Fitzgerald (13) were used in calculating the intermolecular second moment; it was found to be 9.0 gauss^2. The predicted rigid lattice second moment for β-phase ethyl stearate is 27.5 gauss^2.

According to the theory of Gutowsky and Pake, the second moment of the resonance absorption line should decrease when molecular reorientation becomes sufficiently rapid (14). Therefore some molecular motion should occur in ethyl stearate at −77° C or higher. Other studies have indicated that in simple long-chain hydrocarbons, the end methyl groups may be free to rotate about their C_3 axes at low temperatures (15). If this motion occurs in ethyl stearate the second moment should be reduced to 23.1 gauss^2. The results show that the methyl end groups probably do not rotate at −77° C or even at 0° C, and it is suggested that the difference between the rigid lattice and experimental second moments at these temperatures is due to torsional oscillation about the long axis of each chain (5, 16). At 24° C the proton resonance absorption line has a complicated structure and it is apparent that motion other than torsional oscillation is taking place. The innermost component of this line is similar to those narrow components that have been found in the resonance absorption spectra of several long-chain hydrocarbon compounds a few degrees below their melting points (5, 6, 15). These narrow peaks are thought to be due to the somewhat unhindered and random motion of molecules or parts of molecules in crystal lattice defects (6). Since the correlation frequency of the motion associated with such narrow peaks is usually in the order of several megacycles (14, 16), it seems likely that this motion contributes to the radio-frequency dielectric dispersion observed in β-phase ethyl stearate.

It can be seen from Fig. 2 that there is no abrupt change in T_1 as ethyl stearate passes from the liquid to the solid α-phase. Thus the freshly formed α-phase seems to contain molecules in a state of motion similar to that of the liquid. As the α-phase ages the amplitude of the first pulse decay decreases, while T_1 remains constant. This could be explained if the molecules in rapid, random motion gradually become part of another structure in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

which the motion is much more restricted, for the resonance line may then have a width too broad to be observed with the pulse apparatus available. These rapidly moving molecules may represent included liquid or zones of disorder associated with the α-phase crystals. It was assumed that the narrow component of the α-phase resonance absorption curve shown in Fig. 1 represented these separate zones in the sample; therefore only the broad component was used to obtain the experimental second moment for the solid.

Ethyl stearate in the α-phase has been shown by X-ray investigation to possess hexagonal symmetry with the hydrocarbon chains arranged parallel and about 4.12 Å apart (1). A rigid lattice intermolecular second moment of 7.7 gauss^2 and a total second moment of 26.2 gauss^2 was found for this model. If the molecules rotate about their long axes, as is generally believed (1), then the second moment should be 7.8 gauss^2. This is larger than the experimentally observed value of 6.6 gauss^2; however, a slight flexing of the rotating chains could qualitatively account for this difference (5). Alternatively, a predicted value of 6.6 gauss^2 is obtained if the methyl groups at the ends of the rotating chains move independently about their C_3 axes.

THE BEHAVIOR OF D-GLUCURONIC, D-GALACTURONIC, AND D-MANNURONIC ACID IN DILUTE AQUEOUS SODIUM HYDROXIDE

I. R. SIDDIQUI[1] AND C. B. PURVES

Received October 3, 1962

ABSTRACT

Two percent aqueous sodium hydroxide at room temperature, preferably for 24 hours, was used to obtain the Lobry de Bruyn – van Ekenstein transformation products. The transformations proceeded much more slowly than in the case of the hexoses; complex changes in specific rotation occurred, and equilibrium among the products was not attained, probably because acidic non-reducing substances formed at a comparable rate. After 24 hours, 39% of D-glucurone was recovered unchanged, together with 9% of D-mannuronic acid and 2% of keto acid probably based on fructose. D-Mannurone gave the same products, but unchanged starting material once more predominated. D-Galacturonic acid was recovered in 58% yield together with 12% of D-taluronic acid, a new substance characterized as a crystalline monohydrated brucine salt. A trace of a keto acid, presumably derived from D-tagatose, was also formed.

INTRODUCTION

During a recent study (1) it was incidentally noticed that D-galacturonic acid appeared to be much more resistant to the oxidizing action of chlorous acid, and also to the Lobry de Bruyn – van Ekenstein transformation in 1% aqueous sodium hydroxide, than was an aldohexose. It was also known (2) that glycosides of uronic acids were unusually resistant to acid hydrolysis. These observations suggested that the chemical behavior of the aldehyde group in uronic acids should be studied in its own right, and this article is concerned with the behavior of uronic acids in cold, dilute alkali. Applications of the Lobry de Bruyn – van Ekenstein transformation to reducing carbohydrates and a few polyuronides have been reviewed (3, 4); more drastic conditions were necessary to epimerize the aldonic acids (3, 5, 6) and galactaric acid (7). D-Galacturonic acid with aqueous calcium or strontium hydroxide was reported to yield some 5-keto-L-galactonic acid, but other reducing substances were produced with baryta. D-Glucuronic acid behaved similarly (8), but lime water converted the 4-O-methyl derivative into a dicarboxylic acid (2).

Preliminary work, carried out by our former colleague E. W. H. Böhme, involved keeping D-glucurone in 1% aqueous sodium hydroxide at room temperature for various times, then removing cations on an ion-exchange resin and chromatographing the effluent on paper. Glucuronic acid or glucurone appeared to be almost completely stable under the conditions cited. The present research therefore employed 2, 6, and 12% aqueous sodium hydroxide at room temperature for periods of 2, 5, 7, and 24 hours. When the chromatograms were developed with naphthoresorcinol a faint blue spot indicated the presence of a keto acid, while a subsequent treatment with water vapor at 70° brought out two new blue spots. This behavior was characteristic of uronic acids (9), and control experiments showed that the greater of these two spots was unchanged glucuronic acid. The acidic nature of these products was substantiated by their negligible movement on paper chromatograms eluted by a basic solvent system. After the glucurone had been in

the alkali for a week, the naphthoresorcinol and *o*-aminodiphenyl sprays failed to develop any spots on the paper chromatograms; other chromatograms developed with a bromophenol blue spray, however, contained five or six spots corresponding to non-reducing acids of lower molecular weight. It appeared, therefore, that the Lobry de Bruyn – van Ekenstein transformation was accompanied by a rather rapid sequence of degradation reactions. These reactions were not investigated in the present research.

Since the experiments showed that 2% aqueous sodium hydroxide at room temperature for about 24 hours produced maximum amounts of the two new spots, these conditions were used in subsequent work. D-Mannurone produced a chromatographic pattern superposable on that from D-glucurone, with the exception that the major component was unchanged mannuronic acid. Thus the results suggested that glucurone and mannurone did not yield the same equilibrium mixture of glucuronic, mannuronic, and fructuronic acids, probably because side reactions competed on approximately equal terms with the Lobry de Bruyn – van Ekenstein transformation.

Under the same conditions, D-galacturonic acid yielded a chromatographic spot corresponding to the starting material, together with a minor spot. D-Galacturonic acid was then isomerized on a larger scale and preparative paper chromatography was used to recover from the product both unchanged galacturonic acid (58%) and D-taluronic acid (12%), the former being isolated in a crystalline condition and the latter, a new compound, as a crystalline, monohydrated brucine salt. The crude brucine taluronate contained traces of another brucine salt which gave the naphthoresorcinol test for the salt of a keto acid, presumably the unknown D-tagaturonic acid. To investigate this possibility, the isomerized product was converted to a methyl ester methyl glycoside mixture which was then reduced with lithium aluminum hydride and finally hydrolyzed with aqueous acid. When separated by paper chromatography, the product yielded crystalline D-galactose and an uncrystallized D-talose which was characterized as the crystalline methylphenylhydrazone. The chromatogram also yielded a substance responding to the naphthoresorcinol test and having an R_F value in the range expected for keto sugars. Only a trace, however, could be isolated, and its identity with D-tagatose was not definitely proved.

A larger-scale isomerization of D-glucurone, followed by quantitative paper chromatography, yielded 39%, 8.5%, and 1.9% of glucuronic, mannuronic, and presumably fructuronic acid, the mole ratio being approximately 20:5:1. Reduction and subsequent hydrolysis of the corresponding mixture of methyl glycoside methyl esters gave a mixture of neutral sugars from which paper chromatography recovered D-glucose and D-mannose. The former, which crystallized, was also identified as N-*p*-nitrophenyl-β-D-glucosylamine dihydrate; the latter, which failed to crystallize, was characterized as the corresponding crystalline derivative of mannose. Fructose was recovered in amounts too small for positive identification.

Since control experiments showed that glucose readily yielded both mannose and fructose when kept dissolved in 1% sodium hydroxide for 2 hours, glucuronic, mannuronic, and galacturonic acids differed from the hexoses by failing to yield substantial quantities of keto isomers. Fischer and Schmidt (10), however, recently showed that when sodium salts of the above uronic acids were heated in aqueous solution at pH 7 and 100° for 2 hours or more, the Lobry de Bruyn – van Ekenstein transformation at C_2 was suppressed in favor of isomerism at C_5, D-glucuronic acid, for example, yielding 40% or more of L-iduronic acid. The influence of temperature and hydrogen ion concentration on the uronic acids thus appears to be complex, and worthy of further study.

EXPERIMENTAL

The following mixtures (v/v ratios) were used for paper chromatograms: (A) ethyl acetate:acetic acid:water (9:2:2); (B) *n*-butanol:formic acid:water (500:115:383); (C) ethyl acetate:pyridine:water (8:2:1); (D) ethyl acetate:acetic acid:water (3:3:1). Reducing sugars were detected with A, an *o*-aminodiphenyl spray (11); keto sugars with B naphthoresorcinol; after development, the latter chromatograms were treated with water vapor at 70° to reveal uronic acids (9). Spray C, bromophenol blue in 95% ethanol, was used to detect acids (12). To remove formic or acetic acid completely, the chromatograms were dried *in vacuo* at 110° for 8 hours before being sprayed. Whatman No. 3MM paper with a wick of No. 1 paper was used in preparative paper chromatography, the sheets measuring 46.5 cm by 57 cm.

Optical rotations were measured on a photoelectric precision polarimeter to 0.005° and were equilibrium values unless otherwise stated. All specific rotations were measured at 25±1° and at the sodium D line wavelength. Evaporations were carried out at 35° in a rotary film evaporator. All the uronic acid samples used for control purposes were chromatographically pure. Amberlite IR-120 resin (Rohm and Haas Company) was used to deionize the solutions.

Preliminary Experiments

Samples, 25 mg, of D-glucurone were kept dissolved in 10-ml volumes of 2%, 6%, and 8% aqueous sodium hydroxide at room temperature. After 2, 5, 7, and 24 hours, 1-ml aliquots were mixed with 2 ml of the ion-exchange resin and were then spotted on chromatograph paper. The use of solvents A and B with spray A in each case revealed D-glucuronic acid as the major component, and small amounts of two other substances ($R_{glucurone}$, 0.47, 0.38 in solvent A; 0.50 and 0.42 in solvent B). Spray B detected only the component of $R_{glucurone}$ 0.47, 0.50 and this reaction for a fructuronic acid was very weak; subsequent development with water vapor at 70° yielded blue spots for all the components but that for the keto acid was still weakest. No movement occurred in the basic solvent C. When the action of the alkali was prolonged for 7 days, paper chromatography showed the presence of no reducing products whatever. Solvent B and spray C yielded faint spots of R_F 0.26, 0.34, 0.40, 0.45, 0.55, and 0.65, which were thought to be those of non-reducing acids of lower molecular weight. The maximum production of new reducing substances occurred when the 2% sodium hydroxide acted for 24 hours.

A similar treatment of D-mannuronic acid ended in paper chromatograms with spots superposable on those in similar chromatograms from D-glucurone, with the difference that D-mannuronic acid instead of D-glucuronic acid was the major component. An examination of D-galacturonic acid under the same conditions gave chromatograms showing much unchanged starting material and a small amount of a compound with $R_{glucurone}$ 0.49 in solvent A, a blue spot being developed by spray B followed by the water vapor treatment. The accompanying changes in specific rotation (Table I) were complex.

*One percent solutions in 2% aqueous sodium hydroxide at room temperature.
†Four percent solution in 3% sodium hydroxide.

Isolation of Talose and Taluronic Acid

(*a*) A solution of D-galacturonic acid, 1 g, in 100 ml of 2% aqueous sodium hydroxide, was kept at room temperature, the specific rotation decreasing from +14.3 after 30 minutes to −0.9 after 24 hours. The solution was then deionized with 50 ml of Amberlite IR-120 resin and was evaporated to a syrup, 900 mg. This syrup was separated on eight sheets of chromatographic paper with solvent A and elution of the appropriate strips gave 454 mg of galacturonic acid and 95 mg of the uronic acid of $R_{glucurone}$ 0.49. These products were separately heated under reflux for 8 hours with 2% methanolic hydrogen chloride, and the resulting methyl ester methyl glycosides were separately reduced with an excess of lithium aluminum hydride (13) in tetrahydrofurane. The methyl glycosidic groups were hydrolyzed from the products in *N* sulphuric acid for 10

For personal use only.

hours at 100°, and paper chromatography of the two syrups yielded one spot with the R_F and staining properties of galactose in one case and of talose in the other. Crystallization from 95% ethanol gave D-galactose, m.p. 167–170°, and specific rotation +85.5° (*c*, 4.17 in water).

Since the recovery of talose was too small to permit identification, the experiment was repeated with 5 g of D-galacturonic acid. After hydrolysis of the mixture of methyl hexosides, 2.2 g, the product was separated on 12 sheets of paper to yield 1.6 g of D-galactose, 0.15 g of uncrystallized talose, and traces of ketose. A solution of all of the talose fraction in 1 ml of water was mixed with 1 ml of a solution made from 25 g of 1-methyl-1-phenylhydrazine, 100 ml of ethanol, and 3 ml of glacial acetic acid (14). After being kept for 12 hours at 37°, the mixture was cooled to 0°, and 24 hours later 7 mg of crystals was removed. These crystals had m.p. 154–155° and a specific rotation of −4.6° (*c*, 0.63 in methanol), whereas the recorded melting points of the methylphenylhydrazone of talose were 154° (15) and 220–222° (16).

The trace of a ketose recovered from the chromatograms had an R_F value and staining properties appropriate to a ketohexose and therefore appeared to be tagatose.

(*b*) A second 5-g sample of D-galacturonic acid was treated with aqueous sodium hydroxide, the solution was freed of cations, all as described above, and was then chromatographed on 36 sheets of paper, using solvent A. Elution of the appropriate strips gave 2.74 g of galacturonic acid and 0.56 g of taluronic acid. After allowing 6% for locating the strips, these yields corresponded to 58% and 12% respectively. The galacturonic acid had m.p. 103–107° and specific rotation +50.5° (*c*, 1.97 in water), after crystallization from aqueous ethanol, whereas the original sample had m.p. 103–107° and a rotation of 47.9° (*c*, 2.94 in water).

Attempts to crystallize the taluronic acid were unsuccessful. A 200-mg sample was therefore heated at 100° for 10 minutes in 60 ml of water containing 480 mg of brucine. After cooling the solution, excess brucine was removed by three extractions with chloroform, the aqueous residue was concentrated to about 10 ml, and was diluted with acetone. A slight turbidity was removed on the centrifuge, and concentration of the clear liquor yielded a syrup which was dissolved in aqueous ethanol. The slow evaporation of this solution deposited crystals of brucine taluronate monohydrate; m.p. (decomp.) 151–154° with softening at 145°; specific rotation −20.5° (*c*, 1.02 in water). Anal. Calc. for $C_{29}H_{36}O_{11}N_2,H_2O$: C, 57.2; H, 6.2; N, 4.62%. Found: C, 57.0; H, 6.14; N, 4.76%.

The minute amount of acetone-insoluble material removed from the above brucine salt, when chromatographed on paper with naphthoresorcinol as the spray, yielded a single blue spot. This behavior suggested that a trace of the unknown tagaturonic acid was present.

Products from the Transformation of D-*Glucurone*

(*a*) A solution of 1 g of D-glucurone in 100 ml of 2% aqueous sodium hydroxide was decationized after 24 hours and was concentrated to a syrup, 1.1 g, which was quantitatively chromatographed on 16 sheets of paper using solvent A. Fraction 1, 284 mg, was glucuronic acid; fraction 2, 87 mg, mannuronic acid; fraction 3, 18 mg, an unidentified keto acid; fractions 4 and 5, traces of unidentified material; fraction 6, 80 mg, glucurone. After correction for a 6% loss in the guide strips of the chromatograms, the yields were: glucuronic acid plus glucurone, 39%; mannuronic acid, 9.2%; unknown keto acid, 1.9%.

Fractions 4 and 5 were not investigated. The others were separately converted to the methyl ester glycosides, reduced, and hydrolyzed to the free sugars as previously described. Chromatography in solvents A, C, and D with sprays A and B showed that fractions 1 and 6 contained glucose; fraction 2, mannose with traces of glucose and a ketose; fraction 3, like the trace of ketose in fraction 2, had staining properties (naphthoresorcinol) and an R_F value identical with those of fructose, and a trace of mannose was also present.

The combined syrup, 150 mg, from fractions 1 and 6 was heated under reflux for 15 minutes with 3 ml of a solution made from 9 g of *p*-nitroaniline, 200 ml of methanol, and 0.14 ml of concentrated hydrochloric acid. After being filtered while hot, the solution deposited crystals which were twice recrystallized from methanol. The product, m.p. 184–185° and specific rotation −215° (*c*, 1.09 in dry pyridine), was N-*p*-nitrophenyl-β-D-glucopyranosylamine dihydrate, the reported constants (17) of which were m.p. 184° and $[\alpha]_D^{20}$ −201° (*c*, 1.0 in dry pyridine).

(*b*) To identify mannose, a 5-g sample of D-glucurone was treated as described in (*a*) to yield 2 g of the neutral sugars. Of this mixture, 1.2 g was separated on 12 sheets of paper (solvent D) to yield 0.52 g of glucose and 70 mg of uncrystallized mannose, together with a minute amount of fructose. The glucose crystallized and after recrystallization from aqueous ethanol had the correct melting point and specific rotation. The syrupy mannose fraction, 70 mg, was converted to the crystalline N-*p*-nitrophenyl-β-D-mannosylamine dihydrate, which had the specific rotation −335° (*c*, 0.185 in dry pyridine) and m.p. 219°. The recorded rotation was $[\alpha]_D^{20}$ −325° (*c*, 0.16 in dry pyridine) and m.p. 219°. A mixed melting point with an authentic sample was not depressed.

ACKNOWLEDGMENTS

The authors wish to thank Professor J. Riechlein for a sample of D-talose, Mr. A. E. Castagne for carrying out the microcombustions, and the National Research Council of Canada for a grant in aid of research.

THE PROTON RESONANCE SPECTRA OF BENZYL ACETONE

STEVEN S. DANYLUK[1]
Department of Chemistry, University of Toronto, Toronto, Ontario
Received September 12, 1962

ABSTRACT

The proton resonance spectra of benzyl acetone (4-phenyl-2-butanone) are reported in a variety of solvents at 23° C. A marked solvent dependence is noted for the CH_3 group and the methylene protons adjacent to the keto group. The shifts to high field in aromatic solvents are interpreted in terms of a specific dipole-induced interaction with solvent molecules.

The signals for the two non-equivalent pairs of methylene protons show changes in coupling constant with temperature. From this it is concluded that rapid rotation occurs about the C—C bond in the temperature range investigated with an increase in population of the trans conformation at low temperature. Significant changes in relative chemical shifts are also noted with temperature change for the two pairs of methylene protons and are attributed to the formation of weak molecular complexes in aromatic solvents.

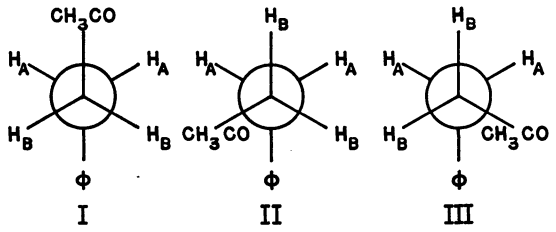
INTRODUCTION

The rate of interconversion about the C—C bond in 1,2-disubstituted ethanes of the type CH_2XCH_2Y is generally quite rapid (1, 2, 3) and the averaged chemical shifts and coupling constants are observed under normal conditions. A substantial decrease in the rotation rate and a preferential population of one conformation can be effected either by lowering the temperature sufficiently or by introducing bulky substituents on the ethane-like skeleton. Solvents may also exert an influence on the rotation rate, particularly in cases where specific intermolecular interactions are possible between solvent molecules and substituent groups.

In this work we report the proton resonance spectra for benzyl acetone in a number of solvents at 23° C and over the temperature range −85° to 95° C in several solvents. It might be expected that introduction of bulky substituents such as the phenyl and keto groups would strongly hinder or block entirely rotation about the "ethane-like" C—C bond in this compound. The proton resonance spectrum would then consist of superimposed A_2B_2 and ABCD type spectra (4) corresponding to the trans, I, and equivalent gauche II, III conformations respectively.



An additional effect arising from interactions between the polar carbonyl group in benzyl acetone and solvent molecules would also influence the spectrum for benzyl acetone.

[1]*This work was initiated during the tenure of an N.R.C. postdoctoral fellowship, 1958–60.*

EXPERIMENTAL

All of the chemicals used were of White label or reagent grade; benzyl acetone was obtained from the Aldrich Chemical Company and was redistilled before use. The concentration of benzyl acetone was 10 mole% in each of the solutions investigated. No significant changes in chemical shift (i.e. greater than 0.5 c/s) were noted for more dilute solutions. Spectra were recorded at 23±1° C with a Varian DP60 spectrometer operating at 60 Mc/s and equipped with a flux stabilizer. The signal separations were measured relative to internal tetramethylsilane by the audio side-band technique (5) and are accurate to ±0.3 c.p.s. Spectra were recorded for several solutions over a temperature range of −85° to 95° C using a thermostatted temperature control device described previously (6).

The proton resonance spectrum for the partially deuterated benzyl acetone, $C_6H_5CH_2CD_2COCD_3$, prepared by Dr. Leitch of the National Research Council, was measured in several solvents and aided in the assignment of the methylene proton signals.

RESULTS AND DISCUSSION

The proton resonance spectrum for benzyl acetone shows a marked dependence on the type of solvent used. This is clearly illustrated in Fig. 1, which shows the signals for the

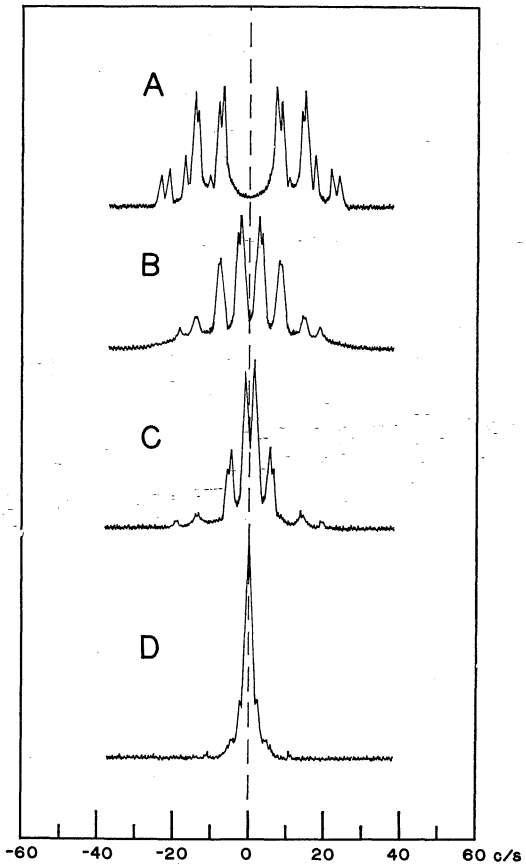


FIG. 1. Proton resonance spectra of benzyl acetone at 23° C. (A) 10 mole% in benzene; (B) pure benzyl acetone; (C) 10 mole% in carbon disulphide; (D) 10 mole% in acetone.

two magnetically non-equivalent pairs of methylene protons in several different solvents. A well-defined A_2B_2 type spectrum is observed in benzene solution while an almost completely collapsed spectrum results in acetone.

*Chemical shifts are reported for 10 mole% solutions relative to internal tetramethylsilane and are accurate to ±0.3 c/s. The J_{AB} values are accurate ±0.2 c/s.

assumed to be equal on the basis of the 14-line spectrum observed in benzene solution (7). The signals to the low field side of the A_2B_2 midpoint are assigned to the proton pair (A) adjacent to the phenyl ring on the basis of chemical shifts observed for the methylene protons of $C_6H_5CH_2CD_2COCD_3$. Only a very slight solvent dependence is noted for the chemical shift of the proton pair (A) closest to the ring. On the other hand, the proton pair (B) adjacent to the carbonyl group shows fairly large chemical shift changes. Aromatic solvents, with the exception of pyridine, shift the B protons to high field while polar aliphatic solvents such as acetone and acetonitrile act in the opposite direction. Thus, for example, the relative shifts ($\delta_B-\delta_A$) are 32.9 c/s in benzene, 2.0 c/s in acetone, and 14.8 c/s in an inert non-polar solvent *n*-hexane. The relative shift $\delta_B-\delta_A$ for pure benzyl acetone is somewhat larger than an earlier value of 12.6 c/s reported by Braillon (8).

The internal shift changes with solvent for the CH_3 group, Table I, parallel those observed for the B proton pair. For example, in benzene the shift to high field relative to the *n*-hexane value, 18.5 c/s, is very similar to that observed for the B protons, 21.3 c/s.

The coupling constant J_{AB} is identical in all of the solvents investigated at 23° C and is close to the mean value of J_{trans} and J_{gauche} coupling constants observed for other disubstituted ethanes (7). The present J_{AB} value of 8.0±0.2 c/s is slightly lower than the J_{AB} value reported for dibenzyl acetone, 8.6 c/s (8).

The proton resonance spectra for pure benzyl acetone and solutions in CS_2, *n*-hexane, and toluene were of the A_2B_2 type over a fairly wide temperature range, −85° to 95° C. No indication of ABCD spectra corresponding to gauche conformations II and III was evident even at low temperatures, −85° C. These results indicate that rapid rotation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

occurs about the C—C bond even at low temperatures despite the presence of bulky substituents.

A small but detectable decrease of J_{AB} from 8.3 c/s at −20° C to 7.3 c/s at 95° C was noted in toluene solutions. The measured coupling constant represents, in the present case, the weighted average of the trans J_T and gauche J_G coupling constants (7, 9) and is given by $J_{AB} = pJ_T+(1-p)J_G$, where p is the population of the trans conformation. Accordingly, the increase of J_{AB} with decreasing temperature is indicative of a preferential population of the trans conformation at lower temperatures; $J_T > J_G$ for disubstituted ethanes (7). A satisfactory estimate of the energy barrier could not be determined, however, since the temperature dependence did not follow the expected exponential behavior.

The relative shift $\delta_B-\delta_A$ also shows significant changes with temperature in the solvents investigated, Fig. 2. In aliphatic solvents, both polar and non-polar, the relative shift

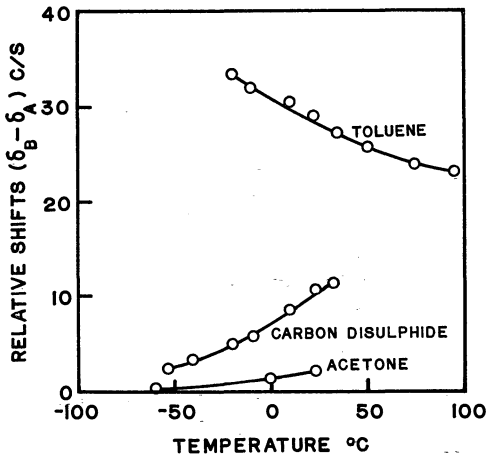

FIG. 2. Temperature variation of the relative shifts for the methylene protons.

increases in each case with increasing temperature. Thus, in carbon disulphide $\delta_B-\delta_A$ increases from 2.5 c/s at −53° C to 12.2 c/s at 45° C. Although the change of $\delta_B-\delta_A$ with temperature in the inert solvents *n*-hexane and carbon disulphide is a good indication of population changes for the trans and gauche conformations, it is not a satisfactory parameter for estimating rotational energy barriers in the present system because of the possibility of complicating solute–solute interactions.

In non-polar aromatic solvents, on the other hand, $\delta_B-\delta_A$ shows a substantial decrease with increasing temperature; for example, in toluene, $\delta_B-\delta_A$ decreases from 33.0 c/s at −20° C to 23.1 c/s at 95° C. A similar change is noted in benzene. The internal shift change with temperature for the CH_3 group parallels the behavior of the B protons in toluene and benzene. In contrast, the chemical shift for the A protons is relatively insensitive to temperature changes.

The preceding internal shift changes with temperature are very similar to those observed recently by Schneider and Hatton (10) for acetonitrile, *p*-benzoquinone, and N,N-dimethylformamide in toluene. Temperature coefficients, $d\delta/dT$, ranging from −0.02 to −0.18 c/s per °C were observed to be dependent upon the concentration and nature of the solute. These low field shifts with increasing temperature have been attributed to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

formation of molecular complexes between polar solute molecules and aromatic solvent molecules (10).

The formation of weak molecular complexes between polar solutes and aromatic solvents has been conclusively shown for a large number of systems (11,* 12, 13).

Both the high field shifts for the CH_3 protons and B protons in benzene and toluene as compared with aliphatic solvents (Table I) and the $\delta_B - \delta_A$ changes with temperature in the aromatic solvents can be interpreted in terms of weak complex formation. Accordingly, a specific dipole-induced interaction between benzyl acetone and the aromatic solvent molecule results in the formation of a molecular complex whose configuration is illustrated in Fig. 3. In this complex the carbonyl group is directed away from the aromatic ring

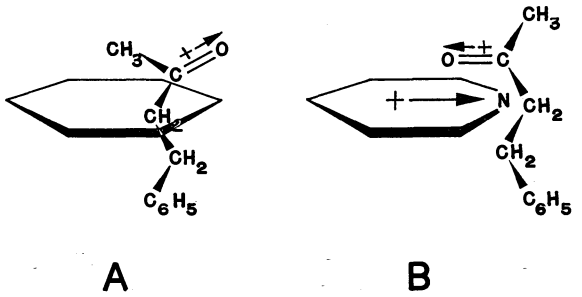

FIG. 3. (A) Configuration of the 1:1 complex between benzyl acetone and benzene; (B) Configuration of the 1:1 complex of benzyl acetone and pyridine.

forcing both the CH_3 group and the B methylene protons to lie above the plane of the ring. Both the CH_3 protons and B protons will therefore be shifted to high field in benzene and toluene solutions as compared with aliphatic solvents. Furthermore, an increase in temperature would favor dissociation of the molecular complex and a shift to low field as observed. On the other hand, the A protons lie off the aromatic ring and only a small shift to high field would occur in toluene (approximately 6 c/s) as compared with the shift in aliphatic solvents.

The internal shifts $\delta_B - \delta_A$ in a polar aromatic solvent such as pyridine appear to be anomalous. However, in this case it is likely that the carbonyl group aligns itself along the polar pyridine ring as illustrated in Fig. 3. On this model the CH_3 group and B protons lie off the plane of the ring and will therefore not be influenced significantly by the ring current of pyridine.

An estimate of the effect of different solvents on the rate of rotation is complicated by polar and association effects on the chemical shifts. Qualitatively, the onset of "free" rotation about the C—C bond at 23° C as indicated by the averaging of δ_B and δ_A is favored, according to the present results, in strongly polar aliphatic solvents such as acetone, methanol, and acetonitrile, while aromatic solvents have the opposite effect.

THE O-INSIDE CONFORMATION OF 1,3:2,4-DI-O-METHYLENE-L-THREITOL[1]

R. U. LEMIEUX[2] AND J. HOWARD[3]
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received September 25, 1962

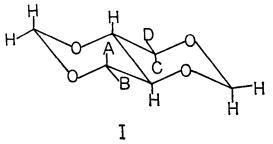
ABSTRACT

1,3:2,4-Di-*O*-methylene-L-threitol was shown by measurement of its dipole moment and nuclear magnetic resonance spectrum to exist in the so-called *O*-inside conformation as would have been predicted by Mills.

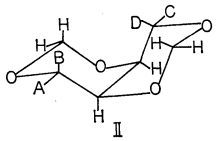
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The cyclic methylene acetals obtained as products of the reaction of sugar alcohols (glycitols) with formaldehyde in the presence of hydrochloric acid were extensively studied by Hudson and his co-workers in the 1940's. The results were extended and reviewed by Zissis and Richtmyer in 1954 (1). A set of simple empirical rules was devised in order to relate the structures of the products obtained with the configurations of the sugar alcohols. Barker, Bourne, and Whiffen (2) in 1952 refined the rules by viewing the sugar alcohol in the planar zigzag arrangement for the carbon chain rather than the Fischer projection formulas used by Hudson and his associates. In 1955, Mills (3) pointed out that the configurations of the sugar alcohols used as reactants is only incidental in these considerations. The composition of the product which is obtained in these reversible acetalation reactions is dependent only on the relative thermodynamic stabilities under the prevailing conditions of the many possible acetals which may form. Therefore, unless the product is one of kinetic rather than thermodynamic control, a rationalization of the courses of reaction should proceed from a consideration of the various possible products rather than from the starting material.

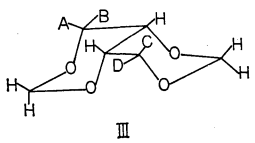
On the basis of a near-planar conformation for the 1,3-dioxolane ring, Mills (3) could conclude that, in general, *O*-methylene cyclic acetals will tend to exist in the staggered arrangement provided by the 1,3-dioxane type of structure. The polyhydric, straight-chained sugar alcohols can afford, depending on their configurations, both *trans*-(I) and cis-fused, six-membered, bicyclic structures. The cis structure can exist with each of the 1,3-dioxane rings in the chair conformation in two possible conformations which have been termed (3) the *H*-inside (II) and *O*-inside (III) conformations. As would be expected from the general principles of conformational analysis, these bicyclic structures would



I



II



III

be most favorable when the axial substituents are hydrogens. Mills' survey (3) of the known facts related to the main products formed in acetalation reactions of carbohydrates led him to the conclusion that the *O*-inside conformation is inherently more favorable

[1]*Presented at the 43rd National Meeting of the Chemical Institute of Canada, Ottawa (see Chem. Can.* **12**, *No. 4, 65 (1960)).*
[2]*Present address: Department of Chemistry, University of Alberta, Edmonton, Alberta.*
[3]*National Research Council of Canada postdoctoral fellow, 1959–61.*

than the *H*-inside conformation. Although the arguments presented by Mills in drawing this conclusion were exceedingly convincing, all the evidence presented was indirect. In view of the considerable importance of this matter to conformational analysis in carbohydrate chemistry, it seemed desirable to gain direct evidence by determining the conformation of the 1,3:2,4-di-*O*-methylene derivative of L-threitol wherein, for structures II and III, A, B, C, and D are all hydrogen atoms. Direct evidence seemed desirable especially since the driving force for the formation of the *O*-methylene derivative of the sugar alcohols under the reaction conditions used by Hudson and his collaborators is great and the formation of a given derivative need not reflect the favorableness of its structure so much as the unfavorableness of the other possible derivatives. Thus, for example, the formation of 1,3:2,4-di-*O*-methylene-ribitol (I, A = B = C = H and D = CH_2OH) in only 18% yield (4) could not have been anticipated on the basis of an inherently unfavorable structure.

1,3:2,4-Di-*O*-methylene-L-threitol was readily prepared by reaction of L-threitol with methylal in the presence of sulphuric acid. The nuclear magnetic resonance spectrum (Fig. 1) for the compound provided an indication of the presence of 1,3-dioxane rather

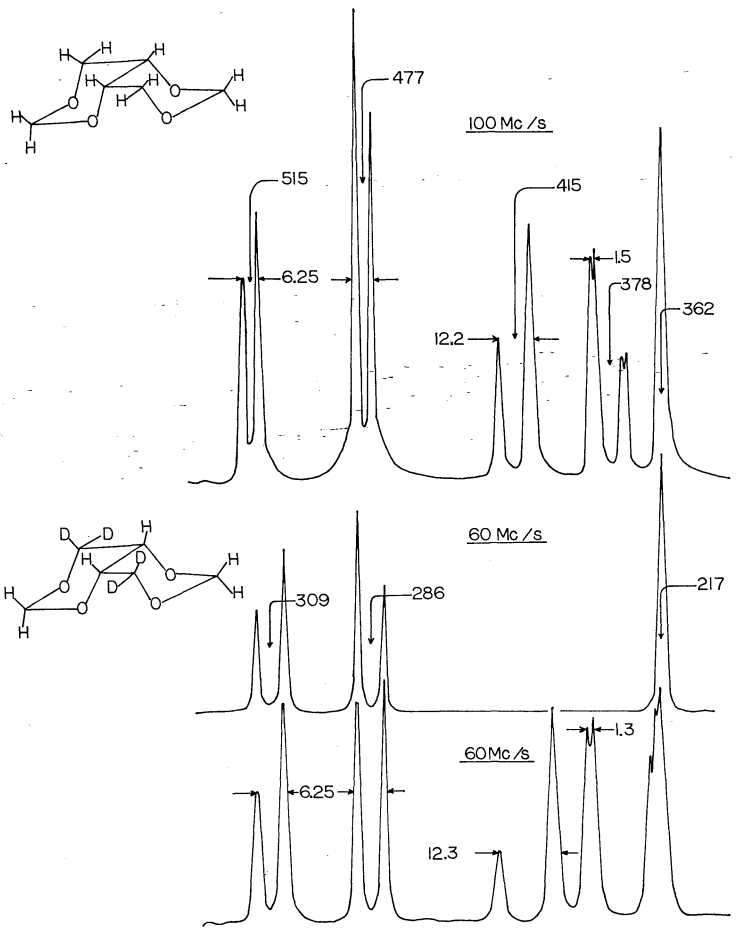


FIG 1. The proton magnetic resonance spectra of 1,3:2,4-di-*O*-methylene-L-threitol (top spectrum at 100 Mc/s and lower at 60 Mc/s) and the 1,1,4,4-tetradeuterio derivative (60 Mc/s) in chloroform. The chemical shifts are in cycles per second from tetramethylsilane.

For personal use only.

than 1,2-dioxolane rings since the strong chemical shift (0.4 p.p.m.) observed for the *gem*-hydrogens of the *O*-methylene groups is not expected for the flexible dioxolane ring but can arise (5) in a conformationally rigid 1,3-dioxane wherein the axial hydrogen is diamagnetically shielded by the gauche C—O bonds. High conformational rigidity was also indicated by the high melting point, 174.5–175°, for such a simple, low-molecular-weight compound. Definitive evidence for the structure of the compound was obtained through the observation that the compound in 2 *N* sulphuric acid and 0.08 *N* periodic acid at 45° underwent hydrolysis to the extent of 0.65 mole of formaldehyde per mole *without* the consumption of a detectable amount of the oxidant. Under the same conditions, dioxolane rapidly underwent hydrolysis with the simultaneous consumption of 1 mole of periodic acid per mole of dioxolane. Therefore, the di-*O*-methylene-L-threitol could not have the 1,2:3,4-bicyclic ring structure since this structure would inevitably liberate vicinal glycol which would be rapidly attacked by the periodate ion.

The dipole moments for the two possible conformations for 1,3:2,4-di-*O*-methylene-L-threitol (II and III with A = B = C = D = H) were calculated by vector analysis (6). Using the tetrahedral angle of 109°28′ for the carbon valence angles, 105° for the oxygen valence angles, and bond lengths of 1.43 Å and 1.54 Å for the C—O and C—C bonds, respectively, a dipole moment of 4.2 D units was estimated for the *O*-inside conformation and 1.9 D units for the *H*-inside conformation. The main uncertainties in these calculations likely would arise from the oxygen valence angle and the assumed carbon–oxygen bond moment. The dipole moment of 1,3-dioxane in benzene of 2.13 D units at 25° observed by Walker and Davidson (7) was used in the calculations in preference to the individual bond moments reported from measurements made on other ethers. Our calculations showed that variation of the oxygen valence angle in the range 102° to 111° would affect the dipole moment of the *O*-inside conformation by only about 0.7% and that of the *H*-inside conformation by about 8%. The dipole moment of the compound was found to be 4.00±0.07 D units at 25°, in excellent agreement with the calculated value for the *O*-inside conformation.

The results indicate that 1,3:2,4-di-*O*-methylene-L-threitol exists in benzene solution at 25° to an extent of at least 90% in the *O*-inside conformation. A gauche interaction between two methylene groups on a carbon bridge can be expected to destabilize a compound by 0.9 kcal/mole (8). On the other hand, a gauche interaction between oxygen atoms appears to be in the range 0.35–0.55 kcal/mole (9, 10). Mills (3) anticipated the relative magnitudes of these interaction energies on the basis of the van der Waal radii of the atoms involved and assigned the greater stability of the *O*-inside conformation on this basis. It is to be noted, however, that two of the gauche interactions between the methylene groups in the *H*-inside conformation are by way of C—O bridging atoms. In view of the fact that the C—O bond is about 0.11 Å shorter than the C—C bond, these interaction energies can be expected to be substantially greater than the 0.9 kcal/mole estimated as the non-bonded interaction energy of gauche methylene groups in a hydrocarbon. Recently, Foster and his co-workers (11) have established the *O*-inside conformation for 1,3:2,4-di-*O*-benzylidene-L-threitol.

The n.m.r. spectrum of the hydrogens in the threitol residue of 1,3:2,4-di-*O*-methylene-L-threitol in the *O*-inside conformation (III) arises from a six-spin proton system which can be classified as $A_2M_2X_2$ (12). A comparison of the spectra at 60 Mc/s in Fig. 1 allows the conclusion that the bridgehead hydrogens produce their signal at highest field, 3.62 p.p.m., and therefore comprise the X-protons. The doublet centered at 4.15 p.p.m. can be assigned to equatorial hydrogens (A-protons) since these hydrogens, those at positions

B and D in III, are less shielded by C—C and C—O bonds in gauche relationship than are the axial hydrogens at positions A and C in III. (5). The quartet centered at 3.78 p.p.m. must on this basis be assigned to these latter hydrogens, which become the M-protons of the $A_2M_2X_2$ system.

The coupling constants J_{AX} and J_{MX} can be expected (13) to be about 2 c.p.s. if the compound is in the *O*-inside conformation (III) but about 2 and 10 c.p.s., respectively, if the compound is in the *H*-inside conformation. Thus, a decision as to the conformation of the compound can be made on the basis of the magnitude of J_{MX}. The spacings for the quartet centered at 3.78 p.p.m. (M-protons) do not reflect the coupling constants since their values are different for the spectra (Fig. 1) measured at different applied magnetic fields. An appreciation of the second-order effects which may arise in such a system in view of the lack of chemical shift between the X-protons could only be properly ascertained by the calculation of theoretical spectra (14). A number of calculations were kindly provided by Dr. C. A. Reilly of the Shell Development Company. The spectrum was anticipated with reasonable accuracy with $J_{AX} = 0.3$ c.p.s., $J_{MX} = 1.6$ c.p.s., and J_{XX} very nearly zero. It is therefore clear that the compound is in the *O*-inside conformation as indicated by the dipole moment measurements. On the basis of the assignments, the bridgehead hydrogens are more strongly coupled with the axial than with the equatorial hydrogens of the C-methylene groups. This result, on the basis of the Karplus curve (13), can be taken as evidence that the compound exists in an *O*-inside conformation which is distorted in order to relieve the gauche interactions between the oxygen atoms. Since the relative magnitudes of J_{AX} and J_{MX} are opposite to those expected on the basis of a time-averaged spectrum made up of contributions from *O*- and *H*-inside conformations, the results further suggest that the concentration of the latter conformation must be exceedingly small.

From the point of view of n.m.r. spectroscopy it is of interest to note that the signals for the equatorial hydrogens of the *O*-methylene groups of 1,3:2,4-di-*O*-methylene-L-threitol are substantially broader (double the half-band width) than those of the geminal but axial hydrogens. This difference partially disappeared on deuteration of the terminal carbons of the threitol residue. Therefore, these results clearly show that there must exist an orientation effect in the long-range coupling of hydrogens over four bonds in the manner now well established for the coupling of hydrogens over three bonds (5, 13).

The experimental portion describes the preparation of L-threitol. This procedure in our hands was more convenient than published methods (15, 16).

EXPERIMENTAL

Diethyl L-Tartrate

A mixture of L-tartaric acid, 151 g (1 mole), 400 ml of dry ethanol, and 1.5 g of *p*-toluenesulphonic acid was refluxed in a Soxhlet extractor which contained 80 g of Linde Type 4*a* molecular sieves (heated at 400° prior to use) in the extraction chamber to serve as a drying agent. After 24 hours, the ester, 179 g (87% yield), b.p. 142° at 10 mm pressure, $[\alpha]_D^{25°}$ +8.5° (liquid), was isolated by fractional distillation. These constants are in agreement with the literature values (17).

Diethyl 2,3-O-Cyclohexylidene-L-tartrate

A mixture of diethyl L-tartrate, 52 g (0.25 mole), 150 ml of cyclohexanone, 1.5 g *p*-toluenesulphonic acid, and 150 ml of ligroin (30–60°) was refluxed in a Soxhlet extractor containing molecular sieves as described above. After 48 hours, the optical rotation of the mixture had reached a constant value. The mixture was washed with 10% aqueous sodium carbonate and the residue was submitted to fractional distillation *in vacuo* after removal of the ligroin. A fraction, 64 g, b.p. 105° at 2 mm pressure, was identified as 1-cyclohexylidenecyclohexane-2-one (20). A second fraction, 41 g (58% yield), b.p. 152° at 2 mm pressure, was the expected product, $[\alpha]_D^{26°}$ −27.1° (liquid). Calc. for $C_{14}H_{22}O_6$: C, 58.80; H, 7.40%. Found: C, 58.76; H, 7.38%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

2,3-O-Cyclohexylidene-L-threitol

A solution of 28.6 g (0.1 mole) of diethyl 2,3-*O*-cyclohexylidene-L-tartrate in 50 ml of dry tetrahydrofuran was added to a stirred solution of 9 g of lithium aluminum hydride (0.24 mole) in 250 ml of dry tetrahydrofuran at such a rate as to maintain the reflux temperature. The addition was complete in 15 minutes and the stirring was continued an additional 15 minutes. The excess hydride was then destroyed by the slow addition, with stirring, of 20 ml of ethyl acetate. A solution of 28 g of potassium hydroxide in 100 ml of water was added. After stirring, the solids were isolated by decantation and triturated twice with 20-ml portions of diethyl ether. The solutions were combined and washed with 25 ml of water. Evaporation left a viscous oil, 20 g. A small portion was distilled at 140° and 0.5 mm pressure to give a colorless oil which crystallized after standing. Two recrystallizations from a 1:1 mixture of ether–ligroin (30–60°) provided the analytical sample, m.p. 49–50°; $[\alpha]_D^{25°}$ −3.35° (*c*, 8.2 in ethanol). Calc. for $C_{10}H_{18}O_4$: C, 59.75; H, 8.97%. Found: C, 59.33; H, 8.99%. The remainder of the viscous oil was hydrolyzed to L-threitol without further purification.

L-*Threitol*

The crude 2,3-*O*-cyclohexylidene-L-threitol, 15 g, was dissolved in 200 ml of 0.1 *N* hydrochloric acid and the solution was refluxed for 2 hours. After cooling, the aqueous solution was extracted with 50 ml of ether to remove the cyclohexanone and then concentrated under reduced pressure to about 20 ml. A 1:1 mixture of ether:ethanol, 100 ml, was added and after standing for 7 hours at 5°, L-threitol, 4.1 g, crystallized out. Addition of 200 ml of ether to the mother liquor provided a further 1 g of material. The total yield was 57% of colorless crystals, m.p. 86–88°, $[\alpha]_D^{25°}$ −4.1 (*c*, 4.2 in water). These constants agree with those published by Klosterman and Smith (16).

1,3:2,4-Di-O-methylene-L-threitol

L-Threitol, 5 g (0.041 mole), was added to 250 ml of methylal containing 0.17 g of concentrated sulphuric acid. The mixture was then refluxed in a Soxhlet extractor which contained 60 g of calcium chloride to remove methanol formed in the condensate. After 12 hours, the L-threitol had dissolved. The refluxing was continued for a further 12 hours. The methylal solution was then shaken with 1 g of sodium carbonate until moistened indicator paper showed the solution to be neutral. The solution was clarified by filtration and the methylal was removed by evaporation under reduced pressure to leave an oily liquid. The oil was distilled at 6 mm pressure. The first fraction was a small amount of liquid and this was followed at 150° (bath temperature) by a substance which condensed as long crystalline needles. The yield was 3.5 g (59% yield) of material melting at 173–175°. Recrystallization from 1:1 chloroform–ligroin (60–80°) raised the melting point to 174.5–175°, $[\alpha]_D^{25°}$ −4.1° (*c*, 2.1 in water). Calc. for $C_6H_{10}O_4$: C, 49.31; H, 6.84%. Found: C, 49.11; H, 6.84%.

The di-*O*-methylene-L-threitol, 82 mg (0.566 mmole), was dissolved in 25 ml of 0.16 *M* periodic acid. Ten milliliters of 9.5 *N* sulphuric acid was then added and the solution was diluted to 50 ml with water. The solution, together with a reagent blank, was kept at 45°, and 5-ml aliquots were analyzed after various intervals of time.

No uptake of periodate could be detected over a period of 6 days when the solution was analyzed using the standard arsenite procedure. The formaldehyde content was determined according to the procedure described by Reeves (18) except that the periodate was reduced by iodide at pH 4.75 in order to prevent further hydrolysis of the acetal. No detectable amount of the dimedone derivative of formaldehyde was obtained after 1 day. However, after a 6-day reaction time, 11.6 mg of the derivative melting at 188–189° was obtained. This amount corresponds to the liberation of 0.65 mole of formaldehyde per mole of the di-*O*-methylene-L-threitol.

1,1,4,4-Tetradeuterio-1,3:2,4-di-O-methylene-L-threitol

The compound, m.p. 171–173°, $[\alpha]_D^{25°}$ −5.9° (*c*, 3.7 in water), was prepared on a reduced scale using the same procedures as outlined above starting from L-tartaric acid except that lithium aluminum deuteride was used to reduce the diethyl 2,3-*O*-cyclohexylidene-L-tartrate.

Dipole Moment Measurements

The measurements were made using the equipment described by Davidson (19) and the dipole moments were calculated as described by Walker and Davidson (7). Measurements were made on five independent solutions of different concentrations. The dipole moment determined for 1,3:2,4-di-*O*-methylene-L-threitol in benzene at 25° was 4.00±0.07 units.

ACKNOWLEDGMENTS

The authors are deeply indebted to Dr. D. W. Davidson for the use of his facilities to measure the dipole moments reported herein and the guidance he provided in the calculations and interpretations. The 100 Mc/s spectra were kindly provided by Drs. J. N. Shoolery and L. F. Johnson of Varian Associates. The research was supported by the National Research Council of Canada.

FORMATION OF DIASTEREOISOMERIC ORTHOACETATES OF D-MANNOSE: N.M.R. SPECTRAL EVIDENCE[1]

A. S. PERLIN

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received October 9, 1962

ABSTRACT

Diastereoisomeric 1,2-orthoacetates of D-mannose are formed under conditions of the Königs–Knorr synthesis. This is shown by the isolation of two crystalline isomers of β-D-mannose 1,2-(benzyl orthoacetate), and also by examination of the nuclear magnetic resonance (n.m.r.) spectra of several D-mannose orthoacetates. The diastereoisomers show notable differences in respective chemical shifts for the *C*-methyl and other protons and these variations, together with isomer-ratio data, suggest that the major isomer of a given pair possesses the configuration in which the *C*-methyl group is *endo*- and the OR group is *exo*-. On acid hydrolysis the orthoacetates yield mainly 2-*O*-acetyl-D-mannose, the structure of which is confirmed by n.m.r. spectral evidence.

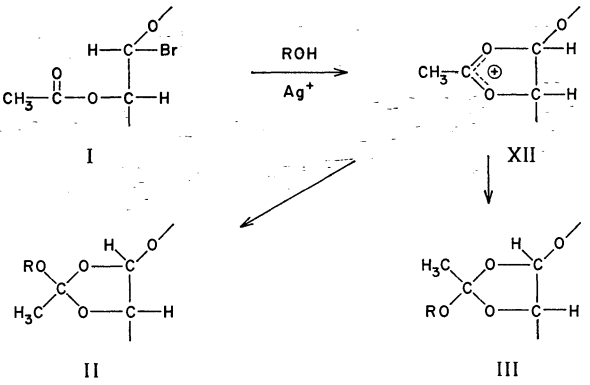
The Königs–Knorr condensation of a 1,2-*trans*-acetohalogen sugar (I) with an alcohol leads to the formation of a 1,2-orthoacetate, frequently in high yield (1, 2, 3, 4). Although two stereoisomeric forms (II and III) of the orthoester are possible, only one isomer has usually been obtained in the many syntheses recorded (3). The single exception is the isolation by Talley, Reynolds, and Evans (5) of two disaccharide orthoacetates from the reaction of 2,3,4,6-tetra-*O*-acetyl α-D-mannosyl bromide with 1,2,3,4-tetra-*O*-acetyl-β-D-glucose. However, additional evidence has now been obtained showing that diastereoisomeric orthoacetates of D-mannose are formed under conditions of the Königs–Knorr synthesis.



One of the first carbohydrate orthoesters to be characterized was β-D-mannose 1,2-(methyl orthoacetate)3,4,6-triacetate (2, 6), prepared by the silver-catalyzed condensation of tetra-*O*-acetyl α-D-mannosyl bromide with methanol. In the current study, examination of the crude product from this reaction by nuclear magnetic resonance (n.m.r.) spectroscopy showed that two non-equivalent *C*-methyl and *O*-methyl groups were present (Fig. 1B), and indicated that the product contained two orthoacetates in

[1]*Issued as N.R.C. No. 7114.*

Presented in part to the Organic Chemistry Division, 45th Annual Conference of the Chemical Institute of Canada in Edmonton, Alberta, June, 1962.

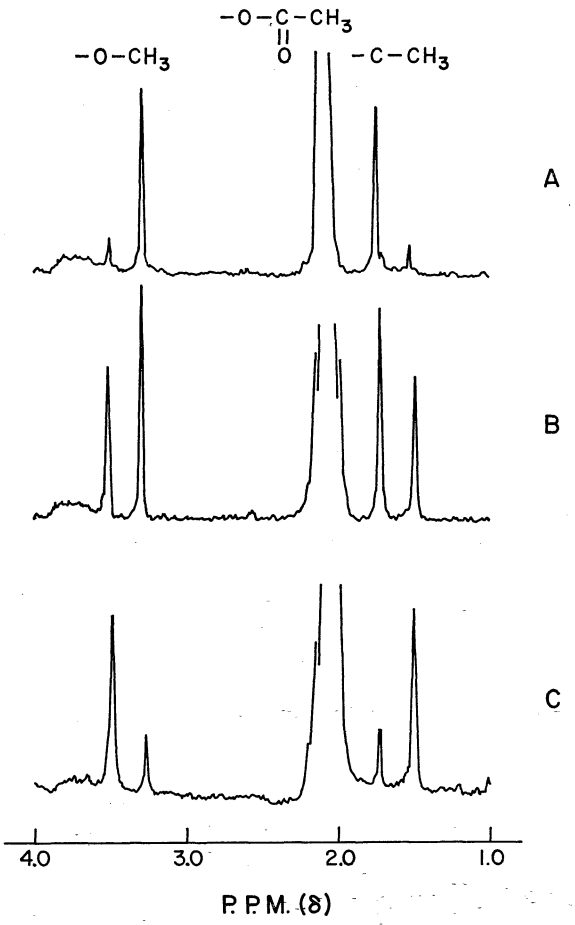


FIG. 1. Partial n.m.r. spectrum of β-D-mannose 1,2-(methyl orthoacetate) 3,4,6-triacetate: A, purified crystalline isomer; B, crude reaction product; and C, syrupy isomer.

a ratio of about 3:2. The relative intensity of these signals was different for the crystalline material isolated from the product, and repeated recrystallization afforded two fractions (one, as a syrup), each of which accounted primarily for one of the *C*-methyl and *O*-methyl chemical shifts (Fig. 1A and 1C). From the physical constants of the crystalline fraction (IV), it was clear that the material used for structural studies by Bott, Haworth, and Hirst (6) consisted essentially of this one isomer. The syrupy isomer (V) remains to be fully characterized.

More definitive evidence for the formation of diastereoisomeric orthoacetates was provided by preparation of the benzyl derivatives. The crude reaction product in this instance also showed chemical shifts for two distinct *C*-methyl groups, in a ratio of about 2:1. A crystalline triacetate (VI) isolated appeared to consist of a single isomer (n.m.r. spectrum), and on deacetylation yielded a crystalline orthoacetate (VII) ($[\alpha]_D$ +27°) which clearly showed one *C*-methyl signal (Fig. 2A). By deacetylating the material contained in the mother liquor from VI, a second crystalline D-mannose benzyl orthoacetate (VIII) ($[\alpha]_D$ −15°) was then obtained. The n.m.r. spectra of these two orthoacetates (Fig. 2A and 2B) differed substantially in the respective chemical shifts found

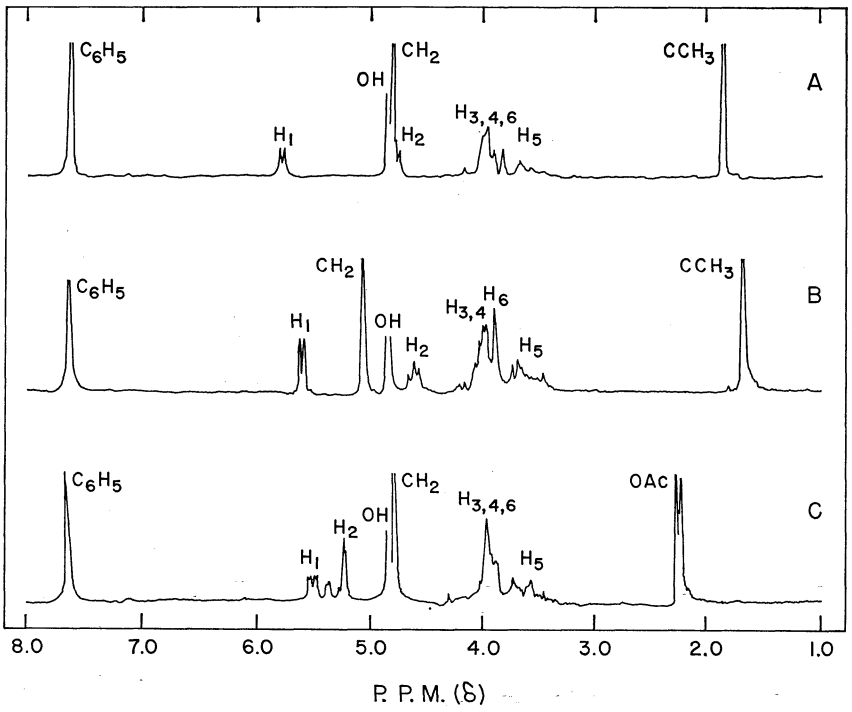

FIG. 2. The n.m.r. spectra of: A, β-D-mannose 1,2-(benzyl orthoacetate) (VII); B, β-D-mannose 1,2-(benzyl orthoacetate) (VIII); and C, 2-*O*-acetyl-D-mannose, prepared from VII or VIII by acid hydrolysis.

for the *C*-methyl, *O*-methylene, and anomeric protons. That both possess the 1,2-orthoacetate structure was shown by the fact that each isomer rapidly consumed only 1 mole of lead tetraacetate in pyridine (7, 8). Molecular models suggest that the α-D-bromide (I) could alternatively yield a 1,6-orthoacetate; however, such a compound would be expected to consume close to 3 moles of the oxidant (7).

Further evidence for the close steric relationship of orthoacetates VII and VIII was provided by acid hydrolysis, which converted each to the same monoacetate (IX) (Fig. 2C). Formation of the latter was clearly apparent in the rapid disappearance of the *C*-methyl signal (Fig. 2A and 2B) and its replacement by a signal attributable to the acetoxyl group (Fig. 2C). This group undoubtedly was at carbon-2 of IX as shown by the following observations: (*a*) the chemical shift for the anomeric proton at relatively high field (see (9)) indicated that the acetoxyl group was not on carbon-1;* (*b*) the appearance of a signal at 5.2 p.p.m. could be ascribed to the paramagnetic effect of the newly formed acetoxyl group on an adjacent secondary proton† (see ref. 10); (*c*) the relatively low chemical shift for the acetoxyl protons is indicative of an axial orientation (i.e., the 2-acetate) (9); (*d*) the monoacetate preparations were resistant to oxidation by lead tetraacetate, which is to be expected only of the 2- (or 1-) isomer (11). Although these observations agree with an early proposal by Pacsu (3) that acid hydrolysis of a 1,2-orthoacetate should yield a 2-acetate, they need not apply for orthoacetates in

**A small percentage of the 1-acetate was sometimes produced, for in certain of the hydrolysis experiments the n.m.r. spectrum showed a weak doublet at 5.9 p.p.m., consistent with the presence of the β-anomeric acetate (9).*

†*The cis-orientation of the 2- and 3-hydroxyl groups makes for the possibility of acetyl migration from position 2 to 3.*

general. Thus, it has been shown recently (12) that opening of a 1,2-orthoacid ring in the D-glucose series leads to formation of a 1-*O*-acetyl derivative.

The n.m.r. spectroscopy is well suited to the characterization of orthoacetates because the chemical shift for the *C*-methyl protons generally is at higher field than that of protons encountered in other types of carbohydrate structures (9). Also, ready differentiation from other *C*-methyl groups* is possible because of the marked acid lability of orthoesters and (as noted above) the characteristic spectral changes produced during the *C*-methyl → acetoxyl interconversion. However, satisfactory detection of the appropriate signal sometimes may be dependent on the solvent used. Thus the spectrum of IV in chloroform clearly showed the presence of a *C*-methyl group, but this was not apparent with pyridine as solvent. The spectrum of the deacetylated material (V), also in pyridine, indicated that this effect was due to screening of the *C*-methyl signal by that of the acetoxyl protons of the parent triacetate. Integration of the proton signal areas may provide useful analytical data for compounds of this class much more readily than the conventional methods. For example, the n.m.r. spectrum of an acetylated dimeric D-mannose orthoacetate (14) (also see below) shows that one *C*-methyl group and seven acetoxyl groups are present, confirming the earlier data obtained by hydrolytic and saponification procedures.

Coupling constants for the anomeric protons of the various orthoacetates (either in chloroform, deuterium oxide, or pyridine) were found to be 2.7–3.0 c.p.s. According to the Karplus relationship (15), these values correspond to a dihedral angle of about 50° for the H—C_1—C_2—H structure, reflecting the distortion of the chair towards a half-chair conformation, which is to be expected from fusion of the 5-member orthoester group at positions 1 and 2 of the sugar molecule. Molecular models suggest that this distortion should be somewhat greater, and the resulting projected angle perhaps 35–40°. The agreement with theory is much better when the orthoester structure is fused to the D-glucose ring, since a coupling constant of 5.0 c.p.s. is found for the anomeric proton of D-glucose ethyl 1,2-orthoacetate (16), which corresponds to a dihedral angle of about 35°. Hence, although such variation may indicate that the Karplus relationship cannot be applied accurately to some ring systems (see ref. 17), it is possible also that the D-mannose ring of these orthoesters is somewhat closer to possessing a regular chair conformation than might have been anticipated.

Chemical shifts for protons of the orthoester ring in each compound appear to fall into one of two patterns (Fig. 3), providing a possible basis for relating the diastereoisomeric orthoacetates. Thus the anomeric proton, the 2-proton, and the *C*-methyl protons are appreciably *less* shielded, and the OR protons (R = methyl or methylene) *more* shielded, in IV and VII than in V and VIII. Because of the differences in relative orientation of substituents on the orthoester ring, factors which contribute to shielding of a given substituent may have little effect on others more remotely situated. Comparing the diastereoisomers, therefore, it is understandable that for one, the *C*-methyl shift may be to lower field and the OR shift to higher field, and that the situation will be reversed for the other isomer. Hence these data suggest that the configuration of the orthoester group is the same in IV and VII, and that isomers V and VIII possess the opposite configuration.

Protons of the *O*-methyl and *O*-methylene groups of IV and VIII have chemical shifts equivalent to those of the corresponding protons of the parent alcohols (compare Fig. 2B and 2C; similarly, the signal for the *O*-methyl protons, both of deacetylated IV and

**The n.m.r. spectral characteristics of a wide variety of C-methyl groups have been described recently by Anet (13).*

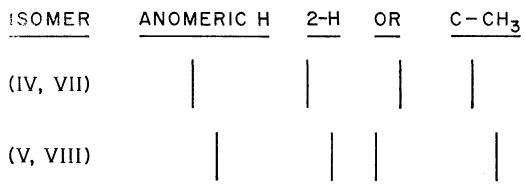

FIG. 3. Schematic representation of relative chemical shifts for various protons of diastereoisomeric orthoacetates of D-mannose.

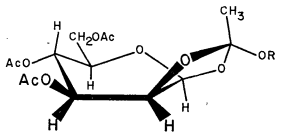
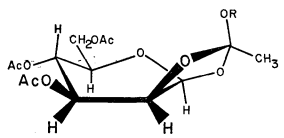
of the methanol liberated on addition of acid, is at 3.45 p.p.m.). Therefore, they appear to be affected little by other parts of the orthoacetate molecule. In V and VIII, however, these protons are less shielded and the shift is 0.25–0.30 p.p.m. to lower frequencies. Molecular models indicate that the OR group is located further from possible shielding effects when in the *exo*-orientation than in the *endo*-, leading to the suggestion that isomers IV and VII are more likely to have structure X, and isomers V and VIII, structure XI. On the same basis, relative shielding of the *C*-methyl protons should follow the inverse relationship, and the chemical shift at lower field for IV and VII than for V and VIII is also in accord therefore with these assigned configurations. Since chemical shifts for the anomeric protons and 2-protons are in the same direction as that of the *C*-methyl protons (Fig. 3) it may be pertinent that in X all of these protons appear to



X



XI

lie in close proximity to three oxygen atoms.* In XI, however, the environment about these protons would appear to be less electronegative and therefore less likely to contribute to decreased shielding.

Other data also are not inconsistent with these assignments of configuration. Lemieux and Cipera (16) have pointed out that nucleophilic attack on the cyclic intermediate ion (XII) should be favored from the side trans (exo) to the pyranose ring. The isomeric ratios of 3:2 and 2:1 (found for the methyl and benzyl derivatives respectively) indicate only moderate stereoselectivity, but compounds IV and VII are nonetheless the major components. An even higher degree of selectivity would be expected on this basis with a hydroxylic component more hindered than the primary carbinols used. One example in which a secondary (anomeric) position is involved in orthoester formation is found in the Königs–Knorr "side reaction" of tetra-*O*-acetyl α-D-mannosyl bromide (14). The mixture of oligomeric orthoacetates produced gives *only one* detectable *C*-methyl signal, indicating that diastereoisomers are not formed; and the dimeric orthoester isolated from this mixture is known to possess a 1,2,1′-structure (14). Further, the n.m.r. spectrum of the dimer shows it to be a steric counterpart of IV, as seen from the virtual equivalence of the anomeric, 2-, and *C*-methyl protons of the two compounds (Table I).†

**Courtauld atomic models indicate that the C-methyl protons are close to the three ring-oxygen atoms, and that simultaneously the anomeric protons and 2-protons are adjacent to the three oxygen atoms of the orthoester structure.*

†Incidentally, these spectral data confirm that the linkage of the dimer is between the orthoester unit and position 1 of the second unit. In any other arrangement an acetoxyl group would be present at C-1 and a highly characteristic shift at low field (about 6.0 p.p.m. (9)) should result; but such a signal is absent from the spectrum of this orthoester.

TABLE I

Chemical shifts of some proton frequencies for 1,2-orthoacetates (δ, p.p.m.)*

Compound	Anomeric H	2-H	OR	C—CH_3
IV	5.52	4.63	3.29†	1.75
V	5.42	4.40	3.48†	1.51
Dimer	5.55	4.62	—	1.74
VI	5.62	4.74	4.66‡	1.85

*In chloroform.
†R = methyl.
‡R = methylene.

Although these various considerations are speculative, together they favor the tentative assignment of structure X for IV and VII, and of XI for the diastereoisomers V and VIII.

EXPERIMENTAL

Melting points are corrected. Optical rotations were measured at 25°±2° C.

Evaporations were carried out *in vacuo* at 40° C.

The n.m.r. spectra were prepared wtih a Varian A-60 high-resolution spectrometer. The concentration of solute was usually about 10%, and tetramethylsilane was used as the reference standard.

β-D-Mannose 1,2-(Methyl Orthoacetate) 3,4,6-Triacetate

A solution of 2,3,4,6-tetra-*O*-acetyl α-D-mannopyranosyl bromide (0.20 g) in benzene (1 ml) was added dropwise with stirring to a mixture of anhydrous methanol (0.2 ml), benzene (1 ml), and silver oxide (0.20 g). After 1 hour the suspension was filtered, and the filtrate concentrated to a syrup (0.18 g), which partially crystallized. The n.m.r. spectrum of the total product in chloroform showed two *O*-methyl and two *C*-methyl signals (Fig. 1B), indicating the presence of two orthoacetates in a ratio of about 3:2.

A crude crystalline sample of the orthoacetate, m.p. 102–105° C, prepared on a larger scale according to the procedure of Dale (2), gave spectral data similar to that shown in Fig. 1B. After four recrystallizations from cold ether the product had m.p. 106° C and $[\alpha]_D$ −22° (*c*, 5 chloroform); the n.m.r. spectrum of this material is represented by Fig. 1A. Calculated for $C_{15}H_{22}O_{10}$: C, 57.53%; H, 5.98%. Found: C, 57.47%; H, 5.94%.

The ether-soluble product (examined by paper chromatography after deacetylation with sodium methoxide) contained acetates of methyl β-D-mannoside, D-mannose, and an orthoester. By using mixtures of ether–hexane the former two products were crystallized out almost completely, together with additional orthoester. The final syrupy product, $[\alpha]_D$ +12° (*c*, 2.6 chloroform), gave the n.m.r. spectrum represented in Fig. 1C.

Reaction of Tetra-O-acetyl α-D-Mannosyl Bromide with Benzyl Alcohol

The reaction conditions and quantities used above (paragraph 1) were repeated except that benzyl alcohol (0.15 ml) was substituted for the methanol. The partially crystalline crude product (0.21 g) gave an n.m.r. spectrum showing two *C*-methyl signals in a ratio of approximately 2:1.

β-D-Mannose 1,2-(Benzyl Orthoacetate) 3,4,6-Triacetate (VI)

A solution of 2,3,4,6-tetra-*O*-acetyl α-D-mannopyranosyl bromide (15 g) in benzene (50 ml) was added slowly with stirring to benzyl alcohol (10 g) in benzene (25 ml) containing 20 g of suspended silver carbonate. After 4 hours, the suspension was filtered and the benzene evaporated from the filtrate. The thin syrup remaining was taken up in acetone (100 ml) and ether (25 ml), and hexane was added to turbidity affording a product (5.1 g) having m.p. 143–146° C. Recrystallized from acetone–ether–hexane the material had m.p. 146–147° C and $[\alpha]_D$ −1° (*c*, 2.4 chloroform). The integrals of the n.m.r. spectral lines (in chloroform solution) showed the presence of one *C*-methyl group and three acetoxyl groups; the presence of phenyl and acetoxyl groups was confirmed by the infrared absorption spectrum. Calculated for $C_{21}H_{26}O_{10}$: C, 57.53%; H, 5.98%. Found: C, 57.47%; H, 5.94%.

A second crop of crystals (4.2 g) was obtained by further addition of hexane to the mother liquors and, after recrystallization as above, had m.p. 146–147° C and $[\alpha]_D$ −1° (*c*, 1.8 chloroform).

β-D-Mannose 1,2-(Benzyl Orthoacetate) (VIII)

The combined mother liquors from VI were evaporated and excess benzyl alcohol removed by distillation *in vacuo* at 90–100° (bath temp.). Methanol was added to the syrupy residue, the solution was cooled to 5° C, and excess sodium methoxide was added slowly. The solution was stored at 3° for 18 hours, then neutralized with carbon dioxide, filtered, and evaporated. Paper chromatographic examination of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

residue showed the presence of orthoester, benzyl mannoside, and mannose. The residue was extracted thrice with ether, the extract was filtered and concentrated to a syrup which was extracted in turn with acetone (this procedure eliminated most of the mannose). Addition of ether and hexane to the acetone extract promoted crystallization at room temperature. Yield: 1.5 g; m.p. 115–117° C; $[\alpha]_D$ −14.8° (*c*, 1.1 water); $[\alpha]_D$ −17.8° (*c*, 1.9 pyridine). The n.m.r. spectrum (in deuterium oxide) of the product (Fig. 2B) showed the presence of one *C*-methyl group. Calculated for $C_{15}H_{20}O_7$: C, 57.68%; H, 6.46%. Found: C, 57.92%; H, 6.73%.

The orthoester (12 mg) in pyridine (3 ml) was treated at 0° C with a solution of lead tetraacetate (50 mg) in pyridine (3 ml). The uptake of oxidant (moles/mole (minute)), measured iodometrically as described previously (8) was: 0.92 (2), 0.92 (5), 0.96 (10), 1.05 (30), and 1.10 (45).

In a separate oxidation experiment (room temperature), lead tetraacetate solution equivalent to only 0.8 mole/mole was added, and when the solution became colorless it was concentrated. The residue in water was treated with excess oxalic acid, lead oxalate was filtered off, the supernatant solution was neutralized by ion exchange and added to excess sodium borohydride solution. After removal of sodium and borate, the reduction product was found chromatographically to contain glycerol (derived presumably from both halves of the oxidation product) and mannitol; only minor amounts of unidentified compounds were detected.

β-D-Mannose 1,2-(Benzyl Orthoacetate) (VII)

To a solution of VI (1.0 g) in methanol (20 ml) an excess of sodium methoxide was added and the solution was stored at 3° C for 18 hours. The solution was neutralized with carbon dioxide and concentrated, the residue taken up in acetone, and ether and hexane added. A crystalline product was obtained in the cold (yield, 0.65 g) which, after recrystallization from acetone–ether, had m.p. 128–130° C and $[\alpha]_D$ +26.6° (*c*, 1.2 water); $[\alpha]_D$ +42.2° (*c*, 1.9 pyridine). The n.m.r. spectrum (in deuterium oxide) (Fig. 2A) showed the presence of one *C*-methyl group. Calculated for $C_{15}H_{20}O_7$: C, 57.68%; H, 6.46%. Found: C, 57.80%; H, 6.56%. The orthoester was treated at 0° C with lead tetraacetate in pyridine, as above, affording oxidation rate data virtually identical with those for isomer VIII. Reduction of the oxidized orthoester, as above, yielded mainly glycerol and mannitol (paper chromatogram).

Acid Hydrolysis of VII and VIII

The orthoacetate (VII or VIII) (100 mg) was dissolved in deuterium oxide (1 ml), the solvent was evaporated off, and this treatment repeated twice. The deuterated product in deuterium oxide (1 ml) (Fig. 2A or 2B) was treated with one drop of 0.1 *N* hydrochloric acid. Within 2 minutes, examination of the n.m.r. spectrum (Fig. 2C) showed that the signal for the *C*-methyl group was absent and a new signal (acetoxyl protons) at lower field present. Examination of the hydrolyzate by paper chromatography showed the presence (in each) of a product at $R_{rhamnose}$ 1.17, and a minor proportion of mannose (solvent, butanol–ethanol–water (40:11:19); spray, aniline phthalate). (The parent orthoacetates did not chromatograph well in this solvent, but in butanol–pyridine–water (3:1:1) had $R_{rhamnose}$ 2.05 (isomer VII) and 2.15 (isomer VIII), respectively.)

A portion of each hydrolyzate (0.1 ml) was taken up in acetic acid (5 ml) and a solution of lead tetraacetate (30 mg) in acetic acid (5 ml) was added. At 5 and 15 minutes' reaction time the uptake of oxidant by VII was less than 0.1 mole/mole, and by VIII was 0.2 mole/mole.

ACKNOWLEDGMENTS

Nuclear magnetic resonance spectra were measured by Mr. M. Mazurek and Mr. W. C. Haid at the University of Saskatchewan, through the kind cooperation of Prof. K. J. McCallum and Dr. R. A. Abramovitch. The author is indebted also to Prof. R. U. Lemieux and Dr. K. L. McEwen for helpful discussion. Microanalyses were performed by Mr. M. Mazurek.

VAPOR–LIQUID EQUILIBRIA, DENSITIES, AND REFRACTIVITIES IN THE SYSTEM ACETIC ACID – CHLOROFORM – WATER AT 25° C

A. N. CAMPBELL, E. M. KARTZMARK, AND J. M. T. M. GIESKES
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received July 26, 1962

ABSTRACT

The volume changes on mixing of the two binary mixtures acetic acid – water and acetic acid – chloroform and of the ternary mixture acetic acid – chloroform – water have been determined. In the system acetic acid – water a volume contraction occurs, showing a minimum excess molar volume at 50 mole%. Partial molal volume determinations suggest the formation of a mixed association of one molecule of water with one molecule of acetic acid. In the system acetic acid – chloroform the excess molar volume function is positive over the complete concentration range and this suggests the probability of a positive deviation from Raoult's law.

The refractivities of the two binary systems show that the true molecular volumes of acetic acid, water, and chloroform are additive on mixing.

Studies of the vapor–liquid equilibria show that in all three constituent binary systems there is positive deviation from Raoult's law but if the dimerization of acetic acid in the vapor phase is taken into account the vapor pressure behavior of the system acetic acid – chloroform is virtually ideal. The vapor pressures in the ternary system show strong positive deviations from Raoult's law over the complete concentration range. This shows that the line of pseudo-ideality in terms of zero excess molar volume does not really represent ideal behavior. Zero excess molar volume is caused by the counteracting effects of water and of chloroform molecules on acetic acid molecules.

In the two binary systems investigated the experimental data satisfy the Gibbs–Duhem–Margules equation. This proves that treatment for dimerization of acetic acid in the vapor phase is not merely permissible but necessary.

The system acetic acid – chloroform – water is a promising subject of study for the student of the theory of solutions. Acetic acid is highly, perhaps completely, dimerized in the pure liquid state but the addition of water and of chloroform causes the dimer to dissociate. Water, with its high dielectric constant, has the greater effect. Chloroform has a dielectric constant about twice that of benzene, the typical non-dissociating solvent, and the effect of chloroform on the dimerization of acetic acid is not negligible, though much less than that of water. The very low degree of miscibility in the water–chloroform system indicates high repulsion between the molecules of these two substances. This repulsion continues to show itself as a relatively large two-liquid area in the three-component system. The ternary system seemed therefore very suitable for the study of non-ideality from the thermodynamic viewpoint.

The thermodynamic implications of determinations of vapor pressure are well known. In such a system as the present one, vapor pressure determinations should give a more or less quantitative measure of the non-ideality of the system. On the other hand, accurate determinations of density yield partial molal volumes of the constituents, again a presumed measure of non-ideality.

Of the component binary systems, the system acetic acid – water has been frequently investigated, in respect to densities, isobaric boiling points, and isothermal vapor pressures of mixtures of varying composition. The latest data on densities are due to Woodman (1) and to Kohner and Gressman (2), the latter of whom determined the refractive index at 25° C for the helium D-line. Redlich and Nielsen (3) report the apparent molal volumes up to 4 *M* acetic acid.

Isobaric studies have been carried out by numerous workers, usually at atmospheric pressure. Arich and Tagliavini (4) give a bibliography of the subject. Chalov and

Aleksandrova (5) have investigated the boiling point diagram at different constant pressures, and thus deduced the isotherms between 20° and 80°, but the extrapolation methods used for the lower temperature make the results doubtful. Wrewsky *et al.* (6) determined directly the isothermal vapor pressure curves, at 42° and 60°, by an air displacement method essentially the same as that used in the present work. Their results show positive deviations from Raoult's law. The same conclusion results from the work of Arich and Tagliavini (4), who investigated the isotherms at 69.7, 79.9, and 89.9° C. Fredenhagen and Liebster (7), also using the air displacement method, have determined the partial pressures of acetic acid in water at 25° up to 2.545 *N* solutions while Giacalone *et al.* (8) report the partial pressures of water at 34.45° up to a concentration of 0.1529 mole fraction acetic acid. Campbell and Kartzmark (9) report the relative viscosities at 25° C over the complete concentration range.

The system water–chloroform shows a large miscibility gap at 25° C, the limits being 0.8 wt% water and 99.4 wt% water according to Brancker, Hunter, and Nash (10) while Reinders and de Minjer (11) give the lower limit as 0.9 wt% water at 25° C. The latter authors, when investigating the isobaric boiling point diagram, found a minimum boiling point at 56.12° and 2.8% water, under a pressure of 760 mm. There appear to be no data on the vapor pressures or densities of the system acetic acid – chloroform.

The ternary system acetic acid – chloroform – water shows a large area of partial miscibility at 25°, as was first pointed out by Wright (12). The limits of the area for 25° have been most accurately defined by Brancker *et al.* (10). The composition of the plait point can be determined from the law of rectilinear diameters and also by a method recently developed by Tarasenkov (13). The composition at 25° is $CHCl_3$ = 42.3%, CH_3COOH = 42.4%, H_2O = 15.3%. Tarasenkov's rule, though it lacks theoretical justification, appears to work in practice and is worth explaining since it has not received the publicity it deserves. According to Tarasenkov, if the tie lines of the miscibility gap, as represented in Fig. 1, are produced they will intersect on the extension of the base

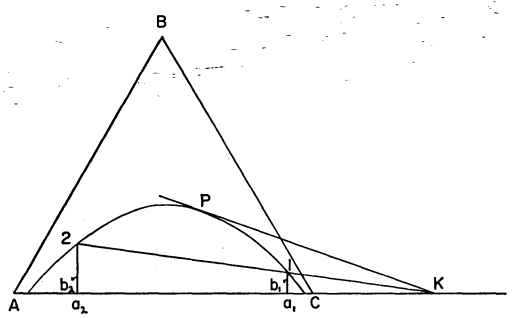

FIG. 1. The method of Tarasenkov to find the plait point in the ternary system. a_1, concentration of A in 1; a_2, concentration of A in 2; b_1, concentration of B in 1; b_2, concentration of B in 2. The origin is chosen at C.

AC at the point K. Slight deviations are considered to be experimental error. The tangent from K to the binodal curve will touch the binodal curve at P, where P is the plait point. It follows also that the ratio of the amounts of the codissolving constituent B in the two layers, for any given tie line, is given by the equation

$$\frac{b_2}{b_1} = \frac{K-a_2}{K-a_1}. \qquad [1]$$

For personal use only.

If the codissolving constituent is not associated in either layer, the above equation gives the distribution coefficient, but this condition is not complied with in the system acetic acid – chloroform – water because acetic acid is largely dimerized in the chloroform layer. Hand (14) discusses the distribution of acetic acid monomers and dimers in the water and chloroform layers.

EXPERIMENTAL

The acetic acid was freed from water by distilling with acetic anhydride, when its density and freezing point were found to be those of pure anhydrous acetic acid. Commercial chloroform is liable to contain a trace of alcohol, added as a stabilizer. To remove this the chloroform was shaken with concentrated sulphuric acid and distilled over calcium chloride. The chloroform so obtained had a density in good agreement with the accepted value. Very pure chloroform is not very stable. It may be preserved in the dark for several days but after that decomposition becomes evident from the acrid smell. Small amounts were therefore prepared at frequent intervals. Distilled water having a specific conductance of 5×10^{-6} mhos/cm at 25° was used.

Analysis of Mixtures

Analyses of mixtures were made by determination of acetic acid content in conjunction with physical properties, viz. density and refractive index. Any ternary mixture can theoretically be analyzed by the determination of two physical properties. Calibration is first done by determining the values of each physical property for a large number of binary and ternary mixtures at a constant temperature. The results are then plotted as curves of "iso-values" (equal density or equal refractive index) against composition on a triangular diagram. For accuracy, it is necessary that the "iso" lines of the two physical properties should intersect at an angle considerably less than 180°. Further necessary requirements are the obvious ones that the physical properties chosen must be such that they can be measured with accuracy and secondly that they should alter markedly with change of composition. In order to analyze a mixture of unknown composition it is only necessary to determine the values of the physical properties for the given mixture: the intersection of the two "iso-curves" then gives the composition. The present problem was simplified by the fact that one component, acetic acid, is readily estimated by titration with standard alkali. If the apex of the composition triangle represents acetic acid, determination of the acetic acid content places the mixture on a line parallel to the base of the triangle. One physical property, e.g. refractive index, is then sufficient to determine the position of the mixture on the horizontal. We measured the refractive index for the D-line (5893 Å) at 25° with an accuracy of ±0.0001. The results of our calibration curve are shown in Fig. 2.

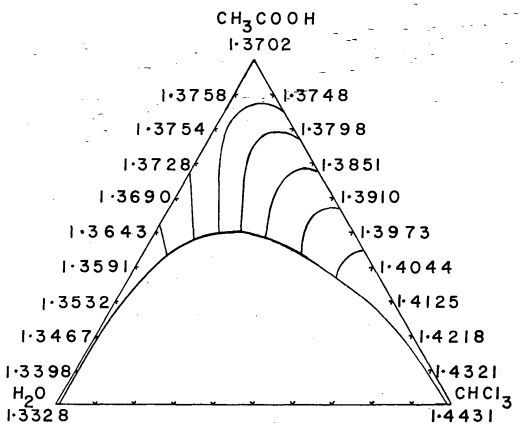

FIG. 2. Curves of equal refractive index at 25° C in the system acetic acid – chloroform – water.

This accuracy enables concentrations in the binary system chloroform – acetic acid to be determined with an accuracy of 0.2 wt%. In the binary system acetic acid – water the accuracy is again 0.2% up to a concentration of 70% acetic acid; at higher acid concentrations the curve of refractive index exhibits a maximum.

For the analysis of ternary mixtures, which is carried out by determining the intersection of the refractive index curve with the horizontal line representing the acetic acid content, the greatest accuracy is obtained in the middle of the triangle but all mixtures can be brought into this area by the addition of a known amount of acetic acid. The overall accuracy is about ±0.5% by weight.

Densities

The densities were determined with an Ostwald–Sprengel type pyknometer in a thermostat controlled at 25±0.005° C. Densities were reproducible to ±0.0002 g/ml. The density data were used in the calculation of molar volume, thus:

[2] $$V_{exp} = \frac{x_1M_1 + x_2M_2 + x_3M_3}{d}$$

whereas the so-called "ideal volume" results as

$$V_{ideal} = x_1\frac{M_1}{d_1} + x_2\frac{M_2}{d_2} + x_3\frac{M_3}{d_3}.$$

Vapor Pressures and Vapor Compositions

The composition of the vapor given off by a given liquid mixture was determined by the air-bubbling method and the total vapor pressure, manometrically: from these data the partial pressures are calculated. Pearce and Snow (15) point out that the air-bubbling method has sources of error which may be serious. The main source of error lies in the fact that it is difficult to measure accurately and conveniently the large volume of air required. Since, at room temperature, the vapor pressures of acetic acid and of water are low, about 24 hours would be necessary to attain a reasonable amount of distillate, at an air speed of 1 liter per hour: this makes it difficult to measure the volume of air exactly. We therefore decided to follow the procedure of Parks and Chaffee (16), in which the vapor pressures are measured with a manometer (static method) and the vapor compositions by isothermal distillation using the air displacement method: this obviates the necessity of measuring the volume of air.

Little need be said about the air saturation method except to draw attention to the design of the saturators. We used those described by Pearce and Snow (15) and by Von Bichowski and Storch (17). The temperature of our measurements was always 25.00±0.05°. In order to ensure saturation we made use of a presaturator maintained at 30.0° C. The presaturator consisted of four units of the type used in the equilibrium bath. The equilibrium bath itself contained eight saturators. After leaving the last unit the air passes into a tube leading to the trap. In order to avoid condensation of vapor in this tube, it is wound with resistance wire right into the trap, as shown in Fig. 3: the current supplied by a copper oxide rectifier maintains this tube at 50–60°. The trap is kept in an acetone – dry ice mixture.

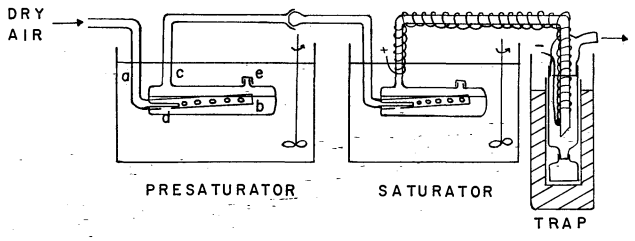

FIG. 3. The isothermal distillation apparatus. *a*, air inlet tube; *b*, slanting tube; *c*, outlet tube; *d*, hole in slanting tube; *e*, filling tube (glass-stoppered).

In the literature it is stated that air speeds up to 10 liters per hour give satisfactory results but we used a speed not exceeding 2 liters per hour. Varying the speed between 0.5 and 2.0 liters per hour gave no larger deviation than 1% by weight, which we believe to represent our experimental error.

EXPERIMENTAL RESULTS AND CALCULATIONS

DENSITY AND VOLUME

Acetic Acid – Water

Table I gives the density and molar excess volume data in terms of concentration.

The molar excess volumes have been calculated using the density data for the pure liquids of Kohner and Gressman (2) and of Woodman (1). When V^E is plotted against mole fraction a minimum of −1.145 ml at 0.5 mole fraction acetic acid is observed.

The partial molal volumes were calculated from our own density data, those of Woodman (1), Kohner and Gressman (2), and Redlich and Nielsen (3). These data are given in Table II.

the same time making use of the binary data. From this plot the equi-excess volume lines of Fig. 4 were interpolated. From Fig. 4 it follows that from the concentration 100 mole% acetic acid to 100 mole% chloroform there must run a curve along which the excess molar volume is zero.

Refractometric Results

Acetic Acid – Water

Table VI contains the refractive indices and molar refractions. The molar refraction calculated from those of the pure components is also given. Finally the apparent molar refraction of acetic acid has been calculated from the formula

$$[4] \qquad \phi R = \frac{R_{\text{exptl}} - x_1 R_1^0}{x_2},$$

where x_1, R_1^0 are the mole fraction and molar refraction of pure water and x_2 the mole fraction of acetic acid.

Acetic Acid – Chloroform

Table VII contains the identical data for this system as is given in Table VI for acetic acid – water.

molecular state of the acetic acid in the vapor phase. This can be done by means of a formula due to Gibbs (18) which gives the relation between vapor density, pressure, and temperature:

$$[5] \qquad \log_{10}\frac{1000(\Delta-1)}{(2-\Delta)^2} = \frac{3520}{T}+\log_{10}P-8.349,$$

where

$\Delta = D/D_1$,

D = experimental vapor density, and

D_1 = 2.073 (ideal density; air = 1.0, i.e. vapor density of monomer).

Wrewsky *et al.* (6) tested this formula on the system acetic acid – water at 42° and 60° C and found that it reproduced their results over the complete concentration range.

Using the above formula it is possible to calculate the molecular weight of the acetic acid in the vapor phase by successive approximations. Complete dimerization is first assumed. From this and the vapor composition data the mole fraction of acetic acid in the vapor is calculated and from this the partial pressure of acetic acid. When this is introduced into the above equation D is obtained and hence an approximate mean molecular weight. This procedure is repeated until no change in the average molecular weight is found. It is thus possible to construct the vapor pressure curves as a function of true mole fraction.

Once the true molecular weight of the acetic acid in the vapor phase is known the percentage dimerization can be calculated and from this again the partial pressures of single and dimerized molecules, respectively, can be obtained. Lambert (19) points out that the plot of log K (K = dimerization constant) vs. $1/T$ does in actual fact yield a linear plot from which the heats and entropies of dimerization can be obtained. Entropies of dimerization usually lie between 20 and 27 cal/deg mole, but Lambert finds from MacDougall's data (20) $\Delta H = -16$ kcal/mole and $\Delta S = +54$ cal/deg mole. Thus the entropy is about twice the maximum hitherto observed for dimerization. More recently, Levy and Davis (21) have investigated this question of the dimerization of acetic acid in the presence of water. They find that a possible equilibrium between acetic acid dimer and acetic anhydride is in fact negligible, the equilibrium being between dimer and monomer molecules. They find a somewhat smaller heat of dissociation, $\Delta H = -14.4$ kcal/mole, with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

corresponding ΔS (at the normal boiling point) of +36.8 cal/deg mole. The high entropy of dimerization is ascribed to the dimers being held together by strong hydrogen bonds.

The equilibrium liquid and vapor compositions expressed in weight percent acetic acid are plotted graphically in Fig. 5. The data of Table IX have been treated by the method outlined above and the results are given in Table X. The corresponding vapor and liquid

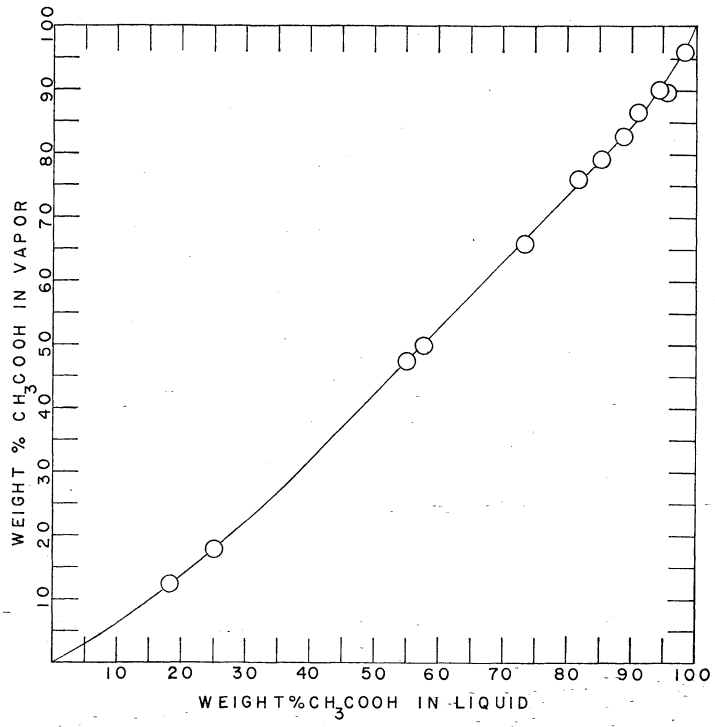

FIG. 5. Liquid–vapor composition equilibrium curve for the system acetic acid – water at 25° C.

of the acetic acid in the vapor phase.* The composition, in weight and mole percent, of coexisting vapor is also reported, as are the average molecular weight of acetic acid in the vapor phase, percentage dimer of acetic acid in the vapor phase, total vapor pressure, partial vapor pressures of water and of acetic acid, partial vapor pressure due to acetic acid dimer P'', partial vapor pressure of monomer P', and the dimerization constant K.

$$[6] \qquad K = \frac{P''}{(P')^2}$$

von Zawidzki (22) applied the Gibbs–Duhem–Margules equation to vapor pressure relations of binary systems. He makes use of the exponential solutions in a modified form, which were found for this equation by Margules (23).

$$[7] \qquad P_1 = Px_1 \exp\left(\frac{\alpha_2}{2}x_2^{\,2} + \frac{\alpha_3}{3}x_2^{\,3}\right)$$

$$[8] \qquad P_2 = Px_2 \exp\left(\frac{\beta_2}{2}x_1^{\,2} + \frac{\beta_3}{3}x_1^{\,3}\right),$$

where $\beta_2 = \alpha_2 + \alpha_3$ and $\beta_3 = -\alpha_3$. For the determination of the constants α_2 and α_3 one of the experimental partial pressure curves is used. The data of Table X were treated by the above method using approximations and smoothed total pressure data. The constants $\alpha_2/2 = 0.41$ and $\alpha_3/3 = -0.30$ are obtained for acetic acid, so that it follows for water that $\beta_2/2 = -0.04$ and $\beta_3/3 = +0.30$. The results are expressed in Table XI, which shows measured and calculated partial pressures.

0.7	0.8	23.1	22.8

**The use of the average molecular weight of the acetic acid in the vapor phase for the calculation of the liquid mole fraction calls for some justification. It is realized by the authors that this "mole fraction" has no actual physical meaning, because in the liquid phase there will be a different degree of association and therefore a different average molecular weight.*

In this study, however, the attempt is made to prove the consistency of the data obtained by means of the Gibbs–Duhem–Margules equation. von Zawidzki (22) points out that in the derivation of the Gibbs–Duhem equation no surface work has been taken into account, but only work of dilution. Because of this, the mole fractions of the components in the liquid phase have to be referred to the molecular weight in the vapor phase. When, therefore, a component shows dimerization in the vapor phase, the calculations must be based on the molecular weight of the dimerizing component. von Zawidzki shows that there are two Gibbs–Duhem equations, one for the monomer and one for the dimer. He also shows that the total partial pressure of the dimerizing component follows a third Gibbs–Duhem equation in which the mole fraction in the liquid phase is calculated by means of the average molecular weight of the dimerizing component in the vapor phase. In the present work, we use the latter equation.

Kamke (24) makes use of the Gibbs–Duhem–Margules differential equation in the following form,

$$[9] \qquad \frac{x d \ln P_1}{dx} + (1-x)\frac{d \ln P_2}{dx} = 0,$$

where x is the mole fraction in the *liquid phase* of the component with the lower boiling point. This leads to the differential equation

$$[10] \qquad \frac{1}{P}\frac{dP}{dx} = -\frac{x-y}{y(1-y)}\frac{dy}{dx},$$

where y = mole fraction in the vapor phase of the component with the lower boiling point.

Kamke now writes

$$[11] \qquad f(y) = \frac{x-y}{y(1-y)}$$

and makes use of this to obtain the curve of excess free energy for a binary system. Defining the molecular free energy of mixing as

$$[12] \qquad \Delta G^{E} = RT(x_1 \ln \gamma_1 + x_2 \ln \gamma_2),$$

where γ_1 and γ_2 are the appropriate activity coefficients, he obtains

$$[13] \qquad \frac{\Delta G^{E}}{RT} = x \ln \frac{Py}{P_1^{0}x} + (1-x) \ln \frac{P(1-y)}{P_2^{0}(1-x)},$$

which leads to

$$[14] \qquad \frac{1}{RT}\frac{d\Delta G^{E}}{dx} = \ln \frac{P_2^{0}}{P_1^{0}}\frac{y(1-x)}{x(1-y)} = \ln \frac{P_2^{0}}{P_1^{0}}\theta,$$

where

$$[15] \qquad \theta = \frac{y(1-x)}{x(1-y)}$$

is the relative volatility and

$$[16] \qquad \frac{1}{RT}\frac{d^2\Delta G^{E}}{dx^2} = \frac{1}{y(1-y)}\left[\frac{1}{1+(1-2y)f(y)+y(1-y)\{df(y)/dy\}} - \frac{1}{1+(1-2y)f(y)+y(1-y)\{-f^2(y)\}}\right].$$

The data of Table X have been used to calculate $f(y)$ as defined by equation [11], and the relative volatility (equation [15]). These results are reported in Table XII together with the quantity

$$P_2^{0}/P_1^{0}\,\theta = 0.664\theta.$$

In Fig. 6, $f(y)$ is given as a function of the mole fraction of water in the vapor phase (y). The ideal curve $f_{\text{ideal}}(y)$ is calculated according to the formula

$$f_{\text{ideal}}(y) = -\frac{1}{a-y},$$

where $a = P_1^{0}/(P_1^{0}-P_2^{0}) = 23.8/(23.8-15.8) = 2.98$. Hence

$$f_{\text{ideal}}(y) = -\frac{1}{2.98-y}.$$

according to the formulae [7] and [8]. Using smoothed data for chloroform, the constants $\alpha_2/2 = 0.155$ and $\alpha_3/3 = -0.16$ are obtained. This gives for acetic acid the constants $\beta_2/2 = -0.085$ and $\beta_3/3 = +0.16$. The final results are reported in Table XV.

parentheses indicate the number of determinations from which the average is obtained. The last column of Table XVIII contains the corresponding total vapor pressures, interpolated from Table XVII. The accuracy of the data is about ±3 mm. Table XIX contains the dimerization data, the mole fraction being again calculated on a dimerized basis.

DISCUSSION OF RESULTS

The System Water – Acetic Acid

When water and acetic acid are mixed there is a contraction in volume. This means that there is a negative excess molar volume function as shown in Fig. 7, in which the

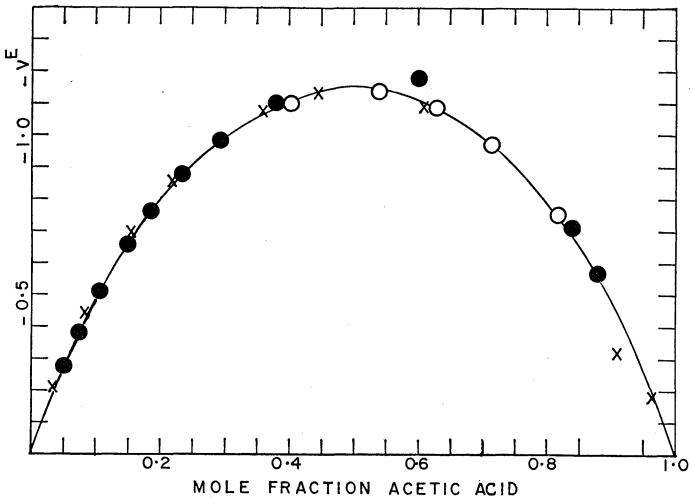

FIG. 7. The excess volume function for the system acetic acid – water at 25° C. ×, Kohner and Gressmann; ●, Woodman; ○, this research.

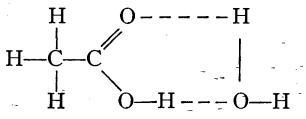
excess volume function is plotted against mole fraction of acetic acid. The minimum negative value, larger than 1 ml mole^{-1} of mixture, occurs at a concentration of 50 mole%. In general, dipole–dipole mixtures show a similar behavior, probably because the dipole–dipole associations of the pure liquids are partially broken up to form mixed associations and this causes the volume to decrease. We suggest that in the present case a mixed association of one molecule of acetic acid and one molecule of water may occur, due to hydrogen bonding, thus:



When the data of Table II are plotted, the partial molal excess volumes are perfectly symmetrical with respect to composition both for water and for acetic acid and this agrees with the above view. This symmetry implies that the changes in liquid structure on addition of water to pure acetic acid and of acetic acid to pure water have similar effects on the structure of the liquid. This is quite contrary to the behavior of the system water – ethyl alcohol, studied by Mitchell and Wynne-Jones (25), where hydrogen bonding is also involved. The viscosities of the water – acetic acid system, as reported by Campbell and Kartzmark (9), also show perfect symmetry, with the maximum at 50 mole%.

From the data on molar refractions (Table VI) it follows that the influence of the mixing process on the true volumes of acetic acid and water is very small. The slight deviations are positive but, as an approximation, it could be said that the true volumes are additive. This is confirmed by the constancy of the apparent molar refraction of the acetic acid.

Table X shows that the dimerization treatment is justified, since, within the experimental error, the "dimerization constant" retains a constant value over the entire concentration range. The amount of dimerization decreases with addition of water.

The partial pressures, calculated from the amount of dimerization by the method of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

von Zawidzki (Table XI), agree with the measured values fairly well, as required by the Gibbs–Duhem–Margules equation.

Figure 8 shows that this system exhibits positive deviation from Raoult's law, and that therefore the excess free energy of mixing, ΔG^E, is greater than zero. There is no maximum

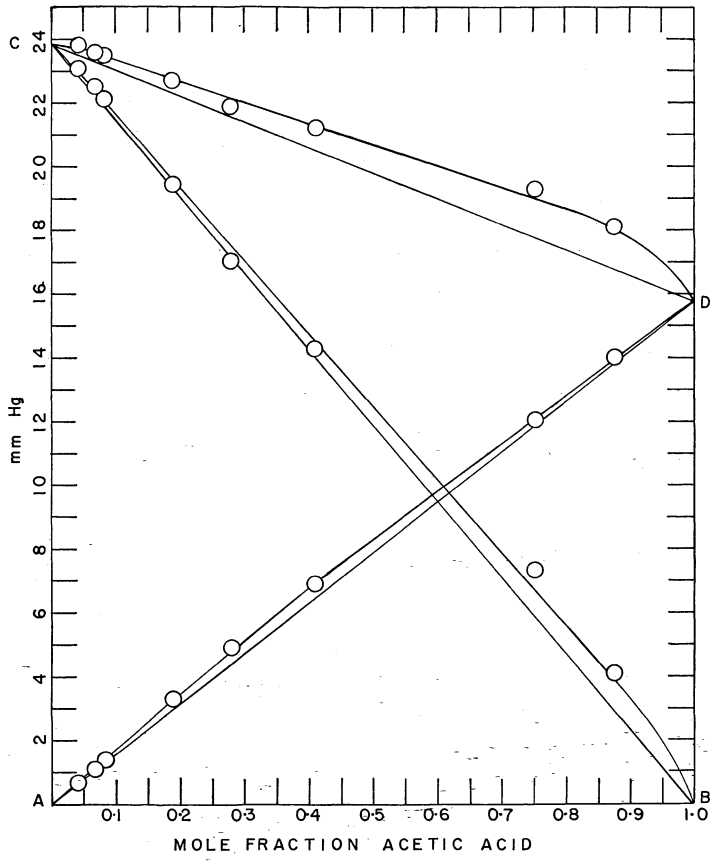


FIG. 8. Total and partial vapor pressure curves on a dimerized basis for the system acetic acid – water at 25° C. CD, total pressure curves; AD, partial pressures of acetic acid; BC, partial pressures of water (the straight lines are the "ideal" curves).

on the vapor pressure curve. Figure 5 also suggests the absence of an azeotropic point, at which the compositions of liquid and coexisting vapor would be the same. Complete separation of the components is therefore possible by an isothermal fractional distillation.

A study of the graph for $f(y)$ (Fig. 6) leads to the conclusion that the second derivative of the excess Gibbs free energy with respect to concentration $d^2\Delta G^E/dx^2$ (equation [16]) is equal to zero somewhere in the concentration region. This means that the $\Delta G^E(x)$ curve will show a point of inflection. The approximate positions of both the maximum and the point of inflection in the $\Delta G^E(x)$ curve are found from the curve in Fig. 9. When 0.664θ becomes equal to unity, the corresponding concentrations are those of the maximum and of the point of inflection. On a non-dimerized basis, the concentrations are 0.7 and 0.1 mole fraction of acetic acid in the liquid phase.

The heats of mixing as reported in the "International critical tables" are positive (heat absorbed) between 15 and 95 mole% acetic acid and for other concentrations negative.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

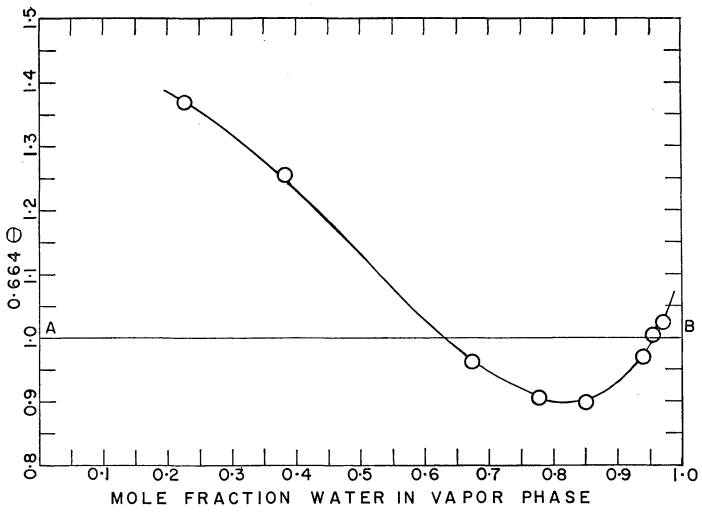

FIG. 9. The relative volatility function in the system acetic acid – water at 25° C. AB, ideal behavior.

From the relation between the excess entropy of mixing and the excess free energy of mixing $\Delta G^E + T\Delta S^E = \Delta H$ (T = constant) it follows that ΔS^E most probably has a negative sign. This seems also to be indicated by the volume contraction which occurs upon mixing. A negative ΔS^E may explain the point of inflection which occurs around 10 mole% acetic acid.

When there is a contraction in volume in dipole–dipole liquids, a negative heat of mixing is to be expected. The fact that, in the system acetic acid – water, the heat of mixing is positive over a large concentration range can be explained in accordance with the ideas of Joerges and Nikuradse (26). Energy is required to break up the individual associations of water and of acetic acid but energy is set free by the new association between the water and acetic acid. The "dissociation" energies may be large. Lambert (19) finds from MacDougall's data (20) that $\Delta H = -16$ kcal/mole. This is due to the fact that a double hydrogen bond is involved. This energy is certainly larger than that required to break up the water association. The number of mixed associations cannot be larger, and is usually smaller, than the total number of dissociations. This means that even the case where

$$[\Delta H_{\text{diss}}]_{\text{I}} + [\Delta H_{\text{diss}}]_{\text{II}} < \Delta H_{\text{ass}}$$

$$(\text{HAc})_2 + \text{H}_2\text{O}_{\text{ass}} \rightleftarrows \text{H}_2\text{O–HAc},$$

a positive ΔH of mixing can result, i.e. the energy required to break up the associations is larger than the energy set free by the mixed association.

The exact determination of the magnitude of ΔG^E from the vapor pressure data is not possible because when there is association in the vapor phase extra terms in addition to those of equation [13] have to be used. These extra terms involve the second virial coefficients, which become more complicated in systems where association occurs in the vapor phase, as has been shown by Lambert (19).

We plan an experimental investigation of the heats of mixing at 25° C and a possible application of statistical thermodynamics in order to obtain a better understanding of ΔG^E function.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

It is hoped that a study of the dielectric behavior of the system will throw some light on the problem of the sign of the ΔS^E function.

The data obtained indicate that the excess free energy function ΔG^E is larger than zero and shows a point of inflection. The heat of mixing, ΔH, has both positive and negative values and shows a point of inflection. The excess entropy of mixing function $T\Delta S^E$ presumably has a negative sign and possibly exhibits a point of inflection. With the aid of these data the system acetic acid – water at 25° C can be classified according to the rules proposed by Kamke (24).

The System Acetic Acid – Chloroform

This system shows an increase of volume on mixing. Although this system is a dipole–dipole mixture, the excess volume is not negative. This indicates a tendency for the original associations to retain their identity rather than to form mixed associations between acetic acid and chloroform molecules. The maximum value of ΔV^E occurs at 45 mole% chloroform and the excess partial molal volume curves do not show a symmetry, unlike the system water – acetic acid. The data for molar refraction of mixtures (Table VII) show that the molar refractions are approximately additive and hence that the true molecular volumes remain practically unchanged on mixing.

Table XIII shows that the dimerization treatment is justified because of the constancy within the experimental error of the "dimerization constant".

The variation in the amount of dimerization of the acetic acid in the vapor phase with concentration follows the same pattern as in the system acetic acid – water. Treatment of the partial pressures calculated on the dimerized basis, according to the method of von Zawidzki shows that with reasonable approximations the Gibbs–Duhem–Margules equation is satisfied, although the values calculated for acetic acid are somewhat on the low side.

From Fig. 10 it follows that the behavior of the system is practically ideal in terms of Raoult's law; there is a very slight tendency to positive deviation. If the pressure is plotted against mole fraction on a non-dimerized basis, the apparent deviation from Raoult's law is very large. From Fig. 10 it follows that the two components can be separated completely by means of isothermal fractional distillation.

A study of Figs. 11 and 12 provides further evidence that the behavior of the system is nearly ideal. In an ideal system the function 0.079θ will be equal to unity for all concentrations. The distribution of the points around the "ideal line" shows that the apparent deviation from ideality is probably due to experimental error.

According to the "International critical tables" the heat of mixing is positive but only data for extreme dilution at both ends of the concentration region are available. Because the excess free energy function ΔG^E is only slightly positive a negative excess entropy can be expected but a definite conclusion with respect to the sign of the excess entropy should be left in abeyance until we have made a more detailed experimental study of the heats of mixing. For this reason classification according to the rules of Kamke is as yet impossible.

The System Acid – Water – Chloroform

Figure 4 shows a line running from pure acetic acid to pure chloroform along which the excess volume ΔV^E is equal to zero. This might seem to indicate that mixtures along this curve behave ideally but, as follows from the pressure data, this pseudo-ideality is merely a result of compensating deviations. Figure 4 also shows that the excess volume in the system water–chloroform is negative over the whole region of concentration.

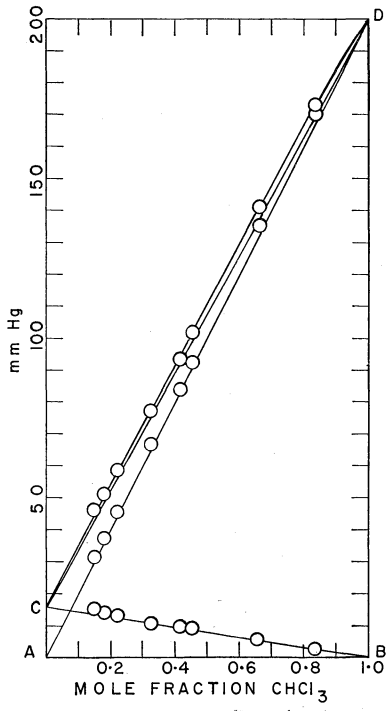

FIG. 10. Total and partial vapor pressure curves on a dimerized basis for the system acetic acid – chloroform at 25° C. CD, total pressure curves; AD, partial pressures of chloroform; BC, partial pressures of acetic acid (the straight lines are the "ideal" curves).

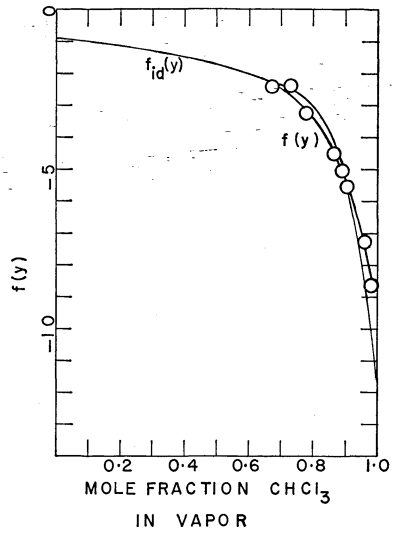

FIG. 11. $f(y)$ for the system acetic acid – chloroform at 25° C.

The results presented in Table XVII show that, in the ternary system, large positive deviations from ideality occur. These large deviations are due to the presence of water and chloroform molecules, which are almost completely immiscible in the binary system. The total vapor pressure of this system is also larger than the sum of those of the two pure

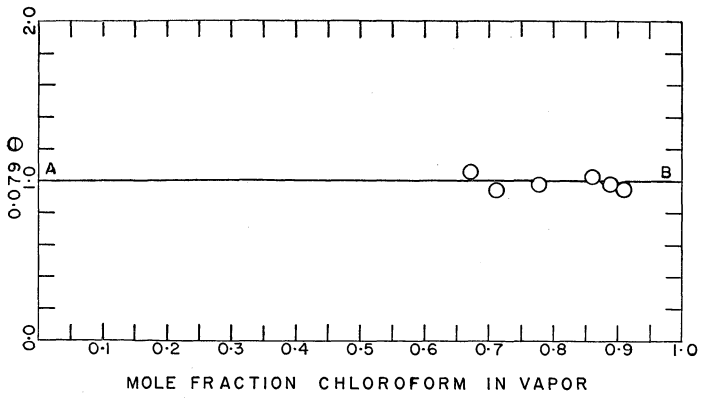

FIG. 12. The relative volatility function for the system acetic acid – chloroform at 25° C. AB, ideal behavior.

components, in the heterogeneous region. This indicates a large positive value for the excess Gibbs free energy ΔG^E. If the concentrations are expressed in mole percent, only a small part of the concentration region is covered, and for this reason it is difficult to show that for concentrations where excess molal volumes is zero, the vapor pressure behavior is not also pseudo-ideal, but, from the general behavior of the vapor pressures, ideality is not to be expected. The heats of mixing, as given in the literature, for the three binary systems also suggest a positive value over the complete concentration region of the ternary system but this has still to be shown experimentally.

From the above discussion it seems probable that the ΔG^E function is positive for all concentrations but more experimental information is necessary to determine the heats and entropies of mixing. A study of the dielectric properties of the system may also throw some light on the latter question. It is therefore not as yet possible to classify this system on the basis of the functions ΔG^E, ΔH, and $T\Delta S^E$ as proposed by Kamke and Kummerle (24).

ABSTRACT

The chloroform and dioxane proton magnetic resonance line positions have been measured relative to an internal tetramethylsilane reference signal as a function of concentration in binary chloroform – 1,4-dioxane mixtures at 28° C. Corrections have been applied to eliminate the effects of the chloroform self-association and of the non-specific interactions of the chloroform dipole. Analysis of the remaining nuclear magnetic resonance line shift in terms of an equilibrium between free chloroform and 1:1 and 2:1 chloroform–dioxane complexes gives the position of the signal from chloroform in the 1:1 complex at −1.20 p.p.m. and in the 2:1 complex at −0.85 p.p.m. relative to the position of the signal from chloroform at infinite dilution in cyclohexane. Data on other binary chloroform systems have been collected from the literature and have been similarly corrected. The results support the hypothesis of a monotonic relation between the proton magnetic resonance line shift and the energy of the hydrogen bonds which are believed to cause the formation of complexes in these systems. The accuracy of the data is not sufficient to give conclusive evidence regarding the linearity of this relation or the structure of the 2:1 chloroform–dioxane complex.

INTRODUCTION

The study of the high-resolution proton magnetic resonance spectrum of a given solute in a variety of solvents has shown that the spectrum depends on the solvent used. The following mechanisms have been found (1–4) to cause this dependence in liquid solutions:

(*a*) The magnetic field inside the solution differs from the external field by an amount which depends on the volume susceptibility of the solution and on the shape of the sample. The susceptibility is different for different solvents and also varies with the solute concentration.

(*b*) The diamagnetic circulation of electric charge which is induced in a solvent molecule by the magnetic field will, in general, depend on the orientation of the molecule relative to the field direction. The molecular susceptibility, which relates the magnetic moment produced by this circulation to the applied field, is represented by a tensor. While the solvent volume susceptibility is determined by the trace of this tensor, the average field experienced by a solute molecule at the surface of the solvent molecule depends on the anisotropy of the tensor and on the shape of the solvent molecule. This "solvent anisotropy effect" is particularly strong in solvents composed of rod- or disk-shaped molecules, for example in carbon disulphide or benzene.

(*c*) Intermolecular forces of the van der Waals type distort the electronic structure of the molecules involved. This distortion affects the diamagnetic electronic circulation and thereby changes the nuclear shielding. Although these interactions are certainly different for different solutes and solvents, their effect on the nuclear magnetic resonance (n.m.r.) spectrum appears to be small (4).

(*d*) A solute molecule carrying a permanent electric dipole polarizes the surrounding medium. The resulting electric reaction field at the solute molecule can be calculated (5) from a knowledge of the electric and geometric characteristics of the solute and medium. The reaction field hinders the diamagnetic electronic circulation and thus affects the nuclear screening.

(*e*) Specific chemical interactions between two or more solute molecules or between solute and solvent molecules may lead to the formation of complexes. The relative position and orientation of two or more molecules is thereby fixed, and the contributions of mechanisms (*b*), (*c*), and (*d*) to the nuclear screening are modified. The interaction frequently occurs through formation of a hydrogen bond, and the magnetic resonance signal from the hydrogen atom forming the bond is then strongly affected. High-resolution proton magnetic resonance spectroscopy is one of the most sensitive tools for the investigation of hydrogen bonds.

The properties of a hydrogen bond can in principle be determined by the methods of quantum chemistry, but the calculations are difficult and give results of only moderate accuracy. A brief survey of recent work is given by Gränacher (6). Models have been devised that qualitatively exhibit the essential characteristics of a hydrogen bond. In the simplest model the electron donor Y and acceptor X—H are considered to be held together by purely electrostatic forces between localized point charges or dipoles (7). The hydrogen atom forming the bond is then situated in a strong electric field which, for linear hydrogen bonds, is directed along the X—H bond axis. Buckingham (8) has published an approximate calculation to determine the change of the proton shielding caused by the application of an electric field E to a covalently bonded hydrogen atom. His result has been experimentally confirmed for weak fields (where the E-term is dominant) by a study of the chemical shifts in carbonium ions (9), and for strong fields (where the E^2-term is dominant) by providing an explanation for the large chemical shifts of the ions OH^- and OH_3^+ (10). Buckingham's calculation, together with the electrostatic hydrogen bond model, predicts a deshielding of the proton involved in the hydrogen bond, i.e. the magnetic resonance line from the hydrogen bonded complex should always occur at a lower magnetic field than the line from the non-associated acceptor molecule. A shift to lower magnetic field is indeed observed for all hydrogen bonds between molecules with negligible magnetic anisotropy. When the anisotropy is not negligible, effect (*b*) adds a contribution to the normal low-field hydrogen bond shift. This additional shift may be to high or low field, depending on the relative orientation of the hydrogen bond and the anisotropy ellipsoid. For example, benzene can act as donor to form a weak hydrogen bond with the bonding proton located on the sixfold axis of the benzene ring (4). The aromatic ring current produces a large diamagnetic effect at this position, and this apparently overcompensates the paramagnetic effect of the electric field in the hydrogen bond, since the observed net shift is to high field. The diamagnetic effect of association with aromatic solvents is clearly demonstrated by the work of Hatton and Richards (11). Similar effects caused by the anisotropy of triple bonds have been observed with substituted acetylenes and nitriles (2).

The great sensitivity of the n.m.r. spectrum for the detection of hydrogen bonds makes it tempting to try and establish a relation between the n.m.r. line shift and other characteristics of the hydrogen bond. A linear relation with the shift of the infrared absorption frequency of the X—H stretching mode has been established for intramolecular hydrogen bonds in aromatic systems (12), and a correlation with bond length parameters has been reported (6) for intermolecular bonds. From a quantum chemical viewpoint the most important characteristic of the hydrogen bond is its bond energy. It has already been presumed (13–15) that the n.m.r. line shift is a monotonic function of the bond energy. It is the purpose of this report to present experimental data for this function in the range of relatively weak hydrogen bonds.

EXPERIMENTAL

A correlation between n.m.r. line shift and hydrogen bond energy can be expected through effect (*e*), which acts by application of mechanisms (*b*), (*c*), and (*d*) to the specific chemical association. Effect (*a*) and the non-specific parts of (*b*), (*c*), and (*d*) also contribute to the observed line shift, and, to isolate the contribution of (*e*), they must be held negligible or else be eliminated by correction of the measured data. Such considerations led to the rejection of hydrogen bonding systems involving aromatic molecules or molecules with triple bonds near the bonding site, to avoid corrections for the specific part of effect (*b*). Secondly, the hydroxyl group can act as donor and acceptor in forming hydrogen bonds. Alcohols, phenols, carboxylic acids, and water can therefore form open dimers with one hydrogen bond, cyclic dimers with two hydrogen bonds, or polymers with open or closed ends. This causes difficulties in the interpretation of the measurements (16) and such compounds were therefore also excluded from this study. Thirdly, measurements of the bond energy were not made in this investigation, but systems were chosen for which this parameter and the association equilibrium constant are known.

A single acceptor, chloroform, was finally chosen and was studied in several donor solvents: 1,4-dioxane, acetone, triethylamine, and diethyl ether. Nuclear magnetic resonance measurements on the dioxane system are here reported for the first time, while data on the other systems were taken from previous work (14, 17). Except for the chloroform dilution shift data determined by Schneider *et al.* (14, 18) all n.m.r. shifts have been measured with reference to the resonance line from an internal reference compound. Abraham (4) has shown that this procedure compensates for effect (*a*) and the non-specific parts of (*b*) and (*c*) even when the reference molecules differ in size or shape from the molecules of the solvent or solute. Schneider *et al.* have applied volume susceptibility corrections to eliminate the contribution of (*a*), while a correction for the non-specific contributions of (*b*) and (*c*) is probably not necessary for the system chloroform–cyclohexane (4). The non-specific contribution of mechanism (*d*) will be discussed in connection with the chloroform dilution shift.

Chloroform Dilution Shift

Several investigators (14, 18, 19, 20) have found a gradual shift of the chloroform n.m.r. line to high field with decreasing concentration of chloroform in inert solvents. The total shift, extrapolated to infinite dilution, is very nearly the same in cyclohexane, *n*-hexane, cyclopentane, and carbon tetrachloride, but uncertainty exists about its magnitude. Values from 0.17 p.p.m. to 0.29 p.p.m. have been reported. This uncertainty may have been caused by insufficient purification of the "reagent" grade chloroform, which usually contains a few percent ethanol to prevent decomposition. Schneider's data (14, 18) have been accepted for this work and are reproduced as curve *c* in Fig. 1. The total dilution shift of 0.29 p.p.m. contains contributions from effects (*d*) and (*e*), and these are discussed in the following.

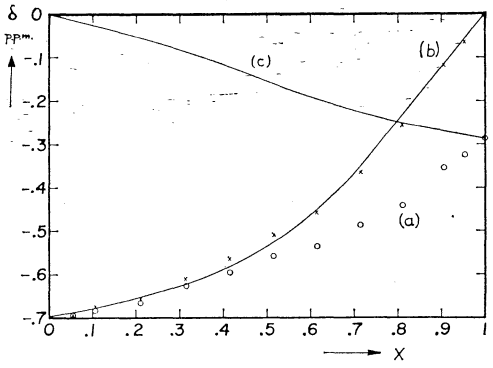

FIG. 1. Shift of chloroform proton magnetic resonance signal vs. chloroform mole fraction X: (*a*) measured in chloroform–dioxane solutions, (*b*) same as *a* but corrected for chloroform dilution shift, (*c*) measured by Schneider *et al.* in chloroform–hydrocarbon solutions. Curve *b* is not equal to the difference between *a* and *c* except at $X = \xi_a = 0$ and at $X = \xi_a = 1$.

The shift in p.p.m. caused by mechanism (*d*) at infinite dilution is given by (4, 5)

$$[1] \qquad \delta = -9.6\times10^{-6}\frac{\mu}{a\cdot b\cdot c}\eta_a[1+(n^2-1)\eta_a]\frac{\epsilon-1}{\epsilon+\beta}.$$

The symbols are explained below, where the numerical values are given for chloroform:

μ	dipole moment of solute molecule	1.02×10^{-18} e.s.u.
a, b, c	semiaxes of solute molecule ellipsoid	2.4 Å, 3.3 Å, 3.3 Å

η_a	shape factor of solute molecule (21)	0.415
n	refractive index of solute	1.44
ϵ	dielectric constant of solvent	4.81
β	$= n^2\eta_a/(1-\eta_a)$	1.53

When the neat chloroform liquid is considered to be a solution of chloroform in chloroform at infinite dilution, the contribution of effect (d) to the total chloroform dilution shift in a solvent of dielectric constant ϵ is given by

[2] $$\delta = -0.23\left(0.60 - \frac{\epsilon-1}{\epsilon+1.53}\right) \text{ p.p.m.}$$

Numerical results are listed in the third column of Table I.

TABLE I

Total dilution shift of chloroform in various solvents

	ϵ	Total shift (d), 10^{-2} p.p.m.	Total shift (e), p.p.m.	Total dilution shift, p.p.m.
n-Hexane	1.89	−7.8	−0.21	
Cyclopentane	1.97	−7.4	−0.22	−0.29
Cyclohexane	2.02	−7.1	−0.22	
CCl_4	2.24	−6.2	−0.23	
Dioxane	2.21	−6.4	−0.22	−0.28
Triethylamine	2.42	−5.5	−0.22	−0.28
Diethyl ether	4.34	−0.7	−0.22	−0.23
Acetone	20.7	+6.6	−0.22	−0.15

Subtraction of shift (d) from the total dilution shift measured in inert solvents gives the values attributed to shift (e) in the first four lines of Table I. Shift (e) is probably caused by self-association of chloroform. Reeves and Schneider (18) have observed a temperature dependence of the total chloroform dilution shift in excess of what might be expected from the temperature variation of the dielectric constants, and this supports the hypothesis of a chemical equilibrium in neat chloroform between species with different n.m.r. line positions. Nikuradse and Ulbrich (22) have reviewed other evidence in favor of this hypothesis. Shift (e) is then determined by the concentrations of the various chloroform species (monomers, dimers, etc.), and in chemical equilibrium these concentrations depend only on the equilibrium constants and on the concentration of chloroform that is not involved in a complex with the solvent. The total shift (e) will therefore be the same in all solvents that give the same equilibrium constants. The solvents listed in Table I have been assumed to satisfy this condition, and the total dilution shift in the last four lines has been determined by adding the calculated total shift (d) to the average of the total shifts (e) in the first four lines.

Chloroform–Dioxane Solutions

These solutions were prepared from "reagent" grade chloroform and "purified" grade dioxane. Both chemicals were purified shortly before the measurements by application of the second of the alternative procedures given by Vogel (23). A number of 10 cm³ samples of different chloroform concentrations was prepared volumetrically. A few drops of tetramethylsilane were added to each sample and approximately ½ cm³ was transferred into the 5-mm n.m.r. sample tubes. Air was not excluded in this sample preparation method but the reproducibility of the results was good, provided that the chloroform and dioxane were freshly purified. Measurements were taken on a Varian V 4302 spectrometer at 56.4 Mc/sec. Chemical shifts of lines from the tetramethylsilane reference line were measured by the usual side band technique. The frequency of the audio oscillator for the generation of side bands was spot-calibrated with the 60 cycle/sec mains' frequency as a standard. The sample temperature was 28±1° C. Points a in Fig. 1 give the measured position of the chloroform resonance line in binary chloroform–dioxane mixtures of various stoichiometric chloroform concentrations, and points a in Fig. 2 represent the analogous results for the dioxane resonance line. The concentrations are given in mole fraction units and the scales for the n.m.r. shift increase towards positive values with increasing magnetic field. Their origins have been shifted from the tetramethylsilane line position by an amount $\delta_a(0)$ and $\Delta_b(0)$ respectively as is explained in the Appendix. At no concentration was any broadening or splitting of the dioxane or chloroform signal noticeable. The mean lifetime of the bonded species must therefore be considerably less than 10^{-3} sec.

A total dilution shift for dioxane of 0.043 p.p.m. was found in dioxane–cyclohexane solutions, as shown by curve c in Fig. 2. These measurements were also made with a tetramethylsilane internal reference, and the cyclohexane line position was not affected by variation of the dioxane concentration.

The measured values a in Fig. 1 were then corrected for the dilution shift to obtain the shift caused by

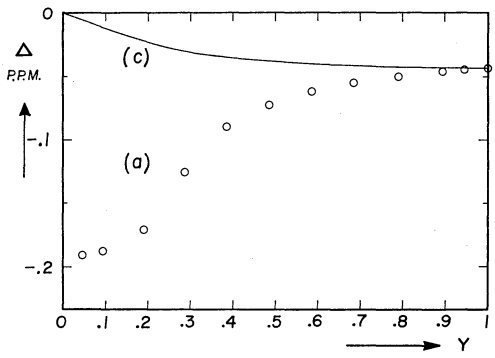

FIG. 2. Shift of dioxane proton magnetic resonance signal vs. dioxane mole fraction Y: (*a*) measured in dioxane–chloroform solutions, (*c*) measured in dioxane–cyclohexane solutions.

dioxane–chloroform hydrogen bonds. It has been assumed for this purpose that the dilution shift of chloroform in dioxane at a non-bonded chloroform concentration ξ_a is equal to the dilution shift of chloroform in cyclohexane at the stoichiometric chloroform concentration $x = \xi_a$. Contribution (*e*) satisfies this assumption if it is caused by self-association with approximately equal equilibrium constants in the two solvents, but an approximation may be involved for contribution (*d*). This approximation will not be serious, however, because Table I shows that the total shift (*d*) in dioxane is not very different from the total shift (*d*) in cyclohexane, and in either case it is only a minor contribution to the total dilution shift. The correction has been carried out on this basis as is explained in greater detail in the Appendix, and points *b* in Fig. 1 have thus been obtained.

McGlashan and Rastogi (24) have deduced from vapor pressure measurements on the chloroform–dioxane system that there exists a 2:1 complex $(CHCl_3)_2 \ldots OC_4H_8O$ in addition to the 1:1 complex $CHCl_3 \ldots OC_4H_8O$. They deduce the bond energies $\Delta H_{1:1} = -8.4$ kj/mole and $\Delta H_{2:1} = -15.1$ kj/mole and also give values for the association equilibrium constants at 50° C. They do not give the probable error for these results, but it can be estimated to be less than 10%. When the bond energy values are used in the van't Hoff equation to convert the equilibrium constants to 28° C, the results are $K_{1:1} = 1.39$ and $K_{2:1} = 1.87$ mole fraction units. A least-squares analysis was carried out with these values to fit a curve to points *b* in Fig. 1, as is described in the Appendix, and this analysis gives the following results:

$$\begin{aligned}
\text{Position of line from chloroform at infinite dilution in cyclohexane } \delta_a(0) &= -6.95_0 \text{ p.p.m. rel. TMS,}\\
\text{H-bond shift in 1:1 complex } \delta_c - \delta_a(0) &= -1.20 \pm 0.01 \text{ p.p.m,}\\
\text{Average H-bond shift in 2:1 complex } \delta_d - \delta_a(0) &= -0.85 \pm 0.02 \text{ p.p.m.,}\\
\text{Position of line from dioxane at infinite dilution in cyclohexane } \Delta_b(0) &= -3.50 \text{ p.p.m. rel. TMS.}
\end{aligned}$$

The mean error of a single measurement is ±0.01 p.p.m. This and the probable errors stated with the results above are a consequence of the limited accuracy of the n.m.r. measurements and sample preparation; they do not take into account any inaccuracy in the values for the equilibrium constants nor the approximations involved in the assumptions made above. The curve calculated with the above values from eq. [A-13] is marked *b* in Fig. 1.

Analysis of points *a* of Fig. 1 in terms of an equilibrium with only a 1:1 complex has been attempted but did not lead to satisfactory results. Measurements on the heat of mixing (25) of chloroform in dioxane also support the existence of the 2:1 complex.

Chloroform–Acetone

The position of the chloroform line relative to the line from an internal reference compound as a function of concentration in chloroform–acetone mixtures has been measured by Huggins *et al.* (17) at 28° C and at −23° C. The authors have analyzed their data in terms of an equilibrium with only a 1:1 complex and without correction for the chloroform dilution shift. They obtain for the bond energy $\Delta H = -10.5$ kj/mole, and for the association equilibrium constant $K = 1.8 \pm 0.6$ mole fraction units.

Kearns (26) has found evidence in the chloroform–acetone system of a 2:1 complex in addition to the 1:1 complex. He has determined the bond energies and equilibrium constants for both complexes. But the freezing point diagram (14) does not support the existence of a 2:1 complex, at least not in the solid phase. Since the n.m.r. data have been satisfactorily explained without postulation of a 2:1 complex, the possibility of the existence of this complex in the liquid phase has been neglected here, and for the 1:1 complex

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the bond energy $\Delta H = -11.3 \pm 2$ kj/mole and the equilibrium constant $K_1 = 1.8 \pm 0.6$ mole fraction units have been accepted.

To find the hydrogen bond n.m.r. shift, Huggins' data must be corrected for the chloroform dilution shift in acetone. This was accomplished by application of eq. [A-13], which yields for $\xi_a = 0$:

$$[3] \qquad \delta_c - \delta_a(0) = \left(1 + \frac{1}{K_1}\right)[\delta(0) - \delta_a(0)] = \left(1 + \frac{1}{K_1}\right)[\delta(0) - \delta(1) + \delta_a'(1)]$$

with $\delta_a(0) = \delta_a(1) - \delta_a'(1) = \delta(1) - \delta_a'(1)$. The symbols are explained in the Appendix. Equation [3] is independent of whether or not a 2:1 complex exists as long as K_1 refers to the formation of only the 1:1 complex. The values $\delta(0) - \delta(1) = -0.68$ p.p.m. from Huggins *et al.* (17) and $\delta_a'(1) = -0.15$ from Table I then give $\delta_c - \delta_a(0) = -1.18$ to -1.52 p.p.m. with the probable value -1.29 p.p.m. for the shift caused by the hydrogen bond in the chloroform–acetone complex. The error range corresponds to the probable error in K_1.

Chloroform–Triethylamine

The n.m.r. shift in the system chloroform–triethylamine has been studied by the same investigators (17) in the same manner as the chloroform–acetone system. The results are $\Delta H = -16.7 \pm 8$ kj/mole, $K = 3.0 \pm 1$ mole fraction units at 28° C, and $\delta(0) - \delta(1) = -1.13$ p.p.m. The chloroform dilution shift in triethylamine was taken from Table I and applied as above to give the shift caused by the hydrogen bond in the chloroform–triethylamine complex $\delta_c - \delta_a(0) = -1.76$ to -2.12 with the probable value -1.88 p.p.m. The uncertainty again reflects the probable error in K.

Chloroform–Diethyl Ether

Evidence for the formation of a 1:1 complex in solutions of chloroform in diethyl ether has been found by McLeod and Wilson (27), who give the bond energy $\Delta H = -25.4$ kj/mole. Earp and Glasstone (28) deduce the value of the association equilibrium constant $K = 0.50$ mole fraction units at 20° C from measurements of the dielectric polarization in this system and, combining this with the measured heat of solution, they find $\Delta H = -29.9$ kj/mole. The average value $\Delta H = -27.7 \pm 2.5$ kj/mole has been accepted for this work and used in the van't Hoff equation to obtain the equilibrium constant $K = 0.36 \pm 0.04$ mole fraction units at 28° C.

The n.m.r. line shift has been measured by Korinek and Schneider (14). They used an external reference compound but applied a correction for effect (*a*) to obtain $\delta(0) - \delta(1) = -0.48$ p.p.m. With the chloroform dilution shift in diethyl ether taken from Table I, there results for the shift caused by the hydrogen bond in the chloroform–diethyl ether complex $\delta_c - \delta_a(0) = -2.68 \pm 0.22$ p.p.m. The uncertainty results from the probable error in K.

Correlation N.M.R. Shift – Hydrogen Bond Energy

The hydrogen bond n.m.r. shift in complexes of chloroform with dioxane (1:1 and 2:1 complexes), acetone, triethylamine, and diethyl ether has been plotted versus the respective bond energy in Fig. 3. The probable

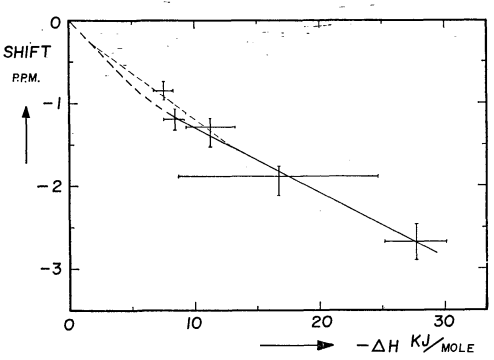

FIG. 3. Nuclear magnetic resonance shift vs. bond energy in complexes of chloroform with dioxane (2:1 and 1:1), acetone, triethylamine, and diethyl ether (in this order from left to right).

errors are indicated by the vertical and horizontal lines at each measured point. The dioxane 2:1 complex involves two hydrogen bonds and the point for this system represents the average n.m.r. shift versus the average energy per bond.

A straight line has been fitted by the method of least squares to the measured points excepting the dioxane 2:1 complex. This line intercepts the ordinate at -0.51 p.p.m. and its slope is -7.86×10^{-2} p.p.m./kj $\times$ mole^{-1}.

DISCUSSION

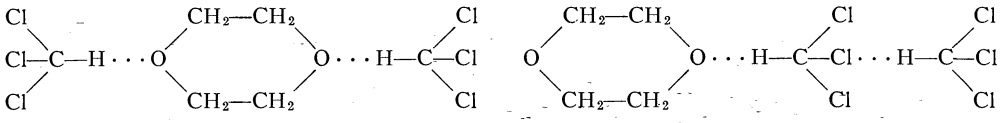
The intercept of −0.51 p.p.m. of the straight line in Fig. 3 is unsatisfactory since zero n.m.r. shift should be expected for zero bond energy. Three explanations may be offered:

(i) The point for the dioxane 1:1 complex and, to a lesser degree, also that for the ether complex is incorrect.

(ii) The intercept is caused by an interaction that has not been considered. Aside from the objection that this argument is more an excuse than an explanation, it fails to account for the location of the dioxane 2:1 point in Fig. 3.

(iii) The relation between n.m.r. shift and hydrogen bond energy is non-linear for energies less than approximately 9 kj/mole. I know of no reason why this relation ought to be linear, and therefore wish to interpret the data concerning the dioxane 2:1 complex with the assumption of this hypothesis:

When the line in Fig. 3 is extrapolated to low energies so as to pass through the origin, it forms a curve with the dioxane 2:1 point on its concave side. This point should lie at the midpoint of a chord to the curve since it represents the linear average of the shifts and energies of the two bonds occurring in the 2:1 complex. The end points of the chord represent the actual shifts and energies of the two bonds, and the construction in Fig. 3 indicates that one bond is considerably stronger than the other. Two conceivable structures for the 2:1 complex are shown below, and structure I is hereby disfavored because its symmetry would require the two bonds to be of equal strength. In structure II, however, the bond to dioxane can be expected to be stronger than the bond between the two chloroform molecules. It is even stronger than the bond in the 1:1 complex if the construction in Fig. 3 is correct, and this may be explained by consideration of the polarization of the middle chloroform molecule in structure II.



I II

Another comment may be made regarding the interpretation of the measurements presented in Fig. 2. The lack of reliable data on the dilution shift curve for dioxane in chloroform hinders a quantitative analysis. If the assumption is made that the dilution shift in chloroform is identical with that in cyclohexane (curve *c* in Fig. 2), then a least-squares analysis analogous to that made for Fig. 1 gives 0.00±0.02 p.p.m. for the shift of the signal from the eight hydrogen atoms of dioxane upon formation of the 1:1 complex, and −0.46±0.02 p.p.m. for the 2:1 complex. Although a good fit to the measured points is obtained with these values, it is unlikely that they have physical significance because the above assumption is probably a poor one. The dioxane molecule carries an electric quadrupole and the theory of Diehl and Freeman (5) is therefore not directly applicable. But when the quadrupole is approximated by two dipoles, this theory indicates that much of the shift represented by points *a* in Fig. 2 may well be caused by effect (*d*), so that very little would remain as evidence of an influence of the hydrogen bond on the shielding of the dioxane hydrogen atoms. Effect (*d*) causes a dilution shift to higher field in cyclohexane and to lower field in chloroform because the dielectric constant of dioxane is intermediate between the dielectric constants of cyclohexane and chloroform.

It is hoped that these speculations will stimulate further investigations and that this work will thereby contribute to our understanding of the hydrogen bond.

ACKNOWLEDGMENTS

I wish to thank Mr. H. R. Andrews for technical assistance and the National Research Council of Canada for financial support of this investigation. I am much obliged to the referee for his comments on an earlier version of this report.

APPENDIX

Consider a solution which has been prepared by mixing A moles of chloroform with B moles of dioxane. The stoichiometric mole fractions are:

[A-1]
$$X = \frac{A}{A+B} \qquad \text{for chloroform,}$$
$$Y = \frac{B}{A+B} = 1-X \qquad \text{for dioxane.}$$

Because of the equilibria

$$CHCl_3 + C_4H_8O_2 \rightleftharpoons CCl_3H \ldots OC_4H_8O,$$

and

$$2CHCl_3 + C_4H_8O_2 \rightleftharpoons (CCl_3H)_2 \ldots OC_4H_8O,$$

there are in the solution

a moles of chloroform not hydrogen bonded to dioxane,
b moles of non-associated dioxane,
c moles of the 1:1 complex,
d moles of the 2:1 complex,

where

[A-2]
$$a+c+2d = A.$$
$$b+c+d = B.$$

For personal use only.

The true mole fractions in the solution are:

$$\xi_a = \frac{a}{a+b+c+d} \qquad \text{for chloroform not hydrogen bonded to dioxane,}$$

$$\xi_b = \frac{b}{a+b+c+d} \qquad \text{for non-associated dioxane,}$$

[A-3]

$$\xi_c = \frac{c}{a+b+c+d} \qquad \text{for the 1:1 complex,}$$

$$\xi_d = \frac{d}{a+b+c+d} \qquad \text{for the 2:1 complex,}$$

with

[A-4] $$\xi_a+\xi_b+\xi_c+\xi_d = 1.$$

Substitution of [A-2] in [A-1] gives with the use of [A-3] and [A-4]

[A-5] $$X = \frac{\xi_a+\xi_c+2\xi_d}{1+\xi_c+2\xi_d}.$$

The equilibrium constants in mole fraction units are

[A-6] $$K_1 = \frac{\xi_c}{\xi_a \times \xi_b} \qquad \text{for formation of the 1:1 complex,}$$

[A-7] $$K_2 = \frac{\xi_d}{\xi_a^2 \times \xi_b} \qquad \text{for formation of the 2:1 complex.}$$

The independent equations [A-4], [A-6], and [A-7] relate the four quantities ξ_a, ξ_b, ξ_c, ξ_d to one another. They can be solved to express three of these quantities in terms of the fourth. Let ξ_a be the independent variable, then the solutions are

[A-8] $$\xi_b = \frac{1-\xi_a}{1+K_1\xi_a+K_2\xi_a^2},$$

[A-9] $$\xi_c = \frac{K_1\xi_a(1-\xi_a)}{1+K_1\xi_a+K_2\xi_a^2},$$

[A-10] $$\xi_d = \frac{K_2\xi_a^2(1-\xi_a)}{1+K_1\xi_a+K_2\xi_a^2}.$$

Substitution of [A-9] and [A-10] in [A-5] gives X as a function of ξ_a in the form

[A-11] $$X = \xi_a \frac{1+K_1+K_2\xi_a(2-\xi_a)}{1+K_1\xi_a(2-\xi_a)+K_2\xi_a^2(3-2\xi_a)}.$$

With the assumption of fast reaction rates for the equilibria considered above, the hydrogen resonance signal of chloroform in mixtures with dioxane appears at a chemical shift δ equal to the weighted average of the signal positions for chloroform molecules not hydrogen bonded to dioxane (δ_a), for chloroform molecules in the 1:1 complex (δ_c), and for chloroform molecules in the 2:1 complex (δ_d):

$$\delta = \frac{a}{A}\delta_a + \frac{c}{A}\delta_c + 2\frac{d}{A}\delta_d.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When this equation is written in the form

$$\delta-\delta_a = \frac{1}{A}\,[c(\delta_c-\delta_a)+2d(\delta_d-\delta_a)],$$

the following relation can be obtained by the use of [A-2], [A-3], [A-9], and [A-10]:

[A-12] $$\delta-\delta_a = \frac{1-\xi_a}{1+K_1+K_2\xi_a(2-\xi_a)}\,[K_1(\delta_c-\delta_a)+2K_2\xi_a(\delta_d-\delta_a)].$$

This relation together with [A-11] gives a representation of a function $\delta(X)$ through the parameter ξ_a.

It has been mentioned above that the chloroform dilution shift causes the position δ_a to depend on the chloroform concentration ξ_a. The function $\delta_a(\xi_a)$ was taken directly from Schneider's measurements (14, 18), whereby the stoichiometric mole fraction of chloroform in inert hydrocarbons has been put equal to the mole fraction ξ_a in dioxane. Introduction of $\delta_a(\xi_a)$ into eq. [A-12] gives finally

[A-13] $$\delta-\delta_a(0)-\delta_a'(\xi_a)[1-F(K_1+2K_2\xi_a)] = F[K_1(\delta_c-\delta_a(0))+2K_2\xi_a(\delta_d-\delta_a(0))],$$

where $\delta_a'(\xi_a) = \delta_a(\xi_a)-\delta_a(0)$ is the chloroform dilution shift (curve c in Fig. 1), and F is an abbreviation defined by

$$F = \frac{1-\xi_a}{1+K_1+K_2\xi_a(2-\xi_a)}\,.$$

In Fig. 1, the points labelled a represent the direct measurements of $\delta-\delta_a(0)$ plotted vs. the stoichiometric chloroform mole fraction X. Points b represent the left-hand side of eq. [A-13] with ξ_a and X related by eq. [A-11]. The values of $\delta_c-\delta_a(0)$, $\delta_d-\delta_a(0)$, and $\delta_a(0)$ were then determined so as to minimize the mean-square deviation of the r.h.s. from the l.h.s. of eq. [A-13], and this gave the results listed in the text. Curve b is a graph of the r.h.s. of eq. [A-13].

PHOTOCHEMICAL SYNTHESES

6. THE FORMATION OF HEPTANDIONES FROM ACETYLACETONE AND ALKENES[1]

P. DE MAYO AND H. TAKESHITA
Department of Chemistry, University of Western Ontario, London, Ontario
Received September 27, 1962

ABSTRACT

The irradiation of acetylacetone in the presence of oct-1-ene, cyclopentene, cyclohexene, and 1-methylcyclohexene gives substituted heptandiones. These diketones may then be cyclized with acid or base. Irradiation of isopropenyl acetate and acetylacetone gives, after cyclization, *m*-5-xylenol. The mechanism of the reaction is discussed: it represents the first cycloaddition to an isolated ethylenic linkage.

Saturated ketones have absorption bands in the ultraviolet at about 280 mμ. This band is associated with an $n \rightarrow \pi^*$ transition of a non-bonded electron on the oxygen atom into an anti-bonding π-orbital (2): α,β-unsaturated ketones have a similar band at somewhat longer wavelength. Such excitation of saturated ketones in condensed phases leads to a number of transformations which follow on the formation of the original excited species. Amongst these are cyclobutanol formation and fission between the α- and β-carbon atoms: both these processes are initiated by γ-hydrogen abstraction by the electron-deficient oxygen atom.[2]

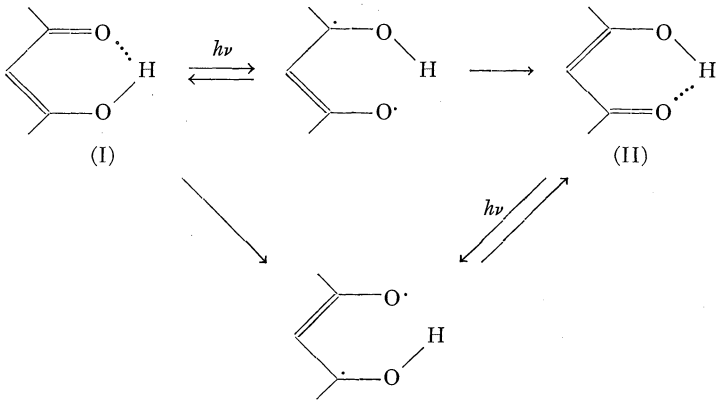
In the presence of substrates which may give stabilized radicals by hydrogen abstraction another course may be followed, particularly when there is no such γ-hydrogen available for intramolecular abstraction. The activated ketone, most probably as the triplet (4, and references cited therein), is converted into the ketyl, which then, in turn, may react with another ketyl or with some other radical derived from the substrate (see, for instance, refs. 5, 6, 7).

The irradiation of acyclic α-diketones also appears to conform to this general pattern. In the absence of a reactive substrate cyclobutanol formation proceeds in high yield (8), whilst in the presence of benzylic (9) or allylic hydrogen (10) alkylation is observed.

The irradiation of β-diketones, on the other hand, does not appear to have been studied up to the present. Acetylacetone, the simplest readily available acyclic β-diketone, exists in solution in hydrocarbons largely in the enolic form (I) (11). In this system γ-hydrogen abstraction is, presumably, strongly favored following $n \rightarrow \pi^*$ excitation, because of the proximity of that hydrogen atom. However, in this special case the ketyl so formed is readily transformed into (II), the tautomer of (I), and differing from it at most in small internuclear distances.[3] Hydrogen abstraction from the solvent may thus be expected to be slow and might not occur provided some other mode of chemical behavior were available to the excited diketone molecule.

Irradiation of acetylacetone in cyclohexene induced a reaction which could be followed by the disappearance of the enol bands at about 6.3 μ. The product, obtained in high yield, appeared homogeneous to gas–liquid chromatographic (g.l.c.) analysis and, significantly, no trace of bicyclohexenyl could be detected. The latter is an inevitable

[1] *Part of the material contained herein formed a preliminary communication (1).*
[2] *For a review of these and other transformations following $n \rightarrow \pi^*$ excitation see reference 3.*
[3] *In the present instance the tautomers are identical, but with other unsymmetrical β-diketones capable of chelation the more general statement applies.*



(I) (II)

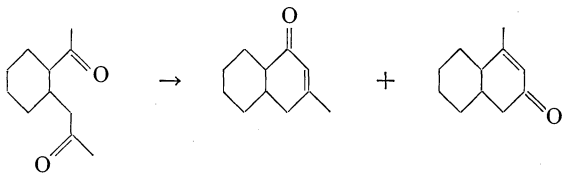
by-product of radical reactions in cyclohexene and in these circumstances its absence could be taken as an encouraging indication of the absence of such processes.

That an $n \rightarrow \pi^*$ excitation was most probably responsible for the observed transformation was established by repeating the irradiation using a pyrex filter. This resulted in a decrease in yield of only one third, whilst under these conditions essentially all the light responsible for $\pi \rightarrow \pi^*$ excitation was cut out.

The product analyzed for a 1:1 adduct of cyclohexene and acetylacetone. It showed no high-intensity absorption in the ultraviolet, had a band in the infrared at 1717 cm^{-1} compatible with saturated ketones, and gave a crystalline dioxime. The n.m.r. spectrum showed the presence of a singlet (6 H) at τ 8.0, suggesting (ref. 12, p. 57) the presence of two acetyl groups, and there was no indication of vinyl hydrogen. Treatment of the diketone with acid led, with the loss of one molecule of water, to the formation of two isomeric unsaturated ketones, characterized as the 2:4-dinitrophenylhydrazones.

Both unsaturated ketones showed, in the n.m.r. spectra, the presence of allylic methyl (singlet, 3 H, τ 8.09) and of one vinyl hydrogen (at τ 4.30, singlet). The infrared spectra (bands at 1674 and 1675 cm^{-5} respectively) suggested the presence of cyclohexenones and hence the formulation of (III), (IV), and (V) for the diketone and the unsaturated ketones respectively.

A distinction between (IV) and (V) was also possible from the infrared spectra. That assigned the structure (V) showed a band at 1415 cm^{-1} attributed to the deformation vibrations of methylene α to the carbonyl (ref. 13, p. 22) whilst that assigned the structure (IV) showed a band at somewhat higher wave numbers (1423 cm^{-1}) attributed to the



(III) (IV) (V)

allylic methylene group (ref. 13, p. 23). The assignments were confirmed in the present instance[4] by reduction of the ketones with sodium borohydride followed by dehydrogena-

[4]*The formation of (IV) had been previously reported by Barrett, Cook, and Linstead (14) as being formed by the condensation of acetylcyclohexene and sodioacetoacetate. Repetition of the preparation showed, however, that here also the product was a mixture of (IV) and (V).*

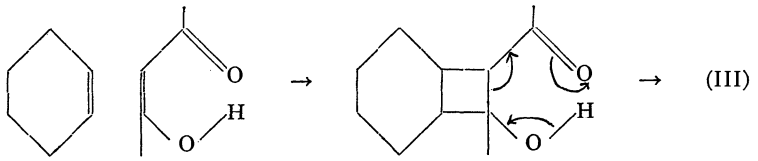
For personal use only.

tion over palladized charcoal. This treatment gave β- and α-methylnaphthalene respectively, which were characterized as the picrates and compared with authentic specimens.

The formation of (III) most probably proceeds through the cyclobutane derivative (VI). The formation of cyclobutane derivatives by the dimerization of unsaturated ketones is well known (15) and the intramolecular addition of an ethylenic linkage to an unsaturated ketone has already been observed (16).[5] The present reaction constitutes the first intermolecular addition to an isolated ethylenic linkage. In support of this view the infrared spectrum of the crude irradiation product showed strong hydroxyl absorption which disappeared on slight warming. These conditions define the stability



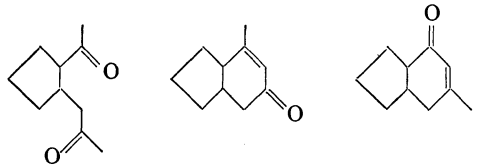
(VI) (III)

of the β-hydroxyketone since the dealdolization may be a purely thermal process (VI, see arrows).

If the mechanism proposed is correct the diketone (III) as originally formed should be cis. Although trans fusions of six- and four-membered rings do occur, and have been prepared recently in the ring D norsteroids (18(*a*)), it seems probable though not mandatory that the lower-energy pathway should be selected here (18(*b*)). However, since the stable configuration of the diketone is trans (both substituents equatorial) it is not impossible that complete or partial inversion may have occurred during distillation. Further equilibration was not attempted since, in general, such conditions are those that lead to cyclization.

Cyclization, irrespective of the stereochemical homogeneity of the starting material, could lead to both cis and trans isomers. The two ketones obtained, (IV) and (V), appeared homogeneous to g.l.c. on several columns, but this criterion must be accepted with reserve since the same was true of a derivative from 1-methylcyclohexene (see below), and this was shown to be a mixture.

Similar irradiation of acetylacetone with cyclopentene gave the expected diketone (VII), characterized as the dioxime. Cyclization with base then gave the ketones (VIII) and (IX), characterized as the 2:4-dinitrophenylhydrazones. The assignment of structure was made on the basis of the methylene deformation frequencies which occurred at the same position as in the cyclohexene series.



(VII) (VIII) (IX)

In those natural products in the alicyclic series in which this present approach might be of synthetic utility a common structural feature is that of an angular methyl group.

[5]*The intermolecular addition of alkenes to unsaturated acids has been observed in these laboratories and will be reported shortly (17). The addition of cyclopentenone to cyclopentene has since been reported by Eaton (27).*

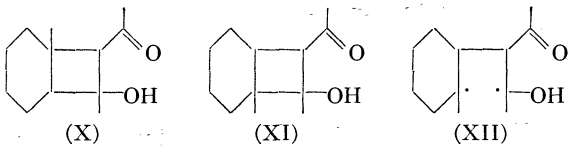
Although the introduction of this feature might be achieved by methylation, an alternative route could be the use of methylcyclohexene as a substrate. Addition of acetylacetone to such an unsymmetrically substituted ethylenic linkage could proceed to give either of the two compounds (X) or (XI). Assuming that the addition is not entirely concerted,[6] then the addition should proceed to give the more stable intermediate biradical. This appears to be the case, for instance, in the related addition of carbonyl groups to methylbut-2-ene to give oxetanes (20; 28; 3, p. 379). In that instance it is the oxygen atom (which is electron deficient because of electron promotion) which attacks the π-bond. In the present case if the α-carbon be presumed to be electron deficient the predicted more stable diradical[7] would be (XII) rather than (XIII). Little analogy can be made with the dimerization of unsaturated ketones (in which, presumably, one molecule of the forming dimer is activated) because of the influence of the phase in which the irradiation is done, and the uncertainty as to whether $n \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$ excitation is involved in any particular example.[8]

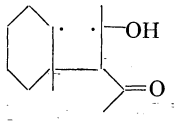
To form the second carbon–carbon bond two opposed steric interactions (methylene and methyl vis-à-vis methyl and hydroxyl) must be overcome. Since, until this final bond formation, the processes are reversible this interaction might be a factor which could depress the rate of (XI) formation as against that of (X). In addition, with sufficient suppression or if the charge separation is small it is conceivable that the radical (XIV), which is more stable still, may be involved, although XIV would be formed from attack of the carbon β to the carbonyl, which may be unfavorable.



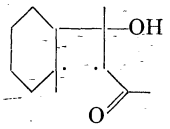
(X)

(XI)

(XII)



(XIII)



(XIV)

Irradiation of methylcyclohexene and acetylacetone led, in this event, to the formation of more than one product, as indicated by g.l.c. analysis, but at the temperature required for preparative separation extensive decomposition occurred together with the formation of cyclized products. The major component (50%) could, however, be isolated by fractional distillation. The remainder appeared to consist of three products one of which accounted for 20–30% of the original material. Its infrared spectrum indicated that it was a diketone but the best specimens were always contaminated with small amounts of cyclized products.

The major product was assigned the structure (XV) for the following reasons. It analyzes correctly, gave a crystalline dioxime, and showed a band in the infrared at 1709 cm^{-1}. Cyclization of (XV) with base gave two unsaturated ketones in the ratio

[6]*The formation of other four-membered rings has also been suggested to be non-concerted (e.g. ref. 19). Recently, results on the dimerization of cyclopentenone have been interpreted (27) to imply either concertion or the lack of effect of stabilizing factors on intermediate species, presumably because of their high energy.*

[7]*Even if the addition has ionic character the same consequence follows since attack of ethylenes is electrophilic.*

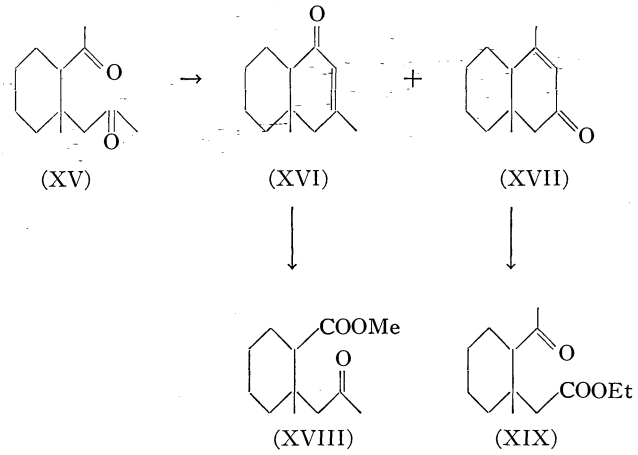
[8]*Thus benzalacetophenone in solution gives head-to-tail union (21), whilst cholestenone gives head-to-tail (22). In coumarin (21) it is more probable that $\pi \rightarrow \pi^*$ activation is involved.*

of 4:1 separable by g.l.c. The major product, (XVI), and the minor product, (XVII), both showed singlets (3 H) for the allylic methyl groups (at τ 8.16 and 8.02) (ref. 12, p. 58) and singlets at (τ 4.31 and 4.34) for one vinyl hydrogen, respectively. The compounds showed, again, the appropriate methylene deformation bands in the infrared. From this evidence it was not possible to distinguish between (XVI) and (XVII) on the one hand and the other two isomers bearing the angular methyl group at the alternative quaternary position on the other.

The unsaturated ketones were, therefore, ozonized to the keto acids, which were converted directly to the esters with diazomethane. The keto ester from (XVI) on g.l.c. was separable into two components characterized as the 2:4-dinitrophenylhydrazones. One, giving a dinitrophenylhydrazone, of m.p. 123–124°, showed a non-equivalent quartet (from the methylene group adjacent to the ketone) at 7.43 and 7.84 ($J \sim 15$ c.p.s.) (see ref. 12, p. 85). The other, giving a dinitrophenylhydrazone of m.p. 118 – ca. 119°, showed a singlet (2 H) at τ 7.44. These keto esters are, therefore, the stereoisomers of (XVIII). The presence of a hydrogen atom at the bridgehead adjacent to the methylene group discussed above would, of course, have led to more complex splitting.

The same observations were made on the 2:4-dinitrophenylhydrazones, that of m.p. 123–124° showing a singlet (2 H) at τ 7.31, the other showing a non-equivalent quartet at τ 7.31, 7.47 ($J \sim 15$ c.p.s.).

The keto ester from (XVII) was homogeneous and also showed a non-equivalent quartet (at ca. τ 7.35, 7.95), in this case partly obscured by a multiplet (see below), again requiring that there be no hydrogen vicinal to the methylene group. In addition, all keto esters showed a multiplet at ca. τ 7.3–7.4 to be attributed to the methine hydrogen next to carbonyl. Other features of the n.m.r. spectrum were in accord with expectation.



(XV) (XVI) (XVII)

(XVIII) (XIX)

The obtention of two keto esters from (XVI) may indicate that although no resolution could be obtained on the columns available (XVI) is a mixture of cis and trans forms. These may differ only slightly in energy (as do certain related decalones (24)). The same may be true of (XVII) also, but epimerization α to the ketone may have taken place after ozonolysis. Such epimerization is, of course, more likely to occur than that α to an ester.

The nature of the other irradiation products can only be inferred since they were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

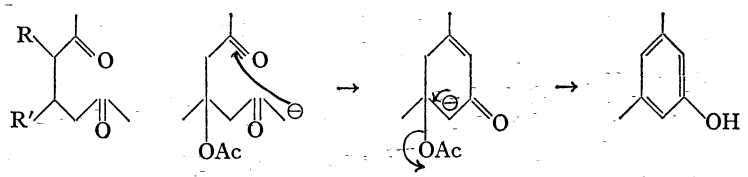
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

not obtained pure, but it seems reasonable, on the basis of the spectral data, to assume that the minor product was, as in the case of oct-1-ene (see below), the isomeric diketone. The formation of *both* diketones is consonant with the concept that steric and electronic factors were opposed, and, indeed, the introduction of the extra methyl group slowed the photochemical addition considerably over that to the simple cycloalkene. Alternative interpretations (see, for instance ref. 27) are, however, presently possible and are under investigation. However, it appears that if a two-step mechanism is involved more than one of the diradicals (XII), (XIII), or (XIV) is concerned, and to a significant extent.

A similar situation with regards asymmetry obtains in oct-1-ene. Irradiation again led to the formation of the two possible diketones. Separation by g.l.c. was difficult because of condensation and decomposition, but pure specimens were obtained by the removal of unsaturated impurities from the chromatographed products by ozonolysis. The structures (XX; R = H, R′ = C_6H_{13}) and (XX, R = C_6H_{13}, R′ = H) were allocated by means of the n.m.r. spectrum. The latter showed a single peak (6 H) at τ 7.94 for the two acetyl groups since they are identically situated, whereas the former showed two closely placed singlets at τ 7.95 and 7.96.

The unsaturated ketonic products from these cyclizations are one double-bond equivalent distant from phenols. The incorporation of a potential double-bond equivalent into the substrate seemed possible using a suitably substituted double bond. This was attempted using isopropenyl acetate.

The irradiation of isopropenyl acetate with acetylacetone in cyclohexane gave a mixture of ketones the separation of which was not attempted. Direct cyclization of the mixture with base and isolation of the acidic material gave *m*-5-xylenol (XXI), through (XXII), identified by melting point, comparison of the infrared spectrum with that published (25), and conversion into the known tribromide (26).



(XX) (XXII) (XXI)

The nature of the products obtained in these irradiations, together with the absence of bicyclohexenyl, appears to indicate that the only reaction is the addition to the ethylenic linkage of the enol. In agreement with the foregoing discussion with regards activation and γ-hydrogen transfer, preliminary results in these laboratories indicate that β-keto esters and cyclic β-diketones behave differently.

EXPERIMENTAL

Materials were reagent grade and were dried over magnesium sulphate and distilled before use. Cyclohexene and cyclopentene were purified by shaking with aqueous ferrous sulphate, dried, and distilled, Oct-1-ene and 1-methylcyclohexene were refluxed over sodium wire and distilled. Before use the hydrocarbons, which were homogeneous to g.l.c. analysis, were filtered through a column of alumina. Nuclear magnetic resonance spectra were recorded on a Varian D.P. 60 instrument. Liquids were run in CCl_4 solution, solids in $CDCl_3$. Irradiations were performed under nitrogen in a water-cooled immersion apparatus using the power of lamp specified. Yields are based on acetylacetone and are not maximal. Ultraviolet spectra were determined in methanolic solution.

The Irradiation of Acetylacetone with Cyclohexene (with A. B. M. A. Sattar)

A solution of the diketone (15.02 g) in cyclohexene (135 ml) was irradiated with an 80-w lamp for 45 hours. After removal of the solvent the product was fractionated on a 40-in. spinning band column to give

the adduct, b.p. 89° at 1.7 mm, n_D^{25} 1.4691 (20.2 g; 78%). Calc. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.91%. Found: C, 72.13; H, 9.62%.

The oxime (hydroxylamine hydrochloride – pyridine at room temperature), crystallized from methanol, had m.p. 165.5–167.5°. Calc. for $C_{11}H_{20}O_2N_2$: C, 62.23; H, 9.50; N, 13.20%. Found: C, 62.45; H, 9.34; 12.90%.

Acid-catalyzed Cyclization of the Cyclohexene Adduct (with A. B. M. A. Sattar)

A solution of the adduct (4.5 g) in ethanol (45 ml) was heated at 80° for 80 minutes with conc. hydrochloric acid (2 ml). After removal of the solvent the product was isolated with chloroform, the chloroform solution washed and dried (Na_2SO_4), and the solvent evaporated. Distillation (b.p. 173–175 at 1.5 mm) gave a mixture (5:3) of two unsaturated ketones (4.04 g; 95%). These were separated by chromatography over a 5-ft silicone SE 30 column at 200°, the separated fractions then being distilled at 180° (bath temp.) at 35 mm to give the following ketones.

(*a*) The unsaturated ketone (IV), n_D^{25} 1.5091, λ_{max} 231 mμ (ε, 19,400), ν_{max} 1675, 1637, 1423 cm^{-1}. Calc. for $C_{11}H_{16}O$: C, 80.18; H, 9.73%. The 2:4-dinitrophenylhydrazone, crystallized from ethyl acetate, had m.p. 201–202°, λ_{max} 380 mμ (ε, 24,000). Calc. for $C_{17}H_{20}O_4N_4$: C, 59.29; H, 5.85; N, 16.27%. Found: C, 59.29; H, 5.82; N, 16.31%.

(*b*) The unsaturated ketone (V), n_D^{25} 1.5160, λ_{max} 237 mμ (ε, 18,500), ν_{max} 1674, 1623, 1415 cm^{-1}. Calc. for $C_{11}H_{16}O$: C, 80.44; H, 9.83%. Found: C, 80.30; H, 9.75%. The 2:4-dinitrophenylhydrazone, crystallized from ethyl acetate, had m.p. 157–158°, λ_{max} 380 mμ (ε, 27,100). Calc. for $C_{17}H_{20}O_4N_4$: C, 59.29; H, 5.85; N, 16.27%. Found: C, 59.57; H, 5.85; N, 16.40%.

Dehydrogenation of Ketone (IV)

The ketone (200 mg) in methanol (10 ml) was added to a solution of sodium borohydride (55 mg) in methanol (3 ml) and water (2 ml) containing a trace of sodium hydroxide (1.0 *N*; 0.02 ml), and the mixture allowed to stand overnight. After acidification with acetic acid the product was isolated with ether and heated at 310° for 12 hours under nitrogen with palladized charcoal (10%; 200 mg). After cooling the charcoal was extracted with ether, and the residue obtained after evaporation of the solvent was treated with saturated alcoholic picric acid (1.5 ml). The picrate (85 mg, m.p. 108–110°) was recrystallized from ethanol to give β-methylnaphthalene picrate, m.p. 114–115° undepressed on admixture with an authentic specimen of the same melting point. The hydrocarbon obtained on regeneration from the picrate had m.p. 31–32° and was undepressed on admixture with an authentic specimen of β-methylnaphthalene of the same melting point. The infrared spectra were identical both in CS_2 and CCl_4 solution.

Dehydrogenation of Ketone (V)

The ketone (200 mg) was reduced in a manner identical with that described above for ketone (IV). Dehydrogenation with palladized charcoal in like manner and treatment of the product with saturated ethanolic picric acid gave the picrate (115 mg), which on crystallization from ethanol had m.p. 139°, undepressed on admixture with an authentic specimen of α-methylnaphthalene of the same melting point. The infrared spectrum of regenerated hydrocarbon was identical with that of an authentic specimen of α-methylnaphthalene in CS_2 and CCl_4 solution.

The Synthesis of Ketones (IV) and (V)

An ethanolic solution of sodioethylacetoacetate (from ethylacetoacetate (2.7 g) and sodium (0.25 g)) and acetylcyclohexene (25 g) was heated on a steam bath at 95° for 6 hours. After dilution with water the product was isolated with benzene. The distillation (149–158° at 3 mm) residue gave the ester mixture (890 mg); no trace of decarboxylated product could be detected by g.l.c. The keto ester (890 mg) was hydrolyzed by refluxing in ethanol (1.5 ml) containing sodium hydroxide (50 mg) and water (0.4 ml) for 3 hours. Extraction of the mixture with ether after dilution with water gave a yellow oil (790 mg). Separation of this by g.l.c. on a silicone Se 30 column at 200° gave ketones (IV) and (V) (1:4) identical in retention times and infrared spectra with the previously described specimens.

Further Irradiations of Cyclohexene and Acetylacetone

(*a*) Cyclohexene (2.4 g) and acetylacetone (11.0 g) in cyclohexane (190 ml) were irradiated with a 350-w lamp for 14 hours. Isolation of the product as described previously gave 2.4 g of material identical in infrared spectra and g.l.c. behavior (diethylene glycol succinate ≡ DEGS column) with that prepared under non-diluted conditions.

(*b*) Cyclohexene (0.82 g) and acetylacetone (1.0 g) were diluted to 190 ml with cyclohexane and irradiated with a 350-w lamp for 5 hours. Material, 1.35 g, identical with the above was obtained.

(*c*) Acetylacetone (20 g) in cyclohexene (135 ml) was irradiated with an 80-w lamp for 15 hours. Gas–liquid chromatographic analysis indicated that 12.3 g (33.2%) of adduct was formed. In an otherwise identical experiment using a pyrex jacket for the lamp 7.09 g (19.2%) of product was obtained identical in infrared spectrum and g.l.c. retention time with the product from unfiltered light.

Irradiation of Cyclopentene and Acetylacetone

A mixture of cyclopentene (130 g) and acetylacetone (15 g) was irradiated with an 80-w lamp for 95

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hours. Removal of the excess cyclopentene by distillation gave a residue of 26 g. This was fractionated by distillation through a 40-in. spinning band column to give the diketone (VII) (17 g), b.p. 129° at 22 mm, n_D^{25} 1.4647, ν_{max} 1712 cm^{-1}. Calc. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%. Found: C, 71.76; H, 9.86%.

The oxime (hydroxylamine hydrochloride – pyridine at room temperature), crystallized from ethanol, had m.p. 138–139°. Calc. for $C_{10}H_{18}O_2N_2$: C, 60.58; H, 9.15; N, 14.13%. Found: C, 60.90; H, 9.21; N, 14.09%.

Base-catalyzed Cyclization of Cyclopentene Adduct

A solution of the diketone (VII) in methanol (100 ml) containing sodium hydroxide (50 mg; 1.2 ml water) was refluxed for 1 hour. The mixture was then neutralized with carbon dioxide, concentrated to about one-third volume under reduced pressure, and the product isolated with benzene. Distillation of the residue after evaporation of the benzene at 125° (bath temp.) at 0.4 mm gave an oil (0.76 g) consisting of two components in the ratio 3:2. These could be separated by g.l.c. on a 10-ft DEGS column at 175° to give the following ketones.

(*a*) The unsaturated ketone (VIII), n_D^{25} 1.5140, λ_{max} 236 mμ (ϵ, 19,100), ν_{max} 1673, 1636, 1418 cm^{-1}. Calc. for $C_{10}H_{14}O$: C, 79.95; H, 9.39%. Found: C, 79.57; H, 9.12%. The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 174–175°, λ_{max} 382 mμ (ϵ, 25,000). Calc. for $C_{16}H_{18}O_4N_4$: C, 58.17; H, 5.49; N, 16.96%. Found: C, 58.24; H, 5.36; N, 17.25%.

(*b*) The unsaturated ketone (IX), n_D^{25} 1.5153, λ_{max} 233 mμ (ϵ, 16,100), ν_{max} 1669, 1640, 1425 cm^{-1}. Calc. for $C_{10}H_{14}O$: C, 79.95; H, 9.39%. Found: C, 79.02; H, 8.99%. The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 146–147°, λ_{max} 380 mμ (ϵ, 23,000). Calc. for $C_{16}H_{18}O_4N_4$: C, 58.17; H, 5.49; N, 16.76%. Found: C, 57.90; H, 5.50; N, 16.57%.

Irradiation of 1-Octene and Acetylacetone

A mixture of oct-1-ene (135 g) and acetylacetone (15.0 g) was irradiated with a 350-w lamp for 57 hours. After removal of the excess octene the residue was distilled to give a low-boiling fraction (87–107° at 0.1 mm) (21 g) and a higher fraction (7 g). Redistillation of the main fraction through a spinning band column gave material, b.p. 90° at 0.1 mm, n_D^{25} 1.4455 (16.6 g), which consisted of two components in the ratio of approximately 3:2 as indicated by g.l.c. analysis on an SE 30 at 207°. Separation preparatively by this means was not possible because of the instability of the diketones at that temperature and decomposition rendered difficult the determination of the exact ratio of products even on the analytical column. The separated fractions were ozonized in chloroform solution cooled in CO_2–acetone (to remove cyclized contaminants), the ozonide decomposed with water, the organic layer extracted with sodium hydrogen carbonate, and the residual oil distilled (ca. 140° at 0.3 mm).

The first peak gave 5-acetylundecan-2-one, n_D^{25} 1.4500, ν_{max} 1719 cm^{-1}. Calc. for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%. Found: C, 73.54; H, 11.36%.

The second peak gave 4-acetonyldecan-2-one, n_D^{25} 1.4466, ν_{max} 1718 cm^{-1}. Calc. for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%. Found: C, 73.50; H, 11.25%.

Irradiation of Isopropenyl Acetate and Acetylacetone

A mixture of isopropenyl acetate (35 g), acetylacetone (15 g), and cyclohexane (160 ml) was irradiated with an 80-w lamp for 186 hours. After removal of the cyclohexane the residual oil was taken up in chloroform and the chloroform washed with sodium hydrogen carbonate. Evaporation of the chloroform gave the crude adduct (6.7 g).

The adduct (4 g) in methanol (150 ml) containing sodium hydroxide (2 N; 5 ml) was refluxed for 1 hour. The mixture was neutralized with carbon dioxide, evaporated, water added, and the mixture extracted with methylene dichloride. The organic phase was then extracted with sodium hydroxide (2 *N*; 4×20 ml), the aqueous extract acidified with sulphuric acid, and the phenolic material (1.04 g) extracted with carbon tetrachloride and distilled *in vacuo*.

The phenol (XXI) had an infrared spectrum (CCl_4) identical with that reported in the literature (25) and on bromination (26) in acetic acid gave tribromo-*m*-xylenol, m.p. (from cyclohexane) 162–163° (Anselmino gives 166–167°). Evaporation of the methylene dichloride layer gave 1.57 g of neutral material, probably unsaturated ketones, which was not further investigated.

Attempted separation of the uncyclized ketones by g.l.c. on DEGS (prep.) led to condensation reactions and decomposition.

Irradiation of 1-Methylcyclohexene and Acetylacetone

(*a*) Acetylacetone (20 g) in 1-methylcyclohexene (180 ml) was irradiated with a 350-w lamp for 56 hours. After removal of the excess hydrocarbon the residual oil was distilled (80–88° at 0.1 mm) to give the crude adduct (25 g).

(*b*) A mixture of acetylacetone (20 g), methylcyclohexene (130 ml), and cyclohexane (40 ml) was irradiated for 90 hours. Isolation of the product and distillation (78–90° at 0.15 mm) gave the crude mixture of ketones (28.5 g). This contained three main components but separation by g.l.c. preparatively was not possible because of condensation reaction induced by the high temperature required. Fractional distillation through a spinning band column gave the main product, (XV), in about 50% yield, b.p. 77° at 0.4 mm, n_D^{25} 1.4739. Calc. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%. Found: C, 72.85; H, 9.86%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The dioxime (hydroxylamine hydrochloride – pyridine at room temperature), crystallized from methanol, had m.p. 175–175.5°. Calc. for $C_{12}H_{22}O_2N_2$: C, 63.68; H, 9.80; N, 12.38%. Found: C, 63.78; H, 9.76; N, 12.09%.

Base-catalyzed Cyclization of Diketone (XV)

A solution of the diketone (XV) (7.0 g) in methanol (150 ml) containing sodium hydroxide (50 mg) was refluxed for 1 hour. The mixture was then neutralized with carbon dioxide, evaporated, diluted with water, and extracted with carbon tetrachloride. The crude material obtained on evaporation (5.8 g) consisted of two products in the ratio of 4:1 separable by g.l.c. on a preparative 10-ft DEGS column at 175°.

The main product, (XVI), had n_D^{25} 1.5154, λ_{max} 237 mμ (ϵ, 16,400), ν_{max} 1668, 1637, 1421 cm^{-1}. Calc. for $C_{12}H_{18}O$: C, 80.55; H, 10.18%. Found: C, 80.43; H, 10.14%. The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 189–190°, λ_{max} 372 mμ (ϵ, 24,500). Calc. for $C_{18}H_{22}O_4N_4$: C, 60.32; H, 6.19; N, 15.63. Found: C, 60.78; H, 6.21; N, 15.52%.

The minor product (XVII) had n_D^{25} 1.5121, λ_{max} 240 mμ (ϵ, 17,000), ν_{max} 1670, 1637, 1415 cm^{-1}. Calc. for $C_{12}H_{18}O$: C, 80.85; H, 10.18%. Found: C, 80.14; H, 9.92%.

The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 146–147°, λ_{max} 386 mμ (ϵ, 25,700). Calc. for $C_{18}H_{22}O_4N_4$: C, 60.32; H, 6.19; N, 15.63%. Found: C, 60.54; H, 6.19; N, 15.37%.

Ozonolysis of the Ketone (XVI)

The unsaturated ketone (XVI) (800 mg) was dissolved in methylene chloride (20 ml), immersed in an acetone–CO_2 bath, and a stream of ozone was passed for 1 hour. Hydrogen peroxide (30%; 2 ml) and aqueous sodium hydroxide (2 *N*; 5 ml) were added and the mixture stirred at room temperature for 5 hours. The mixture was extracted with methylene chloride, the aqueous phase acidified with sulphuric acid (3 *N*), and the acidic material isolated with carbon tetrachloride. Treatment of the crude acid with ethereal diazomethane gave the keto ester mixture (710 mg), which was separated by g.l.c. on a DEGS preparative column at 180° into two isomers in approximately equal amounts.

The keto-ester-I (XVIII) had n_D^{25} 1.4713. Calc. for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%. Found: C, 68.11; H, 9.33%. The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 118–119°, λ_{max} 363 mμ (ϵ, 22,500). Calc. for $C_{18}H_{24}O_6N_4$: C, 55.09; H, 6.17; N, 14.28%. Found: C, 55.34; H, 6.22; N, 14.21%.

The keto-ester-II (XVIII) had n_D^{25} 1.4697. Calc. for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%. Found: C, 67.62; H, 9.18%. The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 123–124°, λ_{max} 361 mμ (ϵ, 20,500). Calc. for $C_{18}H_{24}O_6N_4$: C, 55.09; H, 6.17; N, 14.28%. Found: C, 55.51; H, 6.34; N, 14.14%. The 2:4-dinitrophenylhydrazone did not show a mixed melting point depression on admixture with that from (XVIII), but showed different infrared and n.m.r. spectra.

Ozonolysis of the Ketone (XVII)

The unsaturated ketone (100 mg) was dissolved in methylene dichloride (30 ml), cooled in an acetone–CO_2 bath, and ozone was passed for 40 minutes. Hydrogen peroxide (30%; 2 ml) and aqueous sodium hydroxide (5 *N*; 5 ml) were added and the mixture stirred at room temperature for 5 hours. After removal of the neutral material by extraction the mixture was acidified with sulphuric acid (3 *N*), the acid extracted with carbon tetrachloride and esterified with diazomethane. The oil (80 mg) appeared homogeneous to g.l.c. on a DEGS column. Distillation (bath temp. 180° at ca. 0.6 mm) gave an oil, n_D^{25} 1.4689. Calc. for $C_{12}H_{18}O_3$: C, 67.89; H, 9.50%. Found: C, 67.59; H, 9.94%. The 2:4-dinitrophenylhydrazone, crystallized from methanol, had m.p. 153–154°, λ_{max} 361 mμ (ϵ, 21,600). Calc. for $C_{18}H_{24}O_6N_6$: C, 55.09; H, 6.17; N, 14.28%. Found: C, 55.29; H, 6.13; N, 14.22%.

ACKNOWLEDGMENTS

The authors wish to thank Mr. A. B. M. A. Sattar for the experiments indicated, and Mr. R. E. Klinck for the determination of the n.m.r. spectra. This work was supported by the U.S.A.F. under grant AF-AFOSR-61-6.

THE SULPHURIC ACID SOLVENT SYSTEM

PART IV. SULPHATOCOMPOUNDS OF ARSENIC (III)

R. J. GILLESPIE AND E. A. ROBINSON

Departments of Chemistry, McMaster University, Hamilton, Ontario, and University College, London, England

Received August 31, 1962

ABSTRACT

The cryoscopic and conductimetric behavior of arsenic (III) oxide in 100% sulphuric acid and in dilute oleum have been investigated. It is concluded that in very dilute solutions in 100% sulphuric acid, arsenic (III) oxide forms arsonyl (III) hydrogen sulphate, $AsO.HSO_4$, which is partly ionized to give the AsO^+ cation. Both these species probably exist mainly in solvated forms, e.g., $As(OH)(SO_4H)_2$, and $As(OH)(SO_4H)^+$ respectively. At higher concentrations polymeric species such as $HO.As(HSO_4)OAs(HSO_4)_2$ are present in increasing amounts and eventually the insoluble polymeric compound $[(AsO)_2SO_4]_n$ separates from solution. In oleum the more sulphated species $As(HSO_4)_3$, $[(HSO_4)_2As]_2O$, and $[(HSO_4)_2As]_2SO_4$ are formed. Related structures are proposed for some previously prepared compounds of arsenic (III) oxide and sulphur trioxide.

Sulphuric acid has proved to be a useful reagent for the production of oxycations such as NO^+ and NO_2^+ (1) and other cations such as the triphenylcarbonium ion $(C_6H_5)_3C^+$ and the mesitoyl ion $(CH_3)_3C_6H_2CO^+$ (2). It is also a convenient solvent for these ions, which are very strong Lewis acids, and are unstable in more basic media such as water. The present work is concerned with the possible formation of the ion AsO^+ and it was undertaken as part of a more general study of the formation and stability of other inorganic oxycations in the solvent sulphuric acid.

RESULTS AND DISCUSSION

Solutions of As_2O_3 in 100% Sulphuric Acid

The freezing points and conductivities of solutions of arsenic (III) oxide in 100% sulphuric acid are shown in Tables I and II. As arsenic (III) oxide is only sparingly

soluble in 100% sulphuric acid it was not possible to study solutions more concentrated than approximately 0.1 molal. A white precipitate formed slowly in the more concentrated solutions; somewhat more rapidly at 10° than at 25°. Analysis of the precipitate showed that it had a composition close to $As_2O_3.SO_3$.

The number of moles of hydrogen sulphate ions, γ, formed by the ionization of 1 mole of arsenic (III) oxide was found by comparison of the concentrations of arsenic (III) oxide and of water having the same specific conductance (3) and the number of moles of

†$K_b = [AsO^+][HSO_4^-]/[AsO.HSO_4] = (\gamma-1)[HSO_4^-]/(3-\gamma)$.

If arsenic (III) oxide behaved like N_2O_3 (4), it would ionize according to the equation

$$As_2O_3 + 3H_2SO_4 = 2AsO^+ + H_3O^+ + 3HSO_4^-, \quad [1]$$

for which, if water were fully ionized, $\nu = 6$ and $\gamma = 3$. At the lowest concentration given in Table III the observed values are $\nu = 5.9$ and $\gamma = 2.6$, which agree moderately well with the expected values. However, both ν and γ decrease considerably with increasing concentration. The simplest explanation of this is to assume that $AsO.HSO_4$ is incompletely ionized. The ν and γ factors would then be expected to decrease towards the values of 4 and 1, respectively, which would correspond to the formation of unionized $AsO.HSO_4$ according to the equation

$$As_2O_3 + 3H_2SO_4 = 2AsO.HSO_4 + H_3O^+ + HSO_4^-. \quad [2]$$

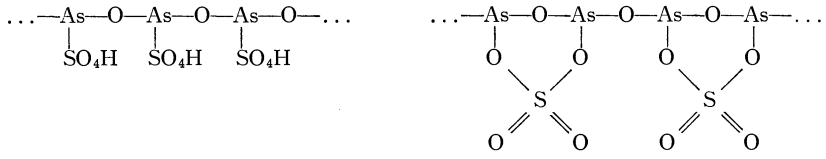
The experimental observations are reasonably consistent with this mode of reaction and an approximately constant value of the dissociation constant of $AsO.HSO_4$ may be calculated from the observed γ values, as is shown in Table III. The only remaining inconsistency is that the decrease in the value of ν is more rapid than that for γ and thus $\nu-\gamma$, which should have a constant value of 3, decreases from 3.4 to 2.7. The initially high value of $\nu-\gamma$ is discussed later; the decrease to values of less than 3 could be accounted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for by polymerization of $AsO.HSO_4$, for example, by the formation of a dimer:

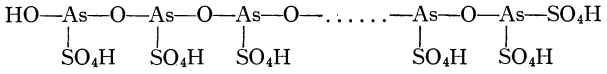
$$As_2O_3 + 3H_2SO_4 = (AsO.HSO_4)_2 + H_3O^+ + HSO_4^-, \qquad [3]$$

$\nu = 3$, $\gamma = 1$, and $\nu - \gamma = 2$. The ready formation of a precipitate even from quite dilute solutions of As_2O_3 is also consistent with the formation of polymers, for which structures I or II seem reasonable:



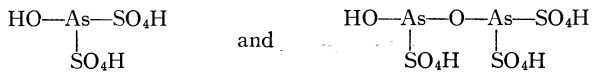
I II

An additional sulphuric molecule is needed to terminate such a chain, giving an —OH group on one end and a hydrogen sulphate group on the other:



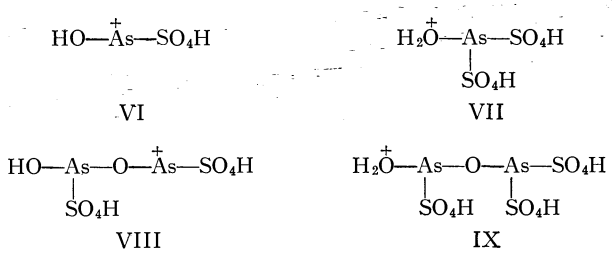
III

The first two members of this series of polymers then represent solvated forms of $AsO.HSO_4$ and $(AsO.HSO_4)_2$, respectively, i.e.,



IV and V

Similarly the species written above as AsO^+ is probably more correctly written in one of the solvated forms VI and VII which can be derived from IV by loss of HSO_4^- or by proton addition. Similar dimeric ions VIII and IX are also possible.



VI VII

VIII IX

The insoluble precipitate of composition $As_2O_3.SO_3$ obtained from the more concentrated solution of As_2O_3 in sulphuric acid may be formulated as $[(AsO)_2SO_4]_n$ with the structure II.

The values of ν would not be expected to be as high as 6.0 even in the most dilute solutions because of the incomplete ionization of the water formed (6). The fact that the observed values are very close to 6.0, and the initial values of $\nu - \gamma$ are higher than the expected value of 3.0, at very low concentrations, can probably be attributed to the formation, under these conditions, of small amounts of $As(HSO_4)_3$, according to equation (v) of Table IV for which $\nu = 8$ and $\gamma = 3$. Evidence for the formation of this and related species in oleum solutions is presented in the following section. Possible modes of ionization, including some which are not consistent with the experimental results, are summarized in Table IV.

TABLE IV

Equations for some possible modes of ionization of As_2O_3 in H_2SO_4

	ν	γ
(i) $As_2O_3 + 3H_2SO_4 = 2AsO^+ + H_3O^+ + 3HSO_4^-$	6	3
(ii) $As_2O_3 + 3H_2SO_4 = 2AsO.HSO_4 + H_3O^+ + HSO_4^-$	4	1
(iii) $As_2O_3 + 6H_2SO_4 = [As(HSO_4)_2]_2O + 2H_3O^+ + 2HSO_4^-$	5	2
(iv) $As_2O_3 + 8H_2SO_4 = [As(HSO_4)_2]_2SO_4 + 3H_3O^+ + 3HSO_4^-$	7	3
(v) $As_2O_3 + 9H_2SO_4 = 2As(HSO_4)_3 + 3H_3O^+ + 3HSO_4^-$	8	3
(vi) $As_2O_3 + 9H_2SO_4 = 2As(HSO_4)_4^- + 3H_3O^+ + HSO_4^-$	6	1
(vii) $As_2O_3 + 9H_2SO_4 = 2As^{3+} + 3H_3O^+ + 9HSO_4^-$	14	9

It is unfortunate that the present measurements do not enable one to distinguish between the AsO^+ ion and the solvated forms VI and VII or between the undissociated molecule $AsO.HSO_4$ and its solvated form IV. The method that was originally used to establish that NO^+ and NO_2^+ exist in solution in sulphuric acid in the unsolvated form as simple diatomic and linear triatomic ions respectively, namely Raman spectroscopy (5), could not be applied in the present case because the solutions that could be obtained were too dilute to give satisfactory Raman spectra of the dissolved species. However, the tendency for the formation of polymeric species in these solutions may well be a consequence of the inability, or at least the reluctance, of arsenic (III) to form multiple bonds. We recall that silicon compounds of the type R_2SiO, which could in principle contain a silicon–oxygen double bond, are, in fact, polymeric. Double bonds are formed only be elements of high electronegativity and on the Pauling scale arsenic has the same electronegativity as boron, namely 2.0, and boron does not form double bonds to oxygen in stable molecules. There are reasons, therefore, for thinking that the free AsO^+ ion may not exist in appreciable concentrations because of a strong tendency to eliminate its double bond by solvation and polymerization. For simplicity, however, we will generally represent IV by the formula $AsO.HSO_4$ and II and VII by the formula of the unsolvated species AsO^+.

Solutions of As_2O_3 in Dilute Oleum

The results of cryoscopic and conductimetric measurements on solutions of As_2O_3 in dilute oleum are given in Tables V and VI and Fig. 1. Addition of arsenic (III) oxide to a

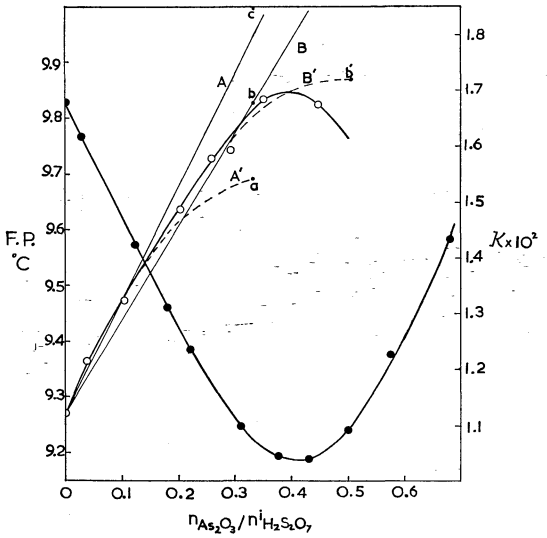

FIG. 1. Freezing points and electrical conductivities of solutions of As_2O_3 in dilute oleum. ○, freezing points; ●, conductivities. A, B, *a*, *b*, *b'*, and *c* are explained in the text and in Table VII.

dilute oleum results in a decrease of the conductivity until a minimum is reached and the conductivity then increases again. The conductivity minimum is reached when $r = n_{As_2O_3}/n^i_{H_2S_2O_7} = 0.42$, where $n_{As_2O_3}$ is the number of moles of As_2O_3 added to $n^i_{H_2S_2O_7}$ moles of $H_2S_2O_7$. The freezing point increases on addition of As_2O_3 to oleum and reaches a maximum at $r = n_{As_2O_3}/n^i_{H_2S_2O_7} \simeq 0.38$.

Since arsenic (III) oxide forms $AsO.HSO_4$ in sulphuric acid its ionization in oleum might be expected to be represented by

$$As_2O_3 + H_2S_2O_7 \rightarrow 2AsO.HSO_4 \rightleftharpoons 2AsO^+ + 2HSO_4^-. \qquad [4]$$

If $AsO.HSO_4$ behaved as a non-electrolyte the conductivity minimum in a titration of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

oleum would occur at $r = 1.0$, and the freezing point of the solution would decrease since each mole of $H_2S_2O_7$* would be replaced by 2 moles of $AsO.HSO_4$ (i.e. $\Delta\nu = 2.00-1.33 = 0.67$).

For the titration of $H_2S_2O_7$ with a base B the position of minimum conductivity is given by

$$n_B/n^1_{H_2S_2O_7} = 0.56(1+0.018/K_b)$$

where n_B is the number of moles of base added to a solution containing $n^1_{H_2S_2O_7}$ moles of disulphuric acid initially, and K_b is the dissociation constant of the base (7).

If $AsO.HSO_4$ behaved as a strong base the conductivity minimum would be predicted at $n_{AsO.HSO_4}/n^1_{H_2S_2O_7} = 0.56$, (7), and therefore for the reaction

$$As_2O_3 + H_2S_2O_7 = 2AsO^+ + 2HSO_4^- \quad [5]$$

the conductivity minimum would occur at $r = 0.22$. The freezing point of the solution would remain approximately constant since the overall reaction up to the conductivity minimum would be

$$As_2O_3 + 3H_2S_2O_7 = 2AsO^+ + 2HS_2O_7^- + 2H_2SO_4, \quad [6]$$

i.e. $\Delta\nu = (3\times1.33)-4.00 = 0$.*

For $AsO.HSO_4$ reacting as a weak base a value of $K_b = 0.011$ mole kg^{-1} may be calculated from the observed composition at the minimum conductivity, in poor agreement with the value of $K_b = 0.12$ mole kg^{-1} obtained above. On the basis of this latter value the conductivity minimum would be expected to occur at $r = 0.24$. It is evident that this scheme of ionization is not consistent with the experimental results.

The experimental results can, however, be accounted for if it is assumed that $As(OH)(HSO_4)_2$ and its dimer, which are formed in 100% sulphuric acid, are further sulphated in oleum according to the equations

$$HO.As(HSO_4)_2 \xrightarrow{SO_3} As(HSO_4)_3 \quad [7]$$

$$HO.As(HSO_4).O.As(SO_4H)_2 \xrightarrow{SO_3} [(SO_4H)_2As]_2O$$

$$\xrightarrow{SO_3} [(HSO_4)_2As]_2SO_4. \quad [8]$$

The corresponding reactions when As_2O_3 is added to oleum would then be

$$As_2O_3 + 3H_2S_2O_7 = 2As(HSO_4)_3 \quad [9]$$

$$As_2O_3 + 2H_2S_2O_7 \rightarrow [(HSO_4)_2As]_2O \quad [10]$$

$$As_2O_3 + 3H_2S_2O_7 \rightarrow [(HSO_4)_2As]_2SO_4 + H_2SO_4. \quad [11]$$

Each of these reactions would lead to an increase in the freezing point of the solution. The corresponding values of $\Delta\nu$ are given in Table VII, which also includes values of ν at the compositions $r = 0.33$ and $r = 0.5$ and the corresponding freezing-point curves are shown in Fig. 1 (curves A and B). The observed freezing points are initially in good agreement with the formation of $As(HSO_4)_3$. The removal of $H_2S_2O_7$, which represses the self-ionization of the solvent, and its replacement by a non-electrolyte will cause the slopes of the freezing-point curves to decrease (A′ and B′ in Fig. 1). At $r = 0.33$ the observed freezing point of the solution agrees well with that expected for reaction [10]. It is certainly much higher than would be expected for the formation of $As(HSO_4)_3$ alone and we conclude that when As_2O_3 is added to oleum, $As(HSO_4)_3$ is formed initially but is gradually

**In dilute solution in sulphuric acid each molecule of* $H_2S_2O_7$ *behaves as approximately* $1\frac{1}{3}$ *particles (6), as a result of the ionization*

$$H_2S_2O_7 + H_2SO_4 \leftrightharpoons H_3SO_4^+ + HS_2O_7^-.$$

TABLE VII

Predicted values of ν for solutions of As_2O_3 in oleum

Reaction	Initial slope $\Delta\nu$	$r = 0.33$		$r = 0.5$	
		ν	F.p.	ν	F.p.
[9]	−2.00 (A)	2.0	9.69 (*a*)	—	—
[10]	−1.67 (B)	2.3	9.83 (*b*)	1	9.87 (*b'*)
[11]	−2.00 (A)	1.0	10.02 (*c*)	—	—
Observed	−2.00	—	9.84	—	9.77

NOTE: A, B, *a*, *b*, *b'*, and *c* refer to curves and points in Fig. 1.

replaced by $[As(HSO_4)_2]_2O$. However, the conductivity at $r = 0.33$ is not much greater than at the conductivity minimum and is considerably smaller than would be expected if one third of the original $H_2S_2O_7$ remained unreacted. It seems necessary therefore to assume that $As(HSO_4)_3$ and the fully sulphated dimer $[(HSO_4)_2As]_2SO_4$ are also present. Complete reaction according to equation [11] would give the freezing point indicated by *c* in Fig. 1.

In a previous paper on conductivity measurements on solutions of acids of the sulphuric acid solvent system (8), it was assumed that the conductivity at the composition $r = 0.33$ was due to the acid behavior of $As(HSO_4)_3$,

$$As(HSO_4)_3 + 2H_2SO_4 = H_3SO_4^+ + As(HSO_4)_4^-,$$

and a dissociation constant for the acid $HAs(HSO_4)_4$ of $K_a = 0.015$ was calculated from the conductimetric results. However, it seems clear that much of the arsenic must be present in the solution in the form of the dimer $[(HSO_4)_2As]_2O$ and a corresponding amount of $H_2S_2O_7$ must also be present. Thus at least part of the observed conductivity at this composition must be due to $H_2S_2O_7$, and the dissociation constant for $HAs(HSO)_4$ quoted above can only be regarded as a maximum value; indeed, it cannot be concluded with certainty that $As(HSO_4)_3$ exhibits any acid properties at all. Figure 2 shows the results

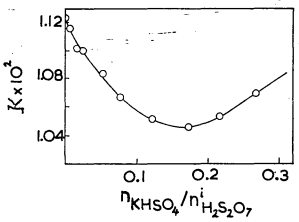

FIG. 2. Electrical conductivities obtained by adding $KHSO_4$ to a solution of As_2O_3 in oleum having the composition $n_{As_2O_3}/n^i_{H_2S_2O_7} = 0.33$.

of an experiment in which $KHSO_4$ was added to a solution of composition $r = 0.33$. The observed decrease in the conductivity may be attributed to the titration of the $H_2S_2O_7$ and perhaps to some extent also to the titration of $HAs(HSO_4)_4$.

From $r = 0.33$ to the maximum freezing point there is only a very small increase of 0.04° in the observed freezing point. This must be attributed to the simultaneous occurrence of the following reactions:

$$4As(HSO_4)_3 + As_2O_3 \rightarrow 3[As(HSO_4)_2]_2O$$
$$2[As(HSO_4)_2]_2SO_4 + As_2O_3 \rightarrow 3[As(HSO_4)_2]_2O.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

If equal amounts of As_2O_3 reacted by each of these reactions there would be no change in the number of particles in solution, and hence no change in the freezing point.

At $r = 0.5$ the formation of $[As(HSO_4)_2]_2O$ would be complete and the solution would be expected to have a maximum freezing point (b' in Fig. 1). The observed freezing point is lower than this. It begins to decrease before $r = 0.5$, presumably because with diminishing $H_2S_2O_7$ concentration in the system some dissociation occurs according to the equation

$$[As(HSO_4)_2]_2O + 2H_2SO_4 \rightarrow 2HO.As(HSO_4)_2 + H_2S_2O_7.$$

Unfortunately these systems appear to be too complicated to be able to obtain any quantitative information from the available experimental data on the amounts of the various species present. However, the following qualitative conclusions seem reasonably well established: When As_2O_3 is first added to oleum it is largely converted to $As(HSO_4)_3$ but with increasing concentration it polymerizes and, in particular, the dimers $[As(HSO_4)_2]_2SO_4$ and $[As(HSO_4)_2]_2O$ are present in increasing amounts. At the composition $r = 0.33$, which corresponds to the stoichiometric composition $As(HSO_4)_3$, all three species appear to be present in equilibrium with some unreacted $H_2S_2O_7$. At $r = 0.5$ the species present are $[As(HSO_4)_2]_2O$ together with some $HOAs(HSO_4)_2$ and $H_2S_2O_7$.

Previous Work

Early workers reported the preparation of several sulphato compounds of trivalent arsenic by dissolving arsenic (III) oxide in sulphuric acid of various strengths, and by reactions between As_2O_3 and sulphur trioxide. Adie (69) obtained a compound corresponding to the composition $As_2O_3.SO_3$ by dissolving arsenic (III) oxide in sulphuric acid of the composition $H_2SO_4.H_2O$, and the compound $As_2O_3.8SO_3$ by dissolving As_2O_3 in hot sulphur trioxide. Several workers have analyzed the sulphato compounds of arsenic obtained from the flues of pyrites burners and all agree that the compositions of the compounds correspond closely to that expected for the compound $As_2O_3.SO_3$ (10). Stavenhagen (11) obtained the same compound by recrystallizing arsenious oxide from sulphuric acid having a composition between $H_2SO_4.H_2O$ and $2H_2SO_4.9H_2O$. However, he obtained the compound $As_2O_3.2SO_3$ from a solution of As_2O_3 in 98% H_2SO_4. Other arsenic (III) oxide – sulphur trioxide complexes which have been reported are $As_2O_3.3SO_3$, $As_2O_3.4SO_3$, and $As_2O_3.6SO_3$ (10). Complex sulphates of arsenic (III) have also been reported, e.g., $2K_2O.As_2O_3.4SO_3$, $CuO.As_2O_3.3SO_3$, $PbO.As_2O_3.2SO_3$ (10).

The compounds $As_2O_3.SO_3$, $As_2O_3.2SO_3$, and $As_2O_3.3SO_3$ are probably closely related to the species that we have found to occur in 100% H_2SO_4 and in oleum, i.e.

$$\begin{aligned} As_2O_3.SO_3 + H_2SO_4 &\rightarrow 2AsO.HSO_4 \\ As_2O_3.2SO_3 + 2H_2SO_4 &\rightarrow [As(HSO_4)_2]_2O \\ As_2O_3.3SO_3 + 3H_2SO_4 &\rightarrow 2As(HSO_4)_3 \\ As_2O_3.3SO_3 + 2H_2SO_4 &\rightarrow [As(HSO_4)_2]_2SO_4. \end{aligned}$$

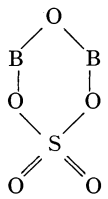
Possible Structures for Sulphatoarsenic (III) Compounds

Recently we have discussed the structures of complex sulphatoboron compounds (12) and have shown that they may be satisfactorily formulated as derivatives of the six-membered ring X, which is closely related to the similar ring XI found in many polyborates. It seems likely that the preference for ring structures is partly a consequence of the inability of boron to form double bonds with oxygen. Since arsenic has the same electronegativity as boron it is reasonable to expect it to show a similar inability to form double bonds and a similar preference for six-membered ring structures.

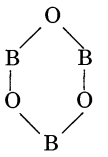
In general, oxygen compounds of arsenic (III) are found to have only single bonds to oxygen and As_4O_6 contains the six-membered ring XII.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

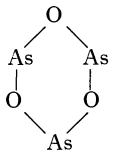
Therefore, we postulate that in the case of sulphatoarsenic compounds the ring XIII is an important structural unit. On this basis $As_2O_3.SO_3$ and $As_2O_3.2SO_3$, for example, may be formulated as in II and XIV.



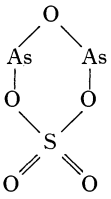
X



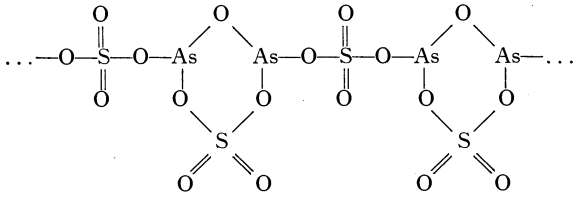
XI



XII



XIII



XIV

The complex sulphatoarsenites mentioned above may also be formulated similarly.

CONCLUSIONS

In very dilute solutions in 100% sulphuric acid, arsenic (III) oxide forms arsonyl (III) hydrogen sulphate, $AsO.HSO_4$, which is partly ionized to give the AsO^+ cation. Both these species probably exist in solvated forms, e.g. $As(OH)(SO_4H)_2$ and $As(OH)SO_4H^+$ respectively, and no conclusive evidence was obtained for the existence of the unsolvated form AsO^+ analogous to the well-known nitrosyl cation NO^+. At higher concentrations polymerized species such as $HO.As(HSO_4)OAs(HSO_4)_2$ are present in increasing amounts and eventually the insoluble polymeric compound $[(AsO)_2SO_4]_n$ separates from solution. In oleum the more sulphated species $As(HSO_4)_3$, $[(HSO_4)_2As]_2O$, and $[(HSO_4)_2As]_2SO_4$ are formed.

EXPERIMENTAL

The apparatus and general procedure for making the cryoscopic and conductimetric measurements has been described elsewhere (13, 14). The cryoscopic ν factors were obtained from the equation

$$\nu = \theta(1+0.002\theta)/6.12m-(m_d/m),$$

where θ is the freezing point depression calculated from the freezing point (10.625°) of hypothetically undissociated sulphuric acid, m is the concentration of arsenious oxide, m_d is the concentration of unrepressed self-dissociation products, and 6.12 is the cryoscopic constant (15). The correction m_d/m for unrepressed self-dissociation was made using the conductimetric γ factors to obtain the concentration of HSO_4^- and assuming that each molecule of arsenious oxide ionizes to give one hydronium ion. The conductimetric γ factors were calculated by comparison with the conductivities of solutions of water in sulphuric acid, as has been described previously (9). The conductimetric titrations were also carried out as previously described (3). The initial concentrations of oleum, in these titrations, were obtained from the specific conductance measurements.

Analytical grade arsenious oxide was dried at 100°.

ACKNOWLEDGMENT

STEREOCHEMISTRY OF ARSENIC

VIII. CYANODIMETHYLARSINE (CACODYL CYANIDE)

N. CAMERMAN AND J. TROTTER

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received September 28, 1962

ABSTRACT

Crystals of cyanodimethylarsine, $(CH_3)_2AsCN$, are triclinic with two molecules in a unit cell of dimensions $a = 6.31$, $b = 8.02$, $c = 6.27$ Å, $\alpha = 110°00'$, $\beta = 119°45'$, $\gamma = 81°47'$, space group $P\bar{1}$. The structure has been determined from projections along the three crystallographic axes, and the mean values of the bond lengths and valency angles (with estimated standard deviations) are: As—C = 1.96±0.03 Å, C—N = 1.16±0.07 Å, ∠ Me—As—Me = 105±2°, ∠Me—As—CN = 91±1½°, ∠ As—C—N = 180±4°. There is an unusually short As....N intermolecular separation, which is indicative of charge-transfer bonding involving donation of nitrogen lone pair electrons to vacant arsenic 4*d* orbitals; the other intermolecular approaches correspond to normal van der Waals interactions.

INTRODUCTION

Previous papers in this series have described the structures of halogenodiphenylarsines. The C—As—C angles are 105°, considerably larger than the value assumed in an electron-diffraction investigation of the corresponding dimethyl derivatives, so that we felt it would be useful to investigate the structure of a compound of this latter type. The halogenodimethylarsines are all liquids at room temperature, but cyanodimethylarsine (cacodyl cyanide), whose structure is described in this present communication, is a solid, m.p. 30°. This is in itself an interesting fact, and suggests that there might be some type of intermolecular interaction.

EXPERIMENTAL

Colorless needle-shaped crystals of cyanodimethylarsine were prepared by the reaction of iododimethylarsine with silver cyanide *in vacuo*, the desired product being purified by sublimation. The compound is very volatile and extremely toxic, and crystals were sealed in thin-walled Lindemann-glass capillaries. The unit cell dimensions and space group were determined from rotation and oscillation photographs about the *a*-axis, and 0*kl* and 1*kl* Weissenberg and *h*0*l* and *hk*0 precession films.

Crystal Data

Cyanodimethylarsine, $(CH_3)_2AsCN$; M, 131.0; m.p. 30° C

Triclinic, $a = 6.31$, $b = 8.02$, $c = 6.27$ Å, $\alpha = 110°00'$, $\beta = 119°45'$, $\gamma = 81°47'$

Volume of the unit cell = 258.7 Å^3

D_{calc} (with $Z = 2$) = 1.68 g cm^{-3}

Absorption coefficients for X rays, $\lambda = 1.542$ Å, $\mu = 76.8$ cm^{-1}; $\lambda = 0.7107$ Å, $\mu = 67.2$ cm^{-1}.

$F(000) = 128$

Space group is $P1$ or $P\bar{1}$. Analysis has proceeded satisfactorily on the basis of $P\bar{1}$.

Due to the extreme volatility and toxicity of the crystals, we made no effort to measure the density, but since it seemed unlikely that it was as low as 0.8 or as high as 3.4 g cm^{-3}, $Z = 2$ was assumed. This was confirmed by the subsequent analysis of the structure.

The intensities of the 0*kl* reflections were recorded on Weissenberg films (Cu $K\alpha$) and of the *h*0*l* and *hk*0 reflections on precession films (Mo $K\alpha$). The estimates were made visually, and the structure amplitudes derived as usual, the absolute scale being established later by correlation with the calculated structure factors. The crystal used had cross section 0.1×0.1 mm and no absorption corrections were considered necessary. Eighty-four independent 0*kl*, forty-eight *h*0*l*, and seventy-seven *hk*0 reflections were observed.

Structure Analysis

The position of the arsenic atom was determined from the three Patterson projections, and the other atoms were then located on electron-density maps computed with signs based on the arsenic contributions alone. Structure factors were then calculated for all three zones, using the scattering factors of Berghuis

et al. (1), with an overall temperature factor $B = 5.1$ Å^2, determined from plots of ln $(|F_c|/|F_o|)$ against $\sin^2\theta/\lambda^2$. Refinement was completed by computing successive Fourier and difference syntheses. The final electron-density projections are shown in Figs. 1 and 2, and measured and calculated structure factors are listed in Table I. The discrepancy factors for the observed planes are: $R(0kl) = 14.7\%$; $R(h0l) = 17.3\%$; $R(hk0) = 14.0\%$.

C_2	0.134	0.329	0.169	0.358	2.397	0.873
C_3	−0.106	0.174	0.339	−1.623	0.573	1.751
N	−0.290	0.191	0.344	−2.786	0.533	1.777

to the triclinic crystal axes and expressed as fractions of the unit cell edges, and *X'*, *Y'*, *Z'* coordinates in Å units referred to orthogonal axis *a'* (= *a*.sin γ), *b*, and *c'* (normal to *a'* and *b*).

The bond distances and valency angles in the molecule are shown in Fig. 3.

Standard Deviations

The standard deviations of the atomic positions, calculated from Cruickshank's (2) formulae, are $\sigma(x) = \sigma(y) = \sigma(z) = 0.005$ Å for As and 0.047 Å for C and N. These values are probably optimistic, especially for the C and N atoms, because two of the projections are poorly resolved.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

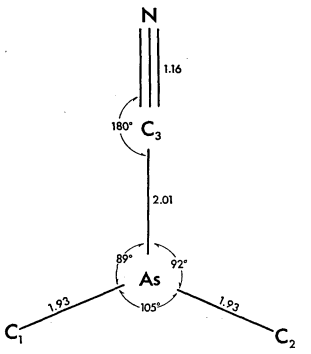

FIG. 3. Measured bond lengths and valency angles.

DISCUSSION

On the basis of the estimated standard deviations, the observed differences between As—CH_3 and As—CN bond lengths are not significant. The mean values of the bond lengths and angles, with standard deviations are:

As—C	= 1.96±0.03 Å
C—N	= 1.16±0.07 Å
∠ Me—As—Me	= 105±2°
∠ Me—As—CN	= 91±1.5°
∠ As—C—N	= 180±4°

The valency angles differ somewhat from those reported for the halogenodimethylarsines, which were determined by electron diffraction (3). The Me—As—Me angle in these halides was assumed to be 96°, the same as in trimethylarsine (4), and this is significantly smaller than the Me—As—Me angle of 105° now measured for the cyano derivative, which is similar to the angle in bromodiphenylarsine, 105° (5), and in chlorodiphenylarsine, 105° (6). The Me—As—CN angles are slightly less than those reported for Me_2AsBr (96°). The As—C and C≡N distances are normal (7).

The shortest intermolecular contact is an As---N separation of 3.18 Å (Fig. 4); this

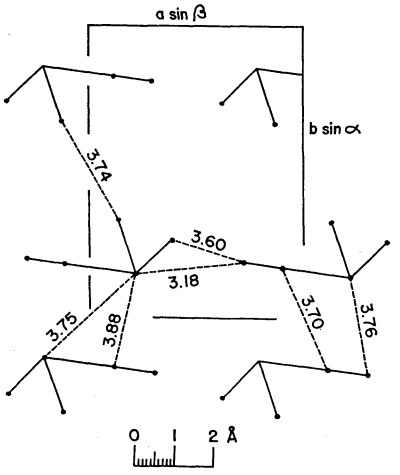

FIG. 4. Projection of the structure along [001], showing the shorter intermolecular contacts.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

is considerably less than the sum of the van der Waals radii (3.5 Å) and suggests a charge-transfer bond involving donation of nitrogen lone pair electrons to the vacant arsenic 4*d* orbitals. The C≡N. . . . As angle is 168°, so that the nitrogen lone pair, which is expected to be collinear with the C≡N bond, is directed towards the arsenic atom. Figure 4 shows that, in addition, the arsenic lone pair (assuming that it makes approximately equal angles with the As—C bonds) is directed away from the nitrogen atom, so that the intermolecular bonding would be little hindered by lone-pair repulsions. Cyanodimethylarsine is a solid at room temperature, probably as a result of this intermolecular bonding, while the corresponding halogen derivatives are liquids. The cyanide melting point is 65° higher than that of the iodide, while in other series such as methyl iodide and cyanide and the corresponding ethyl, propyl, and phenyl derivatives this difference is never greater than 20°. Comparison of these differences with the increases in melting point which usually result from hydrogen bonding suggests that the energy of the charge-transfer bonds is only of the order of one or two kilocalories per mole.

The donor properties of the tripositive state of the Group V*b* elements diminish with increase in atomic number, and are pronounced only for nitrogen; the other members of the group can act as electron acceptors. For arsenic this is illustrated by the formation of complexes between $AsCl_3$ and various aromatic amines, which, although their structures have not been determined, probably involve intermolecular bonds similar to those in cyanodimethylarsine; and by the formation of complex ions such as $AsCl_4^-$.

All the other intermolecular distances in cyanodimethylarsine correspond to normal van der Waals interactions.

The authors are indebted to the National Research Council of Canada for financial support and for the award of a research bursary (to N. C.), and to Dr. W. R. Cullen for suggesting the problem, for some crystal samples and assistance with the preparation of others, and for much helpful discussion.

THE QUENCHING OF MERCURY RESONANCE RADIATION BY HYDROCARBONS: THE EFFECT OF DEUTERIUM SUBSTITUTION

YVES ROUSSEAU AND HARRY E. GUNNING
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received September 19, 1962

ABSTRACT

The effect of deuteration on the quenching cross section (σ_Q^2) has been determined for propane, cyclopropane, isobutane, and propylene. The results were as follows, with the σ_Q^2 values, in Å^2, in parentheses: C_3H_8 (1.2); $CH_3CD_2CH_3$ (0.17); $CD_3CH_2CD_3$ (1.0); C_3D_8 (0.09); cyclo-C_3D_6 (0.29); $(CH_3)_3CH$ (4.8); $(CH_3)_3CD$ (0.44); C_3H_6 (29.8); and C_3D_6 (28.7). The deuterium isotope effect is most pronounced in the secondary C—H bonds of propane, and the tertiary C—H bond of isobutane. In the latter case, the isotope effect is estimated to be 15–16. For propylene, perdeuteration has little, if any, effect on σ_Q^2, indicating that C—H bonds are not involved in quenching. Further implications of the results with respect to the quenching process are discussed.

In recent studies (1, 2) in this laboratory, on the relative initial rates of *n*-propyl and *i*-propyl radical formation in the reaction of Hg $6(^3P_1)$ atoms with propane and the deuterated propanes, unusually large deuterium isotope effects were encountered in the chemical quenching reactions. Furthermore, deuteration, especially of the secondary C—H positions in propane, has been found (3) to change markedly the relative rates of product formation in reaction with Hg $6(^3P_1)$ atoms. In order to assess the overall effects of deuterium substitution in the mercury-photosensitized reactions of hydrocarbons, a knowledge of the quenching cross sections (σ_Q^2) for the deuterated species is clearly necessary. In the present study, the effects of partial and total deuteration on σ_Q^2 for a number of hydrocarbons of current interest in this laboratory have been determined. For the measurements, the very convenient nitrous oxide method developed by Cvetanović *et al.* (4, 5) has been employed. The results of the investigation follow.

EXPERIMENTAL

The light hydrocarbons (Phillips, research grade) and the deuterated hydrocarbons (Merck Sharp and Dohme of Canada) used were all further refined by peak-isolation methods in gas–liquid chromatography. The separations were made with a Burrell, Model K–4 chromatograph on a silica gel column, with helium as the carrier gas. Traces of nitric oxide were removed from the nitrous oxide used, by slow distillation from a trap immersed in liquid oxygen. Further distillation of the nitrous oxide at −131° (*n*-pentane slush) eliminated the remaining contaminants.

For each deuterated hydrocarbon, the isotopic purity was determined by mass spectrometry. The results of the analyses follow, with the composition indicated in parentheses: cyclo-C_3D_6 (92.8%; cyclo-C_3D_5H, 7.2%); $(CH_3)_3CD$ (97.8%; $(CH_3)_3CH$, 2.2%); $CH_3CD_2CH_3$ (98.2; C_3H_8, 1.8%); C_3D_8 (98.8%, C_3D_7H, 1.2%); $CD_3CH_2CD_3$ (100%); C_3D_6 (94.9%; C_3D_5H, 5.1%).

Since the general method employed has been previously described (4), only details specific for our adaptation of the procedure will be given. The mixtures of hydrocarbon and nitrous oxide were exposed under static conditions in a cylindrical quartz cell, 5 cm in diameter, and 5 cm in length. The total pressure was maintained constant throughout at 300 mm. Exposures were 5 minutes in duration, following a period of 3 hours for mercury vapor–liquid equilibration. The temperature for the runs was 25±2°. In the case of the d_6–cyclopropane, the exposure duration was reduced to 2 minutes in order to eliminate polymer deposition on the incident face of the reaction cell.

After each run, the gases were directed into a series of traps at −196°. The non-condensable portion was recovered with a Toepler pump, and analyzed by mass spectrometry.

The absorbed light intensity (I_a) at 2537 Å was determined using the light propane – Hg $6(^3P_1)$ reaction as actinometer (6, 7), with the substrate pressure at 270 mm.

RESULTS AND DISCUSSION

Cvetanović (4) has shown that a linear relation obtains between $1/\Phi(N_2)$ and $(RH)/(N_2O)$, where $\Phi(N_2)$ represents the quantum yield of nitrogen, and $(RH)/(N_2O)$, the molar ratio of hydrocarbon to nitrous oxide in the mixtures. From the propane actinometry, I_a was taken to be 5.50 μeinstein/min, assuming the quantum yield of hydrogen formation to be 0.44 mole/einstein for propane in the constant-rate region—a value consistent with recent work in this laboratory (3) on the variation of $\Phi(H_2)$ with substrate pressure and I_a in this reaction. Under such conditions, $\Phi(N_2)$ becomes unity for pure N_2O, at the pressure of 300 mm used in this study, in accordance with recent conclusions concerning this reaction (5).

The $1/\Phi(N_2)$ vs. $(RH)/(N_2O)$ plots are displayed as follows: the results for the four propanes, C_3H_8, $CH_3CD_2CH_3$, $CD_3CH_2CD_3$, and C_3D_8, are given in Fig. 1; $(CH_3)_3CH$, $(CH_3)_3CD$, n-C_4H_{10}, and cyclo-C_3D_6 in Fig. 2; and the two propylenes, C_3H_6 and C_3D_6, in Fig. 3. For each compound, the best straight line for its $1/\Phi(N_2)$ vs. $(RH)/(N_2O)$ plot

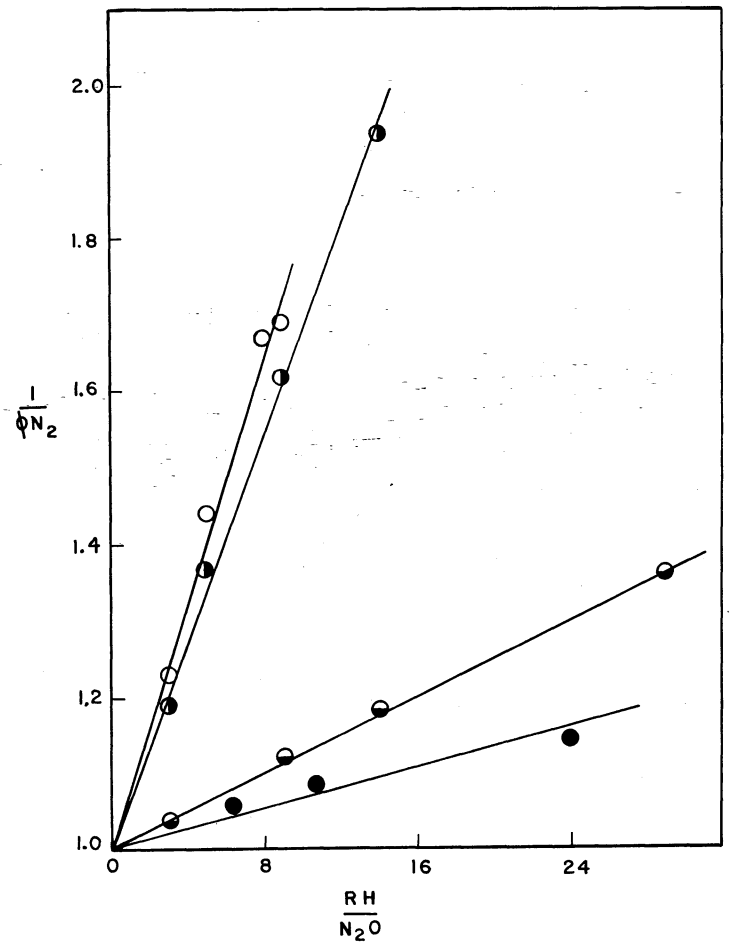

FIG. 1. Plots of $1/\phi(N_2)$ as a function of $(RH)/(N_2O)$ for C_3H_8 (○), $CD_3CH_2CD_3$ (◑), $CH_3CD_2CH_3$ (◒), and C_3D_8 (●).

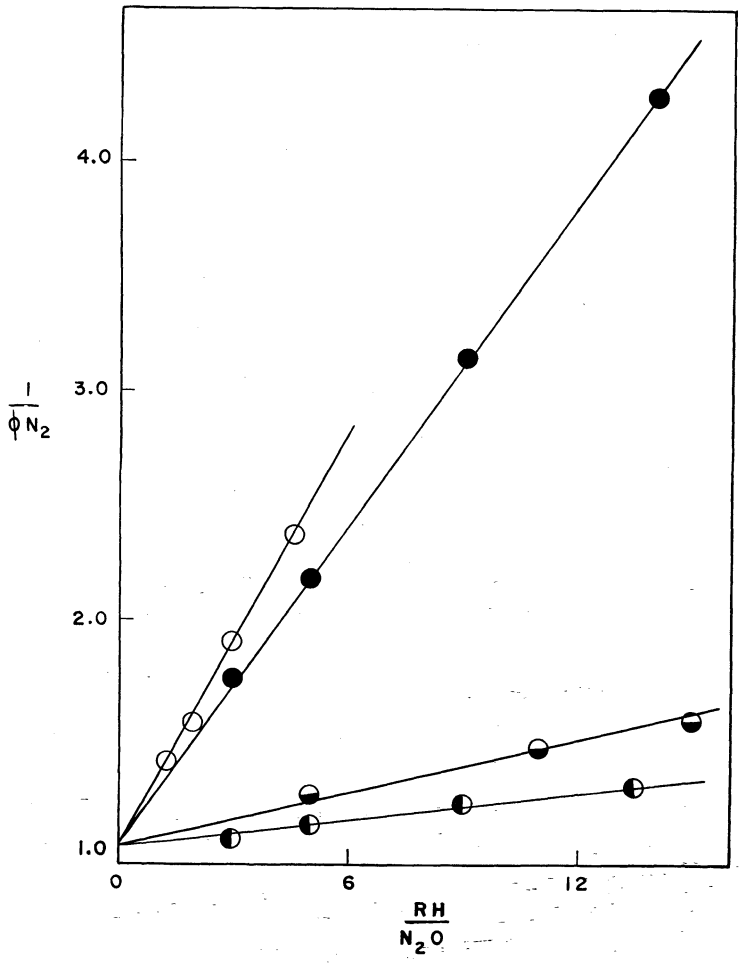

FIG. 2. Plots of $1/\phi(N_2)$ as a function of $(RH)/(N_2O)$ for $(CH_3)_3CH$ (○), $CH_3CH_2CH_2CH_3$ (●), $(CH_3)_3CD$ (◒), and cyclo-C_3D_6 (◐).

was determined by the method of least squares. It will be noted from the figures that each line extrapolates to unity at $(RH)/(N_2O) = 0$. Taking $\sigma_Q^2 = 3.6$ Å^2 for *n*-butane (4), the σ_Q^2 values for the nine hydrocarbons can be calculated from the best slope (S) for each compound and that found (S_{nb}) for the reference standard, *n*-butane, by the relation:

$$3.6/\sigma_Q^2 = (S_{nb}/S)[(1+M(\mathrm{Hg})/M)/(1+M(\mathrm{Hg})/M_{nb})]^{1/2},$$

where M, M_{nb}, and $M(\mathrm{Hg})$ are the molecular weights for the hydrocarbon being studied, *n*-butane, and mercury respectively. The results are summarized in Table I. It is estimated that the overall experimental error in the σ_Q^2 values should not exceed 10%.

From Table I, it is apparent from the results obtained for the four propanes that deuteration of the secondary C—H positions leads to a drastic reduction in the quenching cross section, from 1.2 to 0.17 Å^2. When $CH_3CD_2CH_3$ is now perdeuterated to C_3D_8, σ_Q^2 again decreases from 0.17 to 0.09 Å^2. On the other hand, deuteration of the primary positions only, in propane, to form $CD_3CH_2CD_3$ only reduces σ_Q^2 from 1.2 to 1.0 Å^2. It

would thus appear that the initial interaction between Hg $6(^3P_1)$ atoms and C_3H_8 occurs almost exclusively at the secondary C—H bonds. That this first interaction does not lead directly to secondary C—H bond cleavage is indicated by the fact (1) that at least 42% of the initially formed propyl radicals is normal. In isobutane (Table I) the deuterium isotope effect on σ_Q^2 is seen to be even more marked than in propane. Thus by substituting D for H, in the tertiary position only, σ_Q^2 is reduced by more than 90%, from 4.8 to 0.44 Å². On the other hand, the complete deuteration of cyclopropane reduces σ_Q^2 from 1.1 (8) to 0.29 Å² (Table I)—a somewhat lower deuterium isotope effect than found for propane and isobutane. In short, the deuterium isotope effect on σ_Q^2 for saturated hydrocarbons

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

appears to be greater for hydrocarbons containing at least two types of C—H bonds. Clearly a larger number of saturated hydrocarbons must be examined before generalizations can be made with confidence.

Again from Table I, the effect of deuteration on σ_Q^2 for the typical olefin, propylene, can be seen. Perdeuteration decreases σ_Q^2 by ca. 4% from 29.8 to 28.7 Å^2—a change only slightly exceeding the overall experimental error in the σ_Q^2 values. Thus the initial quenching interaction does not appear to involve the C—H bonds—a conclusion consistent with the formation of a triplet-excited species in the primary process (9).

The overall deuterium isotope effect on the chemical quenching reaction has been discussed elsewhere (2). For isobutane, we can estimate the effect of deuteration of the tertiary (*t*) C—H bond on σ_Q^2 as follows: Taking $\sigma_Q^2(CH_3) = 0.05$ Å^2, from the fact that $\sigma_Q^2(C_2H_6) = 0.10$ Å^2 (4), it follows that $\sigma_Q^2(t\text{-C—H}) = 4.6_5$ Å^2, and $\sigma_Q^2(t\text{-C—D}) = 0.3$ Å^2. Defining the isotope effect as $\sigma_Q^2(t\text{-C—H})/\sigma_Q^2(t\text{-C—D})$, a value of ca. 15–16 is obtained. Since deuteration of the secondary positions in propane was found to increase the relative importance of initial C—H rupture in the CH_3 groups (1), a similar shift toward enhanced methyl C—H cleavage is likely upon deuteration of *t*-C—H in isobutane. Hence the overall deuterium isotope effect on *t*-C—H for the chemical quenching reaction is probably much larger than 15–16.

For saturated hydrocarbons, the quenching cross section is probably determined by the interaction of the *p*-orbital of the Hg $6(^3P_1)$ atom with the sigma bonds of the hydrocarbon. The large deuterium isotope effect found for this interaction should provide insight into the nature of the quenching reaction. This problem is currently under investigation in this laboratory (10).

ACKNOWLEDGMENTS

The authors would like to thank Dr. O. P. Strausz of this laboratory for many helpful discussions. The support of the National Research Council under grant No. T-142 is also gratefully acknowledged.

TOTAL SYNTHESIS OF STEROIDAL DERIVATIVES

II. SYNTHESIS OF HYDROCHRYSENE ANALOGUES AND RELATED COMPOUNDS[1]

JAMES P. KUTNEY, JOHN WINTER,[2] WM. MCCRAE,[3] AND ARNOLD BY
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received July 23, 1962

ABSTRACT

A synthetic sequence leading to the total synthesis of hydrochrysene derivatives possessing the trans–anti–trans backbone is described. The introduction of a ketonic function into ring C of these compounds is also given. It is noted that these substances allow entry into the synthesis of intermediates which have an open ring C.

Recently we reported in the first paper of this series (1), a synthetic sequence leading to the total synthesis of various hydrochrysene analogues. We also indicated that these compounds could serve as effective intermediates for the synthesis of a variety of steroidal derivatives which are not readily accessible from the naturally occurring steroidal compounds. We would now like to present further studies which allow entry into the trans–anti–trans series of hydrochrysene analogues. This series, of course, provides the stereochemical backbone which correlates with that of the natural steroid.

In our previous paper we were able to show that the ketol, I, besides providing entry into the cis–syn–cis hydrochrysene series, can also be converted into the tetracyclic ketone, II. It is obvious that the appropriate reductions of the styrene double bond and the unsaturated carbonyl group in II lead to the generation of new asymmetric centers at the ring junctures. Consequently stereospecific reductions of this ketone would lead to a product with well-defined stereochemistry at the asymmetric carbon atoms. Of the various methods which were available, the Birch reduction was of distinct advantage since the stereochemistry of this method, when applied to the hydrochrysene analogues, has been studied in considerable detail in the fine researches of Johnson and his co-workers (2). We therefore subjected the ketone, II, to the action of sodium (or lithium) in liquid ammonia in the presence of anhydrous ethanol—reaction conditions which were very successful in a related series (2). The expected alcohol, III, which now possessed four new asymmetric centers, could only be isolated in a very poor yield and even then only after considerable difficulty in separation from the undesirable side products. The side products indicated that the aromatic ring was being reduced and it was therefore apparent that the reduction of the olefinic bond of the *p*-methoxystyrene chromophore presented a somewhat different problem to that experienced by Johnson in the *m*-methoxystyrene series. We therefore spent a considerable amount of time in attempting to develop optimum conditions for this reduction. We initially concentrated our efforts on varying the amount of alkali metal (sodium or lithium) relative to the amount of ketone used, and on varying the length of time for the reduction. In all these cases, we were not able to show any substantial improvement to the original yield of the alcohol. We then turned our attention to the use of solutions of alkali metals in amine solvents and found an excellent improvement in the yield of the reduction. When a solution of the ketone in tetrahydrofuran was

[1]*Presented, in part, at the Chemical Institute of Canada, Edmonton Conference, May 27–30, 1962.*

treated with sodium in liquid ammonia in the presence of aniline,* a good yield of a reduction product was obtained. The reduction product in this case, however, was not the alcohol, III, but a compound which possessed a strong carbonyl absorption in the infrared spectrum (5.88 μ). Consideration of the ultraviolet spectrum, with absorption maxima at 277 and 286 mμ characteristic of the 1,2,3,4-tetrahydro-6-methoxynaphthalene system (1), indicated that reduction of both olefinic bonds had occurred. It was therefore obvious that the correct structure of the reduction product was IV. The stereochemistry as depicted in IV is well supported by the previous work of Johnson (2) and very recently a complete confirmation has been provided by Nagata and co-workers (3). These Japanese workers have reported the conversion of the ketone, II, to racemic pregnane and androstane derivatives by a sequence which involves an alkali metal in liquid ammonia reduction of II as an integral step.

The relationship of the saturated ketone, IV, to the alcohol, III, could be readily established by reducing the ketone to the alcohol by means of hydride reagents. The reduction was, in fact, carried out with both lithium aluminum hydride and sodium borohydride in order to determine whether there was any difference in the amount of equatorial alcohol obtained. In both instances the reduction proceeded in very high yield to provide a crystalline product. Chromatographic purification indicated that less than 5% of an epimeric alcohol was present and on the basis of previous work, the predominant alcohol can be assigned the equatorial conformation.

Now that the trans–anti–trans series of hydrochrysene analogues could be obtained in

*We are very grateful to G. Douglas, G. A. Hughes, and H. Smith of the University of Manchester for information regarding this method.

high yield, we considered the introduction of a functional group into ring C of the hydrochrysene skeleton (see III) in order to provide an entry into synthetic intermediates where ring C has been opened. A possible approach to this problem was available from the work of Johnson and collaborators (4) wherein an acetate function was introduced into the C ring (C_{12}) of their hydrochrysene analogue by means of lead tetraacetate. However, it was recognized at the outset that the methoxyl function in III, by virtue of its para relationship to the carbon atom designated as 4*b* (see III), could seriously affect the success of this approach. It was felt, however, that the activation by this methoxyl function which could favor the introduction of substituents at 4*b* instead of the desired position, C_{12}, may be overcome by the ease of reaction at the secondary carbon (C_{12}) relative to the tertiary center (4*b*). Although lead tetraacetate is not the best reagent to evaluate this consideration, we felt that it should be tried first since comparable reactions were already available in the literature. When the acetate, V, of the alcohol was subjected to a reaction with lead tetraacetate, a gummy product was obtained. The ultraviolet spectrum of this material clearly indicated a naphthalenic chromophore and it was therefore apparent that aromatization of ring C had taken place. A number of experiments under varying reaction conditions were attempted but the aromatization reaction was the predominant one in each case and no further characterization of these gummy products was carried out at this stage.

Our next consideration in this direction was N-bromosuccinimide, a reagent which has been shown to react more rapidly at secondary than at tertiary carbon atoms in the mono- and poly-cyclic aromatic series (5). However when we reacted the acetate, V, with this reagent, under a variety of reaction conditions, the results were likewise very discouraging. In all instances it was apparent that the aromatization of ring C was the main reaction which was taking place, presumably via benzylic bromination followed by the elimination of the elements of hydrogen bromide. It was therefore obvious that the introduction of substituents into ring C was seriously hindered by the great tendency of our compounds toward aromatization.

We felt that if the activation of the methoxyl group was, at least in part, to blame for our failures, that we could eliminate this factor by replacing this function by an acetyl group. We therefore subjected the alcohol, III, to a demethylation procedure utilizing methylmagnesium iodide at 175° (6, 7, 8). The product obtained, in excellent yield, was the expected phenolic alcohol, VI. The spectral data for this substance was in complete agreement with the assigned structure. In particular, the ultraviolet spectrum, with its maximum absorption at 282 mμ in neutral solution, showed a bathochromic shift to 300 mμ when taken in alkaline solution. This shift, which is typical of phenolic substances of this type, was an excellent confirmation for the success of the demethylation procedure. Acetylation of this phenolic alcohol provided a good yield of the diacetate, VII. It was now possible to establish whether the diacetate was more suitable for our work. When VII was subjected to the action of N-bromosuccinimide, the isolated product indicated a naphthalenic type of absorption in the ultraviolet spectrum and it was again apparent that the undesirable aromatization reaction was the prevalent reaction which was occurring. In spite of numerous attempts to correct this we were not able to obtain any successful results.

Since the introduction of substitutents into position 12 had failed in our attempts indicated above, it became necessary to consider another approach to this problem. It appeared to us that a direct oxidation of this benzylic position may prove feasible especially since Wintersteiner and co-workers had been successful in preparing 6-keto-estradiol diacetate in this manner (9). Consequently we reacted the diacetate, VII, with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

an aqueous acetic acid solution of chromium trioxide and were able to obtain from the neutral portion of the reaction product, a ketonic substance which indicated absorption at 5.68 μ, 5.80 μ, and 5.97 μ in the infrared spectrum, in complete accordance with expectation for structure IX. The ultraviolet spectrum of this product was also in good agreement with that of 6-ketoestradiol diacetate (9) and this served to establish the chromophoric group depicted in IX. The success of this approach encouraged us to extend this reaction to the methoxy acetate, V. However, it was realized that the methoxyl group may again provide for a preferential attack at the 4*b* position and for this reason the oxidation was carried out under milder conditions. Treatment of V with chromium trioxide in acetic anhydride at 0° provided the desired ketonic product VIII, although the yield was very low. Again the spectral data were in agreement with the assigned structure. The infrared spectrum with bands at 5.84 μ and 5.98 μ and the ultraviolet spectrum with absorption at 222 mμ, 254 mμ, and 322 mμ presented strong evidence for VIII. It was obvious, however, that if the oxidation was to be used in our sequence, it was necessary to improve the yield in this reaction. With this in mind, we felt that any oxidation at the tertiary carbon 4*b* could presumably be eliminated if a sterically large oxidant was used. For this reason, the methoxy-acetate was oxidized with *t*-butyl chromate and indeed a substantial improvement in the yield of VIII was realized. With these results in hand, it was apparent that the desired synthetic intermediates for further study at ring C were now available.

Finally in order to provide some information as to the reactivities at positions 4*b* and 12 in the cis–syn–cis series, we carried out some demethylation experiments on the compound represented by structure X. Reaction of X with methylmagnesium iodide as already indicated for III led in good yield to the phenolic alcohol XI. Acetylation of this compound by the use of isopropenyl acetate and a catalytic amount of *p*-toluenesulphonic acid provided the diacetate, XII.

Now that synthetic pathways have been developed to both the cis–syn–cis and the trans–anti–trans series of these hydrochrysene analogues, further investigations are being conducted to examine the versatility of these intermediates.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethanol on a Cary 14 recording spectrophotometer. Infrared spectra were taken on a Perkin–Elmer Model 21 spectrophotometer. The n.m.r. spectra were taken at 60 megacycles on a Varian A 60 instrument. In all cases tetramethylsilane was the standard set at 10.0 τ units and the positions of the signals are given in the Tiers τ scale. In all cases integration of areas under the signals was carried out and the number of protons corresponding to each signal is indicated in parentheses. The analyses were performed by Dr. A. Bernhardt and his associates, Mulheim (Ruhr) Germany, and by Mrs. Aldridge, University of British Columbia.

Reduction of 2-Methoxy-8-keto-10a-methyl-5,6,8,9,10,10a,11,12-octahydrochrysene

(a) With Sodium in Liquid Ammonia in Presence of Ethanol

Only one typical experiment is recorded here although a number of different experiments were actually done. However, they all provided very similar results.

A solution of the tetracyclic ketone, II (5.0 g), in anhydrous dimethyl cellosolve (150 ml) was added to anhydrous liquid ammonia (700 ml). Anhydrous ethanol (90 ml) was then added and sodium (2.34 g) was added in small pieces, each piece being allowed to dissolve before addition of the next (about 35 minutes). After the sodium had reacted, ammonium chloride (5.5 g) and water were added and the ammonia was allowed to evaporate. The residue was extracted with ether and the ethereal extract was dried over anhydrous magnesium sulphate. Evaporation of the solvent left a brown gummy material. This gummy material was taken up in benzene and chromatographed on alumina (250 g). Elution with a mixture of benzene – ethyl ether (9:1) provided, in the initial fractions, 0.61 g of the saturated tetracyclic ketone, IV, and, in the latter fractions, eluted with benzene – ethyl ether (1:1), 3.19 g of a gummy mixture of alcoholic materials.

These gummy materials were acetylated by refluxing overnight in an excess of acetic anhydride containing several drops of pyridine. The mixture was poured onto cracked ice and allowed to stand for 30 minutes. The resulting oil was extracted with ether and the ether extract was washed successively with aqueous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

sodium bicarbonate and water. After it was dried over anhydrous magnesium sulphate, the solvent was removed and the remaining product was taken up in benzene – petroleum ether and chromatographed on alumina (200 g). Elution with a mixture of benzene – petroleum ether (2:3) provided first a small amount (388 mg) of a solid material which on recrystallization from a mixture of benzene – petroleum ether gave a crystalline substance (261 mg), m.p. 140–141°. Further recrystallization provided an analytical sample, m.p. 142–142.5°; infrared in KBr: 5.78 μ, 8.0 μ; Found: C, 77.06; H, 8.55; O, 14.15. Calc. for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83; O, 14.02. Although the structure of this minor product has not been completely established, it is almost certainly a stereoisomer of the desired acetate, V.

Further elution with benzene–petroleum ether (1:1) and benzene – petroleum ether (3:1) provided the major fraction (1.468 g), which on recrystallization from ethanol gave an analytical sample of the desired trans–anti–trans-2-methoxy-8β-acetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (V), m.p. 101–102°; infrared in KBr: 5.80 μ, 8.03 μ; ultraviolet: λ_{max} 278 mμ (log ϵ 3.08); n.m.r. signals ($CDCl_3$): 9.12 τ (angular methyl, area = 3H), 7.93 τ (CH_3CO, area = 3H), 6.21 τ (CH_3O, area = 3H), 5.28 τ (broad, —C(H)—OAc, area = 1H), multiplet centered at 2.92 τ (aromatic H, area = 3H); Found: C, 76.74; H, 8.67; O, 14.51. Calc. for $C_{22}H_{30}O_3$: C, 77.15; H, 8.83; O, 14.02.

(b) With Sodium in Liquid Ammonia in Presence of Aniline

To a stirred mixture of anhydrous liquid ammonia (300 ml) and aniline (50 ml), sodium (5.0 g) was added in small pieces. A solution of the tetracyclic ketone, II (5.0 g), in anhydrous tetrahydrofuran (100 ml) was added to the blue ammonia solution over a period of 10 minutes. The mixture was stirred for a further 20 minutes, after which time ammonium chloride (12 g) was added in portions. The ammonia was allowed to evaporate and the resulting residue was treated with water and then extracted with ether. The ether layer was washed with dilute hydrochloric acid, aqueous sodium carbonate, and finally with water. After the solution was dried over anhydrous magnesium sulphate, the solvent was removed to yield a crystalline product (3.51 g). This material was recrystallized several times from ethanol to provide the pure trans–anti–trans-2-methoxy-8-keto-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (IV), m.p. 141.5–142° and 145–146°; infrared in CS_2: 5.88 μ; ultraviolet: λ_{max} 277 mμ (log ϵ 3.20), λ_{max} 286 mμ (log ϵ 3.17); n.m.r. signals ($CDCl_3$): 9.06 τ (angular methyl, area = 3H), 6.33 τ (CH_3O, area = 3H), multiplet centered at 3.1 τ (aromatic H, area = 3H). Found: C, 80.77; H, 8.56; O, 10.93. Calc. for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78; O, 10.72.

Synthesis of trans–anti–trans-2-Methoxy-8β-hydroxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (III)

(a) Reduction with Lithium Aluminum Hydride

A solution of the saturated ketone, IV (0.5 g), in warm, anhydrous ether (50 ml), was added to lithium aluminum hydride (0.395 g). The mixture was stirred at room temperature for 1 hour, after which time it was cooled in ice and decomposed with 20% sulphuric acid. The ether layer was separated, washed with water, and then dried over anhydrous magnesium sulphate. The solvent was removed to provide a crystalline product (496 mg) which had a crude melting point of 154–157°. This material was chromatographed on alumina (30 g). Elution with benzene and benzene – ethyl ether mixtures indicated that less than 5% of the epimeric alcohol was present. The product obtained here is completely identical with the product of the sodium borohydride reduction and the appropriate constants are given below.

(b) Reduction with Sodium Borohydride

A solution of the saturated ketone, IV (0.5 g), in hot methanol (20 ml) and water (5 ml), was treated with a solution of sodium borohydride (0.26 g) in methanol (20 ml) and water (5 ml), and the mixture was refluxed for 3 hours. The mixture was then treated with concentrated hydrochloric acid (5 ml) and refluxing was continued for a further hour. The solution was then concentrated *in vacuo* to a volume of 10 ml, water and ether were added, and the ether layer was separated. The ether layer was washed with water and then dried over anhydrous magnesium sulphate. Removal of the solvent provided a crystalline product (497 mg). This material was taken up in benzene and chromatographed on alumina (30 g). Elution with benzene – ethyl ether (8:5:1.5) provided essentially a quantitative recovery of the solid product and it was again possible to show that less than 4% of the epimeric alcohol was present. This solid, on recrystallization from ethyl ether, provided a pure sample of the alcohol, III, m.p. 160–161°; infrared in KBr: 2.89 μ; ultraviolet: λ_{max} 277 mμ (log ϵ 3.20), λ_{max} 286 mμ (log ϵ 3.17); n.m.r. signals ($CDCl_3$): 9.20 τ (angular methyl, area = 3H), 6.18 τ (CH_3O, area = 3H), multiplet centered at 3.0 τ (aromatic H, area = 3H). Found: C, 80.32; H, 9.08. Calc. for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39.

A small sample of this alcohol was acetylated as given above and gave an acetate which was completely identical with V.

Synthesis of trans–anti–trans-2,8β-Dihydroxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (VI)

The tetracyclic alcohol, III (0.1 g), was added in portions to the Grignard reagent prepared in the usual manner from magnesium (1.17 g) and methyl iodide (3.07 ml) in ether. Most of the ether was removed by warming in a stream of nitrogen and finally the last traces were removed *in vacuo*. The residual mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was heated to 175° over the course of 1 hour and then kept at 175–180° for a further hour. The reaction mixture was then cooled in ice, petroleum ether and ethyl acetate were added carefully to decompose the excess Grignard reagent, and the whole mixture was then shaken with dilute sulphuric acid and ethyl acetate. The ethyl acetate layer was separated, washed with water, and finally dried over anhydrous magnesium sulphate. Removal of the solvents provided the phenolic alcohol as a solid powder. This powder was acetylated directly by allowing it to stand in acetic anhydride and pyridine at room temperature for 8 hours. The usual work-up provided an excellent yield (1.15 g) of the expected diacetate. Several recrystallizations from benzene – petroleum ether provided the pure trans–anti–trans-2,8β-diacetoxy-10*a*-methyl-4*b*,5,6,6*a*,7,8,9,10,10*a*,10*b*,11,12-dodecahydrochrysene (VII), m.p. 152–153° and 160–161°; infrared in KBr: 5.67 μ, 5.78 μ, 8.06 μ, 8.33 μ; ultraviolet: λ_{max} 268 mμ (log ε 2.89), λ_{max} 276 mμ (log ε 2.89); n.m.r. signals ($CDCl_3$): 9.23 τ (angular methyl), 7.83 τ, 8.07 τ (CH_3—C(=O)—), 5.38 τ (—CH(OAc)—, area = 1H), multiplet centered at 3.1 τ (aromatic H, area = 3H); Found: C, 74.35, 74.88; H, 7.96, 8.04; O, 17.68. Calc. for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16; O, 17.28.

A sample of the phenolic alcohol was prepared separately from another experiment. On several recrystallizations from benzene – ethyl acetate the substance melted at 234–237°. It was sublimed to provide a pure sample, m.p. 235–238°; infrared in Nujol mull: 2.94 μ, 3.18 μ; ultraviolet: in neutral solution, λ_{max} 282 mμ (log ε 3.36), in alkaline solution, λ_{max} 300 mμ (log ε 3.46).

Synthesis of trans–anti–trans-2-Methoxy-8β-acetoxy-12-keto-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (VIII)

(a) By Oxidation with Chromium Trioxide

The methoxy-acetate, V (504 mg), was dissolved in acetic anhydride (15 ml) and the resulting solution was cooled to 0°. An ice-cold solution of chromium trioxide (225 mg) in acetic anhydride (60 ml) was then added in portions over a period of 2 hours. The reaction mixture was maintained in ice during the course of the addition and for a further 12 hours after addition was complete. The excess oxidant was reduced by the addition of ethanol (10 ml) and the reaction mixture was treated cautiously with ice to hydrolyze the acetic anhydride. The mixture was then neutralized by the addition of potassium hydroxide and the resulting solution was extracted with ethyl ether and ethyl acetate. The combined organic layer was washed with aqueous sodium bicarbonate to remove any residual acetic acid and finally washed with a 1:1 mixture of a saturated aqueous sodium bicarbonate and 1 *N* potassium carbonate solution. This carbonate wash was acidified with hydrochloric acid and extracted with ethyl acetate to yield 73 mg of an acidic fraction.

The original organic layer containing the neutral fraction was dried over anhydrous magnesium sulphate and, after removal of the solvent, provided 452 mg of a crude neutral product. The material was purified by chromatography on alumina (30 g, approx. activity II–III). Elution with benzene provided starting material (155 mg) and further elution with benzene – ethyl ether yielded the desired ketone, VIII (86 mg). This ketone seemed to exist in polymorphic forms and had several melting points, 128°, 145–147°, and 159–161°; infrared in KBr: 5.84 μ, 5.98 μ; ultraviolet: λ_{max} 222 mμ (log ε 4.08), λ_{max} 254 mμ (log ε 3.68), λ_{max} 322 mμ (log ε 3.14); n.m.r. signals ($CDCl_3$): 9.08 τ (angular methyl, area = 3H), 7.99 τ (CH_3CO—, area = 3H), 6.18 τ (CH_3O—, area = 3H), 5.20 τ (—CH(OAc)—, area = 1H), multiplet centered at 2.66 τ (aromatic H, area = 3H). Found: C, 74.10; H, 7.76. Calc. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92.

(b) By Oxidation with t-Butyl Chromate

A solution of *t*-butyl chromate in carbon tetrachloride was prepared according to the procedure of Heusler and Wettstein (10) and aliquots of this solution were then used for the various experiments.

The methoxy-acetate (1.86 g) was dissolved in carbon tetrachloride (50 ml) and the *t*-butyl chromate solution (50 ml) mixed with acetic anhydride (25 ml) was added. The mixture was stirred under reflux for 3 hours and the excess oxidant was then destroyed by stirring with a solution of oxalic acid (15 g) in water (100 ml) for 2 hours. The carbon tetrachloride layer was separated and the solvent was removed *in vacuo*. The residue was taken up in ether and the ether solution was worked up exactly as given in part (*a*) above to give acidic (56 mg) and neutral (1.72 g) materials. The neutral material upon chromatography on alumina (90 g, approx. activity II–III) yielded some starting material (731 mg) and the desired ketone VIII (400 mg).

Synthesis of trans–anti–trans-2,8β-Diacetoxy-12-keto-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (IX)

The diacetate, VII (500 mg), was partly dissolved in glacial acetic acid (1.75 ml) and a solution of chromium trioxide (425 mg) in a mixture of water (0.35 ml) and glacial acetic acid (2.5 ml) was then added. Any evolution of heat was controlled by cooling the flask in a cold water bath. The whole mixture was then stirred at room temperature for 5 hours and then allowed to stand for a further 19 hours. Ethanol (1 ml) was then added to reduce the excess chromium trioxide and the whole mixture was poured into water and extracted with ether. The ether layer was washed with portions of aqueous sodium bicarbonate to remove most of the acetic acid and then washed with a 1:1 mixture of saturated sodium bicarbonate solution and 1 *N* sodium carbonate solution.

The ether layer, now containing only the neutral fraction, was dried over anhydrous magnesium sulphate, and after the solvent was removed, provided 384 mg of a solid residue. This material was taken up in benzene – petroleum ether and chromatographed on Florisil (60 g). Elution with benzene – petroleum ether yielded 165 mg of starting material while further elution with benzene – ethyl ether (10:1) provided the desired keto-diacetate, IX (95 mg), which melted at 243–246° (with some decomposition) after recrystallization from a mixture of petroleum ether and benzene; infrared in KBr: 5.68 μ, 5.80 μ, 5.97 μ; ultraviolet: λ_{max} 218 mμ (log ϵ 4.08), λ_{max} 247 mμ (log ϵ 3.99), λ_{max} 300 mμ (log ϵ 3.36); n.m.r. signals ($CDCl_3$): 9.09 τ (angular methyl), 7.73 τ, 8.01 τ (acetate methyl groups), 5.39 τ (—C(H)—OAc), multiplet centered at 2.60 τ (aromatic H). Found: C, 72.08; H, 7.63; O, 20.80. Calc. for $C_{23}H_{28}O_5$: C, 71.85; H, 7.34; O, 20.81.

Synthesis of cis–syn–cis-2,8α-Dihydroxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (XI)

The cis–syn–cis alcohol, X (0.924 g), was added to an ethereal solution (5 ml) of methylmagnesium iodide prepared in the usual manner from magnesium turnings (0.264 g) and methyl iodide (0.68 ml). This mixture was allowed to stand at room temperature for 1 hour, after which time the ether was removed by being warmed in a stream of nitrogen and finally *in vacuo*. The residual solid reaction mixture was plunged into a bath at 175° and kept at this temperature for 1 hour. An atmosphere of nitrogen was kept over the reaction mixture during this heating period. The mixture was then cooled to room temperature and water was added cautiously to decompose the excess Grignard reagent. The reaction mixture was then treated with ether and dilute sulphuric acid. The organic phase was separated and the aqueous phase was washed with several portions of ether. The combined ether extract was dried over anhydrous magnesium sulphate and the solvent was removed to yield 700 mg of a solid material. Recrystallization of this material from acetone provided the pure phenolic alcohol, XI, m.p. 254–255° (with some decomposition); infrared in KBr: 2.92 μ, 3.18 μ; ultraviolet: λ_{max} 281 mμ (log ϵ 3.36), shoulder at 287 mμ (log ϵ 3.32); n.m.r. signals (pyridine): 9.63 τ (angular methyl, area = 3H), no OCH_3 absorption. Found: C, 79.75; H, 9.23; O, 11.32. Calc. for $C_{21}H_{28}O_3$: C, 79.68; H, 9.15; O, 11.17.

Synthesis of cis–syn–cis-2,8α-Diacetoxy-10a-methyl-4b,5,6,6a,7,8,9,10,10a,10b,11,12-dodecahydrochrysene (XII)

The phenolic alcohol, XI (0.579 g), was treated with isopropenyl acetate (4.5 ml) and *p*-toluenesulphonic acid monohydrate (30 mg) and the whole mixture was heated on a steam bath for 15 minutes. The volume of the reaction mixture was slowly reduced to about one-half the original by a slow distillation (about 15 minutes) and the remainder of the volatile materials was removed *in vacuo*. The residue was then treated with benzene and the benzene extract was washed successively with a saturated solution of sodium bicarbonate and water. The benzene extract was dried over anhydrous magnesium sulphate and the solvent was then removed to provide a yellow gum. This gum was taken up in a mixture of petroleum ether – benzene (9:1) and chromatographed on silica gel (20 g). Elution with benzene yielded the diacetate as a yellow glass. Distillation of this substance at a bath temperature of 190–200° at 0.01 mm provided the pure diacetate, XII, as a light yellow solid glass (280 mg); infrared in KBr: 5.69 μ, 5.81 μ; ultraviolet: λ_{max} 268 mμ (log ϵ 3.28), λ_{max} 275 mμ (log ϵ 3.29); n.m.r. signals ($CDCl_3$): 8.87 τ (angular methyl), 7.97 τ, 7.70 τ (acetate methyl groups), 5.27 τ (—C(H)—OAc), multiplet centered at 2.95 τ (aromatic H). Found: C, 74.83; H, 8.09; O, 17.12. Calc. for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16; O, 17.28.

THE ALKALOIDS OF DELPHINIUM BROWNII RYDB.

THE STRUCTURE OF BROWNIINE[1]

M. H. BENN,[2] M. A. M. CAMERON,[2] AND O. E. EDWARDS
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received October 10, 1962

ABSTRACT

Methyllycaconitine and browniine have been observed to be major alkaloids of *Delphinium brownii*. The latter was proved to have the same skeleton, oxygen location, and stereochemistry as lycoctonine, but a different pattern of O-methylation.

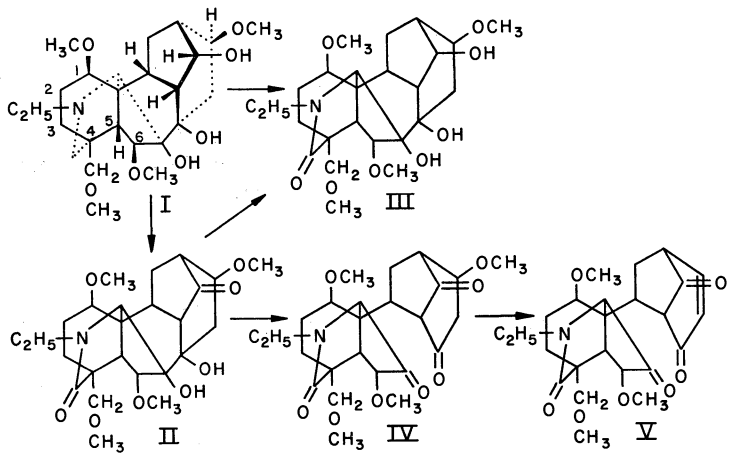
Delphinium brownii is native to the foothills of Alberta. Its alkaloids were examined by Manske (1), who provided evidence that one of them was methyllycaconitine since on hydrolysis the amorphous base gave *l*-methylsuccinic acid, anthranilic acid, and a base resembling lycoctonine. The identity of the latter was subsequently confirmed by Marion (2). We have used the aerial portions of the plant as a source of lycoctonine and have identified the parent alkaloid as methyllycaconitine by comparison with authentic material.[3] In addition we found a new major alkaloid in the plant, which was readily separated from the other alkaloids by virtue of its weaker adsorption on alumina. It was amorphous, but formed a crystalline perchlorate, m.p. 212°, $[\alpha]_D$ +25°.

The new base, which we have named browniine, analyzed correctly for $C_{25}H_{41}O_7N$ and is thus an isomer of lycoctonine. Its infrared spectrum had the same general shape as that of lycoctonine, hydroxyl and ether bands being the most obvious features. We hence proceeded under the assumption that its chemistry would resemble that of lycoctonine, and subjected it to operations that had proved fruitful in defining the functional groups of this alkaloid and related *Delphinium* alkaloids (3, 4). The transformations will be illustrated in terms of the structure deduced below.

Oxidation of browniine (I) with chromium trioxide in pyridine produced a keto lactam (II) (dehydrooxobrowniine) with ν_{max} 1750 cm^{-1} (cyclopentanone) and 1643 cm^{-1} (six-membered lactam). Sodium borohydride reduction of this ketone gave mainly a compound with the original hydroxyl configuration. This was proved by the identity of the reduction product with the hydroxy lactam III produced by oxidation of browniine monoacetate and subsequent hydrolysis. Both oxobrowniine and dehydrooxobrowniine rapidly consumed 1 mole of lead tetraacetate, after which a very slow uptake ensued. The products of the initial reaction were a *seco*diketone ($\nu_{max}^{CHCl_3}$ 1770, 1710, 1650 cm^{-1}) and a *seco*triketone (IV) ($\nu_{max}^{CHCl_3}$ 1750, 1700, 1640 cm^{-1}). The latter pyrolyzed smoothly at 210°, eliminating methanol to give the α,β-unsaturated ketone V ($\nu_{max}^{CHCl_3}$ 1770, 1680, 1646 cm^{-1}). These reactions and spectra corresponded well with those in the lycoctonine series (3) and indicate the presence of two vicinal tertiary hydroxyl groups.

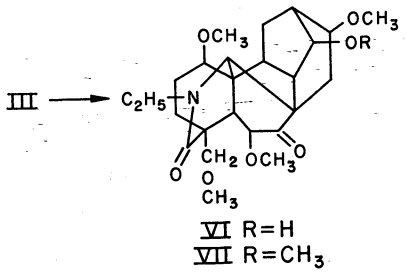
The fact that the triketone and V were colorless excluded position 6 for the secondary hydroxyl of browniine, since the analogues in delpheline chemistry are yellow and red respectively and have distinctive spectra (5). This hydroxyl thus had to be on ring C if the alkaloid had the lycoctonine skeleton. Since the three hydroxyls of browniine were

[1]*Issued as N.R.C. No. 7095.*
[2]*National Research Council Postdoctoral Fellow.*
[3]*We are grateful to Professor R. C. Cookson for a reference sample of the hydriodide of this base.*



accounted for, the primary hydroxyl which is present in lycoctonine was either missing or converted to a methoxyl. A reasonable postulate for the structure of browniine was hence I. If this were correct, correlation with lycoctonine through compound VII should be possible and this was attempted.

Oxobrowniine (III) when heated with 0.2% (v/v) sulphuric acid in acetic acid was converted to the product of pinacolic dehydration, anhydrooxobrowniine (VI). Methylation of VI gave the hydroxyl-free compound VII, which proved identical with the methyl ether of anhydrolycoctonam, which had been prepared by Dr. V. Skaric.[4] Thus browniine has structure I, and merely represents a variation in methylation of a common polyhydroxy precursor of it and lycoctonine.[5] It seems likely that the O-methylation is the last stage of the biosynthesis of these alkaloids.



The infrared spectrum of the α,β-unsaturated triketone V is a remarkable example of trans-spatial interaction of unsaturated functions (6). The normal absorption band for cyclopentanones (ν_{max} ca. 1740 cm^{-1}) was displaced to 1770 cm^{-1} in the mull spectrum of V.

The predominant formation of the compound with an axial hydroxyl in the reduction of the ketone carbonyl of II appears to be the result of shielding of one face of the carbonyl by the nearby axial methoxyl group.

An unusual acid-catalyzed reaction of the *seco*triketone IV was observed. Hot 6 *N* sulphuric acid converted it nearly quantitatively to a mixture of acids, about 25% of

[4]*Unpublished work by L. Marion and V. Skaric, to whom we are grateful for a reference sample.*

[5]*The 6-methoxyl group in the anhydro compounds appears to retain the original configuration under the conditions of the pinacolic dehydration (3).*

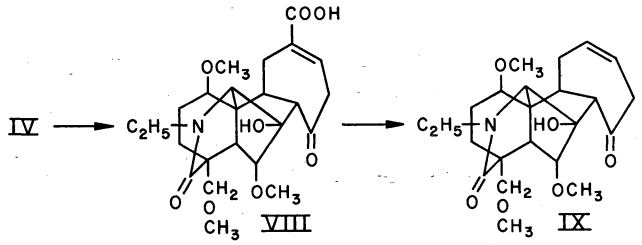
For personal use only.

which crystallized readily. The crystalline acid analyzed for $C_{24}H_{33}O_8N$, and contained only three methoxyl groups. An infrared spectrum of its sodium salt showed the presence of a six-membered or larger-ring ketone (ν_{max} 1698 cm^{-1}) and the lactam carbonyl (ν_{max} 1640 cm^{-1}). Its ultraviolet absorption spectrum had a peak at 213 mμ with ϵ 13,850, corresponding to the absorption of an α,β-unsaturated acid function, superimposed on end absorption due to the lactam function.

The same acid was produced by the action of 6 *N* sulphuric acid on the desmethanol-*seco*triketone V, thus locating the methoxyl which had been eliminated and indicating the origin of the double bond.

The acid decarboxylated smoothly at its melting point to give a non-crystalline hydroxy keto lactam which analyzed for simple loss of carbon dioxide. This had only end absorption in the ultraviolet region, but in the presence of dilute alkali an absorption maximum at 222 mμ rapidly developed. These observations are all consistent with structure VIII for the acid, the product of reverse Claisen reaction on IV followed by internal aldol condensation and elimination of methanol. The decarboxylation product would then be the β,γ-unsaturated ketone IX, rearranging in alkali to the α-β-unsaturated ketone.



Mild treatment of the *seco*triketone with base gave an acid mixture with infrared spectrum nearly identical with that from the product of the acid-catalyzed reaction. However, no crystalline VIII was obtained from it.

Browniine seems potentially valuable for establishing the structure of alkaloids such as delcosine which appear to have a secondary hydroxyl group in the same location.

EXPERIMENTAL

Unless otherwise stated, rotations are of ethanol solutions with $c \simeq 1$, ultraviolet spectra are of solutions in 95% alcohol, and infrared spectra are of nujol mulls.

Isolation of the Alkaloids

(*a*) The aerial portion (upper stems and leaves) of *Delphinium brownii* was collected just before the flowering period in the foothills of the Rocky Mountains in Alberta. The air-dried material was ground and percolated with methanol until a test with Mayer's reagent was faint. The methanol extract was concentrated to a syrup under reduced pressure, the residue taken up in 2 *N* sulphuric acid, and the suspension extracted with ether. The ether layers were back-extracted with 2 *N* sulphuric acid. The combined aqueous layers were adjusted to pH 8 using sodium carbonate, and the weak bases extracted into chloroform. The aqueous solution was then made strongly alkaline and the 'strong' bases extracted into chloroform. The strong bases were recycled through the strong base – weak base separation. Thirty-one pounds of dry plant material yielded 157 g of 'weak' base, 3 g of 'strong' base, and 34 g of ether-soluble neutral and acid substances.

The weak base was hydrolyzed by refluxing in aqueous methanol solution containing 16 g of sodium hydroxide for 1.5 hours. The solvent was removed under reduced pressure, water was added, and the bases extracted into chloroform (yield 130 g). The aqueous layer yielded 4.85 g of amphoteric acids (extracted at pH 5) and 9.5 g of acids.

The hydrolyzed base was dissolved in benzene and adsorbed on alumina, activity IV. Benzene eluted 58 g of base which would not crystallize but which gave a perchlorate (browniine perchlorate) which crystallized from methanol – ethyl acetate mixture. The base eluted with benzene–ether mixtures and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with ether crystallized from aqueous methanol, giving 38 g of lycoctonine. The more strongly adsorbed bases would not crystallize or give crystalline salts, and were not further examined.

(*b*) A 56-lb quantity of dried plant collected during flowering gave 37 g of 'weak' base and 16 g of 'strong' base. A quantity of weak base (13.5 g) was distributed between benzene and buffer of pH 4 in a Craig countercurrent distribution machine with 10 ml in each phase. After 107 transfers the contents of the tubes were recovered. Tubes 1–26 contained 6.7 g of alkaloid with no carbonyl band in its infrared absorption spectrum. It gave 2.0 g of browniine perchlorate. Tubes 27–34 contained mixtures. Tubes 35–42 contained 1.37 g of base with strong carbonyl absorption in the infrared. It gave a crystalline hydriodide (0.8 g) which was proved by mixed melting point and comparison of infrared spectra with an authentic sample[3] to be methyllycaconitine hydriodide.

Browniine

The perchlorate of the base which was readily eluted from alumina was recrystallized from methanol – ethyl acetate mixtures. It melted at 212° and had $[\alpha]_D^{26}$ +25°. It appeared homogeneous by paper chromatography (on Whatman 1 paper with isoamyl alcohol:acetic acid:water:heptane in the ratio 3:3:2:1 as developing solvent[6] and Dragendorff's reagent for location of the spots; R_f 0.59). Its infrared spectrum had peaks at 3400 cm^{-1} (OH), 2840 and 1090 cm^{-1} (OCH_3). Found: C, 52.97; 52.95; H, 7.06, 7.23; N, 2.25; OCH_3, 21.45. Calc. for $C_{25}H_{42}O_{11}NCl$: C, 52.86; H, 7.45; N, 2.47; $4OCH_3$, 21.85. The base liberated from the perchlorate was amorphous. It had $\nu_{max}^{CHCl_3}$ 3460 cm^{-1} (OH) and 1090 cm^{-1} (OCH_3). This was converted to the hydriodide, which crystallized with difficulty from acetone – ethyl acetate. The microcrystalline solid melted at 193–196°. Found: C, 50.75; H, 6.95. Calc. for $C_{25}H_{42}O_7NI$: C, 50.42; H, 7.11.

Browniine Monoacetate

The alkaloid was only slowly acetylated by 1:1 acetic anhydride – pyridine mixture at room temperature. After 36 hours in 40 ml of the mixture, 456 mg of browniine yielded 385 mg of basic acetate and considerable neutral or very weakly basic product. The basic acetate after repeated chromatography on alumina yielded 150 mg of nearly pure crystalline monoacetate (eluted from a 30-fold ratio of neutral alumina, activity III, by benzene and 10% and 20% chloroform in benzene). More strongly adsorbed products contained a contaminant with $\nu_{max}^{CHCl_3}$ 1730 and 1640 cm^{-1}. The crystalline product when recrystallized from hexane separated as needles, m.p. 123–124°. Found: C, 63.72; H, 8.35; OCH_3, 24.08. Calc. for $C_{27}H_{43}O_8N$: C, 63.63; H, 8.51; OCH_3, 24.36. It had ν_{max} 1730 cm^{-1} in chloroform.

Dehydrooxobrowniine (II)

A solution of 1.2 g of browniine in 11 ml of pyridine was added to 2.0 g of chromium trioxide in 15 ml of dry pyridine. The mixture was shaken at room temperature for 18 hours. The bulk of the pyridine was removed below 50° under reduced pressure. To the residue was added 20 g of crushed ice, 30 ml of 3 *N* sulphuric acid, and 20 ml of chloroform. Sulphur dioxide was bubbled into the mixture until a clear green color resulted. The chloroform layer and four subsequent 20-ml chloroform extracts of the aqueous layer were washed with water and saturated sodium bicarbonate solution, combined, dried, and distilled. The 888 mg of pale yellow froth was adsorbed from benzene onto 20 g of alumina of activity IV. Forty milliliters of benzene and 20 ml of 2:1 benzene–chloroform eluted 38 mg of amorphous material. Twenty-five milliliters of 2:1, 50 ml of 1:1, and 25 ml of 1:2 benzene–chloroform mixtures eluted 830 mg of product which crystallized from ether. Yield, 630 mg, m.p. 155–162°. Two recrystallizations from acetone–hexane gave rectangular plates, m.p. 110°, resolidifying, and melting at 170°. From ether–hexane the compound separated as needles, m.p. 169.5–171°, $[\alpha]_D^{24}$ +32°; ν_{max} 1750, 1643 cm^{-1}; λ_{max} 290 mμ, ϵ 27. Found: C, 62.68; H, 7.48. Calc. for $C_{25}H_{37}O_8N$: C, 62.61; H, 7.78.

Oxobrowniine (III)

(*a*) Dehydrooxobrowniine (II) (502 mg) was dissolved in 8 ml of methanol, and 500 mg of sodium borohydride added portionwise over 20 minutes. After a further 20 minutes the reaction mixture was diluted with 30 ml of 4 *N* sulphuric acid and the product extracted into chloroform. The 505 mg of product crystallized with some difficulty when triturated with moist ether; m.p. 75–88° (capillary). After chromatography on alumina (20-fold, activity III), the fractions eluted with benzene–chloroform mixtures and chloroform crystallized from wet ether, m.p. 90–93°, $[\alpha]_D$ +40°. Later an anhydrous form was obtained[7] from ether–pentane mixtures, which melted at 164–169°. Found: C, 62.50; H, 8.20; Calc. for $C_{25}H_{39}O_8N$: C, 62.35; H, 8.16.

(*b*) Browniine monoacetate (97 mg) was dissolved in 5 ml of acetone containing 0.2 ml of water and 0.2 ml of acetic acid. Powdered potassium permanganate was added in small portions until a small excess persisted for 1 hour. Sodium bisulphite solution was added to reduce excess reagent, the suspension filtered, and the filtrate taken to dryness under reduced pressure. The residue was extracted with methylene chloride, and the solution washed with 3 *N* sulphuric acid, 3 *N* sodium carbonate solution, and water. The 68 mg of neutral product was clearly a mixture, with amide bands at 1640 and 1660 cm^{-1}. It was chromatographed

[6]*We are grateful to Dr. K. H. Palmer for suggesting this solvent system.*
[7]*We are indebted to Dr. Z. Stojanac for this observation.*

For personal use only.

on 1.7 g of alumina, activity III. Benzene and 10% chloroform in benzene eluted 3 mg of oil, which was discarded. Twenty-five milliliters of 30% chloroform in benzene and 50 ml of 1:1 benzene–chloroform eluted 36 mg of the desired lactam acetate with $\nu_{max}^{CHCl_3}$ 1730 and 1640 cm^{-1}. Later eluates contained a mixture of this compound with what was probably the N-acetyl compound with ν_{max} 1730 and 1660 cm^{-1}.

The lactam acetate was hydrolyzed by 2 hours on the steam bath with 1 ml of 20% potassium hydroxide and sufficient ethanol to complete solution in the hot mixture. A white froth (37 mg) was produced which had an intense maximum at 1640 cm^{-1} ($CHCl_3$). It was purified by chromatography on 700 mg of alumina, after which it crystallized when hexane was added to a very concentrated solution of the compound in wet methanol. The crystals melted at 89–93° and had $[\alpha]_D$ +41°; ν_{max} 3470, 1640, and 1090 cm^{-1}. The product could also be crystallized from dry ether in an anhydrous form, m.p. 170–171.5°, which proved identical (infrared, mixed m.p., thin layer chromatography, and X-ray powder pattern) with the product described in (*a*).

Secodiketone

Oxobrowniine (54 mg) was dissolved in 20 ml of a saturated solution of lead tetraacetate in acetic acid. After 1 hour 0.97 mole of reagent had been consumed. The excess lead tetraacetate was reduced with sodium bisulphite solution, and aqueous sodium sulphate added to complete precipitation of the lead. The solid was removed by centrifuging, and washed once with methanol. The combined solutions were taken to dryness under reduced pressure and the residue dissolved in methylene chloride. The solution was washed with dilute sulphuric acid, sodium bicarbonate solution, and finally water. It was then dried and the solvent evaporated. The 46 mg of product did not crystallize. It had $\nu_{max}^{CHCl_3}$ 1770, 1710, and 1650 cm^{-1}.

Secotriketone (IV)

A solution of 107 mg of dehydrooxobrowniine (II) in 50 ml of a saturated acetic acid solution of lead tetraacetate was prepared. One-milliliter aliquots were titrated at intervals. After 1.5 hours the molar uptake of reagent was 1.06, after 5 hours, 1.12, and after 21 hours, 1.20.

In a preparative run 560 mg of II was dissolved in 100 ml of saturated lead tetraacetate solution and left at room temperature for 75 minutes. The product was worked up as described for the *seco*diketone. The 543 mg of foam crystallized readily when ether was added. Crop 1 weighed 172 mg and melted at 184–190°. Two further crops totalling 216 mg melted between 150 and 190°. After two recrystallizations from ether the *seco*triketone separated as colorless needles melting at 194–197°; $[\alpha]_D$ 62°; ν_{max} 1763, 1702, and 1650 cm^{-1}. Found: C, 62.49; H, 7.26; OCH_3, 25.67. Calc. for $C_{25}H_{35}O_8N$: C, 62.87; H, 7.39; $4OCH_3$, 25.98. It had $\nu_{max}^{CHCl_3}$ 1750, 1700, and 1640 cm^{-1}.

Desmethanolsecotriketone (V)

Thirty milligrams of the above *seco*triketone was heated at 210° under 5×10^{-4} mm pressure for 5 minutes. It was then allowed to distill over a short path under the same conditions. The distillate yield was nearly quantitative in this run but in others considerable brown residue remained. The distillate crystallized readily from ether, m.p. 150–170°. After several recrystallizations from ether the melting point was 172–175°; $\nu_{max}^{CHCl_3}$ 1770, 1680, and 1646 cm^{-1}. Found: C, 64.56; H, 6.82; OCH_3, 20.96. Calc. for $C_{24}H_{31}O_7N$: C, 64.70; H, 7.01; $3OCH_3$, 20.90.

Anhydrooxobrowniine (VI)

A solution of 500 mg of oxobrowniine (III) in 12 ml of a 0.2% (v/v) sulphuric acid in acetic acid mixture was heated at 83° for 90 minutes. Anhydrous sodium carbonate (0.3 g) was added to the reaction mixture, which was then taken to near dryness under reduced pressure. Water was added, the mixture made alkaline with conc. ammonia, and the product extracted into chloroform. The 544 mg of froth recovered from the chloroform was hydrolyzed by refluxing for 2 hours in a solution of KOH (10%) in 20% aqueous methanol. The methanol was removed under reduced pressure, water added, and the product extracted into chloroform. The 508 mg of hydrolyzate was adsorbed from benzene onto 10 g of neutral alumina, Grade II. Benzene (70 ml) and 3:1 benzene–chloroform (40 ml) eluted 19 mg of oily material, which was discarded. Forty milliliters of 2:1 and 40 ml of 1:1 benzene–chloroform eluted 219 mg of material which crystallized from ether. The more strongly adsorbed material did not crystallize.

The crystalline material was recrystallized from acetone–hexane combination, giving 173 mg of anhydrooxobrowniine, m.p. 192–195°. A further recrystallization raised the melting point to 195–197°. ν_{max} 3600, 1725, 1640 cm^{-1}. Found (sublimed sample): C, 64.97; H, 8.13. Calc. for $C_{25}H_{37}NO_7$: C, 64.77; H, 8.05.

O-Methylanhydrooxobrowniine (VII)

Anhydrooxobrowniine (170 mg) was added to a mixture of 170 mg of sodium hydride and 10 ml of dry dioxane. This was refluxed for 30 minutes after which 2 ml of methyl iodide was cautiously added. After 5 hours' refluxing the mixture was cooled, filtered and the filtrate taken to near dryness under reduced pressure. Water was added and the product extracted into chloroform. The 152 mg of oil recovered from the chloroform slowly crystallized from concentrated ether solution. It was purified by adsorption from benzene onto 3 g of neutral alumina, Grade II. Benzene (20 ml) eluted 115 mg of colorless oil which crystallized readily from ether–pentane mixture. A further 10 ml of benzene eluted 22 mg of less pure material.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The early eluate after three recrystallizations from ether–pentane melted at 120–124°. It had $[\alpha]_D$ 10° (*c*, 1.14 in $CHCl_3$). Found: C, 65.44; H, 8.28. Calc. for $C_{26}H_{39}NO_4$: C, 65.38; H, 8.23. Mixed melting point with a sample of O-methylanhydrolycoctonam (m.p. 119°) was 117–119°. An X-ray powder pattern comparison of the two compounds proved their identity.

Keto Acid VIII

(*a*) When 172 mg of *seco*triketone was dissolved in 10 ml of 6 *N* sulphuric acid on the steam bath, and heating continued for 45 minutes, 175 mg of acid was produced (extracted from chloroform by sodium hydrogen carbonate solution). This crystallized from ethyl acetate – hexane mixtures, giving 57 mg, m.p. 160–178°. After three recrystallizations from the same solvents and one recrystallization from ethyl acetate it melted at 185–188° (decomp.)[8] and had $[\alpha]_D$ 124°. $\nu_{max}^{CHCl_3}$ 3500, 1690, and 1635 cm^{-1}. Equivalent weight 467, pK_a' 5.5 (in 50% aqueous ethanol). Found: C, 62.45; H, 7.38; OCH_3, 19.46. Calc. for $C_{24}H_{33}O_8N$: C, 62.19; H, 7.18; $3OCH_3$, 20.08. Equivalent weight, 463.5. Its sodium salt had ν_{max} at 1698 cm^{-1} (ketone), 1640 cm^{-1} (lactam), 1565 cm^{-1} (COO^-).

(*b*) Desmethanol*seco*triketone (V) (12 mg) was treated as in (*a*) with 1 ml of 6 *N* sulphuric acid. The product was separated into neutral and acidic fractions. The acids crystallized from ethyl acetate, giving 6 mg of crystals, m.p. 174–180° (decomp.), which did not depress the melting point of the product from (*a*).

(*c*) The *seco*triketone was nearly completely converted to acids in 45 minutes in 0.15 *N* sodium hydroxide in aqueous ethanol. No crystalline acid was obtained, however, even after chromatography on silica gel.

Decarboxylation of VIII

The acid (VIII) decarboxylated rapidly at 195° in an evacuated tube. If the pressure was below 10^{-2} mm the product distilled at once. Attempts to induce crystallization from anhydrous solvents and aqueous methanol failed. The material was distilled at 175°, 1×10^{-3} mm. It had $[\alpha]_D$ 150°; ν_{max} 3460, 1690, and 1640 cm^{-1}; end absorption in the ultraviolet. Found: C, 66.42; H, 7.84. Calc. for $C_{23}H_{33}NO_6$: C, 65.85; H, 7.93.

A solution of the decarboxylation product in ethanol containing potassium hydroxide (80 mg in 20 ml) rapidly developed an ultraviolet absorption maximum at 222 mμ, which reached maximum intensity after 2 hours. In a preparative run under the same conditions, however, no α,β-unsaturated ketone could be isolated.

ACKNOWLEDGMENTS

We thank Mr. M. Lesage and Mr. A. Knoll for the isolation of the alkaloids, Mr. H. Seguin for the analysis, and Mr. R. Lauzon for the infrared spectra. We are grateful to Dr. E. H. Moss, Botany Department, University of Alberta, for a generous supply of plant material.

OXIDATION–REDUCTION POLYMERS

II. STANDARD OXIDATION POTENTIALS OF REDOX HOMOPOLYMERS AND THEIR MONOMERIC MODELS[1]

I. H. SPINNER, W. D. RAPER,[2] AND W. METANOMSKI
Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario
Received August 15, 1962

ABSTRACT

A new monomer, 2,5-bis-(2-tetrahydropyranyloxy)-4-methyl-4′-vinyldiphenyl sulphone, has been prepared. The standard oxidation potentials of two linear redox homopolymers, derived from this monomer and the one previously reported (1), and of their intermediate and model compounds, have been measured using continuous and discontinuous titration techniques.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

In Part I (1) we reviewed briefly the literature on redox monomers and polymers, especially those containing hydroquinone units. Since then further contributions in this field have been published.

Cassidy and co-workers (2, 3) have investigated the properties and reactions of methyl-substituted hydroquinones and vinylhydroquinones in their search for redox polymers of improved stability. Manecke and Storck (4) have reported the synthesis of 1- and 2-vinylanthraquinones.

Further condensation-type polymers have been prepared: hydroquinone–resorcinol–formaldehyde (5), pyrogallol–formaldehyde (6), dichlorohydroquinone–trioxane (7), and dimethylhydroquinone–formaldehyde (7). In order to study the redox behavior of these polymers, which in their idealized form would consist of repeating hydroquinone units linked by methylene bridges, model segmers have been synthesized (8, 9) and their standard oxidation potentials measured.

Izoret (10) continued his work on anthraquinone polymers. A new polymer containing hydroquinone units has been prepared by the reaction of a polymeric amine with 2,5-dihydroxyhydrocinnamic acid lactone (11). The reaction of diamines with *p*-benzoquinone led to the synthesis of various aminoquinones (12).

Practical applications of redox polymers in batteries and dielectric compositions have been reported (13–15).

We have continued our investigations of polymers containing repeating hydroquinone units joined through a sulphone bridge to a polystyrene chain. Monomers and model compounds of increased stability were sought.

The organic syntheses are shown schematically below. Isopropylbenzene was chlorosulphonated and then reduced by alkaline sodium sulphite to give *p*-isopropylbenzenesulphinic acid (II). The sulphinic acid was reacted with *p*-benzoquinone to give diphenyl sulphone III, which was used subsequently as a model segmer of polymer X.

A new monomer, 2,5-bis-(2-tetrahydropyranyloxy)-4-methyl-4′-vinyldiphenyl sulphone (VII) was synthesized. The structure of sulphone V has not been positively established regarding the relative position of the $—SO_2Ar$ and $—CH_3$ groups on the hydroquinone

nucleus. The electron demand of the carbonyl oxygens and the low electron affinity of the $-CH_3$ group create a marked deficit at the carbon atom para to the $-CH_3$ group (16); therefore the 4-methyl isomer should be obtained in highest yield. If some 3-isomer is obtained, it should be difficult to pyranylate both phenolic groups since one of the phenolic groups would be sterically hindered. The product obtained experimentally consisted essentially of one isomer which could be fully pyranylated. A very small amount of another isomer which could not be fully pyranylated was also obtained. It is therefore suggested that the isomer used in this work is the 4-methyl isomer.

An additional model segmer (IX) with an ethyl group was synthesized by reducing the bromoethyl side chain of the sulphone VIII.

The intermediate and model compounds were characterized by analysis, infrared spectra, and their standard oxidation potentials.

The monomers were polymerized using α,α'-azodiisobutyronitrile as an initiator. After treatment with acid to expose the phenolic groups, the linear homopolymers (X and XI) were characterized by their standard oxidation potentials. Potentiometric techniques have been used with redox polymers by other investigators (5, 6, 17–19). The sulphur analyses on the polymers X and XI are lower than the theoretical and might suggest that depyranylation was incomplete. On the other hand, all phenolic groups

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

would be exposed during titration in strong acids. Since the titration curves of the polymers were comparatively flat, any error in estimating E_0 through an incorrect assumption of the equivalent weight of the polymers would be within the experimental limits indicated in Table II.

A simplified form of the Nernst's equation was used to calculate the standard oxidation potential (E_0) for the quinone–hydroquinone redox systems:

$$E_h = E_0 + \frac{RT}{2F} \ln \frac{[Ox]}{[Red]} + \frac{RT}{F} \ln [H^+]^*$$

where E_h is the cell potential referred to a standard hydrogen electrode. The difference between the cell potential at 50% and that at 25% oxidation, taken from the titration curve, is called the index potential (E_i) and is theoretically equal to 14.1 mv at 25° C for a simple bivalent redox reaction.

It was realized early in this work that all compounds containing the non-substituted quinone group were unstable under certain titration conditions. In cases where instability was encountered, a discontinuous titration method (20–22) was used. Briefly, predetermined amounts of the oxidant were added to known amounts of the samples to be oxidized and the change of potential with time was recorded. In all cases this change was linear and the cell potential at each stage of oxidation was obtained by extrapolation to zero time, as illustrated in Fig. 1. The value of E_0 reported for all titrations was obtained

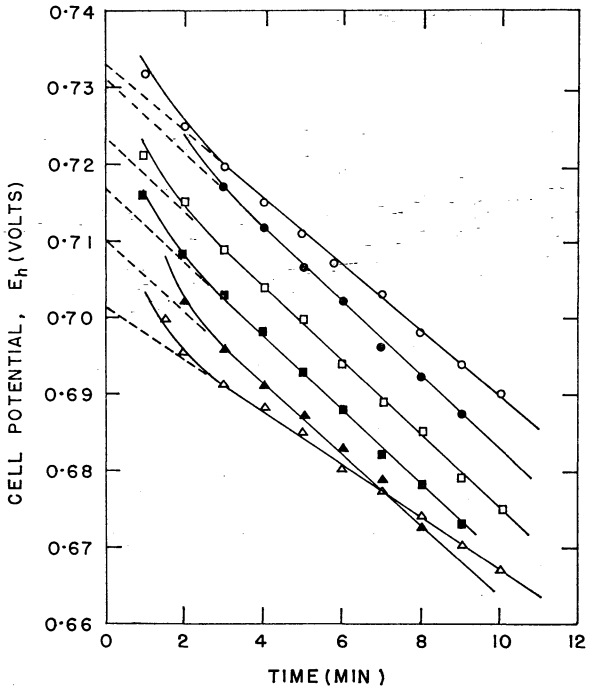

FIG. 1. Discontinuous titration of the sulphone VIII (No. 3, Table II): △ 12.2; ▲ 24.4; ■ 36.7; □ 49.0; ● 61.2; ○ 73.4% oxidation. Points were taken from recorder results.

**This simplified treatment makes the usual assumptions for a weak dibasic acid in strongly acid solution and neglects semiquinone formation, activity coefficients, and liquid junction potential. The term E_0 combines $(RT/2F) \ln K_1K_2$ with E^0, the conventional standard potential.*

by averaging the values calculated from each individual addition of oxidant as illustrated in Table I. The potential decay is a useful index of the instability of the oxidized form of

TABLE I

Discontinuous titration of sulphone VIII (No. 3, Table II), 112 mg (0.628 meq) in 250 ml acetic – sulphuric acid, pH 0.5, 24° C

the compound. A composite curve of the cell potential at zero time versus percentage oxidation leads to the familiar potentiometric titration curve illustrated in Fig. 2.

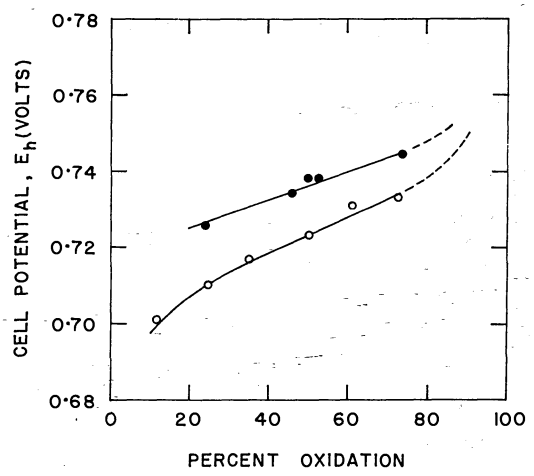

FIG. 2. Discontinuous titration (composite curve) of the sulphone VIII and polymer X (Nos. 3 and 11, Table II): ○ sulphone (pH 0.5); ● polymer (pH 0.3).

Representative examples of continuous and discontinuous titrations are shown in Table II. Hydroquinone and toluhydroquinone were titrated to check the apparatus and various techniques. The mean value of two platinum electrodes has been reported. These electrodes agreed within less than 1 mv for the model compounds and showed a maximum discrepancy of 7 mv for the polymers.

As previously mentioned the oxidized form of sulphone VIII was unstable. Therefore, a discontinuous titration was required for determination of the standard oxidation potential of this sulphone. Titration in various solvents, at different pH and using two oxidants, yielded the same values of E_0 within the experimental error. It was generally found that the decomposition of the oxidized form was much slower in solutions of lower water concentration and of lower acidity. In the case of bromine titrations it might be

suspected that drifting potentials were due to bromination. However, this is not likely, since the redox groups are very sensitive to oxidation and the bromine concentration was less than 0.005 *N*. In any case, if bromination of the quinonoid ring did take place, the potential would have risen rather than fallen during the course of titration. It was also found that the potential decay was about the same for both ceric sulphate and bromine titrations. The secondary reaction of the quinone was first order with respect to the quinone and it is possible that an addition of water, similar to the formation of hydroxynaphthahydroquinone (21) or hydroxyhydroquinone (25), is involved.

The oxidized form of the methyl-substituted sulphone V decomposed very slowly in 50% acetic acid and was completely stable in 80% acetic acid so that redox titration of this compound and its analogous polymer could also be carried out by the continuous method (Fig. 3). The observation that the methyl-substituted polymer was more stable

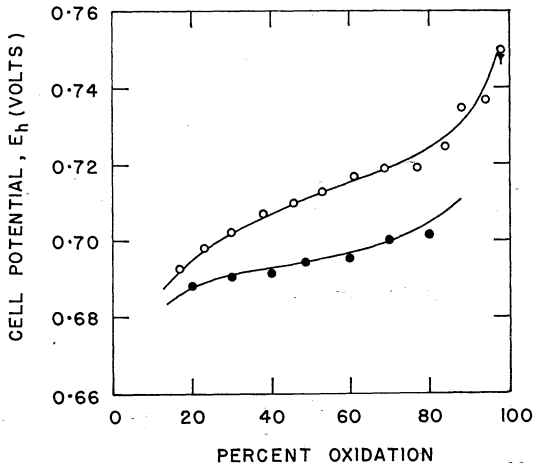

FIG. 3. Continuous titration of the methyl-substituted sulphone V and polymer XI (Nos. 10 and 13, Table II): ○ sulphone (pH 0.25); ● polymer (pH 0.35).

than the unsubstituted polymer agreed with the results of Kun and Cassidy (2).

In addition to the instability mentioned above, all compounds and polymers could not be accurately titrated past about 90% oxidation because of a downward drifting potential.

TABLE III

Standard oxidation potentials

*The difference between E_0 of the compound and that of the parent hydroquinone.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Table III shows that the group R on the non-oxidizable benzenoid ring did not appear to influence the E_0 of the compound to any great extent. However, the nature of the substituent R′ on the quinonoid ring influences the oxidation potential of the compound. Carter in an unpublished contribution quoted by Evans and De Heer (26) stated that there is a linear relationship between the E_0 of many substituted quinones and Hammett's substituent constant (σ_p). We have examined the literature on this point and found such a relationship exists. Data on the derivatives reported here and on other derivatives being examined indicate that a similar relationship may apply for substituted 2,5-dihydroxydiphenyl sulphones.

The addition of the $—SO_2C_6H_4R$ group to the quinones caused an increase in potential over the parent quinone in all cases. This increase ranged from 44 to 66 mv for the hydroquinone derivatives and from 77 to 88 mv for the toluhydroquinone derivatives. The increase in potential is in agreement with the expected effect of the strongly electron withdrawing $—SO_2Ar$ group. Fieser and Fieser (27) reported an increase of 121 mv for 1,4-naphthaquinone with a $—SO_2C_6H_4CH_3$ substituent. The above data and information on other derivatives now being examined indicate that there may be a linear relation between the change in E_0 (after addition of the $—SO_2C_6H_4R$ group) and Hammett's σ_p constant for the original substituent on the quinonoid nucleus.

The polymers were titrated in 80% acetic acid only, because of their limited solubility in other solvents. The oxidized polymer precipitated with the first addition of the oxidant, but seemed to remain well dispersed. The manner in which the measurements on the polymers were taken is illustrated in Fig. 4 and 5. The non-substituted polymer X (Fig. 4) appeared to be considerably more stable than its monomeric analogues (0.3 mv/minute potential decay, as compared to 1.3 mv/minute). The hydroquinone groups seemed to

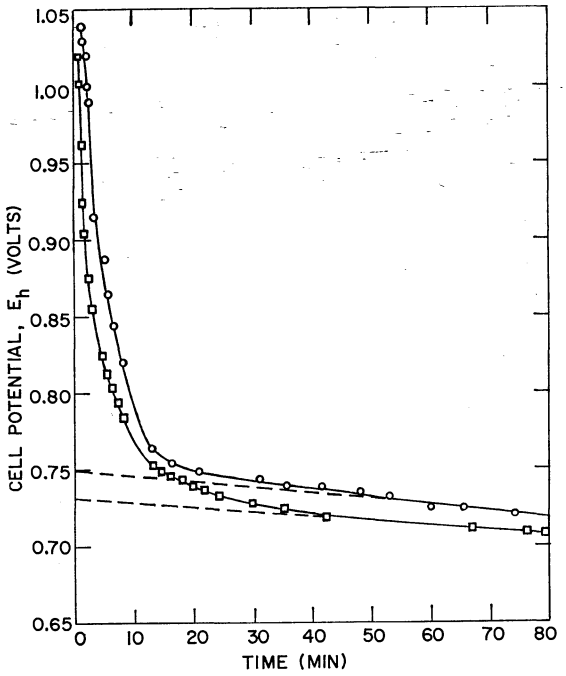

FIG. 4. Discontinuous titration of the polymer X (No. 11, Table II): □ 58.7; ○ 70.6% oxidation.

For personal use only.

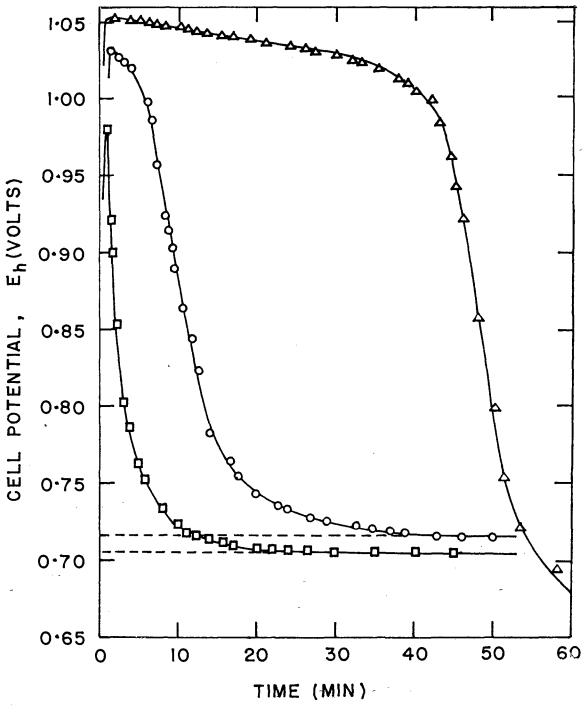

FIG. 5. Discontinuous titration of the polymer XI (No. 12, Table II): □ 51.5; ○ 77.3; △ 109.9% oxidation.

be readily accessible to oxidant, although equilibrium was attained slowly (Fig. 5), as has been noted by other investigators (18, 19). Stable equilibrium potentials were obtained for methyl-substituted polymer XI up to 80% oxidation. A downward drift of potential was obtained at higher percentage oxidation. Figure 5 also illustrates the instability of these materials when an excess of oxidant is used.

A suspension of polymer XI (80% oxidized) was reduced with hydrogen in the presence of a Pd catalyst. This stable polymer could not be completely reduced, probably because of the insoluble nature of the oxidized form. The partially reduced polymer was re-oxidized and for the same degree of oxidation the titration curve compared well with the original titration curve.

It was found that the difference between the E_0's of the polymers and those of the corresponding intermediate and model compounds was small (-13 to $+9$ mv). These results are to be contrasted with those of Robinson, Fernandez-Refojo, and Cassidy (18) and Manecke (19), who reported E_0 values for polymers up to 100 mv higher than those of the model segmers. It is probable that our results are different, because the "substitution" due to polymer growth is far removed from the redox centers. However, the possible influence of polymeric structure on E_0 cannot be overlooked.

Robinson *et al.* (18) have stated that the variation of E_0 with the ratio of the oxidized to reduced form* of their polymers was due to nearest neighbor interactions. Manecke (19) made a similar statement with regard to his data on condensation redox polymers. It

**From the experimental point of view this can be alternatively considered as a deviation of the index potential (E_i) from that expected for the simple bivalent redox reaction.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

should be pointed out that, if titrations are carried out in extremely dilute solutions, these interactions would be mainly between groups on the same chain. Examination of our results indicate that the index potentials of our polymers are closer to the theoretical value for a simple bivalent redox reaction than those of other investigators (18, 19). It thus appears that separation of the redox groups from the backbone chain by the benzene ring has considerably decreased the interaction of adjacent redox groups, as was suggested in Part I (1).

Investigation of more stable monomers and polymers is now in progress.

EXPERIMENTAL*

p-Isopropylbenzenesulphonyl Chloride (I)

This compound has been previously prepared (28, 29), but it was not isolated in a pure form.

Isopropylbenzene (cumene) (50 g, 0.416 mole) was added dropwise to chlorosulphonic acid (447 g, 3.83 mole), the temperature being maintained below 5°. The reaction mixture was poured onto crushed ice and an oil settled. This oil was separated, washed with water, and dried over anhydrous sodium sulphate. Distillation under reduced pressure gave 60 g (66%) of a colorless oil, b.p. 142–143°/12 mm, d_4^{25} 1.225, n_D^{25} 1.5350. Anal. Calc. for $C_9H_{11}ClO_2S$ (218.70): C, 49.42; H, 5.07; Cl, 16.22; S, 14.66. Found: C, 49.44; H, 5.45; Cl, 16.04; S, 14.79%. —SO_2Cl: Calc. 45.5. Found by the method of Barker *et al.* (30) 45.9%.

A derivative, *p*-isopropylbenzenesulphonamide, was prepared by reacting the sulphonyl chloride I with concentrated ammonium hydroxide. Crystallization from 60% ethanol gave white plates melting at 107–107.5° (previously reported 107–108° (31)). Anal. Calc. for $C_9H_{13}NO_2S$ (199.27): C, 54.24; H, 6.58; N, 7.03; S, 16.09. Found: C, 54.27; H, 6.60; N, 6.93; S, 15.94%.

p-Isopropylbenzenesulphinic Acid (II)

The sodium salt of this acid has been prepared by Gilman and Cason (32), but free sulphinic acid has not been reported.

The sulphonyl chloride I (20 g, 0.091 mole) was suspended in a solution of 150 g of sodium sulphite and 10 g of sodium hydroxide in 500 ml of water. The mixture was heated to 70°, stirred for 1 hour, allowed to cool to room temperature, and acidified with concentrated hydrochloric acid. A yellowish oil separated overnight. It was dissolved in 150 ml of diethyl ether and washed repeatedly with water. Evaporation of the solvent left 6.7 g (40%) of a yellowish viscous oil. The crude material gave a strong positive Smiles' test for aromatic sulphinic acids (33). It was used without further purification for the next step.

2,5-Dihydroxy-4′-isopropyldiphenyl Sulphone (III)

A suspension of *p*-benzoquinone (3.9 g, 0.036 mole) in 20% ethanol (150 ml) was added slowly to a suspension of the sulphinic acid II (6.7 g, 0.036 mole) in 20% ethanol (500 ml). The product settled overnight and crystallization from 25% ethanol gave fine, sandy crystals (4.4 g, 42%) melting at 147.5–148°. Anal. Calc. for $C_{15}H_{16}O_4S$ (292.34): C, 61.62; H, 5.52; S, 10.97. Found: C, 61.30; H, 5.66; S, 11.06%. Infrared spectrum: 1156 (s) and 1307 (s) (—SO_2—) (34), 3390 (s) (—OH) (1) cm^{-1}.

A derivative, 2,5-diacetoxy-4′-isopropyldiphenyl sulphone, was prepared by reacting the dihydroxy sulphone III with acetic anhydride and a drop of concentrated sulphuric acid as a catalyst. Crystallization from 30% ethanol gave white plates melting at 139.5–140°. Anal. Calc. for $C_{19}H_{20}O_6S$ (376.41): C, 60.62; H, 5.36; S, 8.52. Found: C, 60.53; H, 5.22; S, 8.43%.

p-(β-Bromoethyl)benzenesulphinic Acid (IV)

The preparation of this compound has been reported in Part I (1). The reduction of the corresponding sulphonyl chloride was carried out in an acid medium, instead of a more conventional reduction by alkaline sodium sulphite, because of the instability of the bromoethyl side chain in alkaline medium. Therefore in every run a large quantity (15–20%) of a by-product, *p*-(β-bromoethyl)phenyl *p*-(β-bromoethyl)benzenethiosulphonate, resulting from the disproportionation of the sulphinic acid, was obtained. This by-product was recrystallized once from 50% ethanol, and then twice from *n*-hexane, yielding white crystals, m.p. 78.5–79°. Anal. Calc. for $C_{16}H_{16}Br_2O_2S_2$ (464.24): C, 41.39; H, 3.47; Br, 34.43; S, 13.82. Found: C, 41.29; H, 3.73; Br, 34.61; S, 13.61%.

The same thiosulphonate was obtained by refluxing freshly recrystallized sulphinic acid IV for 2.5 hours in glacial acetic acid containing 4% of 1:1 sulphuric acid. The reaction mixture was diluted with water and cooled. The precipitate was filtered and recrystallized once from 50% ethanol and twice from *n*-hexane, yielding white crystals, m.p. 78.5–79°. This product gave no depression in mixed melting point with the analyzed sample.

**Melting points are corrected. All ethanol solutions are reported on a percentage by volume basis. Microanalyses were done by Galbraith Laboratories, Inc., Knoxville, Tenn.*

2,5-Dihydroxy-4-methyl-4′-(β-bromoethyl)diphenyl Sulphone (V)

A solution of toluquinone (12.7 g, 0.104 mole) in absolute ethanol (125 ml) was added dropwise to a suspension of the sulphinic acid IV (26 g, 0.104 mole) in 30% ethanol (1 liter). Stirring was continued for 1 hour, the mixture was diluted with 1125 ml of water and chilled for several hours in an ice bath. The precipitate was recrystallized from 25% ethanol, yielding 21 g (55%) of a white product melting at 121–122°. Anal. Calc. for $C_{15}H_{15}BrO_4S$ (371.25): C, 48.53; H, 4.07; Br, 21.53; S, 8.63. Found: C, 48.73; H, 4.14; Br, 21.51; S, 8.74%. Infrared spectrum: 1142 (s) and 1308 (s) (—SO_2—) (34), 3390 (s) (—OH) (1) cm^{-1}.

A derivative, 2,5-diacetoxy-4-methyl-4′-(β-bromoethyl)diphenyl sulphone, was prepared. Crystallization from 25% ethanol gave a white product melting at 59–60°. Anal. Calc. for $C_{19}H_{19}BrO_6S$ (455.33): C, 50.10; H, 4.20; Br, 17.55; S, 7.04. Found: C, 50.16; H, 4.26; Br, 17.46; S, 7.23%.

In certain runs, small amounts of a material of much higher melting point, having all the characteristics of a dihydroxydiphenyl sulphone, were isolated. This was probably 2,5-dihydroxy-3-methyl-4′-(β-bromoethyl)diphenyl sulphone. Repeated recrystallizations from 20% ethanol and mixtures of benzene and petroleum ether yielded a white product melting at 146–147°. Anal. Calc. for $C_{15}H_{15}BrO_4S$ (371.25): C, 48.53; H, 4.07; Br, 21.53; S, 8.63. Found: C, 48.88; H, 4.20; Br, 23.46; S, 9.15%. Infrared spectrum: 1147 (s) and 1302 (s) (—SO_2—) (34), 3390 (s) (—OH) (1) cm^{-1}.

Attempts to pyranylate this material fully under a variety of conditions failed. Only a monopyranylated derivative, 2-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-4′-(β-bromoethyl)diphenyl sulphone, melting at 112–113°, was obtained. Anal. Calc. for $C_{20}H_{23}BrO_5S$ (455.39): C, 52.75; H, 5.09; Br, 17.55; S, 7.04. Found: C, 52.86; H, 5.05; Br, 17.29; S, 7.03%.

The monopyranylated sulphone was easily decomposed by treatment with hydrochloric acid, yielding the dihydroxy sulphone (3-methyl isomer).

2,5-Bis-(2-tetrahydropyranyloxy)-4-methyl-4′-(β-bromoethyl)diphenyl Sulphone (VI)

This preparation was similar to that previously reported for a non-substituted hydroquinone derivative (1). One modification included the precipitation of the final product from an absolute ethanol solution of the crude product by *n*-hexane. The pale yellow solid obtained (4.5 g, 77%) melted at 51–53°. Anal. Calc. for $C_{25}H_{31}BrO_6S$ (539.48): C, 55.65; H, 5.79; Br, 14.81; S, 5.94. Found: C, 55.37; H, 5.50; Br, 14.61; S, 6.29%.

Repeated recrystallizations did not improve the melting point range. This product is believed to be a mixture of stereoisomers of the type discussed previously (1).

2,5-Bis-(2-tetrahydropyranyloxy)-4-methyl-4′-vinyldiphenyl Sulphone (VII)

The procedure was similar to that previously reported for a non-substituted monomer (1). Potassium bromide precipitated during the course of the reaction. A pale yellow liquid (4.1 g, 87%), which gave a negative test for halogen, was obtained. It was insoluble in dilute sodium hydroxide solution, which indicated that the hydroxy groups remained protected. Attempts to purify the monomer VII by distillation were unsuccessful because of its high boiling point and instability at high temperatures.

2,5-Dihydroxy-4′-ethyldiphenyl Sulphone (IX)

2,5-Dihydroxy-4′-(β-bromoethyl)diphenyl sulphone (VIII) (1) (8.5 g, 0.024 mole) was dissolved in a hot solution of 300 ml of water, 70 ml of concentrated sulphuric acid, and 120 ml of glacial acetic acid, to which 0.5 g of zinc had been added. The solution was refluxed for 7 hours during which an additional 4.5 g of zinc was added in small portions. When the solution was diluted with 200 ml of water and cooled, a fluffy white precipitate settled. The crude product was purified by dissolution in 5% sodium hydroxide solution containing a trace of sodium hydrosulphite and precipitation with 25% acetic acid. A white product (3.8 g, 58%) melted at 181.5–182°. Anal. Calc. for $C_{14}H_{14}O_4S$ (278.31): C, 60.42; H, 5.07; S, 11.52. Found: C, 60.15; H, 5.30; S, 11.29%.

A derivative, 2,5-diacetoxy-4′-ethyldiphenyl sulphone, was prepared. Crystallization from 25% ethanol gave white plates melting at 144–144.5°. Anal. Calc. for $C_{18}H_{18}O_6S$ (362.39): C, 59.65; H, 5.01; S, 8.85. Found: C, 59.32; H, 4.81; S, 8.78%.

Poly(2,5-dihydroxy-4′-vinyldiphenyl Sulphone) (X)

2,5-Bis-(2-tetrahydropyranyloxy)-4′-vinyldiphenyl sulphone (1) (3.006 g, 0.0068 mole) and α,α′-azodiisobutyronitrile (30 mg) were dissolved in 15 ml of toluene and heated in a sealed tube at 95–96° for 72 hours. Precipitation with methanol and reprecipitation with petroleum ether (80–100°) from a toluene solution yielded a white fluffy product (1.91 g, 63%), insoluble in 5% sodium hydroxide solution, with a softening range of 165–185°. Anal. Calc. for $(C_{24}H_{28}O_6S)_n$ (444.52): S, 7.21. Found: S, 6.85%.

The polymer was treated with 50% hot acetic acid to remove the tetrahydropyranyl groups, dissolved in dioxane, and precipitated by petroleum ether. A light tan product, soluble in 5% sodium hydroxide (yellow solution), softened at 200–210°. Anal. Calc. for $(C_{14}H_{12}O_4S)_n$ (276.30): S, 11.60. Found: S, 9.79%.

Poly(2,5-dihydroxy-4-methyl-4′-vinyldiphenyl Sulphone) (XI)

The crude monomer VII (2.298, 0.0050 mole) and α,α′-azodiisobutyronitrile (28.3 mg) were heated in a sealed tube at 95° for 24 hours. The very viscous pale amber polymerization product was dissolved in 15 ml of chloroform and precipitation by petroleum ether (80–120°) yielded a white product (1.36 g, 55%),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

insoluble in absolute ethanol and 5% sodium hydroxide solution, sparingly soluble in benzene and toluene, with a softening range of 170–185°. Anal. Calc. for $(C_{25}H_{30}O_6S)_n$ (458.56): S, 6.99. Found: S, 8.66%.

Treatment with 50% acetic acid and precipitation from dioxane solution by petroleum ether gave a white product, soluble in 5% sodium hydroxide solution (yellow solution), with a softening range of 175–185°. Anal. Calc. for $(C_{15}H_{14}O_4S)_n$ (290.33): S, 11.05. Found: S, 10.01%.

Potentiometric Titrations

(a) Apparatus

The assembly consisted of a saturated calomel electrode connected by a saturated potassium chloride bridge* to the titration vessel equipped with two bright platinum electrodes, a glass electrode, and a magnetic stirrer. The cell potentials were measured using a precision differential d-c. voltmeter (Model 801H, John Fluke Mfg. Co.). The change of potential with time was measured using a potential recorder (Model A-70, John Fluke Mfg. Co.). Nitrogen was purified by passage through Fieser's solution (36) and lead acetate solution.

(b) Continuous Titration

These titrations were performed in a conventional manner (35). Some of the experimental runs are listed in Table II. Between 0.685 and 1.01 meq of the compound to be titrated in 80 ml of solvent was used in each titration.

(c) Discontinuous Titration

A typical titration (No. 3 in Table II) is described. A stock solution of the sulphone VIII (equiv. wt. 178.61), containing 2.8010 g (0.0157 equiv.) in 250 ml of 90% acetic acid, was prepared. Ten milliliters of this solution (112.0 mg, 0.628 meq) was added to 240 ml of the acetic–sulphuric acid in the titration vessel. Nitrogen was bubbled through the solution and the solution stirred for 1/2 hour. One milliliter of the oxidizing agent, 0.0768 *N* ceric sulphate (corresponding to 12.2% oxidation), was added rapidly and the cell potential recorded using a potential recorder. The potential at zero time was obtained by extrapolation of the potential–time curve (Fig. 1). The same procedure was repeated by taking another 10 ml of the stock solution, adding 2.0 ml of the oxidant (corresponding to 24.4% oxidation), and recording the change of potential with time again. A third curve was obtained when 3.0 ml of the oxidant (36.7% oxidation) was added to another 10 ml sample, and so on. A composite titration curve was then constructed from the initial (zero time) potentials (Fig. 2). The standard oxidation potential (E_0) was calculated, as shown in Table I.

GALVANIC STRESS POTENTIALS OF METALS

S. TAN AND KEN NOBE

Department of Engineering, University of California, Los Angeles, California

Received October 22, 1962

ABSTRACT

The electrode potential of silver, brass, and steel wires under tensile stress have been measured in aqueous solutions of silver nitrate, copper sulphate, and ferrous sulphate, respectively. The stress potentials were continuously measured with a stabilized d-c. microvolt amplifier which made possible the study of the transient and the steady-state period during loading and unloading. The stressed silver and steel electrodes were cathodic with respect to the reference electrode, and the e.m.f. was approximately a linear function of the stress. The slope of the e.m.f.–stress curve for silver increased with decrease in electrolyte concentration. The stressed brass electrode was anodic with respect to the reference electrode and the e.m.f. varied linearly with stress only for 1 *N* $CuSO_4$.

INTRODUCTION

The electrode potentials of silver, brass, and steel wires mechanically stressed in the elastic region have been measured in air-saturated aqueous solutions of silver nitrate, copper sulphate, and ferrous sulphate, respectively. A theoretical analysis of the effect of stress on the electrode potential of metals has been made by Flood (1). Some previous investigations have been reviewed by Fryxell and Nachtrieb (2), and it is evident that there is considerable disagreement among the investigators concerning the sign of the electrode potential of the stressed metal electrodes. In the investigation reported here, the stress potentials were observed with instrumentation which made possible a continuous measurement of the e.m.f. during the loading and the unloading process. Thus, the behavior of these stressed electrodes in the transient as well as in the steady-state region could be observed. In addition, the effects of electrolyte concentration on the stress potentials were studied.

EXPERIMENTAL

The galvanic cell consisted of the metal wire as the test electrode aligned along the axis of a cylindrical tube of the same metal. The metal wire was coated with a thin coat of lucite to eliminate the erratic behavior of the electrode potential caused by reactions occurring at the air–solution interface. Further details and a schematic drawing of the cell are given elsewhere (3).

The e.m.f. of the cell was measured with a Leeds and Northrup d-c. microvolt amplifier. The input impedance of the amplifier was greater than 10^7 ohms. A continuous trace of the amplifier output was obtained with a Leeds and Northrup Speedomax recorder.

The metal wires used in this investigation were silver, gauge B. & S. No. 20, C.P. grade 99.9% pure; brass, gauge B. & S. No. 22 (70% Cu, 30% Zn); black annealed steel, gauge B. & S. No. 20 (99.8% Fe).

The wires were cleaned with abrasive powder and etched in dilute nitric acid, rinsed several times with double-distilled water, and coated with a lucite film. A portion of the lucite film, 1 cm in height, was removed to allow the metal surface to come in contact with the solution.

Since the no-load e.m.f. of the galvanic cell was usually greater than 1 mv and the stress potentials were often considerably smaller, a bucking potential was introduced to mask out the initial potential. The e.m.f. of the cell stabilized 1 to 2 hours after the solution was introduced into the cell. A fresh cell was used for each run, and measurements were taken at room temperature.

For each value of tensile stress, the load was added and removed several times. Special care was taken not to exceed the elastic limit of the metal during each run by taking stress–strain measurements simultaneously.

RESULTS AND DISCUSSIONS

The e.m.f. measurements of the silver cell were made in the tensile stress range 0 to 6700 g/mm^2. These measurements were made in 1 *N*, 0.1 *N*, 0.01 *N*, and 0.001 *N* silver

nitrate solutions. No attempt was made to control the oxygen content other than to air-saturate the solutions since Fryxell and Nachtrieb (2) observed that the exclusion of oxygen did not appreciably affect the e.m.f.

In each run the stress potentials were both reproducible and reversible. With the application of the load, the potential of the test electrode became more positive with respect to the unstressed reference electrode (the Gibbs–Stockholm convention for the sign of the electrode potential is adopted in this paper). The e.m.f.–time response which is shown in the inset of Fig. 1 indicated that the electrode potential of the stressed wire

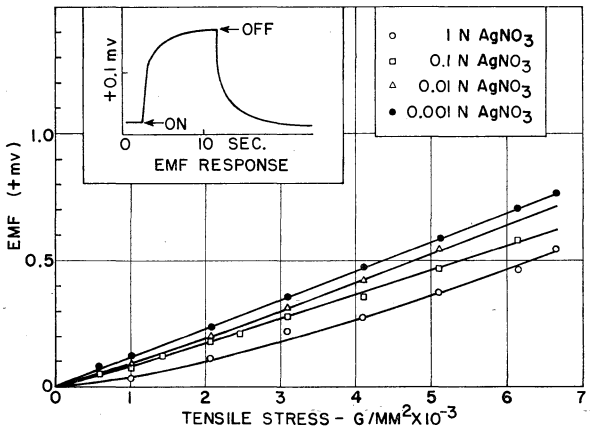

FIG. 1. Electromotive force of stressed silver electrodes.

increased monotonically with time and approached a steady-state value asymptotically (i.e., became more noble). With the removal of the load the electrode potential returned to the original no-load value in the same manner, but in the opposite sign direction to the loading process.

The experimental results of the silver – silver nitrate cells are shown in Fig. 1. For each concentration the e.m.f. values were approximately a linear function of the tensile stress. The slope of the e.m.f.–stress curve increased with decrease in concentration.

The effects of electrolyte concentration on the potentials induced by stress of silver electrodes were similar to those recently reported for copper and zinc-plated copper (3). The similarity lies between the steady-state potential of silver and the maximum amplitude of the potential response of copper. The maximum amplitude of the potential response was not the steady-state potential for copper as it was for silver. For copper, the maximum potential response attained during the transient period was explained by theoretical considerations of the electrical double-layer. The following equation was derived for the maximum transient potential, $\Delta E = -1(1-\mu)E_{0\epsilon}$ where μ is Poisson's ratio for the metal electrode, ϵ is the strain, and E_0 is the electrical potential across the double-layer at no-load. Since E_0 is a function of concentration and determined from the Nernst relation, ΔE is expressed as a function of strain and electrolyte concentration.

Fryxell and Nachtrieb (2) investigated silver electrodes (99.98% pure) in 0.1 M silver nitrate solutions. They observed that the e.m.f. was stable and reproducible for silver stressed in elastic tension and compression. Their e.m.f. measurements were taken with a Leeds and Northrup K2 potentiometer and, as a consequence, they were not able to record a continuous e.m.f.–time response. They did not observe any e.m.f. dependence

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

on concentration. Their results indicated that the e.m.f. of the silver electrodes was linear with stress up to 10,000 p.s.i. with a slope of 0.078±.021 mv per 1000 p.s.i. The slope of the e.m.f.–stress curve obtained in this investigation for silver in 0.1 *M* silver nitrate solution was 0.067 mv per 1000 p.s.i., which is in good agreement with the results of Fryxell and Nachtrieb.

The e.m.f.–time response and the e.m.f.–tensile stress results for the brass – copper sulphate cells* are shown in Fig. 2. The e.m.f. induced by stress was measured in the

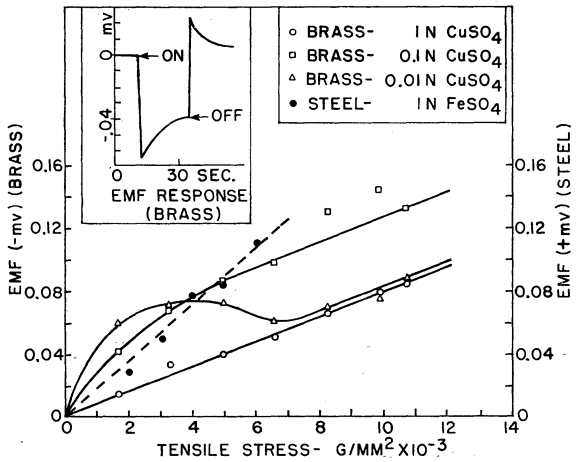

FIG. 2. Electromotive force of stressed steel and brass electrodes.

tensile stress range from 0 to 10,800 g/mm². The electrolyte concentrations were 1 *N*, 0.1-*N*, and 0.01-*N* copper sulphate solutions. On loading, the test electrode shifted to a more negative potential with respect to the reference electrode. During the transient period, the e.m.f. attained a maximum value almost instantaneously and decayed exponentially to a steady-state value. The removal of the load resulted in a mirror image of the e.m.f.–time curves for the loading process. The e.m.f.–time responses were similar to those reported for copper (3). The steady-state potentials for the brass were considerably different from the no-load value. The potentials of the copper, however, approached asymptotically the no-load potential.

E.m.f.–stress data for the steel cell were obtained only for the 1 *N* ferrous sulphate solution and are shown in Fig. 2. The e.m.f.–time reponse curve is not shown since it was similar to the silver – silver nitrate cell. However, the relaxation time for steel was somewhat less than for silver. The e.m.f.–time responses were both reproducible and reversible as the silver and brass cells. The stressed electrode shifted to a more positive potential with respect to the unstressed electrode. Runs with lower concentrations of ferrous sulphate were attempted, but the data were not reproducible within each run since steady-state conditions were difficult to attain at those concentrations.

Giulotto (4) observed for iron in 0.05 *N* $FeSO_4$ that the stressed electrode assumed more positive potentials than the unstressed electrode. His results indicated a linear relationship between e.m.f. and tensile stress with a slope of 80 microvolts per 10,000 p.s.i. The data obtained in this investigation of mild steel (99.8% Fe) in 1 *N* $FeSO_4$ resulted in an e.m.f.–stress slope of 129 microvolts per 10,000 p.s.i. and compares reasonably well with Giulotto's results for iron.

**Flood's analysis does not apply to brass–*$CuSO_4$ cells.*

WALLACH REARRANGEMENT OF UNSYMMETRICALLY SUBSTITUTED AZOXYBENZENES AND OXIDATION OF AZO DERIVATIVES[1]

JOGINDER SINGH,[2] PRITAM SINGH, J. L. BOIVIN, AND PAUL E. GAGNON
Department of Chemistry, Laval University, Quebec, Que.
Received August 22, 1962

ABSTRACT

The Wallach rearrangement of 3-chloro-3′-methyl- and 3-methyl-3′-nitro-azoxybenzene gave rise to the corresponding 4′-hydroxyazo derivatives with the hydroxyl group attached to the benzene ring adjacent to the trivalent nitrogen bridge, while 2,2′,5,5′-tetrachloro-4′-nitro- and 2′-nitro-4,4′,5,5′-tetrachloro-azoxybenzene were hydroxylated in the ortho and para positions respectively on the ring adjacent to the pentavalent nitrogen bridge.

Oxidation of 3-methyl-3′-nitro- and 3-chloro-3′-methyl-azobenzene gave rise to the corresponding α-isomers, which was proved by the bromination and reduction products.

The ultraviolet and visible absorption spectra of the unsymmetrically and symmetrically substituted azo- and azoxy-benzenes prepared have been recorded and briefly discussed.

INTRODUCTION

In a previous paper (1), the nitration and reduction of some symmetrically substituted azo- and azoxy-benzenes were reported. It was thought of interest to apply the Wallach rearrangement to unsymmetrically substituted azoxybenzenes and also to study the oxidation of azo derivatives, and to correlate the ultraviolet and visible absorption spectra of unsymmetrically and symmetrically substituted azo- and azoxy-benzenes prepared to their degree of conjugation.

DISCUSSION OF RESULTS

Wallach Rearrangement

The Wallach rearrangement or the isomerization of azoxybenzenes to the corresponding *p*-hydroxyazobenzenes has been extensively studied. However, the reaction mechanism is controversial. There is one belief that the isomerization proceeds through a cyclic oxide intermediate as evidenced by the use of N^{15} and O^{18} (2, 3). There is another postulated mechanism in favor of ionic intermediates (4) which give rise to *p*-hydroxyazo compounds by nucleophilic attack of OSO_3H^- or OSO_2Cl^- and subsequent hydrolysis.

In this paper, the Wallach rearrangement was applied to some unsymmetrically substituted azoxybenzenes. The formation of only one corresponding hydroxyazo compound in the case of 3-methyl-3′-nitro- and 3-chloro-3′-methyl-azoxybenzene during Wallach rearrangement with chlorosulphonic acid and concentrated sulphuric acid indicates that the rearrangement proceeded through the same type of intermediate in both cases and is independent of the nature of the reagent used, the hydroxyl group being in the para position of the ring adjacent to the trivalent nitrogen bridge. The reaction mechanism might be shown by the following scheme involving monocation formation:

The Wallach transformation of the α-isomer 2,2′,5,5′-tetrachloro-4′-nitroazoxybenzene (1) gave the *p*-hydroxyazo compound, the hydroxyl group entering the benzene ring attached to the pentavalent nitrogen. Also in the case of the α-isomer 2′-nitro-4,4′,5,5′-tetrachloroazoxybenzene (1), the hydroxyl group entered the ring not containing the nitro group.

Oxidation

3-Methyl-3′-nitro- and 3-chloro-3′-methyl-azobenzene were oxidized with hydrogen peroxide in acetic acid at 85–90° C to give the corresponding azoxybenzenes. To ascertain the structure of the azoxy compounds, they were brominated and the bromo derivatives reduced to the corresponding amines. In the case of 3-methyl-3′-nitroazobenzene, the oxygen of the azoxy group proved to be adjacent to the benzene ring carrying the methyl group. The electron-repelling nature of the methyl group increases the availability of lone pairs of electrons of the nitrogen atom attached to the ring, while the electron-attracting effect of the nitro group on the other ring deactivates its adjacent nitrogen to the attack of electrophilic oxygen of peracetic acid (5).

3-Chloro-3′-methylazobenzene was also oxidized into the α-isomer of 3-chloro-3′-methylazoxybenzene. In this case, the attacking electrophilic oxygen went on the nitrogen adjacent to the benzene ring carrying the chlorine, as was shown by the bromination and reduction products isolated.

Ultraviolet and Visible Absorption Spectra

The absorption spectra of the symmetrically (1) and unsymmetrically substituted azo- and azoxy-benzenes synthesized have been determined in the ultraviolet and visible and the results are given in Tables I and II.

As usually observed with the azo- and azoxy compounds, three regions of absorption were exhibited; there were absorption bands in the regions 2100 to 2900 Å, 3000 to 3800 Å, and 4100 to 4300 Å.

In this work all the tetra-, penta-, or hexa-substituted azo- and azoxy-benzenes gave absorption bands in three main regions I, IA, and II. Region I showed a single peak of high intensity at about 2400 Å which is attributed to the substituted benzene rings (6). Region IA exhibited one band at about 2600 Å which is ascribed to the azophenyl group (6). Region II had, usually, a broad band of high intensity at 3000 to 4000 Å, which is explained by the conjugation of the azo linkage and the aromatic rings (6). On substitution of a nitro group at the 4′-position in tetrasubstituted azo- and azoxy-benzene and of bromine in disubstituted compounds, a pronounced bathochromic shift was observed. The transformation of 2,2′-disubstituted azo compounds to the corresponding azoxy compounds resulted in an hypsochromic shift (7).

2,2′-Dimethyl-3,3′-dichloroazo- and azoxy-benzene and their nitro derivatives showed

absorption bands at the same wavelength as 2,2′-dimethyl-5,5′-dichloro-azo- and -azoxybenzene and their nitro derivatives, but with different intensities. This effect was probably due to the chlorine atoms which are in meta position to the azo and azoxy groups.

However, the 4,4′-diacetylamino derivatives of 2,2′-dimethyl-3,3′-dichloro- and 2,2′-dimethyl-5,5′-dichloro-azoxybenzene showed different absorption bands in region II. This difference could be ascribed to the effect of different dielectric constants of the solvents used such as dioxane or N,N-dimethylformamide. The same effect was also noticed with 2,2′-dimethyl-3,3′-dichloro-4,4′-dinitroazobenzene and 2,2′-dimethyl-4,4′-dinitro-5,5′-dichloroazobenzene with ether and chloroform as solvents.

EXPERIMENTAL

3-Methyl-3′-nitroazobenzene

A solution of *m*-nitrosotoluene (5.0 g, 0.041 mole) in ethanol and acetic acid (50 ml, 1:1 by volume) was warmed to 50° C and poured quickly into a warm solution of *m*-nitroaniline (5.0 g, 0.036 mole) in glacial acetic acid (50 ml). After thorough mixing, the reaction was allowed to proceed at room temperature for 12 hours. The mixture was diluted with water and extracted with ether. The ethereal extract was washed first with a 10% solution of sodium hydroxide, then with dilute HCl, and finally with distilled water. The process was repeated until the aqueous layer in each case was colorless. The ether was evaporated and the residue was crystallized from ethanol, m.p. 80–81° C. Yield, 1.7 g (18.4%). Calc. for $C_{13}H_{11}N_3O_2$: N, 17.4%. Found: N, 17.6%.

3-Chloro-3′-methylazobenzene

m-Nitrosotoluene and *m*-chloroaniline reacted as above gave the azo compound in 48% yield, m.p. 65° C. Calc. for $C_{13}H_{11}N_2Cl$: Cl, 15.4%. Found: Cl, 15.3%.

Wallach Rearrangement

3-Chloro-3′-methyl-4′-hydroxyazobenzene

3-Chloro-3′-methylazoxybenzene (1.0 g, 0.004 mole) was dissolved in sulphuric acid (*d*, 1.84, 20 ml) and kept at room temperature for 1 hour. The mixture was diluted with water and the precipitate filtered. The solid was dissolved in aqueous sodium hydroxide (5%) and precipitated with dilute hydrochloric acid. Crystallization from petroleum ether (b.p. 65–110° C) gave red crystals, m.p. 128–130° C. Yield, 0.4 g (40%). Calc. for $C_{13}H_{11}N_2OCl$: Cl, 14.4; N, 11.3%. Found: Cl, 14.2; N, 11.4%. Reduction with Sn and HCl gave 2-hydroxy-5-aminotoluene, which was identified as the dibenzoyl derivative, m.p. 194° C (lit. 194° C) (13). When sulphuric acid was replaced by chlorosulphonic acid at −8° C, the same results were obtained (13).

The other hydroxyazo compounds were prepared by the same method as above from the corresponding azoxy derivatives (1) and identified by the isolation of the reduction products as indicated in Table III.

Oxidations

3-Chloro-3′-methylazoxybenzene

3-Chloro-3′-methylazobenzene (2.3 g, 0.0099 mole) was dissolved in a mixture of glacial acetic acid (80 ml) and hydrogen peroxide (30%, 20 ml) and the solution stirred on a water bath for 6 hours. After dilution with water, the solid was filtered and crystallized from petroleum ether (30–65° C), m.p. 57–58° C. Yield, 2.4 g (99%). Calc. for $C_{13}H_{11}N_2OCl$: Cl, 14.4%. Found: Cl, 14.3%.

Bromination of 3-Chloro-3′-methylazoxybenzene

3-Chloro-3′-methylazoxybenzene (2.0 g, 0.0081 mole) was dissolved in glacial acetic acid (15 ml) and treated with an acetic acid solution of bromine (30%, 15 ml). A tiny crystal of iodine was added and the mixture heated on a water bath. After 1 hour, the reaction mixture was diluted with water and the excess bromine destroyed with sodium sulphite. Extraction with ether and crystallization from hot ethanol gave a bromo compound, m.p. 124° C. Yield, 1.1 g (33.5%). Calc. for $C_{13}H_9N_2OBr_2Cl$: BrCl, 48.8%. Found: BrCl, 46.9%. This compound gave a positive fluorescein paper test (14) for bromine. On reduction with Sn and HCl and subsequent benzoylation, a benzoyl derivative was prepared. Purification by chromatography on alumina (activity 3) and elution with petroleum ether (b.p. 65–110° C) gave a crystalline compound of m.p. 120° C in the first fraction. This compound did not depress the melting point of the benzoyl derivative prepared from *m*-chloroaniline. The second fraction came down as an oil which could not be crystallized. However, the positive fluorescein paper test showed the presence of bromine.

3-Methyl-3′-nitroazoxybenzene was obtained by the above method, m.p. 102–103° C. Calc. for $C_{13}H_{11}N_3O_3$: N, 16.3%. Found: N, 16.5%. It was brominated to give a compound melting at 111–112° C. Calc. for $C_{13}H_{10}N_3O_3Br$: Br, 23.8%. Found: Br, 24.0%. This bromo derivative was reduced and benzoylated as above to yield the dibenzoyl derivative of 1,3-diamino-4-bromobenzene, m.p. 186° C, and the monobenzoyl derivative of *m*-toluidine, m.p. 124° C.

PROTONATED γ-PYRONES*†

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received October 3, 1962

ABSTRACT

The vibrational spectra of several salts of 4-pyrone and 2,6-dimethyl-4-pyrone have been measured in the solid state. Deuterium replacement has been used to identify motions of the hydrogen atom which is located on the carbonyl oxygen atom and forms a hydrogen bond with the anion.

Bands due to OH stretching vibrations have been observed from 2086 cm^{-1} in the HCl salt to 3310 cm^{-1} in the hexachloroantimonate of 2,6-dimethyl-4-pyrone. In-plane hydrogen-deformation modes of the OH group have been found near 1300 cm^{-1} with a much smaller range in the different salts than the stretching vibration. For the 4-pyrone salts the OH stretching vibrations were at similar frequencies, and the in-plane hydrogen-deformation frequencies were close to 1340 cm^{-1}. Bands due to the out-of-plane deformation were not observed.

Aqueous solutions of 2,6-dimethyl-4-pyrone hydrochloride at various concentrations showed the presence of both protonated and neutral molecules.

INTRODUCTION

A comparison of the vibrational spectra of several Lewis acid complexes of 2,6-dimethyl-4-pyrone with that of the pyrone hydrobromide has clarified the assignments of γ-pyrones and also shown that the carbonyl oxygen atom was the basic site and not the heterocyclic oxygen atom (1).

These results are part of a general emerging pattern which shows, contrary to previous views, that carbonyl oxygen atoms can often be more basic than ether oxygen atoms. The circumstances leading to enhanced basicity in carbonyl groups have been discussed in detail (2, 3). The γ-pyrones satisfy most of the required conditions.

The basic nature of the γ-pyrones has been known for over 50 years since the pioneering work of Collie and co-workers (4). The structural details, however, were clouded by new conceptions on the quadrivalence of oxygen, based on ultraviolet absorption spectra (5), then a newly emerging art. Thus the heterocyclic oxygen atom was regarded as the basic site, partly by analogy with the alleged salt of dimethyl ether with HCl, which showed up as a dystectic point in an equimolar mixture of the two components (6). The concept of the hydrogen bond was not, of course, known at that time.

With the advance of modern spectroscopic methods, coupled with a fund of knowledge of spectroscopic behavior of many compounds, came a re-evaluation of the situation. Wolkenstein and Syrkin (7) examined the Raman spectrum of 2,6-dimethyl-4-pyrone hydrochloride in aqueous solution, and after noting little difference between the salt and the pyrone pronounced the carbonyl group as the protonation site. Similar conclusions were reached by Kahovec and Kohlrausch (8). The infrared spectra of several thiapyrones were recorded by Tarbell and Hoffman (9), who favored protonation of the carbonyl group in salts of such compounds. Phillips (10) deduced from the Raman spectrum of an aqueous solution of 4-pyrone hydrochloride that protonation was most likely to occur at the carbonyl oxygen atom. Tsubomura (11) also commented on some

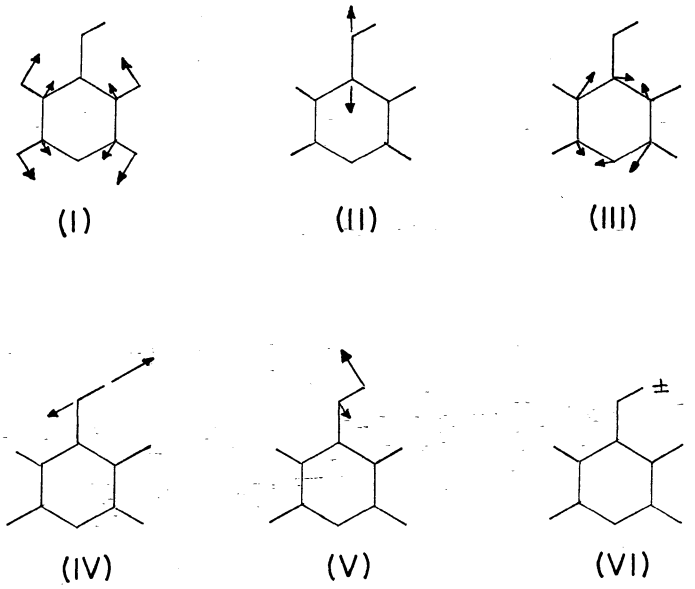
similar compounds. Crystallographic data for the hydrobromide (12) revealed a monoclinic crystal with the following parameters: $a = 6.89$ Å; $b = 15.52$ Å; $c = 15.51$ Å; $\beta = 94.9°$. There were eight molecules per unit cell.

In order to make confident assignments for the vibrations involving the proton a series of γ-pyrones salts has been prepared, along with some deuterated analogues, and their infrared spectra recorded with a prism-grating spectrometer.

RESULTS AND DISCUSSION

2,6-Dimethyl-4-pyrone Salts

The infrared absorption bands in the various recorded spectra are collected in Table I. As shown previously (1) the bands near 1490 cm^{-1} are due to carbonyl stretching vibrations (II), the 1645 cm^{-1} bands being the C=C stretching mode, or a ring vibration having these characteristics, as in I. The strong band near 1555 cm^{-1} must also be due to a ring mode (III) involving stretching of C=C bonds (see below).



The prominent feature in the spectrum of the hydrochloride at 2086 cm^{-1}, with several subbands on either side, can only be due to the motion of a hydrogen atom attached to the carbonyl oxygen atom (IV). Its breadth, intensity, and position are all consistent with a strong interaction between the hydrogen atom and the halide ion. The frequencies and approximate half-widths of these bands for different anions are collected in Table II.

The behavior on deuteration has been observed for many of the salts studied and is quite characteristic of hydrogen bond formation. The OH bands move to lower frequencies, as shown in Table II, with a ratio of ν_{OH}/ν_{OD} close to 1.3. This is in keeping with a fairly pure hydrogen stretching motion.

The behavior of a protonated molecule forming a hydrogen bond with an anion had been discussed previously for pyridinium salts (13 and references therein to other systems). The pyrone salts presently considered exhibit a very similar behavior to the pyridinium series. As the size of the anion increases and the force field weakens the band attributed to the OH stretching vibration recedes to higher frequency. However, there is not a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

great deal of evidence of significant sharpening of the bands, as some half-widths in Table II show. Nor is there any gross change in the intensity of the band in its passage to higher frequencies. While these measurements of intensity and half-width can be at best only a rough guide, they should be internally consistent. The half-widths in the deuterated compounds, however, do show a significant decrease.

The in-plane hydrogen-deformation mode (V) has been assigned to a medium-strong band which occurs near 1300 cm^{-1} in most of the compounds. On deuteration this moves to about 1000 cm^{-1}, the ratio δ_{OH}/δ_{OD} being, again, about 1.3, showing that the vibration is a reasonably pure one with little coupling with other modes (see Table III). The other vibration with which the in-plane hydrogen-deformation mode might be expected to couple is the carbonyl vibration which is at about 1490 cm^{-1}. In alcohols, and probably phenols, coupling between ν_{CO} and δ_{OH} is likely, since both have similar force constants and frequencies. In the present case, however, a separation of about 190 cm^{-1} is sufficient to preclude serious interaction, as is shown by the negligible change in ν_{CO} on deuteration.

It has been asserted that strong hydrogen bonds are associated with low stretching frequency and high bending frequency of the XH bond. In the series of pyridinium salts recently described (13) only a very rough relation was found between ν_{NH} and δ_{NH}. In the present case similar behavior was observed. A plot of ν_{OH} against δ_{OH} revealed a general trend with an inverse proportionality but with a wide scattering of points.

Accompanying the 1300 cm^{-1} band a weaker absorption near 1240 cm^{-1} was always present. This band moved to lower frequency on deuteration, to near 945 cm^{-1}, the ratio being about 1.3, showing a fairly pure vibration. The possibility that this could be an overtone of a strong band near 600 cm^{-1}, perhaps due to a torsional OH (or out-of-plane) motion, was discounted since no strong band in this region was found when a spectrum was recorded on an instrument without the limitations of NaCl optics. The assignment to a CD bending mode was also rejected since no stretching vibration was visible, and there is evidence that the hydrogens in the 3-position in 2,6-dimethyl-4-pyrone do not readily exchange (10). Coupling of the deformation mode in the unit cell seems the most likely cause of the splitting of this band, especially since the unit cell of the HBr salt is known to contain eight molecules (12).

The in-plane hydrogen-deformation mode being reasonably well assigned, an out-of-plane bending mode would be expected. No band has been found, however, in the appropriate place and with the right shift on deuteration. It must be concluded that this band is too low in frequency to be observed on a spectrometer equipped with sodium chloride optics.

Several other assignments are suggested in Table I, based on previous experience (1) and by comparison with similar molecules (10).

Aqueous Solutions of 2,6-Dimethyl-4-pyrone Hydrochloride

Previous studies of the Raman spectra of aqueous solutions of γ-pyrone salts (7, 8, 10) revealed very small differences between the spectra of the neutral pyrone and the salts. These small differences resulted in the assignment of the carbonyl oxygen atom as the probable protonation site. In view of the obvious differences between the infrared spectra of the neutral molecule and the salts, the aqueous solution spectra were required to explain these conflicting views. The bands in the spectra of aqueous solutions are shown in Table IV.

The spectrum of 2,6-dimethyl-4-pyrone in aqueous solution shows clearly two main strong bands at 1660 and 1582 cm^{-1}. These are assigned respectively to the ring mode I and the carbonyl vibration. The lower value of ν_{CO} in aqueous solution must be due

to a hydrogen-bonded species CO···H—OH. These values of ν_{CC} and ν_{CO} fall reasonably well on a curve constructed from the values previously quoted in 2,6-dimethyl-4-pyrone complexes (1).

In the spectra of aqueous solutions of 2,6-dimethyl-4-pyrone hydrochloride, a band near 1490 cm^{-1} due to the carbonyl vibration of the protonated molecule should be observed. In aqueous solution the carbonyl proton may be hydrogen bonded, not to the Cl^- ion, as in the solid, but to the oxygen atom of a water molecule, and it would therefore be reasonable to assume a change in ν_{OH}. Such an interaction would not be expected to cause much alteration in ν_{CO} (for example, in $CHCl_3$ solution the hydrochloride has a carbonyl frequency at 1490 cm^{-1}, in almost exactly the same place as in the solid phase).

The spectra of the aqueous solutions do show the 1490 cm^{-1} band, indicating the presence of the protonated species, and this band gets more intense relative to other

bands as the solution gets stronger. All the solutions gave spectra containing two doublets, at about 1660 and 1642 cm^{-1} and at about 1582 and 1555 cm^{-1}. Their intensities vary with the concentration. The low-frequency component of each doublet increases in intensity relative to the high-frequency one with increasing solution strength. Both these doublets are broad. The higher-frequency pair of bands is due to a C=C vibration (I) and indicates a proportion of both neutral and protonated species. The lower-frequency pair is not related, the 1582 cm^{-1} band being ν_{CO} interacting with H_2O, the 1555 cm^{-1} band being another ring mode (III). (See Table I.) This band was not confidently assigned previously (1) as in many of the complexes it was obscured by other bands.* The intensities again, though, indicate the presence of both species. The two sets of bands, together with the 1490 cm^{-1} band, show that the more dilute the solution the less the proportion of protonated material. Bands lower in frequency than 1400 cm^{-1} appear at about the same frequency in both materials.

It appears possible therefore to offer an explanation of the statement made previously that the Raman shifts in protonated and neutral molecules, *in aqueous solution*, are so similar (7, 8). In the Raman effect the OH stretching vibration produces only weak bands. The perturbed carbonyl vibration may also be expected to give rise to a weak band, since the protonated species has only C_s symmetry. For these reasons, therefore, the 2086 and 1490 cm^{-1} shifts were overlooked and the 1642 and 1555 cm^{-1} shifts regarded as due to the same vibration as in the neutral molecule. The broadness of the bands and the difficulty of exactly measuring the center also added complications.

**The spectrum of 2,6-dimethyl-4-thiopyrone contains two strong bands at 1640 and 1559 cm^{-1}. Since the* CS *stretching vibration is well removed from this region these two bands can be attributed to vibrations of type I and III respectively. In the* HBr *salt, these two bands are little changed in position at 1632 and 1528 cm^{-1}.*

It is significant that Wolkenstein and Syrkin (7) quoted a medium line at 1494 cm^{-1} in the aqueous solution of 2,6-dimethyl-4-pyrone hydrochloride, while the neutral molecule in aqueous solution had a very weak line at 1493 cm^{-1}. Kahovec and Kohlrausch (8) did not observe this line. The former authors used a solution approximately 2.3 *M* in the salt whereas the German authors used a solution of about 0.4 *M* (2 g hydrochloride in 5 ml H_2O).

4-Pyrone Salts

The bands in the spectra of 4-pyrone salts are shown in Table I; the OH stretching vibrations occur in positions similar to those of the 2,6-dimethyl-4-pyrone salts and show similar movements on deuteration (see also Table II). The in-plane hydrogen-deformation frequencies are close to 1340 cm^{-1} and, as for the 2,6-dimethyl-4-pyrone salts, are accompanied by a lower-frequency band near 1200 cm^{-1} (see Table III). On deuteration both bands disappear to be replaced by two new bands near 1050 and 1000 cm^{-1}. The ratios 1340/1050 = 1.28 and 1200/1000 = 1.20 indicate that mechanical effects may have some role in the value of the lower frequency. If the alternative ratios are considered, 1340/1000 = 1.34 and 1200/1050 = 1.14, then the higher-frequency band behaves normally, but the low ratio for the 1200 cm^{-1} band is difficult to understand.

The carbonyl vibration in the 4-pyrone salts also comes close to 1490 cm^{-1} and the C=C stretching vibration (I) moves to lower values in the salts, 1610 cm^{-1} compared with 1660 cm^{-1} in the neutral pyrone. The existence of some mechanical interaction between these two vibrations in the neutral pyrone, as proposed by Phillips (10), is therefore confirmed. These similarities between 4-pyrone and 2,6-dimethyl-4-pyrone are reasonable, and to be expected, as the replacement of a hydrogen atom by a methyl group is not expected to result in large changes in the properties of the carbonyl group, or its ability to protonate.

A few weak bands have been noticed in the 4-pyrone deuterated salts that have no analogue in the normal salts. These were at 1528, 1320, and 1229 cm^{-1} in the DCl salt, and at 1530, 1318, and 1226 cm^{-1} in the DBr salt. These must be attributed to combination tones or overtones of some band or bands associated with a low-frequency vibration involving the OD group. Strong bands in the 4-pyrone salts at 1185, 941, and 848 cm^{-1} could be combined with low-frequency vibrations at about 368 and 290 cm^{-1}, giving the following possible summation tones: 1185+368 = 1553 (1530); 941+368 = 1309 (1320); 941+290 = 1231 (1230); 848+368 = 1216 (1230). In the absence of a study of the deuterated molecules in the low-frequency region little progress can be made with these assignments. The possibility that exchange occurred between the ring protons and the deuterium in the acid is present, but is considered small since no indication of CD stretching absorption bands was noted.

In support of the assignments made for γ-pyrone salts the spectra of many 4-pyridone salts show almost identical features (14). The proton stretching bands occur in the same region and move to higher frequencies as the anion gets larger. The in-plane hydrogen-deformation vibration is near 1300 cm^{-1} (and is also doubled), moving close to 1000 cm^{-1} on deuteration. This is so similar to the 4-pyrone series that a similar structure, i.e. protonated at the carbonyl group, is suggested. Nuclear magnetic resonance experiments have been interpreted as being consistent with this view (15). N-Protonation can be rejected on a further count; such a structure would be similar to tertiary amine salts, which have bending modes near 1400 cm^{-1}, for example, trimethylamine salts,

For personal use only.

1420 cm^{-1} (16, 17); N-alkylpiperidine salts, 1400 cm^{-1} (14); triphenylamine salts, 1390 cm^{-1} (17). The absence of a band near 1400 cm^{-1} with the appropriate shift on deuteration is strong evidence against N-protonation.

EXPERIMENTAL

The Spectra

A Perkin–Elmer model 221 prism-grating spectrometer was used to record the spectra. Solid-state spectra were of emulsions of the finely ground solid in nujol and fluorolube. Aqueous solution spectra were of thin films trapped between Irtran plates. Difference spectra were obtained by inserting a thin film of water between Irtran plates in the reference beam. A trial and error method of exact compensation was used by varying the pressure on the plates. While small differences in intensity were noted in various spectra no shifts in position in bands below about 1700 cm^{-1} were observed. The water bands in the 3-μ region varied considerably, but have not been used for diagnostic purposes.

2,6-Dimethyl-4-pyrone Salts

2,6-Dimethyl-4-pyrone was prepared from dehydroacetic acid by boiling with concentrated HCl followed by evaporation of the liquid to give the hydrated HCl salt. This was then recrystallized from pyridine to give the pyrone, which was then recrystallized from methanol. M.p. 131–133°.

Hydrochloride.—1 g 2,6-dimethyl-4-pyrone in 10 ml $CHCl_3$ and 50 ml ether when treated with anhydrous HCl gave a copious precipitate of the salt. M.p. 153–155°. This was used without further treatment. Due to its hygroscopic nature and ready hydration to the dihydrate it was handled in a dry box. To prepare the DCl salt a CCl_4 solution of the anhydrous pyrone was treated with excess DCl in a vacuum system. The excess DCl and all solvent were removed by evacuation, the solid being subsequently handled in a dry box.

Hydrobromide.—Exactly the same techniques as for the HCl salt were used. M.p. 192–193°. DBr was used to make the deuterated salt.

Hexabromostannate.—The hydrobromide was prepared as above, and redissolved in $CHCl_3$. Excess $SnBr_4$ then precipitated a white deposit of the hexabromostannate. M.p. 195–197°.

Hexachlorostannate.—Same procedure using $SnCl_4$. M.p. 210–213°.

Hexachlorotitanate.—Same procedure using $TiCl_4$. Dry box handling was necessary.

Hexachloroplatinate.—1.24 g 2,6-dimethyl-4-pyrone was dissolved in 20 g 10% aqueous $H_2PtCl_6 . 6H_2O$. After 4 days light brown crystals started forming. M.p. 188–190°. The deuterated material was made by twice exchanging with a 100-fold excess of D_2O and removing the excess D_2O *in vacuo*.

Hexachloroantimonate.—The procedure for the hexabromostannate was followed but with HCl and $SbCl_5$. M.p. 92–94°.

Hydroiodide.—Aqueous HI was shaken with ether, the ethereal layer after separation being added to a solution of the pyrone in a little $CHCl_3$ and excess ether. The pale yellow solid so formed was used without further purification. M.p. 176–179°.

Perchlorate.—1.68 g aqueous 70% perchloric acid was added to 1.24 g pyrone in 3 ml H_2O, and excess H_2O removed *in vacuo*. M.p. 78–80°.

Trichloromercurate.—An acetone solution of the pyrone:$HgCl_2$ complex was treated with dry HCl gas, and a deposit of the solid was found when the excess solvent was removed on a vacuum line. M.p. 118–120°.

Hexachlorozirconate.—A solution of the pyrone.HCl in $CHCl_3$ was added to a $CHCl_3$ solution of $ZrCl_4$, giving a white precipitate of the complex salt. M.p. 257–259°.

Aqueous Solutions

Aqueous solutions of 2,6-dimethyl-4-pyrone hydrochloride were prepared from the dihydrate. Solutions 1.0, 2.5, and 5.0 *M* were used. The solution of the pyrone in water was 2.5 *M*.

4-Pyrone Salts

4-Pyrone was prepared by the decarboxylation of chelidonic acid by heating with copper powder to about 300° C.

Hydrochloride.—Dry HCl gas was passed into a solution of pyrone in $CHCl_3$ and ether. The white solid so formed, m.p. 132–134°, was used without further treatment, and due to its hygroscopic nature, handled in a dry box. The deuterated salt was prepared from a CCl_4 solution of the pyrone and DCl using a high-vacuum apparatus. The excess fluid was decanted, leaving a white solid which was subsequently handled in a dry box. Attempts to remove solvent by evacuation resulted in decomposition of the solid.

Hydrobromide.—The pyrone in a little $CHCl_3$ and excess ether when treated with HBr gas gave a white solid. An indeterminate melting point was observed with charring between 150° and 180°. The DBr salt was obtained from a benzene solution of the pyrone though not with complete isotopic exchange. All deuterated salts were made by exchange with excess D_2O unless otherwise stated. Melting points were taken in sealed capillary tubes and are uncorrected.

INFRARED SPECTRA OF COMPLEXES OF 4-PYRIDONES*†

DENYS COOK

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received October 19, 1962

ABSTRACT

The infrared spectra of many complexes of Lewis acids with some 4-pyridones have been recorded. Large shifts to lower frequencies of about 100 cm^{-1} have been observed in a band near 1560 cm^{-1} as the Lewis acid strength increased. Much smaller shifts of about 5 to 10 cm^{-1} in a band near 1640 cm^{-1} were noted. The former band has therefore been designated as the carbonyl frequency, and the latter as a ring mode involving CC stretching.

The donor site of 4-pyridones is therefore the carbonyl group, and not the nitrogen atom. Protonated 4-pyridones have similar spectra, and are consistent with O-, not N-protonation.

INTRODUCTION

In a recent paper (1) it was shown how the carbonyl frequency in 4-pyrones could be correctly identified by forming Lewis acid complexes of the pyrones and observing a very large shift to lower frequency for the carbonyl vibration, but a much smaller one for the other ring modes. A further point became clear in that 4-pyrones protonate at the carbonyl oxygen atom, and not at the heterocyclic oxygen atom (2).

In the 4-pyridones a situation similar to that in the 4-pyrones exists, namely, that a higher-frequency band at 1640 cm^{-1} (chloroform solution) and a lower-frequency band at 1560 cm^{-1} have not been clearly assigned. At first sight the 1640 cm^{-1} band would be assigned to ν_{CO} and the 1560 cm^{-1} band to ν_{CC}, a ring mode, probably similar to ν_8 in benzene. In 2,6-dimethyl-4-pyrone the carbonyl frequency in its unperturbed state (some slight interaction with the ring mode was observed) was found close to 1645 cm^{-1}. It would therefore be a little surprising to find a carbonyl frequency near 1640 cm^{-1} for the 4-pyridones. In 4-pyrones the degree of participation of the lone-pair electrons on the heterocyclic oxygen atom in ring conjugation was assumed to be small. In pyridones there is good reason for believing the N—R bond to be coplanar with the ring, with the nitrogen lone pair electrons in a $p\pi$-type orbital which can participate in an extended molecular orbital over all the heavy atoms. A lower bond order, and therefore frequency, should be expected for the carbonyl group in 4-pyridones than in 4-pyrones. The same sort of arguments have been used by Bellamy and Rogasch (3) in their paper on solvent shifts of polar bands in 1-methyl-4-pyridones.

A further objective of the present work was to investigate the ability of the ring nitrogen atom in 4-pyridones to coordinate Lewis acids or protons. It has been suggested that the 4-pyridone cation contains a quaternary nitrogen atom (4, 5), though some recent n.m.r. experiments have discounted this suggestion (6). It should be said that the present work is consistent with protonation at the oxygen atom and not at the nitrogen atom.

RESULTS

Table I shows the bands in the various spectra of 1,2,6-trimethyl-4-pyridone complexes. The band at 1635 cm^{-1} in the pure solid varies by only a few reciprocal centimeters

*Contribution No. 53.

in the complexes and in a random manner. The band at 1560 cm^{-1} in the pure 4-pyridone shows a trend to lower frequencies as the Lewis acid gets stronger.

This behavior is closely duplicated by the 1-ethyl-2,6-dimethyl-4-pyridone complexes. Table II shows the bands abstracted from the spectra. The absorption band at about 1638 cm^{-1} does not move consistently in any direction but is scattered around a central value of about 1638 cm^{-1}. This, and the other band at about 1550 cm^{-1}, are assigned to ring vibrations. The band at 1566 cm^{-1} moving progressively to 1461 cm^{-1} is the carbonyl stretching vibration. All other bands are in approximately constant position.

The hydrochloride of each pyridone has also been prepared and the bands are listed in the tables for comparison.

DISCUSSION

These new values for carbonyl frequencies of 4-pyridones shown in the tables appear much more reasonable when compared with other carbonyl frequencies, as was noted by Bellamy and Rogasch (3). Furthermore, they introduce additional support for the contention previously advanced that the heterocyclic oxygen atom in 4-pyrones does not participate, or at least, to a very small extent, in conjugation with the ring. In this connection the data in Table III are of interest. In the compounds in series II there is no change in carbonyl frequency when CH_2 (II*a*) is replaced by O (II*b*). Since little difference in geometry is expected in the two compounds, and inductive effects should be of secondary importance, the degree of interaction of the oxygen lone pair electrons with other π-electrons is inferred to be small. (A similar small degree of interaction has also been suggested for the alkoxy oxygen atom in phenyl acetate (7).) On NH-substitution, there is a significant drop in frequency in both series, I*c* and II*c*, a certain amount of which is due to hydrogen bonding. When the opportunity for this is removed by alkyl substitution (I*d*), the compound still has a lower frequency than the oxygen compound (I*b*), and all other things being equal, must be due to a lower bond order in the CO group. Furthermore, while anthrone (II*a*) and xanthone (II*b*) are both nearly colorless, acridone (II*c*) has a pronounced yellow color.

The carbonyl frequency shifts observed on complex formation seem a little smaller than the corresponding shifts in the 4-pyrone series. In the present series the largest one is about 100 cm^{-1}, while in the 4-pyrone series it was about 150 cm^{-1}. These figures are not strictly comparable since the same Lewis acids were not used in each series. One would have expected larger shifts for the 4-pyridones than for the 4-pyrones, on the assumption that the former are better donors than the latter. (Susz has recently summarized (8) the results of carbonyl shifts in various complexes of ketones with Lewis acids, and found that the shift, $\Delta\nu$, for the same Lewis acid increased in the series acetone < 4-heptanone < acetophenone < benzophenone. This is in the order of decreasing carbonyl frequency, ionization potential, and therefore increasing donor ability (7, 9).) There are a few irregularities in the shifts that one particular Lewis acid generates with different donors. In some unpublished work on xanthone complexes the BBr_3 complex gives next to the BI_3 complex the largest shift, whereas in the 4-pyridones $TiCl_4$ and $SbCl_5$ give larger shifts. The xanthone complex shifts have been compared with the ethyl acetate shifts measured by Lappert (10), and though the general orders are similar there are some anomalies.

It should be emphasized at this point that in the complexes little variation occurs in the position of any band with the exception of that due to the carbonyl stretching vibration, which is perturbed to lower frequency, and is an acceptable criterion of complex

formation at the carbonyl oxygen atom. Additional evidence is now available which helps to confirm this view. The evidence is derived from studies of complexes of Lewis acids with heterocyclic molecules, in which the donor atom is the ring heterocyclic atom. Pyridine complexes have been exhaustively studied (11–17) and experiments are in progress in this laboratory with complexes of benzothiazole, benzoxazole, and similar compounds. The conclusion being formed is that these complexes reveal spectra quite different from the parent heterocycle, but that over the whole range of Lewis acids the spectra remain remarkably similar to each other, with but minor changes in frequency in some bands. In the pyridine complexes it has been noted that there seems to be a trend towards higher frequency in a band near 1000 cm^{-1} due to the breathing mode as the Lewis acid gets stronger (16). This is only about 20 cm^{-1}, however, and even this figure may be somewhat high as there was some discrepancy in the frequency of the compound at the head of the list, as determined in two laboratories. In benzothiazole and benzoxazole complexes the similarity of the spectra for different Lewis acids has been noted, but detailed analysis is not sufficiently advanced to be able to see if the trend as shown by the pyridine series is duplicated. The conclusion to be drawn is that a very useful method of distinguishing between complex formation at ring donor atoms, or at exocyclic donor atoms, is possible. The former give practically no change, or, at most, a slight increase in frequency in the breathing mode, while the latter give spectra having one band which shows a large, progressive decrease in frequency as the Lewis acid strength in the complex increases.

4-Pyridones protonate readily. The spectra of the protonated materials are very similar to those of the complexes, with additional bands due to the hydrogen vibrations. It has been suggested (3, 4) that the nitrogen atom was the protonation site, but n.m.r. studies have been interpreted as supporting protonation at the carbonyl oxygen atom (6). The results of the present work are in better agreement with the latter view. In the first place the carbonyl frequency is displaced to about 1480 cm^{-1}. Protonation at the nitrogen atom would have a minor effect on the carbonyl frequency, and would result in a shift to a higher frequency if anything, because of the inductive effect of the formal positive charge on the nitrogen atom. Secondly, protonation at the nitrogen atom would result in a structure similar to that of a tertiary amine salt.* These have bending frequencies at about 1400 cm^{-1}: trimethylamine salts, 1420 cm^{-1} (18); N-alkylpiperidine

**Although* HN^+ *stretching modes are analytically of little value, the* HN^+ *bending mode shows promise of being an excellent group frequency, and diagnostically very useful in determining the type of nitrogen atom.*

For personal use only.

salts, 1400 cm^{-1} (17); triarylamine salts, 1390 cm^{-1} (19). The pyridone salts have bands due to in-plane hydrogen deformations at about 1290 cm^{-1}, close to values for a hydrogen atom attached to a trigonal nitrogen or oxygen atom, for example, pyridinium salts, 1240 cm^{-1} (20); benzothiazolium salts, 1210 cm^{-1} (17); 4-pyrone salts, 1340 cm^{-1} (2); 2,6-dimethyl-4-pyrone salts, 1300 cm^{-1} (2); N,N-dicyclohexylacetamide salts, 1300 cm^{-1} (21). It is hoped to publish more details of the 4-pyridone salts shortly.

EXPERIMENTAL

The Spectra

A Perkin–Elmer model 221G prism-grating spectrometer was used to record the spectra. Those of solids were obtained as emulsions in nujol and fluorolube.

Materials

The compounds and complexes were prepared as follows.

1,2,6-Trimethyl-4-pyridone and Complexes

1,2,6-Trimethyl-4-pyridone was prepared from 2,6-dimethyl-4-pyrone by the reaction with methylamine. M.p. 241–243°. Hydrate 110–111°.

$CdCl_2$ complex was prepared from equimolar ethanolic solutions of each component. It was recrystallized from ethanol. M.p. over 300° C.

$HgCl_2$ complex was prepared by mixing hot acetone solutions of equivalents of each compound. The resulting white precipitate was recrystallized from acetone/methanol and melted at 191–193°. Found: C, 23.62%; H, 2.96%; N, 3.36%. Calc. for $C_8H_{11}NO.HgCl_2$: C, 23.5%; H, 2.70%; N, 3.43%.

$ZnCl_2$ complex was prepared in the same way as for the $HgCl_2$ complex. M.p. over 300°. Found: C, 35.77%; H, 3.94%; N, 5.09%. Calc. for $C_8H_{11}NO.ZnCl_2$: C, 35.2%; H, 3.94%; N, 5.09%.

$CaCl_2$ complex was prepared from acetone/ethanol solutions of equivalents, giving a white solid. M.p. over 300°.

$SnBr_4$ complex was obtained by adding 1 equiv of $SnBr_4$ to a $CHCl_3/CCl_4$ solution of 2 equiv of the pyridone. The precipitate was used without further treatment after filtering in a dry box. M.p. 284–286°

HCl salt was made from a solution of the pyridone in a little absolute ethanol and excess ether by saturating with HCl gas. The solid hydrochloride melted at 260–261°. Found: HCl, 22.2%. Theory: HCl, 22.36%.

1-Ethyl-2,6-dimethyl-4-pyridone and Complexes

The pyridone was prepared by the reaction of 2,6-dimethyl-4-pyrone and ethylamine. M.p. 158–161°. Hydrate 72–74°.

HCl salt was precipitated from a solution of the pyridone in a little dry ethanol and excess ether with HCl gas. M.p. 242–244°. Found: HCl, 19.2%. Theory: HCl, 19.44%.

$CoCl_2$ complex was prepared by mixing equivalents of hot ethanolic solutions of the two components, giving a deep blue solid on cooling. M.p. 267–269°. Found: C, 49.84%; H, 5.41%; N, 6.29%. Calc. for $(C_9H_{13}NO)_2.CoCl_2$: C, 50.0%; H, 6.02%; N, 6.48%.

$CdCl_2$ complex was prepared in the same way. M.p. 258–261°. Found: C, 31.65%; H, 3.74%; N, 4.00%. Calc. for $C_9H_{13}NO.CdCl_2$: C, 32.3%; H, 3.89%; N, 4.19%.

$HgCl_2$ complex precipitated when hot acetone solutions of equivalents were mixed and cooled. M.p. 165–167°. Found: C, 25.60%; H, 3.32%; N, 3.25%. Calc. for $C_9H_{13}NO.HgCl_2$: C, 25.6%; H, 3.08%; N, 3.32%.

$ZnCl_2$ complex crystallized when warm solutions of an equivalent of each component in acetone were mixed and allowed to cool. M.p. 257–262°. Found: N, 4.89%. Calc. for $C_9H_{13}NO.ZnCl_2$: N, 4.88%.

$SnBr_4$ complex was precipitated when 1 equiv of $SnBr_4$ in CCl_4 was added to 2 equiv of the pyridone in a little $CHCl_3$ and excess CCl_4. M.p. 110–114°.

BBr_3 complex was made by mixing CH_2Cl_2 solutions of equivalents in a small pyrex cell and removing excess CH_2Cl_2 on a vacuum line.

$TiCl_4$ complex was prepared in the same way. Found: C, 30.8%; H, 4.06%. Calc. for $C_9H_{13}NO.TiCl_4$: C, 31.6%; H, 3.81%.

$SbCl_5$ complex was prepared by the addition of $SbCl_5$ to a $CHCl_3/CCl_4$ solution of the pyridone. M.p. 160–165°. Found: C, 24.18%; H, 3.42%; N, 2.94%. Calc. for $C_9H_{13}NO.SbCl_5$: C, 24.0%; H, 2.89%; N, 3.11%.

The preparations listed after the $ZnCl_2$ complex were performed throughout in the dry box. All melting points were determined in sealed capillary tubes and were uncorrected.

ACKNOWLEDGMENT

The technical assistance of Miss C. D. Anderson is gratefully acknowledged.

INFRARED SPECTRA OF XANTHONE:LEWIS ACID COMPLEXES*†

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received October 19, 1962

ABSTRACT

Xanthone, a member of the γ-pyrone species, which have basic carbonyl groups, forms an excellent series of solid complexes with Lewis acids. In these complexes the carbonyl oxygen atom is the donor site, and the carbonyl stretching vibration moves to progressively lower frequency as the Lewis acid strength increases. The carbonyl frequency in the BI_3 complex, 1400 cm^{-1}, is one of the lowest encountered in complexes of this type.

The wide range of Lewis acids used to form these complexes has enabled a quantitative estimate of the Lewis acid strength to be made, which compares reasonably well with previous estimates.

INTRODUCTION

The γ-pyrones have basic carbonyl groups and form salts with mineral and organic acids (1). They also form stable complexes with Lewis acids (2). The perturbation of the carbonyl stretching frequency in Lewis acid complexes of 2,6-dimethyl-4-pyrone was used recently to identify the carbonyl vibration in such pyrones, and to prove the site of protonation as the carbonyl oxygen atom. Later, all the vibrations due to motions of the proton were identified by the study of several salts and their deuterated analogues (3).

In the 2,6-dimethyl-4-pyrone complexes only a small range of Lewis acids was used. This was due in part to the ease with which the Lewis acid, MX_n, could be hydrolyzed (unless scrupulous precautions against adventitous moisture were taken) to produce halogen acids HX, which either protonated the pyrone directly, or in combination with the Lewis acid as $H^+MX_{n+1}^-$. Fortunately, xanthone is free from this limitation, as it forms solid protonated salts only with difficulty (4, 5). Thus a wide range of Lewis acids, including those susceptible to hydrolysis could be used without fear of protonation of the base.

The solid complexes so formed have been examined from the point of view of the Lewis acid's ability to coordinate the free electron pair of the carbonyl oxygen atom, for which the term Lewis acidity, or Lewis acid strength is used. A satisfactory criterion and comparison of Lewis acid strength is the free energy of formation of a complex having a coordinate bond between Lewis acids and a constant donor, in the absence of constraints due to steric factors. The technique of measuring such properties involving precise measurements of equilibrium constants and heats of mixing is painstaking and time consuming. In principle, the relative perturbation of the stretching frequency of a carbonyl group with different Lewis acids should give similar information (6). This criterion will be examined for the complexes discussed in this paper.

RESULTS AND DISCUSSION

Consideration of the spectra of the 2,6-dimethyl-4-pyrone complexes (2) led to the conclusion that the carbonyl stretching vibration and the double-bond stretching vibration (ring mode of A_1 species) were reversed in position, the CO vibration being at lower frequency but with a slight interaction between them. The unperturbed value

was estimated to be at about 1645 cm^{-1}. The value of ν_{CO} in xanthone, 1663 cm^{-1}, is an acceptable one, and is not subject to the same confusion as in 2,6-dimethyl-4-pyrone. Alteration of the character of the double-bond vibration at 1607 cm^{-1} in xanthone is doubtless part of the cause of this.

The infrared spectra of the xanthone complexes show that most of the absorption bands are hardly shifted in frequency, though minor alterations in intensity occur. The band attributed to the carbonyl stretching vibration at 1663 cm^{-1} in the free pyrone (CCl_4 solution) moves progressively to lower frequency in the Lewis acid complexes (Table I shows the frequencies attributed to this vibration). This has come to be regarded

as a satisfactory criterion of complex formation at a carbonyl group. The only other possible donor site in xanthone is the heterocyclic oxygen atom. A growing body of evidence (7) suggests that the Lewis acid complexes formed at a heterocyclic atom give spectra that are different from the parent heterocycle but are similar amongst themselves. A small trend, about 20 cm^{-1}, in the breathing mode, ν_1, in pyridine complexes was noted as the Lewis acid was altered (8).

The absorption band due to the carbonyl stretching vibration in the complexes is not difficult to recognize as it is usually the strongest band in the spectrum. Occasionally, when the perturbed frequency is close to another band, such as the 1607 cm^{-1} band, a little difficulty was observed, though the intensity criterion usually permitted a good choice. Some slight interaction may be present, too, to shift the ring modes somewhat. The perturbation of the carbonyl frequency is very large for some of the stronger Lewis

For personal use only.

acids; $\Delta\nu_{CO}$ for the BI_3 complex is 263 cm^{-1}, the carbonyl frequency being 1400 cm^{-1}. This is a good deal larger than the largest previously reported, which is 191 cm^{-1} in the BBr_3 complex of ethyl acetate (6). This may be connected with the fact that the carbonyl group in xanthone is more polarizable than that in ethyl acetate.

Electron deficiency in Lewis acids and the lack of quantitative data on the acid strength has been discussed by Lappert (6). The basis for his scale of relative acid strength was the shift in ν_{CO} in the Lewis acid complexes of ethyl acetate. These measurements are compared with the present ones in Table I, along with some from other Lewis acid complexes. In Table II the xanthone measurements are compared with results on relative

‖Relative acid strength increases down each column. Values in parentheses are misplaced compared with the xanthone values.

Lewis acid strengths derived from colorimetric studies (9), acylation rates (10), and general Friedel–Crafts activity (11, 12). There are many discrepancies. Since the reaction mechanisms in the substitution reactions are not known, the precise significance of the rate measurements is in doubt. If the same mechanism operated in all cases this would simplify the issue, but at least two plausible mechanisms have been suggested (13).

It would be surprising, however, if better agreement were obtained between the spectroscopic measurements, because several factors can influence the interaction. There is first of all the question of the physical state of the complex. In principle, perturbations in gas phase complexes would give the most faithful indication of the Lewis acid strength, but it is almost certain that such measurements are impracticable. It is therefore important to compare measurements made on the same phase, so that lattice effects etc. may be comparable.* Secondly, and more important, is the effect of steric factors. Lappert has

*There is a small possibility, too, in open-chain compounds, for example, esters, that the angle C—C—O may be different in the complexes than in the free ester, due to lattice effects. These angular changes may have a mechanical effect on ν_{CO} (14) and may introduce some uncertainty. Such angular alterations would be expected to be negligible in heterocyclic compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

argued, without quoting supporting evidence, that steric limitations in ethyl acetate complexes are small. This view, in fact, is open to question, since it has recently been suggested that in some BF_3 complexes of carbonyl compounds even an α-methyl group results in some hindrance. Bulkier groups, therefore, would furnish even larger hindering agencies (15).

The effect of such hindrance is to prevent the closest approach of the Lewis acid to the carbonyl oxygen atom that would be demanded by purely electronic considerations. The perturbation of ν_{CO} would then be underestimated, and the Lewis acid would be apparently weaker than it should be. These effects would tend to be larger for Lewis acids with large central atoms of high valency bound to the larger halogen atoms.

This hindrance, of course, exists in xanthone complexes, and it may be even greater than that in the ethyl acetate complexes since the portion of the fused ring in xanthone next to the carbonyl group resembles an ethyl group. No quantitative estimate can be made in the absence of a knowledge of the dimensions of the molecule.

The conclusion to be drawn from the existing data seems to be that when the strength of a Lewis acid is quoted it is necessary to stipulate the base, or donor, against which this was measured. Efforts are being made to find donors which are free from undesirable properties. The principle requirements are:

(1) adequate donor ability to form stable, nonhygroscopic complexes;
(2) inability to form protonated salts;
(3) absence of bulky groups which cause hindrance;
(4) large polarizability of the functional group so that weak complex formation produces a large effect;
(5) absence of mechanical effects on the perturbed group.

None of the donors considered hitherto have satisfied all these requirements, and it may be that they are mutually exclusive. One compound which satisfies the first four, and possibly the fifth, is benzaldehyde, and complexes of Lewis acids with this donor are currently being studied.

Comments on the relative positions of the different Lewis acids will be deferred until more data become available with different donors.

EXPERIMENTAL

Materials

The complexes were prepared by familiar methods. The Lewis acid, if gaseous (BF_3, PF_5, BCl_3), was passed into a $CHCl_3$ solution of xanthone, diluted with excess Freon 113; if liquid ($SnCl_4$, $SnBr_4$, $TiCl_4$, $TiBr_4$, SbF_5, $SbCl_5$, BBr_3), it was added, in an inert atmosphere, to a $CHCl_3$ solution of xanthone; if solid, a solution of the Lewis acid ($CoCl_2$, $CaBr_2$, $HgCl_2$, $HgBr_2$, $ZnCl_2$, $BiCl_3$, $InCl_3$, $FeCl_3$, $FeBr_3$, $ZrCl_4$ in acetone, $CaCl_2$, $CdCl_2$ in ethanol, $AlBr_3$ in benzene, $AlCl_3$ in ether, BI_3 in carbon tetrachloride) was added to a solution of xanthone in the same solvent. Occasionally, if no solid phase was precipitated by these operations, evaporation of the solvent ($HgBr_2$, $ZnCl_2$, $BiCl_3$) or removal *in vacuo* ($InCl_3$, $FeCl_3$, $FeBr_3$, $ZrCl_4$) gave the required solid complex.

Analysis of the complexes (microanalytical methods for carbon and hydrogen, X-ray fluorescence spectroscopy for metal and halogen) revealed in all cases that could be determined (some complexes were too hygroscopic) a 1:1 stoichiometry, except 2-xanthone:3$CoCl_2$, 2-xanthone:$SnBr_4$. It is assumed that those compounds that were too sensitive for analysis were 1:1 compounds for Lewis acid types MX_2, MX_3, and MX_5, and 2:1 for the type MX_4. The spectra of all the compounds studied substantiated the formulation of the complexes as indicated.

Spectra

The spectra of the finely ground solids in emulsion in nujol and fluorolube were recorded on a Perkin–Elmer model 221 prism-grating spectrometer. For the complexes which were sensitive to atmospheric moisture all operations were carried out in a dry box.

PHASE EQUILIBRIUM STUDIES FOR THE TERNARY SYSTEM URANYL NITRATE – NITRIC ACID – WATER

J. GAUNT, I. J. BASTIEN, AND M. ADELMAN
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received June 5, 1962

ABSTRACT

Phase equilibrium studies were carried out on the system $UO_2(NO_3)_2$–HNO_3–H_2O between the temperatures of −10° C and +49.1° C over a wide concentration range of both $UO_2(NO_3)_2$ and HNO_3. No phase separation occurred above 49.1° C for the concentrations studied. The three hydrates of $UO_2(NO_3)_2$ were identified in the solid phase, and a new complex of $UO_2(NO_3)_2$, possibly $UO_2(NO_3)_2.3HNO_3$, was separated as the solid phase at higher nitric acid concentrations.

Studies on the hydrates of uranyl nitrate (1–8) have been carried out by several investigators as have solubility studies of aqueous solutions (9, 11) and crystallization temperatures (12).

Investigation of the three-component system $UO_2(NO_3)_2$–HNO_3–H_2O has, however, been confined to two limited studies, that of Coloni (12) on solubility at 25°, and that of Hart and Morris (13) on the crystallization temperatures of solutions of varying concentration.

In view of the increasing importance of more detailed data for the effective processing of uranyl nitrate solutions, this investigation was undertaken to obtain the phase diagrams for the three-component system over a wider range of temperature and concentration than was previously available from existing data. The system was studied at 49.1, 30.2, 0.0, and −10° C, and nitric acid concentrations up to 80%.

Uranyl nitrate hexahydrate, trihydrate, and dihydrate were found in the solid phase at nitric acid concentrations below 75%. In the regions of higher nitric acid concentration a fine crystalline solid was obtained whose composition, as suggested by the "method of wet residues" was $UO_2(NO_3)_2.3HNO_3$.

EXPERIMENTAL

The uranyl nitrate solutions were prepared by dissolving the uranyl nitrate hexahydrate in varying concentrations of nitric acid. In the regions of high nitric acid concentration, the hexahydrate was dissolved in more concentrated acid and the crystals obtained were redissolved in increasing concentrations of nitric acid and red fuming nitric, s.g. 1.59.

Each sample was saturated at a temperature above that at which the determinations were made and transferred to glass-stoppered bottles. The samples were then placed in constant-temperature baths regulated to give an accuracy of ±0.2° C. A minimum period of 48 hours was allowed to bring the samples to equilibrium.

Weighed samples of the liquid phases and residues were taken and diluted to appropriate volumes for analysis. The total uranium content was determined by titrating the reduced form with ceric sulphate (14), standardized against electrolytic iron. The nitric acid was determined by the direct titration method of Brothers *et al.* (15). All solid phases were analyzed by the "method of wet residues".

RESULTS

The compositions of the liquid phases are reported (Table I) in weight percent of uranyl nitrate and nitric acid. The percentage of water may be obtained by difference.

DISCUSSION

In studying the ternary system, the invariant points were not always obtainable; however, the general behavior of the system as shown in Fig. 1 is quite evident. Only in the

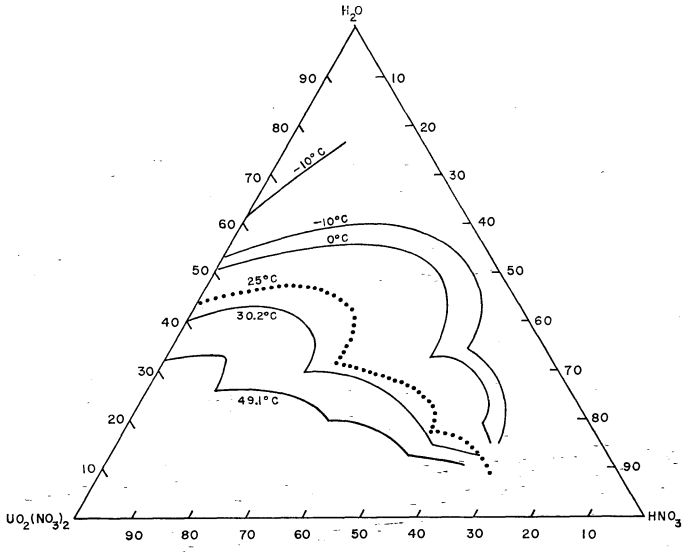

FIG. 1. Ternary system $UO_2(NO_3)_2$–H_2O–HNO_3: —solutions examined in the study; ... solubility data (12).

regions of high nitric acid concentration is the behavior of the system remarkable. It should, nevertheless, be pointed out that in order to obtain these concentrations of nitric acid, it was necessary to use red fuming nitric acid. Experimental difficulties make it improbable that a solid free of nitrogen dioxide may be obtained by equilibration at the temperatures indicated. It is assumed in this study that $UO_2(NO_3)_2.3HNO_3$ existed in the free state or a reaction occurred in the system. If the latter is feasible, other nitrogen oxide addition products may have formed. It would, therefore, be of interest to investigate this region more fully. The existence of uranyl nitrate complexes with oxides of nitrogen has been previously reported (16, 17).

At temperatures above 49.1° C, no phase separation was evident in the concentration range studied.

ACKNOWLEDGMENT

The authors wish to thank Atomic Energy of Canada Limited for financial support and encouragement, as well as for the uranyl nitrate used in these studies.

PHASE EQUILIBRIUM STUDIES FOR THE QUATERNARY SYSTEM URANYL NITRATE – ALUMINUM NITRATE – NITRIC ACID – WATER

ROBERT D. THIBODEAU AND M. ADELMAN
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received June 5, 1962

ABSTRACT

The quaternary system $UO_2(NO_3)_2$–$Al(NO_3)_3$–HNO_3–H_2O was studied in the temperature range 0–20° C, and the concentration range of 0–1.5 *M* $Al(NO_3)_3$ and 0–10 *N* HNO_3. From the data, phase diagrams were prepared. No phase separation was evident at 30° C and above, for the concentrations studied.

A knowledge of the phase behavior for the system $UO_2(NO_3)_2$–$Al(NO_3)_3$–HNO_3–H_2O is of value in connection with the recovery of spent reactor rods. Dissolution in nitric acid of the heterogeneous uranium rods encased in aluminum jackets is the initial step in aqueous processes for the recovery of fissionable materials.

The ternary system $UO_2(NO_3)_2$–HNO_3–H_2O was investigated initially by Coloni (1). Extension of this work has been done by Gaunt (2) and Bastien (3). The salting out effect at 25° C of NH_4NO_3, $Ca(NO_3)_2$, $Mg(NO_3)_2$, and $Zn(NO_3)_2$ on the system $UO_2(NO_3)_2$ – 1.5 *N* HNO_3 – H_2O was studied by Kurnakova and Nikolaev (4). However, the only published information on the system $UO_2(NO_3)_2$–$Al(NO_3)_3$–HNO_3–H_2O is the freezing point study for concentrations of 0.20 *M* $UO_2(NO_3)_2$, 0–0.6 *M* nitric acid, and 0–2.0 *M* $Al(NO_3)_3$ by Slansky (5). This study was carried out at temperatures of 0, 10, and 20° C over a limited range of aluminum nitrate concentration corresponding to that resulting from the dissolution of the reactor rod aluminum casement.

EXPERIMENTAL APPARATUS AND METHODS

Thirty-three solutions were made up ranging from 0 to 10 *M* HNO_3 inclusive and 0.5 *M*, 1.0 *M*, and 1.5 *M* $Al(NO_3)_3$. Ten milliliters of each of these solutions was pipetted into a glass bottle containing sufficient uranyl nitrate hexahydrate (approximately 25 g) to saturate the solutions. The bottles were sealed with polyethylene tops, heated to effect complete dissolution, then suspended in a constant-temperature (±0.1° C) circulating water bath for 48 hours. It was established by repeated analysis that equilibration was attained within 12 hours.

Samples of the liquid phase were extracted through a filter pipette, weighed, and diluted to 100 ml. Aliquots were analyzed for uranium by titrating the reduced form with ceric sulphate. The nitric acid content was determined by a procedure based on the method of Brothers and Olmstead (6) by which the aluminum was precipitated as the double salt by potassium fluoride, according to the reaction

$$Al^{+++} + 6KF \rightarrow K_3AlF_6 + 3K^+. \quad [1]$$

The uranium was precipitated according to the reaction

$$UO_2^{++} + 4KF \rightarrow K_2UO_2F_4 + 2K^+. \quad [2]$$

The free nitric acid was titrated with standardized sodium hydroxide to a phenolphthalein end point.

The aluminum was separated from the uranium by the addition of ammonium bicarbonate solution. The $Al(OH)_3$ formed was separated by centrifuging and decanting, then it was dissolved in hot H_2SO_4 and analyzed by the volumetric oxine method (7).

All methods of analyses were developed to an accuracy of 1% as determined on standard substances. All analyses were performed in duplicate.

The choice of axes and the general method of graphical representation was selected to best indicate the physical phenomena involved with increasing concentration of aluminum nitrate.

EXPERIMENTAL RESULTS

A typical set of experimental results representing the composition of saturated solutions made from 0.5 *M*, 1.0 *M*, and 1.5 *M* aluminum nitrate is given in Table I and shown graphically on Fig. 1. Results for the systems at 10 and 20° C are summarized in Tables II and III and shown graphically on Figs. 2 and 3. Figure 4 gives the composite phase

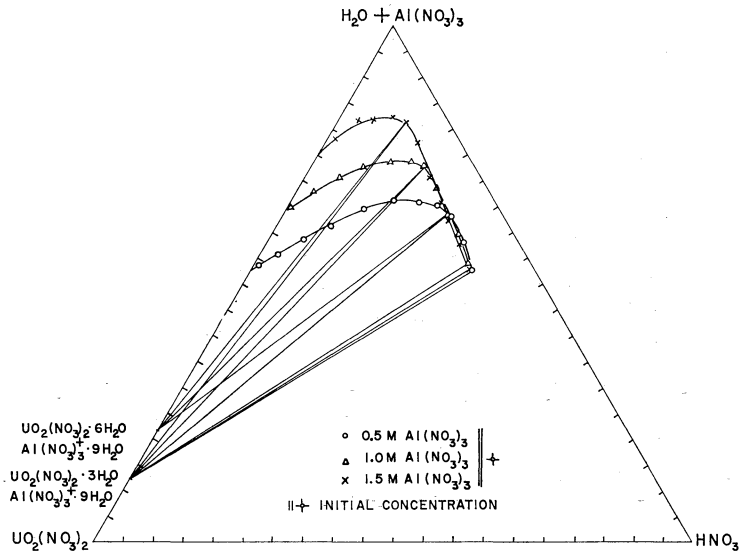

FIG. 1. The system at 0° C.

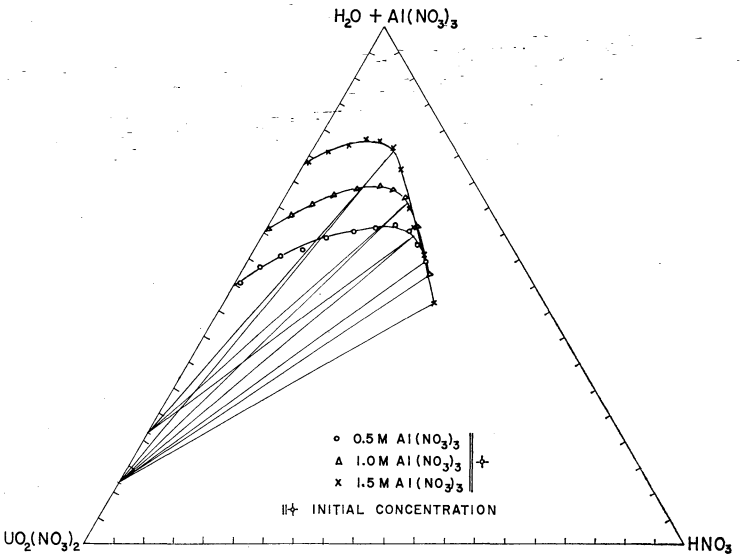

FIG. 2. The system at 10° C.

diagram for the system at the three temperatures studied. In solutions of low concentration of nitric acid and saturated with uranyl nitrate and aluminum nitrate, the solid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

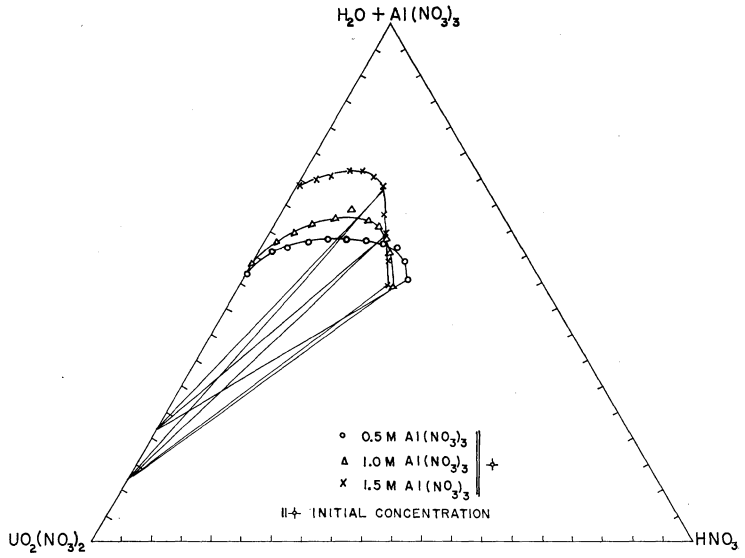

FIG. 3. The system at 20° C.

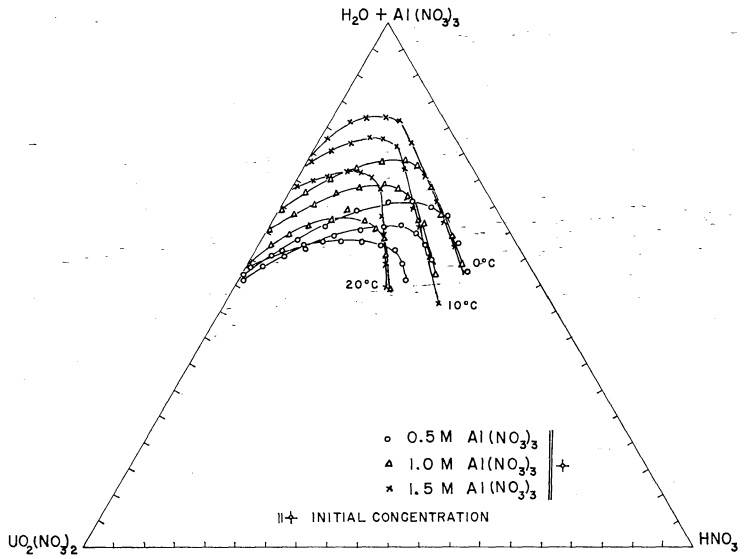

FIG. 4. Composite phase diagram for the system at 0, 10, and 20° C.

phase is $UO_2(NO_3)_2.6H_2O$ and $Al(NO_3)_3.9H_2O$. In solutions of high nitric acid concentration the solid phase consisted of $UO_2(NO_3)_2.3H_2O$ and $Al(NO_3)_3.9H_2O$. The exact position of the invariant point where the solid was composed of the hexahydrate and trihydrate of uranyl nitrate and the enneahydrate of aluminum nitrate was not determined.

At temperatures of 30° C and above, no phase separation was evident, for all the concentrations studied at the lower temperatures.

INCREASE IN THE ANODIC OVERPOTENTIAL OF ELECTROPOLISHED ALUMINUM ON EXPOSURE TO DRY AIR AT 25° C—A FILM THICKNESS OR SPECIFIC IONIC CONDUCTANCE EFFECT

M. J. DIGNAM[1]

Anode potential measurements of the type indicated in the title were made by Hart (1), who interpreted them in terms of an oxide film whose thickness increased in accordance with the Mott–Cabrera theory of metal oxidation (2). The present data cast considerable doubt on this interpretation, suggesting instead a mechanism involving a change in the specific ionic conductance of the film.

Specimens of superpurity aluminum were electropolished in an ethanolic perchloric acid solution, rinsed, dried, and stored at 25° C over activated alumina (3). Anode potentials were measured, using a method previously reported (3), at a current density of 3×10^{-6} amp/cm^2 in aqueous boric acid adjusted to pH = 6.0 with ammonia. The potentials, measured against a large-area platinum cathode (3), were reproducible to ±0.02 v. Later, several of the measurements were repeated employing a standard calomel reference electrode. Using the information so obtained and assigning the potential 1.42 v (3) to the reaction $2Al + 3H_2O \rightarrow Al_2O_3 + 3H_2$ at 1 atm of H_2 and 30° C, an additive correction of 2.43 v was calculated and applied to the original potential measurements to convert them to true anodic overpotentials (i.e. potentials against the hypothetical reversible electrode, Al, Al_2O_3/OH^-).

Figure 1 illustrates the present data, and Hart's data, from which 0.33 v has been

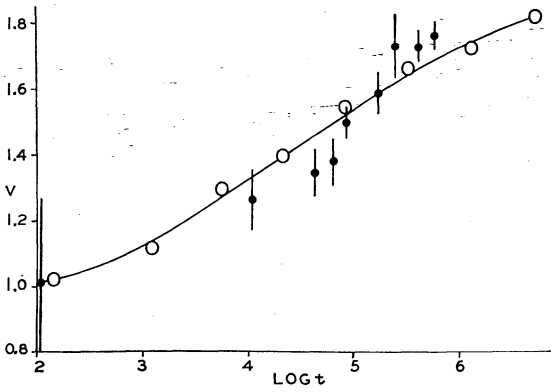

FIG. 1. Anodic overpotential for aluminum versus the logarithm of the time elapsed since electropolishing (present data open circles, Hart's data vertical lines; V in volts, t in seconds).

subtracted to facilitate comparison of potential changes. Comparison of absolute potentials cannot be made since Hart's potentials were measured against a working aluminum cathode of unknown electrochemical behavior. The two sets of data show changes in the anodic potential in agreement to within the sum of their deviations.

DISCUSSION

According to Hart's interpretation, the overpotential, V, should vary with the exposure time, t, in the manner $1/V = -C\log(t+\tau)+C'$, C, τ, and C' being constants for fixed temperature, C and τ positive. This equation predicts the slope, $dV/d\log t$, to be an increasing function of $\log t$ (or V), whereas it is seen to decrease appreciably for large values of t. Also, the oxidation parameters calculated by Hart differ considerably from those calculated from oxidation studies in oxygen between 250 and 450° C (4), and from anodic oxidation studies (5).

Interpreting the results in accordance with the oxidation law reported by Eley and Wilkinson (6), the curve is of the correct shape, but the predicted slope, $dV/d\log t$, is larger by a factor of 10^2 than that observed.

The increase in the overpotential is undoubtedly due to an increase in the oxide film resistance brought about by an increase in film thickness, a decrease in specific ionic conductance, or perhaps by a combination of both these processes. Since the first of these possibilities is in conflict with the facts, the second will be investigated.

As will be shown, the results are quite consistent with a mechanism involving a second-order decay of ionic current carriers according to the model proposed by Bean, Fisher, and Vermilyea (7). Their equations, describing high-field ionic conduction processes, can be written (8, 3, 9):

$$I = 2qa\nu n \exp -(U-Eaq)/kT \qquad [1]$$

$$dn/dt = A-Bnm, \qquad [2]$$

where $A = N\nu \exp -[W-E\lambda q]/kT$; and $B = 2a\nu\sigma \exp -[U-Eaq]/kT$. I and E are the current density and electric field strength in the oxide, n the carrier concentration (interstitial cations) of charge q and vibrational frequency ν, U and a the activation energy at zero field and activation distance for interstitial cation transport, m the concentration of trapping sites (cation vacancies) with capture cross-sectional area σ, N the concentration of sites at which Frenkel defects may form, and W and λ the activation energy at zero field and activation distance for formation of a Frenkel defect.

The films under discussion are assumed to be of constant thickness and to have been formed during electropolishing at the high current density of 0.5 amp/cm^2. Immediately following electropolishing, n should therefore be high, decreasing subsequently with time in accordance with equation [2]. Initially, then, $Bnm \gg A$, and in fact the present results are only consistent with the assertion that this inequality applies over the entire time period investigated. Accordingly, integration of equation [2] gives:

$$1/n = (B/\alpha)[1-(1-\alpha/Bn_0) \exp -\alpha t], \qquad [3]$$

where $\alpha = B(n_0-m_0)$, n_0 and m_0 being the values of n and m at $t = 0$. The overpotential, V, is obtained from equation [1] on setting $E = V/\delta$, δ being the film thickness, and substituting for n the expression given in equation [3]. Thus:

$$V+Y = K\log(t+t_0)+K', \qquad [4]$$

where $K = 2.303kT/qa$; $K' = K\log(I\sigma/q)+V'$; $t_0 = 1/Bn_0$; $Y = K\log[\alpha t(1-1/Bn_0t)]/[1-(1-\alpha/Bn_0)\exp -\alpha t] \simeq K\log[\alpha t/(1-\exp -\alpha t)]$ for $n_0 \gg (n_0-m_0)$; and V' is the electrical potential across the film that arises from chemisorption of oxygen on the alumina in accordance with the Mott–Cabrera theory (2, 10), during exposure of the metal to air.

The data are plotted in Fig. 2 according to equation [4], the values for the parameters being: $K = 0.21_0$ v; $K' = 0.49$ v; $t_0 = 220$ seconds; and $\alpha = 4.5\times10^{-7}$ sec^{-1}. The

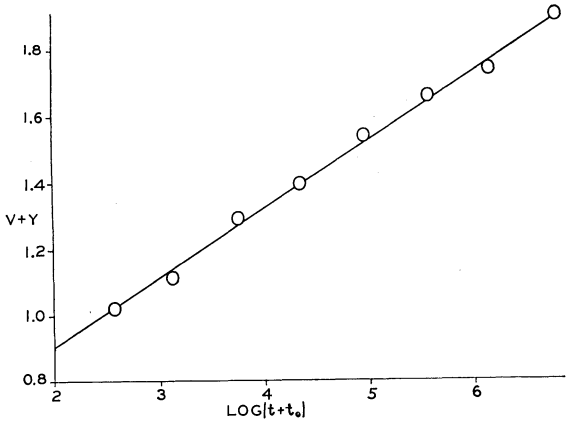

FIG. 2. Anodic overpotential data for aluminum plotted according to equation [4] (V and Y in volts, t and t_0 in seconds).

average deviation of the points from the straight line is ±0.015 v, which is within the experimental scatter.

To check further the credibility of this proposed mechanism, secondary calculations were made using the following values for the parameters: $kT = 0.0252$ ev; $q = 3\times$ (charge on electron); $a = 1.2_4\times10^{-8}$ cm, and $\sigma = 5\times10^{-15}$ cm^2 (both values reported in a recent publication (9)); $I = 3\times10^{-6}$ amp/cm^2; $V' = 0.73$ v (a value deduced from oxidation studies in the temperature range 250 to 450° C (4)); and $\nu = 2\times10^{12}$ sec^{-1}.

From K, the result $\delta = 13.0$ Å is obtained. This value is somewhat greater than the 10 Å found to form on aluminum when it is exposed to dry oxygen for 2 hours at 25° C (11), in agreement with expectations if the proposed mechanism is accepted.

From α and t_0, $(n_0-m_0)/n_0 = 10^{-4}$, indicating a slight excess of metal in the film following electropolishing. This conclusion is consistent with the expectation that aluminum forms a metal excess oxide.

From the relation $1/t_0 = 2a\nu\sigma n_0 10^{V'/K} \exp -U/kT$ and the inequality $n_0 \ll$ the concentration of lattice cations, 4×10^{22} cm^{-3}, the result $U < 1.1$ ev is obtained. Once again this result is reasonable, comparing favorably with estimates of U for tantala films (12).

Finally, K' may be calculated as 0.41 v, which is in excellent agreement with the observed value 0.49 v. Such good agreement must be considered largely fortuitous as the estimated errors in the experimental and calculated values are 0.05 v and 0.1 v respectively.

It remains now to check the consistency of the initial assumption that δ is constant. The rate of growth of the film is given by equation [1] with E replaced by V'/δ and n replaced by the expression given in equation [3]. Integration of this rate expression assuming the change in δ, $\Delta\delta$, small compared with δ gives:

$$[5] \qquad \Delta\delta = (\Omega/\sigma) \ln [(\exp \alpha t - 1 + \alpha t_0)/\alpha t_0],$$

where Ω is the volume per metal atom in the oxide and is 2.5×10^{-23} cm^3 for alumina. For $t = 5.72\times10^6$ seconds, the longest time period, $\Delta\delta = 5.8$ Å, which would correspond to an increase of about 0.4 v (5) in the overpotential if the specific conductivity remained

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

constant. The value of σ used for this calculation was measured at a field strength about double that present during the supposed film growth. Since σ would be expected to increase substantially with decreasing field, this value for $\Delta\delta$ should be regarded as an upper limit.

In summary, the proposed mechanism is consistent with the data and with other available information. It is very unlikely that changes in film thickness alone are responsible for the overpotential changes, although it seems probable that the processes involved are somewhat more complex than those outlined herein.

EXCHANGE RATE AND ACTIVATION ENERGY OF EXCHANGE FOR N,N-DIMETHYLANILINE IN TRIFLUORACETIC ACID

W. F. Reynolds* and T. Schaefer

The exchange rate of N,N-dimethylaniline in trifluoracetic acid has been determined by n.m.r. techniques. The rate of change of the lifetime of the protonated aniline has been used to calculate a value for the activation energy of proton exchange.

Under conditions of slow exchange, a doublet is observed for the N,N-dimethyl group. The doublet separation is equal to the H^+—H_3C coupling constant. As the exchange rate increases the doublet collapses into a single, averaged peak. In the region of intermediate lifetime, an equation similar to that proposed by Gutowsky and Holm (1) may be used to calculate the lifetime of protonated N,N-dimethylaniline:

$$\text{(I)} \qquad \frac{\text{separation of peaks}}{\text{separation of peaks at large } \tau} = \left[1-\frac{1}{2\pi^2\tau^2[J_{(H^+-H_3C)}]^2}\right]^{1/2}.$$

τ = lifetime of protonated species in seconds, $J_{(H^+-H_3C)}$ = coupling constant in cycles/sec. The original equation was intended for exchange between two chemically non-equivalent positions, in which case [coupling constant] is replaced by [chemical shift]. The estimation of lifetime is more difficult for high and low exchange rates and involves a study of line

EXCHANGE RATE AND ACTIVATION ENERGY OF EXCHANGE FOR N,N-DIMETHYLANILINE IN TRIFLUORACETIC ACID

W. F. REYNOLDS* AND T. SCHAEFER

The exchange rate of N,N-dimethylaniline in trifluoracetic acid has been determined by n.m.r. techniques. The rate of change of the lifetime of the protonated aniline has been used to calculate a value for the activation energy of proton exchange.

Under conditions of slow exchange, a doublet is observed for the N,N-dimethyl group. The doublet separation is equal to the H^+—H_3C coupling constant. As the exchange rate increases the doublet collapses into a single, averaged peak. In the region of intermediate lifetime, an equation similar to that proposed by Gutowsky and Holm (1) may be used to calculate the lifetime of protonated N,N-dimethylaniline:

$$\text{(I)} \qquad \frac{\text{separation of peaks}}{\text{separation of peaks at large } \tau} = \left[1-\frac{1}{2\pi^2\tau^2[J_{(H^+-H_3C)}]^2}\right]^{1/2}.$$

τ = lifetime of protonated species in seconds, $J_{(H^+-H_3C)}$ = coupling constant in cycles/sec. The original equation was intended for exchange between two chemically non-equivalent positions, in which case [coupling constant] is replaced by [chemical shift]. The estimation of lifetime is more difficult for high and low exchange rates and involves a study of line

Holder of an N.R.C. Studentship 1961–62.

widths (1). The calculated values of τ at different temperatures may be used to obtain an activation energy for proton exchange, using the following equation (1):

$$\text{(II)} \qquad \log_{10}\left[\frac{1}{2\pi\tau J_{(H^+-H_3C)}}\right] = \log_{10}\left[\frac{k_0}{\pi J_{(H^+-H_3C)}}\right] - \frac{E_A}{2.303RT}.$$

E_A = activation energy, k_0 = frequency factor. This equation is in the standard slope plus intercept form and a plot of $\log_{10}[1/(2\pi\tau J)]$ vs. $1/T$ should give a value for the activation energy from the slope.

EXPERIMENTAL

The sample solution contained 10.0 mole% N,N-dimethylaniline in CF_3COOH. Both chemicals were Eastman Grade as supplied by Distillation Products Ind. and were used without further purification. The sample was degassed and sealed in an evacuated 5 mm O.D. sample tube.

Spectra were run on a Varian dual purpose 60 Mc spectrometer. Temperature control was provided by a temperature device constructed at the National Research Council (2). Temperature was measured by an iron–constantan thermocouple attached to a Minneapolis-Honeywell Brown recording potentiometer. The temperature was kept constant and measured within 0.2° C.

The separation of the doublet peaks was measured by placing side bands of the doublet on both sides of itself, approximately 20 cycles/sec away. Each spectrum was repeated 10 times forward and reverse. Side-band frequencies were measured by a Hewlett–Packard Model 521 C electronic counter.

RESULTS

Measured values of doublet separations, as well as root mean square deviation in these values, are given in Table I. The temperature range was chosen so that the exchange rate

could be calculated, using equation (I). At higher temperatures, where the two peaks were broad and almost coalesced, the error in measuring the separation was very large. At lower temperatures, small differences in the measured separations result in large errors in the calculated exchange rates.

The constancy of the measured separation at the two lowest temperatures would indicate that the condition of slow exchange is fulfilled at these temperatures. Therefore, the coupling constant should be the same as the measured separation.

The limits of error in measurements of temperature and τ are shown in Fig. 1 by the rectangular boxes. The solid line gives the least-squares plot for the last six measurements. The measured value for 46.8° C was not included in the least-squares plot due to the

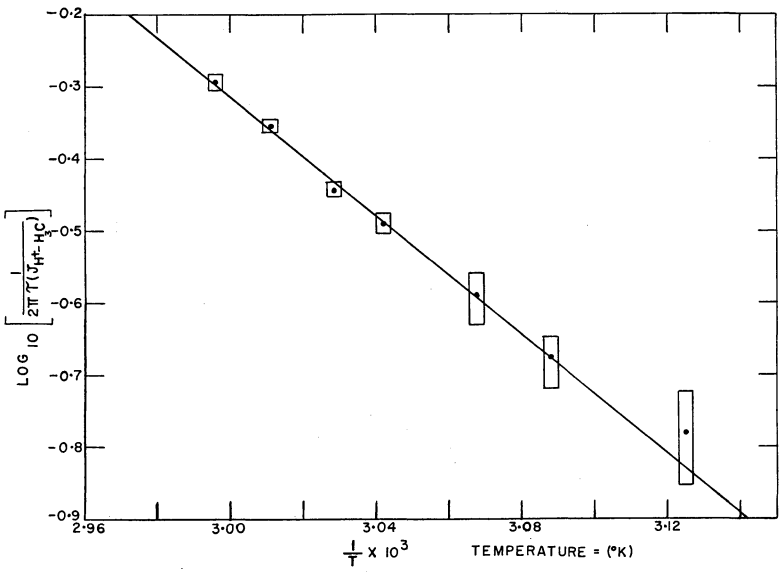

FIG. 1. Temperature dependence of the amino proton exchange rate of N,N-dimethylaniline in trifluoracetic acid.

large possible error. The slope of the line was $-4.11\times10^{3°}$ K. The most extreme values of slope which could be obtained for lines passing through the limits of experimental error were $-3.64\times10^{3°}$ K and $-4.55\times10^{3°}$ K. A further uncertainty of $0.25\times10^{3°}$ K is introduced due to possible error in the value of the coupling constant. By multiplying by the constant $2.303R$, the value of 18.8 ± 3.2 kcal/mole was obtained for the activation energy of proton exchange.

The value of k_0, the frequency factor, was calculated from equation (II). The calculated value was 1.7×10^{13} sec^{-1} with a possible range of 6×10^{11} to 4×10^{14} sec^{-1}. The frequency factor represents the internal vibration frequency of the protonated molecule. The value obtained is considerably higher than those obtained elsewhere, by n.m.r., for different molecules (1). However, its magnitude is in agreement with the classical theory of unimolecular reactions, in which the frequency factor should lie in the range 10^{12} to 10^{14} sec^{-1} (3).

Complete collapse of the doublet should occur when the exchange rate exceeds the value $2\pi J_{(H^+-H_3C)}$. By extrapolation from the graph, the temperature at which this exchange rate would be exceeded is 69° C. As expected, the doublet collapse occurs over a range of temperature, starting at about 65° C. It is impossible to determine the exact temperature at which the peaks overlap.

The exchange rate is strongly a function of concentration. A 5 mole% solution of N,N-dimethylaniline in acid showed no appreciable change in doublet separation up to 150° C. Higher temperatures could not be obtained due to the high vapor pressure of the solvent.

It is planned to study the effect of base concentration and pH upon the exchange rate for N,N-dimethylaniline and similar substituted anilines. A series of ring-substituted N-alkyl anilines will be investigated to determine the effect of substituent groups upon exchange rates and activation energies. Non-aqueous acids with a larger liquid range will also be used.

THE PREPARATION OF SOME NEW 1-PHENYL-2-NITROETHANOL DERIVATIVES

R. A. HEACOCK AND O. HUTZINGER

An improved method for the synthesis of 1-phenyl-2-nitroethanol derivatives, substituted in the 3- and 4-positions of the benzene ring (of the general type shown in formula III), has recently been described (1). The preparative procedure involved condensation of a suitable aldehyde (I) with excess nitromethane (II: $R_5 = H$) at about 5°, in the presence of sodium hydroxide in aqueous alcoholic solution, using a very short reaction time ($\gtrsim$60 seconds).

This communication describes the preparation of eight further examples of this class of compound containing two, three, or four substituents in the benzene ring. (In all cases, the substituents in the 3- and 4-positions of the aromatic ring were either methoxy or benzyloxy groups.) Uusally, no particular difficulties were encountered when the condensation was carried out with nitroethane (II: $R_5 = CH_3$) instead of nitromethane (II: $R_5 = H$). However, 4-benzyloxy-3,5-dimethoxybenzaldehyde, which condensed readily with nitromethane under the conditions described above, could not be induced to condense with nitroethane by this technique. The following new 1-phenyl-2-nitroethanol derivatives have been prepared: 4-benzyloxy-3,5-dimethoxy-α-nitromethylbenzyl

*The crude product, an oil, was stirred with concentrated sodium bisulphite solution for 20 minutes before recrystallization from benzene.
†LP = light petroleum (b.p. 60–80°); B.D.H. AnalaR grade.

5-iodo-3,4-dimethoxy-6-nitro-α-nitromethylbenzyl alcohol (III: $R_1 = R_2 = OCH_3$; $R_3 = I$; $R_4 = NO_2$; $R_5 = H$); 5-iodo-3,4-dimethoxy-6-nitro-α-(1-nitroethyl)-benzyl alcohol (III: $R_1 = R_2 = OCH_3$; $R_3 = I$; $R_4 = NO_2$; $R_5 = CH_3$).

Unsuccessful attempts were made to condense 3-benzyloxy-4-methoxybenzaldehyde and 3,4-dibenzyloxybenzaldehyde with nitromethane using this procedure; in both cases the starting material was essentially recovered unchanged, even when considerably longer reaction times were employed. The failure of these two aldehydes to condense with nitromethane under the conditions employed is not altogether surprising in view of the fact that veratraldehyde would not condense with nitroalkanes in similar circumstances (cf. ref. 1).

EXPERIMENTAL

Aldehydes

4-Benzyloxy-3,5-dimethoxybenzaldehyde.—A solution of 4-hydroxy-3,5-dimethoxybenzaldehyde (12.0 g), potassium hydroxide (4 g), and benzyl chloride (9.0 g) in ethanol (60 ml) was boiled under reflux for 4 hours. The product was poured into water, and the aqueous reaction mixture repeatedly extracted with ether. The ethereal extract was washed with aqueous potassium hydroxide and water, dried (Na_2SO_4), and on evaporation to dryness, afforded a pale yellow oil, which on purification by distillation in vacuum (b.p. 190° at 0.5–1.0 mm) and recrystallization first from 95% ethanol and finally from benzene/light petroleum (b.p. 80–100°) afforded 4-benzyloxy-3,5-dimethoxybenzaldehyde as colorless prisms, m.p. 63°. Kratzl *et al.* prepared this compound by a somewhat different procedure but report the same melting point (2).

3,4,5-Trimethoxybenzaldehyde and 6-nitroveratraldehyde.—These compounds were obtained from the Aldrich Chemical Company.

5-Iodoveratraldehyde.—This compound was prepared by the methylation of 5-iodovanillin by the method of Dominguez *et al.* (3).

5-Iodo-6-nitroveratraldehyde.—This compound was prepared by the nitration of 5-iodoveratraldehyde, the nitroaldehyde being purified via its bisulphite derivative (4).

1-Phenyl-2-nitroethanol Derivatives (General Procedure) (cf. Ref. 1)*

Aqueous sodium hydroxide (10%; 1.05 mole) was added with stirring to a mixture of the aldehyde and nitromethane (2–3 mole) dissolved in a suitable solvent (see Table I) at ca. 5°; the product was vigorously stirred for a further 30–45 seconds. Aqueous acetic acid (2%) was then added to halt the reaction and decompose the sodium derivative of the nitroalcohol; the crude product separated out as a yellow to colorless solid or oil. After being allowed to stand at 4° for 1 hour, the crude product was filtered and purified by repeated recrystallization from a suitable solvent.

In the previous note on this subject (1), it was reported that 95% alcohol was invariably used as a solvent for this type of reaction mixture. However, in several of the cases described above, the solubility of the aldehyde in 95% ethanol was quite low, and it was necessary to use mixtures of absolute alcohol and dioxane to ensure complete solution of all the reactants.

This investigation was supported by grants from the Department of National Health and Welfare (Ottawa) and the Government of Saskatchewan (Department of Public Health).

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS XII. RACEMIZATION OF *sec*-BUTANOL[1]

R. J. WITHEY[2] AND E. WHALLEY

1. INTRODUCTION

The acid-catalyzed racemization of *sec*-butanol (1, 2), which is usually assumed to go via a pre-equilibrium proton transfer, is about twice as fast as the acid-catalyzed exchange of oxygen between *sec*-butanol and the solvent, so that inversion occurs at each substitution. The rates of both processes are approximately proportional to the acidity function h_0 and it was concluded (1), because of this, that the slow step is unimolecular

$$C_2H_5.CH_3CHOH_2^+ \rightleftharpoons C_2H_5.CH_3CH^+ + H_2O.$$

The Zucker–Hammett hypothesis (3) on which this conclusion is based has since been shown to be invalid (4, 5), and so there was no evidence about the mechanism. In fact the occurrence of inversion at every exchange can be interpreted to favor a bimolecular slow step, and Bunnett (6), who has reinterpreted the rates in concentrated acids, concludes that they show that the slow step is bimolecular. We have therefore attempted to learn more about the mechanism by measuring the volume of activation (see ref. 7 and later papers) for the racemization.

2. EXPERIMENTAL METHODS AND RESULTS

sec-Butanol was resolved via the brucine salt of its hydrogen phthalate ester by the method of Kantor and Hauser (8). The alcohol, b.p. 98–99° C, $[\alpha]_D^{20°} = +13.28°$, was obtained by hydrolyzing the resolved ester. The highest specific rotation reported (9) is 13.52°, so the alcohol appeared to be at least 98% optically pure.

Reagent grade perchloric acid (1.012 *M*) was used as catalyst. About 1.3 g of *sec*-butanol in 50 cm³ of acid solution was used for each run, resulting in an initial optical rotation of about 1°.

The rotation was measured with a Rudolph model 70 polarimeter which was modified to allow changes of rotation of 0.001° to be measured. The front cover was removed and a rigid brass beam was bolted to the graduated circle. A ball bearing pressed into the end of the beam rested on the head of a micrometer graduated in 0.0001 in. The reproducibility was better than ±0.0001 in., which corresponded to about ±0.001°. Since the rotation during a run changed by only ½–1°, direct readings of the micrometer were used to calculate the first-order rate constants. A 4-dm micropolarimeter tube of volume ~5 cm³ was used and at least 10 readings of the rotation were taken for each sample. Infinity readings were determined by keeping samples of the reaction solution in sealed ampoules at 100.3° C for at least 10 half-lives. The rotation was always zero within the experimental error.

The pressure system was similar to that described previously (10). About eight samples were taken during each run.

Formation of olefin during the reaction at ordinary pressure was tested for by the method used by Bunton, Konasiewicz, and Llewellyn (1). In 24 hours, less than 0.4% of the alcohol was converted to olefin, and so any conversion can be ignored.

The first-order rate constants k_1, which are accurate to about ½%, and second-order rate constants k_a ($= k_1/c_{HClO_4}$, where c_{HClO_4} is the concentration of perchloric acid at the temperature and pressure (11) of the experiment) are listed in Table I. They agree well with previous measurements (1) at 99.8° when allowance is made for the small difference in temperature. The volume of activation defined as

$$\Delta V^{\ddagger} = -RT\partial \ln k_a/\partial p$$

is $-0.7 \pm \sim 0.5$ cm³ mole^{-1}. In fact, the racemization is more nearly first order in h_0 than in concentration of hydrogen ion (1, 2), and so the increase in rate due to compression of the acid may be somewhat greater than the increase in density. This would make the real volume of activation, calculated from the pseudo

second-order rate constant k_1/h_0, less negative than the above value. This would have no effect on the conclusions drawn in the next section.

3. DISCUSSION

A bimolecular mechanism

$$H_2O + d\text{-}sec\text{-}C_4H_9OH_2^+ \rightarrow l\text{-}sec\text{-}C_4H_9OH_2^+ + H_2O$$

would have a volume of activation of around -8 or -10 cm^3 mole^{-1} (7). A unimolecular mechanism

$$d\text{-}sec\text{-}C_4H_9OH_2^+ \underset{k_2}{\overset{k_1}{\rightleftharpoons}} sec\text{-}C_4H_9^+ + H_2O$$

$$sec\text{-}C_4H_9^+ + H_2O' \xrightarrow{k_3} l\text{-}sec\text{-}C_4H_9O'H_2^+,$$

where H_2O' is a different water molecule from that formed from the alcohol and which presumably attacks from the opposite side of the *sec*-butyl ion, would give a volume of activation of about zero or slightly positive whatever the relative magnitudes of k_2 and k_3. The measured volume of activation of $-0.7 \pm \sim 0.5$ cm^3 mole^{-1} clearly shows that the mechanism is unimolecular. The entropy of activation, which is about 12 cal mole^{-1} deg^{-1} (2), in consistent with this mechanism, but does not support it except on purely empirical grounds (7).

The modification of the Zucker–Hammett relation proposed by Bunnett (6) indicates that the mechanism is bimolecular, and it is therefore not valid for the racemization of *sec*-butanol.

GAS CHROMATOGRAPHIC SEPARATION OF HYDROGEN ISOTOPES ON ACTIVATED ALUMINA*

M. VENUGOPALAN† AND K. O. KUTSCHKE

The quantitative separation of hydrogen, hydrogen deuteride, and deuterium using a chromia–alumina column operated at 77° K with neon as the carrier gas was reported by Smith and Hunt (1, 2). Subsequently Moore and Ward (3), Shipman (4), and Furuyama and Kwan (5) have shown that good isotopic separation results with helium as the carrier gas on columns of alumina "coated" with ferric oxide. It was observed by Moore and Ward (3) that columns of strongly activated (480° C, 8 hours) reagent-grade alumina (apparently iron-free) also lead to ortho–para equilibration. We have confirmed this observation and applied this method successfully to the quantitative analysis of micromole quantities of the hydrogen isotopes.

Pyrex columns packed with alumina were activated at 450° for 1 week in flowing helium and operated at 77° K. Detection was by means of a katharometer (Gow-Mac Model 9285) with prior oxidation over hot CuO (3, 4). Two grades of alumina (activated alumina, Aluminum Company of America; alumina for adsorption, Fisher Scientific Company) showed similar chromatographic behavior for the same particle size.

Commercial hydrogen and deuterium were passed through a palladium thimble and stored in 1-liter bulbs at 110 mm pressure. Hydrogen deuteride was prepared by slowly passing the vapors from well-outgassed heavy water over lithium aluminum hydride deposited on glass wool. Several first samples of the HD generated were analyzed mass spectrometrically. A purity of 95% was observed, the remainder being H_2 and D_2. A chromatographic analysis of the same HD, run at maximum sensitivity, showed no peak for H_2 and D_2; for these conditions an amount of H_2 equal to 1% of the HD taken could have been detected readily. It seems probable that much of the 5% H_2 and D_2, indicated as an impurity by mass spectrometric analysis, arose from partial equilibration of the HD in the ion source of the instrument. After storage for 6 months, small amounts (<3% each) of H_2 and D_2 could be detected in the HD by the gas chromatograph. Mass spectrometric analysis at this time indicated the presence of about 5% each of H_2 and D_2.

Each of the three storage bulbs was attached to the vacuum system with two capillary stopcocks; the volume between the stopcocks was chosen to contain approximately one micromole of gas, which could be transferred quantitatively to a gas burette for measurement. A sample could be removed from the gas burette and sealed, behind a thread of solid mercury, into a length of 3 mm o.d. tubing; such sample tubes were crushed in the stream of carrier gas. Mixtures of the isotopes could be prepared in analogous fashion.

A typical chromatogram of micromole quantities of the hydrogen isotope mixture is shown in Fig. 1. The H_2, HD, and D_2 peaks appeared at 13.5, 17.9, and 28.2 minutes respectively for the column and flow conditions specified in the caption.

Preliminary calibration curves of peak areas for H_2, HD, and D_2 were linear in the range 0.5 to 4 μmoles of the isotopes; for smaller quantities some curvature was noted in each plot. The slopes of the straight-line portions of these plots were 0.254, 0.267, and 0.238 (arbitrary units) for H_2, HD, and D_2 respectively. Work is in progress to establish the precise shape of the calibration curve in the region of 10^{-7} moles.

low volatility. They have been characterized by their mass spectra, which give a peak corresponding to the fragment $^{+}HgC{\equiv}CH$. Further work on these interesting new compounds is in active progress and will be reported in detail later.

EXPERIMENTAL

Ethylethynyl Mercury, $C_2H_5HgC{\equiv}CH$

A magnetically stirred solution of ethynylmagnesium bromide, freshly prepared by the method given in reference 5 from 2.07 g (0.086 atoms) of magnesium in 125 ml of tetrahydrofuran, was cooled in ice–water, while there was added dropwise, over a period of 50 minutes, a solution of 8.75 g (0.0247 mole) of ethyl mercuric iodide (1) in 50 ml of tetrahydrofuran. A slow current of dry nitrogen was passed through the apparatus all the while. After addition of the solution had been completed the reaction mixture was stirred for 17 hours at room temperature. It was then cooled to +5° and added slowly to a stirred ice-cold mixture of 450 ml of 6.6% aqueous ammonium nitrate and 190 ml of ether. The lower aqueous layer was separated and extracted twice with two 100-ml portions of ether. The combined ether extracts were washed with two 200-ml portions of water and dried over anhydrous magnesium sulphate. After evaporation of solvent under reduced pressure 5.37 g of yellow crystalline product with a characteristic bad odor remained. Sublimation of the crude material at room temperature under a pressure of 1 mm gave 4.6 g of white crystalline sublimate, m.p. 71–72°. Yield: 73.4%.

The mass analysis of the compound showed peaks at 254, 255, and 256 corresponding to $C_2H_5Hg^{200}C_2H$, $C_2H_5Hg^{201}C_2H$, and $C_2H_5Hg^{202}C_2H$ and also peaks at 225, 226, and 227, which in turn corresponded to $Hg^{200}C{\equiv}CH$, $Hg^{201}C{\equiv}H$, and $Hg^{202}C{\equiv}CH$.

The authors are indebted to Dr. F. P. Lossing of these laboratories for the mass analysis of the compound.

THE PREPARATION OF 2,3-DICYANO-5,6-DICHLOROQUINONE (D.D.Q.)

P. W. D. Mitchell

An intensive program of work on hydrogen-transfer reactions started by Linstead and Braude in 1951 (1) led to many interesting observations of the value of quinones as dehydrogenating agents. D.D.Q. was found by these authors to be of particular interest in this respect. Thus it was shown (2, 3) that D.D.Q. was capable of converting tetralin almost quantitatively into naphthalene in 2 hours at 80°. Recently, D.D.Q. has been used successfully in steroid chemistry to oxidize allylic alcohols into the corresponding α,β-unsaturated ketones (4), and to effect the conversion of Δ^4- and $\Delta^{4,6}$-steroidal 3-ketones into the corresponding $\Delta^{1,4}$- and $\Delta^{1,4,6}$-ketones in excellent yields (5). It is evident from the examples given by Petrow (4, 5) that D.D.Q. is a valuable reagent.

The quinone was prepared previously by Linstead and co-workers (2, 8), who improved the original method of Thiele and Günther (6, 7). This still involved a five-step sequence

low volatility. They have been characterized by their mass spectra, which give a peak corresponding to the fragment $^{+}HgC{\equiv}CH$. Further work on these interesting new compounds is in active progress and will be reported in detail later.

EXPERIMENTAL

Ethylethynyl Mercury, $C_2H_5HgC{\equiv}CH$

A magnetically stirred solution of ethynylmagnesium bromide, freshly prepared by the method given in reference 5 from 2.07 g (0.086 atoms) of magnesium in 125 ml of tetrahydrofuran, was cooled in ice–water, while there was added dropwise, over a period of 50 minutes, a solution of 8.75 g (0.0247 mole) of ethyl mercuric iodide (1) in 50 ml of tetrahydrofuran. A slow current of dry nitrogen was passed through the apparatus all the while. After addition of the solution had been completed the reaction mixture was stirred for 17 hours at room temperature. It was then cooled to +5° and added slowly to a stirred ice-cold mixture of 450 ml of 6.6% aqueous ammonium nitrate and 190 ml of ether. The lower aqueous layer was separated and extracted twice with two 100-ml portions of ether. The combined ether extracts were washed with two 200-ml portions of water and dried over anhydrous magnesium sulphate. After evaporation of solvent under reduced pressure 5.37 g of yellow crystalline product with a characteristic bad odor remained. Sublimation of the crude material at room temperature under a pressure of 1 mm gave 4.6 g of white crystalline sublimate, m.p. 71–72°. Yield: 73.4%.

The mass analysis of the compound showed peaks at 254, 255, and 256 corresponding to $C_2H_5Hg^{200}C_2H$, $C_2H_5Hg^{201}C_2H$, and $C_2H_5Hg^{202}C_2H$ and also peaks at 225, 226, and 227, which in turn corresponded to $Hg^{200}C{\equiv}CH$, $Hg^{201}C{\equiv}H$, and $Hg^{202}C{\equiv}CH$.

The authors are indebted to Dr. F. P. Lossing of these laboratories for the mass analysis of the compound.

THE PREPARATION OF 2,3-DICYANO-5,6-DICHLOROQUINONE (D.D.Q.)

P. W. D. Mitchell

An intensive program of work on hydrogen-transfer reactions started by Linstead and Braude in 1951 (1) led to many interesting observations of the value of quinones as dehydrogenating agents. D.D.Q. was found by these authors to be of particular interest in this respect. Thus it was shown (2, 3) that D.D.Q. was capable of converting tetralin almost quantitatively into naphthalene in 2 hours at 80°. Recently, D.D.Q. has been used successfully in steroid chemistry to oxidize allylic alcohols into the corresponding α,β-unsaturated ketones (4), and to effect the conversion of Δ^4- and $\Delta^{4,6}$-steroidal 3-ketones into the corresponding $\Delta^{1,4}$- and $\Delta^{1,4,6}$-ketones in excellent yields (5). It is evident from the examples given by Petrow (4, 5) that D.D.Q. is a valuable reagent.

The quinone was prepared previously by Linstead and co-workers (2, 8), who improved the original method of Thiele and Günther (6, 7). This still involved a five-step sequence

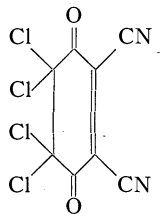
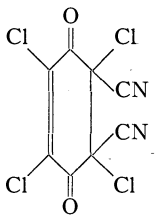
from 2,3-dicyanohydroquinone involving oxidation to the quinone, addition of hydrogen chloride, the repetition of these steps, and a final oxidation of the dichlorodicyanohydroquinone.

It has now been found that chlorination of 2,3-dicyanohydroquinone in refluxing acetic acid (a procedure based on that for preparation of 2,3-dichloroquinone (9, 10)) gives a crystalline compound (3–4 molecular equivalents of Cl_2) which redissolves after the introduction of a total of 7 molecular equivalents of Cl_2. The crystalline compound proved to be 2,3-dicyano-5,6-dichlorohydroquinone (40–50% yield); thus four steps of the older method of preparation are eliminated.

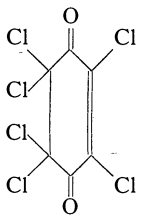
The solution from the prolonged chlorination was taken to dryness. The crystalline residue contained four chlorine atoms and one or more carbonyls (λ_{max} 1733 cm^{-1}). It appeared to oxidize activated charcoal, giving hydrogen chloride and a 70% yield of D.D.Q. These facts and analogy to the hexachlorocyclohexenedione (V) prepared by Zincke (11) and the tetrachlorocyclohexadione of Clark (12) suggest structures IV*a* or IV*b* for this compound. It is presumed that D.D.Q. is an intermediate in the formation of IV since it can be converted into IV by chlorine.



IV*a*



IV*b*



V

A greatly improved procedure for the oxidation of the hydroquinone to D.D.Q. by vigorous shaking of a slurry of the compound in aqueous ethanol containing 5% hydrochloric acid with benzene and lead dioxide was developed. An 80% yield of the quinone concentrated in the benzene phase. No D.D.Q. was formed in the absence of hydrochloric acid.

The following scheme summarizes the reactions described above for the preparation of D.D.Q.

EXPERIMENTAL

2,3-Dicyano-5,6-dichlorohydroquinone

2,3-Dicyanohydroquinone (10 g) and glacial acetic acid (100 ml) were heated to gentle reflux in a three-necked flask fitted with a stirrer, condenser, and gas inlet tube. Dry chlorine was then passed into the clear solution at a rate of about 0.2 g per minute and after 1 hour a crystalline solid began to separate from the refluxing solution. After a further 30 minutes, chlorination was stopped, the contents of the flask cooled to room temperature, and the solid separated by filtration. It was washed with chloroform (50 ml) and dried. The yield of chunky white crystals was 6.4 g (44%). The product was practically insoluble in hot water and could be crystallized from aqueous ethanol as needles, unchanged on heating to 300° (lit. (6), blackens at 265°).

2,3-Dicyano-5,6-dichlorobenzoquinone

2,3-Dicyano-5,6-dichlorohydroquinone (10 g) was suspended in a solution of ethanol (40 ml) and 5% hydrochloric acid (110 ml)[1] contained in a stoppered Erlenmeyer flask. Benzene (220 ml) was added, followed by lead dioxide (44 g), and the contents of the flask shaken vigorously by hand for 5 minutes. The emulsion was then filtered through a Büchner funnel containing a layer of celite, and the residue washed with benzene. The combined filtrates were transferred to a separating funnel, the aqueous layer removed, and the organic phase washed twice with a small quantity of water. Concentration of the dried benzene solution yielded red crystals of the quinone, and precipitation was completed by the addition of light petroleum (30–60°). The solid was separated by filtration and washed with a little petrol. When dry the quinone was yellow and melted at 206–209° (lit. (6) m.p. 203°). The yield was 8.3 g (83%).

The Tetrachlorodicyano Derivative

2,3-Dicyanohydroquinone (20 g) was dissolved in refluxing acetic acid (200 ml), and chlorine passed into the stirred solution at a rate of about 0.2 g per minute. Chlorination was continued until the crystalline precipitate of dicyanodichlorohydroquinone had redissolved. This occurred when about 7 molar equivalents of chlorine had been introduced. Chloroform (100 ml) was added to the cooled solution and a small quantity of dicyanodichlorohydroquinone (3.26 g) removed by filtration. The filtrate was evaporated *in vacuo* and the semicrystalline residue triturated with a mixture of benzene and *n*-hexane. A pale yellow solid (20 g) was obtained. It crystallized from *n*-hexane in needles, m.p. 130–132°, and was readily soluble in ether, benzene, ethanol, and chloroform. The compound was unstable in aqueous ethanol. It sublimed readily at 100° and 0.1 mm. The sublimate was colorless and melted at 130–131°.

Calc. for $C_8O_2N_2Cl_4$: C, 32.25; N, 9.41; Cl, 47.61. Found: C, 32.45; N, 9.51; Cl, 47.06, 47.22.

Infrared (CS_2): carbonyl absorption at 1733 cm^{-1}, C≡N at 2260 cm^{-1}, C–Cl at 790 and 765 cm^{-1}, strong band at 1137 cm^{-1}, weak C=C at 1558 cm^{-1} ($CHCl_3$).

Ultraviolet: no maxima in range 220 to 350 mμ (ϵ at 220 mμ = 14,500).

Preparation of D.D.Q. from the "Tetrachloro Compound"

The above compound (1 g), m.p. 130–131°, was dissolved in benzene (20 ml) and the solution refluxed for 40 minutes with charcoal (1 g). The solution was filtered and the orange-red-colored filtrate concentrated to about 10 ml, when red crystals separated. These were removed and washed with a little *n*-hexane. The dried material weighed 0.55 g (73%) and had m.p. 210–213°. It crystallized in long amber-colored needles from chloroform, m.p. 215–217°.

Calc. for $C_8N_2O_2Cl_2$: Cl, 31.25; N, 12.34. Found: Cl, 31.71, 31.88; N, 11.88, 11.81.

Infrared ($CHCl_3$): C=O at 1696 cm^{-1}, C=C at 1560 cm^{-1}, strong band at 1175 cm^{-1}, C≡N at 2240 cm^{-1}.

Ultraviolet: λ_{max} at 238 mμ (ϵ 11,950); 257 mμ (ϵ 10,700); 290 mμ (ϵ 8,900); 345 mμ (ϵ 1,360); 482 mμ (ϵ 870).

Measurement of the Acid Liberated during the Treatment of the Tetrachloro Compound with Charcoal

The compound (151 mg) was refluxed in benzene (10 ml) containing charcoal (0.5 g). A slow stream of nitrogen was passed through the solution and then into *N*/10 sodium hydroxide solution. After 2 hours a total of 4.65 ml of alkali had been neutralized. If two molecules of hydrochloric acid were obtained from the *tetrachloro* compound, the alkali equivalent would be 10 ml. Since the compound is believed to be hydrogen free, it is assumed that the source of the hydrogen is the charcoal.

Preparation of the Tetrachloro Compound by Chlorination of a Mixture of Chlorinated Dicyanoquinones

The mixture (15 g) was obtained by the lead dioxide oxidation of an incompletely chlorinated sample of dicyanodichlorohydroquinone and contained 2,3-dicyanoquinone, 5-chloro-2,3-dicyanoquinone, and D.D.Q. It was dissolved in acetic acid (50 ml) and chlorinated at reflux temperature for 30 minutes. A small quantity of solid (1.7 g), identified as dicyanodichlorohydroquinone, was separated from the cooled solution, which was then evaporated *in vacuo*. The residue was crystallized from benzene and gave 7.5 g of the *tetrachloro*

[1]*When the concentration of hydrochloric acid was reduced to 2%, the yield of quinone was lower, and with 1% hydrochloric acid no quinone was obtained.*

compound, m.p. 130–132°. The filtrate was diluted with benzene (50 ml) and refluxed with charcoal (5 g) for 30 minutes. The resulting orange solution, after filtration and evaporation, yielded 4.5 g of D.D.Q., m.p. 213–215°.

METHANOLYSIS OF CARBOHYDRATE ORTHOACETATES[1]

A. S. PERLIN

Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan

Received November 5, 1962

ABSTRACT

Acid methanolysis of D-mannose 1,2-(methyl orthoacetate) 3,4,6-triacetate (I) yields mainly 3,4,6-tri-*O*-acetyl-D-mannose (II). D-Glucose 1,2-(ethyl orthoacetate) 3,4,6-triacetate (VIII) yields 3,4,6-tri-*O*-acetyl-D-glucose and methyl 3,4,6-tri-*O*-acetyl-β-D-glucopyranoside. The rate of methanolysis of II differs little from that of VIII, in marked contrast to the relative rates of hydrolysis of these compounds in aqueous acid. Several concurrent reactions appear to take place in methanol initiated by protonation at different positions on the orthoester ring.

During isolation, II is converted partially to 2,4,6-tri-*O*-acetyl-D-mannose (VI), a novel instance of acyl migration in the sugar series. Structural assignments for these two triacetates are based on chemical and proton magnetic resonance spectral data. The 2-acetate group of VI migrates during methylation, both II and VI yielding the same 2-*O*-methyl ether.

Orthoacetates undergo a rapid optical rotatory change in cold dilute methanolic hydrogen chloride. Dale (1), who first reported this property, obtained a small yield of methyl 2,3,4,6-tetra-*O*-acetyl-β-D-mannoside as the only identifiable product formed by methanolysis of β-D-mannose-1,2-(methyl orthoacetate) 3,4,6-triacetate (I). However, a related disaccharide orthoester [4-*O*-β-D-glucopyranosyl-β-D-mannose 1-2-(methyl orthoacetate) hexaacetate] was shown by Isbell (2) to furnish a hexaacetate of the disaccharide. Both types of products were isolated from the methanolysate of β-L-rhamnose 1,2-(methyl orthoacetate) 3,4-diacetate, i.e., the β-L-rhamnoside triacetate and a syrupy fraction that contained 3,4-di-*O*-acetyl-L-rhamnose (3). Pacsu has suggested (4) that transesterification occurs in these reactions between the orthoester group and the solvent, affording a derivative in which carbons-1 and -2 are unsubstituted. Intermediate formation of some 1,2-*trans* acyl chloride appeared to be the most likely source of the 1,2-*cis*-glycoside.

The methanolysis reaction has now been examined further as a route to some partially acylated sugars and as a means for characterizing complex orthoesters (5). The early experiment of Dale on the D-mannose orthoacetate (I) has been repeated and found chromatographically to yield mainly a partially acetylated D-mannose (II) and a small proportion of each of the anomeric glycosides.* When treated with lead tetraacetate in acetic acid the mixture of products rapidly consumed about 0.8 mole of oxidant per mole and, in place of II, the chromatogram now showed the presence of a pentose derivative (III). Hence II appeared to be 3,4,6-tri-*O*-acetyl-D-mannose, the product expected on the basis of Pacsu's proposed mechanism, and it thus amounted to about 80% of the total

[1]*Issued as N.R.C. No. 7165.*

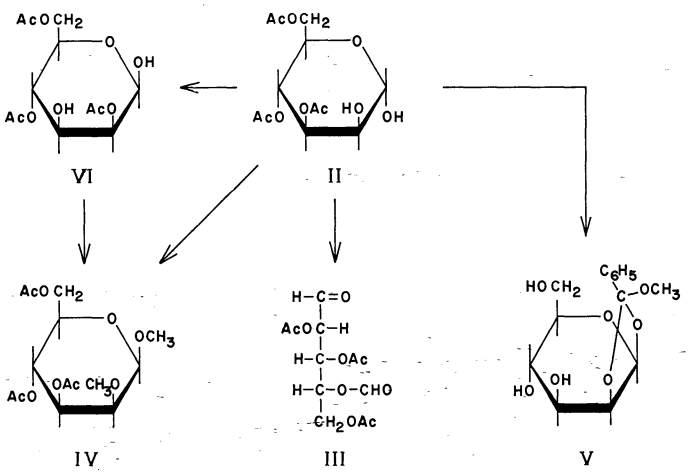
Presented to the Organic Chemistry Division, 45th Annual Conference of the Chemical Institute of Canada in Edmonton, Alberta, June, 1962.

**The methanolysis conditions are critical in that prolonged treatment yields products that correspond to di- and mono-acetates, as well as free mannose (cf. ref. 6).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

product. By column chromatography on silicic acid using chloroform–ether as eluant, or by countercurrent distribution between chloroform and water, II was readily isolated in a chromatographically pure condition. In the course of several preparations three different crystalline modifications of this product were obtained. One of these appeared to be hydrated and had m.p. 59° C; the other two were polymorphic forms of the anhydrous triacetate and had m.p. 98° or 108° C. All rapidly consumed 1 mole of lead tetraacetate and, from their optical rotatory properties, appeared to be α-anomers.

The product formed in the lead tetraacetate oxidation of II was a crystalline pentose derivative to which is assigned the structure 2,3,5-tri-*O*-acetyl-4-*O*-formyl-*aldehydo*-D-arabinose (III). Treatment of II with methyl iodide – silver oxide afforded methyl 3,4,6-tri-*O*-acetyl-2-*O*-methyl-β-D-mannopyranoside (IV) (7). When II was benzoylated, the acetate–benzoate treated with hydrogen bromide followed by methanol in the presence of silver carbonate, and the product deacetylated, β-D-mannose 1,2-(methyl orthobenzoate) (V) (8) was obtained. Assuming that no acetyl migration occurred during each of the treatments, these findings establish that II is 3,4,6-tri-*O*-acetyl-D-mannose. Additional evidence for this assignment is given below.



During isolation, II was converted in part to a triacetate (m.p. 170° C) (VI) which did not consume lead tetraacetate, was poorly soluble in organic media, and appeared from optical rotatory data to be a β-anomer. The compound dissolved readily in water and was recovered from the mutarotated solution, which thus showed that position 1 was unsubstituted. Therefore, the resistance to glycol cleavage meant that position 2 must have been acetylated. Because of the favorable orientation of the 2- and 3-hydroxyl groups of D-mannose, it appeared that VI could have been formed from II by migration of an acetyl group from position 3 to 2. Perhaps less likely was the alternative of successive migrations from position 6 to 1 to 2. Hence two feasible structures for VI were those of the 2,4,6- or the 2,3,4-triacetate.

A choice between these possibilities was readily provided by proton magnetic resonance spectroscopy. The spectra for several D-mannose derivatives,* including II, showed that when the primary group is not acetylated the signal for the two C_6 protons is close to

**The reference compounds were D-mannose, its 2-acetate (9), its α- and β-hexaacetates, 2,3,4,6-tetraacetate, and αβ-1,2,3,4-tetraacetate (8), and methyl α-D-mannoside. For some, the solvent was chloroform and for others, deuterium oxide; according to R. U. Lemieux (private communication) the chemical shift for a given proton generally appears at about the same frequency with each of these solvents.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

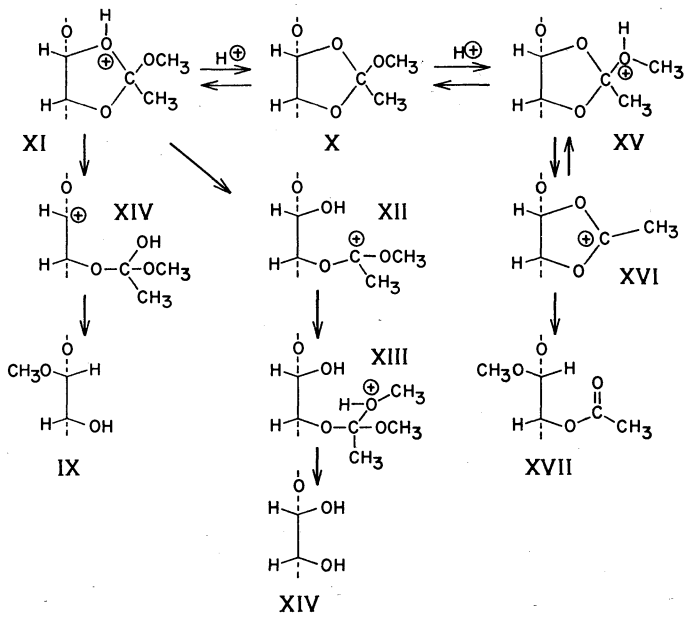
3.9 p.p.m. When acetylated, however, the typical paramagnetic shift (see ref. 10) of 0.3–0.4 p.p.m. is observed and the proton frequencies are about 4.2 p.p.m. Aside from the signals of the acetoxy protons, all signals in the spectrum of VI were at frequencies lower than 4.2 p.p.m., clearly indicative of an acetoxyl group at C_6. The spectrum of VI was similar to that of the 3,4,6-triacetate (II), which is to be expected because chemical shifts for the 2-, 3-, and 4-protons of D-mannose acetates are approximately the same (11). However, neither spectrum was well resolved. In each, signals for three protons were grouped closely together in the region 5.1–5.4 p.p.m., and signals for four protons in the region 4.2–4.4 p.p.m. Presumably, the relative positions for the H_2 and H_3 signals in the spectra of II and VI were interchanged, that is, the H_2 signal of II (or the H_3 signal of VI) was included in the broad band at higher field, whereas the H_3 signal of II (or the H_2 signal of VI) was included in the band at lower field. The absence of proton signals at frequencies of 5.9 to 6.1 p.p.m. confirmed that the anomeric hydroxyl group of each isomer was not acetylated (11). All of the acetoxy protons of II were closely equivalent, in agreement with the all-equatorial orientation assigned above, but the acetoxy-proton signals of VI were resolved into a major component at 2.22 p.p.m. and a minor component at 2.30 p.p.m., the latter perhaps corresponding to the presence of an axial acetate group at C_2 (11). These data, therefore, support the designation of VI as 2,4,6-tri-*O*-acetyl-D-mannose and of II as 3,4,6-tri-*O*-acetyl-D-mannose.

Most instances of acyl migration in the sugar series occur in the direction *away from* the anomeric center (12, 13), although the hydrolysis of acylated glycosyl halides may involve migration from C_2 to C_1 (e.g. ref. 14). Hence the formation of triacetate VI from triacetate III appears to be a novel type of rearrangement in that the direction is *towards* the anomeric center but does not actually involve C_1. This rearrangement takes place under the seemingly mild conditions to which II is subjected during isolation, although the compound is stable in water, dry or moist pyridine, or acetic acid. Triacetate VI is also stable in these solvents, but when treated with methyl iodide and silver oxide yielded the 2-*O*-methyl β-D-glycoside (IV), the same product as was formed on methylation of II. In the latter instance, therefore, the migration conforms to that generally observed in the methylation of partially acylated sugar derivatives (12, 13), the 2-acetate group migrating back to position 3.

Acid methanolysis of α-D-glucose 1,2-(ethyl orthoacetate) 3,4,6-triacetate (VII) (15) afforded two products in about equal proportion. These products were readily separated by countercurrent distribution between chloroform and water. One (VIII) was a syrupy triacetate which consumed 1 mole of lead tetraacetate and yielded pentose derivative III, and hence undoubtedly was 3,4,6-tri-*O*-acetyl-D-glucose; the other was methyl 3,4,6-tri-*O*-acetyl-β-D-glucoside (IX). Both of these products have been prepared from 1,2-anhydro-D-glucose triacetate (16, 17).

From the studies referred to at the outset and the current findings it is seen that the predominant type of product formed by acid methanolysis of 1,2-orthoacetates is that represented by 3,4,6-tri-*O*-acetyl-D-mannose (II) and -glucose (VIII). As visualized by Pacsu (4), its formation likely involves transesterification between the orthoester and the hydroxylic solvent. Thus, protonation of the orthoacetate (X) can lead successively to XI and the rearranged ion XII, and solvent attack can then give (protonated) orthoester XIII. By a similar sequence involving protonation of the C_2-oxygen of XIII, the acyclic orthoester group can be removed as methyl orthoacetate, and a 3,4,6-triacetate (XIV) thus liberated. The overall result should be the same if the reaction is initiated by protonation of the C_2-oxygen of X, except that in the intermediates corresponding to XII and XIII carbon-1, rather than -2, would be substituted.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



If rearrangement of XI occurs with opening of the C_1-oxygen bond, the orthoacid ion XIV would be formed. Solvent attack on the latter and transesterification of the orthoacid group could then yield a 3,4,6-triacetate of the methyl glycoside (i.e., IX). Because of the 1,2-*cis* orientation of XI and the 1,2-*trans* arrangement in the derived glycoside, ion XIV may be regarded as analogous to the ionic intermediate associated with nucleophilic substitution of 1,2-*cis* acyl halides (18). Protonation of the *O*-methyl group (as in XV) can give cyclic ion XVI, which, by rearward solvent attack, yields the 1,2-*trans* acyl glycoside (XVII, e.g., the α-D-mannoside). As pointed out by Pacsu (4), the 1,2-*cis* acyl glycoside could be formed via the 1,2-*trans* acyl chloride.

Methanolysis rates for the D-mannose- and D-glucose orthoacetate (I and VIII) differ by less than a factor of two (0.056 and 0.10 minutes^{-1}, respectively). In marked contrast, the D-glucose isomer is hydrolyzed by aqueous acid 19 times as fast as the D-mannose orthoester (19), this large difference being attributed to differences in stability of the transient cyclic ions (corresponding to XVI) involved in the hydrolyses. With a change of solvent from water to methanol, however, the course of reaction is altered and other types of pathways become more important. Presumably, also, the steric influence of the epimeric sugars on the relative stability of the cyclic carbonium ions (and hence on the hydrolysis rates (19)) is less of a factor with acyclic ions of the type visualized as intermediates in the methanolysis reactions.

EXPERIMENTAL

Melting points are corrected. Optical rotations were measured at 25±2°. Solutions were concentrated *in vacuo* at 40–45° C.

Nuclear magnetic resonance spectra were prepared with a Varian A60 spectrometer, chloroform or deuterium oxide being used as solvents and tetramethylsilane as the reference compound.

Methanolysis of β-D-Mannose 1,2-(Methyl orthoacetate)-3,4,6-triacetate (I)

To a solution of the crystalline orthoester (I) in methanol (350 mg in 4 ml; α_D −1.08°) was added a solution of hydrogen chloride in methanol (70 mg in 5 ml); the observed rotation changed to 0.30° within 1 minute, remaining constant during the next 10 minutes. Excess silver carbonate was then added and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

solution concentrated to a syrup (wt., 280 mg). Paper chromatographic examination of the syrup showed the presence of a major product ($R_{mannose}$ 4.3) and a minor product ($R_{mannose}$ 3.2); after deacetylation, the syrup contained mainly mannose, and methyl α- and β-D-mannoside as minor constituents. With longer methanolysis periods the proportion of product $R_{mannose}$ 3.2 increased, and a third material ($R_{mannose}$ 2.2) as well as free mannose were then detected.

The syrup (14.7 mg) in acetic acid (1 ml), when treated with lead tetraacetate solution (50 mg in 3 ml acetic acid), consumed (moles/mole (minute)): 0.80 (5); 0.85 (10); 0.85 (20), based on (approximate) m.w. of 306. Chromatographic examination of the oxidation product showed the presence mainly of material giving typical color reactions for pentose.

When the orthoester (I) in methanol was first deacetylated with sodium methoxide and the solution then acidified with methanolic hydrogen chloride, mannose was found chromatographically as the major product.

3,4,6-Tri-O-acetyl-α-D-mannose (II)

(*a*) The syrupy reaction product (2.80 g) obtained as above (methanolysis period, 5 minutes) was taken up in chloroform and added to a column of silicic acid (2×15 cm). First, the column was developed with chloroform (1000 ml), and then with chloroform:ether (95:5). Fractions of the eluate (100 ml) were collected and each examined by paper chromatography before and after deacetylation with sodium methoxide. Fractions 3–17 contained a mixture of the acetylated anomeric glycosides and tetraacetyl mannose (0.83 g); fractions 18–56 contained syrupy product II (1.35 g) which, on extraction into ether, afforded crystalline material (0.9 g), m.p. 108–109° C; $[\alpha]_D$ 51° → 39° (72 hours) (*c*, 1.4 chloroform); $[\alpha]_D$ 23° → 8° (eqm.) (*c*, 0.9 water). Calculated for $C_{12}H_{18}O_9$: C, 47.06%; H, 5.92%. Found: C, 47.01%; H, 5.82%.

The crystalline product obtained in this way in another experiment had m.p. 96–98° C, $[\alpha]_D$ 22° → 7° (eqm.) (*c*, 2.3 water); when recrystallized from ether by seeding with the higher-melting form, the m.p. was 106–109° C. Calculated for $C_{12}H_{18}O_9$: C, 47.06%; H, 5.92%; acetyl, 42.16%. Found: C, 47.01%; H, 5.86%; acetyl, 42.1%.

(*b*) The crude methanolysis product (650 mg) in chloroform (10 ml) was subjected to countercurrent extraction (four stages) against water (10-ml portions). By paper chromatography, water layers 1 and 2 were found to contain most of II (350 mg and 50 mg, respectively) whereas chloroform layer 4 contained most of the glycoside fraction (90 mg). Extraction of syrupy II with ether gave crystalline material of m.p. 95–97° C.

Material isolated from the aqueous phase in a second experiment had m.p. 57–59° C, $[\alpha]_D$ 12° → 8° (*c*, 1.1 water). This product rapidly consumed approximately 1 mole of lead tetraacetate per mole. Calculated for $C_{12}H_{18}O_9 \cdot H_2O$: C, 44.44%; H, 6.22%. Found: C, 45.02%; H, 6.24%.

2,3,5-Tri-O-acetyl-4-O-formyl-aldehydo-D-arabinose (III)

Triacetate II (m.p. 108–109° C; 0.20 g) in acetic acid (25 ml) was treated with a solution of lead tetraacetate in acetic acid (0.28 g in 12.5 ml). After 20 minutes the solvent was evaporated off, the residue was triturated several times with ether, and the ether extract was concentrated, affording a product of m.p. 84.5–85° C, $[\alpha]_D$ +88° (*c*, 1.4 benzene), λ_{max} 293 mμ (in ether). Calculated for $C_{12}H_{16}O_9$: C, 47.37%; H, 5.30%; neut. equiv., 76.0. Found: C, 47.42%; H, 5.34%; neut. equiv., 76.5 (by cold alkaline saponification). The saponification mixture was acidified and distilled, the distillate giving a positive mercuric chloride test for formic acid.

Methyl 3,4,6-Tri-O-acetyl-2-O-methyl-β-D-mannoside (IV) from II

Triacetate II (m.p. 96–98°; 0.63 g) was suspended in methyl iodide (15 ml); anhydrous calcium sulphate (6.0 g) and silver oxide (4.0 g) were added; and the mixture was heated under reflux for 7 hours. The solids were filtered off and washed with ether, the combined filtrates on concentration yielding a partially crystalline residue (0.65 g). The latter was triturated with ether, and the solids were recrystallized from ethanol–ether; m.p. 148–149° C, $[\alpha]_D$ −65° (*c*, 1.7 chloroform) (lit. (7): m.p. 146° C, $[\alpha]_D$ −46°). Calculated for $C_{14}H_{22}O_9$: C, 50.29%; H, 6.63%. Found: C, 50.21%; H, 6.68%.

The deacetylated product consumed 1.0 mole of lead tetraacetate per mole (in glacial acetic acid containing potassium acetate (20)). Hydrolysis of the deacetylated glycoside with 0.5 *N* sulphuric acid yielded a reducing sugar ($R_{rhamnose}$ 1.0) which was attacked very slowly by lead tetraacetate; in the presence of potassium acetate, the sugar was oxidized readily yielding formaldehyde. These oxidation properties are characteristic of a 2-substituted hexose (21).

The ether-soluble fraction (0.25 g) ($[\alpha]_D$ 0°) appeared, from chromatographic examination after deacetylation, to contain more of IV, as well as a high proportion of methyl β-D-mannoside and a trace of the α-D-glycoside.

β-D-Mannose 1,2-(Methyl orthobenzoate) (V)

Triacetate II (m.p. 96–98° C; 0.20 g) in pyridine (10 ml) was treated with benzoyl chloride (2 ml) at 3° C for 18 hours. The product was extracted into chloroform, the extract was washed successively with sodium bicarbonate solution, tartaric acid solution, and water, then dried, and saturated with hydrogen bromide. After 6 hours the extract was again washed with bicarbonate solution and water, and concentrated. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

syrup residue, in benzene (1 ml), was added to methanol (10 ml) containing silver carbonate (1 g), the suspension was shaken for 2 hours, filtered, and the filtrate concentrated (yield, 0.20 g; $[\alpha]_D$ −61°, *c*. 5.7 methanol). Excess barium methoxide was added to a solution of the syrup in methanol, the solution was neutralized with carbon dioxide after 2 hours, filtered, and evaporated. The infrared absorption spectrum and paper chromatographic mobility of the syrupy product were indistinguishable from those of syrupy β-D-mannose 1,2-(methyl orthobenzoate) (8).

2,4,6-Tri-O-acetyl-β-D-mannose (VI)

After elution of II from the silicic acid by chloroform:ether (as described above), additional material (0.66 g from 2.8 g of the crude methanolysate) was obtained by washing the adsorbent with acetone. When triturated with ether, the product solidified; m.p. 163–167° C, $[\alpha]_D$ −38° → 18° (eqm.) (*c*, 1.1 water); $[\alpha]_D$ −70° → 4° (18 hours) (*c*, 1 pyridine). Treated with lead tetraacetate in acetic acid for 20 minutes, the compound consumed only a trace of oxidant; little oxidation occurred also when pyridine was the solvent, the compound being tested both before and after mutarotation had occurred. Calculated for $C_{12}H_{18}O_9$: C, 47.06%; H, 5.92%; acetyl, 42.16%; mol. wt., 306. Found: C, 47.09%; H, 5.95%; acetyl, 41.9%; mol. wt., 271 (in water at 37°, by vapor pressure thermometry).

An aqueous solution of VI, after mutarotation had occurred, was concentrated and stored at 3° C, affording crystals of m.p. 170–171°, which were shown by X-ray diffraction to be unchanged starting material. Calculated for $C_{12}H_{18}O_9$: C, 47.06%; H, 5.92%. Found: C, 46.82%; H, 5.92%.

Triacetate VI also was obtained following countercurrent extraction of the methanolysate (as described above), in admixture with II, the latter being removed by washing with ether.

Methyl 3,4,6-Tri-O-acetyl-2-O-methyl-β-D-mannoside (IV) from VI

Triacetate VI (0.30 g) was suspended in methyl iodide (10 ml); anhydrous calcium sulphate (3.0 g) and silver oxide (2.0 g) were added; the mixture was heated under reflux for 18 hours and then extracted with chloroform. The extract was concentrated and the residue was remethylated, giving 0.23 of a partially crystalline product. The solid portion was separated out in ether and, on recrystallization from ethanol–ether, had m.p. 148–149° C; the X-ray powder diagram was indistinguishable from that of IV. The ether extract (0.10 g), $[\alpha]_D$ −10° (*c*, 2 chloroform), appeared, from chromatographic examination after deacetylation, to consist of IV and a second component of slightly greater R_f, in about equal proportions. On treatment with lead tetraacetate – potassium acetate in acetic acid the deacetylated glycoside mixture consumed 0.6 mole of oxidant per mole, indicating the presence of the 3-*O*-methyl ether as a minor component.

Methanolysis of α-D-Glucose 1,2-(Ethyl orthoacetate) 3,4,6-triacetate

The orthoester (15) (0.10 g) in methanol (2 ml) (α_D 2.14°) was treated with methanolic hydrogen chloride (0.2 ml, 2%); in 2 minutes the observed rotation was α_D 3.53°, and at 5 minutes 3.30°. Excess of ethereal diazomethane was added and the solution concentrated to a syrup (0.08 g). Chromatographic examination of the product showed the presence of a major component travelling slightly slower than II; after deacetylation, glucose and methyl glucoside were detected in about equal proportion. On treatment with lead tetraacetate in acetic acid the observed uptake of oxidant (moles/mole (minute)) by the syrup was 0.25 (15), 0.37 (30), 0.48 (85), 0.50 (270).

3,4,6-Tri-O-acetyl-D-glucose (VII)

To the orthoester (1.0 g) in methanol (20 ml) was added methanolic hydrogen chloride (2 ml, 2%) and after 2 minutes the solution was neutralized with silver carbonate. The filtrate was acidified slightly with acetic acid, concentrated, and the syrupy residue (0.79 g) was subjected to a four-stage countercurrent extraction between chloroform (25-ml portions) and water (15-ml portions). Water layers 1 and 2 and chloroform layers 1 and 2 were combined and concentrated to yield a syrup (0.38 g). Calculated for $C_{12}H_{18}O_9$: C, 47.06%; H, 5.92%; acetyl, 42.16%. Found: C, 46.93%; H, 6.04%; acetyl, 40.9%.

The syrup (0.10 g) in acetic acid (20 ml) was treated with lead tetraacetate (0.13 g) and, when a negative starch–iodide test was obtained, the reaction mixture was worked up as in the oxidation of II, the ether extract affording crystals (0.06 g) having m.p. 83–85°, undepressed by admixture with III.

Methyl 3,4,6-Tri-O-acetyl-β-D-glucoside (VIII)

The material contained in chloroform layers 3 and 4 afforded a crystalline product (0.23 g) from ethanol–ether–hexane; m.p. 97–99° C, $[\alpha]_D$ 18.5° (*c*, 1.1 chloroform) (lit. (16): m.p. 95° C, $[\alpha]_D$ 19°). Calculated for $C_{13}H_{20}O_9$: C, 48.75%; H, 6.29%; acetyl, 40.25%. Found: C, 48.57%; H, 6.17%; acetyl, 40.0%.

When fully acetylated the product afforded methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucoside, m.p. 104–106° C, the X-ray powder diagram of which was indistinguishable from that of an authentic specimen.

Rates of Methanolysis of Orthoesters

β-D-Mannose 1,2-(methyl orthoacetate) 3,4,6-triacetate (15.3 mg) or α-D-glucose 1,2-(ethyl orthoacetate) 3,4,6-triacetate (16.2 mg), in methanol (1 ml), was treated with 0.25 *N* methanolic hydrogen chloride (0.005 ml). From the observed changes in optical rotation of the solutions, first-order rate constants were calculated:

THE THERMAL DECOMPOSITION OF AZOMETHANE

I. EFFECT OF ADDED OLEFIN AND NITRIC OXIDE[1, 2]

ABSTRACT

The addition of ethylene and propylene reduces the rate of azomethane decomposition as measured by the rate of nitrogen production, and also reduces the ratio CH_4/N_2 in the products, but the reduction in the value of both quantities is different for each of the two olefins. In 100% decomposition, ethylene and propylene both increase somewhat the ratio (nitrogen recovered)/(azomethane decomposed). These results are interpreted to mean that there is in fact a short chain in the pyrolysis, but that ethylene and propylene are unsuitable inhibitors.

The addition of a few millimeters of NO reduces the rate to a minimum which is lower than that with added propylene or ethylene (apparent chain length 2 to 3), but further addition of NO increases the rate again. Identical result is obtained in a packed vessel. The yield of methane, ethane, and ethylene is reduced to almost zero with a sufficient amount of NO. The ratio (NO consumed)/(nitrogen produced) reaches the value of two in the neighborhood of the rate minimum. It is concluded that the net inhibited rate, i.e. rate corrected for the stimulatory effect of NO, refers to the initial unimolecular process $CH_3N_2CH_3 \rightarrow 2CH_3 + N_2$. The rate as well as the activation energy of this process is found to be pressure dependent.

It is shown by the use of the isotopic nitric oxide ^{15}NO that about one-half of the rate increase at higher NO pressures is due to nitrogen produced from NO. The remainder of the rate increase is accounted for by a NO-induced decomposition of azomethane.

INTRODUCTION

Azomethane has long been believed to represent a good example of a unimolecular reaction. All earlier studies were done by the manometric method (1), but when the products were analyzed and found complex (2) doubts arose about the significance of manometric results, and about the unimolecularity of the reaction. Later, the reaction was studied by the toluene-carrier technique and followed by the rate of appearance of nitrogen (3), and the new results were still consistent with the old. Recently, however, the toluene-carrier results were disavowed (4). New work by the static method by Steel and Trotman-Dickenson (4), in which the reaction was followed by analyzing for nitrogen, revealed that propylene inhibited the reaction at higher pressures of azomethane, but accelerated it at lower pressures of azomethane; at a sufficiently high pressure of propylene the rate became independent of initial azomethane pressure. These results were interpreted by the authors to mean that the effect of propylene was twofold: increase in the rate of reaction due to an increased rate of energization, and inhibition of a short chain in azomethane. The presence of surface effects was cited by the authors as further proof for the presence of a chain in the decomposition.

In the presence of toluene, however, no inhibition was observed, at least in the range of azomethane pressures studied by the authors, and the limiting rate reached at high toluene pressure was below the limiting rate at high propylene pressure.

[1]*Experimental work done at the University of North Carolina under a grant from the National Science Foundation.*

[2]*Based in part on a paper presented before the Division of Physical Chemistry, 139th Meeting of the American Chemical Society, St. Louis, Mo., March 1961.*

Thus, while these results do indicate the probable existence of a reaction chain in azomethane, the exact chain length, as well as the amount of inhibition, if any, obtainable with toluene or propylene, remains in doubt. It was therefore decided that further investigation of the inhibition of azomethane was warranted.

EXPERIMENTAL

I. Azomethane

Azomethane was prepared by the method of Renaud and Leitch (5): *sym*-dimethyl hydrazine hydrochloride (purchased from the K & K Laboratories, Jamaica, N.Y.) was treated with excess alkali to liberate the free base. This alkaline mixture was then added, under constant stirring, to a suspension of yellow mercuric oxide in water. When the pressure was reduced, azomethane escaped and was collected in a liquid nitrogen trap, from which it was distilled by three trap-to-trap distillations through two 1-m lengths of 20 mm I.D. tubing packed with KOH and P_2O_5, respectively, and then into a blackened storage flask.

An attempt to purify azomethane by gas chromatography was unsuccessful. Azomethane cuts obtained from crushed firebrick columns with a variety of partitioning liquids (Octoil-S, dioctyl phthalate, dimethyl formamide, cuprous chloride in benzonitrile, polyethylene glycol 400) and examined by infrared spectroscopy generally revealed the presence of numerous impurities not present in the sample before "purification". Purification, when required, was therefore done by orthodox means. The spectrum of fresh azomethane was generally identical with the published datum (6); impurities, when present, turned out to be an assortment of the various chlorinated methanes.* Azomethane containing any absorption at or above 13 μ (methyl chloride, methylene chloride, chloroform) was discarded; azomethane with traces of carbon tetrachloride (absorption at 12.6 μ) was purified by distillation at dry ice temperature. To facilitate this operation, and to keep the decomposition of azomethane at a minimum, the gas was kept in dry ice at all times, and when required, samples withdrawn by a distillation into a trap immersed in liquid nitrogen. During manipulations, azomethane gas was shielded from daylight by painting all connecting tubing black and by working in subdued daylight when necessary; its exposure to room temperature was kept to a minimum. With this procedure, different batches of azomethane gave identical rates of decomposition within experimental error.

II. Other Materials

Propylene, ethylene, and nitric oxide were "C.P." grade gases obtained from the Matheson Co. The hexafluoroethane was a gift from the DuPont Co. The olefins and the C_2F_6 were purified by three bulb-to-bulb distillations and dried by passage through KOH and P_2O_5 tubes. These gases contained less than 0.1% of impurity as determined by gas chromatography.

Nitric oxide was purified as described by Calvert, Thomas, and Hanst (7), followed by three trap-to-trap distillations and drying by passage through KOH and P_2O_5 tubes. The nitric oxide so obtained had about 0.4% of nitrous oxide, as determined by gas chromatography. This impurity was removed by subliming the NO from a trap immersed in liquid oxygen to a trap immersed in liquid nitrogen. This procedure, though tedious, is very effective: The N_2O content was thus reduced to 0.06%, as determined by gas chromatography.

The isotopic nitric oxide, ^{15}NO, stated to contain 97.7 ± 0.3 atom% ^{15}N (this quantity includes nitrogenous impurities), was purchased from the Isomet Corp., Newark, N.J. This NO, as received, contained about 0.3% of nitrous oxide. Sublimation, described above, reduced this content to 0.02%. Assuming, as seems reasonable, that the isotopic composition of the N_2O was roughly the same as that of the bulk NO, the purification process did not change the isotopic composition of NO.

III. Apparatus

A conventional static system was employed. The reaction vessel was placed inside a furnace with a heavy iron core and thick insulation of glass wool all around. The temperature of this furnace was controlled by a platinum wire winding wound between the heater windings in the manner described by Schneider and Hollies (8). This platinum winding was part of a resistance bridge, the output of which was fed to a mirror galvanometer, which, in turn, actuated a photoelectric relay by means of an optical lever. This arrangement was capable of maintaining the temperature inside the reaction vessel (as determined at the location of the thermocouple) within $\pm 0.02°$ C.

The temperature was measured with an iron–constantan thermocouple calibrated at the melting point of tin (231.9° C), cadmium (320.9° C), and zinc (419.5° C). Readings were taken with a Leeds & Northrup Type K potentiometer.

The majority of runs were done in a spherical reaction vessel fabricated from a 250-ml spherical Pyrex flask and provided with a radial thermocouple well. The surface-to-volume ratio of this vessel was about 0.75 cm^{-1}. Packed runs were done in a similar vessel made from a 1000-ml spherical Pyrex flask packed with 217 pieces of 7 mm O.D. Pyrex tubing, each about 4 cm long, with fire-polished ends. The surface-to-volume ratio of this flask was about 5.7 cm^{-1}. Prior to use each flask was carefully cleaned with fuming sulphuric acid. Vessels so cleaned gave reproducible results from the very start, the rate of the second run

*The authors are indebted to Mr. G. Beaudoin for help in the determination of impurities.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

generally corresponding to the constant reproducible value. Upon removal, the inside of such a vessel showed a thin uniform carbonaceous film resembling a photographic neutral density filter.

The gas chromatograph used consisted of a Perkin–Elmer Model 154-B thermistor detector placed inside an insulated box. The temperature inside this box was regulated at 40.25±0.05° C by means of a mercury regulator and relay. The detector circuit was in all essentials similar to that of the Perkin–Elmer. The output signal was displayed by a Brown "Elektronik" recorder Model 153.

Helium (purchased from the Southern Oxygen Co., Charlotte) was used as carrier gas; it was purified by passage through a charcoal trap immersed in liquid nitrogen. The helium flow was maintained at about 40 ml/min, as determined by a capillary flowmeter calibrated by a wet gas meter.

Gases for analysis by gas chromatography were collected, measured, and injected in the column by the simple apparatus shown in Fig. 1. It functions as follows: By pumping with the Toepler pump, the gas to

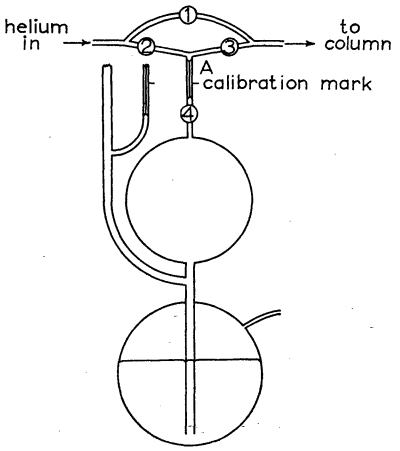

FIG. 1. Combination Toepler pump and sample injection device.

be analyzed is collected in the Y-shaped calibrated volume A enclosed by the calibration mark and by stopcocks 2 and 3. While pumping is in progress, carrier gas is routed through a bypass (stopcock 1 open, stopcocks 2 and 3 closed, stopcock 4 closed between pump strokes). When pumping is complete, mercury is brought to the calibration mark, and the pressure inside A is read on a scale attached to the manometer arm of the Toepler pump. Stopcock 4 is then closed, and stopcocks 2 and 3 opened, in that order, and stopcock 1 closed. The sample has now been injected into the carrier gas stream.

IV. Procedure

In a typical experiment, a mixture of azomethane with foreign gas was prepared by measuring out the requisite amounts of each gas in a gas buret. Prior to expansion in the reaction vessel, the gases were thoroughly mixed by raising and lowering mercury in a 500-ml flask 30 times. The reaction was allowed to proceed to no more than 5% conversion in every case. At the end of the selected reaction time, the reaction was quenched by expanding the gases into a trap immersed in liquid nitrogen. After 5 minutes, non-condensable gases were pumped out by means of a Toepler pump, measured, and injected in the gas-chromatographic column in the manner described under Section III. When nitric oxide was present as foreign gas, the non-condensable fraction, in addition to nitrogen and a trace of methane, contained also nitric oxide, owing to the appreciable vapor pressure of nitric oxide at liquid nitrogen temperature (about 0.1 mm at −196° C).

In experiments with the isotopic nitric oxide, ^{15}NO, it was necessary to remove the nitric oxide from the non-condensable fraction because of possible interference in a subsequent mass-spectrometric analysis. The non-condensable fraction (including ^{15}NO) was collected as above; a small aliquot was then analyzed by gas chromatography to determine roughly its content in nitric oxide. A slight excess of pure oxygen (Air Reduction Co. "Assayed Reagent Oxygen") was then added, and the NO_2 removed by passing the gas five times through a U trap immersed in liquid nitrogen. Next another aliquot was taken for analysis to make sure that all the nitric oxide has been removed. The sample was then sealed in a break-seal bulb for analysis on a mass spectrometer. In these experiments the extent of decomposition of azomethane was 8% in order to increase the amount of nitrogen for analysis.

In runs in which the consumption of nitric oxide was measured, the non-condensable fraction was first pumped off at −196° C, the trap containing the reaction products placed in liquid oxygen, and the nitric oxide then pumped off and measured (vapor pressure of NO at −183° C is about 4 mm). Total nitric oxide recovered was the sum of NO pumped off at −196 and −183° C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

When analysis was made for C_2 and C_3 hydrocarbons, nitrogen and methane were first removed at −196° as above. The trap containing the reaction products was then placed in a pentane slurry (−130°), left standing for 5 minutes, and the C_2+C_3 fraction pumped off with a Toepler pump, measured, and injected in a column for analysis. If nitric oxide was present, it had to be removed first, either with oxygen or by pumping at −183° C. The former procedure was preferred in runs in which the NO consumption was not measured. The latter procedure resulted in the presence of some NO in the C_2+C_3 fraction, but this caused no interference. NO also caused the presence of N_2O in the C_2+C_3 fraction. A small part of the N_2O found was originally present in the NO as an impurity (see Section II), but most of it was produced in the reaction. The N_2O figures reported under Results have been corrected for the N_2O impurity in NO.

V. Analysis

All analyses were done by quantitative gas chromatography. The non-condensable fraction was analyzed on a 3-m ¼-in. copper column filled with 40–60 mesh high-activity charcoal (Burrell, cat. No. 341–10). The column was capable of separating nitrogen, nitric oxide, carbon monoxide, and methane. The separation of CO from NO was incomplete if an excess of NO was present, but the CO could still be detected as a small peak in the NO tail.* None of the reaction mixtures analyzed, however, showed the presence of even a trace of CO.

The column was calibrated for nitrogen and methane by injecting a known amount of each gas on the column and measuring the corresponding peak area on the chromatogram. The calibration was then checked on synthetic nitrogen–methane and nitrogen – nitric oxide mixtures. About 20 calibration points each were obtained for nitrogen and methane, spaced over the range 0–20 μmole. Peak areas were measured with a polar planimeter, in duplicate determination, and also by multiplying peak height by width at half-height. It turned out that the latter method offered a precision at least as great as duplicate planimetering, and was considerably faster; it was therefore adopted. A similar conclusion was reached by Janák (9). Weighing of cut-out chromatograms was not feasible because of great seasonal variations in ambient humidity.

The calibration was linear over the entire range, and the calibration factor, determined by the method of least squares, showed a standard deviation of ±0.8% for nitrogen and ±1.6% for methane. The ratio of calibration factors (= ratio of sensitivities) for nitrogen and methane was 1.14, in agreement with the figure 1.17 determined by Messner *et al.* (10). First-order rate constants were calculated from the amount of nitrogen found, assuming ideal gas behavior.

The presence of nitric oxide affected the quantitative results for nitrogen to some extent when the amount of NO relative to nitrogen was large. It was found that nitric oxide produced an enhancement of the nitrogen peak. That this was not due to the presence of nitrogen in the NO was established by numerous purification experiments. This "nitrogen shadow" increased linearly with the amount of NO, corresponding to 1.2% of the NO present in the sample injected in the column. An appropriate correction was applied to the nitrogen peak in cases where the amount of NO present was large enough to make this correction significant. It is interesting to note that a similar enhancement of the nitrogen peak due to NO was observed by Smith *et al.* (11), although these authors used a very different column and obtained NO by difference.

Several calibration runs were done with nitric oxide, but it soon became apparent that an accuracy comparable with that for nitrogen was attainable only under special precautions. The amount of nitric oxide was therefore obtained by difference in cases where this information was desired.

The C_2+C_3 fraction was analyzed on a 3-m, ¼-in. copper column filled with activated alumina (Burrell, cat. No. 341–35). This column was capable of separating nitrogen and methane, but not N_2–NO or NO–CH_4 mixtures, which were eluted as one peak. Ethane, nitrous oxide, ethylene, propane, and propylene were well separated. The column was calibrated for ethane, nitrous oxide, ethylene, and propane in the manner described above for the non-condensable fraction. The ratios of sensitivities ethane to ethylene and ethane to propane were 1.03 and 0.84, respectively, compared with 1.06 and 0.79 determined by Messner *et al.* (10). This column was also used for checking nitric oxide for nitrous oxide impurity.

RESULTS

I. Inhibition by Olefin

The results of inhibition experiments with ethylene and propylene at 275.9° C are shown in Fig. 2. The initial azomethane pressure was kept constant at 22.2 mm in each case. The limiting inhibited rate in the presence of propylene, about 2.25×10^{-5} sec^{-1}, is in agreement with the results of Steel and Trotman-Dickenson (4), who found a limiting rate of about 2.2×10^{-5} sec^{-1} at 276.3° C and 19.7 mm of azomethane.

Table I gives results of runs carried to completion, i.e. 100% conversion. The theoretical reaction time for 99.9% reaction was calculated from rate constants read off the graph

**The separation of O_2 and N_2 was likewise incomplete, but it was good enough to permit the detection of a small amount of one gas in the presence of a large amount of the other.*

TABLE I

Total decomposition runs at 275.9° C

	Azomethane only	Ethylene present	Propylene present
Initial pressure of azomethane (mm)	22.2	22.2	22.2
Initial pressure of foreign gas (mm)	—	168.5	167.0
Reaction time (hr)	89	82	82
Theoretical reaction time for 99.9% decomposition (hr)	60	75	84
Nitrogen recovery (%)	78.5	86.0	82.0
CH_4/N_2 ratio in non-condensables	1.0	0.46	0.44

in Fig. 2 for the appropriate olefin pressure. These results are the average of at least two runs in each case. Nitrogen recovery is defined as (nitrogen found)/(nitrogen input), the nitrogen input being equal to 100% azomethane decomposed. The results for unadulterated azomethane are essentially identical with those reported by Riblett and Rubin (2).

II. Inhibition by Nitric Oxide

Typical results of inhibition experiments with nitric oxide in an ordinary and packed vessel are shown in Fig. 3 for an initial azomethane pressure of 40 mm. The figure does not show results of propane analyses since no propane was found even at the lowest nitric oxide pressure, although in the absence of nitric oxide propane was formed in amounts comparable with ethylene yields. On the other hand, the quantities of CH_4, C_2H_6, and C_2H_4 found in the presence of more than 20 or 30 mm NO, though small, were not zero. It is seen that in the presence of NO packed runs actually gave rates closer to unpacked values than in the absence of NO. All previous investigators (12, 13, 14) agree that packing has little influence on the rate. In addition, nitric oxide showed no residual effect of the sort reported by Szabó and Márta (15) in the case of the NO-inhibited decomposition of propionic aldehyde, since unadulterated azomethane decomposed at the usual higher rate when introduced in the reaction vessel immediately after a series of experiments with NO.

The ascending portion of the rate constant vs. NO pressure plot is linear within experimental error. The broken line represents an extrapolation of the linear part back to zero NO pressure, calculated by the method of least squares. This extrapolated rate will be called the "net inhibited rate", k_0.

Some of the runs shown in Fig. 3 were repeated using the isotopic nitric oxide ^{15}NO

*$\Delta P_{29} = P_{29} - 0.00735P_{28} - 0.048P_{30}$.

0.73 mole% (16), so that the contribution from this source is equal to $0.00735P_{28}$, and the fraction of nitrogen, of natural isotopic composition, from azomethane, $f_{N_2}^{azo}$, is then:

$$f_{N_2}^{azo} = \frac{1.00735P_{28}}{P_{28}+P_{29}+P_{30}}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

The rate constant calculated on the basis of ordinary nitrogen, i.e. corrected for the nitrogen *not* formed from azomethane, is given in the last column of Table II under "k_{corr}". The natural abundance of the isotopic species $^{15}N_2$ was ignored, since the amount is only 0.0014 mole% (17).

The amount of NO decomposed to nitrogen can be calculated by observing that of 100 molecules of NO that have reacted, 97.7 will be ^{15}NO and 2.3 ^{14}NO. Since it obviously requires 2 molecules of NO to form N_2, the composition of the reaction products will be very nearly 2.3 molecules $^{14}N^{15}N$ and 47.7 molecules $^{15}N_2$ per 100 molecules NO, or $P_{29} = 0.048P_{30}$. This neglects the chance of two molecules of ^{14}NO reacting to form $^{14}N_2$. The fraction of nitrogen originating from NO, $f_{N_2}^{NO}$, is then:

$$f_{N_2}^{NO} = \frac{1.048P_{30}}{P_{28}+P_{29}+P_{30}}.$$

ΔP_{29}, defined as $P_{29}-0.00735P_{28}-0.048P_{30}$, is the remainder of the 29 peak that cannot be accounted for by the isotopic composition of nitrogen in the reactants. It remains fairly constant throughout the range of NO pressures, which would suggest either an experimental error in the isotopic analysis, or perhaps a slight fractionation of nitrogen in the course of the azomethane synthesis. In Fig. 4 k_{corr} is plotted, where the solid line

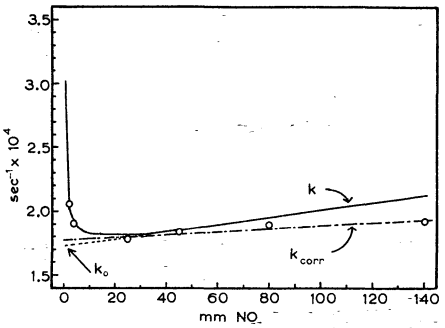

FIG. 4. Extrapolation for "net inhibited rate" k_0. Full line is k from Fig. 3; circles are k_{corr} from Table II. $(A)_0 = 40$ mm; 303° C.

represents k from Fig. 3. and the circles are values of k_{corr} from Table II. It is seen that the plot of k_{corr} vs. NO pressure is of the same type as the plot of k, i.e. a rapid initial drop followed by a slow linear increase. The dot–dash line in Fig. 4 is a least-squares straight line calculated for the linear ascending portion of k_{corr}. The "net inhibited rate" extrapolated from k is 1.73×10^{-4} sec^{-1}, while that extrapolated from k_{corr} is 1.78×10^{-4} sec^{-1}. The discrepancy between the two is probably somewhat less than the estimated experimental error, so that it may be concluded that both k and k_{corr} extrapolate essentially to the same "net inhibited rate".

Figure 5 shows results of inhibition experiments at 5 mm azomethane initial pressure. In this case, in addition to analyses for CH_4, C_2H_6, C_2H_4, and N_2O, the consumption of NO was also measured. The dependence of the various product yields on initial NO pressure is quite analogous to the pattern shown in Fig. 3. Analyses for propane are not reported since no propane was found even at the lowest NO pressure.

It was not possible to measure NO consumption at higher azomethane pressures because the linear part of the ascending portion of the rate curve then shifts to higher NO pressures. The NO consumed, a small number, is then given by the difference between two large numbers, NO (initial) — NO (final), which results in poor accuracy.

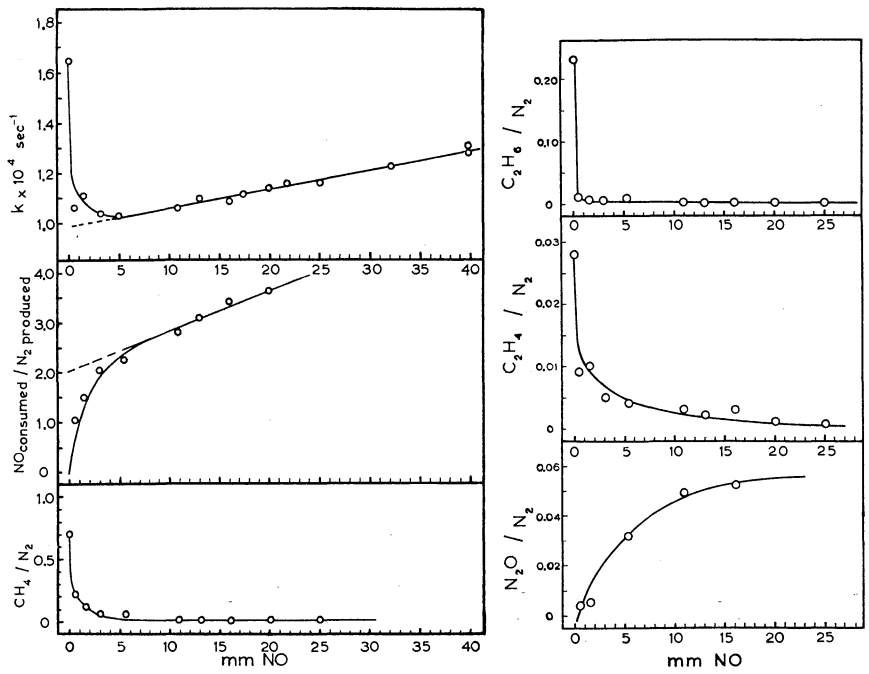

FIG. 5. Nitric oxide inhibition at 303° C. Azomethane initial pressure $(A)_0$ constant at 5 mm. Broken lines are extrapolations to zero NO pressure. Common NO scale.

Figure 6 shows the results of nitric oxide inhibition at 275.9° C and at three different initial azomethane pressures, covering an almost 200-fold pressure range. The results of

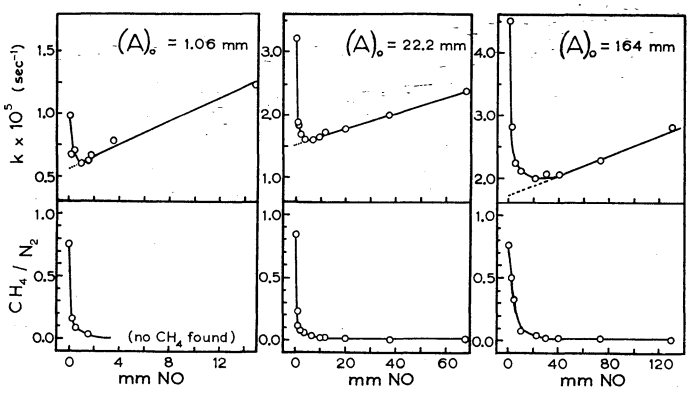

FIG. 6. Nitric oxide inhibition at 275.9° C and at three different initial pressures $(A)_0$ of azomethane. Dotted line indicates extrapolation for "net inhibited rate".

analyses for methane, the other major product after nitrogen, are also given. It is seen that at each azomethane pressure the general pattern is identical with results shown in Figs. 3 and 5. Only linear portions of the ascending parts of the rate curves are shown. At $(A)_0 = 22.2$ and 163.5 mm, linearity ceases above about 120 mm NO, and at $(A)_0 = 1.06$ mm above approximately 20 mm NO.

The "net inhibited rate", k_0, has been determined by means of the above extrapolation procedure at two additional temperatures for each of the three azomethane pressures. From these the activation energy and the pre-exponential factor, together with the corresponding standard deviation, were calculated for each pressure. The complete results, including those plotted in Fig. 6, are shown in Table III.

DISCUSSION

No discussion of these results is possible without making first some assumption about the mechanism of azomethane decomposition in the absence of inhibitor. It is generally agreed that the first step in the decomposition is the process

$$CH_3N{=}NCH_3 \rightarrow CH_3 + CH_3N{=}N.$$

Thermochemical arguments have been advanced (3) to show that the $CH_3N{=}N$ fragment is highly unstable and will rapidly, if not immediately, decompose according to

$$CH_3N{=}N \rightarrow CH_3 + N_2.$$

Consideration of the potential energy surface involved shows that the simultaneous splitting of the two methyls,

$$CH_3N{=}NCH_3 \rightarrow 2CH_3 + N_2, \qquad [1]$$

affords a reaction path of lowest energy (8). In any event, it is very likely that there is one nitrogen formed per C—N bond broken, the rate of this bond rupture being the information desired.

There exist numerous proofs for the presence of methyl radicals in the system (19), the most recent of which (20) is the demonstration that in the gas phase photolysis of azomethane in the presence of 1,4-cyclohexadiene almost all of the carbon ends up as methane.

At low conversion, provided the fragment $CH_3N{=}N$ has no appreciable lifetime, the main secondary reaction is likely to be

$$CH_3 + CH_3N{=}NCH_3 \rightarrow CH_4 + CH_2N{=}NCH_3. \qquad [A]$$

Since the rate of the azomethane decomposition is followed by the rate of formation of nitrogen, the above reaction will affect the rate only if the ultimate fate of the $CH_2N_2CH_3$ radical is the formation of nitrogen. If it does form nitrogen, then a methyl radical scavenger should decrease the rate as measured by the rate of formation of nitrogen. If, on the other hand, the fragment $CH_3N{=}N$ is relatively long lived, the possible complications are numerous, the most obvious of which is that in the presence of a radical scavenger there could be fewer than one nitrogen formed per C—N bond broken. A simple test (see below) shows that this is not the case.

I. Inhibition by Olefin

If the fragment $CH_3N{=}N$ is relatively long lived, the following possibility arises: ethylene (21) and propylene (22) are known to polymerize under the influence of methyl radicals from azomethane. If this polymer were to scavenge some of the $CH_3N{=}N$ fragments, the nitrogen yield (i.e. the rate) could be reduced, even if the $CH_2N{=}NCH_3$ radical yielded ultimately no nitrogen, that is, even if there were no chain.

Experiments summarized in Table I were designed to test this possibility. A scavenging of the fragments $CH_3N{=}N$ by propylene or ethylene would manifest itself in the reduction of the ratio (N_2 found)/(azomethane decomposed) relative to unadulterated azomethane. Such is not the case, which means that $CH_3N{=}N$ is very short lived, or that no scavenging

NO pressure range (mm)	1.6–15	3–9	3–9	19–123	7–120	20–120	60–140	40–130	80–140
$\log_{10}$ (A)		14.45±0.65			17.24±0.19			17.28±0.23	
$E_{activation}$ (kcal/mole)		49.4±1.7			55.5±0.5			55.4±0.6	

NOTE: "Chain length" is defined as the uninhibited rate divided by k_0. "CH_4/N_2" means the value of this ratio at the high end of the "NO pressure range"; the latter indicates the range of NO pressures over which the rate increases linearly.

of this fragment takes place. The fact that the ratio actually increases in the presence of ethylene and propylene does not necessarily mean, however, that reaction [A] starts a chain in azomethane, since ethylene and propylene could merely prevent methyl radicals from adding to azomethane (to form hydrazines) and might thus increase the amount of azomethane available for formation of nitrogen.

Results shown in Fig. 2, which refer to less than 5% decomposition, show that both ethylene and propylene reduce the rate, i.e. inhibit the formation of nitrogen. The possibility of a reaction of the fragment $CH_3N{=}N$ with olefin having been eliminated, it must be concluded that some nitrogen is prevented from being formed via reaction [A], that is, that the radical $CH_2N{=}NCH_3$ ultimately yields nitrogen.

The answer to the question of how propylene or ethylene interferes with the formation of nitrogen depends on the assumed mode of action of olefin as inhibitor. A theory has been suggested by Laidler and Wojciechowski (23) according to which the inhibiting action of propylene is due to a special type of chain mechanism initiated via hydrogen abstraction by the allyl radical formed from propylene by thermal cracking. The latter reaction has an activation energy of 78 kcal/mole (23), and thus its rate would be negligible around 300° C (about 10^{11} times smaller than the rate at 600° C, where the pyrolysis of propylene proceeds at a convenient rate). However, allyl could still be formed by hydrogen abstraction from propylene by methyl radicals, a reaction that has a low activation energy (24, p. 296). There is evidence (25) that the allyl radical is relatively stable at low temperatures and does not abstract hydrogen until about 500° C. It would thus appear that at low temperatures, such as those encountered in the present work, propylene acts solely as a radical remover, i.e. the mechanism suggested by Laidler and Wojciechowski does not apply here, as in fact it would not apply in any propylene inhibition below 500° C.

It is seen (Fig. 2) that propylene and ethylene each inhibit the nitrogen production to a different extent. The yield of methane, the next major product after nitrogen, is also reduced by ethylene and propylene, but again to a different extent by each. If propylene, and presumably also ethylene, act only as radical removers, selective removal of the $CH_2N{=}NCH_3$ radical by simple addition would reduce the yield of nitrogen but not the yield of methane. Hydrogen abstraction by this radical from propylene, for example, would reduce the yield of nitrogen and leave the yield of methane unaffected. Neither of these two possibilities is evidently the predominant factor (Fig. 2). The complete removal of methyl radicals by simple addition to ethylene or propylene (to form a C_3 and C_4 radical, respectively) would reduce the rate to the same limiting value for both inhibitors and stop the formation of methane altogether. Clearly, such is not the case, so that if methyl radical addition occurs, it is not an efficient process. Another argument against such an addition is the low stability of radicals formed by addition (26). It should be noted that there is found less methane in the presence of ethylene than in the presence of propylene. This is what might be expected from the fact that propylene is more readily attacked by methyl radicals to form methane (24, p. 296). Hence it would seem that at least some methyl radicals are removed by hydrogen abstraction from olefin.

It must be concluded that of the four possible processes, hydrogen abstraction or addition by CH_3 and $CH_2N{=}NCH_3$, the experimental results on methane formation do not point to any one process as the dominant one. It is probable that all four processes occur simultaneously in the presence of ethylene and propylene, the relative importance of each process depending on the olefin. It is interesting to note that toluene seems to have no inhibiting effect at all (4) and this despite the fact that toluene should react with methyl radicals (to form CH_4) at about the same rate as propylene (24, p. 296). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

picture is further complicated by the circumstance that below about 100 mm of azomethane the decomposition is in the pressure-sensitive region, so that the addition of a fairly complex molecule, such as propylene or toluene, tends to increase the rate of the unimolecular part of the decomposition. This effect can be clearly seen in the observation (4) that at 0.9 mm of azomethane, propylene and toluene both actually *increased* rate.

The inhibition by olefin thus appears to be a fairly complex process and while it leaves little doubt that there is in fact a chain in the decomposition, experimental results offer no clear-cut evidence that any of the three olefins mentioned is capable of completely stopping the chain in azomethane. In short, ethylene, propylene, or toluene are not "good" chain suppressors in the azomethane decomposition.

II. Inhibition by Nitric Oxide

A. Comparison with Other Work

Nitric oxide, being a simple molecule, can be reasonably expected to add little to collisional activation in the pressure-sensitive region of the azomethane decomposition, so that, from this point of view at least, it is more a desirable inhibitor than olefins.

First experiments with NO were reported by Davis, Jahn, and Burton (27), who photolyzed (for an unspecified time) mixtures of about 100 mm azomethane and 10 mm NO between 20 and 222° C. Nitric oxide reduced the yields of methane and ethane to very small values, particularly at the higher temperatures. Calvert *et al.* (7) found nitrogen and nitrosomethane as the only products of flash photolysis of azomethane–NO mixtures at 25° C. Jahn and Taylor (28) pyrolyzed, around 300° C, mixtures of about 100 mm azomethane and 200 mm NO; the extent of decomposition was usually around 50%. Only insignificant quantities of hydrocarbon were found in the products, and the rate decreased by a factor of about two relative to the rate in absence of NO.

Neither of these studies is directly comparable with the present work, the first two because they are low-temperature photolyses, and the third on account of the large extent of decomposition. A high extent of decomposition may lead to misleading results, as shown by the experiments of Steacie and Folkins (29), who found in the case of the NO-inhibited decomposition of butane that after the reaction had progressed to 25 or 50% of completion the rate increased again. Nevertheless, the present work (Fig. 3) confirms the general feature of these studies. The novel feature is the accelerating effect of NO at higher NO pressures, a pattern that—unlike the case of propylene inhibition (4)—is seen to persist over an almost 200-fold range of initial azomethane pressures (Fig. 6) and over the entire temperature range investigated (Table III). It is understandable that Jahn and Taylor should have missed this effect since they did not study the rate as a function of NO pressure.

It will be noticed that the amount of NO required to reduce the rate to a minimum is appreciable, of the order of several millimeters of mercury, in contrast with traces of NO sufficient to inhibit the decompositions of hydrocarbons (26). The effect of NO on azomethane thus resembles somewhat the acetone pyrolysis in the presence of NO (30), which is not too surprising in view of certain similarities between the structures of the two molecules. Unfortunately, the acetone inhibition results refer to 50% reaction, so that they are not as reliable as might be desired. The chain length in both cases is quite small (acetone: < 1 (30), azomethane: 1.7 to 3.1 (Table III)), which is the reason why appreciable pressures of NO are required to produce noticeable inhibition: the small chain length indicates that many chains are broken even in the absence of NO; if NO is to have a noticeable effect, it must break many more chains, which will not happen unless NO pressure is appreciable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

There is, however, one effect in which the NO-inhibited decomposition of acetone and azomethane differ: in the former case it is found by extrapolation that both NO and propylene reduce the rate to the same minimum value, while in the present case the minimum rate with NO is lower than the minimum rate in the presence of propylene (cf. Figs. 2 and 6). This difference between acetone and azomethane, if it does not represent a complication due to the high extent of decomposition in the acetone work, can be accounted for by different behavior of propylene at low and high temperatures discussed above in connection with olefin inhibition, considering that the acetone inhibition was studied at 570° C. Calculations have been made (26) to show that if methyl radicals disappear in the presence of propylene and NO by the processes

$$CH_3 + C_3H_6 \rightarrow CH_4 + C_3H_5$$

$$CH_3 + NO \rightarrow \text{products},$$

respectively, propylene should be several hundred times less effective than NO as inhibitor. The present data, while offering no direct support for this conclusion, at least do not contradict it. Although the rate curve in the presence of propylene (Fig. 2) appears to reach a limiting value at one hundred millimeters propylene or so, it could actually have a small downward slope and it is not impossible that at a pressure of a few atmospheres of propylene the rate could decrease to the NO value.

It should be noted that also in all other cases where propylene and NO reduce the rate to the same limiting value: propionaldehyde (31), diethyl ether (32), and *n*-pentane (33), the pyrolyses were studied above 500° C. The inhibition of acetaldehyde at 525° C (34), where propylene is more effective than NO, is an exception. In all these cases, and in many olefin decompositions as well (35), NO at higher concentrations increases the rate again, so that the stimulatory effect of NO seems to be the rule.

B. The Nature of the Inhibited Reaction

Arguments presented in Section I show that there is a chain in azomethane, due probably to the formation and subsequent decomposition of the $CH_2N{=}NCH_3$ radical. The observed inhibition with NO (Figs. 3 and 5) is consistent with such an interpretation. A reduction in rate implies the removal of $CH_2N{=}NCH_3$, or of its precursor, the methyl radical. Since the bulk of hydrocarbons must be due to subsequent reactions of methyl radicals, the drastic reduction by NO of the yield of hydrocarbons (Fig. 3) indicates the removal of methyl radicals rather than removal of $CH_2N{=}NCH_3$. It could be objected to this line of argument that since no analyses were made for C_4 and higher hydrocarbons, NO could conceivably catalyze methyl radical reactions in such a fashion as to favor the formation of higher hydrocarbons. It seems, however, extremely unlikely that there should exist a pathway permitting the synthesis of higher hydrocarbons from methyl radicals in such a way as to leave not more than a trace of CH_4 and C_2H_6 and no propane or propylene at all. Thus the absence of lower hydrocarbons necessarily means also the absence of higher hydrocarbons.

From Fig. 3, which refers to 40 mm azomethane, it is seen that while in the absence of NO there are about 9 methane and 1 ethane molecules formed per 10 nitrogen molecules produced, at 141 mm NO the production amounts only to 4 methane and 4 ethane molecules per 1000 molecules N_2, which is very small indeed, and amounts to 0.48% of the methane and 2.8% of the ethane produced in the absence of NO. The drop-off is less rapid in methane than in ethane production. At 5 mm of azomethane (Fig. 5) conditions are quite analogous. Evidently the ethane production is more sensitive to a reduction in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

methyl radical concentration than is the methane production, which is to be expected because the rate of ethane production is second order in $[CH_3]$, while methane production is first order in $[CH_3]$.

If the scheme for the decomposition of unadulterated azomethane given at the beginning of the Discussion is correct, a methyl radical will have a choice of recombining to form ethane, or to react further and continue a chain, forming methane in the process. Absence of ethane and methane then would mean that the methyl radical does neither, i.e. reacts preferentially in some other way, so that the chain is stopped short. There seems to be little doubt now that methyl radicals are removed (7) by the process

$$CH_3 + NO \rightarrow CH_3NO, \qquad [2]$$

although it is generally appreciated that the nitrosomethane might decompose further at higher temperatures. If the methyl radicals are removed by the overall process

$$CH_3 + NO \rightarrow \text{products other than } N_2 \text{ or hydrocarbon} \qquad [B]$$

then one nitric oxide molecule must be consumed per methyl, and since two methyls are formed per nitrogen molecule produced, a complete, or almost complete removal of methyl radicals by NO according to [B] should lead to the consumption of two molecules of NO per nitrogen molecule produced. The consumption of NO is shown in Fig. 5. The ratio (NO consumed)/(N_2 produced) rises quickly with increasing NO pressure and reaches the vicinity of 2 just about at the same time as the ratios CH_4/N_2 and C_2H_6/N_2 become very small. Beyond this point the amount of NO consumed continues to rise at a smaller rate, probably due to a secondary reaction with azomethane. This complicating factor can be roughly corrected for by extrapolation to zero NO pressure (broken line in Fig. 5); the extrapolated value of (NO consumed)/(N_2 produced) is still around 2. These results are similar to those obtained by Hoare (36) in the photolysis of acetone + NO mixtures at 200° C. At low pressures of NO there is one NO molecule consumed per 2.2 to 2.3 methyl radicals, while at high NO pressures the consumption exceeds one NO molecule per methyl radical.

The reduction in the yield of hydrocarbon and the amount of NO consumed thus both support the conclusion that at NO pressures corresponding roughly to the minimum in the rate curve, and beyond, nearly all radicals are removed from the system by a process of the type represented by [B]. This means that under these conditions the chain reaction in azomethane is for all practical purposes completely stopped. The very small amount of hydrocarbon formed, even at the highest NO pressures (except at 1 mm azomethane where the amount was too small to be detected), can be due either to a small portion of the methyl radicals remaining unscavenged, or to a small dissociation of CH_3NO. It remains now to elucidate the nature of the residual, fully inhibited reaction. The fact that the rate, after reaching a minimum, slowly rises again (Figs. 3, 5, and 6) while the amount of hydrocarbon produced remains very low, or actually keeps decreasing, indicates a complicating process, not connected with the radical scavenging just described. For the purpose of discussion, this complication can be ignored for NO pressures not too much beyond the minimum rate.

The school of Hinshelwood believes that the reaction fully inhibited by NO is molecular, at least in part. In the case of azomethane, the molecular reaction would give nitrogen and ethane in one step, so that C_2H_6/N_2 should approach unity at some sufficiently high NO pressure. This is not the case, so that the residual reaction is not molecular to any significant degree. However, even if it were assumed that the value $C_2H_6/N_2 = 0.004$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

found at high NO pressures represents the extent of molecular reaction, it would be difficult to explain why under those conditions CH_4/N_2 is equal to 0.004 and not to zero, for the presence of methane implies the presence of methyl radicals.

It seems equally unlikely that the residual reaction is a surface reaction since the azomethane decomposition is rather insensitive to surface effects (see Experimental), and the rate in the presence of NO is not affected by a change in the surface-to-volume ratio. Furthermore, the activation energy of the residual reaction, which is about 55 kcal/mole (Table III), is certainly much too high for a surface reaction. The residual reaction could, however, be of the kind where chains are started and terminated at the walls, which would be insensitive to a change in the S/V ratio; in addition, the rate of nitrogen formation need not involve the rate of the surface initiation or termination, so that the activation energy criterion would no longer apply. It will be shown in more detail in a forthcoming publication that the residual reaction behaves like a typical unimolecular reaction, including rate increase by inert gas (C_2F_6). If the accelerating effect of inert gas is merely a diffusion effect, it would mean that the species responsible for chain initiation and termination at the wall are different, and that their diffusion coefficients in C_2F_6 are also different, with the net result that the average chain length is increased. Now the rate of a diffusion-controlled process in a spherical vessel is given (37) by

$$\text{rate} = 2\pi^2 D/3d,$$

where D = diffusion coefficient of the species under consideration, d = diameter of the vessel. Since the diameter is inversely proportional to the S/V ratio, packing the vessel in the absence of C_2F_6 should have an effect on rate. This does not happen, and hence the effect of inert gas is not attributable to a surface reaction.

It has been suggested that the fully inhibited reaction might be a new kind of chain reaction (26). The consensus of opinion at the present time (35, 38, 39) seems to favor a chain reaction initiated by a hydrogen abstraction by NO to form HNO and a radical. The question in the case of azomethane is whether at the point where the rate goes through a minimum, and where very little hydrocarbon is produced, an important part of the nitrogen is produced from azomethane by a NO-induced reaction. (It is shown in the following section that at this point practically all the nitrogen comes from azomethane.) By implication, this means that the rate of the process [1] should be at least an order of magnitude slower than the NO-induced process, which might be

$$CH_3N_2CH_3 + NO \rightarrow HNO + CH_2N_2CH_3, \qquad [C]$$

the $CH_2N_2CH_3$ radical then giving nitrogen. One important feature of nitrogen production via such a reaction is of course that no nitrogen is produced when there is no nitric oxide. In other words, if this reaction were important at relatively low pressures of NO, the rate vs. NO pressure curve should extrapolate to zero rate at zero NO pressure without too much strain on the imagination. A glance at k_{corr} in Fig. 4 shows that such an extrapolation would be an exercise in gamesmanship. A similar argument would lead to the rejection of the alternative reaction

$$CH_3N_2CH_3 + 2NO \rightarrow 2CH_3NO + N_2. \qquad [D]$$

There are other difficulties. With reaction [C] or [D] as the important source of nitrogen [1] must be very slow. To account for the high rate in the absence of NO, one would have to suppose a chain of considerable length. Rate supported by a long chain should then show appreciable inhibition by very small amounts of NO, which is not observed. Also,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the amount of inhibition by propylene and ethylene might be expected to be higher than it is. Moreover, a long chain would imply high rate for the decomposition

$$CH_2N_2CH_3 \rightarrow N_2 + \text{other products.}$$

Now the radical $CH_2N_2CH_3$ can be expected to resonate between two structures

$$\cdot CH_2—N{=}N—CH_3 \text{ and } CH_2{=}N—\dot{N}—CH_3.$$

Thermochemical data on azo compounds are too scanty to permit even an estimate of the resonance energy involved, but some resonance stabilization can be reasonably expected. As a result, the radical $CH_2N_2CH_3$ is very likely to react rather sluggishly, making a long chain in azomethane improbable. The odds are thus against an important NO-induced reaction in the neighborhood of minimum rate.

The remaining possibility for the residual (fully inhibited) reaction is that it represents the primary process of the chain, i.e. the unimolecular fission of the C—N bond,

$$CH_3N{=}NCH_3 \rightarrow 2CH_3 + N_2. \qquad [1]$$

This reaction is free of all the qualitative objections raised against the other possibilities, and so it permits a simple explanation of the inhibition phenomenon. It is unfortunate that the inhibited reaction is complicated by a NO-induced reaction, so that the rate of [1] can be obtained only after a correction for the NO-induced process has been made. However, the short extrapolation necessary to obtain this "net inhibited rate" (Fig. 4) is unlikely to lead to a very large discrepancy from the actual value.

The important quantitative parameters of the residual reaction [1], based on the "net inhibited rate", are summarized in Table III. The pressure-dependent activation energy (55.5 kcal at 22 mm) is higher than that determined by Steel and Trotman-Dickenson (4) (51.6 kcal around 20 mm), which refers to the activation energy of unadulterated azomethane, i.e. the chain process. This rise in activation energy is easily understood in terms of chain inhibition, since in blocking a chain path of lower activation energy inhibition makes the rate entirely dependent on the initial step with the highest activation energy of the sequence. The concomitant rise in the pre-exponential factor is less easily understood in elementary terms. However, it will be shown in a forthcoming publication that the residual reaction has all the features of a typical unimolecular reaction, and that the high pre-exponential factor can be satisfactorily accounted for from the entropy change in the activated state. Thus the assumption that the fully inhibited reaction corresponds to process [1] leads to consequences that are self-consistent.

C. The NO-induced Reaction

Since both azomethane and NO contain nitrogen, and the rate of azomethane decomposition is measured by the rate of formation of nitrogen, the accelerating effect of NO is ambiguous, that is, the rate increase at high NO pressures could be due to the production of nitrogen either from azomethane or from NO. Experiments with the isotopic nitric oxide, ^{15}NO, summarized in Table II, were designed to permit a distinction between the two possible sources of nitrogen. Column 4 of Table II shows that there is in fact formation of molecules $^{15}N_2$, i.e. part of the rate rise is only apparent, being due to nitrogen formed by the decomposition of NO. Quantitatively these results will not have much meaning unless isotopic exchange reactions involving nitrogen are slow at the temperature of the experiment.

Johnston and Anstett (40) measured the rate of approach to thermal equilibrium in mixtures of $^{14}N_2$, $^{15}N_2$, and $^{14}N^{15}N$. They found that no thermal exchange took place in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

1 month at room temperature or in 19 hours at 850° C. Another possible exchange reaction is

$$^{14}N_2 + {}^{15}NO \rightarrow {}^{14}NO + {}^{14}N{}^{15}N,$$

the rate of which does not appear to have been measured. It can be roughly calculated from statistical mechanics, by considering only the symmetry numbers of the corresponding partition functions, that the equilibrium constant of this reaction, K, is given by

$$K = \frac{[^{14}N^{15}N][^{14}NO]}{[^{14}N_2][^{15}NO]} \sim 2.$$

If, as seems reasonable for a short azomethane run, ^{14}NO remains at 2.3% of total NO (no change in initial isotopic composition), we have $[^{14}NO]/[^{15}NO] = 0.0235$, so that, with reference to Table II, there should be $P_{29}/P_{28} \sim 2/0.0235 = 85$. The experimental results are not anywhere near this figure, which would mean that equilibrium is approached very slowly. Presumably any exchange reaction involving molecular nitrogen would be slow. The fact that ΔP_{29} (Table II) is independent of NO pressure can also be cited as evidence against any important exchange.

The values of k_{corr} in the last column of Table II were calculated on the assumption that no $^{14}N_2$ was lost by exchange. However, even if it were assumed that the entire 29-peak was the result of exchange, the values of k_{corr} would be affected to not more than 1%, which is less than the experimental error in the rate constant. It can therefore be concluded, with reference to Fig. 4, that about one-half of the upward slope in the positive catalysis region of the rate curve is due to the decomposition of azomethane.

The fraction of the N_2 arising from the decomposition of NO is given in Table II under $f^{NO}_{N_2}$. This decomposition is quite small, at 140 mm NO only 8.8% of the total nitrogen formed comes from NO (Table II), which, at 8% decomposition of 40 mm azomethane present initially represents 8.8% of 3.2 mm = 0.28 mm N_2 originating from NO, i.e. 0.56 mm NO decomposed out of 140 mm, which amounts to 0.4% decomposition of NO. This amount, even though it is the largest recorded in Table II, is small enough to make it appear possible that this nitrogen might arise by a slight thermal decomposition of NO at the temperature of the experiment. However, Wise and Frech (41) have studied the thermal decomposition of NO and found it to be heterogeneous and second order in NO below 1000° K, with the rate constant given by

$$k_{het} = 1.4 \times 10^4 \exp(-21{,}400/RT) \text{ cc/mole-sec.}$$

It can be calculated from this information that at 303° C and 140 mm NO the time required for 1% thermal decomposition is over 7000 hours, so that the amount of NO decomposed thermally at this temperature in the course of a typical run of a few minutes is negligible. The conclusion is then that azomethane, or its decomposition products, provokes slight decomposition of nitric oxide to form N_2.

The first-order rate constant for the formation of nitrogen from nitric oxide, defined as

$$k^{NO}_{N_2} = \frac{1}{NO}\frac{d(N_2^{NO})}{dt},$$

is plotted against NO pressure in Fig. 7; initial azomethane pressure is constant at 40 mm. The rate constant depends linearly on NO pressure, which means that nitrogen is formed from NO in a reaction second order in NO. The plot, however, does not extrapolate to $k^{NO}_{N_2} = 0$ at zero pressure of NO, which might suggest that the reaction has a first-order

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

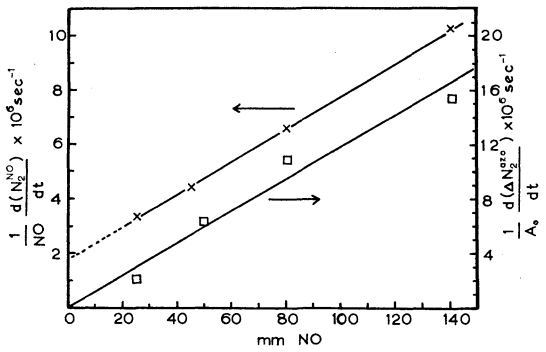

FIG. 7. Plot vs. NO pressure of the first-order rate constant for nitrogen formation from NO (×, left scale), and of the first-order rate constant for the NO-induced formation of nitrogen from azomethane (□, right scale).

heterogeneous component amounting to about 2×10^{-6} sec^{-1}. This is about one-hundredth of the rate of the initial step [1] so that the latter is not appreciably affected.

The formation of nitrogen from nitric oxide has been postulated by several workers as due to a reaction with nitrosomethane. Yakubovich *et al.* (42) observed that NO reacts very easily with CF_3NO at room temperature. The mixture turns immediately brown from N_2O_4, and after several weeks there accumulates some trifluoronitromethane and *N,N*-bis(trifluoromethyl)hydroxylamine nitrite. No other experimental details are given. The mechanism postulated is

$$CF_3NO + 2NO \rightarrow CF_3N(NO)ONO \xrightarrow{+NO} CF_3\cdot + N_2 + 2NO_2,$$

followed by further reactions of $CF_3\cdot$, NO, and CF_3NO to give the nitromethane and hydroxylamine derivative. A rapid reaction, however, seems to be incompatible with the postulated third-order kinetics. Levy (43) heated nitrosomethane in the presence of NO and found nitromethane by infrared analysis. Batt and Gowenlock (44) studied the decomposition of nitrosomethane monomer at 250–525° C and found that the disappearance of CH_3NO was first order and was accelerated by NO, which was itself consumed; a non-condensable gas was produced which they thought was nitrogen. They suggested elimination of nitrogen via methyl diazonium nitrate, which then decomposes into methyl nitrate ester and nitrogen:

$$CH_3NO + 2NO \rightarrow CH_3N_2^+NO_3^- \rightarrow CH_3ONO_2 + N_2.$$

This scheme is not necessarily at variance with the previous observations on the formation of nitromethane, since the nitrate ester would decompose above 200° C, and it has been shown that ethyl nitrate, for example (45), produces nitromethane as one of the decomposition products. Christie (46) found that CH_3NO and NO react at toom temperature to form an unidentified product Y in a third-order process

$$CH_3NO + 2NO \rightarrow Y,$$

with a minimum value of 0.1 liter^2 mole^{-2}sec^{-1} for the third-order rate constant.

Since the presence of some CH_3NO can be reasonably expected in the mixture of decomposing azomethane and NO, the present results on the formation of nitrogen from NO lend some support to the previous work just cited. The heterogeneous component found in this work finds an analogue in surface effects which plagued the study of CH_3NO decomposition (44). As for the homogeneous part of the reaction, it is convenient to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

consider the reaction scheme given in the Appendix. It is assumed there that every methyl radical ends up as CH_3NO (Section IIB), and that CH_3NO decomposes only in a third-order reaction with NO to yield nitrogen, or in a first-order reaction to yield some other product (44). It turns out that the kinetics depends on the relative magnitudes of k_4 and $k_3(NO)_0^2$, where k_4 is the first-order rate constant for the decomposition of CH_3NO (believed to yield the oxime $CH_2{=}NOH$ as the first step (44)), k_3 is the third-order rate constant for the process

$$CH_3NO + 2NO \rightarrow N_2^{NO} + \text{products},$$

and $(NO)_0$ = initial concentration of nitric oxide.

A crude estimate of E_4 has been made by Gowenlock, Trotman, and Batt (47), who proposed the value of 40 kcal/mole. Assuming a "normal" pre-exponential factor of 10^{13} sec^{-1}, this gives $k_4 = 7\times10^{-3}$ sec^{-1} at 303° C. Since most unimolecular reactions seem to have an "abnormal" pre-exponential factor (18), the possibility of an "abnormal" value for the CH_3NO decomposition must be considered. Assuming for this factor a maximum value of 10^{17} sec^{-1}, the value of k_4 at 303° C will be below 10^{-2} sec^{-1} only if $E_4 > 50$ kcal/mole. Now since the above authors estimate the dissociation energy $D(CH_3{-}NO) = 57\pm4$ kcal/mole, regeneration of radicals will be prevented as long as $E_4 < 57$ kcal/mole, so that inhibition by NO is still consistent with a value of E_4 around 50 kcal/mole or so. It seems that $k_4 \sim 7\times10^{-3}$ sec^{-1} is not an unreasonable value for k_4; however, in view of what has been said above, it is manifest that this value is subject to a considerable uncertainty, perhaps a factor of several powers of 10. The upper limit for k_3 can be taken as 10 $liter^2$ $mole^{-2}sec^{-1}$, a value somewhat higher than the usual value of third-order rate constants involving nitric oxide (24, p. 310), and $(NO)_0^2$, for the highest pressure used, is 1.5×10^{-5} $mole^2$ $liter^{-2}$, so that the maximum value of $k_3(NO)_0^2$ works out to 1.5×10^{-4} sec^{-1}. Finally, t, the experimental reaction time, is of the order of 500 seconds. Owing to the large uncertainty in k_4 it is best to consider three possible values of k_4.

(*i*) $k_4 \ll 10^{-4}$ sec^{-1}.—This leads to $k_4 \ll k_3(NO)_0^2$ for the range of NO pressures of interest, and from the Appendix, Case II, it is seen that $d(N_2^{NO})/dt$ becomes independent of NO, contrary to experiment (Fig. 7). If $k_4 \sim k_3(NO)_0^2$ (i.e. if k_4 is close to 10^{-4} sec^{-1}), the plot of

$$\frac{1}{(NO)_0}\frac{d(N_2^{NO})}{dt} \equiv k_{N_2}^{NO}$$

versus $(NO)_0$ should show a distinct curvature, likewise contrary to experiment. Obviously, then, under these conditions CH_3NO cannot reach a steady state. For Case I (Appendix), we note that the exponent in the exponential becomes smaller than unity (for $t = 500$ seconds), so that we can write, by expanding the exponential and keeping only the first two terms,

$$1 - \exp\left[-\{k_4+k_3(NO)_0^2\}t\right] \sim \{k_4+k_3(NO)_0^2\}t$$

and

$$(CH_3NO) \sim 2k_1(A)_0t,$$

so that

$$d(N_2^{NO})/dt \sim 2k_1k_3(A)_0(NO)_0^2t.$$

This expression can be integrated:

$$\int_0^x d(N_2^{NO}) = 2k_1k_3(A)_0(NO)_0^2\int_0^{t_x} tdt,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where x is the amount of nitrogen formed from NO in the time interval t_x. Integration gives

$$x = k_1k_3(A)_0(NO)_0^2t_x^2,$$

where x and t_x are experimental quantities. Under these conditions, then, experiment should satisfy the relation (for $(A)_0$ = const.)

$$x/(NO)_0^2t_x^2 = \text{const.}$$

(ii) $k_4 \sim 10^{-1}$ *to* 10^{-3} *sec*$^{-1}$.—Here we have roughly $k_4 \gg k_3(NO)_0^2$ (except, perhaps, at the highest NO pressure used), so that Case II in the Appendix yields

$$d(N_2^{NO})/dt = 2k_1k_3(A)_0(NO)_0^2/k_4,$$

a relation that satisfies the linear dependence shown in Fig. 7. Integrating

$$\int_0^x d(N_2^{NO}) = \frac{2k_1k_3}{k_4}(A)_0(NO)_0^2\int_0^{t_x} dt$$

we get

$$x = 2k_1k_3(A)_0(NO)_0^2t_x/k_4,$$

where x and t_x have the same significance as before. Under these conditions CH_3NO can reach a steady state and theory predicts that, for $(A)_0$ = const.,

$$x/(NO)_0^2t_x = \text{const.}$$

As for Case I in the Appendix, provided $k_4 < 2\times10^{-3}$ sec^{-1}, we still have an exponent smaller than unity in the exponential, and Case I thus leads to the same relation as under (i). For $k_4 > 2\times10^{-3}$ sec^{-1}, Case I gives the relation shown below under (iii).

(iii) $k_4 \gg 10^{-3}$ *sec*$^{-1}$.—This value of k_4 leads to $k_4 \gg k_3(NO)_0^2$, so that Case II in the Appendix yields the same relation as under (ii) above. In Case I, we observe that, for t = 500 seconds, under these conditions

$$\exp[-\{k_4+k_3(NO)_0^2\}t] \ll 1,$$

so that

$$(CH_3NO) = 2k_1(A)_0/k_4,$$

and

$$d(N_2^{NO})/dt = 2k_1k_3(A)_0(NO)_0^2/k_4,$$

which is the expression obtained under Case II. In other words, with $k_4 \gg 10^{-3}$ sec^{-1} CH_3NO cannot accumulate in the system.

These considerations show that some choice between the various possibilities can be made by observing the value of the ratios $x/(NO)_0^2t_x^2$ and $x/(NO)_0^2t_x$. The pertinent data are summarized in Table IV. Although the evidence is not overwhelming (a larger

TABLE IV

variation in t_x would have been desirable), it can nevertheless be seen that $x/(NO)_0^2t_x$ is reasonably constant, while $x/(NO)_0^2t_x^2$ is not, as might have been expected merely from looking at Fig. 7. This result means that

(*a*) k_4 is of the order of 10^{-3} sec^{-1} or larger;
(*b*) CH_3NO reaches a steady state.

It is now possible to set a lower limit on the value of k_3, where

$$k_3 = xk_4/2k_1(A)_0(NO)_0^2t_x.$$

Taking $x/(NO)_0^2t_x = 3\times10^{-8}$ $mm^{-1}sec^{-1} = 10.8\times10^{-4}$ liter $mole^{-1}sec^{-1}$, and the value of $2k_1(A)_0$ being 4.3×10^{-7} mole $liter^{-1}sec^{-1}$ for the conditions of the experiment, we get

$$k_3 \geqslant 2.5 \text{ liter}^2 \text{ mole}^{-2}\text{sec}^{-1}.$$

This is a reasonable value for a third-order rate constant involving nitric oxide (24, p. 310), which would suggest that the proposed mechanism for the formation of nitrogen from nitrosomethane is entirely feasible.

The amount of nitrogen produced from azomethane ($(A)_0 = 40$ mm) by the NO-induced reaction, ΔN_2^{azo}, can be obtained by subtracting from the total amount of nitrogen produced from azomethane ($f_{N_2}^{azo}$, Table II), the amount of nitrogen corresponding to the "net inhibited rate" ($k_0 = 1.78\times10^{-4}$ sec^{-1}, the extrapolated value of k_{corr} from Fig. 4), which represents nitrogen formed in the initial step of the decomposition (Section IIB). The first-order rate constant for nitrogen formation by the NO-induced reaction, defined as

$$k_{N_2}^{azo} = \frac{1}{A_0}\frac{d(\Delta N_2^{azo})}{dt},$$

is shown plotted against NO pressure in Fig. 7. Plotting against $NO^{1/2}$, $NO^{3/2}$, or NO^2 results in distinctly curved plots, so that despite the rather poor straight line it must be concluded that the plot is linear with respect to NO, i.e. the reaction is first order in NO. Not much more can be deduced about the NO-induced decomposition of azomethane from the present results. The presence of N_2O (Fig. 5), if it is due to the oft-postulated reaction (without much evidence, cf. refs. 48, 49)

$$2HNO \rightarrow N_2O + H_2O,$$

would suggest the presence of HNO, which might lend some credence to hydrogen abstraction by NO. N_2O was also found in the products when NO was added to decomposing 2,2′-azoisobutane (50).

The information that the formation of ΔN_2^{azo} is first order in NO means that very likely one molecule of NO is used up for each molecule of ΔN_2^{azo} formed. It was shown above that quite probably for each molecule of N_2^{NO} formed two molecules of NO are used up. The amount of NO consumed shown in Fig. 5 can now be used to attempt a sort of crude nitric oxide balance. The "net inhibited rate" at $(A)_0$ is 5 mm is 9.8×10^{-5} sec^{-1}, assuming that for each nitrogen formed at this rate 2 molecules of NO are consumed (1 for each methyl), and that every nitrogen produced in excess of this "net inhibited rate" is due to a secondary reaction; then to account for the observed ratio of (NO consumed)/(N_2 produced) = 3.64 at 20 mm NO, there must be 13.8 molecules of NO consumed for every molecule of ($\Delta N_2^{azo} + N_2^{NO}$) formed. The latter process can reasonably lead to the consumption of not more than three molecules of NO; clearly, then, the bulk of NO at NO pressure above the minimum rate takes part in reactions that do not yield nitrogen.

While the present study accounts for most of the NO used up around minimum rate, it offers no information about the fate of the portion of NO molecules consumed at higher NO pressures.

ACKNOWLEDGMENTS

The authors are greatly indebted to Mr. L. Landau and Dr. J. S. Drury of the Oak Ridge National Laboratory, Oak Ridge, Tenn., for the mass spectrometric analyses reported in this work.

APPENDIX

Assume that the formation of N_2^{NO} is described by the following sequence of reactions:

$$CH_3N_2CH_3 \rightarrow 2CH_3 + N_2^{azo} \qquad k_1$$

$$CH_3 + NO \rightarrow CH_3NO \qquad k_2$$

$$CH_3NO + 2NO \rightarrow N_2^{NO} + \text{products} \qquad k_3$$

$$CH_3NO \rightarrow \text{products} \qquad k_4$$

The stationary concentration of CH_3 is:

$$(CH_3) = 2k_1(A)/k_2(NO),$$

where (A) stands for the concentration of azomethane. Hence,

$$\begin{aligned} d(CH_3NO)/dt &= k_2(CH_3)(NO) - k_3(CH_3NO)(NO)^2 - k_4(CH_3NO) \\ &= 2k_1(A) - \{k_4 + k_3(NO)^2\}(CH_3NO). \end{aligned} \qquad \text{(I)}$$

Case I. CH_3NO Accumulates in the System

Equation (I) can be integrated, assuming $(A) = (A)_0$, $(NO) = (NO)_0$, where the subscript indicates initial conditions; this approximation is justified by the low conversion used in this work. We get

$$\int_0^{(CH_3NO)} \frac{d(CH_3NO)}{2k_1(A)_0 - \{k_4 + k_3(NO)_0^2\}(CH_3NO)} = \int_0^t dt.$$

The result of the integration, after some rearranging, is

$$(CH_3NO) = \frac{2k_1(A)_0}{k_4 + k_3(NO)_0^2}\,[1 - \exp\,(-\{k_4 + k_3(NO)_0^2\}t)],$$

so that

$$\begin{aligned} d(N_2^{NO})/dt &= k_3(CH_3NO)(NO)^2 \\ &= \frac{2k_1k_3(A)_0(NO)_0^2}{k_4 + k_3(NO)_0^2}\,[1 - \exp\,(-\{k_4 + k_3(NO)_0^2\}t)]. \end{aligned}$$

Case II. CH_3NO Reaches a Steady State

In this case, $d(CH_3NO)/dt = 0$, and

$$(CH_3NO) = \frac{2k_1(A)}{k_4 + k_3(NO)^2} = \frac{2k_1(A)_0}{k_4 + k_3(NO)_0^2}$$

$$d(N_2^{NO})/dt = \frac{2k_1k_3(A)_0(NO)_0^2}{k_4 + k_3(NO)_0^2}.$$

RÉSUMÉ

L'éthylène et le propylène diminuent la vitesse de décomposition de l'azométhane, vitesse mesurée par la vitesse de formation de l'azote. Ils diminuent aussi le rapport CH_4/N_2 dans les produits, mais la diminution dans la valeur des deux quantités est différente pour chacune des deux oléfines. Dans la décomposition à 100%, l'éthylène et le propylène augmentent un peu le rapport (azote récupéré)/(azométhane décomposé). L'interprétation de ces résultats indique la présence d'une courte chaîne dans la pyrolyse, et aussi que l'éthylène et le propylène ne sont pas convenables comme inhibiteurs.

Lorsqu'on ajoute quelques millimètres de NO, la vitesse de la réaction diminue pour atteindre un minimum, qui est inférieur à celui obtenu avec le propylène ou l'éthylène (longueur de chaîne apparente: 2 à 3). La vitesse de réaction augmente ensuite en fonction de la pression de NO. Un résultat identique peut être obtenu dans un récipient garni de tubes de verre. Le rendement en méthane, en éthane et en éthylène est réduit presqu'à zéro par une pression suffisante de NO. Le rapport (NO détruit)/(azote formé) atteint la valeur de deux aux environs du minimum de la vitesse de réaction. On peut conclure que la vitesse inhibée nette, c.-à-d. corrigée de l'effet stimulant du NO, est celle du processus monomoléculaire initial $CH_3N_2CH_3 \rightarrow 2CH_3 + N_2$. La vitesse ainsi que l'énergie d'activation de ce processus s'avèrent dépendantes de la pression.

On a prouvé au moyen de l'oxyde nitrique isotopique ^{15}NO qu'à peu près une moitié de l'acroissement de la vitesse de réaction aux pressions élévées de NO est dûe à l'azote formé à partir de NO. L'autre moitié est attribuée à une décomposition de l'azométhane déclenchée par NO.

THE ELECTRON DENSITY DISTRIBUTIONS IN HYDRIDE MOLECULES

I. THE WATER MOLECULE[1]

R. F. W. Bader and G. A. Jones[2]
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received October 18, 1962

ABSTRACT

The electron density distribution for the water molecule in its equilibrium configuration is determined by requiring that the forces exerted on the nuclei by this distribution (as calculated by the Hellmann–Feynman theorem) balance the nuclear forces of repulsion. The density distribution is expressed in terms of equivalent orbitals, and to achieve electrostatic equilibrium it is found necessary to have an angle between the bonding orbitals which is less than the structural bond angle (bent bonds), to delocalize the equivalent orbitals and to place the lone pair electrons in sp hybrid orbitals. Further, a discussion of the forces operative in XH_2 and XH_3 molecules (X = C, N, O) leads to an explanation of the observed bond angles and to general conclusions regarding the hybridization to be expected in such molecules.

INTRODUCTION

The electron density distributions for molecules which contain lone pair electrons are of considerable interest to chemists. The work of Lennard-Jones, Pople, and Coulson (1–4) has stressed the important role that lone pairs of electrons can play in the determination of molecular geometries and dipole moments. The effects are, of course, most prominent when the lone pair electrons are found in orbitals with a large amount of directional character (i.e., p atomic orbital character) such that the orbitals project out from the nucleus. With these results in mind Pople (2) and Pople and Duncan (3) have performed calculations for the water and ammonia molecules which indicate that the hybridization in these molecules is indeed close to sp^3. This implies that the lone pair electrons in these molecules possess their maximal directional character and hence they are predicted to exert prominent effects in determining the dipole moment and bond angle.

In this paper we propose to determine the electron density distribution for the water molecule through a consideration of the *forces* exerted on the nuclei by the distribution. There are a number of reasons for adopting this approach, two of them being the great sensitivity of the forces to the degree of hybridization and to the molecular geometry. It should be remembered that the very existence of the electronic forces is a direct result of molecule formation. Another advantage stems from the obvious fact that when the molecule is in its equilibrium configuration the resultant force acting on any nucleus in the molecule must be zero. Given a nuclear framework with the observed equilibrium bond lengths and bond angles it is a simple matter to calculate the forces of repulsion acting on a nucleus due to presence of the other nuclei. The forces of attraction exerted by the electron density distribution are thus also known since they must be equal and opposite to the nuclear forces of repulsion for the attainment of electrostatic equilibrium. It is well known that the Hellmann–Feynman theorem allows one to calculate the forces acting on a nucleus in a molecule if the electron density function is known. Alternatively,

[1]*Abstracted from the thesis submitted by G. A. Jones in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*
[2]*Recipient of a Commonwealth Scholarship.*

knowing the forces as we do at electrostatic equilibrium, we may reverse this procedure and calculate the equilibrium electron density from our knowledge of the forces. Thus the requirement of zero resultant forces provides one with a number of constraints which, through the use of the Hellmann–Feynman theorem, any proposed density function must fulfill. These constraints may be used to fix a corresponding number of parameters in the density function. For example, in the water molecule three parameters in the density function may be determined by observing the requirement that the resulting forces exerted on the oxygen nucleus along the symmetry axis and on the hydrogen nuclei along the bonds and perpendicular to the bond axes must be zero. The remaining force components give trivial conditions as they are zero by symmetry alone. Therefore, the criteria of zero resultant forces may be used to fit a relatively sophisticated density function to any nuclear framework.

The Determination of the Density Distribution

We shall determine the electron density distribution for the water molecule within the framework of the single-configuration L.C.A.O. molecular orbital theory. The equivalent orbital representation is used so as to retain the concepts of lone pair and bonding electrons. Slater atomic orbitals with suitable screening constants are employed to approximate the atomic orbitals. The $2s$ function on oxygen is made orthogonal to the $1s$ orbital on the same atom. All the calculations are carried out for a bond length of 1.81 a.u. and a bond angle of 104.45° (5).

We assume that the inner pair of electrons on the oxygen atom are in a pure $1s$ orbital (a point we shall reconsider later in the paper) and that the $1s$ atomic orbital does not contribute to any of the valence orbitals. Then the most general orbitals that can be written for the water molecule are, for the bonding orbitals,

$$\phi_{b1} = \lambda[\cos \epsilon_b\, 2s + \sin \epsilon_b\, 2p_1] + \mu[s_1 - \delta s_2]$$
$$\phi_{b2} = \lambda[\cos \epsilon_b\, 2s + \sin \epsilon_b\, 2p_2] + \mu[s_2 - \delta s_1],$$

and for the lone pair orbitals,

$$\phi_{l1} = \cos \epsilon_l\, 2s + \sin \epsilon_l\, 2p_3$$
$$\phi_{l2} = \cos \epsilon_l\, 2s + \sin \epsilon_l\, 2p_4.$$

The s_1 and s_2 denote $1s$ orbitals on $H_{(1)}$ and $H_{(2)}$ respectively and $2s$ and $2p_i$ are atomic orbitals centered on the oxygen nucleus. The directions of p_1 and p_2 are shown in Fig. 1 (note that they do not necessarily coincide with the bond axes) and p_3 and p_4 determine the directions of the lone pair orbitals.

These orbitals embody five parameters:

(i) ϵ_b and ϵ_l, the hybridization parameters of the bonding and lone pair orbitals;

(ii) λ/μ, the polarity factor for the bonding orbitals;

(iii) α, the angle between the p functions of the bonding orbitals; it is termed the orbital angle as opposed to the bond angle $\mathscr{E}$, and when $\alpha \neq \mathscr{E}$ the bonds are termed "bent";

(iv) δ, the parameter which determines the extent of delocalization of the equivalent orbitals.

The requirement that all four of the molecular orbitals be mutually orthogonal gives rise to three conditions which determine the hybridization parameters ϵ_b and ϵ_l and the angle between the lone pair orbitals. These three conditions, together with the one determining the relative values of λ and μ once their ratio is known, are given in the Appendix.

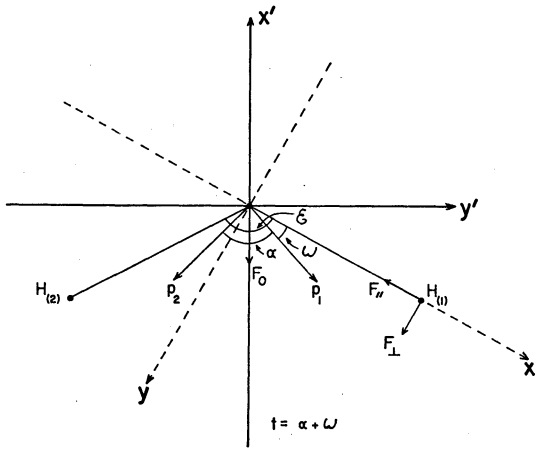

FIG. 1. The coordinate system used in the calculations. The arrows indicate the direction of a positive force. R is the distance between the hydrogen nuclei and d is the bond length.

The requirement of zero resultant forces may be employed to fix the remaining three parameters, λ/μ, α, and δ. The three electronic forces (those due to the electron density distribution) to be determined are shown in Fig. 1. $F_\perp$ is the force on $H_{(1)}$ perpendicular to the O—H bond axis, $F_\parallel$ is the force on $H_{(1)}$ along the O—H bond axis, and F_O is the force on the oxygen atom along the x' axis. The Hellmann–Feynman theorem states that the total force acting on any nucleus in a molecule is simply the sum of the classical electrostatic forces due to the other nuclei and to the three-dimensional electron density distribution.* We have previously demonstrated the capabilities of the Hellmann–Feynman theorem in predicting reasonable magnitudes for the forces found in simple molecules (6). Moreover, its application gives a readily understandable interpretation of the forces operative in a molecule (7).

Since the orbitals we are to employ are mutually orthogonal and doubly occupied, the electron density is

$$\rho = 2(\phi_{b1}^2+\phi_{b2}^2+\phi_{11}^2+\phi_{12}^2+\phi_o^2),$$

where ϕ_o is the innermost orbital of the oxygen atom. As previously explained (5, 6) the force exerted on a nucleus by the electron density distribution is simply the sum of the forces exerted by the density obtained from each of the orbitals. The three conditions for electrostatic equilibrium are given below, where $F_\perp$, $F_\parallel$, and F_O will refer to the magnitudes of the electronic forces:

$$F_\perp = F_\perp(\phi_{b1}^2)+F_\perp(\phi_{b2}^2)+2F_\perp(\phi_1^2) = (1/R^2)\cos(\mathscr{E}/2)$$

$$F_\parallel = F_\parallel(\phi_{b1}^2)+F_\parallel(\phi_{b2}^2)+2F_\parallel(\phi_1^2)+F_\parallel(\phi_o^2)$$

$$= (8/d^2)+(1/R^2)\sin(\mathscr{E}/2)$$

$$F_O = 2F_O(\phi_b^2)+2F_O(\phi_1^2) = (2/d^2)\cos(\mathscr{E}/2).\dagger$$

We may thus discuss separately the forces exerted by the bonding and the lone pair

*A discussion of the application of this theorem to molecular problems may be found in references 6, 7, and 8.

†Where no distinction is made between the forces exerted by ϕ_{b1} and ϕ_{b2} or ϕ_{11} and ϕ_{12}, the two forces are equal. A common factor of eight, the nuclear charge on the oxygen atom, has been removed from the nuclear and electronic force on oxygen.

electron densities. Explicit expressions for all of the forces are given in the Appendix together with all the details of the calculation. During the discussion of these forces we shall be most interested in the relative magnitudes of the various orbital contributions. Three sets of density functions will be considered, from the simplest embodying only ϵ_b, ϵ_l, and λ/μ to one including all five parameters. Each distribution will be regarded in the light of whether or not it can simultaneously satisfy all three of the zero force conditions. In addition we shall require that the distribution give the correct dipole moment, of magnitude 0.724 a.u.

Case I. Equivalent Localized Orbitals Directed Along the O—H Bonds

The set of orbitals with $\alpha = \mathscr{E}$ (bonds pointing at the hydrogen atoms) and $\delta = 0$ (the equivalent orbitals are completely localized) is the simplest that one can construct for the water molecule. Of the three remaining parameters, ϵ_b and ϵ_l are determined by the orthogonality conditions, leaving only λ/μ to be determined by any of the force conditions or the dipole moment. This was the set of orbitals employed by Pople and Duncan (2, 3) in their determination of the electron density distribution in the water molecule. They fixed the polarity parameter λ/μ by requiring that the density function give the observed dipole moment. We shall reinvestigate this same density function in terms of the forces it exerts on the hydrogen and oxygen nuclei.

First a word about the density function. Disregarding the overlap with the hydrogens for the moment, an orbital angle of 104.45° on the oxygen atom gives orbitals very close to sp^3 which occur at an orbital angle of 109°28′ ($\epsilon_b = \epsilon_l = 60°$). The decrease from the tetrahedral angle to 104.45° slightly increases the amount of p character in the bonding orbitals and increases slightly the $2s$ character of the lone pair orbitals. Anticipating bent bonds, in the limit of an orbital angle of 90°, the bonding orbitals become pure p ($\epsilon_b = 90°$) and the lone pair orbitals become sp hybrids ($\epsilon_l = 45°$). Because of the overlap with the hydrogen $1s$ orbitals the amount of p character in the bonding orbitals at any value of the orbital angle is increased over what it would be if the overlap were zero. Similarly the amount of $2s$ in the lone pair orbitals is slightly decreased by the presence of the hydrogen atoms.

Since the bond orbitals in case I are directed at the hydrogen atoms, the order of hybridization is automatically fixed. A variation of λ/μ, the only remaining parameter, brings about only small variations in ϵ_b and ϵ_l, ϵ_b changing from 79° to 73° and ϵ_l from 56.0° to 56.5° for a change in λ/μ from 1.0 to 1.5. Thus the lone pairs are always dominant in this case, as ϵ_l is fixed close to 60°, the value for sp^3 orbitals. The correct dipole moment is obtained at a $\lambda/\mu = 1.07$ with $\epsilon_b = 77.8°$ and $\epsilon_l = 56.0°$.* Since all the factors vary so little with λ/μ in this case, it will be sufficient to consider the forces† obtained for this one point, and they are given in Table I. Consider first the electronic force exerted on the hydrogen nucleus at right angles to the bond, $F_\perp$. Since the electron distribution in ϕ_{b1} possesses axial symmetry along the O—$H_{(1)}$ bond, $F_\perp(\phi_{b1}^2)$ is zero. The density in ϕ_{b2} attracts $H_{(1)}$ but the lone pairs exert a force in the opposite direction, tending to open up the bond angle, which almost cancels the attractive force of ϕ_{b2}. The resultant electronic attractive force $F_\perp$ is thus very much less than the nuclear force of repulsion. The electronic forces on $H_{(1)}$ along the bond are also insufficient to overcome the repulsive force. The case of the forces operative on the oxygen nucleus is very similar to that for $F_\perp$. The lone pairs exert a force which is almost equal and opposite to the attractive

*These values for λ/μ, ϵ_b, and ϵ_l are slightly different than those obtained by Duncan and Pople (1.06, 85°, and 55° respectively) as we have used a different value for the effective nuclear charge in the hydrogen 1s orbital.

†All forces in this paper are given in atomic units: 1 a.u. = $e^2/a_o^2 = 8.2377 \times 10^{-3}$ dynes.

TABLE I

The forces for case I

	$F(\phi_{b1}^2)$	$F(\phi_{b2}^2)$	$2F(\phi_1^2)$	$F(\phi_o^2)$	Total electronic force	Nuclear repulsion
$F_\perp$	0.0000	0.1206	−0.1046	0.0000	0.0160	−0.0748
$F_\parallel$	0.6812	0.3058	0.8120	0.6105	2.4095	−2.5384
F_O	0.4845	0.4845	−0.9446	0.0000	0.0244	−0.3740

forces of the bonding electrons. The net result is a large negative force acting on the oxygen nucleus almost equal to the total nuclear force of repulsion.

This simple density distribution does not come close to satisfying the conditions of zero resultant forces. The reasons for this are clear. The projection of the lone pair electron density out to the back of the molecule in approximately sp^3 orbitals results in unreasonably large forces tending to pull the oxygen atom back and to open up the bond angle. While such a simple distribution function can duplicate the observed dipole moment it does so only through the presence of prominent lone pairs of electrons and at the expense of a low polarity factor λ/μ for the bond orbitals. (The atomic dipole moment for the lone pair electrons in this case is 1.24 a.u. where the total dipole moment in these same units is 0.72.) It is clear that the equilibrium forces will be attained only by greatly reducing the prominence of the lone pair electrons.

Case II. Localized Equivalent Orbitals with Bent Bonds

The above requirement may be attained by allowing the bonds to bend. By relaxing the restraint that the orbital angle α must equal the bond angle $\mathscr{E}$ we may allow the bonding orbitals to attain more p character and at the same time increase the s character of the lone pair electrons. Increasing the s character in the lone pair orbitals can increase the angle β between the lone pair orbitals from 109°28′ (sp^3 hybrids) to a limiting value of 180° (sp hybrids). In the limit of sp hybridization the lone pair orbitals project out above and below the plane of the molecule at right angles to the O—H bonds. In this limit they will neither exert a force on the oxygen nucleus or on the hydrogen nuclei in the perpendicular direction, nor will they contribute an atomic dipole moment.

The parameters ϵ_b and ϵ_1 may again be determined by the orthogonality conditions [1] and [2] for various assumed values of α and λ/μ. We may then examine the forces predicted by the various density distributions so obtained, which give the correct dipole moment. The smallest value which the angle α may attain is determined by the requirement that the two orthogonality conditions [1] and [2] possess real solutions for ϵ_b and ϵ_1. It is found that the limiting value of α, approximately 87°, is almost independent of the ratio of λ/μ. This value of α gives an ϵ_b of 107.61° and an ϵ_1 of 45.06°, which implies sp hybridization for the lone pair orbitals. If the hydrogens were absent this would of course occur at an angle of 90° between the two bonding orbitals, which would now be pure p bonds. However, because of the overlap with the hydrogens the orbital angle necessary to decrease the p character in the lone pair to that of sp must now be less than 90° (i.e., 87°) and correspondingly the bonding orbitals must now contain negative $2s$ character (the cos ϵ_b is now negative) to the extent of about 9%. Thus depressing the p character of the lone pair orbitals to values close to that found in sp hybrids is obtained only at the expense of introducing negative $2s$ character into the bonding orbitals.

The nature of the results for bent bonds is as follows. As α is decreased the lone pairs become less prominent, and the dipole moment can be met only by increasing the polarity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the OH bond. Thus, while for an $\alpha = 104.45°$ the correct dipole moment is found to occur at a $\lambda/\mu = 1.07$, at $\alpha = 87°$, the value of λ/μ must be increased to 1.45 to attain the same moment. The forces vary in a regular manner with α. In Fig. 2 we show the

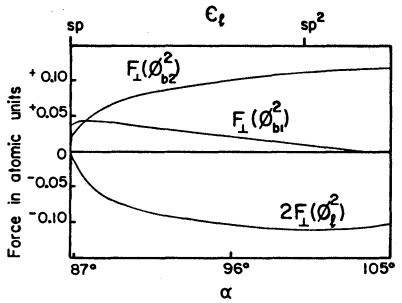

FIG. 2. The orbital contributions to $F_\perp$. The scale for ϵ_l given at the top of the figure is not a linear one.

variation with α of the orbital components to the perpendicular force on the hydrogen atom, $F_\perp$, for a λ/μ of 1.45. We choose this value of λ/μ since it contains (at $\alpha = 87°$) the best forces so far obtained, gives the correct dipole moment, and illustrates the general behavior for all the λ/μ values. From Fig. 2 we note that both $F_\perp(\phi_{b2}^2)$ and $-F_\perp(\phi_l^2)$ decrease with decreasing α, $F_\perp(\phi_{b2}^2)$ because of the decreasing amount of $2s$ character in ϕ_b and $F_\perp(\phi_l^2)$ because of the increasing $2s$ character in ϕ_l, which pulls the lone pair orbitals from behind the molecule onto the z axis. The contributions from ϕ_{b2} and the two lone pair orbitals are almost symmetrically placed about the zero force line and their contributions thus largely cancel. This leaves only the force from ϕ_{b1} to counteract the nuclear repulsion. $F_\perp(\phi_{b1}^2)$ increases as α decreases since charge is moved off the O—$H_{(1)}$ bond axis and placed alongside the bond, where it exerts a perpendicular force of attraction on $H_{(1)}$. However, $F_\perp(\phi_{b1}^2)$ never attains a value great enough to overcome the nuclear repulsive forces. The maximum attractive force of magnitude 0.04814 a.u. is attained at $\alpha = 87°$ and is insufficient to balance the nuclear repulsion of -0.07482 a.u.

The forces exerted on the oxygen nucleus present a similar picture. The large negative force due to the lone pair electrons can be reduced by bending the bonds. However, as these low values of α (and thus of $F_O(\phi_l^2)$) are obtained only by introducing negative $2s$ character into the bonding orbitals, the decrease in force exerted by the lone pair electrons is obtained only at the expense of a decrease in the positive forces exerted by the bonding electron density. The best result is again attained at $\alpha = 87°$, where the values of $2F_O(\phi_l^2)$ and $2F_O(\phi_b^2)$ are -0.02926 and 0.2844 a.u. respectively. This gives a final net force of -0.1188 a.u., which while it represents an improvement by a factor of three over the value obtained with $\alpha = \mathscr{E}$ is still far from a zero force. The electronic force exerted on $H_{(1)}$ along the bond is increased to 2.518 a.u. This is a great improvement over that obtained in case I and the net force is now decreased to only -0.020 a.u.*

The introduction of bent bonds has reduced the error in the perpendicular force on hydrogen by one-half, in the force on oxygen by one-third, and has come close to predicting a zero force on hydrogen along the bond. However, no combination of ϵ_b, ϵ_l, λ/μ, and α is capable of giving a density function which results in values of $F_\perp$ and F_O

The forces F_O and $F_\parallel$ will be discussed in greater detail in a following section.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

large enough to even approach small net forces. To better the forces it is necessary to "bend" the bonds more than is possible in case II. Furthermore, it is necessary to ensure that a smaller amount of negative $2s$ character is introduced into the bonding orbitals when the lone pairs are forced towards sp hybridization. Both of these conditions may be met by delocalizing the bonding orbitals.

Case III. Delocalized Equivalent Orbitals with Bent Bonds

It is well known (2, 4) that the exact transformation of a set of molecular orbitals into the corresponding set of equivalent orbitals will not in general result in completely localized bonding orbitals. Although it was at one time hoped that the amount of delocalization or mixing of the components of different bond orbitals would be negligibly small this has not proved true in known cases. We wish to show that it is of crucial importance in the description of the water molecule. The delocalization in this case requires the introduction of the $1s$ orbital of $H_{(2)}$ into ϕ_{b1} and of the $1s$ orbital of $H_{(1)}$ into ϕ_{b2}. The amount of delocalization will be designated by δ, as shown in the general expressions for ϕ_{b1} and ϕ_{b2}.

Introduction of delocalization into the bonding orbitals has a very pronounced effect upon the electron density distribution. The reasons for this are easy to understand. By subtracting some $H_{(2)}(1s)$ from the $H_{(1)}(1s)$ function and vice versa we effectively reduce the overlap between the two hydrogen atoms and between the hydrogens and the oxygen $2s$ and $2p$ orbitals as well.* The immediate result of this reduced overlap between the hydrogens is that the bonding orbitals may now approach much more closely than was previously possible, thus allowing the bonds to bend to a much greater degree. It should be recalled that the requirement of orthogonality between orbitals is simply the way in which the Pauli exclusion principle is satisfied. By placing electrons with the same spin functions in orbitals which overlap we obviously violate the Pauli exclusion principle. Thus the requirement of orthogonality between two orbitals made up of components with finite overlap places a definite limitation on their possible proximity in space. The reduced overlap of the hydrogens not only allows for a greater degree of bending of the bonds but does so at smaller values of ϵ_b. Thus whereas with $\delta = 0$, an $\alpha = 87°$ was obtained with an $\epsilon_b = 108°$, the same value of α with $\delta = 0.355$ may be attained at an ϵ_b of approximately 60°, thus avoiding, or at smaller values of α, greatly reducing, the introduction of negative $2s$ character in the bonding orbitals. In addition the introduction of delocalization, again because of the decreased hydrogen overlap integrals, gives smaller values of ϵ_l for a given value of ϵ_b. Thus delocalization corrects just those deficiencies which were noted in consideration of the case II densities.

In Table II we show the effect which the introduction of δ has on the electronic forces. All of the forces listed below are calculated from density distributions which have the

TABLE II

The forces for case III

correct dipole moment. The introduction of delocalization increases $F_\perp$ and F_O very markedly, giving electron density distributions which have the correct dipole moment and yield close to the correct values for the electronic forces. The forces $F_\perp$ and F_O increase with increasing values of δ. $F_\parallel$ passes through a maximum in the region $0.35 < \delta < 0.40$ and, therefore, it is not possible to satisfy all of the forces simultaneously. However, special considerations arise in the case of the forces operative on the oxygen atom.

The value of F_O reported in Table II is the contribution of the valence electrons only. Up to this point the inner shell electrons on the oxygen atom have been assumed to be in a spherically symmetrical distribution on the oxygen nucleus. However, it is a known fact that a spherical charge distribution, when in the presence of an electric field, will polarize to the extent necessary to overcome the force exerted by the field.* It is also known that variational calculations predict slight polarizations of the inner shell orbital through the introduction of $2p$ character (10). The same slight polarization of the oxygen inner shell electrons in the present case can readily account for the final discrepancy of 0.04 a.u. in F_O. We can fix this additional parameter, the amount of $2p$ introduced into the inner shell orbital ϕ_o, by using the observed dipole moment as another constraint which the density function must fulfill. We then have six conditions to fix the six parameters. Taking

$$\phi_o = N(1s_o - k2p_{x'})$$

($2p_{x'}$ is directed along the x' axis of Fig. 1, i.e., away from the hydrogens) a value of $k = 0.0044$ is sufficient to balance the total calculated electronic force with the nuclear repulsive force exerted on the oxygen atom. This small amount of polarization is realistic and does not change the reported values of $F_\parallel$, $F_\perp$, or the dipole moment. Nor does the introduction of polarization seriously upset the orthogonality conditions. The non-orthogonality of the orbital ϕ_o with the bonding orbitals is 0.003 and with the lone pair orbitals is only 7×10^{-6}. This can be corrected for by reorthogonalization, which changes the final force on oxygen by only 2×10^{-4} a.u. Both the introduction of $2p_{x'}$ into ϕ_o and the subsequent reorthogonalization change the forces on hydrogen by the same small amount.

Undoubtedly, part of the remaining discrepancy in the forces on hydrogen could be removed by allowing for polarization of the hydrogen atoms as well. However, the forces are not nearly as sensitive to polarization of the hydrogens as they are to inner shell polarizations. Polarization of inner shell electrons displaces charge density very close to the nucleus and hence gives rise to a large atomic force term. Since the density around the hydrogen nuclei is not contracted to this same extent the relevant force integral is much smaller. For example, an amount of polarization of the hydrogen density comparable to that suggested for the inner shell on oxygen increases $F_\parallel$ by only 0.003 a.u. compared to a total electronic force of $\sim$2.5 a.u.

We have arrived at an expression for the electron density distribution for the water molecule which gives the correct dipole moment, satisfies the requirement of zero resultant forces for the oxygen nucleus, and comes close to satisfying this same condition for the hydrogen nuclei as well. The remaining forces on hydrogen are reasonably small and correspond to those encountered in an O—H bond compression of two one-hundredths of an Angstrom and to a change in the bond angle of 1.5°. The essential features of the

*The question of inner shell polarization has been discussed by Salem and Wilson (9) from the standpoint of the Hellmann–Feynman theorem. These authors point out that the problem of treating the inner shell electrons is simplest when there is no appreciable overlap with other orbitals. This is true in the present case as the overlap of ϕ_o with the 1s orbitals on hydrogen is so small that it can be ignored.

distribution vary only slightly with δ. Thus even though our inability to achieve final electrostatic equilibrium makes it difficult to decide on a final value of δ (a value close to 0.5 is indicated) we can specify the values of the remaining parameters within small bounds. The value of ϵ_b will be within a few degrees of 98°. This gives bonding orbitals which are 98% $2p$ in character and contain a very small amount of negative $2s$ character. The bonding orbitals from oxygen are thus essentially pure p bonds. The value of ϵ_l is always within one-hundredth of a degree from the value of 45°, which corresponds to sp hybrids directed above and below the molecular plane, with no component projected out the back of the molecule. This orbital picture is close to that obtained from a qualitative use of valence bond theory with the exception of course that this distribution is for a bond angle of 104.45° and not the 90° molecule predicted by valence bond theory. The bonds are, therefore, necessarily strongly bent with an orbital angle of approximately 59°. This gives ω (the angle between the bond direction and the orbital direction) a value of approximately 22°. It is also found that the bonding orbitals are quite polar with a λ/μ of approximately 1.5. An electron density contour map for the distribution with $\delta = 0.5$ is given in Fig. 3 and the expressions for the orbitals are

$$\phi_{b1} = 0.486474(s_1) - 0.243237(s_2) - 0.109490(2s) - 0.633912(2p_{x'}) + 0.358651(2p_{y'})$$
$$\phi_{l1} = 0.707105(2s) + 0.707107(2p_{z'}) + 0.001814(2p_{x'}).$$

The most radical difference between this electron density distribution and that proposed by Pople (and widely quoted, for example by Coulson (4) in his book "Valence") is the decrease in the prominence of the lone pair electrons. The lone pair orbitals according to Pople are sp^3 in character, projected out the back of the molecule, as opposed to the sp hybrids found in this work. The lone pair electrons in the present density distribution do not make a significant contribution to the dipole moment as opposed to Pople's case where they were predicted to make up almost the complete electronic contribution. Consequently, the present distribution predicts a much greater polarity for the O—H bonds than found by Pople. Again the present results agree with earlier views, that the dipole moment of the water molecule is due largely to the polarity of the bonds.* Pople (2) states that his calculations probably do overestimate the p character of the lone pair electrons. He stressed that the most important single factor in determining the bond angle of water was the repulsion between the lone pairs and that the angle between the lone pair orbitals should thus be as large as possible. By not allowing for bent bonds or delocalization the minimum angle they could obtain was close to 109° as determined by the molecular geometry. By allowing the bonds to bend, this lone pair repulsion can be reduced to its minimum, which occurs when they occupy sp hybrid orbitals.

The danger of believing hybridization to be determined by molecular geometry has of course been pointed out before, specifically for the water molecule by Shull and Ellison (10), who have carried out a S.C.F. L.C.A.O. M.O. treatment for the water molecule. Their results predict an equilibrium bond angle of 120°, a dipole moment which is too low by 0.3 D, and a binding energy 77% of the observed value at the correct bond angle. It is of interest to compare the orbitals obtained by them at 105° (not their equilibrium angle) with the present results. They too predict p bonds to the hydrogen atoms with a very small amount of negative $2s$ character. Their orbital angle is 69° as opposed to the 59° obtained here. They also arrive at lone pair orbitals which are closer to sp than sp^3. Their value for ϵ_l is in fact 47° (53% $2p$ character), as compared to 45°

**The fact that the bonds are bent in the present case lowers the value λ/μ required to meet the observed dipole moment.*

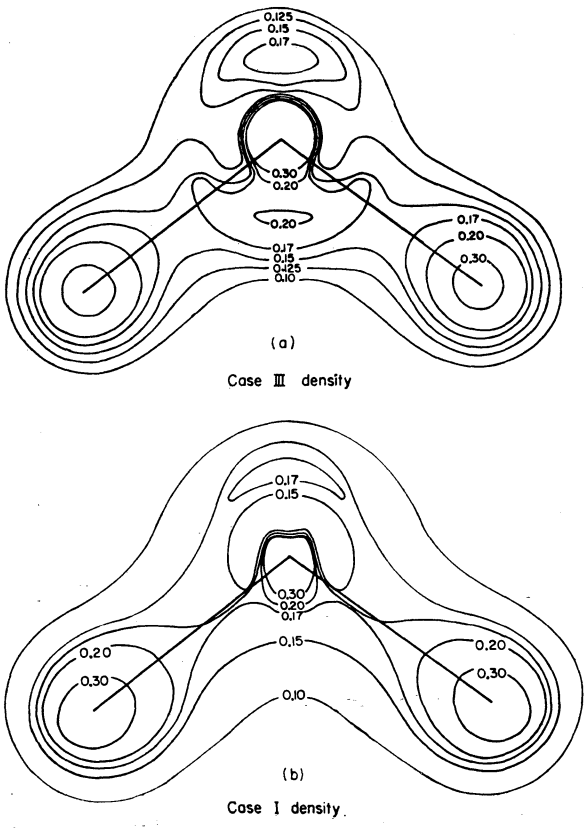

FIG. 3. Electron density contour maps for the density due to the valence electrons in the plane of the water molecule. Map (*a*) is for case III with $\delta = 0.5$, the best approximation to the density we have obtained. Map (*b*) is for the Pople-like distribution described in case I with prominent lone pairs. Map (*b*) is included for comparison to illustrate the effect of bent bonds and delocalization on the electron density. In distribution (*b*) there is a large bulge of density, due to the prominent lone pairs, projected out behind the oxygen nucleus which is responsible for the large imbalance in the forces on oxygen and on the hydrogens. In distribution (*a*) this same charge is more symmetrically placed with respect to the oxygen atom. Distribution (*a*) gives an accumulation of charge just below the oxygen atom which exerts an attractive force on all three nuclei. There is a valley in the (*b*) distribution along this same line. Distribution (*a*) clearly accumulates more charge in the binding regions between the nuclei than does distribution (*b*).

(50% $2p$ character) in the present case. It should be emphasized that with this value of ϵ_1 Shull and Ellison were not able to achieve an energy minimum at this angle.

To illustrate that results obtained by the present electrostatic method will not be radically different from those obtained by variational calculations we have used the orbitals determined by Shull and Ellison at the predicted equilibrium angle of 120° to calculate $F_\perp$. The component of the nuclear repulsion at this angle is 0.0508 a.u. and $F_\perp$ is found to be 0.0548 a.u., i.e., a force slightly larger than that required to balance the repulsive forces. This agreement is as good as can be expected as Shull and Ellison did not do a sufficient number of calculations to determine the energy minimum to an accuracy greater than approximately ±5°. This result would indicate that their true calculated minimum comes at an angle slightly less than 120°. Shull and Ellison (10) point out that the total electronic energy calculated for the water molecule by the variational method changes by only 0.13% as the bond angle is varied from 90° to

180°. As stated in the introduction, a force calculation is free from this defect and thus provides a method for determining densities which is more sensitive and more immediate than one based on a consideration of the energies.

The Electron Density Distributions and Geometries of the Hydride Molecules XH_2 and XH_3

The electron density distribution we have derived for the water molecule has two distinctive features: the lone pair electrons are in orbitals with the maximum amount of $2s$ character and the bonding electrons are in orbitals of almost pure $2p$ character. We wish now to illustrate, through the use of some general force curves to be given below, that an electron distribution of this type is to be expected for all hydride molecules which contain lone pair electrons, i.e., *in hydride molecules which possess at least one lone pair of electrons the bond orbitals will be primarily of p character and the lone pair orbitals will contain close to the maximum possible amount of s character.*

To see clearly what effects hybridization has on the forces exerted by the lone pair and bonding electrons we consider a simple diatomic hydride molecule X—H. The general expression for the normalized bond orbital due to the overlap of some hybrid of s and p orbitals on X with a $1s$ orbital on H is

$$\phi_b = \lambda[\cos \epsilon_b\, 2s + \sin \epsilon_b\, 2p] + \mu 1s,$$

and for a lone pair orbital directed out the back of the X atom along the bond axis,*

$$\phi_l' = \cos \epsilon_l'\, 2s - \sin \epsilon_l'\, 2p.$$

The forces exerted on the X atom along the bond axis by the electron density distribution are, for the bonding orbital,

$$F_{bx} = \lambda^2[4 \cos \epsilon_b \sin \epsilon_b\, A_x(2s,2p)] + \mu^2[2P_x(1s,1s)] + 4\lambda\mu[\cos \epsilon_b\, O_x(2s,1s) + \sin \epsilon_b\, O_x(2p,1s)],$$

and for the lone pair orbital (the direction of this force is opposite to that for F_{bx}),

$$F_{lx} = -4 \cos \epsilon_l' \sin \epsilon_l'\, A_x(2s,2p).$$

These expressions illustrate the three kinds of force expressions encountered in an atomic orbital description of an electron density:

$A_x(2s,2p)$—the force exerted on the X nucleus due to the s–p hybridization of the density on that nucleus. The same term in the electron density expression gives rise to the so-called atomic dipole.

$P_x(1s,1s)$—the force exerted on the X nucleus by the charge density situated at the hydrogen nucleus. Integrals of this type (i.e., the force on one atom due to the density situated entirely on another atom) are termed penetration integrals as their value is determined by the extent to which nucleus X penetrates the charge density on the other atom. The integral thus determines the extent to which the one nucleus is shielded from the other.

$O_x(2s,1s)$; $O_x(2p,1s)$—the force exerted on the X nucleus due to the charge density contained in the overlap regions of the $2s$ and $2p$ orbitals with the $1s$ orbital.

In Fig. 4 we have plotted F_{bx} and F_{lx} versus their hybridization parameters for orbitals corresponding to an O—H bond. The forms of these curves are the same for any X—H molecule. The force F_{bx} is shown for a λ/μ value of 1.00. In the limit of

*The lone pair hybridization parameter is primed in this case so that it will not be confused with ϵ_l, the one used to denote the hybridization of two equivalent lone pairs.

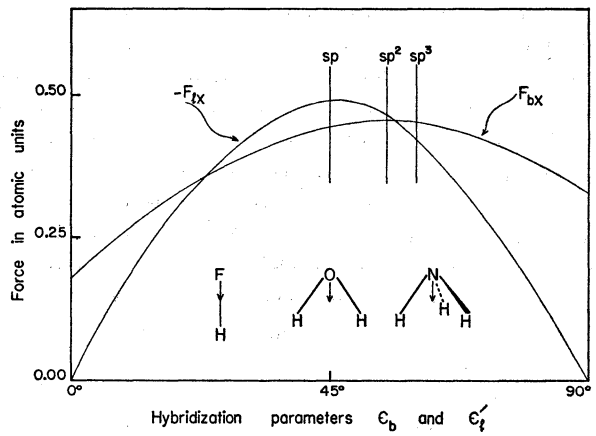

FIG. 4. The forces exerted on the X nucleus in HX by the lone pair and bonding electron densities as a function of their respective hybridization parameters ϵ_l' and ϵ_b.

$\lambda/\mu = \infty$, F_{bX} will of course equal $-F_{lX}$. For values of λ/μ only slightly greater than unity ($\sim$1.4) the two end points of F_{bX} drop slightly and the maximum in the curve is slightly increased. We assume that any other electron pairs present on the X nucleus are in s or p_π orbitals and thus they exert no force on the X nucleus since their density is symmetrically placed around X. The force exerted on X by the lone pair is zero for pure s or pure p orbitals but increases rapidly with hybridization to a maximum corresponding to an sp hybrid. This force is due entirely to the atomic force term $A_X(2s,2p)$. The force due to the bonding pair of electrons is of some interest. It gives the order of the forces exerted on X versus hybridization as

$$sp^2 \sim sp \sim sp^3 > p > s.$$

The hybrid orbitals exert the greatest force on X, and the force due to a pure p orbital on X is considerably greater than that due to a pure s orbital on X when forming a bond with hydrogen. This increased force of a $2p$ bond over an $2s$ bond with hydrogen is due almost entirely to a much greater value of $O_X(2p,1s)$ as compared to $O_X(2s,1s)$ (a factor of almost three for O—H bonds). This is to be expected as the overlap of a p bond with a $1s$ orbital on H places most of the overlap charge density along the bond axis, where it exerts a maximum force. The increase in the forces encountered in the s–p hybridizations is due to the presence of the atomic force term $A_X(2s,2p)$ which results from the polarized charge density relatively close to the X nucleus.

We can employ Fig. 4 in a qualitative application of the proposed rule to all 3 of the 10 electron hydrides, NH_3, H_2O, and HF. For each of these molecules we are interested in considering the resultant force on the N, O, and F nuclei as indicated for each case in Fig. 4. Each of these molecules, as it turns out, has but one lone pair of electrons which can exert a force on the heavy nucleus. The ammonia molecule has one lone pair orbital and it is directed along the force axis, in the negative direction. Its hybridization can vary from pure s to approximately sp^3. The two equivalent lone pair orbitals of the water molecule which can vary from sp to approximately sp^3 may be considered equally well as a single p_π orbital perpendicular to the plane of the molecule (which exerts no force on the oxygen atom) and a second orbital in the plane directed along the force axis which can vary from pure s to approximately sp^2. Linear combinations of these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

two orbitals give back the two equivalent lone pair orbitals.* The three lone pairs of electrons in hydrogen fluoride occupy two p_π orbitals which exert no force on the fluorine nucleus and a hybrid orbital along the bond axis which may vary from pure s to pure p. F_{1X} thus applies directly to all three of these molecules, as does F_{bX} for HF. For H_2O and NH_3 components of F_{bX} for each bond must of course be taken along the indicated force axis. The components are such that the two O—H bonds in H_2O and the three N—H bonds in NH_3 add up very close to that of a single O—H and N—H bond respectively along the direction of the force. In actual fact new force components appear in F_{bX} for H_2O and NH_3 ($O_X(2s,2p_\pi)$ for example) at the expense of those indicated. It will be apparent that these effects do not alter the nature of the general results we wish to obtain here. This may be seen by comparing F_{bX} with the exact force expression for $F_O(\phi_b^2)$ given in the Appendix.

It is obvious from Fig. 4 that the lone pair of electrons in any of these three molecules cannot be placed in an orbital which is strongly s–p hybridized if electrostatic equilibrium is to be attained. Large hybridization of the lone pair results in a negative force on the X atom which is greater than or only slightly less than the attractive force exerted by the bonding electrons, and an insufficient amount of attractive force would remain to compensate for the nuclear repulsion. The force due to the lone pair electrons can be decreased either by placing them in an almost pure $2p$ or pure $2s$ orbital. The direction taken is determined by which of the two alternatives gives the best bonding force, as the hybridization parameters ϵ_b and ϵ_1' are, of course, not independent. If the lone pair is pushed towards pure $2p$ bonds the bonding orbital approaches pure $2s$, which as we have seen is not as effective as a pure p bonding orbital in the force it exerts on the X nucleus. Thus by placing the lone pair electrons in an almost pure $2s$ orbital and the bonding electrons in an orbital largely $2p$ in character the negative force of the lone pair electrons can be reduced at the expense of only a small decrease in the force exerted by the bonding electrons. In HF this is achieved simply by making the bonding orbital largely $2p$ in character and the lone pair thus becomes mostly $2s$. In H_2O and NH_3 the same result is achieved by bending the bonds. Since the hybridization in these molecules, if determined by the molecular geometry, would place the lone pair in either an sp^2 or sp^3 orbital for H_2O and NH_3, respectively, bent bonds are an absolute necessity in order to remove the great imbalance in forces created by the lone pair electrons. It should be recalled that delocalization of the bonding orbitals in H_2O also operated so as to increase the amount of s character in the lone pair orbitals for a given amount of s–p hybridization (and hence a larger force) in the bonding orbitals. This is the principal reason for the delocalization in molecules such as H_2O and NH_3.

A consideration of the forces exerted on the hydrogen atom by the same two orbitals in HX leads to an identical conclusion, i.e., that in these molecules the lone pairs will be largely $2s$ and the bonding orbitals largely $2p$. A consideration of the forces exerted on the hydrogen nucleus in this model are also of use in understanding why certain hydride molecules are bent as opposed to being linear, or pyramidal as opposed to being planar. The expressions for these forces are

$$\begin{aligned} F_{bH} = {} & 2\lambda^2[\cos^2\epsilon_b\, P_H(2s,2s) + \sin^2\epsilon_b\, P_H(2p,2p) \\ & +2\cos\epsilon_b \sin\epsilon_b\, P_H(2s,2p)] \\ & +4\lambda\mu[\cos\epsilon_b\, O_H(1s,2s) + \sin\epsilon_b\, O_H(1s,2p)]; \end{aligned}$$

*ϵ_1 *gives the hybridization in water for two equivalent lone pairs and* ϵ_1' *gives the hybridization of a single lone pair in water when the second pair is placed in a* p_π *orbital. When* ϵ_1' *gives pure* s, ϵ_1 *gives* sp *and when* ϵ_1' *gives* sp^2, ϵ_1 *gives* sp^3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

$$F_{1H} = 2[\cos^2 \epsilon_1' P_H(2s,2s) + \sin^2 \epsilon_1' P_H(2p,2p) - 2 \sin \epsilon_1' \cos \epsilon_1' P_H(2p,2s)].$$

The lone pair and bond densities both exert an attractive force on the hydrogen nucleus. Hybridization increases the force due to the bonding electrons on the hydrogen nucleus and as can be seen from Fig. 5, the order of the forces as determined by the hybridization on X is

$$sp^3 \sim sp^2 \sim sp > p > s.$$

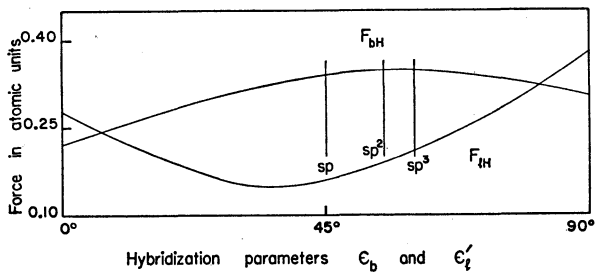

FIG. 5. The forces exerted on the H nucleus in HX by the lone pair and bonding electron densities as a function of their respective hybridization parameters ϵ_l' and ϵ_b.

Aside from a slight reordering of the forces for large hybridizations the results are the same as for the forces on the X atom, with a $2p$ bond exerting a much stronger force than that of a bond formed by a $2s$ orbital from the X atom. The force exerted by the lone pair, F_{1H}, undergoes a great decrease when hybridization on X is extreme. The contributions to F_{1H} are all of the penetration type. Hybridization results in charge being removed from the hydrogen side of X and being placed on the side remote from hydrogen. This explains the great decrease in shielding (i.e., decrease in the value of F_{1H}) as hybridization on X becomes important. Thus large hybridization results in a great increase in the repulsive force on hydrogen as the lone pair no longer effectively shields its part of the nuclear charge on X. Again, of the two possibilities the greatest possible force is achieved by making the bonds largely p in character and the lone pair largely s.

With these general curves for the variation of the forces on hydrogen versus hybridization in mind, we may go on to consider the question of bond angles. Consider the general expression for the electronic force exerted on the hydrogen nucleus along the O—H bond axis in H_2O. For a linear or bent molecule this can be written as

$$F_\parallel = F_{b1}+F_{b2}+F_{l1}+F_{l2}+F_{1s},$$

where F_{b1} designates the force on $H_{(1)}$ due to its bonding orbital, F_{b2} the force on $H_{(1)}$ due to second bonding orbital, F_{l1}, F_{l2}, and F_{1s} the forces due to the two lone pairs and the inner shell electrons.

The total nuclear repulsion between the O and H nuclei can be written as $4(-2/d^2)$ where d is the O—H bond length. Then the four pairs of electrons contained in ϕ_{b1}, ϕ_{l1}, ϕ_{l2}, and ϕ_{1s} can each be considered as exerting a force opposed to a nuclear contribution of $-2/d^2$. In the same way the pair of electrons in ϕ_{b2} must balance the force of $1/R^2 \cdot (\sin \mathscr{E}/2)$, where R is the H—H separation. This is a useful device for the following reason. Consider the pair of electrons in ϕ_{1s}. They are tightly held around the oxygen nucleus and at the bond distance d the hydrogen nucleus has not effectively penetrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

this charge distribution. Thus this pair of electrons should effectively shield a nuclear charge of two units. This is precisely what is found, as F_{1s} equals $2/d^2$, i.e. $P_H(1s_o,1s_o)$ equals simply $1/d^2$ and for two electrons we obtain an exact screening of two units of nuclear charge. In a linear H_2O molecule, ϕ_{11} and ϕ_{12} are both p_π orbitals. For very large values of d, the value of any penetration integral is simply $1/d^2$ as there is no penetration of the charge density. However, for values of d corresponding to those observed in stable molecules the value of $P_H(2p_\pi,2p_\pi)$ is much less than $1/d^2$ as π orbitals place charge above and below the bond axis and poor shielding results. Thus electrons in p_π orbitals do not effectively shield their share of the nuclear charge. The force exerted by a pair of electrons in a bonding orbital is generally greater than $2/d^2$ as charge is actually moved off the nuclei and concentrated between them, leading to an increase in the effectiveness of the electron density in attracting the nuclei. We thus have non-bonding or inner shell electrons whose presence leads to a zero net force; we have lone pair electrons in p_π orbitals whose presence leads to a net force of repulsion; and bonding electrons which lead to a net attractive force. We now consider what happens to these various contributions as the bond angle is decreased from 180°.

(i) F_{b1} decreases in value as the molecule is bent since the hybridization changes from approximately sp to almost pure p. F_{b2} increases markedly on bending the molecule as the density contained in ϕ_{b2} is now moved closer to $H_{(1)}$. The nuclear repulsion also increases as the hydrogens approach one another but F_{b2} (which is always greater than $\sin(\mathscr{E}/2)\ (1/R^2)$) increases much more rapidly. The net result of decreasing the bond angle is an almost constant or at most a slightly decreasing contribution to the force on $H_{(1)}$ due to the bonding electrons.

(ii) As the bond angle is decreased from 180° one of the lone pair orbitals takes on an increasing amount of $2s$ character and in the limit becomes a pure $2s$ orbital. A $2s$ orbital is much more effective at screening a nucleus that is a $2p_\pi$ orbital. Furthermore, the remaining p character of this same orbital now assumes p_σ character with respect to $H_{(1)}$ as the molecule is bent. The penetration integral for p_σ actually exceeds $1/d^2$. Thus the effect of bending the molecule is to obtain a much greater screening of the oxygen nucleus and hence a large increase in the force of attraction due to one of the lone pairs. The force due to the second lone pair orbital is independent of bond angle as it remains a p_π orbital.

This is the reason for a bond angle of less than 180° for the water molecule. In decreasing the bond angle the attractive force of the bonding electrons remains almost constant but the attractive force of the lone pair electrons increases greatly as the p_π orbital assumes $2s$ character, resulting in a much greater shielding of the oxygen nucleus.

Precisely the same reasoning holds for the pyramidal form of NH_3 being more stable than the planar form. In bending the hydrogens out of plane the forces due to the bonding electrons decrease only slightly for the same reasons given for water. The lone pair orbital, however, changes from a p_π orbital to a $2s$ orbital in the limit. Thus again by bending the hydrogens out of the plane the shielding of the nitrogen nucleus is greatly increased, leading to a greater force of attraction on the hydrogens and a more stable molecule. The planarity of CH_3^+ and BH_3 and the pyramidal shape of CH_3^- are easily explained on the same basis. In CH_3^+ and BH_3 there are no lone pair electrons. The molecules thus gain nothing by bending. They would in fact undergo a slight decrease in force, as the bonding orbitals would change from approximately sp^2 in the planar form to some hybrid approaching pure p, and Fig. 5 illustrates that this is unfavorable. The CH_3^- ion on the other hand is isoelectronic with NH_3 and again can reach a more

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

stable configuration by assuming a pyramidal shape and thereby can increase the shielding of the carbon nucleus. The methyl radical CH_3 with but one electron in the p_π orbital in its planar form will obviously be a borderline case and a firm prediction could be made only by a complete calculation. However, a comparison of the values of $P_H(2p_\pi,2p_\pi)$ and $P_H(2s,2s)$ would suggest that the difference between these two penetration integrals for an occupation by only one electron might not be sufficient to cause the molecule to bend.

In summary, one concludes from a consideration of the electronic forces exerted on the hydrogen nuclei in XH_2 and XH_3 molecules that the main factor determining their most stable configuration is the presence or absence of at least one lone pair of electrons in a single orbital. XH_2 and XH_3 molecules which do not possess an unshared pair of electrons obtain their maximum force on the hydrogen nuclei in their linear and planar forms respectively.* For XH_2 and XH_3 molecules with lone pair electrons the largest electronic force on hydrogen is attained by decreasing the bond angle. This converts one lone pair $2p_\pi$ orbital into a $2s$ orbital, which screens the X nucleus much more effectively than does a $2p_\pi$ orbital. To attain this limiting form for the lone pair orbital it is not necessary to decrease the bond angle to 90°. By bending the bonds as discussed in detail for H_2O it is possible to attain this limiting form at intermediate angles. In fact the extent to which it is possible to bend the bonds to reach this limiting case will determine the final bond angle. The discussion regarding the hybridization in the bent or non-planar forms of the hydride molecules also demonstrated that the bonds must be bent at these intermediate angles if the X nucleus is to achieve electrostatic equilibrium.

It is only in hydride molecules such as CH_3^+ or CH_4 which do not possess lone pairs of electrons that the full benefit of the large attractive forces associated with sp^2 or sp^3 hybridization can be realized. In methane the density distribution of every projected orbital is directed to a hydrogen nucleus and thus no large imbalance occurs in the forces exerted on the carbon atom. The conclusions we have reached in this paper concerning the factors governing the shapes of XH_2 and XH_3 molecules are the same as the empirically based rules advanced by Walsh (11). Our method of arriving at these conclusions and our interpretations of them are entirely different from his.

It should not be assumed that the density distribution advanced for the water molecule in this work is inconsistent with an almost tetrahedral structure for ice. The bonds in the water molecule have been predicted to be quite polar. Thus the proximity of hydrogen nuclei belonging to neighboring water molecules can easily bring about an increase in the p character of the lone pair orbitals and a corresponding decrease in the angle β between these orbitals. The presence of the partially unshielded hydrogen nuclei would now balance the large forces which the lone pairs exert in this position on the oxygen nucleus and on the hydrogens, tending to open up the bond angle. A familiarity with the sensitivity of electronic forces to hybridization and external centers of force would lead us to predict a substantial change in the electron density distribution upon hydrogen bonding. An increase in the orbital angle with a corresponding increase in the amount of s–p hybridization in the bonding orbitals would accompany the increased hybridization of the lone pairs. Thus the lone pair orbitals can approach sp^3 hybridization when hydrogen bonded for the same reasons that such hybridization is possible in the methane

**The molecules BH_2 with one unshared p_π electron and CH_2 with two unshared electrons in two distinct p_π orbitals (in their linear forms) are borderline cases as is CH_3. The singlet state of CH_2 with both unshared electrons in a single orbital should be bent.*

molecule. It is this favorable methane-like distribution which the water molecule can approach when hydrogen bonded in ice.

ACKNOWLEDGMENTS

We wish to thank the staff of the computing center at the University of Ottawa for their generous assistance with these calculations. Special thanks are due to Miss O. Boshko for writing the program to calculate the three-center integrals, and to Mr. P. Sefton for help with the general program. We also acknowledge the assistance of Miss V. Zahradnitzky and Mr. D. Hill in checking the numerical work.

APPENDIX

The Atomic Orbitals and Orthogonality Conditions

The atomic orbital functions employed in the calculation are of the Slater type. It is a well-recognized fact that variational calculations indicate a substantial increase in the hydrogen 1*s* orbital exponent over the free atom value when the hydrogen is involved in bond formation. Some recent calculations by Ransil illustrate this point (15). We have employed a value of 1.32 (as opposed to 1.00, the free atom value, employed by Pople and Duncan (3) and Shull and Ellison (10)) which was obtained by the use of a formula previously discussed (6). This formula relates the orbital exponents to the free atom and united atom (in this case neon) limits through a correlation of the molecular orbitals. That the method is reliable is illustrated by the calculation of the orbital exponent for hydrogen in HF. This exponent has been determined by Ransil in a variation calculation (15) and the best value is found to be 1.32. An application of the formula gives a value of 1.34. Both the formula and the results of variational calculations predict only small changes in the exponents of the 1*s* inner shell and 2*s* and 2*p* orbitals on the atoms bonded to hydrogen. We have repeated a large number of the calculations using these slightly different values and find no significant changes in our results. We have, therefore, employed the free atom values of the orbital exponents for the $1s_o$, 2*s*, and 2*p* orbitals on oxygen. These values are 7.700 for $1s_o$ and 2.275 for 2*s* and 2*p*.

It is most important in force calculations that all the important orthogonality conditions be met. Particularly important is the condition of orthogonality between the 2*s* and 1*s* orbitals on the same atom. Thus the oxygen 2*s* orbital indicated in all the formulae is the orthogonalized one

$$2s = (1-S_o^2)^{-\frac{1}{2}}(2s'-S_o 1s_o),$$

where 2*s*′ is the nodeless Slater orbital, and S_o is the overlap integral between 2*s*′ and $1s_o$. The only orthogonality neglected in the present calculations is that between the 1*s* orbital on oxygen, $1s_o$, and the hydrogen 1*s* orbital. The overlap between $1s_o$ and $1s_H$ is very slight and consequently the magnitudes of the force integrals due to this overlap are so small that they can be neglected without incurring any error to the accuracy employed in the present calculations.

In the following formulae we denote the overlap integrals between the oxygen 2*s* and 2*p* orbitals with a hydrogen 1*s* orbital as S_2 and S_3 respectively and that between the two hydrogen 1*s* orbitals as S_1.

When the two lone pair orbitals are expressed in their equivalent form, the $2p_z$ orbital makes a constant contribution of $1/\sqrt{2}$. Since this $2p_z$ orbital makes no contribution

to F_O or $F_\perp$ and a constant contribution to $F_\parallel$ it greatly simplifies all of the calculations if the lone pair orbitals are taken instead as the orthogonal set:

$$\phi'_{11} = \cos \epsilon'_1\, 2s + \sin \epsilon'_1\, 2p'_3$$
$$\phi'_{12} = 2p_z,$$

where p_3' is directed in the plane of the molecule along the x' axis. This is the alternative form of the lone pair orbitals discussed earlier in the paper. The hybridization parameters ϵ_1 and ϵ_1' are easily related: $\cos \epsilon_1 = (1/\sqrt{2}) \cos \epsilon_1'$, $\sin \epsilon_1 = (1/\sqrt{2}) \sin \epsilon_1'/\cos (\beta/2)$, where β is the angle between the lone pair orbitals. The requirement that the equivalent lone pair orbitals be orthogonal gives $\cos \beta = -\cot^2 \epsilon_1$.

The following equations [1] and [2] are the relationships obtained by requiring the orbitals to be mutually orthogonal. For orthogonality between the bonding orbitals we obtain:

$$[1] \quad \lambda^2[\cos^2 \epsilon_b + \sin^2 \epsilon_b \cos \alpha] + \mu^2[S_1(1+\delta^2) - 2\delta] + 2\lambda\mu[S_2 \cos \epsilon_b\, (1-\delta) + S_3 \sin \epsilon_b\, (\cos t - \delta \cos \omega)] = 0$$

and for orthogonality between the bonding and lone pair orbitals

$$[2] \quad \tan \epsilon_1' = \frac{S_2(1-\delta) + (\lambda/\mu) \cos \epsilon_b}{S_3 \cos (\mathscr{E}/2)\, (1-\delta) + (\lambda/\mu) \sin \epsilon_b \cos (\alpha/2)} = \tan \epsilon_1 \cos (\beta/2).$$

A third condition obtained from the normalization of the bonding orbitals allows one to determine the absolute values of λ and μ once their ratio is known. This condition is

$$[3] \quad \lambda^2 + \mu^2[1+\delta^2-2\delta S_1] + 2\lambda\mu[S_2 \cos \epsilon_b\, (1-\delta) + S_3 \sin \epsilon_b\, (\cos \omega - \delta \cos t)] = 1.$$

When it was realized that a total of five parameters would be required to describe the density distribution of the water molecule the calculations were programmed for machine computation on an IBM 650. The sequence of steps employed in the program are as follows. For a particular choice of λ/μ, δ, and α, the parameter ϵ_b is obtained from equation [1]. Equation [1] as written can be solved only by a trial and error method. However, since ϵ_b is $(90 \pm m)$ where m is less than 15°, $\cos \epsilon_b$ and $\sin \epsilon_b$ can be expanded in terms of m. Retaining terms to the order of m^2 converts equation [1] into a quadratic expression in m. This method and equation [1] as it stands give identical results well within the accuracy required. As an example, for $\delta = 0.3$, $\lambda/\mu = 1.4$, and $\alpha = 70.00°$, both methods give $\epsilon_b = 95.87°$. Equation [2] was then used to obtain ϵ_1' and equation [3] to obtain λ and μ. In the program this was followed by a calculation of $F_\perp$, $F_\parallel$, F_O, and the dipole moment.

The Calculation of the Forces

All of the force integrals are of the form

$$\int \mathscr{D}_{\alpha x} \phi_i \phi_j d\tau,$$

where $\mathscr{D}_{\alpha x}$ is the expression for the x-component of the electric field due to nucleus α, and ϕ_i and ϕ_j are atomic orbitals (7). The positions of ϕ_i and ϕ_j with respect to atom α generate either $A_\alpha(\phi_i,\phi_j)$, $P_\alpha(\phi_i,\phi_j)$, or $O_\alpha(\phi_i,\phi_j)$ integrals as explained earlier in the text. General formulae for all the penetration integrals (two- and three-center forms) have been given previously (12) and the formulae for the O_α integrals may be obtained from tables published by Coulson (13). All the force expressions are for double occupation

For personal use only.

of the orbitals and $2p_x$, $2p_y$, and $2p_z$ refer to the $2p$ atomic orbitals directed along the x, y, and z axes of Fig. 1.

The Forces on Hydrogen

All the forces calculated for hydrogen refer to the hydrogen atom labelled $H_{(1)}$. The component of the electric field $\mathscr{D}_{\perp H}$, which appears in the integrals for the perpendicular forces on hydrogen, is in the direction indicated for $F_\perp$ in Fig. 1, except for the integrals $P_H(1s_2,1s_2)$ and $O_H(1s_1,1s_2)$. In these two latter integrals the field component was taken along the line joining the two hydrogens, and the proper component of the resulting force (cos ($\mathscr{E}$/2)) was then taken along the direction of $F_\perp$. These two integrals are primed for this reason.

$$\begin{aligned}
F_\perp(\phi_{b1}^2) = {} & 2\lambda^2[2\cos\epsilon_b \sin\epsilon_b \sin\omega\, P_H(2s,2p_y)+2\sin^2\epsilon_b\cos\omega\times \\
& \sin\omega\, P_H(2p_x,2p_y)] +2\mu^2[\delta^2 P'_H(1s_2,1s_2)-2\delta O'_H(1s_1,1s_2)] \\
& + 4\lambda\mu[\sin\epsilon_b \sin\omega\, O_H(1s_1,2p_y)-\delta\{\cos\epsilon_b\, P_H(2s,1s_2) \\
& + \sin\epsilon_b\cos\omega\, P_H(2p_x,1s_2) + \sin\omega\sin\epsilon_b\, P_H(2p_y,1s_2)\}] \\
F_\perp(\phi_{b2}^2) = {} & 4\lambda^2[\cos\epsilon_b \sin\epsilon_b \sin t\, P_H(2s,2p_y) + \sin^2\epsilon_b\cos t\sin t\times \\
& P_H(2p_x,2p_y)] + 2\mu^2[P'_H(1s_2,1s_2)-2\delta O'_H(1s_1,1s_2)] \\
& + 4\lambda\mu[\cos\epsilon_b\, P_H(2s,1s_2) + \sin\epsilon_b\{\cos t\, P_H(2p_x,1s_2) \\
& + \sin t\, P_H(2p_y,1s_2) - \delta\sin t\, O_H(1s_1,2p_y)\}] \\
2F_\perp(\phi_1^2) = {} & 4[\sin^2\epsilon'_1 \sin(\mathscr{E}/2)\cos(\mathscr{E}/2)\, P_H(2p_x,2p_y) \\
& - \sin\epsilon'_1\cos\epsilon_1'\sin(\mathscr{E}/2)\, P_H(2s,2p_y)]
\end{aligned}$$

The component of the electric field $\mathscr{D}_{\parallel H}$ for the forces on hydrogen along the bond has the direction indicated by $F_\parallel$. This $\mathscr{D}_{\parallel H}$ was employed in all the integrals but $P_H(1s_2,1s_2)$ and $O_H(1s_1,1s_2)$, which were calculated as in $F_\perp$ but multiplied by sin ($\mathscr{E}$/2) to obtain the proper component for $F_\parallel$.

$$\begin{aligned}
F_\parallel(\phi_{b1}^2) = {} & 2\lambda^2[\cos^2\epsilon_b\, P_H(2s,2s) + \sin^2\epsilon_b\{\cos^2\omega\, P_H(2p_x,2p_x) \\
& + \sin^2\omega\, P_H(2p_y,2p_y)\} + 2\cos\epsilon_b\sin\epsilon_b\cos\omega\, P_H(2s,2p_x)] \\
& + 2\mu^2[\delta^2 P''_H(1s_2,1s_2)-2\delta O''_H(1s_1,1s_2)] \\
& + 4\lambda\mu[\cos\epsilon_b\, O_H(1s_1,2s) + \sin\epsilon_b\cos\omega\, O_H(1s_1,2p_x) \\
& - \delta\{\cos\epsilon_b\, P_H(2s,1s_2) + \sin\epsilon_b\cos\omega\, P_H(2p_x,1s_2) \\
& + \sin\epsilon_b\sin\omega\, P_H(2p_y,1s_2)\}] \\
F_\parallel(\phi_{b2}^2) = {} & 2\lambda^2[\cos^2\epsilon_b\, P_H(2s,2s) + \sin^2\epsilon_b\{\cos^2 t\, P_H(2p_x,2p_x) \\
& + \sin^2 t\, P_H(2p_y,2p_y)\} + 2\cos\epsilon_b\sin\epsilon_b\cos t\, P_H(2s,2p_x)] \\
& + 2\mu^2[P''_H(1s_2,1s_2)-2\delta O''_H(1s_1,1s_2)] \\
& + 4\lambda\mu[\cos\epsilon_b\, P_H(2s,1s_2) + \sin\epsilon_b\cos t\, P_H(2p_x,1s_2) \\
& + \sin\epsilon_b\sin t\, P_H(2p_y,1s_2) - \delta\cos\epsilon_b\, O_H(1s_1,2s) \\
& - \delta\sin\epsilon_b\cos t\, O_H(1s_1,2p_x)] \\
2F_\parallel(\phi_1^2) = {} & 2[\cos^2\epsilon'_1\, P_H(2s,2s) + \sin^2\epsilon'_1\{\cos^2(\mathscr{E}/2)\, P_H(2p_x,2p_x) \\
& + \sin^2(\mathscr{E}/2)\, P_H(2p_y,2p_y)\} - 2\cos\epsilon'_1\sin\epsilon'_1\cos(\mathscr{E}/2)\times \\
& P_H(2s,2p_x) + P_H(2p_z,2p_z)] \\
F_\parallel(\phi_o^2) = {} & 2P_H(1s_o,1s_o)
\end{aligned}$$

The Forces on Oxygen

It is most convenient in the calculation of the orbital contribution to F_O to employ a number of different field components for $\mathscr{D}_o$ in the calculation of the integrals. For those integrals which contain a $2p$ orbital $\mathscr{D}_o$ was directed along the $2p$ orbital in question and the proper component along F_O then taken. For those involving the $1s$ and $2s$ orbitals $\mathscr{D}_o$ was directed along the bond axis and the proper component again taken along F_O. As stated in the introduction a common factor of eight, the nulcear charge on oxygen, has been omitted from the expressions for F_O and the nuclear repulsion.

$$\begin{aligned} F_O(\phi_b^2) = {} & 2\lambda^2[2\cos\epsilon_b \sin\epsilon_b \cos(\alpha/2)\, A_o(2s,2p_1)] \\ & + 2\mu^2[\cos(\mathscr{E}/2)\,(1+\delta^2)P_o(1s_1,1s_1) - 2\delta P_o(1s_1,1s_2)] \\ & + 4\lambda\mu[\cos(\mathscr{E}/2)\cos\epsilon_b\,(1-\delta)O_o(2s,1s) \\ & + \sin\epsilon_b \cos(\mathscr{E}/2)\, O_o(2p_x,1s)(\cos\omega - \delta\cos t) \\ & + \sin\epsilon_b \sin(\mathscr{E}/2)\, O_o(2p_y,1s)(\sin\omega - \delta\sin t)] \end{aligned}$$

$$2F_O(\phi_1^2) = -4\cos\epsilon_1' \sin\epsilon_1' A_o(2s,2p_{x'})$$

$$F_O(\phi_o^2) = 4N^2 k A_o(1s_o,2p_{x'}),$$

where $p_{x'}$ is directed along the x′ axis. The expression for $F_O(\phi_o{}^2)$ applies when ϕ_o contains $2p_{x'}$ character with coefficient k.

A number of three-center integrals occur in these calculations. For the forces on hydrogen they are $P_H(2s,1s_2)$, $P_H(2p_x,1s_2)$, and $P_H(2p_y,1s_2)$ for both the parallel and perpendicular cases. The integrals represent the forces exerted on $H_{(1)}$ in the direction of $F_\perp$ (with $\mathscr{D}_{\perp H}$) or $F_\parallel$ (with $\mathscr{D}_{\parallel H}$) due to the overlap charge density between the $2s$ and $2p$ orbitals on oxygen with the $1s$ orbital on $H_{(2)}$. We have recently published an account of a method for evaluating these integrals (12). The method employs a series expansion centered on the oxygen atom for $\mathscr{D}_{\perp H}$ and $\mathscr{D}_{\parallel H}$ in terms of Gegenbauer polynomials coupled with the method of Coulson and Barnett (14) for the expansion of the $1s$ orbital of $H_{(2)}$ on the same center. Since six such integrals had to be evaluated at a number of bond angles a numerical method employing an IBM 650 computer was also developed for their evaluation. The two methods gave good agreement. For example, $P_H(2p_y,1s_2)$ for the perpendicular case when evaluated by the expansion method was found to be equal to 0.050331 a.u. and by the machine method to equal 0.049962 a.u.

There is one three-center integral involved in the calculation of F_O. It is $P_o(1s_1,1s_2)$, i.e., the force on oxygen due to the overlap charge density between the two hydrogen atoms. This integral is expected to be small in magnitude and it occurs in F_O with a small coefficient. For these reasons the charge density $\rho(1s_1,1s_2)$ was approximated by

$$\rho(1s_1,1s_2) = \tfrac{1}{2}S_1(1s_1^2+1s_2^2).$$

When integrated over all space the correct charge density and the approximate expression both yield S_1. Thus the approximate density expression represents the same total amount of charge and places it in approximately the proper position. With this approximation

$$P_o(1s_1,1s_2) = S_1 P_o(1s_1,1s_1)\cos(\mathscr{E}/2).$$

Numerical Values of the Overlap and Force Integrals

In the following, the symbol $2s'$ refers to the nodeless Slater $2s$ orbital for oxygen and $2s$ to the orthogonal form $2s = 1.02841(2s' - 0.2334501s_o)$.

BIOSYNTHESIS OF PLANT CONSTITUENTS

I. THE COMPLETE DEGRADATION OF 2-DEOXY-D-RIBOSE AND SOME 2-DEOXY-D-HEXOSES[1]

A. M. UNRAU AND D. T. CANVIN
Department of Plant Science, University of Manitoba, Winnipeg, Manitoba

Received September 28, 1962

ABSTRACT

A simple procedure is described whereby the complete stepwise degradation of 2-deoxy-D-ribose was achieved. Yields as high as 90% or better of the available carbon was obtained. The 2-deoxy pentose was reduced (KBH_4) to the corresponding polyol and the latter oxidatively cleaved with periodate. Formic acid (C_4) was converted to CO_2 quantitatively by oxidation with HgO. Formaldehyde and β-hydroxypropionaldehyde were oxidized with bromine. Formic acid (C_5) thus formed was converted to CO_2 in quantitative yields and the hydroxy acid decarboxylated with permanganate; thusly C_3 was obtained. The acetic acid (from C_1 and C_2) was extracted with ether and subsequently degraded by the Schmidt–Phares procedure. The procedure was further used to degrade some 2-deoxy hexoses.

DISCUSSION

It has been suggested that 2-deoxy-D-ribose is formed by either of two pathways in animal and bacterial systems, namely an aldol-type condensation of acetaldehyde and D-glyceraldehyde-3-phosphate to yield 2-deoxy-D-ribose-5-phosphate (1), or a pathway involving the direct reduction of the riboside or ribotide to the 2-deoxy pentose (2). High deoxyribose-5-phosphate aldolase activity has been found in tumor extracts (3); however, investigations on *Escherichia coli* (4) and mammalian tissue (5) have indicated that a ribose compound is a precursor of deoxyribose or that both appear to have a common precursor. Purified aldolase from *Lactobacillus plantarum* was found to be specific for acetaldehyde, L-glyceraldehyde-3-phosphate, and a number of other aldoses but not for D-glyceraldehyde-3-phosphate (6). Studies on bacteriophage-infected *E. coli* indicated that about 60% of the sugar was elaborated via an oxidative pathway involving 6-phosphogluconate and no evidence for a C_2+C_3 condensation mechanism was found (7). Further evidence for reduction of ribose to deoxyribose has appeared (8). The above routes for the elaboration of 2-deoxy-D-ribose in animals and bacteria may be extended to higher plants. This aspect is under investigation by the authors. In either case, when C^{14}-labelled possible precursors are considered or used to determine the biosynthetic pathway, a procedure whereby the products may be degraded in some detail is essential. Recently, Jones and associates have reported on the biosynthesis of rhamnose and a heptose in a bacterial species in which they describe in some detail the degradation of these particular sugars (9).

In this communication, a relatively simple procedure is described whereby each of the five carbons of 2-deoxy-D-ribose may eventually be isolated as barium carbonate, and their radioactivity, if any, might then be determined. Reduction of the dexoy pentose with sodium or potassium borohydride (10) gave the corresponding polyol, which upon periodate oxidation liberated the required amount of formaldehyde (11). Three easily differentiable products are obtained in this oxidation, namely formic acid, β-hydroxypropionaldehyde, and formaldehyde. Formic acid, from C_4, was quantitatively oxidized to carbon dioxide using mercuric oxide (12). The two aldehydes were then oxidized with

[1]*Contribution No. 66.*

bromine to the corresponding acids. Formic acid thus generated from formaldehyde was oxidized to carbon dioxide as described and, thusly, C_5 was obtained quantitatively.

β-Hydroxypropionic acid was quantitatively decarboxylated with alkaline permanganate (12), and carbon dioxide, which constitutes C_3, was collected as barium carbonate. The remaining two-carbon fragment, which constitutes C_1 and C_2 of the original propionic acid derivative, was oxidized with acid permanganate to give acetic acid. The latter was extracted with ether and converted to the sodium salt. The salt was heated in an oven at 100° C for 4 to 6 hours, or overnight, after which time the residue was treated with the Schmidt–Phares reagents (12). A good yield of carbon dioxide, constituting C_1, was obtained upon treatment with sodium azide. The methyl amine was oxidized to carbon dioxide using alkaline permanganate. This last step thus yielded C_2. The steps yielding C_5, C_4, and C_3 of the 2-deoxy pentose were quantitative. A small loss of carbon was usually encountered in the Schmidt–Phares degradation of acetic acid. However, in the two steps of this reaction sequence essentially equal quantities of carbon dioxide were obtained.

The utility of the described procedure was established using suitable model compounds. For this purpose, standard formic acid, formaldehyde, and β-hydroxypropionic acid solutions were used. In this manner, quantitative recoveries were obtained for formic acid alone and when mixed with the other two compounds. It was also shown that formaldehyde, in admixture with the two acids, was transformed to the corresponding acid upon bromine oxidation, and the generated formic acid was again recovered quantitatively as carbon dioxide. β-Hydroxypropionic acid was obtained by hydrolysis of β-propiolactone with concentrated barium hydroxide. Excess barium hydroxide was converted to the water-insoluble carbonate and the solution of barium β-hydroxypropionate standardized by determining barium as barium sulphate. The acid was quantitatively decarboxylated with alkaline permanganate either by itself or in admixture with formic acid and formaldehyde, from which the latter two had been removed as carbon dioxide by the previously described reactions.

Controlled reaction conditions, i.e. pH, temperature, were found necessary for best results. In the mercuric oxide oxidations of formic acid, a pH of 5.0 to 5.5 was most desirable. This was particularly important after bromine oxidation of formaldehyde to formic acid. A bath temperature of 75–80° C was found sufficiently high. The combination of greater acidity and higher temperatures greatly reduced the yield of carbon dioxide from the propionic acid derivative. This is believed to be due to the tendency of β-hydroxy carboxylic acids to lose water at high temperatures. The resulting acrylic acids under these conditions would then proceed to form acrylate polymers. Very high alkalinity in the permanganate oxidation of the β-hydroxypropionic acid resulted in overoxidation whereas very weakly alkaline conditions gave much less than expected yields of carbon dioxide. It was found that the addition of 2 to 3 ml of 0.5 *N* sodium hydroxide to the neutral solution containing an excess of permanganate gave quantitative yields. The reaction mixture, after acidification, could be aerated at length without further carbon dioxide liberation. Persulphate oxidation (12) of the residue remaining after the above reactions indicated that the expected two-carbon fragment was present.

The acidified reaction mixtures containing permanganate were left at room temperature for about 16 hours to convert the two-carbon fragment to acetic acid. Ether extraction of the mixture followed by neutralization of the extract, evaporation to dryness, and persulphate oxidation of the residue gave almost theoretical yields of carbon dioxide. It was therefore apparent that the ethanol formed in the alkaline permanganate decarboxylation of β-hydroxypropionic acid was effectively oxidized to acetic acid. As indicated

For personal use only.

previously, somewhat less than the expected amount of carbon dioxide was obtained in the Schmidt–Phares oxidation of acetate.

The procedure was extended for the complete carbon degradation of some 2-deoxy hexoses, namely 2-deoxy-D-galactose and 2-deoxy-D-glucose. In these instances, C_4 and C_5 both yield formic acid upon periodate oxidation of the corresponding polyols and therefore cannot be differentiated in this degradative procedure.

EXPERIMENTAL

Preparation and Degradation of Barium β-Hydroxypropionate

To β-propiolactone, 1.608 g, was added a concentrated solution of barium hydroxide (about 50% excess) and the solution heated to 60° C for 30 minutes. Excess barium hydroxide was converted to the insoluble carbonate by bubbling a stream of CO_2 through the solution. The precipitate was removed and the solution brought to 250 ml. The amount of barium salt per milliliter of solution was determined by acidification of 2-ml aliquots with 2 *N* sulphuric acid (5 ml) and weighing the dry precipitate ($BaSO_4$). To remove other possible organic impurities, the solution was evaporated to a small volume (30 ml) and added, with vigorous stirring, to 200 ml acetone. The gummy precipitate was redissolved in water (50 ml) and the solution heated (85–90°) to remove acetone, the volume again adjusted to 250 ml, and the solution standardized:

$BaSO_4$ from 2 ml before purification	17.3 mg
$BaSO_4$ from 2 ml after purification	17.2 mg

Decarboxylation with $KMnO_4$

To 3 ml of the above solution in a 50-ml distillation flask was added alkaline permanganate solution (1.5 ml) (oxidant solution consisted of 0.1 *M* NaOH, 0.2 *M* $KMnO_4$, and 0.02 *M* $MnSO_4$). The flask was fitted to an aeration train and the contents held at room temperature for about 45 minutes. Before acidifying the solution, the train was swept with nitrogen for 10 to 15 minutes. The solution was acidified (2 *N* H_2SO_4, 1 ml) and the CO_2 swept into a $Ba(OH)_2$ trap. The precipitate ($BaCO_3$) was collected on tared porcelain planchets, dried, and weighed. These results and those obtained from the decarboxylation of malic acid, made as a further check of the reaction, are given in Table I.

TABLE I

Weight of $BaCO_3$ (mg)			
β-Hydroxypropionate		Malic acid

21.5	20.6	39.9	39.4
21.5	22.0	40.3	39.4
29.5	31.3		
24.5	24.0		

Degradation of Remaining Two-carbon Fragment From β-Hydroxypropionate

The acidified solution was left at room temperature overnight to facilitate oxidation of the initial product, ethanol, to acetic acid. The solution was thereupon thoroughly extracted with ether and the moist ether solution evaporated almost to dryness. The residue was made alkaline by addition of a few drops of 0.5 *N* NaOH and the solution evaporated to dryness followed by overnight drying at 100° C. The residue was then treated with reagents according to the Schmidt–Phares (12) procedure and the CO_2 from the carboxyl group and subsequently from methylamine collected as $BaCO_3$. The results are summarized in Table II.

TABLE II

Persulphate Oxidation of the Two-carbon Fragment from β-Hydroxypropionate

Several samples of β-hydroxypropionate were decarboxylated as described previously and the residual mixtures left overnight at room temperature. The residue was oxidized with persulphate according to a prescribed procedure (12). The results are summarized in Table III.

TABLE III

Weight of $BaCO_3$ (mg)

Sequential Degradation of a Mixture of Formic Acid, Formaldehyde, and β-Hydroxypropionate

For this series of reactions, a mixture of the above three compounds containing known quantities of each was treated in the following manner: Formic acid was converted to CO_2 by oxidation with mercuric oxide in the usual manner (11). The train was fitted with a cold-water condenser to prevent the escape of formaldehyde. After all the CO_2 had been swept into the $Ba(OH)_2$ trap, the flask containing the reaction mixture was removed, wrapped with aluminum foil, and 4 to 5 drops of bromine added. The contents were swirled vigorously, and after 30 minutes, excess bromine removed by aeration, the pH of the solution adjusted to 4.5–5.0, more HgO added, and the evolved CO_2 collected as usual. The solution was then made alkaline (pH about 11–12), $KMnO_4$ reagent added (3 ml), and after 30 to 40 minutes, the solution again acidified and the CO_2 collected as $BaCO_3$. The oxidation mixture containing the two-carbon fragment was left overnight and thence treated with the Schmidt–Phares reagents as described previously. The results are summarized in Table V.

TABLE V

Weight of $BaCO_3$ (mg)							
HCOOH		CH_2O		β-Hydroxypropionate			
Expected	Obtained	Expected	Obtained	C_1	C_2	C_3	Expected
24.1	23.4	30.9	30.0	26.5	20.1	22.5	26.4
34.0	27.5	16.8	17.5	15.1	12.0	12.9	16.0
24.1	22.2	15.7	15.9	16.9	14.2	15.0	16.2

Total Degradation of 2-Deoxy-D-ribose

To a small quantity (16.2 mg) of this sugar in water (2 ml) was added potassium borohydride (about 15 mg) and the mixture left overnight at room temperature. The solution was acidified (H_2SO_4) to about

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

pH 5 and sodium metaperiodate (7.5 mg) added. After standing the solution for 20 minutes, sodium arsenite (about 15 mg) was added and the pH again adjusted to about 5. The formic acid formed was oxidized to CO_2 as described. Formaldehyde and β-hydroxypropionaldehyde were simultaneously oxidized to the corresponding acids with bromine. The degradation sequence described previously was thereupon followed. In this manner, several samples of the 2-deoxy pentose were degraded. The results are given in Table VI.

TABLE VI

	Weight of $BaCO_3$ (mg)					
				β-Hydroxypropionate		
	Expected	HCOOH	CH_2O	C_1	C_2	C_3
(16.2 mg)	23.8	20.0	21.0	19.5	18.0	18.8
(13.7 mg)	20.1	19.0	20.2	18.3	17.0	21.0

(8.8 mg)	12.9	12.6	13.2	12.0	10.6	11.2

Degradation of Some 2-Deoxy-D-hexoses

The above procedure was applied to the degradation of 2-deoxy-D-glucose and 2-deoxy-D-galactose. In this case, two molar proportions of formic acid would be produced from the corresponding alditols (C_4 and C_5). The results are summarized in Table VII.

TABLE VII

	Weight of $BaCO_3$ (mg)

*Values for this column should be twice those of corresponding values in the first column since both C_4 and C_5 are obtained here.

Formaldehyde Production upon Periodate Oxidation of Polyols

Small quantities of 2-deoxy-D-ribose and 2-deoxy-D-hexoses were reduced with potassium borohydride in the usual manner. The generated polyols were oxidized with periodic acid, and the formaldehyde evolved was periodically estimated by a described procedure (11, 13). The results are summarized in Table VIII.

TABLE VIII

AZA STEROIDS

II. SYNTHESIS OF 6-AZA STEROIDS—A NOVEL CLASS OF AZAANDROSTANE ANALOGUES

JAMES P. KUTNEY, ROY A. JOHNSON, AND I. VLATTAS
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received July 23, 1962

ABSTRACT

A synthesis of N-benzyl-6-azacholestane is described and the generality of the approach is exemplified by the successful synthesis of 17β-hydroxy-N-benzyl-6-azaandrostane. This represents the first synthesis of a 6-aza derivative in the androstane series.

For personal use only.

In recent years there have been numerous investigations concerned with the effect of substituents attached to the normal steroid skeleton on the biological properties of these important substances. These investigations have brought forth the realization that very dramatic alterations in these properties are indeed encountered when such substituents as halogen, particularly fluorine, hydroxyl, and methyl are placed at rather specific positions in the molecule (1–3). These steroidal derivatives still possess the basic steroid skeleton so that the nature of the molecule is not altered to a very significant extent. In this connection, it appeared of interest to us to consider a more substantial alteration in the chemical nature of steroidal substances in order to determine whether any appreciable differences in the biological activity of these molecules are associated with this change. We therefore considered the replacement of one or more carbon atoms of the cyclopentanoperhydrophenanthrene system by a hetero atom.

The introduction of a nitrogen atom into the steroid nucleus has attracted the interests of chemists for some time. However, inspection of the older literature reveals that most of the aza steroids represent analogues in which one of the rings of the skeleton has been expanded from a 6- to a 7-membered ring or in the case of ring D from a 5- to a 6-membered cycle. Very recently some successful syntheses of 4-aza steroids possessing the true steroid skeleton have been reported (4) and some interesting biological properties of these compounds have been described (5).

Our interest in the chemistry and biological properties of aza steroids led us to initiate studies in this area. Our initial considerations were directed toward the synthesis of ring B aza steroids since we felt that the introduction of a nitrogen atom in this ring would allow the retention of a Δ^4-3-keto moiety in ring A—a structural feature present in most of the active steroidal hormones. At the time that our work was initiated, there were no ring B aza steroids known although, since that time, two laboratories have independently reported some work on 6-aza cholestane derivatives (6, 7). Our own work in this area has been briefly described, in part, in a preliminary communication (8). This paper outlines, in detail, a general approach to the synthesis of 6-aza steroids and describes the first synthesis of a 6-aza derivative in the androstane series.

In considering a synthetic approach to this class of compounds, it became apparent that investigations in the cholesterol series would be of distinct advantage since larger quantities of the appropriate starting materials were obviously available. In this regard, a particularly attractive sequence involved the utilization of intermediates in which ring B had been opened since it was clear that the appropriate cyclization of such compounds

would lead to substances possessing the nitrogen atom in the ring system. This type of cyclization had been observed in ring A in the elegant researches of Woodward and co-workers on the total synthesis of steroids (9) and more recently by Uskokovic and Gut (4). The application of this reaction to ring B has been independently completed by Jacobs and Brownfield (6) and by the present authors (8).

Of a number of alternatives which could be used to open ring B, the ozonization of the appropriate α,β-unsaturated ketone system appeared most attractive since the ozonization of such systems had been studied in ring A (10) and, in one instance, in ring B (11).

Oxidative ring opening of 7-oxocholesteryl acetate to 5-oxo-5,7-seco-6-nor-3-cholesten-7-oic acid (I) was initially conducted by ozonolysis in glacial acetic acid followed by oxidative hydrolysis of the intermediate ozonide with aqueous hydrogen peroxide and treatment of the reaction mixture with sodium hydroxide in order to separate the desired acidic components from any neutral products. The initial intermediate, 3β-acetoxy-5-oxo-5,7-seco-6-norcholestan-7-oic acid (VI), readily lost the elements of acetic acid to provide I, a result also obtained by the American workers (6). The conjugated carbonyl chromophore present in I was reflected in its spectral data (226 mμ, 5.97 μ), and other evidence cited below served to establish the chemical structure. Since the ozonization product was an attractive intermediate for the preparation of 6-aza steroids it became necessary to obtain significant yields in this reaction. Under the reaction conditions mentioned above, the yield of I was low (22%) and in spite of numerous experiments wherein such reaction conditions as temperature and quantity of ozone used were varied, we were not able to raise the yield of acidic material. This difficulty was subsequently overcome by conducting the ozonolysis reaction under conditions where the ester was generated directly and is discussed in the later portion of this paper.

The conversion of the unsaturated keto acid to the saturated keto acid (II) was readily accomplished by catalytic hydrogenation and this provided us with the necessary intermediate for investigating the appropriate cyclization reactions to generate 6-aza steroidal analogues. As anticipated, the mild reaction conditions of Uskokovic and Gut (4) wherein anhydrous ammonia at room temperature is utilized were unsuccessful with our keto acid, II. However, when II was treated with refluxing benzylamine for 18 hours (9), an excellent yield of the expected enol lactam (III) was obtained. This material possessed the characteristic infrared absorption and, in particular, had an ultraviolet spectrum typical of these types of lactams (4, 6). The enol lactam was readily reduced to give an excellent yield of the expected product, N-benzyl-6-aza-5ξ-cholestan-7-one (IV), which possessed no absorption in the ultraviolet but still retained the lactam absorption in its infrared spectrum. Finally, reduction of IV with lithium aluminum hydride afforded the desired N-benzyl-6-aza-5ξ-cholestane (V).

VI

It is pertinent to point out that in contrast to the American workers (6), who have devoted most of their attention to the parent 6-aza cholestane, we have concentrated our efforts on the N-benzyl-6-aza analogues. We feel that the presence of a tertiary nitrogen atom, as in the N-benzyl series provides more suitable intermediates for the reintroduction of an oxygen function at C_3 since undesirable double-bond migrations might be expected when a secondary nitrogen atom is present. Indeed, Jacobs and co-workers (6) have already suggested a migration of the C_4–C_5 double bond in their isolation of 6-aza-5-cholestene, a situation quite unlikely to occur in the N-benzyl series.

We would now like to exemplify the generality of the above approach by presenting the first synthesis of a 6-aza derivative in the androstane series.

The appropriate starting material 3β,17β-diacetoxy-5-androsten-7-one was readily converted to 17β-hydroxy-5-oxo-5,7-seco-6-nor-3-androsten-7-oic acid (IX) by ozonolysis and hydrolysis of the ozonide, as indicated above. As in the cholestane series, the yield of the desired product was quite low when the reaction was conducted under various conditions in acetic acid as solvent. The spectral data were again consistent with the structural assignment. Catalytic reduction of IX proceeded smoothly at room temperature to yield 17β-hydroxy-5-oxo-5,7-seco-6-norandrostan-7-oic acid (X), which, on treatment with refluxing benzylamine, provided an excellent yield of the desired enol lactam (XI). The unsaturated lactam on reduction with Adams catalyst in glacial acetic acid yielded 17β-hydroxy-N-benzyl-6-aza-5ξ-androstan-7-one (XII). As expected, the characteristic absorption of the enol lactam was no longer present in the ultraviolet spectrum of the reduction product but the typical lactam absorption was still evident in the infrared spectrum. This substance was finally reduced with lithium aluminum hydride to the desired 6-aza compound, 17β-hydroxy-N-benzyl-6-aza-5ξ-androstane (XIII).

The success of this last sequence allows entry into a novel class of androstane analogues and it should be of interest to determine whether any significant modifications in biological properties are associated with these compounds. It is clear that since the necessary starting substances are readily available in the progesterone series, the corresponding 6-aza derivatives should also be easily obtained in this series and, in turn, in the adrenocortical hormone series.

It was evident to us that although the above approach was of considerable applicability, it suffered from the fact that the ozonolysis reaction provided the desired product in low yield. Consequently, a considerable amount of experimentation was done to find optimum conditions for this reaction. Although we have not been able to obtain the corresponding acidic products in substantially higher yields, we have been able to overcome the difficulty by preparing the neutral esters directly from the ozonization. It appeared to us that it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

may be of advantage to conduct the ozonolysis in non-acidic solvents and in particular in the presence of an alcohol so that the direct conversion of the ozonide to an ester would be possible. Indeed when we carried out this reaction in a solvent mixture of methylene chloride – methanol at −78°, we obtained the unsaturated keto ester (VII) from the neutral portion of the reaction product. In addition, the acidic portion contained a significant amount of unsaturated keto acid (I) so that the actual yield of starting material has been substantially increased.

It became necessary to confirm our suspicions that the unsaturated keto ester (VII) could be used effectively as a starting material. For this reason, we subjected VII to catalytic reduction and obtained the expected keto ester (VIII) as a beautifully crystalline substance. The structure of VIII was finally confirmed when the reduction product was treated with benzylamine, and the enol lactam which resulted was shown to be identical in every respect with N-benzyl-6-aza-4-cholesten-7-one (III). In this manner, the overall yield of the enol lactam from 7-oxocholesteryl acetate was raised to 40%. This marked improvement now makes the above approach a very attractive one indeed. It was not necessary to extend our studies to the androstane series since at the time that our investigations in the cholesterol series were being conducted Atwater, in his paper on 6-oxa-androstane derivatives (12), indicated that the analogous ozonolysis reaction provided the corresponding B-nor seco ester in yields up to 73%. It is now clear that the extension to the androstane series is valid.

EXPERIMENTAL

All melting points were determined on a Fischer–Johns apparatus and are uncorrected. The ultraviolet spectra were recorded in 95% ethanol on a Cary 14 recording spectrophotometer and the rotations were taken in 1% chloroform solutions. The n.m.r. spectra were taken at 60 Mc on a Varian A60 instrument. The values are given in the Tiers τ scale with the signal of tetramethylsilane, which was used as the internal standard, set at 10.0 τ units. Analyses were performed by A. Bernhardt, Mulheim (Ruhr), Germany, and by Mrs. Aldridge, University of British Columbia.

5-Oxo-5,7-seco-6-nor-3-cholesten-7-oic Acid (I)

Solutions of 7-oxocholesteryl acetate (25.0 g) in glacial acetic acid (100 ml) were ozonized in 5-g portions at 25° over a period of 20 minutes at a rate of 0.1 mole per hour. The solution attained a bright yellow color during the course of the ozonization but this color slowly disappeared when the ozonide was treated with 30% hydrogen peroxide (19 ml) and water (50 ml, for each 5-g portion). After the solution had been allowed to stand for 15 hours at room temperature, the solvent was removed under reduced pressure and the residue was taken up in ether. The ether solution was washed with water and then extracted with 5% aqueous sodium hydroxide to remove all acidic components. The basic extract was acidified with dilute hydrochloric acid and this acid layer was extracted with ether. The ether extract was dried over anhydrous magnesium sulphate, the solvent was evaporated to yield 20.3 g of a viscous oil. Chromatography of this oil on silica gel (500 g) gave the keto acid (I) as an oil when elution with chloroform was carried out. Crystallization from hexane gave 4.86 g (22%) of virtually pure, crystalline keto acid, m.p. 179–183°. Three recrystallizations from hexane gave analytically pure acid (I) as colorless needles, m.p. 183–184°; $[\alpha]_D$+79°; λ_{max} 226 mμ (log ϵ 3.93); infrared in chloroform: 5.86 μ, 5.97 μ; lit. (6). Found: C, 77.82; H, 10.46; O, 12.09; neutralization equivalent, 394; mol. wt. (Rast), 402. Calc. for $C_{26}H_{42}O_3$: C, 77.56; H, 10.51; O, 11.92; mol. wt., 402.

When the ozonization was carried out as above with the exception that the acidic materials were extracted from the reaction mixture with dilute potassium carbonate instead of sodium hydroxide, another acidic oil was obtained from the carbonate layer after acidification and ether extraction. This oil (3.51 g from 5.0 g of starting material) on chromatography on silica gel and elution with chloroform yielded a fraction (3.5 g) which crystallized from ether – petroleum ether, m.p. 171–177°. Although not pure, this material is beyond doubt predominantly 3β-acetoxy-5-oxo-5,6-seco-6-norcholestan-7-oic acid (VI) as evidenced by no absorption in the ultraviolet and its infrared spectrum in (KBr): 5.75 μ, 5.78 μ, 5.83 μ, 5.88 μ, 8.03μ.

This was further confirmed when the above material was converted, in essentially quantitative yield, to the unsaturated keto-acid (I) by merely shaking an ether solution of this substance with 5% aqueous sodium hydroxide, acidifying the alkaline layer, and extracting again with ether.

5-Oxo-5,7-seco-6-norcholestan-7-oic Acid (II)

The unsaturated keto-acid (I) (0.398 g) was reduced over 10% palladium on charcoal (0.4 g) in ethanol (30 ml) at room temperature and atmospheric pressure. The hydrogen uptake was virtually complete in 15

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

minutes, after which time the catalyst was filtered off and the solvent removed under reduced pressure. The remaining white solid crystallized from hexane yielding 0.237 g of the saturated keto-acid (II), m.p. 188–193°. Three additional recrystallizations from hexane gave an analytical sample, m.p. 192–194°; $[\alpha]_D$+91°; infrared in KBr: 5.83 μ, 5.89 μ; lit. (6). Found: C, 76.80; H, 10.84; O, 12.11. Calc. for $C_{26}H_{44}O_3$: C, 77.17; H, 10.98; O, 11.86.

N-Benzyl-6-aza-4-cholesten-7-one (III)

The saturated keto-acid (II) (4.0 g) was dissolved in benzylamine (19 ml) and refluxed for 18 hours in a nitrogen atmosphere. The cooled yellow reaction mixture was taken up in ether and extracted with aqueous hydrochloric acid until the extract was acidic to litmus. The ether layer was then washed once with 5% aqueous sodium hydroxide and once with a saturated salt solution and then dried over anhydrous magnesium sulphate. Evaporation of the solvent, after removal of the drying agent by filtration, yielded a light yellow oil. Crystallization from methanol afforded 3.93 g (84%) of colorless crystals, m.p. 135–140°. Three recrystallizations from methanol gave pure N-benzyl-6-aza-4-cholesten-7-one (III) as long, flat crystals, m.p. 139–141°; $[\alpha]_D$ +93°; λ_{max} 237 mμ (log ϵ 4.05); infrared in KBr: 6.10 μ, 6.02 μ; lit. (6). Found: C, 82.92; H, 10.33; N, 3.01; O, 3.48. Calc. for $C_{33}H_{49}NO$: C, 83.31; H, 10.38; N, 2.94; O, 3.36.

N-Benzyl-6-aza-5ξ-cholestan-7-one (IV)

The enol lactam (III) (0.50 g) was hydrogenated in acetic acid (40 ml) over 0.05 g of platinum oxide at room temperature and atmospheric pressure. The uptake of hydrogen stopped after 1 hour, and the catalyst was filtered off. The solvent was removed *in vacuo* and the remaining oil was placed in a vacuum desiccator and allowed to stand, over solid potassium hydroxide, for several hours. The oil (0.487 g, 90%) crystallized from ether–methanol and melted at 141–145°. Three recrystallizations from ether–methanol provided an analytical sample of the lactam (IV), m.p. 143–145°; $[\alpha]_D$+63°; infrared in Nujol: 6.08 μ. Found: C, 83.19; H, 10.53; N, 3.19; O, 3.50. Calc. for $C_{33}H_{51}NO$: C, 82.96; H, 10.76; N, 2.93; O, 3.35.

N-Benzyl-6-aza-5ξ-cholestane (V)

N-Benzyl-6-aza-5ξ-cholestan-7-one (0.50 g) was dissolved in anhydrous ether (100 ml) and refluxed for 24 hours with lithium aluminum hydride (0.6 g), which was initially placed in a Soxhlet extractor and gradually brought into the vessel by the refluxing ether. The excess hydride was decomposed by cautious addition of moist ether and water, followed by refluxing for 0.5 hours. The inorganic solids were filtered off and the ether solution was dried over anhydrous magnesium sulphate. Removal of the solvent yielded 0.423 g (87%) of a light yellow oil which crystallized from ether–methanol (0.410 g), m.p. 65–68°. Two further recrystallizations from ether–methanol yielded N-benzyl-6-aza-5ξ-cholestane, m.p. 68–69°; $[\alpha]_D$+71°. Found: C, 85.42; H, 11.27; N, 3.30. Calc. for $C_{33}H_{53}N$: C, 85.46; H, 11.52; N, 3.02.

17β-Hydroxy-5-oxo-5,7-seco-6-nor-3-androsten-7-oic Acid (IX)

A solution of 3β,17β-diacetoxy-5-androsten-7-one (3.42 g) in glacial acetic acid (125 ml) was treated with ozone for 15 minutes at room temperature at a rate of 0.1 mole per hour. The resulting yellow solution was treated with dilute hydrogen peroxide (3 ml) and water (15 ml) after 20 minutes and then allowed to stand at room temperature for 20 hours. During this time, the solution lost its yellow color. The excess acetic acid was then removed *in vacuo* and the oily residue was taken up in ether. The ether solution was washed with 5% aqueous sodium hydroxide and water to remove acidic components. The alkaline extracts were made acidic by the addition of dilute hydrochloric acid and this acidic material was then extracted with ether. The ether extract was dried over anhydrous magnesium sulphate, the drying agent removed by filtration, and the solvent evaporated to yield 1.6 g of a glassy acidic material. This material was chromatographed on silica gel (100 g) and elution with chloroform – 2½% methanol yielded a glassy material (0.96 g, 36%) which crystallized from ether – petroleum ether (0.92 g), m.p. 142–148°. Two further recrystallizations from ether – petroleum ether gave shiny crystals which appeared to have a double melting point, 145–150° and 195–200°, probably due to strong solvation. However, after the crystals had dried at 100°/0.1 mm for several hours, the melting point was greatly improved and a pure sample melted at 203–204°; $[\alpha]_D$+88°; λ_{max} 227 mμ (log ϵ 3.98); infrared in KBr: 2.94 μ, 5.81 μ, 6.04 μ. Found: C, 70.65; H, 8.52; O, 21.14. Calc. for $C_{18}H_{26}O_4$: C, 70.56; H, 8.55; O, 20.89.

17β-Hydroxy-5-oxo-5,7-seco-6-norandrostan-7-oic Acid (X)

A solution of the unsaturated keto-acid (IX) (0.896 g) in 95% ethanol (50 ml) was hydrogenated over 0.54 g of 10% palladium on charcoal at room temperature and atmospheric pressure. After the uptake of hydrogen was complete (20 minutes), the catalyst was filtered off and the solvent removed *in vacuo* to yield an oily product (0.75 g). Chromatography of this oil on silica gel (50 g) gave the product as an oil by elution with chloroform – 2½% methanol. This oil (0.70 g) slowly crystallized when it was left standing and after two recrystallizations from hexane gave pure 17β-hydroxy-5-oxo-5,7-seco-6-norandrostan-7-oic acid (0.65 g), m.p. 228–229; $[\alpha]_D$+96°; infrared in KBr: 2.90 μ, 5.81 μ, 5.93 μ. Found: C, 69.67; H, 9.01; O, 21.23. Calc. for $C_{18}H_{28}O_4$: C, 70.09; H, 9.15; O, 20.76.

17β-Hydroxy-N-benzyl-6-aza-4-androsten-7-one (XI)

A solution of the saturated keto-acid (X) (0.553 g) in benzylamine (10 ml) was refluxed gently for 15

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hours in a nitrogen atmosphere. The cooled, yellow solution was taken up in ether and washed with dilute hydrochloric acid until the aqueous layer was acidic. The ether solution was then washed once with 5% aqueous sodium hydroxide followed by water and finally dried over anhydrous magnesium sulphate. The drying agent was filtered off and the ether evaporated to yield a light yellow oil (0.56 g). Chromatography of this oil on silica gel (50 g) gave 0.46 g (68%) of an oil when the column was eluted with benzene–chloroform (1:1). This oil crystallized from ether–hexane as colorless needles, m.p. 105–109°. Three further recrystallizations gave an analytical sample, m.p. 109–110°; $[\alpha]_D$+102; λ_{max} 237 mμ (log ϵ 4.02); infrared in KBr: 6.11 μ, 6.02 μ. Found: C, 79.49; H, 8.82; N, 3.72; O, 8.30. Calc. for $C_{25}H_{33}NO_2$: C, 79.11; H, 8.76; N, 3.69; O, 8.43.

17β-Hydroxy-N-benzyl-6-aza-5ξ-androstan-7-one (XII)

A solution of the enol lactam (0.185 g) in glacial acetic acid (30 ml) was hydrogenated over platinum oxide (0.050 g) at room temperature and atmospheric pressure for 2 hours. The catalyst was filtered off and the acetic acid was removed *in vacuo* to yield 0.168 g (90%) of an oil. The oil was chromatographed on silica gel (19 g) and the oily product was eluted with benzene–chloroform (1:1). This oil crystallized upon standing and was recrystallized from acetone – petroleum ether as colorless needles, m.p. 134–136°; $[\alpha]_D$−1°; infrared in KBr: 2.93 μ, 6.13 μ. Found: C, 78.73; H, 9.61; N, 3.90; O, 8.66; active H, 0.27. Calc. for $C_{25}H_{35}NO_2$: C, 78.69; H, 9.25; N, 3.67; O, 8.38; active H, 0.264.

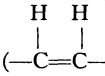
17β-Hydroxy-N-benzyl-6-aza-5ξ-androstane (XIII)

The saturated lactam (XII) (0.90 g) was dissolved in anhydrous ether (100 ml) and refluxed for 24 hours with lithium aluminum hydride (1.0 g), which was initially placed in a Soxhlet extractor and gradually brought into the reaction vessel by the refluxing ether. The reaction mixture was then allowed to stand for a further 56 hours at room temperature. The excess hydride was decomposed by the dropwise addition of an ether–acetone solution. Water (1 ml) was then added cautiously and the reaction mixture was warmed on a steam bath for 0.5 hour. The inorganic salts were filtered off and washed with ether and the combined ether solutions were dried over anhydrous magnesium sulphate. Filtration and evaporation of the solvent gave a colorless oil which slowly crystallized. The yield of solid crystalline product was 0.843 g (97%). Recrystallization of the solid from petroleum ether gave needles, melting point 109–111°, which, after two more recrystallizations from the same solvent, provided a pure sample of the aza steroid, m.p. 111–112°; $[\alpha]_D$ +67°. Found: C, 81.57; H, 10.34; N, 4.14; O, 4.51. Calc. for $C_{25}H_{37}NO$: C, 81.69; H, 10.15; N, 3.81; O, 4.35.

Methyl 5-Oxo-5,7-seco-6-nor-3-cholesten-7-oate (VII)

A solution of 7-oxocholesteryl acetate (5.0 g) in dichloromethane (75 ml) and absolute methanol (25 ml) was ozonized at −78° until the solution had attained a blue color (about 20 minutes at a rate of 0.1 mole per hour). The solution was allowed to warm to room temperature, 30% aqueous hydrogen peroxide (0.7 ml) and water (1.7 ml) were added, and the mixture was then allowed to stand at room temperature for 16 hours. The organic phase was separated and the aqueous phase was extracted several times with dichloromethane. The organic extracts were combined, washed with water, and then dried over anhydrous magnesium sulphate. Evaporation of the solvent after removal of the drying agent by filtration provided a viscous clear oil. This oil was taken up in ether and the ethereal solution was washed with 5% aqueous sodium hydroxide to remove any acidic materials. The workup of this aqueous layer is given below.

The ether layer was washed with water and dried over anhydrous magnesium sulphate, and the solvent was removed to provide a viscous, neutral oil (3.3 g). This neutral oil was taken up in dioxane, treated with 5% aqueous sodium hydroxide (30 ml), and the whole mixture was stirred for 30 minutes. This mixture was then treated with 1.5 liters of water and extracted exhaustively with ether in a continuous extraction apparatus. The resulting ether extract was washed with water, and dried over anhydrous magnesium sulphate. The solvent was removed to yield a viscous oil (2.25 g). This oil was taken up in benzene and chromatographed on silica gel (80 g). The desired unsaturated keto ester was eluted with benzene as a clear viscous oil (1.76 g) and, in spite of numerous attempts, it resisted all efforts to obtain it in crystalline form. Infrared in CCl_4: 5.98 μ, 5.81 μ; λ_{max} 227 mμ (log ϵ 3.84); $[\alpha]_D$ +83; n.m.r. signals (CCl_4): sharp signal at



6.5 τ (−$COOCH_3$), multiplets at 4.25 τ and 3.8 τ (—C=C—C=O). Found: C, 77.52; H, 10.31. Calc. for $C_{27}H_{44}O_3$: C, 77.83; H, 10.65.

The aqueous alkaline layer from the potassium hydroxide in dioxane treatment was acidified with hydrochloric acid and the resulting mixture was extracted with ether. The ethereal extract was washed with water, then dried over anhydrous magnesium sulphate. Removal of the solvent yielded an acidic material (0.7 g).

This acidic material (0.7 g) was reduced over 10% palladium on charcoal (0.4 g) in ethanol at room temperature and atmospheric pressure. The catalyst was filtered off and the solvent was removed under reduced pressure. This crude reduction product was chromatographed on silica gel (16 g) and a solid material (200 mg) which was obtained upon elution with benzene–chloroform turned out to be 5-oxo-5,7-seco-6-norcholestan-7-oic acid (II). This was identified by infrared comparison and mixed melting point with an authentic sample.

The original aqueous alkaline extract of the product resulting directly from the ozonization was acidified with hydrochloric acid and this acidic mixture was then extracted with ether. The ether extract was washed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with water, and dried over anhydrous magnesium sulphate. Removal of the solvent yielded an acidic material (1.94 g).

Methyl 5-Oxo-5,7-seco-6-norcholestan-7-oate (VIII)

The unsaturated keto ester, VII (1.65 g), was hydrogenated over 10% palladium on charcoal (1 g) in ethanol at room temperature and atmospheric pressure. The catalyst was removed by filtration and the solvent evaporated to yield a white solid. This solid was taken up in benzene and chromatographed on silica gel (60 g). Elution with benzene provided a white crystalline material (1.5 g) which on several recrystallizations from benzene yielded an analytical sample, m.p. 81–83°; $[\alpha]_D^{28}$ +97°; infrared in KBr: 5.90 μ, 5.80 μ; lit. (6). Found: C, 77.30; H, 10.96. Calc. for $C_{27}H_{46}O_3$: C, 77.46; H, 11.08.

N-Benzyl-6-aza-4-cholesten-7-one from VIII

The saturated keto ester, VIII (1 g), was refluxed in benzylamine (2.5 ml) for 20 hours in a nitrogen atmosphere. The resulting reaction mixture was taken up in ether and the ethereal solution was washed with dilute hydrochloric acid to remove any benzylamine. This solution was then washed with 5% aqueous sodium hydroxide, water, and finally dried over anhydrous magnesium sulphate. Removal of the solvent gave a white solid (1.1 g) which, upon recrystallization from ethanol, provided a pure sample of the enol lactam, III (0.95 g).

ACKNOWLEDGMENT

The authors are very grateful to Professor Jacobs and Dr. Brownfield for providing them with several comparison samples. Financial aid from the National Research Council of Canada and from the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service, grant No. CY-5037, is very gratefully acknowledged.

REARRANGEMENT STUDIES WITH C^{14}

XIV. THE REACTION OF 2-*p*-ANISYLETHANOL-1-C^{14} WITH THIONYL CHLORIDE[1]

C. C. LEE, DONNA NEWMAN, AND D. P. THORNHILL[2]

Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received October 12, 1962

ABSTRACT

Reaction between 2-*p*-anisylethanol-1-C^{14} and thionyl chloride was carried out with pyridine, *n*-hexane, toluene, dioxane, or excess thionyl chloride as solvent. The 2-*p*-anisylethyl chloride obtained showed rearrangement of the C^{14} label from the C-1 to C-2 positions ranging from about 0.5% for the reaction in pyridine to about 46% for the reaction in excess thionyl chloride. The results can be explained on the basis of varying degrees of involvement of the ethylene-*p*-methoxyphenonium chlorosulphite ion pair, thus supporting the suggestion that thermal decomposition of alkyl chlorosulphites to give chlorides may be considerably ionic in character.

INTRODUCTION

It is generally agreed that the reaction of thionyl chloride with an aliphatic alcohol involves the formation of an alkyl chlorosulphite which is thermally decomposed to give the alkyl chloride (1). Since the suggestion that the decomposition of the chlorosulphite has considerable ionic character (2), and that the S_Ni reaction is quite similar to the S_N1 reaction in that both involve ion pairs (3), a number of studies on the ionic nature of this reaction have been reported (1, 4–8). Among these were investigations on isotope position rearrangements in the thermal decomposition, in a number of solvents, of allyl-1-C^{14} chlorosulphite (4) and of 2-butyl-1-C^{14} chlorosulphite (8). The present paper reports the extents of rearrangement of the C^{14} label, and discusses the mechanistic implications of these rearrangements, in the reaction between 2-*p*-anisylethanol-1-C^{14} and thionyl chloride, with pyridine, *n*-hexane, toluene, dioxane, or excess thionyl chloride as solvent.

RESULTS AND DISCUSSION

2-*p*-Anisylethanol-1-C^{14} (I) has been synthesized by Jenny and Winstein (9) from reaction of *p*-methoxybenzyl chloride with sodium cyanide-C^{14}, followed by hydrolysis and treatment of the resulting *p*-anisylacetic acid-1-C^{14} (II) with lithium aluminum hydride. In the present work, II was obtained from reaction of carbon dioxide-C^{14} with *p*-methoxybenzylmagnesium chloride. This route to II is less time consuming and permits the use of carbonate instead of the more costly cyanide as the source of C^{14}. The preparation of the Grignard reagent requires special conditions of high dilution and use of amalgamated magnesium (10, 11); otherwise, the coupling product, *p*,*p*′-dimethoxydibenzyl, will result. The reduction of II to I was effected with lithium aluminum hydride (9). That all the C^{14}-label was located in the C-1 position of I was shown by the oxidation of I to essentially inactive *p*-anisic acid.

Reaction of I with thionyl chloride was carried out in pyridine, *n*-hexane, toluene, dioxane, or excess thionyl chloride as solvent. 2-*p*-Anisylethyl-*x*-C^{14} chloride (III) was obtained in yields ranging from 23 to 67% for the different runs in the different solvents. From the reaction carried out in *n*-hexane, besides the chloride III, some di-2-*p*-anisylethyl sulphite (IV) was recovered. Similarly, when the reaction of I with thionyl chloride was

tried in diethyl ether, with or without the presence of pyridine, the only product isolated was sulphite IV. It is known that reaction of an excess of alcohol with thionyl chloride in ether and pyridine will give dialkyl sulphite (5). In the current experiments, the general procedure involves allowing the alcohol and a small excess of thionyl chloride to stand at room temperature overnight followed by several hours of refluxing. In the cases where IV was isolated as a product, namely in reactions with *n*-hexane or with ether as solvent, possibly the decomposition of the chlorosulphite to chloride is quite slow because of the relatively low temperature of reflux and because of the nonionizing nature of these solvents. Consequently, if the conversion of alcohol I to chlorosulphite is not 100% complete, the chlorosulphite formed could react with the remaining alcohol to give sulphite IV rather than decompose to give chloride III.

For the degradation of III, it was first converted, through the Grignard reagent and reaction with carbon dioxide, to a solid derivative, 3-*p*-anisylpropanoic acid-*x*-C^{14} (V). Oxidation of V with alkaline permanganate yielded *p*-anisic acid (VI) whose radioactivity would correspond to the amount of C^{14} in the C-2 position of III. The activity of VI, expressed as a percentage of the activity of V, is, therefore, a measure of the percentage rearrangement of the C^{14} label from the C-1 to C-2 positions in the reaction of 2-*p*-anisylethanol-1-C^{14} (I) with thionyl chloride to give 2-*p*-anisylethyl-*x*-C^{14} chloride (III). The results from degradation of III, obtained from reactions in the various solvents, are summarized in Table I.

TABLE I

Rearrangement in the reaction between 2-*p*-anisylethanol-1-C^{14} (I) and thionyl chloride

Reaction solvent	Specific activity* of *p*-anisic acid (c.p.m./mmole)		% rearrangement†	
	Run 1	Run 2	Run 1	Run 2
(Oxidation of I)	60		0.03	
Pyridine	1,105	950	0.5	0.4
n-Hexane	8,764	9,722	3.8	4.2
Toluene	36,730	33,560	16.0	14.6
Dioxane	103,100	101,900	44.8	44.3
Thionyl chloride	107,700	105,000	46.8	45.6

*Radioactivity was measured in a liquid scintillation counter. Each sample, weighing about 10 mg, was dissolved in 20 ml of toluene containing 4 g/l. of DPO and 100 mg/l. of POPOP and then counted for a sufficient length of time to give at least 10,000 counts. Under these conditions, use of toluene-C^{14} as internal standard showed a slight degree (about 1%) of quenching for both *p*-anisic acid and 3-*p*-anisylpropanoic acid, which would not significantly alter the calculated % rearrangement.

†All reactions were carried out using the same stock of alcohol I whose specific activity, assayed as 3-*p*-anisylpropanoic acid (V), was 230,200 c.p.m./mmole. Individual samples of V derived from various runs agree with this value within ±1%. Therefore, % rearrangement = (specific activity of *p*-anisic acid/230,200) × 100.

The rearrangements recorded in Table I may be best accommodated by assuming the involvement of ion pair VII, or its equivalent, in the decomposition of 2-*p*-anisylethyl-1-C^{14} chlorosulphite. The structure of the carbonium ion moiety of VII, the ethylene-*p*-methoxyphenonium ion, is the same as that suggested by Jenny and Winstein (9) as intermediate in the solvolysis of 2-*p*-anisylethyl-1-C^{14} *p*-toluenesulphonate. The collapse of VII to give final products (3) would result in the formation of 2-*p*-anisylethyl-1-C^{14} chloride and 2-*p*-anisylethyl-2-C^{14} chloride.

For the reaction in pyridine, the extent of rearrangement observed is very small. This is in agreement with expectation that the process is almost completely S_N2 in character

VII

(12, 13). Exclusive S_N2 reaction would lead to no rearrangement as was noted in the decomposition of 2-butyl-1-C^{14} chlorosulphite in pyridine (8). For the present system, the 0.4–0.5% rearrangement observed in pyridine is beyond experimental error, indicating some contribution from VII even in pyridine. Mixture of chlorides resulting from rearrangement has been reported for the reaction between α- or γ-methylallyl alcohol and thionyl chloride in pyridine; the findings were explained on the basis of the S_N2 mechanism along with some contribution from the S_Ni ion-pair mechanism (5).
