to zerovalent has arisen from the observation that bis-benzene-chromium (0) forms a brownish addition complex with aluminum trichloride in benzene (6). Upon hydrolysis of the brownish complex with oxygen-free water or oxygen-free alkaline water solution, bis-benzene-chromium(0) was obtained accompanied by bis-benzene-chromium cation. The formation of bis-benzene-chromium cation is explained with difficulty by a mechanism involving simple hydrolysis of such a complex under an inert gas atmosphere. Fischer and Fritz (7) have formulated the complex as $3Cr^{+1}(C_6H_6)_2[AlCl_4]\cdot 4AlCl_3$. The addition reaction of bis-benzene-chromium and aluminum trichloride in benzene was thus expressed as follows:

$$3Cr^0(C_6H_6)_2 + 8AlCl_3 + 6C_6H_6 \rightarrow 3Cr^{+1}(C_6H_6)_2[AlCl_4]\cdot 4AlCl_3.$$

The mechanism of the hydrolysis of the addition complex was also described by an electron disproportionation shown as follows:

$$2Cr(C_6H_6)_2^+ \rightarrow Cr(C_6H_6)_2 + Cr^{+2} + 2C_6H_6$$
$$Cr^{+2} \rightarrow Cr^{+3} + e^-$$

Hein and Kartte (8) have provided strong evidence that the addition reaction of bis-arene-chromium and aluminum trichloride may cause an electron transfer. A complex, $[(C_6H_5C_6H_5)_2Cr]_3Al_4Cl_{12}$, was obtained from the addition reaction of bis-diphenyl-chromium(0) and aluminum trichloride in benzene. The empirical formula of the complex is $[(C_6H_5C_6H_5)_2Cr][AlCl_4]$. The following similar type complexes have been obtained from the reaction of bis-arene-chromium(0) and aluminum halide in various solvents: $[(C_6H_5C_6H_5)_2Cr]_3Al_4Br_{12}$; $[(C_6H_5C_6H_5)_2Cr][AlBr_4]\cdot\frac{1}{4}C_6H_4$; $(C_6H_5C_6H_5)_2CrAlI_4$; $(C_6H_5C_6H_5)_2CrAlCl_4\cdot\frac{1}{4}C_6H_6\cdot\frac{1}{4}CH_2Cl_2$; $(C_6H_6)(C_6H_5C_6H_5)CrAlCl_4\cdot\frac{1}{2}C_6H_6$.

Although the formulations of the addition products by the two groups of investigators are not exactly the same, it seems to be conclusively established that oxidation, an electron transfer, occurs during an addition reaction of a bis-arene-chromium compound and aluminum halide. These results, however, have not yet provided conclusive elucidation of the mechanism of the formation of bis-arene π-complex by the reductive Friedel–Crafts reaction. Even in this reaction, it is not unreasonable to assume that a highly active metal is produced in the course of π-complex formation. Immediately after the formation of bis-arene-chromium(0) through the transition stage of π-radical hybridization of arene and "radical metal", the π-complex may be oxidized with aluminum trichloride, forming a new addition complex.

Based upon the hypothesis of the existence of a so-called "radical metal" during the course of the formation of π-complex by most of the reported preparative methods, other new synthetic methods for π-complex may be found by devising ways of producing such a "radical metal" in the presence of arene. If a suitable reducing agent for transition metal halide in an arene environment were found, a new synthetic method for bis-arene π-complexes, more pertinent and more broadly applicable than the known methods, might result. For this purpose, triethylaluminum was chosen as the reducing agent.

A mixture of triethylaluminum, a transition metal halide, and an arene in a normal hydrocarbon solution (e.g. *n*-heptane) was heated at 130–140° (bath temperature) for 10 to 30 minutes. The reaction mixture was digested with a small amount of methanol below 0°. The slurry was hydrolyzed with water under an atmosphere of air. In most cases, the filtrate contained a π-complex ion (hydroxide) which could be isolated as the iodide, tetraphenylboron salt, or other salt forms. If π-complex ion is sparingly soluble in water, it should be extractable with methanol or acetone from a precipitate. By this method, a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

number of known chromium π-complexes with arenes, e.g. toluene, xylene, mesitylene, diphenyl, and fluorene, have been prepared.

A bis-mesityl-iron π-complex and several other new arene π-complexes, e.g. a bridged bis-benzene-chromium-1,1′(β,γ-diphenyltetramethylene)-bis-benzene-chromium iodide, have been prepared. These new π-complexes will be described in detail after completion of the characterization of their structure and properties. This new method has proved to be extraordinarily successful and widely applicable. This method, at least, has one advantage: no rearrangement or fission of an alkyl group in the arene molecule occurs during the reaction, while aluminum chloride, in the reductive Friedel–Crafts reaction, may cause such undesirable reactions.

EXPERIMENTAL

Bis-mesitylene-chromium Salt

To a mixture of 2.4 g (0.02 mole) of mesitylene, 1.58 g (0.01 mole) of chromic trichloride anhydride, and 10 ml of *n*-heptane in a Schlenk tube, 0.01–0.03 mole of triethylaluminum was added at room temperature. The mixture was stirred and was heated by an oil bath in which the temperature was gradually raised to 140°. After the mixture was heated at 140° for about 15–30 minutes, the temperature was gradually dropped to room temperature during a period of 1 hour. The reaction mixture was cooled by a dry ice – acetone mixture or ice water and was decomposed under a nitrogen gas stream with methanol, which was carefully added dropwise. The decomposed mixture was finally hydrolyzed with water. An additional 100 ml of water was added to the hydrolyzed solution and the solution was filtered. To the filtrate, a solution of sodium tetraphenylboron salt in water was added until no further precipitation was observed. A golden yellow bis-mesitylene-chromium π-complex salt was isolated by filtration. A π-complex iodide salt can be obtained by the addition of a potassium iodide solution in water instead of an aqueous sodium tetraphenylboron salt solution.

These π-complexes thus obtained were shown to be identical, by infrared spectroscopy, with known authentic samples prepared by the reductive Friedel–Crafts method. Other known complexes, and the new bis-arene π-complexes previously mentioned, were prepared in a similar fashion.

Hydrolysis of Reaction Mixture

During another preparation of bis-mesitylene-chromium π-complex as described above, the reaction mixture was hydrolyzed with oxygen-free water at 0 to ~5° C. A total of 100 ml of water was added. After hydrolysis, some oxygen-free benzene was added to the mixture followed by vigorous shaking. The hydrocarbon layer was crystal clear and did not contain any π-complex in the zerovalent state. The yellowish filtrate from the water layer gave bis-mesitylene-chromium tetraphenylboron salt by the addition of an aqueous solution of sodium tetraphenylboron.

DISCUSSION

There have been several methods described for producing a highly active transition metal in the radical state:

(*a*) a homolytic cleavage of the metal–carbon bond of an organotransition metal (9);

(*b*) reduction of a transition metal halide with aluminum metal (3);[3]

(*c*) treatment of iron metal with diluted acid followed by washing with water, alcohol, and ether (10).

π-Complexes have been produced from methods (*a*) and (*b*). Method (*a*) is a clear case of producing a so-called "radical metal". The course of the mechanism of the aryl coupling reaction based on the new hypothesis of the existence of π-radical hybridization is shown in Fig. 1.

In II, Fig. 1, dotted loops indicate the sp^2 orbitals on the benzene rings and 3*d* orbitals of the metal, when the covalent bond between the metal and carbon atoms cleaves homolytically. Electrons in the center shell of the metal and the π-system P_z electrons of the carbon atoms are stimulated to an excited state. An antibonding π–π^* system on the

[3]*As previously described, it is not clear whether the transition metal halide is reduced to the cation or the zerovalent state.*

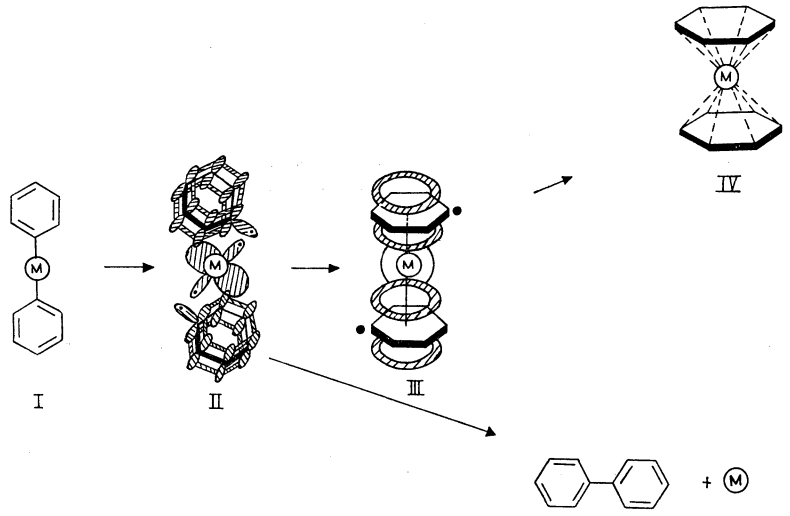

FIG. 1.

benzene rings hybridizes with the very close excited electron orbital of the metal atom. Formation of a hypothetical diradical π-complex III or a coupling reaction of the excited phenyl rings to form biphenyl with the elimination of the metal atom may then follow. It has been assumed with supporting evidence (9) that a π-complex forms through π-radical hybridization in the Grignard method.

The explanation of the course of the mechanism of π-complex formation by applying the simple molecular orbital picture described above well visualizes the role of the "radical transition metal atom". As previously mentioned, trivalent chromium might also be reduced to an active chromium state, possibly to a "radical metal atom" state, during the course of the reaction in the reductive Friedel–Crafts method. In this case, chromium (III) is reduced in an arene environment to an active chromium atom which hybridizes with π-systems on the arene to form a π-complex (0) which might then be oxidized to a cation with aluminum chloride. The sequence of π-radical hybridization occurring in the two methods, the decomposition of aryl transition metal and the reductive Friedel–Crafts reaction, is quite different. Arene π-ligands in the latter case are not attached to the metal atom before the occurrence of "π-radical hybridization", while the arene π-ligand in the former case is attached with a σ-covalent bond and thus it never leaves the metal atom from the beginning to the end of π-complex formation.

In the new method reported here, the situation between the metal atom and arene is quite similar to that of the reductive Friedel–Crafts method. No experimental evidence has been provided as to whether the π-radical metal atom forms π-bonding with the arene after formation of the radical metal, or at precisely the time when it forms by the reduction of metal halide with the reducing agent.

The following experiment has revealed that bis-arene π-complex cation is the sole product of the reaction by the new method. When the reaction mixture was hydrolyzed with oxygen-free water, only bis-arene-chromium cation was produced as π-complex. Since the formation of aluminum chloride is expected from the reaction of chromic chloride and triethyl aluminum, bis-arene-chromium(0) should be oxidized with aluminum trichloride as seen in the reductive Friedel–Crafts reaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Considering the results of the formation of 1,1′-(β,γ-diphenyltetramethylene)-bis-benzene-chromium iodide from the reaction of chromic chloride, triethylaluminum, and *trans*-stilbene by the new method, a reductive coupling reaction of *trans*-stilbene evidently occurred and thus chromic hydride might be formed as an intermediate in the formation of "radical metal atom". The details of the formation and properties of new bridged bis-benzene-chromium will be reported elsewhere.

ELECTRONIC EFFECTS IN ORGANOMAGNESIUM REACTIONS[1,2]

JOEL D. CITRON[3] AND ERNEST I. BECKER[4]
Chemical Laboratories, Polytechnic Institute of Brooklyn, Brooklyn, N.Y., U.S.A.

Received October 29, 1962

ABSTRACT

The kinetics of the first part of the reaction between para-substituted benzonitriles and diethylmagnesium have been studied. The rarely isolated intermediate products, the ketimines, have been isolated and identified. The kinetic constants fit a Hammett plot, with rho equal to +1.57.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

Recently, a precise, convenient procedure was reported for following kinetics of the Grignard reaction (1). The purpose of this investigation was to use this method in evaluating the electronic effect of *p*-substituents in the reactions between the substituted benzonitriles and diethylmagnesium.

EXPERIMENTAL

Reagents

The magnesium used has been previously described (1). All other reagents for kinetics, with the exceptions noted below, were purified in the usual manner. Diethylmagnesium in tetrahydrofuran was prepared by the method of Storfer and Becker (1). The solutions were colorless and were standarized by the method of Gilman *et al.* (2). No precipitate was observed when test portions of the diethylmagnesium solutions (approximately 0.5 to 1 ml) were hydrolyzed in acidified silver nitrate solution. All work with organomagnesium compounds was carried out in an atmosphere of either nitrogen or argon.

α,α,α-Trifluoro-p-tolunitrile

A solution of α,α,α-trifluoro-*p*-tolylmagnesium bromide was prepared in the usual manner from 40 g (0.18 mole) of α,α,α-trifluoro-*p*-bromotoluene in 175 ml anhydrous ether. The Grignard solution was then filtered through a glass-wool plug into an addition funnel.

In a 500-ml flask equipped with stirrer, gas inlet tube, and condenser was placed 125 ml of anhydrous ether. Twelve grams (0.20 mole) of cyanogen chloride (3) were distilled into the flask. The cyanogen chloride solution was cooled in an ice bath and the Grignard solution added over a period of 2.5 hours. After standing overnight, the mixture, which had separated into two layers, was hydrolyzed with cracked ice and then dilute sulphuric acid. The ether layer was dried with anhydrous sodium sulphate, distilled on a steam bath, and the residue was then vacuum distilled, yielding two fractions: the first, 10.1 g, boiling from 35 to 58° at 6 mm; the second, 6.1 g, boiling from 58 to 62° at 5.5–6.0 mm (total 16.2 g, 0.094 mole, 52.5%). The higher-boiling fraction was then purified for analysis by three-stage fractional freezing and one crystallization from pentane, m.p. 36.4–37.4° (reported (4) 36–37°). The total yield of purified nitrile was 5.9 g (0.035 mole, 19.1%). Anal. Calc. for $C_8H_4F_3N$: C, 56.15; H, 2.36; N, 8.19. Found: C, 56.07; H, 2.60; N, 8.10.

4′-(Trifluoromethyl)-propiophenone

The title compound was made via bis(α,α,α-trifluoro-*p*-tolyl)cadmium by the method of Gilman and Nelson (5). The organocadmium was prepared through the corresponding Grignard reagent using 10 g (0.044 mole) α,α,α-trifluoro-*p*-bromotoluene and 4.5 g (0.025 mole) cadmium chloride. The mixture was then treated with 3.8 ml (0.044 mole) propionyl chloride. After hydrolysis, the organic layer was concentrated on a steam bath and the residue extracted with Girards "T" reagent. After hydrolyzing the Girard derivative with hydrochloric acid, and extracting the ketone with ether, 1.25 g (0.0057 mole, 12.9%) of a solid, m.p. 35.6–36.8°, was obtained. The ketone was crystallized twice from pentane and once from ethanol–water, m.p. 35.6–37.0°. Anal. Calc. for $C_{10}H_9F_3O$: C, 59.41; H, 4.49. Found: C, 59.45; H, 4.58.

[4]*To whom inquiries should be directed.*

Method of Analysis

This method is based upon that described in reference 1. An aliquot of the solution under study was hydrolyzed in a known excess of sulphuric acid (10.00 ml of 0.06–0.10 *N*) containing ethanol (about 10 ml) to dissolve the organic materials present. The solution was heated to just below the boiling point for 15 minutes to dissolve the magnesium compounds present, and was then back-titrated while hot with sodium hydroxide solution (0.04–0.06 *N*) to the methyl red end point.

Blanks were run to determine whether the organic species present affected the results. Approximately 0.1–0.2 g each of nitrile and substituted propiophenone were added to a mixture of 5 ml sulphuric acid and 5 ml ethanol. After heating to just below the boiling point for 15 minutes, the solutions were back-titrated while hot using methyl red indicator. The results were the same within experimental error as a blank using only sulphuric acid.

Kinetics

The apparatus and reaction conditions have been previously described (1). Before starting a run, a measured volume of a standardized solution of diethylmagnesium in tetrahydrofuran was introduced into the reaction vessel. At time zero, a thermostatted standard solution of the nitrile in tetrahydrofuran was introduced into the diethylmagnesium solution. At appropriate intervals, samples were withdrawn by syringe for analysis. All solutions remained homogeneous during and after the kinetic runs. The ratios of nitrile to diethylmagnesium ranged from 1:1 to 2.5:1, and the concentration of diethylmagnesium ranged from 0.10 to 0.22 *M*.

Reaction Products

(1) 2,4,6-Tris-(*p*-chlorophenyl)-*s*-triazine was isolated in preliminary runs with *p*-chlorobenzonitrile when the nitrile:Et_2Mg ratio exceeded 2:1. At 30° in tetrahydrofuran, with a 3:1 ratio, a precipitate, the triazine, appeared after 24 hours, m.p. 332.0–332.9°. It was identified by elemental analysis, mixed melting point, 332.3–333.2°, with an authentic sample, m.p. 332.6–333.6° (reported (6) 335°), and identity of their infrared spectra. The triazine was very insoluble in tetrahydrofuran at 30°.

An attempt was made to increase the yield of triazine. Twenty-five milliliters of a 0.5 *M* Et_2Mg (0.0125 mole) solution in tetrahydrofuran and 5.0 g (0.0445 mole) *p*-chlorobenzonitrile were refluxed for 3 days. A precipitate appeared after the first 24 hours. A mixture of 20 ml of water and 5 ml of concentrated hydrochloric acid was added, filtration affording 1.49 g (45.6% theoretical, after subtracting the amount of nitrile consumed in ketimine formation) of crude triazine.

(2) 2,4-Dinitrophenylhydrazone derivatives of *p*-substituted propiophenones were prepared by adding the ketone to an excess of a stock solution (1) of 2,4-dinitrophenylhydrazine and recrystallizing the precipitates. The data are summarized in Table I.

Ketimines

The method used was that of Pickard and Tolbert (7). Ethylmagnesium bromide was employed with the nitrile in ether. The imines were handled under anhydrous conditions at all times, as they appeared to be very sensitive to hydrolysis. The physical constants will be found in Table II.

RESULTS

The initial concentration of nitrile was calculated from the number of moles added and the initial volume of the reaction mixture. The initial concentration of diethylmagnesium was obtained by the above method, or by extrapolating the early points (less than 10% reaction) back to zero time; the agreement between the two methods was an internal check on the technique for each run (see reference 1).

A second-order rate equation, first order in diethylmagnesium and first order in nitrile, gave consistent values for the rate constant (eq. [1]). The rates thus obtained are shown

$$\text{rate} = k[Et_2Mg][\text{nitrile}] \quad [1]$$

in Table III, together with the appropriate data for the Hammett plot. The Hammett

plot is given in Fig. 1, and the ρ is +1.57. The Hammett plot and all kinetic curves were fitted by the method of least squares.

DISCUSSION

The precision of the analytical procedure made possible the study of the initial rates of the reaction. This point is significant, since it was shown earlier (1) that only half of the available ethyl groups react, and that for this half two reaction rates are observed. It is within the time for reaction of this first quarter of the available ethyl groups that the data were obtained in the present work.

For personal use only.

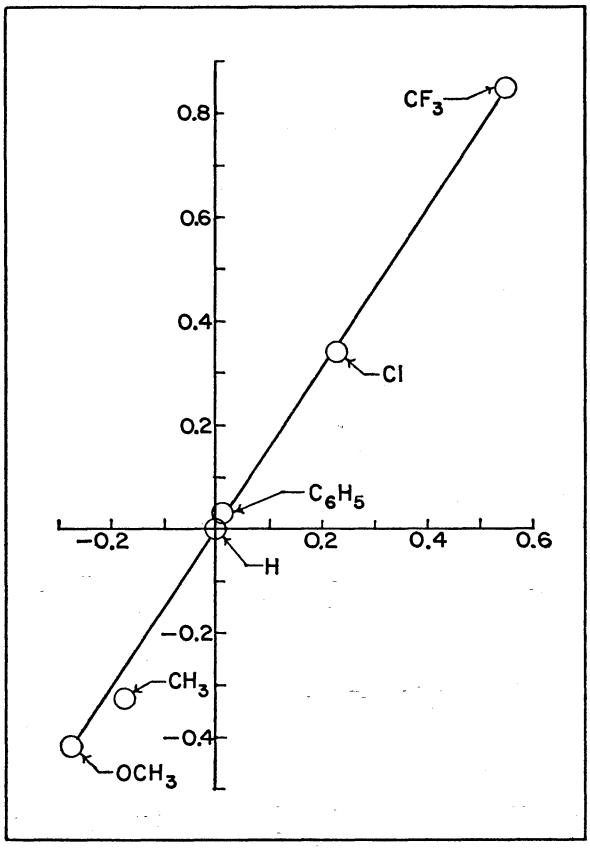

FIG. 1. Hammett plot of reaction rate constants. Slope (ρ) = +1.57. Ordinate: log (k/k_0); abscissa: σ.

The linearity of the Hammett plot affirms that the nitriles taken here react by the same mechanism. The value of ρ, +1.57, indicates that the rate-determining step involves a dipolar, but probably not ionic, species as befits a solvent of low dielectric constant such as tetrahydrofuran.

The mechanism previously proposed (1) for the first part of the reaction can be used to explain the electronic effects of the substituents. The role of the solvent is not considered in this mechanism. The increased rate with the electron-attracting chlorine atom in the

For personal use only.

para position is consistent with the rearrangement of the complex as the slow step, since that step requires the transfer of a negative ethyl group to an electron-deficient center—the nitrile carbon atom. Conversely, electron-releasing groups, such as CH_3 and OCH_3, should decrease the rate by increasing the electron density at the nitrile carbon atom, making the transfer of a negative ethyl group there more difficult, which is the case.

Prior workers in this area of research have employed competition experiments and found the effect of substituents to be in qualitative agreement with the results obtained here. Thus, Gilman and Lichtenwalter (9) found the order of reactivities to be $Cl > H > CH_3 > OCH_3 > N(CH_3)_2$ for the reaction between phenylmagnesium bromide and the *p*-substituted benzonitriles in ethyl ether. In a study of the competitive reaction between *p*-substituted benzophenones and 1-naphthol against methylmagnesium iodide in phenetole, Lewis and Wright (10) obtained a ρ of $+0.362$.

The appreciable changes in the rate with changes in substituent obtained in the reactions with benzonitriles appear to be significantly different from those reported by Dessy and Salinger (11) for the reaction of *p*-substituted benzalanilines with ethylmagnesium bromide in ethyl ether. In that study the authors claim that essentially no change in rate is observed with the methoxy or chloro groups.

THE VAPOR PHASE POLYMERIZATION OF ETHYLENE ON AN ORGANOTITANIUM CATALYTIC SURFACE[1]

F. H. C. EDGECOMBE
Du Pont of Canada Limited, Research Division, Kingston, Ontario
Received October 29, 1962

ABSTRACT

The polymerization of ethylene has been studied in the gas phase on a solid catalyst formed by the reaction of an organotitanium vapor with a solid crystalline titanium compound deposited on the walls of a reaction vessel.

The rate of polymerization of ethylene was found to be, initially, of first order but as the reaction proceeded departure from the first-order case was observed.

Experiments conducted under the condition of constant pressure as well as the usual constant-volume state enabled us, with the aid of an analogue computer, to devise a mathematical model which explained the experimental results in an unique fashion.

A measure of the rate constant for catalyst decay was also obtained as well as the activation energy for the overall propagation step in the polymerization of ethylene.

The discovery of stereospecific polymerization processes capable of leading, by poly-addition of olefinic units, to high yields of sterically regulated polymers has created a tremendous surge of interest in polymer chemistry.

In spite of all the effort which numerous investigators have expended upon the study of coordination catalysis no adequate description of the mechanism of action of the catalyst nor complete kinetic analysis of the polymerization process has been formulated to date.

The catalyst systems themselves are many and varied. The majority of catalysts do involve a complex of a transition metal and a metal organic compound. Nonetheless even the most cursory survey of what is now an immense patent literature concerning these systems will indicate the diversity of materials capable of the polymerization of alpha olefins. There are very few of the elements in the periodic table which cannot be found playing some role in some system of what is now rather loosely termed coordination catalysis.

The work which we are about to describe deals with the study of one of the more common types of catalyst, the system of transition metal and metal organic compound previously mentioned, but differs from the majority of such systems in that the active species contains but one metal element. The choice of a single-metal system was made in order to simplify so far as possible the mechanism of the catalytic function.

All the polymerizations studied have been carried out by the reaction of a gaseous monomer at a solid catalytic surface under conditions of constant temperature and either constant volume or constant pressure.

EXPERIMENTAL

Apparatus

The apparatus, illustrated in Fig. 1, was in essence a simple two-manifold high-vacuum system provided with a high-capacity two-stage rotary vacuum pump; liquid nitrogen cooled traps; a reaction vessel, to be described later, immersed in a water bath the temperature of which was controlled within ±0.1° C; glass

[1]*Presented at the Symposium on Organometallic Compounds, Vancouver, British Columbia, September 4–6, 1962, sponsored by the Inorganic Chemistry Division, Chemical Institute of Canada, and the Department of Chemistry, University of British Columbia, with the support of the National Research Council, Ottawa, in cooperation with the University Extension Department.*

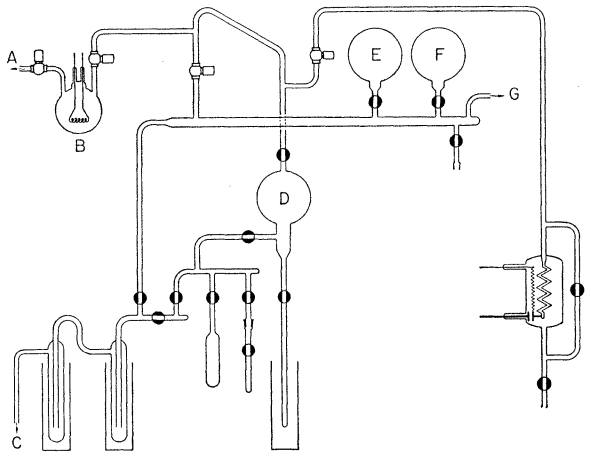

FIG. 1. Apparatus. A, to gas chromatograph; B, reaction vessel; C, to pump; D, mixing bulb; E, hydrogen; F, ethylene; G, to mercury manometer.

bulbs for the storage of monomer and other gaseous reactants; storage facilities for catalyst components; an all-glass pressure-measuring device; mercury manometer and automatic apparatus which could be used to maintain the pressure of the system constant.

The reaction vessel was a pyrex glass bulb into which was sealed, through uranium glass, a tungsten electrode of the sort found in fluorescent light fixtures. Entrance into the reaction vessel from the vacuum manifold was through a Springham greaseless stopcock fitted with a Viton A diaphragm and O ring. Exit from the vessel into an automatic gas chromatograph was made by means of a Hoke A431 all-metal bellows valve attached by a kovar glass to metal seal. Similar Hoke valves were used in those places where catalyst contact with greased stopcocks was deemed to be undesirable.

Since the catalyst has been found to be photochemically unstable to room lighting all transparent parts of the reaction line with which catalyst came in contact were externally blackened with a dispersion of colloidal graphite.

Pressures were automatically recorded to a precision of ± 0.05 cm of Hg by means of a small glass spiral used in a differential fashion and accurately calibrated against a mercury manometer. This pressure-measuring device, previously described by Edgecombe and Jardine (1), was constructed in such a way that pressure changes within the system varied the capacitance of a simple plate condensor. These capacitance variations were in turn fed to a capacitance transducer which transposed them into a voltage, a form suitable for amplification and strip chart recording.

The course of the polymerization could also be followed by gas chromatography. An automatic gas chromatograph was devised (2) which could remove at regular intervals very small samples of gaseous monomer from the system and record their concentration.

When it was necessary to carry out the polymerization under conditions of constant pressure two procedures were used. In the first instance the pressure of monomer in the reaction vessel was manually returned to the initial pressure after a short period of polymerization and this process repeated so that the record of pressure change with time as recorded on the strip chart recorder gave a sawtooth pattern. At a later stage of our investigation a more refined method was used to maintain a constant pressure. This device took the form of an automatic gas burette and is described elsewhere (3). It consisted essentially of a servo actuated screw raising the level of a container of mercury which was connected to a calibrated gas burette. Control was obtained by using the pressure-measuring device described previously and the pressure of the system could be maintained constant to within less than 0.01 cm of the initial pressure of 10 cm of Hg. The device was also capable of providing a continuous record of the time rate of volume change within the system.

Preparation of Materials

Ethylene

The ethylene used was a chemically pure grade supplied by Matheson Inc. and was taken directly from its cylinder by a suitable feed system and stored in a large bulb on the vacuum line. Although high-sensitivity gas chromatography could detect no impurity in the stored material several experiments were carried out in which the ethylene to be used was first passed through a purification train consisting of a 10-ft column of silica gel, a 2-ft column of ascarite, two washings with triisobutyl aluminum, and a 2-ft column of alumina. Ethylene thus treated reacted in no way different from that taken directly from the cylinder.

For personal use only.

Hydrogen and Helium

The hydrogen used in the reaction for the formation of titanium trichloride was of chemically pure grade and was not subjected to further purification.

The helium used as a carrier gas in the gas chromatographic system was of very high purity and was not treated in any way before use.

Titanium Tetrachloride

Fisher certified reagent grade titanium tetrachloride was used in the catalyst formation. It was distilled from a trap on the vacuum line immediately before use.

Titanium Trichloride

The titanium trichloride used in the catalyst preparation was formed within the reaction vessel by the action of $TiCl_4$ vapor and hydrogen at a tungsten filament heated to bright red. The reaction may be represented as

$$2TiCl_4 + H_2 \xrightarrow{\text{heat}} 2TiCl_3 + 2HCl.$$

The HCl vapor was immediately pumped off. The $TiCl_3$ formed was the alpha variety, i.e. purple $TiCl_3$. Experiments have shown that the $TiCl_3$ is laid down each time on the walls of the reaction vessel in a consistent pattern and if similar voltages are applied to the filament for identical periods of time reproducible quantities of $TiCl_3$ are produced.

A study was carried out in which the $TiCl_3$ deposit was carefully washed out of the reaction vessel with dilute nitric acid and a Volhard analysis performed to determine the chloride content. The amount of $TiCl_3$ deposited for a 35-minute reaction period with a voltage of 22 v a-c. applied to the filament from 1 cm pressure of $TiCl_4$ in a volume of 400 ml was determined to be 7.95×10^{-5} mole (average of 17 experiments).

Dimethyl Zinc

Dimethyl zinc was used in the formation of the catalyst precursor CH_3TiCl_3. It was prepared in the following manner. Anhydrous zinc chloride was melted in a glass container and then cooled in an atmosphere of dry nitrogen. The fused zinc chloride was powdered in a mortar and transferred in the nitrogen atmosphere to a three-neck round-bottom flask purged with nitrogen. One neck of the flask was closed off. A condenser was fitted into one of the remaining necks and a dropping funnel containing trimethyl aluminum adapted to the third neck.

The entire system was purged with nitrogen. A stream of nitrogen was directed over any openings to the atmosphere in the system. Trimethyl aluminum was slowly added to the zinc chloride and the mixture heated to 50° C until it was evident that a reaction had commenced. The heat was removed and the reaction

$$(CH_3)_3Al + ZnCl_2 \rightarrow (CH_3)_2Zn + CH_3AlCl_2$$

continued, the material refluxing under its own heat of reaction. When all signs of reaction had disappeared the vessel was cooled in a dry ice – acetone mixture and transferred to a spinning band column through which the $(CH_3)_2Zn$ was distilled into a cooled glass container and finally redistilled into a storage trap on the vacuum line.

Formation of Catalyst

Five millimeters of Hg pressure of dimethyl zinc contained in a 4-liter mixing bulb was condensed and isolated in a cold finger surrounded by liquid nitrogen. The bulb was next pumped out and 10 mm of Hg pressure of titanium tetrachloride vapor distilled into it. The $(CH_3)_2Zn$ in the cold finger was quickly warmed to slightly above room temperature and was expanded into the bulb, where it mixed and reacted with the $TiCl_4$. The reaction represented by the following equation takes place:

$$Zn(CH_3)_2 + 2TiCl_4 \rightarrow 2CH_3TiCl_3 + ZnCl_2.$$

CH_3TiCl_3 is a vapor and $ZnCl_2$ a solid. The $ZnCl_2$ settles out leaving CH_3TiCl_3, which has been shown by infrared spectroscopy to be free of zinc compounds and unreacted $TiCl_4$.

CH_3TiCl_3 was then expanded into the evacuated reaction vessel upon which a layer of $TiCl_3$ had been deposited. The reaction between CH_3TiCl_3 and $TiCl_3$ was allowed to proceed for a fixed time after which the residual CH_3TiCl_3 and the $TiCl_4$ produced by the reaction was pumped out.

$$CH_3TiCl_3 + TiCl_3 \rightarrow TiCl_4 + CH_3TiCl_2$$

CH_3TiCl_2 is the active catalyst and is thought of as an alkylated $TiCl_3$ surface.

Infrared Instrumentation

In the discussion reference will be made to several infrared analyses. A Perkin–Elmer Model 221 double-beam spectrophotometer fitted with sodium chloride optics was used to record the infrared spectra from 4000 to 650 cm^{-1}. A Perkin–Elmer single-beam, double-pass Model 112 spectrophotometer with cesium bromide optics was used for the region 650 to 290 cm^{-1}.

The infrared gas cells used in this work were of pyrex, 10 cm in length and fitted with a vacuum stopcock. CsBr windows were sealed on with glyptal in such a manner that the cells were vacuum tight.

THE CATALYTIC SYSTEM

Before presentation of the kinetic data, a few comments on the catalytic system which we have used are in order.

The existence of methyl titanium trichloride has been known for some time. During the years 1955 and 1956 this laboratory carried out a rather exhaustive study of its physical and catalytic properties. It was found that CH_3TiCl_3 vapor alone was extremely stable in the dark at room temperature, Fig. 2, and that in the pure form either in

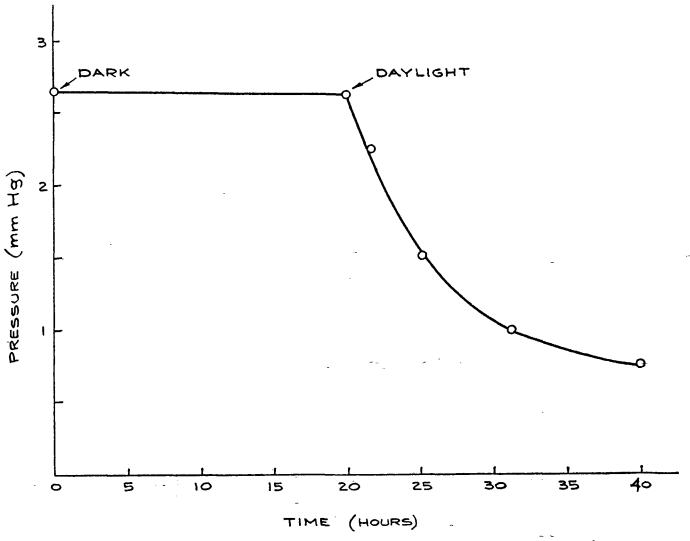

FIG. 2. Stability of gaseous $TiCl_3CH_3$.

hydrocarbon solution or the vapor state possessed little or no catalytic activity. If, on the other hand, one partially decomposed CH_3TiCl_3 by photochemical or thermal means, a catalyst, active for the polymerization of ethylene, was formed. It was also found, by an infrared technique, that during the decomposition of CH_3TiCl_3 in cyclohexane solution $TiCl_4$ was formed, Fig. 3.

Van Heerden (4), discussing a paper by Natta, drew attention to a Hoechst patent (5) which mentioned that $TiCl_3$ forms an active system for polymerization when reacted with tetravalent alkyl titanium halides. Dr. Van Heerden further reported that in his own laboratory the combination of CH_3TiCl_3 and brown $TiCl_3$ formed by the thermal decomposition of CH_3TiCl_3 was an extremely active system. His explanation of the experimental results is applicable to the system which we are describing and consequently warrants repetition.

The Ti—C bond in the tetravalent titanium alkyl halide seems too stable to give a rapid "aufbau" reaction under the mild conditions of low-pressure ethylene polymerization. The unique character of the Ti—C bond has become apparent in an infrared analysis (6) of CH_3TiCl_3 carried out in this laboratory and to be published shortly. It has become evident that the CH_3 group present in CH_3TiCl_3 does not possess the infrared character of the normal metal organic methyl group and therefore the Ti—C bond is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

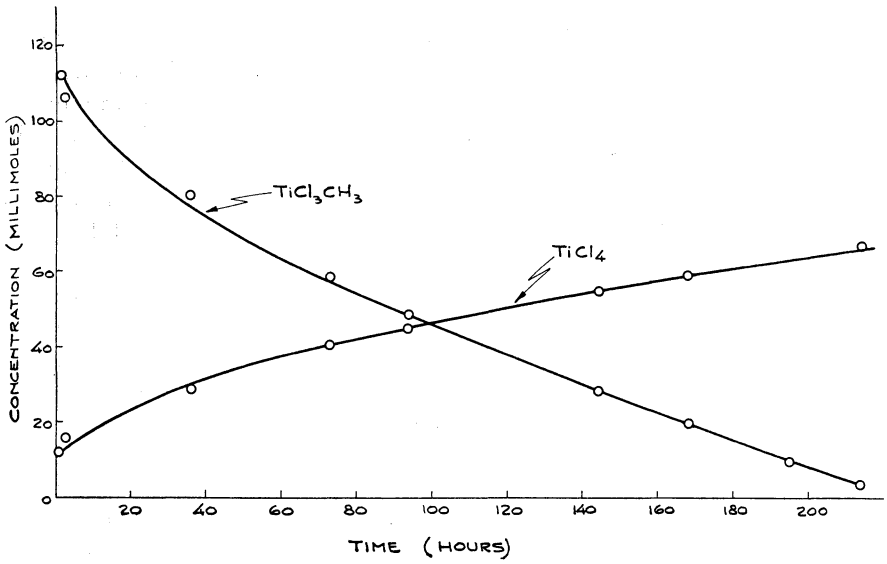

FIG. 3. Decomposition of $TiCl_3CH_3$ in cyclohexane in the dark at 25° C.

not a normal metal carbon bond. (Rodriguez's (7) work using D_2O to hydrolyze methyl titanium trichloride also emphasizes this last fact since he found all of the mixed CDH groups present in his products.) Van Heerden's studies also show that a solution of CH_3TiCl_3 in the absence of $TiCl_3$ does not give the aufbau reaction or at least the rate of such a reaction is very small in comparison with the polymerization rate in coordination catalyst systems. De Vries' (8) work in the same laboratory as Van Heerden found that only those alkyl titanium chlorides are unstable which can decompose in a bimolecular reaction by the disproportionation of two alkyl groups to an olefin and an alkane, i.e. those compounds having an H atom on a β-C atom in the alkyl group. CH_3TiCl_3 lacking H atoms on β carbon atoms is consequently stable.

Arlman and De Jong (9) discussed the work of Beerman and Bestian (10) regarding the decomposition of CH_3TiCl_3. The decomposition appeared autocatalytic and the addition of extra $TiCl_3$ increased the rate of decomposition. It was suggested that the reaction takes place predominantly at the surface of $TiCl_3$ crystals.

The preparation of the catalyst system used in our study is described in detail in the section of this paper dealing with experimental methods. The CH_3TiCl_3 vapor is reacted with a deposit of purple $TiCl_3$, i.e. the alpha form prepared in a pure state. An infrared examination of the formation of this catalyst has shown that $TiCl_4$ is formed during the reaction of the vapor and the solid. If the surface is pumped for an hour or more to remove any remaining $TiCl_4$ and then a small quantity of moist helium is brought into contact with it, methane is formed and has been detected by gas chromatography. No ethane has been found in the system.

From the foregoing discussion we postulate the following reaction to explain the formation of a catalyst active for ethylene polymerization:

$$TiCl_3 + CH_3TiCl_3 \rightarrow CH_3TiCl_2 + TiCl_4,$$

CH_3TiCl_2 being the active species. The active site might well be a chlorine vacancy in the crystal lattice, a mechanism well described by Cossee (11).

KINETICS

The literature which has been built up since the advent of the polymerization of olefines by coordination catalysts contains many discussions of the kinetics of ethylene polymerization. A large variety of catalytic systems has been studied and numerous postulations made as to the factors controlling the rate of reaction. The majority of such investigations have dealt with polymerization in hydrocarbon solution and have involved catalysts generally formed *in situ*. Relatively few investigations have been carried out in the absence of solvent and the investigation of Eden and Feilchenfeld (12) represents one of these. It should be mentioned that we do not consider the fixed bed catalysts such as the chromium oxide system of Phillips Petroleum and the nickel, cobalt, and molybdenum oxide systems of Standard Oil as belonging to the class of coordination catalysts which we are considering.

Most investigations dealing primarily with catalysts formed by the reaction of aluminum alkyls and titanium or vanadium halides have shown that the rate curves for ethylene polymerization are complex. Ludlum, Anderson, and Ashby (13) divide their observed rate curve into three regions. Fukui (14) and his co-workers, using a somewhat different system than Ludlum, have delineated four regions in their overall rate curve. Badin (15) and Chien (16) have two regions and Gilchrist (17) by virtue of the time period of his observations finds but one. Most authors do, however, in spite of their divisions of the rate curve, observe a region in which the rate of polymerization of ethylene is first order in ethylene. Several people, among them Fukui (14) and Gilchrist (17), have found second-order dependence but often it is possible to postulate ethylene being a necessary substituent in the catalyst-forming step of their reaction scheme. It is commonly observed that the rate eventually departs from first order, and several explanations to be discussed later have been postulated to explain this fact.

Figure 4 represents the change in ethylene concentration with time for a constant-volume system in which gaseous ethylene is polymerized on the alkylated $TiCl_3$ surface previously described. Figure 5 is the same experiment plotted as a first-order reaction. It is evident that the rate of reaction obeys the first-order rate law during the first 50 minutes but then departs from that law and must be expressed in some different form.

Figure 6 shows the polymerization of ethylene under a condition approximating constant pressure; this condition was obtained in the manner previously described, i.e. returning the pressure to the initial value at frequent, regularly spaced intervals. It is obvious from this figure that the initial rate is changing. Figure 7 shows the polymerization of an alpha olefin under conditions of constant pressure using the automatic gas burette to control the pressure. The curve represents the volume change as a function of time. If one considers the general equation for a first-order process,

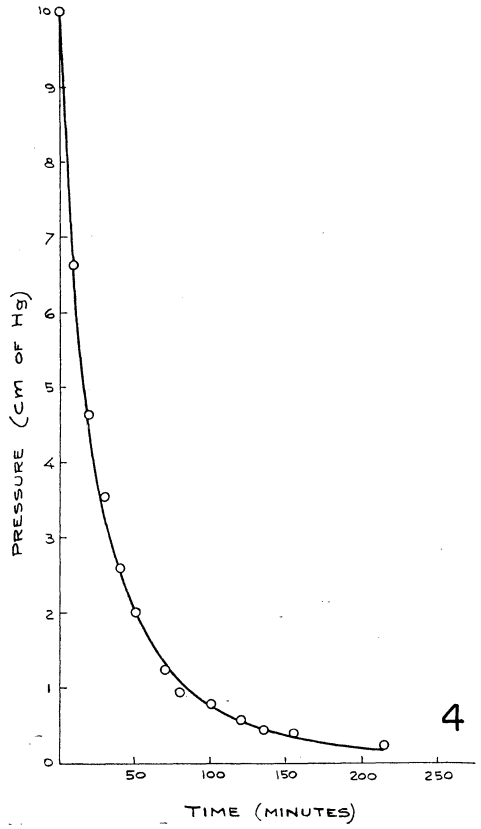
$$dn/dt = -k_1C,$$

where $n \equiv$ number of moles and $C \equiv$ number of moles/liter $= n/V$, assuming perfect gas $n = PV/RT$, $C = P/RT$ it is easily shown that

$$dV/dt = -k_1,$$

i.e. for a first-order process the rate of change of volume should be constant.

Since the result of the constant-pressure experiment is not a straight line it is evident



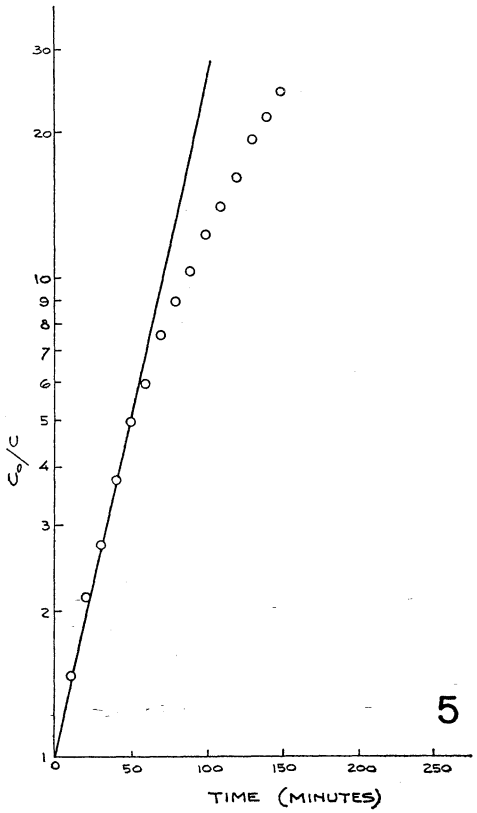


FIG. 4. The polymerization of ethylene. Ethylene concentration as a function of time.
FIG. 5. The polymerization of ethylene. First-order plot.

that the reaction is not entirely first order. A consideration of a second-order process at constant pressure would give

$$dV/dt = -k_2P,$$

which would also be a straight line under the conditions of reaction.

The amount of curvature evident in the time rate of change of volume of Fig. 7 is a measure of the departure from either first or second order. From the constant-volume experiments it is evident that the rate deviates from the first-order case.

The initial attempt to explain our kinetic data was based on the following mathematical analysis. In the first approximation the following differential equations were said to govern the progress of the polymerization step. It is to be borne in mind that the catalyst is preformed and active. No initiation reaction is necessary.

[1] $$-dE/dt = k_1E$$

[2] $$-dC/dt = k_2(E_0-E)C$$

[3] $$k_1 = k_3C$$

$E \equiv$ concentration of ethylene at time t, $E_0 \equiv$ initial concentration of ethylene, $C \equiv$ concentration of catalyst at time t, $C_0 \equiv$ initial concentration of catalyst.

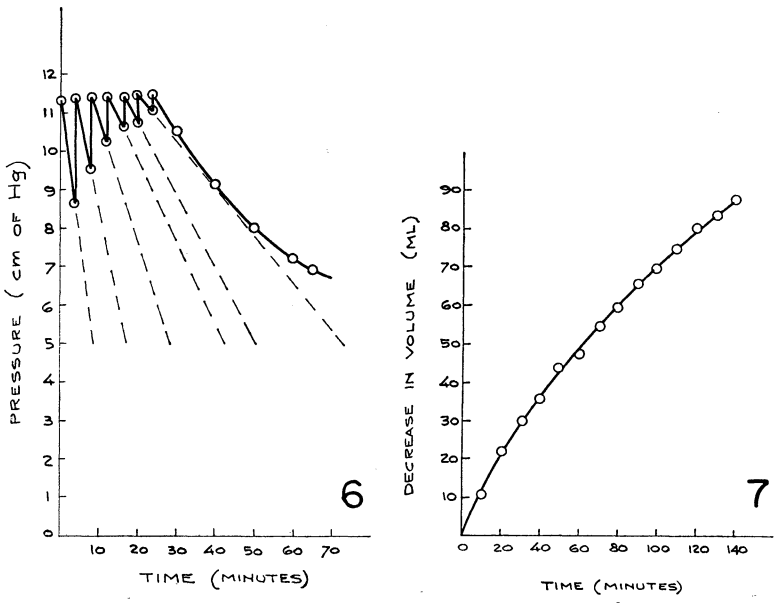

FIG. 6. The polymerization of ethylene at constant pressure.
FIG. 7. The polymerization of an α olefin at constant pressure (automatic gas burette).

Equation [1] represents the first-order polymerization mechanism.

Equation [2] was derived in an intuitive fashion and represents the decrease in effective catalyst concentration (i.e. number of active sites) brought about by buildup of polymer around the site. This explanation for the decrease in polymerization rate has been suggested by Feilchenfeld and Jeselson (18) and also by Ludlum and his co-workers (13).

Equation [3] links the rate of polymerization with the concentration of catalyst.

Rewriting [1]

$$dE/dt = -k_3CE.$$

For ease in manipulation we shall make concentration and time terms dimensionless. Dividing by E_0 and letting E/E_0 be represented by Y

$$dY/dt = -k_3CY.$$

Dividing by C_0 and letting C/C_0 be represented by X

[4] $$dY/dt = -k_3C_0XY.$$

Transposing [2]

[5] $$dX/dt = -k_2E_0(1-Y)X.$$

At $t = 0$, $k_3C_0 = k_{1_0}$ (the initial rate constant) and $X = Y = 1$. Let $k_3C_0 \equiv \lambda$ and $\lambda t \equiv \tau$, and normalizing time, [4] becomes

[6] $$dY/d\tau = -XY$$

and [5] becomes

[7] $$dX/d\tau = -\alpha(1-Y)X,$$

where $\alpha = k_2E_0/k_3C_0$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Equations [6] and [7] were then set up on an analogue computer and a family of solutions developed for various values of α. The solutions thus generated were then compared with the experimental curve and it was found that the solution obtained for an α value of 0.32 closely fitted the experimental results.

The experimental results just applied to the theoretical equations have been obtained from measurements made in a constant-volume system. If the theory is to be correct it should also apply to measurements made under constant pressure. The analogue computer was wired so as to perform a hypothetical constant-pressure experiment using the theoretical equations outlined previously. The results of this experiment showed that the theoretical equations were not adequate to describe the changing initial rate data found experimentally.

A new system of equations was then set up. The rate of catalyst decay was said to be proportional to the *rate* of ethylene polymerization. In this particular case equation [6] does not change but equation [7] becomes

$$dX/d\tau = -\alpha(X\,Y)X. \qquad [8]$$

It was found that the solutions generated using equations [6] and [8] fitted the constant-pressure experiments, but failed to satisfy the constant-volume data.

The third case considered was that in which the catalyst decayed in a purely exponential fashion. In this instance equation [7] takes the form

$$dX/d\tau = -kX. \qquad [9]$$

Once again, it was found that the solutions of the differential equations did not fit all of the experimental situations.

The mathematical expressions were again studied and it was found that if both constant-pressure and constant-volume conditions were to be met, another term would have to be introduced into equation [7]. The expressions

$$dY/d\tau = -X\,Y$$

and

$$dX/d\tau = -\{\alpha(1-Y)X + \beta X\}, \qquad [10]$$

where βX represents exponential catalyst decay, gave a solution which satisfied all conditions. β is a constant equal to K/k_3C_0 in the normalized expressions given above, K being the decay rate constant.

The specific solution fitting the experimental measurements has a value of $\alpha = 0.38$ and a value of $\beta = 0.10$. It is evident from the expressions given above that in the initial stages of reaction the falloff in rate is due solely to catalyst decay, which has been shown to be slow from a study of experiments in which the catalyst was aged previous to the introduction of ethylene. As polymer builds up around the active site less monomer is able to reach it and the rate begins to drop.

The diffusion processes which have some influence on the chemical process are at present under study.

Estimation of the Rate Constant for Catalyst Decay

If we consider the initial stages of the polymerization and also assume that the only catalyst decay process of importance during that particular stage is normal exponential decay the constant-pressure experiments may be used to estimate the rate constant

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of this decay process. It is recognized that the above approximation is rather great but nonetheless the calculation is included since the method might find application to other processes.

Consider the curvature of the time rate of change of volume depicted in Fig. 7. Under conditions of constant pressure

$$dV/dt = -k_E n_{cat}, \tag{11}$$

where $V \equiv$ volume, $t \equiv$ time, $k_E \equiv$ a rate constant for volume change, $n_{cat} \equiv$ number of moles of catalyst or number of active sites.

Making use of our aforementioned assumption involving first-order catalyst decay

$$dn_{cat}/dt = -k_{cat} n_{cat}. \tag{12}$$

Integrate [12] and apply the condition that $n_{cat} = n_0$ at $t = 0$

$$n_{cat} = n_0 \epsilon^{-k_{cat} t}. \tag{13}$$

Put [13] into [11]

$$dV/dt = -k_E n_0 \epsilon^{-k_{cat} t}.$$

At $t = 0$

$$dV/dt = -k_E n_0.$$

Let $\phi = (k_E/k_{cat})n_0$, then at $t = 0$,

$$dV/dt = -k_{cat}\phi.$$

Also it may be shown that

$$\begin{aligned} \Delta V &= (k_E/k_{cat})n_0[\epsilon^{-k_{cat} t} - 1] \\ &= \phi[\epsilon^{-k_{cat} t} - 1]. \end{aligned}$$

Select any pair of values of ΔV and t. Find, by trial and error, various values of ϕ and k_{cat} which fit. Plot ϕ as a function of k_{cat}. Repeat for other values of ΔV and t which are widely separated.

The intersection of the family of curves, Fig. 8, denotes unique values of k_{cat} and ϕ.

A value of $k_{cat} = 1.6 \times 10^{-2}$ min^{-1} has been determined from a number of experiments.

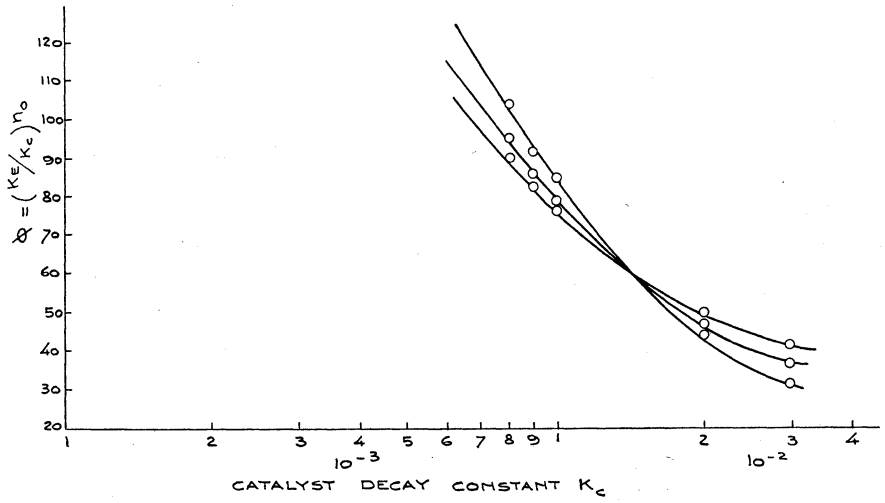

FIG. 8. Estimation of rate constant for catalyst decay.

Activation Energy for the Polymerization of Ethylene

The initial rate constant of polymerization of ethylene was measured at temperatures of 30° C and 40° C as well as 21° C. (The catalyst in all cases was formed at 21° C.) A plot of the log of the rate constant as a function of reciprocal absolute temperature was drawn. A straight line resulted and the activation energy for the overall polymerization reaction was calculated from the slope. This was found to be approximately 10 kcal/mole in agreement with Badin's (15) value of 10 kcal/mole for the polymerization of ethylene in the catalyst system $TiCl_4$ + $(isobutyl)_3Al$ and Natta's (19) value of 11.7 kcal/mole for a cyclopentadienyl catalyst system.

NEW CONSIDERATIONS IN ORGANOGERMANIUM-SULPHUR CHEMISTRY[1]

MALCOLM C. HENRY AND WENZEL E. DAVIDSON[2]
Organic Chemistry Laboratory, Pioneering Research Division, U.S. Army Laboratories, Natick, Mass., U.S.A.
Received October 29, 1962

ABSTRACT

The successful synthesis of sodium triphenylgermanethiol (1), $(C_6H_5)_3GeSNa$, and disodium diphenylgermanedithiol, $(C_6H_5)_2Ge(SNa)_2$, have made it possible to carry out reactions with RX type compounds yielding a variety of organogermanium-sulphur compounds. In addition, triphenylgermanethiol, $(C_6H_5)_3GeSH$, has been synthesized for the first time. Reactions of these compounds are related to analogous group IV element compounds. Physical and chemical properties of these new compounds are also discussed.

Although many organogermanium compounds have been prepared within the last 20 years, only relatively few papers (17 out of about 400) have dealt with thiogermanium compounds. Basically two methods are available for synthesizing tetraalkyl- and tetraaryl-thiogermanes (2–6):

$$GeCl_4 + 4NaSR \rightarrow Ge(SR)_4 + 4NaCl$$

$$GeCl_4 \cdot 2C_5H_5N + 4RSH \rightarrow Ge(SR)_4 + 2C_5H_5N \cdot HCl$$

Bis-trialkyl(aryl) sulphides, $R_3GeSGeR_3$, have been prepared by Burschkies (7) by the reaction of substituted monobromogermanes with sodium sulphide. Anderson (8, 9) has synthesized a group of triethylgermanethiol derivatives as follows:

$$Et_3GeOAc + ArSH \rightleftharpoons Et_3GeSAr + HOAc.$$

It should be noted that this method is limited to those cases where the product acid is the most volatile compound of the reaction mixture.

Finally, a few compounds of the types R_2GeS (10–15), $R_2Ge(SCN)_2$ (16), and $(R_2GeS)_2S$ (17), where R is usually an alkyl substituent, have also been reported.

The sparsity of information about this general area of organogermanium chemistry and more specifically about the chemistry of di- and tri-phenylgermanethiol derivatives prompted us to investigate possible methods for preparing these general types of compounds.

RESULTS AND DISCUSSION

Generally considered, organogermanium and organosilicon compounds exhibit rather similar properties. Considerable difference exists, however, between the hydrolytic stability of germanium–sulphur and silicon–sulphur bonds.

Due to the stability of the recently described sodium triphenylgermanethiol, $(C_6H_5)_3GeSNa$ (1), attempts were made to prepare the analogous compounds of the other group IV elements. Sodium triphenylsilanethiol, $(C_6H_5)_3SiSNa$, could not be formed under the preparative conditions used (hydrated sodium sulphide) probably due to

hydrolysis of the initially formed product. Sodium triphenyltinthiol, $(C_6H_5)_3SnSNa$, was prepared and one derivative, $[(C_6H_5)_3SnSGe(C_6H_5)_3]$, prepared from the salt. The initial sodium salt for the case of the tin compound could not be recrystallized and the crude powder was used directly for the subsequent reaction with the RX compound, in this case triphenylbromogermane. Other work in our laboratories (18) has shown that sodium triphenylleadthiol, $(C_6H_5)_3PbSNa$, existed in solution only and was not stable enough to be isolated. Reactions with RX type compounds were carried out in solution, however, and derivatives were prepared to establish the existence of the unstable salt.

Attempts to prepare bis-triphenylgermanium disulphide by halogenation of sodium triphenylgermanethiol failed. Instead a cleavage of the germanium–sulphur bond was observed. Reaction of the sodium salt with sulphonyl chlorides or hydrogen peroxide yielded the bis-triphenylgermanium disulphide, a bright yellow compound melting at 171° C. The reaction is as follows:

$$Ph_3GeSNa + RSO_2Cl \rightarrow [Ph_3GeSSO_2R + NaCl]$$

$$2Ph_3GeSNa + RSO_2Cl \rightarrow Ph_3GeSSGePh_3 + RSO_2Na + NaCl$$

$$(C_6H_5)_3GeSNa \xrightarrow{H_2O_2} (C_6H_5)_3GeSSGe(C_6H_5)_3,$$

where R = $-CH_3$, $-C_6H_4CH_3$-*p*. It is interesting to note that the analogous carbon compound, bis-triphenylmethyl disulphide, $(C_6H_5)_3CSSC(C_6H_5)_3$, is colored only in solution. Analogous silicon, tin, and lead compounds are unknown. The bis-triphenylgermanium trisulphide (obtained by the reaction of sodium triphenylgermanethiol with sulphur chloride, SCl_2 (1)) is slightly yellow.

Etienne's method (19) for the synthesis of triphenylsilanethiol was successfully used for the preparation of the analogous triphenyl germanethiol, $(C_6H_5)_3GeSH$, as follows:

$$(C_6H_5)_3GeBr + H_2S + C_5H_5N \rightarrow (C_6H_5)_3GeSH + C_5H_5N \cdot HBr.$$

This white, crystalline compound is stable in dry air; however, in the presence of moist air a slight hydrogen sulphide odor developed. It is known that triphenylmethylthiol easily splits off hydrogen sulphide in the presence of moisture in contrast to the more stable aliphatic thiols (20).

Oxidation of triphenylgermanethiol with iodine produced bis-triphenylgermanium disulphide as follows:

$$2(C_6H_5)_3GeSH + I_2 \rightarrow (C_6H_5)_3GeSSGe(C_6H_5)_3 + 2HI.$$

Reaction with acrylonitrile under a variety of conditions gave no addition to the carbon–carbon double bond. Instead, bis-triphenylgermanium sulphide was produced along with the evolution of hydrogen sulphide. Similar results were obtained when the thiol was reacted with benzoyl chloride or other halides in the presence of equivalent amounts of pyridine. If pyridine was used as solvent, reactions between the thiol and RX compounds could be carried out without difficulty and the expected products, $(C_6H_5)_3GeSR$, isolated in good yield as follows:

$$(C_6H_5)_3GeSH + RX \xrightarrow{C_5H_5N} (C_6H_5)_3GeSR + HX.$$

Reaction of triphenylgermanethiol with dithiocyanogen, $(SCN)_2$, did not yield the expected sulphur-thiocyanogen compound but rather the simpler germanium-thiocyanogen compound and elemental sulphur. This reaction will be further studied since

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the formation of elemental sulphur indicates that the thiocyanate derivative of triphenylgermanethiol at least existed as an intermediate as follows:

$$(C_6H_5)_3GeSH + (SCN)_2 \rightarrow [(C_6H_5)_3GeSSCN] + HSCN$$
$$\downarrow \text{ decomp.}$$
$$(C_6H_5)_3GeSCN + S^0.$$

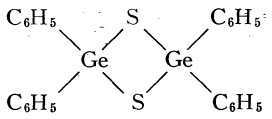
Since the syntheses of sodium triphenylgermanethiol and triphenylgermanethiol were reasonably facile and useful for synthesizing a variety of organogermanium derivatives, it was of interest to prepare the corresponding disubstituted compounds, which should lead to interesting polymer-forming materials. The same method used in the synthesis of the monosodium salt was applied with success to diphenyldibromogermane as follows:

$$(C_6H_5)_2GeBr_2 + 2Na_2S \rightarrow (C_6H_5)_2Ge(SNa)_2 + 2NaBr.$$

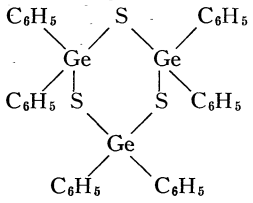
A white crystalline material was isolated in good yield which, upon examination, turned out to be the trihydrate of disodium diphenylgermanedithiol. This compound is not soluble in benzene but soluble in alcohol, acetone, tetrahydrofuran, and dimethylformamide. The dehydrated product is not as stable as the hydrate and seems to decompose.

Thus far, only a few reactions have been performed with this compound. It reacts with triphenylbromogermane forming the expected, known bis-triphenylgermylthio diphenylgermane, $(C_6H_5)_2Ge[(SGe(C_6H_5)_3]_2$ (1). Reaction of the trihydrate with methyl iodide produced a liquid which according to its infrared spectrum is probably diphenyldimethylthiogermane. Elemental analyses and molecular weight determinations indicate that the compound was not analytically pure.

Benzoyl chloride (and *p*-nitrobenzoyl chloride) react with the trihydrate to form diphenylgermanium sulphide and benzoic acid (*p*-nitrobenzoic acid). It is probable that the halide reacted first with the water of the hydrate to form hydrochloric acid, which then interacted with the sodium salt to form diphenylgermanium sulphide, $[(C_6H_5)_2GeS]_n$. This sulphide exists, as shown by melting points and molecular weight determinations, in both dimeric and trimeric forms:

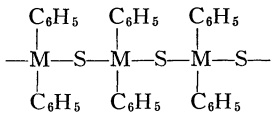


m.p. 203° C



m.p. 170° C

Similar dimers and trimers are known in the case of dialkylsilicon sulphides (21). Diphenylsilicon sulphide is reported to exist only in the dimeric form (22) while analogous organotin and -lead sulphides apparently form only trimers (14). Thus far, there is no evidence for the existence of an open-chain structure of the type



where M = Si, Ge, Sn, or Pb.

Successful attempts to synthesize diphenylgermanedithiol have not been realized. There is some evidence that it may exist in solution; however, it is analogous to carbon-*gem*-thiols and not expected to exhibit a high degree of stability.

EXPERIMENTAL

Melting points were carried out on a Kofler hot stage or a Thomas-Hoover melting point apparatus and are uncorrected. Molecular weight determinations were carried out using a Mechrolab vapor pressure osmometer, Model 301A.

Synthesis of Triphenylgermanethiol

Triphenylbromogermane, 10 g, was dissolved together with 2.1 g pyridine in 150 ml benzene in a round-bottom flask. The clear solution was stirred (magnetic stirrer) at room temperature while hydrogen sulphide gas was bubbled through for a period of 90 minutes. A white precipitate (4.1 g) of pyridine hydrobromide formed during the reaction period and was subsequently filtered. The filtrate was evaporated in vacuum at 25–30° C to dryness. A white crystalline substance (8.65 g; 97% yield), m.p. 110–114, remained in the flask. After recrystallization from benzene, there was obtained 7.6 g of white prisms with a yield of 86% pure triphenylgermanethiol. The molecular weight found was 336 (in benzene); calculated 336.88. The infrared spectrum showed the characteristic SH absorption, at 2450 cm^{-1}. Found: Ge, 21.57; S, 9.49; C, 64.08; H, 4.83. Calc. for $C_{18}H_{16}GeS$: Ge, 21.55; S, 9.52; C, 64.10; H, 4.79.

Oxidation of Triphenylgermanethiol with Iodine

A solution of 0.5 g of triphenylgermanethiol dissolved in 25 ml benzene was added to 25 ml distilled water in a separatory funnel. Iodine, 0.19 g, dissolved in 25 ml benzene was added in four parts to the mixture, which was thoroughly agitated after each addition in order to remove the hydrogen iodide as it is formed. The iodine color disappeared after 2 minutes. After separation of the aqueous phase, the benzene solution was washed with 20 ml of 1% sodium hydroxide, 20 ml water, then dried with anhydrous sodium sulphate, filtered, and evaporated in vacuum. A yellow crystalline substance, 0.45 g, with m.p. 160–170° C, was isolated. Recrystallization from toluene yielded 0.25 g yellow, bis-triphenylgermanium disulphide, m.p. 171–172. A mixed melting point with an authentic sample gave no depression.

Reaction of Triphenylgermanethiol with Benzoyl Chloride in Pyridine

Benzoyl chloride, 1.67 g (11.9 mmoles), was added to a stirred solution of triphenylgermanethiol, 4 g (11.9 mmoles), during the course of a few minutes. Heat was evolved and the solution turned slightly yellow. It was stirred 30 minutes and then evaporated in vacuum. The residue was dissolved in 20 ml benzene and transferred into a separatory funnel. To remove the last traces of pyridine, the benzene solution was extracted twice with dilute sulphuric acid (1–2%), then washed twice with water. After the benzene phase had been dried with anhydrous sodium sulphate, it was filtered and again evaporated in vacuum. Yield: 4.7 g of crude benzoylthiophenylgermane (90%). It was recrystallized from petroleum ether (60–110°) and yielded 3.7 g of the pure compound (70%), m.p. 145.5° C.

Reaction of Triphenylgermanethiol with Thiocyanogen

*(1) Preparation of $(SCN)_2$ (Lit.: H. Lecher and K. Simon. Ber. **54**, 632 (1921))*

One milliliter bromine was dissolved in 150 ml of ice-cold ether (anhydrous), and 7.5 g lead thiocyanate was added immediately. The mixture was stirred until the bromine color disappeared (about 30 minutes), the solution filtered into a round-bottom flask, and the filtrate washed with 20 ml ether.

(2) Reaction of Triphenylgermanethiol with the $(SCN)_2$ Solution

A solution of 6.2 g triphenylgermanethiol in 30 ml ether was added rapidly to the stirred $(SCN)_2$ solution. After 15 minutes, the clear solution was evaporated in vacuum at normal temperature and the slightly yellow residue (m.p. 100–105°) was recrystallized from petroleum ether 60–110°. Yield: 3.8 g white crystals, m.p. 105°. From the filtrate an additional 0.8 g was isolated and about 150 mg of bright yellow crystals which were identified as elemental sulphur. Yield: 68% for $(C_6H_5)_3GeSCN$. Analysis: Calc. for $(C_6H_5)_3GeSCN$: Ge, 20.00; S, 8.85; C, 63.10; H, 4.18. Found: S, 9.04; C, 62.90; H, 4.20. Mol. wt.: Calc.: 362. Found: 352.

A heated aqueous suspension of the compound with ferric ion gave the characteristic red color of ferric thiocyanate.

Preparation of the Thiocyanate from the Reaction of Triphenylgermaniumbromide with Leadthiocyanate

One gram $(C_6H_5)_3GeBr$ was stirred with a suspension of 2 g lead thiocyanate in benzene (20 ml) for 1 hour. It was filtered, the filtrate evaporated, and the residue recrystallized from petroleum ether 60–110°. Yield: 0.4 g (42%) white crystals, m.p. 105°. Mixed m.p. 105° (with $(C_6H_5)_3GeSCN$). (The filtrate was discarded.)

Synthesis of Disodium Diphenylgermanedithiol, $(C_6H_5)_2Ge(SNa)_2 \cdot 3H_2O$

Diphenyldibromogermane, 5 g (16 mmoles), dissolved in 25 ml of benzene, was added dropwise over a 30-minute period into a round-bottom flask (cooled in an ice bath) containing an alcoholic suspension of sodium sulphide pentahydrate, 10 g (60 mmoles). The solution was stirred for 1 hour and filtered. The filtrate was evaporated to dryness, leaving a slightly yellow residue (12.5 g), which was extracted with 40 ml benzene at room temperature for 30 minutes. After filtration and a final washing of the insoluble residue with an

additional 15 ml of benzene, the combined filtrates were evaporated to about a 20-ml volume. Shiny crystalline plates formed upon standing. Filtration of the crystals and washing with small amounts of benzene resulted in more crystals being formed in the filtrate. In this manner, a second and third crop of crystals could be collected. (Yield based on total three fractions, 4 g (79%). Final evaporation of the filtrate yielded a yellow "oil like" residue. These fractions are all transparent crystalline plates soluble in alcohol and water with a strong alkaline reaction, insoluble in benzene, hexane, heptane, carbon tetrachloride, and petroleum ether. In addition, there was no melting point up to 330° C. Attempts at recrystallization by dissolution in alcohol and addition of benzene or petroleum ether were not successful.

Analytical Results and Conclusions

Elemental analyses of the disodium diphenylgermanedithiol were as follows: Calc. for $(C_6H_5)_2Ge(SNa)_2$: C, 42.80; S, 19.02; H, 2.99. Found: C, 36.60; S, 16.12; H, 4.25.

As a result of the above analyses and because the S:C ratio in the analyzed product is 1:6 in agreement with the proposed disodium diphenylgermanedithiol, we suspected that the compound contained water of hydration. Therefore, 0.4549 g of the compound was stored for 2 days in a vacuum desiccator over phosphorus pentoxide. During this period the crystals lost 0.0608 g of weight, an amount equal to a 13.4% weight loss. Further standing produced no additional weight loss. The theoretical amount of water in disodium diphenylgermanedithiol trihydrate is 13.5%.

Thus, upon re-examination of the analytical data, based upon a trihydrate, it appeared that this compound was the stable organogermanium trihydrate. Calc. for $(C_6H_5)_2Ge(SNa)_2 \cdot 3H_2O$: C, 36.90; S, 16.35; H, 4.10.

Reaction with Diphenyldibromogermane

One gram of the trihydrate was dissolved in 20 ml ethanol, and 0.99 g diphenyldibromogermane dissolved in 20 ml benzene was added. The mixture was stirred for 1 hour. A white crystalline precipitate appeared and H_2S was developed. The mixture was evaporated in vacuum, the residue extracted with benzene, filtered, and again evaporated to yield 1.44 g of product with m.p. 165–197° C. After two recrystallizations from benzene, two fractions were isolated.

Fraction 1.—0.3 g fine needles, m.p. 198.5–200.5°. Mol. wt. found: 516 (benzene); 531 (chloroform). Theoretical molecular weight based on dimer: 517.7.

Fraction 2.—0.3 g small plates with m.p. 170–173°. Mol. wt. found: 754 (benzene); 774 (chloroform). Theoretical mol. wt. calculated for trimer: 776.

Reaction with Triphenylbromogermane

A solution of 229.5 mg of triphenylbromogermane was added to a solution of 100 mg of disodium diphenylgermanedithiol trihydrate dissolved in 20 ml of absolute alcohol. The mixture was stirred for 90 minutes and then evaporated to dryness. The residue was extracted with boiling benzene and cooled. The crystals which separated were identified as bis-triphenylgermylthio diphenylgermane by melting point and mixed melting point with an authentic sample, 162° C.

ACKNOWLEDGMENT

The authors are grateful to C. DiPietro of these laboratories for the microanalyses.

THE ELECTRONIC STRUCTURES AND REACTIVITIES OF $Mn(CO)_5X$ COMPLEXES[1, 2]

ABSTRACT

The bonding in $Mn(CO)_5X$ complexes is described in terms of molecular orbitals. The axial CO group is assumed to be bonded much more strongly to Mn than the other four CO groups. The molecular orbital energy level scheme thus derived successfully accounts for the principal features of the electronic spectra of $Mn(CO)_5X$ complexes in different solvents. The first charge transfer band is assigned as an $n(Mn) \rightarrow \pi^*(CO)$ type transition. This $n \rightarrow \pi^*$ assignment is supported by the fact that the maximum of the band for $Mn(CO)_5Br$ is shifted to higher energies on increasing the polarity of the solvents employed.

Kinetic studies of $Mn(CO)_5X$–^{14}CO exchange reveal that the axial CO is more inert than the other four CO groups; also, the rates of ^{14}CO exchange of the four equivalent CO groups in $Mn(CO)_5X$ complexes depend strikingly on the nature of the X^- ligand. A consistent interpretation of the above results and the observed kinetics of some typical substitution reactions of $Mn(CO)_5X$ complexes is presented in terms of the derived electronic structural description.

Carbon monoxide, cyanide ion, and nitric oxide form the simplest transition metal complexes in which π-bonding involving empty π-antibonding ligand molecular orbitals is an important part of the overall electronic structural description. The $Mn(CO)_5X$ complexes (X = Cl, Br, I, NO_3, CH_3, etc.) are of particular interest since they are representative of the important class of metal carbonyls and nitrosyls which have a distorted octahedral structure with one particularly strong metal–ligand bond (1).

This paper presents a molecular orbital description of the electronic structures of the $Mn(CO)_5X$ complexes. The spectral properties and chemical reactivities of the complexes are discussed in terms of the derived molecular orbital energy level scheme.

MOLECULAR ORBITALS FOR $Mn(CO)_5X$ COMPLEXES

The $Mn(CO)_5X$ complexes have a distorted octahedral structure (C_{4v}), as shown in Fig. 1. Both infrared (2) and kinetic studies (3, 4, 5) (*vide infra*) indicate that the axial CO is bound considerably more tightly to Mn than the four CO's in the *xy* plane. This implies that there is more [Mn—C]O π-bonding for the axial CO, with the result that the Mn—C(5) distance is shorter than Mn—C(1–4), and the C—O(5) distance is longer than C—O(1–4).

The orbital transformation scheme for the C_{4v} symmetry is summarized in Table I. The general bonding scheme is rather complicated, since all metal and ligand orbitals of the same symmetry may interact. However, it is useful to describe the principal features of the electronic structure.

There is a strong σ-bond between the Mn and CO(5), involving mainly the $(3d_{z^2}+4s)$ metal orbital combination and the carbon $2s$ and $2p_z$ orbitals. The π-bonding between Mn

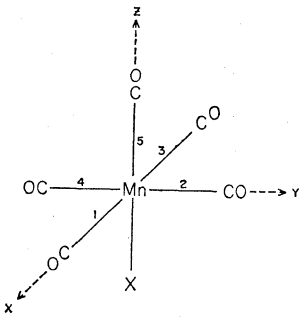

FIG. 1. Structure of $Mn(CO)_5X$.

TABLE I

Orbital transformation scheme for $Mn(CO)_5X$ complexes with C_{4v} symmetry

		Ligand orbital totals	
Representation	Mn orbitals	σ	π
a_1	$3d_{z^2}$, $4s$, $4p$	3	1
a_2	—	—	1
b_1	$3d_{x^2-y^2}$	1	1
b_2	$3d_{xy}$	—	1
e	($3d_{xz}$, $3d_{yz}$) ($4p_x$, $4p_y$)	1	4

and CO(5) involves mainly the metal $3d_{xz}$, $3d_{yz}$, and the CO(5) π-bonding (π^b) and π-antibonding (π^*) molecular orbitals. The $4p_x$, $4p_y$ metal orbitals may also interact in this π-molecular orbital system to some extent, although they participate mainly in σ-bonding. This Mn—CO(5) π-interaction yields one strongly bonding, one virtually nonbonding, and two antibonding molecular orbitals.

The four σ-bonds between Mn and the four CO's in the xy plane are formed using the $(4s-3d_{z^2})$, $3d_{x^2-y^2}$, $4p_x$, and $4p_y$ metal orbitals and the $(2s+2p_z)$ carbon orbitals. The metal $4p_z$ orbital may be used to σ-bond with the σ-orbital of the axial X^- ligand.

For π-bonding purposes the four CO's in the xy plane have exclusive claim only to the $3d_{xy}$ metal orbital. The other metal orbitals of the right symmetry for π-bonding with the planar CO's ($4p_x$, $4p_y$, $4p_z$, $3d_{xy}$, $3d_{yz}$) all are involved either in σ-bonding ($4p_x$, $4p_y$, $4p_z$) or stronger π-bonding ($3d_{xy}$, $3d_{yz}$). The p_x, p_y π-orbitals of the X^- ligand may interact with the $3d_{xz}$, $3d_{yz}$ metal orbitals. As a result, the nonbonding π-molecular orbital (mostly composed of the Mn $3d_{xz}$, $3d_{yz}$) from the Mn—CO(5) π-system is made more unstable, while the π-molecular orbital mostly localized on the X^- ligand is made slightly bonding.

The single electron molecular orbital energy level scheme for the bonding situation described above is shown in Fig. 2. Coulomb energies are taken in the order

$$\sigma(CO,X) < \pi^b(CO) < \pi(X) < 3d < 4s < \pi^*[CO(5)] < \pi^*[CO(1\text{–}4)] < 4p.$$

The π^*[CO(5)], π^*[CO(1–4)] energy order is taken consistent with the infrared (2) and kinetic evidence (3, 4, 5) (*vide infra*). To simplify the diagram (Fig. 2), all the single electron π^b and π^* molecular orbitals mostly localized on the planar CO's are grouped together in a box and are indicated as [π^b, CO(1–4)] and [π^*, CO(1–4)], respectively.

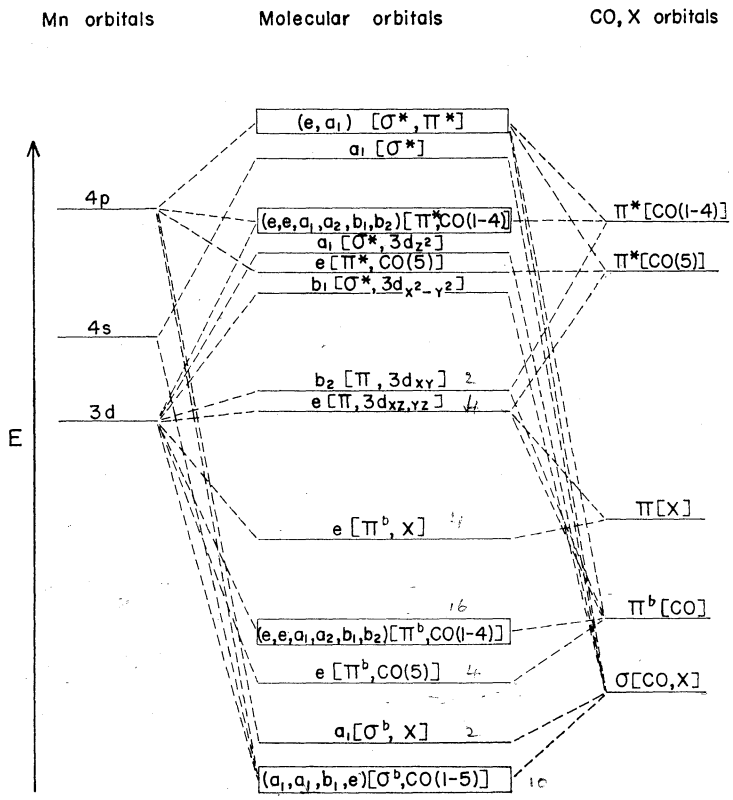

FIG. 2. Single electron molecular energy level scheme for $Mn(CO)_5X$.

ELECTRONIC SPECTRA OF $Mn(CO)_5X$ COMPLEXES

A $Mn(CO)_5X$ complex contains Mn^+ ($3d^6$), five CO's (10 σ, 20 π^b electrons), and one X^- (2 σ, 4 π electrons). Thus a total of 42 electrons are assigned to the single electron molecular orbital level scheme. The ground state is $[\sigma^b, CO(1\text{–}5)]^{10}[\sigma^b, X]^2[\pi^b, CO(5)]^4$-$[\pi^b, CO(1\text{–}4)]^{16}[\pi^b, X]^4[\pi, 3d_{xz,yz}]^4[\pi^*, 3d_{xy}]^2 = {}^1A_1$. The electronic transitions of lowest energy fall into five categories and will be considered separately. In order to estimate the energy range of each type of transition it is necessary to have values for some of the coulomb energies. These values (with references) are given in Table II.

A. Transitions Mostly Localized on the Central Mn, or the d–d transitions

These are the transitions

$$b_2[\pi^*, 3d_{xy}] \rightarrow b_1[\sigma^*, 3d_{x^2-y^2}] \ ({}^1A_1 \rightarrow {}^1A_2),$$
$$b_2[\pi^*, 3d_{xy}] \rightarrow a_1[\sigma^*, 3d_{z^2}] \ ({}^1A_1 \rightarrow {}^1B_2),$$
$$e[\pi, 3d_{xz,yz}] \rightarrow b_1[\sigma^*, 3d_{x^2-y^2}] \ ({}^1A_1 \rightarrow {}^1E),$$
$$e[\pi, 3d_{xz,yz}] \rightarrow a_1[\sigma^*, 3d_{z^2}] \ ({}^1A_1 \rightarrow {}^1E).$$

Since the value (6) of the d–d splitting parameter Δ for $Cr(CO)_6$ is considerably greater than 30,000 cm^{-1}, 30,000 cm^{-1} will be taken as a lower limit for Δ in the $Mn(CO)_5X$ complexes. Therefore the d–d bands for $Mn(CO)_5X$ complexes may reasonably be expected to appear at such high energies that they will be masked by charge transfer bands.

TABLE II
Estimated orbital energies for $Mn(CO)_5X$ complexes

Orbital	Energy (cm^{-1})
$3d$(Mn)	− 70,000[a]
	− 85,000 (I)[b]
π(X)	− 90,000 (Br)[b]
	− 95,000(Cl)[b]
π^b[CO(1–4)]	−110,000[c]
π^*[CO(5)]	− 40,000[d]
π^*[CO(1–4)]	− 30,000[d]

[a]Data for Mn(I) from Moore (C. E. Moore. Atomic energy levels. U.S. Natl. Bur. Std. Circ. 467. 1949 and 1952).
[b]Ionization potentials corrected for the estimated residual negative charges, −0.25 (Cl), −0.20 (Br), and −0.15 (I).
[c]Ionization potential of CO from Field and Franklin (F. H. Field and J. L. Franklin. Electron impact phenomena. Academic Press, New York. 1957. p. 280), which gives an upper limit for the orbital energy.
[d]From spectroscopic data, see G. Herzberg, Spectra of diatomic molecules, Van Nostrand, New York, 1950, p. 452; π^* level for CO(5) is estimated to be 10,000 cm^{-1} more stable than π^* for CO(1–4), in agreement with kinetic and infrared evidence.

B. Charge Transfer from X to Mn

The first such transition would be $e[\pi^b, X] \rightarrow b_1[\sigma^*, 3d_{x^2-y^2}]$ ($^1A_1 \rightarrow {}^1E$). The energy of this transition is expected to fall in the range 50,000–60,000 cm^{-1}, considering that the $e[\pi^b, X]$ is more stable than −85,000 cm^{-1}. The next transition is $e[\pi^b, X] \rightarrow a_1[\sigma^*, 3d_z]$ ($^1A_1 \rightarrow {}^1E$), of even higher energy.

C. Charge Transfer from π^b Molecular Orbitals Mostly Localized on the CO's to Mn

The lowest-energy transitions of this type would be $(e,e,a_1,a_2,b_1,b_2)[\pi^b, CO(1–4)] \rightarrow b_1[\sigma^*, 3d_{x^2-y^2}]$ ($^1A_1 \rightarrow {}^1E$, ^1E, $^1B_1$, $^1B_2$, $^1A_1$, $^1A_2$), calculated to appear in the range 70,000–80,000 cm^{-1}.

D. Charge Transfer from Mn to π^* Molecular Orbitals Mostly Localized on the CO's

The lowest-energy transition is $b_2[\pi^*, 3d_{xy}] \rightarrow e[\pi^*, CO(5)]$ ($^1A_1 \rightarrow {}^1E$), estimated at about 30,000 cm^{-1}. There are a number of excited states at slightly higher energies, due to the transitions $e[\pi, 3d_{xz,yz}] \rightarrow e[\pi^*, CO(5)]$ ($^1A_1 \rightarrow {}^1A_1$, $^1A_2$, $^1B_1$, $^1B_2$) and $b_2[\pi^*, 3d_{xy}] \rightarrow (e,e,a_1,a_2,b_1,b_2)[\pi^*, CO(1–4)]$ ($^1A_1 \rightarrow {}^1E$, ^1E, $^1B_1$, $^1B_2$, $^1A_1$, $^1A_2$). The highest-energy excited states of the $Mn \rightarrow CO(\pi^*)$ type are due to the transition $e[\pi, 3d_{xz,yz}] \rightarrow (e,e,a_1, a_2,b_1,b_2)[\pi^*, CO(1–4)]$ ($^1A_1 \rightarrow {}^1A_1$, $^1A_2$, $^1B_1$, $^1B_2$, $^1A_1$, $^1A_2$, $^1B_1$, $^1B_2$, ^1E, ^1E, ^1E, ^1E) and are expected to appear around 45,000 cm^{-1}.

E. Charge Transfer from X to π^* Molecular Orbitals Mostly Localized on the CO's

The first transition of this type is $e[\pi^b, X] \rightarrow e[\pi^*, CO(5)]$ ($^1A_1 \rightarrow {}^1A_1$, $^1A_2$, $^1B_1$, $^1B_2$), expected to appear at about 50,000 cm^{-1}.

A summary of these transitions and their expected energies is given in Table III.

The electronic spectra of $Mn(CO)_5X$ complexes (X = Cl, Br, I) show two bands below 50,000 cm^{-1}, one in the 43,000–50,000 cm^{-1} and one in the 25,000 cm^{-1} region. These spectra are given in Table IV. It is clear from the discussion above that $Mn[3d(\pi^*)] \rightarrow CO(\pi^*)$ charge transfer will appear at lowest energy, and thus the two bands are assigned as follows: 25,000 cm^{-1} band: $b_2[\pi^*, 3d_{xy}] \rightarrow e[\pi^*, CO(5)]$ ($^1A_1 \rightarrow {}^1E$); 43,000–50,000 cm^{-1} band: $e[\pi, 3d_{xz,yz}] \rightarrow (e,e,a_1,a_2,b_1,b_2)[\pi^*, CO(1–4)]$ ($^1A_1 \rightarrow {}^1A_1$, $^1A_2$, $^1B_1$, $^1B_2$, $^1A_1$, $^1A_2$, $^1B_1$, $^1B_2$, ^1E, ^1E, ^1E, ^1E). The 25,000 cm^{-1} band in $Mn(CO)_5X$ complexes may be considered as being related to the 35,780 cm^{-1} band ($^1A_{1g} \rightarrow {}^1T_{1u}{}^{(1)}$) in $Cr(CO)_6$,

[b]In cyclohexane solution. Spectra taken with a Cary 14 spectrophotometer.
[c]Not measured above 30,000 cm^{-1}.

just as the 43,000–50,000 cm^{-1} $Mn(CO)_5X$ band may be related to the 44,480 cm^{-1} band ($^1A_{1g} \rightarrow {}^1T_{1u}{}^{(2)}$) in $Cr(CO)_6$ (6).

The assignment of the 25,000 cm^{-1} band as due to a charge transfer transition is supported by the sensitivity of the band maxima to solvent changes (1). No appreciable solvent shift would be expected for a *d–d* transition. The large intensity of the 43,000–50,000 cm^{-1} band is consistent with a charge transfer process.

The bands due to the transitions $b_2[\pi^*, 3d_{xy}] \rightarrow (e,e,a_1,a_2,b_1,b_2)[\pi^*, CO(1-4)]$ and $e[\pi, 3d_{xz,yz}] \rightarrow e[\pi^*, CO(5)]$ probably do not differ appreciably in energy from the observed high- and low-energy bands and consequently are not resolved, or, more likely, are simply buried under the intense 43,000–50,000 cm^{-1} band.

A third band, at 48,830 cm^{-1}, is observed for the $Mn(CO)_5I$ complex. This band is assigned as a combination of $I[\pi^b] \rightarrow Mn[3d(\sigma^*)]$ and $I[\pi^b] \rightarrow CO(5)[\pi^*]$ charge transfer. Of the complexes investigated, the $Mn(CO)_5I$ complex would be expected to show this type of charge transfer at the lowest energy (ca. 50,000 cm^{-1} estimated—see Table III). The fact that this band obviously lies at considerably higher energies in $Mn(CO)_5Cl$ and $Mn(CO)_5Br$ strongly supports the assignment.

INFRARED SPECTRA OF $Mn(CO)_5X$ COMPLEXES

The $Mn(CO)_5X$ complexes show three bands in the 2000 cm^{-1} infrared region. The vibrations in $Mn(CO)_5X$ expected to appear with some intensity in the 2000 cm^{-1} region are

$$Mn\text{—}\overleftarrow{C}\text{—}\overrightarrow{O}(5)\ A_1{}^{(1)}$$

$$Mn\text{—}\overleftarrow{C}\text{—}\overrightarrow{O}(1\text{–}4)\ A_1{}^{(2)}$$

$$(1)\overrightarrow{O}\text{—}\overleftarrow{C}\text{—}Mn\text{—}\overleftarrow{C}\text{—}\overrightarrow{O}(3)\ E$$

$$(2)\overrightarrow{O}\text{—}\overleftarrow{C}\text{—}Mn\text{—}\overleftarrow{C}\text{—}\overrightarrow{O}(4)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The expected intensities are $E > A_1^{(1)} \gg A_1^{(2)}$; this feature is discussed by Orgel (2).

The infrared spectra and assignments for the $Mn(CO)_5X$ complexes are given in Table V. In all cases, the $A_1^{(1)}$ vibration occurs at the lowest energy, indicating that

TABLE V

Infrared spectra of $Mn(CO)_5X$ complexes[a]

Complex	Vibration[b]		
	$A_1^{(1)}$	$A_1^{(2)}$	E
$Mn(CO)_5Cl$	2005	2145	2055
$Mn(CO)_5Br$	2010	2140	2050
$Mn(CO)_5I$[c]	2017	2136	2056

[a]Similar spectra have been obtained in cyclohexane and carbon tetrachloride solutions. See ref. 7.
[b]In chloroform solutions. Intensities are in the order $E > A_1^{(1)} \gg A_1^{(2)}$. All spectra taken using a Perkin–Elmer Model 421 spectrophotometer.
[c]From Abel *et al.* (E. W. Abel, M. H. Bennett, and G. Wilkinson. Chem. Ind. (London), 441 (1960)).

CO(5) has lower bond order than CO(1–4). In terms of the molecular orbital bonding scheme, this means that the π^*[CO(5)] orbitals participate more than the π^*[CO(1–4)] orbitals in the π-molecular orbitals mostly localized on Mn. This is, of course, just the result that was used as a guide earlier.

REACTIONS OF $Mn(CO)_5X$ COMPLEXES

The discussion of reactions of $Mn(CO)_5X$ complexes will be divided into two parts: carbon monoxide exchange reactions and substitution reactions involving displacement of CO.

A. Carbon Monoxide Exchange Reactions

The kinetics and mechanism of carbon monoxide exchange with $Mn(CO)_5X$ (X = Cl, Br, and I) were reported earlier (3); the kinetic data are summarized in Table VI. Three

TABLE VI

Rates of equatorial CO exchange in $Mn(CO)_5X$ in toluene at 31.8° C[a]

Complex	$k \times 10^4$ (sec^{-1})
$Mn(CO)_5Cl$	30
$Mn(CO)_5Br$	1.2
$Mn(CO)_5I$	0.15

[a]From ref. 3.

definite conclusions can be drawn: (1) at 31.8° C and in toluene, one carbon monoxide exchanges more slowly than do the other four, (2) the rate of exchange of the four CO's does not depend on the concentration of carbon monoxide, and (3) the rate of CO exchange depends on X, with $Mn(CO)_5Cl > Mn(CO)_5Br > Mn(CO)_5I$.

That four CO's exchange faster than the fifth is consistent with the molecular orbital bonding scheme for $Mn(CO)_5X$. There is more [Mn—C]O π-bonding for the axial CO, and since exchange proceeds by dissociation, the nonequivalence with respect to exchange of the five carbon monoxides is to be expected. Furthermore, the results indicate that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

active intermediate with reduced coordination number must contain nonequivalent carbonyls in order to account for the experimental observations.

The relative rates of exchange of the four equatorial CO's at 31.8° C are in the order 200:8:1 for $Mn(CO)_5Cl$, $Mn(CO)_5Br$, and $Mn(CO)_5I$, respectively. This order is consistent with the ultraviolet and infrared spectra. The transition $e[\pi, 3d_{xz,yz}] \rightarrow (e,e,a_1,a_2, b_1,b_2)[\pi^*, CO(1\text{–}4)]$ occurs at 49,600 cm^{-1} for $Mn(CO)_5Cl$, 44,200 cm^{-1} for $Mn(CO)_5Br$, and 43,480 cm^{-1} for $Mn(CO)_5I$. The energies of these electronic transitions indicate that the $e[\pi, 3d_{xz,yz}] \rightarrow (e,e,a_1,a_2,b_1,b_2)[\pi^*, CO(1\text{–}4)]$ separation is greatest for the chloride and smallest for the iodide. This is to be expected since highest π-polarizability of the iodide ion raises the energy of its $e[\pi, 3d_{xz,yz}]$ orbitals with respect to those of the bromide and chloride complexes. Thus, $\pi^*[CO(1\text{–}4)]$ participation is greatest with the iodide and least with the chloride, which effectively means strongest equatorial Mn—CO bonds for $Mn(CO)_5I$.

The infrared spectra of $Mn(CO)_5X$ complexes show that the frequency of the $A_1^{(2)}$ carbon–oxygen vibrational mode decreases from the chloride to the iodide (see Table V). This is consistent with stronger Mn—C equatorial bonds in the carbonyl iodide.

Recently, Hieber and Wollmann (4) showed that if the CO exchange is carried out at higher temperatures (40° C, benzene solvent) somewhat different results are obtained. With the chloride and bromide, all five CO's exchange, four faster than the fifth, as evidenced by a nonlinear semilogarithmic plot of the data. However, with the iodide, all five CO's seem to exchange at about the same rate. Approximate relative rates of exchange of the four equatorial CO's are 110:9:1 for the chloride, bromide, and iodide, respectively.

These results can be explained on the basis of the infrared spectra and values of activation energy for dissociation of equatorial carbonyls in these compounds, obtained by Angelici and Basolo (5). These values are 27.4, 29.8, and 32.2 kcal, for the chloride, bromide, and iodide, respectively, consistent with the order of reactivity of these complexes. The infrared spectra indicate that all axial CO's are bound more tightly than the equatorial CO's and that the axial Mn—C bond is strongest in $Mn(CO)_5Cl$ and weakest in $Mn(CO)_5I$. Thus activation energies for dissociation of the fifth CO are higher than those for the planar carbonyls and probably follow the reverse trend, that is, the chloride would have the highest activation energy. Therefore, it is possible that at a higher temperature the rates of exchange of two different kinds of CO's in the iodide become comparable, whereas in the chloride and bromide, nonequivalence is still observed.

B. Substitution Reactions

That the axial CO's are bonded more strongly than the four equatorial CO's is further supported by recent kinetic studies of Angelici and Basolo (5). The results are summarized in Table VII.

Many tertiary phosphines, arsines, and stibines, as well as phosphites and pyridine react with $Mn(CO)_5X$ according to the equation

$$Mn(CO)_5X + L \rightarrow Mn(CO)_4LX + CO,$$

where L is one of the above neutral ligands. With some ligands L the reaction proceeds further to yield disubstituted products, $Mn(CO)_3L_2X$.

Kinetic studies of the former reaction show that the formation of monosubstituted products is independent of the nature and concentration of the entering ligand, but depends on the first power of the $Mn(CO)_5X$ concentration. Thus, a dissociative (S_N1) mechanism has been proposed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

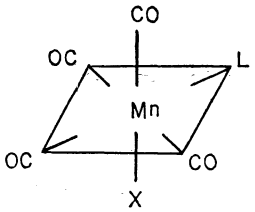
			C_5H_5N	31.8	13[b]
$Mn(CO)_5I$	0.0171	0.208	$As(C_6H_5)_3$	35.1	0.824
	0.0175	0.203	$P(C_6H_5)_3$	35.1	0.844

[a]From ref. 5.
[b]In toluene; concentrations of $Mn(CO)_5Br$ and L were not specified. See ref. 5.

Since the rate of replacement of CO by L is the same as the rate of exchange of the four equatorial carbon monoxides, it follows that L enters an equatorial position. Thus, the structure of monosubstituted products must be



As before, the rate of replacement of CO is affected by the nature of X, with $Mn(CO)_5Cl > Mn(CO)_5Br > Mn(CO)_5I$. Such an order is to be expected since the reactions proceed by dissociation of an equatorial CO. Thus, the combined substitution and exchange kinetic results strongly support the bonding scheme presented earlier.

It would be of interest to compare reactivities of the manganese group pentacarbonyl halides. On the basis of infrared spectra of these compounds (7), one might predict that with all three metals—manganese, technetium, and rhenium—one carbon monoxide will be more inert than the other four. Also, for exchange or substitution of the equatorial CO's, the chloride complexes will react more readily than the bromide complexes, and the bromide complexes still faster than the iodide complexes. Thus all of these compounds would fit the molecular orbital bonding description presented above. Furthermore, the infrared spectra indicate that the equatorial carbonyls should be most labile with rhenium and least so with manganese, and the metal–carbon bond strength of the axial CO's should follow the reverse order, that of manganese being the strongest. Experimental results on the technetium and rhenium compounds are still lacking.

METALLOCENE CHEMISTRY—A DECADE OF PROGRESS[1]

M. D. RAUSCH

Research and Engineering Division, Monsanto Chemical Company, Saint Louis, Mo., U.S.A. and Department of Chemistry, University of Kansas, Lawrence, Kan., U.S.A.

Received October 29, 1962

ABSTRACT

One of the most significant new frontiers in chemistry during the past decade has been the stabilization and study of π-organic derivatives of the transition metals. Over 60 elements are now known to form one or more cyclopentadienyl compounds. The aromatic-type reactions displayed by ferrocene and related complexes have also been extensively investigated. Ferrocene will undergo alkylation, acylation, sulphonation, metalation, arylation, formylation, aminomethylation, and other reactions characteristic of a highly reactive aromatic system. π-Cyclopentadienyl derivatives of vanadium, chromium, manganese, ruthenium, and osmium as well as certain π-arene complexes of chromium exhibit ring substitution reactions in varying degrees. Other metallocenes undergo ring addition reactions.

The orientation effects of substituents on reactions of substituted ferrocenes have been studied. A variety of unique oxidation, reduction, dehydration, and rearrangement reactions are known in metallocene chemistry. Haloferrocenes and mercuriferrocenes are readily converted to biferrocenyl. Recent rate investigations have established that carbonium ions adjacent to metallocene nuclei possess unusual stabilization as a result of direct metal participation.

The chemistry of organometallic compounds has always intrigued chemists since the very beginning of this field over a century ago. Through the intervening years many outstanding discoveries have been made, and these discoveries have had a profound effect on the science of chemistry and chemical technology. In spite of extensive research in organometallic chemistry during the period from about 1830 to 1950, the preparation and study of organic derivatives of transition metals remained largely an enigma. The early work along these lines is well summarized in a recent review by Cotton (1).

The accidental discovery of ferrocene in 1951 was a major event in organometallic chemistry. The isolation of this unique organo-iron compound has provided a tremendous stimulus for research leading to many other types of novel organo-transition metal derivatives. Detailed studies on these derivatives in turn have contributed greatly to a better understanding of carbon – transition metal bonding.

Certainly the most extensively investigated organo-transition metal complexes during the period from 1951 to the present have been those in which the cyclopentadienyl group is present. Over 60 of the chemical elements have now been shown to form cyclopentadienyl derivatives. No doubt the ability of this group to form organometallic and organometalloidal compounds with so many elements results from the variety of ways it can enter into bonding. In a very broad sense cyclopentadienyl compounds of metals and metalloids can be classified according to whether the ring-metal bonding is principally ionic, principally covalent, or principally π-type. It must be emphasized that these distinctions are not mutually exclusive, and that a given metal-cyclopentadienyl may possess bonding characteristics of several of these types. The chemistry of cyclopentadienyl compounds of metals and metalloids has recently been summarized by the present author (2).

[1]*Presented at the Symposium on Organometallic Compounds, Vancouver, British Columbia, September 4–6, 1962, sponsored by the Inorganic Chemistry Division, Chemical Institute of Canada, and the Department of Chemistry, University of British Columbia, with the support of the National Research Council, Ottawa, in cooperation with the University Extension Department.*

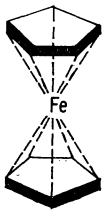
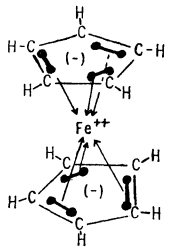
During the past 10 years many other organic groups containing π-electron systems have been shown to form π-metallo derivatives. Groups of this sort include ethylene, the allyl group, various cyclobutadienes, arenes, the cycloheptatrienyl group, cyclooctatetraene, and many others. When one considers the large number of potential π-ligands and the fact that nearly all the transition metals have now been found to form organometallic π-complexes, it is no wonder that this area has been such a fertile new frontier in chemistry!

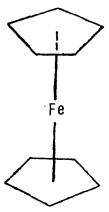
Ferrocene itself has been shown to possess a pentagonal antiprismatic structure in the crystal state (I) (3). The compound is diamagnetic and has a dipole moment of zero. The high symmetry of ferrocene results in a strikingly simple infrared spectrum (4). The nuclear magnetic resonance spectrum shows only one type of hydrogen resonance at about 4 p.p.m. downfield from tetramethylsilane.



I



II



III

While the "sandwich" structure of ferrocene is well established, the precise nature of the ring-metal bond is still in dispute (5). Two hypotheses can be briefly mentioned. Fischer and co-workers (6) regard ferrocene and related compounds as penetration complexes in which two negatively charged rings, each containing three pairs of π-electrons, are coordinated in an approximately octahedral arrangement around a positively charged metal atom. In ferrocene the metal is Fe^{II}, and the complete filling of hybrid d^2sp^3 metal orbitals results in an inert gas configuration (II).

Moffitt (7) and others regard the ring-metal bonding in ferrocene to result largely from a delocalized covalent bond between the metal atom and two cyclopentadienyl radicals. A two-electron bond of this sort results from overlap of a π-orbital of suitable symmetry in each ring with the $3d_{xz}$ and $3d_{yz}$ orbitals of iron. Four π-electrons thus remain in each ring and are not involved in the principal bonding, while filled $3d$ orbitals of the metal lie in the xy-plane between the two cyclopentadienyl rings (III).

A variety of chemical and physical properties of ferrocene and related substances can be advantageously explained using either concept of bonding. The essential difference between these hypotheses appears to be in the *degree* in which π-electrons participate in bonding with metal orbitals.

Shortly after the isolation of ferrocene, a subsequent important discovery was made by Woodward, Rosenblum, and Whiting (8). These investigators noted the failure of ferrocene to undergo Diels–Alder type reactions and its resistance to catalytic hydrogention. They reasoned that because of its remarkable stability, ferrocene might behave like an aromatic substance. These suppositions proved to be correct as ferrocene was readily acylated under Friedel–Crafts conditions to form acyl derivatives. Indeed, the name *ferrocene* was given to biscyclopentadienyliron because of its chemical similarity to benzene.

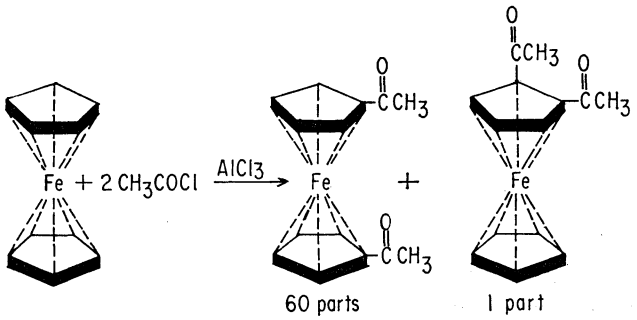
The successful acylation of ferrocene set off a vigorous research effort that has resulted in the establishment of a new field of chemistry, metallocene chemistry. In recent years, a variety of π-cyclopentadienyl derivatives of ruthenium, osmium, manganese, vanadium, and chromium have been shown to exhibit certain aromatic-type reactions in varying degrees. Metallocenes can thus be broadly classified as ferrocene-type compounds which exhibit aromatic substitution reactions. In addition, the name *metallocene* has been applied to many other metal-cyclopentadienyl compounds which might be expected to possess aromatic character but which fail to survive the reaction conditions required for aromatic substitution. It should be noted, however, that certain compounds in this category do exhibit various addition reactions. Metallocenes represent a new class of heterocyclic compounds in which a transition metal, in a manner similar to nitrogen, oxygen, and sulphur in classical heterocycles, not only is an integral part of the structure but actually participates in many reactions.

Although metallocene chemistry is only 10 years old, the literature is already profuse. In this view, a brief outline of the many aromatic-type substitution reactions of metallocenes will first be presented. Emphasis will be given to specific substituent and metal effects, and to the synthetic utility of each type of ring-substitution reaction. Finally, a number of important recent topics in metallocene chemistry will be discussed. These will include the formation of biferrocenyl and polyferrocenylenes, interannular resonance effects, α-carbonium ion stabilization, rearrangements, and ring-addition reactions.

Acylation

The acylation of metallocenes has been investigated more extensively than any other substitution reaction. The Friedel–Crafts reaction between ferrocene and acetyl chloride in the presence of aluminum chloride serves as a good example. When equimolar amounts of these reactants are employed, monoacetylferrocene is formed almost exclusively (9, 10). When an excess of acetyl chloride and aluminum chloride is employed, a mixture of two isomeric diacetylferrocenes is produced, and the products can be separated by careful chromatography on activated alumina (9). It should be noted that nearly all metallocenes are highly colored and can be advantageously separated by column chromatography.

The major product is the heteroannular disubstituted derivative, 1,1′-diacetylferrocene (IV), while a very small amount of a homoannular isomer, 1,2-diacetylferrocene (V), is also obtained. The first acetyl group appears to deactivate the substituted ring toward further electrophilic substitution, and the second acetyl group preferentially enters the opposite ring.



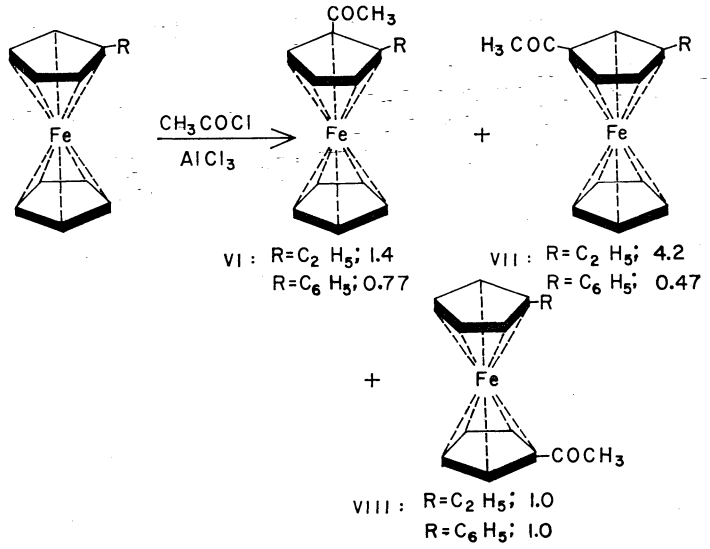
IV V

The structure of isomer IV was confirmed by degradative evidence. Under conditions of high temperature and pressure, this product was catalytically hydrogenated to ethylcyclopentane to the exclusion of cyclopentane and diethylcyclopentane (11). The structure of isomer V was shown by haloform oxidation to the diacid followed by facile anhydride formation (12).

The exceedingly high reactivity of ferrocene in Friedel–Crafts acylations is exemplified by the fact that mild catalysts such as stannic chloride (13), boron trifluoride (14), zinc chloride (15), and phosphoric acid (16) can be used with considerable success. When ferrocene and anisole were allowed to compete for a limited amount of acetyl chloride and aluminum chloride, acetylferrocene was the sole product isolated (10).

The remarkable reactivity of ferrocene in acylation reactions is reminiscent of the marked reactivity of thiophene in classical heterocyclic chemistry. A novel means of comparing the reactivities of these two aromatic systems has recently been reported by Schlögl and Pelousek (17). 2-Thenylferrocene (ferrocenyl-2-thienylmethane) was prepared by acylation of ferrocene with thenoyl chloride and subsequent reduction. Acetylation of 2-thenylferrocene produces a variety of acetylated derivatives. From the products obtained, it appears that ring substitution occurs in the following decreasing order: thiophene (5-position); ferrocene (heteroannular ring); ferrocene (homoannular ring, 3-position).

The acylation of other substituted ferrocenes has also received increasing attention in recent years. The nature of the substituent markedly affects the location of the entering acetyl group. Acetylation of monoethylferrocene, for example, produces three isomeric acetylethylferrocenes: the 1,2-isomer (VI, R = C_2H_5), the 1,3-isomer (VII, R = C_2H_5), and the 1,1′-isomer (VIII, R = C_2H_5) (9). The isolation of three positional isomers of



this type is completely consistent with the concept that the two cyclopentadienyl rings in ferrocene are rotating in all but the crystalline state. From the amounts of each isomer formed and the number of non-equivalent ring positions, site reactivities can be calculated, the 1′-position being arbitrarily assigned a value of unity.

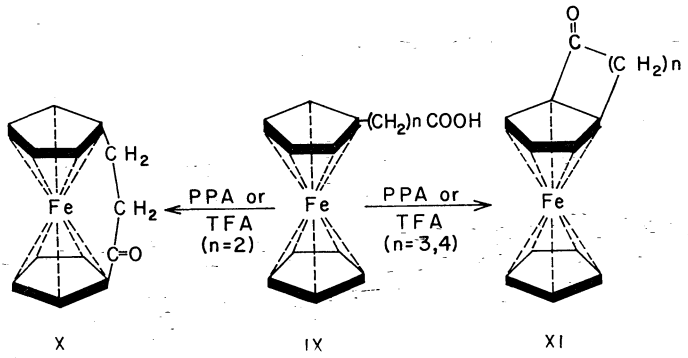
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

From the site reactivities given under each isomer, it can readily be seen that acylation is enhanced in the substituted ring compared to the unsubstituted ring, as might be expected by the presence of an electron-releasing alkyl group. Further, substitution at the 3-position is favored over the 2-position. This result is corroborated by similar studies involving the acetylation of 1,1′-dimethylferrocene, in which it was found that the 3-position was also favored (18). Acylation at the 3-position was even more pronounced in the case of 1,1′-diisopropylferrocene, suggesting that steric factors play an important role in determining the mechanism of homoannular acylation of alkylferrocenes.

While acetylation of phenylferrocene also produces three similar acetylphenylferrocenes (VI, VII, VIII; R = C_6H_5) (as well as a very small amount of an isomer in which the phenyl group is acetylated), the site reactivities are quite different (19, 20). It can be seen that the ring bearing the phenyl substituent is deactivated compared to the unsubstituted ring. In contrast to alkylferrocenes, the 2-position is favored over the 3-position. It has been postulated that this is the result of enhanced resonance stabilization of the transition state in substitution involving electrophilic attack at the 2-position.

Preliminary studies involving the acetylation of aralkylferrocenes such as benzylferrocene indicate substitution occurs in the unsubstituted ring (17). Detailed site reactivity studies have not yet been reported.

Another interesting series of reactions involving acylation concerns bridging or cyclization of ω-ferrocenylcarboxylic acids. β-Ferrocenylpropionic acid (IX, n = 2), when

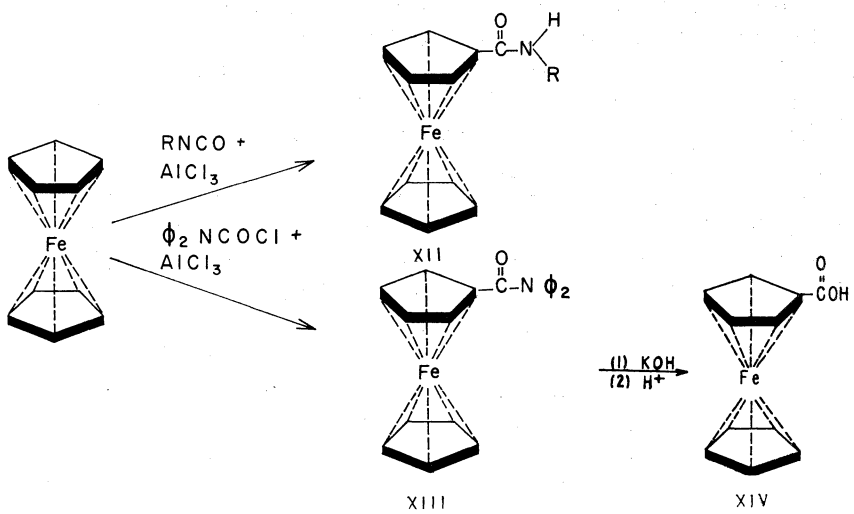


X IX XI

treated with either polyphosphoric acid or trifluoroacetic anhydride, yields the bridged ketone 1,1′-α-ketotrimethyleneferrocene (X) (21). Ferrocenylbutyric or valeric acids (IX, n = 3, 4) produce homoannular cyclized products (XI, n = 3, 4). By means of related sequences of reactions, ferrocenes containing two (22), three (23), and four (24) trimethylene bridges have now been prepared. Indeed, it appears that the interesting situation may soon arise in which the centrosymmetric iron atom is completely enclosed in an "alkylene cage"!

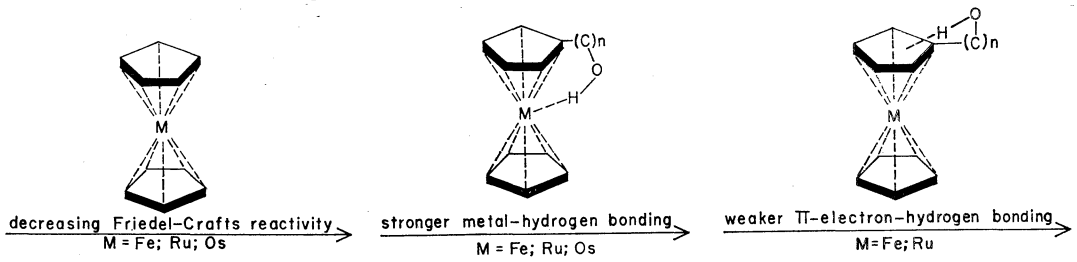
While acylations of metallocenes are usually carried out with acid halides, acid anhydrides, or carboxylic acids, a number of other acylating agents have been reported. The reaction of ferrocene with various isocyanates and aluminum chloride leads to N-substituted ferrocenecarboxamides (XII) (25). Use of ruthenocene in place of ferrocene leads to analogous results (26). The preparation of N-phenylferrocenecarboxamide from phenyl isocyanate in this manner has been used as a proof of structure for the product obtained from the Beckmann rearrangement of benzoylferrocene oxime (27).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



A useful synthetic technique involves the acylation of ferrocene with diphenylcarbamyl chloride (28). The product, diphenylcarbamylferrocene (XIII), is readily hydrolyzed to ferrocenecarboxylic acid (XIV). Acylation of diphenylcarbamylferrocene followed by hydrolysis produces good yields of 1′-acylferrocenecarboxylic acids.

Several years ago Rausch, Fischer, and Grubert found that the ruthenium and osmium analogues of ferrocene, viz., ruthenocene and osmocene, likewise undergo acylation in varying degrees (26, 29). Under identical conditions in which the acylation of ferrocene leads solely to 1,1′-diacylferrocenes, mixtures of mono- and di-acylruthenocenes were obtained from ruthenocene acylations, and osmocene yielded only monoacylation products. These studies as well as competition experiments indicate that the electrophilic reactivity of Group VIII metallocenes markedly decreases proceeding from ferrocene to osmocene.



The precise reason for this marked gradation in electrophilic reactivity is not yet clear. It has been tentatively suggested that the availability of bonding π-electrons in each cyclopentadienyl ring decreases in the order ferrocene > ruthenocene > osmocene as a result of stronger ring-metal bonding in the case of the heavier metal complexes (26). Such a trend in metal–ligand bond strength is known to occur in metal–olefin complexes, and might result from enhanced back-donation from filled metal orbitals to ring antibonding π-orbitals. Enhanced d_π–p_π bonding of this sort would tend to strengthen the metal–ligand bond as a whole. It should be mentioned that infrared (4, 26), thermochemical (30), and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

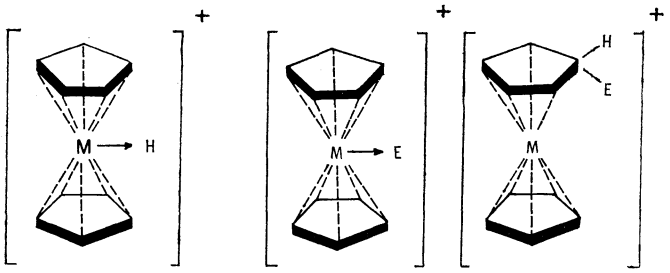
mass spectra studies (31) are in accord with the concept of stronger ring-metal bonding in ruthenocene and osmocene compared to ferrocene.

Other investigators have recently defined several types of hydrogen bonding in metallocenyl alcohols (32, 33). They have shown that hydrogen bonding between the hydroxyl hydrogen and the central metal atom becomes stronger proceeding from the ferrocenyl to the osmocenyl alcohol. Conversely, hydrogen bonding to the π-electron density of the cyclopentadienyl ring appears weaker in ruthenocenyl alcohols compared to ferrocenyl alcohols. It has also been shown that ruthenocenecarboxylic acid is nearly twice as acidic as its iron analogue, XIV (26).

Another topic that is closely related to these results concerns the protonation of metallocenes. A number of metallocenyl hydrides of rhenium, molybdenum, and tungsten have been shown to behave as bases and are soluble in dilute aqueous acids (34). The remarkable basicities of these compounds have been ascribed to the presence of filled metal orbitals that are not involved in primary ring-metal bonding, and to a possible angular configuration of the rings. Although much less basic, Group VIII metallocenes can be protonated in boron trifluoride hydrate (35). High-resolution nuclear magnetic resonance studies on these protonated metallocenes show the presence of a proton resonance at very high fields relative to tetramethylsilane, and indicate the presence of a highly shielded proton that is bonded directly to the metal atom.

The nuclear magnetic resonance data further indicate that the apparent ease of protonation of Group VIII metallocenes decreases from ferrocene to osmocene. It is striking that this gradation in reactivity parallels the trends observed in acylation studies. Hydrogen atoms of ferrocene are known to be readily substituted by deuterium when ferrocene is dissolved in anhydrous deuterosulphuric acid (36). Protonation can thus be considered as a simple form of electrophilic substitution. It is possible that the transition state for other electrophilic substitution reactions involves initial interaction of the electrophile with a filled metal orbital, followed by rearrangement to an endocyclic σ-complex (37).

Metallocenes may therefore undergo electrophilic substitution by a mechanism fundamentally more complex than that which pertains to substitution in benzenoid systems. Clearly, more studies are needed along these lines in order to define specific metal effects on the properties and reactions of these remarkable compounds.



decreasing ease of protonation: M = Fe, Ru, Os

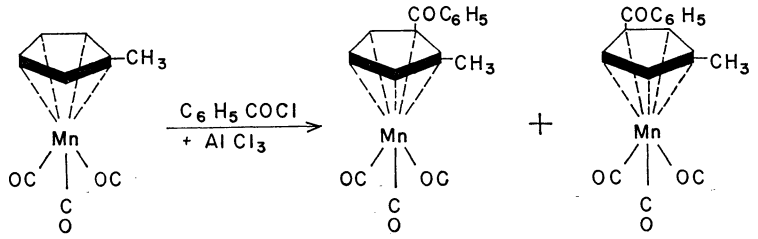
E = Electrophile

Acylmetallocenes undergo many reactions shown by acylbenzenes, and a detailed discussion will not be presented here (38). Reductions with either lithium aluminum hydride or sodium borohydride give the corresponding carbinols, while Clemmensen

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

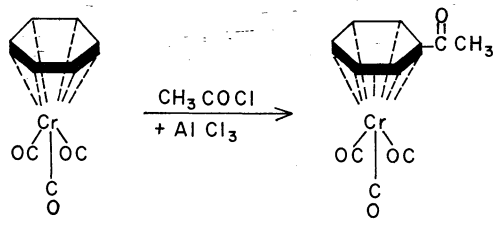
reduction, reduction with lithium aluminum hydride plus aluminum chloride, catalytic hydrogenation, etc., yield corresponding alkyl derivatives. Acetylferrocenes undergo a variety of base condensation reactions and can be oxidized to ferrocenecarboxylic acids without apparent oxidation of the iron atom.

Still other π-cyclopentadienyl-metal compounds have been shown to undergo acylation. The successful acylation of cyclopentadienylmanganese tricarbonyl has opened up yet another interesting aromatic-type system for exploration (39–43). An example of this type concerns the benzoylation of methylcyclopentadienylmanganese tricarbonyl (XV) (40). Both 1-methyl-2-benzoylcyclopentadienylmanganese tricarbonyl (XVI) and the corresponding 1,3-isomer (XVII) are readily obtained. Cyclopentadienylvanadium tetracarbonyl (44, 45) and cyclopentadienylchromium dicarbonyl nitrosyl (46) can also be acylated under Friedel–Crafts conditions.



XV XVI XVII

Attempts to bring about acylation reactions of bisbenzenechromium and bistoluenechromium have thus far failed, the ring-metal bond being readily cleaved under the reaction conditions involved (47). On the other hand, benzenechromium tricarbonyl (XVIII) has recently been acylated to produce acetophenonechromium tricarbonyl (XIX), the ring-metal bond in this case remaining intact (48, 49).



XVIII XIX

Formylation

Ferrocene is similar to other highly reactive aromatic systems in that it is readily formylated by N-methylformanilide in the presence of phosphorus oxychloride (16, 50–53). Only the monosubstituted product, ferrocenecarboxyaldehyde (XX), is produced even when a large excess of formylating agent is used. Ferrocenecarboxaldehyde, like benzaldehyde, is readily reduced to the corresponding carbinol and undergoes the Cannizzaro reaction with alcoholic potassium hydroxide solution. While ferrocenecarboxaldehyde apparently does not undergo a self-benzoin condensation it will condense with benzaldehyde to form a mixed benzoin. The low carbonyl stretching frequency

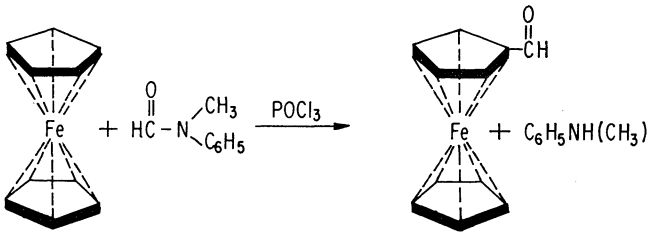
For personal use only.



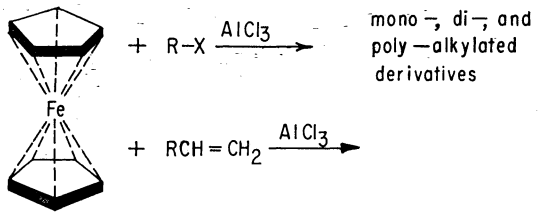
XX

(1670 cm^{-1}) compared to the value for benzaldehyde (1704 cm^{-1}) indicates strong polarization of the carbonyl group. This point is also reflected in the remarkable basicity of ferrocenecarboxaldehyde, since it forms a solid hydrochloride from ether solution and hydrogen chloride (52).

It is timely at this point to mention some recent studies of Arnett and Bushick (54). These investigators have determined the pK_A values for the conjugate acids of ferrocenyl ketones in aqueous sulphuric acid. They have found, for example, that acetylferrocene is over 2000 times more basic than is acetophenone and 85 times more basic than is *p*-hydroxyacetophenone. These data support the concept (*vide infra*) that metallocenyl groups are strongly electron releasing compared to the phenyl group and that they possess extraordinary ability to delocalize adjacent positive charges.

Alkylation

Ferrocene is readily alkylated by alkyl halides, alcohols, or olefins to produce alkylated derivatives (55, 56). The exceedingly great reactivity of ferrocene under these conditions results in the formation of mixtures of mono-, di-, tri-, and poly-alkylated products, and the yield of any one alkylation product is usually low. As in benzenoid chemistry, the



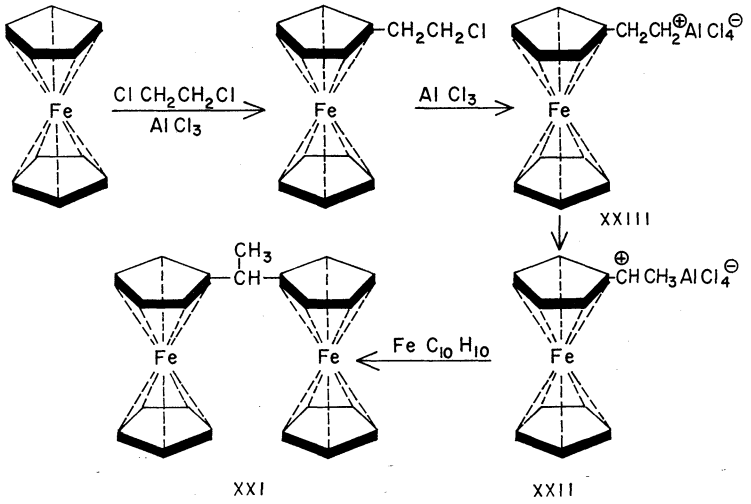
introduction of an alkyl group into the ferrocene nucleus facilitates subsequent alkylation in the same ring. Aralkylferrocenes can be conveniently prepared by reaction of ferrocene with substituted carbinols such as triphenylcarbinol in the presence of a Lewis acid, the reactions being carried out in the melt phase (57).

Alkylferrocenes can serve as useful synthetic intermediates, since it has recently been shown that they are conveniently oxidized by activated manganese dioxide to carbonyl compounds (58). Methylferrocene, for example, can be converted to ferrocenecarboxaldehyde without apparently oxidizing the iron atom. Another interesting oxidation involves conversion of the 1,1′-dimethylcobalticinium cation to the corresponding dicarboxylic acid cation by means of alkaline potassium permanganate solution (59).

The Friedel–Crafts alkylation of ferrocene with ethylene chloride has been the subject of considerable investigation. It was initially reported by Nesmeyanov and co-workers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that the reaction produced "diferrocenylethane" and appreciable amounts of polymeric material (60). Rinehart and co-workers later proved that the low molecular weight product was 1,1-diferrocenylethane (XXI) instead of the expected 1,2-isomer (61). The anomalous

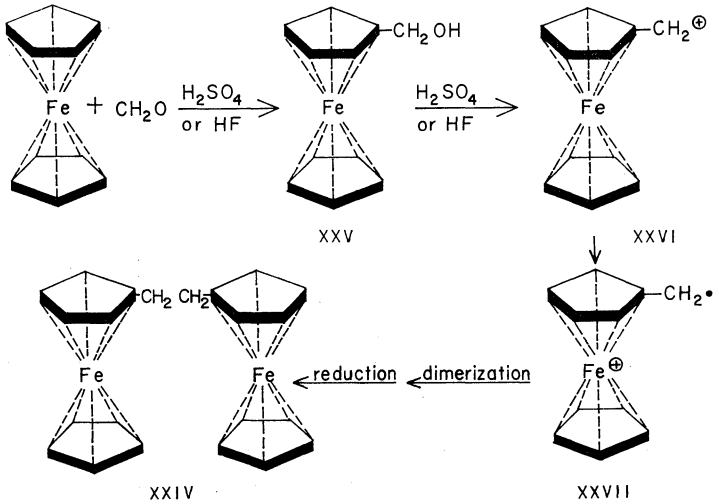


product is postulated to result from a hydride ion rearrangement in the transition state, the driving force resulting from the enhanced stability of the α-ferrocenylcarbonium ion XXII compared to the primary carbonium ion XXIII formed initially.

Nesmeyanov and co-workers have also recently reported that this reaction produces yet another alkylated product, pentaethylenediferrocene, in which two ferrocene units are purported to be connected by five ethylene bridges (62).

Aldehyde Condensation

The reaction of ferrocene and formaldehyde in either concentrated sulphuric acid or liquid hydrogen fluoride, followed by reduction, produces a compound containing two ferrocenyl and two methylene groups (63–65). After several incorrect assignments had



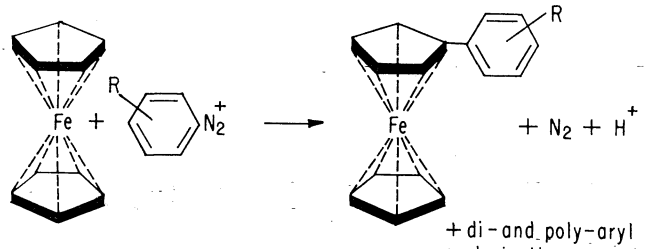
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

been proposed for the structure of this condensation product, Rinehart and co-workers showed by an unequivocal synthesis that the product was 1,2-diferrocenylethane (XXIV) (66). The mechanism of this reaction presumably involves the initial formation of ferrocenylcarbinol (XXV), followed by ionization in the strongly acidic media to the ferrocenylmethylcarbonium ion (XXVI). Conversion to radical ion XXVII followed by dimerization and subsequent reduction produces the product. This mechanism is supported by the fact that ferrocenylcarbinol under the same acidic conditions also yields 1,2-diferrocenylethane. Further, the intermediate dicationic dimerization product has been isolated as a dipicrate.

Ferrocenecarboxaldehyde and ferrocene condense to form a deep blue diferrocenylmethine cation. The cation can be isolated in crystalline form as a perchlorate (67).

Arylation

The great reactivity of ferrocene toward electrophilic reagents prompted an early examination of its behavior with aryldiazonium salts. Azoferrocenes were expected to be formed by analogy to the reactions of phenol and related reactive aromatic compounds. The reactions instead were found to proceed with elimination of nitrogen and the products were arylferrocenes (XXVIII). Conversions of this sort now constitute the most convenient means of preparing these substances, an alternative method being direct synthesis from arylcyclopentadienes and iron chlorides (68).



XXVIII

Various investigators have studied this reaction using aqueous acetic acid (19, 69) or water–ether mixtures (13, 70) as the reaction medium. Weinmayr has reported the successful arylation of ferricenium salts in aqueous sulphuric acid (71). The products of the arylation reactions are mono-, di-, and poly-arylferrocenes. While earlier studies indicated that the diaryl products had a 1,1′-configuration, Rosenblum and co-workers have recently found that all possible structurally isomeric diarylferrocenes (1,1′; 1,2; 1,3) are produced in this manner (72). Ferrocene can also be phenylated in cyclohexane solution in the presence of N-nitrosoacetanilide (69) although the free-radical mechanisms originally proposed for this reaction and the diazonium arylation are questionable (72).

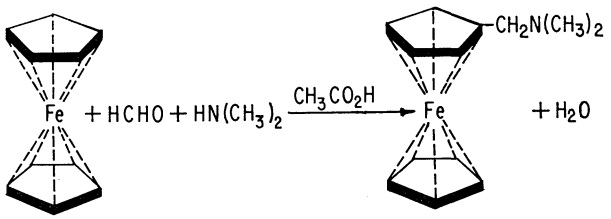
Monosubstituted alkyl-, acyl- and aryl-ferrocenes undergo arylation to form primarily heteroannular disubstituted ferrocenes (69, 73). Attempts to arylate 1,1′-diacylferrocenes, however, result in rupture of the ring-metal bond. Bozak and Rinehart have recently presented spectral evidence that the iron-free product resulting from the reaction of 1,1′-diacetylferrocene and benzenediazonium chloride is 6-methyl-6-hydroxy-2-phenylazofulvene (74), rather than a 1,2,3-oxadiazine structure originally proposed (73, 75, 76).

Aminomethylation

Hauser and Lindsay first showed that ferrocene undergoes a Mannich-type reaction with formaldehyde and dimethylamine to form dimethylaminomethylferrocene (XXIX)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(77). This amine is readily converted to a methiodide, and the latter quaternary salt has proved to be an important synthetic intermediate in ferrocene chemistry. Reduction of the methiodide of XXIX with sodium amalgam, for example, produces methylferrocene



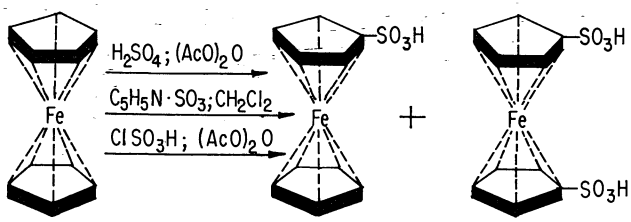
XXIX

in high yield (78). Treatment with solutions of potassium cyanide or potassium hydroxide yields ferrocenylacetonitrile and ferrocenylcarbinol, respectively (77, 79, 80). Reaction with potassium amide in liquid ammonia results in a Stevens rearrangement to give β-dimethylaminoethylferrocene (81, 82).

Aminomethylation of methylferrocene results in substitution apparently at the 3-position, while phenylferrocene reacts in a similar manner to produce primarily the heteroannular aminomethylated product (83, 84). Pauson and co-workers have reported that aminomethylation of 1,1′-dithiomethylferrocene results in introduction of the dimethylaminomethyl group at both the 2- and 3-positions, the ratio being 1.9:1 (85).

Sulphonation

Ferrocene can readily be sulphonated by either sulphuric acid or chlorosulphonic acid in acetic anhydride (64, 86). The products, ferrocenesulphonic acid (XXX) and ferrocene-1,1′-disulphonic acid (XXXI) are obtained together with products resulting from



XXX XXXI

oxidation. A second synthetic technique has employed either pyridine or dioxane adducts of sulphur trioxide as sulphonating agents. Ferrocene, phenylferrocene, and ferrocene-carboxylic acid have been sulphonated in this manner (84, 87, 88). These substituents deactivate the substituted ring, and the products are the heteroannular sulphonic acids. Sulphonation of cyclopentadienylmanganese tricarbonyl is also readily accomplished (89).

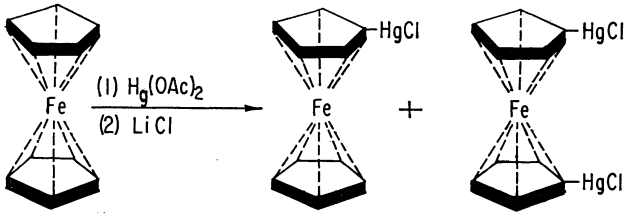
The sulphonic acids of these metallocenes can be converted to sulphonyl chlorides, sulphonamides, etc., by appropriate reagents. Reduction of ferrocenesulphonyl chloride by lithium aluminum hydride produces the rapidly oxidized ferrocenethiol in quantitative yield (86). Both the sulphonic acid of cyclopentadienylmanganese tricarbonyl as well

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

as the corresponding sulphinic acid (obtained by sodium sulphite reduction of the sulphonic acid) have been converted to sulphones (89).

Mercuration

Ferrocene, like thiophene, furan, and other so-called "superaromatic" systems, reacts readily with mercuric acetate to form mercurated derivatives. Nesmeyanov and co-workers first reported that ferrocene could be mercurated under relatively mild conditions in either ethyl ether – alcohol or benzene–alcohol solution (13). The acetoxymercuri-ferrocenes formed in this manner are usually treated with an alcoholic solution of an alkali metal halide. The resulting products, chloromercuriferrocene (XXXII) and 1,1′-di(chloromercuri)ferrocene (XXXIII), can be conveniently separated by extraction with *n*-butyl alcohol.

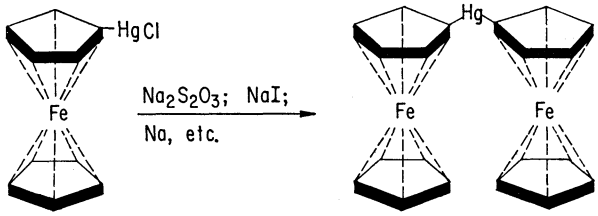


XXXII XXXIII

In a more detailed study of this reaction, Rausch, Vogel, and Rosenberg determined optimum conditions for the synthesis of either mercurated ferrocene (90). Ruthenocene has also been mercurated using glacial acetic acid as the solvent, but pure products could not be separated (26).

Mercurated ferrocenes have proved to be useful intermediates in the synthesis of various halogenated ferrocenes. Iodoferrocene, for example, is readily formed by treatment of chloromercuriferrocene with iodine, followed by decomposition of the resulting iodine complex with aqueous sodium thiosulphate (91). Dihaloferrocenes can be prepared in low yield starting with 1,1′-di(chloromercuri)ferrocene and either iodine or bromine. This indirect route to haloferrocenes, as well as the method involving cupric halide cleavage of ferrocenylboronic acids (*vide infra*), has been of much value in ferrocene chemistry. Attempts to bring about halogenation directly lead either to halogen-containing complexes or oxidative rupture of the ring-metal bond with formation of pentahalocyclopentanes (11, 65, 91).

A well-known reaction in organomercury chemistry consists of the conversion of arylmercuric chlorides to diarylmercury compounds by means of solutions of sodium iodide or sodium thiosulphate. Treatment of chloromercuriferrocene readily produces diferrocenylmercury (XXXIV) under these conditions (13, 90).

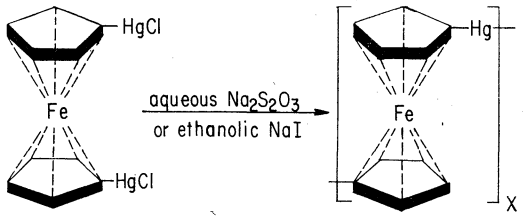


XXXIV

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Both chloromercuriferrocene and diferrocenylmercury undergo metal interchange reactions with organolithium reagents to form ferrocenyllithium (92–94). Ferrocenyl Grignard reagents can also be prepared by the reaction of haloferrocenes and magnesium under controlled conditions (95).

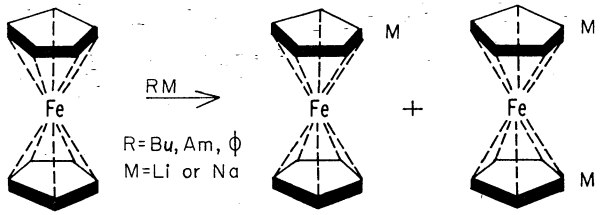
Reaction of 1,1′-di(chloromercuri)ferrocene with sodium iodide or sodium thiosulphate solutions might be expected to lead to higher homologues of diferrocenylmercury in which ferrocene units are bridged by atoms of mercury. Reactions of this type have produced apparently polymeric products whose spectra and composition are consistent with structures such as XXXV, although the very limited solubility of the products has thus far precluded reliable molecular weight measurements (96).



XXXV

Metalation

Another very important substitution reaction of ferrocene is its ability to undergo metalation with organolithium and organosodium compounds. Metalation with *n*-butyllithium in ethyl ether, first reported by Nesmeyanov and co-workers (13) and independently by Benkeser, Goggin, and Schroll (97), leads to rather low yields of ferrocenyllithium (XXXVI, M = Li) and 1,1′-ferrocenylenedilithium (XXXVII, M = Li).



XXXVI XXXVII

It was subsequently shown that the use of the mixed solvent ethyl ether – tetrahydrofuran 1:1 leads to greatly improved yields of lithioferrocenes, and this procedure has been extensively used in further synthetic applications (98).

Similar reactions of ferrocene with phenylsodium or *n*-amylsodium lead to the corresponding sodiated products (XXXVI, XXXVII, M = Na) (99, 100). The steric course of both metalation reactions has been studied, and it has been proved that dimetalation occurs in opposite cyclopentadienyl rings (101).

Several investigations have been directed at the metalation of substituted ferrocenes (100, 102). Rinehart and co-workers have recently found that 1,1′-dimethylferrocene is metalated in the ring and not at the methyl group, in contrast to the metalation of toluene.

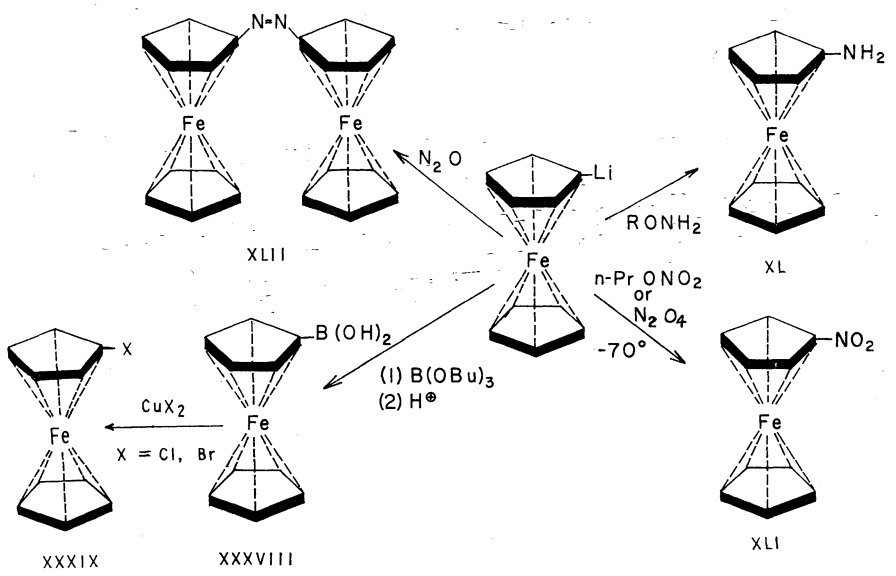
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Both ruthenocene and osmocene have been metalated with *n*-butyllithium (26). It has been shown that under comparable conditions ruthenocene is metalated to a greater extent than is ferrocene.

Carbonation and subsequent hydrolysis of either lithiated or sodiated metallocenes lead to the corresponding carboxylic acids. Ferrocenecarboxylic acid and ferrocene-1,1′-dicarboxylic acid are readily produced in this manner and can be conveniently separated by extraction of the former with ethyl ether or benzene. The reaction of metalated ferrocenes with various chlorosilanes has led to a variety of trialkylsilylferrocenes (90, 97, 101).

Metalated ferrocenes have served as very valuable intermediates for the synthesis of a number of other derivatives. Treatment of lithiated ferrocenes with tributyl borate followed by hydrolysis leads to ferroceneboronic acid (XXXVIII) as well as the diboronic acid (103). Ferroceneboronic acid, like benzeneboronic acid, is readily cleaved by cupric bromide or cupric chloride to form the corresponding halo derivatives (XXXIX). Ferrocene-1,1′-diboronic acid reacts in the same manner, and either one or two carbon–boron bonds can be cleaved. Further reactions of this type have led to a variety of mixed dihaloferrocenes (103, 104).

Another important reaction of ferroceneboronic acid and haloferrocenes consists of their facile conversion to ferrocenyl acetate on treatment with cupric acetate. Ferrocenyl acetate in turn has been hydrolyzed to hydroxyferrocene, the ferrocene analogue of phenol (105).



Aminoferrocene (XL) can be prepared in low yield by treatment of O-methylhydroxylamine or O-benzylhydroxylamine with ferrocenyllithium (106, 107). Nitroferrocene (XLI), unattainable by direct nitration of ferrocene, can be isolated from the reaction of ferrocenyllithium and either *n*-propyl nitrate or dinitrogen tetraoxide at −70° (108, 109). A similar reaction between ferrocenyllithium and nitrous oxide leads to azoferrocene (XLII) (110).

Although attempts to acylate bisbenzenechromium under Friedel–Crafts conditions have thus far resulted in cleavage of the ring-metal bond, the successful metalation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

this π-arene complex using amylsodium has been recently reported (111). The resulting metalated products can be carbonated and esterified to yield a mixture of mono-, di-, and poly-substituted carbmethoxy derivatives of bisbenzenechromium. Gas chromatographic analysis of the dicarbmethoxy portion indicates that the meta isomer is the main component (112). Homoannular dimetalation of bisbenzenechromium is therefore in contrast to heteroannular dimetalation of Group VIII metallocenes.

Oxidation and Reduction

Various oxidation and reduction reactions of substituted metallocenes have already been discussed. It should be mentioned in addition that a large number of substituted metallocenes have been oxidized chronopotentiometrically at a platinum foil in acetonitrile solution (113, 114). Electron-withdrawing substituents decrease the ease of oxidation, while electron-donating substituents increase the ease of oxidation, with respect to the parent metallocenes. A plot of chronopotentiometric quarter-wave potentials, $E_{1/4}$, versus Hammett para sigma constants shows a definite linear relationship. The $E_{1/4}$ values for ruthenocene and osmocene indicate that these metallocenes are more difficultly oxidized than ferrocene, in agreement with earlier qualitative observations (30).

Ferrocene can also be oxidized to the ferricenium cation, $(FeC_{10}H_{10})^+$, by polarographic oxidation, by chemical oxidizing agents such as ferric chloride or ceric sulphate, or simply by passing air through a suspension of it in concentrated acid (115). The deep blue, dichroic cation can readily be reduced to ferrocene by means of reducing agents such as stannous chloride or ascorbic acid (71, 115).

Stronger conditions of oxidation lead to complete rupture of the cyclopentadienyl–iron bond. Attempts to nitrate ferrocene using ethyl nitrate in the presence of sodium alkoxides led to considerable amounts of nitrocyclopentadienylsodium and iron oxides (53). It is interesting to note, however, that a similar reaction of phenylferrocene and ethyl nitrate leads to low yields of *p*-nitrophenylferrocene, the cyclopentadienyl ring remaining attached to the iron in this case (84). Earlier studies have shown that the introduction of a phenyl substituent into ferrocene results in a marked decrease in the oxidation potential (116). Treatment of ferrocene with bromine or chlorine is also reported to result in destruction of the ferrocene nucleus, the products including pentahalocyclopentanes (11).

While initial attempts to hydrogenate ferrocene under relatively mild conditions were not successful, extensive treatment with hydrogen in the presence of a nickel catalyst at 300–350° and under 280 atm absolute pressure results in the formation of cyclopentane (11). Although ferrocene is extremely resistant to catalytic hydrogenation, it can be readily reduced by lithium, in ethylamine the products being metallic iron and cyclopentadiene (117).

Interannular Electronic Effects

We have seen how a substituent on one cyclopentadienyl ring in ferrocene markedly affects subsequent ring substitution reactions. While certain transformations of this type are at least partially determined by steric factors, it seems certain that resonance and inductive interactions also play a very important role in determining orientation. A detailed knowledge of electronic transmissions both within and across the cyclopentadienyl rings is as yet not fully understood, since the precise nature of the bonding in ferrocene is still uncertain.

Several additional studies have confirmed interannular electronic interactions in ferrocene. Early investigations by Nesmeyanov and co-workers and by others demonstrated the electron donor properties of the ferrocenyl group (118). Aminoferrocene, for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

example, is approximately 20 times stronger a base than is aniline, while benzoic acid is several times more acidic than is ferrocenecarboxylic acid. Moreover, acidities and basicities of this sort are markedly affected by substituents on the opposite cyclopentadienyl ring.

A portion of this data is summarized in Table I, in which the acidities of a number of heteroannular ferrocenecarboxylic acids are compared. It can readily be seen that introduction of an electron-releasing alkyl group into the unsubstituted ring lowers the acidity of the corresponding acid, while the introduction of an electron-withdrawing group increases the acid strength.

TABLE I

Interannular electronic effects in ferrocene

	R	pK_A	(68% CH_3OH, 20°)
	H	6.29	(ϕ-COOH, 5.93)
	C_2H_5	6.43	
	C_4H_9	6.50	
	$COOCH_3$	6.08	
	$COCH_3$	5.91	
	CN	5.82	
	SO_2NH_2	5.56	

In related studies, Little and Eisenthal have found that a plot of similarly obtained pK_A values for substituted forrrocenecarboxylic acids versus Hammett para sigma constants yields a satisfactory straight line (119). These investigators have also recently measured the second-order rate constants for the esterification of a series of heteroannular substituted ferrocenecarboxylic acids with diphenyldiazomethane (120). Logarithms of the rate constants correlated well with the corresponding acid constants and with Hammett para sigma constants. These results quantitatively relate interannular electronic effects in ferrocene and suggest that resonance interactions across the cyclopentadienyl rings parallel the effects between substituents in para-substituted benzoic acids.

The carbonyl stretching frequencies of a number of heteroannular ferrocenecarboxylic acids have been measured (121). The spectral shifts vary in the direction expected from the electronic effects of the substituent groups, and parallel the effects of these substituents on the acid constants. Little and Clark have also demonstrated resonance interaction of the ferrocenyl group in ferrocenylazobenzenes by measuring shifts in the absorption maxima in the visible and ultraviolet spectra (122).

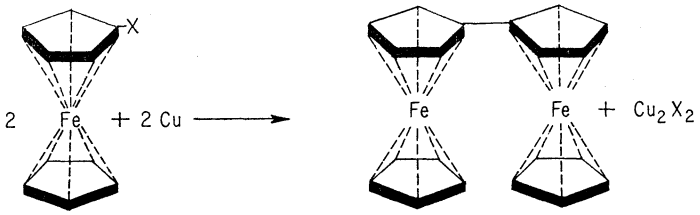
Biferrocenyl and Polyferrocenylenes

During the course of studies relating to the synthesis of certain trialkylsilylferrocenes from lithiated ferrocenes and trialkylchlorosilanes, Rausch and co-workers detected minute amounts of a dark orange crystalline substance which was subsequently shown to be biferrocenyl on the basis of analytical evidence (123, 124). In order to provide an unequivocal synthesis and a more satisfactory route to this compound, several alternative routes were investigated.

It was reasoned that if ferrocene behaved as an aromatic system, then haloferrocenes should undergo the Ullmann coupling reaction. Biferrocenyl (XLIII) was obtained from this reaction and was shown to be identical in every respect with the anomalous material isolated previously (125, 126). Surprisingly, it was found that the reaction of iodoferrocene

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

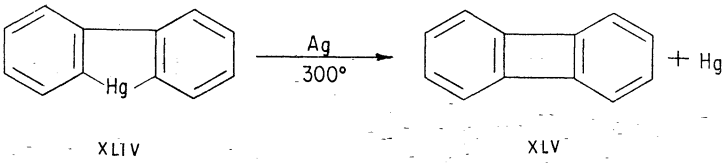
and copper produces biferrocenyl in practically quantitative yield, even at temperatures as low as 60°.



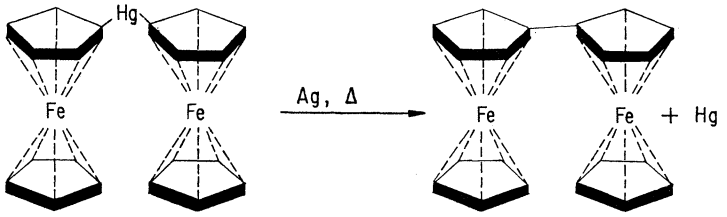
XLIII

Additional studies showed that iodoferrocene was approximately as reactive as 1-iodo-2-nitrobenzene under Ullmann conditions. A mixed Ullmann reaction involving these two reactive aryl halides produced 2-nitrophenylferrocene. Ullmann condensations of iodoferrocene with various sodium phenoxides and sodium arenethiolates likewise lead to ferrocenyl aryl ethers and sulphides, respectively (126, 127).

Another approach to the synthesis of biferrocenyl was suggested by the work of Wittig and Herwig (128). These investigators found that *o*-biphenylenemercury (XLIV; actually this compound has been shown to be a cyclic tetramer) and silver when heated at 300° resulted in the elimination of mercury and the formation of biphenylene (XLV). Rausch showed that a similar reaction involving diferrocenylmercury and silver at elevated temperatures produced biferrocenyl in yields of 30–61%, depending on the conditions



XLIV XLV



XLIII

(92, 96). The other products from the reaction included mercury, ferrocene, and quite probably polyferrocenylenes.

Nesmeyanova and Perevalova in some related studies involving diferrocenylmercury and palladium black obtained similar results (129). Their yields of biferrocenyl amounted to only 1–6%, however. It is postulated that the reactions proceed via homolytic scission of the carbon–mercury bond with the formation of ferrocenyl radicals.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Biferrocenyl has also been obtained from the interaction of ferroceneboronic acid with ammoniacal silver oxide solution (103). Ferrocenyl Grignard reagents decompose at elevated temperatures to give ferrocene and biferrocenyl (95). Treatment of ferrocenylmagnesium bromide with cobaltous chloride likewise gives biferrocenyl in high yield (95).

Korshak and co-workers have reported that the reaction of ferrocene and butyl peroxide produces polyferrocenylenes. The benzene-soluble portion of this polymer is reported to melt over 300° and to have a molecular weight between 2500 and 7000 (130). Polyferrocenylenes prepared in this manner have been shown to be paramagnetic compared to diamagnetic ferrocene (131).

α-Metallocenyl Carbonium Ions

A number of observations have been made which qualitatively suggest that carbonium ions adjacent to metallocene systems possess unusual stability. Ferrocenecarboxaldehyde, for example, is soluble in dilute hydrochloric acid (15), ferrocenyl carbinols such as ferrocenylphenylcarbinol form ethers with great ease (27), and ferrocenylmethylcarbinol can be dehydrated to vinylferrocene under exceedingly mild conditions (132). The concept of stabilizations of this type has also been used to explain certain anomalous ring substitution reactions as explained in the preceding sections.

Richards and Hill have recently obtained quantitative evidence for the stabilization of α-metallocenyl carbonium ions (133, 134). They have shown that solvolyses of methylmetallocenylcarbinyl acetates proceed via a carbonium ion mechanism, and that these acetates solvolyze with rates greater than even that of triphenylmethyl (trityl) acetate. Further, the relative rates of solvolysis and thus the order of carbonium ion stabilities increase proceeding from the iron to the osmium acetate. A portion of this data is summarized in Table II.

TABLE II

Relative rates of solvolysis of methylmetallocenylcarbinyl acetates

Acetate	Relative rate (80% acetone, 30°)
Trityl	0.15
Methylferrocenylcarbinyl	1.00
Methylruthenocenylcarbinyl	1.36
Methylosmocenylcarbinyl	5.37

Buell, McEwen, and Kleinberg have observed that weak acids such as hydrogen azide and acetic acid add readily across the double bond of vinylferrocene (XLVI, M = Fe) (135). They have postulated that the mechanism of addition proceeds via intermediate formation of the α-ferrocenylcarbonium ion (XLVII, M = Fe), followed by conversion to the acetate (XLVIII, M = Fe). Stabilization of carbonium ions of this type can result from overlap of filled metal orbitals with the vacant *p*-orbital of the carbonium ion.

The extraordinary reactivity of vinylferrocene under these conditions prompted a study of the rates of addition of absolute acetic acid to vinylmetallocenes (XLVI, M = Fe, Ru, Os). The relative rates are given in Table III.

It is interesting to note that the relative rate data closely parallel the results obtained in the solvolysis studies. Such a result might be expected from reactions proceeding through similar transition states. The observed order of relative rates may result from better overlap as the size of the central metal atom and the polarizability of its electron

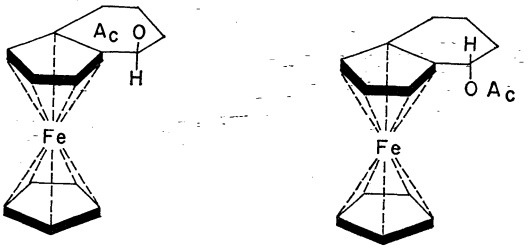
shell increase. This would result in increased stabilization and therefore ease of formation of the carbonium ions proceeding from lighter to heavier metal complexes.

Trifan and Bacskai as well as Hill and Richards have reported the preparation and solvolysis of exo acetate XLIX and endo acetate L (134, 136). It was shown that the



XLIX L

relative rate of solvolysis for the exo acetate was several thousand times greater than for the endo isomer, indicating it is much more favorable for the acetate group to leave in a position trans to the metal rather than cis. Metal electrons must therefore be directly participating in backside displacement of the acetate anion in the rate-determining ionization process. The fact that the exo alcohol is the *sole* alcohol formed from either solvolysis reaction is further evidence for backside metal participation in the transition state.

Rearrangements

The remarkable aromatic reactivity of metallocenes has prompted a number of investigations in which substituted metallocenes have been subjected to conditions which promote molecular rearrangements in benzenoid chemistry.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Weliky and Gould obtained the pinacol of benzoylferrocene by bimolecular reduction of this ketone using methylmagnesium bromide and cobaltous chloride (27). The pinacol rearranged with remarkable ease in the presence of hydrogen chloride to the pinacolone, phenylbenzoyldiferrocenylmethane, indicating that the ferrocenyl group had migrated.

These investigators also found that benzoylferrocene oxime rearranges under alkaline conditions via its *p*-benzenesulphonate ester to give N-phenylferrocenecarboxamide. This result indicates that the phenyl group is anti to the hydroxyl group in the oxime. Attempts to rearrange the oxime under the usual acidic Beckmann conditions were not successful.

A number of investigators have observed the ease with which ferrocenoyl azide undergoes Curtius rearrangement to ferrocenyl isocyanate (107, 137–139). This rearrangement has been useful for the synthesis of a variety of ferrocenylamines and urethanes.

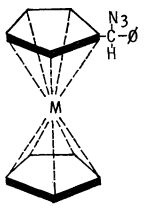
The rearrangements described above involve migration of a ferrocenyl group, together with its pair of bonding electrons, to an electron-deficient terminus. In 1,2-shifts of this type, rearrangement occurs on a side chain to which the migrating groups are attached.

Attempts to bring about rearrangements which are known to proceed via cyclic transition states have thus far been unsuccessful in metallocene chemistry. Attempts to effect Claisen rearrangement of ferrocenyl allyl ether have led to hydroxyferrocene instead of the expected rearrangement product (140). The mechanism of the Claisen rearrangement is believed to involve a cyclic transition state in which a dienone intermediate is formed. Cyclic intermediates of this sort are apparently not favored in ferrocene chemistry, due to the complex electronic interactions of the ring π-electrons with the iron atom.

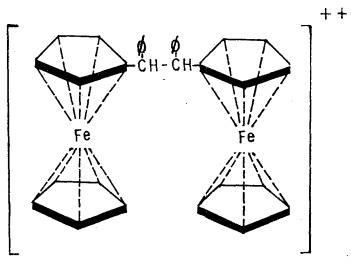
Azoferrocene has been subjected to the benzidine rearrangement under conditions which readily promote the rearrangement of azobenzene (141). Again the rearrangement fails, the products instead being aminoferrocene and iron oxide. While the mechanism of the benzidine rearrangement is still in doubt, it also probably involves a cyclic transition state.

Treatment of the methiodide of N,N-dimethylaminomethylferrocene with potassium amide in liquid ammonia results in a Stevens-type rearrangement to produce N,N-dimethylaminoethylferrocene (82). The corresponding benzene analogue behaves quite differently, the product being derived from an ortho substitution rearrangement. Such a rearrangement in the ferrocene series would involve a transition state consisting of two fused five-membered rings (142).

The most thoroughly studied rearrangement to date in metallocene chemistry has concerned the acid-catalyzed decomposition of metallocenylphenylcarbinyl azides. Reaction of the ferrocenyl azide (LI, M = Fe) with concentrated sulphuric acid in chloroform solution afforded nitrogen and a complex mixture of products, including ferrocenecarboxaldehyde, aniline, the diasterioisomeric dications of 1,2-diferrocenyl-1,2-diphenylethane (LII), and these diasterioisomers in their neutral state (143). The isolation



LI



LII

For personal use only.

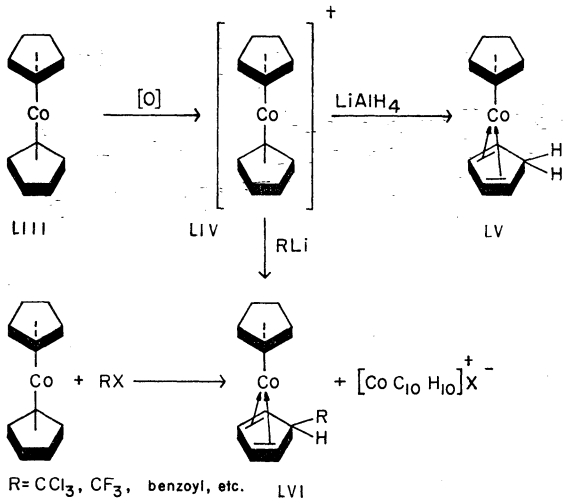
of ferrocenecarboxaldehyde and aniline to the exclusion of benzaldehyde and aminoferrocene clearly indicates preferential migration of the phenyl group in this reaction. It is postulated that the reaction mechanism involves protonation of both the azido group and the iron atom. In the rearrangement step the phenyl group would be better able to migrate to the electron-deficient nitrogen than the protonated ferrocenyl group. The formation of the dications LII can be explained by partial formation of the ferrocenylphenylcarbonium ion, followed by intramolecular oxidation–reduction to a radical–ion and subsequent coupling of the latter. The dications are in part reduced to the neutral diasterioisomers by oxidation–reduction reactions with other ferrocene derivatives present in the reaction system.

In related studies involving ruthenocenylphenylcarbinyl azide (LI, M = Ru) preferential phenyl migration was again found to occur, and the reaction products included ruthenocenecarboxaldehyde and aniline (144). The corresponding osmium azide (LI, M = Os) behaved quite differently than the iron and ruthenium analogues in that no products of rearrangement could be detected.

Ring Addition Reactions

Attempts to promote ring substitution reactions on the biscyclopentadienyls of nickel (nickelocene) and cobalt (cobaltocene) have not yet been successful. On the other hand, these metallocenes do exhibit certain remarkable ring addition reactions, and it is appropriate to consider such reactions at this point.

Cobaltocene (LIII) contains one unpaired electron and is readily oxidized to the cobalticinium ion (LIV). This cation is remarkably stable, since it is isoelectronic with



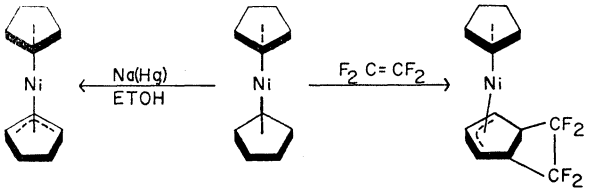
ferrocene, and is not attacked by oxidizing agents such as ozone or boiling aqua regia. Attempts to reduce cation LIV by means of lithium aluminum hydride or sodium borohydride lead to partial hydrogenation of one of the cyclopentadienyl rings, the product being cyclopentadienylcobalt-cyclopentadiene (LV) (145).

Cobaltocene reacts directly with a variety of organic halides to produce equimolar amounts of cobalticinium halides and 1-endo-substituted compounds (LVI) (59, 145–148). Cobalticinium ion readily undergoes nucleophilic addition with various organolithium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

reagents to produce 1-endo-substituted compounds of the same type. Attempts to transform the latter into asymmetric substituted cobalticinium ions have not been successful (59).

Treatment of nickelocene (LVII) with sodium amalgam in ethanol results in partial reduction of one of the cyclopentadienyl rings, thus enabling nickel to attain an inert gas electronic configuration (149). The structure of the product, cyclopentenyl-cyclopentadienylnickel (LVIII) has been confirmed by nuclear magnetic resonance studies



LVIII LVII LIX

as well as by an independent synthesis. Nickelocene undergoes facile addition of dimethyl acetylenedicarboxylate to give an adduct possessing a norbornadienyl group (150). Tetrafluoroethylene likewise adds to one of the cyclopentadienyl rings of nickelocene (151). On the basis of proton and F^{19} nuclear magnetic resonance studies, the product is believed to have a structure such as LIX.

Cobaltocene also undergoes addition of tetrafluoroethylene to yield the unusual binuclear bridged compound LX (152).

ELECTRONEGATIVITY

III. ORBITAL ELECTRONEGATIVITIES AND ELECTRON AFFINITIES OF TRANSITION METALS[1, 2]

JÜRGEN HINZE[3] AND H. H. JAFFÉ
Department of Chemistry, University of Cincinnati, Cincinnati, Ohio, U.S.A.
Received October 29, 1962

ABSTRACT

The orbital electronegativities of the neutral transition metals of the first transition series have been calculated by the Mulliken formula for a wide variety of hybrid states. The electron affinities needed in the process have been calculated by isoelectronic and isoconfigurational extrapolation.

ORBITAL ELECTRONEGATIVITIES

In the first article (1) of this series electronegativities have been evaluated and reported for a variety of valence states of the neutral elements of rows one and two of the periodic system. Mulliken's definition (3) of electronegativity, given as

$$\chi = \frac{I+E}{2}, \qquad [1]$$

has been used for the evaluation since this definition has the best theoretical foundation (4, 5) and can account sensitively for any valence state variations, provided the appropriate valence state ionization potentials and valence state electron affinities are used. In the second article (2) of this series the entire much-confused concept of electronegativity has been reinvestigated, and the following conclusions have been reached:

(*a*) Electronegativity is the property, not of an atom, but of an orbital of an atom in its valence state.

(*b*) The values of such orbital electronegativities depend strongly on the valence state considered, and, in the case of hybrids between *s* and *p* electrons, increase linearly with increasing *s* character of the hybrid orbital considered.

(*c*) Orbital electronegativity has meaning only for an orbital before it has formed a bond. For the analogous but distinctly different property of an orbital after bond formation and charge exchange the term *bond* electronegativity is suggested.

(*d*) Mulliken's definition does not yield orbital electronegativities of vacant (virtual) orbitals or doubly occupied orbitals. However, a new definition was arrived at which includes Mulliken's definition as a special case for singly occupied orbitals.

This definition was given as

$$\chi_j = \partial E(n_j)/\partial n_j \qquad [2]$$

[1]*Presented at the Symposium on Organometallic Compounds, Vancouver, British Columbia, September 4–6, 1962, sponsored by the Inorganic Chemistry Division, Chemical Institute of Canada, and the Department of Chemistry, University of British Columbia, with the support of the National Research Council, Ottawa, in cooperation with the University Extension Department.*
[2]*For Part II see reference 2.*
[3]*Present address: Department of Chemistry, Rice University, Houston 1, Texas.*

where n_j is the occupation of the orbital considered, j, and E is the energy of the atom as a function of this occupation. The energy relation postulated for this function is

$$E = a+bn_j+cn_j^2, \qquad [3]$$

in which the constants a, b, and c can be determined from the known valence state ionization potentials and electron affinities. With this definition it is possible to evaluate orbital electronegativities for vacant and doubly occupied orbitals, and for partially charged atoms and groups. Combination of [2] and [3] gives eq. [1] for singly occupied orbitals, i.e., $n = 1$.

It is the purpose of this work to examine the dependence of the orbital electronegativity in the transition series on the *valence* state, not *oxidation* state. Here the picture is considerably complicated by the much larger variety of possible hybrids due to the availability of d orbitals. Computations of orbital electronegativities for a few hybrids of the transition elements have already been done (6), but the need for a more extensive investigation becomes apparent if it is realized that a priori quantum mechanical computations do not readily yield answers for molecules containing transition elements, since such systems are too complex. It is possible, however, to obtain valuable information in such complex systems by different semiempirical methods, such as ligand field theory (7), Mulliken's "Magic Formula" (8), or various forms of molecular orbital theory. Such semiempirical methods can make good use of electronegativities as well as valence state ionization potentials, electron affinities, and promotion energies, all of which are obtained and reported in this work.

The essential part of the evaluation of orbital electronegativities, following eq. [1], is the determination of the valence state ionization potentials, I_v, and valence state electron affinities, E_v. The valence state ionization potentials are obtained by subtracting and adding to the ground state ionization potential the corresponding promotion energies of the atom, P^0, and of the positive ion, P^+, respectively. Analogously the valence state electron affinities are obtained by adding and subtracting to the ground state electron affinities the promotion energies of the atom, P^0, and negative ion, P^-, respectively. Methods for the computation of promotion energies of atoms and positive ions are known (1), and ground state ionization potentials obtainable from spectroscopy are tabulated (9), hence the evaluation of valence state ionization potentials is straightforward. However, difficulties arise in the evaluation of valence state electron affinities. The promotion energy of negative ions, although not directly obtainable, can be extrapolated, as generally done, from isoelectronic sequences (1). However, no ground state electron affinities of the transition elements are available, consequently such values had to be determined in this work, as described in Part I (1).

Procedure

The computations of the promotion energies and hence the valence state ionization potentials and electronegativities are in general the same as described in detail in the first paper of this series (1).

(1) The hybrids listed in Table I, to which the computations are confined, are constructed using group theory and the procedure outlined by Kimball (10).

(2) The valence state promotion energies for these hybrids are evaluated using the method of Mulliken (3) and Van Vleck (11), i.e., the valence state energies are expressed as linear combinations of Slater parameters, the valence state equations.[4]

[4]*The coefficients of the valence state equations are evaluated using an IBM 650 electronic computer and a program written and described by Zung (12).*

TABLE I

The hybrids considered

Point group	Configuration	Orbitals	Geometry
Two-orbital hybrids			
$D_{\infty h}$	(sp)	$\frac{1}{\sqrt{2}}s \pm \frac{1}{\sqrt{2}}z$	Linear
$D_{\infty h}$	(dp)	$\frac{1}{\sqrt{2}}\sigma \pm \frac{1}{\sqrt{2}}z$	Linear
C_{2v}	(p^2)	x, y	Rectangular
C_{2v}	(ds)	$\frac{1}{\sqrt{2}}s \pm \frac{1}{\sqrt{2}}\delta$	Rectangular
C_{2v}	(d^2)	$-\frac{1}{\sqrt{2}}\sigma \pm \frac{1}{\sqrt{2}}\delta$	Rectangular
Three-orbital hybrids			
D_{3h}	(sp^2)	$\frac{1}{\sqrt{3}}s + \frac{\sqrt{2}}{\sqrt{3}}x$ $\frac{1}{\sqrt{3}}s - \frac{1}{\sqrt{6}}x \pm \frac{1}{\sqrt{2}}y$	Trigonal planar
D_{3h}	(dp^2)	$-\frac{1}{\sqrt{3}}\sigma + \frac{\sqrt{2}}{\sqrt{3}}x$ $-\frac{1}{\sqrt{3}}\sigma - \frac{1}{\sqrt{6}}x \pm \frac{1}{\sqrt{2}}y$	Trigonal planar
D_{3h}	(d^2s)	$\frac{1}{\sqrt{3}}s + \frac{\sqrt{2}}{\sqrt{3}}\delta$ $\frac{1}{\sqrt{3}}s - \frac{1}{\sqrt{6}}\delta \pm \frac{1}{\sqrt{2}}\delta'$	Trigonal planar
D_{3h}	(d^3)	$-\frac{1}{\sqrt{3}}\sigma + \frac{\sqrt{2}}{\sqrt{3}}\delta$ $-\frac{1}{\sqrt{3}}\sigma - \frac{1}{\sqrt{6}}\delta \pm \frac{1}{\sqrt{2}}\delta'$	Trigonal planar
C_{3v}	(d^2p)*	$\frac{1}{\sqrt{3}}z + \frac{\sqrt{2}}{\sqrt{3}}\delta$ $\frac{1}{\sqrt{3}}z - \frac{1}{\sqrt{6}}\delta \pm \frac{1}{\sqrt{2}}\delta'$	Trigonal pyramid
Four-orbital hybrids			
T_d	(sp^3)	$\frac{1}{2}(s+x+y+z)$‡	Tetrahedral
T_d	(d^3s)	$\frac{1}{2}(s+\pi+\pi'+\delta)$‡	Tetrahedral
D_{4h}	(dsp^2)	$\frac{1}{2}(s+x+y+\delta)$‡	Square planar
D_{4h}	(d^2p^2)	$\frac{1}{2}(\sigma+x+y+\delta)$‡	Square planar
C_{3v}	(d^2sp)	$\frac{1}{2}(s+z+\delta+\delta')$‡	Trigonal pyramid
C_{3v}	(dp^3)	$\frac{1}{2}(\sigma+x+y+z)$‡	Trigonal pyramid
C_{3v}	(d^3p)	$\frac{1}{2}(\sigma+\pi+\pi'+z)$‡	Trigonal pyramid
C_{4v}	(d^4)	$\frac{1}{2}(\sigma+\delta+\pi+\pi')$‡	Tetragonal pyramid

TABLE I (*Concluded*)

Point group	Configuration	Orbitals	Geometry
Five-orbital hybrids			
D_{3h}	(dsp^3)†	$0.314s-0.485\sigma+\frac{\sqrt{2}}{\sqrt{3}}x$	
		$0.314s-0.485\sigma-\frac{1}{\sqrt{6}}x\pm\frac{1}{\sqrt{2}}y$	Trigonal bipyramid
		$0.594s+0.384\sigma\pm\frac{1}{\sqrt{2}}z$	
D_{3h}	(d^3sp)*	$\frac{1}{\sqrt{3}}s+\frac{\sqrt{2}}{\sqrt{3}}\delta$	
		$\frac{1}{\sqrt{3}}s-\frac{1}{\sqrt{6}}\delta\pm\frac{1}{\sqrt{2}}\delta'$	Trigonal bipyramid
		$-\frac{1}{\sqrt{2}}\sigma\pm\frac{1}{\sqrt{2}}z$	
C_{4v}	(d^2sp^2)†	$0.059s-0.496\sigma\pm\frac{1}{\sqrt{2}}x+\frac{1}{2}\delta$	
		$0.059s-0.496\sigma\pm\frac{1}{\sqrt{2}}y-\frac{1}{2}\delta$	Tetragonal pyramid
		$0.993s+0.117\sigma$	
C_{4v}	(d^4s)	$\frac{1}{\sqrt{5}}s-\frac{1}{\sqrt{20}}\sigma\pm\frac{1}{\sqrt{2}}\pi+\frac{1}{2}\delta$	
		$\frac{1}{\sqrt{5}}s-\frac{1}{\sqrt{20}}\sigma\pm\frac{1}{\sqrt{2}}\pi'-\frac{1}{2}\delta$	Tetragonal pyramid
		$\frac{1}{\sqrt{5}}s+\frac{2}{\sqrt{5}}\sigma$	
C_{4v}	(d^4p)	$\frac{1}{\sqrt{5}}z-\frac{1}{\sqrt{20}}\sigma\pm\frac{1}{\sqrt{2}}\pi+\frac{1}{2}\delta$	
		$\frac{1}{\sqrt{5}}z-\frac{1}{\sqrt{20}}\sigma\pm\frac{1}{\sqrt{2}}\pi'-\frac{1}{2}\delta$	Tetragonal pyramid
		$\frac{1}{\sqrt{5}}z+\frac{2}{\sqrt{5}}\sigma$	
Six-orbital hybrids			
O_h	(d^2sp^3)	$\frac{1}{\sqrt{6}}s\pm\frac{1}{\sqrt{2}}z+\frac{1}{\sqrt{3}}\sigma$	
		$\frac{1}{\sqrt{6}}s\pm\frac{1}{\sqrt{2}}x-\frac{1}{\sqrt{12}}\sigma+\frac{1}{2}\delta$	Octahedral
		$\frac{1}{\sqrt{6}}s\pm\frac{1}{\sqrt{2}}y-\frac{1}{\sqrt{12}}\sigma-\frac{1}{2}\delta$	

*No choice of coefficients yields equivalent orbitals; thus, standard coefficients are chosen.
†The coefficients are chosen so that all orbitals are equivalent, i.e., yield the same overlap integral in an iron (ψ) – carbon (sp^3) bond.
‡The other three hybrids are given by the same combinations, but with signs: $++--$, $+-+-$, and $+--+$.

(3) Substitution of the Slater parameters, Table II, into the valence state equations derived gives the promotion energies required of atoms, positive ions, and negative ions, P^0, P^+, and P^-, respectively.

(4) The valence state ionization potentials and electron affinities are obtained from the corresponding ground state potentials, Table III, as

$$I_v = I_g + P^+ - P^0$$

and

$$E_v = E_g + P^0 - P^-.$$

TABLE III
Ground state electron affinities and ionization potentials

Element	E_g (ev)	I_g (ev)
Ca	0.11	6.11
Sc	0.46	6.56
Ti	1.25	6.83
V	1.19	6.74
Cr	3.54	6.76
Mn	1.17	7.34
Fe	3.13	7.90
Co	3.29	7.86

Finally, the orbital electronegativities are given in Mulliken's scale as

$$\chi_M = \frac{I_v + E_v}{2},$$

which are converted to Pauling units by (1):

[4] $$\chi_P = 0.336(\chi_M - 0.615).$$

The Slater Parameters

The Slater parameters used for the evaluation of the valence state promotion energies of atoms and positive ions are those obtained previously (13) by an extensive fitting of Slater equations to the corresponding observed atomic energy levels (9). For the evaluation of promotion energies more Slater parameters are needed than can be obtained from one configuration alone. Consequently it is necessary to use those Slater parameters which are obtained when several configurations are fitted simultaneously. This implies that equivalent parameters have the same value in different configurations. That this is not true is known. However, it has been shown (13) that the uncertainties inherent in Slater's treatment of the many-electron atom are not increased significantly by assuming that the Slater parameters are equal for different configurations. In fact, the representation of spectroscopic data by Slater's equations is often better if different configurations are considered simultaneously rather than any one configuration individually. Thus, in the level of the approximations necessary to use empirical Slater parameters, it is valid to use values obtained from fitting several configurations simultaneously. The values used are listed in Table II, where the values in parentheses, not obtainable directly, had to be estimated as follows.

The values of $G_1(sp)$ of Co, Ni, and Cr^+ through Ni^+ are estimated so that they follow the same general trend indicated by the parameters determined. The parameters $G_1(sp)$ and $G_2(sd)$ of Cu cannot be evaluated independently from the atomic energy levels observed; however, the parameter $G_1(sp)+G_2(sd)$ is obtained, which gives the value of $G_1(sp)$ after $G_2(sd)$ has been estimated. The values of $W(d^{n-2}sp)$ of Co, Ni, and Fe^+ are obtained by adding to the corresponding apparent $W(d^{n-2}sp)$'s determined, which include some $G_1(sp)$, the values of $G_1(sp)$ estimated. Similarly the value of $W(d^{n-2}sp)$ of Mn^+ is obtained by adding to the value determined the values of $G_1(sp)$ and $F_2(pd)$ estimated. The $W(d^{n-2}sp)$'s of Cr^+, Co^+, and Ni^+ as well as the $W(d^{n-2}s^2)$'s of V^+ and Ni^+ are determined so that they follow the trend indicated by the other parameters. Only the value of $F_2(pp)$'s must be assumed freely. Fortunately the $F_2(pp)$'s are known to be small and of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

no great importance here, since they will influence only the energies of valence states with several p electrons, and such states are rather high in energy anyway. With the $F_2(pp)$ assumed, it is possible to calculate the values of $W(d^{n-2}p^2)$ of the elements Sc, Ti, V, Mn, and Sc^+ from the apparent values computed which contain $-5F_2(pp)$. All other $W(d^{n-2}p^2)$ which had to be extrapolated are obtained from the relation

$$W(d^{n-2}p^2) \approx 2W(d^{n-2}sp) - W(d^{n-2}s^2), \quad [5]$$

which implies that the promotion of two s electrons to p electrons requires twice as much energy as the promotion of one. Here the change of the electronic interaction of the different configurations is neglected. This is not too serious, since the d electron configuration is kept constant and the other changes, involving only one electron pair, are small.

The values of $F_2(dd)$ and $F_4(dd)$ of Ca cannot be obtained separately, thus they had to be assumed inside the range of the values determined. The same is true for Co^+, where the parameter obtained is $F_2(dd)-5F_4(dd)$. Here $F_2(dd)$ is calculated after $F_4(dd)$ has been assumed. The assumed $F_4(dd)$ of Co^+ permits also the evaluation of $G_2(sd)$ from the parameter $G_2(sd)+21F_4(dd)$ computed. With the values of $G_1(pd)$ and $G_3(pd)$ which have been estimated for Co^+ it is finally possible to calculate the values of $W(d^n)$, $W(d^{n-1}s)$, $W(d^{n-1}p)$, and $W(d^{n-2}s^2)$ from the parameters obtained from spectral data, $W(d^n)-49F_4(dd)$, $W(d^{n-1}s)-147F_4(dd)$, $W(d^{n-1}p)-18G_1(pd)-189G_3(pd)-147F_4(dd)$, and $W(d^{n-2}s^2)-294F_4(dd)$, respectively.

The Slater parameters for negative ions cannot be determined from spectral data, since no spectra of negative ions are observed. Their magnitude is extrapolated linearly from the corresponding parameters of atom and positive ion in an isoelectronic sequence. Such a linear relation has been shown for lighter elements by Rohrlich (14) and is here assumed to hold also for the transition series, since there is no other method on hand to estimate the parameters or valence state promotion energies of negative ions. However, it must be pointed out that the Slater parameters of negative ions reported in Table II are relatively uncertain, since only two known numbers in an isoelectronic sequence could be used for the extrapolation. Furthermore, it should be noted that the W's given for negative ions have no *absolute* significance, since they are not based on the ground state of the negative ions; the same is true for the valence state promotion energies reported for negative ions.

Results

The present paper considers only the elements Ca through Cu, and the ions Sc^+ through Cu^+. This restriction is necessary because of the limitations of experimental information on spectroscopic states involving incompletely filled d shells; for other elements of the third period the evaluation of the Slater–Condon parameters needed is not possible. Consequently, P^- values, and hence electronegativities of d-hybrid orbitals are obtainable only for the elements Sc to Co.

In Table IV the resulting orbital electronegativities of these elements are given in Pauling's units together with the corresponding promotion energies P^0, P^+, and P^- and the valence state ionization potentials and electron affinities, I_v and E_v, respectively.

There are numerous possible ways of distributing the non-valence electrons of the valence shell. Only distributions of maximum multiplicity have been considered, in keeping with Hund's rule, except where the s orbital is not included in the hybrid; s^2 configurations were also considered. In no case was occupation of hybrid orbitals by valence electrons considered.

*The six numbers of this column refer, in order, to the number of electrons occupying the $d_{z^2} = \sigma$, $d_{xz} = \pi$, $d_{yz} = \pi'$, $d_{x^2-y^2} = \delta$, $d_{xy} = \delta'$, and s orbitals.

Computations have been made for all possible arrangements of the non-bonding electrons in the available orbitals. Reported, however, are only those arrangements of the non-valence electrons which give rise to the lowest promotion energy of the atom.[5] These distributions of the electrons in the orbitals not involved in hybridization are given in column 3 of Table IV.

GROUND STATE ELECTRON AFFINITIES

The extensive efforts made to evaluate or determine electron affinities have been carefully reviewed by Pritchard (16), but in spite of all attempts no electron affinities of transition elements have been reported so far. Experimental and extrapolation methods seem to fail; the previous, as well as the more recently derived, extrapolation methods (17, 18) are reported to hold only for the first two rows of the periodic system. The method of Ginsberg and Miller (19), which they claim will hold for heavier elements as well, cannot be applied in the transition series.

Most of the extrapolations of electron affinities described are based on a relation between the ionization potentials of atoms in successive states of ionization in an isoelectronic sequence. Such methods must fail when the ground states in the isoelectronic sequence considered are not identical, which is the case in the transition series. Generally such extrapolation formulas will require the use of equivalent ionizations in an isoelectronic sequence. This may be illustrated on the sequence of ionizations required to extrapolate the electron affinity of scandium. The corresponding ground state ionizations are:

$$\begin{array}{llll} Sc^- & d^2s^2\ (^3F_2) \rightarrow Sc & ds^2\ (^2D_{1\frac{1}{2}}) & = E_g \\ Ti & d^2s^2\ (^3F_2) \rightarrow Ti^+ & d^2s\ (^4F_{1\frac{1}{2}}) & = I_1 \\ V^+ & d^4\ (^5D_0) \rightarrow V^{++} & d^3\ (^4F_{1\frac{1}{2}}) & = I_2 \\ Cr^{++} & d^4\ (^5D_0) \rightarrow Cr^{+++} & d^3\ (^4F_{1\frac{1}{2}}) & = I_3 \end{array}$$

[5]*A complete listing of the results for all distributions of non-valence electrons is given by Hinze (15).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A sequence of equivalent transitions, which could be used for the extrapolation is:

Sc^-	$d^3s\ (^5F_1) \rightarrow Sc$	$d^3\ (^4F_{1\frac{1}{2}}) = T_0$
Ti	$d^3s\ (^5F_1) \rightarrow Ti^+$	$d^3\ (^4F_{1\frac{1}{2}}) = T_1$
V^+	$d^3s\ (^5F_1) \rightarrow V^{++}$	$d^3\ (^4F_{1\frac{1}{2}}) = T_2$
Cr^{++}	$d^3s\ (^5F_1) \rightarrow Cr^{+++}$	$d^3\ (^4F_{1\frac{1}{2}}) = T_3$

Generally, ionizations of type $d^ns \rightarrow d^n$ have been chosen here for the equivalent transitions, since only in such cases are sufficient spectral data available.

Extrapolation Procedure

Edlén's extrapolation method (18) was chosen here since it appears to give the best representation with a minimum of initial information. The method suggested by Johnson and Rohrlich (17), apparently equally reliable, requires higher and more ionization potentials for the extrapolation, which is a decided disadvantage, especially in the transition series, where higher ionization potentials are quite uncertain. Edlén obtains the electron affinity T_0 from the successive *equivalent* ionizations T_1, T_2, and T_3 respectively by the following expression,

$$[6] \qquad T_0 = 3T_1-3T_2+T_3+\frac{3\left(T_1-2T_2+T_3-\frac{2R}{n^2}\right)\left(-T_1+2T_2-T_3+\frac{6R}{n^2}\right)}{T_1-4T_2+3T_3-\frac{12R}{n^2}},$$

where R is the Rydberg constant and n the principal quantum number.

Since equivalent ionization processes of an isoelectronic sequence should be used in this expression, it is necessary to reduce the ground state ionizations to such values. This is done by adding and subtracting the appropriate term values, W, to the ground state potentials.

In the above example we obtain,

$$\begin{array}{lllll} \text{Ti} & d^2s^2\ (^3F_2) & \xrightarrow{I_1} & \text{Ti}^+ & d^2s\ (^4F_{1\frac{1}{2}}) \\ & \Big\downarrow W \quad 0.81\text{ ev} & & & \Big\downarrow W^+ \quad 0.11\text{ ev} \\ \text{Ti} & d^3s\ (^5F_1) & \xrightarrow[6.12\text{ ev}]{T_1 = I_1-W+W^+} & \text{Ti}^+ & d^3\ (^4F_{1\frac{1}{2}}) \end{array}$$

$$I_1 = 6.82\text{ ev}$$

The required ground state ionization potentials and term values are obtained from Moore's tables (9). The T values generally calculated for the transition $d^ns \rightarrow d^n$ are listed in Table V together with the T_0 values obtained by extrapolation.

TABLE V

Isoelectronic electron affinities and ionization potentials

		T_1 (ev)	T_2 (ev)	T_3 (ev)	T_0 (ev)	
$d^2s\ (^4F_1)$	$d^2\ (^3F_2)$	5.71	13.57	23.86	0.74	Ca^-
$d^3s\ (^5F_1)$	$d^3\ (^4F_1)$	6.12	14.33	24.82	0.56	Sc^-
$d^4s\ (^6D_1)$	$d^4\ (^5D_0)$	6.48	15.01	25.94	0.75	Ti^-
$d^5s\ (^7S_3)$	$d^5\ (^6S_2)$	6.76	15.64	26.91	0.65	V^-

A major difficulty is the determination of the ground state electron affinities from the calculated T_0 values. For this it is necessary to know the energy difference between the state considered of configuration $d^n s$ and the ground state of the negative ion. These values must be calculated since no spectra of negative ions are observed. These energy differences have been evaluated by setting up the Slater equations of the required states and using the Slater–Condon parameters for the corresponding negative ions, Table II. The extrapolation of these parameters needed has been described above. In Table III the ground state electron affinities obtained are listed, together with the ground state ionization potentials of the same atoms.

Discussion

There are two major sources of error in the method described, and the electron affinities obtained cannot be expected to be highly accurate. One uncertainty is introduced by the use of Edlén's extrapolation and the possible inaccuracy of the ionization potentials used. This uncertainty is believed to be small, an opinion supported by the small variation of the T_0 values extrapolated.

The second source of error is considerably more serious, as the method of obtaining the term values, W^-, for negative ions is much more doubtful. The linear extrapolation of Slater–Condon parameters from the corresponding isoelectronic sequence is quite questionable, especially since in many cases only two members of such a sequence are known. Unfortunately there exists no better simple method to obtain the values required.

In spite of such uncertainties inherent in the procedure, the values obtained are not only of the right order of magnitude, but they reflect also the changes and trends expected on chemical grounds. It is expected and observed that the values increase in going from Ca to V; the value calculated for Ti seems somewhat too large. The sudden rise observed for the electron affinity of Cr must be anticipated, since here the transition $d^5s^2 \rightarrow d^5s$ gives rise to the ground state electron affinity, i.e., removal of an s electron, while in all other cases the transition is $d^n s^2 \rightarrow d^{n-1}s^2$, removal of a d electron. The low value obtained for Mn appears reasonable because of the special stability of the half-filled shell. The removal of the extra d electron beyond the half-filled shell will not require much energy on account of the missing additional exchange energy of state d^6s^2 with respect to d^5s^2.

The sudden rise to the values of Fe and Co seems to be too drastic and values about 1 ev lower would be anticipated in the light of the Ca $\rightarrow$ V rise. This inconsistency is undoubtedly due to an overestimation of the term splitting of the negative ion. Unfortunately there is no method known at the moment by which more reliable values for the electron affinities of the transition metals can be obtained. But these roughly estimated values obtained here give at least a lead about magnitude and order, and are sufficient for the use in electronegativity calculations, for which purpose they have been determined. This is especially true here since the electronegativity computations are made especially to investigate the valence state dependence of the orbital electronegativities, and the differences between the electronegativities for different valence states of the same atom are not affected by the ground state electron affinities used. On the other hand, an uncertainty in the ground state electron affinity of 1 ev results only in an error of 0.16 Pauling electronegativity units in the electronegativities computed. This weakens the comment frequently made about Mulliken's definition of electronegativity, saying, although Mulliken's definition is best justified and should give the most reliable values, it cannot be used since the electron affinities are not available. However, it will always be possible to estimate the electron affinities with an uncertainty limit of less than 1 ev.

It is remarkable to what degree the orbital electronegativities obtained depend on the hybrids considered. Unfortunately, due to the complexity of the hybrids, it is rather difficult to obtain a general and simple relation about the value of the orbital electronegativity as a function of s, p, or d character of the hybrids involved. Universally the electronegativities increase slightly with increasing s character of the orbitals and steeply with increasing p character. Similarly, the orbital electronegativity is generally higher for higher bonding valence states than for lower bonding ones. These increases, especially the steep increase with increasing p character, lead to some electronegativity values which are astonishingly high. Such are, for example, the values for the octahedral valence state d^2sp^3 of Cr, Mn, Fe, and Co. The explanation of such high values for just this valence state with an extremely high promotion energy cannot be given immediately. The meaning of these high values however will be investigated. Readily explainable are the unfamiliar high electronegativity values of other hybrids with high p character, and consequently high promotion energy. All these unstable hybrids can be substituted either completely or to any intermediate amount by other linear combinations of atomic orbitals, giving rise to more stable hybrids with the same geometry but electronegativities more in the familiar range. In this sense it is possible to substitute the unstable trigonal hybrids sp^2 and dp^2 by the hybrids d^2s or d^3. The tetrahedral hybrid sp^3 can be substituted by the more stable d^3s; actually any intermediate substitution of the three p orbitals by the corresponding d orbitals will lead to a tetrahedral hybrid. The low-energy hybrids d^3p and d^2sp can substitute for the unstable dp^3. By substituting the s orbital by the d_{z^2} orbital, the high-energy dsp^2 hybrid can be reduced to the more stable d^2p^2 hybrid with the same symmetry; similarly the unstable dsp^3 hybrid is transformed into the low-energy d^3sp hybrid by substituting d for p orbitals.

A relation between the s, p, and d character of the hybrid orbitals and the electronegativity seems desirable. From the orbital electronegativity data given, the relation

$$\chi_h = a\chi_s + b\chi_p + c\chi_d \qquad [7]$$

is suggested. Here χ_h, χ_s, χ_p, and χ_d are the orbital electronegativities of the hybrid, the s, the p, and the d orbitals respectively, and a, b, and c give the amount of s, p, and d character respectively of the hybrid considered. From the data reported for different hybrids, the electronegativities of pure s, p, and d orbitals are easily evaluated using eq. [7], which in turn, with these electronegativities of the pure orbitals, can be used to evaluate the electronegativity of any intermediate and second-order hybrids. However, eq. [7] holds only if similar hybrids are considered, that means hybrids which will form the same number of bonds, and if the distribution of the non-valence electrons is equal.

A KINETIC INVESTIGATION OF THE REACTION OF METHYLMAGNESIUM BROMIDE WITH BENZOPHENONE[1, 2, 3, 4]

NORBERT M. BIKALES[5] AND ERNEST I. BECKER[6]
Chemical Laboratories, Polytechnic Institute of Brooklyn, Brooklyn, N.Y., U.S.A.

Received October 29, 1962

ABSTRACT

The reaction of methylmagnesium bromide with benzophenone in tetrahydrofuran was found to be homogeneous and essentially quantitative. The rates of this reaction were measured by following the decrease in absorbance of benzophenone in the ultraviolet as a function of time. Variables examined were concentrations of reactants, magnesium bromide, and temperature. Values were derived for the rate constants, and the energy and entropy of activation. The reaction was found to be initially first order in each reactant, but the rate decreased faster with time than would be predicted from the simple second-order rate equation. The implications of these findings are discussed.

In the present investigation, the second (1) in a series concerned with the study of Grignard kinetics, an analytical procedure was developed which made it possible to study the kinetics of the reaction between benzophenone and methylmagnesium bromide or dimethylmagnesium. It is the purpose of this paper to report the results and to discuss their significance to the mechanism of the Grignard reaction.

EXPERIMENTAL[7]

Apparatus

Instrumentation

A Cary Model 14 recording spectrophotometer was used for recording the ultraviolet spectra. This instrument was equipped with a jacketed cell compartment permitting temperature control and a gas inlet allowing the compartment to be flushed with nitrogen. Vapor phase chromatographs were obtained on a Perkin–Elmer Fractometer, Model 154.

Glassware

Kinetic runs were carried out in stoppered, calibrated, matched quartz cells (American Instrument Co.) of either 1-, 10-, or 20-mm lengths. A 20-mm cell was especially constructed with a jacket to permit circulation of coolant.

Calibrated syringes equipped with stainless steel needles were used for transfer and measurement of reagents. Deliveries could be reproduced with an average of 2 parts per thousand.

All glassware was dried in an oven at 130° and stored in an atmosphere of dry nitrogen until use.

Temperature Control

Water from a constant temperature bath (±0.02°) was pumped through the jacket of the Cary cell compartment as well as through the jacket of the cell itself (in the case of the 20-mm cell). Temperature readings were made in the bath and inside the compartment using calibrated thermometers reading to 0.1° and 0.2°, respectively (estimates possible to 0.02° and 0.04°). Heat exchange from the compartment walls to the cell was greatly facilitated by a rapid flow of nitrogen (ca. 20 liters min^{-1}), which also provided an inert atmosphere.

Timer

An electric stopwatch ("Time-It") allowing readings to 0.01 minute was used.

[7]*Additional details, including kinetic data for all runs, may be found in the reference cited in footnote 2.*

Preparation of Reagents

Reagents were prepared, stored, and transferred in an atmosphere of dry nitrogen. In order to avoid the possible introduction of moisture through repeated sampling, fresh reagents were prepared at frequent intervals. Thus, a total of four preparations of methylmagnesium bromide and seven preparations of benzophenone were carried out for the kinetic runs.

Magnesium

Ingots of sublimed magnesium (Dow) were milled into turnings using a Carballoy cutting tool, with special care being taken to prevent contamination. The turnings were washed with ether, dried *in vacuo* and stored in an atmosphere of dry nitrogen. Methyl bromide (Matheson) was purified by passage successively through concentrated sulphuric acid and phosphorus pentoxide (2, p. 213). Vapor phase chromatographic analysis indicated the presence of a possible maximum of 0.018% of impurities. Tetrahydrofuran (DuPont) was stored over lithium aluminum hydride and fractionally distilled under nitrogen as required. Vapor phase chromatographic analysis showed that impurities amounted to a maximum of 0.007%. 1,2-Dibromoethane (Eastman) was fractionally frozen twice and then distilled from phosphorus pentoxide; b.p. 130.5°; $n_D^{26.5}$ 1.5350, (lit. (2, p. 239) b.p. 131.6°; n_D^{15} 1.5416, dn/dt −0.00058). Dioxane was purified by the method of Fieser (3) and stored over sodium in the dark in an atmosphere of nitrogen. Ethyl ether anhydrous (Mallinkrodt) was distilled from lithium aluminum hydride immediately prior to use. Nitrogen prepurified (Air Reduction) was passed through a 20-cm drying tower containing Ascarite and Drierite.

Methylmagnesium bromide was prepared under nitrogen from magnesium and methyl bromide in the conventional fashion. At the completion of the reaction, the mixture was forced through a fritted-glass filter directly into the storage vessel with nitrogen pressure. The filtrate was clear and virtually colorless. The solution was analyzed for base content by the Gilman method (4) and for halogen content by a Mohr titration (5). A typical analysis of a Grignard solution gave a base content of 0.936 *N* and a halogen concentration of 0.980 *N*, corresponding to a Br/CH_3 ratio of 1.047.[8]

Care was necessary to avoid the presence of residual methyl bromide at the end of the reaction. In several cases, where large excesses of methyl bromide were allowed to remain in solution, the Grignard reagent was completely consumed in a coupling reaction:

$$(CH_3)_2Mg \cdot MgBr_2 + 2CH_3Br \rightarrow 2MgBr_2 + 2C_2H_6.$$

This reaction produced in about a day a saturated solution of magnesium bromide giving a negative Gilman test (14). The precipitated magnesium bromide was a white, crystalline solid, solvated by 3 moles of tetrahydrofuran, as indicated by Mohr titration. Anal. Calc. for $3C_4H_8O \cdot MgBr_2$: Br, 39.9%. Found: Br, 38.2%. The infrared spectrum showed a bathochromic shift of the strong tetrahydrofuran bands from 1075 to 1040 cm^{-1} and from 920 to 885 cm^{-1}.

Dimethylmagnesium in tetrahydrofuran was prepared by the procedure which Storfer and Becker (1) had used in preparing diethylmagnesium.

Magnesium bromide was prepared from 1,2-dibromoethane and magnesium directly in tetrahydrofuran. The solution was clear and only faintly yellow, unlike the product from magnesium and bromine which was invariably dark.

Benzophenone

Benzophenone (Eastman) was washed successively with dilute alkali, dilute acid, and then recrystallized successively from chloroform, petroleum ether (three times), and ethanol to a melting point of 47.9–48.0°. Solutions were handled only in subdued light. The product was stored under dry nitrogen in the dark.

Standard solutions were prepared by distilling tetrahydrofuran directly into the storage vessel containing the ketone. Analyses were carried out by ultraviolet spectroscopy.

Ultraviolet Spectra

All spectra were measured in freshly distilled tetrahydrofuran.

Benzophenone

There were two major peaks in the ultraviolet spectrum: a strong peak at 251 mμ, ϵ 1.82×10^4, and a much weaker maximum at 343.5 mμ, ϵ 128±1. There was also a trough at 308 mμ.

The peak at 343.5 mμ followed Beer's law over the range of concentrations from 6.47×10^{-4} *M* to 1.09×10^{-1} *M*. Little or no photolysis was observed when a 5.5×10^{-3} *M* solution was irradiated in the spectrophotometer with monochromatic light (343.5 mμ) for 12 hours.

1,1-Diphenylethanol

1,1-Diphenylethanol absorbed at the following peaks: 253 mμ, ϵ 380; 258 mμ, ϵ 453; 264 mμ, ϵ 356. A less distinct maximum was present at 268 mμ, ϵ 247, and a shoulder at 248 mμ. There was no absorption in the 300–400 mμ range.

Methylmagnesium Bromide and Magnesium Bromide

A 0.086 *M* solution of methylmagnesium bromide had only a slight absorption in the 340–400 mμ range

[8]*Wotiz et al. (6–12) have used a* Br/Mg *ratio in describing their Grignard reagents. Thus a reagent consisting of* $R_2Mg + \frac{1}{2}MgBr_2 = 0.66$. *We prefer to express this information by a* Br/R *ratio (= 0.50 in this case) from which the molar ratio is more easily derived (1, 13).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

($A \leqslant 0.02$; 20-mm cell). The absorbance increased with decreasing wavelength, reaching 0.85 at 300 mμ. Solutions of magnesium bromide did not absorb in the 300–400 mμ range.

Mixtures of Benzophenone and Magnesium Bromide

A yellow color formed upon mixing benzophenone with methylmagnesium bromide; simultaneously, the absorbance increased in the 300–400 mμ range. The formation of a yellow color and the spectral changes were noted even when the molar ratio of magnesium bromide to benzophenone was as low as 0.018.

While the yellow color was invariably present, it was observed, however, that the spectral changes were not reproducible because of a faint haziness present even at the 0.018 *M* ratio cited above.

The color was found to vanish immediately upon the addition of even small amounts of methylmagnesium bromide, with regeneration of the benzophenone spectrum.

To 0.50 ml of 0.100 *M* (0.050 mmole) of benzophenone in a 1-mm cell, there was added 0.70 ml of 0.224 *M* (0.16 mmole) magnesium bromide. The solution immediately turned yellow and the absorbance exceeded the limit of the instrument (2.0) at 344 mμ. A few minutes after the addition of the bromide, 0.050 ml of 0.52 *M* (0.026 mmole) methylmagnesium bromide was added with shaking. The color vanished instantly. The benzophenone spectrum reappeared with an absorbance of 0.52 at the 344 mμ maximum, which was exactly the value calculated taking into account the dilution of the original benzophenone solution (little reaction had yet taken place).

The Reaction of Methylmagnesium Bromide with Benzophenone

Product Analysis

To 1.82 g (0.0100 mole) of benzophenone in 10 ml of tetrahydrofuran, there was added 10.5 ml of 0.520 *M* (0.0109 equiv) methylmagnesium bromide. A moderate exotherm was noted. The solution was diluted to 25.00 ml and allowed to stand in a dry box protected from light for 5 days. The solution was clear throughout this time. Three 1.00-ml aliquots were then withdrawn, diluted to 100 ml each with tetrahydrofuran containing 0.10 ml of 6 *M* HCl, and examined in the ultraviolet. The spectrum matched that of pure 1,1-diphenylethanol. The remainder of the reaction mixture was treated with 20 ml of saturated ammonium chloride solution in water and extracted three times with a total of 100 ml of ether. After having been dried with Drierite, the ether solution was evaporated, yielding 1.70 g (97.7%) of a white solid, m.p. 79.5–80.5° (lit. (15) m.p. 81°). Recrystallization successively from ethanol, petroleum ether, and ethanol gave a product, m.p. 80.0–80.4°. The infrared spectrum of the crude material likewise matched that of the recrystallized material, with the possible exception of a trace (<2%) of residual ketone. Fractional crystallization (petroleum ether – methanol) failed to reveal any other impurities.

Analytical Procedure

The benzophenone peak at 343.5 mμ was found to lie in a region where neither the product nor the Grignard reagent had any significant absorption. A direct measure of concentration could therefore be obtained from the absorbance at that wavelength, either after quenching or more simply during reaction itself. The validity of this method was confirmed in experiments wherein methylmagnesium bromide was added to benzophenone solutions containing a reagent capable of destroying the Grignard reagent. Thus, when 0.0236 g (1.30×10^{-4} mole) of benzophenone was dissolved in 49.00 ml of tetrahydrofuran containing 0.20 ml (5.0×10^{-3} mole) of methanol, and 1.00 ml of 0.873 *M* (8.73×10^{-4} mole) methylmagnesium bromide was added slowly with good agitation, the absorbance found (20-mm cell) was 0.667 vs. 0.666 calculated from the absorptivity of pure benzophenone. Similar experiments gave absorbance readings of 0.828 and 0.414 vs. the calculated values of 0.820 and 0.410, respectively. Methanol, in the amounts used, had no effect on the absorptivity of benzophenone itself. Quenching of partially reacted mixtures likewise gave good agreement of observed absorbance values with those calculated based on benzophenone content.

An additional check on the accuracy of the method consisted in the extrapolation of the experimental curve of absorbance vs. time obtained in kinetic runs from the first measured point (ca. 10 seconds after mixing of reagents) to time zero. Invariably, the extrapolated curve was smooth and corresponded at time zero with the calculated absorbance.

Kinetics

(a) Exploratory runs.—A number of experiments were made in order to obtain an estimate of the rate to be expected in the kinetic runs. In a typical case, the initial concentrations were $[BP]_0 = 0.140$ *M* and $[MMB]_0 = 0.195$ *M*. Samples (1 ml) were withdrawn from the reaction mixture, quenched with tetrahydrofuran containing some methanol, diluted to 25 ml, and analyzed spectroscopically. After 11 minutes of reaction at 30.0°, the benzophenone had been completely consumed (no absorbance at 343.5 mμ) and the normal spectrum of 1,1-diphenylethanol had appeared with an absorbance at 258 mμ, agreeing with the expected value. For the 5.00-mm cell: calc.: *A*, 1.27; found: *A*, 1.30.

(b) General procedure.—To the well-dried cell there was added a measured amount of standard benzophenone solution and, if needed, tetrahydrofuran. The cell was then placed into the compartment of the Cary spectrophotometer and sufficient time was allowed for temperature equilibrium to be reached. The benzophenone spectrum was measured in the 300–400 mμ range, after which the wavelength setting of the instrument was fixed at 343.5 mμ. A measured amount of standard Grignard reagent was added, a timer was started, and the recording of absorbance was begun. Inasmuch as the chart was driven by a synchronous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

motor, a direct plot of absorbance at the peak vs. time was obtained. The time elapsed between the addition of the Grignard reagent and the beginning of the recording of absorbance was about 10 to 15 seconds. When the initial, fast reaction had subsided, complete spectra in the 300–400 mμ range were obtained periodically. The cell was kept tightly stoppered throughout the reaction. For the lower concentrations of benzophenone (ca. 5×10^{-3} M), the jacketed 20-mm cell was used. Higher concentrations required either a 10-mm or a 1-mm cell. When the reaction was allowed to proceed for long periods (for example for 5 hours, or overnight), the spectrum of benzophenone was occasionally observed to change in appearance; a decrease in the depth of the trough at 308 mμ and the appearance of a new maximum at 333 mμ were noted. Absorbance readings when this occurred were rejected in the calculations. Reaction mixtures were completely homogeneous and colorless, except as noted before; only reactions in which homogeneity was observed throughout were used in the kinetic study.

Calculations

Benzophenone concentrations were obtained from an equation derived from Beer's law:

$$[\mathrm{BP}] = \frac{A}{\epsilon \times l} = \frac{A}{128 \times l}\ , \qquad [1]$$

where A was the absorbance, [BP] was in moles/liter, and l, the length of the cell, was in cm. Volumes of reaction mixtures were calculated from the volumes of methylmagnesium bromide and benzophenone solutions added.

Concentrations of methylmagnesium bromide at time t were obtained from

$$[\mathrm{MMB}]_t = [\mathrm{MMB}]_0 - x = [\mathrm{MMB}]_0 - [\mathrm{BP}]_0 + [\mathrm{BP}]_t \qquad [2]$$

on the assumption that the stoichiometry of the reaction involves 1 mole of each species (eq. [3]):

$$\mathrm{C_6H_5{-}\underset{\underset{\mathrm{O}}{\|}}{C}{-}C_6H_5} + (\mathrm{CH_3})_2\mathrm{Mg\cdot MgBr_2} \rightarrow \mathrm{CH_3{-}\overset{\overset{\mathrm{C_6H_5}}{|}}{\underset{\underset{\mathrm{C_6H_5}}{|}}{C}}{-}O{-}Mg_2(CH_3)Br_2.} \qquad [3]$$

Since the spectrophotometer gave a continuous record of absorbance vs. time, i.e., an infinite number of points, sufficient values of absorbance (corrected, if necessary, for absorbance of the blank) were converted to concentrations to obtain an adequate representation of the reaction. Thus, in the early, rapid part of the reactions, 5- or 10-second intervals were chosen. Later, concentrations were calculated only for every 20 or 30 seconds. Toward the end of the reaction, absorbance values were taken at intervals of several minutes. Data thus obtained for [BP] and [MMB] at various times of reaction were plotted using log {[BP]/[MMB]} or log {[MMB]/[BP]} as the ordinate and time as the abscissa to test agreement with the second-order equation (16):

$$kt = \frac{2.303}{(a-b)} \log \frac{b(a-x)}{a(b-x)}\ .$$

Inasmuch as the data thus plotted did not lie on a single straight line in any of the experiments, a line was fitted in each run for the early part of the reaction only (as in Fig. 1). This line was drawn visually (16) so as to accommodate as many points as possible, including the point at time zero, without exceeding the estimated precision of the measurements. From the slope of this line there was obtained a rate constant for the early part of the reaction, k(initial):

$$k(\mathrm{initial}) = \frac{2.303\left(\log \frac{[\mathrm{BP}]_2}{[\mathrm{MMB}]_2} - \log \frac{[\mathrm{BP}]_1}{[\mathrm{MMB}]_1}\right)}{(t_2-t_1)([\mathrm{BP}]_0-[\mathrm{MMB}]_0)}\ .$$

Data for the early parts of all runs, including those illustrated in Figs. 3 and 4, were plotted on a scale similar to that shown on Fig. 1.

The initial rate, $-d[\mathrm{BP}]/dt$, was derived from the change in absorbance during the first 5 seconds actually recorded (not extrapolated) in a run by inserting the data into the unintegrated rate equation and fitting the results using a computer.

RESULTS

Order of the Reaction

Benzophenone and methylmagnesium bromide have been reported to react without the side reactions of enolization and reduction (18, 21); the high yield of 96% of addition product was verified in these experiments.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The speed of the reaction in tetrahydrofuran precluded a sampling technique for following the reaction. However, the rate could be measured spectrophotometrically by observing continuously the decrease in absorbance of the 343.5 mμ peak of benzophenone. The absorbance followed Beer's law over a 170-fold range of concentrations.

Twelve runs were made to test the reproducibility of the reaction rate constant. That the reaction was initially second order was determined from the slopes of the straight lines afforded by the second-order plots for the first phase of the reaction (Fig. 1). Second-order plots made for approximately the first 60 seconds gave k(initial) = 0.192±0.013 liter mole^{-1} sec^{-1} at 25.0° (Table I). Furthermore, mathematical analysis of the data

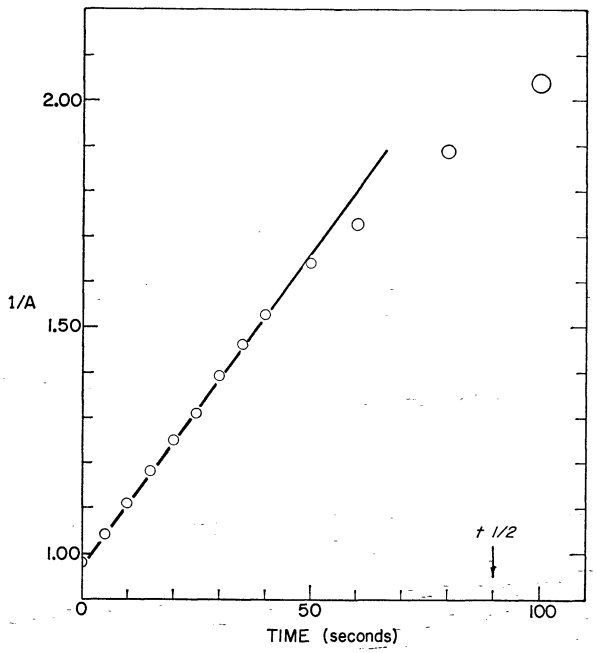

FIG. 1. Second-order plot for the first half-life of run 4 ([MMB]$_0$/[BP]$_0$ = 1.01). Plot of the reciprocal of the absorbance at 343.5 mμ vs. time. Data for the early parts of all runs were plotted on a larger scale so as to permit a more accurate determination of k(initial).

TABLE I

Rate constants derived from initial rates (25.0°)

Run	[BP]$_0$ ×10^2, M	[MMB]$_0$ ×10^2, M	[MMB]$_0$/[BP]$_0$	k(initial), liter mole^{-1} sec^{-1}

showed that the following equation described the initial rate:

$$-\frac{d[\mathrm{BP}]}{dt} = 0.18[\mathrm{BP}]^{0.89}[\mathrm{MMB}]^{1.1},$$

where 0.18 is in liter mole^{-1} sec^{-1}. These results establish the first-order dependence in each component.

However, graphical analysis also showed that the simple second-order dependence was not followed throughout the reaction. After about 30–40% conversion, the data deviated increasingly from a straight line. Correlations for 0, 0.5, 1, 1.5, 2, and 3 orders likewise failed to give a straight line over the whole range of the data.

A further characteristic of the kinetics was that after half of the methyl groups in the solution was consumed, the rate of further consumption of methyl groups decreased to, at most, 1/85th of that of the first half of the total methyl groups. For kinetic analysis of the initial phase of the reaction, one half of the methyl groups could therefore be regarded as inactive. Thus, the term "half-life" refers to the consumption of one-half of the kinetically significant methyl groups, or to one-quarter of the total methyl groups present in solution at the beginning of reaction.[9] The spectrophotometric method of measurement was not sufficiently accurate in the later stages of reaction to permit an evaluation of the order throughout since measurements of the rate were much less precise.

Similarly to the findings at 25°, a straight line of log {[MMB]/[BP]} vs. t could be fitted to the data only for the early part of the reaction in runs made at other temperatures. The initial-rate constants calculated from the slopes were found to be 0.0312 liter mole^{-1} sec^{-1} at 1.0°, 0.119 at 15.0°, 0.181 at 25.0°, and 0.248 at 35.0° (Table II).

TABLE II
Effect of temperature on the rate

Run	Temperature, °C	$[BP]_0$ $\times 10^3$, M	$[MMB]_0$ $\times 10^2$, M	k(initial), liter mole^{-1} sec^{-1}
11	1.0	5.57	1.81	0.0320
20	1.0	5.07	2.00	0.0303
16	15.0	5.18	1.78	0.119
8	25.0	5.52	1.77	0.186
9	25.0	5.41	1.75	0.176
10	35.0	5.29	1.71	0.251
19	35.0	5.50	1.74	0.244

The logarithms of the rate constants obtained at the various temperatures were plotted as a function of the reciprocal of absolute temperature (Fig. 2), as required by the Arrhenius equation (16). Since the data deviated somewhat from linearity, the slope was calculated by the method of least squares. The energy of activation derived from this calculation was E_a = 11 kcal/mole. Lines were also drawn with a minimum and maximum slope for the data. They indicated that E_a fell in the range of 10–13 kcal/mole. The entropy of activation $\Delta S^{\ddagger}$ corresponding to these extremes was −28 and −18 e.u., while E_a = 11 kcal/mole gave a value for the entropy of activation of −25 e.u. at 25°.

Effect of Magnesium Bromide

The effect of magnesium bromide on the rate was investigated at 25° in three ways:

(*a*) magnesium bromide was premixed with methylmagnesium bromide and the mixture was added to benzophenone (runs 13 and 14);

[9] *A similar assumption was made by Storfer and Becker in the case of the kinetics of addition to nitriles (1).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

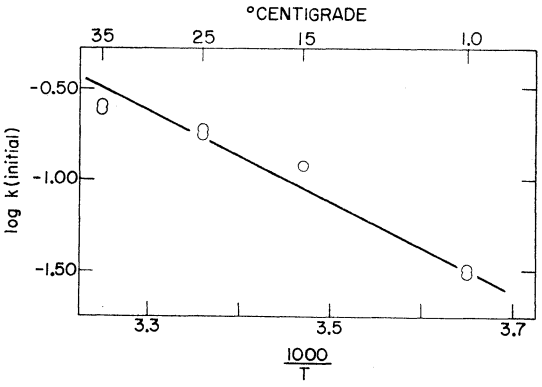

FIG. 2. Effect of temperature on rate.

(*b*) methyl Grignard reagent free of magnesium bromide (i.e., dimethylmagnesium) was allowed to react with benzophenone (runs 21, 22, 24, and 25);

(*c*) magnesium bromide was added to dimethylmagnesium, and the mixture was allowed to react with benzophenone (run 23).

In method (*a*), when sufficient magnesium bromide was added to the Grignard reagent to give a $[MgBr_2]/[BP]_0$ ratio of about 1 in the reaction mixture, the rate decreased as compared to a similar run with no added magnesium bromide. Thus, under comparable conditions, except for the presence of added magnesium bromide, the rate constant fell to 0.045 liter mole^{-1} sec^{-1} from an average of 0.192 for the ordinary Grignard reagent. The time for which the MMB–$MgBr_2$ mixture was allowed to stand did not seem to affect the results; in run 13, the mixture was allowed to stand for 40 minutes before use, while in run 14 it was used immediately (see Table III and Fig. 3). Yet, the rate constants

TABLE III

Effect of magnesium bromide on rate (25.0°)

		Methylmagnesium compound		
Run	$[BP]_0$ $\times 10^2$, *M*	Concn. at t_0 $\times 10^2$, *M*	Br/CH_3	*k*(initial), liter mole^{-1} sec^{-1}
21	0.482	1.66	0.00	0.407
22	7.08	7.32	0.00	0.403
24	7.08	7.32	0.00	0.403
25	7.73	4.04	0.00	0.40
Average of 12 runs			0.99–1.05	0.192±0.013
23	5.55	5.15	1.00	0.199
13	0.537	1.70	1.29	0.044
14	0.530	1.67	1.29	0.045

were virtually identical. The spectrum of benzophenone had a normal appearance in these experiments.

The experiments with dimethylmagnesium [DMM], $(CH_3)_2Mg$, method (*b*), showed that this reagent was slightly more reactive than the ordinary Grignard reagent, the initial rate giving a constant of 0.40 liter mole^{-1} sec^{-1}, as compared to an average of 0.192 for $(CH_3)_2Mg \cdot MgBr_2$ (Fig. 4). The concentrations investigated covered about the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

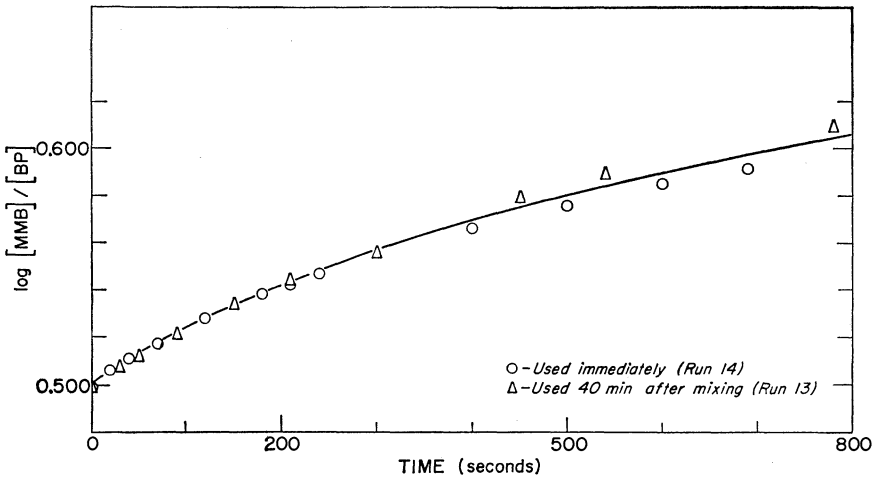

FIG. 3. Runs with added magnesium bromide ($Br/CH_3 = 1.29$).

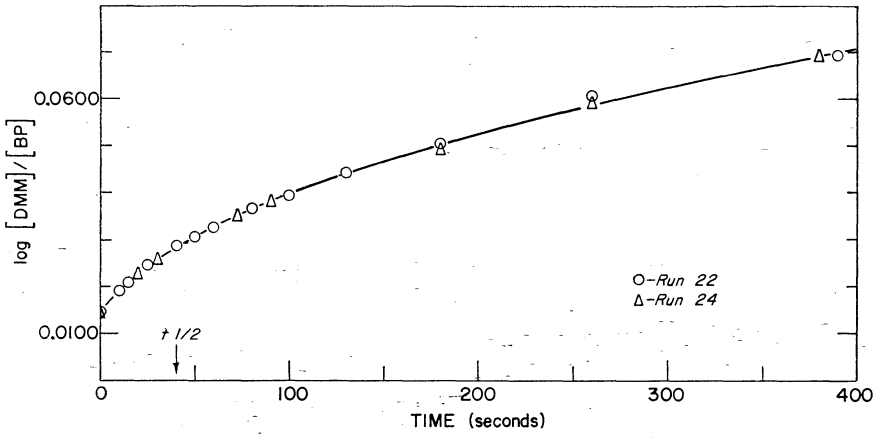

FIG. 4. Runs with dimethylmagnesium.

same range as that studied for methylmagnesium bromide. As with methylmagnesium bromide, the initial stages of the reaction followed second-order kinetics (Table III). On the other hand, no agreement in rate constants was found when the data were tested for adherence to third-order kinetics: runs 21, 22, 24, and 25 gave values of 26, 7.1, 7.1, and 13 liter^2 mole^{-2} sec^{-1}, respectively, for the third-order initial-rate constants.

The equivalency of an equimolar mixture of dimethylmagnesium and magnesium bromide to that of methylmagnesium bromide (1) (method (*c*)) was tested in run 23. The specific rate constant found was 0.199 liter mole^{-1} sec^{-1} in good agreement with that observed with the Grignard reagent made from methyl bromide and magnesium (Table II).

When magnesium bromide was mixed with benzophenone, a deep yellow color appeared with concurrent increase in absorbance in the 300–400 mμ range. These effects were noted even at a molar ratio of 0.018 of magnesium bromide to ketone and could be ascribed at least in part to gradual precipitation of what probably was a complex. The color

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

disappeared instantly with regeneration of the benzophenone spectrum when either methylmagnesium bromide or dimethylmagnesium was added to the mixture.[10]

Effect of Products on Rate

An experiment was carried out to determine the influence of products of the reaction upon a subsequent run. A kinetic run was first made under normal conditions, $[BP]_0 = 0.0871\ M$, $[MMB]_0 = 0.0696\ M$, at a temperature of 37.0°. The rate of disappearance of benzophenone was measured, and reaction was allowed to go to completion, based on a 1:1 stoichiometry (equation [3]). The value of k(initial) was 0.299 liter mole^{-1} sec^{-1}. More benzophenone was then added followed by a second quantity of methylmagnesium bromide, giving $[BP] = 0.0909\ M$ and $[MMB] = 0.0638\ M$. The rate was then measured again and found to be only 0.189 liter mole^{-1} sec^{-1}. Thus the rate was slower by 37% in the presence of products of the reaction.

DISCUSSION

The study reported here represents one of the first successful kinetic investigations of the reaction of a Grignard reagent with a ketone.[11] In view of past failures, our success may be attributed to the choice of the methylmagnesium bromide – benzophenone system offering a minimum of problems with side reactions, to the availability of a recording instrument permitting a continuous measurement of a property proportional to concentration, to careful handling of reagents, and to the use of a solvent wherein the reaction mixture is homogeneous.

The observations made in the past that reactions of Grignard reagents with carbonyl compounds were rapid have been confirmed in the present experiments. The rates observed readily serve to explain previous failures to obtain kinetic data. A rough approximation of the relative reactivity of benzophenone as compared to benzonitrile may be derived from our results and those of Storfer and Becker (1). Both sets of experiments were conducted in tetrahydrofuran, but in the previous investigation ethylmagnesium bromide was used while our runs were made with methylmagnesium bromide. At 30°, Storfer and Becker found an initial rate constant of 6.4×10^{-4} liter mole^{-1} sec^{-1}. Interpolation of our data (Fig. 2) gave a value of 2.4×10^{-1} for k(initial) at that temperature. The rate with benzophenone was therefore 370 times as fast as that with benzonitrile. The difference in reactivity between benzophenone and benzonitrile may actually be even larger since Wotiz *et al.* (6) have found that ethylmagnesium bromide reacted 17 times as fast as methylmagnesium bromide. Assuming the same ratio of reactivities is applicable here, then benzophenone is 6300 times as reactive as benzonitrile toward the same Grignard reagent.

Since the Grignard reagent is now believed to have the $R_2Mg\cdot MgX_2$ structure (40), the question as to whether both alkyl groups have the same reactivity has recently received some attention. Thus, Wotiz (6–12) assumed that such differences existed and assigned rate constants of 1.3×10^{-2} and 2.5×10^{-3} liter mole^{-1} sec^{-1} for reaction of the first and second ethyl groups, respectively, toward 1-hexyne. It has previously been demonstrated that in some cases reaction of the second 50% of the alkyl groups could

[10]*The benzophenone spectrum was normal in appearance when the organomagnesium reagent was added within a few minutes after mixing of the magnesium bromide with benzophenone. When the complex was allowed to stand for about 15 minutes or longer, coagulation had proceeded to such an extent that quantitative regeneration was more difficult because of heterogeneity of the mixture. These difficulties have thus far prevented a comparison of rates of method (a) with an alternative where magnesium bromide is premixed with benzophenone followed by addition of methylmagnesium bromide.*

[11]*Apparently, Anteunis' work (27) was carried out simultaneously and independently.*

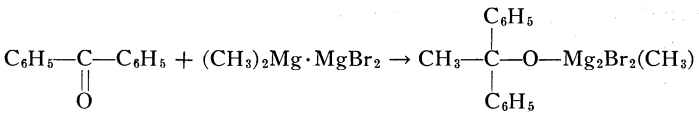
For personal use only.

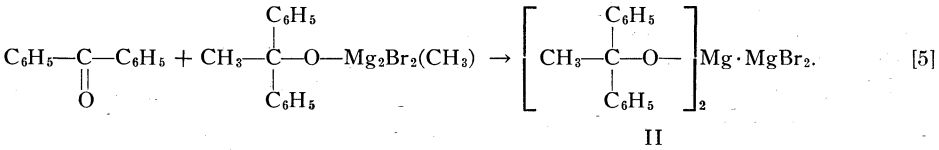
actually be so slow as to be negligible (1). Thus, alkylmagnesium reagents gave only 50% conversions based on ethyl when benzonitrile was the substrate, but higher conversions could be obtained with benzaldehyde. Dessy and Salinger (17) likewise found only 50% conversion of ethyl groups in the reaction with Schiff bases.

In our own case the reaction of methylmagnesium bromide and dimethyl magnesium with benzophenone eventually resulted in consumption of all the methyl groups. Lewis and Wright (18) likewise had obtained yields of about 86% when the reaction was allowed to proceed in ether for 5 hours at reflux. The intermediate I must therefore have been capable of further reaction, and the overall process can then be represented as:



[4]

I



[5]

II

However, here too the reactivity of the intermediate I was probably much lower than that of methylmagnesium bromide since the specific rate had fallen by a factor of at least 85 when 50% conversion based on the total original methyl content was exceeded. This significant decrease in rate permitted us to neglect reaction [5] for kinetic purposes, although the reaction was shown to take place and should be taken into account for synthetic purposes.

From these considerations it appears that there are differences in reactivity between Grignard reagents and intermediates of the type I which still contain alkyl groups attached to magnesium, and that the reactivity of the latter can vary depending on the nature of the substrate. The lesser reactivity of alkyl groups in compounds such as I can be rationalized on the ground that they are attached to magnesium atoms with lower electron densities than in the Grignard reagent. Stated another way, the greater electronegativity of oxygen and of nitrogen than of carbon causes the O—Mg and the N—Mg bonds to be more ionic than the C—Mg bond in the Grignard reagent. Since reaction of these compounds with substrates such as nitriles or ketones probably involves transfer of the alkyl group with its pair of electrons, such a reaction would be hindered.

Mechanism of the Reaction

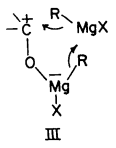
The mechanism most frequently cited for the addition of a Grignard reagent to a ketone is that proposed by Swain. According to Swain, a complex of ketone and Grignard reagent is first formed which can be converted to the product only by the intervention of a second mole of Grignard reagent:

$$G + K \underset{k_2}{\overset{k_1}{\rightleftharpoons}} C \qquad [6]$$

$$C + G \xrightarrow{k_3} P + G, \qquad [7]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where G is the Grignard reagent, K is the ketone, C is the complex, P is the product, and III is the transition state in the step *b* represented by equation [7].



III

No product was stated to form with equimolar or less than equimolar amounts of Grignard reagent (19) because of stability of the complex toward internal reaction. A necessary implication of this hypothesis is that the equilibrium must be far toward the complex and that it must be reached very rapidly in relation to reaction [7]. Otherwise, the uncomplexed Grignard reagent could play the role of the second mole of G, and reaction [7] would take place. A further result is that kinetically the reaction is of third order, first order in ketone and second order in Grignard reagent. The validity of this mechanism may be questioned for the following reasons:

(1) Our kinetic measurements indicate that the reaction is initially first order in benzophenone and first order in methylmagnesium bromide.[12] This finding is in harmony with the results recently published by Miller, Gregoriou, and Mosher (20), who determined from the relative amounts of addition versus reduction in a hindered ketone that the reaction proceeds by consecutive, *second-order* kinetics.

(2) We have found the reaction of methylmagnesium bromide with benzophenone to take place in tetrahydrofuran at ratios of $[MMB]_0/[BP]_0$ as low as 0.302. Even on the basis of the RMgX formulation for the Grignard reagent, this would correspond to a ratio of $[CH_3MgBr]_0/[BP]_0$ of only 0.604, or less than 1. Furthermore, at equimolar concentrations based on the RMgX formulation, product analyses showed essentially quantitative yields of 1,1-diphenylethanol, thus substantiating the belief that the disappearance of benzophenone observed spectroscopically led to product, and not solely to a complex of starting materials.

(3) It has been reported (18) that the reaction in ether of equivalent amounts of methylmagnesium bromide and benzophenone gave yields of about 86% of product regardless of whether the ketone was added slowly to the Grignard reagent, or whether inverse addition was used. No product other than complex should have been formed by the inverse addition technique, if Swain's mechanism held.

(4) The evidence on which the existence of a stable complex has been based is in our view by no means conclusive. In the frequently cited (1, 21–25) paper by Pfeiffer and Blank (26), the contents of which were incorrectly credited by Swain (19) to Gilman and Jones (24), the following experiment is reported: "We examined the behavior of benzophenone toward ethylmagnesium bromide. Experiment I. Both components were reacted in a molar ratio of 1:1 in ethereal solution while cooling with ice. A dirty, white precipitate formed which rapidly changed to an oily mass and hence could not be filtered or analyzed. The ethereal solution as well as the precipitate was heated for 5 hrs. at reflux on a water bath. After cooling, the reaction mixture was treated with water and aqueous ammonia until the odor of ammonia was detected. After having been shaken well, the ethereal solution was separated, washed with water, dried with sodium sulfate,

[12]*It is worth noting that from a kinetic point of view, the order in Grignard reagent does not depend on the fact that it is* $R_2Mg \cdot MgX_2$ *rather than* RMgX.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and concentrated on the water bath. The residue was at first oily, but most of it solidified after having been seeded with a few crystals of benzophenone. After having been pressed dry on a porous plate, the crystals melted at 49–51°. A mixed m.p. with benzophenone gave no depression. The greater part of the benzophenone was therefore recovered unchanged."[13]

It is to be noted that the authors hydrolyzed *the entire reaction mixture together*. Thus, the recovery of some benzophenone could be ascribed simply to incomplete reaction (possibly because of lesser reactivity of an intermediate similar to I). No quantities, yields, analyses, or isolation were reported to justify in any way the conclusion that the precipitate was a complex of starting materials. It is because of these serious defects that it is felt that the experiment does not merit the importance that has been attached to it. This has already been pointed out by Nesmeyanov and Sazanova (28), who repeated Pfeiffer and Blank's work, but isolated the precipitate immediately. They found that the latter gave, upon hydrolysis, the desired carbinol in 79% yield.[14]

(5) Swain's experiments with added magnesium bromide (30), which he considered to support his mechanism, may be open to different interpretations. McBee, Pierce, and Meyer (31) found no detectable amounts of complexing between magnesium bromide and fluorinated carbonyl compounds. Yet the presence of magnesium bromide in ethylmagnesium iodide favored the addition reaction at the expense of reduction. This is the same effect which Swain had ascribed to prior complexing of the carbonyl compound with magnesium bromide. The authors (31) also found that addition was favored in the absence of magnesium bromide when pyridine was used as solvent and believed that changes in polarity of the medium may be the important factor.[15]

Cram (32) has pointed out that the added magnesium bromide may have shifted the Schlenk equilibrium (equation [8]) (21) toward RMgX and that the results may be rationalized if it is assumed that R_2Mg is a better reducing agent than RMgX. In the light of Dessy's work on the constitution of the Grignard reagent, this is tantamount to stating that R_2Mg is a better reducing agent than $R_2Mg \cdot MgX_2$.

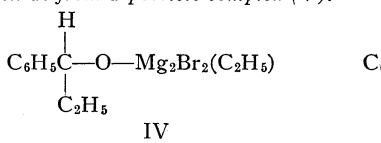
$$R_2Mg + MgX_2 \rightleftharpoons 2RMgX \qquad [8]$$

In our own work, spectral evidence has been presented that magnesium bromide was *not* complexed with benzophenone in the presence of methylmagnesium bromide. It

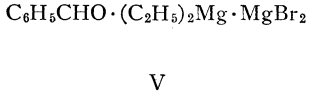
[13]*A complete translation of Pfeiffer and Blank's main experiment is given here, because language difficulties may have hindered its full understanding by some of the authors who have referred to it. Kharasch and Reinmuth, for example, erroneously believed that the oil was separated before hydrolysis (21, p. 141). Anteunis (27) similarly stated that the complex was "isolated".*

[14]*The work of Meisenheimer (29) has also been cited (21, 24, 26) in support of a complex. A precipitate obtained in the reaction of benzaldehyde with ethylmagnesium bromide was filtered and found to release some ethane upon hydrolysis. This fact was considered by Meisenheimer to be strong evidence for the presence of benzaldehyde complexed with Grignard reagent in the precipitate.*

Based on the RMgX *structure then in use, such a conclusion was reasonable. On the other hand, in view of Dessy's recent work on the structure of ethylmagnesium bromide (40) and the growing evidence for lesser reactivity of the second half of the alkyl groups, one may assume that the ethane could have originated from the product (IV) as well as from a possible complex (V).*



IV



V

[15]*It is worth noting that in Swain's experiment the reaction mixture was heterogeneous since concentrated solutions of magnesium bromide form two phases in ether. Furthermore, no experiments were reported wherein 1 mole of Grignard reagent was actually replaced by a mole of magnesium bromide—the Grignard reagent was present in both experiments in a 2:1 ratio to the ketone, based on the* RMgX *formulation.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

may instead have been complexed with the Grignard reagent,[16] in analogy to the proposals of Doering and Noller (33) and of Stewart and Ubbelohde (34). Attention has been called to such a possibility by Meyer (25), by Smith (35), and by Hamelin (36).

(6) The recently published investigation by Anteunis (27, 37) which purports to support the Swain mechanism appears to us to suffer from two major defects. The data published do *not* support the conclusion that the reaction is of third order, and the reaction was carried out in an ether–benzene solvent system wherein the reaction is *heterogeneous*. The concentrations were varied only over a less than a fourfold range, yet the third-order rate "constants" varied from 0.165 to 0.425 liter^2 mole^{-2} sec^{-1}. Furthermore, the calculated rate constants at equal Grignard concentrations were significantly different depending on whether the rate was measured in the beginning or toward the middle of the reaction; thus, k_3 when measured in a run starting at 0.159 M of Grignard reagent was 0.36 liter^2 mole^{-2} sec^{-1}, but k_3 was only 0.158 when a reaction beginning at 0.350 M had decreased to 0.157 M. These inconsistencies are not compatible with third-order kinetics. For the reaction of benzophenone with dimethylmagnesium, Anteunis (37) reports for only one concentration and one temperature. A calculation for second-order k from his data at $-15.2°$ gives 0.316 liter mole^{-1} sec^{-1} to be compared with 0.0312 liter mole^{-1} sec^{-1} obtained here at 1.0°. The difference in rate is probably due to the different solvent systems employed, Anteunis using ether–benzene, which would be much less coordinated to magnesium.

It may be concluded, therefore, that the concept of the Grignard reaction with a ketone proceeding via a *stable* complex of the type described by Swain is not supported by the published evidence nor by the results of the present investigation.

While we feel that the Swain and Pfeiffer–Blank mechanism is ruled out, the results of the present investigation do not permit us to draw any firm conclusions as to a possible substitute. The kinetics were found to be complex and additional work is required, especially to establish the reasons for the decrease in rate with time and with added magnesium bromide.

It is noteworthy that similar deviations from simple second-order kinetics have been observed in the past in the case of reaction with alkynes (6–12) and with benzonitrile (1). In both cases, competitive, consecutive second-order reactions were assumed to account for the deviation. In the latter case, it was further believed that the Grignard reagent was composed of various species with different reactivities. Both of these assumptions appear to be reasonable and a detailed analysis of the mechanism may have to await a better understanding of the constitution of Grignard reagents.

From the information presently available, the following mechanism is tentatively proposed:

$$G + K \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C_1 \overset{k_2}{\rightarrow} I \qquad [9]$$

$$I + K \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} C_2 \overset{k_4}{\rightarrow} II, \qquad [10]$$

where the rate-determining steps are k_2 and k_4 and the equilibrium is far toward the

[16] *If complexing of magnesium bromide with Grignard reagent did take place, its rate must have been rapid since the spectrum of benzophenone was regenerated immediately upon addition of methylmagnesium bromide to a mixture of magnesium bromide and benzophenone. Also, there was no difference in rates between run 14, where a mixture of magnesium bromide with methylmagnesium bromide was used immediately, and run 13, where the mixture was allowed to stand for 40 minutes before reaction with benzophenone.*

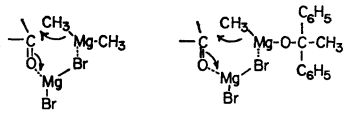
reactants. The transition states for the rate-determining steps may then be visualized as VI and VII wherein use is made of Dessy's structure of the Grignard reagent:[17]



VI VII

This mechanism is in accord with our finding of second-order kinetics for the early part of the reaction, and with Mosher's conclusion (20) that addition and reduction proceed by the same kinetic order. Since reduction is believed to proceed by way of a six-membered cyclic transition state, it is reasonable to assume that addition would also. This is further supported by analogy with the Meerwein–Ponndorf–Verley reduction, which is believed to have a similar transition state. A recent investigation has shown that the energy and entropy of activation for the reaction of benzophenone with aluminum isopropoxide are 14 kcal/mole and −31 e.u., respectively (39). The similarity with our results of 11 kcal/mole and −25 e.u. is striking. For pinacolone – methylmagnesium bromide in ether, Anteunis found E_a 14.5±0.6 kcal/mole.

Finally, some comments may be made as to the structure of the Grignard reagent. We have provided additional confirmation that equimolar mixtures of dimethylmagnesium and magnesium bromide are equivalent to the Grignard reagent. The fact that even small amounts of magnesium bromide drastically altered the ultraviolet spectrum of benzophenone but that nevertheless the spectrum was normal in the presence of methylmagnesium bromide permits the conclusions that less than 1.8%, if any, free magnesium bromide is present in this Grignard reagent and that dimethylmagnesium may complex with more than 1 mole of magnesium bromide (33, 34, 36).

ACKNOWLEDGMENTS

OBSERVATIONS ON ALKYLBORANES[1, 2, 3]

C. A. LUTZ AND D. M. RITTER
Department of Chemistry, University of Washington, Seattle, Wash., U.S.A.

Received October 29, 1962

ABSTRACT

Some synthesis and exchange reactions of diborane and its alkyl derivatives and of the higher boron hydrides were reviewed as background for new work.

In pursuit of an idea prompted by knowledge of the deuterium and B^{10} exchanges found for the reactive and unstable higher boron hydrides B_4H_{10} and B_5H_{11}, mono- and di-methyldihydropentaborane and methyltetraborane have been prepared by direct reaction between the parent higher hydrides and 1,2-dimethyldiborane or monomethyldiborane. The identity and the reactions of each product have been delineated by gas chromatographic separation, gas density, and mass, infrared, and n.m.r. spectrometry. The H^1 n.m.r. spectrum of dihydropentaborane has been reinterpreted and used to decide that monomethyldihydropentaborane is probably a B_{III} derivative which displays stereoisomerism.

To confine the topic within proportions suitable for a symposium this paper concerns mostly alkylation reactions in which carbon atoms are transferred from sites in one boron compound to sites in another, thus excluding almost completely the extensive material on hydroboration.

As a preliminary, consider some facts about the boron hydrides. They occur in two types, the open pyramidal and the closed pyramidal structures, with the commonest members, diborane, tetraborane-10, pentaborane-11, as examples of the first class and pentaborane-9 and decaborane-14 of the second. The former are the labile, reactive hydrides, the latter the ones of lesser reactivity. Exchange and interconversion reactions show the labile hydrides to maintain effective steady-state concentrations of reactive fragments;[4] the more stable ones do not (1, 2).

Diborane is convertible to the other hydrides by pyrolysis (3) and by interactions such as that with tetraborane (4):

$$B_4H_{10} + B_2H_6 \rightleftharpoons B_5H_{11} + H_2.$$

Three boron and deuterium exchanges exemplify models for alkylation reactions: (*a*) self-exchange of diborane, (*b*) diborane exchange with pentaborane-9, and (*c*) diborane exchange with pentaborane-11. The first is 3/2 order involving successively dissociation of diborane and a borane–diborane displacement reaction with $E^{\ddagger} = 22$ kcal. Deuterium exchanges three times faster than boron. Similarly, the second is 1/2 order in diborane (dissociation) and first order with respect to pentaborane-9, but without boron exchange, $E^{\ddagger} = 27$ kcal. Since the third, pentaborane-11 – diborane exchange, is 1/2 order with respect to the higher hydride and first order in diborane the dissociation is that of pentaborane-11 and the displacement is borane–diborane. With these varying patterns

For personal use only.

available there remains now to observe to what degree the alkylation reactions coincide in type with the isotopic exchanges and the hydride interconversion reactions.

In the case earliest examined, methyl–hydrogen exchange gave all the possible methyl derivatives in the reactions begun by treating diborane with trimethylborane (5, 6). From organo group transfer the results so far include also higher *n*-alkyl diboranes (7), phenyl derivatives (8), carborocyclic diboranes (9), and B-methylborazoles (10). Qualitatively the lower alkyl diboranes disproportionate at comparable rates without regard for what group is the substituent, but in mono-*n*-butyldiborane some degree of kinetic stability appears (11). The cause may resemble the entropy-determined stability of the carborocyclic derivatives (9), and also govern the relative stability of the 1,2-disubstituted diboranes (6, 12). The kinetic stabilities of the methyldiboranes are in the order 1,2-di $\gg$ 1,1-di > tri > mono > tetra. From curiosity an investigation was begun a few years ago concerning this ordering, and the nature of the reactions of formation and disproportionation. This has developed into a general inquiry into kinetics and equilibria in the alkylation of the boranes with some results summarized in the next paragraphs.

The reaction between diborane and trimethylborane appears first order in each reactant. Since one of these is itself a borane, through analogy with the boron and deuterium exchange reactions it seemed logical to search for borane–borane reactions, together with displacements, as the means of methyl group transfer. An early interpretation of the results seemed consistent with this conclusion (13), but subsequent determination of an activation energy of ~11 kcal (14) was inconsistent with any scheme for which the activation energy would need to have a value at least half the bridge-bond dissociation energy for diborane as one of several components. Presently the data can be best interpreted as denoting two consecutive second-order reactions at temperatures 0–35° C:

$$\tfrac{3}{2}B_2H_6 + BMe_3 \xrightarrow{k_1} 1,1\text{-}B_2H_4Me_2 + B_2H_5Me$$

$$B_2H_5Me + BMe_3 + \tfrac{1}{2}B_2H_6 \xrightarrow{k_2} 2\ 1,1\text{-}B_2H_4Me_2.$$

Viewed as reactions with B_3 transition states these can be seen to be analogous with the borane displacement step in the diborane self-exchange, and in the B_5H_{11} exchange sequence.

The monomethyldiborane dismutation, quite unlike the easily predicted course of dissociation and reassembly, appears to proceed through a second-order process. In pyrex glass reactors induction periods and several-fold variations in the velocity constants suggest a heterogeneous reaction, but no pronounced influence is exerted upon the rate by tenfold increase in surface–volume ratio. The reaction proceeds to an equilibrium:

$$2MeB_2H_5 \rightleftharpoons B_2H_6 + (BH_2Me)_2,$$

which has been completely defined at ordinary temperatures[5] (11, 14).

Reaction of trimethylborane with pentaborane-9 at temperatures up to 135° C gives no methylation (15), though at 235° C methyldiboranes with hydrogen give methylated derivatives of pentaborane-9 (16) in a reaction probably so drastic as to defy logical analysis. Alkyl pentaborane-9 and alkyldecaborane derivatives have been synthesized by methods not involving other alkylboron compounds as reagents (17, 18, 19). Since the less stable hydrides, tetraborane, B_4H_{10}, and dihydropentaborane or pentaborane-11, B_5H_{11}, could scarcely be alkylated by such drastic means, though dimethylenetetraborane is made in the hot–cold reactor (20), reactions analogous to the synthesis reaction for

[5]*In the range 273.2° K to 309.7° K, through equilibrium constants described by the equation* $\ln(K \pm 5 \times 10^{-4}) = -1.5971 - (281.46/T)$. *(*$\Delta H$ *= 559 cal/mole,* F_{298}^0 *= 1505 cal/mole, and* $\Delta S^\circ = -3.17$ *e.u.)*

For personal use only.

B_5H_{11} and to the isotope exchange processes for B_5H_{11} and B_4H_{10} were adopted, using in each case momomethyldiborane or 1,2-dimethyldiborane as the reactants, instead of diborane, as described in the equations

$$B_4H_{10} + \tfrac{1}{2}(BH_2Me)_2 \rightleftharpoons B_5H_{10}Me + H_2$$
$$B_5H_{11} + B_2H_5Me \rightleftharpoons B_5H_{10}Me + B_2H_6$$
$$B_4H_{10} + B_2H_5Me \rightleftharpoons B_4H_9Me + B_2H_6.$$

The results obtained illustrate that these alkylation reactions, like those of the diboranes, proceed in conformance with the analogies suggested by the exchange processes.

EXPERIMENTAL

The vacuum line operations used were those developed by Stock (21) and by Schlesinger and his co-workers, and described by Sanderson (22). Separation of products was accomplished by gas chromatography in almost all cases. The design, construction, and operation of the type of chromatograph employed has been described previously (23). The purity of samples used for physical measurements was monitored by gas chromatography before and after each measurement. In no case did the impurities exceed 0.5%.

Molecular Weights

Molecular weights were determined in duplicate by the gas density method. Care was taken to minimize contact with stopcock grease.

Infrared Spectra

Infrared spectra were obtained with a Perkin–Elmer Model 21 spectrometer using both sodium chloride and calcium fluoride optics and cells of either 5 or 10 cm length constructed with minimum cell volume. Atmospheric absorption peaks were used for calibration and reported values are accurate within ~5 cm^{-1}.

Nuclear Magnetic Resonance Spectra

A Varian (Model 4311) high-resolution nuclear magnetic resonance spectrometer operating at 60 Mc was used. The substances B_5H_{11} and $B_5H_{10}Me$ were used neat without an internal reference. All sample tubes were prepared in vacuum and stored in liquid nitrogen to prevent decomposition. The scales of the spectra were established in all instances by the standard side-band technique.

Analysis of the H^1 spectrum of B_5H_{11}, needed as a reference for characterizing $B_5H_{10}Me$, was begun by recognizing that peaks 1, 2, 10 (Fig. 1(*b*)) with an area ratio 1.95:4.05:1.00 represent respectively the lowest-field members of two quartets, *a* and *b*, and the highest-field member of a third, *c*. These quartets were

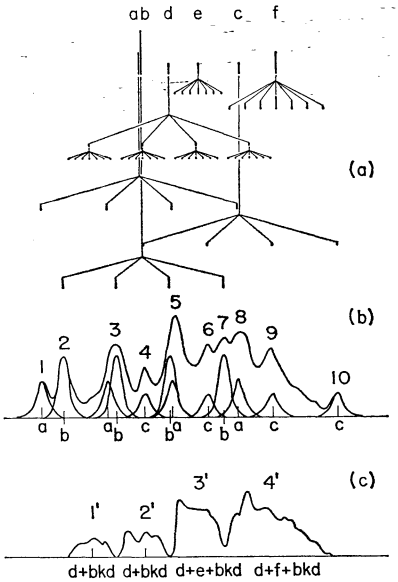

FIG. 1. H^1 n.m.r. spectrum of B_5H_{11} (field increasing to right): (*a*) diagrammatic display of resonances; (*b*) experimental trace with components *a*, *b*, *c*; (*c*) difference trace containing *d*, *e*, *f*, and background (*bkd*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

subtracted from the total band envelope to give the difference trace shown in Fig. 1(*c*). This was recognized as the sum of a quartet, each member broadened by splitting into unresolved septets, *d*, and two unresolved septets, *e* and *f*. Resonances *d* overlap *e* and *f*.

The presence of B^{10} nucleii makes these comparisons somewhat less correct than desirable but not fatally so.[6] The intensities of the B^{11}-split resonances are reduced slightly, and there appear as background unresolvable resonances of B^{10} origin, for which correction can be made in the following way. The whole original band envelope had an area 22.47 cm²; the difference trace was 14.99 cm² comprising 1′, 2′, 3′, 4′ of area 1.18, 1.93, 4.38, and 7.50 cm², respectively. Peak 10, taken as unity, had an area 0.60 cm², and from this and the areas of 1′, 2′ backgrounds of 0.58 cm² and 1.33 cm², respectively, were calculated for those peaks. For 3′ the background was taken equal to that of 2′, 1.33 cm², and the sum of backgrounds for 1′ and 2′ was assumed as background for 4′. Then from 3′ and 4′ each 0.60 cm² was subtracted for the *d* component. The remainders were, for 3′ 2.45 cm^{-2} and for 4′ 5.09 cm² in the ratio approximately 1:2, representing respectively four units and eight units of intensity.

Mass Spectra

All mass spectra were obtained with a Consolidated Model 20–103 mass spectrometer using a rhenium filament. The fractionation effect at varying pressures was often used to detect impurities. Ionizing voltages of 70 v and 8–14 v were used.

The isotopic ratio $B^{11}/B^{10} = 4.00$ was used, as is customary (25), to reduce the polyisotopic abundances to the monoisotopic values, and for the methyl derivatives a C^{13} content of 1.108% was assumed.

Gas–Liquid Chromatographic Properties

To separate compounds with a wide range of retention times as quickly as possible a variety of flow rates and columns was used. The flow rates of helium carrier gas were in the range of 1–70 ml/min. The columns had "Standard White Oil #9" as the stationary phase supported on Johns-Mansville firebrick (crushed and sieved to 32–65 Taylor mesh) in a weight ratio of 0.38:1. After removal of the solvent for the white oil the column packing was dried *in vacuo* for at least 24 hours. Diborane was passed through the column a number of times before use. Column lengths varied from 25–95 cm and internal diameters from 0.4 to 1.0 cm.

The relative retention times of all relevant compounds are found in Table I.

TABLE I

Gas chromatographic properties—relative retention times

Compound	Relative retention time	Compound	Relative retention time
B_2H_6	3.2	B_4H_9Me	97
B_2H_5Me	7.3	B_5H_9	100
BMe_3	11.1	B_5H_{11}	148
1,1-$B_2H_4Me_2$	16.5	B_5H_8Me	278
1,2-$B_2H_4Me_2$	21.3	$B_5H_{10}Me$	410
B_4H_{10}	29.5	B_6H_{10}	477
$B_2H_3Me_3$	53.2	$B_5H_9Me_2$	847

Preparations and Reactions

Tetraborane and dihydropentaborane were prepared from diborane by the "hot–cold" tube reactor method (26). The crude products were purified by repeated passes through the gas chromatograph with appropriate cuts, until the products were chromatographically pure.

All the methyldiboranes except 1,2-dimethyldiborane were obtained by fractionating the desired compound from a large storage bulb containing diborane, boron trimethyl, and mixed methyldiboranes. Final purification was accomplished by repeated passes through the gas chromatograph. Dimethyldiborane was prepared by allowing monomethyldiborane to disproportionate to diborane and 1,2-dimethyldiborane at room temperature followed by gas chromatographic separation.

Methyldihydropentaboranes were prepared by use of monomethyl- and dimethyl-diboranes in (*a*) reaction with tetraborane or (*b*) exchange with dihydropentaborane.

(*a*) Tetraborane (0.2 mmole) and a methyldiborane mixture (mostly dimethyldiboranes) (0.2 mmole) were heated at ~1 atm pressure and 100° C for 15 minutes. Diborane was removed by passing the mixture through a U-tube cooled to −145°, and the remaining components were separated by gas chromatography. The components were methyldiboranes, tetraborane, pentaborane, dihydropentaborane, identified

For personal use only.

by their infrared spectra (27, 28); 2-methylpentaborane, identified by its infrared spectrum, 0° vapor pressure, and mass spectrum (16); and the two new substances methyl- and dimethyl-dihydropentaborane. The yield of all methylpentaboranes combined was less than 5%, and solid hydrides formed extensively.

(*b*) Dihydropentaborane (0.2 mmole) and a mixture of mono- and di-methyldiboranes (0.2 mmole) were held at 35° for 15 minutes. Diborane was removed by passing the mixture through a U-tube cooled to −145°, and the reaction was continued at 35° for another 15-minute period. Gas chromatography served to separate the residual starting materials, diborane, pentaborane-9, and the new substance methyldihydropentaborane, the latter two in yields of 7% and 64%, respectively, based upon the original dihydropentaborane. A trace of dimethyldihydropentaborane was always formed, and from larger-scale preparative experiments it was accumulated until sufficient material was obtained for characterization. $B_5H_{10}CH_3$ v.p. 0° C 21.0 mm; mol. wt.: found 79.2, 80.0; calc. 79.2.

Methyltetraborane was prepared from tetraborane (5.0 mmoles) and a mixture of monomethyldiborane and dimethyldiboranes (15.0 mmoles) contained in a 500-ml bulb, allowed to stand at room temperature for 2 days, and then heated to 45° C with a water bath for 4 hours. The reaction mixture was fractionated through a U-tube cooled to −90° C and the portion retained by the bath was passed through the gas chromatograph. Because the g.l.c. relative retention times of methyltetraborane and pentaborane differ only as 97 and 100, respectively, repeated passage through the chromatographic column was necessary, with sample partition practiced at each step, until a single peak for a substance of constant properties was attained. Approximately 0.4 mmole of B_4H_9Me was obtained. Molecular weight: found 66.8, 68.0; calculated 67.4. The compound was also characterized by infrared and mass spectra shown in Tables XII, and IX, and X respectively.

Methyldihydropentaborane decomposition was observed in two experiments.

(*a*) A sample of the purified substance was left standing for 30 minutes at room temperature. The gas chromatograph trace of the material then showed $B_5H_{10}Me$ 83.8%, B_5H_{11} 10.1%, $B_5H_9Me_2$ 6.1%. The inequality of the latter two amounts can be explained by further disproportionation to give $B_5H_8Me_3$ with a too long retention time for observation.

(*b*) After 15 minutes of heating at 90° a sample of $B_5H_{10}Me$ contained 70% starting material, 7.2% B_5H_{11}, ~1% B_5H_8Me, a trace of B_5H_9, and 7.6% diborane and methyldiboranes. The material balance was 85.8%; the unaccounted for balance was presumably converted to solid hydrides and possibly to $B_5H_9Me_2$.

Reactions of methyldihydropentaborane were observed with (*a*) diborane and with (*b*) diethyl ether (29).

(*a*) Methyldihydropentaborane (0.3 mmole) and diborane (3.0 mmole) were mixed for 30 minutes at room temperature. The products, separated by gas chromatography and identified by infrared spectra, contained methyldiboranes, a trace of pentaborane, dihydropentaborane (72% conversion), some starting material, with a material balance of 96%.

(*b*) Methyldihydropentaborane (0.5 mmole) was condensed with a slight excess of diethyl ether. The tube was held at −78° C for 5 minutes and at 0° C for 10 minutes. The products, separated by gas chromatography and identified by their infrared spectra, were pentaborane, dihydropentaborane, starting material. Only a very small sample of material with a long retention time was obtained, heavily contaminated with dimethyldihydropentaborane. A polyisotopic mass spectrum of the sample is shown in Table II.

RESULTS AND DISCUSSION

Identification and characterization of the compounds $B_5H_{10}Me$, $B_5H_9Me_2$, B_4H_9Me rest upon data collected by mass, n.m.r., and infrared spectroscopy, necessitating that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

results for the parent substances be examined for comparison. The older data were obtained on samples, purified by fractional condensation, which inescapably contained impurities now removable by gas chromatography.

Polyisotopic mass spectra of B_5H_{11} are found in Table III. The parent group and the

subgroups, readily distinguished in the B_5H_{11} spectrum at 11 v, are a small parent peak $(B_5H_{11})^+$ at *m/e* 66, and subgroups at *m/e* 52, *m/e* 39, *m/e* 27, and *m/e* 14 composed of ions of the type $(B_4H_8)^+$, $(B_3H_6)^+$, $(B_2H_5)^+$, and $(BH_3)^+$ respectively. A partial monoisotopic mass spectrum for B_5H_{11} is shown in Table IV. The previously noted tendency of boron hydrides to lose hydrogen atoms in pairs (29) is also observed in the monoisotopic B_5H_{11} spectrum and in that for the $(B_4H_8)^+$ subgroup.

Polyisotopic mass spectra of $B_5H_{10}Me$ at ionizing voltages of 70 and 12 v are found in Table V. A parent peak at *m/e* 80 is observed in neither spectrum. Although the spectrum at 70 v is essentially continuous from *m/e* 21 to 79, making it difficult to identify the subgroups, certain similarities between this spectrum and the spectrum of B_5H_{11} can be seen. The peak with highest intensity in both the B_5H_{11} and $B_5H_{10}Me$ spectrum occurs at six mass units below the parent peak at *m/e* 60 in the B_5H_{11} spectrum and at *m/e* 74 in the $B_5H_{10}Me$ spectrum. Doubly charged ions are observed at *m/e* $34\frac{1}{2}$, *m/e* $35\frac{1}{2}$, and *m/e* $36\frac{1}{2}$, which correspond, considering the methyl group in $B_5H_{10}Me$, to the ions observed in the B_5H_{11} spectrum in the range *m/e* $27\frac{1}{2}$–$30\frac{1}{2}$.

In the polyisotopic spectrum of $B_5H_{10}Me$ at 12 v the subgroups are clearly visible and can be compared with the subgroups observed in the B_5H_{11} spectrum at low ionizing voltage. The first subgroup below the parent group in the $B_5H_{10}Me$ spectrum, beginning at *m/e* 66, is composed of ions of the type $(B_4H_7Me)^+$. This corresponds to the $(B_4H_8)^+$ subgroup from the B_5H_{11} molecule. Another subgroup may be hidden under the $(B_4H_7Me)^+$ subgroup, namely the $(B_5H_{10})^+$ group, which would appear at *m/e* 65 as a result of the loss of the methyl group from the $B_5H_{10}Me$ molecule. The subgroup beginning at *m/e* 53 probably is composed of ions of the type $(B_3H_5Me)^+$, and corresponds to the $(B_3H_6)^+$ subgroup which begins at *m/e* 39 in the B_5H_{11} spectrum. Another subgroup, resulting from the loss of a BH_2Me group from the $B_5H_{10}Me$ molecule, is probably hidden beneath the $(B_3H_5Me)^+$ subgroup. The subgroup beginning at *m/e* 41 is most likely composed of ions of the type $(B_2H_4Me)^+$ and $(B_3H_6)^+$, while the subgroup beginning at *m/e* 28 contains

ions of the type $(BH_3Me)^+$ and $(B_2H_5)^+$. The purity of the sample and the correctness of the molecular formula for $B_5H_{10}Me$ were confirmed by the monoisotopic spectrum calculated for the parent peak as shown in Table VI. The qualitative agreement between

the monoisotopic spectra of $B_5H_{10}Me$ and B_5H_{11} is excellent. The alternation of intensities observed in the monoisotopic spectrum of B_5H_{11} and other boron hydrides is also observed in the $B_5H_{10}Me$ spectrum. The three most intense ions in the parent group of $B_5H_{10}Me$, in order of decreasing intensity, are $(B_5H_6Me)^+$, $(B_5H_8Me)^+$, and $(B_5H_4Me)^+$, while in the parent group of B_5H_{11} the three most intense ions are $(B_5H_7)^+$, $(B_5H_9)^+$, and $(B_5H_5)^+$, in the same order.

Polyisotopic mass spectra of $B_5H_9Me_2$ are found in Table VI. Considerably more cracking to fragments of low mass occurs in the $B_5H_9Me_2$ spectra than in the spectra of B_5H_{11} or $B_5H_{10}Me$. At an ionizing voltage of 9 v the parent group and the subgroup can be clearly distinguished. The subgroup beginning at *m/e* 80 contains ions of the type $(B_4H_6Me_2)^+$ and is analogous to the subgroups containing ions of the type $(B_4H_8)^+$ and $(B_4H_7Me)^+$ in the spectra of B_5H_{11} and $B_5H_{10}Me$, all the result of BH_3 loss. It is likely that a subgroup resulting from the loss of a methyl group from the molecule underlies the $(B_4H_6Me_2)^+$ subgroup. The subgroup beginning at *m/e* 66 probably is the result of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the loss of a BH_2Me group from the molecule, leaving a subgroup composed of ions of the type $(B_4H_7Me)^+$.

A partial monoisotopic mass spectrum of $B_5H_9Me_2$ is found in Table VII. The parent group is very similar to those of B_5H_{11} and $B_5H_{10}Me$. The loss of hydrogen atoms in

*Ionizing voltage 12 v.
†Ionizing voltage 11 v.

pairs is again observed. The ion $(B_5H_5Me_2)^+$, the most intense in the parent group, is analogous to the ions $(B_5H_6Me)^+$ and $(B_5H_7)^+$, which are the most intense ions in the parent groups of the monoisotopic $B_5H_{10}Me$ and B_5H_{11} spectra.

The mass spectrum of a sample of $B_5H_9Me_2$ which had been allowed to stand at room temperature for a few minutes contains a group of ions in the range *m/e* 96–107, which is very likely the parent group of the compound $B_5H_8Me_3$. This indicates that $B_5H_9Me_2$ probably undergoes a disproportionation reaction to form $B_5H_{10}Me$ and $B_5H_8Me_3$ similar to the disproportionation of $B_5H_{10}Me$.

Polyisotopic mass spectra of B_4H_{10} and B_4H_9Me are found in Tables VIII and IX. No parent peaks are found in either the B_4H_{10} or B_4H_9Me spectra. At 70 v the highest masses for B_4H_{10} and B_4H_9Me occur at *m/e* 52 and *m/e* 66 respectively, in each case two mass units below the parent peak. Highest intensities occur at *m/e* 49 and *m/e* 63 respectively, in each case five mass units below the parent peaks. Doubly charged ions are observed at *m/e* $22\frac{1}{2}$, *m/e* $23\frac{1}{2}$, and *m/e* $24\frac{1}{2}$ in the B_4H_{10} spectrum and at *m/e* $28\frac{1}{2}$, *m/e* $29\frac{1}{2}$, and *m/e* $30\frac{1}{2}$ in the B_4H_9Me spectrum. Both these series of doubly charged ions have masses 9, 7, and 5 mass units less than their respective parent peaks. Doubly charged ions probably occur at the even masses in these regions of the spectra but are masked by more intense singly charged ions.

At 11 v highest intensities occur at *m/e* 50 and *m/e* 64 for B_4H_{10} and B_4H_9Me respectively. Since the subgroups and the parent group do not overlap in the B_4H_9Me spectrum at 11 v it is possible to identify some of the subgroups. The subgroup which begins at *m/e* 53 is most likely composed of $(B_4H_9)^+$, $(B_4H_8)^+$, . . . ions. The subgroup beginning at *m/e* 41 could be composed of ions of the type $(B_3H_8)^+$ or of ions of the type $(B_2H_4Me)^+$.

Partial monoisotopic mass spectra of B_4H_{10} and B_4H_9Me at 11 v are found in Table X. In the calculation for B_4H_9Me the assumption which led to minimum residues was that the subgroups at *m/e* 45–53 and *m/e* 34–41 were composed solely of ions of the type $(B_4H_9)^+$ and $(B_2H_4Me)^+$.

The interpretation of the H^1 n.m.r. spectra of B_5H_{11} and $B_5H_{10}Me$ rests upon the structure determination for the parent substance (30, 31). Owing to the presence of B_5H_9

*Ionizing voltage 11 v.

impurity, almost impossible to remove completely by fractional condensation but easily eliminated by gas chromatography, the earlier normal spectra (32, 33) can scarcely have been interpreted satisfactorily, although multiplet structure collapse by "spin saturation" did resolve four types of H^1 in the proper ratio of 6 as B—H, 3 as B—H—B, and 1 as unique apical B—H (32).

The most recent H^1 n.m.r. spectrum for highly purified B_5H_{11}, shown in Fig. 1, was dissected as described in the experimental part. The observed peaks, 1 through 10, have been assigned as: quartet *a* to the two H^1 linked to the two back-based B_{II} atoms; quartet *b* to the four H^1 linked to the two forward-based B_{III} atoms; quartet *c* to the single H^1 linked to the apical B_I atom and projected upward from the pyramid. From the difference trace there have been assigned to account for intensity groups, 1′ through 4′: the quartet *d* arising from the unique H^1, bonded to the apical B_I atom at a distance 1.09 ± 0.19 Å (30); additionally each member of the quartet appears broadened through splitting into an unresolved septet owing to the bridge-bonding of this H^1 to the two B_{III} atoms at distances 1.77 ± 0.19 Å (30); the unresolved septet *e* from the back bridge-bond B_{II}—H—B_{II} atoms and the unresolved septet *f* from the two side bridge-bonds B_{II}—H—B_{III}. The assigned areas are in the proper ratio *a*:*b*:*c*:*d*:*e*:*f* as 2:4:1:1:1:2, and the locations of the band centers without exception are consistent with the excess charge densities calculated for the B_5H_{11} framework (34), as (B_I) $-0.14e$, (B_{II}) $+0.08e$, and (B_{III}) $-0.01e$. The *J* values calculated from the spectrum are, in c.p.s.: *a*, $B_{II}H$, 152; *b*, $B_{III}H$, 123; *c*, B_IH, 148; *d*, B_IH (unique), ~124; *e*, $B_{II}HB_{II}$, ≈18; *f*, $B_{II}HB_{III}$, ≈33; unique $B_{III}HB_{III}$, ≈15.

The H^1 n.m.r. spectrum of methyldihydropentaborane is shown in Fig. 2, where it is compared with the H^1 spectrum for B_5H_{11}. The low-field resonances belonging to quartets *a* and *b* are the ones detectably influenced by the methylation. The separation of peaks 1 and 2 has been obliterated; peak 1 has been diminished slightly; peaks 2, 3, 5, 8 have been diminished to a greater extent, and a tendency toward fusion can be noted between peaks 8 and 9. The largest contribution to peaks 2, 3, 5 is from resonances *b*, assigned to protons on B_{III} atoms. It is proposed that one of these, a frontal pyramid-base boron atom, is the site of the methyl group.

Resonances from the methyl group protons arise prominently in the spectrum, as a pair, probably owing to stereoisomerism which can be deduced by examining the *a* and *c* resonances. An apical location is excluded by the unaltered intensity of peak 10, a *c* quartet member. While the *a* intensity, peak 1, is slightly diminished this has another

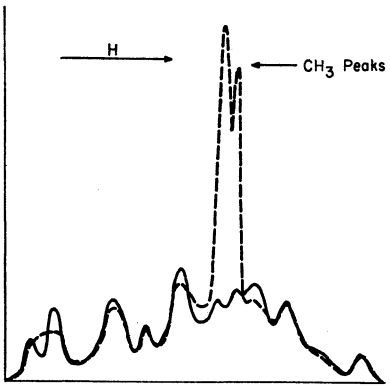

FIG. 2. H^1 n.m.r. spectrum of $B_5H_{10}Me$.

interpretation than assignment of B_{II} boron atoms as sites of isomeric methyl groups. Instead this must be considered together with the intensity increment between peaks 1, 2 and 8, 9. Suppose the degeneracy of the resonances from the B_{II}-linked protons were removed so each had a slightly different chemical shift. There then would be two resonances a and a'. Such alteration could occur through inductive (+I) feeding of electron density into the polyhedron from the methyl group, whereby one site of lowest excess charge, B_{II}, would experience an increase in charge density, disymmetrically, owing to the disymmetric location of the methyl group. Thus would one resonance be shifted slightly to higher field. It is to be concluded therefore that the methyl group is located on a B_{III} atom, that the isomerism is geometric, and that an inductive effect has possibly been observed in a delocalized polyhedral system.

The infrared spectra of the B_5 molecules are shown in Fig. 3, Table XI, and of the B_4

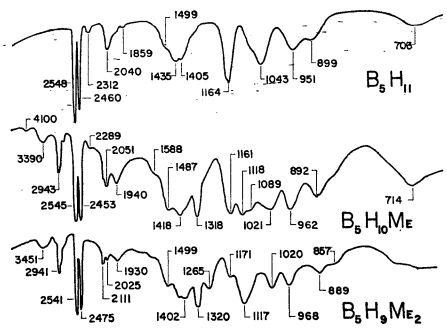

FIG. 3. Infrared spectra of B_5H_{11} and its methyl derivatives.

molecules in Fig. 4, Table XII.[7] The assignments are tentative ones, made by analogy and without detailed consideration of the molecular dynamics. To a degree B_5H_9 can be considered a model for B_5H_{11}. The symmetry of the latter is lower, and there are additional structural features: BH_2, three distinct BHB bridge types, one possibly unsymmetrical, and an open edge on the pyramid. Regardless of these departures, the assignments were made consistent with those for B_5H_9 (24), with reference to data on the non-pyramidal

[7]*Though similar results on the parent molecules have been published previously (28), never have they been tabulated in detail from measurements on highly purified samples. They are therefore included for comparison.*

methyldiboranes (27) for the other structural features. In general the spectra of the two methyl derivatives of B_5H_{11} are simply the sum of the B_5H_{11} features, sometimes displaced about 10–20 wave numbers, and the methyl group frequencies scarcely altered from those in the methyldiboranes (27).

In B_4H_{10} the most prominent structural feature is the dual pair of bridges holding the molecule together. If a charge density relation for B_{II} and B_{III} atoms in tetraborane is assumed similar to that in dihydropentaborane, the bridge vibrations should give such changes in dipole moment as to make the bridge frequencies a prominent feature in the B_4H_{10} spectrum. So it is found that the band at 2120 cm^{-1}, assignable as a bridge stretching

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

frequency, is more intense than the similar band in any other boron hydride, excepting tetramethyldiborane.

The shape of the 2120 band in B_4H_{10} is altered in the methyl derivative. The original band intensity is lowered and a new component almost as intense appears 60 cm^{-1} higher. This would seem to arise from the introduction of disymmetry and to the introduction of an increased reduced mass at the outer end of the bridge system. A similar alteration occurs in the dimethylene tetraborane spectrum, where the shift is to 2150 cm^{-1}, and the intensity loss by the original band is much greater (20). In general the alteration of 5–50 cm^{-1} in B_4H_{10} frequencies upon methylation is somewhat greater than that found for B_5H_{11}.

The methyl-derived frequencies clearly discernable in the B_4H_9Me spectrum are the CH stretch and the B—CH_3 deformation at 2950 and 1428 cm^{-1}, respectively. Others in the 900–1100 cm^{-1} domain are so nearly coincident with bands of B—H origin as not to be separately assignable.

One interesting result of methylation is the obliteration of resolution for the bands between 836 and 856 cm^{-1}. This region is much too low for observation of methyl-derived frequencies, and tentatively the assignment has been made to BH_2B stretching modes. These could be increased in number by methylation of the B_{III} boron atom.

ABSTRACT

The reactions of Me_3Al with Me_2NNMe_2 and $Me_2NCH_2NMe_2$ have yielded complexes whose n.m.r. spectra suggest cyclic structures. They have the formulas $Me_3Al{:}Me_2NNMe_2$ and $Me_3Al{:}Me_2NCH_2NMe_2$ respectively. Me_3Al reacts with $Me_2NCH_2CH_2NMe_2$ to form a complex with a linear structure and the formula $Me_3Al{:}Me_2NCH_2CH_2NMe_2{:}AlMe_3$.

The reactions of $H_3Al{:}NMe_3$ with several methyl hydrazines have yielded the following compounds: $[-Al(HNNHMe)NHNMe-]_n$, $[-HAlNNMe_2-]_n$, $H_2Al-NHNEt_2$, $[(-HAlNNEt_2-){:}NMe_3]_n$, and $H_2Al-NMe_2$. No reaction occurred between $H_3Al\cdot(Et_2O)_n$ and tetramethylhydrazine and the reaction of 3 moles of H_2NNMe_2 with 1 mole of $H_3Al{:}NMe_3$ yielded a compound for which no structural formula could be assigned, but which had emperical formula $C_4H_{15}N_5Al$.

INTRODUCTION

Our recently reported (1) studies of the reactions of aluminum trialkyls and their trimethylamine complexes with methyl hydrazines have led to a number of new compounds which are formed by two general reactions established by Brown and Davidson (2) and Wiberg and May (3):

$$R_3Al + R_2NNR_2 \rightarrow R_3Al{:}R_2NNR_2 \quad [1]$$

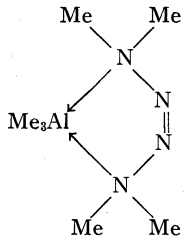
$$R_3Al + HRNNR_2 \rightarrow R_2Al-NRNR_2 + RH. \quad [2]$$

Also recently reported (4, 5) was a study of the reactions of tetramethyltetrazene with Me_3Al, $Me_3Al{:}NMe_3$, and $H_3Al{:}NMe_3$. This work may also be summarized by two general reactions:

$$R_3Al + Me_2NN{=}NNMe_2 \rightarrow R_3Al{:}Me_2NN{=}NNMe_2 \quad [3]$$

$$2R_3Al \text{ (or } 2R_3Al{:}NMe_3) + Me_2NN{=}NNMe_2 \rightarrow 2R_2Al-NMe_2 + N_2 + RH + (NMe_3) + C_hH_{2h}N_2\cdot \quad [4]$$

An n.m.r. investigation of the trimethylaluminum–tetramethyltetrazene adduct (reaction [3]) indicated that it had a symmetric structure and that upon pyrolysis, not only were $Me_2Al-NMe_2$ and nitrogen obtained, but also a red polymer, tetramethyltetrazene, and small amounts of methyl azide and methane. From these data, the following structural formula was proposed:



[1]*Presented at the Symposium on Organometallic Compounds, Vancouver, British Columbia, September 4–6, 1962, sponsored by the Inorganic Chemistry Division, Chemical Institute of Canada, and the Department of Chemistry, University of British Columbia, with the support of the National Research Council, Ottawa, in cooperation with the University Extension Department.*

The purpose of this paper is to report a study of the reactions of aluminum hydride trimethylamine with alkyl hydrazines and to report the results of structural studies of compounds formed from the reactions of Me_3Al and $M_3Al{:}NMe_3$ with tetramethylhydrazine, N,N,N′,N′-tetramethylmethylenediamine, and N,N,N′,N′-tetramethylethylenediamine.

The reactions of methyl hydrazines with aluminum hydride produce compounds which are more difficult to characterize than the corresponding compounds obtained from the Me_3Al and $Me_3Al{:}NMe_3$ reactions. Most of the products had low vapor pressures and were not distillable or sublimable and the reactions generally did not follow the scheme set forth in reactions [1] and [2]. In a few cases the products were shock sensitive and exploded when handled.

The reactions of Me_3Al and $H_3Al{:}NMe_3$ with difunctional tertiary amines have yielded complexes whose n.m.r. spectra suggest pentacoordinated aluminum involved in four- and five-membered ring systems (see the above structural formula for $Me_3Al{:}Me_2NN{=}NNMe_2$).

EXPERIMENTAL

Apparatus and Reagents

The apparatus and procedures employed have been described previously (1, 4). The amines and hydrazines were distilled from CaH_2 before use and the hydrocarbon solvents, which were reagent grade, were used without treatment. The trimethylaluminum was vacuum distilled at 25° C before use and the $Me_3Al{:}NMe_3$ and $H_3Al{:}NMe_3$ were vacuum sublimed before use. The elemental analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, New York.

The n.m.r. spectra were obtained with a Varian Associates Model V-4302 spectrometer at 60 Mc. Liquid samples, containing approximately 5% benzene, were sealed under vacuum in 5-mm pyrex tubes. The solid samples were dissolved in benzene to approximately 15% by weight and then sealed in the tubes. All spectra were taken at 30° C.

Reaction of Aluminum Hydride Trimethylamine with Hydrazine and Methylhydrazine

The reaction of $H_3Al{:}NMe_3$ with hydrazine in *n*-octane produced a white solid which detonated when handled after the solvent had been removed. This extreme shock sensitivity made characterization difficult; however, a hydrolysis with methanol yielded no active hydrogen and an aluminum assay gave the value 35.0%. The infrared spectrum also showed no Al—H band at 5.5 μ, but an NH band at 3.1 μ and an NH_2 band at 6.3 μ. These data suggest the reaction

$$n\mathrm{H_3Al{:}NMe_3} + 2n\mathrm{H_2NNH_2} \rightarrow \left[\begin{array}{c} \text{NHNH}_2 \\ | \\ \text{—Al—NHNH—} \end{array}\right]_n + 3n\mathrm{H_2} + n\mathrm{NMe_3}.$$

The calculated percentage aluminum is 32.6% for the product of the above equation.

The reaction of $H_3Al{:}NMe_3$ with methylhydrazine resulted in a product which was not as shock sensitive as the hydrazine product and hence a somewhat better characterization was possible. With methylhydrazine being used as the reaction medium, 8.57 g of H_2NNHMe was vacuum transferred onto 0.206 g (2.32 mmole) of $H_3Al{:}NMe_3$ at −196° C. After the reaction mixture had warmed to room temperature, 143.6 ml (6.42 mmole) of hydrogen and 52.2 ml (2.24 mmole) of trimethylamine were evolved. The powdery white solid which remained after the excess methylhydrazine was removed gave an elemental analysis which is in fair agreement with the formula $C_2H_9N_4Al$: Anal. Calc.: C, 20.69; H, 7.81; N, 48.26; Al, 23.24. Found: C, 18.39; H, 7.81; N, 52.80; Al, 23.56.

Hydrolysis of the product yielded no active hydrogen and the infrared spectrum showed no Al—H band at 5.6 μ, but did show an NH band at 3.15 μ. These data suggest the following reaction:

$$n\mathrm{H_3Al{:}NMe_3} + 2n\mathrm{H_2NHNMe} \rightarrow \left[\begin{array}{c} \text{NHNHMe} \\ | \\ \text{—Al—NHNMe—} \end{array}\right]_n + 3n\mathrm{H_2} + n\mathrm{NMe_3}.$$

The reaction may also be conducted in hydrocarbon solvent.

Reaction of Aluminum Hydride Trimethylamine with 1,1-Dimethylhydrazine and 1,1-Diethylhydrazine

The reactions of $H_3Al{:}NMe_3$ with H_2NNMe_2 and H_2NNEt_2 appear, on the basis of analytical data, to produce different compounds of unusual structure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

With 1,1-dimethylhydrazine being used as the reaction medium, 20 g of H_2NNMe_2 was vacuum transferred to a vessel containing 0.461 g (5.18 mmole) of $H_3Al{:}NMe_3$ at −196° C. After the resulting mixture was warmed to room temperature and left to stand overnight, a crop of clear crystals deposited on the walls of the reaction flask and 296 ml (12.7 mmole) of hydrogen was evolved. The crystalline product (m.p. 193–194° C) could not be vacuum sublimed (0.05 mm at 70° C), but an elemental analysis gave values which are in good agreement with the formula $C_4H_{15}N_5Al$: Anal. Calc.: C, 29.99; H, 9.44; N, 43.73; Al, 16.84. Found: C, 30.16; H, 9.43; N, 43.80; Al, 16.84.

The infrared spectrum of the product showed no Al—H band at 5.5 μ and no NH_2 band at 6.3 μ, but did have a band at 3.05 μ for N—H. As expected, hydrolysis with methanol showed no active hydrogen. The same product may be obtained by reacting 3 moles of H_2NNMe_2 per mole of $H_3Al{:}NMe_3$ in heptane.

In another experiment, a starting ratio of 2 moles of H_2NNMe_2 per mole of $H_3Al{:}NMe_3$ was used in a reaction carried out in pentane. A white, powdery solid was obtained which showed no melting or apparent decomposition up to 250° C, and elemental analysis gave results which agree with the formula $C_2H_7N_2Al$: Anal. Calc.: C, 27.91; H, 8.19; N, 32.55; Al, 31.34. Found: C, 27.01; H, 8.69; N, 31.90; Al, 31.17. The infrared spectrum of the product showed a strong Al—H band at 5.6 μ, but no band for either NH at 3.0 μ or NH_2 at 6.3 μ. The structures of these two materials will be discussed later.

The reaction of $H_3Al{:}NMe_3$ with H_2NNEt_2 gave a white non-volatile solid when the starting ratio of reagents was 1:1 and a non-volatile, viscous liquid when the starting ratio of reagents was 2 moles of H_2NNEt_2 per mole of $H_3Al{:}NMe_3$. In a typical reaction using a 2:1 ratio of reagents, 0.688 g (7.72 mmole) of $H_3Al{:}NMe_3$ in 25 ml of *n*-heptane was combined with 1.27 g (16.3 mmole) of H_2NNEt_2 at −196° C. After the mixture had warmed to room temperature and was allowed to stand overnight, the solvent was removed and the product analyzed. The analysis gave values which agree with the formula $C_7H_{20}N_3Al$: Anal. Calc.: C, 48.53; H, 11.64; N, 24.25; Al, 15.57. Found: C, 48.41; H, 11.04; N, 24.60; Al, 16.00. Also, 360 ml (16.1 mmoles) of hydrogen and 53.5 ml (2.38 mmole) of trimethylamine were evolved. Hydrolysis of 0.1780 g (1.03 mmole) of the product with methanol gave 13.3 ml (0.594 mmole) of hydrogen. The infrared spectrum had a strong Al—H band at 5.55 μ and a weak N—H band at 3.1 μ.

From these data, the reaction appears to be:

$$n\mathrm{H_3Al{:}NMe_3} + n\mathrm{H_2NNEt_2} \longrightarrow \left[\begin{array}{c} \mathrm{H} \\ \mathrm{-Al-N-} \\ \cdots \quad \diagdown \\ \mathrm{NMe_3\ NEt_2} \end{array}\right]_n + 2n\mathrm{H_2}.$$

In a reaction where the starting ratio was 1:1, 0.936 g (12.0 mmole) of H_2NNEt_2 was vacuum transferred to a 50-ml vessel containing 0.919 g (10.3 mmole) of $H_3Al{:}NMe_3$ and 20 ml of *n*-heptane at −196° C. The mixture was allowed to warm to room temperature and to stand overnight. By the end of this period most of the solids had dissolved and 314 ml (14.0 mmole) of hydrogen had evolved. An attempt was made to separate the trimethylamine from the heptane, but only 81.8 ml (3.65 mmole) of pure material could be recovered. Elemental analysis of the crude product gave results which agreed with the formula H_2Al—$NHNEt_2$: Anal. Calc.: C, 41.36; H, 11.28; N, 24.13; Al, 23.23. Found: C, 42.06; H, 10.72; N, 24.06; Al, 23.56.

Hydrolysis of 0.231 g (1.97 mmole) of crude product with methanol gave 52.5 ml (2.34 mmole) of hydrogen and pyrolysis of 0.330 g (2.81 mmole) at 100° C for 6 hours (gas evolution ceased) yielded 66.0 ml (2.95 mmole) of hydrogen. From these data the reaction appears to be:

$$\mathrm{H_3Al{:}NMe_3} + \mathrm{H_2NNEt_2} \rightarrow \mathrm{H_2Al{-}NHNEt_2} + \mathrm{H_2} + \mathrm{NMe_3}.$$

Reaction of Aluminum Hydride Trimethylamine with Trimethylhydrazine

In absence of solvent, 1.58 g (12.3 mmole) of $HNMeNMe_2$ was transferred to 1.80 g (20.2 mmole) of $H_3Al{:}NMe_3$ at −196° C. After the mixture had warmed to room temperature (30 minutes), 234 ml (10.5 mmole) of hydrogen and 132 ml (5.90 mmole) of trimethylamine were evolved. The crude product was then pumped to remove any traces of $HNMeNMe_2$. A white crystalline solid (m.p. 93–95° C) remained which, when analyzed, proved to be H_2Al—NMe_2: Anal. Calc.: C, 32.87; H, 11.03; N, 19.17; Al, 36.92. Found: C, 32.72; H, 10.82; N, 19.70; Al, 36.55. A quantitative yield of H_2Al—NMe_2 was obtained.

Reaction of Aluminum Hydride Etherate with Tetramethylhydrazine

From 1.50 g of $LiAlH_4$ and 1.00 g of $AlCl_3$ an etherate solution of $AlH_3 \cdot n\mathrm{Et_2O}$ was prepared. After the LiCl had been removed by filtration, 20 ml of Et_2O containing 1.00 g of Me_2NNMe_2 was added to the $AlH_3 \cdot n\mathrm{Et_2O}$. The mixture was refluxed for an hour and then the ether and any excess Me_2NNMe_2 were removed under vacuum. A powdery white solid remained which could not be sublimed at 55° C under 0.05 mm vacuum. An infrared spectrum of the solid showed only the very broad band of polymeric aluminum hydride at 5.5 μ. Treatment of a portion of the solid with a large excess of trimethylamine gave a quantitative yield of $H_3Al(NMe_3)_2$. From these data it was concluded that no reaction had occurred.

The reaction was repeated with $H_3Al{:}NMe_3$, but the starting materials were recovered unreacted.

Reaction of Trimethylaluminum with N,N,N′,N′-Tetramethylethylenediamine

Into 5.55 g (75.7 mmole) of Me_3Al at −196° C was distilled 9.12 g (78.6 mmole) of $Me_2N(CH_2)_2NMe_2$ and 20 ml of *n*-heptane. The mixture was allowed to warm to room temperature and to stand for 2 hours.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The solvent and any unreacted starting materials were removed by vacuum transfer, leaving a white crystalline mass in the reaction vessel. Also obtained from the reaction was 81.0 ml (3.61 mmole) of methane.

The crude product was vacuum sublimed at 75° C and a 76 mole% yield of white crystals (m.p. 136–137.5 (decomp.)) was obtained. Elemental analysis gave results which agreed with the formula $Me_2N(CH_2)_2$-$NMe_2(Me_3Al)_2$: Anal. Calc.: C, 55.35; H, 13.16; N, 10.76; Al, 20.72. Found: C, 54.92; H, 13.07; N, 10.92; Al, 19.61.

Hydrolysis of 0.268 g (1.03 mmole) of sublimed material with methanol yielded 139 ml (6.23 mmole) of methane. These data indicate that the reaction

$$Me_3Al + Me_2N(CH_2)_2NMe_2 \rightarrow \begin{matrix} Me_3Al & & AlMe_3 \\ \cdot\cdot & & \cdot\cdot \\ Me_2N(CH_2)_2NMe_2 \end{matrix}$$

had occurred.

This complex has been found to react almost quantitatively with trimethylamine. Treatment of 0.630 g (2.62 mmole) of $(Me_3Al)_2$:$Me_2N(CH_2)_2NMe_2$ with 7.37 mmole of NMe_3 gave 0.660 g (5.03 mmole) of Me_3Al:NMe_3 (composition confirmed by elemental analysis).

Reaction of Trimethylaluminum with N,N,N′,N′-Tetramethylmethylenediamine

Under vacuum, 3.23 g (31.7 mmole) of $Me_2NCH_2NMe_2$ was transferred to a 50-ml reaction vessel containing 2.26 g (30.0 mmole) of Me_3Al and 20 ml of *n*-heptane at −196° C. The mixture was allowed to warm to room temperature and stand for an hour. The heptane and any excess amine were removed by vacuum transfer. The remaining white solid was vacuum sublimed at room temperature onto a −78° C cold finger. The sublimate (m.p. 33–35° C) was obtained in approximately 80 mole% yield.

Elemental analysis of the sublimate gave values which agree with the formula Me_3Al:$Me_2NCH_2NMe_2$: Anal. Calc.: C, 55.10; H, 13.24; N, 16.07; Al, 15.47. Found: C, 55.24; H, 13.55; N, 15.84; Al, 15.73. Hydrolysis of 0.364 g (2.46 mmole) of sublimate with methanol gave 146 ml (6.51 mmole) of methane. These data indicate that a 1:1 adduct is formed.

Reaction of Aluminum Hydride Trimethylamine with N,N,N′,N′-Tetramethylmethylenediamine

In the absence of solvent, 1.64 g (16.1 mmole) of $Me_2NCH_2NMe_2$ was vacuum transferred to a 50-ml vessel containing 1.34 g (15.0 mmole) of H_3Al:NMe_3 at −196° C. The mixture was allowed to warm to room temperature and stand for 2 hours. During this period the H_3Al:NMe_3 dissolved in the amine. The solution was then vacuum sublimed at room temperature onto a −78° C cold finger. The sublimate melted at room temperature (25–26° C) and elemental analysis gave results which agree with the formula H_3Al:Me_2NCH_2 NMe_2. Anal. Calc.: C, 45.42; H, 12.97; N, 21.20; Al, 20.41. Found: C, 45.21; H, 12.97; N, 21.00; Al, 20.22.

Hydrolysis of 0.167 g (1.26 mmole) of the sublimate with methanol gave 156 ml (3.74 mmole) of hydrogen. These data indicate the formation of a 1:1 complex by the reaction

$$H_3Al{:}NMe_3 + Me_2NCH_2NMe_2 \rightarrow H_3Al{:}Me_2NCH_2NMe_2 + NMe_3.$$

The yield of sublimate was approximately 60 mole% of initial H_3Al:NMe_3.

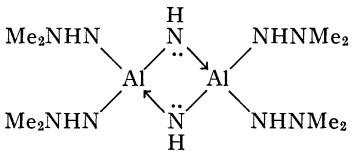
DISCUSSION

Reaction of Aluminum Hydride Trimethylamine with Hydrazines

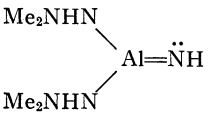
From the experimental data presented above, a few preliminary observations may be made about these reactions. In contrast to the reactions of aluminum alkyls with hydrazines (equations [1] and [2]), aluminum hydride does not appear to follow any systematic reaction scheme. The products vary depending upon the starting ratios of reagents and the solvents employed. Also, in almost all reactions, the products could not be purified, because of their insolubilities and low vapor pressures. It appears that most materials obtained were polymeric, having no sharp melting points or crystalline character.

An illustration of the problems encountered is the variety of results obtained from the reactions of aluminum hydride trimethylamine with 1,1-dimethylhydrazine and 1,1-diethylhydrazine. In the case of 1,1-dimethylhydrazine one reaction was carried out with the hydrazine acting as solvent and heat sink. A sharp-melting crystalline solid was obtained which several elemental analyses indicated has the emperical formula $C_4H_{15}N_5Al$. The structure of this compound is difficult to determine, because the Al/N ratio is odd and Al/C ratio is even. If it had formed via reaction [1] or [2] the Al/N ratio would be even, i.e., 1:2, 1:4, etc., or if trimethylamine were still adducted to the molecule, the Al/C ratio would be odd. The structure which fits all the data available is:

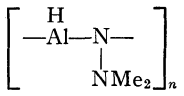
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



or:

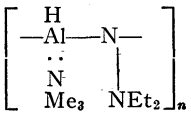


In the other example cited above when the starting ratio of H_2NNMe_2 to $H_3Al{:}NMe_3$ was 2:1 and the reaction was run in pentane, a material with the formula $C_2H_7N_2Al$ was obtained. The best formula for the analytical and infrared data is the previously unreported polymer



This structure is unusual because both hydrogen atoms have been removed from the hydrazine nitrogen atom.

However, 1,1-diethylhydrazine also appears to react with $H_3Al{:}NMe_3$ in a similar manner when the starting ratio of the hydrazine to $H_3Al{:}NMe_3$ is 2:1. In this case a trimethylamine molecule still appears to be associated with the aluminum atom; hence, the structure may be



If the starting ratio of reagents is changed to 1:1, a reaction which follows equation [2] occurs and the compound $H_2Al{-}NHNEt_2$ is produced. It is one of the few examples of the behavior observed in the corresponding trimethylaluminum – alkyl hydrazine reactions.

The reaction of aluminum hydride trimethylamine with trimethylhydrazine did not produce the expected $H_2Al{-}NMeNMe_2$, but instead gave a quantitative yield of $H_2Al{-}NMe_2$. This result creates a problem of accounting for the hydrazine residues. So far we have been able to detect only trimethylamine in the condensables, but it would appear that another material, perhaps methylamine or dimethylamine, is present.

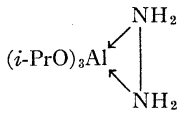
Our final surprise in this series of reactions was the fact that freshly prepared aluminum hydride etherate would not react with tetramethylhydrazine yet would react with trimethylamine to form aluminum hydride bis-trimethylamine. As a first approximation, it was assumed that trimethylamine and tetramethylhydrazine were compounds of equal basicity, but it appears that trimethylamine is basic enough to break up the aluminum hydride polymer and aluminum–ether bonds while tetramethylhydrazine is not.

Trimethylaluminum Difunctional Amine Complexes

Our recent finding (5) that trimethylaluminum forms a symmetric complex with tetramethyltetrazene and the recent report by Bains and Bradley (6) of the preparation of $(i\text{-PrO})_3Al{:}H_2NNH_2$ have led us to examine the reactions of trimethylaluminum with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

tetramethylhydrazine, N,N,N′,N′-tetramethylmethylenediamine, and N,N,N′,N′-tetramethylethylenediamine. We have proposed the structure shown in the Introduction for the tetrazene complex and Bains and Bradley (6) have suggested the chelate



as one of two possibilities for the structure of the tris-isopropoxy-aluminum – hydrazine complex.

Trimethylaluminum forms a 1:1 complex with tetramethylhydrazine and two cryoscopic molecular weight determinations on 0.086 and 0.083 molal solutions showed the complex to be monomeric in cyclohexane. The n.m.r. spectrum of a 15% solution in benzene (Fig. 1) shows only one peak for both Al-methyl protons and N-methyl protons. This

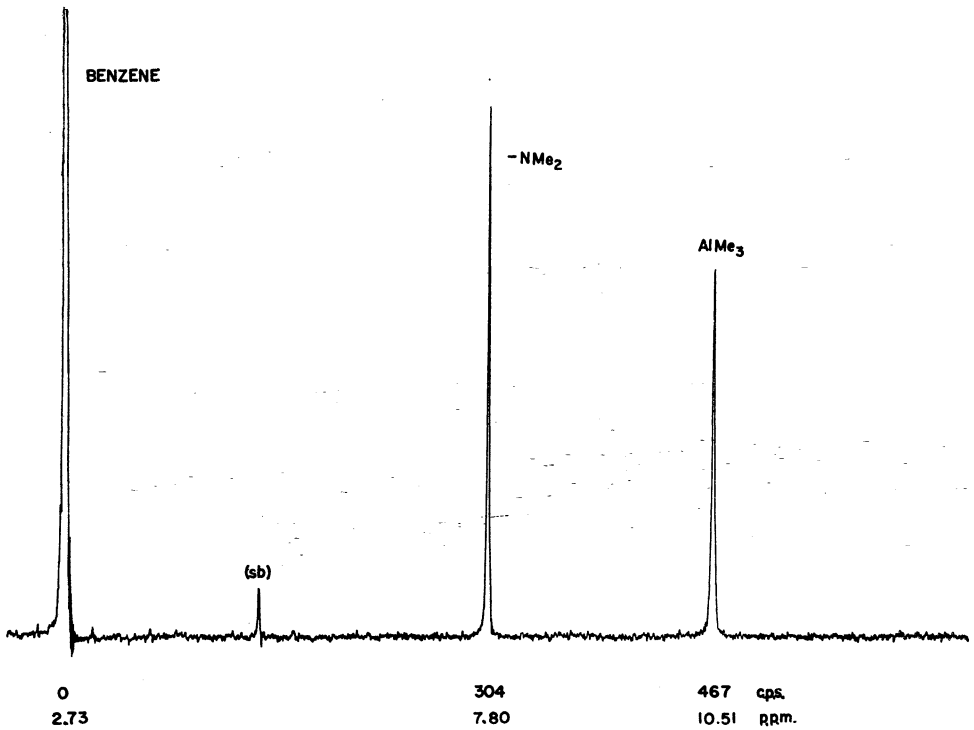


FIG. 1. The n.m.r. spectrum of $Me_3Al:Me_2NNMe_2$ (m.p. 66.0° C), at 60 Mc, of a 15 wt% solution in benzene.

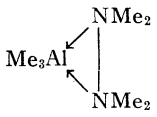
information leads us to the chelate structure proposed earlier by Fetter and Bartocha (1) for this type of complex, namely,



The 1:1 complex formed in the reaction of trimethylaluminum with N,N,N′,N′-tetramethylmethylenediamine appears to be slightly associated in benzene, for two freezing

For personal use only.

point depression molecular weight measurements of 0.048 molal and 0.051 molal solutions gave the values 246 and 232 respectively (calc. for monomer: 174). The n.m.r. spectrum of a 15% solution in benzene (Fig. 2) shows one peak each for Al-methyl proton, N-methyl

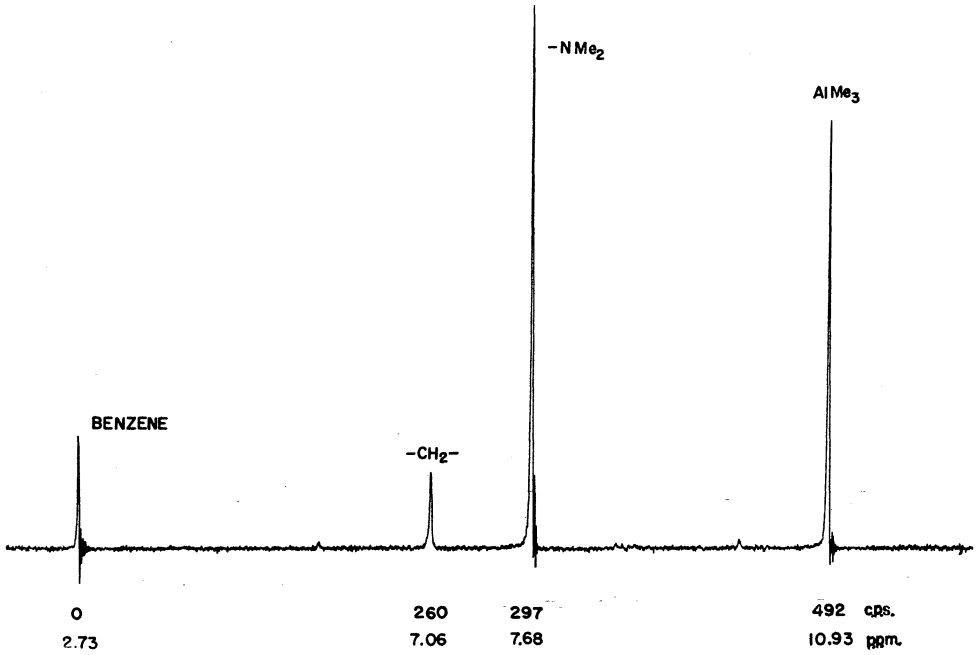

FIG. 2. The n.m.r. spectrum of $Me_3Al{:}Me_2NCH_2NMe_2$ (m.p. 35° C), at 60 Mc, of a 15 wt% solution in benzene.

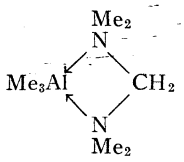
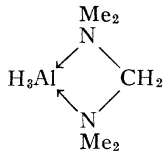
protons, and methylene protons. This result also suggests a chelated complex with the structure



Aluminum hydride trimethylamine also appears to form a complex of similar structure as a result of reaction with N,N,N′,N′-tetramethylmethylenediamine. This complex also appears to be associated in benzene, for two measurements on 0.125 molal and 0.107 molal solutions gave the values 167 and 164 respectively (calc. for monomer: 132). The n.m.r. spectrum (Fig. 3) shows a single peak only for N-methyl protons. The methylene protons appear to be split and the Al-protons were not detectable at the concentration of complex used in the sample. Although the n.m.r. spectrum is not as clear as in the trimethylaluminum case, the structure



appears to fit the available data best.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

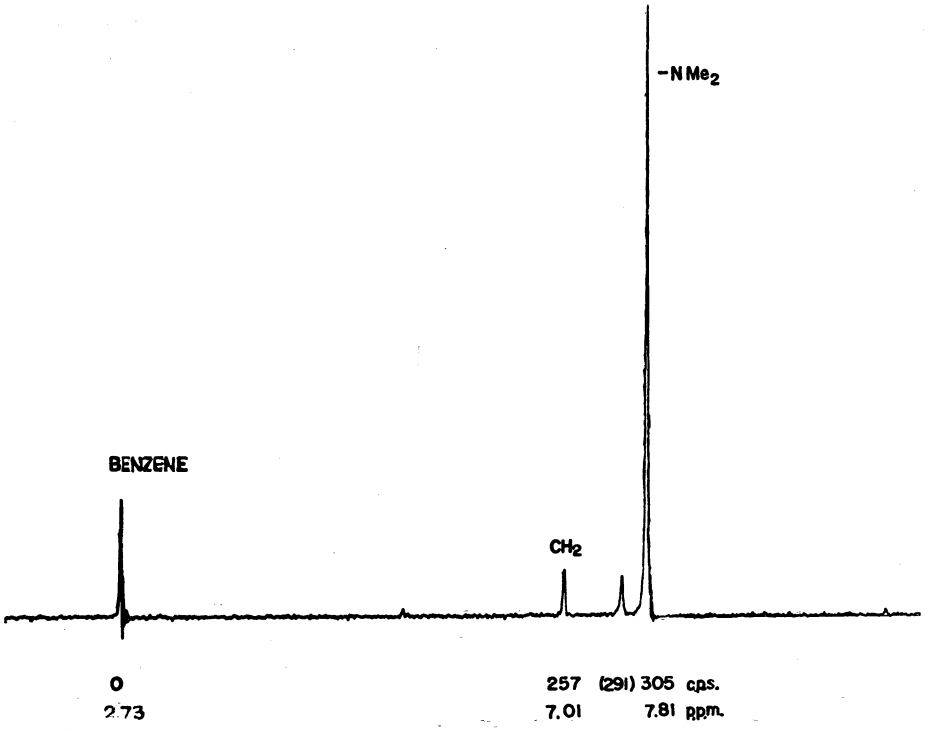


FIG. 3. The n.m.r. spectrum of $H_3Al{:}Me_2NCH_2NMe_2$ (m.p. 25° C), at 60 Mc, of a 15 wt% solution in benzene.

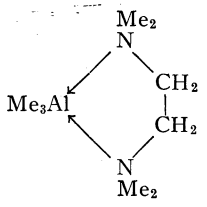
When another methylene group is present in the difunctional tertiary amine, as in the case of N,N,N′,N′-tetramethylethylenediamine, the nature of the bonding to trimethylaluminum changes considerably. Instead of obtaining the anticipated five-membered chelate ring



obtained by Davidson and Wartik (7) for the corresponding aluminum hydride complex, a trimethylaluminum molecule bonds to each of the —NMe_2 groups. Cryoscopic molecular weights also indicate that this complex is associated. Two determinations with 0.069 and 0.084 molal solutions gave the values 359 and 342 respectively (calc. for monomer: 260).

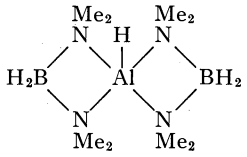
It is tempting from the data presented to make the generalization that any difunctional tertiary amine will form a bis-adduct with trimethylaluminum if there are two or more intervening carbon atoms, and that with one or no carbon atoms intervening, a chelate complex will form. Other reactions with model amines are planned to determine the validity of this hypothesis.

The status of aluminum hydride complexes appears to be somewhat different. The work of Wartik and Davidson (7) and the work presented here suggest that cyclic complexes

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

are formed with difunctional tertiary amines with up to at least two intervening methylene groups.

Some of the structures proposed above involve pentacoordinate aluminum. As the ligand chemistry of aluminum becomes more extensive the appearance of what seems to be a rather stable pentacoordinate condition appears more frequently. Ruff and Hawthorne (8) first proposed the pentacoordinate state for dimeric aluminum hydride trimethylamine and recently Ruff (9) has reported the compound $HAl(NMe_2)_2 \cdot 2BH_2NMe_2$ for which he proposed (among others) the structure



Aluminum hydride bis-trimethylamine, which is thermally more stable than the monocomplex, also requires a pentavalent aluminum. The data available so far, however, do not provide conclusive evidence in most cases and the final proof may be obtained from single crystal X-ray studies.

A word of caution should be made concerning molecular weight data. In most cases the compounds appear to be associated in freezing benzene, but it would require a more thorough study of concentration effects and perhaps vapor phase determinations to get a clearer understanding of association of monomeric species. Also, low-temperature n.m.r. studies of some of the above complexes are being studied to determine whether association occurs.

MECHANISMS OF THE REACTIONS OF DIETHYLZINC WITH ISOPROPANOL AND WATER[1]

R. J. HEROLD, S. L. AGGARWAL, AND V. NEFF
Central Research Laboratories, The General Tire & Rubber Company, Akron, Ohio, U.S.A.
Received November 22, 1962

ABSTRACT

Reactions of diethylzinc with isopropanol and water were studied by means of infrared absorption and gas evolution. The former method was found to be more reliable. Ethylzinc isopropoxide, formed from diethylzinc and isopropanol, was shown to be stable in the presence of excess isopropanol. The reaction of diethylzinc with water was found to proceed in a two-step manner, the product of the first being ethylzinc hydroxide. The decomposition of ethylzinc hydroxide was found to be first order with respect to itself and independent of diethylzinc.

INTRODUCTION

The reaction of zinc alkyls with compounds containing active hydrogens has been used in the past for qualitative and quantitative estimation of active hydrogen concentrations (1, 2). Generally, such procedures have been carried out with an excess of metal alkyl and little attention has been paid to the zinc-containing reaction products. Haurowitz noted that in many cases reaction of zinc alkyls with organic compounds containing active hydrogens is not complete. Specifically in the case of benzyl alcohol only 60% of the expected ethane is evolved. Tolkatschev (3) and Menard and Aston (4) found, however, that both ethyl groups can be removed from diethyl zinc with methanol and acetoxime respectively.

Current interest in the reaction products of zinc alkyls with water and with alcohols is derived from their use as catalysts. Furukawa *et al.* (5, 6, 7) and Stewart (8) have shown the usefulness of such reaction products for the polymerization of epoxides and of aldehydes. Furukawa concluded that the reaction product of diethylzinc with water results from the initial formation of ethylzinc hydroxide followed by reaction of this intermediate with diethyl zinc. Although quite plausible, his suggestion is not supported by proof of the existence of the intermediate, nor by kinetic data to show the bimolecular nature of its reaction with diethylzinc.

In the studies reported herein, we have: (1) shown that ethylzinc isopropoxide formed from diethylzinc and isopropanol is stable in the presence of excess isopropanol in heptane solution; (2) shown that ethylzinc hydroxide is formed as an intermediate in the reaction of diethylzinc and water in ether solution; and (3) worked out the kinetics of the disappearance of ethylzinc hydroxide in the presence of various concentrations of diethylzinc in dimethoxyethane (glyme) solution. Two methods were used to study this latter reaction, namely, measurements of (1) the change in infrared absorption intensity at 2.9 μ (hydroxyl) and (2) ethane gas evolution as a function of time. However, these two methods give rate curves which are quite different. Since a lag in the evolution of ethane appeared to be the reason for this discrepancy, the kinetic analysis was based on the infrared results. The initial portions of the gas evolution rate curves were nevertheless useful in obtaining an indication of the activation energy of the process.

EXPERIMENTAL

Reactions of Diethylzinc with Isopropanol

These reactions were carried out in heptane solution under nitrogen by adding the alcohol slowly to stirred solutions of diethylzinc. Gas was evolved and slightly hazy solutions were formed which cleared slowly, giving very small amounts of precipitate. The solid may have been the reaction product of traces of water in the isopropanol with the diethylzinc. Evaporation of the clear liquid yielded a white solid which was unstable in air. Infrared absorption measurements were used to determine the nature and extent of the reaction.

Reactions of Diethylzinc with Isomeric Butanols

The reactions of diethylzinc with normal, secondary, and tertiary butanols were studied in 1,2-dimethoxyethane (glyme) solution. The reactions were carried out at 0° and the extents of reaction measured by means of both gas evolution and infrared absorption. Clear solutions were obtained up to ratios of 2 to 1 of normal and secondary butanols to diethylzinc. Cloudy solutions and copious precipitates resulted from the 1:1 reaction product of diethylzinc with tertiary butanol. Cloudy solutions also resulted upon the addition of solutions of each of the alcohols to solutions of ethylzinc hydroxide.

Reactions of Diethylzinc with Water

These reactions were carried out in 12-oz beverage bottles sealed with perforated crown caps backed with butyl rubber which allowed additions, gas evolution, and sampling through the use of syringes and stainless steel hypodermic needles. Early experiments were started with a nitrogen atmosphere but later it was realized that the data were more reliable when all of the solutions were saturated with ethane. Such a solution of water in glyme was added to a solution of diethylzinc in glyme at 0° C. The addition was made along the side of the bottle with vigorous agitation by means of a magnetic stirring bar. The addition was made with the aid of a mechanically driven syringe since the times of addition of the water solution sometimes required as long as 40 minutes in order to minimize temperature rise. The syringe used in the transfer was cooled with dry ice to avoid degassing. Clear colorless solutions resulted from this technique. The gas liberated by the reaction was allowed to evolve as formed through a wet test meter filled with water saturated with ethane. After the addition was completed a sample was usually removed for infrared measurement and the beverage bottle was removed from the ice bath and placed in a constant-temperature bath for the gas evolution measurement.

Table I summarizes the conditions and results of the kinetic experiments. Most of the experiments were done at the same initial diethylzinc concentration (column 1). However, since part of this was reacted

TABLE I

Representative kinetic experiments

Et_2Zn initial (moles/l.)	H_2O added (moles/mole Et_2Zn)	Concn. at start of kinetic measurements (moles/l.)		C_2H_6 evolved (moles/mole H_2O)	
		EtZnOH	Et_2Zn	First step	Second step
0.87	0.31	0.27	0.60	1.02	0.86
0.87	0.62	0.53	0.34	1.00	0.87
1.25	0.61	0.76	0.49	1.01	0.95
0.87	0.92	0.80	0.07	1.00	0.65
0.87	0.97	0.84	0.03	1.00	0.90

away by water at various mole ratios (column 2), it was the excess diethylzinc concentrations (column 4) and the initial ethylzinc hydroxide concentrations (column 3) which were of interest kinetically. As shown in column 5 the ethane evolved during the first step was very nearly 1 mole per mole of water except at very low water ratios. This may have been associated with inherent measurement errors which were larger in proportion to the amounts measured in these experiments. The amounts of gas liberated in the second step were always less than, but usually close to, 1 mole per mole of water.

The infrared measurements were made at room temperature (30° C), but most of the gas evolution measurements were made at 15° C because the decomposition was sufficiently rapid and exothermic at 30° C that the temperature rose significantly in the beverage bottles. No such temperature rise is expected to have occurred in the infrared cell due to the large surface-to-volume ratio.

The infrared samples were pressured into cells closed at each end with stopcocks. Pressure helped minimize bubbling in the cells. It was found that cells smaller than 0.10 mm were often unsatisfactory in that the bubbles were sometimes trapped in the center areas of such cells and thus vitiated the results.

The rates measured in the infrared experiments cannot be taken as absolute measurements since the temperature was not measured or controlled beyond being in a thermostated room. It is supposed that a

slight temperature adjustment occurred during the first 2 to 4 minutes of each experiment, after which time a steady state was reached and maintained.

Two methods of following the decrease of hydroxyl absorption were used. The first is illustrated in Fig. 1. The spectrometer was set to repeat the 2.5 to 3.5 μ region once each 100 seconds. The depth of the peak

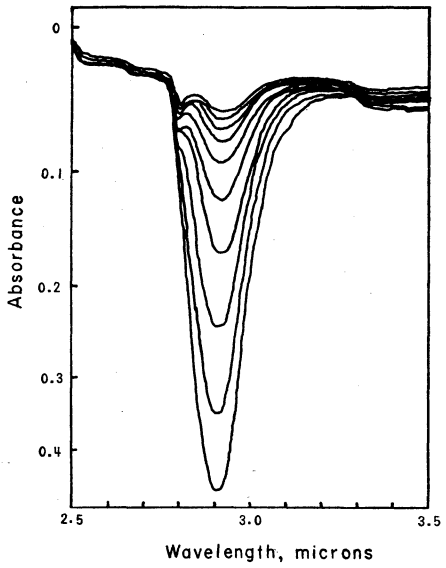

FIG. 1. Disappearance of EtZnOH at 30° C (100-second time intervals).

(log I/I_0) from the background estimated for each experiment was taken as a measure of relative concentration. The other method consisted of running the spectrometer at a fixed wavelength (2.91 μ) and making a mark at intervals of from 20 to 60 seconds.

RESULTS AND DISCUSSION

Reactions of Diethylzinc and Alcohols

Figure 2 shows the significant portions of the infrared spectra of ~5% solutions of isopropanol in heptane, and the 1:1 reaction product of isopropanol and diethylzinc in heptane. Cells of the same thickness were used (0.047 mm). The absorbances and assignments of the important bands in these spectra are given in Table II. The marked increase in the intensities of these absorption bands in the spectrum of the 1:1 reaction product

over that of isopropanol may be attributed to the formation of a more heteropolar carbon–oxygen band in the zinc alkoxide.

In Table III are given absorbances at 2.95 μ (hydroxyl) and at 8.96 μ and 12.15 μ (isopropoxyl) for solutions of diethylzinc and isopropanol at various mole ratios of the

TABLE III

Absorbances of diethylzinc–isopropanol reaction products

Isopropanol to diethylzinc (mole ratio)	Absorbances		
	2.95 μ	8.96 μ	12.15 μ
0.674	0	1.04	0.662
0.956	0	1.66	1.051
1.91	0.621	1.68	0.993
2.87	1.23	1.63	0.981

reactants. These solutions were prepared by adding the required amounts of isopropanol to solutions containing about 0.42 mole of diethylzinc per liter of heptane. As shown, the intensities of the bands at 8.96 μ and 12.15 μ do not increase for mole ratios of isopropanol to diethylzinc greater than 1:1, suggesting that the reaction proceeds according to the equation

$$(C_2H_5)_2Zn + i\text{-}C_3H_7OH \rightarrow C_2H_5ZnOC_3H_7 + C_2H_6. \quad [1]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

At the mole ratio of 0.674:1 isopropanol to diethylzinc the decrease in intensities of the alkoxyl bands is approximately that expected from the reaction as shown above. Further, no hydroxyl absorption occurs in the 0.674:1 and 0.956:1 mole ratio experiments, whereas hydroxyl absorption does occur for mole ratios greater than 1:1. The intensities of the hydroxyl band for the 1.91:1 and 2.87:1 mole ratio experiments are, within experimental error, equal to that expected on the above 1:1 reaction between isopropanol and diethylzinc. Furthermore the absorption band at 10.1 μ assigned to the ethyl group attached to zinc is present in all of the spectra, even at mole ratios of 2.87:1.

These results show that the alcoholysis of diethylzinc does indeed proceed according to reaction [1] above, and unexpectedly, the second ethyl group bonded to zinc is not replaced in the presence of an excess of the alcohol. No satisfactory explanation for the stability of the second ethyl group has yet been deduced. Three possible explanations have occurred to us as follows: (1) that electronic changes are induced by the zinc–oxygen bond to strengthen the zinc–carbon bond; (2) that a stable complex is formed between one or more alcohol molecules and an ethylzinc isopropoxide molecule; and (3) that diethylzinc, which has been shown (9) to exist as an ion pair, ($ZnEt^+Et^-$), reacts toward active hydrogen containing compounds in a two-step manner, the first, much more rapid step involving the ethyl anion.

The reactions of diethylzinc with normal, secondary, and tertiary butanols were studied in the hope of developing a method for the determination of excess diethylzinc in the presence of compounds containing ethyl–zinc–oxygen structures. This would have been useful in the kinetic studies reported later in this paper. They were carried out in 1,2-dimethoxyethane (glyme) in order to make them applicable in that system. However, reactions of these alcohols in glyme solution did not stop at a ratio of 1 to 1. Both gas evolution and infrared absorption indicated partial reaction of a second mole of each of the alcohols. Here again, however, there remained considerable unreacted alcohol in the presence of zinc–ethyl bonds. The difference between these results and the prior results with isopropanol is supposed to be due to the effects of the solvents used. Heptane would of course tend to suppress ion separation and promote hydrogen bonding as compared to an ether as solvent.

Nature of the Reaction of Diethylzinc with Water

Initial attempts to determine the nature of the diethylzinc reaction products by infrared absorption indicated the absence of hydroxyl groups. These experiments were done after indeterminate periods of aging. Gas evolution data, however, strongly suggested that hydroxyl groups should have been present, since at low temperatures only 1 mole of gas per mole of water appeared to be evolved. More careful analysis of the gas evolution showed, moreover, that following the initial rapid evolution of 1 mole of gas per mole of water slow evolution continued, finally amounting to very nearly another mole of gas. This prompted us to observe the infrared spectra of the solution immediately after the water addition was completed. Figure 3 shows a portion of the spectrum of such a sample with a strong hydroxyl absorption at 2.90 μ. It should be noted that there is no companion band at 6.12 μ as would have been expected if the hydroxyl band was due to residual water. Rerunning the spectra after aging the solution overnight or for short periods in the infrared cell reduced or completely eliminated this absorption. Measurements of the hydroxyl band at various concentrations of water and diethylzinc have shown it to vary in the manner expected for the formation of ethylzinc hydroxide by reaction [2].

$$(C_2H_5)_2Zn + H_2O \rightarrow C_2H_5ZnOH + C_2H_6 \qquad [2]$$

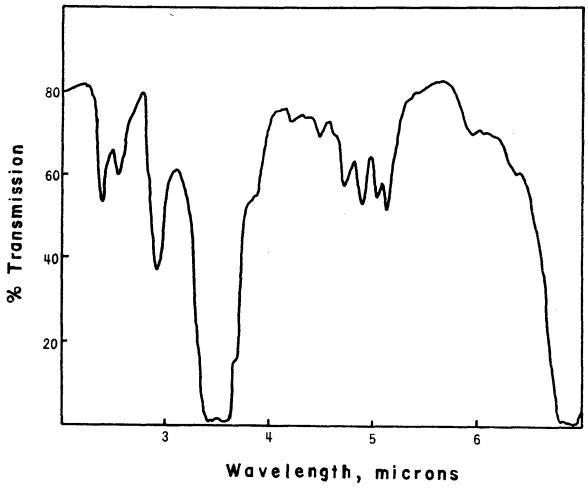

FIG. 3. Infrared spectrum of Et_2Zn–H_2O reaction product in glyme immediately after addition of H_2O.

So far the properties of ethylzinc hydroxide have only been observed in solution. The molar absorptivity of its hydroxyl absorption is 97 ± 9 (liters/mole cm). As shown later, it has half-life periods in the range of 6 minutes at 30° C, 35 minutes at 15° C, and 220 minutes at 0° C. From these data it may be inferred to be a "stable" compound at -60° C and below. This was confirmed at -78° C, at which temperature there was no change in its infrared spectra over a 4-day period.

No such intermediate was isolated from the reaction of triethylaluminum with water at 0° C. Also, when triethylaluminum is added to a solution of ethylzinc hydroxide at 0° C, practically instantaneous evolution of the theoretical amount of ethane (based on the active hydrogen concentration) occurs. It is inherent in the data presented in the following that diethyl zinc reacts very slowly, if at all, with ethylzinc hydroxide. This appears to be in contradiction to the reactivity of zinc and aluminum alkyls toward active hydrogens as reported by Nelson (10).

KINETICS OF THE DISAPPEARANCE OF ETHYLZINC HYDROXIDE

Infrared Studies

Figure 4 shows representative data from early infrared measurements of the disappearance of ethylzinc hydroxide plotted as concentration of hydroxyl versus time. The general shape of the curves is exponential. However, it will be noted that there are short initial periods of linear or actually increasing slope in some of the plots. Figure 5 shows the first-order plots of these same data and another run at a ratio of [EtZnOH] to [Et_2Zn] equal to 0.17. It is of interest to notice that the reactions follow first-order kinetics during an appreciable extent of the reaction in all of these cases. First-order kinetics did not fit the reaction scheme suggested by Furukawa for the reaction of this intermediate, namely,

$$C_2H_5ZnOH + (C_2H_5)_2Zn \rightarrow C_2H_5ZnOZnC_2H_5 + C_2H_6 \quad [3]$$

$$2C_2H_5ZnOH \rightarrow C_2H_5ZnOZnOH + C_2H_6. \quad [4]$$

The other salient fact from the early data is that the rates are not affected to an appreciable extent by the concentration of excess diethylzinc. This may be seen by

For personal use only.

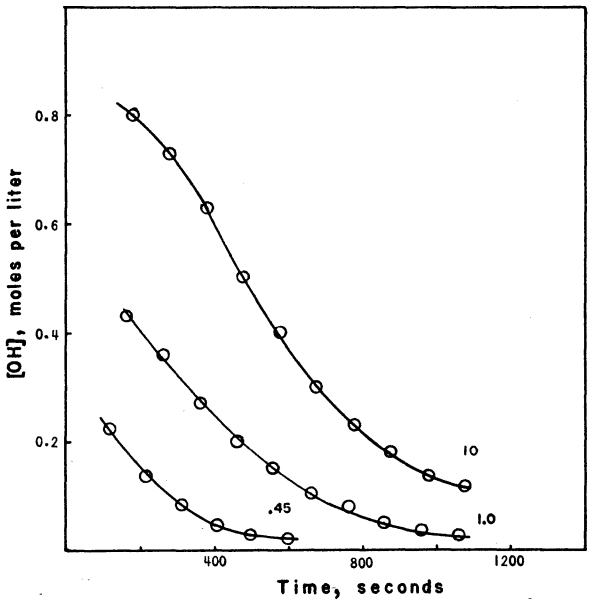

FIG. 4. Disappearance of EtZnOH as measured by infrared at 30° C for different (EtZnOH)/(Et_2Zn) ratios.

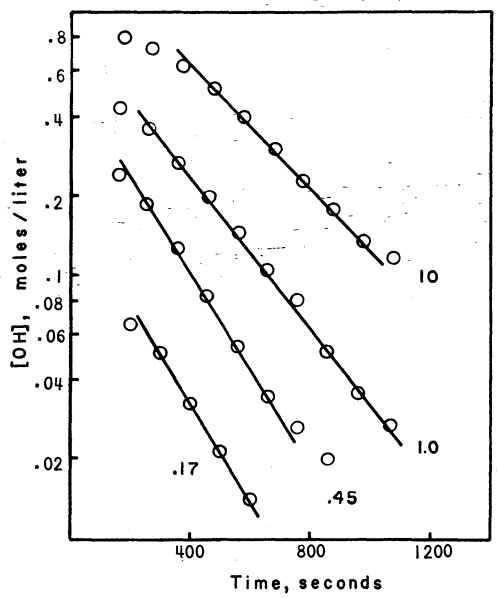

FIG. 5. Disappearance of EtZnOH as measured by infrared at 30° C for different (EtZnOH)/(Et_2Zn) ratios.

comparing the rate constants for runs made with ratios of initial concentrations of ethylzinc hydroxide to diethylzinc of 0.18 and 11.5. The rate constants were 4.2×10^{-3} and 2.8×10^{-3} sec^{-1} respectively.

With these facts in mind more accurate experiments were carried out at the extremes

For personal use only.

of concentrations of these reactants, i.e. at ratios of ethylzinc hydroxide to diethylzinc of 0.05 and 32 as well as at equal concentrations. By means of the rate equation:

$$-\frac{d[\mathrm{OH}]}{dt} = k[\mathrm{C_2H_5ZnOH}]^n[(\mathrm{C_2H_5})_2\mathrm{Zn}]^m, \qquad [5]$$

separation of the possibility of pseudo orders from real reaction orders was made. The overall orders of these reactions were calculated by the fractional life period method (11). These were found to be 0.80, 0.83, and 0.83 for the experiments at ratios of [EtZnOH] to $[(Et)_2Zn]$ of 0.05, 1.0, and 32 respectively. The latter value was for the part of the curve following the initial slow portion. Including this portion would have resulted in a lower value.

Thus, at the low ratio of [EtZnOH] to $[Et_2Zn]$, where $[\mathrm{EtZnOH}] \ll [\mathrm{Et_2Zn}]$

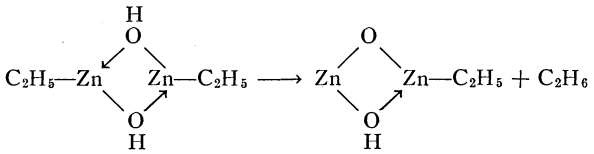
$$-\frac{d[\mathrm{OH}]}{dt} = k'[\mathrm{C_2H_5ZnOH}]^n,$$

where $k' = k'[(\mathrm{C_2H_5})_2\mathrm{Zn}]^m$; therefore $n = 0.80$. At equal concentrations of these species, i.e. where $[\mathrm{EtZnOH}] = [(Et)_2Zn]$,

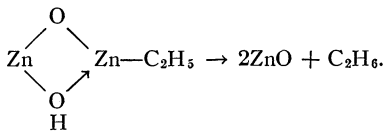
$$-\frac{d[\mathrm{OH}]}{dt} = k[\mathrm{C_2H_5ZnOH}]^{m+n}.$$

Since $m+n = 0.83$, and $n = 0.80$, the value of $m \cong 0$. This result agrees with the prior one that diethylzinc concentration is not a part of the rate expression for this reaction. The low order of reaction in the case of the experiment in which the ratio of [EtZnOH] to $[Et_2Zn]$ was high, i.e. where $[\mathrm{EtZnOH}] \gg [(Et)_2Zn]$, shows that the disappearance of hydroxyl cannot be accounted for by a bimolecular reaction of ethylzinc hydroxide with itself as in equation [4].

The deviations from first-order behavior at the beginning of the reaction suggested that the mechanism might involve a reaction in which the concentration of an intermediate built up until a steady state was reached. One such mechanism involves the assumption that ethylzinc hydroxide exists in this system as a dimer. The known tendency of zinc to coordinate with oxygen atoms suggested this to be a reasonable possibility. Decomposition of this dimer may be considered to take place in the following set of first-order series reactions:



[6]



[7]

The fact that zinc oxide is one of the products could account for the apparent colloidal nature of the system as judged from Tyndall scattering of light. Excess diethylzinc perhaps stabilizes the zinc oxide particles in ether solution.

As will be shown in the following detailed analysis of this pair of first-order series reactions the mechanism accounts very well for the decomposition kinetics at and below a 1.2 ratio of [EtZnOH] to $[Et_2Zn]$. However, it does not account for the initial slow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

phase of the reaction at high ratios of these reactants. In order to account for this it seems necessary to suggest that the reaction is autocatalytic at high ratios of [EtZnOH]. On the other hand excess diethylzinc may act as a catalyst at low ratios of these reactants.

Detailed analyses of first-order series reactions similar to those in [6] and [7] have been made by Esson (13) and French (14). Applying a similar analysis to reactions [6] and [7], we obtained a theoretical rate expression as follows:

$$A \xrightarrow{k_1} B + D$$

$$B \xrightarrow{k_2} C + D$$

where A = $[C_2H_5ZnOH]_2$; B = $[C_2H_5ZnOZnOH]$; C = 2ZnO; D = C_2H_6.
Setting

$$\alpha = \frac{[A]}{[A]_0} \quad \text{and} \quad \beta = \frac{[B]}{[A]_0}$$

and defining

$$\tau = k_1 t \quad \text{and} \quad \kappa = \frac{k_2}{k_1}$$

the following differential equations express the above reactions:

$$\frac{d\alpha}{d\tau} = -\alpha \qquad [8]$$

$$\frac{d\beta}{d\tau} = \alpha - \kappa\beta. \qquad [9]$$

Substituting the solution of equation [8], $\alpha = e^{-\tau}$, into equation [9] gives:

$$\frac{d\beta}{d\tau} + \kappa\beta = e^{-\tau}. \qquad [10]$$

The solution of differential equation [10] is:

$$\beta = \frac{1}{\kappa - 1}[e^{-\tau} - e^{-\kappa\tau}].$$

We know that [OH] = 2[A]+[B]. By letting ϵ = [OH]/$[OH]_0$, where $[OH]_0 = 2[A]_0$, we obtain

$$\epsilon = \frac{[A]}{[A]_0} + \frac{[B]}{2[A]_0}$$

or

$$\epsilon = \alpha + \frac{\beta}{2}$$

or

$$\epsilon = e^{-\tau} + \frac{1}{2(\kappa - 1)}[e^{-\kappa} - e^{-\kappa\tau}].$$

A family of plots of ϵ versus log τ were obtained for different values of κ between 100 and 0.02. The experimental plots of ϵ versus log t were matched to one of the family, thus determining κ, by shifting horizontally along the log t axis. From the amount of shift along log t with respect to log τ, values of k_1 were determined. The data for [EtZnOH] to [Et_2Zn] ratios of 1.2 and below fit quite well for $\kappa = 2$. The fit of the theoretical and experimental data are shown for [EtZnOH]/[Et_2Zn] ratios of 0.05, 1.0 and 32 in Fig. 6.

As noted previously the absolute values of the rate constants are not significant probably because of temperature variation.

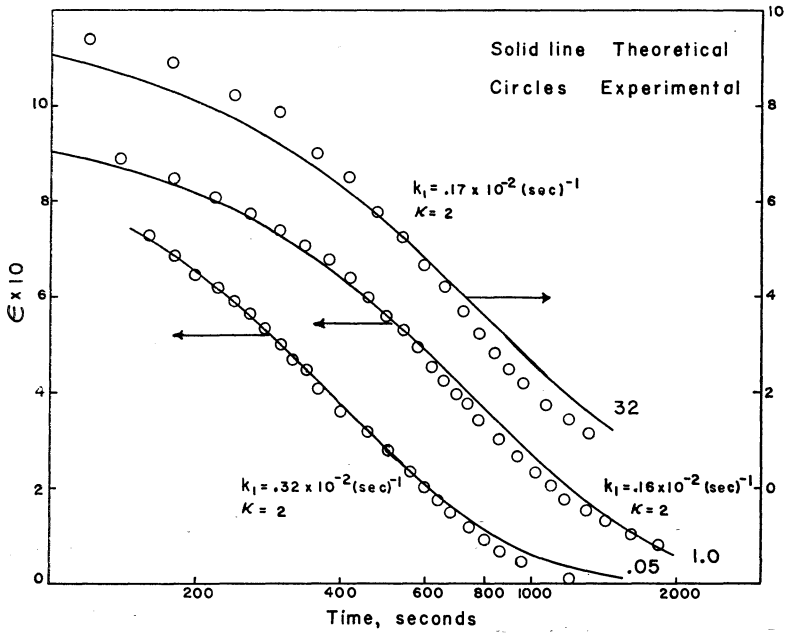

FIG. 6. Fit of experimental data and theoretical expression for various (EtZnOH)/(Et_2Zn) ratios.

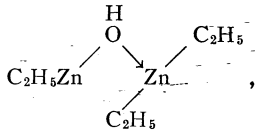
An alternate suggestion is that ethylzinc hydroxide coordinates with diethylzinc as well as with itself. The decomposition of this "mixed dimer", i.e.



would be expected to be first order with respect to ethylzinc hydroxide. At low [EtZnOH] to [Et_2Zn] ratios, where this form would be favored, the initial deviation from first-order behavior could be ascribed to temperature equilibration. On the other hand at high [EtZnOH] to [Et_2Zn] ratios, where the ethylzinc hydroxide dimer would be favored, the very much larger deviation could be considered as characteristic of this chemical species and need not be considered as anomalous behavior. The similarity of the stabilized first-order rates at high and low ratios of [EtZnOH] to [Et_2Zn] would be taken as coincidentally similar behavior of the two dimeric species. The similar kinetic behavior between experiments at [EtZnOH] to [Et_2Zn] ratios of 0.05 and 1.0 suggests that formation of the "mixed dimer" may be favored over the ethylzinc hydroxide dimer. In the ethylzinc hydroxide dimer case the colloid which is believed to be formed during these reactions would be zinc oxide. For the case involving a complex of ethylzinc hydroxide and diethylzinc it would be necessary to suppose a colloid formed of the molecule EtZnOZnEt.

Gas Evolution Studies

Figure 7 shows representative first-order plots of the gas evolution data. These plots also show slight to considerable deviation from first-order behavior at the start, just as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

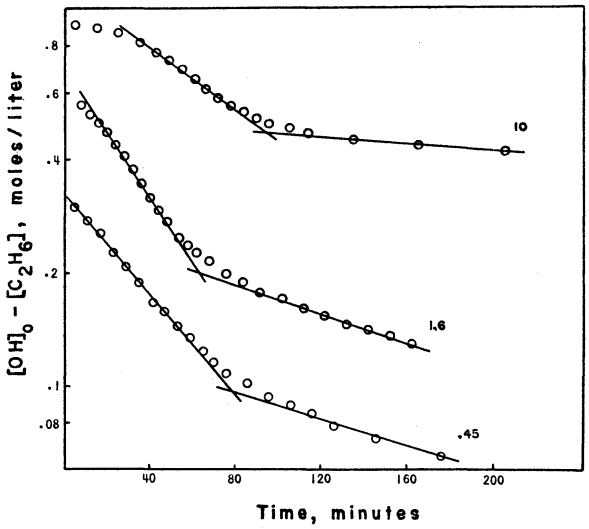


FIG. 7. Apparent disappearance of EtZnOH as measured by ethane evolution at 15° C.

was noted in the plots of data from infrared measurements. However, the plots degenerate from first-order behavior between 40 and 70% reaction (compared to over 90% in most of the experiments measured by infrared). There follow in some cases what appear to be another first-order region.

The discrepancy between the two methods is brought into focus by examination of Figure 8, which shows the results of an experiment in which both the gas evolution and hydroxyl absorption decrease were measured on the same solution at 15° C. It shows that not only does the gas evolution first-order plot deviate at a smaller extent of reaction but that the apparent rate is appreciably slower than that indicated by infrared absorption. In the absence of a clear-cut indication of the reason for this discrepancy the writers

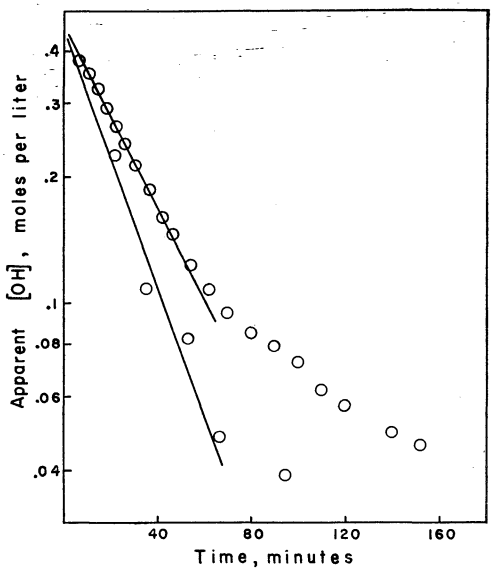

FIG. 8. Decomposition of EtZnOH at 15° C.

have intuitively supposed that the infrared method was less open to systemic error than was the gas evolution method. The volume of ethane equivalent to the maximum discrepancy between the two methods in the above experiment is in the range of one third of its solubility. Such a solubility variation might be expected in a developing colloidal dispersion. That such a colloidal phase was present was suggested (1) by light scattering measurements and (2) by the yellow color of the solutions combined with their lack of distinct ultraviolet absorption bands. The yellow color always developed during the evolution of the second mole of ethane per mole of water originally added. Saegusa and co-workers (12) found that the "soluble" portion of the reaction product of diethylzinc and water prepared in hexane was of colloidal nature in benzene.

Among alternate ideas to explain this discrepancy the following were considered: (1) This discrepancy was caused by the difference in surfaces of the reaction vessels used, i.e. the glass of the beverage bottles and the sodium chloride of the infrared cells. To check this a gas evolution experiment was carried out with dried powdered salt in a beverage bottle. The evolution of gas was somewhat faster in this experiment. However, the apparent hydroxyl decrease slowed down drastically as in the other experiments in the range of 50% disappearance. (2) It was possible that the infrared measured only half of the reaction, i.e. that the absorption occurring at 2.9 μ was specific for ethylzinc hydroxide, and that other products also containing hydroxyl groups, such as EtZnOZnOH, absorbed elsewhere or much less strongly. The weak absorption at 2.8 μ as shown in Fig. 1 is within the hydroxyl range. It decreases with time at a somewhat slower rate than does the strong absorption at 2.9 μ. If this were the correct interpretation an explanation of the large difference in extinction coefficient between these two absorptions would be required. However, the data shown in Fig. 7 do not rule out this alternative.

The following similarities between the infrared absorption decrease and gas evolution data appear to make conclusions on the basis of the latter data reasonable: (1) The first-order rates were affected very little by excess diethylzinc concentration. (2) Experiments at high ratios of [EtZnOH] to [Et_2Zn] showed slow initial rates. Accordingly, the first-order rates from gas evolution measurements were used to estimate the overall activation energy of the process. The rather low order of reliability of the 30° C experiment may be appreciated by examination of its first-order plot (Fig. 9). The initial slow portion was

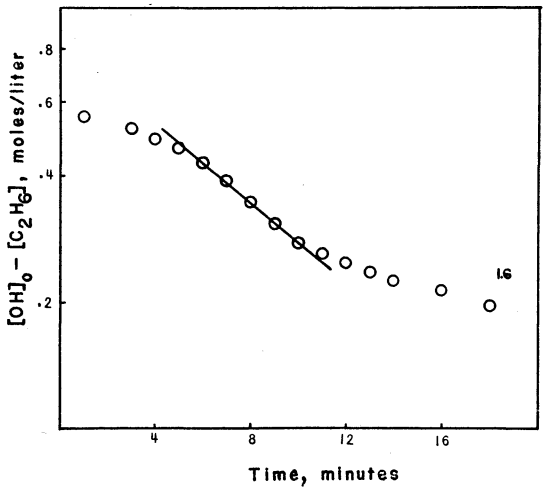

FIG. 9. Apparent disappearance of EtZnOH as measured by ethane evolution at 30° C.

due to temperature equilibration from 0° to 30°, which took up an appreciable part of the reaction time. However, use of this rate along with first-order rates at 15° and 0° gave the Arrhenius plot as shown in Fig. 10. The activation energy on this basis was 19 kcal/mole.

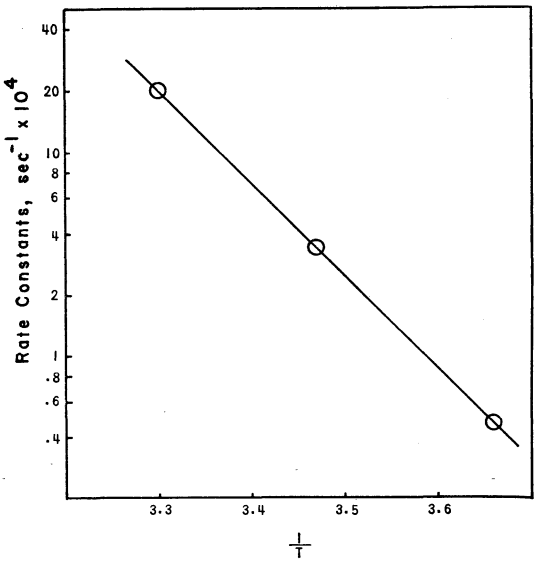

FIG. 10. Temperature dependence of rates of decomposition of EtZnOH.

The overall conclusion from these experiments appears to be that the second ethyl group of diethylzinc is less liable to reaction than the first. This conclusion may be necessarily limited to reactions involving active hydrogens and to cases in which the first carbon zinc bond is transformed into an oxygen–zinc bond.

ACKNOWLEDGMENTS

The writers wish to acknowledge the encouragement and helpful suggestions of Dr. E. E. Gruber, Dr. R. A. Briggs, and Dr. R. Livigni of the General Tire Laboratories, as well as of Dr. J. P. Fugassi of Carngeie Institute of Technology and Dr. C. C. Price of the University of Pennsylvania. Our thanks also to Dr. W. O. Phillips for help in programming the computer, to Mr. P. Suman for the infrared measurements, and to Mr. J. L. Cowell for experimental assistance.

CHARACTERIZATION OF THREE HEMICELLULOSES FROM THE WOOD OF AMABILIS FIR (ABIES AMABILIS)

E. C. A. SCHWARZ[1] AND T. E. TIMELL[2]

Department of Chemistry, McGill University, and the Pulp and Paper Research Institute of Canada, Montreal, Que.

Received January 9, 1963

ABSTRACT

An arabino-4-*O*-methylglucuronoxylan (10:14:76), a water-soluble galactoglucomannan (1:1:3), and an alkali-soluble galactoglucomannan (0.1:1:3) have been isolated in yields of 7, 4, and 8% from the wood of amabilis fir (*Abies amabilis*). The structure of the polysaccharides was established by methylation and periodate oxidation techniques. The xylan ($\bar{P}_n$ 106) contained side chains of (1 → 2)-linked 4-*O*-methyl-α-D-glucuronic acid and (1 → 3)-linked α-L-arabinofuranose residues, both attached directly to a linear framework of (1 → 4)-linked β-D-xylose residues. The galactoglucomannans ($\bar{P}_n$ 76 and 95) contained (1 → 6)-linked α-D-galactopyranosyl residues attached directly to a backbone of (1 → 4)-linked β-D-mannose and β-D-glucose residues. Partial hydrolysis of the two hexosans yielded 10 and 13 oligosaccharides, respectively, containing (1 → 4)-β-D-mannose, (1 → 4)-β-D-glucose, and (1 → 6)-α-D-galactopyranose residues. The molecular rotations of a series of mannooligosaccharides corresponded to a value of −54° for the specific rotation of an infinitely long mannan. It is concluded that the main hemicelluloses in amabilis fir wood are the same as those occurring in the wood of gymnosperms from other genera. The same three hemicelluloses are also present in the bark of this species.

Among the gymnosperms, members of the genera *Ginkgo*, *Larix*, *Picea*, *Pinus*, *Thuja*, and *Tsuga* have been extensively studied with regard to their main hemicellulose constituents (1). No member of the genus *Abies*, however, has so far been similarly investigated although many fir species are both widespread and valuable. The present investigation is concerned with the isolation and constitution of the three principal hemicelluloses in the wood of amabilis fir (*Abies amabilis*) (Douglas) Forbes). The polysaccharides occurring in the bark of this tree have previously been examined in detail (2, 3).

RESULTS AND DISCUSSION

When amabilis fir wood was partially hydrolyzed, the acid portion of the hydrolyzate consisted of galacturonic acid, 4-*O*-methylglucuronic acid, a galacturonosyl rhamnose, probably admixed with a galacturonosyl glucose, and a 4-*O*-methylglucuronosyl xylose. The first aldobiouronic acid has previously been isolated from pine wood (4, 5). The third was fully identified as 2-*O*-(4-*O*-methyl-α-D-glucosyluronic acid)-D-xylopyranose. It probably originated from the xylan portion of the wood.

For isolation of the hemicelluloses, the wood was partially delignified with chlorous acid and the holocellulose was extracted with aqueous potassium hydroxide, giving two polysaccharides, which were separated by repeated treatment with barium hydroxide.

TABLE I

General characteristics of three hemicelluloses

Polysaccharide	Percentage of wood	$[\alpha]_D$, deg	Solvent	$\bar{P}_n$	Constituent sugar residues						Periodate consumed per repeating unit	
					Gal	Glu	Man	Ara	Xyl	Uron. acid	Calc.	Found
Arabino-4-*O*-methyl-glucuronoxylan	7.0	−40	Water	106				10	76	14	86	81
Galactoglucomannan A	4.1	−8	Water	76	1	1	3				6.0	6.0
Galactoglucomannan B	8.1	−38	Alkali	95	0.1	1	3				4.2	4.3

The soluble portion was an arabino-4-*O*-methylglucuronoxylan, while the barium hydroxide complex gave a water-soluble galactoglucomannan. Extraction of the residual holocellulose with aqueous sodium hydroxide – borate yielded an alkali-soluble galactoglucomannan. Yields, sugar composition, and other characteristics of the hemicelluloses are presented in Table I.

The wood contained approximately 25% hemicelluloses. The combined yield of pure polysaccharides was 19.2%, corresponding to a recovery of 77%. The relative sugar compositions and specific rotations were typical of each of the three polysaccharides. Number-average degrees of polymerization ($\bar{P}_n$) were determined by osmometry with organo-soluble derivatives. The value for the xylan was similar to those reported for other softwood xylans (1). The water-soluble galactoglucomannan (A) had a lower molecular weight than the alkali-soluble type. All three hemicelluloses had probably been degraded by the action of the chlorous acid used for delignification.

The xylan was methylated, giving a fully substituted derivative with 95 xylose residues per average molecule. The partly methylated sugars obtained on hydrolysis were separated on columns of exchange resin and charcoal–Celite, resulting in the six compounds in Table II. These results, in conjunction with the nature of the 4-*O*-methylglucuronosyl

TABLE II

Sugars obtained on hydrolysis of the methylated arabino-4-*O*-methylglucuronoxylan

Component	Moles	Component	Moles
2-*O*-Methyl-D-xylose	10	2,3,4-Tri-*O*-methyl-D-xylose	1
3-*O*-Methyl-D-xylose	3	2,3,5-Tri-*O*-methyl-L-arabinose	10
2,3-Di-*O*-methyl-D-xylose	48	2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucuronic acid)-3-*O*-methyl-D-xylopyranose	14

xylose, show that the hemicellulose consisted of at least 100 (1 → 4)-linked β-D-xylopyranose residues, every fifth of which carried a (1 → 2)-linked 4-*O*-methyl-α-D-glucuronic acid residue directly linked to the xylan backbone. The arabinofuranose residues, one per eight xylose, all occurred as non-reducing end groups, linked (probably directly) to position 3 of the xylose residues. In analogy with other softwood xylans (6), the arabinose was probably present in the α-L-configuration. The polysaccharide contained only 1.2 non-reducing xylose end groups per average molecule, virtually equivalent to a linear structure.

The two galactoglucomannans were methylated to completion and hydrolyzed. The mixtures of partly methylated hexoses were resolved on charcoal–Celite, giving the compounds presented in Table III. Polysaccharide A evidently consisted of a backbone

TABLE III

†In water.
‡Octaacetate derivative.

galactose residues were present as non-reducing end groups. Most likely, they occurred as α-D-galactopyranose residues, linked directly to the hexosan framework by (1 → 6)-glycosidic bonds. Although it contained 10 times less galactose residues, the structure of galactoglucomannan B was evidently the same.

Additional structural evidence was obtained by an examination of the 23 oligosaccharides formed on partial hydrolysis of the two hemicelluloses. The results are summarized in Table IV. The two galactose-containing oligosaccharides on partial hydrolysis gave 6-*O*-α-D-galactopyranosyl-D-mannose, thus showing the mode of attachment of the galactose residues. All other oligosaccharides contained only (1 → 4)-β-links. Methyl β-D-mannopyranoside is hydrolyzed by acids 3.0 times faster than the corresponding glucoside (7) while mannobiose is hydrolyzed 2.5 times more rapidly than cellobiose (8). As pointed out by Lindberg (9), a trisaccharide of the type G → G → M would therefore be present in noticeable amounts during the earlier stages of a partial hydrolysis in spite of the 1:3 ratio between the randomly distributed glucose and mannose residues. It is interesting to note that for polysaccharide B approximately equal quantities were found of compounds G → G → M and M → G → M. The amount of the former was in both cases much larger than that of cellobiose, as can be expected from statistical considerations (9). Many of the oligosaccharides obtained here have previously been isolated from similar galactoglucomannans (10, 11). With the exception of the mannotetraose, however, none of the tetra-, penta- or hexa-saccharides have so far been reported.

If molecular rotations and degrees of polymerizations of the five mannooligosaccharides are plotted according to Freudenberg (12), a straight line can be drawn, extrapolation of which gives a specific rotation of −54° for an infinitely long polysaccharide composed exclusively of (1 → 4)-linked β-D-mannose residues. Assuming a degree of polymerization of 15 for mannan A from vegetable ivory (13), its calculated specific rotation in water or aqueous alkali (6) should be −48°. Experimental values reported are −46° and −48° (14, 15), a good agreement in spite of the probable presence of some α-(1 → 4)- and perhaps also (1 → 6)-linkages in ivory nut mannan A.

When the three polysaccharides were oxidized with periodate, the results presented in Table I were obtained. The calculated and found values agreed quite well, thus confirming the other structural evidence.

The combined evidence shows that the three main hemicelluloses in the wood of amabilis fir, and probably in all other species of the genus *Abies*, are a water-soluble arabino-4-*O*-methylglucuronoxylan, a water-soluble galactoglucomannan, and an alkali-soluble galactoglucomannan with only a few galactose residues. One or both of the hexosans might be partly acetylated in the native state (16). The relative amount, molecular weight, and detailed structure of the polysaccharides are the same as has been previously found for corresponding hemicelluloses from the wood of other gymnosperms. The latter thus appear to be very uniform with respect to the nature of their major polysaccharides, the larches forming a notable exception. It is interesting to note that the same also applies to the nature of their lignin, which is of the coniferyl type except in trees from a few genera (17). All three polysaccharides studied here have previously (2, 3) been isolated from the bark of the same tree.

EXPERIMENTAL

Specific rotations were measured at equilibrium at 25° and referred to 589 mμ. Melting points are corrected. Demethylations were carried out with boron trichloride (18). Degrees of polymerization of polysaccharides (19) and oligosaccharides (20, 21) were determined as described elsewhere. Evaporations were carried out *in vacuo* at 50°.

Paper Chromatography

Solvents used for separating the sugars were ethyl acetate – acetic acid – water (A) (9:2:2) and (B) (18:7:8), (C) *n*-butanol–pyridine–water (10:3:3), (D) ethyl acetate – pyridine – water (8:2:1), and (E) butanone–water–ammonia (90:8:2). Whatman No. 1 and 3MM filter papers were used for the first four solvents. For solvent E a 3MM paper provided with a wick of No. 50 paper was used. Paper electrophoresis was carried out with No. 3MM paper and 0.05 *M* borate at 750 v for 5 hours. *o*-Aminodiphenyl was used as spray reagent and for quantitative sugar analysis (22).

Wood

Standard methods of analysis (23) indicated that the wood meal (40–60 mesh, extractive free) contained 44% cellulose, 29.2% lignin, 6.3% pentosans, 2.6% uronic anhydride, 1.4% acetyl, and 0.2% ash.

Partial Hydrolysis of Wood

Wood meal (200 g) was hydrolyzed with sulphuric acid in the usual way. After neutralization (barium hydroxide), filtration through Celite, treatment with Amberlite IR-120 (acid form) exchange resin, filtration, and concentration, acidic sugars were adsorbed on a column of Dowex 1-X4 (acetate form) exchange resin and subsequently removed by elution with aqueous acetic acid. The mixture of sugar acids (5.0 g) was resolved into four fractions on a column of Darco G-60 charcoal–Celite by gradient elution with 2 to 40% aqueous ethanol. The first two acids corresponded in rate of movement on the paper chromatogram (solvent A) to galacturonic acid (0.93 g) and 4-*O*-methylglucuronic acid (0.41 g). The fourth fraction (0.045 g) on hydrolysis gave rise to galacturonic acid, rhamnose, and a trace of glucose.

The third fraction consisted of an aldobiouronic acid which gave xylose and 4-*O*-methylglucuronic acid on hydrolysis and had $[\alpha]_D$ +86° (*c*, 1.0 in water). Anal. Calc. for $C_{12}H_{20}O_{11}$: OCH_3, 9.1%. Found: OCH_3, 9.2%. The derived methyl ester methyl glycoside of the trataacetate derivative (24) had m.p. and mixed m.p. 202° and $[\alpha]_D$ +101° (*c*, 0.5 in chloroform). The infrared spectra of the two compounds were identical with those of authentic samples.

Isolation of Hemicelluloses

Chlorite holocelluloses were prepared in two experiments from wood (2×1200 g) by the method of Wise, Murphy, and D'Addieco (25). Yields: 73.1 and 76.0%. Holocellulose(700 g) was exhaustively extracted with 24% (w/w) aqueous potassium hydroxide to give a mixture of polysaccharides (106 g, 11.1% of wood). Addition of barium hydroxide to an alkaline solution of the mixture gave a precipitate, which was recovered. This process was repeated twice. The final solution yielded an arabino-4-*O*-methylglucuronoxylan (67 g, 7.0%) which contained arabinose, uronic acid, and xylose (solvents A and D) in a ratio of 10:14:76 and had $[\alpha]_D$ −40° (*c*, 1.5 in water). Anal. OCH_3, 3.05%; uronic anhydride, 15.0%. The first two barium hydroxide precipitates were combined, and the polysaccharides were recovered and dissolved in alkali for a second precipitation with barium hydroxide. After a third similar precipitation the product (galactoglucomannan A) contained only traces of arabinose and xylose and had a ratio of galactose:glucose:mannose of 2:120:59. Yield: 39 g, 4.1% of wood, $[\alpha]_D$ −8° (*c*, 3.0 in water).

The residual holocellulose was extracted with 17% aqueous sodium hydroxide containing 4% boric acid to yield a polysaccharide (77 g, 8.1% of wood) which contained galactose, glucose, and mannose residues in a ratio of 0.1:1:3 and had $[\alpha]_D$ −38° (*c*, 2.4 in 10% sodium hydroxide).

Xylan

On oxidation with 0.05 *M* sodium metaperiodate the xylan consumed 81 moles of oxidant per 76 anhydroxylose units. The number-average molecular weight of the fully acetylated xylan (osmometry) was 31,000, corresponding to 106 xylose residues in the backbone of the average macromolecule.

Methylation of the Xylan

Xylan (13.5 g) was methylated four times with dimethyl sulphate and alkali to give a partly methylated product (11.5 g), which was further methylated by the procedure of Kuhn and co-workers (26) .The fully methylated product (8.5 g) showed a negligible band in the hydroxyl region of the infrared spectrum and had $[\alpha]_D$ −42° (*c*, 2.0 in chloroform). Anal. Calc. for a fully methylated and esterified xylan: OCH_3, 39.6%. Found: OCH_3, 39.5%. The molecular weight of the methylated xylan (osmometry) was 21,400, corresponding to 95 xylose residues in the xylan framework.

The methylated xylan (4.1 g) was subjected to methanolysis and acidic and neutral glycosides were separated with anion exchange resin, giving 1.0 and 2.9 g of material, respectively. The acid glycoside was a partly methylated aldobiouronic acid whose methyl ester was reduced with lithium aluminum hydride to give methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucosyl)-3-*O*-methyl-β-D-xylopyranoside, m.p. and mixed m.p. 164–165°, $[\alpha]_D$ +84° (*c*, 1.5 in water). Its infrared spectrum was identical with that of an authentic specimen. Anal. Calc. for $C_{16}H_{30}O_{10}$: OCH_3, 40.6%. Found: OCH_3, 40.4%. The neutral fraction was hydrolyzed and the sugars were separated by gradient elution with aqueous ethanol from charcoal–Celite. The five compounds obtained are given in Table II.

Identification of Methylated Sugars

Preliminary examination of all sugars was carried out by paper chromatography (solvent E) and by paper electrophoresis, using authentic specimens as comparison.

*2-O-Methyl-*D*-xylose.*—The crystalline sugar had m.p. and mixed m.p. 133–134° and $[\alpha]_D$ +35.5° (*c*, 1.5 in water). Anal. Calc. for $C_6H_{12}O_5$: OCH_3, 18.9%. Found: OCH_3, 18.4%.

*3-O-Methyl-*D*-xylose.*—The sirupy compound had $[\alpha]_D$ +17° (*c*, 1.8 in water). The aniline derivative had m.p. and mixed m.p. 136–137°. Anal. Calc. for $C_6H_{12}O_5$: OCH_3, 18.9%. Found: OCH_3, 18.7%.

*2,3-Di-O-methyl-*D*-xylose.*—The sirup, $[\alpha]_D$ +21.5° (*c*, 1.5 in water), was crystallized from ethyl acetate, m.p. 92°. The aniline derivative had m.p. 130° and $[\alpha]_D$ +194° (*c*, 1.3 in ethyl acetate). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3, 34.6%.

*2,3,4-Tri-O-methyl-*D*-xylose.*—This compound, which could not be induced to crystallize, had $[\alpha]_D$ +19.8° (*c*, 2.5 in ethanol). Demethylation gave only xylose. Anal. Calc. for $C_8H_{16}O_5$: OCH_3, 48.4%. Found: OCH_3, 47.6%.

*2,3,5-Tri-O-methyl-*L*-arabinose.*—Demethylation of this sirupy compound gave only arabinose. The 2,3,5-tri-*O*-methyl-L-arabonamide had m.p. 130–132° and $[\alpha]_D$ +17.5° (*c*, 1.0 in water).

Galactoglucomannan A

Periodate oxidation of the polysaccharide gave a consumption of oxidant of 1.20 mole per anhydrohexose residue. The molecular weight of the nitrated polysaccharide (osmometry) was 27,000, corresponding to 76 glucose and mannose residues per average molecule.

Methylation of Galactoglucomannan A

The polysaccharide was methylated successively in the usual way by the Haworth, Kuhn, and Purdie methods to give a product (4.3 g) which exhibited no hydroxyl absorption in the infrared and had $[\alpha]_D$ −7° (*c*, 2.0 in chloroform). Anal. Calc. for a fully methylated hexosan: OCH_3, 45.6%. Found: OCH_3, 45.0%. The molecular weight was 21,400, corresponding to a $\bar{P}_n$ of 84. The product was subjected to methanolysis and hydrolysis and the methylated sugars were separated by gradient elution with aqueous ethanol on charcoal–Celite. Six fractions were obtained, giving the sugars listed in Table III.

Identification of Methylated Sugars

*2,3- and 3,6-Di-O-methyl-*D*-mannose.*—The first fraction was a mixture of these two sugars in an approximate ratio of 10:1, as indicated by paper electrophoresis, using authentic compounds as comparison. Demethylation gave only mannose.

*2,3-Di-O-methyl-*D*-glucose.*—This sugar had $[\alpha]_D$ +45° (*c*, 1.0 in water) and gave only glucose on demethylation. It was chromatographically and electrophoretically identical with an authentic sample.

*2,3,6-Tri-O-methyl-*D*-mannose.*—This sirupy compound had $[\alpha]_D$ −12.2° (*c*, 3.0 in water). The 1,4-di-*p*-nitrobenzoate had m.p. and mixed m.p. 188–189° and $[\alpha]_D$ +33° (*c*, 1.0 in chloroform). The aniline derivative had m.p. and mixed m.p. 125–127° and $[\alpha]_D$ −152° (*c*, 1.0 in methanol).

*2,3,6-Tri-O-methyl-*D*-glucose.*—The crystalline compound had m.p. and mixed m.p. 120–121° and $[\alpha]_D$ +70.5° (*c*, 1.0 in water). The 1,4-di-*p*-nitrobenzoate derivative had m.p. and mixed m.p. 189–190° and $[\alpha]_D$ −33.5° (*c*, 1.0 in chloroform).

*2,3,4,6-Tetra-O-methyl-*D*-galactose.*—The sirupy compound had $[\alpha]_D$ +109° (*c*, 1.0 in water) and gave galactose on demethylation. The aniline derivative had m.p. and mixed m.p. 192–193°.

*2,3,4,6-Tetra-O-methyl-*D*-mannose.*—This fraction on demethylation gave mannose and a trace of glucose and had $[\alpha]_D$ +5.5° (*c*, 4.0 in water).

Partial Hydrolysis of Galactoglucomannan A

The polysaccharide (10 g) was partially hydrolyzed at 98° with 45% aqueous formic acid (200 ml) for 3.5 hours. Chromatographic examination (solvents A, B, and C) indicated the presence of approximately 50% monosaccharides, 30% lower (D.P. 2–6) oligosaccharides and 20% higher oligomers. The mixture (8 g) was resolved on a charcoal–Celite column with 2–35% aqueous ethanol after removal of monosaccharides with water. Many of the oligosaccharides obtained (D.P. 3–6) were further purified by preparative paper chromatography (solvents B and C). The sugars are presented in Table IV in the approximate order in which they were eluted from the column. The 10 oligosaccharides were characterized, whenever possible, through their melting point and specific rotation. Total hydrolysis before and after reduction with sodium borohydride established the component sugars and the nature of the reducing end group. Partial hydrolysis, with or without prior reduction, and characterization by paper chromatography of the oligosaccharides formed yielded information concerning the sequence of the constituent sugar residues. Whenever possible, the degree of polymerization was also determined. The procedures are described in detail only for the two galactose-containing compounds.

*O-α-*D*-Galactopyranosyl-(1 → 6)-O-β-*D*-mannopyranosyl-(1 → 4)-O-β-*D*-mannosyl-(1 → 4)-*D*-mannose.*—This compound had $[\alpha]_D$ −7° (*c*, 3.5 in water) and on complete hydrolysis gave mannose and galactose in a ratio of 3:1. The degree of polymerization was 3.7. Partial hydrolysis yielded 6-*O*-α-D-galactopyranosyl-D-mannose, and (1 → 4)-β-linked mannobiose and mannotriose, all three chromatographically identical with authentic specimens. Complete hydrolysis of the reduced oligosaccharide gave mannose and galactose in a ratio of 2:1.

*O-α-*D*-Galactopyranosyl-(1 → 4)-O-β-*D*-mannopyranosyl-(1 → 4)-O-β-*D*-mannosyl-(1 → 4)-O-β-*D*-mannosyl-(1 → 4)-*D*-mannose.*—This compound had $[\alpha]_D$ −11° (*c*, 2.0 in water) and on total hydrolysis yielded mannose and galactose in a ratio of 4:1. The degree of polymerization was 4.7. Partial hydrolysis gave 6-*O*-α-D-galactopyranosyl-D-mannose, mannobiose, mannotriose, and mannotetraose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

Galactoglucomannan B

This polysaccharide on oxidation with sodium metaperiodate consumed 1.05 mole of oxidant per anhydrohexose unit. The nitrate derivative had a molecular weight of 27,000, corresponding to 95 glucose and mannose residues per average molecule.

Methylation of Galactoglucomannan B

The polysaccharide (18 g) was methylated in succession by the methods of Haworth, Kuhn, and Purdie to give a material (8.5 g) with $[\alpha]_D$ −23° (*c*, 2.0 in chloroform) and a methoxyl content of 45.1%. Its infrared diagram contained no hydroxyl band. After methanolysis and hydrolysis, the mixture of methylated sugars was resolved by charcoal chromatography into six main fractions.

Identification of Methylated Sugars

*2,3-Di-O-methyl-*D*-glucose and -mannose.*—These sugars had rates of movement on the paper chromatogram and electrophoretogram identical with those of authentic compounds. Demethylation gave glucose and mannose, respectively.

*2,3,6-Tri-O-methyl-*D*-mannose.*—This sirup had $[\alpha]_D$ −11.8° (*c*, 3.5 in water). The 1,4-di-*p*-nitrobenzoate had m.p. and mixed m.p. 188–189° and $[\alpha]_D$ +33° (*c*, 0.6 in chloroform). The aniline derivative had m.p. and mixed m.p. 125–126° and $[\alpha]_D$ −149° (*c*, 0.9 in methanol).

*2,3,6-Tri-O-methyl-*D*-glucose.*—This compound had m.p. and mixed m.p. 120–121° and $[\alpha]_D$ +69° (*c*, 3.1 in water).

*2,3,4,6-Tetra-O-methyl-*D*-galactose.*—Demethylation of this fraction, which had $[\alpha]_D$ +101° (*c*, 1.0 in water), gave galactose with traces of glucose and mannose.

*2,3,4,6-Tetra-O-methyl-*D*-mannose.*—This fraction gave mannose on demethylation and had $[\alpha]_D$ +5.3° (*c*, 3.3 in water).

Partial Hydrolysis of Galactoglucomannan B

Partial hydrolysis was carried out as described for galactoglucomannan A. The sugar mixture was resolved by a combination of charcoal and paper chromatography to give 13 oligosaccharides, given in Table IV in the approximate order in which they were eluted from the charcoal column. The oligomers were characterized as described above.

CONSTITUTION OF THREE HEMICELLULOSES FROM THE WOOD OF ENGELMANN SPRUCE (PICEA ENGELMANNI)

A. R. MILLS[1] AND T. E. TIMELL[2]

Department of Chemistry, McGill University, and the Pulp and Paper Research Institute of Canada, Montreal, Que.

Received January 14, 1963

ABSTRACT

An arabino-4-*O*-methylglucuronoxylan (10:70:12), a water-soluble galactoglucomannan (1:1:3), and an alkali-soluble galactoglucomannan (0.2:1:3) have been isolated in yields of 8.0, 1.0, and 8.1% from the wood of Engelmann spruce (*Picea engelmanni*). The xylan consisted of a linear framework of (1 → 4)-linked β-D-xylose residues to which were directly attached single side chains of (1 → 2)-linked 4-*O*-methyl-α-D-glucuronic acid and (1 → 3)-linked α-L-arabinofuranose residues. The galactoglucomannans were both composed of a backbone of (1 → 4)-linked β-D-mannose and β-D-glucose residues, some of which carried directly attached side chains of (1 → 6)-linked α-D-galactopyranose residues. Partial hydrolysis of the water-soluble galactoglucomannan yielded, among other oligosaccharides, a trisaccharide composed of galactose, glucose, and mannose residues. It is concluded that the main polysaccharides in the wood of Engelmann spruce are the same as those in most other gymnosperms. In the bark of this tree, the water-soluble galactoglucomannan is replaced by one or several polysaccharides of an entirely different composition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In connection with a study of the polysaccharides occurring in the bark of Engelmann spruce (*Picea engelmanni* Parry), it became of interest to establish the nature of the hemicelluloses present in the wood of the same species, thus making possible a comparison. The present paper is concerned with the isolation and constitution of the three main hemicelluloses in Engelmann spruce wood.

RESULTS AND DISCUSSION

Partial acid hydrolysis of the wood gave three sugar acids, namely galacturonic acid, 4-*O*-methylglucuronic acid, and 2-*O*-(4-*O*-methyl-α-D-glucosyluronic acid)-D-xylopyranose, the last two probably originating from an acidic xylan.

Extraction of chlorite holocellulose with alkali and application of the barium hydroxide method as described earlier (1) gave an arabino-4-*O*-methylglucuronoxylan and two galactoglucomannans, the properties of which are summarized in Table I. Since the wood contained approximately 24% hemicelluloses, the total recovery was 75%. Losses occurred in the isolation of galactoglucomannan A, but it is nevertheless probable that the present wood contained less of this hemicellulose than did other softwoods (2). The degree of polymerization of the same polysaccharide was higher than that of other galacotglucomannans of this type (2). This might have been the result of a preferential loss of low molecular weight material during the isolation. In other respects, the three hemicelluloses appeared to be typical of those generally occurring in the wood of gymnosperms.

After complete methylation, the xylan contained 88 xylose residues per average molecule and on methanolysis and hydrolysis gave the six compounds given in Table II. The results show that the xylan consisted of at least 90 (1 → 4)-linked β-D-xylose residues, forming a framework to which were directly attached (1 → 3)-linked L-arabinofuranose and (1 → 2)-linked 4-*O*-methyl-α-D-glucuronic acid residues. Evidence presented elsewhere (3) indicates that the former groups were probably present in the α-L-configuration. Partial

TABLE I
General characteristics of hemicelluloses

Polysaccharide	Percentage of wood	$[\alpha]_D$, deg	Solvent	$\bar{P}_n$	Constituent sugar residues						Branch points per average molecule	Periodate consumed per repeating unit	
					Gal	Glu	Man	Ara	Xyl	Uron. acid		Calc.	Found
Arabino-4-*O*-methyl-glucuronoxylan	8.0	−35	Water	92				10	70	12	None	80	80
Galactoglucomannan A	1.8	−7	Water	100	1	1	3				One	6.0	5.9
Galactoglucomannan B	8.1	−40	Alkali	107	0.2	1	3				None	4.4	4.2

TABLE II

Sugars obtained on hydrolysis of original (A) and partially hydrolyzed (B) *O*-methylxylans

Component	Moles A	Moles B	Component	Moles A	Moles B
2-*O*-Methyl-D-xylose	8	2	2,3,4-Tri-*O*-methyl-D-xylose	1	1
3-*O*-Methyl-D-xylose	2	4	2,3,5-Tri-*O*-methyl-L-arabinose	9	0.1
2,3-Di-*O*-methyl-D-xylose	49	55	2-*O*-(2,3,4-Tri-*O*-methyl-α-D-glucuronic acid)-3-*O*-methyl-D-xylopyranose	10	12

hydrolysis of the arabino-4-*O*-methylglucuronoxylan gave a 4-*O*-methylglucuronoxylan almost devoid of arabinose but with nearly the same degree of polymerization (82). The relative amounts and the nature of the sugars obtained on hydrolysis of this polysaccharide (Table II) show that removal of the arabinose groups produced no additional non-reducing xylose end groups in the macromolecule. *All* arabinose residues were accordingly attached directly to the xylan backbone. In addition, it is also clear that the original polysaccharide was linear.

The two galactoglucomannans, after complete methylation, contained 93 and 103 glucose and mannose residues per average molecule. The sugars obtained on hydrolysis are presented in Table III. Both polysaccharides evidently consisted of a backbone of

TABLE III

Sugars obtained on hydrolysis of methylated galactoglucomannans A and B

Component	Moles A	Moles B	Component	Moles A	Moles B
2,3-Di-*O*-methyl-D-mannose	4	1.2	2,3,6-Tri-*O*-methyl-D-glucose	8	18
2,3-Di-*O*-methyl-D-glucose	4	0.7	2,3,4,6-Tetra-*O*-methyl-D-galactose	8	2
2,3,6-Tri-*O*-methyl-D-mannose	25	56	2,3,4,6-Tetra-*O*-methyl-D-mannose	1	1

approximately 100 (1 → 4)-linked β-D-mannose and β-D-glucose residues to which were attached various amounts of (1 → 6)-linked α-D-galactopyranose end groups. Galactoglucomannan A contained on the average 1.2 and compound B 0.3 branch points per molecule.

These conclusions were corroborated by the nature of the oligosaccharides obtained on partial hydrolysis of the two polysaccharides, given in Table IV. The occurrence of a galactopyranosyl-(1 → 6)-mannosyl-(1 → 4)-mannose suggests that the galactose residues were attached directly to the glucomannan framework in galactoglucomannan A. The isolation of a trisaccharide consisting of galactose, glucose, and mannose residues is noteworthy. This compound, albeit not fully characterized, was chromatographically homogeneous in several solvent systems. Its composition offers the first proof of a chemical linkage between galactose, glucose, and mannose residues in this type of wood. It also constitutes strong evidence for the triheteropolymer nature of the water-soluble galactoglucomannans occurring in the wood of all gymnosperms so far investigated (2, 4). That the latter should consist of a mixture of a galactomannan and a glucomannan, as has been suggested (5), now appears highly unlikely.

Results obtained on oxidation of the three polysaccharides with periodate are given in Table I. The data agree well with the other structural evidence.

‡In water.
§Octaacetate derivative.

The principal hemicelluloses in Engelmann spruce wood are the same as those found in the wood of other gymnosperms, such as Norway spruce (6–10), Sitka spruce (11, 12), and white spruce (13, 14). In amabilis fir, the same three hemicelluloses occur both in the wood and the bark of the tree (1). Interestingly enough, this is not the case with Engelmann spruce. The bark of this tree contains an alkali-soluble galactoglucomannan and probably also an acidic arabinoxylan. The water-soluble galactoglucomannan, however, is entirely missing, its place being taken by one or several polysaccharides of an entirely different composition (15). The nature of these hemicelluloses will form the subject of a later communication.

EXPERIMENTAL

General experimental conditions and methods of paper chromatography were the same as those used in an earlier paper (1).

Wood

Standard analytical methods showed that the wood (40–60 mesh, extractive free) contained 43% cellulose, 28.0% lignin, 9.2% pentosans, 3.3% uronic anhydride, 1.3% acetyl, and 0.3% ash.

Acidic Sugars

Wood meal (100 g) was hydrolyzed with sulphuric acid, acidic sugars in the hydrolyzate were separated from neutral sugars, and the mixture of uronic acids was finally resolved by charcoal chromatography as described earlier (1). Three fractions were obtained. The first (0.50 g) consisted of galacturonic acid. The second was an *O*-methylated hexuronic acid (1.20 g) with $[\alpha]_D$ +50° (*c*, 1.7 in water). Anal. Calc. for $C_7H_{12}O_7$: OCH_3, 15.0%; equiv. wt., 208. Found: OCH_3, 15.0%; equiv. wt., 203. Reduction of the methyl ester methyl glycoside with lithium aluminum hydride gave a compound chromatographically identical with 4-*O*-methyl-D-glucose, $[\alpha]_D$ +47° (*c*, 2.0 in water). Anal. Calc. for $C_7H_{14}O_6$: OCH_3, 16.0%. Found: OCH_3, 16.1%. The third fraction (2.5 g) was an aldobiouronic acid with $[\alpha]_D$ +84° (*c*, 1.8 in water), giving 4-*O*-methylglucuronic acid and xylose in hydrolysis. The tetraacetate derivative of its methyl ester methyl glycoside had m.p. and mixed m.p. 201–202° and $[\alpha]_D$ +98° (*c*, 1.0 in chloroform). Anal. Calc. for $C_{22}H_{32}O_{15}$: OCH_3, 17.3%. Found: OCH_3, 17.3%. Its infrared diagram was identical with that of an authentic sample.

Isolation of Hemicelluloses

Chlorite holocellulose (890 g, 72% of wood) was extracted with aqueous potassium hydroxide and the mixture of polysaccharides (180 g, 14.5% of the wood) was resolved by the barium hydroxide method into an arabino-4-*O*-methylglucuronoxylan (98 g, 8.0%) and galactoglucomannan A (22 g, 1.8%) as described previously (1). The residual holocellulose was extracted with aqueous sodium hydroxide – borate to give galactoglucomannan B (100 g, 8.1%).

Xylan

When oxidized with 0.05 *M* sodium metaperiodate, the xylan consumed 80 moles of oxidant per repeating unit. The number-average molecular weight of the acetate derivative, as determined by osmometry, was 26,200, corresponding to a degree of polymerization of 92.

Methylation of the Xylan

The xylan (20 g) was methylated by the procedures of Haworth and Kuhn to give a fully methylated derivative with $[\alpha]_D$ −56° (*c*, 1.0 in chloroform) and no hydroxyl band in its infrared spectrum. Anal. Calc. for the fully methylated and esterified xylan: OCH_3, 39.6%. Found: OCH_3, 39.2%. The molecular weight (osmometry) was 20,600 ($\bar{P}_n$ = 88).

After methanolysis, the acid (1.71 g) and the neutral (5.60 g) glycosides were separated with exchange resin. The methyl ester of the acid fraction was reduced with lithium aluminum hydride, giving methyl 2-*O*-(2,3,4-tri-*O*-methyl-α-D-glucosyl)-3-*O*-methyl-α,β-D-xylopyranoside, m.p. and mixed m.p. 167–168° and $[\alpha]_D$ +84° (*c*, 1.0 in water). Hydrolysis gave 3-*O*-methylxylose and 2,3,4-tri-*O*-methylglucose. Anal. Calc. for $C_{16}H_{30}O_{10}$: OCH_3, 40.6%. Found: OCH_3, 40.7%. The infrared spectrum of the compound was the same as that of an authentic sample.

The mixture of neutral glycosides was hydrolyzed and resolved on charcoal–Celite by gradient elution with aqueous ethanol, giving six partly methylated compounds (Table II).

*2-O-Methyl-*D*-xylose.*—This compound (315 mg) had m.p. and mixed m.p. 134–135° and $[\alpha]_D$ +30° (*c*, 1.2 in methanol). Anal. Calc. for $C_6H_{12}O_5$: OCH_3, 18.9%. Found: OCH_3, 18.5%.

*3-O-Methyl-*D*-xylose.*—This sirup (66 mg) had $[\alpha]_D$ +18° (*c*, 1.2 in water) and gave an aniline derivative with m.p. and mixed m.p. 134–135°. Anal. Found: OCH_3, 18.6%.

*2,3-Di-O-methyl-*D*-xylose.*—This fraction (2.15 g) contained no 3,4-di-*O*-methylxylose as indicated by paper electrophoresis. Crystallization from ethanol gave a product with m.p. 98–100° and $[\alpha]_D$ +24° (*c*, 1.7 in water). Anal. Calc. for $C_7H_{14}O_5$: OCH_3, 34.8%. Found: OCH_3, 34.7%. The aniline derivative, when

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

crystallized from ethyl acetate, had m.p. 140–142° and $[\alpha]_D$ +197° (*c*, 2.3 in ethyl acetate). Anal. Calc. for $C_{13}H_{19}O_4N$: OCH_3, 24.5%. Found: OCH_3, 23.5%.

*2,3,4-Tri-O-methyl-*D*-xylose.*—This compound (47 mg), when crystallized from benzene, had m.p. and mixed m.p. 90–91° and $[\alpha]_D$ +17° (*c*, 0.9 in ethanol). Anal. Calc. for $C_8H_{16}O_5$: OCH_3, 48.4%. Found: OCH_3, 48.2%.

*2,3,5-Tri-O-methyl-*L*-arabinose.*—This sirup had $[\alpha]_D$ −27° (*c*, 0.7 in water) and gave only arabinose on demethylation with boron trichloride. Anal. Found: OCH_3, 48.0%. The 2,3,5-tri-*O*-methyl-L-arabonamide had m.p. 129–130°.

Methylation of the Partially Hydrolyzed Xylan

Arabino-4-*O*-methylglucuronoxylan (20 g) was dissolved in aqueous hydrochloric acid (350 ml) and the pH adjusted to 2.3. After being kept at 90° for 4 hours, the solution was poured into ethanol (4 liters) and the precipitate (14.2 g) was collected. Chromatographic analysis indicated only traces of arabinose residues. The partly hydrolyzed xylan (14 g) was methylated in the usual way to give a product (8 g) which contained no hydroxyl groups and had a methoxyl content of 39.8%. The partially methylated sugars obtained on hydrolysis (3.5 g) were resolved by charcoal chromatography to give four compounds and a trace of tri-*O*-methylarabinose. 2-*O*-Methylxylose (95 mg) and 3-*O*-methylxylose (192 mg) were only characterized chromatographically.

*2,3-Di-O-methyl-*D*-xylose.*—This compound (2.79 g) had m.p. and mixed m.p. 98–100° and $[\alpha]_D$ +25° (*c*, 1.6 in water). Anal. Found: OCH_3, 34.4%. The aniline derivative had m.p. and mixed m.p. 140–142°.

*2,3,4-Tri-O-methyl-*D*-xylose.*—This sugar (55 mg) had m.p. and mixed m.p. 91–92° and $[\alpha]_D$ +17° (*c*, 1.2 in ethanol). Anal. Found: OCH_3, 48.3%.

Galactoglucomannan A

The galactoglucomannan, after three precipitations with barium hydroxide, contained residues of galactose, glucose, and mannose in a ratio of 1:1:3. This ratio remained unchanged after one additional precipitation with Fehling's solution. The polysaccharide consumed 1.18 mole of periodate per anhydrohexose residue. The molecular weight of the nitrate derivative was 35,000 ($\bar{P}_n$ = 100).

Methylation of Galactoglucomannan A

Galactoglucomannan A (15 g) was methylated successively by the procedures of Haworth, Kuhn, and Purdie to give an almost fully substituted product (5 g). Anal. Calc. for a fully methylated hexosan: OCH_3, 45.6%. Found: OCH_3, 45.0%. The molecular weight was 23,800 ($\bar{P}_n$ = 93). Methylated sugars obtained on hydrolysis (0.5 g) were separated by preparative paper chromatography (solvent E) to give six fractions.

*2,3-Di-O-methyl-*D*-mannose.*—This fraction (30 mg) on demethylation gave mannose and a small amount of glucose. Paper electrophoresis indicated the presence of the 2,3-derivative.

*2,3-Di-O-methyl-*D*-glucose.*—Demethylation of this fraction (29 mg) gave only glucose. The sugar was chromatographically and electrophoretically identical with an authentic specimen.

*2,3,6-Tri-O-methyl-*D*-mannose.*—This sirupy sugar (206 mg) had $[\alpha]_D$ −7° (*c*, 1.1 in water). The di-*p*-nitrobenzoate derivative had m.p. and mixed m.p. 187–188°.

*2,3,6-Tri-O-methyl-*D*-glucose.*—The crystalline sugar (64 mg) had m.p. and mixed m.p. 118–119° and $[\alpha]_D$ +72° (*c*, 1.0 in water).

*2,3,4,6-Tetra-O-methyl-*D*-galactose.*—The sirup (67 mg) had $[\alpha]_D$ +109° (*c*, 2.3 in water). The aniline derivative had m.p. and mixed m.p. 190–191° and $[\alpha]_D$ −135° (*c*, 0.3 in pyridine).

*2,3,4,6-Tetra-O-methyl-*D*-mannose.*—This fraction (9 mg) had $[\alpha]_D$ +17° (*c*, 0.9 in chloroform) and on demethylation gave mannose only.

Partial Hydrolysis of Galactoglucomannan A

The hemicellulose (10 g) was treated with 45% aqueous formic acid (400 ml) at 100° for 2 hours. Yield: 9.4 g. Oligosaccharides were separated by gradient elution with aqueous ethanol from a charcoal–Celite column and further purified by preparative paper chromatography. The eight oligosaccharides obtained are given in Table IV.

Galactosyl mannosyl mannose.—This sugar contained galactose and mannose in a ratio of 1:2. Partial hydrolysis gave mannobiose and a compound chromatographically identical with 6-*O*-α-D-galactopyranosyl-D-mannose.

Glucosyl mannosyl mannose.—This trisaccharide gave glucose and mannose in a ratio of 1:2 on complete hydrolysis while partial hydrolysis gave glucosyl mannose and mannobiose.

A triose (galactosyl glucosyl mannose).—This trisaccharide was chromatographically homogeneous in several solvent systems. Complete hydrolysis gave galactose, glucose, and mannose in equimolar portions while partial hydrolysis gave glucosyl mannose. After reduction with sodium borohydride, only galactose and glucose were observed.

Galactoglucomannan B

After two precipitations with barium hydroxide, galactoglucomannan B contained residues of galactose, glucose, and mannose in a ratio of 0.2:1:3. Fehling's solution was less suited for removal of residual xylan. The hemicellulose consumed 1.02 mole of periodate per anhydrohexose unit. The nitrate derivative had a molecular weight of 37,500 ($\bar{P}_n$ = 107).

For personal use only.

Methylation of Galactoglucomannan B

The polysaccharide (15 g) was methylated successively by the methods of Haworth, Kuhn, and Purdie to give a product (7 g) with a methoxyl content of 44.8% and a molecular weight of 22,700 ($\bar{P}_n$ = 103). The mixture of partly methylated sugars obtained on hydrolysis (1.5 g) was resolved by preparative paper chromatography (solvent E) to give six fractions.

*2,3-Di-O-methyl-*D*-mannose and -glucose.*—These two compounds (18 and 11 mg) on demethylation gave mannose and glucose, respectively. They were tentatively characterized from their behavior on paper chromatography and electrophoresis.

*2,3,6-Tri-O-methyl-*D*-mannose.*—This sirupy compound (859 mg), $[\alpha]_D$ −10° (*c*, 2.3 in water), gave a di-*p*-nitrobenzoate derivative with m.p. and mixed m.p. 188–189° and $[\alpha]_D$ +33° (*c*, 1.0 in chloroform).

*2,3,6-Tri-O-methyl-*D*-glucose.*—This sugar (282 mg) had m.p. and mixed m.p. 117–118° and $[\alpha]_D$ +70° (*c*, 1.7 in water).

*2,3,4,6-Tetra-O-methyl-*D*-galactose.*—The sirup (30 mg), $[\alpha]_D$ +95° (*c*, 0.7 in water), gave only galactose on demethylation. The aniline derivative had m.p. and mixed m.p. 192–193° and $[\alpha]_D$ −135° (*c*, 0.7 in pyridine).

*2,3,4,6-Tetra-O-methyl-*D*-mannose.*—This fraction had $[\alpha]_D$ +25° (*c*, 0.5 in chloroform) and gave mannose on demethylation.

Partial Hydrolysis of Galactoglucomannan B

Galactoglucomannan B (20 g) was treated with 45% aqueous formic acid (400 ml) at 100° for 3 hours to give a mixture of glycoses (14 g). The oligosaccharides were separated in the usual way to give the compounds presented in Table IV.

Mannosyl glucosyl mannose.—Complete hydrolysis of this compound gave mannose and glucose in a ratio of 2:1. Partial hydrolysis yielded mannosyl glucose and glucosyl mannose.

REACTIONS OF IODINE ATOMS WITH *n*-BUTENES

I. CIS–TRANS ISOMERIZATION OF BUTENE-2[1]

MARGARET H. BACK[2] AND R. J. CVETANOVIĆ
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received January 28, 1963

ABSTRACT

In the interaction of iodine atoms with butene-2 at 65° C no addition products are observed although cis–trans isomerization of the butene occurs readily. Iodine atoms have been generated by photolyzing iodine in three spectral regions. The limiting quantum yield of the isomerization reaction is about 0.1 at 4358 Å. The low quantum yield shows that chain reactions, similar to those observed in olefin photochlorinations and photobrominations, do not take place. A mechanism involving initial formation of π-complexes between iodine atoms and butene-2 is tentatively considered.

INTRODUCTION

A study of the relative rates of addition of various reagents to olefins in the gas phase has been in progress for the past several years (1). Such studies provide information on the nature of the process of addition to double bonds and whether in this process the attacking species behaves as an electrophilic, nucleophilic, or radical reagent. The variation of the rate constants for addition with structure of the olefins has shown that in their reactions with olefins, oxygen atoms (2) and ozone (3) behave as electrophilic reagents, while hydrogen atoms (4) have the character of radical (electroneutral) reagents. As an extension of this series a study of the addition of iodine atoms to olefins was begun and this paper reports the first results.

The photoiodination of the butenes, propylene, and ethylene in chloroform solution was studied by Forbes and Nelson (5) and quantum yields for disappearance of iodine were found to be of the order of 1. The addition product of iodine atoms with the butenes, diiodobutane, was found to be unstable at room temperature and the reaction was done at −70° C. Since the diiodobutane was not stable at temperatures required for the gas phase study (6), butene-2 was chosen for the reference olefin in the present work in the hope that the cis–trans isomerization would provide a measure of the rate of reaction of iodine atoms with the double bond.

EXPERIMENTAL

Materials

Reagent grade iodine was sublimed once and sealed off in a reservoir. Phillips Research Grade butene was used after two bulb-to-bulb distillations. *cis*-Butene was found to contain less than 0.1% *trans*-butene. Oxygen was prepared by heating potassium permanganate, and Red-band grade of nitrogen was obtained from Linde Air Company.

Apparatus

The experiments were done in a cylindrical Pyrex cell 10 cm long and 5 cm in diameter. A high-pressure mercury arc lamp, Mazda type ME/D, was used and a roughly parallel beam was obtained using a 250-cc flask as a spherical lens. A 935 phototube and microammeter, placed beyond the reaction vessel, were used to measure relative light intensities. The lamp, flask, reaction cell, and phototube were mounted on an optical bench and the reaction cell was enclosed in a thermostatted oven.

For experiments with light of wavelength greater than 5000 Å, Corning filter 3-69 was used and the

[1]*Issued as N.R.C. No. 7294.*

[2]*National Research Council Postdoctoral Fellow 1959–1961. Present address: Chemistry Department, University of Ottawa, Ottawa, Canada.*

flask was filled with a dilute solution of copper sulphate. For some experiments a solution of $NdCl_3$ (7) was used to isolate the mercury line 5461 Å. For light of wavelength less than 5000 Å, a filter solution was made of 6.2 g of copper sulphate and 75 cc of concentrated ammonium hydroxide diluted to 1 liter (8). The flask provided a path length of about 8 cm for absorption. To isolate the mercury line 4358 Å, Corning filter 3-74 was used with this solution.

A few experiments were done using a low-pressure mercury resonance lamp and Corning filter 7-54. In this case a quartz reaction vessel of similar dimensions replaced the Pyrex cell and the flask was not used.

Iodine was admitted to the reaction vessel at its equilibrium vapor pressure from a constant-temperature reservoir through a heated stopcock. The pressure was calculated from the expression (9)

$$\log_{10} p_{\text{atm}} = -\frac{3512.8}{T} - 2.013 \log_{10} T + 13.3740.$$

The reaction vessel and iodine reservoir were separated from the main manifold by a large trap filled with glass beads and maintained at −78° C. This provided an effective means of keeping iodine from the main manifold and mercury from the reaction vessel.

Procedure

It was found necessary, in order to eliminate heterogeneous reaction, to avoid condensation of butene and iodine together. After allowing the iodine pressure to equilibrate for 10 minutes the reservoir was closed and butene admitted by momentarily connecting the reaction vessel to a bulb containing the appropriate quantity of gaseous butene. The pressure of butene always exceeded that of iodine so that no iodine escaped the cell. Nitrogen and oxygen were admitted in a similar manner from a much larger reservoir and in this case the pressure of nitrogen or oxygen was much greater than the combined pressures of iodine and butene.

Pressures of iodine ranged from 0.5 mm to 5 mm and of butene from 1 to 25 cm. Highest pressure of nitrogen used was 46 cm and of oxygen 20 cm. Most of the experiments were done at 65° C and at conversions of about 2%, where a back reaction could be neglected. Fine copper or nickel screens were used to reduce the incident light intensity.

Analysis

The hydrocarbon products were analyzed on a 50-ft gas chromatographic column of dimethylsulpholane on firebrick at 25° C.

Measurement of Light Intensity

Potassium ferrioxalate was used as an external actinometer (10) with light of wavelengths 4358 Å and 2537 Å. A cylindrical cell about 1 cm thick and of the same diameter as the reaction cell was placed first in front of and then behind the reaction vessel, and measurements were taken with and without iodine in the vessel.

RESULTS

The reaction of iodine atoms with *cis*-butene-2 caused isomerization to *trans*-butene-2 and at conversions of less than 3% no other products were observed. Experiments with long times of irradiation showed that the final ratio of *trans*-butene/*cis*-butene approached the equilibrium value at 65° C, 0.726 (11). Even at these high conversions there was no evidence for the formation of heavier products and it may be assumed that the diiodobutane was not an important product.

Several series of experiments were done with constant iodine pressure and variable butene pressure, utilizing light from three spectral regions for production of iodine atoms: region (*a*) $\lambda > 5000$ Å; region (*b*) $\lambda < 5000$ Å; region (*c*) $\lambda = 2537$ Å. Only wavelengths transmitted by Pyrex were included in region (*b*). The two regions (*a*) and (*b*) correspond to the banded region and the continuum, respectively, of the iodine spectrum. In the banded region predissociation occurs, yielding two ground state atoms (12), while in the continuum direct dissociation gives one ground state, $^2P_{3/2}$, and one excited state, $^2P_{1/2}$, atom (13).

In regions (*a*) and (*b*) the initial rapid increase in the rate as the butene pressure was increased was followed by a much slower increase at higher butene pressures. Typical series of results are shown in Fig. 1(*a*, *b*, and *c*). A few series of experiments were done with constant butene pressure and variable iodine pressure, with incident light of wave-

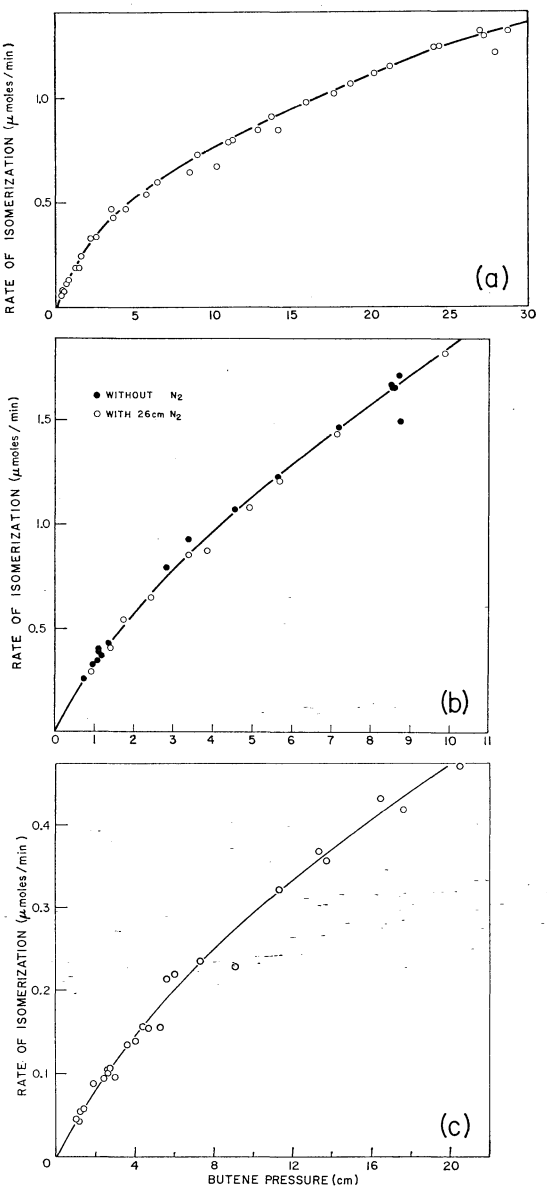

FIG. 1(*a*). Dependence of rate of isomerization on butene pressure at wavelengths > 5000 Å (temp. 54° C, iodine pressure 2 mm).

(*b*). Effect of nitrogen additions on the rate of isomerization at wavelengths > 5000 Å (temp. 65° C, iodine pressure 4 mm).

(*c*). Dependence of rate of isomerization on butene pressure at 4358 Å (temp. 65° C, iodine pressure 4 mm).

length greater than 5000 Å, one of which is shown in Fig. 2. In this case a limiting rate was reached at about 4 mm of iodine.

The dependence of the rate on the absorbed light intensity at various pressures of iodine and of butene is shown in Fig. 3(*a–f*). At high light intensities the rate was a linear function of the intensity, but in each case extrapolated to a small positive intercept.

In the banded region, using the mercury green line, 5461 Å, addition of butene or nitrogen to iodine caused an increase in the light absorbed by the iodine, as measured by the phototube. A maximum increase of about 28% was observed. The ratio of the absorption with added gas to the absorption with iodine alone as a function of added gas is shown in Fig. 4. This increased absorption is most probably the effect of pressure on

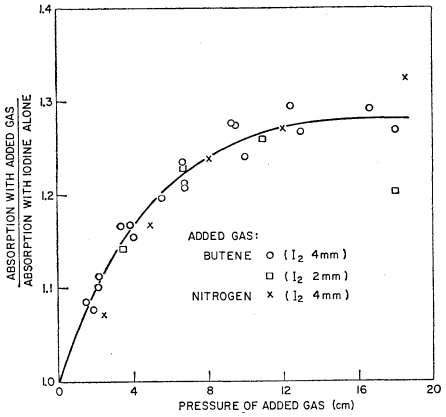

FIG. 4. Effect of additions of butene and nitrogen on light absorption by iodine in the banded region.

the width of the absorption band of the iodine molecule. Obviously such an effect would not occur in a region of continuous absorption and indeed was not observed with light of wavelength less than 5000 Å.

Addition of nitrogen, on the other hand, did not appear to increase the concentration of iodine atoms in the banded region by increased predissociation of the iodine molecule (Fig. 1(*b*)). Pressures of up to 45 cm of nitrogen were added to 4 cm of butene and 2 mm of iodine, under which conditions the indirect effect of the nitrogen on the rate as a result of the increased light absorption by the iodine was almost within the experimental error in rate measurements. The rate of isomerization itself was not increased and in fact gradually decreased slightly, probably due to the effect of nitrogen as a third body in removing iodine atoms.

Oxygen caused a more pronounced drop in the rate of isomerization, but still a large excess (about 10 times that of butene) was required to decrease the rate by 25%. It seems likely that this decrease was again the result of removal of iodine atoms by recombination on oxygen, which might be much more efficient than recombination on nitrogen. With still greater pressures of oxygen, reactions with butene took place, but this aspect was not pursued further.

A series of experiments was done at a temperature of 98° C with 4 mm of iodine using light in the banded region. The rate of isomerization was increased by about a factor of three and approached a limiting rate higher than that at 65° C.

The Quantum Yield

Region (b)

The quantum yield measurements were made with light of wavelength 4358 Å since the potassium ferrioxalate solution absorbs too weakly at wavelengths greater than 5000 Å to permit a reliable measurement of the light intensity in that region. The average incident intensity at 4358 Å was 4×10^{19} quanta/min. Absorption by iodine at 4 mm was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

16% or 6.6×10^{18} quanta/min. Using the values for the rate of isomerization shown in Fig. 1(*c*) a plot of $1/\phi$ against $1/p$ is shown in Fig. 5. From the intercept the upper limit

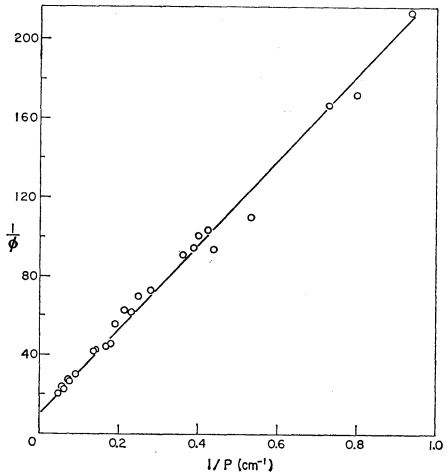

FIG. 5. Plot of the reciprocal quantum yield against reciprocal pressure at 4358 Å. (The data are from Fig. 1(*c*).)

of ϕ is seen to be approximately 0.1. The assumption is made, of course, that the primary quantum yield for production of iodine atoms is 2, but there seems little doubt of this for wavelengths less than 5000 Å. This very low value makes it at once apparent that the reaction is not a chain process with iodine atoms as the chain carriers, such as is observed in the similar reactions of bromine and chlorine atoms.

Region (c)

The few experiments done with the low-pressure mercury resonance lamp, region (*c*), are shown in Fig. 6. At 2537 Å the average total incident intensity was 3×10^{17} quanta/

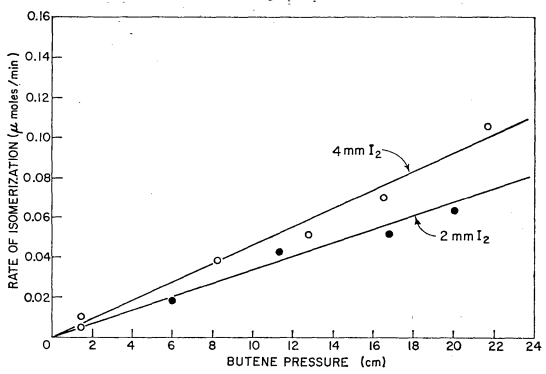

FIG. 6. Dependence of rate of isomerization on butene pressure at 2537 Å (temp. 65° C).

min, with about 2×10^{16} quanta/min absorbed by 4 mm of iodine. Under these conditions of low light intensity absorbed the rate was a linear function of the butene pressure over the range of pressures studied.

DISCUSSION

Of the two possible species which may cause isomerization, an iodine atom or an excited iodine molecule, the former appears the more probable in the present system. Only light of wavelength greater than 5000 Å would form an excited iodine molecule with sufficient lifetime to undergo energy transfer. However, the similarity of the kinetics of isomerization with incident light of wavelength both above and below 5000 Å suggests that the same species is operative in both cases. Furthermore, addition of nitrogen, and oxygen, especially, would be expected to quench excited molecules more efficiently than is indicated by the results.

Mechanism of Isomerization

Regions (a) and (b)

In discussing the mechanism of isomerization of *cis*-butene by iodine atoms the following observations must be considered:

(*a*) The rate of isomerization was not first order with respect to butene.

(*b*) The rate was linearly dependent on the light intensity for high light intensities, extrapolating to a small positive intercept.

(*c*) The limiting quantum yield for isomerization was about 0.1.

The first result indicates that isomerization does not occur entirely by the simple addition of an iodine atom to *cis*-butene followed by dissociation of the radicals so formed to give a certain fraction, α, of *trans*-butene:

$$C + I \rightarrow R \qquad [1]$$

$$R \rightarrow \alpha T + (1-\alpha)C + I, \qquad [2]$$

where C and T refer to *cis*- and *trans*-butene respectively. In this case the rate of isomerization would be a linear function of the butene pressure. However, if butene is also an efficient third body for recombination of iodine atoms, then an increase in butene pressure would have the effect of reducing the iodine atom concentration. If the rate of recombination is appreciable compared to the rate of isomerization, then the rate of isomerization will not increase linearly with butene pressure but will approach a limiting value.

$$R + I \rightarrow \alpha T + (1-\alpha)C + I_2 \qquad [2a]$$

The fact that the quantum yield approached a limiting value much less than 1 may be interpreted to mean that butene acts as a third body for the recombination of iodine atoms without necessarily undergoing isomerization. In other words the reaction of an iodine atom with butene does not always form a radical in which rotation about the C—C bond may occur. The interaction complex then must preserve the rigidity of the double bond and be sufficiently stable to allow recombination of iodine atoms by further reaction of the complex with another iodine atom. Such a structure may be a π-complex of an iodine atom with the double bond. These have been postulated (14) to occur in the recombination of iodine atoms with various third bodies and in the reaction of oxygen atoms and ozone with olefins (13).

$$C + I \rightarrow C{:}I \qquad [3]$$

$$C{:}I \rightarrow C + I \qquad [4]$$

$$C{:}I + I \rightarrow C + I_2 \qquad [5]$$

The linear dependence of the rate of isomerization on the absorbed light intensity raises the problem of the order of the recombination reaction of iodine atoms in the present

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

system. In the flash photolysis experiments (14, 15) the rate of recombination of iodine atoms is second order in iodine atoms. In the present system the concentration of iodine atoms is less than that under the conditions of flash photolysis. Hence in this case, also, recombination will be second order in iodine atoms and the concentration of iodine atoms will depend on the square root of the absorbed light intensity. In order for the rate to appear linear with respect to light intensity under these conditions the rate of isomerization must also be second order in iodine atom concentration. Reactions [2] and [2*a*] will not give this dependence.

This situation will occur if isomerization proceeds not only by reactions [1] and [2] but by a certain fraction of the encounters represented by reaction [5]. If this reaction takes place by the simple abstraction of the iodine atom from the π-complex formed in [3] then isomerization would not be expected to occur. However, if 2,3-diiodobutane is formed as an intermediate, rotation about the C—C bond becomes possible and in the subsequent decomposition to butene and iodine isomerization may occur.

$$\mathrm{C{:}I} + \mathrm{I} \rightarrow \mathrm{CI_2} \qquad [6]$$

$$\mathrm{CI_2} \rightarrow \alpha\mathrm{T} + (1-\alpha)\mathrm{C} + \mathrm{I_2} \qquad [7]$$

The linear dependence of the rate on the absorbed light intensity rules out the occurrence of isomerization by reaction [2*a*], which would lead to a dependence on the square root of intensity. Thus recombination of iodine atoms on butene appears to occur entirely by reactions [3], [4], [5], and [6]. This would suggest that the complex formed in [3] has a longer life than the radical formed in [1]. The heat of formation of the C_4H_8I radical may be very roughly estimated to be 25 kcal/mole.* With this value the radical is unstable toward the formation of butene-1 by 7 kcal/mole and slightly more for butene-2. On the other hand Christie *et al.* (15) have found values of a few kcal/mole for the heats of formation of several complexes formed by interaction of an iodine atom and a hydrocarbon molecule. Rand and Strong (16) also found a complex formation between iodine atoms and benzene when iodine was flash photolyzed in benzene solution. They found that the complex disappeared by a second-order mechanism and might be more stable than the complex formed between iodine molecules and benzene. By analogy, the complex formed in [3] might well be more stable than the radical and have a lower energy barrier for formation.

If the mechanism of isomerization may be described by the following reactions,

$$h\nu + \mathrm{I_2} \rightarrow 2\mathrm{I} \qquad [1a]$$

$$\mathrm{I} + \mathrm{C} \rightarrow \mathrm{R} \qquad [1]$$

$$\mathrm{R} \rightarrow \alpha\mathrm{T} + (1-\alpha)\mathrm{C} + \mathrm{I} \qquad [2]$$

$$\mathrm{I} + \mathrm{C} \rightarrow \mathrm{C{:}I} \qquad [3]$$

$$\mathrm{C{:}I} \rightarrow \mathrm{C} + \mathrm{I} \qquad [4]$$

$$\mathrm{C{:}I} \rightarrow \mathrm{R} \qquad [1a]$$

$$\mathrm{C{:}I} + \mathrm{I} \rightarrow \mathrm{C} + \mathrm{I_2} \qquad [5]$$

$$\mathrm{C{:}I} + \mathrm{I} \rightarrow \mathrm{CI_2} \qquad [6]$$

$$\mathrm{CI_2} \rightarrow \alpha\mathrm{T} + (1-\alpha)\mathrm{C} + \mathrm{I_2} \qquad [7]$$

$$\mathrm{I} + \mathrm{I_2} \rightarrow \mathrm{I_3} \qquad [8]$$

$$\mathrm{I_3} \rightarrow \mathrm{I} + \mathrm{I_2} \qquad [9]$$

$$\mathrm{I_3} + \mathrm{I} \rightarrow 2\mathrm{I_2}, \qquad [10]$$

**Values used in this estimation (17): $H_{f25}(C_4H_{10}) = -29.8$; $D(sec\text{-}C_4H_9\text{—}H) = D(sec\text{-}C_3H_7\text{—}H) = 94$; $D(H_2) = 103.2$; $D(I_2) = 35.35$; $D(sec\text{-}C_4H_9\text{—}I) = 48$; $D(sec\text{-}C_4H_8I\text{—}H) = D(sec\text{-}C_4H_9\text{—}H)$.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

the rate of isomerization (r_i) equals $\alpha[k_2(R)+k_7(CI_2)]$. Therefore, for second-order atomic recombination (i.e. $k_9 \gg k_{10}(I)$ and $k_4 \gg (k_5+k_6)(I)$),

$$r_i = \frac{\alpha\left(k_1+k_{1a}\frac{k_3}{k_4}\right)(C)\sqrt{I_a}}{\sqrt{\left(k_6\frac{k_3}{k_4}(C)\right)}\sqrt{\left(\frac{k_5+k_6}{k_6}+\frac{k_{10}k_8k_4(I_2)}{k_6k_9k_3(C)}\right)}} + \frac{\alpha I_a}{\frac{k_5+k_6}{k_6}+\frac{k_{10}k_8k_4(I_2)}{k_6k_9k_3(C)}}$$

and

$$r_i\,(\%) = \frac{100\alpha\left(k_1+k_{1a}\frac{k_3}{k_4}\right)\sqrt{I_a}}{\sqrt{\left(k_6\frac{k_3}{k_4}(C)\right)}\sqrt{\left(\frac{k_5+k_6}{k_6}+\frac{k_{10}k_8k_4(I_2)}{k_6k_9k_3(C)}\right)}} + \frac{100\alpha}{(C)}\times\frac{I_a}{\frac{k_5+k_6}{k_6}+\frac{k_{10}k_8k_4(I_2)}{k_6k_9k_3(C)}}.$$

At constant pressures of C and I_2

$$r_i = K_1\sqrt{I_a} + K_2I_a.$$

The intensity dependence plots (Fig. 3(*a–f*)) extrapolated to a small intercept and it may be seen that such behavior is consistent with this mechanism. Plots of $r_i/I_a^{\frac{1}{2}}$ against $I_a^{\frac{1}{2}}$ for each series of intensity dependence curves gave straight lines from which values for K_1 and K_2 were obtained. The ratio $(k_1k_4+k_{1a}k_3)^2/k_3k_4k_6$ was equal to the (intercept)^2/slope. Table I shows this ratio as well as values for K_1, K_2, $K_1I_a^{\frac{1}{2}}$, and K_2I_a for each series

*r_1, r_{1a}, r_6, and r are, respectively, rates of reactions [1], [1*a*], [6], and the total isomerization.

of experiments covering a wide range of iodine and butene concentrations. The proportion of the isomerization which occurs by reactions [6] and [7] is greatest when the I_2/butene ratio is largest. Absolute values for the ratio $k_{10}k_8k_4/k_6k_9k_3$ may not be obtained from these plots since only relative values for I_a were measured.

The observed dependence of the isomerization rate on the concentration of the reactants is qualitatively in agreement with the considered mechanism. A detailed quantitative treatment is precluded by the appreciable experimental scatter and by the complexity of the rate expressions. The proposed reaction mechanism is therefore of a tentative character. Both reactions [1] and [1*a*] have been included into the mechanism to show that the kinetic expressions are independent of whether the iodobutyl radicals (R) are assumed to be formed by direct addition of iodine atoms or by rearrangement of π-complexes (C:I).

Region (c)

Reactions [5] and [6] would be expected to be less efficient at low light intensities and

this is shown by the experiments using the mercury resonance line 2537 Å (Fig. 6). The light absorbed in this region was about 300 times less than that at 4358 Å. Although the points are scattered there appeared to be no curvature in the plot of rate against butene pressure. The quantum yield divided by the equilibrium trans/cis value reached unity at about 7 cm of butene and continued to increase as the butene pressure was increased. The rate of reaction [6] thus appears to be considerably reduced at these light intensities. At the same time, the more highly energetic iodine atom formed in this region may make reaction [1] much faster relative to [3].

REACTIONS OF IODINE ATOMS WITH *n*-BUTENES

II. INTERCONVERSION OF BUTENE-1 AND BUTENE-2[1]

MARGARET H. BACK[2] AND R. J. CVETANOVIĆ
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received January 28, 1963

ABSTRACT

In the vapor phase reaction of iodine atoms with *n*-butenes at 65° C appreciable double-bond migration takes place in addition to the readily occurring geometrical isomerization. No detectable quantities of iodine-containing hydrocarbons are observed. In contrast to this, appreciable amounts of 1,3-butadiene and the corresponding amounts of hydrogen iodide are formed although direct abstraction of a hydrogen atom from butene by an iodine atom is unlikely in view of the endothermicity of this reaction. Formation of 1,3-butadiene is counterbalanced by its hydrogenation back to the original butene and its isomers and a steady state concentration is reached in the course of the reaction. As a consequence of this balancing of dehydrogenation and hydrogenation steps there is an induction period in the formation of butene-2 in the reaction of iodine atoms with butene-1 and a large part of butene-2 is found to be derived from the butadiene initially produced. To explain the occurrence of the endothermic steps, it is assumed that the initial iodine atom – butene adduct (iodobutyl radical or π-complex) interacts with a second iodine atom. Reaction mechanism is tentatively discussed.

INTRODUCTION

In the study of the interaction of iodine atoms with *cis*-butene-2 (1) (Part I) it was found at large conversions, used in order to determine the final equilibrium ratio of *trans*-butene/*cis*-butene, that small amounts of butene-1 and butadiene were formed as well. The following results report the investigation of this additional reaction of iodine atoms with *n*-butenes.

EXPERIMENTAL

The apparatus and methods were the same as those used in Part I. Butadiene was Phillips Research Grade and was analyzed by gas chromatography with the column described in Part I. Fully deuterated butadiene was obtained from Merck, Sharpe and Dohme, Montreal, and was shown by mass spectrometric analysis to consist of 66.7% C_4D_6 and 33.3% C_4D_5H. Hydrogen iodide was analyzed by titration with silver nitrate using eosin as indicator and also with sodium hydroxide using phenolphthalein as indicator. Small amounts of oxygen were added by first mixing with a large amount of nitrogen.

RESULTS

The reaction of iodine atoms with butene-1 produced butadiene and *cis*- and *trans*-butene-2 and the reaction with *cis*-butene-2 produced *trans*-butene-2, butadiene, and butene-1. Hydrogen iodide was analyzed from 11 experiments and found to be approximately twice the molar quantity of butadiene formed. The results are given in Table I. The variation in the yield of products with time of reaction is shown in Figs. 1 and 2. The formation of butadiene from *cis*-butene was about 15 times slower than the rate of cis–trans isomerization. The rate of production of butadiene was roughly about one and a half times as fast from butene-1 as from butene-2 (Fig. 3), while the overall conversion of butene-1 to butene-2 was about seven to eight times faster than the reverse reaction (Fig. 4).

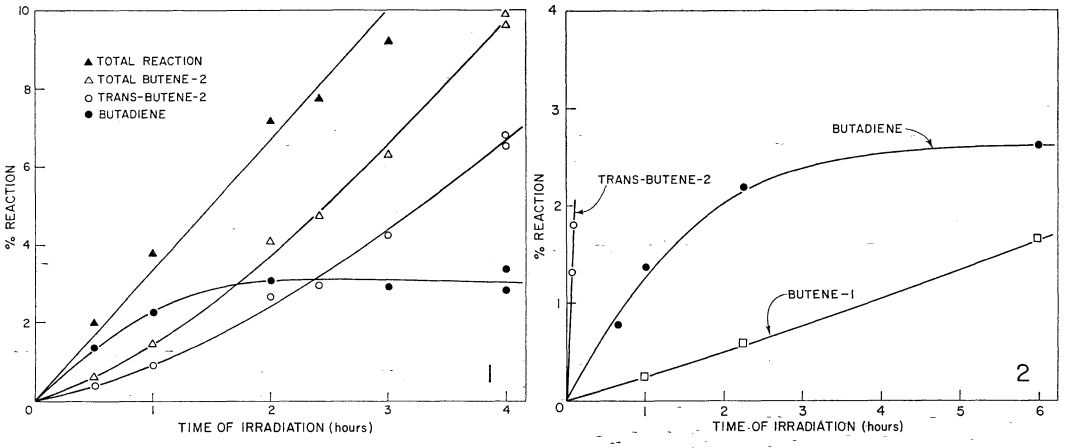

FIG. 1. Time dependence of the yields of products of the reaction of butene-1 with iodine atoms (temp. 65° C, wavelength > 5000 Å, pressure of butene-1 1.7 cm, pressure of I_2 4 mm).

FIG. 2. Time dependence of the yields of products of the reaction of *cis*-butene-2 with iodine atoms (temp. 65° C, wavelength > 5000 Å, pressure of *cis*-butene-2 1.4 cm, pressure of I_2 4 mm).

The recovery of C_4 hydrocarbons, or compounds volatile at −78° C, was never less than 98% and the loss was not related to the extent of reaction. The same loss occurred in blank experiments with no irradiation in which no products were formed and was probably due to some absorption of butene in stopcock grease. It was therefore concluded that non-volatile products were not formed in the reaction to a significant extent.

Addition of butadiene to butene-1 in approximately 1:1 ratio increased the production of butene-2 by almost a factor of two. Results of experiments with added butadiene-d_6 are shown in Table II. Only about half of the product butene-2 was formed from the deuterated butadiene, although the deuterated butadiene was greatly in excess over that formed in the reaction.

The composition of the butene-2 fraction from the reaction with butene-1 is shown as a function of reaction time in Fig. 5. Although the extrapolation is not precise it seems likely that *cis*- and *trans*-butene-2 are formed initially in approximately equal amounts, but by subsequent reaction with iodine atoms, gradually approach their equilibrium proportions.

The effect of pressure of butene-1 on the rate of reaction (Fig. 6) was similar to that observed for the isomerization of butene-2, and, as in the latter reaction, the effect of

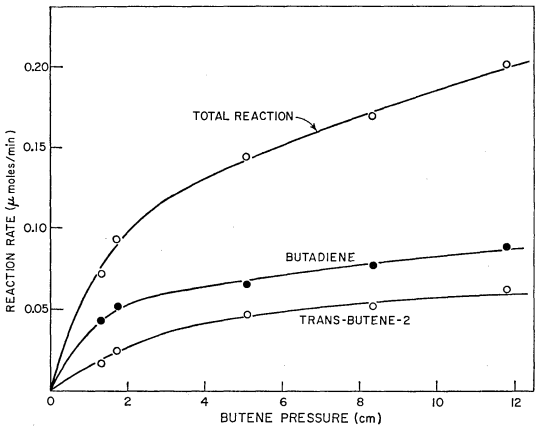

FIG. 6. Dependence of the rates of product formation on pressure of butene-1 in the reaction of iodine atoms with butene-1 (temp. 65° C, wavelength > 5000 Å, pressure of iodine 4 mm, irradiation time 1 hour).

the butene as a third body for the recombination of iodine atoms presumably resulted in the tendency for the levelling off of the rate at high butene pressures.

The rate of production of butadiene from butene-1 was a linear function of the light intensity over the range studied (Fig. 7). Since the rate of recombination of iodine atoms

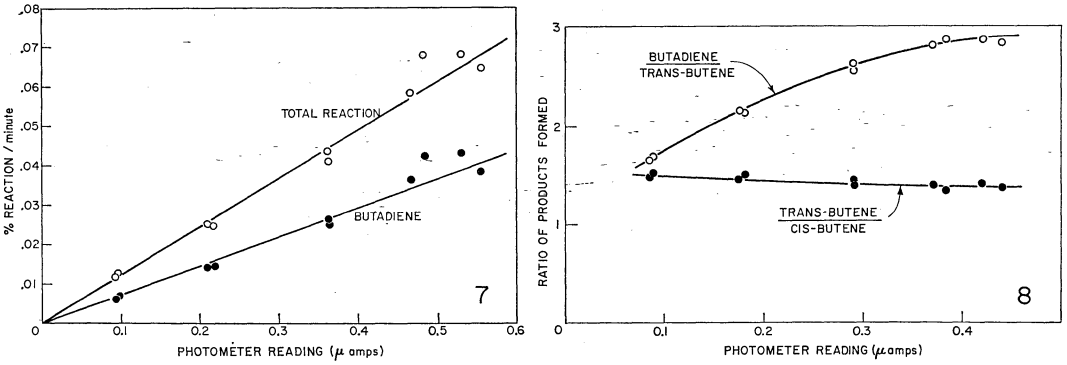

FIG. 7. Dependence of the reaction rates on light intensity in the reaction of iodine atoms with butene-1 (temp. 65° C, wavelength > 5000 Å, pressure of butene-1 ca. 14 mm, pressure of iodine 4 mm, % reaction ca. 2.5).

FIG. 8. Light intensity dependence of the ratios of the products formed in the reaction of iodine atoms with butene-1 (temp. 65° C, wavelength > 5000 Å, pressure of butene-1 1.4 cm, pressure of iodine 4 mm).

in the present system was proportional to $(I)^2$, this suggests that the rate of formation of butadiene was also dependent on the square of the iodine atom concentration and was probably a type of reaction similar to that suggested in Part I for iodine atom induced cis–trans isomerization of butene-2. The ratio of *trans*-butene-2/*cis*-butene-2 formed was practically independent of the light intensity for constant percentage conversion. The ratio of butadiene to *trans*-butene-2, however, increased with increasing light intensity. These ratios are shown in Fig. 8.

Addition of nitrogen had no effect on the rate of reaction of butene-1, except for a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

slight decrease due to the competition of the nitrogen as third body for removal of iodine atoms. The ratios of the products, butadiene and *cis*- and *trans*-butene-2, remained the same. The effect of oxygen on the products at constant pressures of butene, iodine, and nitrogen and constant reaction time is shown in Fig. 9. The yield of butadiene was

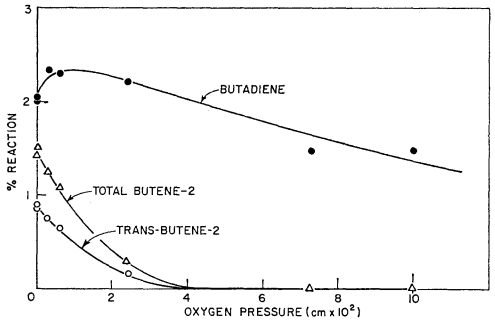

FIG. 9. Effect of additions of oxygen on the products formed in the reaction of iodine atoms with butene-1 (temp. 65° C, wavelength > 5000 Å, pressure of butene-1 1.4 cm, pressure of iodine 4 mm; HI was not determined).

increased somewhat with very small amounts of oxygen and then gradually decreased in a manner similar to the decrease in the rate of isomerization of butene-2 on addition of oxygen. The effect of oxygen on the production of butene-2 was more drastic. A ratio of oxygen/butene-1 of about 0.03 was sufficient to reduce the percentage formation of butene-2 from 1.5 to less than 0.04. The effect of oxygen on the yield of butadiene as a function of time is shown in Fig. 10. A fixed quantity of air was added in each experiment

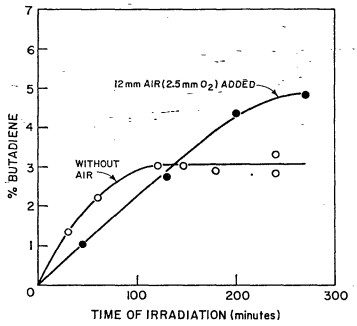

FIG. 10. Effect of oxygen additions on the yields of butadiene at various irradiation times in the reaction of iodine atoms with butene-1 (temp. 65° C, wavelength > 5000 Å, pressure of butene-1 1.4 cm, pressure of iodine 4 mm).

and the pressure of oxygen was sufficient to suppress completely the production of butene-2. The yield of butadiene was first below that found without oxygen, as was expected from Fig. 9. However, the final steady state yield of butadiene was about 50% greater than that observed with no added oxygen. In these experiments an estimate of the oxygen consumed was made by gas chromatographic analysis of the oxygen/nitrogen ratio before and after the irradiation. In each case the oxygen consumed was roughly equivalent to the yield of butene-2 in the absence of oxygen.

DISCUSSION

Butadiene was an unexpected product of the reaction of iodine atoms with butene-1 and butene-2 because hydrocarbons have not generally been found to lose hydrogen atoms by reaction with iodine atoms (2, 3). Excited molecules of iodine activated by 1849 Å light (4) were found to attack C—H bonds in methane and ethane, but the energy content of such molecules was so large that the reaction was not endothermic. Recently (5), both *n*-propyl iodide and isopropyl iodide and hydrogen iodide have been found as products of the reaction of iodine atoms with propane at 49° C, although the quantum yield was low, about 2×10^{-4}. The reaction was thought to occur by the formation of a collision complex RHI with subsequent attack by another iodine atom. A similar type of mechanism is indicated by the present results and with olefins the second iodine atom reacts faster than with paraffins.

The time dependence of the reaction products both from butene-1 and butene-2 and the production of deuterated butene-2 when deuterated butadiene was added to butene-1 are strong indications that butadiene was an intermediate product in the interconversion of butene-1 and butene-2 by reaction with iodine atoms. The butadiene was accompanied by hydrogen iodide and as this accumulated in the system a back reaction occurred to regenerate, finally, butene. In other words, the product butene was a secondary product and not formed by direct isomerization, through the formation of a short-lived C_4H_8I radical, for example. The rate of formation of butadiene and hydrogen iodide from butene-1 and butene-2 was roughly similar, but the rate of formation of butene-2 from butadiene was much faster than that of butene-1, as might be expected from the greater thermal stability of butene-2.

Butadiene Formation

It is rather unlikely that the initial step in the formation of butadiene is the abstraction of a hydrogen atom from butene by an iodine atom. This process is at least 10 kcal/mole endothermic and would be very slow at 65° C. Nevertheless the formation of butadiene from butene requires the removal of two hydrogen atoms by two iodine atoms to form two molecules of hydrogen iodide. This may occur by two slightly different mechanisms.

(*a*) An iodine atom may abstract a hydrogen atom from the radical or the π-complex formed by addition of an iodine atom to butene (C_4H_8I):

$$I + C_4H_8 \rightarrow (C_4H_8I) \quad [1]$$

$$I + (C_4H_8I) \rightarrow C_4H_7I + HI. \quad [2]$$

In either case the process would be exothermic and the product would be a molecule of iodobutene. Since the recovery of butene (as butene or butadiene) was virtually complete even at very long periods of irradiation the yield of this product could have been only very small so that fast subsequent reactions, keeping its steady state concentration low, would have to be assumed. A repetition of this sequence would yield butadiene:

$$C_4H_7I + I \rightarrow C_4H_7I_2 \quad [3]$$

$$C_4H_7I_2 + I \rightarrow C_4H_6I_2 + HI \quad [4]$$

$$C_4H_6I_2 \rightarrow C_4H_6 + I_2. \quad [5]$$

The formation of butadiene would thus occur in two steps, the molecule C_4H_7I being the intermediate.

(*b*) The cis–trans isomerization of butene-2 was postulated in Part I to occur through the intermediate formation of 2,3-diiodobutane. The subsequent dissociation of this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

unstable compound, usually to give butene and iodine, could be assumed to give, a small fraction of the time, butadiene and two molecules of hydrogen iodide in one step:

$$C_4H_8I_2 \rightarrow C_4H_6 + 2HI. \quad [6]$$

An analogous process is direct formation of 2HI and butadiene in reaction [2]. The probability of each of these mechanisms will be considered later.

Butene Formation

A detailed mechanism of the reverse formation of butene from butadiene would be difficult to propose at present. Several broadly similar alternatives are possible. The process probably begins by addition of an iodine atom to form a C_4H_6I radical (or a π-complex) followed by reaction with hydrogen iodide. This could give one of the iodobutene isomers and a further similar series of steps could then yield $C_4H_8I_2$. Since significant amounts of non-volatile products were not formed it may be concluded that the diiodobutane molecule, $C_4H_8I_2$, dissociates rapidly to butene and iodine and the 1,4-diiodobutane (a stable compound) is not formed. This would require that the initial addition of iodine atoms occurs at one of the two internal carbon atoms and, furthermore, that the addition and abstraction occur in such a way that both butene-1 and butene-2 may be formed. The following reaction scheme, for example, would meet these requirements:

$$C_4H_6 + I \rightarrow H_2C{=}CH{-}\overset{H}{\underset{\cdot}{C}}I{-}CH_2 \quad [7]$$

$$C_4H_6I + HI \rightarrow H_2C{=}CH{-}CHI{-}CH_3 + I \quad [8]$$

$$C_4H_7I + I \rightarrow H_2\dot{C}{-}CHI{-}CHI{-}CH_3 \quad [9]$$

$$H_2C{-}CHI{-}CHI{-}CH_3 \rightarrow H_2\dot{C}{-}CH{=}CH{-}CH_3 + I_2 \quad [10]$$

$$\rightarrow H_2C{=}CH{-}\dot{C}H{-}CH_3 + I_2 \quad [11]$$

$$C_4H_7 + HI \rightarrow C_4H_8 + I. \quad [12]$$

If the radical formed in [9] is stable and reacts with hydrogen iodide before decomposing the result would be the formation of 2,3-diodobutane, which would then decompose to give butene-2 and iodine. However, the formation of butene-1 could not occur without hydrogen-atom migration. Intermediate formation of resonance-stabilized methallyl radicals, as in reactions [10] and [11], would be more likely to produce butene-1 and butene-2 in ratios consistent with their thermal stability by abstracting hydrogen from HI (reaction [12]). Inasmuch as methallyl radicals are indeed formed as intermediates, it is not necessary to postulate the unlikely non-terminal addition of iodine atoms in reaction [7].

The probability of mechanism (*a*) and (*b*) may now be discussed in more detail. The fact that the production of butadiene is not, or is very slightly, inhibited by oxygen may be adequately explained by mechanism (*b*) whereby butadiene is formed without the intermediate formation of a radical. However, the probability of simultaneous formation of two molecules of HI in reaction [6] may be quite low. Mechanism (*a*) accounts more easily for the results of the experiments with added butadiene-d_6 which showed that about half the product butene was not formed from butadiene. If the molecule C_4H_7I appears in both the breakdown to butadiene and the buildup to butene it follows that the C_4H_7I molecule may be converted back to C_4H_8 without necessarily going all the way to C_4H_6. This would still allow an induction period for the formation of the product butene-2 since the reaction [12] depends on a sufficient concentration of hydrogen iodide in the system. Thus the product butene may not all be formed by the buildup from butadiene.

For personal use only.

The effect of oxygen on the series of reactions [1] to [5] is difficult to predict. The production of butadiene may not be inhibited if oxygen reacts with the C_4H_8I radical in the same way as the iodine atom reacts, to abstract a hydrogen atom. This may even increase the production of butadiene and in fact a small increase was observed. This effect is shown both in Fig. 8 and Fig. 9, where the increase occurs at a different percentage reaction for different amounts of added oxygen. With larger amounts of oxygen the additional effect of an efficient third body for recombination of iodine atoms may lower the overall rate of reaction as discussed in Part I.

The abstraction of hydrogen by oxygen may also inhibit the re-formation of butene-1 and butene-2 since the hydrogen atom thus abstracted would very likely be made unavailable for the reactions involving conversion of butadiene to butene. Inhibition by oxygen in this sequence could, however, also occur after reaction [11].

The linear dependence of the rate of production of butadiene on light intensity is the result of either mechanism (*a*) or (*b*). In each case the rate of butadiene formation is proportional to $(I)^2$ and since $(I)^2$ is proportional to I_a, the rate of formation of butadiene is thus proportional to I_a. It should be noted that in contrast to the cis–trans isomerization of butene-2 no evidence for an additional rate proportional to the first power of the iodine atom concentration was observed.

ACKNOWLEDGMENTS

The authors are grateful to the Analytical Section of this division for hydrogen iodide determinations by NaOH titration and to Dr. A. W. Tickner for mass spectrometric analyses.

THE X-RAY DIFFRACTION PATTERNS OF ALUMINUM CARBIDE Al_4C_3 AND ALUMINUM OXYCARBIDE Al_4O_4C

J. H. Cox and L. M. Pidgeon
Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario
Received December 20, 1962

ABSTRACT

An X-ray investigation of the compounds aluminum carbide, Al_4C_3, and aluminum oxycarbide Al_4O_4C yielded data which differed from that in the A.S.T.M. files. The aluminum carbide pattern was similar in many ways to that calculated by Stackelberg and Schnorrenberg (Z. Physik. Chem., Sect. B, **27**, 37 (1934). Minor differences occurred in the Al_4O_4C pattern.

INTRODUCTION

During an investigation of the aluminum–oxygen–carbon system (2), an X-ray powder analysis of the high-temperature reaction products indicated that either there were unknown compounds present in the system or there was some error existing in the standard X-ray files. Since a differential thermal analysis indicated that there were no reactions occurring to produce any unknown compounds, it was thought that errors in the patterns for the compounds in this range (the oxycarbide, Al_4O_4C, and the carbide, Al_4C_3) were responsible. Therefore, samples of Al_4O_4C and Al_4C_3 were prepared and analyzed.

EXPERIMENTAL

Apparatus

The samples were prepared in a graphite crucible in the high-temperature, resistance-heated, vacuum furnace described elsewhere (2). Subsequently, they were removed from the furnace and examined with a high-angle diffractometer using a copper target and nickel filter. The X-ray samples were prepared according to the recommendations of Klug and Alexander (3) and were scanned at speeds ranging from 1° per min to 1/8° per minute.

Method

Aluminum carbide was prepared by reacting the stoichiometric proportions of aluminum and graphite at 1250° C, and subsequently holding the product at 1500° C for 12 hours under an atmosphere of argon. A second method of production consisted of reacting alumina and graphite for 6 hours at 1900° C under argon.

The oxycarbide was prepared by holding for 24 hours a stoichiometric mixture of alumina and carbon just above the equilibrium temperature (determined elsewhere (2)) of 1695° C under a pressure of 90 mm Hg.

The Al_4C_3 prepared by the reaction of metal and graphite possessed the characteristic yellow color associated with the compound and tended to give an X-ray pattern in which the peaks were somewhat wider than those of the carbide obtained by the reaction of alumina and carbon. The latter form was composed of very hard purplish black crystals. The oxycarbide Al_4O_4C was found as a mauve powder.

RESULTS AND DISCUSSION

Table I is a comparison of the *d* values and relative intensities produced from samples of the carbide obtained by reacting alumina and carbon (type A) and aluminum and carbon (type B). It can be seen that type A (obtained from the alumina–carbon reaction) produced a pattern which showed several high-angle values which were not present in type B. These values were of low intensity and it was probable that in the more "amorphous" type B carbide they were indistinguishable from the background in the diffractograms.

According to Stackelberg and Schnorrenberg (1), the aluminum carbide lattice is rhombohedral with $a = 8.53$ Å, $\alpha = 22°28'$. For presentation purposes, the X-ray patterns have been converted to a hexagonal basis. Table II compares the hexagonal indices for

be seen that the experimental pattern is much closer to that calculated than either the standard files or Schnorrenberg's own work.

The standard pattern for the Al_4O_4C was from the work of Foster *et al.* (5), who have also commented upon the appearance of unknown planes during the X-ray analysis of some Al–O–C melts. Their findings are listed in Table III and are compared with the experimental pattern obtained in the present work.

It is suggested that difference between the two patterns was due to the small size of the samples used by Foster *et al.* (5) and to the non-equilibrium manner in which they were formed. Their samples were small crystals which had condensed onto the cold portions of their reaction assembly under extreme conditions while the samples used in the present work were obtained under equilibrium conditions.

CONCLUSIONS

An expanded X-ray diffraction pattern for aluminum carbide, Al_4C_3, was obtained which was more similar to that obtained by Stackelberg and Schnorrenberg (1) than to the A.S.T.M. standard pattern. The pattern also possessed many high-angle peaks not listed by either Schnorrenberg or the A.S.T.M. files.

A pattern for the aluminum oxycarbide Al_4O_4C was found which differed in detail from that of Foster *et al.* (5). The difference was thought to be due to non-equilibrium conditions of formation in the earlier work.

PERIODATE OXIDATION OF MESQUITE GUM[1]

G. G. S. DUTTON AND A. M. UNRAU[2]
Department of Chemistry, University of British Columbia, Vancouver, British Columbia
Received January 14, 1963

ABSTRACT

Mesquite gum was subjected to the Smith procedure involving periodate oxidation, reduction, and mild hydrolysis. The main D-galactose chain was fragmented to a greater extent than expected. The quantity of glycerol formed indicated the presence of a considerable number of $1 \rightarrow 6$ linkages while the formation of threitol showed the presence of $1 \rightarrow 4$ linkages. Several small oligosaccharides terminated by a glycerol residue were isolated together with an oligosaccharide of D.P. 30. Further periodate oxidation of the latter gave a product with D.P. 24 which was in turn oxidized to a compound consisting largely of D-galactose and glycerol. Reduction of the acidic fraction gave mainly 2-*O*-methyl-D-erythritol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Mesquite gum contains L-arabinose, D-galactose, and 4-*O*-methyl-D-glucuronic acid. The results of methylation studies and graded hydrolysis on the gum have been reviewed (1) and a generalized structure for the polysaccharide has been proposed. The methylation data do not permit the deduction of a unique structure but it is clear that the gum is highly branched and the isolation of relatively large amounts of 2,4-di-*O*-methyl-D-galactose suggests that the main chain is composed of galactose units linked $1 \rightarrow 6$ and/or $1 \rightarrow 3$. The main chain is known to be substituted by arabinofuranose units and by uronic acid units. If the majority of the D-galactopyranose units are substituted at C_3, either by linkage to another unit of the main chain or by a side chain, then the main structure should undergo little degradation on oxidation with periodate. The terminal uronic acid and arabinofuranose units should, however, be readily removed by periodate oxidation followed by reduction ($NaBH_4$) and mild acid hydrolysis (2). This technique has been successfully applied to oat glucan (2), brome grass hemicellulose (3), oat hull hemicellulose (4), laminarin (5), apple and cherry wood hemicelluloses (6). When mesquite gum was oxidized with periodate, reduced, and hydrolyzed in this manner considerably more degradation occurred than was expected.

The gum (8 g) was dissolved in water and oxidized in the dark with periodic acid for 96 hours. Periodate and iodate ions were removed by the addition of barium carbonate and the polyaldehyde was reduced with sodium borohydride. Excess hydride was destroyed and the solution was evaporated to dryness and the residue treated several times with methanol to remove borate.

A sample of the polyalcohol was completely hydrolyzed and gave threitol, glycerol, arabinose, and galactose in an approximate molar ratio of 1:10:30:10. The 1:4 glycerol: sugar ratio suggested that some glycerol probably arose from $1 \rightarrow 6$-linked galactopyranose units in the main chain in addition to that from arabinofuranose and galactopyranose end-units. The presence of threitol confirmed the existence in the polymer of $1 \rightarrow 4$ galactopyranose residues (1). The major part of the polyalcohol was hydrolyzed with 0.2 *N* hydrochloric acid for 10 hours at room temperature and the acid neutralized with lead carbonate. The filtered solution was passed through cation and anion exchange resins and the neutral eluate was evaporated to small volume. The acidic materials on the anion resin were subsequently eluted and examined (0.91 g). The neutral eluate was concentrated to a small volume and poured into an acetone–alcohol mixture, yielding a

[1]*Presented at the 142nd American Chemical Society Meeting, Atlantic City, New Jersey, September, 1962.*
[2]*Present address: Department of Plant Science, University of Manitoba, Winnipeg, Manitoba.*

precipitate, oligosaccharide A (2.60 g), which was subsequently further degraded to oligosaccharide B. The supernatant from this precipitation contained compounds of low molecular weight (2.71 g). The balance from the 8 g of gum presumably consisted of volatile two-carbon fragments such as glycollic aldehyde.

The present paper is concerned with the nature of the neutral, low molecular weight components; oligosaccharides A and B; and the acidic material. The degradation is shown schematically in Fig. 1. The results presented here show that the Smith degradation is a powerful method for the investigation of the fine structure of polysaccharide gums.

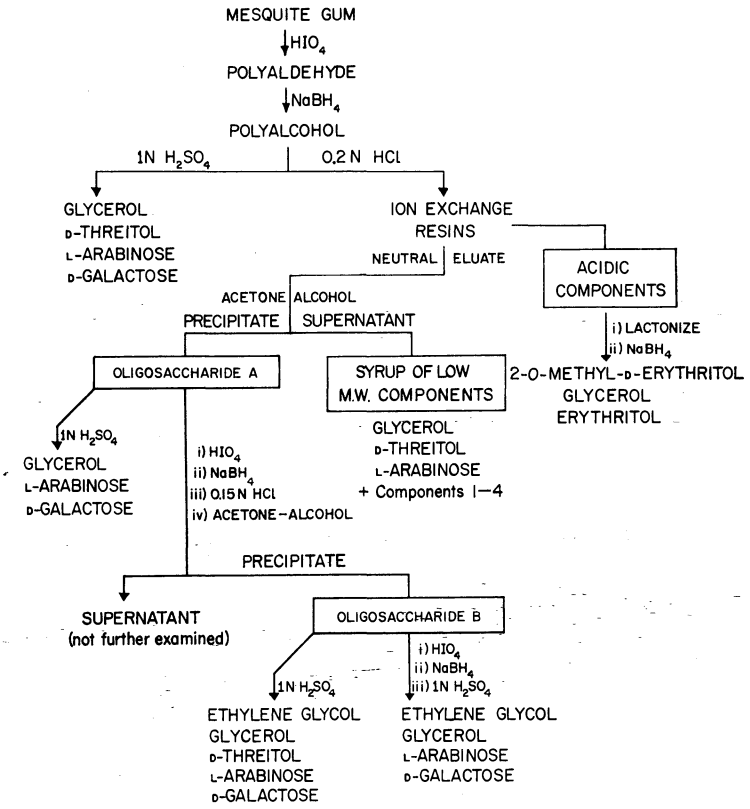

FIG. 1. The periodate degradation of mesquite gum.

The Low Molecular Weight Material

Chromatographic examination of the neutral sirup showed it to contain three non-reducing compounds with R_f values less than glucose (components 2, 3, and 4), presumably substituted arabinose and/or galactose units, and other components which corresponded in R_f values to threitol, glycerol, and arabinose. A non-reducing compound (component 1) with a greater mobility than threitol was also present; however, no ethylene glycol was detected. D-Threitol and glycerol were identified as their *p*-nitrobenzoates, L-arabinose as the crystalline sugar, and the other components as follows.

Component 1, $[\alpha]_D$ 5° in water, had an R_g of 2.31 in ethyl acetate – acetic acid – water (8:2:2) (solvent A), 2.22 in ethyl acetate – pyridine – water (9:2:2) (solvent B), and upon hydrolysis with mineral acid gave arabinose and glycerol in a molar ratio of 1:1. Periodate

oxidation, reduction ($NaBH_4$), and hydrolysis gave glycerol and ethylene glycol in a 1:1 molar ratio. In the periodate degradation of this component, formaldehyde was formed, and assuming that one arabinofuranose unit was linked to the primary hydroxyl of glycerol, the calculated degree of polymerization (D.P.) was found to be 2. Component 1 is therefore 1-*O*-L-arabinofuranosyl glycerol.

Component 2, $[\alpha]_D$ 39° in water, had an R_g of 0.90 in solvent A, 0.98 in solvent B, and upon hydrolysis gave glycerol and arabinose in an approximate molar ratio of 1:3. Periodate degradation gave formaldehyde corresponding to a D.P. of 3 to 4 and hydrolysis of the derived polyalcohol gave ethylene glycol, glycerol, and arabinose in an approximate molar ratio of 1:3:1. As in the periodate degradation of component 1, ethylene glycol arose from glycerol glycosidically bonded through C_1. Glycerol arose from arabinofuranose end-units and internal units presumably linked through C_5. The majority of molecules apparently also contained one arabinofuranose unit linked through C_2 or C_3, presumably C_2 from the methylation data (1).

Component 3, $[\alpha]_D$ 87° in water, had an R_g of 0.59 in solvent A, 0.46 in solvent B, and upon hydrolysis gave glycerol and arabinose in a molar ratio of about 1:4. Periodate oxidation gave formaldehyde corresponding to an approximate D.P. of 5 and hydrolysis of the derived polyalcohol gave ethylene glycol, glycerol, and arabinose in a molar ratio of approximately 1:4:1. Here again, it is believed that ethylene glycol arose from a glycerol unit glycosidically bonded at C_1 whereas arabinofuranose end-residues and internal arabinofuranose units linked through C_5 would furnish glycerol. Apparently almost all of the molecules contained one arabinofuranose unit linked through C_2.

Component 4, $[\alpha]_D$ 64° in water, had an R_g of 0.21 in solvent A and 0.22 in solvent B. Hydrolysis gave glycerol, arabinose, and galactose in an approximate molar ratio of 1:5:1. A trace of threitol appeared to be present. Oxidation with periodate resulted in the formation of formaldehyde the quantity of which corresponded to a D.P. of about 7. Hydrolysis of the polyalcohol gave ethylene glycol, glycerol, and arabinose in a ratio of approximately 1:4:3. Each molecule apparently contained one galactose unit and since no appreciable threitol was formed upon periodate degradation, the hexose residue must have been linked through C_6. Consequently, this hexose moiety was thus most likely linked through C_6 and C_3 in the original polymer. About 60% of the molecules apparently contained an arabinofuranose unit linked through C_2 while the other pentose units were apparently linked through C_5 in order to furnish glycerol in the periodate oxidation. Ethylene glycol would again have arisen from a glycerol residue linked through C_1.

The similarity in the structure of components 1–4 indicates that the arabinose side chains are of unequal length and the composition of component 4 suggests that the maximum number of arabinose units which may be joined together is six. There is, however, no evidence at present to show that all the arabinose units are linked to each other and the possibility of having two arabinose chains joined to galactopyranose at C_6 and C_3 etc. cannot be discounted. It would appear that the shorter arabinose chains are joined $1 \rightarrow 6$ to galactopyranose units rather than $1 \rightarrow 3$ and that these galactopyranose units are oxidized by periodate.

Examination of Oligosaccharides A and B

Acid hydrolysis of the non-reducing oligosaccharide A gave galactose, arabinose, and glycerol in an approximate molar ratio of 12:18:1. By analogy with components 1–4 it was assumed that each molecule was terminated by a glycerol residue linked through C_1. On this basis the amount of formaldehyde liberated on periodate oxidation of oligo-

saccharide A corresponded to a D.P. of 28. Reduction of the polyaldehyde and repetition of the mild acid hydrolysis gave a product (oligosaccharide B) which was precipitable in a 3:1 acetone–alcohol mixture. The supernatant contained only glycerol and a small amount of polymeric material, indicating that oligosaccharide A was not greatly degraded by periodate oxidation. Complete hydrolysis of oligosaccharide B gave ethylene glycol (from glycerol residues linked through C_1), glycerol (from terminal, non-reducing arabinofuranose and 1 → 6-linked galactopyranose units), D-threitol (from 1 → 4-linked galactopyranose units), L-arabinose, and D-galactose in an approximate ratio of 1:6:1.5:13:11. The nearly 1:1 ratio of galactose:arabinose indicated that each galactose unit was still substituted by an arabinofuranose unit at C_3 with a few hexose units still carrying two pentose residues. The presence of some threitol suggested that some galactose residues were linked by 1 → 4 bonds. The amount of ethylene glycol found by the periodate – chromotropic acid analysis (7) and by weight corresponded to an approximate D.P. of 30, hence in close agreement with that obtained by formaldehyde analysis of the periodate oxidation mixture. The alcohols were converted to the corresponding *p*-nitrobenzoates and the sugars were obtained crystalline.

A small quantity of twice-degraded mesquite gum, i.e. oligosaccharide B, was oxidized with periodate as described above. A small quantity of formaldehyde was released, presumably from some glycosidically bound threitol end-residues. Reduction ($NaBH_4$) and complete acid hydrolysis gave ethylene glycol, glycerol, arabinose, and galactose in an approximate molar ratio of 1:9:2:10. The amount of ethylene glycol found suggested a D.P. of about 22. Assuming that the small quantity of formaldehyde formed in the periodate oxidation came from threitol end-groups and adding this to the molar proportion of ethylene glycol, the estimated D.P. would then be about 24. This value indicated that about six or seven arabinose units were removed from each oligosaccharde molecule in the third periodate degradation. The rather large proportion of glycerol can be explained, as indicated above, as arising from arabinofuranose units and from a few threitol end-residues.

The Acidic Components

The acidic material obtained from the initial mild acid hydrolysis was eluted from the anion exchange resin with alkali and deionized. The residue obtained on evaporation was heated under vacuum to effect lactonization and the product dissolved in aqueous methanol to which sodium borohydride was added. The reduction proceeded overnight when the solution was evaporated to dryness and treated with methanolic hydrogen chloride to remove borate. Deionization finally yielded a sirup which was shown to contain 2-*O*-methyl-D-erythritol as the major component together with smaller amounts of glycerol and erythritol. The molar ratio was 19.4:1.6:1.

The 2-*O*-methyl-D-erythritol was obtained as expected from terminal units of 4-*O*-methyl-D-glucuronic acid. Glycerol would arise from terminal glucuronic acid units and erythritol from a glucuronic acid substituted at C_4 by a group other than methoxyl, e.g. arabinofuranose. About 1 in 20 of the acid groups occurred in this latter manner while 2 in 20 appeared to be unsubstituted glucuronic acid. It seemed unlikely that the glycerol and erythritol were artifacts arising from an incomplete separation of the acidic and neutral components since erythritol was not detected in the latter. Similar results have been obtained in the investigation of the acidic constituents of applewood and cherrywood xylans (6).

This periodate study on mesquite gum confirms the complexity and highly branched

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

nature of the polysaccharide. The isolation and characterization of D-threitol provide definite evidence for 1 → 4-substituted galactopyranose units and examination of the acidic fraction indicates the probable occurrence of acids other than 4-*O*-methyl-D-glucuronic acid in the gum.

EXPERIMENTAL

Chromatographic separations were carried out on Whatman No. 1 and No. 3MM papers for analytical and preparative purposes respectively using the descending technique and the following solvents: A, ethyl acetate – acetic acid – water, 8:2:2; B, ethyl acetate – pyridine – water, 9:2:2; C, butanone–water azeotrope.

Reducing compounds were detected with *p*-anisidine trichloroacetate and non-reducing compounds with ammoniacal silver nitrate. R_g values refer to D-glucose = 1.00.

Reducing sugars were determined by the phenol – sulphuric acid method (8) and polyols by periodate oxidation to formaldehyde, which was determined with chromotropic acid (7).

Evaporations were carried out under reduced pressure with a bath temperature of 40° C. Melting points are uncorrected. Specific rotations are equilibrium values determined at 22±2° C in water unless otherwise stated.

1. Periodate Degradation

Mesquite gum (8.0 g) was dissolved in water (200 ml), the solution was cooled (5° C), and periodic acid (40 mmoles dissolved in 50 ml water) added. The oxidation proceeded at 5° C and in the dark. After 96 hours, 0.46 mole of periodate per sugar unit had been consumed and no change was observed in the periodate uptake thereafter. The periodate and iodate ions were removed by precipitation with barium carbonate and the polyaldehyde was reduced with sodium borohydride (250 mg per gram of original gum). After 34 hours, the solution was neutralized and evaporated to dryness. The residue was treated several times with methanolic hydrogen chloride to remove borate.

2. Complete Acid Hydrolysis of Polyalcohol

A small portion (about 40 mg) of the residue was boiled with mineral acid (1 *N* H_2SO_4, 15 ml) for 8 hours, after which the solution was neutralized ($BaCO_3$), deionized, and evaporated. The residue was chromatographed in solvents A, B, and C, and glycerol, threitol, arabinose, and galactose were found to be present. The ratio of the components was determined chromatographically and a typical analysis gave 1.3, 13.2, 40.1, and 12.9 μmoles of threitol, glycerol, arabinose, and galactose, respectively, or a molar ratio of approximately 1:10:30:10.

3. Mild Acid Hydrolysis of Polyalcohol

The bulk of the residue was dissolved in 0.2 *N* hydrochloric acid (50 ml) and left at room temperature for 10 hours, when the acid was neutralized with lead carbonate. The filtered solution was passed through cation and anion exchange resin columns in that order and the neutral effluent evaporated to a small volume (25 ml). Addition of this solution with vigorous stirring to a 1:1 acetone–alcohol mixture gave an amorphous, white precipitate which was collected by centrifugation and dried by solvent exchange to yield 2.6 g (oligosaccharide A). The acidic material was later eluted from the anion exchange resin, see Section 6. The experiments on oligosaccharide A are reported in Section 5 and the nature of the non-precipitable components in the mother liquor is described in Section 4.

4. Characterization of Low Molecular Weight Components

The supernatant from the precipitation of oligosaccharide A and the combined washings were evaporated to a thick sirup (2.71 g). Chromatographic examination revealed the presence of glycerol, threitol, and arabinose and four other non-reducing components (components 1 to 4), one with an R_f greater than arabinose, the other three with R_g values less than 1.0. The sirupy mixture was resolved on sheets of Whatman 3 MM paper using solvent A. Where necessary, components were rechromatographed to attain maximum homogeneity. *Glycerol*, 280 mg, treated with *p*-nitrobenzoyl chloride and pyridine in the usual manner, gave the corresponding tri-*p*-nitrobenzoate, m.p. and mixed m.p. 189–191° C (9). D-*Threitol*, 185 mg, was converted to the tetra-*p*-nitrobenzoate, m.p. and mixed m.p. 222–224° (5). L-*Arabinose*, 415 mg, crystallized spontaneously, m.p. and mixed m.p. 158–159°, $[\alpha]_D$ 103° (*c*, 0.3).

Component 1

Component 1, 135 mg, $[\alpha]_D$ 5° (*c*, 1.4), R_g 2.31 in solvent A, 2.22 in B, gave upon hydrolysis (1 *N* H_2SO_4, 8 hours) arabinose and glycerol. Typical paper chromatographic analysis of the hydrolyzate gave 5.0 μmoles arabinose and 4.85 μmoles glycerol, hence a molar ratio of arabinose:glycerol of 1:1. A portion (65 mg) of component 1 was oxidized with periodate (25 ml 0.5 *M* periodic acid) at 5° C. Formaldehyde was determined after 48 hours (constant) and amounted to 8.1 mg, which corresponded to a D.P. of 2. Periodate and iodate were precipitated ($BaCO_3$) and sodium borohydride (30 mg) was added to the solution, which was left for 24 hours at room temperature. The solution was evaporated, treated with several volumes (15 ml) of methanolic hydrogen chloride (2%) to remove borate, and the residue was boiled with acid (1 *N* H_2SO_4,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

15 ml) for 8 hours. After neutralization ($BaCO_3$), deionization of the filtrate, and evaporation, chromatographic examination of the residue showed the presence of glycerol and ethylene glycol. A typical chromatographic assay gave glycerol, 2.40 μmoles, and ethylene glycol, 2.55 μmoles. The approximate molar ratio of glycerol:ethylene glycol is therefore 1:1. Hence component 1 is 1-*O*-L-arabinofuranosyl glycerol.

Component 2

Component 2, 164 mg, $[\alpha]_D$ 39° (*c*, 1.6), R_g 0.90 in solvent A, 0.98 in B, gave upon hydrolysis glycerol and arabinose in a molar ratio of approximately 1:3. Treatment of a portion (82 mg) with periodate, as described for component 1, released 6.05 mg formaldehyde, corresponding to a D.P. of 4. Hydrolysis of the polyalcohol gave ethylene glycol and glycerol in an approximate molar ratio of 1:3.

Component 3

Component 3, 139 mg, $[\alpha]_D$ 87° (*c*, 1.4), R_g 0.59 in solvent A, 0.46 in B, was analyzed as described for component 1. Acid hydrolysis of a portion gave glycerol and arabinose in a 1:4 molar ratio. Traces of threitol and galactose also appeared to be present. Periodate oxidation of a portion (69 mg) released 3.70 mg formaldehyde, corresponding to an approximate D.P. of 5. Hydrolysis of the polyalcohol gave ethylene glycol and glycerol in molar ratio of approximately 1:4.

Component 4

Component 4, 76 mg, $[\alpha]_D$ 64° (*c*, 0.8), R_g 0.21 in solvent A, 0.22 in B, gave upon acid hydrolysis glycerol, arabinose, and galactose in a molar ratio of 1:5:1. A trace of threitol was also noted. Periodate oxidation of a portion (37 mg) released 1.13 mg formaldehyde, which corresponded to an approximate D.P. of 8. Hydrolysis of the polyalcohol gave ethylene glycol, glycerol, and arabinose in a ratio of about 1:4:3.

The hydrolyzates of components 4, 5, 6, and 7 were combined and the mixture resolved using Whatman 3MM paper and solvent A. *Glycerol*, treated with *p*-nitrobenzoyl chloride in the usual manner, gave the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 189–191° C. L-*Arabinose* crystallized spontaneously, m.p. and mixed m.p. 157–159° C, $[\alpha]_D$ 102° (*c*, 0.4). D-*Galactose* sirup crystallized on nucleation, m.p. and mixed m.p. 164–165°, $[\alpha]_D$ 78° (*c*, 0.5). *Threitol* was present in very small quantity and identified only by paper chromatography.

The hydrolyzates of the polyalcohols of components 4, 5, 6, and 7 were also combined and the mixture resolved as described above. *Ethylene glycol* was converted to the corresponding di-*p*-nitrobenzoate, m.p. and mixed m.p. 138–141° C (10). *Glycerol* likewise was converted to the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 188–191° C. L-*Arabinose* sirup crystallized on nucleation, m.p. and mixed m.p. 156–158° C, $[\alpha]_D$ 100° (*c*, 0.35). *Galactose* was present in small quantity and identified by paper chromatography.

5. Characterization of Oligosaccharide A

(a) Acid Hydrolysis

A portion (0.80 g) of the oligosaccharide, $[\alpha]_D$ 14° (*c*, 0.8), was boiled with 1 *N* sulphuric acid (25 ml) for about 10 hours. The solution was neutralized ($BaCO_3$), deionized, and evaporated to a sirup. Chromatographic examination revealed the presence of glycerol (minor quantity), arabinose, and galactose in a molar ratio of about 1:18:12. The apparent D.P. of the non-reducing oligosaccharide was thus about 31. The sirup was resolved using Whatman 3 MM paper and solvent A. L-*Arabinose*, 375 mg, crystallized spontaneously, m.p. and mixed m.p. 157–159° C, $[\alpha]_D$ 102° (*c*, 0.8). D-*Galactose*, 302 mg, also crystallized spontaneously, m.p. and mixed m.p. 165–166° C, $[\alpha]_D$ 79° (*c*, 0.5). *Glycerol*, 13 mg, was transformed to the tri-*p*-nitrobenzoate in the usual manner, m.p. and mixed m.p. 187–190° C.

(b) Periodate Oxidation

A quantity of the oligosaccharide, 1.0 g, was suspended in 0.1 *M* periodic acid solution (60 ml) and kept at 5° C. After 48 hours, 2.99 mmoles of periodate was consumed and 3.01 mmoles after 72 hours with no change thereafter. Formaldehyde was determined and the 7.16 mg found corresponded to an approximate D.P. of 28. Periodate and iodate were removed ($BaCO_3$) and the polyaldehyde was reduced ($NaBH_4$, 350 mg). After 24 hours, the solution was evaporated, borate was removed, and the solution acidified with hydrochloric acid (to 0.15 *N*). When the solution had stood at room temperature for 2 hours, the acid was neutralized and the filtered solution was passed through anion and cation exchange resin columns and the effluent evaporated to a small volume. The product was precipitable in a 1:3 alcohol–acetone mixture to give a white amorphous material (oligosaccharide B). Part (150 mg) of this solid was saved for further periodate oxidation (see (*c*) below) and the remainder (about 250 mg) was boiled with mineral acid (1 *N* H_2SO_4, 20 ml) for 8 hours. After neutralization and evaporation of the solution, chromatographic examination of the residue revealed the presence of galactose, arabinose, glycerol, ethylene glycol, and threitol. The molar ratio was 11:13:6:1:1.5 respectively. The mixture was resolved by paper chromatography. *Ethylene glycol*, 11 mg, was converted to the di-*p*-nitrobenzoate, m.p. and mixed m.p. 138–141° C (9). *Glycerol*, 55 mg, gave the tri-*p*-nitrobenzoate, m.p. and mixed m.p. 189–191° C. *Threitol*, 15 mg, was converted to the tetra-*p*-nitrobenzoate, m.p. and mixed m.p. 221–223° C. L-*Arabinose*, 120 mg, crystallized spontaneously, m.p. and mixed m.p. 157–158° C, $[\alpha]_D$ 101.5° (*c*, 0.45). D-*Galactose*, 100 mg, crystallized upon nucleation, m.p. and mixed m.p. 165–166°, $[\alpha]_D$ 78.5° (*c*, 0.85).

(c) Periodate Oxidation of Twice-Degraded Gum (Oligosaccharide B)

A small quantity (53 mg) of oligosaccharide B obtained in the previous experiment (Section 5(*b*)) was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dissolved in 0.1 *M* periodic acid solution (25 ml) and left at 5° C for 96 hours. A small quantity (about 2.0 μmoles) of formaldehyde was released. The periodate and iodate were removed ($BaCO_3$) and to the solution was added sodium borohydride (20 mg). After 24 hours at room temperature, the solution was evaporated, borate was removed, and the residue boiled with mineral acid (1 *N* H_2SO_4, 20 ml) for 8 hours. After neutralization ($BaCO_3$), deionization, and evaporation of the solution, paper chromatographic examination of the sirup revealed the presence of ethylene glycol, glycerol, arabinose, and galactose in an approximate molar ratio of 1:9:2:10. The formaldehyde:ethylene glycol:glycerol:arabinose:galactose ratio was approximately 2:1:9:2:10.

6. Isolation and Characterization of Acidic Residues

The anion exchange resin was eluted with alkali and the sodium ions subsequently adsorbed on a cation exchange resin. The acidic solution was evaporated and traces of hydrochloric acid were removed by repeated evaporation of 20-ml volumes of methanol. The residue was finally transferred to a tube fitted with a cold finger kept packed with solid carbon dioxide and the contents heated, under vacuum, for 2 hours at 80–90° C. The residue was dissolved in aqueous methanol, sodium borohydride was added (1.35 g), and the solution was left overnight. Evaporation of the solution to dryness followed by treatment with methanolic hydrogen chloride to remove borate and deionization gave a neutral sirup (0.905 g). Chromatographic analysis of the sirup revealed the presence of 2-*O*-methyl-D-erythritol in major amount and minor quantities of glycerol and erythritol. A portion of the sirup was resolved using Whatman 3 MM paper and solvent C. *Glycerol*, 7.8 mg, was converted to the corresponding tri-*p*-nitrobenzoate, m.p. and mixed m.p. 187–189° C. *Erythritol*, 6.5 mg, gave the tetra-*p*-nitrobenzoate, m.p. and mixed m.p. 248–250° C (10). *2-O-Methyl-D-erythritol*, 140 mg, $[\alpha]_D$ 30° (*c*, 2.8 in methanol), was converted to the corresponding tri-*p*-nitrobenzoate (6), m.p. and mixed m.p. 218–220° C, $[\alpha]_D$ −18° (*c*, 0.9 in pyridine). The molar ratio of erythritol:glycerol:2-*O*-methyl-D-erythritol was 1:1.6:19.4. The ratio of uronic acid to other sugar units estimated from the above results is approximately 1:7.

THE LOW-FREQUENCY DIELECTRIC PROPERTIES OF ETHYLENE OXIDE AND ETHYLENE OXIDE HYDRATE[1]

D. W. DAVIDSON AND G. J. WILSON[2]
Division of Applied Chemistry, National Research Council, Ottawa, Canada
Received October 3, 1962

ABSTRACT

The static dielectric constant of liquid ethylene oxide has been measured between 158 and 286° K. The hydrate of ethylene oxide exhibits a dispersion–absorption region characterized by static dielectric constants about one-third as large as those of ice and by relatively large "high-frequency" dielectric constants ($\epsilon_1 = 7.5$ at 0° C). This region may be approximately described as a circular arc locus, but may be represented somewhat better by a superposition of two (or three) semicircular dispersions. In either case, the activation energy for the relaxation of water molecules, to which this region is ascribed, is ca. 6.7 kcal/mole, except at low temperatures, where it becomes smaller. Experimental values of ϵ_1 agree roughly with those calculated for comparatively rapid orientation of ethylene oxide molecules in the cavities of the hydrate. Such orientation may account for absorption maxima observed at 11 Mc/sec and above 100 Mc/sec at 90° K.

Within the past 12 years the crystal structures of the so-called "gas hydrates" have been determined. The gas molecules occupy cavities in a solid framework which consists of hydrogen-bonded water molecules. The arrangement of the oxygen atoms in the simplest class of gas hydrate, as outlined by Claussen (1), Pauling and Marsh (2), and von Stackelberg and Müller (3), corresponds to the cubic space group O_h^3—$Pm3n$, with a_0 equal to about 12 Å, and 46 molecules in the unit cell. Each unit cell of this structure contains 6 large cavities enclosed by 2 parallel hexagons and 12 pentagons of hydrogen-bonded water molecules, and 2 small cavities enclosed by 12 penatgons. The diameters of the cavities are, respectively, 5.9 and 5.2 Å (3).

The dielectric properties of these hydrates should be capable of providing information about two important aspects of their behavior: (*a*) the nature of the relaxation of the water molecules, which form a solid structure somewhat looser than that in ice, and (*b*) the nature of the barriers which oppose reorientation or rotation of the gas molecules occluded in the cavities.

This report presents results of a dielectric study of the hydrate of ethylene oxide whose structure conforms (4) to von Stackelberg's structure I as outlined above. Observations have been made of a relatively low-frequency dispersion–absorption region attributed to the relaxation of water molecules in this hydrate, and some study has been made of a second absorption region at relatively high frequencies and low temperatures which is possibly related to the rotation of the ethylene oxide molecules in the cavities. To ensure that these absorption effects cannot be ascribed to the presence of ethylene oxide as a separate phase, the dielectric properties of liquid and solid ethylene oxide were also examined.

EXPERIMENTAL METHODS

Ethylene Oxide

Samples of ethylene oxide (Matheson, 99.7% minimum purity) for measurements on the liquid were crudely fractionated at reduced pressure, followed by direct distillation of the middle fraction into the dielectric cell. The vapor pressure of one sample before the cell was filled was 49.6 cm at 0° (vs. 49.51 cm from the equation of Giauque and Gordon (5)). Ethylene oxide directly from the cylinder was used in the

[1]*Issued as N.R.C. No. 7306.*
[2]*N.R.C. Postdoctoral Fellow, 1961–1962.*

preparation of the hydrate. Gas chromatographic analysis with a hydrogen-flame detector showed negligible content of combustible impurities.

Preparation of the Hydrate

A number of attempts to prepare hydrates of various gases by bubbling the gas through liquid water near 0° in cells of different design did not provide satisfactory samples for electrical measurements, mainly because of incomplete filling of the interelectrode region. Because of its high boiling point (11°) and miscibility with water, ethylene oxide readily formed a hydrate *in situ*. Aqueous solutions in the cell were slowly frozen from below. Usually the ethylene oxide concentration was initially slightly in excess of the composition $C_2H_4O \cdot 5.75H_2O$ corresponding to all the cavities filled. The growth of a crack-free layer of uniform thickness could be followed initially by observation through the Lucite windows of the cell used for the bridge measurements. Later stages of freezing could not readily be followed because of the limited transparency of the samples. Subsequent cooling to dry ice temperature caused cracking ("starring") in the vicinity of the windows.

Electrical Measurements

Measurements were made in the frequency range between 0.040 and 500 kc/sec with a General Radio Model 716 Capacitance Bridge and Guard Circuit and conventional oscillators and tuneable detectors. The cell used in conjunction with the bridge was similar to the one of Auty and Cole (6). The guarded electrode (diameter 1 in.) and guard ring (outer diameter 2 in.), separated by a 0.010-in. gap, were mounted on a Teflon plate attached to a shaft extending through the top of the cell, by which the distance between the upper electrode assembly and the parallel lower electrode (diameter 2 in.) could be adjusted. Electrode separations were in the range 0.6 to 1.0 cm. In the initial measurements bare brass electrodes were used; later the electrodes were gold-plated. Gold-plating appeared not to affect appreciably the experimental properties, even at low frequencies. Temperature control and measurement were essentially as previously described (7).

Some measurements were also made with a Boonton RX Meter at temperatures between +5° and −40° and also near the boiling point of liquid nitrogen. The cell, for these high-frequency measurements, consists of two cylindrical coaxial electrodes of stainless steel, of which the outer (inside diameter 1/2 in.) is screwed into a brass tube so as to bear against a Teflon disk which forms the bottom of the cell. The tube in turn is threaded to fit the coaxial adapter of the RX Meter. The inner electrode (3/8 in. long, 1/16-in. diameter) penetrates the Teflon disk and ends in a pin which fits the central socket of the adapter. For the measurements near liquid nitrogen temperature, a center electrode of 1/4-in. diameter was used. The required temperature was achieved by circulation of cold liquid through a brass jacket. Since the metal connections between the bottom of the cell and the Meter cabinet were only 2.5 in. long (to minimize inductance effects) there was considerable heat conduction to the sample. This did not appear to affect appreciably the sample temperature for fast circulation rates at −40°, but was serious when liquid nitrogen was passed through the jacket. In the latter case the sample temperature was some 10° to 20° above liquid nitrogen temperature and a temperature gradient of several degrees occurred across the sample; there was also a cooling effect on the zero balance controls of the Meter which served to increase the uncertainties of the measurements.

A number of transient measurements were also made at temperatures below −130° with photographic and pen-recorder techniques. These results are not reported in detail because of lack of reproducibility and comparably large experimental uncertainties, which made their analysis ambiguous (see below).

Samples of ethylene oxide itself were studied in a three-electrode cell of the Gross–Taylor type (8), enclosed in a copper can provided with fittings which permitted the sample to be distilled into the cell. Measurements were made at at least two frequencies, including 100 and 200 kc/sec.

The conductivity of liquid ethylene oxide at relatively high temperatures was sufficiently great that it was thought possible that the value of the static dielectric constants calculated from the bridge data might be affected. Application of a d-c. "deionizing field" of 1000 volts/cm considerably reduced the conductivity. After 15 minutes, the conductivity of a sample at −25° was reduced from 5×10^{-7} to 4×10^{-8} $ohm^{-1}cm^{-1}$. Some hours were required at −25° for the conductivity to return to half its original value, the rate of increase increasing with temperature. Values of the dielectric constant measured at 100 kc/sec were insignificantly affected by change in conductivity. After one sample had been subjected to the field for several hours at 0° and the sample distilled off, the cell constant was found to have increased by 0.3% and the cathode to be coated with a thin layer of gelatinous material not readily soluble in benzene or water. Similar observations, following pre-electrolysis of nitrobenzene, were reported by Parry (9). It is possible that some polymerization of ethylene oxide took place at the cathode.

A d-c. forefield was also applied to a sample of ethylene oxide hydrate, as discussed below.

RESULTS AND DISCUSSION

Ethylene Oxide

The static dielectric constants of liquid ethylene oxide, measured for three samples at 41 temperatures between 158 and 286° K, may be expressed by $\epsilon_0 = -6.89 + 5842/T$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with an average deviation of ±0.4%. Consistent differences between the measured dielectric constants and those given by the above expression were noted only at temperatures near 160° K, where the experimental values were greater by about 0.2. The experimental values are plotted vs. temperature in Fig. 1.

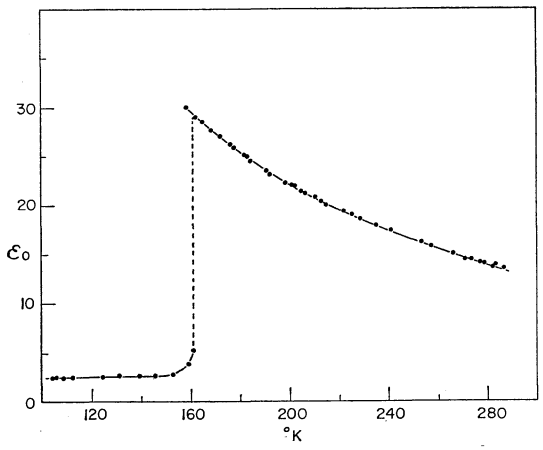

FIG. 1. Static dielectric constants of ethylene oxide.

The values of ϵ_0 previously reported (10) at temperatures to −30° are lower than our values by some 6%.

Studies of gaseous ethylene oxide have given dipole moments in the range 1.88 to 1.91 D (11, 12). The dipole moment μ_0 calculated from the liquid data (ϵ_0 = 14.50, d = 0.8917 g/cm³ at 0° C (13)) by use of the Onsager equation is greatly dependent upon the value taken for n_∞^2, as derived from A, the intercept of the molar polarization vs. $1/T$ curve of the gas. For A = 11.4 cm³/mole (11), μ_0 = 1.97 D, and for A = 12.9 cm³/mole (12), μ_0 = 1.88 D, both at 0° C. Values of μ_0 calculated from the density data of Maass and Bloomer (14) show little dependence on temperature to −50°.

The small dielectric constant of solid ethylene oxide (ca. 2.7, see Fig. 1) shows no contribution from dipolar orientation.

ETHYLENE OXIDE HYDRATE

(a) Relaxation Attributable to Water Molecules

Nature of the Relaxation Behavior

Several complex plane loci, all for the same sample, are illustrated in Fig. 2. The locus of Fig. 2 (*e*) resembles the Cole–Cole circular arc (15), modified by an additional (and variable) polarization effect at lower frequencies. Even at frequencies high enough that the latter effect may be assumed to have a negligible influence on the shape of the locus, however, the circular arc does not accurately describe the experimental behavior, as is shown by the tendency for ϵ'' to approach the real axis at right angles at high frequencies and by the departure from linearity of the log v/u vs. log f plot (15) of Fig. 3, where $v^2 = (\epsilon_0-\epsilon')^2+(\epsilon'')^2$ and $u^2 = (\epsilon'-\epsilon_1)^2+(\epsilon'')^2$.

A somewhat more satisfactory representation (illustrated in Fig. 4) is by a superposition of two semicircular dispersion regions whose relaxation times differ by a factor of about 3 and whose relative amplitudes are in a ratio of about 2:1, the greater contribution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

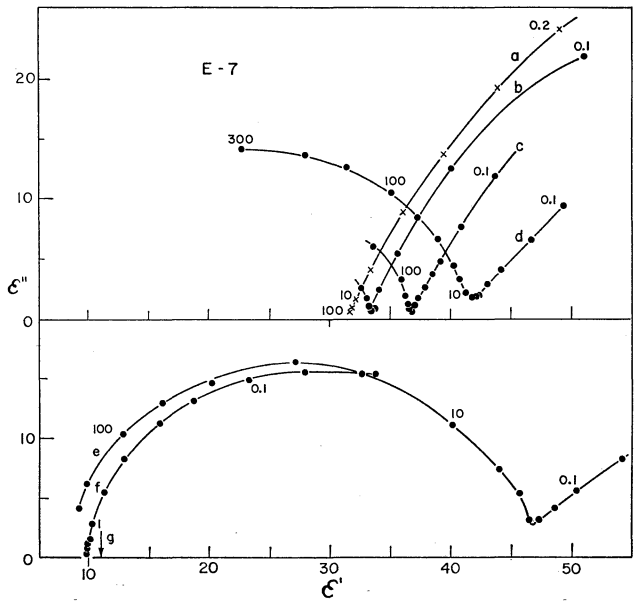

FIG. 2. Cole–Cole plots for ethylene oxide hydrate at: *a* 2.2°, *b* −16.8°, *c* −35.5°, *d* −52.0°, *e* −77.2°, *f* −130.0°, *g* −162.5°. Numbers are frequencies in kc/sec.

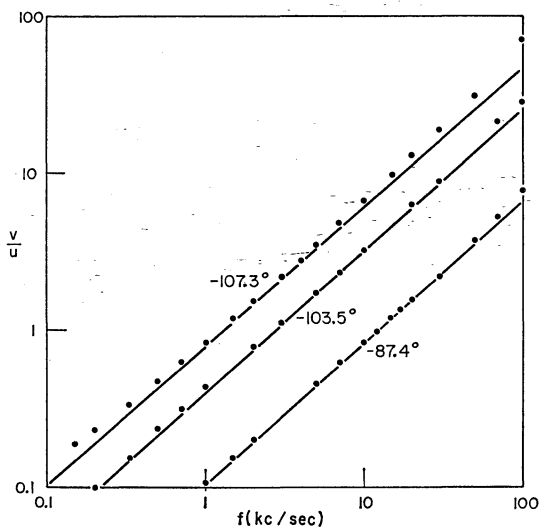

FIG. 3. Plots of log (v/u) vs. log (frequency) for three different samples. v and u are the lengths of lines between points in the complex plane and ϵ_0 and ϵ_1 respectively.

being made by the region with the larger relaxation times. Because of overlap at low frequencies with the additional polarization effect, it is difficult to assess the adequacy of this representation in the low-frequency range. Most samples, like that of Fig. 4, showed some indication of the presence of a small, third dispersion region, although some did not.

In view of the degree of arbitrariness connected with resolution of the observed loci

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

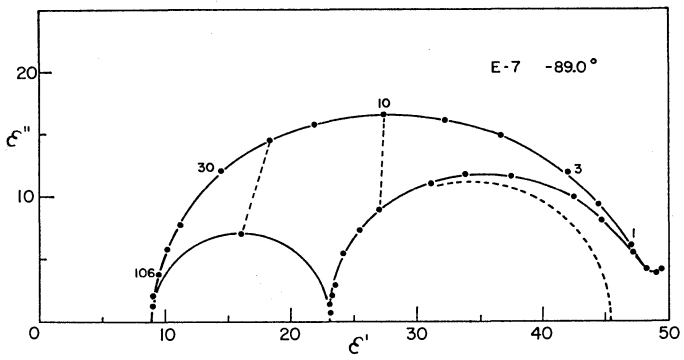

FIG. 4. Plot illustrating approximate resolution into two semicircles.

into two or three semicircles, we have preferred to represent the experimental behavior approximately in terms of the Cole–Cole α function, particularly for evaluation of relaxation times. As in the similar case of acetone hydrate (16) we attribute this dispersion–absorption region to relaxation of the water molecules of the hydrate structure and refer to the corresponding limiting value of ϵ' at low frequencies as the "static dielectric constant" ϵ_0.

Before discussing this dispersion region further, we shall briefly consider the effects of air gaps, of possible contamination of the sample with ice or liquid phase, and of the low-frequency polarization.

Effect of Air Gaps

In spite of attempts to allow the upper electrode assembly to follow the contraction of the samples with decrease of temperature, they invariably appeared to crack at low temperatures. Below about −70° the measured static dielectric constants of the best samples tended to decrease, or to remain almost unchanged, as the temperature fell.

An air gap of uniform thickness a fraction δ of the total interelectrode distance results in an apparent complex dielectric constant $\epsilon^*_{(app)}$, for the sample, which is related to the true complex dielectric constant ϵ^* of the hydrate by the series condenser formula

$$\frac{1}{\epsilon^*_{(app)}} = \delta + \frac{1-\delta}{\epsilon^*}$$

or

$$\epsilon^*_{(app)} = \frac{\epsilon^*}{1+\delta(\epsilon^*-1)}.$$

This results in lower apparent values of the limiting low- and high-frequency dielectric constants

$$\epsilon_{0\,(app)} = \frac{\epsilon_0}{1+\delta(\epsilon_0-1)}$$

$$\epsilon_{1\,(app)} = \frac{\epsilon_1}{1+\delta(\epsilon_1-1)}.$$

Since ϵ_0 is more than four times as large as ϵ_1, a finite δ has a more pronounced effect on the apparent value of the static dielectric constant than on the limiting high-frequency value. In fact (cf. Fig. 7, below) the experimental values of ϵ_1 always increased with decreasing temperature. In general our results are consistent with the presence of δ's less than 0.01 at temperatures above −150°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

For a single relaxation process, the relaxation time in the presence of an air gap becomes

$$\tau_{(app)} = \frac{1+\delta(\epsilon_1-1)}{1+\delta(\epsilon_0-1)}\tau_0,$$

and for less simple relaxation processes the effect is qualitatively the same: a shift of the dispersion regions toward higher frequencies. It is apparent that an air gap in series with parallel linearly independent relaxing units will reduce the separation in frequency of the resulting dispersion regions by shifting the low-frequency region more. At the same time the linear independence is removed. For the small δ's associated with temperatures at which dispersion occurred at bridge frequencies some small reduction in the slope of $d(\ln \tau_0)/d(1/T)$ with decreasing temperature is to be expected, but no qualitative change in the shape of the dispersion.

Effects of Ice and Excess Ethylene Oxide

One sample, after a series of runs, exhibited deep channels extending downward from the upper electrodes which may have been escape routes for ethylene oxide. Some ethylene oxide may also have been lost during the freezing process. Since the relaxation rate of hexagonal ice is some 1000 times slower than that of the water in the hydrate at 0° and this ratio increases with decreasing temperature, one should expect small quantities of ice merely to result in somewhat lower values of the complex dielectric constant. However, analysis shows that a thin layer of ice, in series with the hydrate sample, gives rise to a secondary absorption region at lower frequencies than that of the hydrate, but at considerably higher frequencies than that characteristic of ice itself. Thus a layer of ice of thickness a fraction 0.02 of the sample thickness would show, in addition to the relatively unchanged absorption of the hydrate, a second absorption maximum at a frequency some 35 times as great as a sample of ice alone. It is possible that the presence of ice may contribute to the polarization observed on the low-frequency side of the hydrate dispersion curve, but it cannot account for its principal characteristics.

From the broad, flat top of the liquidus curve of the ethylene oxide – water system (14), we infer that ethylene oxide present in excess will appear as a small quantity of almost water-free liquid. The measurements on liquid ethylene oxide showed no dispersion in the frequency range of that shown by the hydrate. There were no breaks in the ϵ_1 vs. $1/T$ curves (Fig. 7, below) to suggest the abrupt formation of an appreciable quantity of liquid above a eutectic temperature.

Low-frequency Polarization

The rise in ϵ'' and ϵ' observed in all samples at low frequencies is approximately proportional to $\omega^{-1/2}$. This dependence on frequency is considerably less than that which would follow from the charging and discharging of an air-sample interface for a sample displaying a finite air gap and a finite d-c. conductance. At frequencies sufficiently low that there are no contributions from the dispersion region defined by ϵ_0 and ϵ_1 the apparent dielectric constant, given above, reduces to

$$\epsilon^*_{(app)} = \frac{\epsilon_0 - i\epsilon''}{1+\delta(\epsilon_0-1)-i\delta\epsilon''},$$

where ϵ'' is related to k, the conductivity in ohm^{-1}cm^{-1}, and ω, the frequency in radians sec^{-1}, by

$$\epsilon'' = \frac{1.13\times10^{13}k}{\omega}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Separating the real and imaginary parts of $\epsilon^*_{(app)}$ gives, for small values of δ,

$$\epsilon''_{(app)} = \frac{1.13\times10^{13}k(1-\delta)}{\omega[1+\delta(\epsilon_0-1)]^2}$$

$$\epsilon'_{(app)} = \frac{\epsilon_0}{1+\delta(\epsilon_0-1)} + \frac{\delta}{\omega^2}\frac{(1.13\times10^{13}k)^2}{[1+\delta(\epsilon_0-1)]^2}.$$

As with similar effects in ice (17) and acetone hydrate (16), application of a d-c. field results in a considerable reduction of the low-frequency polarization (Fig. 5). This suggests

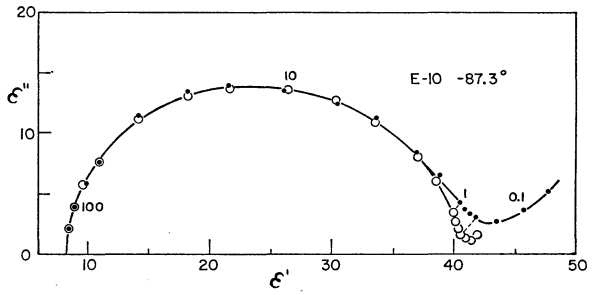

FIG. 5. Effect of application of a d-c. voltage of 1000 v/cm for 17 hours.

that the origin lies in a relatively slow buildup of space charge arising from the presence of ions in the sample. It can be shown that contributions to the complex dielectric constant which are proportional to $\omega^{1/2}$ on the high-frequency side of a polarization region are equivalent to a charging current which is proportional, for short times after application of a ramp voltage, to $(\text{time})^{1/2}$, as found for acetone hydrate (16).

Relaxation Times

Relaxation times, expressed in terms of the τ_0 of the circular arc representation, are shown in Fig. 6. The straight line drawn corresponds to an activation energy for orientation of the water molecules in ethylene oxide hydrate of 6.7 kcal/mole.

Analysis of a number of dispersion curves in terms of the two semicircles mentioned above yields two sets of relaxation times, each of which shows very nearly the same temperature dependence as τ_0.

The experimental relaxation times of Fig. 6 show a trend toward a smaller dependence on $1/T$ with decreasing temperature, which is the direction to be expected from the presence of an increasing air gap. However, this trend is already apparent at comparatively high temperatures where appreciable air gaps are not to be expected. Moreover, the transient measurements at much lower temperatures show the trend to become much more pronounced. An instance of this is given by the data of Table I, which refers to the transient current (expressed in units of capacitance equal to the cell constant) following application of ramp voltage pulse. The experimental data may be represented, about equally well, by

(I) $$\epsilon(t) = \epsilon_1+(\epsilon_0-\epsilon_1)\sum_{n=1}^{\infty}\frac{(-1)^{n-1}x^{n(1-\alpha)}}{\Gamma[1+n(1-\alpha)]},$$

with $\epsilon_1 = 11.57$, $\epsilon_0 = 50.74$, $\alpha = 0.313$, $x = 1/46.25$, and by

(II) $$\epsilon(t) = 11.57+14.66(1-e^{-t/9.5})+24.51(1-e^{-t/109}).$$

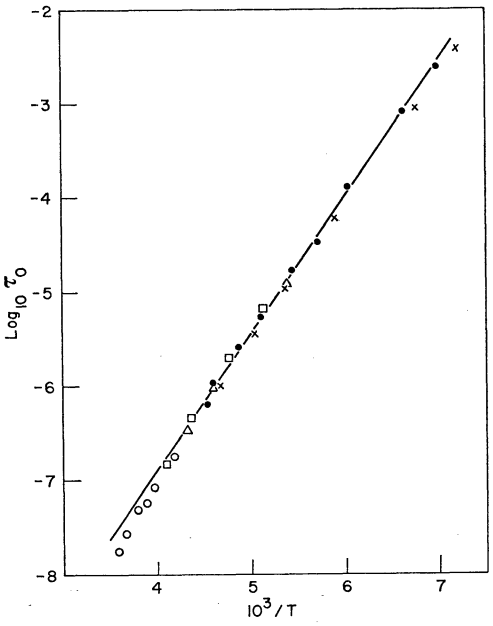

FIG. 6. Dependence of relaxation times on temperature: O, RX Meter results; other points, bridge measurements on various samples.

TABLE I

Comparison of experimental transient data at −182.7° with calculated values

Time (sec)	Experimental $\epsilon(t)$	Calculated $\epsilon(t)$	
		I	II
0	11.57 (bridge data)	(11.57)	(11.57)
4.75	18.6	19.3	18.4
9.5	22.9	23.1	22.9
19	28.0	27.8	28.2
38	33.2	33.4	33.2
76	38.8	38.8	38.6
95	40.5	40.4	40.6
124	42.4	42.0	42.9

Equation (I) results from integration of the current response function (for systems showing the circular arc behavior) for a step voltage pulse (18).[3] Equation (II) is equivalent to the previously mentioned resolution of the complex $\epsilon(i\omega)$ locus into two semicircles. On either basis, the relaxation times at this temperature are of the order of 100 times smaller than those given by linear extrapolation in $1/T$ of relaxation times given by analysis of the bridge data at higher temperatures. We are unable to offer an explanation of this fall in apparent activation energy at low temperatures, which is supported by other transient results.

Static Dielectric Constants

These values for ethylene oxide hydrate are only about one-third as great as the static

[3]*We are indebted to Mrs. M. Helfenstein and Dr. S. D. Baxter of the N.R.C. Computation Centre for evaluation of the sums of (I) for various values of* α.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dielectric constants of ice at comparable temperatures. This result points to an almost complete lack of correlation between the direction of the dipole moment of a water molecule and the average resultant dipole moment of surrounding molecules, that is, to a Kirkwood correlation parameter g of the order of unity. The explanation may lie in the mirror symmetric arrangement of the six water molecules around any pair in the hydrate structure, in contrast to the predominantly centrosymmetric arrangement in hexagonal ice (19). This is accompanied by the presence of pentagonal rings whose resultant moments tend to be small (16).

High-frequency Dielectric Constants

The experimental values of ϵ_1 are shown in Fig. 7. These tended to increase with

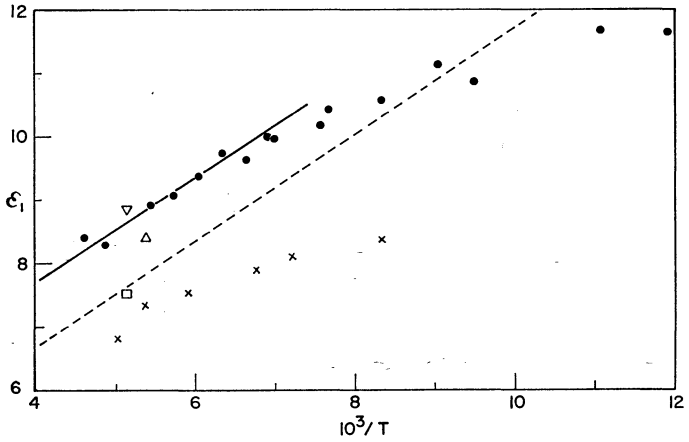

FIG. 7. "High-frequency" dielectric constants (various samples).

decreasing temperature, although less so at low temperatures than would be expected if no cracks were present in the samples. Some variation in ϵ_1 may also be associated with different degrees of cavity occupation.

The high value of ϵ_1 may be ascribed to a considerable freedom of orientation of ethylene oxide molecules in the cavities. The previous treatment (16), based on the presence of acetone molecules in the larger cavities of von Stackelberg's structure II, must be modified for ethylene oxide to take into account the presence of molecules in the small as well as the large cavities of structure I. In the terminology of reference 16, the radii of the large and small cavities of structure I are $a_L = 2.95$ Å, $a_S = 2.6$ Å. For ethylene oxide $\mu_0 = 1.90\times10^{-18}$ e.s.u. and $\alpha = 4.5\times10^{-24}$ cm^3/molecule, which, together with $T = 273°$ and $\epsilon_\infty = 3$, leads to a contribution to the Maxwell polarization from the orientation of the occluded molecules of $P_2 = (5.7\times10^{-23}y_L\nu_L+6.3\times10^{-23}y_S\nu_S)E$. For values of the cavity concentrations ν_L and ν_S obtained from the unit cell dimensions and for all cavities filled ($y_L = y_S = 1$), one finds $\epsilon_1 = 6.4$; for only the large cavities filled ($y_L = 1$, $y_S = 0$), $\epsilon_1 = 5.5$. The experimental value of ϵ_1 for the "best" samples is about 7.5 at 0° C.

The broken line in Fig. 7 represents the variation of the computed value of ϵ_1 with temperature, with all the cavities assumed filled and variations in the cavity concentrations neglected. The highest experimental values are about one unit higher than, and tend to run parallel to, the computed line, down to temperatures of about −120°. At lower temperatures cracks in the samples apparently cause the experimental values to fall below the calculated ones.

(b) Relaxation Probably Attributable to Ethylene Oxide Molecules

RX Meter measurements on two of three samples cooled to about 90° K showed absorption and dispersion behavior as illustrated in Fig. 8. The third showed a rise in

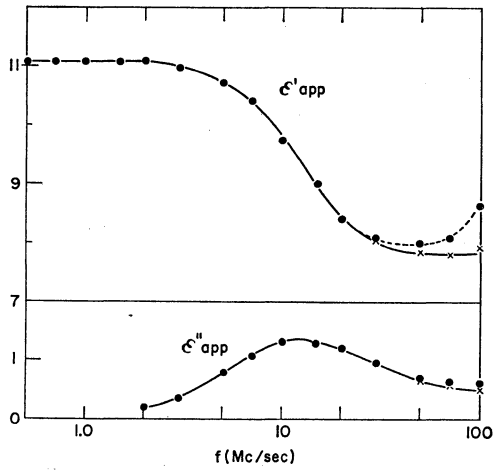

FIG. 8. Dependence of apparent dielectric constants and loss on frequency near 90° K. Points × have been corrected for inductance.

ϵ'' at high frequencies, but not the maximum near 11 Mc/sec. The considerable uncertainties of measurements at this temperature (see *Electrical Measurements*, above), especially in the absolute values of ϵ' and ϵ'', should be emphasized. One may speculate that the absorption peak at 11 Mc/sec arises from the restricted rotation of ethylene oxide molecules in the smaller cavities, the one at some frequency above 100 Mc/sec from rotation in the larger cavities, and the absence of the first peak in one sample from a low ethylene oxide content. Unfortunately the difficulties of proper temperature control at low temperatures have so far prevented an estimate of the activation energy involved.

CONCLUSIONS

The general relaxation behavior of the water molecules in ethylene oxide hydrate is consistent with the crystal structure. In particular, an activation energy for orientation of water molecules no more than one-half as great as that in ice may be related to the presence of O—O—O angles which may be as small as 103.8° and as large as 125.2° (based on the water coordinates of Pauling and Marsh (2)) and to O—O distances which are apparently some 0.05 Å longer than those in ice (3). This looser hydrogen-bonded structure should lead both to a greater concentration of Bjerrum defects (19) and to their greater mobility, provided the latter involves a classical diffusion process.

Within the space group O_h^3—$Pm3n$ the water molecules occur at three different site types (*k*, *i*, *c*), around which the positions of neighboring water molecules differ. There are four types of hydrogen bond (*k*–*k*, *k*–*i*, *k*–*c*, *i*–*i*), of which some may be "weaker" than others. For example, at the *k* sites within the hexagonal rings the angles between the *k*–*k* and *k*–*c* bonds (125.2°) show the greatest departure from the tetrahedral value and these bonds may be somewhat weaker than those of the *k*–*i* or *i*–*i* type. Such a non-equivalence of molecules and bonds is consistent with a broader absorption than that found in ice, particularly if the absorption is due to the relaxation of individual molecules

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

by the migration of orientational defects rather than by some cooperative process involving a great many molecules, as appears to occur in liquids exhibiting strong intermolecular hydrogen bonding.

The general similarity between the low-frequency dielectric properties of the hydrates of ethylene oxide and acetone (16) may be significant, in view of their different structures. Ethylene oxide forms a "gas hydrate" (von Stackelberg's structure I) (4), whereas acetone forms a "liquid hydrate" (structure II) (20). The question of the generality of this kind of behavior within the group of clathrate hydrates awaits study of other hydrates. As is apparent from the foregoing, certain experimental difficulties stand in the way of accurate low-frequency measurements on these systems. Preliminary study of other structure I hydrates suggests that the general dielectric characteristics are similar to those of ethylene oxide hydrate, but that the precise relaxation rates of the water molecules vary with the nature of the occluded molecules.

THE PREPARATION, PROPERTIES, AND STRUCTURE OF 2,6-BIS-(ALKYLAMINO)-2,5-HEPTADIEN-4-ONES[1]

DENYS COOK
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario
Received January 21, 1963

ABSTRACT

2,6-Bis-(alkylamino)-2,5-heptadien-4-ones have been prepared by the action of aqueous amines on (1) 3-acetyl-4-hydroxy-6-methyl-2-pyrone (dehydroacetic acid), (2) 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone, (3) 3-carboxy-2,6-dimethyl-4-pyrone, (4) 2,6-dimethyl-4-pyrone, (5) 2,6-dihydroxy-2,5-heptadien-4-one. The reactions are facile and proceed smoothly at temperatures near, or slightly above, room temperature. In (1) the first products are 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrones, followed by the 2,6-bis-(alkylamino)-2,5-heptadien-4-one. The other reactions yield only the latter product, but in all cases it decomposes to the 4-pyridone at higher temperature, or on prolonged reaction or by the action of acid.

The 2,6-bis-(alkylamino)-2,5-heptadien-4-ones are pale yellow compounds with a slight violet fluorescence. Infrared, n.m.r., and ultraviolet spectra are consistent with an open-chain, internally hydrogen-bonded structure.

INTRODUCTION

The reaction of dehydroacetic acid (I) (3-acetyl-4-hydroxy-6-methyl-2-pyrone) with amines to give 4-pyridones (IV) has been known for a very long time (1). It has now been found that precursers to the pyridones are open-chain compounds 2,6-bis-(alkylamino)-2,5-heptadien-4-ones (III), which are isolable, stable compounds. The preparation of these compounds from 4-pyrones has been noted by Spooner (2), whose work has been confirmed.

Several other methods of preparation of the 2,6-bis-(alkylamino)-2,5-heptadien-4-ones from substituted 2- and 4-pyrones have been discovered, and will be described, together with some comments on the reaction paths.

EXPERIMENTAL

2,6-Bis-(alkylamino)-2,5-heptadien-4-ones (III)

These were prepared by the following methods.

1A. Reaction of 3-Acetyl-4-hydroxy-6-methyl-2-pyrone (Dehydroacetic Acid) (I) with Aqueous (~25% w/v) CH_3NH_2

The quantities in Table I were warmed on a steam bath (~50°) for 0.5 hour (i, 24 hours; ii, 16 hours) then allowed to cool.

TABLE I

	DHA (I)		aq. CH_3NH_2			H_2O		Yield

a, R = CH_3
b, R = C_2H_5

In iii, after about 0.2 hour, pale yellow crystals with a slight violet fluorescence appeared (III*a*). The products in parentheses crystallized from the filtrate.

II*a*, 3-(1-methyliminoethyl)-4-hydroxy-6-methyl-2-pyrone, m.p. 127–128° (anhydrous—by efflorescence of hydrate, by gentle heating *in vacuo*).

III*a*, 2,6-bis-(methylamino)-2,5-heptadien-4-one, m.p. 164.5–165.5° (from ligroin, b.p. 35–60°). Found: C, 64.40%; H, 9.69%; N, 16.60%. Calc. for $C_9H_{16}N_2O$: C, 64.25%; H, 9.59%; N, 16.65%. Infrared (CCl_4, CS_2): 1571 vs, 1436 m, 1413 m, 1312 m, 1283 s, 1168 w, 1068 m, 1029 w, 812 w, 796 m, 786 w, sh, 704 w cm^{-1}. Nuclear magnetic resonance (CCl_4): CH_3, 110; CH_3(N), doublet at 174 (J = 6); CH, 280; NH, ~600, very broad. All values in c.p.s. downfield from tetramethysilane as internal reference. Integrated intensities in the ratio 6, 6, 2, ~2, respectively.

IV*a*, 1,2,6-trimethyl-4-pyridone.$3H_2O$, m.p. 110–111° (hydrate from water). Found: C, 50.39%; H, 8.61%; N, 7.31%. Calc. for $C_8H_{11}NO.3H_2O$: C, 50.31%; H, 8.97%; N, 7.33%. M.p. 244–246° (anhydrous—by gentle heating *in vacuo*) (3).

1B. Reaction of Dehydroacetic Acid (I) with Aqueous $C_2H_5NH_2$

The quantities in Table II were warmed on a steam bath (~50°) for 1 hour (ii, 2 hours, vi, vii, 0.5 hour) then allowed to cool.

In experiments iv to viii, after about 0.5 hour, pale yellow crystals with a slight violet fluorescence appeared (III*b*). The products in parentheses crystallized from the filtrate.

II*b*, 3-(1-ethyliminoethyl)-4-hydroxy-6-methyl-2-pyrone, m.p. 68–69° (hydrate from 50% v/v aq. acetone), m.p. 85–86° (anhydrous — by efflorescence of hydrate, or by gentle heating *in vacuo*). Found: C, 61.60%; H, 6.35%; N, 7.33%. Calc. for $C_6H_{13}NO_3$: C, 61.52%; H, 6.71%; N, 7.18%.

III*b*, 2,6-bis-(ethylamino)-2,5-heptadien-4-one, m.p. 91–92° (from ligroin, b.p. 35–60°). Found: C, 67.53%; H, 9.45%; N, 14.04%. Calc. for $C_{11}H_{20}N_2O$: C, 67.30%; H, 10.27%; N, 14.27%. Infrared (CCl_4, CS_2): 1571 vs, 1436 m, 1369 w, 1300 m, 1260 m, 1133 m, 1090 m, 1060 w, 1030 w, 1000 w, 791 m cm^{-1}. Ultraviolet (methylcyclohexane): 370, 360, 285 sh, 232 mμ. Nuclear magnetic resonance (CCl_4): $CH_3(CH_2)$, triplet at 75 (J = 7); CH_3, 109; CH_2, quintet at 194 (J = 6.5); CH, 265; NH, ~600, very broad. All values in c.p.s. downfield from tetramethylsilane as internal reference. Integrated intensities in the ratio 6, 6, 4, 2, ~2, respectively.

IV*b*, 1-ethyl-2,6-dimethyl-4-pyridone.$3H_2O$, m.p. 72–74° (hydrate from water). Found: N, 6.94%. Calc. for $C_8H_{11}NO.3H_2O$: N, 6.83%. M.p. 158–161° (anhydrous—by gentle heating *in vacuo*) (3).

2. Reaction of 3-(1-Methyliminoethyl)-4-hydroxy-6-methyl-2-pyrone (IIa) with Aqueous Amine

3-(1-Methyliminoethyl)-4-hydroxy-6-methyl-2-pyrone (II*a*) (4.5 g) was warmed on the steam bath (~50°) for 0.2 hour with 12.5 ml 25% aqueous CH_3NH_2 (0.1 mole), when the typical pale yellow, violet fluorescing solid precipitated. After the mixture was cooled and filtered, 2.28 g 2,6-bis-(methylamino)-2,5-heptadien-4-one (III*a*) was obtained, identical in all respects with that prepared previously; 1.03 g 1,2,6-trimethyl-4-pyridone.$3H_2O$ (IV*a*) crystallized from the filtrate.

3. Reaction of 3-Carboxy-2,6-dimethyl-4-pyrone (VII) with Aqueous Ethylamine

3-Carboxy-2,6-dimethyl-4-pyrone was prepared from dehydroacetic acid by the action of 85% H_2SO_4 as described by Collie and Hilditch (4). 3-Carboxy-2,6-dimethyl-4-pyrone (8.4 g, 0.05 mole) was slurried with 18 g H_2O, then 18 g $C_2H_5NH_2$ was added. The solid went into solution as an exothermal reaction took place, followed very quickly by precipitation of a light yellow solid with typical pale violet fluorescence. This product (19.5 g) was the 2,6-bis-(ethylamino)-2,5-heptadien-4-one, identical in all respects with that previously prepared.

4. Reaction of 2,6-Dimethyl-4-pyrone (V) (DMP) with Aqueous Ethylamine

The quantities in Table III were warmed on a steam bath (~50°) for 1 hour (iii, 0.7 hour) then allowed to cool.

In all these experiments after ~0.5 hour light yellow crystals with typical pale violet fluorescence (III*b*) appeared in solution. The products in parentheses crystallized from the filtrate.

5. Reaction of 2,6-Dihydroxy-2,5-heptadien-4-one (VI) (Diacetylacetone) with Aqueous Ethylamine

2,6-Dihydroxy-2,5-heptadien-4-one was prepared from 2,6-dimethyl-4-pyrone (V) (12.4 g, 0.1 mole) in 40 ml H_2O to which was added 17.1 g $Ba(OH)_2$ (0.1 mole) in 500 ml hot water, precipitating the barium salt of VI, 22.9 g. This was dissolved in 100 ml 3 *N* HCl and extracted with $CHCl_3$ (2×100 ml), which on evaporation gave VI, 7.27 g, 52%, m.p. 58–59°. Found: C, 59.10%; H, 6.90%. Calc. for $C_7H_{10}O_3$: C, 59.14%; H, 7.08%. Infrared (CCl_4/CS_2): 1590 vs, 1482 s, 1471 m, 1460 m, 1228 s, 1183 m, 1139 s, 1030 m, 1005 w, 950 w, 898 s, 818 s, 782 w, 745 m cm^{-1}. Ultraviolet (methylcyclohexane): 328 sh, 322, 316 mμ. Nuclear magnetic resonance (CCl_4): CH_3, 118; CH, 304; OH, 842. All values in c.p.s. downfield from tetramethylsilane as internal reference. Some weak resonances at slightly lower field are indicative of a small amount of the keto form. They are being investigated further and will be reported in due course.

TABLE III

	DMP (V)		$C_2H_5NH_2$			H_2O		Yield
	g	mole	g	mole	Ratio	g	Product	g
i	12.4	0.1	4.5	0.1	1	36	III*b*	1.4
							(V)	6.0
ii	12.4	0.1	9.0	0.2	2	36	III*b*	9.6
							(V)	5.2
iii	12.4	0.1	18.0	0.4	4	36	III*b*	17.2
							(IV*b*)	3.0
iv	12.4	0.1	27.0	0.6	6	36	III*b*	15.4
							(IV*b*)	4.0

2,6-Dihydroxy-2,5-heptadien-4-one, (6.6 g, 0.047 mole), 18 g ethylamine (0.40 mole), and 18 g H_2O were heated on a steam bath. After 1 minute all the solid was in solution, but after 3 minutes a pale yellow solid with typical pale violet fluorescence developed, and the reaction was apparently complete in 8 minutes. This solid, 9.46 g, 81%, was the 2,6-bis-(ethylamino)-2,5-heptadien-4-one, identical in all respects with that prepared previously. The filtrate yielded 0.75 g 1-ethyl-2,6-dimethyl-4-pyridone.$3H_2O$ (IV*b*).

Reaction of 2,6-Dimethyl-4-pyrone with Anhydrous Amine

2,6-Dimethyl-4-pyrone (12.4 g, 0.01 mole) was treated with 9.0 g anhydrous ethylamine (0.2 mole). No reaction was observed, and after evaporation of the ethylamine the pyrone was recovered completely, and had the same infrared spectrum as the starting material.

Reaction of Dehydroacetic Acid with Anhydrous Amine

Dehydroacetic acid (I) (16.8 g, 0.1 mole) was treated with 9.0 g anhydrous ethylamine (0.2 mole). An exothermal reaction took place accompanied by partial solution of the acid in the amine. After evaporation of the excess amine the remaining solid was recrystallized from absolute ethanol, giving 15.9 g, 82%, anhydrous 3-(1-ethyliminoethyl)-4-hydroxy-6-methyl-2-pyrone (II*b*).

Dehydroacetic acid (I) (3.36 g, 0.02 mole) was dissolved in a small amount of $CHCl_3$ and excess ether. About 1.8 g anhydrous ethylamine (0.04 mole) was added, giving a white precipitate, ethylammonium dehydroacetate (X), m.p. 71–73°. Found: C, 56.40%; H, 7.41%; N, 6.19%. Calc. for $C_{10}H_{15}NO_4$: C, 56.32%; H, 7.09%; N, 6.57%. When dry ethylammonium dehydroacetate was heated overnight on a steam bath (~50°) the resulting product was 3-(1-ethyliminoethyl)-4-hydroxy-6-methyl-2-pyrone (II*b*), identical with previous preparations.

Reaction of 2,6-Bis-(ethylamino)-2,5-heptadien-4-one with H_2O

2,6-Bis-(ethylamino)-2,5-heptadien-4-one (III*b*) (1.33 g) and 20 g H_2O were boiled together for 0.5 hour. On cooling the solution and evaporation of excess water a white solid, recrystallized from water as long needles, 0.72 g, 52%, proved, from its infrared spectrum, to be identical with 1-ethyl-2,6-dimethyl-4-pyridone.$3H_2O$ prepared previously.

Reaction of 2,6-Bis-(ethylamino)-2,5-heptadien-4-one with HCl

2,6-Bis-(ethylamino)-2,5-heptadien-4-one (III*b*) (2.12 g) was dissolved in $CHCl_3$, and dry HCl gas was passed into the solution. A white solid precipitated immediately. This gave an infrared spectrum containing a superposition of the bands due to 1-ethyl-2,6-dimethyl-4-pyridone.HCl and $C_2H_5NH_2$.HCl.

The infrared spectra were recorded on a Perkin–Elmer 221 prism-grating spectrometer. A Varian A–60 spectrometer was used to record the n.m.r. spectra, and the ultraviolet spectra were determined on a Beckman DK–2 spectrophotometer. Melting points were determined in sealed capillary tubes and are uncorrected. Microanalyses were done in the Analytical Laboratory, Dow Chemical of Canada, Limited.

DISCUSSION

The experimental results have shown that 2,6-bis-(alkylamino)-2,5-heptadien-4-ones can be made, under the appropriate conditions, from 2,6-dihydroxy-2,5-heptadien-4-one (VI), 3-carboxy-2,6-dimethyl-4-pyrone (VII), and 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone (II). All these reactions proceed smoothly and quickly and can be considered in turn.

The clue to the structure of the 2,6-bis-(alkylamino)-2,5-heptadien-4-ones came from the reaction of 2,6-dihydroxy-2,5-heptadien-4-one (VI) with RNH_2. The infrared spectra of these compounds (see Experimental and Figs. 1 and 2) have many similarities, both showing

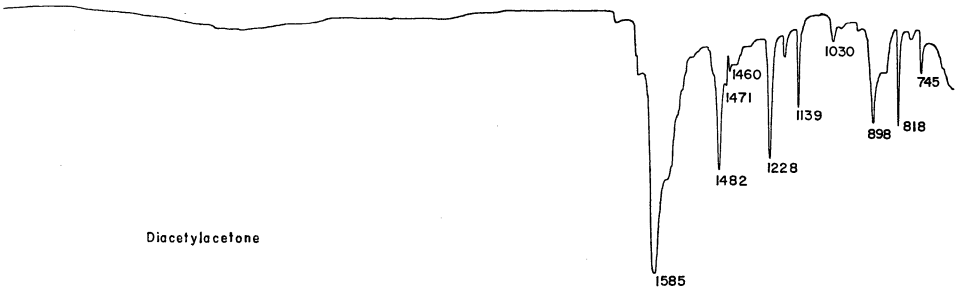

FIG. 1. Infrared spectrum of 2,6-dihydroxy-2,5-heptadien-4-one.

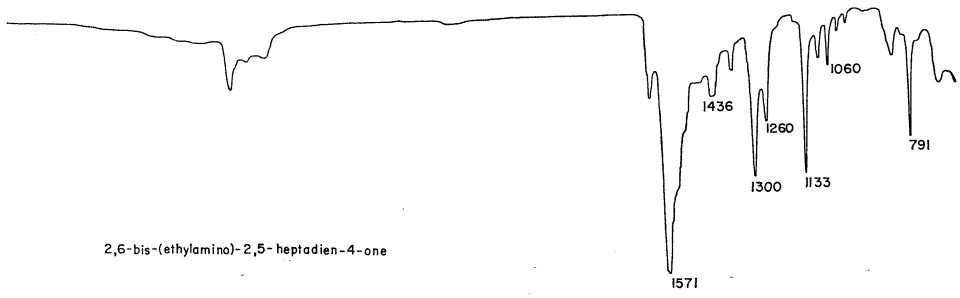

FIG. 2. Infrared spectrum of 2,6-bis-(ethylamino)-2,5-heptadien-4-one.

an intense carbonyl band at ~1571 cm^{-1} for the amino compound (III), and at about ~1590 cm^{-1} for the hydroxy compound (VI). These values are in keeping with our knowledge of carbonyl frequencies, as the following rough calculation shows: 1715 (aliphatic carbonyl) − 2×35 (conjugation) − 2×32 (internal hydrogen bond) = 1581 cm^{-1}. This is also confirmatory evidence that the compounds, as solids and in CCl_4/CS_2 solution, are in the dienol and diamino form. A heptane-2,4,6-trione should have a carbonyl absorption near 1715 cm^{-1}. VI is a white solid (λ_{max} = 316 mμ) whereas compounds III are pale yellow (λ_{max} = 370 mμ) with pale violet fluorescence. These facts tend to confirm that the oxygen atom in the OH group in VI participates in the conjugation in the system to a smaller extent than the nitrogen atom in the RNH group in III (3). The latter shifts the absorption into the visible region, and alters other excited molecular levels to permit fluorescence.

The reaction between 3-carboxy-2,6-dimethyl-4-pyrone and aqueous amines to give III involves opening the 4-pyrone ring. This probably occurs by nucleophilic attack on the carbon atom in the 2- or 6-position by OH^- or amine. The resulting compound, VIII, is seriously hindered and while rotation about the 3,4- and 4,5-bonds relieves some of this strain (IX) the carboxyl group is still hindered. Facile decarboxylation is therefore permitted to give III either directly or from the diketo form of IX.

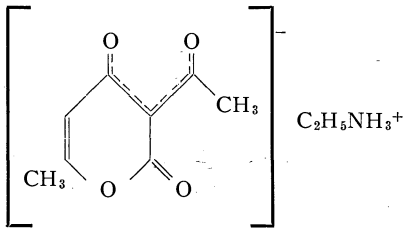
3-(1-Alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone already contains (in the keto-amine form) a replica of half of the 2,6-bis-(alkylamino)-2,5-heptadien-4-one structure. Opening of the 2-pyrone ring by nucleophilic attack of hydroxyl ion or amine at position 6, followed by rotation about the 4,5-bond, would produce a structure analogous to IX. The subsequent reaction would be exactly as for the 3-carboxy-2,6-dimethyl-4-pyrone just described.

It remains to consider the reactions of dehydroacetic acid and 2,6-dimethyl-4-pyrone with aqueous amines. In the case of dehydroacetic acid the reaction with low molecular ratios of amine produces only the 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone, suggesting that the condensation proceeds more easily than the ring opening. A concomitant effect may be an insufficiently basic medium to effect ring opening. The solubility of the compounds, too, plays an undetermined part in the reactions. When the anhydrous amine is used in the reaction the only compound resulting is the 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone, and the reaction is very fast. When the two reactants are mixed in an inert medium, for example, by the action of anhydrous amine on a $CHCl_3$/ether solution of dehydroacetic acid, precipitation of the insoluble ethylammonium dehydroacetate (X) results. This is easily and irreversibly transformed, under mild



X

conditions, into 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone (II), by elimination of water. It seems likely, then, that the first reaction product of dehydroacetic acid with aqueous amines is the condensation product, subsequent reaction being as described above for 3-(1-alkyliminoethyl)-4-hydroxy-6-methyl-2-pyrone with aqueous amines.

Aqueous amines react quickly with 2,6-dimethyl-4-pyrone, opening the ring to form the open-chain compound with the OH groups replaced at some stage in the reaction by RNH groups. Again, nucleophilic attack by hydroxyl ion or amine at carbon atoms 2 or 6 seems to be responsible for ring opening.

The ease with which these reactions proceed suggests some of the possible facile mechanisms for synthesis of nitrogen heterocycles of biogenetic significance.

ACKNOWLEDGMENTS

The assistance of Miss C. D. Anderson in preparing some of the compounds and recording their spectra is gratefully acknowledged. The microanalyses were kindly performed by Mr. K. Sketris and Mr. G. A. Whitehouse, and the ultraviolet spectra were taken by Mr. W. T. Sanders. Dr. J. S. McIntyre is thanked for recording the n.m.r. spectra.

THE NON-LINEARITY OF BIS-ARYLMERCURY COMPOUNDS

W. C. Horning, F. Lautenschlaeger, and G. F Wright
Department of Chemistry, University of Toronto, Toronto, Ontario
Received November 30, 1962

ABSTRACT

The measured distortion polarizations of a group of bis-arylmercury compounds show that they do not exhibit exalted atom polarizations. The apparent orientation polarization of each is appreciable. Two of them, which are substituted symmetrically with methoxyl or nitro, exhibit moments expected from the rotation which is generated in such substances. By comparison of bis-4-bromophenylmercury^{202} with the analogue containing the ordinary isotopic mixture of mercury the apparent moments are shown to be unrelated to nuclear asymmetry. The conclusion is unaltered that the apparent moments of bis-arylmercury compounds are due to effective non-linearity in the C—Hg—C bond.

In continuation of our search to explain the apparently anomalous electric moments of bis-arylmercury compounds (1) we have re-examined and extended the work of Hampson (2), who originally observed the anomalies. Essentially we have arrived at a conclusion which partakes of Hampson's original explanation as a "flexibility moment", which was later generally endorsed by Sidgwick (3) as not unexpected when mercury is involved.

Hampson's opinion that he had measured an orientation polarization of bis-phenylmercury and its symmetrical *p*-methyl, fluoro, chloro, and bromo analogues was not generally accepted. In particular there were some (4) who tried to attribute the anomaly to atom polarization, an argument which Coop and Sutton themselves questioned on the basis of the unrealistic force constant which would be required. Finally the question whether diphenylmercury exhibited an abnormally high atom polarization was for the first time put to the test of experiment (1, 5) and was answered in the negative.

Indeed the value obtained by direct measurement of distortion polarization (P_D, i.e. P_{E+A}) for diphenylmercury was found to be lower than that expected according to the commonly used methods of calculating molecular refraction (MR, i.e. P_E) by addition of the constituent atom refraction according to Eisenlohr (6) or of the bond refractions according to Vogel (7). Since the low distortion polarization implies a definite dipole moment which is unexpected among bis-mercurials it is necessary to decide why these distortion polarizations are low. Consequently the distortion polarizations of a series of bis-mercurials have been examined by the method of dielectric constant determination with compressed wafers of randomly oriented powders together with a number of other substances more or less related. The results are shown in Table I, where the differences between P_D and an average of MR_D by the methods of Eisenlohr and Vogel are shown in the last column.

The distortion polarization (P_D) of diphenylmercury has been redetermined with a result in good agreement with the 57.1 cc reported previously (1). The low value (negative difference) is reflected in comparable differences for the series of substituted diphenylmercurys, items 2–8 inclusive. On the other hand item 9, dimesitylmercury, shows a distortion polarization which is higher than the average of MR_D. But this exception at least conforms with the least of the negative differences among items 2–8 inclusive, namely di-*p*-tolylmercury. Evidently methyl groups exert a compensating effect.

It has been suggested earlier (8) that the negative discrepancy wherein the experimentally determined distortion polarization is lower than the summation value of atom (6) or bond (7) polarizabilities might be ascribed to "negative exaltation" due to substituent phenyl groups. This suggestion was based on the low molecular refractions found for substances in which resonance hydridization exists (9).

This hypothesis seems to be supported by the results of Table I. It may be seen (item 16) that a typical alkyl bis-mercurial does not have P_D lower than MR_D. Alternatively examination of items 12 and 14 as well as 17–34 shows that the presence of phenyl groups or of polynuclear aromatization leads to P_D values which are less than the MR_D calculation.

Of course, these negative values are abnormal in the sense that P_D ought always exceed MR_D since the latter is the measure of the electronic polarization P_E of which P_D is inclusive. In view of the many abnormalities we have encountered it is gratifying to find that a series of saturated alcohols and amines (items 32–37, item 50) seems to behave normally. However, esters, lactones, and lactams (items 40–42 incl.) show positive differences which probably indicate abnormally high atom polarization (P_A).

High atom polarizations have been found previously (10) for nitramines and this series has been extended with items 28–30 inclusive. It is of interest that the lowest of these values (benzylnitroguanidine) involves a substance containing a phenyl group. The high

†Polyethylene wax (2%) has been used to consolidate these wafers and correction has been made for contribution of this contaminant to the dielectric constant.

value for 2,3-dinitrohexane (item 38) is also of interest, indicating that it may be the nitro group in all of these compounds which is responsible for the high P_D. For example the nitro group seems to compensate for the lowering of P_{E+A} by phenyl in *p,p'*-dinitrobibenzyl (item 10).

An unexpected group of low P_D values has been found for four of the diastereomers of 1,2,3,4,5,6-hexachlorocyclohexane, especially unexpected since the effect of aliphatic halogen seems to compensate the aromatic effect in α,α'-hexachloroxylene. The group indicates that the distortion polarization effects are still not entirely explainable.

Discrepancy between experimentally determined P_D and the MR_D summations may arise from positive as well as negative exaltation. The high positive differences shown by the *o*-nitroacetophenone azines (items 53 and 54, kindly supplied by Fleming and Harley-Mason, Cambridge (11)) may reasonably be attributed to exaltation of P_E due to the conjugated system between the nitro groups. It is significant that the cis–cis isomer shows a much higher enhancement than the trans–trans.

Probably these distortion polarizations of the azines would be yet higher were it not for some negative effect of the phenyl groups. Such compensation seems to occur in the unsaturated aromatics of items 55–57 inclusive in Table I, which have been furnished to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

us by Dr. Hoffman of American Cyanamide Company (12), to whom we are grateful. The effect of individual phenyl groups is exemplified by 2,2,5,5-tetraphenyl-3-hexyne, where the high negative exaltation is remindful of substances such as tetraphenylethylene and 1,2,3,4-tetraphenylbutadiene (1). By contrast the tetraphenylallene shows about half the negative exaltation of the alkyne, while the more cumulated butatriene shows less than half again. It is reasonable to assume that the negative effect of four phenyl groups is compensated by positive exaltation of the cumulated unsaturation.

It must be admitted that designation of exaltation in cumulenes is highly speculative, necessarily because no measurements of P_E have been made. The determination of refractive index in respect of the several axes of organic chemical crystals in general is difficult and unprecise. In conesquence few studies have been made. It is to be hoped that a novel method for determination of reactance of crystals at optical frequencies will be developed, and work is proceeding in this laboratory. Meanwhile positive abnormalities in distortion polarization must be assigned vaguely to either atom or electron exitation.

We choose to attribute the positive values of items 11, 13, and 15, Table I, to exaltation of P_E, if for no other reason than the ostensible difference between items 7 and 13 as well as items 7 and 9 and item 15, namely a mercury atom. This barrier should prevent exaltation arising from conjugation in biphenyl, although it must be noted that a large positive value is found for item 11 wherein a methylene group appears to interrupt conjugation. However, conjugative characteristics have been observed before among diphenylmethanes (13, 14). This small interposing atom will allow steric interaction between the phenyl groups which would be obliterated by a mercury atom.

To summarize the data of Table I it would appear that the experimental method for wafer dielectric constant gives usable values of distortion polarization. To be sure, there are anomalies, but the discrepancies between the P_D from the wafer method and P_E by summation of atom or bond refractions would seem to be due more to deficiencies in the summation method than to error in the experimental method with wafers. In the calculation of dipole moments we shall use distortion polarization values derived by both methods, but we rely principally on the experimental value.

In Table II we have recalculated the dipole moments reported by Hampson in terms of experimentally determined P_D. Besides diphenylmercury we have redetermined only one of Hampson's substances. An apparent moment lower than his is reported in Table III for bis-*p*-bromophenylmercury but our solvent and temperature are different and indeed we were not trying to check his result. Instead we wished to compare the substance made from mercury of symmetrical isotope 202 with that prepared from ordinary mercury which contains 16.9% of Hg^{199} and 13.2% of Hg^{201}, both of which nuclei are unsymmetrical. As may be seen from Table III the moment of the sample containing 97% of Hg^{202} is indistinguishable from that containing the ordinary isotopic mixture. The result (that dissymmetry of the nucleus, especially when it is heavy, will not affect valence stereochemistry) is not unexpected.

The apparent moment of bis-*p*-xenylmercury (Table III) is higher than that of diphenylmercury, roughly by the amount that conforms with calculation of the greater charge separation between para hydrogen and mercury in the xenyl versus the phenyl group when a C—Hg—C bond angle of about 140° is assumed. On the other hand the apparent moments of divinylmercury and bis-β-naphthylmercury are appreciably lower than has been observed for diphenylmercury, as would be expected in consideration of the lesser resultant charge separation, by contrast with the *p*-hydrogen of the phenyl group, in either the vinyl or β-naphthyl substituents.

*Analyzed in carbon tetrachloride at 20° instead of benzene.
†Analyzed in dioxane at 40° instead of benzene at 20°.

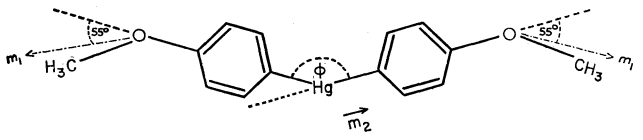
Two of the entries of Table III are those of bis-mercurials in which the substituent constitutes a rotator of appreciable polarity. Therefore, a symmetrical bis-arylmercury of this kind will be comprised of either two or three rotators depending whether the C—Hg—C linkage is linear or angular. In fact the 3-rotator molecule ought to have a higher orientation polarization than the corresponding 2-rotator version according to the generalized equation (15), where ϕ is the C—Hg—C bond angle and θ is the moment angle of the other rotators:

$$\text{(I)} \qquad \mu_{obs}^2 = 2m_1^2+2m_2^2+2[-m_1^2\cos^2\theta\cos(180°-\phi)-2m_1m_2\cos\theta\cos(180°-\phi) +2m_1m_2\cos\theta - m_2^2\cos(180°-\phi)].$$

The first of these substances, bis-*p*-anisylmercury, has been chosen because the electric moment of 4,4′-dimethoxybiphenyl (the same constellation of atoms except for mercury) has been determined (16) with care, and has been found to correspond with that which would be expected if the phenyl groups were colinear and the methoxy groups were randomly rotating. This moment of di-*p*-anisyl is 1.52 D in benzene at 25°, i.e. only slightly lower than the apparent moment in benzene (1.60 or 1.65 D at 20° depending on choice of P_D) of bis-*p*-anisylmercury. This small difference does not imply near linearity of the C—Hg—C bond, but rather that the moment is not very sensitive to differences in bond angle at the central linkages. With this limitation a C—Hg—C bond angle may be calculated by use of reported bond moments.

The bond moment of the aromatic C—O—CH_3 bond has been specified (17) as $m_2 = 1.30$ D with a moment angle of 55°. A zero bond moment for C—Hg has been assigned (18, 19) for C—Hg—X (X = halogen), which is realistic in view of the extreme resistance of primary and secondary alkylmercuric halides toward acid fission (16). But it is not realistic for bis-mercurials, which split easily upon acid treatment. Consequently a bond moment for C—Hg in bis-mercurials was devised (20) from the polarizations of mercuracyclohexane and mercuracycloheptane after assuming a C—Hg—C bond angle of 140°. This bond moment, 1.3 D with mercury positive in respect of carbon, will be used in the current calculations as one limit, with zero C—Hg bond moment as the other.

Together with the observed moment of bis-*p*-anisylmercury (1.63 D) one may apply these bond moments to equation (I) to find that the C—Hg—C bond angle ϕ (Fig. 1) is



I

FIG. 1.

about 160° if the C—Hg bond is taken at 1.3 D or about 130° if it is taken at zero. Therefore, if the methoxyl groups in bis-*p*-anisylmercury and bis-*p*-anisyl are freely rotating the mercurial and the biphenyl cannot both be colinear.

Comparison between *m*,*m*′-dinitrobiphenyls and bis-*m*-nitrophenylmercury is not so direct because rotation does not seem to be free in the biphenyl. If free rotation existed in *m*,*m*′-dinitrobiphenyl the observed measurement ought to be 4.9 D according to the relationship (21)

$$\text{(II)} \qquad \mu_{res} = 2\mu_{C-NO_2}\sin\theta\cos\phi/2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

for all possible values of ϕ, where $\theta = 60°$ and ϕ is the angle between the radial components of the C—NO_2 group moments, here assumed to be 4.0 D. It may be seen that this resultant moment for free rotation is the same as that for ϕ fixed at 90°.

According to Table III the observed moment of *m,m'*-dinitrobiphenyl is 4.0 D in benzene at 20°, indicating that the trans conformation is strongly favored; in terms of a fixed structure the angle ϕ is 130°. This value is 19° lower than that reported (22) from a consideration of Kerr constants but an azimuthal angle greater than 90° is indicated by either consideration.

According to the moments of nitrated biphenyls which have been determined here and elsewhere the circumstance of free rotation is unlikely. Indeed, the value nearest to the 4.9 D indicative of free rotation is 5.12–5.23 in benzene at 25° reported (22, 23, 24) for *o,o'*-dinitrobiphenyl, in which the ortho groups would certainly be obstructive. Alternatively one may calculate a fixed angle ϕ of 83° (92–93° according to ref. 22) by means of equation (II), presuming that this artificiality reflects the mean position of axial rotation in the molecule. On the same basis ϕ for 2,2',4,4'-tetranitrobiphenyl ($\mu_{obs} = 4.38$ D in benzene at 25°) (24) may be specified as 101° from the cis–cis coplanar conformation assuming that the para nitro groups are not involved (25).

Our values may be realistic in view of the observed moment (4.5 D., Table III) of dinitrobimesityl. Here fixation ought to be most closely approximated because of the methyl group obstruction, so the calculated angle ϕ, 99°, ought roughly to describe the actual condition of the molecule.

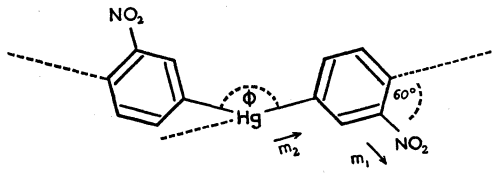
Obviously the methyl group obstruction in dinitrobimesityl prevents the trans as well as the cis conformation. According to the moment (4.0–4.1 D, Table III) observed for *m,m'*-dinitrobiphenyl there is a tendency in the meta isomer (in contrast to ortho) for transalignment of nitro groups since ϕ, 109° from cis coplanarity, is greater than the angle observed when methyl obstruction is present.

These results from the nitrated biphenyl series are of interest and deserve further study, which is at present being made here in respect of temperature. However, they contribute little for comparison with *m,m'*-diphenylmercury so the necessarily non-linear bis-*m*-nitrophenylmethane (26, 27) has also been examined. Assuming that the phenyl groups are freely rotating, that $\mu_{C-H} = 0.3$ with hydrogen positive, and that methylene valences are tetrahedral the resultant moment ought to be 5.5 D. Since the observed moment (Table III) is 5.1 D one might guess that the methylene group is not tetrahedral. Calculation of the C_6H_5—CH_2—C_6H_5 angle (which will be close to the bond angle) in terms of the observed moment gives an apparent value of 97°. Any deviation from the tetrahedral angle might be expected to be higher than 109° in view of the spectral evidence (13, 14) and of the 115° angle suggested for unsubstituted diphenylmethane (28). Moreover a diminution to 97° ought seriously to affect free rotation because of nitro group interaction. In consequence we are inclined toward the view that free rotation does not occur in bis-*m*-nitrophenylmethane, but as a consequence of resonance hybridization rather than obstruction.

These nitrophenyl models have been chosen for comparison with bis-*m*-nitrophenylmercury, for which the C—Hg—C bond angle is sought. If this bond were linear and the phenyl groups were freely rotating the moment ought to be that calculated under the same circumstances for *m,m'*-dinitrobiphenyl, namely 4.9 D if $\mu_{C-NO_2} = 4.0$. The observed moment is 5.61 D in dioxane at 40°. This moment would be obtained with linear C—Hg—C only if the nitro groups were in the cis quadrant, in terms of a fixed structure if they were radially inclined at 72°. But experience with the *m*-nitrobiphenyls shows that lack of free-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

dom in rotation tends toward the trans conformation. The information about bis-*m*-nitrophenylmethane does not contradict the tendency. Therefore, no explanation for the high moment of bis-*m*-nitrophenylmercury is apparent except that of a non-linear C—Hg—C linkage (Fig. 2) especially since the chance of conjugative effects via the large



II

FIG. 2.

mercury atom is remote. In any case such conjugative effects would themselves tend to create non-linearity in C—Hg—C.

The calculation of the C—Hg—C angle according to equation (I) is of interest. Depending on choice of C—Hg bond moment from 0 to 1.3 D the resultant C—Hg—C angle will vary from 94° to 123°.

Of course the dioxane at 40°, which is required by solubility limitation, may be expected to enhance the moment by about 0.2 D (20) over that which would be observed in benzene, but a recalculation on the basis of a resultant moment of 5.4 D gives C—Hg—C angles of 110° for $\mu_{C-Hg} = 0$ and 133° for $\mu_{C-Hg} = 1.3$ D. Since there is no present evidence for postulation of a C—Hg bond moment greater than 1.3 D it would seem that the angle in bis-*m*-nitrophenylmercury is more acute than any yet encountered among bis-mercurials. This circumstance is not abnormal if the groups attached to a mercury atom are relatively free to assume positions directed by their own force fields with minimal influence of the large central atom.

EXPERIMENTAL

Bis-p-bromophenylmercury

(a) Using Ordinary Mercury

A solution of 4.95 g (0.248 mole) of *p*-bromophenylboronic acid, m.p. 286–290° C (29), in 110 ml of boiling 1% aqueous sodium hydroxide was filtered and then stirred just below the boiling point while a solution of 3.40 g (0.00992 mole) of mercuric nitrate in 50 ml of 0.4% nitric acid was added during 30 minutes. The resulting suspension was boiled for 15 minutes and then maintained below the boiling point for 2 hours until all traces of mercuric oxide had disappeared. The suspension was then suction-filtered and the cake was washed with 100 ml of distilled water, 5.25 g (103%, vacuum-dried at 50° C). This crude product was crystallized from 125 ml of 7:3 dioxane–water. The water-washed, vacuum-dried white needles melted at 246–251° C (4.25 g, 83%). A second crop (0.74 g, 15%) melted at 244–249° C.

The melting point range seems to be caused by polymorphism. The microcrystalline plates melt on the Koffler microstage at 224–230° C and transform to long prismatic needles. Transformation usually is not complete although conversion was complete in one instance, with remelting at 254.5–256° C. The mercurial is soluble in dioxane, benzene, dimethylformamide, and chloroform but only slightly soluble in other common solvents.

(b) Using Hg^{202}

To the solution of 1.558 g (0.00775 mole) of 4-bromophenylboronic acid in 100 ml of 10% aqueous sodium hydroxide at 80° C was added dropwise during 30 minutes a solution of 0.52 g of 97.66% mercuric^{202} nitrate in nitric acid estimated to be about 3 *N* (sample was used as received from Oak Ridge, Tennessee). Yellow

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

colloidal mercuric oxide began to form during the initial addition, but 10 minutes elapsed before the product began to appear. Finally 3 *N* nitric acid was added until the pH was 8–9, and the resulting orange-tinted suspension was boiled for 15 minutes and allowed to cool during 3 hours, after which the suspension was colorless although the aqueous phase was faintly greenish-yellow. The cold system was filtered, the product being washed with 150 ml of water in three portions. Thus, bis-mercurial, 1.373 g, was dissolved in hot 70:30 dioxane–water, leaving 0.0389 g of grey-green insoluble matter. The cooled solution yielded 1.1223 g, m.p. 245.5–250° C. Dilution of the filtrate to 1:9 dioxane–water ratio yielded 0.001 g, m.p. 244–247.5° C. Total yield is 96.4% of theoretical.

Recovery of isotopic mercury from residues or solutions was effected by evaporation to dryness, then solution of the residue in 5% oleum and concentrated nitric acid (2:1). The solution was diluted with water, evaporated almost to dryness, and the residue was dissolved in an amount of water such that the sulphuric acid concentration was about 50%.

4-Bromophenylmercuric Chloride

A solution of 0.190 g (0.00037 mole) of bis-4-bromophenylmercury in 20 ml of boiling acetone was treated during 10 minutes with a solution of 0.203 g (0.00075 mole) of mercuric chloride in 25 ml of acetone. The slightly milky suspension was treated with 20 ml of water, the mixture let stand overnight and filtered, 0.230 g, m.p. 256–259° C. Distillation of acetone and addition of water to the filtrate gave 0.035 g more, m.p. 256–260° C. The total yield was 91% of theoretical.

m,m'-Dinitrobiphenyl

To a dark brown solution of 27.4 g (0.1 mole) of *m,m'*-dinitrobenzidine (30), m.p. 265°, prepared by mortar grinding in 65 ml of concentrated sulphuric acid, was added dropwise into the mortar not more than 50 ml of water. The slurry was transferred to an Erlenmeyer flask by means of 10 ml of concentrated sulphuric acid. To this system at −15° was added ground potassium nitrate at such a rate as to maintain, with stirring, a temperature of −5°. To the completed reaction (test portion water soluble) was added 220 ml of absolute ethanol. The system was boiled until nitrogen evolution was complete, then diluted with 200 ml of water. The filtered precipitate was washed acid free by means of water, air dried 21 g (86%), m.p. 193–196° C. Crystallization twice from benzene, then from acetic acid, and finally repeatedly from absolute ethanol would not raise the melting point above 200° (31) but the yellow product was not highly crystalline. A benzene solution (1.55 g in 60 ml) was then chromatographed on an alumina (160–170 mesh, 180° for 8 days) column (I.D. 2 cm by 20 cm long) using benzene as developer. The colorless first eluates yielded dinitrobiphenyl, m.p. 201.5–203°, which may be obtained as long needles by crystallization from acetone. The substance was characterized by conversion to *m,m'*-diacetaminobiphenyl, m.p. 256–257.5° C (32).

Bis-m-nitrophenylmethane

The substance was prepared by the method of Schoepff (26) but his melting point as well as that of Thorpe and Wildman (27) was exceeded by successive crystallizations from benzene, acetic anhydride, and petroleum ether (b.p. 90–100°, 550 ml/g). The last melting point, 176–178.5°, was not increased by elution from alumina (180° activation) by means of chloroform.

Physical Measurements of Solid Substances

These measurements were identical with those described in previous papers (1) except that flotation densities are now more satisfactory since we have used hexafluorobenzene (d_4^{20}, 1.63) – hexane mixtures as flotation media. Most organic substances are insoluble in this system and less trouble is encountered in removal of bubbles by centrifugation.

The solid dielectric constant measurement of dicyclohexylmercury was complicated by the tendency of the sample (prepared by reduction of cyclohexylmercuric bromide by means of hydrazine hydrate in ether) to decompose to mercury, cyclohexane, and cyclohexene in air. It was found that the sample was stable in air at 25° for 60 hours if 2% of 2,5-di-*tert*-butylhydroquinone was intimately incorporated with it. The dielectric constant and density were measured for this mixture and then corrected for the corresponding constants of the antioxidant.

The extrapolation plots of wafer thickness versus apparent dielectric constant for *trans*-2,2,4,4-tetramethylcyclobutane-1,3-diol (A), dicyclohexylmercury (B), *m,m'*-dinitrobimesityl (C), dimesitylmercury (D), and *m,m'*-dinitrobiphenyl (E) have been selected as typical of the 58 entries of Table I, and are shown in Fig. 3.

Physical Measurements of Solutions

The total polarizations recorded in Table III were determined by methods outlined previously (1). Acceptance of a result was dependent on the correlation of $V_{solvent}$ and $\epsilon_{solvent}$ with extrapolated value of V and ϵ when apparent V and ϵ for the several concentrations fitted an extrapolatable straight line. Typical extrapolations of specific volume (V) and dielectric constant (ϵ) are shown for *m,m'*-dinitrobiphenyl (A) and dinitrobimesityl (B) in Fig. 4.

EFFETS STÉRÉOÉLECTRONIQUES DANS LA DÉSAMINATION NITREUSE DES *tert*-BUTYL-4 AMINOMÉTHYL-1 CYCLOHEXANOLS *cis* ET *trans*

H. FAVRE ET D. GRAVEL[1]
Département de Chimie, Université de Montréal, Montréal, Qué.
Reçu le 31 Août, 1962

RÉSUMÉ

La désamination nitreuse du *tert*-butyl-4 aminométhyl-1 cyclohexanol *cis* (groupe —CH_2NH_2 axial) conduit à la *tert*-butyl-4 cycloheptanone (89%), à l'époxyde *cis* du *tert*-butyl-4 méthylène-1 cyclohexane (6%) et à la *tert*-butyl-4 cyclohexanone (5%). L'isomère *trans* (groupe —CH_2NH_2 équatorial) donne la cétone agrandie (79%), l'époxyde correspondant (20%) et la *tert*-butyl-4 cyclohexanone (1%). L'aminométhyl-1 cyclohexanol se comporte comme l'isomère *trans*. Ces résultats indiquent que tout se passe comme si le cours de la réaction dépendait de la conformation de départ du groupe —NH_2, avec comme intermédiaire un ion diazonium ou un ion carbonium reflétant la conformation de l'ion diazonium.

Dans une note récente nous signalions la présence d'époxyde de *tert*-butyl-4 méthylène-1 cyclohexane *cis* (VIII) à côté de la *tert*-butyl-4 cycloheptanone (IX) dans les produits de la désamination nitreuse du *tert*-butyl-4 aminométhyl-1 cyclohexanol *cis* (II*b*) (1). Nous retrouvons dans cette réaction le comportement stéréospécifique de deux amino-alcools à géométrie bien définie: l'amino-2 cyclohexanol *trans*, diéquatorial (Fig. 1: A, D = CH_2; B, C = H; E = OH), qui par désamination engendre le formyl cyclopentane (2) par migration d'un groupe méthylène, et l'amino-2β 5α-cholestanol-3α *trans*, diaxial (Fig. 1: B, E = CH_2; A, C = H; D = OH), qui engendre l'époxyde correspondant -2α,3α (3). Tout se passe comme si l'amine de départ engendrait un ion diazonium qui réagira par migration ou réaction du groupe *trans-dans un plan*. D'autres exemples sont donnés d'orientation du cours de la réaction par l'ion diazonium dans la réaction d'extension de cycle de Tiffeneau (4, 5).

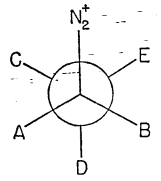

FIG. 1.

Il nous a paru intéressant de tenter de définir, pour la réaction de Tiffeneau, les facteurs stéréoélectroniques. Notre but était d'étudier principalement la formation des époxydes et de déterminer le rapport cétone agrandie-époxyde. Les *tert*-butyl-4 aminométhyl-1 cyclohexanols *cis* et *trans* (II*b*) et (II*a*) nous ont paru particulièrement appropriés à cette fin: la symétrie de ces molécules fait qu'il ne se formera qu'un époxyde dans chaque cas, et une seule et même cétone agrandie pour lesquels la chromatographie en phase gazeuse offre d'intéressantes possibilités de dosage. De plus, la présence stabilisatrice du groupe *tert*-butyle (6) assure la présence d'un groupe aminométhyle axial dans l'isomère *cis* et équatorial dans l'isomère *trans*,[2] ce qui nous semble couvrir les aspects conformationnels

[1]*Boursier du Conseil National de Recherches du Canada, 1958–1962.*
[2]*Nous avons adopté comme configurations cis et trans les relations spatiales entre les substituants carbonés.*

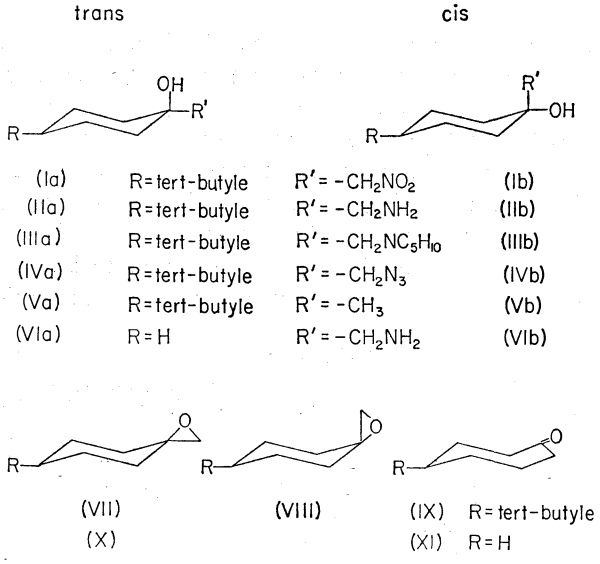
principaux de la réaction de Tiffeneau. Pour fins de comparaison, nous avons repris l'étude de la désamination nitreuse de l'aminométhyl-1 cyclohexanol (7), pour laquelle un mécanisme mettant en jeu un ion carbonium était avancé (8).



RÉSULTATS

Nous avons déjà montré (1) que l'action du nitrométhane sur la *tert*-butyl-4 cyclohexanone en présence d'éthylate de sodium conduisait aux deux nitro-alcools isomères I*a* et I*b*: l'isomère *cis* I*b*, p.f. 86–87°, constitue 95% environ du mélange et s'isole très facilement par cristallisation; sa réduction conduit à l'amino-alcool *cis* II*b*, caractérisé comme chlorhydrate, p.f. 235–236° (décomp.). Le nitro-alcool *trans* I*a*, p.f. 56–57°, fut isolé des nitro-alcools bruts après de nombreuses cristallisations.

Nous montrons dans ce mémoire que le nitro-alcool *trans* se réduit en amino-alcool de même configuration II*a*, dont le chlorhydrate fond à 254–255° (décomp.). Il est évident que le passage par le nitro-alcool I*a* ne convenait pas à la préparation de grandes quantités d'amino-alcool *trans*. Cross et Whitham (9) ayant fait une brève mention que le mélange des époxydes VII et VIII obtenu par l'action de l'acide perbenzoïque sur le *tert*-butyl-4 méthylène-1 cyclohexane était riche en époxyde *trans* VII, nous avons vu dans ce mélange un produit de départ convenable pour la synthèse de l'amino-alcool *trans* II*a*. En traitant en effet ce mélange d'époxydes par l'azoture de sodium, puis en réduisant sur platine le mélange des azido-alcools IV*a* et IV*b* nous avons obtenu un mélange des amino-alcools *cis* II*b* et *trans* II*a* duquel il est facile, par cristallisation, d'isoler le *tert*-butyl-4 aminométhyl-1 cyclohexanol *trans* (II*a*), dont le chlorhydrate fond à 254–255° (décomp.).

Le mélange des époxydes VII et VIII fut réduit par l'hydrure de lithium et d'aluminium en un mélange des méthyl-1 *tert*-butyl-4 cyclohexanols *cis* (V*b*) et *trans* (V*a*) connus (10, 1, 11, 12) contenant 70% d'isomère *trans* selon l'analyse par chromatographie en phase gazeuse. Cette technique montre que le mélange des époxydes VII et VIII est également de 30.4–69.6%, ce qui nous permet d'attribuer à ces composés les configurations *cis* et *trans*: c'est donc bien, comme le mentionnent Cross et Whitham (9), l'époxyde *trans* qui se forme en prépondérance.

For personal use only.

Les désaminations nitreuses furent réalisées selon le procédé décrit par Tchoubar (7), soit l'action *in situ* d'acide nitreux sur l'amino-alcool en solution dans de l'acide acétique aqueux 25%. Deux méthodes analytiques ont été employées pour doser les époxydes: (*a*) chromatographie en phase gazeuse et (*b*) isolement des pipéridino-alcools issus des époxydes.

(*a*) Le mélange brut des composés neutres issus de la désamination nitreuse des amino-alcools II*a*, II*b* et VI*a* a été chromatographié en phase gazeuse: le chromatogramme montre bien séparés la cétone agrandie (soit IX, soit XI) et l'époxyde semicyclique (VII, VIII ou X). La présence d'un troisième composé est, de plus, décelée. Au départ des *tert*-butyl-4 aminométhyl-1 cyclohexanols *cis* et *trans* il s'agit de la *tert*-butyl-4 cyclohexanone, qui fut isolée et caractérisée par son point de fusion et son spectre infrarouge. La désamination nitreuse de l'aminométhyl-1 cyclohexanol engendre de la cyclohexanone, caractérisée par chromatographie en phase gazeuse par la technique du rehaussement des pics (13, p. 27). Les valeurs quantitatives sont rapportées au Tableau I.

TABLEAU I

Résultats qualitatifs et quantitatifs des désaminations nitreuses des *tert*-butyl-4 aminométhyl-1 cyclohexanols *cis* et *trans* et de l'aminométhyl-1 cyclohexanol

Produit de départ	Méthode*	Époxyde	Cétone agrandie	Cétone de rétrogradation
tert-Butyl-4 aminométhyl-1 cyclohexanol *cis*	Chim.	VIII 5.5%	—	—

*Chim.: méthode chimique, par pesée des pipéridino-alcools issus des époxydes. Chrom.: par dosage par chromatographie en phase gazeuse.
†*tert*-Butyl-4 cyclohexanone.
‡Cyclohexanone.
§Les valeurs trouvées par chromatographie en phase gazeuse sont précises à ±1–2%.

(*b*) Les époxydes, dans la série *tert*-butylée, ont aussi été dosés gravimétriquement par la formation et l'isolement des pipéridino-alcools III*a* et III*b* (1). Les résultats sont très satisfaisants et concordent avec ceux obtenus par chromatographie en phase gazeuse, mais la méthode est extrêmement laborieuse.

Nous avons cherché à mettre en évidence le diol décrit par Tchoubar (7), mais sans succès. Nous sommes en mesure d'affirmer qu'il ne se forme pas comme produit primaire de la réaction. Nous avons par contre isolé, dans la désamination de l'amino-alcool II*b*, un composé azoté, p.f. 216–218°, dont la constitution n'a pas été élucidée; comme il ne se forme qu'en très petite quantité (2.6% environ) sa présence dans les produits de désamination n'altère pas la validité de nos dosages.

DISCUSSION

Il ressort clairement des résultats rapportés au Tableau I qu'il existe une différence appréciable dans les rapports cétone agrandie-époxyde entre les *tert*-butyl-4 aminométhyl-1 cyclohexanols *cis* et *trans*. Il apparait aussi que l'aminométhyl-1 cyclohexanol,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

en donnant une proportion d'époxyde de 20%, réagit à la manière du *tert*-butyl-4 aminométhyl-1 cyclohexanol *trans*, donc avec le groupe aminométhyle en conformation équatoriale: on pouvait prévoir que l'aminométhyl-1 cyclohexanol allait exister plutôt sous la conformation VI*a* que VI*b*, le groupe $—CH_2NH_3^+$ axial amenant une plus grande énergie d'interactions non liées que le groupe —OH axial (valeurs A: —OH = 0.8 (6), $—CH_2CH_3$ = 1.86 (14) kcal/mole; le groupe $—CH_2NH_3^+$ est en effet l'isostère du groupe $—CH_2CH_3$).

Les différences entre les *tert*-butyl-4 aminométhyl-1 cyclohexanols *cis* et *trans* sont de deux ordres: l'isomère *trans* donne environ trois fois plus d'époxyde que l'isomère *cis*; l'isomère *cis* conduit à 5% de *tert*-butyl-4 cyclohexanone (cétone de rétrogradation formée par perte d'un atome de carbone), tandis que l'isomère *trans* en donne 1%.

Le schéma de la désamination nitreuse semble bien établi (15) jusqu'à l'ion diazonium:

$$R—NH_2 \rightarrow R—NHNO \rightarrow R—N{=}NOH \rightarrow R—N_2^+ \rightarrow R^+$$

$$\searrow \quad \swarrow$$

produits

Ensuite, pour la formation même des produits de réaction, certains travaux (4, 5, 16, 17) permettent d'avancer l'ion diazonium, certains travaux par contre justifient l'ion carbonium (18, 19, 20, 21) comme source première.

Nous retiendrons, au début de cette discussion, l'ion diazonium pour engendrer les produits de réaction et par le fait même la théorie des "4 centres *trans-dans un plan*". Nous sommes de plus enclins à suivre Streitwieser (17) dans ses conclusions, à savoir que la réaction est amorcée par le départ d'une molécule d'azote qui entraîne à sa suite le centre D (Fig. 1) qui migre, plutôt que par l'attaque, par le centre D, du carbone porteur de l'ion diazonium pour en libérer la molécule d'azote.

Donc, en accord avec le principe de la migration *trans-dans un plan*, XV et XVI (équiprobables) donneront la cétone agrandie par migration d'un lien $C—CH_2$ et XIV fournira l'époxyde par migration d'un doublet électronique du groupe OH et élimination d'un proton. Si les trois conformères XIV, XV et XVI étaient équiprobables, il y aurait formation de 66.6% de cétone agrandie et de 33.3% d'époxyde.[3] L'examen des formules XII et XIII, combiné à celui des formules XIV à XVI, nous montre que les trois rotamères XIV, XV et XVI ne peuvent être équiprobables. En effet si l'on admet que les groupes NH_3^+ occupent le même volume qu'un groupe méthyle, on trouve, d'après les travaux d'Allinger et Shih-En Hu (14) sur l'éthylcyclohexane, que dans l'isomère *trans* (XII) les conformations XV et XVI sont favorisées par rapport à XIV par une différence d'énergie de 0.9 kcal. Cette différence d'énergie entre 0° et 27° donne d'après la formule de distribution des populations ($-\Delta F = 2.3\ RT \log K$) de 19 à 22% pour XIV et de 78 à 81% pour XV et XVI prises ensemble. L'expérience (voir Tableau I) montre que la désamination nitreuse de l'amino-alcool *trans* II*a* conduit en fait à 20% d'époxyde VII. Par le même raisonnement, pour l'isomère *cis* II*b* la population XIV (équivalente à XIII; D = NH_3^+ ou N_2^+; E, F, = —H) est à toute fin pratique inexistante, parce que de très haute énergie comparée aux populations XV et XVI. L'époxyde VIII ne devrait pas se former dans ces conditions. Il s'en forme pourtant 6%.

Pour expliquer cette formation un remplacement de type frontal du groupe N_2^+ par le groupe —OH de la molécule à la manière de la molécule d'eau avancée par Mills dans le cas de la rétention de configuration lors de la désamination nitreuse de certaines amines

[3]*Ce raisonnement n'est valable qui si les populations relatives des rotamères ne varient pas lorsque l'ion ammonium (l'amine) est transformé en ion diazonium.*

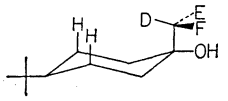
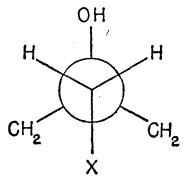
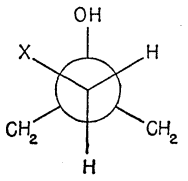
(XII)



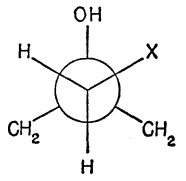
(XIII)



(XIV)



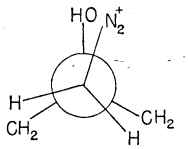
(XV)



(XVI)

(X=NH_3^+, NH_2, N_2^+)

alicycliques (16, 22) a retenu notre attention. Le diagramme XVII illustre les conditions stéréoélectroniques du remplacement de type frontal que nous postulons dans le cas de l'amino-alcool *cis* XIII.



(XVII)

Ce remplacement frontal serait rendu possible par le fait que l'ion diazonium libère une molécule d'azote neutre et qu'il n'y a donc pas d'opposition de charges de même nature comme dans les déplacements S_N2 par exemple, où les espèces, celle qui se fixe et celle qui quitte le carbone, sont toutes deux négatives et demandent nécessairement une attaque "par l'arrière". De plus, le lien carbone–azote dans l'ion diazonium est long et faible, diminuant de ce fait l'encombrement stérique causé par le groupe diazonium lors d'une attaque sur le carbone. Et enfin le groupe —OH est à proximité immédiate de cet ion diazonium, au moment même de sa formation.

Il suffirait donc que l'ion diazonium subisse une rotation ou une oscillation de 60° environ pour passer des conformations XV et XVI à la conformation XVII. Il y aurait alors compétition entre la migration *trans-dans un plan* du groupe —CH_2— (XV et XVI) et la substitution frontale par l'un des doublets de l'oxygène du groupe —OH (XVII). La formation de 6% d'époxyde indique que seulement 6% des populations XV et XVI subiraient cette rotation.[4] Streitwieser et Coverdale (22) admettent que le mécanisme de déplacement frontal de Mills explique très bien les résultats obtenus dans la désamination de la cyclohexylamine (D)-2 *cis*.

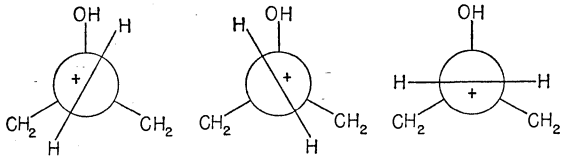
Comme nous venons de le montrer la conformation de l'ion diazonium semble être responsable de l'orientation de la réaction vers l'extension de cycle ou la formation de

[4]*Il se pourrait que les populations XV et XVI, par des oscillations, conduisent naturellement à la formation d'époxyde; une partie des 20% d'époxyde trans pourrait ainsi être formée de cette manière. Il faudrait nécessairement admettre que la formation de l'époxyde serait plus lente que celle de la cétone agrandie.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

l'époxyde. De cette façon, les migrations seraient contrôlées par la conformation de moindre énergie de la molécule. Cependant, Collins et ses collaborateurs ont, dans la série des diaryl-propanolamines et diaryl-propylamines, proposé un ion carbonium classique comme intermédiaire donnant directement naissance aux produits de la réaction (18, 23, 24). Cette théorie, tout en écartant les possibilités d'avoir des ions carboniums pontés et de l'assistance de la part de groupes voisins dans l'étape intermédiaire de la réaction, ne réfute cependant pas l'idée de l'ion diazonium et du mécanisme *pull–push* de Streitwieser (17). En effet, Benjamin et Collins (18) mentionnent dans un article que leurs conclusions reposent sur la *supposition* que "l'attaque *topside* par un groupe phényle dans la proportion de 26.5% doit nécessiter une rupture complète du lien carbone–azote qui en retour implique qu'un ion carbonium classique doit être formé". Il est intéressant de noter que la théorie de l'ion carbonium de Benjamin, Collins et collaborateurs (18, 23, 24) et Felkin (19) peut aussi conduire à la même interprétation de nos résultats que la théorie de l'ion diazonium.

L'ion diazonium se décomposant en ion carbonium plat, les conformations XV et XVI deviennent alors XVIII et XIX, qui par rotation peuvent conduire à XX.



(XVIII) (XIX) (XX)

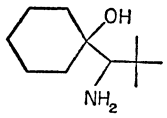
Dans le série *trans* les trois ions diazonium XIV (19–22%), XV (40%) et XVI (40%) engendreraient les ions carbonium XX, XVIII et XIX dans des rapports de 19–22, 40 et 40% qui réagiraient le premier pour donner l'époxyde, les deux autres pour donner l'agrandissement de cycle. Si le mécanisme en est un *topside* à la manière de Benjamin, Wilder et Collins (24) il n'y a strictement aucune différence entre le mécanisme par l'ion diazonium et ce mécanisme par ion carbonium. Dans la série *cis*, le rotamère XIV n'existant pas, il faudrait que 6% des rotamères XVIII et XIX tournent de 60° environ pour engendrer XX. Ce qui revient à dire que ce mécanisme de réaction est analogue à celui de Mills (16). Il est évident que les résultats obtenus dans ce travail ne permettent pas de trancher le noeud de l'épineuse question de savoir si l'intermédiaire véritable qui oriente et contrôle la réaction, est un ion diazonium ou un ion carbonium.

Il semble que tout se passe comme si l'ion diazonium agissait comme intermédiaire donnant directement naissance aux produits de réaction par un mécanisme de type concerté où la migration des groupes est contrôlée par les conformations de groupe ammonium (ou diazonium) dans la molécule. Ces conformations primaires peuvent être décelées par le truchement d'interactions non liées et peuvent servir à des fins de diagnostic et de prévision du cours que suivra la réaction.

Quant à la formation de cétone de rétrogradation, la divergence dans les pourcentages obtenus pour les isomères *cis* et *trans* (5% et 1%) nous paraît assez significative.

Elphimoff-Felkin et Gault (20) ont déjà observé la formation d'une quantité appréciable de cétone de rétrogradation (cyclohexanone) dans la désamination nitreuse de l'amino-alcool XXI. Ces auteurs expliquent ce résultat par un mécanisme faisant appel à un ion carbonium qui se réarrange, par analogie au cas de English et Bliss (25), qui ont observé des scissions dans les réactions de désamination nitreuse d'amino-alcools-1,3 aliphatiques.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



(XXI)

La formation de diazométhane (43%) a récemment été observée (26) dans la désamination nitreuse de l'aminométhyltriméthylsilane, dans lequel la liaison Si—CH_2NH_2 est faible; elle se brise lorsque l'amine est transformée en ion diazonium, probablement à cause du caractère fortement électrophile de celui-ci.

Ainsi un mécanisme selon lequel il y aurait formation de diazométhane nous paraît digne de mention, la différence dans la cétone de rétrogradation produite par chacum des amino-alcools *cis* II*b* et *trans* II*a* reflétant la décompression stérique plus grande dans le cas du groupe —CH_2—N_2^+ axial.

Remarque sur l'attribution des configurations cis–trans aux tert-butyl-4 aminométhyl-1 cyclohexanols IIb et IIa

La preuve de la configuration *cis* de l'amino-alcool II*b*, dont le chlorhydrate fond à 235–236° et que l'on prépare à partir du nitro-alcool I*b*, p.f. 86–87°, fut effectuée de la manière suivante (1). L'amino-alcool fut désaminé; le mélange de *tert*-butyl-4 cycloheptanone, de *tert*-butyl-4 cyclohexanone et d'époxyde fut réduit par l'hydrure de lithium et d'aluminium; le mélange des alcools secondaires et tertiaires résultant fut oxydé par l'acide chromique en un mélange d'alcool tertiaire et de cétones; par chromatographie sur alumine l'alcool tertiaire fut isolé et caractérisé comme *tert*-butyl-4 méthyl-1 cyclohexanol *cis*, par comparaison avec un échantillon authentique. Cette preuve de structure demande qu'il n'y ait aucun changement de configuration au cours des étapes: désamination, réduction et oxydation; c'est ce que nous avions admis (1).

Depuis la présentation de cette preuve nous avons repris l'étude de l'oxydation chromique des *tert*-butyl-4 méthyl-1 cyclohexanols *cis* et *trans* et nous avons constaté que, dans les conditions d'oxydation les deux alcools tertiaires subissent une certaine inversion de configuration: 29% d'inversion après 48 heures de contact et 37% après 72 heures pour l'isomère *cis*, 10% d'inversion après 72 heures pour l'isomère *trans*, tels que mis en évidence par chromatographie en phase gazeuse, sans compter la formation d'autres produits qui font présentement l'objet d'une étude particulière.

Devant ces résultats, qui auraient pu invalider la preuve de configuration présentée, nous avons repris la preuve en mettant en œuvre l'isomère *cis* et en omettant l'étape ambigüe qu'est l'oxydation, c'est-à-dire en analysant par chromatographie en phase gazeuse le mélange brut des alcools secondaires et tertiaires issu de la réduction: le chromatogramme montre l'absence totale d'alcool tertiaire *trans*, la présence de l'alcool tertiaire *cis* à côté des alcools secondaires. C'est donc bien le nitro-alcool de p.f. 86–87° et l'amino-alcool dont le chlorhydrate fond à 235–236° qui possèdent la configuration *cis*.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés en tubes capillaires, avec un thermomètre étalonné avec des substances pures de point de fusion connu en provenance du Bureau des Standards de Washington. Les spectres infrarouges ont été déterminés au moyen d'un spectrophotomètre Perkin–Elmer, modèl 21, optique NaCl. Les chromatogrammes en phase gazeuse ont été obtenus au moyen d'un chromatographe Burrell, modèle K2, sauf indication contraire; les colonnes utilisées ont toujours un diamètre intérieur de 6 mm; les conditions variables (température, adsorbant, longueur de la colonne) sont indiquées pour chaque chromatogramme. Du point de vue qualitatif, les pics ont été repérés sur les chromatogrammes par la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

méthode du rehaussement des pics avec des échantillons authentiques (13, p. 27). Du point de vue quantitatif, la méthode de triangulation fut mise en oeuvre (13, p. 33); nous avons vérifié par des mélanges appropriés que les surfaces mesurées correspondent bien aux pourcentages relatifs des composés analysés lorsque les fonctions étaient différentes, les conductivités thermiques pouvant être différentes. Les corrections qu'il faudrait apporter sont très petites: aussi ont-elles été négligées. Les résultats quantitatifs qui figurent dans ce travail en provenance de la méthode chromatographique en phase gazeuse sont donc les rapports des surfaces telles qu'elles apparaissent sur les chromatogrammes, sans corrections: les valeurs indiquées sont précises à ±1–2%. Les analyses centésimales sont de W. Manser, Ingénieur, Herrliberg, Suisse, et de C. Daesslé, Micro Analyses, Montréal.

(1) Chlorhydrate de tert-butyl-4 aminométhyl-1 cyclohexanol trans (IIa)

(1.1) Première méthode: par réduction du nitro-alcool trans Ia

En suivant fidèlement le mode opératoire décrit par Dauben *et al.* (27), on obtient à partir du nitro-alcool I*a*, p.f. 56–57° préparé selon la référence 1, 80 mg (78%) de chlorhydrate de *tert*-butyl-4 amino-éthyl-1 cyclohexanol (II*a*), paillettes incolores (méthanol–éther), p.f. 254–255° (décomp.). Calculé pour $C_{11}H_{24}ONCl$: C, 59.57; H, 10.91; N, 6.32%. Trouvé: C, 59.59; H, 10.99; N, 6.39%. Le point de fusion de ce chlorhydrate en mélange avec l'isomère *cis*, p.f. 235–236° (décomp.), décrit (1), est de 225–235°, avec décomposition partielle.

(1.2) Deuxième méthode: par réduction d'azido-alcools

(1.21) Époxydes cis et trans du tert-butyl-4 méthylène-1 cyclohexane (VIII et VII)

A 8.9 g de *tert*-butyl-4 méthylène-1 cyclohexane, préparé selon la référence 10, on ajoute d'un coup 157 ml d'une solution chloroformique d'acide perbenzoïque contenant 10.5 g de peracide. Le mélange s'échauffe et doit être refroidi sous le robinet. On ajoute un peu de sulfate de sodium anhydre et la fiole conique est déposée au réfrigérateur pendant 3 jours. La solution est filtrée et le filtrat lavé par une solution d'hydroxyde de sodium à 10%, une solution saturée de chlorure de sodium puis séché et évaporé. On obtient 9.5 g (96% brut) du mélange des époxydes *cis* et *trans* VIII et VII, p.é. 130° à 56 mm, n_D^{26} = 1.4590. Calculé pour $C_{11}H_{20}O$: C, 78.51; H, 11.98. Trouvé: C, 78.26; H, 11.61%.

L'analyse du produit brut par chromatographie en phase gazeuse, sur une colonne de 1 m contenant 15% de β,β′-oxydipropionitrile, adsorbé sur du Chromosorb-W, a donné à 136° deux pics. Le premier représente l'isomère *trans*, 69.6% du mélange, le deuxième l'isomère *cis*, 30.4%.

Les configurations *cis–trans* ont été établies par réduction du mélange des époxydes en méthyl-1 *tert*-butyl-4 cyclohexanols *cis* (V*b*) et *trans* (V*a*) connus (10, 1, 11, 12).

A une suspension agitée de 113 mg d'hydrure de lithium et d'aluminium dans 5 ml d'éther anhydre, on ajoute une solution de 500 mg du mélange des époxydes VII et VIII dans 10 ml d'éther. La solution est ajoutée goutte à goutte de façon à maintenir un léger reflux de l'éther. Le mélange est chauffé à reflux pendant 30 minutes, puis le complexe décomposé par addition à 0° de 1 ml d'eau, suivi de 5 ml d'une solution aqueuse d'acide sulfurique à 10%. Le mélange est extrait par de l'éther et la solution éthérée lavée par une solution de bicarbonate de sodium à 10%, de l'eau saturée de chlorure de sodium puis, séchée sur du sulfate de sodium anhydre et évaporée à travers une colonne de Widmer. On isole une huile incolore, 452 mg (90%), qui cristallise après quelques instants. L'analyse du produit brut par chromatographie en phase gazeuse, sur une colonne de 1 m contenant 13% de β,β′-oxydipropionitrile adsorbé sur Kromat F.B., a donné à 135° deux pics. Le premier correspond à 70% de méthyl-1 *tert*-butyl-4 cyclohexanol *trans* (V*a*), le deuxième correspond à 30% de l'isomère *cis* (V*b*). Nous en concluons que l'époxyde représentant 69.6% du mélange est l'isomère *trans* (VII) et que celui représentant 30.4% est l'isomère *cis* (VIII).

(1.22) tert-Butyl-4 azidométhyl-1 cyclohexanols cis (IVb) et trans (IVa)

Une solution de 2 g du mélange des époxydes VIII et VII préparé plus haut, dans 30 ml de méthanol, est chauffée à reflux. On y ajoute goutte à goutte 1.6 g d'azoture de sodium en solution dans 4 ml d'eau. La solution se colore en jaune dès le début de l'addition. Le mélange est agité et chauffé à reflux pendant 3 jours et 20 heures. Le méthanol est évaporé sous vide sur un bain d'eau à 40°. On isole un semi-solide blanc. Ce résidu est repris par de l'éther et la solution éthérée lavée par de l'eau distillée jusqu'à neutralité, séchée sur du sulfate de sodium anhydre et évaporée, à travers une colonne de Widmer.

On obtient 2.2 g d'une huile jaune dont la distillation fournit 2.07 g (83%) du mélange des *tert*-butyl-4 azidométhyl-1 cyclohexanols *cis* et *trans* (IV*b* et IV*a*), p.é. 138° à 13 mm, n_D^{21} = 1.4868. Spectre infrarouge (liquide pur): 3420 cm^{-1}; vibration O—H, lié; 2110 cm^{-1}: vibration —N═N═N (asymétrique); 1290 cm^{-1}; vibration —N═N═N (symétrique).

(1.23) tert-Butyl-4 aminométhyl-1 cyclohexanol trans (IIa)

Un gramme du mélange des azido-alcools IV*a* et IV*b* préparé plus haut, en solution dans 100 ml de méthanol, est hydrogéné en présence de 100 mg d'oxyde de platine sous une pression de 3.4 atm. Après 24 heures, le mélange est filtré et le filtrat acidifié par addition de 6 ml d'acide chlorhydrique concentré, puis évaporé sous vide sur un bain d'eau à 50°. On isole un solide blanc qui après lavage à l'éther pour enlever les neutres donne 710 mg (67.8%) du mélange des chlorhydrates des deux amino-alcools *cis* II*b* et *trans* II*a*. Après deux recristallisations dans un mélange méthanol–éther on isole 251 mg (23.9%) du chlorhydrate du

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

tert-butyl-4 aminométhyl-1 cyclohexanol trans (II*a*), p.f. 251–252° (décomp.), ne donnant pas de dépression de point de fusion en mélange avec l'échantillon préparé en (1.1).

(2) Désaminations nitreuses des amino-alcools IIa et IIb

(2.1) Dosage des époxydes par la méthode chimique

(2.11) Désamination du tert-butyl-4 aminométhyl-1 cyclohexanol trans (IIa)

A 940 mg du chlorhydrate de l'amino-alcool *trans* II*a*, en solution dans 20 ml d'eau, on ajoute 5.0 ml de soude 1.0 *N* pour libérer l'amine de son sel et 9.2 ml d'acide acétique glacial, ce qui donne une solution de l'amino-alcool dans l'acide acétique à 25%. La petite quantité de chlorure de sodium ne nuit pas à la réaction. Le mélange est refroidi à 0° et une solution de 0.88 g de nitrite de sodium dans 3.5 ml d'eau est ajoutée, goutte à goutte, en 45 minutes. Le mélange est ensuite agité à 0° pendant 2 heures, puis neutralisé par addition d'une solution d'hydroxyde de sodium à 20%, sans que la température ne s'élève au dessus de 0°. On cesse l'addition de la soude au moment où l'amino-alcool qui n'a pas réagi commence à se séparer sous forme de précipité blanc. On ajoute assez d'acide acétique glacial pour redissoudre le précipité puis 15 gouttes en excès. La solution légèrement acide est extraite par de l'éther. On obtient une solution aqueuse acide A et une solution éthérée B. La solution éthérée est lavée par une solution aqueuse de bicarbonate de sodium à 5%, par de l'eau saturée de chlorure de sodium puis séchée et évaporée à travers une colonne de Widmer. On obtient une huile jaune pesant 672 mg (94%), qui est reprise par 10 ml de méthanol et 1 ml de pipéridine puis chauffée à reflux pendant 2 heures. Le solvant est évaporé sous vide à 50° et le résidu repris par 100 ml d'éther anhydre. Cette solution éthérée est lavée par de l'eau jusqu'à neutralité, puis, extraite par trois portions de 10 ml d'acide chlorhydrique aqueux à 10%.

On examine séparément les solutions aqueuses acides (C) et la solution éthérée (D). Les solutions aqueuses acides (C) réunies sont évaporées sous vide (11 mm). On obtient 327 mg de chlorhydrate brut, qui par cristallisation dans un mélange méthanol–éther fournit le chlorhydrate de *tert*-butyl-4 pipéridinométhyl-1 cyclohexanol *trans*, p.f. 254–255° (décomp.). Calculé pour $C_{16}H_{32}ONCl$: C, 66.29; H, 11.13; N, 4.83%. Trouvé: C, 66.23; H, 11.22; N, 4.78%. Le spectre infrarouge du chlorhydrate brut montre une bande double à 1596 et 1620 cm^{-1}, correspondant à une fonction $—NH_3^+$ provenant du chlorhydrate de l'amino-alcool de départ II*a*; le mélange brut (327 mg) contient 75% et 25% des chlorhydrates de pipéridino-alcool III*a* et d'amino-alcool de départ II*a* respectivement. La solution éthérée (D) est lavée par une solution de bicarbonate de sodium (10%), par de l'eau saturée de chlorure de sodium, puis séchée et évaporée. On obtient ainsi 391 mg de *tert*-butyl-4 cycloheptanone brute (bande à 1705 dans le spectre infrarouge).

Les eaux-mères acides (A) obtenues plus haut sont rendues très alcalines par addition d'une solution d'hydroxyde de sodium à 20% et extraites par du chloroforme. L'extrait est lavé par de l'eau jusqu'à neutralité, puis l'amino-alcool II*a* en est extrait par trois lavages par de l'acide chlorhydrique aqueux à 10%. Les solutions d'acide chlorhydrique sont réunies et évaporées sous vide (11 mm), à 50°, pour abandonner 98 mg du chlorhydrate de l'amino-alcool II*a* qui n'a pas réagi, identifié par son spectre infrarouge.

Bilan de la réaction.—Des 940 mg de chlorhydrate de l'amino-alcool II*a* mis en réaction, 82 mg ont été récupérés en C et 98 en A. Les 760 mg d'amino-alcool II*a* qui ont effectivement réagi ont donné: 245 mg de pipéridino-alcool.HCl III*a* obtenus en C, soit 24.5% correspondant à autant d'époxyde *trans* VII, et 391 mg de *tert*-butyl-4 cycloheptanone isolée en D, soit 67.8%. Dans un deuxième dosage nous avons obtenu: 18.3% d'époxyde et 82% de *tert*-butyl-4 cycloheptanone.

(2.12) Désamination du tert-butyl-4 aminométhyl-1 cyclohexanol cis (IIb)

Par la méthode de dosage décrite en (2.11) nous avons obtenu à partir de 1.2 g du chlorhydrate de l'amino-alcool II*b*: 70.3 mg d'amino-alcool II*b* non entré en réaction, 82 mg (5.5%) du chlorhydrate du pipéridino-alcool III*b*, *cis*, correspondant à autant d'époxyde *cis* VIII, et 768 mg (89.3%) de cétone caractérisée comme *tert*-butyl-4 cycloheptanone dans un travail précédent (1); dans ce travail (1) nous avons également caractérisé le chlorhydrate du pipéridino-alcool III*b*. Nous montrons plus loin, à la section (2.21), que la *tert*-butyl-4 cycloheptanone décrite ici contient en fait de la *tert*-butyl-4 cyclohexanone, mais il n'est pas possible de la déceler par ce mode opératoire.

Deux autres essais ont donné 6.1 et 5.7% de chlorhydrate de pipéridino-alcool *cis* III*b*, correspondant à autant d'époxyde *cis* VIII.

(2.2) Dosage des époxydes par chromatographie en phase gazeuse

(2.21) Méthode expérimentale de la désamination nitreuse

La méthode de désamination dans ce cas-ci, est un peu différente de celle rapportée en (2.11). En effet, 1.5 g du chlorhydrate de l'amino-alcool, en solution dans 25 ml d'une solution aqueuse d'acide acétique à 25%, sont traités à 0° par un excès de nitrite de sodium (3 moles pour 1 mole d'amino-alcool) en solution à 25% dans l'eau.

Le mélange est agité à 0° pendant 2 heures, puis, neutralisé jusqu'à pH 10 par addition d'une solution de soude à 20%, sans que la température ne s'élève au dessus de 0°. Le mélange est extrait par de l'éther et la solution éthérée lavée par de l'eau saturée de chlorure de sodium, puis, séchée sur du sulfate de sodium anhydre et évaporée à travers une colonne de Widmer. On isole ainsi le produit brut de la réaction, en solution dans un peu d'éther. Les restes de l'éther ne sont pas évaporés sous vide afin de ne rien perdre des produits de la réaction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(2.22) Dosage des époxydes

L'analyse du produit brut de la réaction est faite par chromatographie en phase gazeuse. Le produit brut des désaminations en solution dans un peu d'éther fut chromatographié sur une colonne de 2.5 m contenant du Kromat F.B. fixant 20% de Polyester de Craig (succinate); température: 210°; débit d'hélium: 40 ml/min.

Les résultats qualitatifs et quantitatifs des désaminations sont les suivants:

Désamination de l'amino-alcool cis IIb

1er essai: A = 6.1% d'époxyde *cis* VIII
B = 4.6% de *tert*-butyl-4 cyclohexanone
C = 89.2% de *tert*-butyl-4 cycloheptanone (IX)

2ième essai: A = 4.6% d'époxyde *cis* VIII
B = 5.1% de *tert*-butyl-4 cyclohexanone
C = 90.3% de *tert*-butyl-4 cycloheptanone (IX)

Désamination de l'amino-alcool trans IIa

A = 20.0% d'époxyde *trans* VII
B = 1.2% de *tert*-butyl-4 cyclohexanone
C = 78.8% de *tert*-butyl-4 cycloheptanone (IX)

Les pics correspondant aux époxydes *cis* VIII et *trans* VII ont été repérés en ajoutant le mélange des époxydes VIII et VII préparé plus haut en (1.21) au mélange de désamination. Il n'y a pas d'inconvénient à ajouter le mélange des époxydes *cis* et *trans*, car il est peu résolu sur la colonne utilisée. Les pics correspondant à la *tert*-butyl-4 cyclohexanone et à la *tert*-butyl-4 cycloheptanone ont été repérés sur le chromatogramme par la méthode du rehaussement des pics (13, p. 27), la *tert*-butyl-4 cyclohexanone pure, p.f. 50.5–52.5°, et la *tert*-butyl-4 cycloheptanone préparée en (2.11) servant d'échantillons authentiques.

Désamination de l'aminométhyl-1 cyclohexanol (VI)

1er essai: A = 19.4% d'époxyde X
B = trace (< 1%) de cyclohexanone
C = 80.6% de cycloheptanone (XI)

2ième essai: A = 20.0% d'époxyde X
B = trace (< 1%) de cyclohexanone
C = 80.0% de cycloheptanone (XI)

Par la méthode du rehaussement des pics (13, p. 27) nous avons repérés les composés A, B et C sur les chromatogrammes, l'époxyde étant préparé selon la méthode décrite en (1.21), la cycloheptanone et la cyclohexanone étant des échantillons commerciaux.

(2.23) Isolement de la tert-butyl-4 cyclohexanone des produits de la désamination nitreuse du tert-butyl-4 aminométhyl-1 cyclohexanol cis (IIb)

L'analyse par chromatographie en phase gazeuse, des produits de la désamination nitreuse de l'amino-alcool *cis* II*b*, montre qu'il y a environ 5% de *tert*-butyl-4 cyclohexanone de présent dans le mélange. L'analyse fut réalisée sur deux colonnes différentes: (*a*) 20% de Polyester de Craig (succinate) adsorbé sur du Kromat F.B.; longueur de la colonne: 2.5 m; température: 212°. (*b*) 30% d'huile de Silicone No. 550 adsorbée sur du Kromat F.B.; longueur de la colonne: 1 m; température: 195°.

Pour isoler la *tert*-butyl-4 cyclohexanone nous avons procédé de la manière suivante. Une désamination nitreuse fut réalisée sur 5.0 g du chlorhydrate de l'amino-alcool *cis* II*b*, à la façon décrite en (2.21). Le produit brut de la désamination est agité pendant la nuit avec 10 ml d'une solution aqueuse d'acide sulfurique à 1%, puis extrait par de l'éther. La couche éthérée est lavée par une solution de bicarbonate de sodium à 10%, par de l'eau saturée de chlorure de sodium puis séchée sur du sulfate de sodium anhydre et évaporée à travers une colonne de Widmer. On isole ainsi 3.6 g de mélange brut.

L'analyse par chromatographie en phase gazeuse montre deux pics, *tert*-butyl-4 cyclohexanone et *tert*-butyl-4 cycloheptanone, confirmés par la méthode du rehaussement des pics (13, p. 27).

Le produit brut (3.6 g), en solution dans 200 ml d'éther de pétrole (p.é. 30–40°), fut chromatographié sur 105 g d'alumine Fisher pour chromatographie. L'élution de la colonne donne: (*a*) par de l'éther de pétrole (p.é. 30–40°), 2.37 g d'une huile jaunâtre, constituée de 3.3% de *tert*-butyl-4 cyclohexanone et de 96.7% de cétone agrandie IX; (*b*) par un mélange éther de pétrole 90% – éther anhydre 10%, 0.46 g d'huile jaunâtre, constituée de 6.6% de *tert*-butyl-4 cyclohexanone et de 93.4% de cétone agrandie IX; (*c*) par un mélange éther de pétrole 50% – éther anhydre 50%, 0.06 g d'une huile avec un peu de solide; (*d*) par de l'éther anhydre, un mélange éther 95% – chloroforme 5% et un mélange éther 85% – chloroforme 15%, 0.15 g d'un solide blanc, p.f. 216–218°, après recristallisation dans du méthanol (fines aiguilles). La constitution de ce composé (trouvé: C, 68.25; H, 10.60; N, 9.47%) n'est pas connue.

Les fractions *a* et *b* sont réunies (2.83 g) et mises en solution dans 2 ml de méthanol. Le mélange est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

ensuite injecté dans un appareil de chromatographie en phase gazeuse Fisher Prep/Partitioner, modèle 24, dans les conditions suivantes: une colonne (50×5 cm) suivie de trois colonnes (50×2.5 cm), chargées de Columpak sur lequel est adsorbé 20% de Dow-Corning Silicone Fluid No. 200. Températures: colonnes, 150°; "flash-evaporator", 270°; cellule, 200°. Eluant: azote, 1.6 atm.

On sépare aisément: premièrement le méthanol, qui ne fut pas isolé; deuxièmement la *tert*-butyl-4 cyclohexanone, isolée sous forme de solide blanc, p.f. 47–49°, caractérisée par point de fusion mixte et spectre infrarouge; troisièmement la *tert*-butyl-4 cycloheptanone (IX), isolée sous forme d'huile incolore.

(3) Oxydations chromiques

Une solution de 100 mg de l'alcool tertiaire (V*a* ou V*b*) dans 2.5 ml d'acide acétique glacial est agitée en présence de 100 mg d'anhydride chromique pulvérisé, à la température du laboratoire (25–26°).

Le mélange est étendu d'eau puis d'éther et l'acide acétique neutralisé par addition de bicarbonate de soude en poudre. Les solutions éthérées sont lavées par de l'eau saturée de chlorure de sodium, réunies, séchées et évaporées jusqu'à environ 2 ml.

L'analyse par chromatographie en phase gazeuse à 135° sur une colonne de 1 m contenant 13% β,β'-oxydipropionitrile adsorbé sur du Kromat F.B., montre les résultats suivants:

Alcool	Temps de contact	Alcool *cis* V*b*	Alcool *trans* V*a*
trans V*a*	70 heures	10%	90%
cis V*b*	70 heures	63%	37%
cis V*b*	47 heures	71%	29%

REMERCIEMENTS

Nous exprimons nos remerciements au Conseil National des Recherches du Canada, pour une bourse (D. G.) et un octroi de recherches (H. F.), ainsi qu'aux Etablissements Dow Chemical of Canada Limited, Montréal, pour la quantité généreuse de *tert*-butyl-4 cyclohexanone mise à notre disposition.

Received January 25, 1963

ABSTRACT

The effect of electric fields on the γ-radiolysis of ethane, propane, and the butanes has been investigated briefly at 800 mm pressure, with dose rates between 2×10^{10} and 400×10^{10} ev/cc sec. Yields of hydrogen were reduced when a saturation field was applied, except with ethane at low dose rate, where a slight increase in hydrogen yield was observed. With propane and *n*-butane, the yield of hydrogen in the presence of a saturation field was independent of dose rate, while with ethane, it decreased with decreasing dose rate. At the same time, a dose rate dependence was discovered in the simple radiolysis, in the absence of any field, of ethane, propane, and *n*-butane, a decrease in the yield of hydrogen at low dose rates being observed. An explanation of these observations is suggested in terms of a competition between neutralization of ions in the gas phase and diffusion of ions to the wall. High dose rates should favor the former process, and low dose rates the latter. At sufficiently high dose rates, all ions should be neutralized in the gas phase. At sufficiently low dose rates, all ions should diffuse to the wall before neutralization, and it is suggested that the radiolysis under these conditions should closely resemble that in the presence of a saturation field at higher dose rates.

The application of an electric field to a gas during irradiation offers a potential means of distinguishing between products arising from ions and those formed from neutral species. In practice, the interpretation of the results is very complex, and except for the work of Essex and his collaborators at Syracuse (1), mostly concerned with α-radiation, the method has not been widely used in radiation chemistry. The present work was undertaken to study the effects of electric fields on the γ-radiolysis of some simple hydrocarbon gases, using a saturation-current method (2) to measure absolute product yields. In the course of the work, a hitherto unsuspected dependence of hydrogen yield on dose rate was discovered, which appears to be closely related to the action of applied fields on the radiolysis.

EXPERIMENTAL

The preparation and purification of hydrocarbon samples for irradiation have been previously described (2, 3). Gases were irradiated in cylindrical vessels of 60-mm o.d. and about 500- to 600-cc volume. Two experiments with propane were done in a smaller vessel of the same design and length, but with about one-half the diameter and one-quarter the volume. The measurement of saturation ion current and of hydrogen yield has been described (2). Electric fields were always applied with the central electrode positive, so that the positive ions were drawn to the other electrode, the graphite-coated wall of the cylindrical vessel. Hydrogen was the only product measured, and the extent of decomposition was always small enough that "internal" scavenging was negligible, and the measured yields were very close to their true initial values (3). Ethylene scavenger was added in some experiments, in which case the hydrogen yield was extrapolated to zero scavenger concentration (3).

Two Co^{60} γ-ray sources were used, one of about 200 c,* the other a 1300-c A.E.C.L. "Gammacell". By a suitable choice of distance from the source, or appropriate shielding, dose rates varying from about 2×10^{10} to 300×10^{10} ev/cc sec were obtainable.

RESULTS AND DISCUSSION

Tables I to IV summarize the hydrogen yields from the radiolysis of ethane, propane, *n*-butane, and isobutane, measured under a variety of conditions of dose rate, electric field, and added scavenger. The dose rate in each case was calculated from the measured saturation current, combined with values of W of 24.9 for ethane, and 24.0 ev/ion pair for propane and the butanes (2). Values of M/N were obtained directly from the measure-

ments of saturation ion current and hydrogen production, while G-values were calculated from M/N via W. The experiment numbers in these tables are assigned arbitrarily, for reference purposes, and do not signify the order in which the experiments were done. In some instances, a single experiment number represents an average of several measurements.

Figure 1 shows the effect of an electric field on the yield of hydrogen from the radiolysis of n-butane at an approximately constant dose rate of about 11×10^{10} ev/cc sec. The

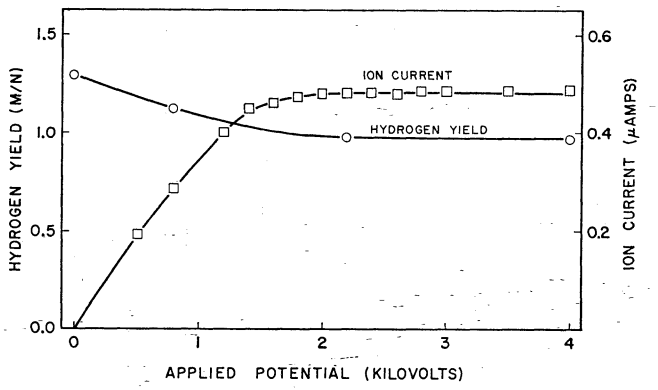

FIG. 1. The effect of electric fields on the yield of hydrogen from the γ-radiolysis of n-butane.

dependence of ion current on the applied voltage is also shown for comparison. It should be noted that in computing M/N for experiments at voltages below saturation, N was always the saturation value. The decrease in the hydrogen yield is seen to have parallelled the rise in the ion current, becoming constant in the saturation region. This behavior suggests that the effect of the field was simply associated with the removal of ions to the cathode, and became constant when this removal was complete. The lack of change in the saturation region shows that electron impact by electrons accelerated in the field was not contributing to the hydrogen production up to the highest voltages used. Similar data for isobutane may be seen in Table IV. Propane and ethane were studied only with saturation fields, somewhat above the minimum voltage required for saturation. This minimum voltage increased steadily in going from ethane to propane to butane, presumably due to differences in rates of diffusion of ions in the three gases. It also depended somewhat on the diameter of the central anode, which in several of the radiolysis vessels consisted of graphite-coated 5 mm o.d. Pyrex tubing instead of the 1.5-mm tungsten wire used in the original vessel (2). Slightly lower minimum voltages were required for saturation with the thicker central electrode, and the saturation current plateaus were perfectly

For personal use only.

flat, eliminating the very slight increase in ion current evident in Fig. 1, which was presumably due to slight electron multiplication effects caused by the high local field strength immediately surrounding the tungsten wire.

In Fig. 2, the dependence of hydrogen yield on the $\log_{10}$ of the dose rate is shown for the radiolysis of ethane, propane, and *n*-butane, with no field applied. With propane and

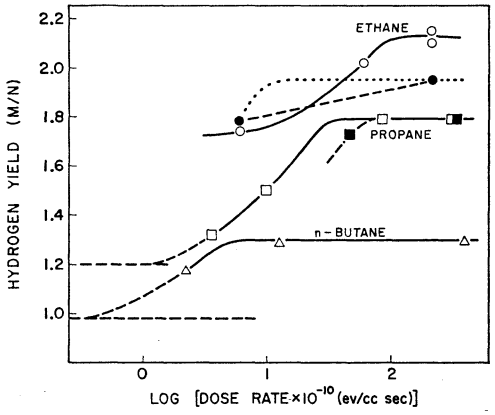

FIG. 2. The effect of dose rate on the yields of hydrogen from the γ-radiolysis of ethane, propane, and *n*-butane: ●, ethane with saturation field; ○, ethane with no field; □, propane with no field; ■, propane in small reaction vessel, with no field; △, *n*-butane with no field.

butane, the hydrogen yield was independent of dose rate at high dose rates, but showed a progressive decrease with decreasing dose rate at lower dose rates, with a maximum decrease of about 25% observed with propane at the lowest dose rate studied. Ethane showed a similar decrease, but a constant yield at high dose rate was not attained. The curves in Fig. 2 have been drawn, not as the simplest curves through the experimental points, but as will be seen shortly, to support a particular interpretation of the data.

With propane, *n*-butane, and isobutane, the application of a saturation field caused a marked reduction in the yield of hydrogen. With propane and *n*-butane, the values of these reduced yields of hydrogen were practically independent of dose rate (expts. 17–19, 23, 25–26), an observation which suggests a very simple explanation of the dose rate dependence in the absence of a field. With no applied field, neutralization may occur in the gas phase or at the surface of the vessel. Neutralization in the gas phase should be second order in ions, while diffusion to the wall is a first-order process, so that high dose rate, and consequent high ion concentration, should favor the former, and low dose rate the latter. In the one limit, at sufficiently high dose rate, gas phase neutralization should become fast enough that no ions reach the wall before being neutralized. In the other limit, at sufficiently low dose rate, all the ions should diffuse to the wall before appreciable neutralization can occur in the gas phase. If, as the effect of applied fields suggests, the hydrogen yield is lowered when ions are neutralized at the wall, then a sigmoid dependence of hydrogen yield on dose rate should be observed, with plateaus independent of dose rate at sufficiently high and low dose rates. Furthermore, if the effect of a saturation field is simply one of removing ions to the surface before neutralization, then the lower plateau should coincide with the dose-rate-independent hydrogen yield in the presence of a saturation field. The curves for propane and *n*-butane in Fig. 2 have been drawn in accordance with this hypothesis.

All the results obtained with propane and *n*-butane are, as far as they go, in agreement

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

with this simple explanation, although with neither gas was a lower plateau reached. The experiments with isobutane were done at constant dose rate, and so are no test of the theory. The results obtained with ethane are somewhat embarassing to the suggested explanation. The hydrogen yields from ethane measured in the absence of a field follow a sigmoid curve (Fig. 2), although neither an upper nor a lower plateau was reached. The hydrogen yield in the presence of a saturation field, however, was not independent of dose rate, and at the lowest dose rate, the application of a saturation field actually increased the hydrogen yield. This increase was barely within the accuracy of the measurements, but a similar increase was also found in the presence of scavenger (expts. 7–10), and it is interesting that Williams and Essex, using α-rays, found an increased yield of ethane decomposition when a field was applied (4).

Two explanations of the deviation of ethane from the simple theory seem possible. The first is that ethane is a special case, due to some peculiarity of the radiolysis mechanism, so that the hydrogen yield does not follow the simple behavior observed with propane and butane. The second explanation is that ethane is not a special case, but has merely been studied at dose rates low enough to show the fallacy of the simple theory, and that propane and butane would show similar deviations when studied at sufficiently low dose rates. Thus the hydrogen yield from ethane in the presence of a saturation field could follow the dotted curve in Fig. 2, and only the two experiments at the lowest dose rates would disagree with the simple theory.

In support of the suggested competition between gas phase neutralization and diffusion to the wall is the progressive shift of the sigmoid curves towards higher dose rate in going from butane to propane to ethane. Such a shift would be predicted by the dependence of the rate of diffusion on molecular weight of the medium, perhaps combined with larger cross sections for the neutralization of the larger ions; the same factors are reflected in the fact that a higher voltage was required for saturation in butane than in ethylene (2). Similar shifts of the sigmoid curves should also arise from a change in diameter of the radiolysis vessel, or from a change in pressure. Two experiments, 15 and 16, were done with propane in a smaller vessel, and the results are shown in Fig. 2 (filled squares). The vessel diameter was about one-half that of the regular vessels, so that the average distance of ions from the wall was roughly halved, and the rate of diffusion to the wall should have been approximately doubled. The results of these experiments are compatible with the expected shift towards higher dose rate, as the curves are drawn, but this is by no means conclusive.

Clearly, more data are required to determine the validity of the suggested explanation of the observed dependence on dose rate. The most obvious need is for further experiments at higher dose rates with ethane, and at lower dose rates for all three gases. Unfortunately, the lowest dose rates used are already becoming inconvenient: for example, at the lowest dose rate used with butane, 60 hours of irradiation yielded about 0.25 μmole of hydrogen. Keeping in mind that the scale in Fig. 2 is logarithmic, the extension of the present data much further towards lower dose rates begins to become impractical. A more hopeful approach would be to shift the sigmoid curves to higher, more convenient dose rates by working with lower pressures and smaller radiolysis vessels, which should favor diffusion to the walls.

Finally, if the suggested explanation of the present results proves correct, there are several interesting implications. The first of these is that in any study of the radiolysis of hydrocarbon gases, it is important to determine where the experiments lie on the dose rate dependence curve, keeping in mind that the sigmoid curve may be shifted by changes in molecular weight, pressure, and dimensions of the radiolysis vessel. There would seem

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

to be marked advantages, both practical and theoretical, in working at dose rates on the upper plateau, where neutralization occurs entirely in the gas phase. In this region, surface effects should be minimized, and the nature of the surface and the dimensions of the radiolysis vessel should have little influence on the measured yields. It might be noted that recent measurements of yields from the radiolysis of propane reported from this laboratory were made at dose rates well below the upper plateau (2).

A second implication is that the upper plateau of the dose rate dependence curve should also be the best region in which to study the effects of electric fields. The application of a saturation field should cause a change from neutralization entirely in the gas phase to neutralization entirely on the surface. Resultant changes in product yields should then be a maximum, and should permit the simplest possible interpretation in terms of a modification of the neutralization "cracking" reactions by their occurrence at a surface. In the present work, ethane, propane, *n*-butane, and isobutane showed, upon application of a saturation field in the high dose rate region, a loss of hydrogen of 0.18, 0.56, 0.33, and 0.40 molecule per ion pair. There is thus no obvious one-to-one correspondence between ions neutralized at the surface and loss of hydrogen. This may reflect an inefficiency in the quenching by the surface of the excited molecules formed by neutralization, or more probably means that not all ions yield hydrogen upon neutralization in the gas phase, with some undergoing dissociation of C—C bonds rather than splitting off H_2 or H. Loss of hydrogen atoms by reaction with the graphite electrode, following their formation by a neutralization reaction at the surface, is also a possibility. With *n*-butane, about 75% of the hydrogen lost when a saturation field was applied was "scavengeable" by ethylene, and presumably came from atomic hydrogen (expts. 21–23, 25, 26–28). The experiments with ethane in the presence of scavenger were not done in the upper plateau region of dose rate; the percentage change in hydrogen yield upon application of a saturation field was much the same as that found in experiments with pure ethane (Table I).

A further implication arises from a comparison of the rate of diffusion of ions to the wall, calculated from a simple random walk formula, with the rate of gas phase neutralization based on a recombination coefficient between 10^{-6} and 10^{-8} cc/sec (5). Despite the uncertainties of these calculations, it seems clear that the rate of diffusion of positive hydrocarbon ions to the wall is several orders of magnitude too slow to compete effectively with gas phase neutralization even at the lowest dose rates used in the present experiments. This implies that the diffusion of free electrons, which is many times faster than that of positive ions, must be the rate-controlling process in the competition (5, 6). Gas phase neutralization is prevented, of course, when the electrons reach the wall, even though the positive ions stay much longer in the gas phase. This conclusion is not unexpected, as it is known that saturated hydrocarbons do not readily form negative ions (7).

At the present time, there is almost nothing known about the modes of decomposition of the highly excited species that must be formed when a hydrocarbon ion is neutralized. Much more experimental work, using a variety of techniques, and with complete product analysis, will be required before much can be said about this very elusive phase of the radiolysis process.

ELECTRODE PROCESSES WITH A PRECEDING CHEMICAL REACTION: EFFECT OF THE DIFFUSE DOUBLE LAYER

S. K. RANGARAJAN
Central Electrochemical Research Institute, Karaikudi, India
Received December 10, 1962

ABSTRACT

The effect of migration in the diffuse double layer on the concentration field of the reactive species is analyzed assuming that the electrode reaction $O + ne \rightleftharpoons R$ is preceded by a chemical reaction $Y + \beta X \rightleftharpoons O$ ($Z_X = 0$). Comparison is made with the solutions derived already by Hurwitz and also by Matsuda for particular cases.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The influence of the migration in the diffuse double layer on the interfacial concentrations of the reactive species has been discussed in detail in a previous communication (1). Therein, it has been assumed that the reaction scheme is $O + ne \rightleftharpoons R$ with no preceding chemical reaction. (Specific adsorption will be assumed absent in the discussions.)

It is proposed to extend the treatment to a case where the electrode reaction is preceded by a chemical reaction $Y + \beta X \rightleftharpoons O$. Here, X is assumed to be a neutral substance so that $Z_Y = Z_O$. The steady-state solutions for this problem have been given by Hurwitz (2), and in the present paper we derive a modified expression for the same. The limiting behavior (viz. $\nu \gg 1$ or $\xi_0 \rightarrow \infty$) of the steady-state solutions do not differ appreciably. But otherwise, expressions obtained are different. In some cases at least, particularly for $|Z_i/Z| = m$, integer, the rigorous solutions assume relatively simpler forms.

Matsuda's solution (3) wherein the condition $Z_Y = Z_O$ has been relaxed at the expense of the inequality $K \ll 1$ has also been discussed. A general solution to the problem $Z_O \neq Z_R$ and K assuming any finite value is under investigation.

The reaction scheme is

[*a*] $$O^{z_O} + ne \rightleftharpoons R^{z_R}$$

[*b*] $$Y + \beta X \underset{k_b}{\overset{k_f}{\rightleftharpoons}} O^{z_O} \qquad (Z_X = 0).$$

The solution given below can as well be extended to the case $Y \rightleftharpoons O + \beta X$.

(i) Y and X are not reduced or oxidized; (ii) X is a neutral substance, so that $Z_Y = Z_O$; and (iii) a large excess of the species X as compared to O and Y is present, and consequently the concentration changes of X are negligible. Thus, the homogeneous chemical reaction [*b*] is *formally* monomolecular.

For such a case the concentration distribution is given by the system of equation [1] to [8]:

[1] $$\partial C_O/\partial t = -\partial Q_O/\partial x + k_f C_Y (C_X^0)^\beta - k_b C_O$$

[2] $$\partial C_Y/\partial t = -\partial Q_Y/\partial x - k_f C_Y (C_X^0)^\beta + k_b C_O$$

[3] $$(Q_O)_{x=0} = \pm I(t)/nF$$

[4] $$(Q_Y)_{x=0} = 0 \qquad \text{(cf. assumption (i))}$$

[5] $$[C_O(x,t)]_{x=\infty} = C_O^0$$

[6] $$[C_Y(x,t)]_{x=\infty} = C_Y^0$$

[7] $$C_O(x,0) = C_O^0 \exp(-Z_i F\phi/RT)$$

[8] $$C_Y(x,0) = C_Y^0 \exp(-Z_i F\phi/RT)$$

with

[9] $$Q_i = -D\{\partial C_i/\partial x + (Z_i F/RT)C_i(d\phi/dx)\} \qquad (i = O, Y).$$

In deriving the solution one must a priori know the dependence of ϕ on x. It is assumed in this paper that the diffuse double layer structure is determined entirely by a Z–Z supporting electrolyte and the potential distribution $\phi(x)$ in the layer obeys Gouy–Chapman theory, i.e.,

[10] $$d\phi/dx = -(2RT/|Z|F)\kappa \sinh(|Z|F\phi/2RT),$$

with

$$1/\kappa = (RT\epsilon/8\pi Z^2F^2C_i)^{\frac{1}{2}}.$$

Transforming the variables $C_O(x,t)$, $C_Y(x,t)$ into M and N, defined by

[11] $$M = C_Y(x,t)+C_O(x,t) \text{ and}$$

[12] $$N = [C_Y(x,t)-(1/K)C_O(x,t)] \exp(\mu t),$$

where

$$\mu = k_f(C_X^0)^\beta + k_b \text{ and } K = (k_f/k_b)(C_X^0)^\beta,$$

we rewrite the equations and the boundary conditions given by [1] to [8] as

[13] $$D\cdot\partial/\partial x[\partial M/\partial x + (Z_O F/RT)M(d\phi/dx)] = \partial M/\partial t$$

[14] $$D\cdot\partial/\partial x[\partial N/\partial x + (Z_O F/RT)N(d\phi/dx)] = \partial N/\partial t$$

[15] $$M_{t=0} = \exp(-Z_O F\phi_0/RT)(C_O^0+C_Y^0) = M^0 \exp(-Z_O F\phi_0/RT)$$

[16] $$M_{x=\infty} = (C_O^0+C_Y^0) = M^0$$

[17] $$N_{t=0} = 0$$

[18] $$N_{x=\infty} = 0$$

[19] $$D[\partial M/\partial x + (Z_O F/RT)M(d\phi/dx)] = \pm I(t)/nF$$

[20] $$D[\partial N/\partial x + (Z_O F/RT)N(d\phi/dx)] = \pm I(t)/nFK \exp(\mu t).$$

It may be noted that equations [13] and [14] are similar to those arising for the mass transfer of the species in the diffuse double layer that are directly discharged (without any chemical reaction preceding or following). Consequently, the solutions of these equations are similar to those given earlier (1). It can be proved that

[21] $$\bar{M}(0,p) = L[M(0,t)] = \exp(-Z_O F\phi_0/RT) \times\left[M^0 \mp \frac{I(p)}{nF\sqrt{(Dp)}}\,\xi_0^{2(l+1)}\,\frac{F(k, k+l+1; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+l+1; 2k+1; 1-1/\xi_0^2)}\right]$$

and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

[22] $$\bar{N}(0,p) = L[N(0,t)] = \exp(-Z_O F\phi_0/RT) \times\left[\pm\frac{L(I(t)\exp(\mu t))}{nF\sqrt{(Dp)}}\,\xi_0^{2(l+1)}\,\frac{F(k, k+l+1; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+l+1; 2k+1; 1-1/\xi_0^2)}\right],$$

where

$$k = (1/\kappa)\sqrt{(p/D)}.$$

Hence

[23] $$L[N(0,t)\exp(-\mu t)] = (p/p+\mu)\bar{N}(p+\mu),$$

where $\bar{N}(o,p)$ is given by [22]. Also

[24] $$L[I(t)\exp(\mu t)] = \bar{I}(p-\mu)\cdot p/(p-\mu)$$

so that

$$\bar{N}(p+\mu) = \pm\exp\left(\frac{-Z_O F\phi_0}{RT}\right)\frac{\bar{I}(p)}{nF\sqrt{\{D(p+\mu)\}}}\,\xi_0^{2(l+1)} \times\frac{p+\mu}{p}\,\frac{F(\gamma, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}{F(\gamma+1, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)},$$

where $\gamma = (1/\kappa)\sqrt{\{(p+\mu)/D\}}$. Equation [23] then gives

[25] $$L[N(0,t)\exp(-\mu t)] = L[C_Y^0(0,t) - (1/K)C_O(0,t)]$$
$$= \pm\exp\left(\frac{-Z_O F\phi_0}{RT}\right)\frac{I(p)}{nF\sqrt{\{(p+\mu)D\}}}\,\xi_0^{2(l+1)}\,\frac{F(\gamma, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}{F(\gamma+1, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}.$$

From [21] and [25] we may obtain the transforms of $C_O(0,t)$ and $C_Y(0,t)$ as

[26] $$\bar{C}_O(0,p) = K(\bar{M}-\bar{N})/(K+1)$$
$$= \frac{K}{K+1}\exp\left(\frac{-Z_O F\phi_0}{RT}\right)\left[M^0 \mp \frac{\bar{I}(p)}{nF\sqrt{(Dp)}}\,\xi_0^{2(l+1)} \times\frac{F(k, k+l+1; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+l+1; 2k+1; 1-1/\xi_0^2)} \mp\frac{\bar{I}(p)}{nFK\sqrt{\{D(p+\mu)\}}}\,\xi_0^{2(l+1)}\,\frac{F(\gamma, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}{F(\gamma+1, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}\right]$$

and

[27] $$\bar{C}_Y(0,p) = (M+KN)/(K+1) = \exp(-Z_O F\phi_0/RT)/(K+1) \times\left[M^0 \mp\frac{\bar{I}(p)}{nF\sqrt{(Dp)}}\,\xi_0^{2(l+1)}\,\frac{F(k, k+l+1; 2k+1; 1-1/\xi_0^2)}{F(k+1, k+l+1; 2k+1; 1-1/\xi_0^2)} \pm\frac{\bar{I}(p)}{nF\sqrt{\{D(p+\mu)\}}}\,\xi_0^{2(l+1)}\,\frac{F(\gamma, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}{F(\gamma+1, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}\right].$$

Also from [12] and [25],

[28] $$\bar{C}_O(0,p) = K\{\bar{C}_Y(0,p) - L[N(0,t)\exp(-\mu t)]\}$$
$$= K\left\{\bar{C}_Y(0,p) \mp\frac{\bar{I}(p)\xi_0}{nFK\sqrt{\{D(p+\mu)\}}}\,\frac{F(\gamma, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}{F(\gamma+1, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}\right\}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The relationship that one would obtain in the absence of chemical reaction can be deduced by allowing $K \rightarrow 0$ and $\mu \rightarrow 0$ so that $\gamma \rightarrow k$.

From [28] we obtain

$$\bar{C}_O(0,p) - K\bar{C}_Y(0,p) = \mp \frac{\bar{I}(p)\xi_0}{nF\sqrt{\{D(p+\mu)\}}} \frac{F(\gamma, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}{F(\gamma+1, \gamma+l+1; 2\gamma+1; 1-1/\xi_0^2)}.$$

Consequently, we observe that

$$[29] \qquad \lim_{t\rightarrow\infty} [C_O(0,t) - KC_Y(0,t)] = \mp [I(t)/nF\sqrt{(D\mu)}]\xi_0 U_l,$$

where

$$U_l = \frac{F(\nu, \nu+l+1; 2\nu+1; 1-1/\xi_0^2)}{F(\nu+1, \nu+l+1; 2\nu+1; 1-1/\xi_0^2)}$$

with

$$\nu = (1/\kappa)\sqrt{(\mu/D)}.$$

The corresponding result that one would obtain in the absence of double layer effects, viz., $\mp I(t)/nF\sqrt{(D\mu)}$, can be derived by allowing $\kappa \rightarrow \infty$ and $\xi_0 \rightarrow 1$.

For large values of t[1]

$$[30] \quad C_O(0,t) = \frac{K}{K+1}\left[M^* \mp \frac{I(t)}{nFD\kappa} a_i \mp \frac{I(t)}{nFK\sqrt{(D\mu)}} \xi_0^{2(l+1)} U_l\right] \exp(-Z_O F\phi_0/RT)$$

approximately, where M* is the value that would be obtained in the absence of chemical reaction and diffuse double layer, and

$$[31] \qquad C_Y(0,t) = (1/K+1)\left[M^* \pm \frac{I(t)a_i}{nFD\kappa} \pm \frac{I(t)\xi_0^{2(l+1)}U_l}{nF\sqrt{(D\mu)}}\right] \exp\left(\frac{-Z_O F\phi_0}{RT}\right).$$

Equation [29] can be rewritten as

$$[32] \qquad \lim_{t\rightarrow\infty} C_O(0,t) = \exp\left(\frac{-Z_O F\phi_0}{RT}\right) K\left\{C_Y^s \mp \frac{I(t)U_i\xi_0^{2(l+1)}}{nFK\sqrt{(D\mu)}}\right\},$$

$C_Y^s(0,t)$ being defined by

$$[33] \qquad C_Y(0,t) = C_Y^s(0,t) \exp(-Z_O F\phi_0/RT).$$

Equation [33] may be compared with that of Matsuda (equation 19 of reference 3) obtained under the assumption that

$$C_Y(0,t) = C_Y^s(0,t) \exp(-Z_O F\phi_0/RT) \qquad (x < \delta, \mu).$$

For the particular cases $|Z_O/Z| = n$ ($n = 1, 2, 3 \ldots$) the expressions take particularly simple forms. For such a case $\xi_0^{2(l+1)} U_l$ becomes

$$\frac{f_n^*(\nu, \xi_0)}{f_n^*(\nu, 1/\xi_0)} \quad \text{or} \quad \frac{f_n^*(\nu, 1/\xi_0)}{f_n^*(\nu, \xi_0)}$$

(refer to Appendix A).

[1]*Implicity assumed here is the inequality* $(1/\kappa\delta_i)\int_0 \exp(|Z_i| F|\phi|/RT)dx \ll 1$ *for the case of attraction, where* δ_i *is the thickness of the diffusion layer.*

DISCUSSION

Matsuda (3) and Hurwitz (2) have given the steady-state solutions for this problem assuming ξ_0 to be large. Whereas the former has limited his investigations to $K \ll 1$ (but making it more generalized by conceding $(Z_Y - Z_O)$ to be different from zero), the latter has solved it without restraining K. It is of interest to compare the steady-state solutions of these authors to that obtained here. A comparison of the functions $\xi_0 U_l$ of this paper, U_α of Hurwitz, and $\xi_0^{-(2p+1)} G_{II}$ of Matsuda (equation 20 of reference 3) will show that at least for integral values of $|Z_O/Z|$ the rigorous solution is simpler and more accurate. It may be proved that the functions $\xi_0 U_l$, U_α, and $\xi_0^{-(2p+1)} G_{II}$ given above become identical asymptotically (i.e. $\nu \to \infty$) (refer to Appendix B).

Hurwitz has discussed the possible dynamic ψ effects for this case. Though his treatment and the expressions for the interfacial concentrations are different from those given in this paper, it can be proved that no difference exists in the conclusions as regards these effects. It may be seen as follows:

[34] $$U_l = \frac{F(\nu, \nu+l+1; 2\nu+1; 1 - 1/\xi_0^2)}{F(\nu+1, \nu+l+1; 2\nu+1; 1 - 1/\xi_0^2)}$$
$$\to 1/\xi_0 \quad \text{for} \quad \nu \gg 1 \quad \text{and} \quad \nu/\xi_0 \gg 1$$
(refer to Appendix B).

Substituting this in equation [30] we show that

[35] $$C_O(0,t) \to \frac{K}{K+1}\left[M^* \mp \frac{I(t)a_i}{nFD\kappa} \mp \frac{I(t)}{nFK\sqrt{(D\mu)}}\xi_0^{(2l+1)}\right] \exp\left(\frac{-Z_O F\phi_0}{RT}\right).$$

Consequently for large ξ_0

[36] $$a_i \cong \xi_0^{2l}/l \quad \text{for} \quad |Z_i/Z| > \tfrac{1}{2} \quad \text{and}$$
$$\cong \ln \xi_0^2 \quad \text{for} \quad |Z_i/Z| = \tfrac{1}{2}.$$

Substituting [34] and [36] in the expression for $C_O(0,t)$ we get

$$C_O(0,t) = \frac{K}{K+1}\left\{M^* \mp \left(\frac{I(t)\xi_0^{(2l+1)}}{nFK\sqrt{(D\mu)}}\right)\left[1 + \frac{K}{l\kappa\xi_0}\sqrt{(\mu/D)}\right]\right\} \exp\left(\frac{-Z_O F\phi_0}{RT}\right)$$

for $|Z_i/Z| > \frac{1}{2}$. Hence if K is so small that $K\nu/\xi_0 \ll 1$ for $|Z_i/Z| > \frac{1}{2}$ and $K\nu \ln \xi_0^2/\xi_0 \ll 1$ for $|Z_i/Z| = \frac{1}{2}$, the limiting velocity V is approximately expressed by

[37] $$V \cong K\sqrt{(D\mu)} \exp(-Z_O F\phi_0/RT) = V_0 \exp(-Z_O F\phi_0/RT) \qquad \text{(static } \psi \text{ effect)}$$

where V_0 is the limiting kinetic rate in the absence of diffuse double layer effects. But, if K is such that $K\nu/\xi_0 \gg 1$ for $|Z_i/Z| > \frac{1}{2}$ and $(K\nu/\xi_0 \ln \xi_0^2 \gg 1$ for $|Z_i/Z| = \frac{1}{2}$, the limiting velocity V is no longer given by equation [37] and for this case

[38] $$V = D\kappa l \xi_0^{-2l} \quad \text{for} \quad |Zi/Z| > \tfrac{1}{2} \quad \text{and}$$
$$= D\kappa/\ln \xi_0^2 \quad \text{for} \quad |Z_i/Z| = \tfrac{1}{2} \qquad \text{(dynamic } \psi \text{ effect).}$$

Under the limiting conditions $\nu \gg 1$ and $\nu/\xi_0 \ll 1$,

$$U_l \to \nu/l\xi_0^2 \quad \text{for} \quad |Z_i/Z| > \tfrac{1}{2} \quad \text{and}$$
$$\to \nu \ln \xi_0^2 \quad \text{for} \quad |Z_i/Z| = \tfrac{1}{2} \qquad \text{(refer to Appendix B).}$$

Substituting in equation [35] we obtain

$$C_O(0,t) = \frac{K}{K+1}\left[M^* \mp \frac{I(t)\xi_0^{2l}}{nFD\kappa l}(1 + 1/K)\right]\exp\left(\frac{-Z_O F\phi_0}{RT}\right)$$

so that the limiting velocity for this case is given by

$$V = \frac{D\kappa l}{\xi_0^{2l}}(K/K+1) \quad \text{for } |Z_i/Z| > \tfrac{1}{2} \quad \text{and}$$

$$= \frac{D\kappa(K/K+1)}{\ln \xi_0^2} \quad \text{for } |Z_i/Z| = \tfrac{1}{2}.$$

It may be noted that the above limiting conditions are arrived at for all K.

The dynamic ψ effect can occur even when ν is small when $\xi_0 \gg 1$ as can be seen by making use of Table I.

TABLE I

Behavior of $U_l\xi_0^{2(l+1)}$ for large ξ_0

$\lvert Z_i/Z\rvert$	$< \frac{1}{2}$	$= \frac{1}{2}$	$> \frac{1}{2}$
	Attraction		
l	< 0	< 0	< 0
$l+1$	> 0	$= 0$	< 0
$U_l\xi_0^{2(l+1)}$	$\frac{\Gamma(-l)\cdot\Gamma(\nu+l+1)}{\Gamma(l+1)\cdot\Gamma(\nu-l)}$	$\frac{1}{\nu \ln \xi_0^2}$	$\xi_0^{-2\lvert l+1\rvert}\frac{\lvert l+1\rvert}{\nu}$
	Repulsion		
l	< 0	$= 0$	> 0
$l+1$	> 0	> 0	> 0
$U_l\xi_0^{2(l+1)}$	$\frac{\Gamma(-l)\cdot\Gamma(\nu+l+1)}{\Gamma(l+1)\cdot\Gamma(\nu-l)}$	$\nu \ln \xi_0^2$	$\xi_0^{2l}\frac{\nu}{l}$

To summarize, the solution of the diffusion equation for the concentration of the reactive species, accounting for the migration effects in the diffuse double layer, is given for the following reaction schematically represented as

$$Y + \beta X \rightleftharpoons O^{z_O} \text{ (or } Y \rightleftharpoons O^{z_O} + \beta X),\ Z_x = 0$$

$$O^{z_O} + ne \rightleftharpoons R^{z_R}.$$

The results obtained in this paper are compared with the steady-state solutions obtained by Hurwitz and Matsuda. It is also shown how their solutions converge to that of the rigorous solution under limiting conditions, (ν and $\xi_0 \to \infty$ so that ν/ξ_0 is finite).

The expressions for the limiting velocities (dynamic ψ effect) are found to be the same as those given by the treatment of Hurwitz.

APPENDIX A

The functions $f_n^*(k,\xi_0)$ are defined by

$$f_1^*(k,\xi_0) = 1+2k\xi_0;$$

$$f_2^*(k,\xi_0) = 3+6k\xi_0+4k^2\xi_0^2+2k\xi_0^3;$$

$$f_3^*(k,\xi_0) = 15+30k\xi_0+24k^2\xi_0^2+(10k+8k^3)\xi_0^3+12k^2\xi_0^4+6k\xi_0^5;$$

$$f_4^*(k,\xi_0) = 105+210k\xi_0+180k^2\xi_0^2+(70k+80k^3)\xi_0^3+(104k^2+16k^4)\xi_0^4 + (42k+48k^3)\xi_0^5+60k^2\xi_0^6+30k\xi_0^7.$$

An interesting property of the function $f_n^*(x,y)$ is the recurrence relation $f_{n+1}(x,y) = (2n+1)f_n+2xy^{2n+1}f_n(1/y)$.

APPENDIX B

By the analytic continuation of the hypergeometric functions

$$F(\nu,\nu+l+1;2\nu+1;1-1/\xi_0^2) = \frac{\Gamma(2\nu+1)\Gamma(-l)}{\Gamma(\nu+1)\Gamma(\nu-l)}F(\nu,\nu+l+1;l+1;1/\xi_0^2) + \frac{\Gamma(2\nu+1)\Gamma(-1)}{\Gamma(\nu)\Gamma(\nu+l+1)}\left(\frac{1}{\xi_0^2}\right)^{-l}F(\nu-l,\nu+l;1-l;1/\xi_0^2).$$

For large ν $(\to\infty)$ such that ν/ξ_0 is finite, we have

$$F(\nu,\nu+l+1;l+1;1/\xi_0^2) \to I_l(2\nu/\xi_0)\frac{\Gamma(l+1)}{(\nu/\xi_0)^l}$$

and

$$F(\nu-l,\nu+1;1-l;1/\xi_0^2) \to I_{-l}(2\nu/\xi_0)\frac{\Gamma(1-l)}{(\nu/\xi_0)^{-l}}.$$

Therefore

$$F(\nu,\nu+l+1;2\nu+1;1-1/\xi_0^2) \to I_l(2\nu/\xi_0) - \nu^{2l+1}\frac{\Gamma(\nu-l)}{\Gamma(\nu+l+1)}I_{-l}(2\nu/\xi_0)\frac{\Gamma(2\nu+1)l\Gamma(l)\Gamma(-l)}{\nu\Gamma(\nu)\cdot\Gamma(\nu-l)}\left(\frac{\xi_0}{\nu}\right)^l.$$

Since

$$\frac{\Gamma(Z+\alpha)}{\Gamma(Z+\beta)} \underset{(Z\to\infty)}{\simeq} Z^{\alpha-\beta},$$

$$\frac{\Gamma(\nu-l)}{\Gamma(\nu+l+1)}\nu^{2l+1} \to 1 \text{ as } \nu\to\infty,$$

and

$$Z\cdot\Gamma(Z)\cdot\Gamma(-Z) = -\pi \operatorname{cosec} \pi Z,$$

we have

$$F(\nu,\nu+1+l;2\nu+1;1-1/\xi_0^2) \to \frac{2\Gamma(2\nu+1)}{\nu\Gamma(\nu)\cdot\Gamma(\nu-l)}\left(\frac{\xi_0}{\nu}\right)^l K_l(2\nu/\xi_0),$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where $K_r(x)$ is defined as equal to $(\pi/2)\{I_{-r}(x)-I_r(x)\}$ cosec $(\nu\pi)$ (appropriate *limit* is to be taken for integral r).

Similarly

$$F(\nu+1, \nu+l+1; 2\nu+1; 1-1/\xi_0^2) \rightarrow \frac{2\Gamma(2\nu+1)}{\Gamma(\nu)\cdot\Gamma(\nu-l)}\left(\frac{\xi_0}{\nu}\right)^{l+1} K_{1+l}(2\nu/\xi_0).$$

Hence

$$U_l = \frac{F(\nu, \nu+l+1; 2\nu+1; 1-1/\xi_0^2)}{F(\nu+1, \nu+l+1; 2\nu+1; 1-1/\xi_0^2)}$$

$$\rightarrow \frac{1}{\xi_0}\frac{K_l(2\nu/\xi_0)}{K_{l+1}(2\nu/\xi_0)} \text{ as } \nu \rightarrow \infty, \nu/\xi_0 \text{ being assumed finite.}$$

Assuming the well-known property of the Bessel functions

$$U_l \rightarrow 1/\xi_0 \quad \text{for} \quad \nu/\xi_0 \gg 1 \qquad \text{and}$$

$$U_l \rightarrow \nu/l\xi_0^2 \quad \text{for} \quad \nu/\xi_0 \ll 1.$$

THE INTERACTION OF SILICON TETRAFLUORIDE WITH METHANOL

J. P. GUERTIN AND M. ONYSZCHUK
Inorganic Chemistry Laboratory, Department of Chemistry, McGill University, Montreal, Que.
Received January 7, 1963

ABSTRACT

Silicon tetrafluoride reacts with methanol in a 1:4 mole ratio, forming the complex $SiF_4.4CH_3OH$, which freezes to a glass at about −20° and is completely dissociated in the gaseous phase at 25°. Conductivity measurements show clearly that it is a very weak electrolyte in methanol solution. Its infrared spectrum does not contain an Si—O bond stretching absorption band. Proton magnetic resonance measurements provide strong evidence of hydrogen bonding between silicon tetrafluoride and methanol. These results indicate that the structure of the complex requires tetracovalent rather than hexacovalent silicon and strong hydrogen bonds between methanol and each of the four fluorine atoms.

INTRODUCTION

Many complexes of silicon tetrafluoride with nitrogen electron-pair donor molecules have been prepared and characterized (1–7); less is known about the interaction of silicon tetrafluoride with oxygen donors. Muetterties (6) has described $SiF_4.2(CH_3)_2SO$, $SiF_4.2(CH_3)_2NCHO$, and $SiF_4.xCH_3COCH_2COCH_3$; the last is a very weak complex of uncertain composition. Gierut *et al.* (8) reported briefly that silicon tetrafluoride reacts with alcohols in a 1:4 mole ratio, yielding unstable addition compounds $SiF_4.4ROH$, where R is CH_3, C_2H_5, iso-C_3H_7, and iso-C_5H_{11}; these results were confirmed by Topchiev and Bogomolova (9), who also suggested that the complex is ionic and contains hexacovalent silicon. However, Holzapfel *et al.* (10) reported that silicon tetrafluoride and methanol produce 1:6 and 1:8 complexes only. With the object of clarifying these conflicting results, we have investigated the interaction of silicon tetrafluoride with methanol using tensimetric titration, conductivity, infrared, and proton magnetic resonance methods. This research is part of a general investigation of the relative electron acceptor power of silicon and germanium tetrafluoride towards oxygen, sulphur, nitrogen, and phosphorus electron-pair donor molecules. This paper describes the peculiar nature of the silicon tetrafluoride – methanol system.

RESULTS AND DISCUSSION

Preparation of $SiF_4.4CH_3OH$

Silicon tetrafluoride (in excess) and methanol when slowly mixed together in a vacuum at 25° produced the 1:4 complex, $SiF_4.4CH_3OH$, a colorless liquid. It formed a glass at about −20° and was completely dissociated in the gaseous phase at 25°. The 1:4 combining ratio was not always reproducible and values in the range 1.00:3.75 to 1.00:4.20 were also obtained. Ratios lower than 1:4 are attributed to the formation of some dimethyl ether by the silicon tetrafluoride catalyzed dehydration of methanol (9); higher ratios are probably due to incomplete reaction of methanol with silicon tetrafluoride. The combining ratio was never 1:6 or 1:8, as claimed by Holzapfel *et al.* (10).

A tensimetric titration of silicon tetrafluoride with methanol (Fig. 1) confirmed the formation of only a 1:4 complex. After each successive addition of methanol to silicon tetrafluoride in this titration, the mixture was warmed to 25° and then cooled to −78°, at which temperature pressure measurements were made. As shown in Fig. 1 the pressure decreased linearly and approached zero after the mole ratio of methanol to silicon tetra-

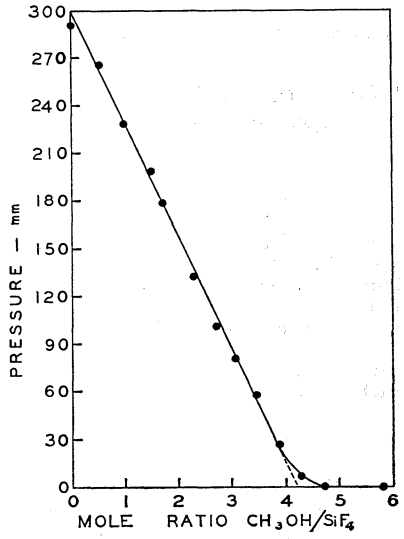

FIG. 1. Tensimetric titration of silicon tetrafluoride with methanol.

fluoride became greater than 4; extrapolation of the linear portion to zero pressure indicates a mole ratio of 4.2. In the reverse titration of methanol with silicon tetrafluoride (Fig. 2), the pressure remained zero until the mole ratio CH_3OH/SiF_4 decreased to 5, when

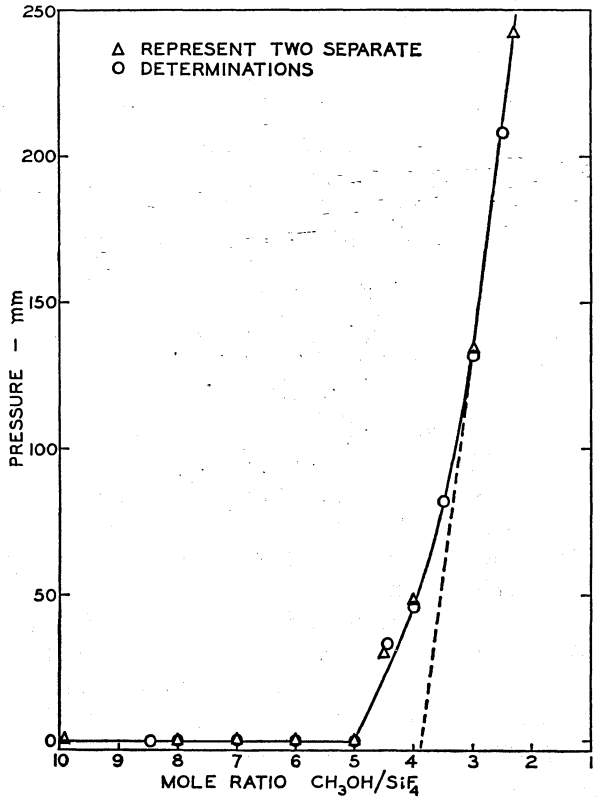

FIG. 2. Tensimetric titration of methanol with silicon tetrafluoride.

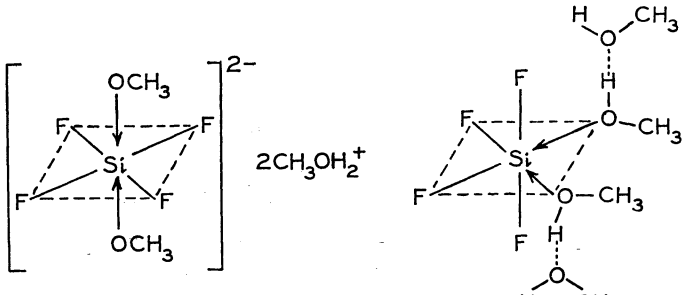
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the pressure increased rapidly as the ratio decreased further; extrapolation of the linear part of this plot to zero pressure gives a mole ratio of 3.85, corresponding to the formation of the 1:4 complex, $SiF_4.4CH_3OH$. The two tensimetric titrations show conclusively that 1:6 and 1:8 complexes are not produced. Attempts were made to measure the dissociation pressure of $SiF_4.4CH_3OH$, but the values were not reproducible and therefore the heat of dissociation of the complex could not be obtained.

Conductivity of $SiF_4.4CH_3OH$

The conductivity of $SiF_4.4CH_3OH$ in methanol was measured to test the suggestion (9) that this complex has the ionic structure I, in which methoxy groups may be in



I II

either cis or trans arrangement. The conductivity measurements are given in Table I and plotted in Fig. 3, where they are compared with the molar conductances of acetic acid (11)

TABLE I

Conductivities of $SiF_4.4CH_3OH$ in methanol

and sodium chloride (12) in methanol. The results and comparisons reveal that $SiF_4.4CH_3OH$ is a very weak electrolyte in methanol; therefore, structure I or any other ionic structure is not valid. Using an empirical method recently described by Levitt (13), we estimated a molar conductance at infinite dilution of 830 mho cm^2 $(g\text{-mole})^{-1}$ l^{-1} for the complex, an equilibrium constant for dissociation of 2.76×10^{-5} mole l^{-1}, and a degree of dissociation of 4.8% for a solution of 0.01 mole l^{-1} concentration.

Infrared Spectrum of $SiF_4.4CH_3OH$

An alternative structure, II, involves octahedral bonding of silicon and hydrogen bonding between methanol and each of the coordinated methanol molecules. The infrared spectrum of such a species should contain an Si—O bond stretching absorption band;

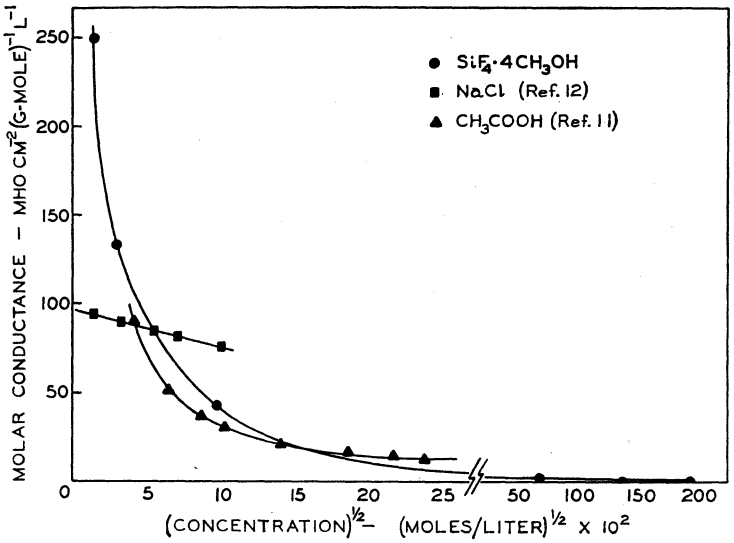

FIG. 3. Comparison of the molar conductances of $SiF_4.4CH_3OH$, NaCl, and CH_3COOH in methanol.

this is usually very strong and occurs at 1085–1105 cm^{-1} in methoxysilanes (14) and alkyldisiloxanes (15). Since the infrared spectra (Fig. 4) of liquid $SiF_4.4CH_3OH$ and its

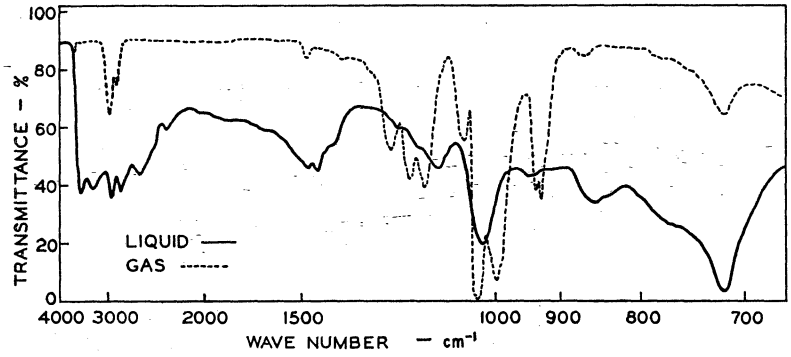

FIG. 4. Infrared spectrum of $SiF_4.4CH_3OH$ and its gaseous products.

gaseous products do not contain a strong band in this region, the complex is not octahedrally bonded and therefore structure II is not valid.

As shown in Table II, the infrared spectrum of the gaseous products of $SiF_4.4CH_3OH$ contains the bands characteristic of gaseous methanol and silicon tetrafluoride, together with bands of medium intensity at 1220, 1170, and 930 cm^{-1}. These bands are characteristic of dimethyl ether (16), which is formed in small amounts by dehydration of methanol with silicon tetrafluoride as catalyst. The fact that the 3680 cm^{-1} band, identified as the bond stretching vibration of the free O—H group, occurs in the same position as in gaseous methanol indicates that there was little or no hydrogen bonding between methanol and silicon tetrafluoride in the gaseous phase at 10 mm pressure. A further indication of the absence of "heavy" molecular species was the low molecular weight, 57.5, of the gaseous mixture.

718 w	720 s				ν(Si—F) octahedral for SiF_6^{2-}

NOTE: w = weak, m = medium, s = strong, v = very.

A comparison of the infrared absorption bands of liquid $SiF_4.4CH_3OH$ with those of liquid methanol and gaseous silicon tetrafluoride, also given in Table II, shows the following noteworthy features. (i) The band at 3300 cm^{-1} in methanol is shifted 40 cm^{-1} lower in $SiF_4.4CH_3OH$, indicating that there is stronger hydrogen bonding in the complex than in pure methanol. (ii) The strong and broad band at 1025 cm^{-1} in $SiF_4.4CH_3OH$ undoubtedly includes the C—O and Si—F bond stretching vibrations. (iii) The band at 720 cm^{-1} also occurs in the gaseous spectrum. This band appeared with almost the same intensity after the liquid sample was washed from the NaCl plates, and after the gaseous sample was removed from the NaCl gas cell. Moreover, the intensity of this band in the gas phase spectrum did not change when the sample pressure was doubled. These observations strongly suggest a surface effect involving the formation of a species which absorbs at 720 cm^{-1}. This species must be SiF_6^{2-} formed by the interaction of SiF_4 with the NaCl plates, as described recently by Heslop *et al.* (17).

Proton Magnetic Resonance Measurements

The indication by the infrared data that hydrogen bonding in liquid $SiF_4.4CH_3OH$ is greater than in pure methanol was investigated further by proton magnetic resonance measurements. Hydrogen bonding between methanol and the fluorine atoms of silicon tetrafluoride should change the electron density and the local magnetic polarizability of the electrons around the hydrogen atom of the OH group and, to a lesser extent, the hydrogen atoms of the CH_3 group of methanol. These effects were observed (Fig. 5) as large and small changes in the chemical shifts (τ) of the OH and CH_3 peaks, respectively. The effect of concentration of silicon tetrafluoride on these shifts was examined by measurements on silicon tetrafluoride – methanol solutions with mole ratios SiF_4/CH_3OH in the range 0 to 0.4. Solutions with ratios greater than 0.4 were not prepared because the

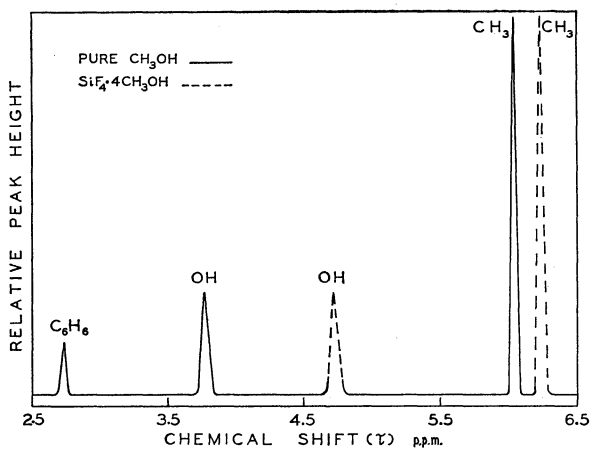

FIG. 5. Chemical shifts of pure methanol and methanol hydrogen bonded to silicon tetrafluoride.

sealed glass sample tubes might have exploded due to internal pressures in the tens of atmospheres.

The plot given in Fig. 6 shows that there is an initial linear and rapid decrease in

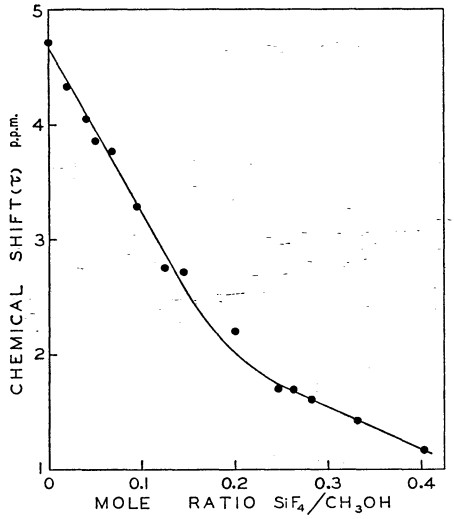

FIG. 6. Variation of the chemical shift of the OH peak with mole ratio of silicon tetrafluoride to methanol.

τ value of the OH peak as the amount of silicon tetrafluoride is increased. The slope of this line changes markedly near a mole ratio of 0.2 and finally becomes constant and smaller than initially. A comparison of the magnitude and direction (from high to low field) of the observed chemical shifts with those of the methanol – carbon tetrachloride and methanol–chloroform systems (18) reveals that (i) hydrogen bonding occurs to a greater extent between silicon tetrafluoride and methanol ($\Delta\tau \sim 3.5$ p.p.m.) than in methanol alone ($\Delta\tau \sim 3.0$ p.p.m.); (ii) successive addition of silicon tetrafluoride does not simply dilute the methanol; if it did, the chemical shift would be towards higher magnetic field strength.

Our interpretation of Fig. 6 is as follows. The chemical shift of the OH peak of pure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

methanol (τ = 4.712 p.p.m.) decreases upon the successive addition of small amounts of silicon tetrafluoride because of the immediate formation of $SiF_4.4CH_3OH$ molecular species and rapid exchange between solvent methanol and methanol hydrogen bonded to silicon tetrafluoride. In order to observe the OH peaks of both types of methanol simultaneously the lifetime of each state must be longer than the reciprocal of the chemical shift (in cycles/sec) between the two states (19). Thus, the single OH peak observed at each mole ratio was an average value. These values decreased as the mole ratio SiF_4/CH_3OH increased, indicating that proportionately more methanol was hydrogen bonded to silicon tetrafluoride. When the ratio became 0.25 all of the methanol was used up in the formation of the $SiF_4.4CH_3OH$ complex. Further addition of silicon tetrafluoride produced secondary concentration effects which were directly proportional to the mole ratio SiF_4/CH_3OH.

The τ values of the CH_3 peak (Fig. 7) decreased gradually and finally levelled off as

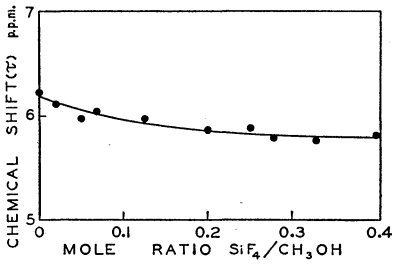

FIG. 7. Variation of the chemical shift of the CH_3 peak with the mole ratio of silicon tetrafluoride to methanol.

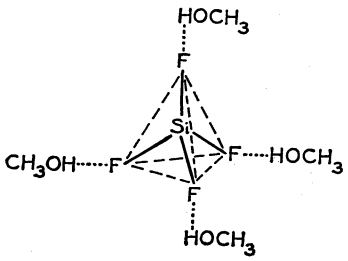
the concentration of silicon tetrafluoride increased. The decrease was not large because the protons of the CH_3 group were observing only secondary effects.

Structure of $SiF_4.4CH_3OH$

The experimental data reveals that the complex in the liquid or solid state (i) has the composition represented by $SiF_4.4CH_3OH$, (ii) is only very slightly dissociated into ions in methanol, (iii) does not contain Si—O bonds, (iv) contains strong hydrogen bonds. The most reasonable explanation of these data is that the complex is tetrahedral with strong hydrogen bonds between methanol and each of the four fluorine atoms (III).



III

EXPERIMENTAL

Most of the materials used in this work were manipulated in a standard pyrex-glass high-vacuum system which had stopcocks and ground-glass joints lubricated with Kel-F grease. The purity of the volatile compounds was determined by measurements of their vapor pressures, molecular weights (M), and infrared spectra. Infrared spectra were recorded on a Perkin–Elmer Infracord double-beam spectrophotometer equipped with sodium chloride optics.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Anhydrous methanol was obtained by refluxing for a few hours 50 ml of the commercial grade material over about 1 g of freshly cleaned Mg turnings to which a few crystals of resublimed iodine had been added. The distillate boiling at 63–64° was collected and redistilled at −23° in the vacuum system. Commercial silicon tetrafluoride was purified by several low-temperature vacuum distillations.

Preparation of $SiF_4.4CH_3OH$

In a typical experiment SiF_4 (10.48 mmole) was combined in a vacuum with methanol (8.44 mmole), and the mixture was kept at 25° for 30 minutes and finally cooled slowly to −115°. Unreacted SiF_4 (8.32 mmole) was recovered by distillation first at −115° and then at −65°. Therefore, SiF_4 (2.16 mmole) had reacted with CH_3OH (8.44 mmole) in a mole ratio of 1:3.91, producing the complex $SiF_4.4CH_3OH$. Infrared and molecular weight measurements showed that the gas phase in equilibrium with the liquid at 25° consisted of SiF_4 and CH_3OH. (Found: M, 57.5. Calc. for CH_3OH: M, 32.1; for SiF_4: M, 104.1.)

Tensimetric Titrations

Preliminary experiments indicated that −78° was a suitable temperature at which to measure total pressures in the tensimetric titration of SiF_4 with CH_3OH. At this temperature the complex is not measurably dissociated and any excess SiF_4 (b.p. −94.8°) would be entirely in the gaseous phase. Measured amounts of methanol were added in successive small amounts (about 2 mmole at a time) to a fixed quantity of SiF_4 (5.43 mmole). After each addition the mixture was warmed to 25° for about 15 minutes before it was slowly cooled to −78°, at which temperature pressure measurements were made. A plot of total pressure against mole ratio of CH_3OH to SiF_4 is shown in Fig. 1. The reverse titration of CH_3OH by addition of SiF_4 gave the results shown in Fig. 2.

Conductivity of $SiF_4.4CH_3OH$

Conductivity measurements were made using a conductivity bridge (Industrial Instruments Model RC 16 B2) and a cell having a cell constant of 0.01. The instrument had a conductivity range of 4×10^{-9} to 5×10^{-2} mho cm^{-1}. Transfer of solutions and measurements were made in a nitrogen-filled dry box to avoid hydrolysis by atmospheric moisture. A sample with the highest concentration of $SiF_4.4CH_3OH$ (see Table I) was prepared in the vacuum system and then transferred to the conductivity cell in the dry box, and its conductivity was measured. Solutions of lower concentration were prepared by successive dilutions with methanol.

Proton Magnetic Resonance Measurements

Proton n.m.r. spectra were recorded on a high-resolution Varian spectrometer with a fixed frequency of 60 Mc. Pure benzene contained in a sealed capillary was used as the external standard (τ = 2.734 p.p.m.). It was placed in a pyrex glass tube, 17 cm long and 5 mm outside diameter, into which solutions of known mole ratio of SiF_4 to CH_3OH were condensed. The sample tube was sealed off in a vacuum at a constriction. The results are shown in Figs. 5, 6, and 7.

ACKNOWLEDGMENTS

We thank the National Research Council for financial assistance in the form of an annual grant (to M. O.). We are grateful to Dr. J. T. Edward for many helpful discussions and to Dr. A. Taurins and Dr. C. Stammer for the n.m.r. measurements.

PSEUDACONITINE, AND THE STEREOCHEMICAL RELATIONSHIP OF THE HIGHLY OXYGENATED ACONITE ALKALOIDS[1]

Y. TSUDA[2] AND LÉO MARION
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received January 31, 1963

ABSTRACT

An alkaloid isolated from *Aconitum spicatum* Stapf has been found to be identical not only with the originally described pseudaconitine but also with 'α-pseudaconitine'. The product of the partial hydrolysis of the base, i.e., veratroylpseudaconine, is dextrorotatory, and not laevorotatory as recorded in the old literature. On heating, pseudaconitine undergoes pyrolysis, loses the elements of acetic acid, and gives rise to pyropseudaconitine. This substance, on treatment with lithium aluminum hydride, is converted to demethoxyisopyropseudaconine which is identical with the Wolff–Kishner reduction product of pyraconine. This correlation establishes that pseudaconitine and aconitine possess the same absolute configuration, which, in the light of previous knowledge, is extended also to indaconitine, delphinine, mesaconitine, and jesaconitine.

For personal use only.

Pseudaconitine, $C_{36}H_{51}O_{12}N$, was first discovered by Wright and Luff (1) in 1878 and its properties were studied by Dunstan and Carr (2), who found that it was hydrolyzed by potassium hydroxide to acetic acid, veratric acid, and the base pseudaconine, $C_{25}H_{41}O_8N$, m.p. 93–94°, $[\alpha]_D$ +38.7° (H_2O). They also reported that mineral acids effected a partial hydrolysis only and gave rise to veratroylpseudaconine, m.p. 199°, $[\alpha]_D$ −38.18° (EtOH). Henry and Sharp (3, 4), who later investigated pseudaconitine further, did not prepare veratroylpseudaconine.

Much later, Marion and Edwards (5) isolated an alkaloid of the same empirical formula and physical properties as pseudaconitine which on hydrolysis gave acetic acid, veratric acid, and pseudaconine of the same formula, melting point, and optical rotation as reported by Dunstan and Carr (2). On partial hydrolysis, however, it gave dextrorotatory veratroylpseudaconine. Hence, the new base and its partial hydrolysis product were designated α-pseudaconitine and α-veratroylpseudaconine (5).

A. Identity of Pseudaconitine

From the roots of *Aconitum spicatum* Stapf,[3] an alkaloid has now been isolated, $C_{36}H_{51}O_{12}N$, which possesses the same physical properties as pseudaconitine. It forms a crystalline perchlorate, mono- and di-acetyl derivatives, and like pseudaconitine yields acetic acid, veratric acid, and pseudaconine, so that it contains two free hydroxyls and two ester groups. On the other hand, partial hydrolysis of the alkaloid gives dextrorotatory veratroylpseudaconine, m.p. 212–214°, $[\alpha]_D$ +38.5 (EtOH), +54.1 ($CHCl_3$), and indeed, the alkaloid is identical (by optical rotation, m.p., m.p. of the mixture, and infrared spectra comparison) with an authentic sample of the α-pseudaconitine of Marion and Edwards (5).

Because of the practically identical properties of the alkaloid from *A. spicatum* and its various derivatives (except the optical rotation of veratroylpseudaconine) with those of pseudaconitine and its corresponding derivatives, it was suspected that the two bases might be identical. It has been possible to obtain a sample of authentic pseudaconitine

[1]*Issued as N.R.C. No. 7299.*
[2]*National Research Council of Canada Postdoctoral Fellow.*
[3]*We wish to express our gratitude to S. B. Penick and Company, who kindly supplied the plant material.*

from the collection of the late Dr. T. A. Henry[4] and a comparison of it with our alkaloid (m.p. of the base and of the mixture, and infrared spectra) has shown the two to be identical. Hence, pseudaconitine is identical with α-pseudaconitine, and the latter designation should be deleted from the literature. Another conclusion is that the sign of the optical rotation of veratroylpseudaconine ($[\alpha]_D$ $-38°18'$, EtOH) recorded by Dunstan and Carr (2) is evidently in error, and the compound is dextrorotatory.

B. Correlation of Aconite Alkaloids

The absolute configuration of aconitine, $C_{34}H_{47}O_{11}N$ (I), has been established by the X-ray crystallographic analysis (6) of demethanolaconinone, II, and by conversion of the alkaloid into a series of lactones (7) of which III is typical. Delphinine, IV, $C_{33}H_{45}O_9N$, was correlated with aconitine by Wiesner *et al.* (8), who transformed both alkaloids into the common intermediate V. Whereas this correlation showed that aconitine and

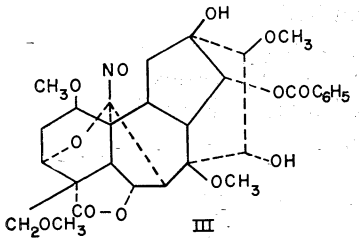
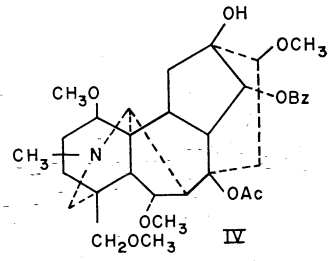
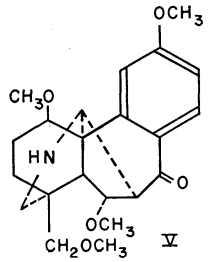
II



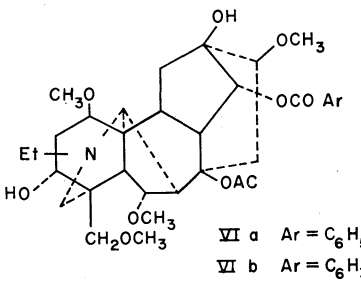
III



IV



V



VI a Ar = C_6H_5
VI b Ar = $C_6H_3(OCH_3)_2$

delphinine possess the same stereochemistry in rings A, B, C, and the nitrogen ring, it did not establish the stereochemical relationships of the D/E ring systems, nor of the benzoyloxy groups in these alkaloids.

[4]*The sample of pseudaconitine was obtained through the kindness of Dr. H. T. Openshaw, The Wellcome Research Laboratories, to whom we express our thanks.*

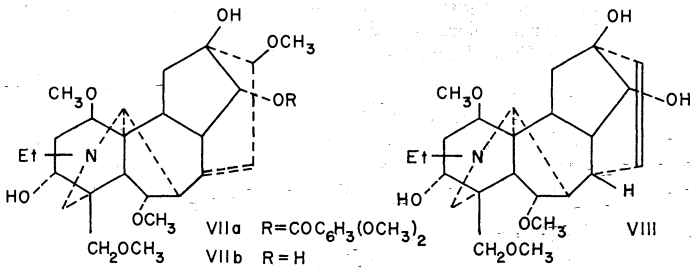
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Recently, the structure of indaconitine, $C_{34}H_{47}O_{10}N$ (VI*a*), an alkaloid hydrolyzable to acetic acid, benzoic acid, and pseudaconine, has been determined by conversion of the alkaloid into delphinine, IV (9). Since the reactions involved in this conversion do not disturb the asymmetric centers of the molecule except for the removal of the hydroxyl in ring A, the stereochemical arrangement present in delphinine is also present in indaconitine.

On the assumption that the ester groups in pseudaconitine and indaconitine are similarly located (for evidence of which see ref. 10), the correlation of the latter with delphinine also proves the structure of pseudaconitine (VI*b*), but it does not establish the position or the stereochemistry of the hydroxyl in ring A.

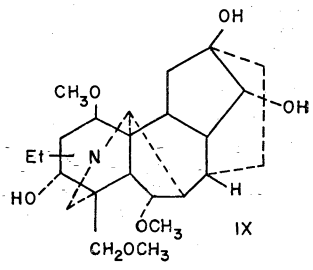
It has now been possible to correlate pseudaconitine with aconitine, and this not only establishes the stereochemistry of the hydroxyl of ring A in both indaconitine and pseudaconitine but also establishes that all the four alkaloids mentioned possess the same stereochemistry.

Pseudaconitine when heated *in vacuo* produced pyropseudaconitine, $C_{34}H_{47}O_{10}N$ (VII*a*), which could not be induced to crystallize. Sharp (4) described pyropseudaconitine as bundles of colorless stout needles, m.p. 132–135°, whereas Marion and Edwards (5) could not obtain the compound in a crystalline state. The n.m.r. spectrum of pyropseudaconitine contained a doublet (δ 5.57, J = 6 c/s) corresponding to one olefinic hydrogen. Further evidence of the olefinic character of the pyro compound was found in pyropseudaconine (VII*b*), its hydrolysis product, which had an infrared absorption spectrum containing a band at 1620 cm^{-1} and an n.m.r. spectrum showing a doublet (δ 5.55, J = 6 c/s), both of which indicated a double bond.



VII*a* R=$COC_6H_3(OCH_3)_2$
VII*b* R=H

VIII



IX

The action of lithium aluminum hydride on VII*a* gave the solid but non-crystalline iso compound demethoxyisopyropseudaconine, $C_{24}H_{37}O_6N$ (VIII), which was well characterized as its crystalline perchlorate, m.p. 256–258° (decomp.). The n.m.r. spectrum of the free base confirmed the structure VIII in showing three methoxyl groups and two poorly resolved signals centered at δ 5.69, indicative of two olefinic protons. Reactions analogous to the bridgehead allylic rearrangement that results in the formation of VIII were reported in connection with neoline (11) and delphinine (12).

Catalytic hydrogenation of the isopyro compound (VIII) gave the saturated product $C_{24}H_{39}O_6N$ (IX), which formed a crystalline perchlorate, m.p. 230° (decomp.). This saturated product, which should have been identical with the Wolff–Kishner reduction product of pyraconitine (perchlorate, m.p. 258–259°, decomp.) described by McCaldin and Marion (13), was quite different. Re-examination of the latter substance revealed that it was not saturated as previously stated (13) but contained one double bond, and that it was identical (by melting point, that of the mixture, infrared and n.m.r. spectra comparison) with demethoxyisopyropseudaconine (VIII). Production of an unsaturated compound in the Wolff–Kishner reduction of an α-methoxyketone appears quite reasonable from a consideration of the reaction mechanism, and is not without precedent (14).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

In the above series of transformations no inversions seem to be possible and, therefore, the conversion of both pseudaconitine and aconitine into a common intermediate supplies rigorous proof that the C-3 hydroxyl and the C-1 methoxyl of pseudaconitine have the same configuration respectively as in aconitine. It can also be concluded that aconitine, pseudaconitine, indaconitine, and delphinine all have the same absolute configuration with the possible but unlikely exception of the C-18 methoxyl group. This group is removed in the correlation of pseudaconitine with aconitine, but it is retained in the transformation of indaconitine into delphinine (9). Hence it has the identical configuration in delphinine, indaconitine, and pseudaconitine, and the configuration is most probably the same as that in aconitine. Concerning the aroyloxy group, its location at C-10 and its orientation are supported by n.m.r. evidence (10).

Mesaconitine, which is N-methyl-N-desethylaconitine (15, 16), and jesaconitine, a base hydrolyzable to acetic acid, *p*-anisic acid, and aconine (17), must also possess this same absolute configuration.

EXPERIMENTAL

The infrared spectra were measured on a Perkin–Elmer double-beam spectrophotometer Model 21B, and the n.m.r. spectra were obtained in $CDCl_3$ solution with tetramethylsilane as an internal reference on an A-60 instrument. The melting points were determined on a Kofler hot stage and were not corrected.

The ground root of *A. spicatum* Stapf was found to contain two major alkaloids, which were separated by chromatography on alumina.

Pseudaconitine

One of these alkaloids was crystallized from methanol, from which it separated as colorless prisms, m.p. 203–205°, $[\alpha]_D$ +24.0° (*c*, 2.5 in $CHCl_3$). Found: C, 62.63; H,7. 41; N, 2.31. Calc. for $C_{36}H_{51}O_{12}N$: C, 62.69; H, 7.45; N, 2.03%. The base agrees in its properties and empirical formula with those of pseudaconitine. It forms a perchlorate crystallizing from methanol–ether as colorless leaflets which on heating begin to sinter at 239° and decompose at 248°. Found: C, 54.49; H, 6.53. Calc. for $C_{36}H_{51}O_{12}N \cdot HClO_4$: C, 54.72; H, 6.58%.

Monoacetylpseudaconitine

Pseudaconitine (90 mg) in pyridine (2 ml) and acetic anhydride (2 ml) was kept overnight at room temperature. The mixture was poured into ice water, made basic with sodium carbonate, and extracted with methylene chloride. The extract was washed with water, dried over sodium carbonate, and evaporated to dryness. Monoacetylpseudaconitine (90 mg) was left as a residual gum which on trituration with *n*-hexane solidified, m.p. 143–147°. When recrystallized with cyclohexane it consisted of colorless needles, m.p. 135–140°. The product was solvated with cyclohexane as shown by the n.m.r. spectrum. It formed a perchlorate which crystallized from ethanol as colorless prisms, m.p. 247–248°, lit. (4) m.p. 225–228°. Found: C, 54.69; H, 6.44. Calc. for $C_{38}H_{53}O_{13}N \cdot HClO_4$: C, 54.84; H, 6.54%.

Diacetylpseudaconitine

Pseudaconitine (90 mg) in acetyl chloride (2 ml) was heated under reflux for 2 hours. The excess acetyl chloride was evaporated *in vacuo* and the residue dissolved in water. The solution was made basic, extracted with methylene chloride, and the extract evaporated to dryness. It left a residual semicrystalline mass, which was chromatographed in benzene solution over alumina (Grade IV, 5×70 mm column). The initial benzene eluate gave an amorphous fraction (18 mg). Further elution with benzene and benzene–chloroform gave pure diacetylpseudaconitine (45 mg). It crystallized from methanol as colorless elongated prisms, m.p. 227–229°, $[\alpha]_D$ +17° (*c*, 2.8 in $CHCl_3$) (lit. (4), m.p. 229°, $[\alpha]_D$ +24° in $CHCl_3$). Found: C, 62.73; H, 7.06. Calc. for $C_{40}H_{56}O_{14}N$: C, 62.09; H, 7.16%. The n.m.r. spectrum contains the signals for the protons of two acetate groups. Diacetylpseudaconitine was also obtained in better yield by acetylation with acetic anhydride and *p*-toluenesulphonic acid.

Pseudaconine

Pseudaconitine (90 mg) was hydrolyzed by heating with 3% methanolic potassium hydroxide (5 ml) for 1 hour on a steam bath. The reaction mixture when worked up in the usual way gave pseudaconine (acetone solvated, m.p. 87–88°, when crystallized from acetone; isopropanol solvated, m.p. 91–92°, when crystallized from that solvent) in excellent yield. Comparison with an authentic sample of pseudaconine (m.p. of the mixture and infrared spectra) confirmed the identity. Pseudaconine is also obtained in good yield by the action of lithium aluminum hydride on pseudaconitine. The isopropanol-solvated compound was used for the following determinations. $[\alpha]_D$ +49° (*c*, 1.9 in $CHCl_3$). Found: C, 62.19; H, 9.02. Calc. for $C_{25}H_{41}O_8N \cdot C_3H_8O$: C, 61.84; H, 9.08%.

Veratroylpseudaconine

A small quantity of pseudaconitine (100 mg) was dissolved in 0.1 *N* sulphuric acid (15 ml) and the solution heated in a sealed tube at 140° for 5 hours. The crude contents of the tube were made alkaline with 0.1 *N* potassium hydroxide and extracted with chloroform. The extract yielded 60 mg of basic material, which was chromatographed on alumina. The benzene–chloroform (2:3) eluate gave a colorless foam which was converted to a perchlorate, m.p. 228–230° after crystallization from ethanol. Found: C, 55.38; H, 7.00; OCH_3, 25.09. Calc. for $C_{34}H_{47}O_{10}N \cdot HClO_4$: C, 55.93; H, 6.63; 6 OCH_3, 25.51%. The base recovered from the salt crystallized from methanol–ether as colorless prisms, m.p. 212–214°; $[\alpha]_D$ +38.5° (*c*, 0.9 in EtOH), +54.1° (*c*, 1.5 in $CHCl_3$).

Pyropseudaconitine

Pseudaconitine (146 mg) was heated in a vacuum (5×10^{-2} mm) at 180° (air bath). An initial vigorous bubbling ceased after ca. 5 minutes. The product was dissolved in chloroform. The solution was washed with dilute sodium carbonate solution and with water, dried, and evaporated. It left a gum which was purified by chromatography on alumina (grade IV, 5×50 mm column). The benzene eluate gave crude pyropseudaconitine (20 mg) and the subsequent benzene–chloroform eluate gave pure (by thin layer chromatography) pyropseudaconitine (100 mg), which could not be induced to crystallize.

Demethoxyisopyropseudaconine

A mixture of pyropseudaconitine (490 mg) and an excess of lithium aluminum hydride in tetrahydrofuran (15 ml) was stirred overnight at room temperature. After the addition of a few drops of water, the reaction mixture was diluted with methylene chloride, filtered, and the solid washed thoroughly with methylene chloride. The combined filtrate and washings was evaporated on the steam bath under reduced pressure, and the residue extracted with 5% hydrochloric acid. The acid extract was washed with three portions of ether, made alkaline with sodium carbonate, and extracted with methylene chloride. This last extract, after drying and evaporation, left a gum which was chromatographed on alumina (grade IV, 5×70 mm column) and the column was eluted first with benzene, then with chloroform, and finally with chloroform containing 10% of methanol. The last two eluates gave pure demethoxyisopyropseudaconine (270 mg) as a colorless foam which could be distilled *in vacuo* (5×10^{-2} mm, air bath 190°). The solid distillate failed to crystallize but thin layer chromatography showed that it was homogeneous. $[\alpha]_D$ +53.5° (*c*, 0.75 in EtOH). It formed a perchlorate which crystallized from acetone–ether as colorless prisms, m.p. 256–258° (decomp.). $[\alpha]_D$ +21° (*c*, 0.85 in EtOH). Found: C, 53.59; H, 7.07. Calc. for $C_{24}H_{37}O_6N \cdot HClO_4$: C, 53.75; H, 7.14%. In admixture with the Wolff–Kishner reduction product of aconitine (13), the melting point was unchanged and the infrared absorption spectra of both compounds were superimposable.

Dihydrodemethoxyisopyropseudaconine

Demethoxyisopyropseudaconine (212 mg) in absolute ethanol (38 ml) was hydrogenated over Adams' catalyst (80 mg) for 15 hours at room temperature. The product, worked up as usual, consisted of a gum (197 mg), which was dissolved in ether, the solution filtered, and the filtrate evaporated to dryness. The residue in benzene solution was chromatographed over alumina (grade IV, 5×70 mm column). The column was eluted with benzene and with benzene containing 5% of chloroform. The second eluate gave a colorless gum (100 mg) which failed to crystallize but formed a perchlorate that crystallized from acetone–ether as colorless prisms, m.p. 229–231° (decomp.). $[\alpha]_D$ −24.8 (*c*, 1.45 in EtOH). Found: C, 53.08; H, 7.20. Calc. for $C_{24}H_{39}O_6N \cdot HClO_4$: C, 53.57; H, 7.49%. The n.m.r. spectrum did not contain any signal corresponding to olefinic protons.

THE SYNTHESIS OF D-*glycero*-D-*manno*-HEPTOSE

R. K. HULYALKAR, J. K. N. JONES, AND M. B. PERRY
Department of Organic Chemistry, Queen's University, Kingston, Ontario
Received December 15, 1962

ABSTRACT

The condensation of D-altrose with nitromethane in alkaline methanol gave the corresponding epimeric 1-deoxy-1-nitroheptitols from which 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol was obtained in 46% yield. The 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol was converted to D-*glycero*-D-*manno*-heptose in 61% yield.

DISCUSSION

D-*glycero*-D-*manno*-Heptose is a component of an extracellular polysaccharide synthesized by *Azotobacter indicum* (1, 2), whose mode of biosynthesis has been studied in this laboratory (3). In the course of these studies it became necessary to synthesize the heptose in order to devise a method for its stepwise degradation to determine the ^{14}C content at the individual carbon atoms in its chain, and to prepare D-*glycero*-D-*manno*-heptose-1-^{14}C.

D-*glycero*-D-*manno*-Heptose was first synthesised in 39% yield by the application of the Fisher cyanohydrin synthesis (4) to D-altrose. Sowden (5, 6) has shown that the sugar series may be ascended by reactions involving the condensation of nitromethane in alkaline media with the aldehyde function of a glycose to give a mixture of epimeric 1-deoxy-1-nitroglycitols which on treatment with acid (Nef reaction (7)) yield the corresponding glycoses. This procedure, which avoids the use of hydrogen cyanide and the reduction of aldonolactones to glycoses encountered in the use of the classical cyanohydrin method for the ascent of the sugar series (8), thus has several practical advantages.

In the present work it was found that D-altrose could be condensed with nitromethane in alkaline methanol solution to give the theoretical yield of the mixed crystalline salts of the epimeric 1-deoxy-1-nitroheptitols from which 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol was obtained crystalline in 46% overall yield. Treatment of the sodium salt of the 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol with 6 *N* sulphuric acid gave a product containing mainly D-*glycero*-D-*manno*-heptose which was contaminated with some unchanged starting material, D-altrose, and some D-*glycero*-D-*gluco*-heptose. Fractionation of this mixture by cellulose column chromatography (9) gave pure D-*glycero*-D-*manno*-heptose (60% yield), which remained a syrup. It is considered that the procedure offers a convenient route for the synthesis of D-*glycero*-D-*manno*-heptose-1-^{14}C using nitromethane-^{14}C.

Several derivatives of D-*glycero*-D-*manno*-heptose were prepared to investigate the possibility of using them for selective degradation studies directed to the determination of the distribution of ^{14}C in the heptose found in the extracellular polysaccharide produced by *Azotobacter indicum* grown in the presence of ^{14}C-labelled substrates. A degradation scheme for D-*glycero*-D-*manno*-heptose has been described in a recent paper (3).

Attempts to prepare D-mannose from the mixed anomeric methyl D-*glycero*-D-*manno*-heptopyranosides by selective scission of the exocyclic C_6–C_7 glycol system with periodate followed by reduction of the aldehyde group produced at C_6, in a way analogous to that used for the synthesis of D-gulose from D-*glycero*-D-*gulo*-heptose (10), gave a low yield

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of D-mannose, which was isolated and characterized as its crystalline *p*-nitrophenylhydrazone (17% yield).

The D-*glycero*-D-*manno*-heptose gave a crystalline diethyldithioacetal derivative which on Raney nickel desulphurization gave 1-deoxy-D-*glycero*-D-*manno*-heptitol. The deoxyglycitol on periodate oxidation consumed the expected amount of periodate and liberated the theoretical amounts of formaldehyde and formic acid.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper by the descending method (11) using the following solvent systems (v/v): (A) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (B) butan-1-ol – ethanol – water (3:1:1); (C) butan-1-ol – pyridine – water (10:3:3).

The sugars were located on the paper chromatograms using the *p*-anisidine hydrochloride spray reagent (12) and the alkaline silver nitrate spray reagent (13).

Condensation of D-*Altrose with Nitromethane*

To a stirred solution of D-altrose (30 g) (prepared by the method of Rosenfeld, Richtmyer, and Hudson (4)) in dry methanol (180 ml) and nitromethane (180 ml) was added a cold solution of sodium (6.3 g) in dry methanol (140 ml), and the reaction mixture was stirred for 7 hours at room temperature. The mixture was kept at −5° overnight and the precipitated sodium salts of the 1-deoxy-1-nitroheptitols (44 g) were collected by filtration, washed with cold methanol and ether, and then dried *in vacuo*.

The sodium salts of the 1-deoxy-1-nitroheptitols (44 g) were dissolved in water (300 ml), the solution was passed down a column of IR 120(H^+) ion-exchange resin to remove sodium ions, and the effluent was concentrated to a syrup. The syrup was dissolved in ethanol (60 ml) and was kept at 5° for 12 hours, when the resulting crystalline product (18.5 g) was collected by filtration, washed with ethanol, and then dried *in vacuo*; m.p. 105–108°.

Hydrolysis of a small portion of the product with sulphuric acid and paper chromatographic examination of the hydrolyzate indicated it to be mainly 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol contaminated with 1-deoxy-1-nitro-D-*glycero*-D-*gluco*-heptitol. A portion (1 g) of the product was recrystallized five times from methanol to give pure crystalline 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol (0.51 g), which had m.p. 109–110° and $[\alpha]_D^{20}$ −6.8° (*c*, 3.8, 75% ethanol). Anal. Calc. for $C_7H_{15}O_8N$: C, 34.85; H, 6.3; N, 5.8%. Found: C, 35.0; H, 6.8; N, 5.5%.

D-glycero-D-manno-*Heptose*

The crude 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol (9 g), dissolved in *N* sodium hydroxide solution (90 ml), was added dropwise with stirring to 6 *N* sulphuric acid (110 ml) cooled externally with ice. After 30 minutes the solution was diluted with water (200 ml) and was adjusted to pH 3 by the addition of saturated aqueous barium hydroxide solution, whereupon 12% aqueous barium acetate solution (100 ml) was added to complete the removal of sulphate ions. The precipitated barium sulphate was removed by filtration, the filtrate was passed down columns of IR 120(H^+) and Duolite A4 (OH^-) ion-exchange resins, and the deionized solution was concentrated to a syrup (7.7 g). Paper chromatographic examination of the syrup showed it to be composed of D-*glycero*-D-*manno*-heptose contaminated with small amounts of unreacted 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol, altrose, and D-*glycero*-D-*gluco*-heptose. The syrup (7 g) was fractionated chromatographically on a cellulose column (4.5×72 cm) using initially butan-1-ol three-quarters saturated with water as the mobile phase, which was changed to butan-1-ol one-half saturated with water after the D-altrose fraction had been eluted from the column. Using a flow rate of 16 ml of solvent per hour, the following fractions were collected in the order indicated: 1-deoxy-1-nitroheptitol (0.60 g, 8.6%); D-altrose (0.832 g, 12%); D-*glycero*-D-*manno*-heptose (4.23 g, 60.5%); mixed D-*glycero*-D-*manno*-heptose and D-*glycero*-D-*gluco* heptose (0.175 g, 2.5%); and D-*glycero*-D-*gluco*-heptose (1.05 g, 15%).

The D-*glycero*-D-*manno*-heptose, which had $[\alpha]_D^{25}$ +21° (equilib. value; *c*, 3.6 methanol), remained a syrup and on paper chromatography in solvent systems A, B, and C it was indistinguishable from an authentic sample; $R_{glucose}$ 0.90 in solvent A and 0.82 in solvent B.

D-glycero-D-manno-*Heptose p-Nitrophenylhydrazone*

The syrupy D-*glycero*-D-*manno*-heptose (0.2 g) in methanol (3 ml) was heated under reflux for 2 hours with *p*-nitrophenylhydrazine (0.2 g), and the mixture was concentrated and taken up in ethyl acetate (3 ml). On cooling, D-*glycero*-D-*manno*-heptose *p*-nitrophenylhydrazone (0.25 g, 63%), having m.p. 171–174°, was collected and after two recrystallizations from ethanol or aqueous acetone gave crystals (0.15 g) which had m.p. 176–177°. Anal. Calc. for $C_{13}H_{19}O_8N_3$: C, 45.2; H, 5.55; N, 12.2%. Found: C, 45.1; H, 5.7; N, 12.1%.

Hexa-O-acetyl-D-glycero-D-manno-*heptose*

D-*glycero*-D-*manno*-Heptose (1.9 g) was dissolved in acetic anhydride (30 ml) containing sulphuric acid (0.3 ml) and after 48 hours the mixture was poured onto ice; the acetate was extracted in the usual way to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

give the derivative from methanol solution as crystals (2.5 g, 59%) having m.p. 135–136°. After two recrystallizations from chloroform – light petroleum (b.p. 40–60°) mixture the crystalline product (2.15 g) had m.p. 139–140° (lit. value m.p. 138–139° (4)) and $[\alpha]_D^{24}$ +65° (*c*, 2.25 chloroform).

D-glycero-D-manno-*Heptonic Acid*

A stirred solution of D-*glycero*-D-*manno*-heptose (0.5 g) in methanol (30 ml) containing iodine (1.4 g) was kept at 40° while 4% methanolic potassium hydroxide solution (25 ml) was added dropwise over 15 minutes. After cooling the mixture to 0° the precipitated potassium D-*glycero*-D-*manno*-heptonate (0.40 g) was collected, washed with methanol, and dried *in vacuo*. D-*glycero*-D-*manno*-Heptono-γ-lactone (0.2 g), prepared from the potassium salt, in water (2 ml), was heated with phenylhydrazine (0.2 ml) for 3 hours and on cooling of the mixture the phenylhydrazide derivative (0.15 g) was obtained. The D-*glycero*-D-*manno*-heptonic phenylhydrazide after two recrystallizations from methanol had m.p. 187–188° and $[\alpha]_D^{25}$ −6° (*c*, 3 water).

Methyl-D-glycero-D-manno-*Heptopyranosides*

D-*glycero*-D-*manno*-Heptose (0.75 g) was heated under reflux with 2% w/v methanolic hydrogen chloride solution (60 ml) for 48 hours. The isolated glycosides (0.75 g), $[\alpha]_D^{25}$ +47° (*c*, 1.7 methanol), failed to crystallize and paper chromatographic examination showed that no unchanged heptose was present.

One mole part of periodic acid (7.4 ml, 0.3 mole) was added slowly to a stirred solution of the methyl D-*glycero*-D-*manno*-heptosides (0.5 g) in water (10 ml) and after 5 hours the iodic acid was removed by passage of the solution through a column of Duolite A4 (OH^-) ion-exchange resin. The eluate was concentrated (ca. 10 ml) and sodium borohydride (0.5 g) was added. After 12 hours at 0°, IR 120 (H^+) resin was added and the solution was then concentrated to a syrup, from which the boric acid was removed by repeated distillation with methanol. The hydrolyzed (dil. H_2SO_4) product when examined by paper chromatography showed the presence of mannose, a trace of D-*glycero*-D-*manno*-heptose, and a non-reducing component tentatively identified as a pentitol. The concentrated hydrolyzate (0.29 g) in methanol (5 ml) was heated for 1 hour with *p*-nitrophenylhydrazine (0.3 g) to give crystalline D-mannose *p*-nitrophenylhydrazone (0.115 g, 17%) having m.p. and mixed m.p. 200–201°.

D-glycero-D-manno-*Heptose Diethyldithioacetal*

D-*glycero*-D-*manno*-Heptose (0.5 g) dissolved in ice-cold hydrochloric acid (0.6 ml) was shaken with ethanethiol (0.6 ml) at 0° for 30 minutes and then kept at −5° overnight. The resulting white crystals were collected and were combined with the crystals obtained on concentration of the neutralized ($PbCO_3$) reaction mixture. The product was recrystallized from ethanol to give D-*glycero*-D-*manno*-heptose diethyldithioacetal (0.48 g, 65%) which had m.p. 155–156° and $[\alpha]_D^{25}$ +29.6° (*c*, 2.1 water). Anal. Calc. for $C_{11}H_{24}O_6S_2$: C, 41.77; H, 7.65; S, 20.2%. Found: C, 41.73; H, 7.51; S, 20.6%.

1-Deoxy-D-glycero-D-manno-*heptitol*

D-*glycero*-D-*manno*-Heptose diethyldithioacetal (0.36 g) in aqueous methanol (10 ml) was desulphurized by refluxing the solution for 6 hours in the presence of Raney nickel (3 g). Concentration of the methanol solution gave 1-deoxy-D-*glycero*-D-*manno*-heptitol as a syrup (0.20 g) which had $[\alpha]_D^{25}$ 0° (*c*, 3.6 methanol).

The periodate oxidation of an aqueous solution of the 1-deoxy-D-*glycero*-D-*manno*-heptitol at room temperature was complete in 1 hour, giving the following final results: 5.10 mole periodate consumed, 3.90 mole formic acid, and 0.93 mole formaldehyde released per mole heptitol.

ACKNOWLEDGMENTS

The authors wish to thank the National Research Council for financial assistance and Queen's University for the award of a scholarship to one of us (R. K. H.). We wish to thank Dr. N. K. Richtmyer for a sample of hexa-*O*-acetyl-D-*glycero*-D-*manno*-heptose.

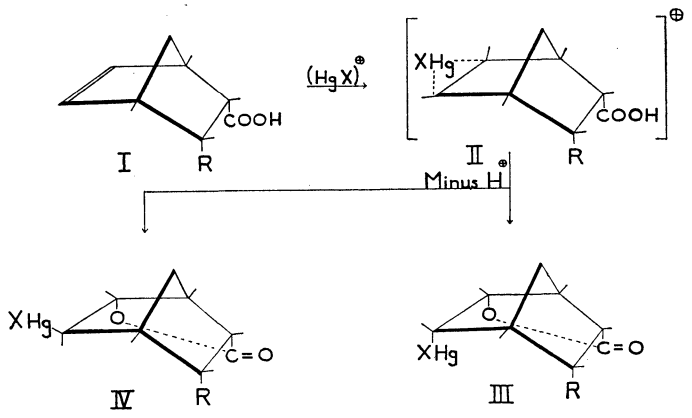
THE OXYMERCURATION OF 1,4-↑↑-METHYLENE-Δ^5-CYCLOHEXENE-2-CARBOXYLIC ACIDS

M. MALAIYANDI AND GEORGE F WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ontario
Received December 7, 1962

ABSTRACT

The oxymercuration of 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↑-carboxylic acid yields two diastereomeric hydroxychloromercurials. Their configurations cannot be specified on the basis of information now available with certainty. The oxymercuration of 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-carboxylic acid also yields two diastereomers, which are designated as 6-↓-hydroxy-5-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone and 6-↓-hydroxy-5-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-dicarboxylic acid, γ-lactone because the former is more easily deoxymercurated than the latter and because their dipole moments match relatively the corresponding moments of the analogous dicarboxylic acid γ-lactones, the configurations of which have been proved chemically. This is the first instance where two diastereomers of opposite configuration have been shown to be formed in an oxymercuration.

During a recent study of the oxymercuration of various substituted [2.2.1]-bicycloheptenes (1) an anomaly has become apparent. The [2.2.1]-bicycloheptenes behave differently from other cyclic alkenes because the oxymercuration is acid catalyzed and the oxymercurials have the ↑↓ (trans) configuration. The exception is the isolable oxymercurial III-C from 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid. The chemical behavior of III-C shows it to be 5-↓-hydroxy-6-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone. But if the reaction proceeds through an ionic intermediate, at least one other diastereomer (probably 5-↓-hydroxy-6-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone, IV-C, ought to be formed. However, this diastereomer, IV-C, has the same solubility characteristics as III-C. Its main chemical difference from III-C, a higher resistance toward deoxymercuration, would not be apparent if it were a contaminant of low concentration. Consequently its presence in small amount might be missed, especially if traces of other diastereomers were present.



I TO IV (R=H)

I-C TO IV-C (R=COOH)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

For this reason we decided to study the oxymercuration of a simpler substance, 1,4-↑↑-methylene-Δ^5-cyclohexane-2-↓-carboxylic acid, I. Since this acid is obtained from pentadiene and acrylic acid (2) in difficultly separable admixture with 1,4-↑↑-methylene-Δ^5-cylohexene-2-↑-carboxylic acid, IV, we have first effected a separation by an oxymercuration of the mixture. Fractional crystallization of the products of oxymercuration leads mainly to two oxymercurials which, when deoxymercurated by means of hydrochloric acid, regenerate I and IV separately. The ratio of 2-↓- to 2-↑-carboxylic acids in the mixture has been found by this method to be 12–13 to 1, thus more in agreement with the 9:1 ratio found by infrared analysis (3) than with the 77:23 ratio reported (4) by separation of I as its iodolactone.

We have treated 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↓-carboxylic acid, I, in water with mercuric acetate, then with sodium chloride, and have obtained a crude 83% yield of mercurials m.p. 183–195°. When this mixture is fractionally crystallized the overall yield is found to be comprised of 77% of one mercurial and 3% of another, the remaining 3% being either more of the major product or else a yet unisolated isomer. We have assigned to the major product, III, the stereo-structure 6-↓-hydroxy-5-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone.

During the progress of the present investigation the oxymercuration of I was reported by Henbest and Nicholls (5), who assigned to their sole product (identical with our major product) the structure 6-↓-hydroxy-5-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone, IV, which we consider to be that of our minor product.

When our major product is treated in methanol with hydrazine a mixture is obtained consisting of 1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid and the mercurial which we specify as IV. Either of III or IV may be reduced by use of sodium borohydride (1, 5) to 6-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone, V (6). The difference between the two mercurials must then rest entirely with the ↓↓ versus ↓↑ relationship of hydroxy and chloromercuri groups. Thus the expectation that acid-catalyzed oxymercuration ought to give more than one product has been realized.

On the basis of chemical reaction the assignment by Henbest and Nicholls is entirely arbitrary. These authors rely factually on the results of an X-ray diffraction study carried out earlier in our laboratory which has since been thought to be non-definitive (1). On the other hand our structure specifications are based on the observation that our minor product is more difficult to deoxymercurate than is our major product. Since the minor product also has a higher dipole moment than the major product we believe that our assignments (major product, III, and minor product, IV) are correct, because of these correlations with proven configurations among the mercurials from the 1,4-↑↑-methylene-Δ^5-cyclohexenedicarboxylic acids (7). Comparison in respect of dipole moment is shown in Table I. The dicarboxylic analogues are in each instance designated by the suffix "C".

The mechanism of oxymercuration for I is assumed to be the same as that for 1,4-↑↑-methylene-Δ^5-cyclohexene-2,3-↓↓-dicarboxylic acid, I-C (1). Although oxymercuration in [2,2,1]-bicycloheptenes is expected to proceed via a mercurinium-ion type of intermediate, II, and thus ought to lead chiefly to IV, the presence of the ↓-carboxylic group may be expected to alter this expectation by preference to an intramolecular addition which would proceed via the undissociated salt, VII. In the absence of external ion attack the major product would be III, similar to formation of III-C from I-C.

We were unable to oxymercurate 1,4-↑↑-methylene-Δ^5-cyclohexene-2-↑-carboxylic acid, VI, in purely aqueous medium because of product contamination with the mercuric salt of VI but we have successfully isolated two hydroxy-chloromercuri-1,4-↑↑-methylene-

VII

cyclohexane-2-↑-carboxylic acids, VIII and IX, by inclusion of 2,5-dioxahexane into the reaction system. The ratio of high-melting (VIII) to low-melting diastereomer (IX) is 4:1. Unfortunately we have not found any chemical reaction by which we can specify either position or configuration for the added groups. The deoxymercuration of VIII is somewhat slower than that of IX. However, no definitive assignment of configuration can be made for them or for the 5-hydroxy-1,4-↑↑-methylenecyclohexane-2-↑-carboxylic acids obtained from them by reduction with sodium borohydride.

One may expect from consideration of the moments of the mercury-free mono- and di-carboxylic acids at the top of Table I that the values for the present pair of bicycloheptane-↓-monocarboxylic acid oxymercuration derivatives will be more meaningful than those obtained for the dicarboxylic acid derivatives (1). For the latter series, an artifically low C—COOH moment (1.2 D) had to be chosen, as would be expected because of mutual rotation interaction of the two carboxyl groups. By contrast, the moments of the bicycloheptanemonocarboxylic acids are approximate to those of many alkanecarboxylic acids, and they differ only by the contribution to polarity from the norbornane ring (1).

No such disparity is to be expected between 6-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone and the analogue with a carboxyl group in the 3-position. Since the latter group is the only rotator, it is to be expected that 6-↓-hydroxy-1,4-↑↑-methylenecyclohexane-2,3-↓↓-dicarboxylic acid, γ-lactone would differ from its carboxylic-free analogue, V, only by the vectorial component due to this rotating carboxylic group. This expectation is confirmed in fact (Table I) by comparison of the moments of V and V-C.

Despite the small difference between μ for V-C and V it is to be expected that analysis of structure V should be less complicated than that of V-C.

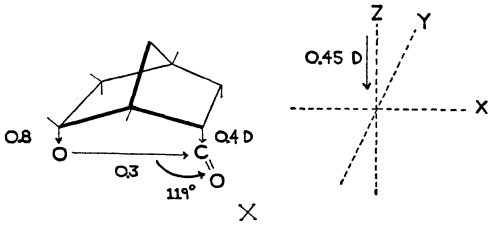
For personal use only.

This may be seen in the vector model:



A slightly different set of bond moments and O—C=O bond angle than the one used for the comparable calculation of the 3-↓-carboxy analogue (1) has been assumed. When the O—C=O group moment resultant (2.54 D) is assumed to be directed 84° from the y-axis a close correlation with the observed value is obtained.

$$\mu_z = 0.4 \cos^2 18° + 0.8 \cos^2 18° + 2.54 \cos 30° + 0.45 = 3.735 \text{ D}$$
$$\mu_x = 0.4 \cos^2 18° - 0.8 \cos^2 18° + 2.54 \cos 119° = -0.88 \text{ D}$$
$$\mu_y = 0.8 \sin^2 18° - 0.4 \sin^2 18° + 2.54 \sin 84° = 2.64 \text{ D}$$
$$\mu_r^2 = \mu_z^2 + \mu_x^2 + \mu_y^2$$
$$\mu_r = 4.66 \text{ D} \qquad \text{found: } \mu = 4.70 \text{ D}$$

In order to calculate the moments of the two diastereomeric chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactones III and IV one must add vectorially to the coordinate moments calculated above the Cl—Hg—C group, for which an angle of 96° is assumed in the present calculation. Then a Cl—Hg moment of 3.4 D is derived from the moment of *n*-propylmercuric chloride (3.70 D) by application of the 96° C—Hg—Cl angle and a C—Hg moment of 1.3 D (1).

The moment of 6-↓-hydroxy-5-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ lactone, III, has been calculated on the assumption that free rotation of the chloromercuri group is impossible, with this group diametrically opposed to the carbonyl group of the lactone. This assumption seems to be reasonable on the basis of the calculation for the carboxyl analogue of III with chloromercuri at the four quadrant positions (1).

$$\mu_z = 3.735 - 1.3 \cos 18° + 3.41 \cos 78°$$
$$\mu_x = -0.880 - 1.3 \cos 72° \cos 18° + 3.41 \cos 12° \cos 60°$$
$$\mu_y = 2.64 + 1.3 \cos^2 72° - 3.41 \cos 12° \cos 30°$$
$$\mu_r = 3.42 \text{ D} \qquad \text{found: } 3.39 \text{ D}$$

This calculation gives a moment value close to that actually determined in dioxane solution at 20°.

The test of the significance of this agreement between calculated and found values for III should be the application of the same parameters to the moment calculation of the diastereomer IV, although, in the absence of hindrance in this isomer, one should assume free rotation of the chloromercuri group. This rotation has been included by calculation of the two modes, 180° removed, of chloromercuri in the plane which includes the z-axis and the 2,5-positions of the norbornane skeleton.

Mode A:
$$\mu_z = 3.735 + 1.3 \cos 72° + 3.41 \cos 78°$$
$$\mu_x = -0.88 + 1.3 \cos^2 18° - 3.41 \cos 12° \sin 60°$$
$$\mu_y = 2.64 + 1.3 \cos 18° \cos 72° + 3.41 \cos 12° \cos 60°$$
$$\mu_r = 7.23 \text{ D}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Mode B: $\mu_z = 3.735 + 1.3 \cos 72° - 3.41 \cos 78°$
$\mu_x = -0.88 + 1.3 \cos^2 18° - 3.41 \cos 12° \cos 30°$
$\mu_y = 2.64 + 1.3 \cos 18° \cos 72° + 3.41 \sin 30° \cos 12°$
$\mu_r = 6.36$ D

The mean of these two resultant moments $[(52.2+40.5)/2]^{\frac{1}{2}}$ is 6.81 D, in reasonable agreement with the experimental value, 6.99 D. It may be noted that the discrepancy (0.18 D) is the same as was observed for the carboxy analogue of IV (1). This discrepancy may still be attributed to a slight obstruction to free rotation.

EXPERIMENTAL

Physical Constants

Dielectric constants of solids and solutions were determined as described previously (8). Melting points have been corrected against reliable standards (9). X-Ray diffraction patterns have been made with Cu K_α (Ni filtered) radiation and are expressed as relative intensities (I/I_1) for d spacings in Angstroms.

Separation of endo- and exo-1,4-Methylene-Δ⁵-cyclohexene-2-carboxylic Acids by Oxymercuration

A. Endo Acid

To a suspension of 28.0 g (0.2 mole) of the diastereomeric mixture of acids (2), m.p. −13° C, d_4^{25} 1.071, n_D^{20} 1.4850, in 500 ml of water was added 64.0 g (0.2 mole) of mercuric acetate. After 1 hour of stirring the system was treated with a slight excess of aqueous sodium chloride. The curdy precipitate, filtered, washed thrice with water, and dried, weighed 72 g (96%), m.p. 178–196° C. It was dissolved in a slight excess of cold 5% aqueous sodium hydroxide except for a small amount of yellow precipitate. After filtration the system was neutralized with 0.5 ml of 1% hydrochloric acid and then saturated with gaseous carbon dioxide. The precipitate, filtered, water-washed, and dried, melted at 195–200° C, 50 g. This precipitate was extracted with a mixture of dioxane and acetone (1:4) to leave 24 g, m.p. 217–219° C. Two crystallizations from the dioxane–acetone mixture left 22 g, m.p. 222–223° C.

This pure chloromercurial was deoxymercurated by warming for 3 minutes at 50° C a suspension of 23.9 g (0.064 mole) in 80 ml of methanol with 12.5 ml (0.13 mole) of conc. hydrochloric acid. The system, which was homogeneous within 15 minutes, was chilled after 1 hour and made alkaline (pH 8.3–10). The mercuric oxide was filtered off (13.6 g, 98.6%) and the filtrate was vacuum evaporated to remove the methanol. The aqueous residue was acidified to pH 3–4 and then was extracted with diethyl ether. Evaporation of the dried extract left 8 g of oil which, when crystallized at −30° C after solution in 30 ml petroleum ether (b.p. 40–60° C), gave 7.0 g (81%) of m.p. 41–42° C. Recrystallization from the same solvent raised this melting point to 44.3–45.0° C. The *p*-phenylphenacyl derivative melted at 134.9–135.4° C (9).

B. Exo Acid

The original liquor from which the oxymercurial m.p. 222–223° C was precipitated was combined with the crystallization liquors and was fractionally evaporated to yield crops of successively decreasing purity which still were mainly the oxymercurial m.p. 222–223° C. Final evaporation left 4.0 g, m.p. 160–178° C, which was crystallized from acetonitrile (10 ml/g) to give 3.0 g (6%) of mercurial m.p. 172–172.4° C.

Deoxymercuration of this mercurial by the procedure outlined above gave a 75% yield of impure 1,4-↑↑-methylene-Δ⁵-cyclohexene-2-↑-carboxylic acid m.p. 35–37° C. Crystallization from petroleum ether (b.p. 40–60° C) raised this melting point to 38–38.5° C. Although it gave the proper *p*-phenylphenacyl derivative (m.p. 131.5–132.2° C) (3) it was still impure. The separation of this exo acid from the diastereomeric mixture is much more satisfactorily accomplished via the iodolactone (4), especially if a mixture of diastereomers rich in exo acid is used. Actually such a mixture yielding 54% of 1,4-↑↑-methylene-Δ⁵-cyclohexene-2-↑-carboxylic acid b.p. 87–95° C (0.01–0.2 mm), m.p. 42–44° C was obtained by alkaline saponification of the 2-cyanonorbornene mixture prepared according to Bruson (10).

Hydroxymercuration of 1,4-↑↑-Methylene-Δ⁵-cyclohexene-2-↓-carboxylic Acid

To a stirred suspension of 9.0 g (0.067 mole) of the unsaturated endo acid in 100 ml of water was added 25.6 g (0.08 mole) of mercuric acetate in small amounts during 15 minutes. After 2 hours of subsequent stirring the system was treated with a slight excess of aqueous sodium chloride. The white precipitate was dissolved in a slight excess of 10% aqueous sodium hydroxide.

After filtration to remove mercuric oxide the system was neutralized by addition of two drops of 5% hydrochloric acid and by saturation with gaseous carbon dioxide. The precipitate was filtered off and washed successively with 5% aqueous acetic acid, water, acetone, and ether; dried weight 21 g (83%), m.p. 183–195° C.

This mixture was dissolved in 1500 ml of boiling dioxane. After filtration to remove 0.45 g of mercurous salt the solution was concentrated under reduced pressure in steps to yield crystal crops weighing 12.95 g,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

m.p. 217–219° C. The final mother liquor (250 ml) was vacuum-evaporated to dryness. The residue (4.2 g, m.p. 167–180° C) was dissolved in 150 ml of hot methanol and this solution was concentrated to a volume of about 120 ml whereby 3.25 g more, m.p. 217–220° C, was obtained. The mother liquor was processed as described below.

The combined crops of crude 6-↓-hydroxy-5-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone, III, m.p. 217–220° C, 16.35 g (77%), were crystallized from 4:1 methanol–dioxane mixture (50 ml/g) to melt at 222–223° C. Anal. Calc. for $C_8H_9O_2HgCl$: C, 25.7; H, 2.41. Found: C, 25.9; H, 2.50.

The infrared spectrum (potassium chloride pellets at 20,000 p.s.i., 24° C) is expressed in wave numbers versus extinction as follows: (716) 6.80; (746) 6.85; (788) 6.94; (842) 7.88; (878) 4.85; (888) 7.71; (900) 8.86; (950) 12.7; (986) 23.9; (1010) 9.53; (1061) 7.88; (1100) 10.9; (1128) 6.75; (1146) 12.3; (1190) 22.6; (1242) 9.46; (1272) 9.60; (1304) 17.3; (1352) 15.0; (1450) 6.35; (1564) 3.79; (1768) 20.0; (1852) 3.65; (1930) 3.10; (1982) 2.95; (2580) 4.79; (2900) 8.42; (3010) 14.2.

The X-ray diffraction pattern was [10] 12.99, [8] 9.55, [7] 2.36, [6] 4.17, [5] 3.69, [4] 3.88, [3] 5.34, [2] 2.03, [1] 6.75.

The final mother liquor from which this crude chloromercurial was isolated yielded upon final vacuum evaporation 0.58 g, m.p. 184–186° C (3%). Crystallization from ethanol (80 ml/g) raised this melting point to 186.5–187° C. Anal. Calc. for $C_8H_9O_2HgCl$: C, 25.7; H, 2.41. Found: C, 25.8; H, 2.46. The X-ray diffraction pattern of this 6-↓-hydroxy-5-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone (IV) was [10] 9.06, [8] 3.14, [6] 4.88, [5] 2.84, [4] 4.50, [3] 5.26, [2] 4.58, [1] 2.36.

The infrared spectrum prepared and described as above is: (722) 31.4; (750) 13.8; (788) 10.6; (816) 7.96; (840) 14.8; (888) 25.0; (938) 13.9; (960) 13.2; (979) 56.7; (1010) 47.6; (1088) 45.2; (1138) 20.0; (1150) 14.7; (1192) 53.2; (1228) 11.2; (1248) 24.5; (1274) 15.9; (1300) 28.0; (1318) 25.5; (1344) 47.3; (1452) 14.1; (1470) 10.3; (1554) 7.52; (1758) 54.7; (2290) 16.5; (3020) 40.2.

This product, IV, also was formed when 7.4 g (0.02 mole) of III, m.p. 222–223° C, in 10 ml of methanol was stirred for 48 hours with 1.4 ml (0.022 mole) of hydrazine hydrate at 35–40° C. After removal of metallic mercury by filtration the system was vacuum-evaporated to leave a residue which was extracted with 100 ml of petroleum ether (b.p. 40–60° C). The extracted residue (vacuum-dried) was washed onto a filter with cold 5% hydrochloric acid, then redried and crystallized from 95% ethanol (10 ml/g) to yield 1.2 g (17%), m.p. 185–186° C. Recrystallization from ethanol (7 ml/g) raised this melting point to 186.5–187° C and a mixture melting point with that obtained by hydroxymercuration was not lowered.

The petroleum ether extract was vacuum-evaporated to leave a residue which was crystallized from acetonitrile (4 ml/g), m.p. 61–62° C, 1.8 g (64%) of crude 1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid. Two recrystallizations from acetonitrile raised the melting point to 64.5–65.3° C. A mixture melting point with an authentic sample (2) was not depressed.

1,4-↑↑-Methylene-Δ⁵-cyclohexene-2-↓-carboxylic Acid, I

A. By Deoxymercuration of III

To a suspension of 30.0 g (0.08 mole) of III, m.p. 222–223° C, in 150 ml of methanol was added 20 ml (0.208 mole) of 36% hydrochloric acid, and the system was warmed to 50° C for 5 minutes, then maintained without heating and with occasional stirring for 15 minutes. The homogeneous system was maintained for 1 hour longer, then was cooled in ice and made alkaline with a slight excess of 10% aqueous sodium hydroxide (pH 7.3–10). After filtration of mercuric oxide the solution was vacuum-evaporated until methanol was gone, then was acidified to pH 3 with hydrochloric acid and was extracted with diethyl ether. Evaporation of the dried extract left a residue (9.45 g, 85%) which when crystallized from petroleum ether (b.p. 40–60° C) melted at 44–45° C, not depressed by admixture with 1,4-↑↑-methylene-Δ⁵-cyclohexene-2-↓-carboxylic acid.

The deoxymercuration of III also may be effected completely in 5 minutes at 24° by treatment of 0.2 g of III with 0.5 ml of 36% hydrochloric acid. The same conversion to the endo unsaturated acid requires 15 minutes by use of 20.4% hydrochloric acid.

B. By Deoxymercuration of IV

When the methanolic deoxymercuration procedure described above was applied to IV a 3-hour reaction time was required to give an 80% yield of crude endo unsaturated acid, m.p. 36–38° C. Crystallization from petroleum ether (b.p. 40–60° C) raised this to 44.5–45.3° C whence a mixture melting point with pure 1,4-↑↑-methylene-Δ⁵-cyclohexene-2-↓-carboxylic acid proved the identity.

When 0.1 g of IV was treated with 0.25 ml of 36% hydrochloric acid for 5 minutes at 24° C, then diluted with 0.25 ml of water, the filterable portion, washed with water and then with diethyl ether, weighed 0.05 g and melted at 185–186° C. A mixture melting point with IV was not depressed. When the initial hydrochloric acid concentration was 20.4% only 15% of IV was deoxymercurated in 15 minutes.

C. By Deoxymercuration of III plus IV

To an intimate mixture of 0.2 g of III and 0.10 g of IV was added 0.5 ml of 36% hydrochloric acid. After 5 minutes at 24° C and then dilution with 0.5 ml of water the filtered solid phase was shown to be 0.045 g

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(45%) of IV of high purity (m.p. 185–186° C). A mixture melting point was not lowered. When 20.4% hydrochloric acid was used the recovery of IV only was 90%, m.p. 184–185° C.

5-↓-Hydroxy-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic Acid, γ-Lactone, V

A. From III

A clear solution of 7.4 g (0.02 mole) of 6-↓-hydroxy-5-↓-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone, III, in 100 ml of 1% aqueous sodium hydroxide was cooled to −2° C and swirled while 2.6 g (0.022 mole) of sodium trimethoxyborohydride was added during 30 minutes. Then the black suspension was allowed to warm to 40° C and was filtered to remove 3.9 g (97%) of mercury.

The cold filtrate was carefully acidified with 5% aqueous sulphuric acid to pH 3 and then was extracted with diethyl ether. Evaporation of the dried extract left 2.15 g (76%), slightly sticky but melting at 146–149° C. After sublimation at 60–65° C at 0.7 mm and threefold crystallization from petroleum ether (b.p. 90–100° C) the melting point was raised to 155.5–156.5° C. A mixture melting point with an authentic specimen (6) was not lowered.

B. From IV

The identical procedure outlined above was applied to 6-↓-hydroxy-5-↑-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↓-carboxylic acid, γ-lactone, IV, with identical result.

Hydroxymercuration of 1,4-↑↑-Methylene-Δ⁵-cyclohexene-2-↑-carboxylic Acid

To a stirred solution of 2.76 g (0.02 mole) of methylenecyclohexene-2-↑-carboxylic acid in 75 ml of 1:1 2,5-dioxahexane–water mixture at 65–70° C was added during 1 hour a solution of 6.4 g (0.02 mole) of mercuric acetate in 50 ml of 98:2 water – acetic acid. After 2 days of subsequent stirring the system was filtered to remove 0.2 g of grey solid and then was made alkaline to pH 10. More grey solid (50 mg) was filtered off and the filtrate, after 2.1 g of sodium chloride was dissolved in it, was acidified by addition of gaseous carbon dioxide. After filtration this solution at pH 5–6 was vacuum-evaporated. The residue was Soxhlet-extracted with absolute alcohol, leaving a solid residue, A, and an extract, B.

Hydroxy-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-carboxylic Acid, VIII

The solid residue, A, was washed with 0.5% hydrochloric acid, then with water, and was filtered to remove 1.2 g (15%) of crude chloromercurial m.p. 199–206° C. Two crystallizations by solution in 25 ml of 1:4 dioxane–ethanol followed by dilution with 15 ml of commercial hexane raised this melting point to 216–217° C. The mother liquors were combined with extract A. The infrared spectrum (potassium chloride pellets at 20,000 p.s.i., 24° C) of the mercurial, VIII, is expressed as wave numbers versus extinction: (3144) 8.21; (2920) 6.26; (2584) 4.37; (1681) 14.6; (1441) 4.81; (1418) 5.60; (1361) 11.3; (1333) 8.46; (1297) 5.48; (1267) 4.81; (1247) 2.25; (1233) 3.99; (1209) 2.92; (1159) 0.84; (1126) 2.48; (1110) 1.00; (1055) 3.91; (1033) 4.99; (1020) 4.42; (1007) 7.17; (967) 2.74; (939) 0.56; (912) 2.58; (883) 2.74; (869) 2.58; (835) 1.92; (777) 2.07; (769) 2.58; (759) 3.81; (723) 4.37; (651) 3.27. Anal. Calc. for $C_8H_{11}O_3HgCl$: C, 24.6; H, 2.81. Found: C, 24.9; H, 3.09. The extrapolated dielectric constant of the pelleted solid (8, 11) (Fig. 1) was found to be 2.347 and its density by flotation was 2.004, so distortion polarization is 60.5 cc by contrast to 53.9 cc calculated additively from Eisenlohr values.

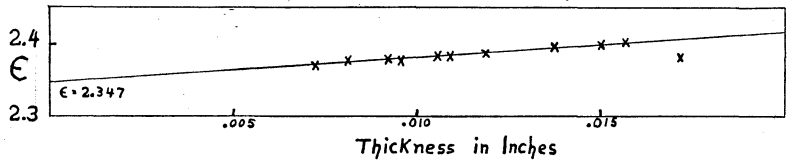


FIG. 1. Extrapolation of apparent ϵ to zero thickness, VIII.

Hydroxy-chloromercuri-1,4-↑↑-methylenecyclohexane-2-↑-carboxylic Acid, IX

The acid and water washings, together with the crystallization mother liquors obtained in the preceding experiment, were combined with extract A above and the whole was vacuum-evaporated to dryness. The residue was eluted with absolute ethanol. The vacuum-evaporated eluate was washed onto a filter with 25 ml of 0.5% hydrocholoric acid; 5 g (64%) of crude chloromercurial, m.p. 159–170° C, was obtained. After two crystallizations from acetonitrile (30 ml/g) the product melted at 171–172° C, identical, by mixture melting point, with that obtained during the original separation of norbornenecarboxylic acids. The infrared spectrum (pellets as described above) expressed as (cm^{-1}) is: (3236) 9.67; (2924) 5.42; (1695) 15.6; (1445) 0.77; (1443) 0.74; (1364) 3.94; (1324) 2.40; (1292) 3.35; (1250) 3.14; (1235) 5.29; (1178) 7.49; (1139) 9.05; (1065) 5.42; (1031) 2.33; (1013) 6.34; (1003) 6.34; (947) 1.74; (911) 3.07; (887) 1.79; (823) 2.07. Anal. Calc. for $C_8H_{11}O_3HgCl$: C, 24.6; H, 2.81. Found: C, 24.9; H, 3.20.

When the entire experiment was conducted without 2,5-dioxahexane for solubilization, the diastereomers

For personal use only.

m.p. 216° C and 172° C were obtained in yields of 8 and 22% respectively; much exo acid was recovered unchanged.

Deoxymercuration Rates of VIII and IX

Into 5 ml of 20% hydrochloric acid at 25° was stirred 0.1 g of finely powdered chloromercurial IX, m.p. 171–172°. After 15 minutes the system was diluted with 10 ml of water and filtered to remove 0.008 g (8%) of the original mercurial. When these conditions were reproduced upon 0.1 g of VIII 52% was recovered unchanged.

When 0.1 g each of VIII and IX were stirred into 10 ml of 20% hydrochloric acid for 15 minutes and then diluted with 20 ml of water the recovered mercurial (0.048 g, 48%) melted at 212–215° and was shown by mixture melting point with an authentic specimen, m.p. 214–216°, to be chiefly VIII.

Reduction of VIII and IX with Sodium Borohydride

A solution of 3.4 g (8.7×10^{-3} mole) of either VIII or IX in 25 ml of 5% aqueous sodium hydroxide was chilled to −5°, and 0.38 g (0.01 mole) of sodium borohydride was added portionwise during 10 minutes. After 1 hour the cooling bath was removed and the system at room temperature was just acidified with 2 *N* hydrochloric acid. The metallic mercury (1.64 g, 94%) was filtered off. The filtrate was five times extracted, with a total of 75 ml of diethyl ether, and this extract, dried by use of sodium sulphate, was distilled under 0.3 mm.

The product from IX boiled at 157–160°, 0.45 g (30%), m.p. 105–110°. Crystallization from benzene raised this melting point to 114–115°. A Nujol mull of this product, X, showed strong hydroxyl absorption at 3430 cm^{-1} and carboxyl absorption at 1704 cm^{-1}. The hydroxyl absorption at 1010 cm^{-1} appeared as a doublet. Anal. Calc. for $C_8H_{12}O_3$: C, 61.5; H, 7.75. Found: C, 61.3; H, 7.59.

The product from VIII boiled at 146–152°, 0.36 g (22%). It melted at 131–135° after crystallization from 2 ml benzene. Recrystallization from the same solvent raised this melting point to 134–136°. The spectrum from this product, XI, resembled that of X except that only a single peak was found at 1008 cm^{-1}. Anal. Calc. for $C_8H_{12}O_3$: C, 61.5; H, 7.75. Found: C, 61.5; H, 7.52.

Electrical Polarization Studies

The high value of distortion polarization (P_D) found for VIII by extrapolation of the dielectric constants of various thicknesses of compressed wafers (11) (Fig. 1) indicates that the calculation of electronic polarization from summation of bond or group refractions may introduce a minor error in the results of Table I. These summations have been used in every instance except for IX, where P_D for VIII was subtracted from the total polarization to arrive at the orientation polarization from which the moment is calculated. The error is slight and it applies also to the determination of dielectric constants for the dicarboxylic acid series (1).

Two grades of dioxane were used for determination (11) of total solute polarizations. Dioxane of $\epsilon = 2.2183$ and $\bar{V} = 0.96803$ was used for the values shown in Fig. 2 and of $\epsilon = 2.2276$ with $\bar{V} = 0.96775$ for the values shown in Fig. 3. Both figures show extrapolations to zero concentration of ϵ and $\bar{V}$ for various strengths of solutions.

COORDINATION POLYMERIZATION OF OLEFINS

CATALYST STUDIES. PART I. THE INFRARED SPECTROSCOPIC INVESTIGATION OF THE SYSTEMS $(CH_3)_3Al$–$TiCl_4$ AND $(CH_3)_2Zn$–$TiCl_4$

ABSTRACT

An infrared spectroscopic investigation of the reaction between titanium tetrachloride and trimethyl aluminum in the vapor phase was carried out at six different reactant ratios. The study defined the course of the initial reactions; demonstrated the importance of equilibria among the products in this system as contrasted with dimethyl zinc – titanium tetrachloride; indicated the relative alkylating power of trimethyl, dimethylchloro, and methyldichloro aluminum toward titanium tetrachloride and methyl titanium trichloride; and supported the view that the active catalyst site in such systems is the titanium–carbon bond in reduced titanium alkyls. A new mode of decomposition of methyl titanium trichloride leading to active catalyst was found which can account for reported variable catalyst activities at Al/Ti ratios less than 1. Individual infrared spectra in the range 1500 to 300 cm^{-1} for trimethyl aluminum, dimethyl aluminum dichloride, methyl aluminum dichloride, methyl titanium trichloride, and dimethyl titanium dichloride as well as those of the initial reaction mixtures are presented.

INTRODUCTION

In spite of very widespread and intensive interest in olefin polymerization catalysts involving transition metal compounds with metal alkyls (coordination catalysts) (1–7), neither the reactions leading to the formation of active catalyst nor the nature of the catalyst species itself have been satisfactorily determined, and to a large extent remain matters for speculation. Aside from the work of Groenewege (8), who carried out an infrared study of the system dimethyl aluminum chloride plus titanium tetrachloride in heptane solution at two different reactant ratios, very little direct physical evidence pertaining to this problem has been published, no doubt because of the considerable experimental difficulties associated with such highly reactive systems. However, as will be demonstrated by the work to be reported, at least for the systems $(CH_3)_3Al + TiCl_4$ and $(CH_3)_2Zn + TiCl_4$, these difficulties may be largely overcome by working in the vapor phase. In this way, the initial and subsequent reactions between the catalyst components have been followed by infrared spectroscopy over essentially the whole range of practically significant reactant ratios.

As the compounds employed and produced in these investigations are in themselves of very great structural and spectroscopic interest, they are discussed at some length from this point of view in a paper which follows (9).

EXPERIMENTAL

Preparation of Materials

$TiCl_4$

The titanium tetrachloride was obtained from the Fisher Scientific Company. It was found to contain very small amounts of hydrogen chloride and phosgene, which were removed by pumping under vacuum. A final bulb-to-bulb fractionation *in vacuo*, the middle cut being retained, gave what appeared to be, on infrared analysis, a pure product.

$(CH_3)_6Al_2$

Trimethyl aluminum (a dimer at room temperature) was obtained from the Ethyl Corporation. This material was then distilled *in vacuo* and stored on the vacuum line.

$(CH_3)_2Zn$

It was found by C. T. Elston of this laboratory that the reaction between anhydrous zinc chloride and trimethyl aluminum produced $(CH_3)_2Zn$, which could be easily separated from the other products by efficient fractional distillation.

Trimethyl aluminum was added slowly from a dropping funnel to powdered anhydrous zinc chloride under nitrogen. The mixture was gently heated to about 50° C and allowed to reflux under its own heat of reaction. On completion of the reaction, dimethyl zinc was distilled from the mixture at 46° C, collected in a flask, cooled to 0° C, and finally redistilled onto the vacuum line, where it was stored. This method produced a very pure form of dimethyl zinc.

Infrared Instrumentation and Procedure

A Perkin–Elmer Model 21 double-beam spectrophotometer, fitted with sodium chloride optics, was used in this work to record the infrared spectra from 4000 to 650 cm^{-1}. A Perkin–Elmer single-beam, double-pass Model 112 spectrometer with caesium bromide optics was used for the region 650 to 290 cm^{-1}. The latter instrument was swept with dry nitrogen during the runs and was calibrated against reference lines of water vapor and methanol.

The infrared gas cells used were of Pyrex, 10 cm in length, and fitted with a vacuum stopcock and side arm. Kel-F grease was employed as a stopcock lubricant, and the CsBr windows were sealed on with glyptal in such a manner that the cells were vacuum-tight and had very little glyptal exposed to their interiors. After each run, the cell was taken apart, the windows repolished, and the cell body thoroughly cleaned and dried. The infrared solution work reported was carried out in a conventional sealed cell with CsBr windows and Teflon spacer.

The quantities of materials to be reacted were measured, using a sensitive spoon gauge. The infrared cell was connected to a high-vacuum system, pumped out, and then, to insure complete dryness and to render inert any potentially harmful materials used in the cell construction, was rinsed for 1 hour with a quantity of the metal alkyl vapor to be used. This vapor was then removed and the desired quantity of metal alkyl frozen out in the side arm of the cell. The required quantity of $TiCl_4$ was next measured and also frozen out in a different section of the side arm. The cell was isolated from the vacuum system and the side arm warmed quickly to allow the materials to react in the vapor phase.

RESULTS AND DISCUSSION

In order to facilitate the discussion, the individual spectra of the pure isolated components of the reaction mixtures will first be presented and briefly discussed to the extent necessary for consideration and understanding of the reaction mixtures. The spectra of the reaction mixtures at six different reactant ratios will next be interpreted. With the exception of carbon–hydrogen stretching vibrations, which occur essentially in the same range as that for hydrocarbons, no bands above 1500 cm^{-1} were observed in this study. Accordingly, the spectra presented cover the range from 1500 to 300 cm^{-1} only.

Individual Component Spectra

All major infrared absorption bands occurring in the spectra at the various ratios of titanium tetrachloride and trimethyl aluminum are found to be satisfactorily accounted for by absorption of the initial reactants, dimeric dimethyl aluminum chloride, dimeric methyl aluminum dichloride methyl titanium trichloride, and dimethyl titanium dichloride. This was established by infrared examination of the suspected compounds synthesized by totally independent means. The available data on the aluminum compounds were either incomplete or of doubtful quality at the time of this investigation, and the methyl titanium chlorides were unknown. Infrared investigations of trimethyl aluminum and the methyl aluminum chlorides in solution have since been reported by Groenewege (8) and more recently by Hoffmann (10), whose data, however, do not extend below 400 cm^{-1}. Spectra of methyl titanium trichloride have been reported by Groenewege (8) and by Karapinka, Smith, and Carrick (11). A more detailed comparison of the spectra will be made in the following paper (9), which deals with the purely spectroscopic aspects of the compounds involved in this research. It is sufficient to say at this point that, while some differences exist, most can be ascribed to frequency shifts and intensity changes between solution and vapor spectra.

$(CH_3)_6Al_2$

Figure 2 is the spectrum of dimeric trimethyl aluminum in the vapor. The absorption maxima occur at 1445, 1255, 1208, 1055, 772, 700, 652, 616, 572, 480, and 369 cm^{-1}.

$(CH_3)_4Al_2Cl_2$

Figure 3 is the spectrum of dimeric dimethyl aluminum chloride prepared by the reaction of hydrogen chloride with trimethyl aluminum in the vapor phase in the ratio of 2 moles of hydrogen chloride to 1 of dimer. The band positions are 1440, 1212, 1050, 720, 588, 581, 487, 440, 343, and 310 cm^{-1}.

$(CH_3)_2AlCl_4$

The caesium bromide spectrum of this compound obtained by reaction of hydrogen chloride and trimethyl aluminum in the appropriate ratio is shown in Fig. 4. Absorptions occur at 700, 675, 587, 483, 423, and 310 cm^{-1}. This spectrum is in excellent agreement with that of Groenewege with the exception of the 423 cm^{-1} band. There was initially some reason to believe that this absorption and the 483 cm^{-1} band, which are dashed in Fig. 4, were spurious. However, insofar as the practical application of these spectra to the identification of components in the reaction mixtures is concerned, the two absorptions at 700 and 675 cm^{-1} were taken to be characteristic of $(CH_3)_2Al_2Cl_4$, while the 720 and 343 cm^{-1} bands were similarly characteristic of the tetramethyldichloro dimer. The detailed consideration of these spectra presented in the following paper (9) substantiates these identifications and discusses the possible origin of the 423 cm^{-1} absorption. These matters, however, have no direct bearing on the results or conclusions of the reaction study.

CH_3TiCl_3

Figure 5 is the spectrum of this compound obtained in the vapor by reaction of dimethyl zinc with titanium tetrachloride in the mole ratio 1:2. In this case, the preparation was carried out on a vacuum line and the volatile product transferred to the cell entirely free from the completely nonvolatile zinc chloride. The bands occur at 1380, 550, 464, and 391 cm^{-1}, the 1380 cm^{-1} band having a barely discernible PQR structure. The pressure in the 10-cm cell was approximately 10 mm Hg, and no other absorptions were found under these conditions. The pure material in the vapor phase was completely stable when kept in the dark. However, exposure to room light did induce decomposition over a period of a day or two to produce a uniform brownish-yellow coating of titanium trichloride on the cell walls. Production of methane was also observed in the infrared cell as the decomposition proceeded. On freezing out, methyl titanium trichloride condenses to a yellow liquid which solidifies to a purple crystalline solid.

Methyl titanium trichloride was first observed by us in the reaction system $(CH_3)_3Al + TiCl_4$. The identity of the spectrum obtained from the independent preparation, using dimethyl zinc, conclusively demonstrated that it was not in any way complexed with aluminum compounds. Measurement of pressure changes during its preparation also showed the compound to be monomeric. All four bands observed decrease in proportion on decomposition, indicating that they are due to a single entity, and the infrared spectrum is entirely consistent with the proposed structure. The pure material when contacted with anhydrous aluminum chloride was shown by infrared to be converted to titanium tetrachloride. That the observed spectrum corresponds to a monomeric uncomplexed titanium compound of formula CH_3TiCl_3 is therefore beyond question.

$(CH_3)_2TiCl_2$

Figure 6 is the spectrum of this compound obtained by the mole-to-mole reaction of dimethyl zinc and titanium tetrachloride. The absorption bands are at 1380, 550, 462, 427, and 396 cm^{-1}. This material is unstable even in the dark and decomposes with a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

"half-life" of about 2 hours under the conditions of the experiment. The pressure studies indicated that exposure to room light does not significantly increase the rate of decomposition.

Reaction Mixture Spectra

The reproducibility of the reactions carried out in the vapor phase by rapid volatilization of the separately condensed components was checked on many occasions and found to be very satisfactory. Wherever possible, the initial pressure of titanium tetrachloride was 9 mm Hg, and the dimeric trimethyl aluminum pressure was adjusted according to the ratio desired. The spectra shown represent the first scan of the reaction products immediately after mixing, and while some changes undoubtedly took place during the runs, it was established that the rate was such as to produce only minor variations in the relative intensities of the observed bands. The spectra were rescanned until no further changes took place. A single experiment frequently extended over several days. The reactant ratios will be expressed in terms of moles aluminum to moles titanium, and the aluminum compounds will be referred to in the discussion as monomers, their dimeric nature being understood. Moreover, the assignment to particular compounds of the various absorption bands found in the mixtures will not be discussed in detail, as they are obvious when reference is made to Figs. 1–6.

Figures 7 to 12 are the initial spectra at Al/Ti ratios of 1/3, 2/3, 1, 2, 8/3, and 4, respectively. At the equimolar reactant ratio, the initial reaction is simply

$$(CH_3)_3Al + TiCl_4 \rightarrow (CH_3)_2AlCl + CH_3TiCl_3. \quad [1]$$

At lower ratios, $(CH_3)_2AlCl$ also alkylates $TiCl_4$ to some degree, evidently achieving an equilibrium state, in agreement with Groenewege, according to the equation

$$(CH_3)_2AlCl + TiCl_4 \leftrightarrows CH_3AlCl_2 + CH_3TiCl_3. \quad [2]$$

At ratios >1, trimethyl aluminum further alkylates titanium tetrachloride to dimethyl titanium dichloride and apparently also when in sufficient excess to trimethyl titanium chloride, although this compound must have only a transient existence, since it is not observed directly. As excess trimethyl aluminum is present at the 4:1 ratio, complete alkylation is not achieved, at least under the conditions of these experiments. Thus,

$$2(CH_3)_3Al + TiCl_4 \rightarrow 2(CH_3)_2AlCl + (CH_3)_2TiCl_2 \quad [3]$$

$$3(CH_3)_3Al + TiCl_4 \rightarrow 3(CH_3)_2AlCl + (CH_3)_3TiCl \quad [4]$$

$$4(CH_3)_3Al + TiCl_4 \rightarrow 3(CH_3)_2AlCl + (CH_3)_3Al + (CH_3)_3TiCl. \quad [5]$$

At ratios of 1 and lower, the principal subsequent event was the photochemical decomposition of methyl titanium trichloride, which took place over periods of 50 to several hundred hours. This shifted the equilibrium of equation [2], causing dimethyl aluminum chloride and titanium tetrachloride to decrease in proportion. At the 1:3 ratio, all volatile products were eventually consumed, indicating an equilibrium according to the equation

$$CH_3AlCl_2 + TiCl_4 \rightleftarrows CH_3TiCl_3 + AlCl_3. \quad [6]$$

The equilibrium lies well to the left, as was independently shown by contacting pure CH_3TiCl_3 with anhydrous $AlCl_3$ to produce $TiCl_4$ almost quantitatively.

At the equimolar ratio, it was observed that, even in the dark, there was a very slow mutual disappearance of methyl titanium trichloride and dimethyl aluminum chloride. A product of this reaction was methyl aluminum dichloride, and the reaction must therefore have occurred according to the equation

$$(CH_3)_2AlCl + CH_3TiCl_3 \leftrightarrows (CH_3)_2TiCl_2 + CH_3AlCl_2. \quad [7]$$

For personal use only.

At ratios >1, $(CH_3)_2TiCl_2$ decomposes thermally at essentially the same rate as when isolated from cocatalyst components.

That the nature of the catalyst-forming reactions found in the vapor phase is essentially the same in solution for the trimethyl aluminum – titanium tetrachloride system and, indeed, for longer-chain aluminum alkyls was demonstrated by subsequent unpublished work by C. T. Elston and, in some cases, by additional infrared data. For example, the transient existence of propyl titanium trichloride in hexane solution was shown by its synthesis from zinc dipropyl and titanium tetrachloride and the observation of absorption bands at 527, 483, and 386 cm^{-1}, which decreased together with time. An unexpected result of this same experiment was that titanium tetrachloride was found to increase as the titanium alkyl decomposed. This was the first time that this had been observed: it did not occur in the vapor phase decomposition studies and had not been noticed in our previous solution studies, where solid and supernatant phases were analyzed by usual methods. A subsequent careful infrared investigation of methyl titanium trichloride decomposition in cyclohexane, however, confirmed the generality of this phenomenon in solution. It was shown by quantitative calibration with known solutions of $TiCl_4$ that, upon completion of the reaction, one-half of the initial titanium content appeared as titanium tetrachloride. During the decomposition, which was followed over a period of 270 hours, the production of the tetrachloride was, moreover, directly correlated with the disappearance of the alkyl.

The usual thermal and photochemical mode of decomposition observed in our work and that of others results in the production of brown titanium trichloride and hydrocarbons:

$$CH_3TiCl_3 \rightarrow CH_3 + TiCl_3. \qquad [8]$$

The solid in this case is not an active catalyst. The production of titanium tetrachloride under the conditions of the infrared experiment is considered to have occurred via the disproportionation

$$2CH_3TiCl_3 \rightarrow (CH_3)_2TiCl_2 + TiCl_4. \qquad [9]$$
$$\downarrow$$
$$?$$

While other mechanisms are possible, this type of reaction is common in metal organic chemistry and offers a very satisfactory explanation of the infrared data. Since it has been demonstrated by ourselves and others that the decomposition of dimethyl titanium dichloride leads to an active catalyst, these observations at least partially account for those cases where activity has been observed at reactant ratios less than or equal to 1. At higher temperatures, the decomposition of methyl titanium trichloride is still more complex and is evidently autocatalytic, as shown by Beermann and Bestian (13).

CONCLUSIONS

The actual sequence of reactions occurring in the system appears to be the simplest imaginable and depends solely on the relative alkylating power of the various aluminum compounds and the stabilities of the titanium methyl products. The *absolute* reaction rates and stabilities for different aluminum alkyls and for different transition metal halides are quite variable, as shown, for example, by Beerman and Bestian (13). However, it seems probable that *relative* alkylating power and stabilities for the various components of other systems involving aluminum alkylating agents are the same as found for the trimethyl aluminum – titanium tetrachloride system.

The high efficiency of catalysts formed by the use of aluminum alkylating agents has

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

frequently been attributed to the formation of aluminum–titanium complexes which act as unusually active catalyst sites. This hypothesis may be necessary to account for the properties of certain stereospecific catalysts, but there seems to be no good reason to postulate complex formation in every case. Certainly there is no evidence for the formation of such complexes in this system. Independent gas phase kinetic studies carried out in this laboratory demonstrated that the catalytic activity of the decomposition products was only two or three times greater when decomposition occurred in the presence of "cocatalyst" components than when pure. If complex formation were necessary for catalytic activity, one would expect this difference to be several orders of magnitude. The particular efficacy of the aluminum alkylated catalysts could equally well be attributed to the more controlled and efficient production of active sites due to the gradation of alkylating power from the trialkyl to the dihaloalkyl. For example, the existence of slow acting, but effective, alkylating agents in equilibrium in the supernatant after initial catalyst formation may continuously generate active catalyst sites during the subsequent polymerization. This may be contrasted with the behavior of metal alkyls such as dimethyl zinc, where the second methyl group is effectively as powerful as the first in alkylating titanium tetrachloride. In this case, the initial reaction is rapid, complete, uncontrolled, and, one might expect, less efficient in producing the particular species which function as catalyst sites.

Although the decomposition products of the reactions were deposited in a uniform film over the cell body and windows, the thickness in the optical path was not sufficient for direct observation of the catalytically active species. The evolution of methane during the decomposition of the methyl titanium compounds was observed by infrared analysis, and methane, ethane, and ethylene were found and quantitatively determined by gas kinetic studies. Methyl groups, however, remain in the solid decomposition product at and above Al/Ti = 1. These observations, together with the fact that catalytic activity may be correlated with solid methyl content, strongly suggest that the modes of decomposition leading to catalytically active products are

$$(CH_3)_2TiCl_2 \rightarrow CH_3TiCl_2 + CH_3\cdot \quad [10]$$

$$(CH_3)_3TiCl \rightarrow CH_3TiCl + 2CH_3\cdot . \quad [11]$$

While these observations and conclusions are at variance with some suggested theories (14) concerning the catalytic activity of such systems, the available factual information from other sources can readily be interpreted in terms of the simple scheme that has been proposed.

In any event, it is apparent that the data considerably narrow the area of speculation permissible concerning the nature of the catalyst species. The body of evidence in our work suggests that the primary site of catalytic activity in this and analogous systems is the Ti—C bond. In view of the very large number of formulations which now appear to be effective in olefin polymerization and in the absence of sufficient detailed information regarding them, attempts to account for their activity in terms of any single hypothesis are premature. Nevertheless, it is clear that transition metal alkyl compounds must be accorded a more significant role in theories of catalyst activity than has sometimes been the case.

ACKNOWLEDGMENT

The authors wish to acknowledge the contribution of Mr. Heinz Demmler, who constructed the sensitive Pyrex spoon gauges essential to this investigation.

THE INFRARED SPECTRA OF TRIMETHYL ALUMINUM, DIMETHYL ALUMINUM CHLORIDE, METHYL ALUMINUM DICHLORIDE, METHYL TITANIUM TRICHLORIDE, DIMETHYL TITANIUM DICHLORIDE, AND SOME DEUTERIUM DERIVATIVES

A. P. GRAY[1]
Du Pont of Canada Limited, Research Centre, Kingston, Ontario
Received August 14, 1962

ABSTRACT

The vapor phase infrared spectra to 300 cm^{-1} are discussed and assignments made for the compounds $(CH_3)_6Al_2$, $(CD_3)_6Al_2$, $(CH_3)_4Al_2Cl_2$, $(CD_3)_4Al_2Cl_2$, $(CH_3)_2Al_2Cl_4$, CH_3TiCl_3, CD_3TiCl_3, and $(CH_3)_2TiCl_2$. The assignments differ significantly from those previously published, but are consistent throughout the series of aluminum compounds and with related spectra. The data are in agreement with a bridged structure for trimethyl aluminum of D_{2h} or C_{2h} symmetry and with a bridged structure of dimethyl aluminum chloride with chlorine bridging. The dimer $(CH_3)_2Al_2Cl_4$ is shown to exist in the trans configuration. Evidence is presented indicating that an impurity is commonly found in spectra of dimethyl aluminum chloride which is identified as the mixed dimer $(CH_3)_3Al_2Cl_3$, aluminum sesquichloride. A number of anomalies observed in the spectra of the methyl titanium compounds are pointed out and discussed.

INTRODUCTION

The compounds involved in the infrared spectroscopic study of the coordination catalyst system presented in the preceding paper (1) are in themselves of very considerable interest. Trimethyl aluminum is the simplest of a number of compounds known or suspected to be associated through bridge alkyl groups and has been the object of many investigational and theoretical studies. The halogen derivatives of trimethyl aluminum are similarly bridged dimers. Although there has been some controversy on the point (2–4), the bridging in these cases is through the halogen atoms. Alkyls of the transition elements are exceedingly rare and, in the case of titanium, only two which have reasonable stabilities have been isolated. The first was phenyltitanium triisopropylate, obtained by Herman and Nelson in 1952 (5), and the second, methyl titanium trichloride, was independently discovered a few years later by a number of workers concerned with coordination catalyst systems (1, 6). Dimethyl titanium dichloride is relatively unstable, but has a sufficient lifetime to allow infrared and possibly some other physical measurements to be made under the usual conditions.

In view of the unusual nature of these compounds, it is of interest to examine the spectra which have been briefly described in the preceding paper in considerably greater detail and to consider some others which are pertinent. It must be admitted, however, that the data to be discussed were for the most part incidental to the main object of the catalyst investigation and the experiments were not always as complete nor as well designed from the spectroscopic point of view as might be desired. Nevertheless, the information derived from the extension of the infrared data to 300 cm^{-1} and from the deuterium derivatives results in significant changes to previously made assignments which seem well founded. Since the spectra were in all cases those of the vapors at low pressure, relatively few fundamentals above 800 cm^{-1} were observed. The strong absorptions in the CsBr

region, however, are those most pertinent to structural considerations; and bands elsewhere are discussed only where relevant to the assignment of the skeletal modes.

EXPERIMENTAL

The preparation and origin of the compounds have been described (1). The fully deuterated trimethyl aluminum was obtained from Merck, Sharp and Dohme of Canada Limited, Research Chemicals Department, Montreal, Quebec. The infrared spectrum indicated that the material was of high isotopic purity. Fully deuterated dimethyl aluminum chloride was obtained as the only volatile product remaining 3 days after the reaction of deuterated trimethyl aluminum with titanium tetrachloride in the mole ratio Al/Ti = 1. The identity of this product was established by analogy with the product of the same reaction carried out several times using light trimethyl aluminum. This was identified as $(CH_3)_2AlCl$ by its independent preparation from $(CH_3)_3Al$ and HCl. A partial spectrum of deuterated methyl titanium trichloride was obtained during this same reaction shortly after mixing. The observed bands were associated with this compound on the basis of their correspondence with the rate of decomposition which had been found many times in the analogous undeuterated system.

The instrumentation and techniques employed have also been described (1). With the exception of the C—H stretching modes of trimethyl aluminum, which were measured with LiF in the Model 112, all other bands above 650 cm^{-1} were observed with NaCl optics in the Model 21. A minimum warm-up time of 4 hours was allowed prior to runs with CsBr. Calibrations in this region were derived from the lines of water vapor, carbon dioxide, and methanol recommended by Downie *et al.* (7).

RESULTS AND DISCUSSION

The observed absorption bands of the various compounds under consideration are summarized in Table I. The corresponding spectra are shown in Figs. 2 to 6 of the preceding paper and in three additional figures in this paper, Figs. 1–3. Reference to other spectra included among those of the preceding paper will sometimes be made.

Trimethyl Aluminum

The generally accepted model of trimethyl aluminum dimer is that of Lewis and Rundle, who from X-ray data showed the skeletal symmetry of the molecule to be D_{2h}, the plane of the outer Al—C bonds being perpendicular to the plane of the bridge (8). The disposition of the methyl hydrogens of the bridge is not known, but if free-rotating, the effective overall symmetry of the molecule remains D_{2h}.

Infrared data on trimethyl aluminum have been reported by Pitzer and Gutowsky (9), Pitzer and Sheline (10), Schomburg (11), and more recently by Hoffmann (12). Previous work has been limited to the NaCl and KBr regions, and no deuterium analogues have been studied. The infrared data, together with the Raman results of Kohlrausch and Wagner (13) and of Hoffmann (12), are consistent with a dimeric formulation of symmetry D_{2h} or C_{2h} based on the number of observed fundamentals and the general absence of Raman–infrared coincidences.

The normal modes which are expected to give rise to infrared absorption or Raman scattering in the frequency range 800 to 300 cm^{-1} and their approximate descriptions are given in Table II, listed according to the symmetry species of the D_{2h} point group. Methyl deformations taking place perpendicular to the planes containing the carbon atoms are referred to as "wags", while those parallel to these planes are "rocks". The A_g and B_g species are Raman active, the B_u species are infrared active, and A_u is inactive in both infrared and Raman.

Previous authors have numbered the skeletal normal modes according to the scheme of Bell and Longuet-Higgins (16). To facilitate comparison, they are similarly numbered in Table II. Nonskeletal modes will be referred to by their approximate description and symmetry species. Where applicable, Table II also contains the frequency ratios of the corresponding modes in light and deuterated compounds.

The assignments given in Table II for the infrared-active species of trimethyl aluminum have been arrived at by application of the usual principles of vibrational analysis and by some arguments based on analogous systems. For example, since methyl rocking modes for dimethyl zinc and dimethyl mercury were found by Gutowsky at 707 and 787 cm^{-1}, respectively (15), it was considered unlikely that nonbridged methyl deformations would fall below 600 cm^{-1}. Bridge methyl deformations, on the other hand, where they occur in the same symmetry species as a skeletal bridge mode, might be expected to interact strongly and fall in frequency. The significance of shifts produced by deuterium substitution was determined by consideration of the deuterium displacements for the methyl deformation bands, 1440 to 1140 cm^{-1}, 1260 to 1036 cm^{-1}, and 1215 to 955 cm^{-1}, which are 1.26, 1.21, and 1.27, respectively. Modes exhibiting shifts in the range 1.2 to 1.3 were therefore considered to be primarily associated with methyl group vibrations, while a ν_H/ν_D ratio tending toward 1.09 was taken to indicate an approach to pure CH_3—Al stretching. Intermediate values are produced by a mixing of modes within the symmetry species. A useful criterion for the correctness of the assignment was the degree of consistency obtained by comparison with the closely related methyl aluminum halides and with the corresponding Raman spectra.

The correlation of the frequencies which has been chosen and indicated in Table II is considered to be the most satisfactory. However, it will be found to differ considerably from those previously proposed. Since the correct assignment of the band at 772 cm^{-1} in trimethyl aluminum is the key to the interpretation which is offered, it is considered in detail.

Comparing the spectrum of trimethyl aluminum (Fig. 2, preceding paper) with that of

§Infrared and Raman data, observed and calculated, ref. 14.

dimethyl aluminum chloride (Fig. 3, preceding paper), it is first observed that there is no band in the latter corresponding to the 772 cm^{-1} absorption, which suggests that it is in some way associated with the methyl bridges. Hoffmann, in fact, has assigned this band to the B_{3u} bridge methyl rock, additional evidence being cited based on mixed alkyl aluminum dimers with methyl bridging, which, at the time of this writing, has not been published. However, the corresponding band in the deuterium compound must be that found at 677 cm^{-1}, $\nu_H/\nu_D = 1.14$, which indicates that the band is more probably an Al—C stretch. This band is therefore taken to be ν_8. The deuterated spectrum of dimethyl aluminum chloride above 500 cm^{-1} (Fig. 2) is seen to be remarkably similar to that of deuterated trimethyl aluminum in contrast with those of the corresponding parent molecules (Figs. 2 and 3, preceding paper). This observation is critical, as it is especially difficult to rationalize this behavior on the basis of Hoffmann's assignment. The 664 cm^{-1} band in deuterated dimethyl aluminum chloride obviously corresponds to 677 cm^{-1} in deuterated trimethyl aluminum. It is of interest to apply the observed deuterium shift of the former band to the latter to arrive at a predicted position of ν_8 in trimethyl aluminum. The result, $1.08 \times 677 = 731$, is seen to be some 40 cm^{-1} lower than the observed value. This is, however, readily accounted for on the basis of a strong interaction with modes of the same species. The B_{1u} species for trimethyl aluminum contains three modes which reasonably may be expected to fall near 700 cm^{-1}: ν_8, an outer methyl rock, and a bridge methyl wag. Assuming accidental coincidence of two or all three of these at approximately 730 cm^{-1}, the displacement of ν_8 to 772 and of the other modes to approximately 700 cm^{-1} is readily understood. This hypothesis accounts for the observed features of the spectra; the interaction does not take place in dimethyl aluminum chloride due to the absence of the bridge methyl wag, and the similarity of the deuterated spectra of trimethyl aluminum and dimethyl aluminum chloride is due to the removal of the interaction on separating ν_8 from the methyl deformation modes.

The tentative assignment of the B_{2u} bridge mode, ν_{13}, to the relatively weak 652 band deserves some comment. Since ν_{13}, by analogy with Klemperer's assignment for aluminum chloride, is expected to be one of the higher bridge modes, it should be in the 600 cm^{-1} region. B_{2u} absorptions are, however, universally found to be weak in the series of compounds with which we are concerned and this mode may not be observed, particularly in this area of heavy overlapping in both light and heavy compounds. Its assignment to 652 cm^{-1} is, however, not unreasonable. While it could equally well be the B_{2u} outer methyl wag, a corresponding outer methyl wag is found at 675 cm^{-1} in methyl aluminum dichloride, and if anything, the trimethyl aluminum mode would be expected to be higher.

The Raman assignments of ν_1, ν_2, ν_3, and ν_{11} are in agreement with those of Hoffmann (12) and previous workers (3, 13). The depolarized 725 cm^{-1} band is taken to be the B_{2g} outer methyl rock solely on the grounds that the other Raman species seem to be weak, only two depolarized Raman lines being found above 300 cm^{-1}. Two other polarized lines are found, however: a weak 632 cm^{-1} shoulder and a quite strong line at 495 cm^{-1}. Hoffmann has assigned the latter to the A_g outer methyl rock. As previously discussed, this is considered to be too low for such a mode, and it would be preferable to consider it as an overtone enhanced by Fermi interaction with ν_2. However, it is interesting to note that the only significant consequence of the molecule's having a symmetry of C_{2h} rather than D_{2h}, but with the same principal axis of symmetry, is that the B_{1g} modes become totally symmetric. If this were the case, then the 632 and 495 cm^{-1} lines would be accounted for by the B_{1g} bridge methyl rock and the bridge stretch, ν_6. A Raman study of the deuterated

compound would be most helpful in settling this matter, but this information has not as yet been obtained.

Dimethyl Aluminum Chloride

The dimeric nature of this material has been established by Brockway and Davidson (17) by electron diffraction and by Davidson and Brown (18) by vapor pressure measurements. Infrared and Raman data have been reported by Groenewege (3) and by Hoffmann (12). Raman data on this compound, and on a variety of other halogen derivatives, were also reported by van der Kelen and Herman (2). It now seems well established that the bridging for this and analogous alkyl aluminum halides is through the halogen atoms.

Before proceeding with the new infrared data for this compound and its deuterium derivative, it is necessary to consider certain inconsistencies which appear in comparing both the present work and previously published spectra. The infrared spectrum of the vapor of dimethyl aluminum chloride (Fig. 3, preceding paper) shows two weak bands at 487 and 440 cm^{-1}. In solution, Hoffmann similarly finds two weak bands, one near 500 and the other at 443 cm^{-1}; the relative intensities are, however, reversed. Groenewege's solution spectra, on the other hand, only barely indicate absorption in this area, although a double-beam instrument was used and the intensity of the other bands indicates that it should be observed, if real. It is also noted that in Fig. 12, preceding paper, which is essentially a strong spectrum of dimethyl aluminum chloride containing some trimethyl aluminum, no 440 cm^{-1} band is found. Groenewege does not find the weak polarized lines at 480 and 410 cm^{-1} found by Hoffmann, although they are in agreement on other lines of comparable intensity. Groenewege has pointed out the discrepancies between his Raman work and that of van der Kelen and Herman, who found six additional lines at 94.5, 343, 480, 531, 685, and 727 cm^{-1}, all polarized. Groenewege considered the 480 and 531 lines as originating from 588 shifts of the *f* and *g* mercury lines, although Hoffmann finds the 480 line also.

All these observations are accounted for on the assumption that van der Kelen and Herman's material was quite heavily contaminated with aluminum sesquichloride, $(CH_3)_3Al_2Cl_3$, which evidently exists as a mixed dimer, and that the presently reported spectra, as well as Hoffmann's, are similarly but slightly impure. The sesquichloride is the initial product obtained in the usual preparation of dimethyl aluminum chloride from the reaction of methyl chloride and aluminum (19). The 487 cm^{-1} band in the infrared is probably an Al—Cl outer stretch and the 440 cm^{-1} band, a bridge mode of the sesquichloride corresponding to either ν_6 or ν_{13} in aluminum chloride, which occur at 438 and 420 cm^{-1}, respectively. Corresponding modes are found in the deuterated spectrum (Fig. 2) at 483 and 430 cm^{-1}. Note that the sesquichloride has no symmetry and all Raman lines are polarized, in agreement with those of the impurity.

Having disposed of these bands, the spectrum of dimethyl aluminum chloride dimer is seen to be quite simple, and the assignments follow from the discussion previously given for trimethyl aluminum. It is observed that the band centered at 585 cm^{-1} appears to be a doublet with maxima at 588 and 581 cm^{-1}, the lower frequency being somewhat stronger. However, a calculation of the expected band contour for a B_{3u} mode (20) predicts a separation of P and R branches of 6.8 cm^{-1}, in good agreement with that observed. Evidently, the Q branch is diffuse and shifted to lower frequency for this particular mode due to a difference in upper- and lower-state inertial moments and the population of many *K* levels (21). This behavior is common for heavy molecules.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The assignment of the Raman modes in this region is essentially the same as that of Groenewege (3).

Methyl Aluminum Dichloride

The infrared spectrum of this compound has been reported by Groenewege (3, 4) and the Raman by van der Kelen and Herman (2). A priori, there would seem to be little doubt, by analogy with its close relatives, that the molecule is dimeric and bridged through chlorine atoms, but one must consider three possible structures for the dimer, corresponding to those of dichloroethylene: the *trans*-1,2-dichloro (C_{2h}); *cis*-1,2-dichloro (C_{2v}); and 1,1-dichloro (C_{2v}) isomers.

The vapor phase spectrum of this compound is shown in Fig. 4, preceding paper. In order to obtain these bands with reasonable intensity, it was necessary to heat the gas cell to approximately 65° C. The spectrum was first scanned in the NaCl region with the Model 21 and was then transferred to the Model 112. No indication of any difficulty was noted until the cell was removed after the CsBr scan to be rerun on the 21. At this point, the contents became cloudy and a white crystalline material began to grow on the relatively cool cell windows. The subsequent NaCl spectrum indicated that the original compound had reacted, most probably because of a leak through the Kel-F stopcock grease, which has a high fluidity, even at these moderately elevated temperatures. Those bands in the CsBr spectrum which were not directly confirmed by observation in the reaction mixture spectra (Figs. 7 and 8, preceding paper) were considered questionable and are dashed in Fig. 4, preceding paper. Groenewege's spectrum is to be preferred.

A consideration of the selection rules for the various possible forms, utilizing the assignments which have been proposed for the compounds previously discussed, indicates that the observed spectra are those of the trans form. The cis isomer is predicted to have 13 infrared-active modes falling in the range 800 to 300 cm^{-1}, and the "symmetrical" isomer should have 11. Moreover, all of these should be Raman active. On the other hand, for the C_{2h} trans model one expects in the infrared, one methyl rock, one methyl wag, one Al—C stretch, one Al—Cl, stretch and two bridge modes. The observed bands fit this scheme extremely well, the corresponding modes being assigned to 700, 675, 587, 483, 402 (or 423), and 310 cm^{-1}, respectively. The Raman spectrum should show a similar distribution of lines, one methyl rock, one Al—C stretch, one Al—Cl stretch, and one bridge stretch (ν_2), all totally symmetric and therefore polarized. Depolarized lines should consist of one methyl wag and one bridge stretch (ν_6). Again, as seen in Table II, the Raman data of van der Kelen and Herman are in agreement with this scheme. The polarized methyl rock corresponding to that in A_g of the D_{2h} point group is not found, nor is the depolarized bridge stretch corresponding to ν_6. However, neither of these were found in any of the spectra of related molecules previously considered.

The assignments are collected in Table II, those associated with Cl modes and comparable to $AlCl_3$ to the right and those involving methyl modes and comparable to the methyl-containing compounds to the left of the column.

Methyl Titanium Trichloride

Infrared data on methyl titanium trichloride as a liquid have been reported by Karapinka, Smith, and Carrick (22) in the NaCl and KBr regions. They find a great many strong combination and overtone bands in addition to fundamentals at 1353, 530, and 460 cm^{-1}, which were also found by Groenewege (3) at 1366, 540, and 459 cm^{-1} in heptane solution. Groenewege attributed a band found by him at 498 cm^{-1} to an impurity, while

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Karapinka *et al.* assigned a similar band at 490 cm^{-1} to the Ti—Cl unsymmetrical stretch. In both cases, this band is undoubtedly due to $TiCl_4$. No such absorption is found in the vapor phase spectrum of Fig, 5, preceding paper, where the fundamentals are located at 1380, 550, 464, and 391 cm^{-1}. Karapinka, Smith, and Carrick used the $TiCl_4$ combination band at 870 cm^{-1} as an indicator of $TiCl_4$ content, but since it is many times weaker than the 500 cm^{-1} fundamental, it is a relatively poor criterion of purity. Even if the sample of CH_3TiCl_3 were initially pure, $TiCl_4$ might well have been subsequently produced by the decomposition mechanism discussed in the preceding paper (1).

The simplest and most probable assumption to make as to the configuration of CH_3TiCl_3 is that, like $TiCl_4$, it is tetrahedral and therefore of C_{3v} symmetry. The skeletal stretching modes should consist of a degenerate —$TiCl_3$ stretch, a symmetrical —$TiCl_3$ stretch, and a symmetrical —Ti—CH_3 stretch. The symmetrical —$TiCl_3$ stretch is assigned to the 391 cm^{-1} band by analogy with the corresponding mode in $TiCl_4$, which is found at 386 cm^{-1} in the Raman effect. In the absence of any further information, one would have to agree with the reasoning of Groenewege in arriving at the assignment of the two remaining strong fundamentals in this region. Since, in all known comparable systems, the degenerate stretch is found at lower frequency than the corresponding mode in the T_d parent molecule, he has assigned his 459 cm^{-1} absorption to this vibration and consequently the 540 band to the Ti—C stretch.

Although the attempted preparation of CD_3TiCl_3 by reaction of $TiCl_4$ with $(CD_3)_3Al$ did not go as smoothly as might have been desired, two bands definitely attributable to this compound were identified at 530 and 405 cm^{-1} (Fig. 3). The band initially found in this spectrum at 500 cm^{-1} was definitely unreacted $TiCl_4$, which disappeared at a faster rate than the two other bands, which decreased in proportion. Additional evidence for the existence of CD_3TiCl_3 in this reaction mixture was the characteristic purple coloration of the condensate on freezing out with liquid nitrogen. The third fundamental was not located, although there was some evidence for a very weak band at 355 cm^{-1}. Previous experiments had shown that, as CH_3TiCl_3 decomposes, a broad band between 400 and 350 cm^{-1} grows in, which is due to the thin coating of $TiCl_3$ being deposited on the windows, so that the behavior of the indicated absorption at 355 cm^{-1} with time was difficult to determine.

In any event, since no band is found between 500 and 400 cm^{-1} other than that at 405 cm^{-1}, it must correspond to the 464 cm^{-1} in the light molecule. Otherwise, it would have to be assumed that the 464 absorption had so diminished in intensity on deuteration as not to be observed and that the 391 cm^{-1} band had shifted up to 405 cm^{-1}. Neither of these possibilities seems very likely. On the other hand, the deuterium shift 464 to 405 cm^{-1} ($\nu_H/\nu_D = 1.15$) seems quite large for a CH_3—Ti stretch, particularly since the product rule for the totally symmetric species would then limit the symmetrical methyl deformation to a shift of approximately 1.18, even if the symmetrical —$TiCl_3$ stretch did not shift at all. However, the small shift, 550 to 530 cm^{-1} ($\nu_H/\nu_D = 1.04$), is approximately that expected for the degenerate —$TiCl_3$ stretch, and everything considered, it seems necessary to reverse Groenewege's assignment and ascribe the 464 cm^{-1} band to the CH_3—Ti stretch. This departure from the usual behavior of non-transition-metal methyl-chloro compounds is but one example of several which are noted.

In particular, the unusually high value of what, at least initially, must be assumed to be the symmetrical methyl deformation at 1380 cm^{-1} has been discussed by Groenewege, who points out the very serious departure of this band from the electronegativity correlation of Sheppard (23) for previously studied methyl compounds. The observed PQR

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

structure and the magnitude of the PR splitting, however, tend to support the assignment to the symmetrical methyl deformation.

That CH_3TiCl_3 is monomeric and has the simplest formula indicated seems to have been well established (1, 5), and the tetrahedral conformation seems most reasonable, but the limited spectroscopic information obtained to date by no means proves this structure.

Dimethyl Titanium Dichloride

The infrared spectrum of $(CH_3)_2TiCl_2$ has not previously been reported. The vapor spectrum is shown in Fig. 6, preceding paper, the bands being found at 1380, 550, 462, 427, and 396 cm^{-1}. Again, the spectrum in the skeletal region is qualitatively what is expected for a tetrahedral compound of the given formula. By analogy with CH_3TiCl_3, the 550 absorption can be assigned to the unsymmetrical Ti—Cl stretch, the 396 band to the symmetrical Ti—Cl stretch, 462 to the unsymmetrical Ti—C stretch, and 427 to the symmetrical Ti—C stretch. Again, the essentially exact coincidence of the 550 and 462 cm^{-1} bands in this compound with those in CH_3TiCl_3 is unusual. The material is not detectably contaminated with CH_3TiCl_3, and its determined thermal stability is very much less than that of the monomethyl compound. In fact, on following the vapor phase decomposition of $(CH_3)_2TiCl_2$, the 462 cm^{-1} band was in the ratio of 1 to 2 with the 550 cm^{-1} band initially, but in the ratio of 1 to 4 towards the end of the decomposition. This behavior is opposite to that expected if the 462 band were due to CH_3TiCl_3, as this compound is the more stable, and one would anticipate that this ratio would approach 1:1 if it were a major contaminant. The change in relative intensities on dissociation does indicate, however, that two components of differing stabilities may be present. The 550 cm^{-1} band contour in the original spectra also indicates the presence of a fifth overlapping band on the high-frequency side. Trimethyl titanium chloride is not likely to be present, as it would be expected to have an extremely short lifetime, nor can any other volatile material be reasonably postulated, considering the method of preparation from $(CH_3)_2Zn$ and $TiCl_4$ in equimolar proportions.

A possible explanation of these observations is that $(CH_3)_2TiCl_2$ may have two isomeric configurations. A planar structure, although suggested with some reluctance, would more satisfactorily account for at least some of the anomalies.

The 1380 cm^{-1} band is again found, but with no resolvable structure. It is presumably a symmetrical methyl deformation.

In view of the spectroscopically unique behavior of the methyl titanium chlorides, a more thorough study than that presented is required in order to arrive at firm structural conclusions and band assignments. Since the deuterium analogues may be prepared readily and cleanly by reaction of $(CD_3)_2Zn$ with $TiCl_4$, data of higher quality may easily be obtained by extension of the preparative and spectroscopic techniques which have been described in this and the preceding paper.

OCCURRENCE OF D-GLUCURONIC ACID IN TAMARACK ARABINOGALACTAN[1]

B. URBAS,[2] C. T. BISHOP, AND G. A. ADAMS
Division of Applied Biology, National Research Council, Ottawa, Canada
Received February 13, 1963

ABSTRACT

The aldobiouronic acid 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose and D-glucuronic acid have been isolated from a hydrolyzate of an arabinogalactan from tamarack (*Larix laricina*). The identity of the aldobiouronic acid and the evidence for homogeneity of the polysaccharide showed that these acidic components are almost certainly constituents of the arabinogalactan.

During the past few years there have been numerous reports on the structural chemistry of water-soluble arabinogalactans from various coniferous woods. This topic has been included in recent reviews (1, 2) and it is clear that the major structural features of these polysaccharides are well established. However, as pointed out by Aspinall (1), several of these arabinogalactans contain small amounts (ca. 2%) of uronic acid. There has been no evidence to show whether these uronic acids are part of the arabinogalactan molecules or whether they occur in contaminating polysaccharides admixed with the arabinogalactans.

The present publication reports the isolation and identification of D-glucuronic acid and an aldobiouronic acid, 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose, from a hydrolyzate of an arabinogalactan from tamarack (*Larix laricina*). Evidence is presented to show that these acidic components almost certainly are constituents of the arabinogalactan.

The arabinogalactan was isolated from tamarack wood and gave no evidence of heterogeneity upon fractionation, free boundary electrophoresis, or ultracentrifugation (3). The main structural features of this polysaccharide were established by methylation studies (3) and by characterization of oligosaccharides produced by partial hydrolysis with acid (4). The results showed that the polysaccharide was a highly branched structure of 1 → 6- and 1 → 3-linked β-D-galactopyranose units to which L-arabinose units were attached, mainly in the form of the disaccharide unit 3-*O*-L-arabinopyranosyl-L-arabinofuranose.

Proof of the way in which the L-arabinose units are attached to the galactan portion of the molecule required isolation of an oligosaccharide which contained the arabinofuranosyl → galactose linkage. Two approaches to this problem were attempted: (*a*) enzymic hydrolysis and (*b*) Aspinall's application (5) of the Mehltretter (6) oxidation. No enzyme system could be found that would hydrolyze this polysaccharide to any significant extent and the oxidation was not successful. However, during the latter work the infrared spectrum of the arabinogalactan was recorded for comparison with the oxidized products. The unoxidized arabinogalactan showed a medium strength absorption band at 1625 cm^{-1} which was attributed to carboxyl groups. Chromatograms of a hydrolyzate of the arabinogalactan showed the presence of hexuronic acids; analysis (7) indicated 2–3% of uronic acid.

A large quantity of the arabinogalactan was hydrolyzed and the acidic components

[1]*Issued as N.R.C. No. 7326.*
[2]*National Research Council Postdoctoral Fellow, 1961–1963.*

were isolated by ion exchange resins. The mixture of acids was resolved by preparative paper chromatography to yield D-glucopyranuronic acid, and 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose. The first of these compounds was identified as crystalline D-glucofuranurono-(6 → 3)-lactone. The aldobiouronic acid yielded glucuronic acid and galactose on hydrolysis. On methylation the aldobiouronic acid gave a crystalline product having melting point and specific rotation in agreement with those reported for methyl 6-*O*-[methyl-(2,3,4,tri-*O*-methyl-β-D-glucosyl) uronate]-2,3,4-tri-*O*-methyl-β-D-galactoside (8, 9); the derived amide had a melting point in agreement with the reported value (9). As confirmatory evidence the fully methylated aldobiouronic acid was hydrolyzed to yield 2,3,4-tri-*O*-methyl-D-glucuronic acid and 2,3,4-tri-*O*-methyl-D-galactose, both characterized as crystalline derivatives.

It is extremely likely that these acidic components were part of the arabinogalactan, which should therefore be called an arabinogalactoglucuronoglycan. The polysaccharide was homogeneous upon fractionation, electrophoresis, and ultracentrifugation (3) and the known wood polysaccharides, if present as trace contaminants, could not give rise to 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose. The only uronic acid containing polysaccharides known to occur in woods are the glucurono- or arabino-4-*O*-methylglucuronoxylan and the pectic substances (1). In the former the glucuronic acid moiety is always joined to a D-xylose unit and the latter yields galacturonic rather than glucuronic acid on hydrolysis. Many plant gums which are exudates give rise to the same aldobiouronic acid as found in the present investigation (10). However, a gum could not have been a contaminant of the arabinogalactan which was extracted from wood from which the bark, and hence any exudates, had been removed.

Roudier and Eberhard (16) have isolated the same aldobiouronic acid from an acid hydrolyzate of maritime pine wood and reported that an arabinogalactoglucuronoglycan could be separated from the hot-water-soluble polysaccharides of that wood by fractionation. This was the first suggestion that this type of polysaccharide was present in wood. More recently Jones and Reid (17) have isolated an arabinogalactoglucuronoglycan from mountain larch. This polysaccharide contained 7.2% of uronic acid, yielded 6-*O*-(β-D-glucopyranosyluronic acid)-D-galactose on partial hydrolysis, and gave rise to 2,3,4-tri-*O*-methyl-D-glucuronic acid on methylation and hydrolysis. It is apparent that arabinogalactoglucuronoglycans may be of more widespread occurrence than has hitherto been indicated.

EXPERIMENTAL

Chromatograms were run by the descending method on Whatman No. 1 and No. 3 MM papers in the following solvent systems (v/v ratio): (A) ethyl acetate:water:acetic acid:formic acid, 18:4:3:1; (B) ethyl acetate:acetic acid:water, 3:1:3 (upper layer); (C) butanone saturated with water; (D) butanone:propan-1-ol:water, 5:3:2. Separated components were detected on the papers by the *p*-anisidine hydrochloride spray reagent (11). Solutions were evaporated under diminished pressure at 35° C or less, melting points are corrected, and all rotations are equilibrium values unless stated otherwise.

Polysaccharide

The isolation, fractionation, electrophoresis, and ultracentrifugation of the polysaccharide were described previously (3). The product showed $[\alpha]_D^{20}$ +12 (*c*, 4% in water); uronic acid, 2–3% (7); nitrogen, nil. The infrared spectrum in potassium bromide was recorded and showed the following absorption bands ((S)—strong, (M)—medium, (W)—weak) (frequencies in cm^{-1}); 3350 (S), 2890 (M), 1625 (M), 1375 (M), 1135 (S), 1050–1075 (S), 875 (W), 770 (W), 700 (W). Because the polysaccharide was devoid of nitrogen the absorption band at 1625 cm^{-1} could not represent amide groups from contaminating protein; this absorption was therefore attributed to uronic acid carboxyl groups.

Isolation of Uronic Acids

Heavily loaded chromatograms of a hydrolyzate of the polysaccharide (solvent A) showed the presence of glucofuranurono-3,6-lactone, glucuronic acid, and an aldobiouronic acid in addition to large amounts of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

arabinose and galactose. The glucuronoarabinogalactan (65 g) was heated on a steam bath with *N* sulphuric acid (1300 ml) for 6 hours. The hydrolyzate was neutralized by barium carbonate, insoluble barium salts were removed by centrifugation, and the clear solution was passed through a column of Amberlite IR-120 ion exchange resin to remove soluble barium. Acidic components were then adsorbed on a column of Dowex 1-X4 (acetate form) which was washed with water until the neutral sugars had been removed (Molisch test). Uronic acids were eluted from the column with *N* formic acid; evaporation of the eluate yielded a mixture (0.5 g) of the acidic components, which was resolved by preparative paper chromatography (solvent A). Three compounds were recovered: D-glucofuranurono-3,6-lactone, D-glucuronic acid, and an aldobiouronic acid. The first two compounds were combined and crystallized from glacial acetic acid to yield D-glucofuranurono-3,6-lactone, m.p. 174–176° C unchanged on admixture with an authentic sample.

The aldobiouronic acid, which showed only one spot on chromatography in solvents A and B, was dissolved in water and neutralized by barium carbonate. The barium salt was precipitated from the aqueous solution by methanol as a white solid (0.28 g), $[\alpha]_D^{25}$ −5° (*c*, 2% in water). A sample (5 mg) of this product was heated with *N* sulphuric acid (1 ml) in a sealed tube at 100° C for 13 hours. Paper chromatography (solvent A) of the hydrolyzate showed the presence of glucuronic acid and galactose.

Methylation of Aldobiouronic Acid

The barium salt (0.28 g) was methylated twice by sodium hydroxide and dimethyl sulphate (12) and the product was recovered from the acidified solution by continuous extraction with chloroform for 3 days. The extract was dried (magnesium sulphate) and evaporated to yield a sirup (0.21 g) which was methylated twice by silver oxide and methyl iodide (13). The yellow, sirupy product (0.21 g) was distilled at 185–195° C (bath temperature) and 0.02 mm of mercury to yield the fully methylated aldobiouronic acid (0.15 g) having no hydroxyl absorption in the infrared. This product had $[\alpha]_D^{26}$ −32.3° (*c*, 1.3% in chloroform) and crystallized spontaneously after 1 week. Recrystallization from ether – light petroleum (b.p. 30–60° C) yielded methyl 6-*O*-[methyl-(2,3,4,tri-*O*-methyl-β-D-glucosyl) uronate]-2,3,4-tri-*O*-methyl-β-D-galactoside, m.p. 86–87° C; reported values for this compound are m.p. 94° C (8, 9), 86–87° C (14), $[\alpha]_D^{18}$ −35° (*c*, 1.2% in chloroform) (14).

In saturated methanolic ammonia the above compound yielded the derived amide, m.p. 194–195° C; N, 3.3%; calc. N, 3.09%; reported (9) m.p. 196° C.

Hydrolysis Products from Methylated Aldobiouronic Acid

The methylated aldobiouronic acid (0.14 g) was heated with *N* sulphuric acid (6 ml) at 95° C for 12 hours. The hydrolyzate was neutralized with barium carbonate and insoluble barium salts were removed by centrifugation and washed three times with water. The combined supernatant solutions were evaporated to dryness, yielding a yellow powder (0.11 g). This powder was extracted with dry ether and the extract was evaporated to give a sirup (0.05 g), $[\alpha]_D^{25}$ +64.6° (*c*, 3.08% in water), which had the same R_f value as 2,3,4-tri-*O*-methyl-D-galactose on paper chromatography in solvents C and D. The sirup was heated under reflux for 2 hours in a solution of absolute ethanol containing aniline (0.02 g). Ethanol was evaporated and the crystalline residue was recrystallized from ethyl acetate to yield *N*-phenyl-2,3,4-tri-*O*-methyl-D-galactosylamine (15), m.p. 164–165° C unchanged on admixture with an authentic sample, $[\alpha]_D^{25}$ +39° (*c*, 0.9% in methanol).

The ether-insoluble material was boiled under reflux for 7 hours with 3% methanolic hydrogen chloride (5 ml). The methanolyzate was neutralized with silver carbonate, filtered, and evaporated to a sirup. Extraction of this sirup with ether yielded methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranosyluronic acid methyl ester, $[\alpha]_D^{22}$ +76° (*c*, 1.5% in water). This compound, in saturated methanolic ammonia, gave methyl 2,3,4-tri-*O*-methyl-α-D-glucopyranosyluronamide (15), m.p. 181–183° C, $[\alpha]_D^{22}$ +127° (*c*, 0.96% in water).

THE ALKALINE CLEAVAGE OF *o*-NITROBENZYLTRIMETHYLSILANE SOLVENT EFFECTS IN THE DIOXANE–WATER SYSTEM

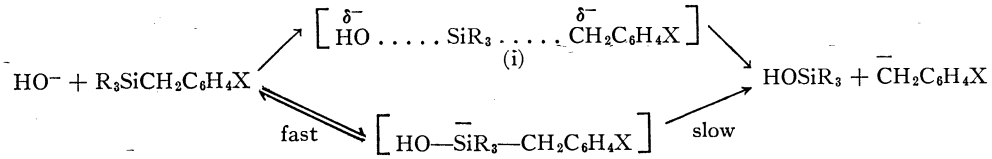
H. R. ALLCOCK[1]
Chemistry Department, University of Leicester, Leicester, England
Received January 16, 1963

ABSTRACT

The kinetics of alkaline cleavage of *o*-nitrobenzyltrimethylsilane were examined in aqueous dioxane media. At high water concentrations, increases in solvent polarity retard the cleavage, as required by a mechanism involving charge dispersion in the transition state. At high dioxane concentrations, solvent polarity increases are accompanied by increases in the rate of reaction, a result which may reflect association between the solvent components.

INTRODUCTION

Benzyl–silicon bonds are cleaved by alkali to yield toluene and silanol (1), and such reactions are known to be facilitated by electron-withdrawing substituents in the aromatic ring of the benzyl group (2). These reactions are believed to involve nucleophilic attack by hydroxide ion on silicon, either by a synchronous bimolecular (S_N2) process (i) or through the formation of a pentacovalent silicon intermediate (ii).



$$^{-}CH_2C_6H_4X + H_2O \longrightarrow CH_3C_6H_4X + OH^{-}$$

(where R is alkyl or aryl)

Eaborn and Parker (2) indicated that in both mechanisms the negative charge, formerly on the hydroxide ion, would become dispersed in the transition state, a fact which should render the reaction susceptible to solvent and salt effects. Since a charge delocalization would result in decreased solvation of the transition state, it can be predicted that an increase in the polarity of the solvent should bring about a small decrease in the rate of reaction (3). The same authors (2) found that the alkaline cleavage rates of several benzyltrimethylsilanes were faster in aqueous methanolic media which contained a higher proportion of water. However, they ascribed this result to the greater nucleophilicity of hydroxide ion than methoxide ion towards silicon, rather than to a solvent effect.

The present investigation was designed to study a solvent system which was free from complications of this type. The medium used was that of dioxane and water, and the silane chosen for this study was *o*-nitrobenzyltrimethylsilane. The rapid cleavage rate of this compound at very low alkali concentrations, coupled with the solubility in aqueous dioxane mixtures, made this silane particularly suitable for a study of solvent effects.

EXPERIMENTAL

Materials

o-Nitrobenzyltrimethylsilane was prepared by the method described by Eaborn and Parker (2). The material used in this work was kindly provided by the same authors.

Distilled water was boiled for 30 minutes to expel dissolved carbon dioxide, and was then stored as described below.

Commercial dioxane (1 liter) was refluxed for 8 hours with *N* hydrochloric acid (1 liter) to hydrolyze ethylene acetal impurity. A steady stream of nitrogen was passed through the solution to remove volatile hydrolysis products. When cooled, the mixture was shaken with sodium hydroxide pellets to remove acid, water, and peroxides, and was allowed to stand overnight over the same reagent. The aqueous layer was separated from the dioxane, and the latter was refluxed for 3 days with finely divided sodium (20 g). The dioxane was then distilled in an all-glass apparatus designed to exclude moisture and, after rejection of the first 30 ml of distillate, the solvent was collected in a closed flask. The concentration of water in this solvent was determined by titration against Karl–Fischer reagent, and was found to be less than 0.5%.

Storage and Burette System

The cleavage of *o*-nitrobenzyltrimethylsilane required the use of very dilute alkali solutions and it was necessary, therefore, to store and measure solvents and reagent solutions in the absence of atmospheric carbon dioxide. The apparatus consisted of storage flasks connected to five microburettes, which were filled by suction, and which opened to the atmosphere through "carbazorb" carbon dioxide extractors and, where necessary, through phosphorus pentoxide drying tubes.

Stock Silane Solution

The silane stock solution was made up to a concentration of 7.5×10^{-4} *M* *o*-nitrobenzyltrimethylsilane in dry dioxane. The silane was weighed on a glass scoop and was washed rapidly with solvent into a graduated flask. The remainder of the solvent was then added after fitting the neck of the flask into a rubber stopper secured a short way up the nozzle of the dioxane-filled burette. The graduated flask was then connected by glass tubing to the microburette system. This procedure ensured that contamination by water vapor and carbon dioxide was reduced to a minimum.

Stock Alkali Solutions

The water-to-dioxane ratio was varied by mixing equal volumes of silane stock solution and diluted alkali solution, the latter being prepared in different mixtures of water and dioxane. A carbonate-free stock solution of 0.121 *N* sodium hydroxide in water was prepared and stored in a polyethylene bottle, which was connected by glass tubing to the appropriate burette. All subsequent alkali solutions were prepared from this stock, which was standardized from time to time against 0.1 *N* potassium hydrogen phthalate solution, using phenolphthalein as indicator. Kinetic measurements were made at three alkali concentrations, 9.65×10^{-3} *N*, 4.83×10^{-3} *N*, and 2.41×10^{-3} *N*, obtained by dilution of 4-ml, 2-ml, and 1-ml portions of the aqueous sodium hydroxide solution to 25 ml of the appropriate aqueous dioxane mixture in a closed flask. The diluted alkali solutions were then transferred by suction to the appropriate microburette. These solutions were prepared before each run and were used within 4 to 5 hours.

Method of Following Silane Cleavage

The disappearance of *o*-nitrobenzyltrimethylsilane was measured spectrophotometrically by the decrease in optical density at 330 mμ, using a Unicam S.P.500 spectrophotometer. The method utilized the difference in ultraviolet absorption spectra between the silane and its cleavage products, since the spectrum of *o*-nitrobenzyltrimethylsilane resembled that of *o*-nitrotoluene but was displaced towards the visible by about 7 mμ. Kinetic runs were carried out in stoppered silica cells contained in a thermoregulated brass block inside the cell compartment of the spectrophotometer. The electrically heated thermoblock contained vertical compartments for two 10-mm cells and apertures for the passage of light. Temperature regulation was by means of a Mullard temperature controller, type E.7594, connected to a thermistor at the base of the block. Temperature calibration was performed by immersing the bulb of a standardized thermometer into solvent contained in each cell, and cell temperatures were checked at regular intervals during the investigation. Temperature variations within the cells did not exceed ±0.02° C at 40° C.

Experimental Procedure

Silane stock solution (10 ml) was measured from the burette system into a 25-ml glass bottle. The bottle was protected from the atmosphere by a rubber stopper on the burette nozzle and by a carbon dioxide trap. By the same technique, diluted alkali in aqueous dioxane (10 ml) was added from the appropriate burette. The solutions were thoroughly mixed with a glass stopper in position. A portion of the mixture was then transferred rapidly by dropper to the prewarmed cell, and the cell stopper was placed in position. The momentary exposure to the atmosphere during filling of the cells appeared to have no effect on the reaction. The second cell was filled with a dioxane solvent blank.

Optical density readings were taken as soon as the solutions were in the cells, and the zero time reading

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was obtained by extrapolation. The solutions reached the temperature of the thermoblock within 3 minutes of entering the cells at 40.15° C, and within 2 minutes at 30.23° C. This was demonstrated by the linearity of the kinetic plots after these times. Using this method, readings could be taken every 15 seconds and the kinetics of fast reactions could be followed accurately. Infinity values were obtained from optical density measurements at 10 times the half-life period. These readings were supplemented by values from portions of the reaction mixtures not used in the cell but placed in a closed reaction vessel in a thermostat bath for the required time. These values were also checked against synthetic end points prepared from solutions of *o*-nitrotoluene. All of the kinetic runs were performed in duplicate.

Calculation of Rate Constants

The rate constant k was calculated from the first-order equation of the form $k = [2.303/(t_2-t_1)] \log_{10} [(D_{t_1}-D_{t_\infty})/(D_{t_2}-D_{t_\infty})]$, where D_{t_1}, D_{t_2}, and D_{t_∞} are the optical densities at time t_1, t_2, and t_∞ respectively, determined at 330 mμ. The rate constants quoted are average values for duplicate runs. The first-order rate constants for a sample run are shown in Table I.

TABLE I

Variation of optical density and first-order rate constant during the alkaline cleavage of *o*-nitrobenzyltrimethylsilane ([NaOH], 4.83×10^{-3} N; temperature, 40.15° C; 26 vol% water in dioxane)

Time (min)	3	5	6	7	8	9	10	∞
10^3D (330 mμ)	636	577	552	529	510	492	474	318

*Graphical, $k = 1.02\times10^{-1}$ min^{-1}; duplicate run, $k = 1.00\times10^{-1}$ min^{-1}.

RESULTS AND DISCUSSION

Kinetic measurements were carried out in a series of water–dioxane mixtures containing from 8 to 75 vol% of water. The limitation of this system was that aqueous alkali solutions were immiscible with dioxane at high dioxane concentrations. This necessitated the use of low sodium hydroxide concentrations, in the range 2.42×10^{-3} N to 9.65×10^{-3} N, and required the use of special techniques to exclude carbon dioxide. Even so, the immiscibility of some solutions made it impossible to examine accurately the region below 16 vol% water at the highest alkali concentration. The results are shown in Table II.

The cleavage reactions were found to be first order in silane, reasonable constancy for the first-order rate constant k being obtained throughout a run. An exception to this behavior was provided by the reactions at the lowest water concentrations (8%), where first-order constants were maintained for the first 50% of the reaction only, a rapid falloff in rate being evident after that point. Evidence was obtained that this anomaly was due

For personal use only.

to removal of alkali by a very slow reaction with residual traces of peroxide. This side reaction did not affect initial rates at low water concentrations and had no significant effect on reactions in media which contained more than 8% water. The rate changes which were observed in different water–dioxane mixtures can thus be attributed to solvent effects.

Cleavage rate measurements at different alkali concentrations demonstrated that the specific rate constant k_s (k/[NaOH]) invariably decreased on moving from a higher to a lower alkali concentration, even though the kinetic plots indicated that alkali was not consumed during the reaction. This may reflect a change in the order of reaction with respect to the alkali, a feature which contrasts with related kinetics in aqueous methanolic media (2).

The results in Table II show that the reaction rate was influenced by changes in the water-to-dioxane ratio of the solvent. As the water content of the medium was increased from 8 to 36 vol% the rate of cleavage increased to a maximum. The position of this rate maximum, between 26 and 36 vol% water, was not changed by the temperature variation or by the change in alkali concentration. As the water content of the solvent was increased above 36 vol%, a moderate decrease in the rate of reaction was evident.

For a reaction between an ion and a dipolar molecule, a plot of log k against the reciprocal of the dielectric constant of the medium should give a straight line of positive slope if the solvent effect is entirely dependent on changes in the solvent polarity (4, 5). The plot for this reaction is shown in Fig. 1. The curves show that, although the reaction may be

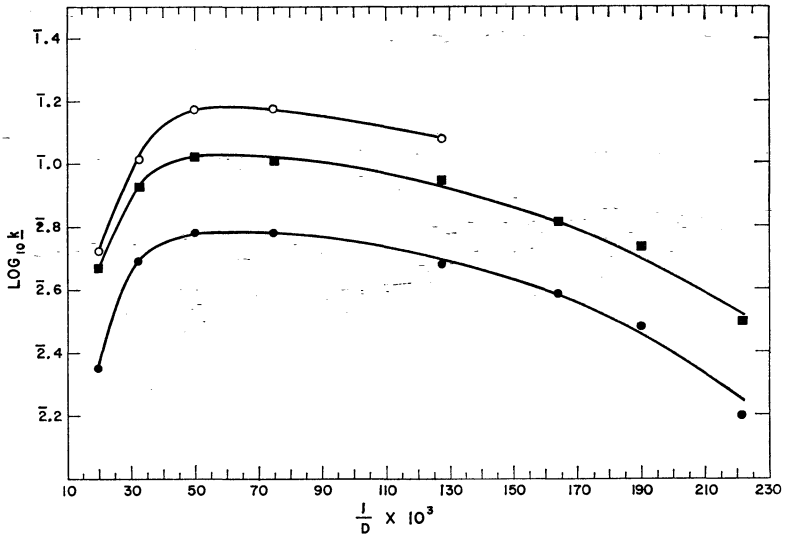

FIG. 1. Plot of the logarithm of rate constants versus the reciprocal of the dielectric constant of the water–dioxane solvent system. ○ [NaOH], 9.65×10^{-3} N; 30.23° C. ■ [NaOH], 4.83×10^{-3} N; 40.15° C. ● [NaOH], 4.83×10^{-3} N; 30.23° C.

dependent on the dielectric constant of the solvent at high water ratios in the manner predicted by theory, this interpretation is not valid in solvents containing less than 36 vol% water.

Rate constants were measured at 30.23° C and 40.15° C over a range of water concentrations from 8 to 75 vol% using 4.83×10^{-3} N sodium hydroxide. Activation energies and $\log_{10} A$ factors calculated from these values are listed in Table III. Changes in the rate

50	10.7	8.71
75	14.1	10.80

*The abnormal deviations for these values are probably due to experimental error.

of reaction are related to changes in both the activation energy and the frequency factor, since both E and $\log_{10} A$ reach a minimum in solvents which contain 12 to 26 vol% water. The absence of a simple linear relationship between E and $\log_{10} A$ over the whole range of solvent polarity changes suggests that water–dioxane mixtures which contain less than about 26 vol% of water have different solvation properties from those which contain a higher proportion of water (6).

The results of the present investigation demonstrate that, for solvent variations between 26 and 75 vol% water in dioxane, the reaction rate is decreased slightly by increases in the dielectric constant of the solvent, an effect which is consistent with the proposed reaction mechanism. The anomalous rate changes in the 8 to 26 vol% water region can be explained in terms of deviations from ideal solvation behavior. Deviations from ideal behavior in the water–dioxane system have been reported previously. The fluidity of water–dioxane mixtures reaches a minimum in the 40 to 50% water region (7, 8), and the density reaches a maximum at 32 wt% water (9). The kinetics of the exchange reaction and hydrolysis of *p*-nitrobenzyl bromide in water–dioxane mixtures show deviations from ideal behavior in media which contain less than 26 vol% of water (10). There is ample evidence that anomalous behavior of this type is due to hydrogen bonding between water and dioxane (11–14), which may reach a maximum in the 30 to 50% water region.

Hydrogen bonding within a solvent will seriously affect the nature of the solvation sheaths surrounding the reactants and the transition state, and will create local polarity effects in the vicinity of the reacting species which are not characteristic of the bulk solvent. It is possible that, as the dioxane concentration is increased beyond a limiting value, hydrogen bonding leads to the incorporation of dioxane molecules into the aqueous solvation sheaths of the polar species. At the highest dioxane concentrations it is likely that ionization of the alkali is retarded due to the absence of free water molecules.

ACKNOWLEDGMENTS

A NEW ASPIDOSPERMA ALKALOID: O-DEMETHYLASPIDOCARPINE[1]

C. FERRARI,[2] S. MCLEAN,[2] LÉO MARION, AND K. PALMER[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received February 20, 1963

ABSTRACT

From the stem bark of *Aspidosperma album* four alkaloids have been isolated. Two of these (aspidoalbine and its N-acetyl-N-depropionyl homologue) have been reported recently and their structures established by Djerassi and his co-workers. The other two consist of aspidocarpine, and a new alkaloid, the structure of which has been determined. It is O-demethylaspidocarpine.

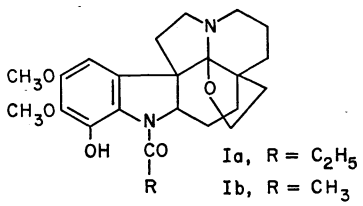
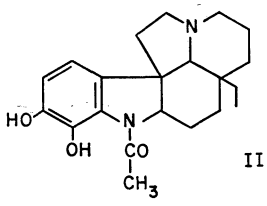
The alkaloids of the stem bark of *Aspidosperma album* (Vahl) R. Dent., collected in British Guiana,[3] have been under investigation in this laboratory for some time. A recent publication (1) reporting the structures of two alkaloids occurring in this plant prompts us to place on record some of our results.

Four bases have been isolated from the bark. Of these, alkaloids I and II are identical with aspidoalbine I*a* and its N-acetyl-N-depropionyl homologue I*b*, whose structures have



Ia, R = C_2H_5
Ib, R = CH_3



II

been determined by Djerassi[4] and his co-workers (1). Since they did not succeed in effecting a clean separation of these two bases and did not report the physical properties of the lower homologue, we now describe a method of separation and record the physical properties of both alkaloids (cf. Experimental). Thin layer chromatography tests showed that the method of separation was effective and produced both alkaloids in a chromatographically pure state.

Alkaloid I and its O-methyl derivative were compared directly with samples of aspidoalbine and O-methylaspidoalbine kindly supplied by Dr. C. Djerassi and found to be respectively identical. Alkaloid II analyzed correctly for N-depropionyl-N-acetylaspidoalbine. Both n.m.r. and infrared spectra indicated the presence of a hydrogen-bonded N-acetyl carbonyl. Alkaloid II gave rise to an O-methyl derivative which, although it had an infrared spectrum superimposable on that of N-depropionyl-N-acetyl-O-methylaspidoalbine, did not yield satisfactory analytical figures. The methyl derivative was hydrolyzed with hydrochloric acid and the product treated with propionic anhydride and pyridine. The purified product of the reaction showed no depression in melting point when mixed with O-methylaspidoalbine, and the two substances had the same optical rotation

and superimposable infrared spectra. Hence alkaloid II is N-depropionyl-N-acetyl-aspidoalbine.

Alkaloid III appeared to be a new base not previously described while the fourth alkaloid proved to be identical in every respect with aspidocarpine (2). Alkaloid III was obtained from the ether eluate of a chromatogram of the crude alkaloids on a kieselguhr/phosphate buffer column. Its analytical figures corresponded to the empirical formula $C_{21}H_{28}O_3N_2$ (m.p. 156–158°). It was soluble in aqueous sodium hydroxide but not in sodium carbonate, and gave a violet coloration with a ferric chloride solution, so that at least one of its three oxygens must be present in a phenolic hydroxyl. It formed a monohydrochloride, m.p. 283°, and hence of the two nitrogens in the alkaloid one only appeared to be basic.

The n.m.r. spectrum of alkaloid III shows a striking resemblance to that of pyrifoline (3) and of aspidocarpine (2) except for the signals corresponding to the two methoxyl groups of the former and the one methoxyl of the latter, which are absent. The peak ($\delta = 11.0$) corresponding to the hydrogen-bonded hydroxyl in the n.m.r. spectrum of aspidocarpine (2) is also found in that of alkaloid III ($\delta = 11.3$). The ultraviolet spectrum (λ_{max} 227 mμ, log ϵ 4.25; 264 mμ, log ϵ 3.85) was similar to that of aspidocarpine (λ_{max} 228 mμ, log ϵ 4.42; 263.5 mμ, log ϵ 3.92). The infrared absorption spectrum contained bands indicative of hydroxyl groups and of an amide carbonyl. Since alkaloid III contained no methoxyl and its empirical formula contained CH_2 less than that of aspidocarpine it was thought probable in view of the foregoing spectral similarities that it could be O-demethylaspidocarpine. If alkaloid III be assumed to have the same skeleton as aspidocarpine, then a phenolic hydroxyl must be attached at C-17 because of its strongly hydrogen-bonded nature, evidenced in the infrared by the marked displacement to lower frequencies (1635 cm^{-1}) of the amide carbonyl absorption, and a characteristic signal in the n.m.r. spectrum.

The correctness of the assumption was confirmed by treatment of alkaloid III with dimethyl sulphate and sodium hydroxide. The reaction gave rise to a dimethyl derivative identical with O-methylaspidocarpine. Consequently, alkaloid III is O-demethylaspidocarpine and its structure is represented by formula II.

O-Demethylaspidocarpine provides a further example of a catechol type of alkaloid of which the first one reported in the aspidospermine series is spegazzinidine (5).

EXPERIMENTAL

All the n.m.r. spectra were taken with a Varian Associates A-60 instrument, and the infrared spectra with a Perkin–Elmer double-beam spectrophotometer Model 21B.

The ground stem bark was extracted first with petroleum ether and then with ethanol–ammonia (11 l. – 1 l.). A crystalline colorless material separated from the petroleum ether extract. It was heated with *n*-heptane to remove the accompanying fat. The insoluble crystalline basic substance was recrystallized from methanol, from which it separated as yellowish prisms. Several recrystallizations raised the melting point to 172–174°. A quantity of the same crystalline substance was also obtained from the basic ethanol extract. When the crude alkaloid of this extract was chromatographed in benzene solution on neutral alumina, the material was found in the first fractions of the eluate.

Aspidoalbine and N-Depropionyl-N-acetylaspidoalbine

The crystalline material was chromatographed on paper under the condition described by Taylor *et al.* (4) and found not to be homogeneous but to consist of two distinct components. This technique was modified to adapt it to the separation of relatively large amounts of material. Whatman No. 3 paper was used and the alkaloid mixture in chloroform was streaked along the base line. It was found convenient to use 240 mg of material for 130 cm of base line. When the chromatogram had developed and the paper had been allowed to hang overnight in air, thin vertical strips were cut from it at 15-cm intervals and sprayed with iodoplatinate reagent. This illustrated how the components had separated. The appropriate zones were cut out from the paper and each was thoroughly extracted with chloroform in a Soxhlet apparatus. Each extract

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was evaporated to a volume of ca. 50 ml, was washed with 5% aqueous sodium carbonate and with water; it was dried over sodium sulphate and was evaporated to dryness. Each residue was dissolved in benzene, passed through a short column of alumina, and eluted with benzene; the products were crystallized from benzene–hexane and then from methanol. From 240-mg of mixture there was obtained 58 mg of alkaloid I (leading zone), colorless prisms, m.p. 174–177°, and 36 mg of alkaloid II (second zone), colorless prisms, m.p. 194–195°.

An easier but not complete separation of the two alkaloids can be achieved by chromatography of the mixture on low-activity (grade V) neutral alumina, and the use of *n*-hexane – chloroform as eluant. Under such conditions pure alkaloid I is first obtained, then a mixture of alkaloids I and II, and finally pure alkaloid II, but most of the mixture is separated into its components.

Alkaloid I, $[\alpha]_D^{25}$ +164° (*c*, 2.12 in chloroform). Found: C, 67.68; H, 7.71; N, 6.70; OCH_3, 14.68. Calc. for $C_{24}H_{32}O_5N_2$: C, 67.27; H, 7.53; N, 6.54; 2 OCH_3, 14.48%. A mixture of alkaloid I with a sample of aspidoalbine[5] (m.p. 168–173°) melted at 166–170°. On a silica gel chromatoplate with chloroform – *n*-hexane – diethylamine (10:20:3) as solvent, alkaloid I gave one spot while the sample of aspidoalbine gave two, one of which had the same mobility as the one spot of the former, and the other corresponded to alkaloid II.

On methylation with dimethyl sulphate and sodium hydroxide, alkaloid I gave rise to an O-methyl derivative, m.p. 128–131°, $[\alpha]_D^{25}$ +9.2° (*c*, 1.84 in methanol). Found: C, 68.17; H, 7.79; N, 6.30; OCH_3, 20.19. Calc. for $C_{25}H_{34}O_5N_2$: C, 67.85; H, 7.75; N, 6.33; 3 OCH_3, 21.04%. In admixture with a sample of O-methylaspidoalbine[5] (m.p. 120–123°), m.p. 120–132°. O-methyl alkaloid I gave one spot on a chromatoplate and the sample of O-methylaspidoalbine gave two, the major one of which corresponded in mobility with the one spot of the former.

Alkaloid II, m.p. 194–195°, had $[\alpha]_D$ +174° (*c*, 1.93 in chloroform). Found: C, 66.38; H, 7.29; N, 6.52; OCH_3, 15.06. Calc. for $C_{23}H_{30}O_5N_2$: C, 66.64; H, 7.30; N, 6.76; 2 OCH_3, 14.96%. λ_{max}^{EtOH} 227 mμ, log ε 4.43; 267 mμ, log ε 4.11. The only difference between the n.m.r. spectrum of alkaloid II and that of aspidoalbine is the replacement of the triplet at 1.26 δ (CH_3) and the quartet at 2.53 δ (CH_2) corresponding to the protons of the N-propionyl group of aspidoalbine by a peak at 2.36 δ corresponding to three protons (N-acetyl). The infrared absorption spectrum contains a band at 1625 cm^{-1} indicative of a hydrogen-bonded N-acetyl carbonyl. Alkaloid II therefore corresponds to the lower homologue of aspidoalbine.

Methylation of Alkaloid II

A quantity of alkaloid II was methylated with dimethyl sulphate and sodium hydroxide following the usual procedure. The product of reaction, after crystallization from aqueous methanol, was shown by thin layer chromatography not to be homogeneous. It was therefore chromatographed on a silica gel plate (20×20 cm), the main band (detected by spraying with water) scraped off and eluted with methanol–chloroform (1:1). The material recovered from the eluate was sublimed at 145° at 10^{-4} mm. Colorless needles were obtained, m.p. 169–173°, which after one more sublimation melted at 175–178.5°. This substance was found by thin layer chromatography to be homogeneous, and to have an infrared spectrum superimposable on that of N-depropionyl-N-acetyl-O-methylaspidoalbine.[5] The product, however, gave consistently low analytical figures. It was therefore hydrolyzed by boiling in 3 *N* hydrochloric acid under reflux for 2.5 hours. The solution was made alkaline and extracted with chloroform. The residue left after evaporation of the chloroform extract was heated on the steam bath for 2 hours with propionic anhydride and pyridine and the product of the reaction chromatographed on a silica gel plate (20×20 cm). The silica gel containing the main band was scraped off and extracted with methanol–chloroform. Evaporation of the extract left a residue which after sublimation consisted of colorless prisms, m.p. 134–137°, $[\alpha]_D$ +9.7° (*c*, 1.76 in MeOH). In admixture with O-methylaspidoalbine (m.p. 127–131°) it melted at 128–135°. Its infrared spectrum was superimposable on that of O-methylaspidoalbine.

Aspidocarpine and O-Demethylaspidocarpine

The alcoholic extract of the bark was fractionated on a 200 g/200 ml kieselguhr/phosphate buffer (pH 5.2) column, using first ether and then chloroform as eluting solvents. Only traces of base were left on the column, which was stripped with ammoniacal chloroform.

Evaporation *in vacuo* of the ether eluate at room temperature left a yellow resin, which was dissolved in boiling benzene and decolorized with charcoal. The filtered cooled solution, left to stand overnight, deposited long pale yellow needles, m.p. 139–140°. After two recrystallizations from benzene the substance consisted of colorless needles, m.p. 149–150°. Chromatography on Whatman No. 1 paper with butanol as solvent showed the substance to be a mixture of two components. Recrystallization from aqueous isopropanol effected a separation and gave pure alkaloid III as colorless plates. The basic mixture recovered from the ether eluate after separation of alkaloid III was chromatographed on grade V neutral alumina. *n*-Hexane – chloroform (4:1) removed first a portion of unidentified material and then the major component of the mixture which, after crystallization from methanol, consisted of colorless prisms, m.p. 166–168°, identical (by melting point of the mixture and infrared spectra) with an authentic sample of aspidocarpine. Further elution of the chromatogram with chloroform removed another portion of unidentified material, and finally with chloroform containing 5% of methanol gave another quantity of alkaloid III.

[5]*This sample was kindly sent to us by Dr. C. Djerassi, to whom we express our gratitude for his cooperation.*

Alkaloid III, m.p. 156–158°, was soluble in aqueous sodium hydroxide but not in sodium carbonate. It gave a violet coloration with ferric chloride solution. A sample of the base was dried at 100° *in vacuo* and used for analysis. Found: C, 70.7; H, 7.96; N, 7.90. Calc. for $C_{21}H_{28}O_3N_2$: C, 70.79; H, 7.86; N, 7.86%. No methoxyl group was present. $[\alpha]_D^{25}$ +125° (*c*, 0.95 in chloroform). The infrared spectrum contained bands at 3320, 2520, 1635 with a shoulder at 1615 and a band at 1584 cm^{-1}. (Aspidocarpine produced infrared bands at 1635 and 1586 cm^{-1}.)

The alkaloid formed a hydrochloride which separated from ethanol–ether as colorless needles containing solvent of crystallization, m.p. 283° (decomp.). On drying at 120° *in vacuo* the salt lost 11% of its weight. The dried sample was used for analysis. Found: C, 64.8; H, 7.48; N, 7.00; Cl, 9.37. Calc. for $C_{21}H_{28}O_3N_2.HCl$: C, 64.18; H, 7.18; N, 7.13; Cl, 9.02%.

Methylation of Alkaloid III

A small sample of alkaloid III was methylated under the usual conditions with dimethyl sulphate and sodium hydroxide. The product of the reaction was sublimed *in vacuo* to remove colored impurities and then chromatographed on silica gel plates with the use of chloroform – *n*-hexane – diethylamine (10:20:3) as solvent. The main band, detected by spraying with water, was scraped off and extracted with chloroform–methanol. The filtered solution was evaporated and the residue crystallized from aqueous methanol, from which it separated as colorless prisms, m.p. 146—150°, $[\alpha]_D^{25}$ −95.4° (*c*, 1.18 in chloroform). It was identical with O-methylaspidocarpine in optical rotation ($[\alpha]_D^{25}$ −94° in chloroform), in melting point and that of the mixture, in plate chromatographic mobility, and in infrared absorption spectra.

ACKNOWLEDGMENTS

We wish to express our thanks to Mr. A. Knoll for the extraction of the plant material, Mr. H. Séguin for the microanalyses, Mr. R. Lauzon for the infrared spectra, and Mr. M. Lesage for the n.m.r. spectra.

ABSTRACT

Gas liquid and thin layer chromatography have been combined into a single microphysicochemical technique. The resolution of two terpenoids found in nature—piperitone and piperitone oxide—is described to illustrate the scope of the novel method of analysis. Occurrence of the epoxide in *Mentha arvensis* (Japanese mint), *Mentha piperita* (Mitcham peppermint), *Eucalyptus dives* Schauer, "Type" ("broad-leaved peppermint"), and *Eucalyptus numerosa* Maiden, var. "A" is reported for the first time. Its presence in these species should prove of biochemical as well as taxonomic interest.

Gas liquid partition and thin layer chromatography are extremely important techniques for the examination of complex natural and synthetic compositions. What were once considered tedious microchemical analyses have through their application become routine assays in research and industrial laboratories alike. Studies to combine both methods into a unified operation were begun in the authors' laboratory some time ago (1). A related investigation was published since by Casu and Cavalotti (2). It is the purpose of the present paper to record the experimental procedures we followed, to report some specific results, and to indicate future applications.

EXPERIMENTAL

Apparatus

Gas chromatograph.—Burrell Kromo-Tog K-2 equipped with thermal conductivity detector cell and separate heating baths for column and detector, respectively.

Column.—Glass tubing, 0.6-cm inside diameter, 215 cm long.

Packing.—Reoplex 400 (10 parts) deposited from ethanolic solution on 60- to 80-mesh, acid-washed Chromosorb W (90 parts). Length of packed column, 200 cm.

Carrier gas.—Helium, inlet pressure 1.1 atm; outlet pressure 1.0 atm.

Recorder.—0 to 1 mv full-scale deflection; 1 second.

Coupling device.—1 mm inside diameter platinum needle approximately 1 in. long, inserted into the exit of the chromatograph and bent slightly to deposit effluents directly on chromatoplates for concomitant TLC-analysis.

Thin layer chromatographic assembly.—According to Stahl; C. Desaga unit.

Materials

Essential oils.—Products from genera *Mentha* and *Eucalyptus*.

Essential oil constituents.—*l*-Piperitone obtained from a hybrid of *M. arvensis*. Experimental sample (1 g) purified by column chromatography over silica gel (25 g) using hexane–ether (10:1) as eluant; $\epsilon^{EtOH}_{max\ 318\ m\mu} = 50.4$; $\epsilon^{EtOH}_{max\ 234\ m\mu} = 13{,}950$. *l*-Piperitone oxide ex *M. sylvestris*: $\epsilon^{EtOH}_{max\ 296\ m\mu} = 48.6$.

Analytical Procedure

Samples ranging from 5 to 10 μl were injected from a Hamilton microliter syringe through silicone seals into the column, operated at 150±2° C. Helium served as carrier gas, its flow rate—measured by the soap bubble method at the exit—being maintained at 75±0.5 ml/min. A current of 200 ma was applied to the hot wire detector and the thermal conductivity cell operated at 200° C. Chart speed was 0.5 in./min.

Emerging fractions were spotted directly on chromatoplates coated with Silica Gel G (Merck) and activated by heating at 120° C for 24 hours prior to use. A 10:1 hexane – diethyl ether mixture was applied for development and a 5% solution of vanillin in concentrated sulphuric acid served as spray reagent.

[1]*National Research Council of Canada Postdoctoral Fellow, 1961–1962.*

Identification of Components and Quantitative Determinations

Hexane solutions containing known amounts of both ketones were prepared for use as reference standards and applied as controls for compound identification and the appraisal of product recovery by the combined technique.

RESULTS AND DISCUSSION

Detection of Ketones by Gas Liquid Partition and Thin Layer Chromatography

Figure 1 shows the gas chromatogram of a Japanese oil of mint (*M. arvensis*), an English

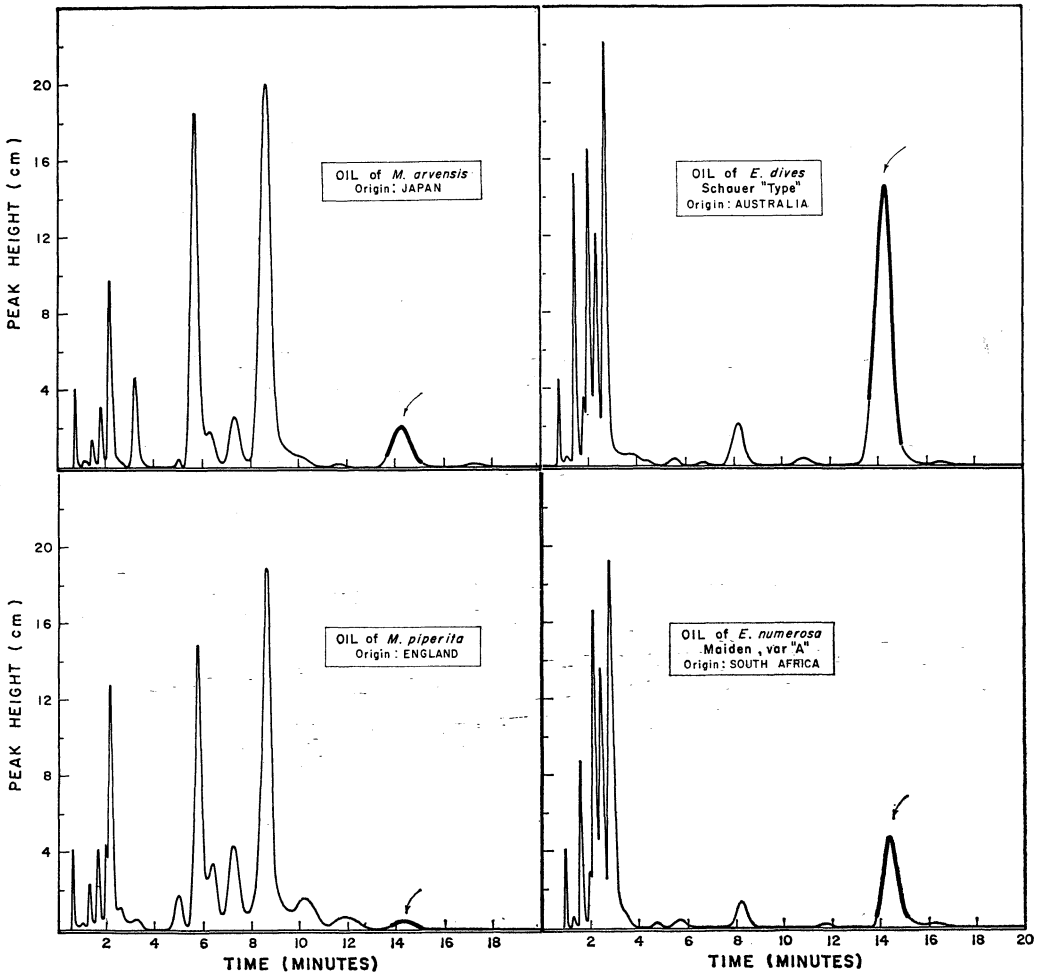

FIG. 1. Gas chromatograms of essential oils from genera *Mentha* and *Eucalyptus*. Analytical peaks reproduced in heavy lines.

oil of peppermint (*M. piperita*), an Australian oil of *E. dives* Schauer, "Type" ("broad-leaved peppermint"), and a South African oil of *E. numerosa* Maiden, var. "A". Analytical fractions examined in accordance with the technique described are reproduced in heavy lines.

Both piperitone and piperitone oxide were found to be present in each of the eluates—the epoxide appearing as a bright purple spot following treatment of the chromatoplate with a 5% solution of vanillin in sulphuric acid and turning dark violet on being heated

For personal use only.

to 100° C for a period of 5 minutes. Sensitivity of spray reagent: 1 γ. Piperitone appeared as a light orange colored spot, becoming deep orange-brown on being heated to 100° C for a 5-minute interval. Sensitivity of spray reagent: 50 γ.

Infrared Examination of Gas Chromatographic Eluates

Characteristic bands permitting distinction of the two ketones are shown in Fig. 2,

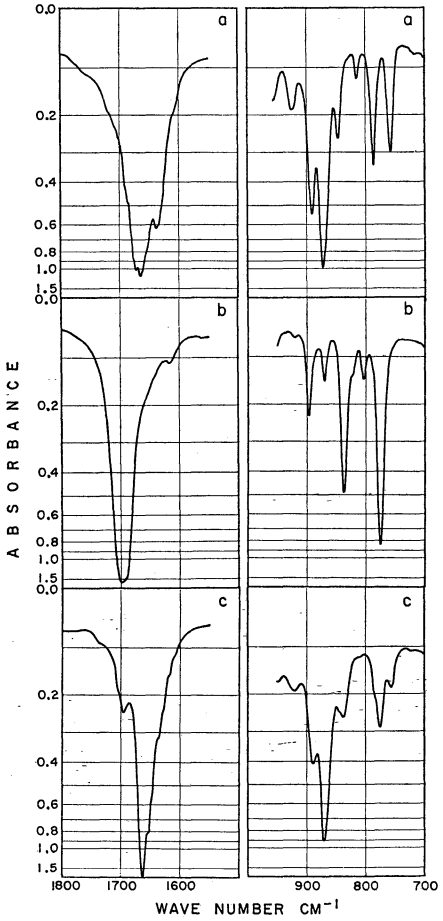

FIG. 2. Characteristic regions in infrared spectra of piperitone (*a*), piperitone oxide (*b*), and "piperitone" effluent from Japanese mint oil (*c*). Reference spectra measured in sealed sodium chloride cells of 0.025-mm path length (piperitone: 950–700 cm^{-1}) and 0.0155-mm path length (piperitone oxide). Carbonyl region of piperitone (1800–1550 cm^{-1}) charted as contact film. Spectrum of gas chromatographic effluent from essential oil obtained by direct deposition of analytical fraction on grooved salt plate (1) following 20-λ sample injection, with instrument (Perkin–Elmer Model 221 spectrophotometer) operated under 5-fold scale expansion.

along with the corresponding spectral features of the "piperitone" effluent from the Japanese mint oil.

Piperitone displays strong absorption at 1665 cm^{-1} (conjugated carbonyl) and exhibits sharp bands at 873, 785, and 760 cm^{-1}. Piperitone oxide shows an intense band at 1695 cm^{-1} (unconjugated carbonyl) and displays marked absorptions at 837 and 775 cm^{-1}.

These criteria of identity permitted detection of the epoxide in the analytical fraction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

collected and examined as previously described (1), distinct bands being observed at 1695 and 775 cm^{-1}. Characteristic piperitone absorptions were found to occur at 1665 and 873 cm^{-1}, an inflection only being detected at 785 cm^{-1} because of marked absorbance by the epoxide at 775 cm^{-1}.

Similar infrared examination of the corresponding eluates from oil of *M. piperita*, *E. dives*, and *E. numerosa* failed to suggest the presence of any other but the major component, i.e., piperitone. Direct thin layer chromatography of the essential oils and their oxygenated fractions isolated via deterpenation over alumina yielded, likewise, negative results. Only coupled gas liquid – thin layer chromatography of the effluents established that both ketones occur in these oils along with still other components of identical or nearly identical retention times, as illustrated in Fig. 3 for Japanese mint oil.

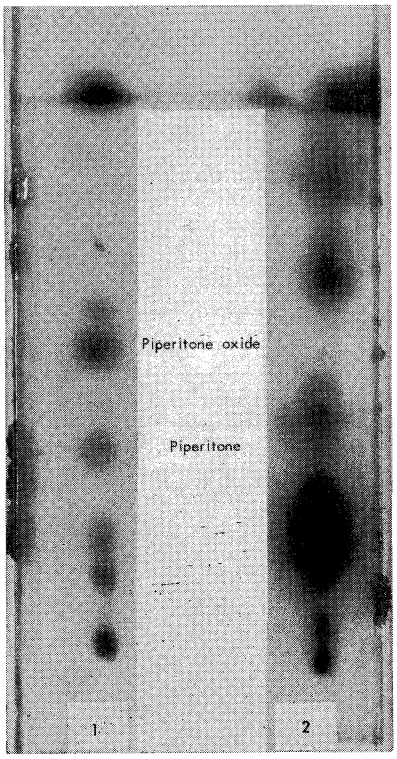

FIG. 3. CGT-chromatogram of "piperitone" effluent from Japanese mint oil (1), and TL-chromatogram of deterpenated sample (2).

Quantitative appraisal of the gas chromatogram recorded for the oil of *M. arvensis* indicated that the sample contained 7.1% of piperitone (3). Quantitative appraisal of the thin layer chromatogram obtained for the analytical peak revealed, however, admixture of the effluent with approximately 4% of piperitone oxide as a genuine constituent of the oil. Piperitone oxide content of whole oil $\sim 0.3\%$. Mere trace amounts of this ketone ($<0.1\%$) were detected in oils of peppermint and eucalyptus. Comparison of color intensities observed with those of comparable concentrations of binary mixtures of the ketones examined simultaneously revealed that product recoveries ranging from 90–95% were realized by the combined technique.

Smooth deposition of gas chromatographic eluates presented no difficulties. The tip of the needle was merely kept just barely touching the glass plate during collection. Surface

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

adsorption by the thin film of finely dispersed coating appears to insure efficient retention of the condensate. If, as in this study, isolated peaks only are being collected for analysis it is advisable to wipe the tip of the needle with a piece of soft tissue paper before deposition of the eluate in order to avoid contamination with material from preceding fractions, or to insert the needle into the apparatus just prior to emergence of the component or components to be examined.

Scope of Analytical Technique

Coupled gas liquid – thin layer chromatography has been applied successfully in our laboratory for the resolution of apparently symmetrical peaks observed in the gas chromatograms of many essential oils and their constituents and we are utilizing the technique routinely for the detection of trace components, the appraisal of sample authenticity, and quantitative determinations.

Because of its sensitivity the method allows for the investigation of oils from single leaf pairs of plants produced by controlled cultivation of pure species and thus eliminates the chance of extrapolation from results obtained with oils from mixed species or non-homozygous strains—a source of serious difficulty for the study of natural products and often justified doubts of the validity of biochemical deductions from physiochemical data (4). The value of the method to the plant breeder and taxonomist is thus obvious.

Since components resolved are characterized immediately by two specific criteria, namely retention time and R_f value, which constants are, in turn, codetermined by a number of closely related physiochemical parameters (5–8) their identities may often be staked and deduced directly from coupled gas liquid – thin layer chromatographic data. Permitting, furthermore, the exploration of all the variables of GLPC, e.g., column substrate, temperature, flow rate, as well as those of TLC, e.g., adsorbent, developer, spray reagent, and simultaneous performance of both analyses without interruption, the technique provides a simple, efficient method not only for the study of essential oils and their constituents but for the examination of complex natural and synthetic compositions generally on an ultramicro scale.

Because of the universal usefulness thus visualized for *C*oupled *G*as liquid – *T*hin layer *C*hromatography, we would like to suggest that it be designated the ***CGTC*** technique.

ACKNOWLEDGMENTS

The authors are indebted to Dr. F. J. Cramer, A. M. Todd Company, Kalamazoo, Mich., U.S.A., for courteously supplying samples of piperitone and piperitone oxide for this study. They also express their appreciation to Dr. Ernest Guenther, Fritzsche Brothers, Inc., New York, U.S.A., for a genuine sample of South African oil of *E. numerosa*, to Dr. Teikichi Hiraizumi, Takasago Perfumery Co., Ltd., Tokyo, Japan, for a representative specimen of oil of *M. arvensis*, and to Dr. F. R. Morrison, Museum of Applied Arts and Sciences, Sydney, Australia, for an authenticated sample of Australian oil of *E. dives*.

ABSTRACT

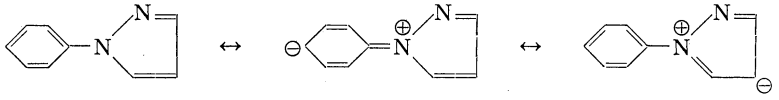
Nitrations of 1-phenylpyrazole (I), 1-*p*-biphenylylpyrazole (II), and 1,5-diphenylpyrazole by "acetyl nitrate" (nitric acid – acetic anhydride) occur selectively in the 4-position of the pyrazole ring, as do brominations of I and II in chloroform solution. These results are in agreement with R. D. Brown's calculations of localization energies for electrophilic substitution in pyrazole.

However, nitration of I by mixed acids at 12° yields 1-*p*-nitrophenylpyrazole, and bromination of I by bromine in concentrated sulphuric acid in the presence of silver sulphate yields 1-*p*-bromophenylpyrazole.

The variations in orientation of substitution can be rationalized if the reacting species of I in strongly acidic solvents is the conjugate acid, in which the pyrazole ring is deactivated by protonation.

INTRODUCTION

Electrophilic substitution in 1-phenylpyrazole (I) often leads to initial attack at the 4-position of the pyrazole ring (for example, bromination in inert solvents (1), Friedel–Crafts acylation (2, 3), chloromethylation (4), and mercuration (4)). However, nitration of 1-phenylpyrazole with mixed acids at 12° introduces the first nitro group into the para position of the phenyl ring, although further substitution occurs readily to yield 4-nitro-1-*p*-nitrophenylpyrazole (cf. Finar and Hurlock (5)).



I Ia Ib

The present paper suggests a simple interpretation of this variation in orientation, and applies this interpretation in establishing conditions for selective 4-nitration of 1-*p*-biphenylylpyrazole (II) and 1,5-diphenylpyrazole (III), for the controlled dinitration of III, for the 4-bromination of II, and for the 1-*p*-bromination of I.

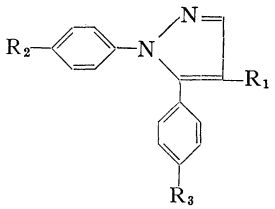
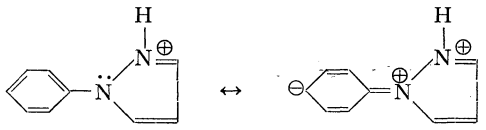
II



III: $R_1 = R_2 = R_3 = H$
V: $R_1 = NO_2$, $R_2 = R_3 = H$
VI: $R_2 = NO_2$, $R_1 = R_3 = H$
VII: $R_3 = NO_2$, $R_1 = R_2 = H$
VIII: $R_2 = R_3 = NO_2$, $R_1 = H$
IX: $R_1 = R_2 = NO_2$, $R_3 = H$

DISCUSSION

We suggest that the different orientation noted in the strongly acidic medium results from protonation of 1-phenylpyrazole to yield the conjugate acid (IV), in which the pyrazole ring would be deactivated towards attack by electrophils, while the +T effect of the 1-nitrogen atom would facilitate substitution at the para position of the phenyl group (cf. IV*a*). If this suggestion is correct, it should be possible to effect changes in the orientation of electrophilic substitution in 1-phenylpyrazole and its derivatives by varying the conditions of reaction so that either the neutral molecule or the conjugate acid is the reacting species.



IV IV*a*

Examples

(a) Selective 4-Nitrations

Although no interpretation along the lines of the above suggestion has been offered previously, an instance of the predicted control of orientation exists in the literature, in that nitration of 1-phenylpyrazole by nitric acid in acetic anhydride at 0° is reported to give 4-nitro-1-phenylpyrazole (in unstated yield) (6). In confirmation (see Experimental) we find that fair yields of 4-nitro-1-phenylpyrazole are obtained. It seems almost certain that this reaction involves attack of protonated acetyl nitrate (the effective reagent in nitrations by nitric acid in acetic anhydride, cf. Bordwell and Garbisch (7)) on the neutral molecule of 1-phenylpyrazole, while Finar and Hurlock's nitration in mixed acids involves attack by nitronium ion on the conjugate acid (IV).

Since the normally favored position of attack by an electrophilic reagent on the neutral molecule of a 1-phenylpyrazole derivative is the 4-position of the pyrazole ring (cf. refs. 1–4), it would be predicted that nitrations of 1-*p*-biphenylylpyrazole and of 1,5-diphenylpyrazole by nitric acid in acetic anhydride would yield 4-substituted derivatives. The results from the nitrations of these compounds are consistent with this prediction, although the structures of the products were not proved absolutely. The structure assigned to the nitro-1-*p*-biphenylylpyrazole, m.p. 170° (i.e., 1-*p*-biphenylyl-4-nitropyrazole), is based on correlations with the infrared and ultraviolet absorption of nitrophenylpyrazoles and other substituted 1-phenylpyrazoles. The positions of the strong bands at the N—O stretching frequencies, in conjunction with others at ca. 690 and 760 cm^{-1}, as observed with compounds possessing monosubstituted phenyl groups (8), can be used to distinguish

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

between the various nitrophenylpyrazoles (see Table I): the similarities between the nitro-1-*p*-biphenylylpyrazole, m.p. 170°, and 4-nitro-1-phenylpyrazole indicate very strongly that the compound is 1-*p*-biphenylyl-4-nitropyrazole. Furthermore, we have noted (9) that a strong band in the region 925–960 cm^{-1} is associated with the C—H vibrations of the pyrazole carbons, and its position in substituted 1-phenylpyrazoles in diagnostic of substitution in the pyrazole ring: absorption in the range 925–942 cm^{-1} is noted for compounds without substituents in the pyrazole ring, while absorption in the range 950–960 cm^{-1} is observed with compounds carrying such substituents. This generalization is valid for approximately 50 substituted 1-phenylpyrazoles prepared in the course of the present series of papers. This band appears at 952 cm^{-1} in the infrared spectra of the nitro-1-*p*-biphenylpyrazole, m.p. 170°, thus providing further support for the assigned structure.

TABLE I

Infrared absorption bands of nitroarylpyrazoles

Compound	Infrared absorption regions (cm^{-1}) (all strong bands)		
	650–1000 (C—H deformation)	1300–1400 (ν_{N-O} sym.)	1500–1560 (ν_{N-O} asym.)
1-*o*-Nitrophenylpyrazole	750, 754, 760, 941	1371	1545
1-*m*-Nitrophenylpyrazole	738, 762, 940	1355	1535
1-*p*-Nitrophenylpyrazole	765, 852, 928	1341	1527
4-Bromo-1-*p*-nitrophenylpyrazole	750, 855, 960	1340	1527
1-(2,4-Dinitrophenyl)-pyrazole	740, 780, 832, 910, 940	1345 br	1530, 1545, 1555
4-Nitro-1-phenylpyrazole	690, 751, 770, 820, 950	1325	1545
Nitro-1-*p*-biphenylylpyrazole, m.p. 170°	692, 748, 765, 820, 952	1325	1541

Evidence from ultraviolet absorption is also consistent with the assigned structure: the ultraviolet absorption spectra of the various nitrophenylpyrazoles are characteristic, as 4-nitro-1-phenylpyrazole is the only isomer having two absorption maxima of approximately equal intensity above 220 mμ. The presumed 1-*p*-biphenylyl-4-nitropyrazole also exhibits two maxima, displaced bathochromically about 30 mμ, as would be expected from the presence of an extra *p*-phenyl substituent (compare 1-phenylpyrazole, λ_{max} 252 mμ, log ε 4.13, and 1-*p*-biphenylylpyrazole, λ_{max} 280 mμ, log ε 4.50). The absorption maxima are listed in Table II.

The nitro-1,5-diphenylpyrazole, m.p. 150°, obtained by nitration of 1,5-diphenylpyrazole in acetic anhydride, is almost certainly 1,5-diphenyl-4-nitropyrazole (V). The

TABLE II

For personal use only.

only likely positions of attack are the 4-position of the pyrazole ring, or the para positions of either the 1- or 5-phenyl groups, and both 1-*p*-nitrophenyl-5-phenylpyrazole (VI), m.p. 117° (10), and 5-*p*-nitrophenyl-1-phenylpyrazole (VII), m.p. 93° (11), are known compounds.

(b) Nitrations in Mixed Acids

Under these conditions, we have assumed that the reacting species of substituted 1-phenylpyrazoles will be the appropriate conjugate acids. Attempted nitration of 1-*p*-biphenylylpyrazole, using the conditions employed for 1-phenylpyrazole (5), yielded mixtures from which no single substances were isolated. The infrared spectra of the mixtures showed broad, strong absorption in the 1350–1370 and 1530–1550 cm^{-1} regions, indicative of polysubstitution (compare the infrared absorption of 1-(2,4-dinitrophenyl)-pyrazole, Table I).

Nitration of 1,5-diphenylpyrazole was more successful: a dinitro-1,5-diphenylpyrazole, m.p. 185°, was obtained by reaction at 0°. This product is assigned tentatively as 1,5-di(*p*-nitrophenyl)pyrazole (VIII). In agreement with this assignment, nitration of 1-*p*-nitrophenyl-5-phenylpyrazole by mixed acids at 0° also yielded the dinitro-1,5-diphenylpyrazole, m.p. 185°, while similar nitration using nitric acid in acetic anhydride at 0° yielded a different dinitro-1,5-diphenylpyrazole, m.p. 147°, presumably 4-nitro-1-*p*-nitrophenyl-5-phenylpyrazole (IX).

(c) 4-Brominations

Balbiano (1) found that the initial product of bromination of 1-phenylpyrazole was 4-bromo-1-phenylpyrazole, while Brain and Finar (12) showed that further reaction took place readily to yield 4-bromo-1-*p*-bromophenylpyrazole. In the present work, in order to have authentic samples of these compounds for detailed comparison with 1-*p*-bromophenylpyrazole (cf. following section), we have repeated the preparations of these compounds using bromine in chloroform solution.

1-*p*-Biphenylylpyrazole underwent bromination in chloroform to yield 1-*p*-biphenylyl-4-bromopyrazole, m.p. 182°, whose structure was established by comparison with authentic samples prepared by two unambiguous routes. One used the sequence 4-bromo-1-phenylpyrazole → 4-bromo-1-*p*-nitrophenylpyrazole → 1-*p*-aminophenyl-4-bromopyrazole → 1-*p*-biphenylyl-4-bromopyrazole, and the other used the free-radical phenylation of 4-bromo-1-phenylpyrazole by benzoyl peroxide (cf. Lynch and Khan (13)). The presence of strong infrared absorption bands at 690 and 760 cm^{-1}, characteristic of a monosubstituted phenyl ring (cf. ref. 8), and at 952 cm^{-1}, assignable to a 1-phenylpyrazole carrying a pyrazole C-substituent (cf. ref. 9), provided additional evidence for the assigned structure of the bromination product of 1-*p*-biphenylylpyrazole.

(d) Selective 1-p-Bromination of 1-Phenylpyrazole

Derbyshire and Waters (14) have shown that solutions of bromine in concentrated sulphuric acid become extremely effective brominating agents on addition of silver sulphate; evidence summarized by Arotsky and Symons (15) indicates that $AgBr_2^+$, rather than protonated hypobromous acid or free bromine cations, is probably the effective electrophilic reagent in such solutions. Use of this Derbyshire–Waters reagent for the bromination of 1-phenylpyrazole gave good yields of 1-*p*-bromophenylpyrazole, m.p. 70°, identical (m.p., mixed m.p., superimposable ultraviolet and infrared spectra) with an authentic sample prepared by an unambiguous synthesis from *p*-bromophenylhydrazine and 1,1,3,3-tetramethoxypropane, and differing in melting point, ultraviolet and infrared absorption from other possible bromination products, i.e., 4-bromo-1-phenylpyrazole or 4-bromo-1-*p*-bromophenylpyrazole. Key differences in the infrared spectra of the three brominated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

compounds include pyrazole C—H deformation bands at 952 and 955 cm^{-1} respectively for 4-bromo-1-phenylpyrazole and 4-bromo-1-*p*-bromophenylpyrazole, and at 935 cm^{-1} for authentic 1-*p*-bromophenylpyrazole and the bromo-1-phenylpyrazole, m.p. 70°, obtained using the Derbyshire–Waters reagent. The positions of these bands confirm that the bromo-1-phenylpyrazole, m.p. 70°, and, of course, authentic 1-*p*-bromophenylpyrazole, carry no C-substituents on the pyrazole ring (cf. ref. 9). Full details of the infrared spectra are given in the Experimental section.

Once again, the change in orientation noted in the sulphuric acid medium is readily interpreted in terms of protonation of 1-phenylpyrazole to the conjugate acid (IV), which undergoes bromination by $AgBr_2^+$ at the para position of the phenyl ring.

An Interpretation of 4-Substitution in the Neutral Molecule of 1-Phenylpyrazole: The Relevance of Localization Energies

Although initial 4-substitution is noted for many electrophilic substitutions in the neutral molecule of 1-phenylpyrazole (cf. above), no interpretation of this orientation has been offered previously. The preference for 4-substitution cannot result from inter-ring conjugation: although conjugative electron transfer by a +T mechanism is possible from the pyrazole ring to the para position of the phenyl ring (structure I*a*), charge transfer to the 4-position can involve only the heterocyclic ring (structure I*b*).

However, it is possible that differences in the electron densities at the 4-position and the para position account for the preferred 4-substitution. We explored this possibility by determining the pK_a values of isomeric acids having their functional groups at either the 4- or 1-*para*-substituted positions of 1-phenylpyrazole, since it is known that the electron density at a given position of a molecule influences the ionization constants of acids or bases whose functional groups are attached to that position (for a discussion of many instances of this influence, see Brown, McDaniel, and Hafliger (16)). The relevant pK_a values were: (*a*) in water at 25°: 4-amino-1-phenylpyrazole cation, 3.22±0.05; 1-*p*-aminophenylpyrazole cation, 3.42±0.20; anilinium ion, 4.58; (*b*) in 1:1 ethanol–water at 25°: 1-phenylpyrazole-4-carboxylic acid, 5.22±0.03; *p*-1-pyrazolylbenzoic acid, 5.32±0.03; benzoic acid, 5.67. Thus, in 1-phenylpyrazole, both the 4-position and the para position of the phenyl ring appear electron deficient with respect to a benzene position, and the results indicate that the electron density at the 4-position is slightly lower than that at the para position of the phenyl ring, since the 4-substituted acids are slightly stronger than the 1-*para*-substituted isomers. Consequently, we must discard the hypothesis that 4-substitution is a result of attack at the position of highest electron density; some other factor must control the orientation.

In this regard, Brown's molecular-orbital calculations for pyrazole (17) are of interest, since the localization energies for electrophilic substitution at various positions in pyrazole suggest that the 4-position is the most reactive; further, for reasonable choices of the relative electronegativity parameter h (defined by $h = (\alpha_N - \alpha_C)/\beta$, where α_N and α_C are the Coulomb integrals of nitrogen and carbon, and β is the standard resonance integral (approximately −20 kcal)), the localization energy for the 4-position in pyrazole is less than that for a benzene position. Typical values, in multiples of $-\beta$, are: benzene, 2.54; pyrazole, 2.10 ($h = 1/2$), 2.25 ($h = 1$). Accepting a current suggestion (18) that the bonds linking aromatic nuclei are essentially single, with minimal inter-ring conjugation, we propose that 1-phenylpyrazole should be regarded simply as a 1-substituted pyrazole with an inductively electron-attracting substituent, where the ease of localization of an electron pair at the 4-position approximates that for pyrazole; consequently, 4-substitution

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is to be expected. Similarly, 1-*p*-biphenylylpyrazole is regarded as virtually independent biphenyl and pyrazole nuclei, and the ease of localization of an electron pair at the 4-position of the pyrazole ring is still product controlling (the localization energies for electrophilic substitution at the 2- or 4-positions of biphenyl (-2.38β and -2.44β respectively) are greater than that for the 4-position of pyrazole). For 1,5-diphenylpyrazole, where the three rings cannot be coplanar, we consider that the 5-phenyl group will have little effect on the localization energy, so 4-substitution is still favored.

Conclusions

Our assumption that the state of protonation of 1-phenylpyrazole derivatives controls the orientation of their electrophilic substitution reactions appears valid, as it satisfactorily predicts the results reported in this paper. It is realized, of course, that the attacking electrophilic reagents differ, in addition to the changes in the predominant substrate species. However, the products from the substitutions effected by both highly selective reagents (e.g., molecular bromine) and by the more reactive, less selective reagents (such as nitronium ion, or "positive bromine") are those of *selective* attack at a single position (*either* the 4- *or* the 1-*para*-position). This rules against any correlation between the nature of the attacking electrophilic reagent and the orientation of substitution, since such a correlation would be expected to reveal itself in a tendency of the more reactive reagents to attack both reactive positions (the 4- and the 1-*para*-position) to give mixtures of products. This is neither in agreement with our results, nor with the experience of previous workers.

EXPERIMENTAL

General

Analyses are by the Schwarzkopf Microanalytical Laboratory, Woodside, N.Y., U.S.A. Melting points were observed using a Fisher–Johns melting point apparatus, and are uncorrected. Infrared spectra were recorded using a Unicam SP 100 spectrophotometer equipped with a SP 130 grating accessory; samples were examined using the potassium chloride disk technique. Ultraviolet spectra refer to solutions in 95% ethanol, and were recorded using a Beckman DK-2A spectrophotometer. A Radiometer Model 4 pH meter was used for the potentiometric titrations.

Substituted 1-Phenylpyrazoles

The following compounds were prepared in excellent yields by the standard condensation of the appropriate substituted hydrazine with 1,1,3,3-tetramethoxypropane in ethanolic hydrochloric acid (cf. Jones (19) and Finar and Hurlock (5)): 1-phenylpyrazole, m.p. 11°, b.p. 246°, n_D^{25} 1.5957; 1-*o*-nitrophenylpyrazole, m.p. 89°; 1-*m*-nitrophenylpyrazole, m.p. 94–95°; 1-*p*-nitrophenylpyrazole, m.p. 170°; 1-(2,4-dinitrophenyl)-pyrazole, m.p. 107°; *p*-1-pyrazolylbenzoic acid, m.p. 268–270° (decomp.) (anal. calc. for $C_{10}H_8N_2O_2$: C, 63.82; H, 4.28%; found: C, 63.82; H, 4.47%); 1-*p*-bromophenylpyrazole, m.p. 70° (anal. calc. for $C_9H_7N_2Br$: C, 48.45; H, 3.16%; found: C, 48.70; H, 3.34%) (ultraviolet absorption: λ_{max} 262 mμ, log ϵ 4.29; infrared absorption: strong bands in the 650–1800 cm^{-1} region at 752, 810, 824, 935, 1050, 1075, 1125, 1205, 1340, 1398, 1495, 1525, and 1600 cm^{-1}); Brain and Finar (12) refer to 1-*p*-bromophenylpyrazole but quote no physical constants. 4-Nitro-1-phenylpyrazole, m.p. 127°, was prepared from sodium nitromalonaldehyde hydrate and phenylhydrazine (5, 6). 1-Phenylpyrazole-4-carboxylic acid, m.p. 220°, was prepared from 4-formyl-1-phenylpyrazole (20) by oxidation with alkaline potassium permanganate. 4-Amino-1-phenylpyrazole, m.p. 104°, and 1-*p*-aminophenylpyrazole, m.p. 45°, were obtained by reduction of the appropriate nitrophenylpyrazole with tin and hydrochloric acid. 1,5-Diphenylpyrazole, m.p. 55°, was prepared by condensation of hydroxymethyleneacetophenone and phenylhydrazine (21), and 1-*p*-nitrophenyl-5-phenylpyrazole, m.p. 117°, was prepared by a similar condensation using *p*-nitrophenylhydrazine (21).

1-p-Biphenylylpyrazole

This compound was obtained by condensation of *p*-hydrazinobiphenyl and 1,1,3,3-tetramethoxypropane, and also by the following route: 1-*p*-aminophenylpyrazole (10.7 g) was diazotized in 10 *N* hydrochloric acid at 0°, and the solution of the diazonium salt was stirred at 7° with benzene, after buffering to pH 5 with sodium acetate, and was allowed to reach room temperature. After 3 hours, evolution of nitrogen had ceased, and the benzene layer was separated and chromatographed on alumina. Evaporation of the eluate, followed by crystallization from ethanol, yielded 7.8 g (53%) of 1-*p*-biphenylylpyrazole, m.p. 126°. Anal. Calc. for $C_{15}H_{12}N_2$: C, 81.80; H, 5.50; N, 12.72%. Found: C, 82.00; H, 5.55; N, 13.00%.

Nitrations in Acetic Anhydride

(a) 1-Phenylpyrazole

A solution of nitric acid (*d* 1.52, 1.5 ml) in acetic anhydride (4 ml), prepared at 15–20°, was cooled to −5° and added to 1-phenylpyrazole (3 g) in acetic anhydride (6 ml) at −5° over 30 minutes. The reaction mixture was allowed to reach room temperature, and was poured onto ice. The precipitate was collected and crystallized from ethanol, yielding 4-nitro-1-phenylpyrazole, m.p. and mixed m.p. 125–127°, having ultraviolet and infrared absorption identical with authentic material. The yield of crystallized product was 2.1 g (53%). Reactions on a larger scale generally gave lower yields, although unreacted 1-phenylpyrazole was recovered.

(b) 1-p-Biphenylylpyrazole

Nitration of 1-*p*-biphenylylpyrazole (0.5 g) under the conditions of part (*a*) gave the presumed 1-*p*-biphenylyl-4-nitropyrazole (0.25 g, 42%), m.p. 170°, after crystallization from ethanol. Anal. Calc. for $C_{15}H_{11}N_3O_2$: C, 67.92; H, 4.18%. Found: C, 67.67; H, 4.41%. For ultraviolet and infrared absorption see tables.

(c) 1,5-Diphenylpyrazole

Nitration of 1,5-diphenylpyrazole (2 g) under the general conditions of part (*a*), except that the temperature of reaction was maintained at 0°, gave the presumed 1,5-diphenyl-4-nitropyrazole (ca. 1 g, 43%), m.p. 150°, after chromatography on alumina and crystallization from benzene. Anal. Found: C, 68.32; H, 4.04%.

(d) 1-p-Nitrophenyl-5-phenylpyrazole

Nitration of 1-*p*-nitrophenyl-5-phenylpyrazole (1 g) under the conditions of part (*c*) gave the presumed 4-nitro-1-*p*-nitrophenyl-5-phenylpyrazole (0.3 g, 26%), m.p. 147°, after chromatography on alumina and repeated recrystallization from ethanol. Anal. Calc. for $C_{15}H_{10}N_4O_4$: C, 58.06; H, 3.25%. Found: C, 57.71; H, 3.32%.

Nitrations in Mixed Acids

(a) 1-p-Biphenylylpyrazole

With mixed acids at 0°, using the conditions employed by Finar and Hurlock (5) for 1-phenylpyrazole, 1-*p*-biphenylylpyrazole yielded amorphous products, sparingly soluble in ethanol and in benzene, having infrared absorption indicative of polysubstitution (cf. Discussion), and giving bluish-violet colors on addition of aqueous sodium hydroxide to their solutions in acetone (Janovsky test, indicative of polynitro-substituted 1-phenylpyrazoles (cf. ref. 5)).

(b) 1,5-Diphenylpyrazole

1,5-Diphenylpyrazole (2 g) was dissolved in the minimum volume of sulphuric acid (*d* 1.84) and cooled to 0°. A mixture of nitric acid (*d* 1.42, 4 ml) and sulphuric acid (*d* 1.84, 5 ml) was added at 0°. The resultant mixture was maintained at 0° for 18 hours and then poured onto ice. The precipitate was collected and crystallized repeatedly from ethanol, yielding the presumed 1,5-di(*p*-nitrophenyl)pyrazole (1.5 g, 55%), m.p. 185°. Anal. Calc. for $C_{15}H_{10}N_4O_4$: N, 18.06%. Found: C, 58.57; H, 3.41; N, 17.94%.

(c) 1-p-Nitrophenyl-5-phenylpyrazole

Nitration of 1-*p*-nitrophenyl-5-phenylpyrazole (1 g) under the conditions of part (*b*), followed by chromatography on alumina and crystallization from ethanol, similarly yielded the presumed 1,5-di(*p*-nitrophenyl)-pyrazole (0.5 g, 44%), m.p. 185°, identical (mixed m.p.) with the product obtained in part (*b*).

Brominations in Chloroform Solution

(a) 1-Phenylpyrazole

Bromine (61 g) was added dropwise to 1-phenylpyrazole (50 g) in chloroform (1000 ml) at 0°. The resulting solution was shaken with an excess of sodium carbonate solution and dried over sodium carbonate. Removal of the solvent, followed by crystallization of the product from ethanol, gave 4-bromo-1-phenylpyrazole (50 g, 65%), m.p. 83° (lit. (12), 81.5–82.5°). Ultraviolet absorption: λ_{max} 263 mμ, log ϵ 4.24. Infrared absorption: strong bands in the 650–1800 cm^{-1} region at 690, 758, 845, 952, 1042, 1202, 1250, 1340, 1386, 1410, 1465, 1502, 1530, and 1600 cm^{-1}.

Further bromination, under conditions similar to the above, of either 4-bromo-1-phenylpyrazole or 1-*p*-bromophenylpyrazole yielded 4-bromo-1-*p*-bromophenylpyrazole, m.p. 81° (lit. (12), 84.5–85°) (mixed m.p. with 4-bromo-1-phenylpyrazole, ca. 72°). Ultraviolet absorption: λ_{max} 270 mμ, log ϵ 4.29. Infrared absorption: strong bands in the 650–1800 cm^{-1} region at 810, 825, 855, 955, 1080, 1340, 1385, 1400, 1500 cm^{-1}.

(b) 1-p-Biphenylylpyrazole

Bromination as for 1-phenylpyrazole, using 1-*p*-biphenylylpyrazole (10 g), yielded 1-*p*-biphenylyl-4-bromopyrazole (7.5 g, 55%), m.p. 182°, after crystallization from ethanol, identical in all respects with authentic samples as prepared below. Anal. Calc. for $C_{15}H_{11}BrN_2$: Br, 26.72%. Found: Br, 26.89%. Ultraviolet absorption: λ_{max} 284 mμ, log ϵ 4.42. Infrared absorption in the 650–1800 cm^{-1} region (cm^{-1}, intensity): 650 w, 690 s, 760 vs, 838 s, 952 vs, 1008 w, 1018 w, 1042 m, 1080 w, 1120 w, 1155 w, 1202 w, 1250 w, 1342 s, 1385 s, 1405 m, 1425 m, 1460 w, 1490 vs, 1535 s, 1610 m.

Syntheses of 1-p-Biphenylyl-4-bromopyrazole

(a) Via 4-Bromo-1-p-nitrophenylpyrazole

To 4-bromo-1-phenylpyrazole (10 g) in sulphuric acid (*d* 1.84, 20 ml) was added, at 0°, a mixture of nitric acid (*d* 1.42, 15 ml) and sulphuric acid (*d* 1.84, 20 ml). The reaction mixture was kept overnight at 0°, poured onto ice, and collected. After crystallization from ethanol, 4-bromo-1-*p*-nitrophenylpyrazole (4.8 g, 40%), m.p. 168° (lit. (22), 168–169°), was obtained. Anal. Calc. for $C_9H_6BrN_3O_2$: C, 40.31; H, 2.24; N, 15.69%. Found: C, 40.57; H, 2.33; N, 15.90%. For ultraviolet and infrared absorption, see tables.

The 4-bromo-1-*p*-nitrophenylpyrazole was reduced quantitatively to 1-*p*-aminophenyl-4-bromopyrazole, m.p. 83°, by tin and hydrochloric acid. The amine was diazotized and the diazo solution used to arylate benzene, employing the conditions noted above for the synthesis of 1-*p*-biphenylylpyrazole. Chromatography on alumina, followed by crystallization from ethanol, yielded 1-*p*-biphenylyl-4-bromopyrazole, m.p. 182°. Anal. Calc. for $C_{15}H_{11}BrN_2$: C, 60.22; H, 3.68%. Found: C, 60.03; H, 4.04; Br, 26.79%.

(b) By Free-radical Phenylation of 4-Bromo-1-phenylpyrazole

Benzoyl peroxide (10 g) was allowed to decompose in 4-bromo-1-phenylpyrazole at 90° for 66 hours. After removal of free benzoic acid (4.0 g) with sodium hydrogen carbonate solution, excess of substrate was removed by steam distillation followed by distillation under reduced pressure. The residue was chromatographed on alumina and crystallized repeatedly from ethanol, yielding 1-*p*-biphenylyl-4-bromopyrazole, m.p. 180°, having ultraviolet and infrared absorption identical with that of sample prepared as in part (*a*).

Derbyshire–Waters Bromination of 1-Phenylpyrazole

1-Phenylpyrazole (10.8 g) and bromine (5.2 ml) were dissolved in a mixture of sulphuric acid (*d* 1.84, 90 ml) and water (10 ml). Finely powdered silver sulphate (17 g) was added, and the mixture was shaken mechanically for 3 hours. Silver bromide was filtered off and the filtrate was poured onto ice. The precipitate was collected and extracted with boiling benzene. 1-*p*-Bromophenylpyrazole, m.p. 67–68°, crystallized on slow evaporation of the benzene. Crystallization from dilute methanol yielded 10.5 g (62%) of 1-*p*-bromophenylpyrazole, m.p. 70°, identical in all respects with an authentic sample (m.p., mixed m.p., superimposable ultraviolet and infrared spectra).

Ionization Constants

Ionization constants of the carboxylic acids were determined by potentiometric titration in 1:1 ethanol–water, and those of the conjugate acids of the aminophenylpyrazoles by differential ultraviolet spectrophotometry of the appropriate ionic species in buffers of varying pH.

ACKNOWLEDGMENTS

We thank the National Research Council for generous support through Operating and Equipment Grants, and Misses D. A. Chalker and J. Murphy, who provided skilled assistance with spectrophotometry.

THE SYNTHESIS AND PROPERTIES OF THE ANHYDROUS HEXACHLOROTITANATES OF RUBIDIUM AND CESIUM

R. L. LISTER AND S. N. FLENGAS
Department of Metallurgical Engineering, University of Toronto, Toronto, Ontario
Received February 1, 1963

ABSTRACT

The hexachlorotitanates of rubidium and cesium have been produced in a closed system, following the reaction

$$2MCl\ (s) + TiCl_4\ (g) = M_2TiCl_6\ (s),$$

where M is respectively Rb and Cs. With the titanium tetrachloride vapor at 1 atm, the optimum temperature for both reactions is 410±10° C.

INTRODUCTION

Because of their relatively high degree of thermal stability, the hexachlorotitanates of the alkali metals offer interesting possibilities as a source of titanium ions for the recovery of titanium metal by fused salt electrolysis.

The most recent methods for producing the hexachlorotitanates involve difficulties, either in producing the truly anhydrous salts or in yielding the stoichiometric compounds.

Thus, Ehrlich and Framm (1) prepared the compounds K_2TiCl_6, Rb_2TiCl_6, and Cs_2TiCl_6 by fractional crystallization at 0° C from an aqueous solution saturated with hydrogen chloride and containing titanium tetrachloride and the corresponding alkali metal chloride as solutes. Unsuccessful attempts were also made to produce the compounds directly in an autoclave by the reaction between titanium tetrachloride and the alkali chloride at 300° C (1).

Morozov and Toptygin (2) have produced the hexachlorotitanates by passing, over the corresponding alkali metal chloride at a specific temperature, chlorine gas saturated with titanium tetrachloride vapor. The method gave 100% yield for Cs_2TiCl_6 only, whereas the rubidium and potassium hexachlorotitanates were obtained mixed with unreacted alkali chlorides.

Pure potassium hexachlorotitanate (K_2TiCl_6) has been prepared in this laboratory by the direct reaction between titanium tetrachloride vapor and finely divided solid potassium chloride, in a closed system (3, 4).

In the present investigation, the method of preparation was further developed, and found to be applicable in the synthesis of the hexachlorotitanates of rubidium and cesium. The compounds obtained in this manner are anhydrous, and of stoichiometric composition.

EXPERIMENTAL

The titanium tetrachloride for use in the preparations was obtained by purification of the commercially pure material. This was achieved by refluxing in the presence of copper filing for about 2 hours and by fractional distillation in a dry atmosphere. The front and end tailings of the distillate were rejected, and the middle portion was stored in sealed containers.

The rubidium and cesium chlorides were of reagent grade and were further purified by sublimation at 800° C in a stream of anhydrous hydrogen chloride. The sublimate was finely ground inside a dry box, screened through a 325-mesh screen, and the −325 fraction was stored in a desiccator for future use.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The rubidium and cesium hexachlorotitanates were produced by the direct reaction, as indicated by the equation

$$2MCl\ (s) + TiCl_4\ (g) = M_2TiCl_6\ (s),$$

where M is respectively Rb and Cs.

Figure 1 shows the reaction apparatus, which was constructed from Pyrex glass.

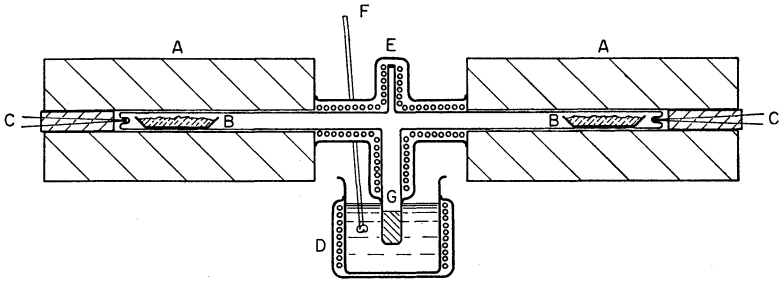

FIG. 1. Reaction apparatus. A = tube furnaces, B = pyrex boats containing the alkali metal chloride, C = temperature-measuring thermocouples, D = thermally regulated silicone oil bath, E = vacuum-sealed outlet, F = stirrer, G = titanium tetrachloride.

The titanium tetrachloride liquid was siphoned into the vertical arm of the reaction tube and frozen through the use of a dry ice – acetone mixture. Weighed amounts of the finely divided cesium and rubidium chlorides were transferred into the Pyrex boats using the dry box. The boats were then placed into the horizontal arms of the reaction tube and the ends were flame sealed. The entire apparatus was evacuated through a side arm tube at F, and sealed under vacuum. The two horizontal tubes containing the RbCl and CsCl respectively were then heated to about 410±10° C, while the titanium tetrachloride in the vertical tube was heated to 135±1° C by means of a temperature-controlled silicone bath oil. At this temperature, the pressure of titanium tetrachloride vapor in the system is slightly less than 1 atm.

After completion of the reaction, the reacted alkali chlorides in the horizontal tubes were cooled to about 150° C and held at this temperature, while the titanium tetrachloride in the reservoir was refrozen to condense the excess vapor still remaining in the reaction tube. The cell was then opened at E, and air was introduced through a calcium chloride drying tube. The products were removed by breaking the cell inside a dry box and were weighed to determine the composition of the reaction product. This determination was based on the weight of $TiCl_4$ reacted with the known amount of alkali metal chloride initially in the cell. The compound was then stored in a desiccator for further use.

Attempts to produce the corresponding compounds of Na_2TiCl_6 and Li_2TiCl_6 by this method were unsuccessful because of their instability.

RESULTS AND DISCUSSION

In all preparations, about 10 g of the −325 mesh alkali chloride was used, and the reaction time was 12 hours. It was found that the optimum reaction temperature was 410±10° C.

The composition of the reaction products from three typical runs is given in Table I.

TABLE I

	Rb_2TiCl_6 composition				Cs_2TiCl_6 composition			
	Weight (%)			Mole ratio of	Weight (%)			Mole ratio of
	Rb	Ti	Cl	$RbCl/TiCl_4$	Cs	Ti	Cl	$CsCl/TiCl_4$
Theoretical	39.60	11.10	49.30	2.00	50.49	9.10	40.41	2.00
Experimental	39.75	11.03	49.22	2.02	51.35	8.92	39.73	2.06
(3 runs)	39.72	11.05	49.23	2.01	50.84	9.09	40.07	2.01
	39.45	11.15	49.40	1.98	51.03	8.99	39.88	2.03

The slight excess of $TiCl_4$ found in some of the products represents adsorbed titanium tetrachloride that can be removed under vacuum.

Experiments done at 350° C and at 450° C yielded products of a lower titanium tetrachloride content. Granular alkali chloride reagent had also a similar inhibitive effect and the reaction with the coarse materials did not yield stoichiometric compounds. The microscopic investigation of such reacted particles indicated the existence of a surface layer of hexachlorotitanate and of an underlying core of unreacted alkali chloride. On the contrary, with the finely ground particles, the reactions proceeded to completion, as indicated by the results in Table I.

Although actual reaction rates were not investigated, it is reasonable to attribute the decreased yield at the higher temperatures to the sintering of the finely divided particles of the alkali chloride. Sintering was actually observed in all preparations done at 450° C, and the behavior of the sintered alkali chloride material should be compared with that of the granular particles mentioned above.

At temperatures below the optimum, sintering was not observed, but the rate of the reaction becomes too slow to complete the reaction within the time of observation. This is also in agreement with the results obtained by Ehrlich and Framm (1) during their autoclave experiments; at 300° C, the reacted titanium tetrachloride was always less than 1 mole%.

PROPERTIES OF THE HEXACHLOROTITANATES

At room temperature, rubidium hexachlorotitanate is light green, while the cesium hexachlorotitanate is yellow-green in color.

With respect to their stability in air, Cs_2TiCl_6 is the more stable, and its hydrolysis is very slow. On the other hand, Rb_2TiCl_6 and K_2TiCl_6 hydrolyze quite readily and should be handled in a dry atmosphere.

The approximate melting points of Rb_2TiCl_6 and Cs_2TiCl_6 were determined in sealed quartz tubes and found to be 686±5° C and 691±5° C respectively.

Diffractometer measurements were also taken on the various batches of the rubidium and cesium hexachlorotitanates. A copper target emitting a wavelength of $K\alpha$ radiation of 1.5418 Å was used with a nickel filter.

Engel (5) has shown that the rubidium and cesium hexachlorotitanates are cubic of the $Fm3m$ space group, and display the hexachloroplatinate crystal structure. Bland and Flengas (6) have shown that potassium hexachlorotitanate is also of this group.

The lattice parameter of the rubidium hexachlorotitanate was determined as 10.011± 0.005 Å, which agrees favorably with 9.9922 Å obtained by Engel (4). The calculated density of the rubidium hexachlorotitanate based on four formulae units per cell (3) is 2.85 g/cc, compared with 2.93 g/cc found by Engel. The experimental density found using reagent grade carbon tetrachloride in a standard density bottle was 2.92 g/cc. The cesium hexachlorotitanate exhibited a lattice parameter of 10.229±0.005 Å compared with 10.219 Å obtained by Engel. The calculated density for the cesium hexachlorotitanate is 3.28 g/cc compared with 3.29 g/cc calculated from the lattice parameter given by Engel. The experimental density was found to be 3.24 g/cc.

Relative peak intensities and the observed interplanar "d" spacings for Rb_2TiCl_6 and Cs_2TiCl_6 are given in Table II. The relative peak intensities and observed "d" spacings for K_2TiCl_6 as determined by Bland and Flengas (6) are also included.

Some of the physical properties of the hexachlorotitanates are summarized in Table III.

THE PHOTOCHEMICAL DECOMPOSITION OF METHYL AZIDE[1]

C. L. CURRIE[2] AND B. deB. DARWENT
The Maloney Chemistry Laboratory, The Catholic University of America, Washington, D.C.

Received December 14, 1962

ABSTRACT

The photolysis of methyl azide has been investigated in the vapor phase at low conversions and over suitable ranges of pressure, temperature, intensity, and wavelength. Under all conditions the principal gaseous product was N_2 with small amounts of H_2 (5–11%), and traces of CH_4, C_2H_4, and C_2H_6. A condensate identified as $(CH_3N)_x$ was also found.

The quantum yield for the production of N_2 is approximately 2, independent of intensity (over a 45-fold range), temperature (17–100° C), and pressure (14–300 mm Hg). The quantum yield decreases slightly with increasing wavelength. Experiments with added CO_2, $CH_3N_2CH_3$, and C_2H_4 indicate the presence of a short chain carried mainly by the CH_3N radical. Excited species probably play some role in the reaction.

I. INTRODUCTION

The mechanism of the thermal decomposition of methyl azide, as proposed by Leermakers (1) and by Rice and Grelecki (2), appears to be rather complex and to involve more than one initial step. However, those experiments were carried to such high conversions that the initial reaction was obscured.

The photolysis of methyl azide has recently been investigated (3) in an inert matrix at low temperatures. Milligan (3) found bands in the infrared corresponding to methylenimine but not to the methylimino radical. He suggested that the methylimino radical isomerizes rapidly because of the excess energy from the photolysis:

$$CH_3N \rightarrow CH_2{=}NH.$$

The photolysis has now been investigated, in the gas phase, at small conversions, as functions of intensity, wavelength, pressure, and temperature. The effects of free radical scavengers and an inert gas have also been investigated.

II. EXPERIMENTAL

1. Materials

(a) Methyl azide.—Prepared by the methylation of sodium azide with methyl sulphate (4). The gaseous azide was dried with calcium chloride and condensed at −80° C. The condensate was distilled through a Vigreaux column and the fraction boiling at 20–21° C collected. That fraction was purified further by trap-to-trap distillation *in vacuo* at −80° C and the middle fraction retained.

(b) Azomethane.—Prepared by the oxidation of symmetrical dimethylhydrazine with cuprous chloride (5). The product was distilled and the middle fraction retained.

(c) Ethylene, carbon dioxide, and hydrogen sulphide.—Obtained commercially (Research Grade). Purified by trap-to-trap distillation *in vacuo* and stored in bulbs.

(d) Potassium ferrioxalate.—Prepared from reagent grade potassium oxalate and ferric chloride (6), with subsequent recrystallization.

2. Apparatus

The apparatus was a rather conventional all-glass high-vacuum system of the type used in gas kinetic studies. Mercury was rigorously excluded to avoid dangers of an explosion (7). A circulating pump, of the type designed by Watson (8), was included in the reaction system to ensure the proper mixing of the gases.

[1]*Presented in part at the meeting of the American Chemical Society, St. Louis, Missouri, March 1961. This is taken from the dissertation submitted by C. L. Currie to the Catholic University of America in partial fulfillment of the requirements for the degree of Doctor of Philosophy.*

This work was supported in part by the United States Army Engineer Research and Development Laboratories, Fort Belvoir, Va., under Contract Numbers DA-44-009-ENG-4139 and DA-44-009-ENG-3574.

[2]*Present address: Woodstock College, Woodstock, Maryland.*

The light source was a quartz-jacketed medium-pressure mercury arc. A grating monochromoter (Farrand Optical Co., Catalog No. 91087) was used in experiments where essentially monochromatic light was required.

3. Analysis

The products of the reaction were divided into three fractions: (*a*) uncondensable gases (N_2, H_2, CH_4), (*b*) C_2 fraction, and (*c*) heavy products.

The uncondensable gases were measured and analyzed by CuO oxidation and mass spectrometric methods.

The C_2 fraction was analyzed by GLPC using a silica gel column, which had been shown to separate ethane and ethylene.

The gaseous portion of the heavy products was also analyzed by GLPC with a column of silicone oil 203 (Dow Corning) on "Chromosorb W" (Fisher Scientific Co.) at room temperature. That column effected a satisfactory separation of HN_3, NH_3, HCN, $CH_3N_2CH_3$, CH_3N_3, and the trace impurities (H_2O, CH_3OCH_3, and CH_3Cl).

The higher-boiling products remained on the walls of the reaction cell and in the first trap, both of which were removable. The products were dissolved in water and analyzed. Hexamethylenetetramine (HMTA) was determined as formaldehyde, according to the spectrometric method of McFadyen (9), after hydrolysis with 2 *N* H_2SO_4. The first few experiments showed clearly that HMTA was equivalent to less than 10% of the N_2 formed and, in subsequent experiments, the solution of the heavy products was subjected to micro-Kjeldahl analysis[3] for total nitrogen.

4. Actinometry

The total incident intensity was measured by the use of potassium ferrioxalate as an actinometer (6, 10), the Fe^{++} produced was measured with a Beckman DU spcetrophotometer. The absorption coefficient of the azide was also measured with the spectrophotometer over the range of wavelengths used in this investigation. The quantum yield was measured at various wavelengths. using essentially monochromatic light from the monochrometer.

When using the full mercury arc, relative intensities were determined from the rate of formation of hydrogen in the photolysis of hydrogen sulphide (11). The intensity was altered by changing the diameter of a hole in a metal screen placed between the mercury arc and the collimating lens.

5. Effect of Added Gases

In these experiments CH_3N_3 was photolyzed alone, to very small conversion, and the rate of formation of N_2 measured. The second gas was then introduced to the residue and the photolysis repeated. The full mercury arc was used in all of these experiments.

III. RESULTS

1. Absorption Spectrum

The ultraviolet absorption of CH_3N_3 was found to exhibit maxima at 2880 Å and below 2400 Å. No structure was found in either band. The absorption obeyed Beer's law accurately between 14 and 300 mm Hg and between 2540 and 3130 Å.

2. Products

The gaseous products consisted predominantly of N_2. Other products were H_2 (6–11%); CH_4 (1%); C_2H_6 (1%). HCN was produced at approximately the same rate as H_2. This ratio of products persisted at all temperatures, pressures, intensities, and wavelengths used. Azomethane was not detected and so amounted to less than 5% of the N_2 formed. The rates of formation of the products were independent of time up to at least 2% conversion.

The heavy product contained small amounts of $(CH_2)_6N_4$ and much larger amounts of other N-containing compounds. The results of two analyses are given in Table I. It is evident that the number of atoms of N in the heavy product is very close to the number of moles of N_2 produced as a gas. This requires that the condensate have the empirical formula CH_3N for a satisfactory material balance. Hexamethylenetetramine accounted for only 3% of the total heavy products. Accordingly, the stoichiometry of the process is largely

$$x CH_3N_3 \rightarrow (CH_3N)_x + N_2,$$

[3]*We are indebted to Robert J. Koegel of the National Institutes of Health for those analyses.*

TABLE I

Nitrogen-containing products and material balance

		Products (moles×10⁶)		
			Condensate	
P (mm Hg)	Decomp. (%)	Gas N_2	$(CH_2)_6N_4$	Total N_2
97.5	5.2	5.06	0.16	2.68
101	4.7	4.70	0.15	2.42

and only a relatively small amount of the azide reacts by other paths leading to the minor amounts of H_2, CH_4, and $(CH_2)_6N_4$ found.

3. Quantum Yield

The effects of wavelength and pressure on the quantum yield of N_2 at 30° C are given in Table II. The conversion never exceeded 1% and was usually lower than 0.1%. ϕ_{N_2} is essentially independent of P and increases with decreasing λ from 1.7 in the region 2750–3130 Å to 2.3 at 2540 Å.

TABLE II

Quantum yields for N_2 production (reaction temp. = 30° C)

CH_3N_3 (mm Hg)	% absorp.	I_0 (einstein min^{-1} ×10⁹)	R_{N_2} (moles min^{-1} ×10⁹)	ϕ_{N_2}
2540 Å				
18	18.0	2.99	1.29	2.4
150	81.5	2.99	5.25	2.2

300	99.0	2.42	5.34	2.2
2750 Å				
14	24.0	18.9	7.59	1.7
80	72.9	18.9	26.5	1.7
150	94.7	18.9	33.5	1.8
2925 Å				
14	26.4	6.50	2.41	1.4
80	82.2	6.50	8.82	1.7
150	96.2	6.50	10.2	1.6
300	99.3	6.50	11.4	1.8
3130 Å				
50	36.9	11.1	6.66	1.6
150	75.0	11.1	15.1	1.8
300	93.6	9.64	15.0	1.7

Consecutive determinations of the incident intensity with the actinometer did not vary by more than ±3%. The agreement with Beer's law was precise enough to suggest that the uncertainty in the measurement of the fraction of light absorbed in the spectrophotometer did not exceed ±1%. The only other factor in the calculation of the absorbed intensity was the path lengths in the spectrophotometer cell and in the reaction cell, 10.0 and 14 cm, respectively. The former was known accurately, but the latter was uncertain to ±1 cm because of the geometry of the cell. Thus the absolute values for the quantum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

yields are probably accurate to ±10%. Accordingly, the dependence on wavelength is thought to be real, especially at the higher pressures, where the essentially complete absorption would minimize the uncertainties in the quantum yield determination.

The quantum yield for the production of nitrogen was also found to be independent of time within the percentage conversions studied (Fig. 1) and essentially independent of

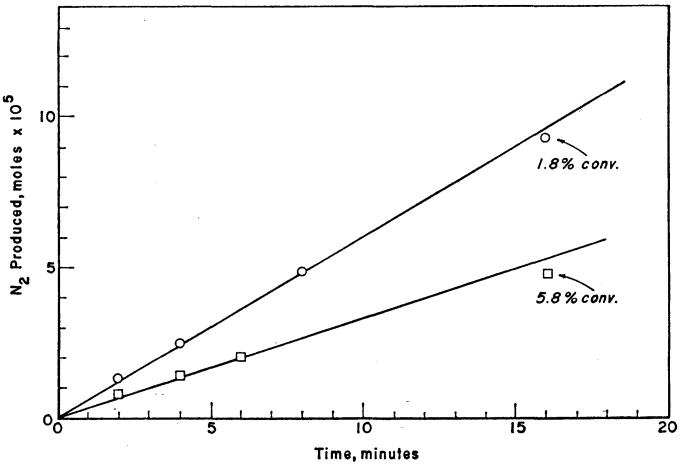

FIG. 1. Effect of time on the production of N_2 at room temperature. Pressure of azide: □ 15 mm Hg; ○ 100 mm Hg.

the intensity ($R_{N_2} \propto I_a^{0.9}$ rather than $I_a^{1.0}$) over a 45-fold variation in intensity and of temperature up to 100° C, the threshold of the thermal reaction.

4. Added Gases

The effect of free radical scavengers and inert gases on the rate of N_2 production was studied to determine the role of free radicals and excited species in the photolysis. The marked inhibition by both C_2H_4 and $CH_3N_2CH_3$, but much smaller inhibition by CO_2 is shown in Fig. 2. The addition of 10% of C_2H_4 reduced the rate of N_2 production by 35% (at 300 mm pressure) to 45% (at 15 mm pressure). The addition of 1% of $CH_3N_2CH_3$ gave the same inhibition as 10% C_2H_4, and as little as 0.03% of the former inhibited the rate of N_2 production by 10%. The inhibiting effect of CO_2 was very much smaller; even 120 times as much CO_2 did not reduce the rate by more than 20%.

5. Hydrogen

The ratio of H_2/N_2 was studied as a function of pressure, wavelength, percentage decomposition, and added gases in an attempt to elucidate the elementary reaction involved in its production. The data in Table III give the ratio as a function of pressure and wavelength. Since H_2 was measured as the difference between two relatively large numbers, the measurement is subject to an uncertainty of about 10%. With this qualification Table III shows that the H_2/N_2 ratio is independent of wavelength and intensity and that it decreases with increasing pressure. The rate of H_2 production was also found to be independent of percentage conversion and much less inhibited by C_2H_4 and $CH_3N_2H_3$ than the rate of N_2 production. The inhibition by CO_2 was about the same for H_2 as for N_2.

*Experiments with 45-fold decrease in intensity.

IV. DISCUSSION

1. *Primary Act*

The fact that N_2 is by far the most prevalent of the gaseous products suggests that the only important primary act is:

$$CH_3N_3 + h\nu \rightarrow CH_3N + N_2. \qquad [0]$$

The very small yields of CH_4, C_2H_4, C_2H_6, and HN_3 suggest that neither of the processes

$$CH_3N_3 + h\nu \nearrow CH_3 + N_3 \qquad [0']$$

$$\searrow CH_2 + HN_3 \qquad [0'']$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is important. Evans *et al.* (12) have shown, on the basis of correlation rules and thermochemical data, that HN_3 should decompose into NH and N_2 rather than into H and N_3, and a similar argument should apply to CH_3H_3.

A previous investigation (1) of the thermal decomposition of CH_3N_3, which reported that C_2H_4 and HN_3 were important products, suggested that reaction [0″] accounted for 25% of the initial step. However, the conversions in that work were extensive, and sometimes complete. In the present investigation a few experiments, in which CH_3N_3 was decomposed thermally at 100° C, to very small conversions, showed that N_2 was the only important gaseous product. Accordingly, it is likely that the C_2H_4 and HN_3 arose from secondary processes and that reaction [0] is the only important initial step in the pyrolysis and in the photolysis.

The dependence of the quantum yield on wavelength suggests that either or both of the CH_3N and N_2 formed in reaction [0] is excited. Although no value for the $CH_3N—N_2$ bond dissociation energy is available, that of the $HN—N_2$ bond has been given as 33 ± 2 (3) and 37 (13) kcal mole^{-1}. Hence, the dissociation energy of the $CH_3N—N_2$ bond is probably not far from 40 kcal mole^{-1}. Since the energy of the incident radiation varied between 91 and 112 kcal mole^{-1}, the CH_3N and N_2 must have shared approximately 50 to 70 kcal mole^{-1} between them; the excess energy may be even greater.

2. Secondary Reactions

The fact that ϕ_{N_2} was always greater than unity in the uninhibited experiments and was decreased by very small concentrations of radical inhibitors suggests that the CH_3N radicals cause further decomposition of the azide, possibly by an insertion type of reaction:

$$CH_3N + CH_3N_3 \rightarrow (CH_3N)_2 + N_2, \qquad [1]$$

where the CH_3N may or may not be excited and the $(CH_3N)_2$ is probably azomethane.

The almost complete independence of ϕ_{N_2} on intensity requires the combination and disproportionation reactions

$$2CH_3N \rightarrow (CH_3N)_2 \qquad [a]$$

$$\rightarrow CH_3NH + CH_2N \qquad [b]$$

to be much less important than reaction [1], even at the lowest pressure of azide. The experiments with inhibitors show that the addition of very small amounts of azomethane drastically reduces the rate of formation of N_2. Accordingly, a reaction between CH_3N and azomethane, probably of the type

$$CH_3N + (CH_3N)_2 \rightarrow (CH_3N)_3, \qquad [2]$$

is considerably faster than reaction [1]. Actually, if azomethane is formed in reaction [1], the fact that no trace of it was detected in the products supports the suggestion that reaction [2] is very fast. The nature of the product of reaction [2] is quite unknown but it does correspond stoichiometrically with the analysis of the heavy products.

A mechanism based only on reactions [0], [1], and [2] gives

$$\phi_{N_2} = 1 + \frac{1}{1+\alpha}, \qquad [A]$$

where $\alpha = k_2(CH_3N_2CH_3)/k_1(CH_3N_3)$. Since the experiments have shown that ϕ_{N_2} is independent of time, it must be assumed that $CH_3N_2CH_3$ rapidly attains a steady state concentration, if it is formed at all. In that event $\alpha = 1$ and the maximum value of ϕ_{N_2}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

would be 1.5. However, the quantum yield actually was within the range 1.7 to 2.3, for monochromatic light, and averaged 2.0 for the unfiltered light. The discrepancy between the calculated and observed values suggests that excited species (CH_3N^* and N_2^*) play some part in the reaction. Processes such as

$$CH_3N^* + CH_3N_3 \rightarrow 2CH_3N + N_2 \quad [3]$$

$$N_2^* + CH_3N_3 \rightarrow CH_3N + 2N_2 \quad [4]$$

would increase ϕ_{N_2} above 1.5. The increase in the quantum yield with decreasing wavelength supports the above suggestion. The experiments with CO_2 using unfiltered light show that ϕ_{N_2} may be reduced as much as 20% by an inert gas. If all the excited species were deactivated in those experiments, the resulting $\phi_{N_2} = 1.6$ agrees satisfactorily with that predicted by equation [A].

The results of the inhibition experiments (Fig. 2) show that the ratio R_1/R_0 is independent of the pressure of azide, as required by equation [A], between 15 and 100 mm. However, there is a decided effect of pressure between 100 and 300 mm; both ethylene and azomethane are less efficient inhibitors at 300 mm than at 100 mm. That effect is contrary to the requirements of equation [A]. The disagreement cannot be ascribed only to hot radical reactions; it does suggest that the reaction may be partly heterogeneous, but this is quite speculative.

Milligan (3) found no evidence for the presence of CH_3N when CH_3N_3 was photolyzed in an inert matrix at 4° K. He suggested that the isomerization:

$$CH_3N \rightarrow CH_2NH, \quad [5]$$

was very rapid. Although the CH_3N radicals may all react in the gas phase with CH_3N_3, in a matrix, in the absence of any other reactant, they may isomerize, as Milligan found.

3. H_2 Production

Since the H_2 formed is only 5–10% of N_2, its production has been neglected to a first approximation. However, the dependence of H_2 on various parameters does offer some information about the H_2 precursor, and thus is of some interest.

The independence of the rate of H_2 production on percentage of conversion indicates that H_2 is not produced from a stable product of the photolysis, e.g., from photolysis of the condensate. One possible reaction for its formation is:

$$CH_3N^* \rightarrow H_2 + HCN, \quad [7]$$

and actually HCN has been found to be produced at approximately the same rate as H_2. No closer correlation can be made between the two quantities since the amount of HCN represented the threshold of detection of the analysis.

The decrease of R_{H_2} with increasing pressure suggests that the H_2 originates from an excited species but the independence of wavelength argues against this, unless the energy of the precursor is approximately independent of wavelength. The pressure effect is probably due to competition between a first-order decomposition of the radical, reaction [7], and a second-order reaction involving the radical, reaction [1]. Another possible interpretation of the pressure effect is that the H_2 is formed by the radical decomposing on the wall and that fewer radicals reach the walls at the higher pressures.

THE PYROLYSIS OF TRIMETHYL GALLIUM

M. G. JACKO[1] AND S. J. W. PRICE
Department of Chemistry, Essex College, Assumption University of Windsor, Windsor, Ontario
Received October 31, 1962

ABSTRACT

The pyrolysis of trimethyl gallium has been studied in a toluene carrier flow system from 686° K to 983° K using total pressures from 6.1 mm to 31.1 mm. The progress of the reaction was followed by measuring the amount of methane, ethane, and ethylene formed. The rate constants decline rapidly if the toluene-to-alkyl ratio is decreased below 45. Part of this decrease has been shown to result from the loss of methyl radicals as ethylbenzene, propane, propylene, and xylenes. In an unseasoned vessel, the decomposition is markedly dependent on surface conditions. In the unpacked conditioned vessel, the reaction is 94% homogeneous in the first bond region and 97% homogeneous in the second bond region.

The decomposition occurs in two steps:

$$Ga(CH_3)_3 \rightarrow Ga(CH_3)_2 + CH_3 \quad [1]$$

$$Ga(CH_3)_2 \rightarrow Ga(CH_3) + CH_3. \quad [2]$$

The analysis of a black solid from the reaction zone is consistent with the formation of $(GaCH_3)_n$. Both rate constants depend on the total pressure in the system, the dependence of k_1 being very slight. A least-squares analysis of the experimental results gives:

$$\log_{10} k_1 (sec^{-1}) = 15.54 - (59{,}500/2.303RT)$$

$$\log_{10} k_2 (sec^{-1}) = 7.94 - (35{,}410/2.303RT).$$

INTRODUCTION

No previous kinetic studies of the thermal decomposition of trimethyl gallium have been reported. The heat of formation of trimethyl gallium has been obtained by the reaction of trimethyl gallium with iodine in benzene solution (1) and by the combustion of trimethyl gallium with oxygen (2). The mean gallium–carbon bond energies obtained from these studies are respectively 56.7±4 kcal/mole and 57.7±2 kcal/mole. In a recent review Long (3), using $D(CH_3—H) = 102.5$ kcal/mole, has recommended a value of 57.5 kcal/mole.

EXPERIMENTAL

Materials

(a) Trimethyl Gallium

Trimethyl gallium was prepared by refluxing pure gallium with dimethyl mercury in an atmosphere of dry nitrogen, using mercuric chloride as catalyst (4). The fraction boiling at 56° C (uncorrected) was degassed by bulb-to-bulb distillation and stored under vacuum at −190° C. Melting point and vapor pressure data were in agreement with literature values (2).

(b) Toluene

(i) Toluene was prepared by the diazotization of *o*-toluidine followed by deamination with sodium hypophosphite. The organic layer was dried over anhydrous calcium chloride and fractionally distilled. The fraction boiling 109–110° C (uncorrected) was dried by refluxing over sodium under vacuum and degassed by bulb-to-bulb distillation.

(ii) Toluene from sulphonic acid (Eastman Organic, X325) has been found to be as suitable as that described above. It was dried by refluxing over sodium under vacuum and then degassed by bulb-to-bulb distillation.

Apparatus and Procedure

The experiments were carried out in a typical toluene carrier flow system in which the reaction zone was 195 cc. In the runs with the vessel packed with quartz tubing, the surface area in the reaction zone was increased by a factor of 10 and its volume reduced to 145 cc. Pressures were measured using a mercury – dioctyl phthalate differential manometer designed to give a magnification of 10 to 1. The trimethyl gallium vapor was injected into the toluene stream through a capillary sealed to the barrel of a stopcock at the top

of the alkyl reservoir. The alkyl and toluene vessels were weighed at the end of each run to determine the amount of each used. In each experiment a pre-run of 4 to 6 minutes during which only toluene was passed was used to stabilize flow conditions. A similar post-run was used to remove all products from the reaction zone while conditions were still stabilized. In a few selected runs using the toluene from sulphonic acid, pre-runs were extended to 30 minutes. During the first 25 minutes the gaseous products were collected and measured. The rate constants obtained agreed with those obtained from the decomposition of toluene from *o*-toluidine (5). An acetone – dry ice trap removed toluene, ethylbenzene, dibenzyl, and similar products. The remaining products were transferred by a diffusion pump to a Le Roy still at −160° C to remove traces of toluene and hydrocarbons higher than C_2. The remaining H_2, CH_4, C_2H_6, and C_2H_4 were transferred past a non-return valve to a gas burette with the aid of a Toepler pump. After the gaseous mixture was measured, a sample was taken for chromatographic analysis.

The chromatographic analyses were carried out using a 2-m silica gel column at 40° C with a flow rate of approximately 20 cc/min. Internal standards were run with each set of analyses so that peak heights could be used. In a few selected runs, the contents of the acetone – dry ice trap were analyzed using a 2-m di-isodecyl phthalate on diatomaceous earth column at 130° C with a flow rate of 28.5 cc/min. This method is sensitive to better than 0.0002 part ethylbenzene or xylenes in toluene.

Analysis of a black solid recovered from the reaction zone was carried out by admitting concentrated hydrochloric acid (12 *N*) to an evacuated bulb containing a weighed sample. After 6 hours' digestion at 75° C, the bulb was cooled to −190° C. The non-condensable products were collected and measured and a sample taken for chromatographic analysis. The mixture in the flask was filtered through a weighed sintered-glass crucible to determine the weight of the insoluble materials. The remaining solution was then twice evaporated to near dryness and then analyzed for gallium by titration with 0.01 *M* potassium ferrocyanide using 3,3′-dimethylnaphthidine in the presence of a trace of ferricyanide as indicator (6).

RESULTS AND DISCUSSIONS

Selected experimental results are given in Tables I and II. Analysis of the data indicates that the thermal decomposition of trimethyl gallium does not occur by the simple release of three methyl radicals. It was found that even at 1075° K no more than two thirds of the theoretical quantity of methyl radicals could be accounted for. This is similar to the decomposition of trimethyl antimony (7) where the formation of $(SbCH_3)_n$ was indicated. To test for the possible formation of a similar gallium polymer, a black deposit scraped from the reaction zone was analyzed as previously described. The results of this analysis indicated: 80% gallium (I) oxide, 12% carbon, and 8% gallium methyl. The carbon is probably due to the decomposition of the carrier in the high-temperature runs. Since limited quantities of air were admitted to the reaction vessel between certain runs to test for surface effects, the Ga_2O could easily be formed from the reaction of O_2 with $(GaCH_3)_n$. Subsequently analyses were carried out on the contents of the acetone – dry ice trap and on the deposit in the furnace following each of a series of experiments. Under conditions such that less than one third of the theoretical yield of methyl radicals was observed, the gallium was found quantitatively in the acetone – dry ice trap. At temperatures above which two thirds decomposition occurred, the gallium was found quantitatively in the reaction vessel, as a thin, apparently non-metallic film. It therefore seems plausible that $GaCH_3$ does not decompose but deposits in the reaction vessel as $(GaCH_3)_n$.

The following mechanism is proposed:

$$Ga(CH_3)_3 \rightarrow Ga(CH_3)_2 + CH_3 \quad [1]$$

$$Ga(CH_3)_2 \rightarrow Ga(CH_3) + CH_3 \quad [2]$$

$$n(GaCH_3) \rightarrow (GaCH_3)_n \quad [3]$$

$$CH_3 + C_6H_5{-}CH_3 \rightarrow C_6H_5{-}CH_2 + CH_4 \quad [4]$$

$$2CH_3 \rightarrow C_2H_6 \quad [5]$$

$$2C_6H_5{-}CH_2 \rightarrow (C_6H_5{-}CH_2)_2. \quad [6]$$

The small amounts of ethylene formed were assumed to arise from the reactions

$$CH_3 + C_2H_6 \rightarrow C_2H_5 + CH_4 \quad [7]$$

$$C_2H_5 \rightarrow C_2H_4 + H. \quad [8]$$

†Molar ratio.

It was apparent from the analysis of the data that the second methyl radical was not released immediately after the first. The pattern of log $k_4/k_5^{1/2}$ shown in Fig. 1 indicates

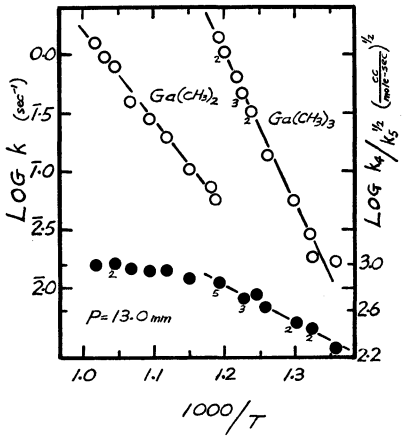

FIG. 1. Arrhenius plot for the pyrolysis of trimethyl and dimethyl gallium and the reaction of methyl radicals with toluene. ○ log k; ● log $k_4/k_5^{1/2}$. Subscripts denote the number of runs averaged to obtain the given points.

that the release of the first two methyl groups might be similar to the successive decomposition of dimethyl zinc, first to zinc methyl and only at much higher temperatures to zinc plus a methyl radical (8). The detailed calculations of k_1 and k_2 have therefore been carried out as for the decomposition of dimethyl zinc, assuming that below 820° K the decomposition of dimethyl gallium is not an important source of methyl radicals.

The mechanism further assumes that reaction [9] is unimportant. The following evidence

$$CH_3 + C_6H_5{-}CH_2 \rightarrow C_6H_5{-}CH_2CH_3 \qquad [9]$$

indicates the validity of this assumption under the experimental conditions used for most runs. First, values of k_1 obtained at 817° K and 13.0 mm pressure using toluene-to-alkyl ratios between 45 and 120 show little variation. Similarly values of k_2 at 916° K and 13.0 mm using toluene-to-alkyl ratios between 45 and 120 show little variation. Previous experiments and calculations (9) also indicate that under similar experimental conditions the loss of methyl radicals according to reaction [9] is negligible. However, as shown in Fig. 2, the value of log k_1 falls sharply when the toluene-to-alkyl ratio is decreased below 45. Values for k_2 are affected similarly. Additional gas chromatographic analyses have shown that the apparent falloff is due in part at least to the formation of propane, propylene, ethylbenzene, and xylenes. Analysis for butanes could not be made at present but these are probably also formed.

The Arrhenius plots shown in Fig. 1 were plotted using k_1's obtained using toluene-to-alkyl ratios of 45 to 120. The simple linear nature of these plots supports the method of calculation used. The curves may be represented by:

$$\log_{10} k_1 \text{ (sec}^{-1}) = 15.54 - (59{,}500/2.303RT)$$

$$\log_{10} k_2 \text{ (sec}^{-1}) = 7.94 - (35{,}410/2.303RT)$$

at 13.0 mm. No other plausible explanation of the results could be found.

The values of k_1 and k_2 were both extremely sensitive to the nature of the surface in the reaction zone. Admission of limited quantities of air to the conditioned vessel between

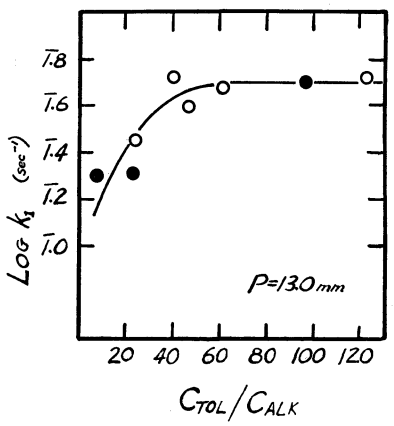

FIG. 2. Variation of k_1 with moles toluene to moles alkyl ratio using fixed toluene concentrations. ○ unpacked vessel at 817° K; ● packed vessel at 801° K.

runs resulted in approximately a 100% increase in k_1 and a 200% increase in k_2 even after pumping over a 48-hour period. Approximately three runs were required to bring values of k_1 and k_2 back to those normally observed in the conditioned vessels. Using a conditioned packed vessel with a surface-to-volume ratio 12 times that of the unpacked vessel gave values of k_1 2.0 times and values of k_2 1.4 times those observed in the unpacked conditioned vessel. It would therefore appear that in the conditioned unpacked vessel, both first and second bond ruptures are predominantly homogeneous processes with a 6% heterogeneous contribution in the first bond region and a 3% contribution in the second bond region.

Both k_1 and k_2 depend upon the total pressure in the system, although the dependence of k_1 is very slight (Fig. 3). The dependence of k_2 is similar to that observed for dimethyl

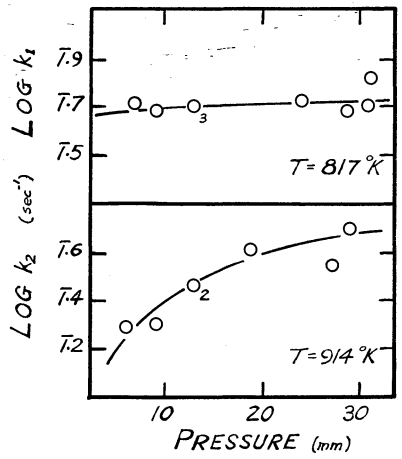

FIG. 3. Variation of k_1 and k_2 with pressure. Subscripts denote the number of runs averaged to obtain the given point.

mercury and dimethyl cadmium (9). Therefore, based solely on unimolecular pressure effects, the value of A_2 would be expected to be of the order 10^{11}–10^{13} sec^{-1}. However,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the observed A_2, 8.71×10^7, is much lower than expected. This is presumably due to a change in multiplicity from triplet to singlet state as the second methyl radical is released from trimethyl gallium.

The pressure dependence of log $k_4/k_5^{1/2}$ is shown in Fig. 4. The falloff with increasing

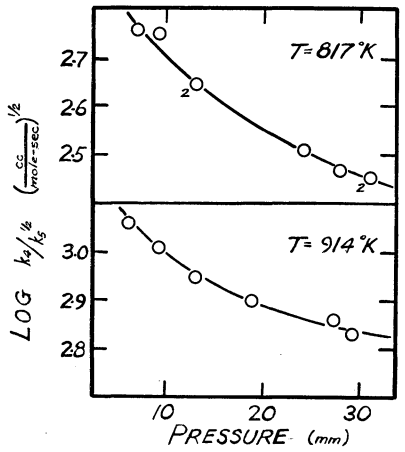

FIG. 4. Variation of $k_4/k_5^{1/2}$ with pressure at 817° K (first bond region) and 914° K (second bond region). Subscripts denote the number of runs averaged to obtain the given point.

pressure is similar to that previously observed (7, 8, 9) and may be attributed to the third-body reqirements of reaction [5].

The experimental evidence although complex would indicate that the activation energies may be approximately related to $D((CH_3)_2Ga—CH_3)$ and $D((CH_3)Ga—CH_3)$. Taking the total strength of the three gallium–carbon bonds equal to 172.4 kcal/mole (3) gives $D(Ga—CH_3)$ equal to 77.5 kcal/mole.

THE REACTION OF ATOMIC HYDROGEN WITH FORMAMIDE VAPOR

J. W. S. JAMIESON
Department of Chemistry, St. John's College, University of Manitoba, Winnipeg, Manitoba
Received June 29, 1962

ABSTRACT

Hydrogen cyanide was the main product of the reaction of hydrogen atoms with formamide vapor; its rate of production was fairly rapid and completely independent of reaction temperature over a wide range. If a hydrogen is abstracted from formamide it must be one of the hydrogens bonded to nitrogen. The results of this investigation suggest the possibility of another free radical chain mechanism, which does not involve hydrogen atoms, for the thermal decomposition of formamide vapor.

INTRODUCTION

When hydrogen atoms are abstracted from amines and similar compounds it is often difficult to determine whether the atom removed had been bonded to carbon or to nitrogen. Thermochemical calculations imply that C—H and N—H bonds have about equal strength.

The experimental evidence is conflicting. Steacie (1) noted that hydrogens attached to nitrogen are probably more labile since methyl radicals react four times more rapidly with ammonia than with methane. On the other hand, Spall and Steacie (2) found that methyl radicals reacted with CH_3COND_2 to give CH_4 predominately, rather than CH_3D.

In an investigation of the reaction of di-*t*-butyl peroxide with ethylenimine, Brinton and Volman (3) assumed that methyl radicals could abstract the imine hydrogen since the activation energy for the abstraction was much lower than the usual values for abstraction of a hydrogen atom from carbon. In 1956, hydrogen atoms were found to react with N-methylethylenimine much more slowly than with ethylenimine (4). Thus it seemed probable that the hydrogen bonded to nitrogen was abstracted from ethylenimine. This conclusion has been supported more recently by Brinton (5), who showed that the rate of hydrogen abstraction by methyl radicals from *t*-butylethylenimine was less than 10% of the rate of the analogous reaction from ethylenimine itself.

It was thought that more definite experimental indication of the site of hydrogen abstraction should be obtainable from a study of the reaction of atomic hydrogen with formamide vapor, particularly if hydrogen cyanide appeared as a major product, since the hydrogen atom of the HCN molecule would almost certainly be the hydrogen originally bonded to carbon in formamide.

EXPERIMENTAL

Materials

Hydrogen, supplied by the Linde Gases Division, Union Carbide Canada Limited, was dried by slow passage through a trap surrounded by liquid nitrogen.

Formamide, melting point 2–3° C, was purchased from Matheson, Coleman and Bell. Low-boiling impurities were removed by distillation.

Ethyl chloride, conforming to the British Pharmacopoeia, was obtained from Ingram and Bell Limited, and was further purified by bulb-to-bulb distillation under vacuum, the first and last fractions being discarded.

Ethylenimine, boiling point 55–56° C, was supplied by Brickman and Company, 546 Sebastopol St., Montreal 22, and was further purified by vacuum distillation.

Apparatus and Methods

The apparatus was a fast flow system of the conventional Wood–Bonhoeffer type. Dry hydrogen gas

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

flowed into both ends of the discharge tube, across the aluminum electrodes of which was a potential drop of about 1100 v a-c. at 300 ma, provided by two Hammond 717×60 transformers with the primaries in parallel and the secondaries in series. Disodium hydrogen phosphate was deposited on the walls of the discharge tube and the reaction vessel to retard the combination of hydrogen atoms.

The mixture of atomic and molecular hydrogen flowed down to the reaction vessel, into the center of which formamide vapor flowed. The rate of flow of formamide vapor was controlled by the temperature of the reservoir. Condensation of liquid formamide in the flow system was avoided by maintaining an increasing temperature gradient from the reservoir to the reaction vessel.

Condensable products of the reaction were trapped with liquid nitrogen below the reaction vessel. The products were then distilled into a removable trap for titration of the HCN formed, using the Liebig–Dénigès method (6) in which the solution was made ammoniacal and titrated with standard silver nitrate solution, potassium iodide being used as indicator. Alternatively, the products could be taken into a Le Roy still which was connected to a gas burette and to an apparatus for analysis by gas chromatography, in which a Beckman No. 17329 di-*n*-butyl maleate column was used with helium as carrier gas, a Gow-Mac thermal conductivity cell Model 9193, TE-II, and a Leeds and Northrup Speedomax Type G, Model "S", one second recorder.

RESULTS AND DISCUSSION

The reaction between formamide and hydrogen atoms was not visible but the extent of reaction could be measured by titration of hydrogen cyanide, which was found to be the main product. The results are shown in Fig. 1. The reaction was studied over a feasible

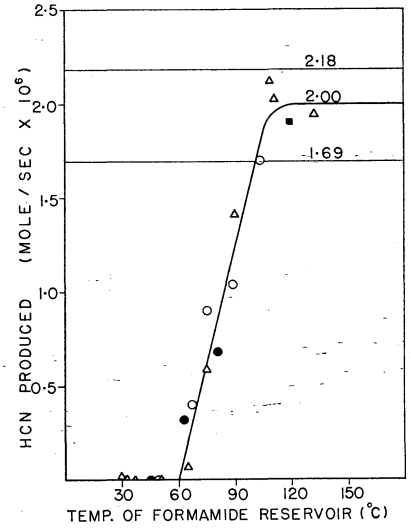

FIG. 1. Hydrogen cyanide produced in the reaction of atomic hydrogen with formamide vapor, over a feasible range of amide flow rates at 43° C (○), 95° C (●), and 195° C (△), and at a high flow rate and 275° C (■).

range of amide flow rates at 43°, 95°, and 195° C, with one experiment at a high flow rate and 275° C.

No reaction was detected until the amide had attained a vapor pressure about equal to the pressure in the reaction vessel, which was 1.10 mm, with the mixture of atomic and molecular hydrogen flowing. (The vapor pressure of formamide is about 0.6 mm at 60° C and 1 mm at 70.5° C.)

The actual flow rate of formamide was not measured but was estimated (7) using the formula of Knudsen for free molecular flow:

$$\text{flow rate} = \frac{4}{3}\sqrt{\left(\frac{2\pi RT}{M}\right)}\cdot\frac{r^3}{l}\cdot\frac{(p_1-p_2)}{RT}\ \text{moles/sec.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

At 110° C, where the vapor pressure of formamide is 12 mm, the calculated flow rate was about 3.9 μmoles/sec. Using Clausing's formula,

$$\text{flow rate} = \frac{20+8\left(\frac{l}{r}\right)}{20+19\left(\frac{l}{r}\right)+3\left(\frac{l}{r}\right)^2}\cdot r^2\sqrt{\left(\frac{\pi RT}{2M}\right)}\cdot\frac{(p_1-p_2)}{RT},$$

which is said to be accurate to within 1.5% for all values of tube length and radius, the calculated flow rate at the same temperature was 3.7 μmoles/sec.

There was no evidence of thermal decomposition of formamide to carbon monoxide and ammonia, which is said (8) to occur near the boiling point (210.5° C), and no production of HCN unless the hydrogen discharge was on. No condensable products other than HCN were detected by gas chromatography or the Le Roy still. (Ammonia should distill at −125° C and HCN at about −100° C.)

The production of hydrogen cyanide did not vary with the reaction vessel temperature over the entire range from 43° to 275° C. Either reactant was completely consumed in an excess of the other at all reaction temperatures. These observations suggest that the reaction is fairly rapid and may have a low activation energy.

At low formamide flow rates the production of HCN was limited only by the amount of formamide vapor available for reaction, while at high formamide flow rates the amount of HCN produced per second was constant and corresponded closely to the rate of flow of hydrogen atoms, which was 2.18 μmoles/sec when measured with ethyl chloride at 26° C and 1.69 μmoles/sec when measured with ethylenimine at 301° C. The data of Fig. 1 do not, however, establish unequivocally the existence of an HCN plateau despite the fact that the hydrogen atom flow rate was purposely kept low. Further experiments at higher formamide flow rates were not attempted due to the possibility of thermal decomposition of formamide in the reservoir at higher reservoir temperatures. It was decided instead to carry out another series of experiments in an unpoisoned reaction system at a still lower hydrogen atom flow rate, which was obtained by using a lower current (115 ma) in the discharge circuit. The results, given in Table I, definitely show the presence of a plateau in HCN production from hydrogen atom attack on formamide vapor.

TABLE I

Establishment of HCN plateau

Temperature of formamide reservoir (°C)	HCN produced (μmoles/sec)
63.5	0.040
87.5	0.21
107.0	0.40
131.0	0.46
157.0	0.46

NOTE: Reaction vessel temperature = 298±4° C.

The hydrogen atom flow rate, estimated from the ethyl chloride reaction in the same system at 300° C, is in agreement with the maximum HCN production from formamide.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Thus, if sufficient formamide is present, a molecule of HCN is produced for each hydrogen atom available for reaction.

The fairly fast primary reaction is probably

$$\begin{matrix} & O & H & & \\ & \| & | & & \\ H-C-N-H & + & H & \rightarrow & H-C\equiv N + H_2 + OH. \end{matrix} \quad [1]$$

The possibility that a hydrogen atom abstracts the hydrogen bonded to carbon seems to be eliminated by the fairly rapid appearance of HCN as the major product. Thus if abstraction occurs it must involve one of the hydrogens bonded to nitrogen. Since it is most improbable that a hydrogen atom would abstract the oxygen from formamide this is further evidence that N—H bonds are weaker and more reactive than C—H bonds, at least toward attack by hydrogen atoms.

It seems likely that reaction [1] occurs in two steps: hydrogen abstraction,

$$HCONH_2 + H \rightarrow HCONH + H_2, \quad [1a]$$

followed by rearrangement and decomposition of the radical,

$$HCONH \rightarrow HCN + OH. \quad [1b]$$

Since reaction [1*b*] is probably endothermic it appears to be necessary to postulate retention by the radical HCONH of the energy released in the first step. The only reasonable alternative would seem to be addition of a hydrogen atom to formamide, followed by molecular rearrangement and decomposition in one step according to reaction [1].

The presence of hydroxyl radicals in the system is inferred from the stoichiometry of reaction [1]. If these radicals had subsequently reacted with H-atoms to form water,

$$H + OH \rightarrow H_2O,$$

the HCN plateau would have been lower, but this reaction would require a third body and would likely be slow. Reaction of molecular hydrogen with OH,

$$H_2 + OH \rightarrow H_2O + H,$$

would have raised the HCN plateau. This reaction does not occur at ambient temperature (9) and is probably slow.

One might also expect hydroxyl radicals to be able to abstract hydrogens from formamide, especially at high formamide flow rates where all the available hydrogen atoms are consumed and formamide is present in excess. Occurrence of such a reaction would, however, almost certainly have raised the HCN plateau and would probably involve a chain reaction with reaction [1*b*] producing chain carriers. There is no evidence of attack on formamide by OH since the HCN plateau is at a flow rate equal to the hydrogen atom flow rate. Thus it appears that the reaction of OH with formamide is so slow that it does not occur.

The experiments reported here provide no indication of the fate of hydroxyl radicals in the present system, although it appears that they cannot undergo reactions such as

$$2OH \rightarrow H_2O + O,$$

since the oxygen atoms thus formed could then give subsequent reactions, such as

$$O + OH \rightarrow O_2 + H,$$

to destroy the simple 1:1 correspondence between available hydrogen atoms and HCN produced. Though there is a very remote possibility that the agreement between the H-atom flow rate and the HCN plateau is fortuitous, there is, however, absolutely no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

evidence for the occurrence of any secondary reactions which consume or produce hydrogen atoms. Therefore it seems necessary to postulate the disappearance of hydroxyl radicals from the system by reactions such as

$$2OH \rightarrow H_2O_2 \qquad [2]$$

or

$$2OH \rightarrow H_2 + O_2 \qquad [3]$$

at the reaction vessel wall or in the cold trap, although neither oxygen nor peroxide was detected among the trapped products.

Discovery of the fairly rapid reaction of hydrogen atoms with formamide to yield HCN would seem to invalidate the mechanism proposed in 1955 by Luft (10) for the thermal decomposition of formamide. This reaction was studied by Berthelot and Gaudechon (8) and more recently by Schwab (11), who found that over 92% of the amide decomposed near its boiling point (170–200° C) to carbon monoxide and ammonia. The formation of HCN accounted for only 4 to 8% of the formamide decomposed.

Schwab calculated an experimental activation energy of 39.4 kcal/mole for the reaction

$$HCONH_2 \rightarrow CO + NH_3, \qquad [4]$$

which agreed reasonably well with a theoretical value of 35 kcal/mole obtained by means of Hirschfelder's rules (12).

Luft (10) thought it unlikely that the thermal decomposition took place by molecular rearrangement according to reaction [4] and postulated a chain mechanism with the primary step

$$HCONH_2 \rightarrow H + CONH_2 \qquad \Delta H \sim 85, \qquad E \sim 85 \qquad [5]$$

followed by several reactions of hydrogen atoms, such as

$$H + HCONH_2 \rightarrow HCO + NH_3 \qquad [6]$$

$$H + HCONH_2 \rightarrow H + CO + NH_3 \qquad [7]$$

$$H + CONH_2 \rightarrow CO + NH_3. \qquad [8]$$

It is, of course, not unlikely that reaction [5] or

$$HCONH_2 \rightarrow HCONH + H \qquad [9]$$

followed by reaction [1] would explain the small amount of HCN production, but there could hardly be extensive formation of hydrogen atoms in the thermal decomposition. Thus Luft's mechanism involving hydrogen atoms as chain carriers is quite unacceptable.

Now, at least, there are fewer possibilities for the correct mechanism of thermal decomposition. It is conceivable that a chain mechanism is still applicable and if so it appears that the major initiation step could only be

$$HCONH_2 \rightarrow HCO + NH_2. \qquad [10]$$

One is tempted, then, to suggest a new chain mechanism in which the NH_2 radicals abstract hydrogen from either formamide or HCO:

$$NH_2 + HCONH_2 \rightarrow NH_3 + CONH_2 \qquad [11]$$

$$NH_2 + HCO \rightarrow NH_3 + CO. \qquad [12]$$

Reaction [11] requires the drastic assumption that NH_2 radicals attack formamide at the formyl group despite the observation that hydrogen atoms abstract hydrogen from the amide group exclusively. The assumption does, however, seem inevitable if a free radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

chain mechanism, which cannot involve hydrogen atoms, is applicable. Spall and Steacie (2) found it necessary to postulate a reaction similar to reaction [11] to explain the formation of ammonia in the photolysis of acetamide.

The $CONH_2$ radicals formed in reaction [11] could decompose thermally according to the reaction

$$CONH_2 \rightarrow CO + NH_2 \qquad [13]$$

as in the photolysis of acetamide (2) with an activation energy of 29 kcal/mole and a frequency factor of 10^{13}. The chain could then be propagated by reactions [11] and [13] and could be terminated by reaction [12].

With the assumption that the radicals attain stationary state concentrations the overall rate of decomposition of formamide would be

$$-\frac{d(HCONH_2)}{dt} = k_{10}(HCONH_2)+k_{11}(NH_2)(HCONH_2)$$
$$= k_{10}(HCONH_2)+k_{11}\left(\frac{k_{10}}{k_{12}}\right)^{1/2}(HCONH_2)^{3/2}.$$

The experimental results (11) do not clearly establish the order of reaction as either first or second. Thus they might correspond to 3/2-order kinetics. The overall specific reaction rate for the chain mechanism now proposed is

$$k \sim k_{11}\left(\frac{k_{10}}{k_{12}}\right)^{1/2}$$

and

$$E_{\text{overall}} \sim E_{11} + \frac{E_{10}-E_{12}}{2}.$$

Heats of reaction may be calculated from known and estimated heats of formation and bond dissociation energies (2, 13, 14). Reaction [10] is about 89 kcal/mole endothermic. This should be approximately equal to the activation energy of reaction [10]. Reaction [11] would be about 24 kcal/mole exothermic, while reaction [12] would be about 78 kcal/mole exothermic.

If E_{11} and E_{12} are small, though not necessarily negligible, E_{overall} could very well have the magnitude to agree with Schwab's experimental data (11).

The proposed mechanism, then, could apply to the thermal decomposition of formamide vapor, although one might argue that the assumption of reaction [11] is too drastic to be acceptable and thus renders any chain mechanism untenable. Such a view would support Schwab's unimolecular decomposition of reaction [4]. It has, however, been pointed out (15) that some other mechanism, probably ionic, might be applicable to the thermal decomposition in the liquid state.

A TISSUE-EQUIVALENT CHEMICAL DOSIMETER SENSITIVE TO 1 RAD[1]

W. A. Armstrong, R. A. Facey, D. W. Grant, and W. G. Humphreys
Defence Research Chemical Laboratories, Ottawa, Canada

Received January 29, 1963

ABSTRACT

The system 10^{-4} *M* terephthalic acid in 4×10^{-4} *M* NaOH is capable of measuring doses of ionizing radiation as low as 500 millirads. The concentration of hydroxyterephthalic acid, determined spectrophotofluorometrically, increases linearly with dose to at least 1000 rads and is independent of dose rate from 0.5 to 1000 rad/min. The energy dependence and stability of the system are also reported.

INTRODUCTION

The irradiation of an aqueous solution of an aromatic compound usually results in the hydroxylation of that compound and many hydroxy aromatics are highly fluorescent. The calcium benzoate dosimeter (1, 2), based on the fluorometric determination of the salicyclic acid formed on irradiation, was developed in this laboratory. Despite its limited usefulness below 30 rads this system exhibits many of the characteristics necessary for a good dosimeter. Consequently attempts were made to find a similar but more sensitive system. Aqueous terephthalic acid (TA) was chosen for investigation for a number of reasons. As its carboxyl groups are para to each other, there is only one isomer of hydroxyterephthalic acid (HTA) and no OH radicals are wasted in the formation of hydroxy acids that do not contribute to the fluorescence measured. In alkaline solution TA does not fluoresce nor does it interfere with the brilliant fluorescence of HTA. Preliminary results showed that the aqueous alkaline terephthalate system is five to six times as sensitive as the benzoate system and is capable of giving a measurable response on irradiation with 500 millirads.

EXPERIMENTAL

Water from a commercial still was redistilled from alkaline permanganate in an all Pyrex glass apparatus incorporating a splash column, and the distillate distilled once again from a similar apparatus. Reagent grade NaOH and Eastman "White Label" terephthalic acid (recrystallized three times from ethanol before being dried overnight at 55° C) were used to prepare the dosimeter solution. The hydroxyterephthalic acid was synthesized by the method of Kuhn (3, 4). Since a commercial sample of HTA was not available and very little information on its properties was found in the literature, the purity of this sample could not be determined accurately. The ultraviolet absorption spectrum of 10^{-4} *M* HTA in 4×10^{-4} *M* NaOH was measured at each major absorption band ($O.D._{246\,m\mu} = 1.099$ and $O.D._{312\,m\mu} = 0.400$). These values should be useful in comparing the relative purities of various samples of HTA. The results of an acid–base titration showed our sample to be 96.9% pure and the appropriate correction was applied to all data. Any unknown impurity in the HTA would change the numerical values of our data by a constant factor but would not change the characteristics of the dosimeter system.

Since widely scattered results have been obtained (5) when vessels cleaned in chromic acid were used for the measurement of very low doses, the Pyrex irradiation vessels were cleaned in an HNO_3–H_2SO_4 mixture (1:3) and washed many times with once-, twice-, and thrice-distilled water. Finally, steam from boiling thrice-distilled water was passed through them.

Samples of 5.0 ml were irradiated either with γ rays from 200 c of Co^{60} or with X rays from a 300 kvp Müller X-ray machine. Filtration of the X-ray beam was: (*a*) 0.9 g/cm² Cu and 0.13 g/cm² Al to give an effective energy of 105 kev when the machine was operated at 250 kvcp; and (*b*) 0.4 g/cm² Al to give an effective energy of 30 kev when the machine was operated at 100 kvcp. For the 50 kvcp X-ray experiments no filtration was used and the effective energy was estimated to be 12 kev (HVL 45.9 mg/cm³ Al).

When Co^{60} γ and 250 kvcp X rays were employed, the samples were irradiated in Pyrex tubes (i.d. 10 mm, o.d. 12 mm) clamped at right angles to the direction of the beam. In order to avoid filtering effects due to

[1]*Issued as D.R.C.L. Report No. 403.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Pyrex, the 100 kvcp and 50 kvcp experiments were carried out by irradiating the samples from above in Pyrex petri dishes (i.d. 5 cm) covered with 1/2 thou Saran plastic sheet to prevent evaporation. These solutions were agitated gently during irradiation to insure homogeneous dose distribution. All dose rates were determined using the revised values for G(salicylic acid) of 0.66, 0.58, 0.52, and 0.46 for Co^{60} γ rays, 105 kev (effective), 30 kev (effective), and 12 kev (effective) X rays respectively (5).

It was confirmed by chromatographic analysis that HTA is the fluorescent compound produced on the irradiation of TA. An irradiated TA sample and a sample of standard HTA were spotted on paper and run with a chloroform:methanol:formic acid:water solvent (solvent system B) (6). After drying, an ultraviolet examination of the chromatogram showed the fluorescent compound in the irradiated sample to have run the same distance as the HTA.

The amount of HTA formed in an irradiated sample of 10^{-4} M TA in 4×10^{-4} M NaOH was determined by comparing its fluorescence intensity with that of a standard HTA solution 10^{-4} M in TA and 4×10^{-4} M in NaOH. The measurements were made with an Aminco-Bowman spectrophotofluorometer using an exciting wavelength of 310 mμ and recording the fluorescence emitted at 420 mμ. Over the range studied, the fluorescence intensity of HTA was found to increase linearly with concentration. The formula used in calculating the concentration of HTA in an irradiated sample is:

$$[\text{HTA}] = \frac{F-B}{F_S-B}\times S,$$

where F is the average of five readings of sample fluorescence, F_S is the average of five readings of standard fluorescence, B is the average of five readings of blank fluorescence, S is the concentration of HTA standard (kept to within a factor of two of the expected sample concentration for greater accuracy). Sample and standard were read alternately to minimize the effect of the fluctuations in the intensity of the xenon lamp light source. When standards less concentrated than 10^{-8} M HTA (equivalent to about 10 rads) were used, it was noticed that the fluorescence intensity increased with prolonged exposure to the ultraviolet light of the fluorometer. By comparing the exposed standard with a fresh one, this effect, presumably due to photochemical oxidation of TA, was corrected for when necessary.

RESULTS

As both TA and HTA are almost insoluble in neutral and acid solutions, the effect of changing pH on the dosimeter mechanism was not extensively investigated. However, the fluorescence characteristics of HTA were shown to be constant throughout the pH range 9 to 12.

The system investigated was 10^{-4} M TA in 4×10^{-4} M NaOH (pH = 10). The results listed in the tables below show the effects of such parameters as dose, dose rate, and radiation energy on G(HTA), the amount of HTA produced expressed in molecules per 100 ev. Each G value is reported as an arithmetic mean with its standard deviation.

The concentration of HTA increases linearly with dose from 1 to at least 1000 rads (Table I) and is independent of dose rate from 0.5 to 1000 rads/min (Table II). The energy dependence (Table II) is almost identical with that of the benzoate system (5). With respect to the value for Co^{60} γ rays, G(HTA) is 12.8% lower for 105 kev (effective) X rays, 24.5% lower for 30 kev (effective) X rays, and 33% lower for 12 kev (effective) X rays.

TABLE II

The effect of dose rate and radiation energy on G(HTA)

Effective energy (Mev)	Dose rate (rads/min)	Dose (rads)	No. of samples	G(HTA)
1.25	0.5	1–100	35	0.94±0.02
1.25	18.8	30.1	6	0.95±0.01
1.25	18.8	950	6	0.97±0.02
0.105	21	33.2	7	0.83±0.01
0.105	21	1050	14	0.81±0.02
0.030	21	30.5	7	0.73±0.03
0.030	21	1000	7	0.70±0.02
0.030	716	1430	5	0.69±0.01
0.012	21	147	19	0.63±0.03

The dosimeter solution is stable for at least a few weeks and exhibits no post-irradiation effect on standing overnight. However, HTA may be formed in small quantities by a photochemical reaction and solutions should be protected from light.

The precision of the dosimeter is about ±5% in the range 1 to 1000 rads. Below 1 rad the precision decreases greatly. This is due to the fact that the fluorescence of an unirradiated blank is equivalent to that produced by a 500-millirad dose. The error in measuring the difference in fluorescence between irradiated sample and unirradiated blank increases enormously when these fluorescences are comparable. This blank fluorescence is equivalent to that of 4×10^{-10} M HTA and is due partly to light scatter in the instrument and partly to trace impurities in the TA.

DISCUSSION

It is believed that the mechanism of the radiation-induced hydroxylation of terephthalic acid in aqueous solution is similar to that previously postulated for the hydroxylation of benzoic acid (7). Reaction with the OH radical is an important step in this process and as G(OH) decreases with decreasing energy G(HTA) will also decrease. Since no chain reaction is involved, no dose rate effect would be expected with the conditions used.

The outstanding characteristic of this system is its high sensitivity. That this sensitivity is due to the analytical technique rather than to high product yield is an important advantage since dosimeters that depend on high product yield for sensitivity are usually dose rate dependent. As this is an aqueous system and hence tissue equivalent, it is ideally suited for radiobiological work in the low dose range.

POLYMÉRISATION PAR LES RAYONS-X DU CHLORURE DE VINYLE À L'ÉTAT DE VAPEUR

JAN A. HERMAN ET PIERRE M. HUPIN
Département de Chimie, Université Laval, Québec, Qué.
Reçu le 15 janvier 1963

ABSTRACT

The polymerization of vinyl chloride in the gas phase by X rays gives a solid polymer of 1140 average molecular weight. The G value of monomer disappearance varies from 100 to 400 and depends on pressure and temperature. From the measure of the rate of polymerization it was possible to deduce the activation energy of the chain propagation steps: 2.5 kcal/mole, and that of the hindered termination process: 7.4 kcal/mole. The negative temperature coefficient of the polymerization is explained by the importance of this hindered termination process.

INTRODUCTION

La polymérisation du chlorure de vinyle gazeux a été étudiée par Mund et ses collaborateurs (1–3) sous l'influence des particules α du radon. Les rendements ainsi obtenus en monomère consommé par 100 ev, $G(-C_2H_3Cl)$, varient entre 40 et 200 et dépendent des conditions expérimentales: dimensions du récipient, pression et température. Les résultats indiquent que, dans les conditions d'irradiation à l'aide des particules α, le polymère est produit par un mécanisme en chaîne, les chaînes cinétiques étant relativement courtes.

Récemment, Puig et Bretton (4) polymérisèrent le chlorure de vinyle à l'état de vapeur par les rayons γ. Dans leurs expériences, la pression varie de 0.5 à 2 atm et la température, entre 20 et 100° C. Les auteurs retrouvèrent sensiblement les mêmes phénomènes qu'avec l'irradiation par les particules α, mais, sous une pression de 1.5 atm et à température ambiante, le rendement $G(-C_2H_3Cl)$ était de l'ordre de 900, indiquant donc une longue chaîne cinétique.

Ces expériences de polymérisation par les particules α et les rayons γ ont le même défaut, les produits de polymérisation s'accumulant au fond du récipient sont soumis à une action constante du rayonnement ionisant, ce qui peut donner lieu à des phénomènes secondaires et compliquer la cinétique. D'autre part, dans les deux cas, la conversion en polymère fut poussée trop loin d'où une certaine difficulté à étudier le stade initial de la réaction de polymérisation.

Nous nous sommes proposés d'étudier la polymérisation par les rayons-X avec faible conversion en polymère de façon à examiner avec plus de détails la cinétique de la phase initiale de la réaction. L'emploi des rayons-X permet de diriger le faisceau rayonnant de telle sorte que le polymère, formé au cours de la réaction et qui se depose sur les parois inférieures du récipient, ne soit plus soumis à l'irradiation. En outre, un réglage facile de l'intensité des rayons-X donne plus de souplesse de manipulation que dans le cas d'irradiation par les particules α du radon ou les rayons γ de Co^{60}.

PARTIE EXPÉRIMENTALE

Le dispositif expérimental (Fig. 1) est essentiellement constitué d'une chambre d'irradiation, d'un manostat réuni à un enregistreur permettant du suivre la disparition du monomère et d'un système de prélèvement d'échantillons gazeux pour analyse.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

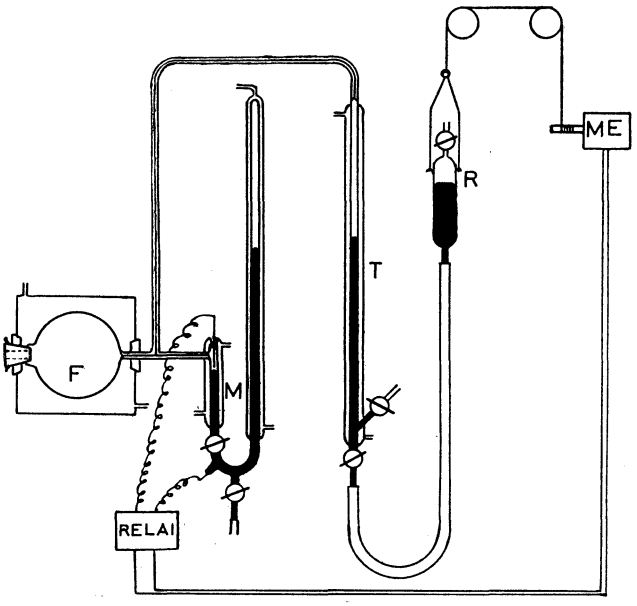

FIG. 1. Schéma de l'appareil de mesure.

La cellule d'irradiation (F) est un ballon sphérique de 500 ml muni d'un rôdage 40/50 où s'insère une pièce de laiton comprenant une fenêtre en aluminium de 0.06 mm d'épaisseur et 19 mm de diamètre. La position de la cellule d'irradiation est telle que les rayons-X la traversent horizontalement; un système de points de repère assure une position reproductible de la chambre de réaction par rapport à la source de rayonnement ionisant. Les rayons-X proviennent d'un tube "Machlett" OEG 60, fonctionnant à 45 kv.

Le manostat relié par un mine tube à la cellule d'irradiation est constitué d'un manomètre, M, porteur de commandes électriques pour le moteur, ME, qui soulève un réservoir de mercure, R, et dirige ainsi la montée du mercure dans le tube calibré, T, du manostat. Afin d'éviter l'influence des variations de la pression extérieure, on fait le vide au-dessus du mercure dans le réservoir R. La sensibilité du manostat dépend de la pression, pour des expériences faites à environ 400 mm Hg elle correspond à l'élévation de pression d'une variation de température de 0.01° C; ce qui exige une thermostatisation adéquate, ainsi l'ensemble manostat – cellule d'irradiation est-il maintenu à une température constante à 0.02° C près. Le moteur électrique, ME, est couplé à un potentiométre permettant l'enrégistrement de la variation de tension qui peut être convertie en volumes de déplacement du mercure dans le tube, T, du manostat.

Afin d'éviter le contact entre les gaz et le lubrifiant des robinets, on a remplacé ces derniers par des valves à mercure.

Le chlorure de vinyle, fourni par la "Matheson Company", est purifié par distillation de trappe à trappe, sous-vide, à la température de l'azote liquide. On a pris soin de n'admettre dans la cellule d'irradiation que la fraction médiane du distillat. L'analyse par chromatographie des gaz ne révèlait aucune impureté.

La dosimétrie du rayonnement ionisant est faite au moyen d'une mesure du courant d'ionisation dans l'argon pur, irradié dans les mêmes conditions que pour le monomère. A cet effet, nous nous sommes servis d'une cellule cylindrique de même diamètre, munie d'une fenêtre en aluminium de mêmes dimensions que pour la chambre de réaction. A l'intérieur de cette cellule, un système d'électrodes parallèles permet de mesurer le courant d'ionisation en fonction de la pression, de l'intensité des rayons-X et de la distance de la fenêtre où pénètre le rayonnement. La connaissance du spectre caractéristique du tube de rayons-X utilisé (5) ainsi que des coefficients d'atténuation atomique pour les rayons-X (6) permet de transposer les courants d'ionisation de l'argon en ceux du chlorure de vinyle.

RÉSULTATS EXPÉRIMENTAUX

Les expériences faites à pression constante portent sur l'influence de la pression, de la température et de l'intensité du rayonnement ionisant sur la vitesse de polymérisation. Au début de l'expérience, on constate quelquefois une période variable d'induction qui semble dépendre de la manière dont le contact électrique initial a été établi dans le manomètre. D'une manière générale, la courbe (Fig. 2) de disparition du monomère en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

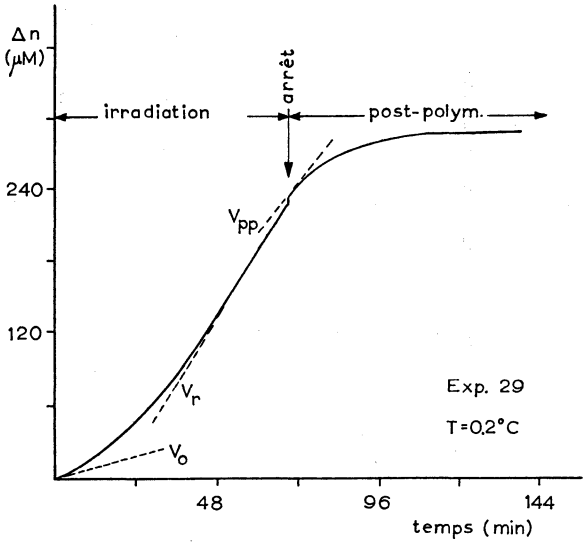

FIG. 2. Allure typique d'une courbe de disparition du monomère, Δn, dans le temps.

fonction du temps est caractérisée par une accélération plus ou moins marquée pouvant durer une vingtaine de minutes. La polymérisation prend ensuite une vitesse de régime, V_r, qui reste constante jusqu'au moins 5% de conversion. Habituellement, nous ne poussions pas cette conversion au-delà de 1%. En interrompant le rayonnement ionisant, une brusque chute de pression apparaît, qui est due au refroidissement interne du gaz. Ensuite, on assiste à une période de post-polymérisation qui débute avec une vitesse comparable à celle de régime et tombe exponentiellement à zéro après 40 minutes environ. La durée des expériences est de 150 minutes en moyenne.

Nous mentionnerons trois sortes de vitesse: V_0, vitesse initiale correspondant à la vitesse après la période d'induction; V_r, vitesse de régime correspondant à la pente stationnaire de disparition du monomère en fonction du temps, et V_{pp}, vitesse initiale de post-polymérisation. La vitesse initiale, V_0, est difficile à mesurer car elle dépend de la perfection de l'enregistrement; de même pour V_{pp}, qui étant partiellement masquée par la chute brusque de température, sa mesure est difficile.

La Fig. 3 illustre la variation des vitesses V_0 et V_r en fonction de la pression pour différentes températures à intensité constante des rayons-X. De façon générale, on constate qui si la vitesse initiale, V_0, augmente avec la température, la vitesse de régime, V_r, diminue, diminution qui a été signalée dans les travaux antérieurs sur la polymérisation du chlorure de vinyle par le rayonnement ionisant (1, 4). Le Tableau I donne les vitesses initiales de post-polymérisation, V_{pp}, en fonction de la pression et de la température.

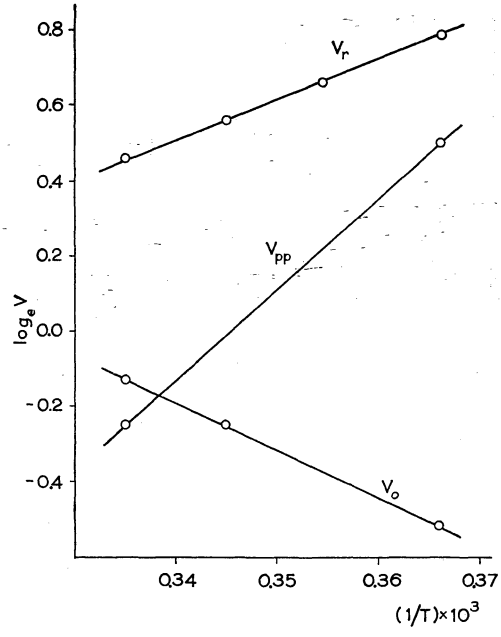

FIG. 4. Relation entre les logarithmes des vitesses et l'inverse de la température.

3.085×10^{-2} (25.2° C et 57 cm Hg). La vitesse de régime répond à une énergie d'activation de régime, E_a^r, négative dont la valeur, tirée de la pente de la Fig. 4, est de -2.1 kcal/mole. Puig et Bretton (4) trouvèrent, pour les rayons γ entre 20 et 100° C, une énergie d'activation de -5.8 kcal/mole pour une densité de 7×10^{-2} mole/litre; de même, Koisumi et ses

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

collaborateurs (7) trouvèrent aussi une énergie d'activation négative entre 10 et 95° C au cours d'une polymérisation du chlorure de vinyle photosensibilisée au mercure. La différence entre notre propre valeur et celle trouvée par Puig n'est qu'apparente, en effet, on constate que le coefficient de température négatif (Fig. 3) augmente avec la pression. D'après nos expériences il s'estompe à environ 30 cm Hg. L'énergie de la post-polymérisation, E_a^{pp}, correspondant à la vitesse initiale du post-effet, est également négative et a pour valeur -4.9 ± 1.0 kcal/mole.

Par contraste, l'énergie d'activation relative à la vitesse initiale, E_a^0, est positive et a pour valeur. 2.5 ± 1.0 kcal/mole; la marge d'erreur qui est importante provient des difficultés de mesures précises. En général, on constate que la polymérisation débute avec une vitesse d'environ 60% de celle de régime.

La Fig. 5 donne les relations, à pression et témperature constantes, entre les logarithmes des vitesses V_0 et V_r et le logarithme de l'intensité du rayonnement mesuré sous forme de

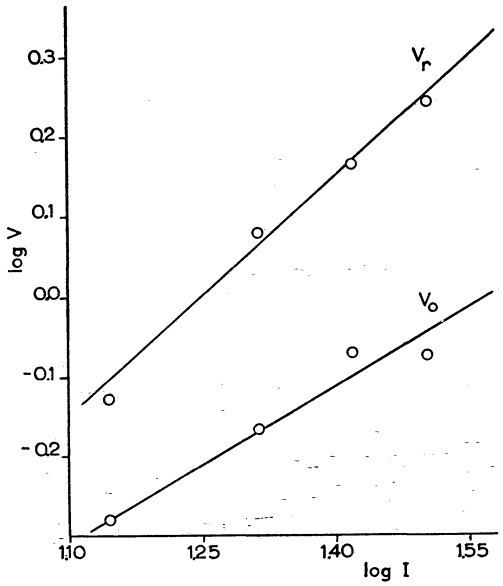

FIG. 5. Relation entre les vitesses initiale, V_0, et de régime, V_r, et l'intensité du rayonnement ionisant.

courant d'ionisation. On remarque de nouveau que l'influence du courant d'ionisation sur la vitesse de consommation du monomère n'est pas la même au départ et au cours du régime stationnaire de polymérisation. La valeur de la pente de la droite de la Fig. 5 est celle de l'exposant de l'intensité d'irradiation et est calculée par les moindres carrés. Au début de la polymérisation cet exposant est égal à 0.52 et devient 1.05 pour le régime stationnaire.

Le polymère apparaît comme un solide blanc qui se dépose au fond du récipient; aux pressions inférieures à 25 cm Hg, c'est un liquide brun, visqueux, qui semble avoir un très bas degré de polymérisation. Ces constations sont en accord avec celles déjà décrites (1) lors de l'irradiation par les rayons α. L'analyse chimique élémentaire du polymère solide (Tableau II) donne des valeurs correspondant assez bien aux valeurs théoriques.

En raison des faibles quantités de polymère recueillies, nous n'avons mesuré que le poids moléculaire global; cette mesure faite par cryoscopie dans le 1,2-dibromoéthane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Théorique	38.43	4.84	56.73

suivant la méthode de Bianchi et Rossi (8) donne 1140, ce qui correspond à un degré de polymérisation moyen $\overline{DP} = 18.2$. Etant donné cette valeur relativement faible, il serait plus logique de parler de télomère.

L'analyse par chromatographie des gaz révèle de l'hydrogène, de l'acétylène, de l'éthylène et de l'acide chlorhydrique. Après une irradiation poussée jusqu'à 2% de conversion, on ne détecte pas de produits plus lourds en concentration supérieure ou égale à 10^{-3} mole/mole, c'est donc que même pas 5% du monomère converti ne se retrouve sous forme de dimère. Par ailleurs, le spectre de masse n'indique également aucune présence de fragment correspondant au dimère.

DISCUSSION

En se limitant au schéma simplifié de la cinétique de polymérisation, on peut représenter la vitesse de propagation, en supposant l'état stationnaire, par l'expression: $R_p = KR_i^x[M]^y$, où R_i est la vitesse d'amorçage, K une constante composée de vitesse, x et y des exposants affectés à la vitesse d'amorçage et à la concentration en monomère [M]. L'analyse de nos résultats donne les relations suivantes pour les vitesses initiales [1] et de régime [2] de la polymérisation:

[1] $$V_0 = K_1 I^{0.52} P^{1.10}$$

[2] $$V_r = K_2 I^{1.05} P^{1.02}.$$

Ces expressions sont équivalentes à celles de la vitesse cinétique de propagation, citée plus haut, puisque dans notre cas la concentration en monomère est représentée par la pression, P, le volume étant constant et la vitesse d'initiation est mesurée par le courant d'ionisation, I. En effet, si l'on considère que chaque paire d'ions conduit finalement à un nombre bien déterminé de radicaux capables d'amorcer des chaînes polymériques, on voit que le courant d'ionisation en est bien une mesure à une constante de proportionnalité près. L'expression [1] de la vitesse initiale correspond bien à une cinétique classique, homogène, la terminaison se faisant par destruction mutuelle des radicaux polymériques. Le fait que la cinétique de polymérisation se conforme initialement à l'expression classique de polymérisation radicalaire, homogène, semble être la meilleure preuve d'un mécanisme radicalaire dans le cas de polymérisation observé. Par contre, l'évolution ultérieure nous est donné par l'expression [2]; l'exposant supérieur à 0.5 dont le courant d'ionisation est affecté montre que la terminaison se fait par un mécanisme autre que la destruction mutuelle de chaînes radicalaires en croissance. Un tel exposant est normal lors de polymérisation en phases hétérogènes et en particulier dans les milieux précipitants; il a été observé à l'état liquide dans de nombreux cas, notamment pour le chlorure de vinyle polymérisé par les rayons γ (9) et par voie photochimique (10). Or, l'observation des phénomènes caractéristiques à la polymérisation à l'etat de vapeur montre bien qu'il s'agit d'une réaction comprenant tous les indices de polymérisation en milieu précipitant. Ce comportement de dépend pas de l'initiation radiochimique, puisqu'il existe des phénomènes identiques par initiation photochimique ou thermique (11–14), mais plutôt de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

nature du milieu, l'acrylonitrile polymérisé en masse en phase liquide ayant un exposant entre 0.7 et 0.8 pour la vitesse d'amorçage aussi bien avec les rayons γ (15, 18) qu'avec les initiateurs chimiques ou la lumière ultraviolette (16, 17). De plus, les systèmes hétérogènes montrent des accélérations initiales et des post-polymérisations semblables à celles de notre cas.

Que l'exposant de la vitesse d'amorçage dans l'expression cinétique [2] soit pratiquement égal à l'unité ne peut être interprété comme une terminaison linéaire des chaînes polymériques en croissance; il faut plutôt envisager une diminution de la vitesse de terminaison par occlusion des radicaux polymériques dans le polymère mort (16, 19).

L'image que nous nous faisons de la polymérisation est la suivante. Initialement les chaînes se terminent aisément, mais il y aurait déjà un important transfert de chaîne sur monomère s'effectuant de manière à garder la nouvelle chaîne en croissance liée physiquement au polymère mort. Il en résulterait un fort accroissement de volume des particules qui s'agglomèreraient par la suite en édifices colloidaux. On observe d'ailleurs un brouillard qui indique une grosseur des particules incompatible avec le degré de polymérisation. Nozaki (20) prévoyait, en considérant la stabilité des radicaux, que le transfert de chaîne est important dans la polymérisation du chlorure de vinyle, ce qui fut d'ailleurs vérifié expérimentalement (11, 21). Dans notre cas, le degré de polymérisation moyen, $\overline{DP}$ = 18.2, comparé à la longueur moyenne d'une chaîne cinétique (Tableau III), confirme ces considérations. Le fait que le transfert s'effectue tout en gardant la nouvelle chaîne en

TABLEAU III

Valeurs $G(-C_2H_3Cl)$ pour la polymérisation

29	52.6	0.2	31.5	118	437

croissance sur le polymère mort peut provoquer un emprisonnement du centre actif et une difficulté de croissance et de terminaison. Pourtant, l'occlusion du centre actif, même s'il ralentit la propagation, prolonge la vie moyenne de la chaîne cinétique et peut ainsi expliquer l'accélération initiale. Ces centres actifs emprisonnés sont aussi responsables de la post-polymérisation. Toutefois l'équilibre dynamique se maintient car il y a toujours autant de radicaux formés, autant de propagation avec terminaison "aisée" et autant de propagation avec terminaison "gênée", le polymère ayant une durée de vie propre. D'autre part, s'il y a transfert sur polymère, celui-ci sera constant si le nombre de particules de polymère mort en suspension est constant; or, ce dernier s'élimine spontanément puisque, par gravité, il tombe au fond du récipient.

Dans le cas de polymérisation radicalaire homogène, l'énergie d'activation positive est normale. On pourrait calculer l'énergie de propagation, E_p, à condition de connaître l'énergie de terminaison classique de destruction mutuelle de deux radicaux polymériques.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

En général, on admet que la terminaison classique en phase gazeuse ne requiert pas d'énergie, on aurait donc pour E_p:

$$E_p = E_a^0 + \tfrac{1}{2}E_t' \sim 2.5 \text{ kcal},$$

et cette grandeur ne peut présenter qu'une valeur inférieure. Burnett (10) trouve pour la polymérisation du chlorure de vinyle en phase liquide une valeur de l'énergie de propagation de 3.7 kcal. Les valeurs sont donc du même ordre de grandeur. Les considérations cinétiques développées plus haut nous forcent toutefois à envisager la terminaison comme autre chose qu'un processus de recombinaison classique de radicaux sans énergie d'activation. En réalité, les terminaisons "gênées" pourraient nécessiter une énergie, E_t'', comparable ou même supérieure à E_p, si elles ont lieu entre radicaux emprisonnés dans un milieu plus ou moins rigide comme le polymère. Dans notre cas, cette énergie de terminaison aurait la valeur suivante:

$$E_t'' = E_p - E_a^{pp} = 2.5 - (-4.9) = 7.4 \text{ kcal}.$$

Dans ce calcul, nous utilisons l'énergie d'activation de post-polymérisation car elle seul correspond à la cinétique de la terminaison "génée" du polymère, toutes les terminaisons classiques de radicaux cessant immédiatement dès que la production de radicaux est arrêtée. Burnett trouve $E_t'' = 7.8$ kcal pour une terminaison qu'il qualifie de linéaire au cours d'une polymérisation hétérogène de C_2H_3Cl en phase liquide (10). La similitude entre cette valeur et la nôtre suggère que le mécanisme est de même nature dans les deux cas, ce qui est compréhensible puisque, suivant l'image que nous nous faisons, l'accessibilité du centre actif emprisonné dans le polymère solide détermine seule la terminaison. Une énergie de terminaison "gênée" plus élevée que l'énergie de propagation serait, par conséquent, à l'origine du coefficient de température négatif observé dans ce système.

L'énergie d'activation de régime, E_a^r, est la résultante de deux processus de terminaison, l'un classique, l'autre "gênée". Il est normal de penser que le processus classique soit d'autant plus important que la quantité de polymère en suspension et la masse moléculaire moyenne du polymère sont plus petits—ce qui aurait lieu à basse pression et/ou température élevée. Par contre, à pression élevée et/ou basse température, il y aurait une prépondérance du deuxième processus. Ceci doit se refléter dans les énergies d'activation de régime et, effectivement, le résultat de Puig et Bretton (4) confirme ce point de vue.

Nous donnons au Tableau III quelques valeurs $G(-C_2H_3Cl)$ de polymérisation sous différentes conditions expérimentales. Les valeurs G sont calculées à partir des rendements ioniques correspondants,* en admettant 25.5 ev pour la formation d'une paire d'ions dans le chlorure de vinyle, valeur proche de celle trouvée expérimentalement pour l'acétylène, l'éthylène et l'éthane (23). En tenant compte des nombreux facteurs, nous estimons l'exactitude de ces valeurs G à $\pm 10\%$.

La quantité $G(-C_2H_3Cl)$ représente, à un facteur de proportionnalité près, la longueur de la chaîne cinétique de polymérisation. Vue sous cet angle, elle permet de comparer les longueurs des chaînes dans diverses conditions.

Une première constatation se dégage de ces données: les valeurs G de la disparition du monomère sont comparables à celles trouvées aux mêmes conditions de pression et de température dans l'irradiation par les particules α (1–3).

Les expériences portant les numéros 31, 32, 33 et 34, faites à pression et température comparables mais à intensité d'irradiation variable, montrent que $G(-C_2H_3Cl)_{\text{régime}}$ ne change pratiquement pas, tandis que $G(-C_2H_3Cl)_{\text{initial}}$ diminue lorsque l'intensité

**Pour la définition et le calcul des rendements ioniques voir référence 22.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

d'irradiation augmente. L'explication en est aisée puisqu'au début la terminaison mutuelle des radicaux polymériques est d'autant plus favorisée que leur nombre est plus grand, c'est-à-dire lorsque l'intensité d'irradiation est plus forte. Il est donc naturel que pour une irradiation de faible intensité on trouve une chaîne cinétique moyenne plus longue. Par ailleurs, une fois que le polymère est apparu en suspension dans le gaz, la terminaison "gênée" détermine la longueur de la chaîne cinétique et elle ne devrait être que peu influencée par le rayonnement ionisant. Par contre, cette même terminaison "gênée" dépend de la pression (expériences 7, 8, 9 et 10) et de la température (expériences 8, 56, 24 et 29); en effet, à température constante, elle doit être d'autant plus facile que le télomère a un poids moléculaire plus faible, donc à basses pressions les chaînes cinétiques sont plus courtes. A pression constante, on doit trouver une terminaison "gênée" d'autant plus difficile que la température est plus basse puisque l'accessibilité du centre actif emprisonné dans le polymère, où la diffusion joue un rôle primordial, est le mécanisme déterminant. Les données expérimentales confirment ces deux aspects. Finalement, $G(-C_2H_3Cl)_{\text{initial}}$ augmente avec la température et la pression, le nombre de collisions donnant lieu à l'accroissement des chaînes étant d'autant plus grand que ces deux paramètres sont plus élevés.

La comparaison du poids moléculaire moyen et de la longueur des chaînes cinétiques, telle que représentée par les valeurs $G(-C_2H_3Cl)$, prouve qu'il y a un transfert important. Le nombre moyen de transfert serait estimable si l'on connaissait le nombre de radicaux formés par paire d'ions (ou par 100 ev) amorçant les chaînes polymériques. A partir des données obtenues il est impossible de déterminer cette grandeur, toutefois, une comparaison avec la valeur de $(k_p/k_t^{1/2}) = 0.05$, trouvée par Jones et Melville (24) lors de la photopolymérisation du chlorure de vinyle à l'état de vapeur, peut nous renseigner sur ce sujet. En exprimant les paramètres de l'équation [1] en unités adéquates: V_0 et I en mole litre^{-1} sec^{-1}, et P en mole litre^{-1}, on trouve pour l'expérience 32 une valeur du coefficient du rendement ionique radicalaire, k_1, de 0.5 ou $G_R = 1.8$. En général, on admet que chaque paire d'ions donne lieu à deux radicaux au moins (25), ce qui voudrait dire que dans notre cas il y aurait un radical susceptible d'amorcer une chaîne polymérique chaque fois que deux paires d'ions seraient formées. Cette valeur nous semble trop élevée, une valeur plus petite nous semblerait plus normale. La valeur de Jones et Melville est sujette à des réserves sérieuses puisqu'elle est calculée d'après l'hypothèse d'une cinétique de polymérisation homogène, ce qui, d'après la description des expériences, ne semble pas être le cas. Nous pouvons donc admettre que $G_R = 1.8$ représente, au plus, la limite supérieure.

Nous remercions le Conseil National des Recherches pour l'aide financière qui a permis de faire cette étude.

NICKEL–MAGNESIA CATALYST AS REVEALED BY ADSORPTION AND ELECTRON OPTICAL STUDIES

N. RAMASUBRAMANIAN[1] AND L. M. YEDDANAPALLI
Chemistry Department, Loyola College, Madras, India
Received February 4, 1963

ABSTRACT

A combined electron diffraction and hydrogen adsorption study on a nickel–magnesia catalyst with 36% nickel is reported. A comparison of the adsorption results with those on the previously reported 79% and 18% catalysts indicates the possibility of the unreduced nickel in the catalysts taking part in high-temperature fast adsorption. The electron optical studies show that there are structural changes taking place during the reduction treatment the catalyst undergoes. However, diffraction study *in situ* appears to be necessary to show, beyond doubt, the presence of reduced and unreduced nickel on the catalyst's surface.

Yamaguchi (1) has employed electron diffraction methods to study the behavior of combined catalysts and, using alternate wavelengths, reported three types. For chemisorption purposes the nature of the surface is of primary importance and an electron diffraction study, using the rather soft electrons, of a catalyst surface before and after the required hydrogen reduction treatment would provide additional information regarding the possible changes the catalyst may undergo during its preparation. In addition to the electron optical studies a study of the adsorption characteristics would enable one to examine the possible correlations existing between the structure and activity of the catalyst. Such a combined study on nickel–magnesia catalyst I is presented here. The adsorption results are compared with those reported earlier (2) on the two catalysts II and III.

EXPERIMENTAL

The method and materials have been fully described in references 2 and 3. It is sufficient to say here that the catalyst I was prepared by reducing the oxides, obtained by precipitation, using 400 ml 1 *N* sodium hydroxide, from the mixed nitrates solution (10 g nickel nitrate and 50 g magnesium nitrate in 300 ml water), at 475° C for 24 hours. The analysis gave a nickel content of 36.16% in the catalyst.

The electron diffraction photographs were taken using a camera length of 50 cm and an accelerating voltage of 50 kv. The specimens were mounted on carbon-coated copper grids for examination in the electron microscope.

RESULTS

The adsorption measurements on catalyst I were carried out in the temperature and pressure ranges 30 to 230° C and 8 to 60 cm Hg, respectively. The Elovich equation was used to analyze the data. The $q - \log t$ plots showed discontinuities and consisted of two linear portions. The initial portions of the room temperature plots were linearized using a t_0 chosen by the trial and error method (4).

Compared to 240° C obtained on catalyst II (2) the temperature at which $\alpha_1 = \alpha_2$ is found to be 90° C on catalyst I from the plots of the α values, at 55 cm Hg, of the two linear portions against temperature. The kinetic data obtained on the three catalysts I, II, and III at 55 cm Hg and 30 and 200° C are plotted in Fig. 1. The fast adsorption or the first-minute adsorption on catalyst I is about 1/10 of that on catalyst II at 30° whereas at 200° they are nearly equal to one another. On catalyst I the slow adsorption at both the

temperatures is much higher than that on the other two catalysts. That there is a difference in activity between the catalysts I and II is also seen from the variation of the α values with pressure given in Table I. In contrast to catalyst II (2) the value of α_2 relative to

show that both the temperature and pressure ranges of appearance of the kinetic stages are different on the two catalysts.

Considering the surface nickel available for chemisorption purposes it was pointed out that the poor hydrogen adsorptive capacity of catalyst III and the fast and the slow adsorptions on catalyst II could be explained on the basis of the presence of different amounts of pure or relatively pure, unreduced and unavailable nickel (2). On catalyst I there thus seems to be available a much higher percentage of unreduced nickel. The fast adsorption, which is much less at room temperature but which, with increasing temperature, becomes high and nearly equal to that on catalyst II, suggests, as discussed later, that unreduced nickel takes part in the fast adsorption also, at higher temperatures.

Generally, most of the catalysts undergo a reduction treatment in hydrogen before use. In the case of the supported metal catalysts, the metal oxide is reduced to the metal and the considerable volume change which results can be expected to have an effect on the structure, particularly of those prepared by the coprecipitation method. Therefore, it was thought that an electron diffraction study of the nickel oxide – magnesium oxide and the reduced oxides may provide some useful information. It is worth mentioning here that no solid solution series has been found between NiO and MgO (5). The electron diffraction patterns, in the case of catalyst I, of the oxides and the reduced oxides are given in Figs. 2(*a*), and 2(*b*) and 2(*c*), respectively, and in Table II the spacings and the

relative intensities of the rings are compared with the literature values for nickel and magnesium oxides. There is a close correspondence between the spacings of nickel and magnesium oxides. The relative intensities of the rings, particularly of the first three, show that in the patterns 2(*a*) and 2(*b*) the major contributions come from magnesia and nickel oxide, respectively. In the pattern (2*b*) of the reduced oxides the strong rings of nickel are not distinctly visible; in the overexposed plate (2*c*) the indication of a faint ring at the spacing 1.75 (between the second and the third rings) becomes more clear. The electron micrographs of the oxides and the reduced oxides are shown in Fig. 3. The reduced oxides show a platelet-like structure, and more gaps than the oxides.

DISCUSSION

The fast and the slow adsorptions, the kinetic stages observed, and the variation of the slow rates of adsorption at the different temperature and pressure conditions studied on the three nickel–magnesia catalysts could be related to the availability of different

amounts of the three types of nickel on the surface. The higher nickel content catalyst II can thus be said to have a higher amount of pure or relatively pure nickel available as is evidenced by the high room-temperature fast adsorption and the low activated or slow adsorption. Moreover, the amount adsorbed compares favorably with that reported for unsupported nickel, prepared by the reduction of pure $Ni(OH)_2$ (6), indicating very little dispersion of nickel in this catalyst. The amount of unavailable nickel becoming high with increase in magnesia content explains the poor adsorptive capacity, and compared to catalyst I, the lower increase between the fast adsorption at 30° and at higher temperatures on catalyst III. The slow adsorption on catalyst I indicates a high percentage of unreduced nickel. This and the fact that compared to catalyst II there is observed a much larger increase between the fast adsorption at room temperature and that at the higher temperatures show that there is every possibility of the unreduced nickel becoming active for fast adsorption also, at the higher temperatures. The observation that in gas removal experiments the rapid desorption per unit pressure change is about eight times lower on catalyst I (3) even though the initial fast adsorption, from which this supposedly takes place, on the catalysts I and II is nearly the same confirms the idea of different types of sites being involved in the high-temperature fast adsorption on these two catalysts.

The electron beam used in the present study corresponds to the soft electrons in Yamaguchi's work (1) and therefore grazed the surface of the samples. The observation that in the reduced oxides' pattern the contribution from NiO is much greater than in the mixed oxides' shows that in the latter it is mainly magnesia that is on the surface, but after the reduction treatment much more nickel oxide becomes available on the surface. Considering the fact that during the reduction of the oxides there is an appreciable decrease in volume accompanying the conversion of NiO (4.1*a*) to Ni (3.5*a*) it is suggested that the mixed oxides is of the second type put forward by Yamaguchi (1) and that the volume decrease during reduction leads to the breakdown of the aggregates, exposing the nickel. It is seen from the width of the rings in the reduced oxides' pattern that the nickel particles are fine and the possibility of air oxidation of the reduced active nickel explains the absence of the distinct diffraction rings due to nickel. Therefore, it is hard to describe the state of nickel on the catalyst's surface, and carrying out the diffraction study of the reduction of the oxides *in situ* may prove beyond doubt the presence of both reduced and unreduced nickel on the surface. Nevertheless, the present study has shown that there are structural changes taking place during the reduction treatment. The effect of hydrogen reduction could also be seen from the micrographs of the oxides and the reduced oxides. The skeletal structure of the latter shows the effect of the decrease in volume during reduction.

THE DEAMINATION OF ALICYCLIC α-AMINOKETONES[1,2]

O. E. EDWARDS AND M. LESAGE
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received February 8, 1963

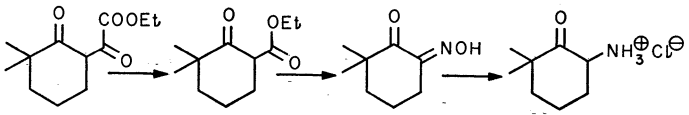
ABSTRACT

The deamination of α-aminocyclohexanones has been shown to give cyclopentane carboxylic acids, bicyclo[3,1,0]hexane-2-ones, and 2-methyl-2-cyclopentene-1-ones. Deamination of 3-*endo*-aminocamphor gave cyclocamphanone, 6-isopropenyl-6-methyl-2-cyclohexen-1-one, and 6-(1′-hydroxy-1′-methylethyl)-6-methyl-2-cyclohexen-1-one.

The formation of bicyclo[3,1,0]hexane by deamination of cyclohexylamine is reported for the first time. The difference between the products from it and bornylamine and those from the corresponding α-aminoketones are rationalized on the basis of the amount of C—C participation in the corresponding carbonium ions.

The nature and fate of carbonium-ion-like intermediates in reactions are very much dependent on the way in which they are formed, on the solvent, and on the steric and electronic environment in which they are developed. The purpose of this study (1) was to examine the fate of carbonium ions located α to a ketone carbonyl. In order to ensure as pure carbonium ion states as possible we generated them by deamination of α-aminoketones.

Preparation of 2-aminocyclohexanone by stannous chloride reduction of 2-oximinocyclohexanone gave a 35% yield of 2-aminocyclohexanone hydrochloride (2). The 2-amino-6,6-dimethylcyclohexanone was prepared as its hydrochloride (I) by the illustrated sequence. The β-keto ester was obtained by the method of Linstead (3). In order to avoid



I

complicating the products unduly, the deaminations were carried out in water using acids whose anions had low nucleophilicity, i.e. sulphuric and perchloric acids, but without any attempt to remove the chloride ions from the original salt in the aminoketone cases.

The products from 2-aminocyclohexanone were separated into readily extractable neutral and acid fractions, and very water soluble material. The latter proved to be mainly adipic acid and 3-hydroxy-2-methylcyclopentanone.

The easily extracted acid (ca. 57%) yield had a strong unpleasant odor. It proved to be a mixture of a readily distillable acid (max. yield ca. 50%) and a non-volatile residue, which was not further studied. The volatile acid proved to be the expected cyclopentanecarboxylic acid, identified by comparison of its physical properties and those of its anilide and amide with authentic samples. This product had been observed earlier by Granger and Técher (4).[3] More recently Baumgarten and Anderson have reported the formation of this acid, and what are probably ϵ-hydroxycaproic and 5-hexenoic acids from 2-aminocyclohexanone (5). The readily extractable neutral products from the deamination of

[1]*Issued as N.R.C. No. 7346.*

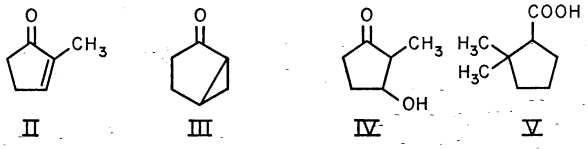
[3]*We regret that we were unaware of their publication when our communications were submitted.*

2-aminocyclohexanone contained diazoketone as one component, as shown by the characteristic band at 2100 cm^{-1} in its infrared spectrum. The mixture was separated by vapor phase chromatography, which showed that at least eight components were present.[4] The two major components were isolated on a preparative scale, then used to make reference solutions. These were used to estimate absolute yields by comparison of areas under the v.p.c. curves.

The main component was formed in an average yield of 16%. It analyzed correctly for C_6H_8O, had λ_{max} 227 mμ (ε 11,200) and 305 mμ (ε 51), and ν_{max} 1705 and 1665 cm^{-1}. Its n.m.r. spectrum had peaks corresponding to an allylic methyl group (τ 8.3) and one vinyl hydrogen (τ 2.7). These correspond to a methylcyclopentenone, with 2-methyl- and 3-methyl-2-cyclopenten-1-ones being the most probable structures. Both were synthesized by known procedures, the 2-methyl isomer following Godchot (6) and the 3-methyl isomer following Robinson (7). The deamination product was identical in all respects with 2-methyl-2-cyclopenten-1-one (II).[5]

The second most abundant component (6.5–9% yield) again analyzed for C_6H_8O. It had strong end absorption in the ultraviolet and ν_{max} 1727 cm^{-1}. This, and the n.m.r. spectrum, which contained no vinyl hydrogen signal, seemed only consistent with the compound being bicyclo[3,1,0]hexan-2-one (III).[6] Comparison of the dinitrophenylhydrazone of the compound with a sample of the derivative of bicyclo[3,1,0] hexan-2-one kindly provided by Dr. N. A. Nelson (8) proved this to be correct.

The other components could not readily be obtained pure with the preparative columns at our disposal. However, the absence of absorption near 1675 cm^{-1} in the infrared spectrum of the neutral product indicated that not more than a trace of conjugated cyclohexenone was present.



II III IV V

A product that we infer to be 3-hydroxy-2-methylcyclopentanone (IV) remained in the aqueous phase after the deamination and separation of the ether layer. When this aqueous solution was made weakly alkaline (pH 8–10) and stirred with ether, 2-methyl-2-cyclopenten-1-one was formed and accumulated in the ether layer. The yield of the hydroxyketone was 7–10%.

The deamination of 6,6-dimethyl-2-aminocyclohexanone (I) gave up to 35% weight yield of methylene-chloride-extractable acid, of which over half was readily distilled under 15 mm pressure. The distillate, which was mainly one component, was purified by further

[4]*In experiments with vapor phase chromatography of diazocamphor no peak was observed corresponding to the diazoketone or its thermal decomposition products. This behavior seems to be characteristic of compounds decomposing during passage through the column. Since no diazocyclohexanone passed unchanged through the v.p.c. columns, we conclude by analogy that none of the observed peaks were due to it or its thermal decomposition products. This conclusion was confirmed when the diazoketone in the total neutral products was destroyed by reaction with aqueous p-toluenesulphonic acid. Only minor changes in the quantity of the other products were observed, with no new product produced.*

[5]*The intensity of the ultraviolet maximum for 3-methyl-2-cyclopentenone cited by Robinson and co-workers is in error.*

[6]*With older instruments with more stray light, maxima in the vicinity of 210 mμ were observed with the bicyclic ketones obtained in this work. However, with a new Carey model 11 spectrophotometer these were absent. We hence consider it likely that all the maxima reported near 210 mμ for simple cyclopropyl ketones are spurious (see also ref. 9).*

For personal use only.

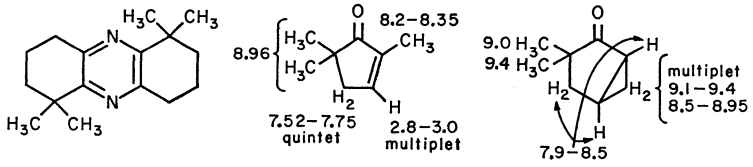
distillation. The acid analyzed for $C_8H_{14}O_2$. The n.m.r. spectrum of its methyl ester had peaks corresponding to two C-methyl groups (τ 8.8 to 9.1), the O-methyl group (τ 6.4), six methylene hydrogens (τ 7.8 to 8.7), and a single deshielded hydrogen as an apparent doublet with a spacing of 8 c.p.s. centered at τ 7.6. These facts and the origin of the acid suffice to prove it to be 2,2-dimethylcyclopentanecarboxylic acid (V). Attempts to convert it to the known 2,2-dimethylcyclopentanone were abortive.

Attempts to prepare V from 2-chloro-6,6-dimethylcyclohexanone under the conditions of the Favorskii reaction[7] failed to give appreciable amounts of the acid. Similarly the action of silver nitrate in aqueous alcohol (11) on 2-bromo-6,6-dimethylcyclohexanone gave no detectable amount of V, although much water-soluble material was produced. It thus appears that the deamination may provide a useful alternative to the Favorskii reaction when one carbon α to the ketone carbonyl is quaternary.

The aqueous solution from the deamination after removal of the readily extractable neutral and acidic products was concentrated to small volume, made strongly acid, and continuously extracted with chloroform. The crystalline acid obtained was identified by analysis and melting point as 2,2-dimethyladipic acid. A sample of the aqueous solution immediately after the deamination failed to give any bisdinitrophenylhydrazone of 6,6-dimethyl-1,2-cyclohexanedione, hence any of the corresponding α-ketol which had been formed must have been completely oxidized to the adipic acid by nitrous acid.

The maximum weight yield of readily extractable neutral products obtained from 6,6-dimethyl-2-aminocyclohexanone was 78%. This was distilled under 15 mm pressure. A relatively non-volatile crystalline residue was obtained with empirical formula $C_{16}H_{24}N_2$. Its infrared spectrum had no carbonyl or isolated azomethine absorption, and its ultraviolet absorption (λ_{max} 289 mμ, ϵ 12,340) was consistent with it being the octahydrophenazine VI. Its n.m.r. spectrum indicated the absence of aromatic hydrogens, the presence of four identical methyl groups (τ 8.75), and two groups of methylene hydrogens centered around τ 7.17 (4 H) and τ 8.17 (8 H) in agreement with this assignment.[8] The volatile neutral products contained diazoketone (ν_{max} 2100 cm^{-1}) and at least nine other components as shown by gas chromatography. The two major ones were shown to be analogous to those from aminocyclohexanone, but in a reversed yield ratio.

The substance corresponding to the first major peak from the gas chromatogram analyzed for $C_8H_{12}O$ and had λ_{max} 228 mμ (ϵ 10,800) and 317 mμ (ϵ 60) and had ν_{max} 1710 cm^{-1}. Its n.m.r. spectrum was consistent with it being 2,5,5-trimethyl-2-cyclopenten-1-one (VII) (see the chemical shift assignments on the figure, given as τ value for deuterochloroform solutions). The other major component also gave correct analyses for $C_8H_{12}O$.



Its ultraviolet spectrum (intense end absorption, λ_{max} 284 mμ, ϵ 46) and its infrared spectrum (ν_{max} 1725 cm^{-1}) resembled those of bicyclo[3,1,0]hexanone. Its n.m.r. spectrum confirmed its identity as 3,3-dimethylbicyclo[3,1,0]hexan-2-one VIII (see assignments on

[7]*See reference 10 for leading references.*

[8]*Baumgarten and Bower (2) observed the formation of decahydrophenazine from 2-aminocyclohexanone. Presumably the nitrous acid dehydrogenated the decahydro derivative in our case.*

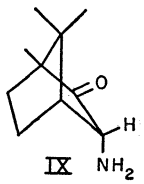
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the figure). The ratio of the areas under the peaks from the gas chromatogram corresponding to the cyclopentenone and the bicyclic ketone were approximately 1:2. The minor components were not identified.

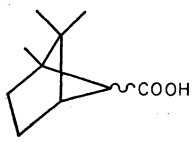
The bicyclic ketone gave no methylcyclopentanone when treated with dilute solutions of sodium hydroxide or perchloric acid in ethanol, hence it is very unlikely that VII was produced from VIII under the mild reaction conditions.

In order to provide the closest possible comparison of the above deaminations with that of a simple amine, we re-examined the deamination of cyclohexylamine. Under the same conditions as used for the aminocyclohexanone studies, the main product (ca. 80%) was cyclohexanol, as found by Hückel (12). Careful v.p.c. examination of the alcohol component failed to reveal the presence of any methylcyclopentanols or hydroxymethylcyclopentane. No cyclohexanone was present but a compound identified by its retention time on a v.p.c. column as cyclohexyl nitrite was formed in up to 14% yield. The hydrocarbon components gave a single peak using a polypropylene glycol column, but were resolved on a silver nitrate–glycol column into cyclohexene and bicyclo[3,1,0]hexane.[9] The yields of these averaged 4% and 2% respectively. No 1-methylcyclopentene was formed.

Finally, to extend our observations on the deamination of α-aminoketones we studied α-aminocamphor. Since the coupling of the 3-hydrogen (τ 5.5) with the bridgehead 4-hydrogen is 5 c.p.s. it appears that the amino group has the endo configuration[10] (13) shown in IX. Deamination of the aminoketone produced a small yield of crystalline acid. This appeared to be a mixture of isomers and was hence not further characterized. By analogy with the aminocyclohexanones this should have structure X.



IX



X

The neutral products contained around 18% of cyclocamphanone XI, identified by comparison with authentic material. Like the bicyclic ketones examined (III and VIII) this had no maximum near 210 mμ in its ultraviolet absorption spectrum.[6]

The major neutral product (62%) analyzed for $C_{10}H_{14}O$ and appeared to be a lightly substituted α,β-unsaturated ketone (λ_{max} 225 mμ (ϵ 13,940); ν_{max} 1680 cm^{-1}) containing a terminal methylene group (ν_{max} 898 cm^{-1}). Its n.m.r. spectrum showed the presence of one somewhat deshielded methyl group (singlet, τ 8.8), an allylic methyl group (singlet, τ 8.3), and the terminal methylene (τ 5.1 and 5.3, two hydrogens). The two vinyl hydrogens on the conjugated double bond appeared as a doublet centered at τ 4.1 (J = 10 c.p.s.) and a multiplet centered at τ 3.2. Reduction of the conjugated double bond with zinc and acetic acid gave a compound with ν_{max} 1710 and 898 cm^{-1}. Its n.m.r. spectrum showed little change except the loss of the signals at τ 4.1 and 3.2. Catalytic reduction of this product using palladium converted it to a dihydro compound, in whose infrared spectrum the 898 cm^{-1} band had disappeared. The signals at τ 5.1 and τ 5.3 were no longer present in its n.m.r. spectrum, and the low-field methyl of the parent compound now resonated at τ 9.1. Taking into account its origin, this evidence was only consistent with the deamination product being 6-isopropenyl-6-methyl-2-cyclohexene-1-one (XII). This

[9]*We are grateful to Dr. H. E. Simmons for a sample of pure bicyclo[3,1,0]hexane.*
[10]*We are grateful to Dr. F. A. L. Anet for suggesting this method of determining the configuration.*

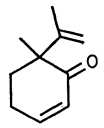
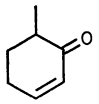
XI



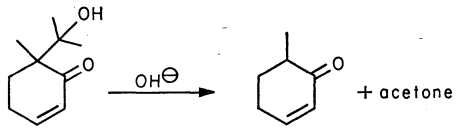
XII



XIII

was proved correct by heating the compound in a 2:1 (v/v) mixture of 12 *N* sulphuric acid in methanol. A new α,β-unsaturated ketone was produced in good yield which analyzed for $C_7H_{10}O$. Its n.m.r. spectrum was in agreement with structure XIII and its 2,4-dinitrophenylhydrazone had the same melting point as that of 6-methyl-2-cyclohexen-1-one (14).

A third product of the deamination was at first missed because of its long retention time. It was observed, however, that if an ether solution of the neutral product was shaken with sodium carbonate solution, or if the mixture was chromatographed on neutral alumina, a new component appeared which was rapidly eluted from the v.p.c. column. This proved identical with XIII. Since XII is inert under these conditions, we conclude that the alkali or alumina was cleaving the alcohol XIV present in the products as shown:



XIV

The yield of XIV was estimated to be around 4%. As far as we are aware XII and XIV represent a new type of fission product of the camphor skeleton.

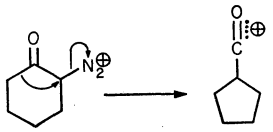
When diazocamphor was treated with acid, the three products XI, XII, and XIII were produced. This confirms the conclusion of Applequist that protonation of diazoalkanes gives the corresponding alkyldiazonium ions (15).

DISCUSSION

The generation of a carbonium ion adjacent to a carbonyl is an energetically unfavorable process due to proximity of the positive charge to the positive end of the carbonyl dipole. This is well illustrated by the inertness of α-haloketones to S_N1 solvolysis (16). It is to be expected then that the developing positive charge in processes which would lead to such a carbonium ion would be delocalized if possible by participation of nearby carbon–carbon and carbon–hydrogen bonds. This expectation is borne out by the high yields of unusual products in the α-aminoketone deaminations.

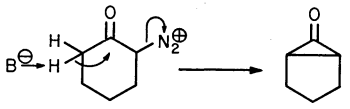
That some α-ketol is produced in the aminocyclohexanone deaminations seems certain since the adipic acids must arise by oxidation of these by nitrous acid. The cyclopentanecarboxylic acids most likely arise by one of three mechanisms:

(*a*) Rearrangement synchronous with C—N bond rupture, giving the acylium ion:



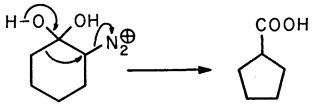
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(*b*) Initial formation of a cyclopropanone as in the Favorskii reaction (8) followed by hydrolytic ring opening:



Since only very weak bases are present to accept the proton in the first stage, this would have the character of C—H bond participation in the dissociation.

(*c*) Hydration of the carbonyl followed by the concerted process shown:

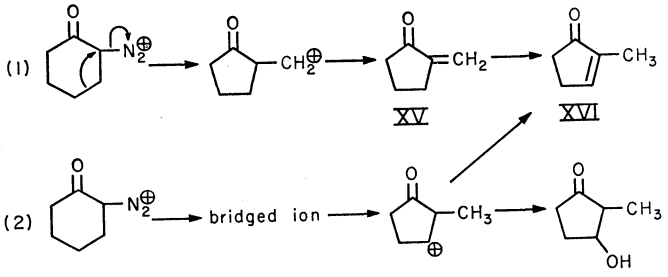


Since the dimethylcyclopentanecarboxylic acid was formed from 2-amino-6,6-dimethylcyclohexanone, for which mechanism (*b*) cannot operate, either (*a*) or (*c*) or both are valid mechanisms in this case.

Of the three mechanisms (*c*) seems to offer the path of least energy to the cyclopentanecarboxylic acids. The opposed dipoles in the amine salt and diazonium ion should favor hydration of the carbonyl (see for example chloral and mesoxalic acid). The diazonium ion could then dissociate, with participation of the 5,6 C—C bond aiding the electron release to the nitrogen. Since the *gem*-dimethyl group adjacent to the carbonyl would make the hydration less favorable on steric grounds, the lower yield of acid obtained in this case relative to aminocyclohexanone deamination can be accounted for.

The major neutral products from the aminocyclohexanones, the bicyclo[3,1,0]hexanones, methylcyclopentenones, and 3-hydroxy-2-methylcyclopentanones, are unusual, although other cases of cyclopropane ring formation in deaminations and deoxygenations in aliphatic compounds have recently been reported (17, 18, 19). The fact that cyclohexenones are absent, or are formed in very low yield, is striking. In addition the relatively low yield of products derived from the α-ketols is in marked contrast to the 94% yield of cyclohexanol and cyclohexyl nitrite from cyclohexylamine.

There appear to be only two simple routes, 1 or 2, to the methylcyclopentenones and 3-hydroxy-2-methylcyclopentanones:



Route 1 is indirect and involves the high energy primary carbonium ion. In addition the rearrangement of XV go XVI would not be expected to take place under the reaction condition (short exposure to a weakly acid medium). We hence consider route 2 to be the most probable one. It has the added attraction of providing a direct path to the three major neutral products.

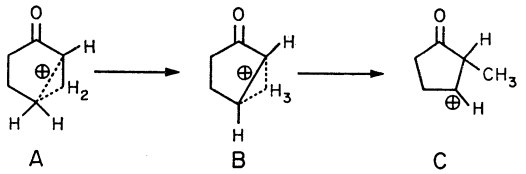
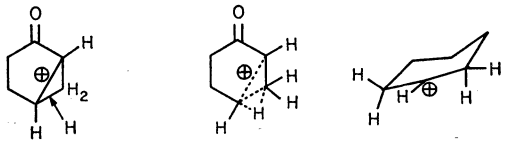
We suggest that the first ion produced is A, in which the positive charge is delocalized by participation of the 3,4 carbon–carbon bond. This is then converted by hydride migration to B, which collapses to the classical ion C, the immediate precursor of the methylcyclopentenone and 3-hydroxy-2-methylcyclopentanone. The hydride transfer in



A B C

the transition of A to B could involve the protonated cyclopropane D or the hydrogen-bridged non-classical ion E. It seems likely that E is the intermediate ion since in dilute acid D would rapidly lose a proton to give the bicyclic ketone III.[11]



D E F

The bicyclohexanones could arise by proton expulsion from A, B, D, or E. An attractive possibility is that E can rearrange to D as well as to B, and that D in turn loses a proton to give the bicyclic ketones.

It now remains to reconcile the differences in product composition between the cyclohexylamine and aminocyclohexanone, and between the bornylamine and aminocamphor deaminations. We consider that these can be accounted for as follows:

The activation energy for the deamination of cyclohexylamine is so low that no assistance from external nucleophiles or neighboring C—C and C—H bonds is needed to aid the approach to the transition state.[12] The 'bare' carbonium ions that result react rapidly with nearby water molecules or nitrite ions.[13] The axial hydrogen on the α-carbon in the ideal planar state of the ion (F) is in a favorable stereo-electronic situation for elimination, and hence the few percent of cyclohexene formed probably arises from this state. The even smaller amount of bicyclo[3,1,0]hexane is presumably formed via a bridged-ion intermediate. No methylcyclopentene or 2-methylcyclopentanol could be detected among the products, which is consistent with the absence of well-developed C—C participation in the carbonium ion.

In contrast, the deamination of the α-aminocyclohexanones, for which we postulate a large amount of C—C participation, gave less than 25% of products derived from the simple carbonium ion. The major products, the bicyclic ketones and methylcyclopentenones, apparently arise from bridged ions as described above. No cyclohexenones could be detected, as expected if very little 'bare' carbonium ion was present in these cases.

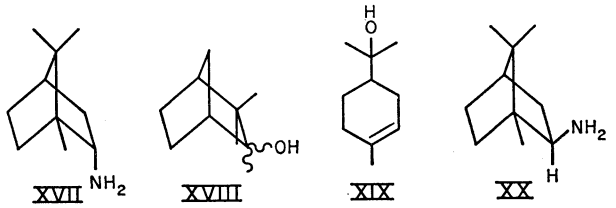
[11]*There is good evidence (20, 21) that symmetrically protonated cyclopropanes (22) are not intermediates in methyl migration in carbonium ion rearrangements, but in our opinion unsymmetrical 'edge-protonated' cyclopropanes are not excluded from consideration by their work. However, we believe such intermediates would give rise in high yield to cyclopropane.*

[12]*This is in agreement with the views of Cram and McCarty (23) and Ridd (24).*

[13]*The retention of configuration in the cyclohexanol (25) could be the result of reaction with water before the ideal planar state of the ion is reached, or selective reaction with the water molecules which had solvated the diazonium ion, on the face of the carbon from which the nitrogen had departed.*

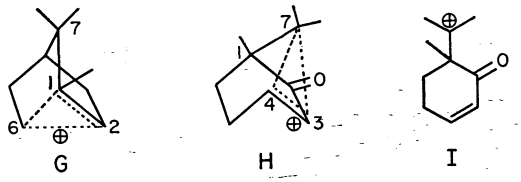
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The deamination of 3-*endo*-aminocamphor gave as major products the monocyclic compounds XII and XIV (74%) and the tricyclic compound XI (18%). In contrast, the fairly comparable bornylamine (XVII) gave mainly camphene and camphene hydrate (XVIII) with 28% of α-terpeneol (XIX) (26). Isobornylamine (XX) gave over 90% camphene and camphene hydrate (27).



XVII XVIII XIX XX

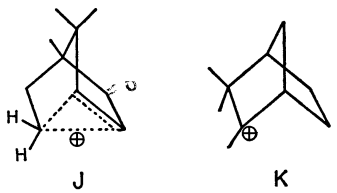
As the positive charge develops on C-2 in the isobornylamine deamination it must be rapidly delocalized by formation of the bornonium ion G, which then gives nearly quantitatively camphene and camphene hydrate. Since in the deamination of bornylamine around 30% of the monocyclic α-terpineol was formed, we can thus conclude that at least this percentage of the molecules doesn't give rise to the ion G. The same conclusion follows from consideration of the fact that the participation of the 1,6 carbon–carbon bond would have to be subsequent to the departure of the nitrogen from the endo face of C-2. We hence suggest that in the bornylamine case an essentially bare carbonium ion is formed, which in part gives the bornonium ion and finally camphene and camphene hydrate, and in part captures the electron pair of the 1,7 carbon–carbon bond, giving the monocyclic terpineol.



G H I

In the aminocamphor deamination no products with rearranged bicyclo[2,2,1]heptane skeleton were observed. We conclude that little bare carbonium ion was formed, consistent with the high activation energy which would be involved in juxtaposition of the two like charges. Instead the developing positive charge is delocalized by participation of the 4,7 carbon–carbon bond with formation of the rather high-energy bridged ion H. This collapses to the classical ion I in which good charge separation is achieved. I gives predominantly the diolefin XII but some of the tertiary alcohol is formed.

The cyclocamphanone formed from aminocamphor could arise from the bare carbonium ion or by conversion of H to the non-classical ion J followed by proton expulsion. The absence of tricyclic compound in the bornylamine case could be partly due to the lower



J K

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

energy of the tertiary carbonium ion K compared to the corresponding secondary carbonium ion from the aminocamphor. This would favor formation of the rearranged skeleton in the former and the tricyclene in the latter case.

It seems desirable to study the deamination of the at-present unknown 3-bornanamines in order to have more perfect comparison with the behavior of aminocamphor.

EXPERIMENTAL

Infrared spectra were taken on a Perkin–Elmer Model 21 spectrophotometer and ultraviolet spectra determined in 95% ethanol on a Cary Model 11 spectrophotometer. Vapor phase chromatography (v.p.c.) was carried out using a Perkin–Elmer Model 154C instrument with thermistor detector. The analytic columns used were 1 m and 2 m × 0.25 in. stainless steel columns with polypropylene glycol on diatomaceous earth packing (column R) and a 2 m×0.25 in. silver nitrate in diethylene glycol on diatomaceous earth packing (column H). The preparative chromatography was done with a 3 m×1 in. column with type R packing. Yields were estimated in the cyclohexylamine and 2-aminocyclohexanone cases by diluting the total neutral extract in ether to a known volume and comparison of the peak areas in the v.p.c. of an aliquot of this with those from ether solutions containing known concentrations of the corresponding substances. In the 2-amino-6,6-dimethylcyclohexanone and aminocamphor cases the yields were estimated roughly by assuming equivalent peak areas per gram for all the volatile products. The n.m.r. spectra were determined in deuterochloroform with tetramethylsilane as internal standard using a Varian A-60 spectrometer.

Deamination of Cyclohexylamine

A solution of 5 g of cyclohexylamine perchlorate and 5 g of sodium nitrite in 20 ml of water was prepared. Five milliliters of ether was added, then the mixture was cooled in ice. To this was added dropwise with stirring 15 ml of 0.1 *N* perchloric acid during 15 minutes. The escaping gas was bubbled through a trap containing cold ether.[14] The reaction mixture was left 10 minutes in the cold bath, then 5 minutes at room temperature. It was neutralized using sodium bicarbonate, then extracted thoroughly with ether. The liquid remaining after careful distillation of the ether was analyzed using vapor phase chromatography on a polypropylene glycol column (Perkin–Elmer R). The main products were cyclohexanol (~80%) and cyclohexyl nitrite (12–14%) with a smaller fraction rich in cyclohexene. Rechromatography of the cyclohexene fraction on Column H showed it to be a mixture of cyclohexene (3–5% yield) and bicyclo[3,1,0]hexane (~2% yield). The latter had retention time identical with that of an authentic specimen.[9]

2-AMINOCYCLOHEXANONE

2-Aminocyclohexanone Hydrochloride[15]

The method of Jaeger and van Dijk (28) was used to prepare 2-isonitrosocyclohexanone.

The isonitrosoketone (9.5 g) was slowly added with shaking to a solution of 40 g of stannous chloride in 50 ml of concentrated hydrochloric acid. Then 24 g of mossy tin was added and the reaction mixture heated on a steam bath for 15 minutes. The resulting solution was diluted with 1 l. of water, and the tin precipitated using hydrogen sulphide. After filtration the clear solution was reduced to dryness *in vacuo* at 40° in a rotating evaporator.

The residue was recrystallized from absolute ethanol, giving 3.85 g (35%) of hydrochloride, m.p. 150–155°. A further recrystallization from ethanol – ethyl acetate gave colorless needles, m.p. 154–155°. Found: C, 47.87; H, 8.15; N, 9.28. Calc. for $C_6H_{12}ClNO$: C, 48.15; H, 8.08; N, 9.36.

Deamination of 2-Aminocyclohexanone Hydrochloride

(*a*) 2-Aminocyclohexanone hydrochloride (800 mg) was dissolved in 3 ml of 0.05 *N* H_2SO_4. To this solution 1.7 g of sodium nitrite, dissolved in 2 ml of water, was added slowly with shaking. The reaction mixture was left at room temperature for ½ hour. It was then basified with sodium bicarbonate and extracted with methylene chloride. The methylene chloride solution was dried and the solvent distilled, giving 400 mg of neutral residue.

The aqueous solution was acidified with 6 *N* H_2SO_4 and extracted with methylene chloride. Then methylene chloride solution was dried over anhydrous sodium sulphate and distilled, leaving 280 mg of acidic material.

(*b*) 2-Aminocyclohexanone hydrochloride (500 mg) was dissolved in 1 ml of water and to this solution 0.5 g of sodium nitrite in 1 ml of water was added. The reaction mixture was cooled in ice water for 10 minutes. Then, with stirring, 1.5 ml of 0.1 *N* perchloric acid was added dropwise to steadily liberate nitrous acid (time 20 minutes). The reaction was left for 10 minutes more in the cold bath and at room temperature for 5 minutes.

An acid-neutral separation as in (*a*) gave 219 mg of acidic material and 88 mg of neutral.

[14]*The ether trap collected no significant amount of product.*

[15]*We thank Mr. Earl Brewer, who first prepared this compound.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Many variations of these conditions were tried, including changing the nature of the acid and its concentration, and varying the temperature rate and order of addition. The conditions in (*b*) gave the highest yield of acid.

(*c*) 2-Aminocyclohexanone hydrochloride (200 mg) was dissolved in 2 ml of 0.2 *N* sulphuric acid and a solution of 0.5 g of sodium nitrite in 1 ml of water was added to it dropwise during 20 minutes. The reaction was then basified with sodium bicarbonate and a neutral acid separation was effected, giving 50 mg of neutral material and 48 mg of acid.

The Neutral Products

The bulk of the neutral product from deamination by method (*a*) was readily extractable into ether. An oil remained after careful distillation of the ether. This contained some 2-diazocyclohexanone, as indicated by the presence of a sharp band at 2100 cm^{-1} in the infrared spectrum of the residue. This absorption disappeared when the mixture was allowed to stand, or when an ether solution of the products was stirred in the presence of aqueous *p*-toluenesulphonic acid without significant change in the composition as indicated by v.p.c. The mixture was separated into two major and 5 minor components by a 2 m×1/4 in. column with R packing at 120° C and a flow rate of 120 cc/min. The minor components had retention times of 7, 13, 14, 15.5, and 22 minutes. The major components are described below.

The presence of another neutral component which remained in the aqueous layers was proved by treatment of the latter with sodium carbonate in the presence of ether. Vapor phase chromatography of the ether solution after concentration showed that 2-methyl-2-cyclopentene-1-one had been produced in 7 to 10% yield.

Bicyclo[3,1,0]hexane-2-one

Retention time 26.5 minutes, yield 6.5–9.2%. It had ν_{max} 1727 cm^{-1}; its ultraviolet spectra showed strong end absorption (ϵ, 1625 at 210 mμ) and λ_{max} 277 mμ (ϵ 370). Found: C, 75.42; H, 8.28. Calc. for C_6H_8O: C, 74.97; H, 8.39. It gave a 2,4-dinitrophenylhydrazone, m.p. 182–185°. This showed no mixed m.p. depression with an authentic sample (m.p. 175–183°) of the dinitrophenylhydrazone of bicyclo[3,1,0]hexane-2-one kindly provided by Dr. N. A. Nelson, and the X-ray powder patterns of the two were identical. The n.m.r. spectrum of the ketone had a series of signals between τ 8.7 and τ 9.2 with intensity equivalent to two protons.

2-Methyl-2-cyclopentene-1-one

Retention time 19.0 minutes. Yield 12.5–19.5%. It had $\nu_{max}^{CS_2}$ 1705 cm^{-1} (C=O), 1640 cm^{-1}, and 785 cm^{-1} (); Its ultraviolet spectrum had λ_{max} 227 mμ (ϵ 11,220), 305 mμ (ϵ 51). Found: C, 74.80; H, 8.16. Calc. for C_6H_8O (96.12): C, 74.97; H, 8.39.

The n.m.r. spectrum of the ketone had a doublet (J = 1.5 c.p.s.) centered at τ 8.3 (), a series of signals from τ 7.8 to τ 7.3, and a multiplet centered at τ 2.7.

Cyclopentanecarboxylic Acid

The readily extractable acids from the deamination of 2-aminocyclohexanone were distilled over a short path at an air-bath temperature of 102° under 8 mm pressure. The clear colorless oil so obtained had a rancid odor. It had n_D^{18} 1.4540 (reported 1.4534) (29). Found: C, 62.64; H, 8.60. Calc. for $C_6H_{10}O_2$: C, 63.13; H, 8.83. The maximum yield obtained using the conditions in (*b*) was 50%.

Its amide was prepared via the acid chloride ($SOCl_2$). After recrystallization from aqueous methanol and sublimation at 70°, 1×10^{-3} mm, it melted at 178–179°. Found: C, 63.38; H, 9.96. Calc. for $C_6H_{11}ON$: C, 63.68; H, 9.80.

The anilide of the acid was prepared from the acid chloride. After sublimation at 90°, 5×10^{-4} mm, it melted at 164–165°. Found: C, 76.03; H, 7.85; N, 7.49. Calc. for $C_{12}H_{15}ON$: C, 76.15; H, 7.99; N, 7.40.

The above derivatives had the same melting point as the amide and anilide of cyclopentanecarboxylic acid prepared by hydrolysis of cyclopentyl cyanide, and showed no mixed melting point depression with the corresponding authentic derivative.

Adipic Acid

Extraction of the acidic aqueous solution in a continuous liquid–liquid extractor using chloroform gave a small quantity of adipic acid characterized by melting point and mixed melting point.

2-Amino-6,6-dimethylcyclohexanone

2,2-Dimethyl-6-ethoxycarboxylcyclohexanone

A mixture of di- and tri-methylcyclohexanones from alkylation of 2-methylcyclohexanone (30) was treated with ethyl oxalate in the presence of sodium ethoxide. Only the 2,2-dimethylcyclohexanone formed an oxalyl derivative (3). This was decarboxylated in the presence of crushed soft glass, the optimum temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

being 170–180°. The resulting 2,2-dimethyl-6-ethoxycarbonylcyclohexanone was distilled: b.p. 125° C under 20 mm.

2,2-Dimethyl-6-isonitrosocyclohexanone

2,2-Dimethyl-6-ethoxycarbonylcyclohexanone (54 g) was stirred (vibro mixer) under nitrogen with a solution of 20 g of sodium hydroxide in 1 l. of H_2O until the solution clarified, i.e., the ester was completely in solution (3–5 hours).

The reaction mixture was cooled in ice and a solution of 17.5 g of sodium nitrite in 50 ml of water was added with stirring and sweeping with nitrogen. After 10 minutes, the solution was acidified with 3 *N* sulphuric acid and left for a further 15 minutes. The solution was then basified and extracted with ether to remove any unchanged ester. It was reacidified and extracted with ether. The ether extracts were dried over anhydrous sodium sulphate. On evaporation of the solvent, the isonitroso compound crystallized. Four crops of crystals totalling 26.7 g (63%) of the isonitroso compound were collected, melting from 110–114°. This was recrystallized from ether–pentane, giving 2,2-dimethyl-6-isonitrosocyclohexanone, m.p. 116–116.5°. Found: C, 62.10; H, 8.40; N, 9.21. Calc. for $C_8H_{13}O_2N$ (155.19): C, 61.91; H, 8.44; N, 9.03.

2-Amino-6,6-dimethylcyclohexanone Hydrochloride

2,2-Dimethyl-6-isonitrosocyclohexanone (3.24 g) was added slowly to a solution of 15 g of stannous chloride in 18 ml of concentrated hydrochloric acid. The mixture was then filtered and the filtrate evaporated to dryness under reduced pressure at 40° C. The residue was taken up in absolute ethanol, giving 2.26 g of crystals, m.p. 172–174° C. This was recrystallized from methanol – ethyl acetate to yield 2-amino-6,6-dimethylcyclohexanone hydrochloride, m.p. 181–182° C. Found: C, 53.47; H, 9.00; N, 7.92. Calc. for $C_8H_{16}ClNO$: C, 54.08; H, 9.07; N, 7.82. The carbon value was low because of traces of ammonium chloride that were difficult to remove.

Deamination of 2-Amino-6,6-dimethylcyclohexanone

(*a*) 2-Amino-6,6-dimethylcyclohexanone hydrochloride (500 mg) was dissolved in 2 ml of 0.05 *N* sulphuric acid and then a solution of 1 g of sodium nitrite in 1 ml of water was added (addition time 15 minutes). There was a vigorous evolution of gas and the reaction mixture became yellow. A layer of yellow oil separated from the solution.

The reaction mixture was basified with sodium bicarbonate and extracted with methylene chloride. The methylene chloride solution was dried over sodium sulphate and distilled, leaving a neutral residue of 230 mg. The aqueous solution was acidified with sulphuric acid and extracted with methylene chloride. The 114 mg of acid which was extracted contained some dimethyladipic acid and other high-boiling acids, so was purified by short-path distillation. The main fraction came over at 75°, 0.5 mm; yield around 60 mg.

(*b*) A solution of 500 mg of amine hydrochloride and 1 g of sodium nitrite in 3 ml of water was prepared. This was cooled to 0°, then 5 drops of 0.05 *N* perchloric acid added slowly with stirring. The mixture was left for 10 minutes in the ice bath, then 5 minutes in the air. A yellow oil separated during the reaction. The readily extractable product gave 273 mg of neutral material and 58 mg of acid.

(*c*) The amine hydrochloride (106 mg) was dissolved in 3 ml of 80% aqueous dioxane, and 1 ml of 5% acetic acid solution was added. This was cooled in an ice bath, then 250 mg of sodium nitrite added in small portions. After gas evolution ceased the reaction mixture was adjusted to pH 8 using sodium bicarbonate. Extraction with methylene chloride gave 30 mg of neutral product. The aqueous solution was then acidified and extracted with methylene chloride, giving 29 mg of acid. These conditions gave the highest yield of acid.

The neutral product from deaminations by method (*a*) was distilled over a short path at bath temperature up to 80° under 10 mm pressure. A residue remained which crystallized from acetone. The crystalline substance could also be obtained by solution of the total neutral product in acetone, from which solution it separated on standing. The more volatile neutral products were separated by vapor phase chromatography using a 2 m×0.25 in. column with R packing at 120° and a flow rate of 50 cc/min. The retention time will be cited in the description of the different compounds. Minor components with retention times of 12, 14, 21, 25, 38, and 42 minutes were not characterized.

sym-Octahydrophenazine VI

The crystalline solid after sublimation at 60°, 5×10^{-4} mm, melted at 125–126°. Its infrared spectrum had no OH, NH, or carbonyl stretching bands. It had λ_{max} 289(ϵ 12,340). Found: C, 78.61; H, 9.84; N, 11.57. Calc. for $C_{16}H_{24}NO$: C, 78.63; H, 9.90; N, 11.46.

2,5,5-Trimethyl-2-cyclopentene-1-one (VII)

Retention time 19 minutes. It had $\nu_{max}^{CS_2}$ 1710 cm^{-1} ($\diagdown$ C=O), 1355 and 1380 cm^{-1} (*gem*-dimethyl), 828 cm^{-1} (R_2C=CHR); λ_{max} 228 mμ (ϵ 10,840), 317 mμ (ϵ 60). The maximum yield was approx. 23%. Found: C, 76.90; H, 9.59. Calc. for $C_8H_{12}O$ (124.18): C, 77.37; H, 9.74.

3,3-Dimethylbicyclo[3,1,0]-2-hexanone (VIII)

Retention time 35 minutes. It had $\nu_{max}^{CS_2}$ 1725 cm^{-1} (C=O), 1355 and 1380 cm^{-1} (*gem*-dimethyl); λ_{max} 284 mμ (ϵ 46). The maximum yield was approx. 46%. Found: C, 77.26; H, 9.60. Calc. for $C_8H_{12}O$: C, 77.37;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

H, 9.74. The compound in dilute ethanol solution of perchloric acid or sodium hydroxide did not give any α,β-unsaturated ketone after several hours at room temperature (followed by ultraviolet absorption).

2,2-Dimethylcyclopentanecarboxylic Acid

The acid fractions from the deamination of 2-amino-6,6-dimethylcyclohexanone were distilled over a short path. The bulk of the volatile acid distilled at a bath temperature of 75° under 0.5 mm pressure. It had $\nu_{max}^{CS_2}$ 1700 cm^{-1}. The maximum yield was 18%. Found: C, 67.34; H, 9.67. Calc. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. The chloride of the acid was prepared by refluxing the acid for 0.5 hour with thionyl chloride This was converted to the *anilide.* After recrystallization from acetone–pentane and sublimation at 90°, 5×10^{-4} mm, this melted at 124.5–125.5°. Found: C, 77.49; H, 8.57; N, 6.44. Calc. for $C_{14}H_{19}NO$: C, 77.38; H, 8.81; N, 6.45.

The methyl ester of the acid, prepared using diazomethane, was distilled over a short path at 25° C under 0.5 mm pressure. It gave a single peak with retention time 30.5 minutes using a 2-m column with R packing at 120° C with flow rate 50 cc/min.

2,2-Dimethyladipic Acid

The acidic aqueous solution remaining after removal of the readily extractable neutral and acidic products from the deamination of 2-amino-6,6-dimethylcyclohexanone was concentrated under reduced pressure until salts began to crystallize. The mixture was extracted thoroughly with chloroform. The crystalline residue after evaporation of the chloroform melted at 88–89°. When recrystallized from chloroform–hexane it had m.p. 89–90° (lit. m.p. 89–90° (31)). Found: C, 54.98; H, 7.97. Calc. for $C_8H_{14}O_4$: C, 55.16; H, 8.10.

Favorskii and Cope Reactions

2-Chloro-6,6-dimethylcyclohexanone

The chlorination of 2,2-dimethylcyclohexanone was carried out under conditions described in Organic Syntheses (32). The product melted at 62–63° after recrystallization from ether followed by sublimation under 1×10^{-2} mm. It had $\nu_{max}^{CHCl_3}$ 1725 cm^{-1} and λ_{max} 287 mμ (ε 26). Found: C, 59.65; H, 8.09; Cl, 22.23. Calc. for $C_8H_{13}OCl$: C, 59.81; H, 8.15; Cl, 22.07.

Attempted Favorskii Reaction

(*a*) A solution of 2-chloro-6,6-dimethylcyclohexanone (300 mg) in 5 ml of 3% potassium hydroxide in 60% aqueous dioxane was heated on the steam bath for 1.5 hours then left at room temperature overnight. The bulk of the solvent was removed under reduced pressure, water added, and the neutral product (103 mg) extracted into methylene chloride. The aqueous layer was then acidified and extracted with the same solvent. No extractable acid was obtained.

(*b*) The chloroketone (250 mg) and 1.2 ml of 4% sodium ethoxide in ethanol were heated for 16 hours at 145°. After hydrolysis in aqueous alcohol 125 mg of neutral material but only a trace of readily extractable acid were obtained.

(*c*) To a solution of 284 mg of the chloroketone in 20 ml of ether was added 300 mg of dry powdered potassium hydroxide. The mixture was heated in the water bath for 2 hours. The readily extractable products were 172 mg of neutral material and 16 mg of acid. The latter had a different infrared spectrum from 2,2-dimethylcyclopentanecarboxylic acid.

2-Bromo-6,6-dimethylcyclohexanone

The bromoketone was formed rapidly when a solution of 1.05 molar equivalents of bromine in ethanol-free chloroform was added dropwise to 2,2-dimethylcyclohexanone in ethanol-free chloroform. After recrystallization from ether–pentane and sublimation at 40°, 1×10^{-3} mm, it melted at 57–58° and had $\nu_{max}^{CHCl_3}$ 1725 cm^{-1} and λ_{max} 292 mμ (ε 32). Found: C, 47.05; H, 6.26. Calc. for $C_8H_{13}OBr$: C, 46.84; H, 6.36.

Action of Silver Nitrate on 2-Bromo-6,6-dimethylcyclohexanone (11)

A very slow reaction took place when a solution of 215 mg of the bromoketone and 510 mg of silver nitrate in approx. 75% aqueous ethanol stood at room temperature. After 6 hours' refluxing, however, 176 mg of silver bromide (1 molar equivalent) had precipitated. The readily extractable products were 55 mg of neutral material and a trace of acid.

α-Aminocamphor

Deamination of α-Aminocamphor

α-Aminocamphor hydrochloride (33) (1.2 g) was dissolved in 8 ml of 0.2 *N* sulphuric acid. A solution of 2 g of sodium nitrite was added dropwise with stirring while the temperature was held at 25° C (addition time 20 minutes). The mixture was then left for 10 minutes, basified with sodium bicarbonate, and extracted with methylene chloride. The neutral products recovered from the methylene chloride were examined using v.p.c. (column R, 1 m, 120° C, flow rate 120 cc/min). Two components were readily eluted, with retention times of 14 and 20 minutes. Their peak areas were in the ratio 1:5 respectively. When a methylene chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution of the neutral product was shaken with 5% sodium hydroxide solution and the contents of the organic phase re-examined a new component, with retention time 6 minutes under the above conditions, was observed. This component also appeared if the deamination mixture was adjusted to pH 9–10 after reaction, left for 0.5 hour, then extracted with methylene chloride.

Cyclocamphanone XI

Retention time, 14 minutes. It was identified by comparison of retention time and melting point with an authentic sample prepared according to Schiff (34) and Takeuchi (35).

Cyclocamphanone was unchanged after 1 hour in approx. 0.1 *N* sulphuric acid in 50% aqueous dioxane. A methylene chloride solution of the ketone was shaken for 10 minutes with 5% sodium hydroxide solution. No trace of other readily eluted compounds was detected by v.p.c. after this treatment. Hence, this ketone is not the source of other products under the conditions of deamination and subsequent work-up.

6-Isopropenyl-6-methyl-2-cyclohexene-1-one (XII)

Retention time 20 minutes. It was redistilled over a short path at 100°, 15 mm pressure, after recovery from the preparative v.p.c. column. It had λ_{max} 225 mμ (ε 8770) and 327 mμ (ε 57); $\nu_{max}^{CCl_4}$ 1680 cm^{-1} ($\diagdown$C=O), 1640 and 898 cm^{-1} ($\diagdown$C=CH$_2$). Found: C, 79.66; H, 9.32. Calc. for $C_{10}H_{14}O$: C, 79.95; H, 9.39.

6-Isopropenyl-6-methylcyclohexanone

6-Isopropenyl-6-methyl-2-cyclohexene-1-one (500 mg) was dissolved in glacial acetic acid. Zinc dust (ca. 0.5 g) was added, and the mixture stirred for 1 hour. It was then diluted with 10 ml of water, filtered, and the filtrate extracted with methylene chloride. The organic phase was washed with sodium bicarbonate solution, then with water. The product remaining in the methylene chloride was distilled over a short path at 100° under 15 mm pressure. It had $\nu_{max}^{CCl_4}$ 1710 cm^{-1} (C=O), 1640 and 895 cm^{-1}. Its n.m.r. spectrum contained a doublet centered at τ 5.2 (2 hydrogens, J = 10 c.p.s.). Found: C, 79.01; H, 10.46. Calc. for $C_{10}H_{16}O$: C, 78.98; H, 10.59.

6-Isopropyl-6-methylcyclohexanone

6-Isopropenyl-6-methylcyclohexanone in 95% ethanol over 30% Pd/C rapidly absorbed 1 mole of hydrogen. The product had $\nu_{max}^{CCl_4}$ 1705 cm^{-1}. Found: C, 77.92; H, 11.90. Calc. for $C_{10}H_{18}O$: C, 77.86; H, 11.76.

6-Methyl-2-cyclohexene-1-one

Retention time, 6 minutes. After collection from the preparative column it was distilled over a short path at 70° under 10 mm pressure. It had λ_{max} 225 mμ (ε 10,350), 317 mμ (ε 56); $\nu_{max}^{CCl_4}$ 1680 and 1620 cm^{-1}. Found: C, 76.58; H, 8.90. Calc. for $C_7H_{10}O$: C, 76.32; H, 9.15. It gave a dinitrophenylhydrazone, m.p. 161–162° (reported m.p. 162° (14)).

A solution of 6-isopropenyl-6-methyl-2-cyclohexene-1-one in a 2:1 mixture (v/v) of 12 *N* sulphuric acid and methanol was refluxed for 1 hour. The product had identical retention time on column R with the 6-methyl-2-cyclohexene-1-one from the deamination reaction.

Reactions of Diazocamphor

(*a*) Finely divided diazocamphor (34, 35) (50 mg) was suspended in 2 ml of 0.2 *N* sulphuric acid for a period of 1 hour. The mixture was basified with sodium carbonate and extracted with methylene chloride. The products were identified by v.p.c. using column R to be 6-isopropenyl-6-methyl-2-cyclohexene-1-one 6-methyl-2-cyclohexene-1-one, and cyclocamphanone.

(*b*) In order to simulate the deamination conditions, 50 mg of finely divided diazocamphor was suspended in 2 ml of 0.2 *N* sulphuric acid, and a solution of 0.5 g of sodium nitrite in 1 ml of water was added. The mixture was left at room temperature for 2 hours. It was then basified with sodium carbonate and extracted with methylene chloride. Vapor phase chromatography on column R showed the readily eluted products to be 6-isopropenyl-6-methyl-2-cyclohexene-1-one and cyclocamphanone.

ACKNOWLEDGMENTS

We are grateful to Dr. F. A. L. Anet for valuable discussions. We wish to thank Mr. H. Seguin for the analyses, Mr. R. Lauzon for the infrared spectra, and Mr. J. Nicholson for n.m.r. spectra.

METHYL 3-NITRO- AND 3-AMINO-3-DEOXY-β-D-GALACTOPYRANOSIDE AND -MANNOPYRANOSIDE[1]

HANS HELMUT BAER AND FRANK KIENZLE
Department of Chemistry, University of Ottawa, Ottawa, Ontario
Received January 31, 1963

ABSTRACT

The steric course of the nitromethane cyclization of L′-methoxy-D-hydroxymethyldiglycolic aldehyde was investigated. Methyl 3-nitro-3-deoxy-β-D-galactopyranoside was shown to arise as a second major reaction product in addition to the previously isolated principal stereoisomer, the *gluco* derivative. The corresponding *manno* stereoisomer is formed to a smaller extent. The configurations of the new methyl nitrodeoxyglycosides were established by conversion into the corresponding amino derivatives and hydrolysis of these latter to the known 3-amino-3-deoxy-D-galactose and -D-mannose hydrochlorides. All the products were obtained in a crystalline state. The reaction lends itself to a facile preparation of the nitrogenous galactose derivatives.

In a previous paper (1) the cyclization with nitromethane of the dialdehyde L′-methoxy-D-hydroxymethyldiglycolic aldehyde (I), which is readily available by periodate oxidation of methyl β-D-hexopyranosides, was reported to furnish a crystalline methyl 3-nitro-3-deoxy-β-D-hexopyranoside in a yield of 40% or better. The product was subsequently (2) established to possess the *gluco* configuration (II). There was evidence that the condensation reaction proceeded to virtual completion although no studies were made concerning the stereoisomeric composition of more than one-half of the mixture of products that was obtained. In view of the results recently elaborated in the anomeric α-hexoside series (3) as well as in anhydro sugars (4, 5) a more thorough investigation of the nitromethane condensation of I appeared to be of interest.

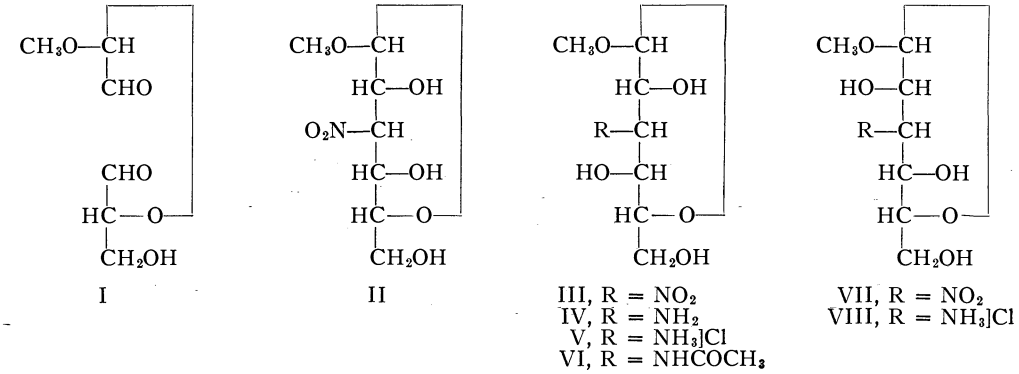
When the cyclization of I had been carried out in methanol in the presence of sodium methoxide, and had been followed by deionization of the solution and collection of the crystallizing nitroglycoside (40% of II and small fractions of undetermined composition[2,3]), there remained in the mother liquor a material which, at the time, failed to crystallize. Hydrogenation of this amorphous residue produced a crystalline aminoglycoside that had not been characterized further.[2] We have now found that the compound so obtained was methyl 3-amino-3-deoxy-β-D-galactopyranoside (IV). It is obvious, therefore, that the parent nitro compound, methyl 3-nitro-3-deoxy-β-D-galactopyranoside (III), was one of the products formed in the nitromethane cyclization in methanolic medium.

In an attempt to improve the preparation of the *galacto* derivatives we investigated the possibility of epimerizing the sodium nitronate of the glucoside II. As was demonstrated recently (3), *aci*-nitroglycoside salts in aqueous solution undergo spontaneous epimerizations at carbon atoms adjacent to the nitro grouping. While the experiments pertaining to the behavior of the glucoside II in aqueous alkali have not yet been concluded, preliminary evidence indicates that II can in fact be converted partly into III in this way. We were thus prompted to transfer the mixture of *aci*-salts, produced in methanol, into an aqueous medium for a short time prior to deionization, or indeed to conduct the whole cyclization in water in the presence of one equivalent of sodium hydroxide. In either case

[1]*Part X in the series "Cyclizations of Dialdehydes with Nitromethane". For Parts IX and VIII see references 5 and 3, respectively.*
[2]*See p. 2869 of reference 1.*
[3]*These fractions have now been shown to contain some methyl 3-nitro-3-deoxy-β-D-mannopyranoside.*

the proportions of II and III appeared to be shifted in favor of the latter, for the yields of isolable II were decreased to 24–25%, and at the same time it became possible to isolate 34% of crystalline III. The results to be described were obtained from cyclization experiments carried out in aqueous solution.

When the mother liquor remaining after the collection of the crystalline nitroglucoside II was inspected by paper chromatography, a pattern of nitro compounds was observed consisting of two major spots (R_f 0.57 and R_f 0.68) and a number of faster-moving weak spots. Whereas a relatively strong spot (R_f 0.68) was due to residual II, an even stronger spot (R_f 0.57) represented two new nitroglycosides, III and VII, which were not separated on paper. Their isolation and configurational elucidation will be described here. The products migrating faster than II were present in small amounts only and have not been identified.[4]



The three nitroglycosides II, III, and VII were separated by fractional crystallization. Methyl 3-nitro-3-deoxy-β-D-galactopyranoside (III) was obtained in 34% yield and hence represented a major reaction product. It melted at 131–132° and had a specific rotation of $[\alpha]_D$ +32.6°. Catalytic hydrogenation furnished the corresponding amine, methyl 3-amino-3-deoxy-β-D-galactopyranoside (IV), with m.p. 175–176° (decomp.) and $[\alpha]_D$ −3.7°. A crystalline hydrochloride (V) and an N-acetyl derivative (VI) of the amino compound were also prepared. The amine IV proved to be identical with the aminohexoside that had been obtained previously but had not been characterized.[2]

Preliminary assignment to IV of the *galacto* configuration was suggested by the proximity of its specific rotation to that of a nitrogen-free analogue, methyl β-D-galactopyranoside ($[\alpha]_D$ −0.4°). It is a well-known rule that substitution of an amino group for a hydroxyl in glycosides has little influence upon the rotation.[5] Final proof was established by acid hydrolysis of IV (or V), which readily furnished known (6) 3-amino-3-deoxy-α-D-galactose hydrochloride. The identification of this amino sugar hydrochloride was corroborated by N-acetylation to 3-acetamido-3-deoxy-β-D-galactose and direct comparison of the latter with an authentic sample (6, 3).

Methyl 3-nitro-3-deoxy-β-D-mannopyranoside (VII) was present in the reaction mixture to a smaller extent than either of the glycosides II or III. It was rather difficult to obtain in pure condition, as multiple recrystallizations, causing loss of product, were

[4]*At least three compounds appeared to be present in the R_f range of 0.77 to 0.90. Accurate values are not available since the products do not separate well. Despite its subordinate amount, part of this material is of peculiar interest as it possesses a distinct growth-inhibiting activity against Bacillus subtilis. This merits further investigation.*

[5]*For literature see reference 4.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

required. Eventually the pure compound was isolated in a yield of about 2%, although in the mixture it amounted to at least 13%. The higher figure was based on the isolation of the corresponding amine following hydrogenation. The nitromannoside VII melted at 136–138° and showed $[\alpha]_D$ −81.7°. Configurational assignment was accomplished by experiments similar to those just described for the galactoside III. Catalytic hydrogenation afforded an aminoglycoside that was crystallized as hydrochloride VIII (m.p. 230–231°, $[\alpha]_D$ −68.5°). It was noted that the molecular rotation of VIII (M_D −15,600) agreed well with that of the nitrogen-free analogue, methyl β-D-mannopyranoside (M_D −13,400). Acid hydrolysis of VIII produced known (7) 3-amino-3-deoxy-α-D-mannose hydrochloride, thus proving the configuration of the glycosides VIII and VII.

A comparison of the above results with those obtained earlier in the α-hexoside series leads to the following conclusion concerning the practical applicability of the nitromethane cyclization. The value of the method for the purpose of preparing nitrogenous hexose derivatives with *gluco*, *manno*, *galacto*, and *talo* configurations is complementary in the two anomeric series. In the α-series (3, 7), *manno* and *talo* derivatives are readily available by the method whereas *gluco* and *galacto* derivatives, although obtainable, are isolated only with some inconvenience. The β-series, on the other hand, lends itself to the facile preparation of *gluco* (1, 2) and, as was shown here, *galacto* derivatives.

EXPERIMENTAL

The melting points were determined in an aluminum block. The optical rotations were taken in 2-dm tubes and refer to solutions in carbon-dioxide-free water; *c*, approximately 1%. All evaporations were done *in vacuo* at 35–40° (bath temperature) unless otherwise indicated. Paper chromatography was performed by the descending technique on Whatman No. 1 paper. The nitro compounds were irrigated with 1-butanol – acetic acid – water (4:1:5, v/v, upper layer) and made visible by spraying with alkali (1 part *N* NaOH + 4 parts methanol + 5 parts butanol) and inspection under an ultraviolet lamp. The amino compounds were irrigated with pyridine – ethyl acetate – acetic acid – water (5:5:1:3, v/v, with pyridine – ethyl acetate – water, 11:40:6, v/v, in the bottom of the tank) and indicated with ninhydrin. R_{gm} = speed relative to glucosamine hydrochloride.

A. The Nitromethane Cyclization

(a) Condensation in Methanolic Solution Followed by Equilibration in Water

L′-Methoxy-D-hydroxymethyldiglycolic aldehyde (I) was prepared and condensed with nitromethane in the presence of sodium methoxide in methanolic solution as described previously (1). After the reaction period of 45 minutes, however, the solution was concentrated rapidly in an efficient evaporator at 20° (bath temperature) to the consistency of a thick sirup. The sirup was immediately dissolved in 10 parts of carbon-dioxide-free water and the solution was allowed to stand for 40 minutes at 23°. It was then cooled in ice water and deionized with Amberlite IR-120 (H^+). For deionization and subsequent crystallization and purification of the nitroglucoside II the earlier directions (1) were followed. There resulted a yield of 25% of purified II.

(b) Condensation in Aqueous Solution

A solution of dialdehyde I (0.08 mole, obtained from 15.52 g of methyl β-D-glucopyranoside) in 100 ml of water was carefully adjusted at 0° with sodium hydroxide to the point of a pink phenolphthalein coloration that persisted for at least 1 minute (3.6 ml of *N* NaOH was required). Upon addition of 4.44 ml of nitromethane (1 molar equiv.) another 80 ml of *N* NaOH was added over a period of 10 minutes at 0°. The solution was then brought to room temperature with running warm water and allowed to stand for 40 minutes. Thereupon the reaction mixture was deionized by being poured into an ice-cold aqueous suspension of 120 ml of Amberlite IR-120 (H^+); stirring was applied for 10 minutes. The solution was decanted from the resin, which was washed several times with water, and the combined liquid was passed over a column containing another 50 ml of fresh exchange resin. The column was finally rinsed with water. Evaporation of the effluent furnished a sirup which was dehydrated by two consecutive evaporations with ethanol and two with ethyl acetate. The partly crystalline residue was triturated with 30 ml of ethyl acetate and the crystals were collected after some standing in the refrigerator. The yield of crude nitroglucoside II was 4.3 g (24.1%).

(c) Methyl 3-Nitro-3-deoxy-β-D-galactopyranoside (III)

The mother liquor that remained after removal of the crystalline nitroglucoside II (cf. preceding Section (*b*)) was shown by paper chromatography to contain major components of R_f 0.57 and 0.68 as well as minor

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

components in the range of R_f 0.77–0.90. The mother liquor was concentrated to a sirup that was inoculated with crystalline nitrogalactoside III.[6] Copious crystallization occurred at 0° within a few hours. The material was triturated with a little ice-cold ethyl acetate and the solid matter isolated and washed with cold ethyl acetate. The yield was 5.6 g (31.6%) of crude III (R_f 0.57) containing some of the *gluco* isomer II (R_f 0.68). Another 400 mg of III which was even purer than the main crop was obtained from the mother liquor, but, curiously enough, only after the nitromannoside VII had been isolated (cf. Section (*d*)). Thus the total yield of III was 34%.

The product was recrystallized by dissolution in the minimum amount of hot acetone and addition of chloroform to incipient turbidity. When the solution was cooled fine thin needles of III separated quickly; $[\alpha]_D^{23}$ +27.8°. Accompanying traces of II were rather difficult to remove. A sample that had been recrystallized five times was at last chromatographically uniform and showed $[\alpha]_D^{23}$ +32.6°. The air-dried product evidently contained solvent of crystallization. It melted upon rapid heating at 87–90°, but upon very slow heating or after drying at 80° at 3 mm the melting point was 131–132°. Slight changes in the infrared spectrum (in nujol) occurred when the air-dried substance was dried at 80° *in vacuo* for several hours, and the same changes resulted when it was kept in the molten state at 95° for a few minutes. The high-melting product when triturated with acetone–chloroform gave again the original spectrum. Anal. Calc. for $C_7H_{13}NO_7$ (223.2): C, 37.67; H, 5.87; N, 6.28. Found: C, 37.02; H, 6.20; N, 6.10.

(d) Methyl 3-Nitro-3-deoxy-β-D-mannopyranoside (VII)

The ethyl acetate filtrate from the main crop of crystalline III contained, besides remnant II and III, the nitromannoside VII, which was isolated in two portions. The first portion (A) crystallized together with II upon concentration of the filtrate and addition of a little ether. The second portion (B) was obtained from the remaining mother liquor by column chromatography.

The crystalline fraction A, after being washed with ice-cold, ether-containing ethyl acetate, weighed 490 mg, melted at 161–164°, and was shown by paper chromatography to contain a considerable amount of II. The material was recrystallized thrice from acetone–chloroform and subsequently treated with a small amount of boiling ethyl acetate. There remained 45 mg of crystals that did not dissolve in the ester. By means of their melting point (201–202°) and infrared spectrum they were identified as nearly pure nitroglucoside II. The acetone–chloroform mother liquors of the successive recrystallizations and the ethyl acetate extract were combined and the solvents removed, leaving a crystalline residue. From this a further 140 mg of somewhat less pure II was separated by one more recrystallization followed by extraction. The combined mother liquor and extract of this second sequence gave upon evaporation a residue which was recrystallized once again from acetone–chloroform. Thus 95 mg of a product with m.p. 133–134° and $[\alpha]_D^{23}$ −66.7° was obtained. It was nitromannoside VII (R_f 0.59) which was still accompanied by a small amount of nitroglucoside II (R_f 0.68).

For the isolation of the second portion of VII (B) the mother liquor from which fraction A had been separated was first reduced to a smaller volume and placed in the refrigerator. In the course of a few days a crystalline deposit was formed (400 mg) which by melting point and infrared spectrum was shown to be additional nitrogalactoside III (cf. preceding Section (*c*)). The mother liquor therefrom was then chromatographed on a cellulose column (3.7 cm×58 cm), the aforementioned solvent system for nitroglycosides being used. Although no satisfactory separation of the remaining nitroglycosides could be so achieved, the process served to remove fast-moving yellow impurities and unidentified by-products. The effluent containing the nitroglycosides afforded a material from which 100 mg of a crystalline mixture of II and VII, and 390 mg (2%) of pure VII (m.p. 136–138°; $[\alpha]_D^{23}$ −81.3°), could be obtained by fractional crystallization with ethyl acetate – ether. Anal. Calc. for $C_7H_{13}NO_7$ (223.2): C, 37.67; H, 5.87; N, 6.28. Found: C, 37.93; H, 5.88; N, 6.27.

B. Amino Derivatives

For hydrogenation of the nitroglycosides, by the use of a platinum catalyst in the presence of one equivalent of dilute hydrochloric acid, the directions given earlier (1, 3) for similar experiments were followed. Chloride ion was removed from the hydrogenated solutions with Dowex-1 (OH^-), grade X2.

(a) Methyl 3-Amino-3-deoxy-β-D-galactopyranoside (IV)

Nitrogalactoside III (223 mg) was hydrogenated to give, after recrystallization from 95% ethanol, 105 mg (54.5%) of colorless needles of IV showing m.p. 173–174° decomp., $[\alpha]_D^{23}$ −3.7° and R_{gm} 1.38. The infrared spectrum, mixed melting point, and R_{gm} value established the identity of the product with the methyl aminodeoxyhexoside that had been obtained previously as a by-product but had not been characterized in detail.[2]

The analytical sample was recrystallized once more from moist ethanol and then showed m.p. 175–176° decomp.; the specific rotation remained unchanged. Anal. Calc. for $C_7H_{15}NO_5$ (193.2): C, 43.51; H, 7.83; N, 7.25; OCH_3, 16.06. Found: C, 43.39; H, 7.54; N, 7.25; OCH_3, 16.20.

For the preparation of IV on a larger scale we found it convenient to hydrogenate directly, i.e., without prior isolation of crystalline III, the total residue from the mother liquor as it was obtained in the nitromethane condensations following removal of the main portion of II (cf. Sections A(*a*) and/or A(*b*)). The

[6]*Seed crystals were first obtained when a similarly prepared sirup was left in a refrigerator for several days.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

overall yields of pure IV were about 21% (based on the original starting material, methyl β-D-glucopyranoside).

Hydrochloride (V).—Evaporation with dilute hydrochloric acid of a sample of IV, followed by trituration of the residue with methanol, furnished clusters of fine needles that were recrystallized from ethanol (95%) – ethyl acetate. It was the hydrochloride V; $[\alpha]_D^{23}$ −3.1°. It melted with decomposition at about 227° on rapid heating; slow heating resulted in gradual darkening without distinct melting.

(b) Methyl 3-Acetamido-3-deoxy-β-D-galactopyranoside (VI)

N-Acetylation of the free base IV (200 mg) as applied earlier to the *gluco* isomer (1, 2) yielded 174 mg (71.3%) of white needles of VI; m.p. 239°, $[\alpha]_D^{23}$ +52°. Anal. Calc. for $C_9H_{17}NO_6$ (235.2): C, 45.95; H, 7.29; N, 5.96. Found: C. 46.13; H, 7.10; N, 5.88.

Hydrolysis of a sample in 4 *N* hydrochloric acid for 3 hours at 100° gave 3-amino-3-deoxy-D-galactose hydrochloride as the only sugar detectable by paper chromatography.

(c) 3-Amino-3-deoxy-α-D-galactose Hydrochloride

Methyl aminodeoxygalactoside IV (160 mg) was hydrolyzed with 32 ml of 4 *N* HCl for 3 hours at 100°. The hydrolyzate was evaporated with addition of several successive portions of water and finally of toluene. The residue upon trituration with ethanol started to crystallize at once and was collected after standing for 2 hours at 0°. The yellowish-white product was recrystallized by dissolution in the minimum amount of water required and addition of excess ethanol. The yields found in several parallel runs were 80–85%. The colorless crystals were chromatographically uniform (R_{gm} 0.90). $[\alpha]_D^{23}$ +109° → +82.0° (final, after 2 hours); final values of samples from parallel runs, +82.1°, +82.7°. Reported values (6), $[\alpha]_D$ +115° → +89° (2 hours). We were unable to confirm the melting point quoted (6), but observed slow decomposition above 200°.

(d) 3-Acetamido-3-deoxy-β-D-galactose

The above hydrochloride (1.25 g) was N-acetylated according to a known procedure (8, 2). There was obtained 996 mg (78%) of an acetamido sugar melting at 162–164°. Repeated recrystallization from ethanol – ethyl acetate afforded a product of m.p. 173° and $[\alpha]_D^{23}$ +92.5° → +118.0° (final, 2.5 hours). Reported (6), m.p. 170–172° and $[\alpha]_D$ +99° → +119° (2.5 hours). Our product and an authentic sample of 3-acetamido-3-deoxy-β-D-galactose kindly supplied by Professor R. Kuhn, Heidelberg, gave identical infrared spectra and a mixed melting point of 171–173°.

(e) Methyl 3-Amino-3-deoxy-β-D-mannopyranoside Hydrochloride (VIII)

(*i*) A sample of 62 mg of nitromannoside VII (not quite pure; m.p. 133–134°) was hydrogenated and afforded, upon evaporation without prior removal of chloride ion, a partly crystalline material. This was recrystallized from ethanol – ethyl acetate to give 45 mg (67%) of oblong, rectangular prisms of VIII; m.p. 230–231° decomp., R_{gm} 1.27, $[\alpha]_D^{23}$ −68.5°.

(*ii*) A nitromethane condensation with 0.04 mole of dialdehyde I had been performed in aqueous solution and had furnished about 25% of crystalline nitroglucoside II. The mother liquor had then been hydrogenated, giving 20.5% of crystalline aminogalactoside as free base IV. (See Sections A(*b*) and B(*a*).) The filtrate therefrom was now evaporated and the residue taken up in water and acidified with 20 ml of *N* hydrochloric acid. Evaporation with several consecutive portions of water followed by ethanol gave a quickly crystallizing residue of amine hydrochlorides. The material was allowed to stand overnight under some ethanol at 0°. The crystals were collected, washed with cold ethanol, and dried. The product (1.184 g, 12.9%) was VIII and showed m.p. 228–229° decomp., and $[\alpha]_D^{23}$ −68.3° after one recrystallization from aqueous ethanol. It was chromatographically uniform (R_{gm} 1.24) and was identified by infrared spectroscopy with the preparation obtained under (*i*). Anal. Calc. for $C_7H_{16}O_5NCl$ (229.7): C, 36.61; H, 7.02; N, 6.10. Found: C, 36.04; H, 6.89; N, 6.39.

The mother liquor after the crystallization of VIII deposited, on standing and careful addition of a little ethyl acetate, a small amount of crystals (36 mg), also melting with decomposition at about 228°. They were, however, identified as aminogalactoside hydrochloride (V) from the results of rotation ($[\alpha]_D^{23}$ −3.15°) and chromatography (R_{gm} 1.39). This was confirmed by acid hydrolysis to yield crystalline 3-amino-3-deoxy-D-galactose, which was identified by its infrared spectrum and chromatogram.

(f) 3-Amino-3-deoxy-α-D-mannose Hydrochloride

A 30-mg sample of pure VIII was hydrolyzed with 6 ml of 4 *N* hydrochloric acid for 3 hours at 100°. The reducing amino sugar hydrocholoride was obtained in crystalline condition as in the previously described (7) hydrolysis of the anomeric glycoside, and was found identical with a specimen from that work by comparison of the infrared spectra, R_{gm} values (1.12), and mutarotation data. $[\alpha]_D^{23}$ +16.5° → +6.1° (2 hours, final).

CORRELATION OF CHEMICAL COMPOSITION AND OPTICAL ROTATION OF NATIVE XYLANS

R. H. MARCHESSAULT, H. HOLAVA, AND T. E. TIMELL
State University College of Forestry at Syracuse University, Syracuse, N.Y., U.S.A.
Received February 11, 1963

ABSTRACT

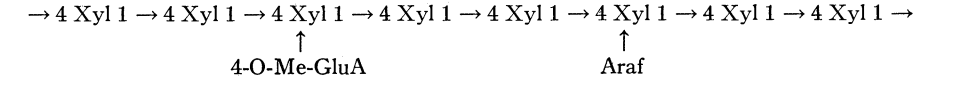
The principle of optical superposition has been used to derive an equation relating the specific rotations of native xylans with their content of 4-O-methylglucuronic acid and/or arabinofuranose residues. The equation is in good agreement with literature data for the 4-O-methylglucuronoxylans and the arabinoxylans. Based on this correlation, an α-L-linkage is suggested for the arabinofuranose residues in various arabinose-containing xylans. Literature rotations for the 4-O-methylglucuronoarabinoxylans are consistently greater than values predicted by the equation. Finally, the rotatory dispersion behavior of acidic and neutral xylans is examined.

I. INTRODUCTION

There is good evidence (1) that the basic structure of many plant xylans and particularly those from wood consists either of a linear or moderately branched chain of β-D-xylopyranose residues, joined by (1 → 4)-glycosidic bonds. The configuration and position of branching, if such exists, has not been established. Wood xylans are known to be heavily substituted along the backbone by (1 → 2)-linked 4-O-methyl-α-D-glucuronic acid residues. Evidence so far accumulated indicates that these substituents occur randomly along the macromolecule. Thus, it has been possible to isolate xylan fractions even from the same plant with varying percentages of uronic acid (2, 3). Hydrolytic fragments averaging 30–60 xylose units completely free of uronic acid have also been isolated from xylans of relatively high acid content (4, 5). Finally, the X-ray diagrams of xylans with varying uronic acid content do not differ (6), whereas the opposite would be expected if the acid groups were regularly spaced.

The acidic softwood xylans also contain arabinofuranose residues. Such residues are especially abundant in the neutral arabinoxylans occurring in cereal gums (1). 4-O-Methylglucuronoxylans from hardwoods are esterified with O-acetyl groups in the xylan backbone (7, 8). Both these substituents can be removed by acidic and alkaline hydrolysis, respectively, in treatments which are very mild, and in the present study, therefore, will be assumed not to alter the remainder of the polymer chemically.

For the purposes of this study, plant xylans are divided into four categories: neutral xylans; acid xylans, i.e. those carrying the 4-O-methyl glucuronic acid side chains; arabinoxylans; and xylans containing both arabinose and acid moieties. The basic structure of the latter is illustrated in Fig. 1. It has been shown (9) that the neutral xylan has the



(Xyl = β-D-xylopyranose, 4-O-Me-GluA = 4-O-methyl-α-D-glucuronic acid, Araf = α-L-arabinofuranose)

FIG. 1. Schematic structure of an arabino-4-O-methylglucuronoxylan.

optical rotation which would be predicted on the basis of the rotation of the β-(1 → 4)-linked oligomers, viz. −102°. Acid xylans and arabinoxylans, however, have rotations

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which differ widely from this value, ranging from −37° down to −108°. To some extent this variation is due to unavoidable contamination by other polysaccharides of significantly different structure and rotation. However, it seems reasonable to assume that most of this variation represents the contribution to the optical rotation by the appended acid and arabinose moieties. It should be possible, therefore, by application of the principle of optical superposition to predict the exact rotation of a xylan with any given composition of acid, arabinose, and xylose units, provided the respective linkages are the same in all polysaccharides of this class. It was the aim of this study to show that present data in the literature are generally in agreement with this hypothesis.

II. THEORETICAL

Let: n be the number of unsubstituted units in a linear xylan chain;
m be the molar rotation of an unsubstituted xylose unit in the chain;
u be the molar rotation of a 4-O-methyl-α-D-glucuronosyl xylose residue in the chain;
σ be the ratio of xylose to the above aldobiuronic acid residue;
ϕ be the molar rotation of a xylan chain with a ratio σ of xylose to aldobiuronic acid groups.

It will be assumed that the chains are long enough to ignore the special contribution of the two end groups, which are presumed to consist of xylose. Should they be acid groups, any special contribution due to their rotation because of this is probably negligible. Present data indicate that this assumption is entirely reasonable (9).

It follows from the principle of optical superposition that the molar rotation per xylose residue of a linear xylan chain with randomly occurring 4-O-methylglucuronic acid substituents is:

[1] $$\frac{\phi}{n\left(1+\frac{1}{\sigma}\right)} = \frac{m\cdot n + u\cdot n/\sigma}{n\left(1+\frac{1}{\sigma}\right)} = \frac{m+u/\sigma}{\left(1+\frac{1}{\sigma}\right)}.$$

Since

[2] $$[\alpha]_D = \frac{\phi}{n\left(1+\frac{1}{\sigma}\right)} \times \frac{1}{\left(132+\frac{190.35}{\sigma+1}\right)},$$

where the factor $[132 + 190.35/(\sigma+1)]$ is the average residue weight of each xylose unit in the polymer backbone with the 4-O-methylglucuronic acid averaged into each, it follows that:

[3] $$[\alpha]_D\left(132+\frac{190.35}{\sigma+1}\right)\left(1+\frac{1}{\sigma}\right) = m+\frac{u}{\sigma}.$$

A plot of the left-hand side of equation [3] for linear xylans of varying acid content should yield a straight line of intercept m and slope u.

The quantity m, available experimentally from the neutral xylan oligosaccharide series, is −13,500. The quantity u is not available at present since it could only be derived from the difference in molar rotations of xylobiose and the symmetrical 4-O-methyltetrauronic acid. It is expected, however, that u will be given to a sufficient approximation by the difference in molar rotation between the aldotetrauronic acid, derived from enzymatic hydrolysis of xylan (10(*a*)), and xylobiose; thus $u = +7900$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Equation [3] is equally applicable to the arabinoxylans, in which case σ becomes the ratio of unsubstituted xylose to the arabinosyl xylose disaccharide and u is replaced by f, the molar rotation of the latter in the chain.

III. OBSERVED ROTATION AND STRUCTURE OF NATIVE XYLANS

The xylan samples used are listed in Table I together with references to the original literature describing their isolation and characteristics.

TABLE I

Aspen	9	− 76.2	−13,000	12
White elm	7	− 66.7	−12,426	13

*Adjusted to value for infinite chain length.

The polysaccharides were dissolved in 10% aqueous sodium hydroxide by shaking the mixture overnight. Some turbidity often remained the following morning. It could be removed by centrifuging in a Servall centrifuge for 2 hours at 10,000 r.p.m. The loss in weight of the solution and change in rotation after centrifuging were shown to be negligible. Optical rotation measurements were made on a model 80 Rudolph polarimeter with photoelectric detection, which was kept in a controlled-temperature room at 19–20° C. Either a 2- or 1-dm tube was used depending on the clarity and/or concentration. Monochromatic radiation was provided by a sodium lamp.

The observed optical data are listed in Table I along with the values of ϕ/n which correspond to the left-hand side of equation [3]. Figure 2 is a plot of the data according

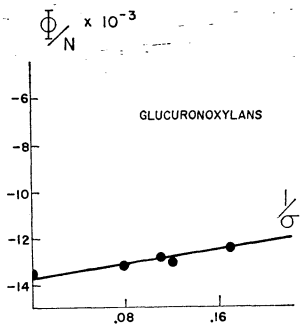

FIG. 2. The molar rotation per unsubstituted xylose residue versus the reciprocal ($1/\sigma$) of the xylose to aldobiouronic acid ratio for hardwood xylans.

to equation [3]. The line corresponds to a theoretical slope of +7900, which fits the data very well.

Similar data for arabinoxylans were compiled from the literature. These are summarized in Table II. Since some of these xylans are reportedly branched, application of equation [3] implies the tacit assumption that the configuration of the branchpoint is the same as that in the main chain and the molar rotation of the xylose at the branch is unaffected.

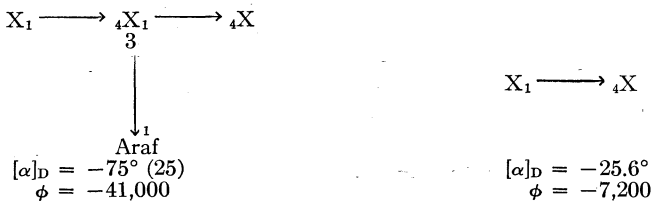
Barley flour	1.6	−104.0	−60,300	18
Wheat flour	1.5	−108.0	−71,400	19

The data in Table II cover an exceedingly broad range of σ values, e.g. when $\sigma = \infty$ there are no arabinose units while $\sigma = 0.5$ means more arabinoxylose than xylose units in the chain, yet all the data fall on a straight line. The slope of this line is −29,400, which should correspond to the molar rotation of an arabinosyl xylose residue in the chain. From the literature, the value for this disaccharide unit can be computed as the difference between the molar rotation of the symmetrical arabinosyl xylotriose and xylobiose:



The calculated value of −33,800 is subject to the assumption that the same equilibrium mixture of anomers is present in solution for the two compounds. Thus, the calculated value and that derived from the plot in Fig. 3 are in reasonable agreement.

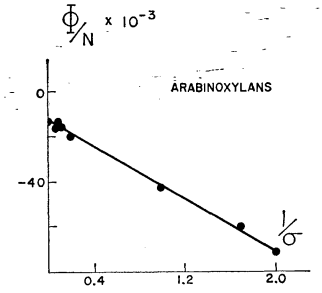


FIG. 3. The molar rotation per unsubstituted xylose unit versus the reciprocal of the xylose to arabinoxylose disaccharide ratio for arabinoxylans.

IV. DISCUSSION

The most important comment concerning the foregoing data, aside from the fact that they confirm the assumptions made in the derivation of equation [3], concerns the difference in sign of the slopes in Figs. 2 and 3. In both cases the slope represents the molar rotation of the disaccharide unit in the chain and since the α-D-configuration of the 4-O-methylglucuronosyl xylose is well established (29), the opposite sign strongly favors the assignment of an α-L-configuration for the arabinosyl xylose unit, which is known to contain an L-arabinofuranose sugar. Application of Hudson's rules to the molar rotation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

for the arabinosyl xylose in the chain also favors the α-L-assignment. Finally, the same configuration was recently suggested by Perlin and co-workers (25) on the basis of enzyme studies.

The apparent value of −29,000 for the molar rotation of the arabinosyl xylose residue in the polymer chain corresponds to an average value of −14,500 for each sugar moiety. Since this is only slightly less than the value of −13,500 for each xylose unit, it is readily understood why arabinoxylans have specific rotations in the same range as the neutral esparto xylan, namely about −100°.

Many native xylans, such as those present in softwoods, contain both 4-O-methylglucuronic acid and arabinose side chains. By a derivation similar to that presented above, it is possible to show that for this class of polysaccharides the following relation holds:

$$[4] \qquad [\alpha]_D\left(132+\frac{190.35}{\sigma+1+\sigma/\mu}+\frac{132}{\mu+1+\mu/\sigma}\right)\left(1+\frac{1}{\sigma}+\frac{1}{\mu}\right)=m+\frac{u}{\sigma}+\frac{f}{\mu},$$

where μ is the ratio of xylose to arabinosyl xylose residues in the chain, f is the molar rotation of this disaccharide unit, and the other symbols are as before. Equation [4] reduces to equation [3] when $\mu = \infty$ (no arabinose side chains). Since σ and μ can be determined experimentally, it is again possible to compute $[\alpha]$ for a given xylan of this class. Table III shows some data taken from the literature for a number of such xylans along with the

*Calculated from equation [4] with: $u = 7900$; $f = -29{,}400$; $m = -13{,}500$.

observed and calculated rotations. The lack of agreement between the experimental values and those derived from the equation is striking. Experimental values are consistently lower than those calculated. This suggests either that the assumed structure is actually not the one on hand or the samples are impure.

V. ROTATORY DISPERSION OF XYLANS

Rotatory dispersion measurements were made on several xylan samples used in this study. A model 80 Rudolph spectrapolarimeter was used over the 350 to 750 mμ wavelength range to record the optical rotation. The results were plotted according to the modified Drude equation:

$$\overline{[\alpha]}_\lambda\lambda^2 = k+\overline{[\alpha]}_\lambda\lambda_c^2$$

where k is the rotation constant and λ_c the dispersion constant. The latter was found to decrease slightly with increasing uronic acid content. The curves are shown in Fig. 4. The extrapolated value for λ_c for a neutral xylan is 207. A summary of the various rotation and dispersion constants for the neutral and acidic xylans is presented in Table IV.

Neutral xylan*	∞	—	207	10% NaOH
Xylohexaose	∞	−24.2	187	H_2O

*By extrapolation to zero acid content.

The distinct difference in λ_c for the neutral xylan and the oligosaccharide is reminiscent of the similar, albeit much greater, difference reported for an oligopeptide series (26). A decisive factor in the latter case is the hydrogen-bond-stabilized alpha-helix, which establishes a regular helical conformation in solution once the chain is composed of a minimum number of monomers. For polysaccharides in a good solvent, the situation is similar to that of a polypeptide in a non-helical solvent, where little or no change in λ_c would be expected. Nevertheless, the observed increase in the dispersion constant in going from the hexamer to the long chain is strongly suggestive of a conformational influence on the optical rotation even in a good solvent. This influence is most probably a simple energetic preference for a certain rotational isomer due to rotation around the bridge C_1—O—C_4 linkage. In this respect the influence of solvent is most probably important.

NOTES

THE INFLUENCE OF A VEHICLE-IMMISCIBLE, ADSORBABLE, THIRD COMPONENT ON THE FLOCCULATION OF LARGE-DIAMETER PARTICLES

J. J. Chessick, A. C. Zettlemoyer, and John B. Christian

INTRODUCTION

Flocculation processes of large-diameter (ca. 0.2 to 0.5 μ) solid particles as a function of the amount of vehicle-immiscible, adsorbable, third component present have rarely been studied. Definitive, mechanistic descriptions are lacking despite recent evidence that structural characteristics of such systems change with amount of flocculant present. Indeed, preliminary results indicate that flocculation processes of such polar solid particles in nonpolar organic vehicles with water as the flocculant should not be expected to conform to a general pattern.

Presentation of the brief results reported here was stimulated by a study of 14 m^2/g $BaSO_4$ – benzene – (flocculant) water systems reported by Smith and Puddington (1).

EXPERIMENTAL

In the prior work of Smith and Puddington (1) $BaSO_4$ evacuated at 200° and dry benzene were mixed asceptically before dispersion and before measurements of sedimentation volumes were made. Water was then introduced at definite and increasing concentrations, also prior to mixing and dispersion.

In the study reported here, a kaolin clay consisting of plate-like particles with an average size of ca. 0.3 μ and the dispersion medium decane were equilibrated at R.H.'s varying from 5.8 to 98% before mixing and dispersion. Dispersion was effected using a typical shaking apparatus for a period of 30 minutes; quantitative data are unavailable but there is little doubt that the systems were subjected to very small work levels. Systems consisting of solids dried over P_2O_5 at 100° and 200° before mixing with dried decane were also investigated. Other techniques used are described below. Sedimentation rates and final sediment volumes (heights) were determined.

RESULTS AND DISCUSSION

Final sedimentation heights for $BaSO_4$–benzene systens as a function of the amount of water associated with the solid, as determined by Smith and Puddington (1), are illustrated qualitatively in Fig. 1. These values were interpreted in terms of flocculation of $BaSO_4$ (the same number of dispersed particles per unit volume of benzene was apparently assumed) in benzene as a result of varying amounts of water adsorbed on the particle surfaces. The sedimentation height at zero water content reflected sedimentation of (little) flocculated, irregular particles (state A, Fig. 1). A voluminous, gel-like sediment (state B) due to rather small amounts of water at junction points between particles accounted for the maximum sediment volume. The formation of large, more sperical flocs at high water content was postulated (state C).

Sedimentation height and sedimentation rate data for the clay – decane – (flocculant) water systems are presented in Figs. 2 and 3, respectively. Final sedimentation heights represented by points I, II, and III of Fig. 2 are for suspensions containing solids dried over P_2O_5 at 100° or 200° before mixing and dispersion in dry decane. These heights decreased slightly with increasing severity of outgassing. Sedimentation rates for these dispersions were the second largest measured (curves D and E, Fig. 3). The combined results reveal that these low volumes resulted, not from minimal flocculation in water-free systems, but as a result of the increased resistance to dispersion of solid agglomerates.

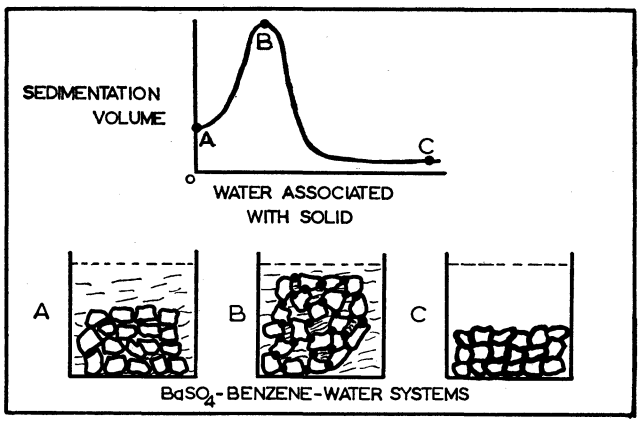

FIG. 1. Final sedimentation heights for $BaSO_4$–benzene suspensions as a function of water content (H. R. Smith and I. E. Puddington, Can. J. Chem., **38**, 1911 (1960); reproduction permission obtained).

This strong agglomeration is due to capillary forces as water is removed progressively, at elevated temperatures, from interparticle pores between primary particles. The results of Smith and Puddington at zero and low water content for 200° activated $BaSO_4$ in benzene could be manifestations of this same phenomenon rather than the postulated (1) sedimentation of only moderately flocculated particles.

Systems made up of kaolin and decane equilibrated separately at 10, 20, 50, and 80% R.H. yielded essentially the same final sedimentation volumes and rates. Thus it is reasonable to conclude that similar initial states of dispersion were achieved. The conclusion that flocculation was due to and independent of the amount of water present in this R.H. range is therefore reasonable.

Equilibration of the components at 98% R.H. decreased the sedimentation volume to the lowest value observed; sedimentation of the 98% R.H. system was almost instantaneous (curve E, Fig. 3). The question arises as to whether excess water prevents dispersion. Upon dispersing 10, 20, 50, 90, or 98% systems and then injecting 0.1 and 0.2 ml H_2O, systems were produced having sedimentation heights all ca. 2.4 cm; this is equal to the value for the 98% R.H. equilibrated system. Adding excess water to these equilibrated systems prior to dispersion also produced a similar sedimentation volume.

Pretreatment of components at 5.8% R.H. led to a decreased sedimentation height relative to the maximum value. To eliminate the possibility of capillarity influences, 10% R.H. dispersed systems were injected with small amounts of P_2O_5 or absolute ethanol equivalent to that calculated amount of water originally present. The sedimentation height decreased to 2.8 cm (point IV, Fig. 2); the sedimentation rate (curve A, Fig. 3) was the *smallest* observed. These combined data support the contention that sedimentation occurred of particles which were less flocculated than in systems at higher water content.

The low sedimentation heights for temperature-evacuated samples (illustrated by points I, II, and III, Fig. 2) in the absence of rate data could have been ascribed to the sedimentation of small, sol-stabilized particles as suggested by Smith and Puddington (1).

Except for high temperature evacuated kaolin in dry decane systems the mechanisms of flocculation proposed by Smith and Puddington (1) can be used to explain the results of Figs. 1, 2, and 3. These are:

(1) The removal of interparticle water from pores between primary particles of an agglomerate by temperature evacuation decreases dispersability. Large irregular aggregates settle rapidly.

(2) Water removed in a manner that eliminates the influence of capillarity permits a sediment of irregular particles which are least flocculated by water. The lowest sedimentation rates are found in these systems.

(3) Water present in systems preconditioned at R.H.'s between 10 and 80% contains the same number of particles per unit volume after dispersion as in systems 2 and 4. Particles flocculate as a consequence of adsorbed water between particles; a more voluminous gel-like sediment results.

(4) At high water contents, more spherical flocs form, made up of a number of originally dispersed units, containing interparticle pore water; instantaneous sedimentation to the lowest volume is observed.

While the same mechanisms were proposed by Smith and Puddington (1), it is important to point out that their experimental findings possibly are not due alone to flocculation of solid particles in comparable initial states of dispersion, particularly at zero and low water contents.

Preliminary data obtained with another small-area oxide reveals the existence of significant differences in flocs formed at water levels different than reported here. A variety of systems need to be studied comprehensively. However, the data obtained in a similar manner for a chloride-process particle were in general agreement with the results of Smith and Puddington (1). Indeed, further investigations revealed that capillary forces due to water removal at 200° C from pores with $BaSO_4$ agglomerates were not important (2).

THE ISOLATION OF 1,8-DIHYDROXY-3-METHYL-9-ANTHRONE FROM THE ROOT OF RUMEX CRISPUS LINN.

Ausat A. Khan

King *et al.* (1) have reported the isolation, from petroleum ether (60–80°), of an anthrone of the heartwood of *Ferrierea Spectabilis* (leguminose), which they named 1,8-dihydroxy-3-methyl-9-anthrone (I). Tsukida (2) has reported the presence of I in plants containing hydroxyanthraquinones and has found that the Japanese *Rumex* species (*Rumex Japonicus*) contains 'chrysophanic acid' (II), Emodin (III), I, and several other anthraquinones in minor quantities. In the present work it is found that the Argentine *Rumex Crispus* contains I as a major constituent and II and III as minor constituents.

I has been isolated in the present work in 0.3% yield from the finely divided roots of *Rumex Crispus* Linn., locally called 'lengua de vaca', as yellow needles, m.p. 206–208°. I was isolated by a convenient process of keeping the extract at 0° for 5 days to give a solid mass, which is deposited on the surface of the vessel. The solid mass was recrystallized from chloroform to give yellow needles of I. Removal of the solvent and fractional crystallization from benzene yielded chrysophanic acid, m.p. 194–196° (3), and Emodin, m.p. 254–256° (4). The total yield of II and III was 0.03% in this variety.

I gave an acetyl derivative, m.p. 234–236°, and with dimethyl sulphate yielded a methyl derivative, m.p. 140–142°.

EXPERIMENTAL

1. Extraction of I

Air-dried finely divided roots (1 kg) of *Rumex Crispus* Linn. (lengua de vaca) were extracted by being refluxed for 6 hours with 1.5 l. of petroleum ether (60–80°). Three more such extractions were carried out and the total extract was kept at 0° for 5 days whereby a solid mass (0.9 g) deposited. It was filtered and crystallized from chloroform as yellow needles, m.p. 206–208°.

The solvent was distilled under reduced pressure whereby a solid mass (0.3 g) separated which when

The total yield of II and III was 0.03% in this variety.

I gave an acetyl derivative, m.p. 234–236°, and with dimethyl sulphate yielded a methyl derivative, m.p. 140–142°.

EXPERIMENTAL

1. Extraction of I

Air-dried finely divided roots (1 kg) of *Rumex Crispus* Linn. (lengua de vaca) were extracted by being refluxed for 6 hours with 1.5 l. of petroleum ether (60–80°). Three more such extractions were carried out and the total extract was kept at 0° for 5 days whereby a solid mass (0.9 g) deposited. It was filtered and crystallized from chloroform as yellow needles, m.p. 206–208°.

The solvent was distilled under reduced pressure whereby a solid mass (0.3 g) separated which when

crystallized from benzene yielded chrysophanic acid (II) as bright yellow needles, m.p. 196–198°, and Emodin (III) as bright orange needles, m.p. 254–256°.

Anal. Calc. for $C_{15}H_{12}O_3$ (I): C, 75.0; H, 5.0%. Found: C, 74.85; H, 4.91%. Anal. Calc. for $C_{15}H_{10}O_4$ (II): C, 70.86; H, 3.96%. Found: C, 70.51; H, 3.8%. Anal. Calc. for $C_{15}H_{10}O_5$ (III): C, 66.67; H, 3.73%. Found: C, 66.32; H, 3.9%.

2. Acetylation of I

A mixture of I (0.2 g), acetic anhydride (9 ml), and pyridine (1.5 ml) was refluxed for 2 hours. The reaction was then allowed to cool and poured onto crushed ice whereby a solid mass separated. It was filtered, washed well, and finally crystallized from aqueous alcohol to yield the acetyl derivatives as colorless needles, m.p. 234–236° (lit. m.p. 236–237°).

Anal. Calc. for $C_{21}H_{18}O_6$: C, 68.8; H, 4.95%. Found: C, 68.6; H, 4.7%.

3. Methylation of I

A mixture of 0.1 g of I, 0.5 ml of dimethyl sulphate in 200 ml of dry acetone, and 3 g of freshly ignited potassium carbonate was refluxed for 48 hours. At this stage a test sample did not give a color with ferric chloride.

The solution was filtered when cool; the residue obtained by removal of the solvent from the filtrate, when crystallized from dilute methanol, yielded colorless needles, m.p. 140–142° (lit. m.p. 142.5–143.5).

Anal. Calc. for $C_{17}H_{16}O_3$; C, 76.1; H, 6.0; 20 Me, 23.4%. Found: H, 6.3; 20 Me, 23.1%.

RELATIVE SIGNS OF PROTON COUPLING CONSTANTS IN 1-CHLORO-2,2-DIMETHYLCYCLOPROPANE

H. M. Hutton and T. Schaefer

Recent studies of the relative signs of spin–spin coupling constants have found that the geminal and vicinal coupling constants in substituted ethanes are opposite in sign (1), in disagreement with the theoretical calculations (2). It has now been established, following a suggestion by Karplus (3), that the one-bond C—H coupling has the same sign as the three-bond H—C—C—H vicinal coupling constants (4) and has the opposite sign to the two-bond H—C—H geminal coupling (5) in substituted ethanes. Since the directly bonded C—H coupling constants are almost certainly positive, one may conclude that J_{gem}^{H-H} is negative and J_{vic}^{H-H} is positive, which would in effect agree with the Dirac vector model (6).

To see whether these results hold true for substituted cyclopropanes, we have used Freeman's proton double-resonance technique (7) on 1-chloro-2,2-dimethylcyclopropane (8). The results of the ABX analysis for this cyclopropane in a 1:5 benzene solution are:

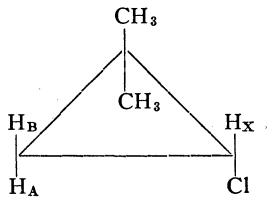
RELATIVE SIGNS OF PROTON COUPLING CONSTANTS IN 1-CHLORO-2,2-DIMETHYLCYCLOPROPANE

H. M. Hutton and T. Schaefer

Recent studies of the relative signs of spin–spin coupling constants have found that the geminal and vicinal coupling constants in substituted ethanes are opposite in sign (1), in disagreement with the theoretical calculations (2). It has now been established, following a suggestion by Karplus (3), that the one-bond C—H coupling has the same sign as the three-bond H—C—C—H vicinal coupling constants (4) and has the opposite sign to the two-bond H—C—H geminal coupling (5) in substituted ethanes. Since the directly bonded C—H coupling constants are almost certainly positive, one may conclude that J_{gem}^{H-H} is negative and J_{vic}^{H-H} is positive, which would in effect agree with the Dirac vector model (6).

To see whether these results hold true for substituted cyclopropanes, we have used Freeman's proton double-resonance technique (7) on 1-chloro-2,2-dimethylcyclopropane (8). The results of the ABX analysis for this cyclopropane in a 1:5 benzene solution are:



$|J_{AB}| = 5.98 \pm 0.17$ c.p.s.* $\quad \nu_B = 22.9$ c.p.s.†
$|J_{AX}| = 4.11 \pm 0.17$ c.p.s. $\quad \nu_A = 30.8$ c.p.s.
$|J_{BX}| = 7.39 \pm 0.17$ c.p.s. $\quad \nu_X = 156.3$ c.p.s.

To determine the relative signs by double irradiation (9), the transitions of this ABX system were labelled according to their origin as the ratio of the coupling constant to the chemical shift approaches zero, assuming $|J_{BX}| > |J_{AB}| > |J_{AX}|$. The decoupling frequencies were calculated for the two possibilities, namely, where the geminal and vicinal couplings have the same sign and the opposite sign. It was convenient to apply the high-amplitude radio-frequency field to the X transitions and observe the results in the AB spectrum. With the reverse procedure ambiguous results were obtained, probably due to the simultaneous disturbance of more than one pair of transitions. The results were as follows:

	Decoupling frequency (c.p.s.)			Decoupling frequency (c.p.s.)	
Signs of J_{AB} and J_{BX}	Calculated	Experimental	Signs of J_{AB} and J_{AX}	Calculated	Experimental
Same	124.5	118±1	Same	132.2	140±1
Opposite	116.5		Opposite	138.4	

The decoupling occurred gradually at the frequencies close to those listed for the case with opposite signs and then remained collapsed for a further increase of about 1 c.p.s. in the modulation frequency. The agreement between the calculated and observed decoupling frequencies is sufficiently good to show that the geminal coupling constant is opposite in sign to the vicinal couplings. In analogy to ethanes we conclude that in cyclopropanes the geminal coupling constant is negative and the vicinal coupling constants are positive. A similar conclusion is indicated by the direct analysis of the proton spectra of cyclopropanecarboxylic acid (10) and 2,2-diphenylcyclopropanecarboxylic acid (11) at low fields. Cyclopropane appears to differ from the substituted ethylene oxides, in which the geminal and vicinal coupling constants have the same sign.‡

ACKNOWLEDGMENTS

SOME NEW TRIARYLARSINES

W. R. CULLEN AND PAMELA E. YATES

During the course of a study of the electronic spectra of the arylarsines it became necessary to prepare some previously unknown triphenylarsines with substituents on the phenyl rings. The present communication describes the preparation of some compounds containing methoxy and trifluoromethyl groups.

The Wurtz-Fittig reaction was used by Michaelis and Weitz (1) to prepare tri(*p*-methoxyphenyl)arsine:

$$CH_3OC_6H_4Br + 6Na + AsCl_3 \rightarrow (CH_3OC_6H_4)_3As + 6NaCl.$$

We have now found that the *o*-methoxy and *m*-methoxy analogues can be prepared by the same method (Table I). However, when the Wutz-Fittig reaction was used to prepare trifluoromethyl-substituted phenylarsines no easily recognizable products were obtained. The successful synthesis of the compounds $(X—C_6H_4)_3As$ (X = *m*-CF_3 and *p*-CF_3) was achieved by reacting the Grignard reagent from the appropriate trifluoromethylphenyl bromide with arsenic trichloride (Table I). The product appeared to be contaminated in both these cases by partially substituted chloroarsines; however, these could be removed by distillation. The *m*-trifluoromethyl compound is most unusual in being a liquid at 20°.

The reaction of the Grignard reagent of *o*-trifluoromethylphenyl bromide with arsenic trichloride gave as a major product a compound which did not contain chlorine and which was shown, by analysis, to contain only two aryl groups for each arsenic atom. The infrared spectrum of the compound contained no —OH band and consequently the compound is best formulated as bis(*o*-trifluoromethylphenyl)arsine oxide (Table I). This suggests that the major product of the reaction was an incompletely substituted derivative of arsenic trichloride which was hydrolyzed to the oxide on working up the reaction mixture.

The authors wish to thank the National Research Council of Canada and the President's Research Fund of the University of British Columbia for financial support. Microanalyses were performed by Mrs. A. Aldridge in the Department of Chemistry, University of British Columbia.

TABLE I

Reactant	Product‡	Yield (%)§	M.p. (°C)‖	B.p. (°C)	Analysis			
					Found		Calc.	
					C	H	C	H
o-$CH_3OC_6H_4Br$*	(*o*-$CH_3OC_6H_4)_3As$	9	200	—	63.5	5.34	63.6	5.31
m-$CH_3OC_6H_4Br$*	(*m*-$CH_3OC_6H_4)_3As$	11	108	—	63.9	5.43	63.6	5.31
p-$CF_3C_6H_4Br$†	(*p*-$CF_3C_6H_4)_3As$	10	90	156–160 (10^{-3} mm)	49.5	2.37	49.4	2.35
m-$CF_3C_6H_4Br$†	(*m*-$CF_3C_6H_4)_3As$	54	—	120–130 (10^{-3} mm) 202–204 (16 mm)	49.4	2.23	49.4	2.35
o-$CF_3C_6H_4Br$†	((*o*-$CF_3C_6H_4)_2As)_2O$	21	200	—**	45.7	2.10¶	45.1	2.14

*Wurtz-Fittig reaction using the procedure of Michaelis and Weitz (1): 50 g of the bromide were refluxed for 36 hours.

†Grignard reaction using the procedure of Challenger and Pritchard (2): 31 g of the bromide was used to make the Grignard reagent and after the arsenic trichloride had been added the mixture was refluxed for 8 hours.

‡All products are colorless.

§No attempt was made to obtain maximum yields. Solids were recrystallized from C_2H_5OH and C_6H_6.

‖Melting points are uncorrected.

¶Also found: Cl, 0.0; As, 20.6%. Calc.: Cl, 0.0; As, 20.1%.

**Working up the reaction mixture first gave an oil which distilled at 120° (10^{-3} mm). The solid oxide was obtained after recrystallization of this fraction from wet alcohol. Thus the oil was probably the compound $(CF_3C_6H_4)_2AsCl$.

STEROIDAL 3-CHLORO-3,5-DIENES

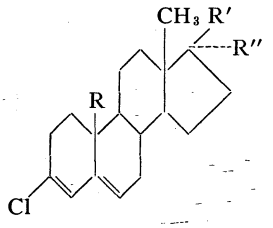
G. W. MOERSCH AND W. A. NEUKLIS

Some time ago, we found in studying the action of $POCl_3$ in dimethylformamide that this reagent converted steroidal Δ^4-3 ketones to 3-chloro-3,5-dienes, in which respect our experience resembled that since reported by Deghenghi and Gaudry (1).

Although previous work by Westphal *et al.* (2), Galinovsky *et al.* (3), Mamlok and Jacques (4), and Barber and Ehrenstein (5) as well as by Ruzicka and Fisher (6) and Kuwada and Miyasaki (7) had failed to indicate biological activity for other types of steroidal 3-chloro-3,5-dienes, we felt that the analogies might not be valid for 19-nor steroids nor in other assays such as myotrophic–androgenic ratio and in pituitary inhibition.

TABLE I

3-Chloro-3,5-dienes



Number	R	R′	R″
I	CH_3	$OCCH_2CH_3$ (O)	H
II	H	$OCCH_3$ (O)	H
III	CH_3	OH	H (cf. ref. 3)
IV*	CH_3	$OCCH_3$ (O)	CH_3
V*	CH_3	CCH_3 (O)	H
VI	CH_3	CCH_3 (O)	OH
VII	CH_3	CCH_3 (O)	$OCCH_3$ (O)
VIII	CH_3	$OCCH_3$ (O)	C≡CH
IX	H	$OCCH_3$ (O)	C≡CH

*Our results for compounds IV and V were essentially the same as those reported by Deghenghi and Gaudry (1).

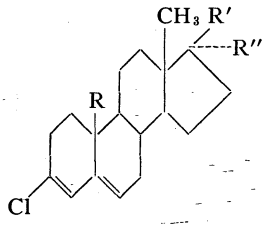
TABLE I

3-Chloro-3,5-dienes



Number	R	R′	R″
I	CH_3	$OCCH_2CH_3$ (O)	H
II	H	$OCCH_3$ (O)	H
III	CH_3	OH	H (cf. ref. 3)
IV*	CH_3	$OCCH_3$ (O)	CH_3
V*	CH_3	CCH_3 (O)	H
VI	CH_3	CCH_3 (O)	OH
VII	CH_3	CCH_3 (O)	$OCCH_3$ (O)
VIII	CH_3	$OCCH_3$ (O)	C≡CH
IX	H	$OCCH_3$ (O)	C≡CH

*Our results for compounds IV and V were essentially the same as those reported by Deghenghi and Gaudry (1).

We found oxalyl chloride to be the most effective reagent, although PCl_5, $POCl_3$, and acetyl chloride could also be used. Hydroxyl groups were protected by acetylation and liberated by base hydrolysis.

The compounds prepared are given as the structures I–IX of Table I. Compounds IV and V were prepared with $POCl_3$ instead of oxalyl chloride. Our 3-chloro-3,5-dienes showed the characteristic ultraviolet absorption, in methanol, at 241–242 mμ with shoulders at 235 mμ and 250 mμ. The $\Delta^{3,5}$ band in infrared was at 1620 cm^{-1} in KBr.

Compounds II, III, and IV were active in a modification of the Hershberger androgenic–myotropic assay (8). We also noted improvement in the M/A ratio.

Compounds VI and IX showed activity in preventing litters in mice. Compounds VI and VII showed some progestational activity in the oral McPhail modification of the Clauberg assay (9). At 2.5-mg daily oral dose for 4 days, the uteri showed proliferation indices of 0.6 and 2.3 respectively.

EXPERIMENTAL[1]

3-Chloro-17β-propionoxyandrosta-3,5-diene (I)

A solution of 3.86 g of testosterone propionate in 40 ml of dimethylformamide (DMF) was added at room temperature with stirring to a reagent prepared by adding 1.1 ml $POCl_3$ to 6 ml DMF at <20° C. The reaction was warmed to 55–80° for 2.5 hours and the dark red reaction mixture cooled to room temperature and treated with 6 g of sodium acetate in 16 ml water, added dropwise with stirring. An orange precipitate formed which was partially dissolved on warming the mixture to 60–80° C for 30 minutes. The mixture was cooled in ice and filtered to collect the yellow product. The solid product was washed with water, dilute bicarbonate solution, and again with water before drying *in vacuo* at 50–60° to yield 3.5 g, m.p. 156–163° C.

Trituration with methanol removed most of the yellow color, leaving 2.27 g, m.p. 166–169°. Crystallization of 1 g from acetone–methanol gave 0.85 g of colorless needles, m.p. 170–172°; $[\alpha]_D^{23}$ −162° (0.53% in $CHCl_3$); λ_{max}^{MeOH} 242 mμ, log ε 4.36. Calc. for $C_{22}H_{31}O_2Cl$ (362.97): C, 71.87; H, 8.91; Cl, 10.15%. Found: C, 72.01; H, 8.74; Cl, 9.89%.

3-Chloro-17β-acetoxyestra-3,5-diene (II)

A solution of 1.0 g of 19-nortestosterone acetate in 25 ml of dry benzene was treated in the cold with 6 ml oxalyl chloride and let stand overnight at room temperature. The solution was then evaporated *in vacuo* at 40–55° C to give a mixture of amber solid and of gum. The product was warmed with dilute sodium bicarbonate solution and cooled in ice. A pale yellow solid was obtained, 0.98 g, m.p. 110–112° C. Two crystallizations from acetone–methanol gave 0.52 g of yellow plates, m.p. 118–120° C; $[\alpha]_D^{23}$ −192° (0.52% in $CHCl_3$); λ_{max}^{MeOH} 242 mμ, log ε 4.34. Calc. for $C_{20}H_{27}O_2Cl$ (334.87): C, 71.73; H, 8.12; Cl, 10.59%. Found: C, 71.65; H, 7.96; Cl, 10.57%.

3-Chloro-17β-hydroxyandrosta-3,5-diene (III)

A solution of 1.22 g of crude 3-chloro-17β-propionoxyandrosta-3,5-diene in 50 ml of 5% methanolic KOH was refluxed for 1 hour. The solution was filtered while hot and treated dropwise with 50 ml of water until a few crystals appeared. It was then cooled in ice and filtered to collect 0.86 g (81%), m.p. 145–147° C. Recrystallization from aqueous ethanol gave 0.53 g, m.p. 146–148° C in agreement with the melting point of 148° reported by Galinovsky *et al.* (3); $[\alpha]_D^{23}$ −150° (0.50% in $CHCl_3$); λ_{max}^{MeOH} 242, log ε 4.37. Calc. for $C_{19}H_{27}OCl$ (306.9): C, 74.35; H, 8.87; Cl, 11.55%. Found: C, 74.22; H, 9.07; Cl, 11.50%.

3-Chloro-17α-hydroxypregna-3,5-dien-20-one (VI)

This compound was prepared in the same manner as I. The yellow product, 1.8 g from 1.85 g of 17α-hydroxyprogesterone, was triturated with methanol (10 ml) and filtered to give 0.87 g, m.p. 190–193° C. Crystallization from methanol and acetone gave 0.54 g of tan crystals, m.p. 199–201° C; $[\alpha]_D^{23}$ −161° (0.50% in $CHCl_3$); λ_{max}^{MeOH} 241, log ε 4.37. Calc. for $C_{21}H_{29}O_2Cl$ (348.9): C, 72.29; H, 8.38; Cl, 10.16%. Found: C, 72.09; H, 8.56; Cl, 10.27%.

3-Chloro-17α-acetoxypregna-3,5-dien-20-one (VII)

Compound VI (2.65 g) in 165 ml of acetic acid was treated with 25 ml of acetic anhydride and 2.65 g of toluene sulphonic acid monohydrate and let stand at room temperature overnight. The reaction was then poured into 1 liter of ice water with shaking and the precipitated solid separated by filtration and washed with water and dilute sodium bicarbonate solution, 2.8 g, m.p. 155–160°. Two crystallizations from aqueous methanol gave 1.13 g of shiny white needles, m.p. 182–185°; $[\alpha]_D^{23}$ −127° (0.55% in $CHCl_3$); λ_{max}^{MeOH} 241, log ε 4.36. Calc. for $C_{23}H_{31}O_3Cl$ (390.9): C, 70.67; H, 7.99; Cl, 9.07%. Found: C, 70.45; H, 8.07; Cl, 9.08%.

[1]*Melting points were determined in capillary tubes and are uncorrected.*

Compound VII was less satisfactorily prepared by a procedure similar to that for compound I.

3-Chloro-17α-ethinyl-17β-acetoxyandrosta-3,5-diene (VIII)

Compound VIII was prepared from ethisterone acetate in similar reaction to that for compound I. The product was extracted with ether from the sodium acetate – water mixture diluted with 200 ml water. There was obtained 1.4 g from 2.0 g of ethisterone acetate. Crystallization of 0.9 g from heptane and acetone gave 0.19 g of pale yellow crystals, m.p. 181–184°; λ_{max}^{MeOH} 241, log ε 4.37; $[\alpha]_D^{23}$ −235° (0.9% in $CHCl_3$). Calc. for $C_{23}H_{29}O_2Cl$ (372.9): C, 74.08; H, 7.84; Cl, 9.51%. Found: C, 73.83; H, 7.79; Cl, 9.80%.

3-Chloro-17α-ethinyl-17β-acetoxyestra-3,5-diene (IX)

This compound was prepared in the manner of compound II. The product solidified on bicarbonate treatment to 2.02 g, m.p. 115–140° C. After two crystallizations from methanol, there was obtained 0.7 g, m.p. 138–140°; λ_{max}^{MeOH} 242, log ε 4.34. The analytical sample was obtained from aqueous acetone, m.p. 138–142° C; $[\alpha]_D^{23}$ −258° (0.58% in $CHCl_3$); λ_{max}^{MeOH} 242, log ε 4.34. Calc. for $C_{22}H_{27}O_2Cl$ (358.9): C, 73.62; H, 7.58; Cl, 9.88%. Found: C, 73.65; H, 7.59; Cl, 10.17%.

A PRELIMINARY STUDY OF SOME DITHIOSEMICARBAZONE–NICKEL(II) COMPLEXES[1]

B. A. Gingras, T. Suprunchuk, O. Bernardini,[2] and C. H. Bayley

We have reported earlier (1) that dithiosemicarbazones (ditscs) form solid 1:1 complexes with copper(II) in which the metal is coordinated tetrahedrally to two sulphur atoms and two nitrogen atoms. Monothiosemicarbazones, on the other hand, form 1:1 complexes with copper(I) whether Cu^+ (2) or Cu^{++} (3) salts are used, the metal in these being probably coordinated linearly in a polymeric structure (3). It has now been found that ditscs react with Ni^{++} salts in aqueous solution to form 1:1 complexes very likely similar in structure to the corresponding copper complexes described before (3).

Nickel complexes were readily obtained with benzil (R = R′ = C_6H_5), 2,3-heptanedione (R = Me; R′ = *n*-butyl), and 2,3-octanedione (R = Me; R = *n*-amyl) ditscs. Diacetyl (R = R′ = Me) and particularly glyoxal (R = R′ = H) ditscs gave complexes for which elementary analyses were variable and inconsistent at first with respect

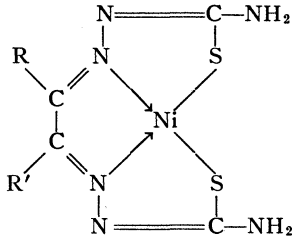
A PRELIMINARY STUDY OF SOME DITHIOSEMICARBAZONE–NICKEL(II) COMPLEXES[1]

B. A. Gingras, T. Suprunchuk, O. Bernardini,[2] and C. H. Bayley

We have reported earlier (1) that dithiosemicarbazones (ditscs) form solid 1:1 complexes with copper(II) in which the metal is coordinated tetrahedrally to two sulphur atoms and two nitrogen atoms. Monothiosemicarbazones, on the other hand, form 1:1 complexes with copper(I) whether Cu^+ (2) or Cu^{++} (3) salts are used, the metal in these being probably coordinated linearly in a polymeric structure (3). It has now been found that ditscs react with Ni^{++} salts in aqueous solution to form 1:1 complexes very likely similar in structure to the corresponding copper complexes described before (3).

Nickel complexes were readily obtained with benzil (R = R′ = C_6H_5), 2,3-heptanedione (R = Me; R′ = *n*-butyl), and 2,3-octanedione (R = Me; R = *n*-amyl) ditscs. Diacetyl (R = R′ = Me) and particularly glyoxal (R = R′ = H) ditscs gave complexes for which elementary analyses were variable and inconsistent at first with respect

[1]*Issued as N.R.C. No. 7302.*
[2]*N.R.C. Summer Student, 1962.*



to the calculated values. In fact, it was believed in the early stages of this investigation that these two complexes contained a varying amount of oxygen, and it was only after repeated careful crystallizations that satisfactory analyses were obtained. It is now believed that the discrepancies in the analyses were due to varying amount of water of coordination in the complex, this water being retained fairly strongly.

It was found that glyoxal ditscs – Ni(II) did not lose water when heated for 3 days at 150° C, or in the drying pistol at 100° C, for the same period of time. An anhydrous glyxoal ditsc – Ni(II) complex for which elementary analyses were satisfactory was obtained only after several recrystallizations from dimethyl sulphoxide (DMSO). The complex dissolves fairly easily in warm DMSO but can only be recovered by addition of water or complete evaporation of the solvent. It is likely that DMSO adds on to the metal, which becomes hexacoordinated in an octahedral configuration (d^2sp^3). This adduct is not too stable as addition of a little water causes precipitation of the complex. When this process of solvation and precipitation is repeated three to four times, the elementary analyses for the resulting complex are satisfactory. It was observed that the addition of water must be carefully controlled since an excess of water favors the formation of the hydrated complex. It was found in two cases (glyoxal and diacetyl ditsc – Ni(II)) where the complexes had been prepared in the complete absence of water that after precipitation from DMSO with water, they contained a fair amount of water: e.g. glyoxal ditsc complex, about 14% and diacetyl ditsc, 8%.

Nickel(II) in a four-coordinated diamagnetic complex is usually square planar (dsp^2) but it is known that the configuration of many nickel(II) complexes changes with ease (4) when the complexes are dissolved in organic solvents. For instance, Willis and Mellor (5) found that a number of diamagnetic nickel(II) complexes react with two molecules of pyridine to form paramagnetic octahedral complexes. This was later confirmed by Basolo and Matoush (4), who were able to isolate some crystalline compounds of nickel(II) hexacoordinated complexes containing two molecules of pyridine. The change of configuration is reversible and the original complex is regenerated by removal of the solvent under vacuum or at elevated temperature.

DMSO is completely removed from the glyoxal complex by vacuum distillation. We have not been able as yet to separate and identify the addition compound formed with the solvent. Pyridine behaves in the same manner as DMSO but it was little used in this work as the various nickel complexes dissolved more readily in DMSO.

In the cases of the longer-chain ditscs (2,3-heptanedione, 2,3-octanedione, and benzil) it is possible that spatial arrangements do not allow further coordination of the metal with water, and good analyses were readily obtained. Identical compounds were obtained whether anhydrous or hydrated nickel salts were used.

Infrared spectra provide further evidence that coordinated water is responsible for the varying analytical results in the case of the nickel complex of glyoxal ditsc. The

spectra of five different samples of this complex, ranging from the anhydrous to the one containing 14% water, were found to be identical. It seems that the particularly broad N—H band of medium intensity in the region 3400–3500 cm^{-1} makes it impossible to detect the water absorption band.

Molecular weights of two ditsc–Ni(II) complexes were measured by the freezing point method in DMSO and the compounds were found to be monomers.* This is in agreement with the results reported by Bahr and Schleitzer (6) on some similar complexes.

EXPERIMENTAL

Ditscs were prepared as described previously (1). The nickel salts were "reagent grade" nickelous sulphate·$6H_2O$, nickelous chloride·$6H_2O$, and anhydrous nickelous sulphate. DMSO was purified by drying over CaO followed by distillation under reduced pressure in an atmosphere of nitrogen.

Glyoxal ditsc – Ni(II)

A solution of $NiSO_4 \cdot 6H_2O$ (2.62 g, 0.01 mole) in water (50 ml) was added dropwise to a boiling solution of glyoxal ditsc (2.04 g, 0.01 mole) in dimethylformamide (100 ml). Reflux was continued for 15 minutes as a dark blue precipitate was formed. After the mixture was cooled, the precipitate was collected by filtration, washed successively with hydrochloric acid (3%), water, dimethylformamide, alcohol, and acetone, and dried. Yield: 2.44 g, 90%; m.p. above 300° C. After repeated crystallizations from DMSO–water, the analysis was satisfactory. Calculated for $C_4H_6N_6S_2 \cdot Ni$: M.W. 260.7; C, 18.4; H, 2.3; N, 32.2; S, 24.3; Ni, 22.5%. Found: C, 19.3; H, 2.7; N, 31.8; S, 23.6; Ni, 21.5%. Several other samples of glyoxal ditsc – Ni(II) complex were prepared by this method or others using nickel chloride or anhydrous nickel sulphate but their analyses are not given since they were variable and showed indefinite amounts of oxygen. As mentioned earlier, however, their infrared spectra were identical.

Diacetyl ditsc – Ni(II)

This was prepared as above using diacetyl ditsc (2.32 g, 0.01 mole) in dimethylformamide (200 ml) and nickelous sulphate·$6H_2O$ (2.62 g, 0.01 mole) in water (50 ml). The precipitate was treated as described earlier and recrystallized from DMSO by careful addition of water. Yield: 2.25 g, 77%; m.p. above 300° C. Calculated for $C_6H_{10}N_6S_2 \cdot Ni$: C, 24.9; H, 3.5; N, 29.1; S, 22.2; Ni, 20.36%. Found: C, 25.2; H, 3.4; N, 29.2; S, 21; Ni, 20.3%.

Benzil ditsc – Ni(II)

The same method of preparation was used starting with benzil ditsc (2.56 g, 0.075 mole) in dimethylformamide (100 ml) and $NiSO_4 \cdot 6H_2O$ (2.62 g, 0.01 mole) in water (50 ml). The precipitate was collected, washed, and dried. After recrystallization from DMSO–water, it had m.p. 187–190° C; 2.2 g, 72%. Calculated for $C_{16}H_{14}N_6S_2 \cdot Ni$: C, 46.6; H, 3.4; N, 20.38; S, 15.5; Ni, 14.2%. Found: C, 46.5; H, 4.0; N, 20.1; S, 15.5; Ni, 13.9%.

This complex was also prepared by a different method using anhydrous nickel sulphate and carrying out the reaction in dimethylformamide alone. As the nickel salt was insoluble, the mixture was refluxed for 1 hour. After cooling of the mixture, and removal of some unreacted material, the solvent was distilled under vacuum. The resulting dark red residue was recrystallized from absolute alcohol; m.p. 190° C, 1.5 g, 50%. Found: C, 46.88; H, 3.26; N, 20.0; S, 14.7; Ni, 13.9%.

2,3-Heptanedione ditsc – Ni(II)

This was prepared by the usual method in dimethylformamide, and the resulting precipitate, after being washed, was recrystallized from absolute ethyl alcohol till constant melting point, 238° C, 1.7 g, 48%. Calculated for $C_9H_{16}N_6S_2 \cdot Ni$: C, 32.65; H, 4.84; N, 25.4; S, 19.35; Ni, 17.75%. Found: C, 32.42; H, 4.99; N, 24.65; S, 17.85; Ni, 17.75%.

2,3-Octanedione ditsc – Ni(II)

This was prepared in the same manner and the complex obtained, after the usual washing, was recrystallized from the DMSO–water mixture followed by two recrystallizations from absolute ethyl alcohol. It had m.p. 246° C, 1.2 g, 35%. Calculated for $C_{10}H_{18}N_6S_2 \cdot Ni$: C, 34.8; H, 5.2; N, 24.35; S, 18.55; Ni, 17.0%. Found: C, 34.3; H, 4.9; N, 24.1; S, 18.5; Ni, 17.1%.

THE COORDINATION OF SEVEN ELECTRON PAIRS

DOYLE BRITTON

In a recent discussion of molecular shapes Gillespie (1)* pointed out that for two to nine electron pairs, coordinated at a fixed distance from a central nucleus with the geometry determined by repulsive forces between the electron pairs, only in the case of seven electron pairs did the geometry change when the assumed repulsive force law was changed. The three reasonable possibilities for seven coordination are shown in Fig. 1.

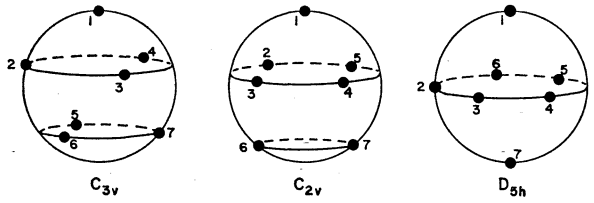

FIG. 1. Arrangements of seven particles on the surface of a sphere.

If the repulsive potential energy of the set of particles on the surface of the sphere is assumed to depend inversely upon the first power of the distance, which would be appropriate to ionic repulsion, the D_{5h} arrangement is found to be most stable. However, if the repulsive potential energy is assumed to depend inversely upon some large power of the distance, corresponding to Pauli forces, or in the limit, to a hard sphere model, the C_{3v} arrangement is found to be most stable. Gillespie suggested that the C_{2v} arrangement would also be stable for some intermediate inverse power dependence of the energy.

With a high-speed computer available to remove the tedium from the computations it seems of interest to check Gillespie's suggestion, and also to see how different in energy the various arrangements are.

For the C_{3v} arrangement there are two adjustable parameters: α = the north latitude of points 2, 3, 4, and β = the south latitude of points 5, 6, 7. For a sphere of radius = 1 the various interparticle distances are given by

$$r_{12}^2 = 2 - 2\sin\alpha$$
$$r_{15}^2 = 2 + 2\sin\beta$$
$$r_{23}^2 = 3\cos^2\alpha$$
$$r_{25}^2 = 2 - \cos\alpha\cos\beta + 2\sin\alpha\sin\beta$$
$$r_{27}^2 = 2 + 2\cos\alpha\cos\beta + 2\sin\alpha\sin\beta$$
$$r_{56}^2 = 3\cos^2\beta$$

and the repulsive energy is

$$E_{C_{3v}}(n) = \frac{3}{r_{12}^n} + \frac{3}{r_{15}^n} + \frac{3}{r_{23}^n} + \frac{6}{r_{25}^n} + \frac{3}{r_{27}^n} + \frac{3}{r_{56}^n}.$$

THE COORDINATION OF SEVEN ELECTRON PAIRS

DOYLE BRITTON

In a recent discussion of molecular shapes Gillespie (1)* pointed out that for two to nine electron pairs, coordinated at a fixed distance from a central nucleus with the geometry determined by repulsive forces between the electron pairs, only in the case of seven electron pairs did the geometry change when the assumed repulsive force law was changed. The three reasonable possibilities for seven coordination are shown in Fig. 1.

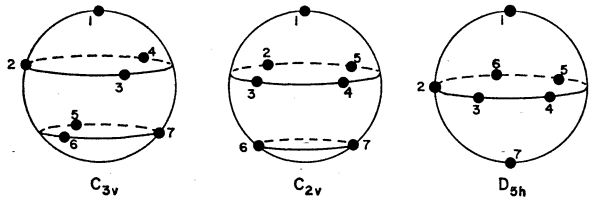

FIG. 1. Arrangements of seven particles on the surface of a sphere.

If the repulsive potential energy of the set of particles on the surface of the sphere is assumed to depend inversely upon the first power of the distance, which would be appropriate to ionic repulsion, the D_{5h} arrangement is found to be most stable. However, if the repulsive potential energy is assumed to depend inversely upon some large power of the distance, corresponding to Pauli forces, or in the limit, to a hard sphere model, the C_{3v} arrangement is found to be most stable. Gillespie suggested that the C_{2v} arrangement would also be stable for some intermediate inverse power dependence of the energy.

With a high-speed computer available to remove the tedium from the computations it seems of interest to check Gillespie's suggestion, and also to see how different in energy the various arrangements are.

For the C_{3v} arrangement there are two adjustable parameters: α = the north latitude of points 2, 3, 4, and β = the south latitude of points 5, 6, 7. For a sphere of radius = 1 the various interparticle distances are given by

$$r_{12}^2 = 2 - 2\sin\alpha$$
$$r_{15}^2 = 2 + 2\sin\beta$$
$$r_{23}^2 = 3\cos^2\alpha$$
$$r_{25}^2 = 2 - \cos\alpha\cos\beta + 2\sin\alpha\sin\beta$$
$$r_{27}^2 = 2 + 2\cos\alpha\cos\beta + 2\sin\alpha\sin\beta$$
$$r_{56}^2 = 3\cos^2\beta$$

and the repulsive energy is

$$E_{C_{3v}}(n) = \frac{3}{r_{12}^n} + \frac{3}{r_{15}^n} + \frac{3}{r_{23}^n} + \frac{6}{r_{25}^n} + \frac{3}{r_{27}^n} + \frac{3}{r_{56}^n}.$$

*This reference should be consulted for earlier literature references in this area.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

For the C_{2v} arrangement there are three adjustable parameters: α = the north latitude of points 2, 3, 4, 5; β = the south latitude of points 6, 7; and γ = half the difference in longitude of points 2 and 3. For a sphere of radius = 1 the various interparticle distances are given by

$$\begin{aligned}
r_{12}^2 &= 2 - 2\sin\alpha \\
r_{16}^2 &= 2 + 2\sin\beta \\
r_{23}^2 &= 4\cos^2\alpha\sin^2\gamma \\
r_{24}^2 &= 4\cos^2\alpha \\
r_{25}^2 &= 4\cos^2\alpha\cos^2\gamma \\
r_{26}^2 &= 2 - 2\cos\alpha\cos\beta\cos\gamma + 2\sin\alpha\sin\beta \\
r_{27}^2 &= 2 + 2\cos\alpha\cos\beta\cos\gamma + 2\sin\alpha\sin\beta \\
r_{67}^2 &= 4\cos^2\beta
\end{aligned}$$

and the repulsive energy is

$$E_{C_{2v}}(n) = \frac{4}{r_{12}^n} + \frac{2}{r_{16}^n} + \frac{2}{r_{23}^n} + \frac{2}{r_{24}^n} + \frac{2}{r_{25}^n} + \frac{4}{r_{26}^n} + \frac{4}{r_{27}^n} + \frac{1}{r_{67}^n}.$$

For the D_{5h} arrangement there are no variable parameters, and for a sphere of radius = 1 the various interparticle distances are given by

$$\begin{aligned}
r_{12}^2 &= 2 \\
r_{17}^2 &= 4 \\
r_{23}^2 &= 4\sin^2(\pi/5) \\
r_{24}^2 &= 4\sin^2(2\pi/5)
\end{aligned}$$

and the repulsive energy is

$$E_{D_{5h}}(n) = \frac{10}{r_{12}^n} + \frac{1}{r_{17}^n} + \frac{5}{r_{23}^n} + \frac{5}{r_{24}^n}.$$

The first and simplest comparison to make is to assume that the particles are held at the distance appropriate to the hard sphere model. The results are given in Table I.

NOTE: The boxes enclose the minimum values at each n.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Since only the relative values of the energy are of interest the actual values as a function of n are given only for D_{5h}, and the values relative to D_{5h} are given for the other geometries.

More realistic is a calculation of the energy where the distance are allowed to adjust to the minimum energy positions. These values were found by mapping the function in the neighborhood of the expected minimum position until the minimum position was found with the desired accuracy. The results are shown in Table II. As before, only the comparison with D_{5h} is given. The values for the positional parameters are also given.

It is apparent from the tables that Gillespie's suggestions are confirmed. First, the C_{2v} arrangement becomes most stable at intermediate values of n. For the hard sphere model this is for n from about 8 to 12; for the equilibrium model this is around $n = 4$. Second, and fairly striking, the energy differences among the forms are quite small fractions of the total energy, so that the actual arrangement will depend importantly upon factors other than the repulsive potential between the ligands.

†The structure of bikhaconitine will be reported in a forthcoming publication.

aromatic protons. This signal must be attributable to a proton attached to a carbon carrying an ester group since it is no longer present in the spectra of the corresponding alkamines. Since the acetoxy group is known to be attached to a quaternary carbon next to a free secondary hydroxyl (4) the signal must be due to a proton attached to the same carbon as the aromatic ester group, and the splitting caused by a neighboring proton. This condition is fulfilled if the aromatic ester group is located at C-10 in which case there is a neighboring proton at C-9 and none at C-11, but would not hold were the aroyloxy group located at C-11, the only other possible position.

It is noteworthy that the magnitude of the coupling constant is in excellent agreement with the assigned configuration of the benzoate group. Dreiding models indicate an H—H dihedral angle of ca. 40° while the dihedral angle for the structure epimeric at C-10 is 80°. According to Karplus (5) $J_{40°}$ is ca. 4 c/s and $J_{80°}$ ca. 0 c/s.

The acetyl group protons in the spectra of the alkaloids listed show signals at unusually high field ($\delta \sim 1.3$). The shift is not due only to the tertiary nature of the acetyl group (cf. *tert*-butyl acetate, $\delta \sim 1.97$), nor is it due only to the ionic nature of the acetoxy group (cf. sodium acetate, $\delta \sim 1.80$).* The signal is shifted back to the usual position in tetraacetylpseudaconine and triacetylbikhaconine ($\delta \sim 1.96$).

The only plausible explanation of this marked shift is that the methyl protons in the acetoxy group come within the shielding range of the aromatic nucleus, and the strongly

anisotropic effect of the aromatic group causes large high-field shifts. This condition is satisfied when the aromatic ester group in the alkaloids is located at C-10, and possesses the configuration already assigned (6). In such an orientation the free rotation of the aromatic ester group is restricted. Since four of the alkaloids listed in the table have previously been correlated (6), it can be concluded that in these the position of the aromatic ester group and its orientation are the same.

POLAROGRAPHY OF 8-HYDROXYQUINALDINE

A. CORSINI AND R. P. GRAHAM

This note is concerned with the polarographic behavior of 8-hydroxyquinaldine (2-methyloxine), particularly in strongly basic solutions. The reduction process is shown to involve one electron and one hydrogen ion, the species undergoing reduction probably being the 2-methyloxine anion. The polarography of this reagent is favorable to its use for the indirect polarographic determination of metal ions.

EXPERIMENTAL

Apparatus

Polarographic measurements were made at 25.5±0.1° C using a pen-recording polarograph (Type 14/3, Tinsley Industrial Instruments, Ltd., London, England). Two capillaries were used; in 0.10 *M* potassium chloride on open circuit, their characteristics were: t = 7.67 sec and m = 0.956 mg/sec; t = 4.82 sec and m = 1.616 mg/sec. Under experimental conditions, at high negative potentials, t was reduced to 3–4 sec. A conventional H-type cell with a saturated calomel electrode was used for investigations of the polarographic behavior of 2-methyloxine.

Measurements of pH were made as described elsewhere (1).

Reagents

The 2-methyloxine and thorium nitrate were obtained as previously reported (1). All other chemicals were analyzed grade.

Polarography of 2-Methyloxine

Polarograms were recorded from aqueous solutions (pH 2.6–14.2) that were 7.0×10^{-4} *M* with respect to 2-methyloxine. Potassium hydrogen phthalate, potassium dihydrogen phosphate, boric acid, and disodium hydrogen phosphate (all examined polarographically for reducible impurities) were used to obtain pH values < 13; for values > 13, the 2-methyloxine was dissolved in 0.5–1.5 *M* sodium hydroxide.

In experiments having to do with the current as a function of the pressure of mercury in the capillary, h_e was varied from 20 to 65 cm.

Polarographic Determination of Thorium

The washed precipitate of the thorium 2-methyloxinate, $Th(C_{10}H_8ON)_4$, obtained as described elsewhere (1), was treated with hot 1.0 *M* sodium hydroxide, which metathesized it to hydrous thoria, freeing 2-methyloxine anion equivalent to the thorium. The solution of this passed through the filter, and was diluted to

POLAROGRAPHY OF 8-HYDROXYQUINALDINE

A. CORSINI AND R. P. GRAHAM

This note is concerned with the polarographic behavior of 8-hydroxyquinaldine (2-methyloxine), particularly in strongly basic solutions. The reduction process is shown to involve one electron and one hydrogen ion, the species undergoing reduction probably being the 2-methyloxine anion. The polarography of this reagent is favorable to its use for the indirect polarographic determination of metal ions.

EXPERIMENTAL

Apparatus

Polarographic measurements were made at 25.5±0.1° C using a pen-recording polarograph (Type 14/3, Tinsley Industrial Instruments, Ltd., London, England). Two capillaries were used; in 0.10 *M* potassium chloride on open circuit, their characteristics were: t = 7.67 sec and m = 0.956 mg/sec; t = 4.82 sec and m = 1.616 mg/sec. Under experimental conditions, at high negative potentials, t was reduced to 3–4 sec. A conventional H-type cell with a saturated calomel electrode was used for investigations of the polarographic behavior of 2-methyloxine.

Measurements of pH were made as described elsewhere (1).

Reagents

The 2-methyloxine and thorium nitrate were obtained as previously reported (1). All other chemicals were analyzed grade.

Polarography of 2-Methyloxine

Polarograms were recorded from aqueous solutions (pH 2.6–14.2) that were 7.0×10^{-4} *M* with respect to 2-methyloxine. Potassium hydrogen phthalate, potassium dihydrogen phosphate, boric acid, and disodium hydrogen phosphate (all examined polarographically for reducible impurities) were used to obtain pH values < 13; for values > 13, the 2-methyloxine was dissolved in 0.5–1.5 *M* sodium hydroxide.

In experiments having to do with the current as a function of the pressure of mercury in the capillary, h_e was varied from 20 to 65 cm.

Polarographic Determination of Thorium

The washed precipitate of the thorium 2-methyloxinate, $Th(C_{10}H_8ON)_4$, obtained as described elsewhere (1), was treated with hot 1.0 *M* sodium hydroxide, which metathesized it to hydrous thoria, freeing 2-methyloxine anion equivalent to the thorium. The solution of this passed through the filter, and was diluted to

volume with 1.0 M sodium hydroxide. The resultant solution (pH 14) was polarographed and, from the measured diffusion current and an appropriate calibration curve, the concentration of thorium in the original solution was assessed.

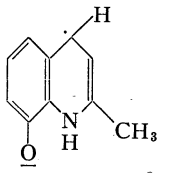
An excellent straight-line calibration curve was obtained for concentrations of thorium (in the original solution) over the 50-fold range from 6×10^{-5} to 3×10^{-3} M (corresponding to concentrations of 2-methyloxine, in the solution polarographed, of 1.2×10^{-4} to 6×10^{-3} M).

RESULTS AND DISCUSSION

We confirmed the observation (2) that the nature of the polarographic wave due to 2-methyloxine is markedly dependent on the pH of the solution, as indeed is so with oxine itself (3). At pH values below about 11, the shapes of the waves suggest complex reduction processes, all too common with heterocyclic nitrogen compounds (4).

Measurements of $i/h_e^{\frac{1}{2}}$ at six pH values in the range 7.6–14.2 were constant at each pH, indicating that the current is diffusion controlled throughout this range. The half-wave potential ($E_{\frac{1}{2}}$) becomes increasingly negative with increasing pH, indicating a reduction process involving hydrogen ions. The relationship between $E_{\frac{1}{2}}$ and pH is linear (at least over the pH range 11.2–14.2): $-E_{\frac{1}{2}} = 0.98+0.061$ pH. The slope of the line is in good agreement with that (0.059) for an electrode reaction involving hydrogen ions and electrons in equal numbers. (Other workers (2) have found 0.084 for the slope.) Plots of E_{de} vs. log $(i/(i_d-i))$ for five pH values in this range were linear, with slopes 0.055 ± 0.002, a value corresponding to that for a reversible electrode reaction involving one electron.

The one-electron, one-hydrogen-ion process in solutions of pH 11 and higher likely represents the reduction of the 2-methyloxine anion (2-methyloxine being substantially fully dissociated at pH $\geqslant$ 11) to a free radical such as:



which undergoes dimerization or disproportionation. A reversible one-electron reaction, involving one hydrogen ion, to a free radical has been proposed (3) for the reduction of oxine at pH $\sim$ 10.

The diffusion coefficient of the 2-methyloxine anion, calculated from the Ilkovic equation using the diffusion currents at pH 11.2 and 12.6 ($\mu \simeq 0.2$–0.3), appropriately determined values of m and t, and taking $n = 1$, was $0.62\pm0.02\times10^{-5}$ cm²/sec. This may be compared with the value 0.80×10^{-5} cm²/sec, calculated (5) from equivalent conductance data, for the anion of quinaldinic acid at 25° C.

The waves obtained from solutions of pH < 11 are complex and resist analysis. Down to pH 7.6 at least, the current is diffusion controlled, and increases with decreasing pH. Some evidence was obtained that at pH 7.6 the reduction process involves two electrons: here, at the ionic strength of the solution, the reagent is largely (98.5%) in the form of undissociated 2-methyloxine (6), and the reduction may be that of the molecule to a dihydro derivative such as 1,4-dihydro-8-hydroxyquinaldine.

The form of the wave obtained from solutions of 2-methyloxine at pH 14 is excellent for analytical purposes, being similar to that of m-nitrobenzoic acid (7), which has been recommended for the indirect polarographic determination of thorium. The diffusion current of 2-methyloxine (or, rather, its anion) is directly proportional to the concentration of reagent, and is not significantly altered by changes in the concentration of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

sodium hydroxide from 0.5 M to 1.5 M; these solutions are polarographically stable for at least 45 hours.

Suitable experiments proved that the decomposition of the thorium 2-methyloxinate with hot sodium hydroxide, and the separation of the organic anion from the hydrous thoria, are strictly quantitative. The precision of the polarographic method varies from $\pm 1\%$ (for a thorium concentration of 3×10^{-3} M) to $\pm 8\%$ (for a concentration of 6×10^{-5} M, or 14 p.p.m.).

This method is of course one for determining 2-methyloxine, and is therefore applicable to any metal ion that can be quantitatively precipitated by this reagent as a compound of reproducible stoichiometry. The method is particularly applicable to thorium, which does not lend itself to direct polarographic determination.

ORGANIC PEROXIDES
VII. OXIDATION OF PHENYLHYDRAZONES WITH BENZOYL PEROXIDE

J. T. Edward and S. A. Samad*

Benzoyl peroxide reacts with aromatic secondary amines to give *o*-benzamidophenols (1) and consequently was expected to react with benzophenone phenylhydrazone (I) to give the phenol VI.

However, the product of the reaction was not a phenol but a neutral yellow solid $C_{26}H_{20}N_2O_2$ having an absorption spectrum (λ_{max} 271 mμ, ϵ_{max} 8030; λ_{max} 400 mμ, ϵ_{max} 222, in ethanol: Fig. 1) characteristic of a phenylazo chromophore (2, 3). Recently Iffland and his colleagues have reported the preparation of phenylazodiphenylcarbinol benzoate (IV) from the reaction of benzophenone phenylhydrazone with lead tetrabenzoate (4), and comparison of a sample of this compound, kindly sent to us by Professor Iffland, with our own compound established their identity.† The mechanism (I → II → III → IV)

Holder of Colombo Plan fellowship, 1957–1960.

†Professor Iffland informs us that he also has established the identity of the products obtained from the reaction of benzophenone phenylhydrazone with lead tetrabenzoate and with benzoyl peroxide by a comparison of their infrared spectra, without isolating the product of the latter reaction.

I II III IV V VI

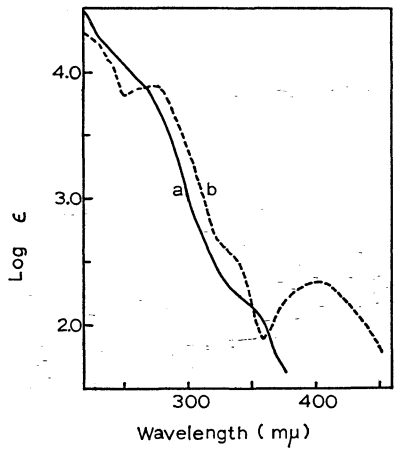

FIG. 1. Ultraviolet absorption of compounds produced by the reaction of benzoyl peroxide with (*a*) benzaldehyde phenylhydrazone, (*b*) benzophenone phenylhydrazone.

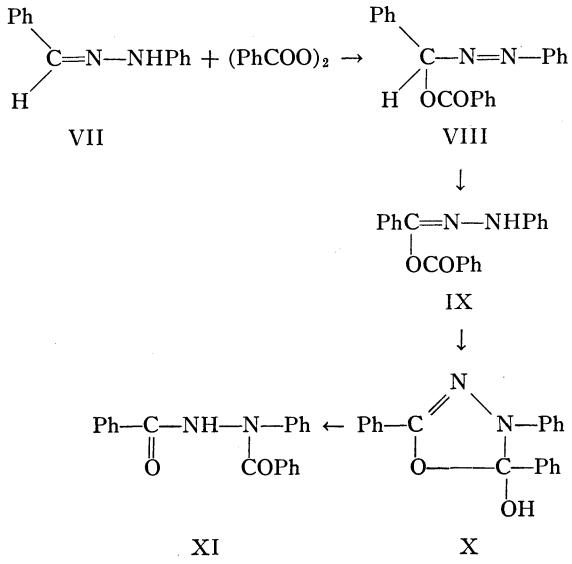
shown above seems likely from the studies of Denney and Denney (5) on the reaction of benzoyl peroxide with secondary amines. The reaction of the ion pair III to give the phenylazo benzoate (IV) rather than the phenol (VI) is probably a consequence of the higher activation energy which would be required in the step III → V leading to the phenol, since in this step a benzenoid is converted into a quinonoid compound.

The reaction of benzaldehyde phenylhydrazone (VII) with benzoyl peroxide gave a compound which was not phenolic and which lacked a phenylazo chromophore (Fig. 1). Its infrared spectrum showed peaks (at 3420 and 1670 cm^{-1}) indicative of an amide grouping (6), and it was identified as α,β-dibenzoylphenylhydrazine (XI) by comparison with an authentic sample prepared by benzoylation of phenylhydrazine hydrochloride in boiling benzene (7). It seems likely that initially the phenylazo compound (VIII) is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



formed, but that in the presence of benzoic acid it rearranges as shown. Ample analogy is found in the literature for the tautomerization of the azo compound (VIII → IX) (3) and for the subsequent migration of the benzoyl group from oxygen to nitrogen via a cyclic intermediate (IX → X → XI) (8).

EXPERIMENTAL

Reaction of Benzoyl Peroxide with Benzaldehyde Phenylhydrazone

Benzoyl peroxide (12.3 g) was added to a solution of benzaldehyde phenylhydrazone (10 g) in benzene (125 ml), and the mixture was left at room temperature overnight. The benzene solution was then extracted with aqueous sodium bicarbonate to remove benzoic acid (6.3 g), washed with water, dried, and allowed to evaporate slowly. A crop of crystalline material (4.45 g; 27% yield) was obtained, and on complete evaporation, a tarry solid (8.5 g). The latter was chromatographed on alumina; elution with benzene–ether gave more crops of crystalline material (4.15 g; 25%). This material on recrystallization from ethanol was obtained as colorless needles, m.p. 181°, undepressed by admixture with authentic α,β-dibenzoylphenylhydrazine (reported m.p. 180° (7)), and having the same infrared spectrum: $\nu_{max}^{CHCl_3}$ 3420 m, 1672 s, 1600 m, 1585 m, 1470 m, 1420 m, 1345 s, 1306 m, 1078 w, 1075 w, 1027 w, 925 w, 732 w cm^{-1}.

Reaction of Benzoyl Peroxide with Benzophenone Phenylhydrazone

A mixture of benzophenone phenylhydrazone (6.0 g) and benzoyl peroxide (5.32 g) in benzene (50 ml) was stirred for 3 hours and then left overnight. After removal of benzoic acid (2.37 g), the benzene solution was washed with water, dried, and evaporated. The gummy residue crystallized from ethanol in yellow needles (5.43 g; 63%), m.p. 147°, raised to 149–152° (melting with gassing)* by recrystallization; this melting point was undepressed by admixture of the material with authentic phenylazodiphenylcarbinol benzoate (4). Calc. for $C_{26}H_{20}N_2O_2$: C, 79.59; H, 5.10; N, 7.14%. Found: C, 79.57; H, 5.15; N, 7.31%. Infrared spectrum: $\nu_{max}^{CCl_4}$ 3090 m, 1743 s, 1498 m, 1457 s, 1318 m, 1270 s, 1177 s, 1090 s, 1067 m, 914 w, 687 s.

The phenylazo benzoate (2.1 g), after hydrolysis with potassium hydroxide (5 g) in refluxing methanol–water (10:1 v/v; 165 ml) for 4 hours, gave benzophenone (isolated in 54% yield as its 2,4-dinitrophenylhydrazone, m.p. 236°) and benzoic acid (85% yield) (cf. ref. 4).

ACKNOWLEDGMENTS

We are grateful to Professor D. C. Iffland for a sample of phenylazodiphenylcarbinol benzoate and for helpful correspondence, and the National Research Council for financial support.

**Iffland and co-workers (4) report a melting point of 159–161°; however, later preparations showed a melting point of 150–152°, possibly because of polymorphism (D. C. Iffland. Private communication).*

IONIZATION OF DEUTERATED ALCOHOLS IN ACID SOLUTION

MICHAEL M. MOCEK AND ROSS STEWART

We wish to report the effect of α-deuterium substitution on the ionization of 4,4′-disubstituted benzhydrols.*

$$Ar_2CHOH + H^+ \rightleftharpoons Ar_2CH^+ + H_2O \qquad K_H$$
$$Ar_2CDOH + H^+ \rightleftharpoons Ar_2CD^+ + H_2O \qquad K_D$$

The pK_{R^+} values for the alcohols are listed in Table I together with the stretching frequencies and the unobscured bending frequencies of the C—H and C—D bonds and the ultraviolet data for the cations. The sign of the isotope effects and their magnitude are

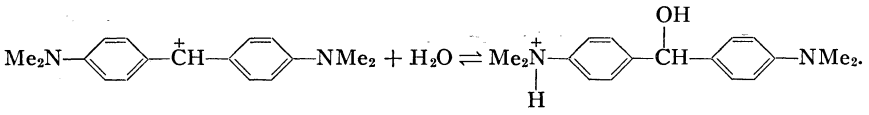
similar to that observed in the solvolysis of α-deuteroalkyl tosylates (2). In both cases the deuterated carbon undergoes a change from tetragonal towards trigonal hybridization as the reaction proceeds.

Electron-withdrawing groups in the aromatic rings appear to cause an increase in the size of the isotope effect. Unfortunately, nitro substituents which should reveal such an effect most clearly cause an unexpected change in the course of the reaction. They so depress the tendency of the alcohol group to ionize that the acid–base equilibrium which is actually set up is protonation of the nitro group itself. This is revealed by the changes which occur in the ultraviolet spectrum as the medium is made more acidic. Instead of a strong absorption band in the visible, which all diarylcarbonium ions exhibit (and which 4,4′,4″-tris(nitrophenyl)methylium ion exhibits (3)), the 4,4′-dinitrobenzhydrol cation is formed with a relatively small spectral change (λ_{max} = 289 mμ in 95% H_2SO_4 and 346 mμ in fuming 40% H_2SO_4) and is half formed in about 102.5% sulphuric acid. Nitrobenzene (λ_{max} = 286 mμ in 95% H_2SO_4) is half protonated in 100.1% sulphuric acid and the cation absorbs at about 350 mμ (4).

The isotope effect listed for Michler's Hydrol, 4,4′-bis(dimethylamino)benzhydrol, was obtained in acetone solution and it should be regarded as approximate only. The difficulty with this compound lies in its complex ionization pattern, in which nitrogen protonation competes with carbonium ion formation. In aqueous solution the maximum extinction coefficient obtained for the carbonium ion shows that the following equilibrium is well to the right:



In acetone solution the equilibrium shifts toward the left as expected (5).

It is interesting that the only ring substituents which cause protonation of the benzhydrol at the substituent in preference to carbonium ion formation at the carbinol are nitro and dimethylamino, two groups which usually differ widely in behavior.

EXPERIMENTAL

Materials

The alcohols were prepared by reduction of the corresponding ketones with $LiAlH_4$ or $LiAlD_4$ essentially as previously described (6). The absence of the α-proton signal in the n.m.r. spectra of several of the alcohols was taken as indication of high isotopic purity.

pK_{R^+} Determination

The ionization constants of the alcohols were determined in sulphuric acid as before (7), the extinction coefficients at complete ionization being determined for both isotopic species. The fading of the carbonium ion color, which was slower for the deuterio ion in each case, required extrapolation to zero time in some cases when measurements near the pK were made.

Carbonium Salts

The perchlorate, fluoroborate, and hexachloroantimonate salts of several of the benzhydryl carbonium ions were prepared and their infrared spectra (mulls) examined. In all cases the intensities of the central C—H (or C—D) bands were too low to be detected. The hexachloroantimonate salt of benzhydrol can be conveniently prepared by simply mixing equivalent amounts of antimony pentachloride and benzhydryl chloride (each a 10% solution in carbon tetrachloride). The immediate yellow precipitate of the salt, $(C_6H_5)_2CH^+SbCl_6^-$, was stable for some time under carbon tetrachloride or even if kept "moist" with carbon tetrachloride. If the solid is "dried" completely, however, it begins almost at once to decompose to a brown tar.

5-(DISUBSTITUTED)AMINO-1,2,3,4-THIATRIAZOLES[1]

EUGENE LIEBER,[2] C. N. R. RAO,[3] C. B. LAWYER, AND J. P. TRIVEDI

Lieber and co-workers (1, 2) have synthesized 5-(monosubstituted)amino-1,2,3,4-thiatriazole derivatives (I) by the diazotization of 4-substituted thiosemicarbazides or by the addition of hydrazoic acid to organic isothiocyanates. The only 5-(disubstituted)amino derivative (III) that has been reported hitherto is that of the dimethyl derivative by Lieber *et al.*, synthesized by the diazotization of 4,4-dimethylthiosemicarbazide (1) and also by the reaction of dimethylamine with 5-chloro-1,2,3,4-thiatriazole (3). In this communication, we report the synthesis of 5-(disubstituted)amino-1,2,3,4-thiatriazoles (III) starting from N,N-disubstituted thiocarbamyl chlorides (II). Preliminary results on the relative thermal stabilities of some of these thiatriazole derivatives are also presented.

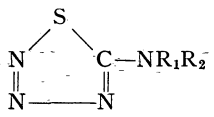
$R_1R_2NC(S)Cl$

(II)



(III)

EXPERIMENTAL

N,N-Disubstituted Thiocarbamyl Chlorides (II)

In a three-necked flask equipped with a mechanical stirrer, a reflux condenser, and a dropping funnel were placed 0.2 mole of the secondary amine and 50 ml of anhydrous ether. The flask was immersed in an ice–salt–water bath. A solution of thiophosgene (0.1 mole) in 50 ml of anhydrous ether was slowly added from the dropping funnel, the reaction temperature being carefully kept below 5° C. The precipitation of amine hydrochloride was noticed immediately. Stirring was continued for about 45 minutes, at the end of which period the reaction mixture appeared oily. The precipitate of the amine hydrochloride formed in the flask was filtered off and the ethereal solution was concentrated. On cooling, pale yellow needles separated from the concentrate. Recrystallizations with chloroform and petroleum ether yielded colorless needles. Following this general procedure, the N,N-disubstituted thiocarbamyl chlorides (II) given in Table I were prepared.

Thermal Decomposition of 5-Substituted 1,2,3,4-Thiatriazoles

The thermal decompositions were studied by heating 0.0015 mole of thiatriazole admixed with sand at 90° C and measuring the nitrogen gas volumetrically at different intervals of time employing an apparatus similar to that described earlier (7, 9).

RESULTS AND DISCUSSION

A few 5-(disubstituted)amino-1,2,3,4-thiatriazoles (II) have been prepared by the reaction of N,N-disubstituted thiocarbamyl chlorides (III) with sodium azide.

Studies on the thermal decomposition of the 5-substituted 1,2,3,4-thiatriazoles have shown that the stability decreases in the order $N(CH_3)_2 > NH_2 > N(C_6H_5CH_2)_2 > C_6H_5NH > CH_3NH$.

A SIMPLE METHOD FOR TRAPPING AND COLLECTING THE GASES NOT CONDENSABLE AT −196° IN A FAST-FLOWING, LOW-PRESSURE SYSTEM[1]

NICK DEMCHUK[2] AND H. GESSER

The separation and analysis of gases in a static system has been developed to the point of routine procedure (1). This includes gases not condensable in liquid nitrogen, such as N_2, CH_4, CO, O_2, and H_2 (2). Gas chromatography has now virtually eliminated such time consuming microanalysis. In a fast-flowing system under low pressures (about 1 mm of Hg) these gases, which are not condensable in liquid nitrogen, can be collected for analysis by sampling a small fraction of the flowing gas with a Toepler pump or a diffusion pump. This method was used by Jamieson and Winkler (3) for the mass spectrometric analysis of CH_4 and N_2 in a hydrogen flowing system. A novel method of collection was used by Versteeg (4), who collected the exhaust gases of the mechanical oil pump, and analysis for CH_4 and H_2 was possible in a nitrogen flowing system.

The use of silica gel as an adsorbing medium at low temperatures is well known but in a fast-flowing system the silica gel, when placed in appropriate traps, tends to restrict the flow of gas and alter the pressure in the reacting system (5). To overcome this difficulty, Steacie and Phillips (5) introduced a diffusion pump between the reaction system and the silica gel trap, which was followed by the mechanical oil pump. A similar system was used by Schiff and Steacie (6), but no quantitative data are given. We have successfully used a much simpler system without altering the characteristics of the flowing system by applying the silica gel to the inside walls of a trap which had previously been coated with a thin film of silicone grease. Such a surface can be removed from the system if the outside of the trap (containing the grease and the silica gel) is on a standard taper joint. Fast-flowing high-vacuum systems generally have two traps in series to insure complete collection of excess reactant and products. This second trap could conveniently serve to contain the silica gel.

The silica gel used (28/200 mesh) was obtained from Fisher Scientific. Dow Corning High Vacuum Silicone Grease was used to stick the gel to the glass trap, which was 15 cm long, with 30-mm O.D. The silica gel was degassed at 170° C prior to use in an experiment. The condensable gases were trapped in the first trap at −196° and the non-condensables were adsorbed in the silica gel trap maintained at −196°. After a reaction was completed, the non-condensable gases were removed from the silica gel at 170°, toeplered into a gas buret, measured, and analyzed.

The results of experiments to measure the trapping efficiency for CO, CH_4, and N_2 in a hydrogen flowing system at 1.05 mm pressure where the flow rate of hydrogen was 1530 μmoles/min are given in Table I.

The amount of gas put in was determined by PVT and time measurements and compared with the amount of gas recovered as measured in a gas buret.

Blank experiments with hydrogen alone showed that less than 1 μmole/min of gas, hydrogen, was trapped by the silica gel. From these results it seems reasonable that any two-component mixture of the above gases, or even the three-component mixture of

CH_4, CO, and N_2, could also be quantitatively trapped in the described manner. Actual experiments with a CO and CH_4 mixture showed from PVT measurements that the trapping is indeed quantitative but a mixing problem was encountered in the preparation of sample mixtures. As an example, a mixture having a prepared ratio for CO/CH_4 of 0.54 was trapped and collected completely but upon analysis by the standard combustion method in a CuO furnace at 210° C (7) it was shown to have the ratio of 0.51. The discrepancy was probably due to non-homogeneity of the original prepared mixture as well as to different rates of effusion of CH_4 and CO through the flowmeter constriction.

NOVEL SYNTHESIS OF 8-MERCAPTOQUINOLINE

H. S. Lee

8-Mercaptoquinoline, the sulphur analogue of 8-hydroxyquinoline, is a most interesting compound. Its dihydrate crystallizes as deep red needles, whereas its anhydrous form is a blue mobile liquid. It is easily oxidized when exposed to air, especially when dissolved in an alkaline solution. The presence of the sulphur atom in this compound might make it a good compound for spectral investigation of n–π^* electronic transition. Further, since its structure is very similar to that of 8-hydroxyquinoline, it may have wide use as an analytical reagent.

In 1908 Edinger (4) synthesized 8-mercaptoquinoline but relatively few investigators have studied the properties and possible uses of this substance. This paper reports a novel synthesis of 8-mercaptoquinoline, involving the reduction of quinoline-8-sulphonyl chloride directly to the corresponding mercaptan. The method has the advantage of requiring only

CH_4, CO, and N_2, could also be quantitatively trapped in the described manner. Actual experiments with a CO and CH_4 mixture showed from PVT measurements that the trapping is indeed quantitative but a mixing problem was encountered in the preparation of sample mixtures. As an example, a mixture having a prepared ratio for CO/CH_4 of 0.54 was trapped and collected completely but upon analysis by the standard combustion method in a CuO furnace at 210° C (7) it was shown to have the ratio of 0.51. The discrepancy was probably due to non-homogeneity of the original prepared mixture as well as to different rates of effusion of CH_4 and CO through the flowmeter constriction.

NOVEL SYNTHESIS OF 8-MERCAPTOQUINOLINE

H. S. Lee

8-Mercaptoquinoline, the sulphur analogue of 8-hydroxyquinoline, is a most interesting compound. Its dihydrate crystallizes as deep red needles, whereas its anhydrous form is a blue mobile liquid. It is easily oxidized when exposed to air, especially when dissolved in an alkaline solution. The presence of the sulphur atom in this compound might make it a good compound for spectral investigation of n–π^* electronic transition. Further, since its structure is very similar to that of 8-hydroxyquinoline, it may have wide use as an analytical reagent.

In 1908 Edinger (4) synthesized 8-mercaptoquinoline but relatively few investigators have studied the properties and possible uses of this substance. This paper reports a novel synthesis of 8-mercaptoquinoline, involving the reduction of quinoline-8-sulphonyl chloride directly to the corresponding mercaptan. The method has the advantage of requiring only

For personal use only.

one step from the sulphonyl chloride to the final product instead of the several steps required by the old Edinger's method.

Best results were afforded when a 20% excess of lithium aluminum hydride was used. More or less hydride gave lower yields. The decomposition of the reduction complex and the excess lithium aluminum hydride with a calculated amount of water and 20% sodium hydroxide (2) (or 15% sodium hydroxide (5)) is not advised in the synthesis of 8-mercaptoquinoline, because it gives poor yields due to the formation of the corresponding sodium salt of the product. It is worth noting that no 8-mercaptoquinoline could be isolated by following the suggestion (1) to employ a 0.5 : 1 mole ratio for hydride to sulphonyl chloride.

EXPERIMENTAL

Quinoline-8-sulphonyl Chloride

A mixture of quinoline-8-sulphonic acid (20 g) and phosphorus pentachloride (25 g) was ground together for 5 minutes, and heated under reflux for 3 hours in an oil bath at 130° C. At the end of this period the contents of the flask became brown and almost all liquefied. After cooling, the crude product was poured onto crushed ice (180 g), neutralized with sodium bicarbonate, and extracted with ether. The ether extract was decolorized with charcoal (2 g) and filtered. After evaporation of the ether, the colorless crystalline sulphonyl chloride (21.1 g, 97%) was dried *in vacuo*. It melted at 118–122° (lit. 122° (4), 128.5–129° (3)).

8-Mercaptoquinoline

A solution of 0.55 g of lithium aluminum hydride in 250 ml of anhydrous ether was added, over a period of 1½ hours, to a solution of 1.83 g of quinoline-8-sulphonyl chloride and 600 ml of anhydrous ether in a 1-liter three-necked round-bottomed flask, fitted with a motor-driven stirrer and a condenser. Ice water was circulated through the condenser. The yellow intermediate was decomposed by the addition of 3 ml of water. Inorganic material was removed by filtration from the yellow ether solution. After the removal, by evaporation, of the solvent, some bluish red residue appeared. 8-Mercaptoquinoline dihydrate, shiny red needles (m.p. 58–59°; lit. 58–59° (4), 58.5° (6)), was obtained by dissolving the residue in dilute sodium hydroxide solution, and then neutralizing the mixture by adding dry ice. Anhydrous 8-mercaptoquinoline, a non-viscous blue liquid, was obtained by drying the red product in a nitrogen atmosphere over sodium hydroxide pellets. The yield was 0.78 g (61%).

For personal use only.

showed strong sterol color reactions. The material responsible for these reactions was isolated by column chromatography and was found to be a white crystalline substance (white plates from acetone), m.p. 148–149° C. This melting point was not depressed by admixture with cholesterol. The substance sublimed and was readily soluble in ether, acetone, chloroform, benzene, ethyl acetate, petroleum ether, and hot alcohol, and was slightly soluble in water and cold alcohol. It was optically active, $[\alpha]_D^{20}$ +39.8° (*c*, 2.123 in chloroform). Its color reactions in a series of seven tests were the same as those obtained with authentic cholesterol.

From the results of elementary analysis and of the osmometric method for molecular weight determination, it was confirmed that the molecular formula corresponded to $C_{27}H_{46}O$.

The substance gave a positive precipitation reaction with digitonin (8). The infrared spectrum in KBr and the ultraviolet spectrum (9) in ethanol were identical with those of cholesterol.

The substance formed the following derivatives: a monomethyl ether, $C_{28}H_{48}O$, m.p. 84° C, $[\alpha]_D^{20}$ −46.6° (*c*, 1.356 in chloroform); a monoacetate, $C_{29}H_{48}O_2$, m.p. 115° C, $[\alpha]_D^{20}$ −47.3° (*c*, 1.985 in chloroform); a benzoate, $C_{34}H_{50}O_2$, m.p. 146° and 180° C, $[\alpha]_D^{20}$ −13.9° (*c*, 1.562 in chloroform); a dibromide (8, 10, 11), $C_{27}H_{46}OBr_2$, m.p. 113° C, $[\alpha]_D^{20}$ −44.6° (*c*, 1.568 in chloroform).

All of the above properties of the substance and its derivatives are the same as those of cholesterol and its derivatives; therefore there seems to be no doubt that the substance is cholesterol.

There have been reports on the isolation of fungal sterols (12). The most abundant in microorganisms is ergosterol, with yields depending both on the species and on the conditions of cultivation (13). Among species of *Penicillium* (14) only traces of ergosterol could be found in mycelium grown in submerged culture, while the felts from surface cultures contained over 1% of the steroid. However, there has been no report on the isolation of cholesterol from fungal metabolic products. Indeed, among plants, only certain of the marine Rhodophyceae have been reported to produce this substance (15). It is very interesting, then, to find that *P. funiculosum* (PRL 1724) is capable of producing cholesterol.

EXPERIMENTAL

Organisms

Penicillium funiculosum Thom (PRL 1724) was used throughout this work. Its identity was confirmed by Miss Dorothy Fennel, who considered it to be an aberrant strain of *P. funiculosum*. Its culture and characteristics are being described elsewhere.

Cultural Methods for Sterol Production

The liquid medium used for shake-flask culture contained glucose 30 g, Difco Bacto-peptone 5 g, distilled water 1000 ml.

The medium was dispensed into 250-ml Erlenmeyer flasks in the amount of 25 ml per flask. The flasks containing the medium were plugged with cotton and autoclaved at 15 lb pressure for 15 minutes. Liquid cultures were grown for approximately 7 days at 24° C on a rotary shaker with a 1/2-in. radius of motion, operating at about 240 r.p.m.

Inoculum

Inoculum for shake-flask cultures was usually prepared from 7-day shake-flask cultures which had been originally inoculated with a suspension of a potato dextrose agar culture blended in distilled water.

Recovery of Sterol from Mycelium

When the wine-red pigmentation of the cultures visually appeared to have reached a maximum, the cultures were bulked and freeze-dried. The resulting solids were extracted with petroleum ether (b.p. 35–60° C) for 48 hours in Soxhlet apparatus. A pale yellow "oil" was recovered from the extract by removal of the petroleum ether by evaporation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Column Chromatography

A slurry of aluminum oxide (30 g Brockman Grade 1) in benzene was used to prepare a column 15 cm long and 2.2 cm in diameter. The sample (1 g) of pale yellow "oil" was dissolved in a minimum amount of benzene and added to the column. The column was eluted, first with benzene and then with benzene – ethyl acetate (4:1). A white crystalline substance (24 mg) was left after evaporation of the solvent from the benzene – ethyl acetate eluates. This substance was recrystallized repeatedly from acetone to give white plates, m.p. 149° C, $[\alpha]_D^{20}$ +39.8 (*c*, 2.123 in chloroform). Found: C, 83.96; H, 12.01; OMe, 0. Calculated for $C_{27}H_{46}O$: C, 83.87; H, 11.99.

Characteristics of Crystalline Material

Solubility.—The substance sublimed and was readily soluble in ether, acetone, chloroform, benzene, ethyl acetate, petroleum ether, and hot alcohol and was slightly soluble in water and cold alcohol.

Molecular weight determination by osmometric method.—Found: 391, 385. Calculated for $C_{27}H_{46}O$: 386.44.

Precipitation reactions with digitonin (8).—One hundred milligrams of digitonin was dissolved in 10 ml of 90% alcohol. A small amount of the crystalline metabolic product was dissolved in alcohol and when added to digitonin alcoholic solution immediately gave a perceptible precipitate.

Color reactions.—The color reactions of the substance obtained from *P. funiculosum* and of authentic cholesterol were positive for the Liebermann (1), Liebermann–Burchard (2), Salkowski (3), Lifschütz (4), and Tshugajeff (5) reactions but negative for the Rosenheim (6) and Tortelli–Jaffe (7) reactions.

Derivatives

Monomethyl ether.—The substance (100 mg) was refluxed with dimethyl sulphate (2 ml) and 5% sodium hydroxide solution (15 ml) for 3 hours. The solution was cooled, neutralized, and extracted with ether. Purification by recrystallization from acetone gave white crystals (66 mg), m.p. 84° C, $[\alpha]_D^{20}$ −46.6° (*c*, 1.356 in chloroform). Found: C, 83.95; H, 12.1. Calculated for $C_{28}H_{48}O$: C, 83.93; H, 12.08.

Monoacetate.—The substance (200 mg) taken in freshly distilled acetic anhydride (5 ml) containing anhydrous sodium acetate (500 mg) was refluxed for 4 hours. The contents were poured onto broken ice, and white crystals separated. Purification by recrystallization from acetone gave white needles (142 mg), m.p. 115° C, $[\alpha]_D^{20}$ −47.3° (*c*, 1.985 in chloroform). Found: C, 81.28; H, 11.30. Calculated for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29.

Benzoate.—The substance (100 mg) was dissolved in anhydrous pyridine (3 ml), and benzoyl chloride (500 mg) was added. The mixture was refluxed for 1 hour and poured onto broken ice. The precipitate was extracted with ether, washed with 5% sodium carbonate solution, and purified by recrystallization from 95% ethanol to give white prisms (52.5 mg), m.p. 146° C (the melting becomes clear at about 180° C), $[\alpha]_D^{20}$ −13.9° (*c*, 1.562 in chloroform). Found: C, 83.18; H, 10.3. Calculated for $C_{34}H_{50}O_2$: C, 83.21; H, 10.27.

Dibromide (8, 10, 11).—The substance (200 mg) in 5 ml of ether was gently warmed and 4 ml of a solution of bromine and sodium acetate in acetic acid added. The dibromide began to crystallize out in a few minutes. The crystalline paste was cooled in an ice bath and stirred with a rod for about 10 minutes to ensure complete crystallization. The crystals were collected on a small suction funnel and washed with an ice-cold ether – acetic acid (3:7) solution to remove the yellow mother liquor. The crystals were finally washed with a little methanol, and dried (111 mg), m.p. 113° C, $[\alpha]_D^{20}$ −44.6° (*c*, 1.568 in chloroform). Found: C, 59.42; H, 8.3; Br. 29.8. Calculated for $C_{27}H_{46}O_2Br_2$: C, 59.36; H, 8.40; Br, 29.28.

Each of these derivatives was prepared from authentic cholesterol with similar results.

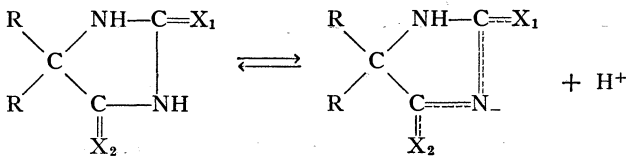
THIOHYDANTOINS
V. IONIZATION OF 2,4-DITHIOHYDANTOINS AS ACIDS

J. T. EDWARD AND O. J. CHIN

Thioamides are more acidic than amides (1) because the thiocarbonyl group is more polarized than the carbonyl group (2). Similarly, 2-thiohydantoin (I; R = H, X_1 = S, X_2 = O) (pK_a ~ 8.5 (3)) is more acidic than hydantoin (I; R = H, X_1 = X_2 = O) (pK_a 9.12 (4)), and so 2,4-dithiohydantoin (I; R = H, X_1 = X_2 = S) would be expected to be more acidic yet, with a pK_a of about 8. We have confirmed this expectation by determining the dissociation constant of the readily available 5,5-dimethyl-2,4-dithiohydantoin (I; R = Me, X_1 = X_2 = S); this should be only very slightly weaker as an acid than 2,4-dithiohydantoin (3).



The absorption spectrum of 5,5-dimethyl-2,4-dithiohydantoin in weakly acidic aqueous solution shows a strong peak at 296 mμ (ϵ 27,600). A peak in this region has been found characteristic of 2,4-dithiohydantoins generally (5). In solutions more alkaline than pH 10 the peak has shifted to 318 mμ (Fig. 1A). In buffer solutions of pH between 5 and 10

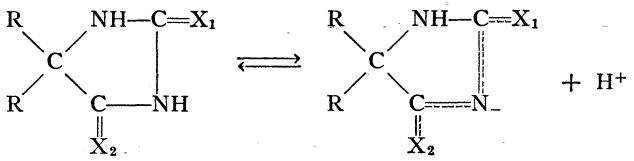
THIOHYDANTOINS
V. IONIZATION OF 2,4-DITHIOHYDANTOINS AS ACIDS

J. T. EDWARD AND O. J. CHIN

Thioamides are more acidic than amides (1) because the thiocarbonyl group is more polarized than the carbonyl group (2). Similarly, 2-thiohydantoin (I; R = H, X_1 = S, X_2 = O) (pK_a ~ 8.5 (3)) is more acidic than hydantoin (I; R = H, X_1 = X_2 = O) (pK_a 9.12 (4)), and so 2,4-dithiohydantoin (I; R = H, X_1 = X_2 = S) would be expected to be more acidic yet, with a pK_a of about 8. We have confirmed this expectation by determining the dissociation constant of the readily available 5,5-dimethyl-2,4-dithiohydantoin (I; R = Me, X_1 = X_2 = S); this should be only very slightly weaker as an acid than 2,4-dithiohydantoin (3).



The absorption spectrum of 5,5-dimethyl-2,4-dithiohydantoin in weakly acidic aqueous solution shows a strong peak at 296 mμ (ϵ 27,600). A peak in this region has been found characteristic of 2,4-dithiohydantoins generally (5). In solutions more alkaline than pH 10 the peak has shifted to 318 mμ (Fig. 1A). In buffer solutions of pH between 5 and 10

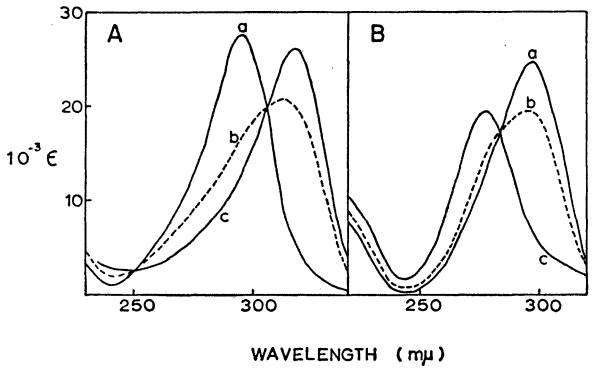


FIG. 1. Ultraviolet absorption of (A) 5,5-dimethyl-2,4-dithiohydantoin at pH (*a*) 2.05, (*b*) 8.00, (*c*) 10.00. (B) 3-methyl-5,5-pentamethylene-2,4-dithiohydantoin at pH (*a*) 6.5, (*b*) 9.71, and in (*c*) 0.1 *N* sodium hydroxide.

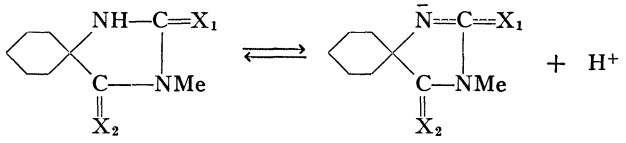
absorption curves intermediate in character are obtained, one of which is shown in Fig. 1A; all pass through an isobestic point at 306 mμ. Evidently ionization takes place in this pH range; from the change in absorption at 318 mμ a mixed dissociation constant pK_a^m (6) of 7.6±0.1* has been calculated by the usual methods (6). Taking account of the ionic strength of the buffer solutions, this indicates a thermodynamic pK_a of 7.7±0.1.

The relatively high acidity of 2,4-dithiohydantoins explains their solubility in aqueous sodium bicarbonate and acetate (7).

Ionization at $N_{(1)}$—H, in contrast to ionization at $N_{(3)}$—H, is accompanied by a shift in the main absorption peak to a shorter wavelength. This is shown in Fig. 1B for 3-methyl-5,5-pentamethylene-2,4-dithiohydantoin (III; $X_1 = X_2 = S$), which has an absorption



III IV

peak at 297 mμ (ε 24,800) in water at pH 6.5, and at 277.5 mμ (ε 19,300) in 0.1 *M* sodium hydroxide and more alkaline solutions. At pH values between 8 and 12 a family of curves passing through an isobestic point a 283 mμ is obtained. From the change in absorption at 260–310 mμ with pH, a pK_a^m of 10.05±0.03 and pK_a of 10.09±0.03 may be calculated. This compares with a pK_a^m of 11.23 for 3-methyl-5,5-pentamethylene-2-thiohydantoin (III; $X_1 = S$, $X_2 = O$) (4), illustrating again the acid-strengthening effect of replacing carbonyl by thiocarbonyl.

EXPERIMENTAL

3-Methyl-5,5-pentamethylene-2,4-dithiohydantoin was prepared according to Carrington and Waring (5), and 5,5-dimethyl-2,4-dithiohydantoin was obtained from Aldrich Chemical Co. Both compounds were crystallized to constant melting point. The spectrum of 5,5-dimethyl-2,4-dithiohydantoin was determined in buffer solutions of pH 2.05, 5.34, 7.00, 7.45, 7.60, 8.00, 8.22, 8.62, 9.04, 10.0, and 11.90, and ionic strength 0.06–0.14 *M* at 20–24°. The spectrum of 1-methyl-5,5-pentamethylene-2,4-dithiohydantoin was determined in buffer solutions of pH 6.5, 8.46, 9.20, 9.71, and 10.41; in sodium hydroxide of pH 11.87; and in 0.1 *M* and 1 *M* sodium hydroxide. The ionic strength of the latter buffer solutions was about 0.01 *M* and the temperature of the determinations 18–21°.

SYNTHESIS OF DEUTERATED CHLOROSILANE AND BROMOSILANE[1]

R. D. VERMA AND L. C. LEITCH

Normal and deuterated chloro- and bromo-silanes were recently required to find out whether SiH_3 or SiD_3 radicals are formed by flash photolysis. Chloro- and bromo-silanes have always been prepared as reported by Stock and Somieski (1) from silane and hydrogen chloride or bromide in the presence of the corresponding aluminum halide. Trideuteriochlorosilane was similarly prepared from tetradeuteriosilane and deuterium chloride by Lord, Robinson, and Schumb (2). Peake (3) informed us in a private communication of the formation of bromosilane in small quantities when a slow current of anhydrous hydrogen bromide is bubbled into a solution of phenylsilane in diphenyl ether. Owing to the low yield of bromosilane obtained by us with this method and because a large amount of deuterium bromide would be required for the synthesis of the deuterated compound, the reaction was tried in a sealed tube with a slight excess of hydrogen or deuterium bromide. Bromo- and chloro-silanes were isolated in 70% yields without the liberation of hydrogen and the formation of di- and tri-halosilanes, unless the reaction time was prolonged from a few days to several months.

EXPERIMENTAL

Phenylsilane

Phenyltrichlorosilane was reduced with lithium aluminum hydride in ether as reported by Nebergall (4).

Bromosilane

Phenylsilane (10.0 g; 0.084 mole) and diphenyl ether (20 ml) were poured into a thick-walled glass tube of 250-ml capacity with a constriction to facilitate sealing later. The tube was attached to the vacuum line and evacuated. Hydrogen bromide (8.3 g; 3.0 ml at −78°; 0.12 mole) was distilled into the tube, which was cooled in liquid nitrogen. It was then carefully sealed at the constriction and transferred to a Dewar flask containing dry ice and acetone at −78°. The tube was allowed to warm up very slowly in the Dewar flask and kept for 1 day at room temperature. It was finally heated for a few hours at 50°. After the tube was cooled to −78° in dry ice and acetone, a nick was made just below the seal, and it was attached to the vacuum line with a piece of thick plastic tubing. The line was evacuated and the seal was broken off at the mark with a pair of pliers. The bromosilane was distilled into a trap and then fractionated from a Dewar at −78°. The yield of liquid with a vapor pressure of 10 mm at −78° was 4.5 ml (6.95 g) or 68.5%.

Chlorosilane

Hydrogen chloride (5.0 l.; 8.1 g; 0.12 mole) gave 4.5 ml (4.63 g) of chlorosilane from 10 g phenylsilane under the same conditions. Yield: 75.5%.

On one occasion the reactants were allowed to stand for 2 months at room temperature before the chlorosilane was isolated. In this instance there was considerable pressure in the tube when it was opened and dichloro- together with trichloro-silane was isolated. The identity of the dichlorosilane was established by vapor pressure measurements and also by the formation of SiHCl radical on flash photolysis of the compound.

Chloro- and Bromo-trideuteriosilane

These compounds were prepared by the same method from deuterium chloride and deuterium bromide and trideuteriophenylsilane. The yields were similar to those obtained with protiated reactants.

THE SYNTHESIS AND SUBSTITUTION REACTIONS OF 3,5-DI-*tert*-BUTYLPHENOL[1]

JOHN W. ELDER[2] AND RAYMOND P. MARIELLA[3]

Department of Chemistry, Loyola University, Chicago, Ill., U.S.A.

Received March 4, 1963

ABSTRACT

3,5-Di-*tert*-butylphenol (I) was synthesized by two independent routes. It was possible to isolate a mononitro and a dinitro product. It was not possible to isolate a trinitrated product (3,5-di-*tert*-butylpicric acid). Bromination of I gave the dibrominated product, and chlorination of I gave a dichlorinated product and a tetrachloro product; the latter was shown to possess the dieneone structure.

Experience has shown that 3- and 3,5-alkyl-substituted phenols could be easily trinitrated to form substituted picric acids (1, 2). Even in the case of *m-tert*-butylphenol (3), where a steric problem might be present, the trinitration proceeded with the same ease as encountered by all the other *m*-alkylphenols previously investigated. In order to present an extreme case of steric crowding, it was decided to synthesize the previously unreported 3,5-di-*tert*-butylphenol (I) and to attempt its trinitration.

The phenol (I) was synthesized through two completely independent paths: one proceeding through 1-bromo-3,5-di-*tert*-butylbenzene, the other through the 3,5-di-*tert*-butylanilinium salt. The methods used in the two syntheses of I follow well-known procedures. These reactions and the substitution reactions carried out on the phenol are shown in Fig. 1.

There can be little doubt of the position of the substituents of 3,5-di-*tert*-butylphenol since the configuration of 3,5-di-*tert*-butyltoluene has been established by Wepster *et al.* (4).

Whether one starts with 3,5-di-*tert*-butyltoluene (IV) (5) or *sym*-tri-*tert*-butylbenzene (II) (6), the final phenol (I) is the same. However, the phenol (I) prepared through the bromo compound route requires less purification than the same phenol (I) obtained through the diazotization method.

The nitration of 3,5-di-*tert*-butylphenol met with considerable difficulties. Nitration by the usual method of adding nitric acid to a sulphuric acid solution of the phenol resulted in the separation of solid (chiefly the mononitro compound) almost as soon as the addition of nitric acid commenced. This could not be prevented even by very high dilutions of the phenol in sulphuric acid. Many variations of technique were attempted; the method of inverse addition given in the experimental part was the most successful, but the mononitro compound was still the major product. It was possible to isolate small quantities

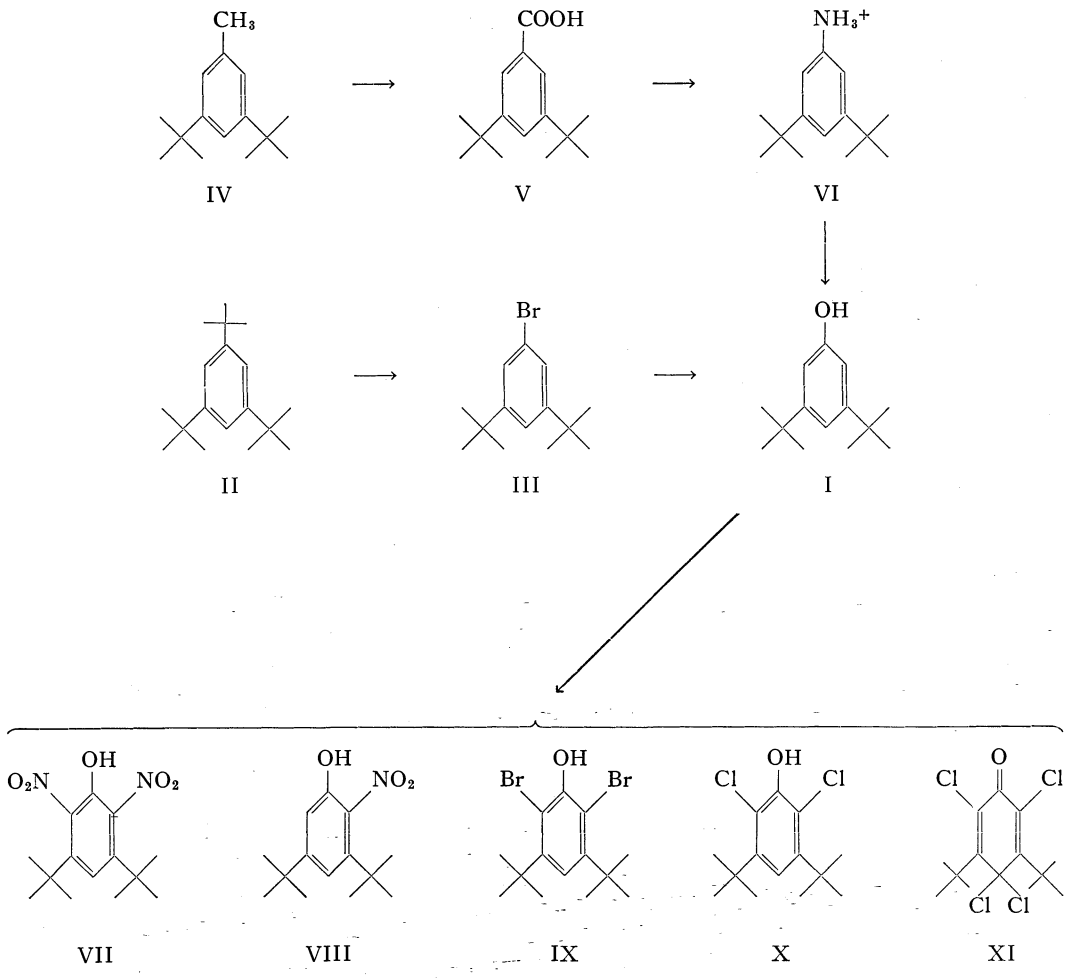

FIG. 1.

of the dinitrated product, but it was not possible to obtain any trinitrated product (3,5-di-*tert*-butylpicric acid).

Bromination of I led quite cleanly to the disubstituted compound, which can be presumed to be 2,6-dibromo-3,5-di-*tert*-butylphenol, since the para position is certainly highly hindered. The chlorination of I was not nearly as clean-cut as the bromination. There were two products formed: a dichloro compound (X) presumably the 2,6-isomer, and a tetrachloro compound (XI) which was analogous to a tetrachloro compound characterized by Zincke and Schaum (7).*

Denivelle and Fort (8) reported that 2,3,4,4,5,6-hexahalocyclohexadiene-2,5-one-1 compounds absorb at 250–280 mμ (in cyclohexane) and 2,2,3,4,5,6-hexahalocyclohexadiene-3,5-one-1 isomers absorb at 350–380 mμ; our compound (XI) had a maximum absorption at 255 mμ (isooctane), and a strong peak at 1685 cm^{-1}.

**By further chlorination of 2,4,6-trichlorophenol, they isolated 2,4,4,6-tetrachlorocyclohexadiene-2,5-one-1. We duplicated their work and found that the dieneone had a strong carbonyl absorption at 1675 cm^{-1}.*

EXPERIMENTAL

Melting points were taken on a Fisher–Johns melting point block and are corrected. Microanalyses were by Microtech Laboratories, Skokie, Illinois. Infrared spectra were determined with a Perkin–Elmer spectrophotometer, Model 21, and the ultraviolet spectra with a Beckman spectrophotometer, Model DU.

1-Bromo-3,5-di-tert-butylbenzene (III)

sym-Tri-*tert*-butylbenzene (II), prepared by the method of Barclay and Betts (9) or that of McCaulay, Lien, and Launer (6), was brominated by the method of Bartlett *et al.* (10) to give a 65% yield of 1-bromo-3,5-di-*tert*-butylbenzene, m.p. 62.5–65.0° C, reported (10) 63–64° C.

3,5-Di-tert-butylphenol (I) (Via the Bromo Route)

A suspension of 10 g (0.038 mole) 1-bromo-3,5-di-*tert*-butylbenzene (III), 1.5 g cupric oxide, and 0.5 g copper powder in 100 ml 10% sodium hydroxide solution was heated in an autoclave with stirring for 24 hours at 275° C. After the bomb had cooled, the contents were washed out with portions of ether and water. The solids were filtered off and the layers separated. The ether layer was extracted with methanolic KOH. The alkaline phase was added to the previous water layer and the methanol was distilled off. The remaining solution was acidified with sulphuric acid and the resultant solid collected. This was purified by vacuum sublimation, yielding 4.2 g (0.020 mole, 53%) 3,5-di-*tert*-butylphenol, m.p. 94–95° C. Anal. Calc. for $C_{14}H_{22}O$: C, 81.49; H, 10.75. Found: C, 81.43; H, 10.57.

The infrared spectrum (KBr disk) contained prominent bands at 3275, 1605, 1465, 1365, 1305, 1250, 955, 855, and 705 cm^{-1}.

Benzoate

The benzoate had m.p. 82.5–83.0° C. Anal. Calc. for $C_{21}H_{26}O_2$: C, 81.25; H, 8.44. Found: C, 81.44; H, 8.53.

1-Naphthylurethan

1-Naphthylurethan had m.p. 162.0–162.5° C. Anal. Calc. for $C_{25}H_{29}NO_2$: C, 79.97; H, 7.79. Found: C, 80.26; H, 7.97.

3,5-Di-tert-butylbenzoic acid (V)

This compound was prepared from 3,5-di-*tert*-butyltoluene (IV) following the method of Schlatter in a 64% conversion, m.p. 171–173° C, reported (5) 172.6–173.0° C.

3,5-Di-tert-butylanilinium sulphate (VI)

A mixture of 36 g (0.153 mole) 3,5-di-*tert*-butylbenzoic acid (V), 108 ml concentrated sulphuric acid, and 315 ml chloroform was stirred in a three-neck flask and heated to 45° C in an oil bath. In small portions, 10.8 g sodium azide was added over the course of 1 hour, and the mixture was stirred for another 4 hours. The mixture was cooled and the chloroform removed under reduced pressure. The residue was poured onto ice, the precipitated amine sulphate collected and recrystallized twice from ethanol, giving 40.0 g (0.071 mole, 93%) 3,5-di-*tert*-butylanilinium sulphate. The sulphate was used in the next step without conversion to the free amine.

3,5-Di-tert-butylphenol (I) (Via the Amine Route)

3,5-Di-*tert*-butylanilinium sulphate (VI) (39.4 g, 0.070 mole) was added to 1000 ml of 20% sulphuric acid solution. After addition of enough ice to bring the temperature to 0° C, 11.2 g, sodium nitrite in 60 ml water was added to the stirred solution over 10 minutes through a separatory funnel whose stem extended below the surface of the solution. The mixture was kept at 0° C for 1 hour with occasional stirring. The liquid was then decanted and added in portions to 300 ml of 20% sulphuric acid solution through which a current of steam was passing. After the liquid had been added, the solid was added in several portions, and the steam distillation continued until no more phenol came over in the distillate. The distillate was extracted with benzene, and the solvent removed by distillation. The remaining solid was purified by vacuum sublimation to give 23.4 g (0.113 mole, 80%) 3,5-di-*tert*-butylphenol, m.p. 93–95° C. This sample was shown to be identical with that obtained from 1-bromo-3,5-di-*tert*-butylbenzene by identical infrared spectra and undepressed mixed melting points.

Polynitration of 3,5-Di-tert-butylphenol

Red fuming nitric acid (75 ml) and 150 ml concentrated sulphuric acid were cooled to 10° C and rapidly agitated as 0.5 g (2.5 mmoles) 3,5-di-*tert*-butylphenol (I) dissolved in 50 ml concentrated sulphuric acid was added dropwise over a 20-minute period. After the addition was complete, the mixture was stirred at room temperature for 4 hours, and then poured on ice. The resulting solid was collected and recrystallized four times from 95% ethanol, giving a sample (0.2 g, 0.17 mmole, 28%) of 2,6-dinitro-3,5-di-*tert*-butylphenol (VII), m.p. 214–215° C (subl.). Anal. Calc. for $C_{14}H_{20}N_2O_5$: N, 9.46. Found: N, 9.00. The infrared spectrum shows a peak at 3450 cm^{-1} which is unchanged with dilution, indicating an intramolecular hydrogen-bonded phenol.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Mononitration of 3,5-Di-tert-butylphenol

3,5-Di-*tert*-butylphenol (I) (1.03 g, 5 mmoles) was dissolved in 100 ml of glacial acetic acid, and the mixture stirred at room temperature while a solution of 0.32 ml 70% nitric acid (5 mmoles) dissolved in 10 ml acetic acid was added over a 10-minute period. The reaction was stirred for another 15 minutes; then the reaction mixture was poured into water and partially neutralized by the addition of solid sodium bicarbonate. The solid was collected, washed with water, and recrystallized four times from pentane, giving 0.6 g (2.4 mmoles, 48%) 2-nitro-3,5-di-*tert*-butylphenol (VIII), m.p. 127.0–128.0° C. Anal Calc. for $C_{14}H_{21}NO_3$: N, 5.57. Found: N, 5.31. The infrared spectrum shows a peak at 3450 cm^{-1} which is unchanged with dilution, indicating an intramolecular hydrogen-bonded phenol.

Polybromination of 3,5-Di-tert-butylphenol

3,5-Di-*tert*-butylphenol (I) (1.03 g, 5 mmoles) was refluxed for 1 hour in 50 ml of acetic acid to which 3.2 g bromine had been added. Evaporation of the solvent and of the excess bromine gave a solid which was recrystallized three times from pentane to give colorless crystals (0.8 g, 2.2 mmoles, 44%) of 2,6-dibromo-3,5-di-*tert*-butylphenol (IX), m.p. 121.5–123.0° C. Anal Calc. for $C_{14}H_{20}Br_2O$: C, 46.17; H, 5.54. Found: C, 46.28; H, 5.72. The infrared spectrum shows a peak at 3430 cm^{-1} which is unchanged with dilution, indicating an intramolecular hydrogen-bonded phenol. A hydrolysis test (refluxing 5 minutes in 5% ethanolic potassium hydroxide, addition of silver nitrate solution) indicated that all halogen was attached to the aromatic ring.

Polychlorination of 3,5-Di-tert-butylphenol

3,5-Di-*tert*-butylphenol (I) (1.03 g, 5 mmoles) was dissolved in 100 ml carbon tetrachloride in a blackened flask. About 1 g of chlorine was bubbled through the mixture over a 10-minute period. The mixture was then refluxed for 30 minutes while chlorine addition was continued at the same rate. The mixture was then cooled, and excess chlorine and the solvent removed at reduced pressure. The residue was a semisolid. Repeated recrystallizations from pentane led to the isolation of two components. The first, a major constituent, was a colorless solid (X), which could not be completely purified (0.8 g, 2.9 mmoles, 58%), m.p. 88.0–89.5° C. Anal. Calc. for $C_{14}H_{20}Cl_2O$: C, 61.09; H, 7.33. Found: C, 60.20; H, 7.01. The infrared spectrum shows a peak at 3430 cm^{-1} which is unchanged with dilution, indicating an intramolecular hydrogen-bonded phenol. The spectrum also showed a small peak at 1685 cm^{-1} which indicates contamination by a small amount of the tetrachloro compound. The hydrolysis test as described above indicated that essentially all the halogen was attached to the aromatic ring.

The second product isolated, a lesser constituent, recovered after six recrystallizations from pentane, was in the form of long colorless needles (XI) (0.1 g, 0.29 mmole, 5.8%), m.p. 160.0–160.5° C. Anal. Calc. for $C_{14}H_{18}Cl_4O$: C, 48.86; H, 5.27. Found: C, 48.97; H, 5.29. The infrared spectrum of this compound shows a strong peak at 1685 cm^{-1} which corresponds to that of an α,β-unsaturated ketone (11). No hydroxyl peak is present in this spectrum.

The ultraviolet spectrum has a maximum at 255 mμ (isooctane), indicating a 2,5-cyclohexadieneone-1 structure (8).

The hydrolysis test, performed as above, indicated the presence of a large portion of alkyl type halide.

ACKNOWLEDGMENT

The authors wish to acknowledge their gratitude to Dr. M. J. Schlatter of California Research Corporation and Dr. A. McCaulay of American Oil Co. for generous gifts of 3,5-di-*tert*-butyltoluene.

PALLADIUM COMPLEXES OF DI-2-THIENYLKETOXIME

WILLIAM J. HOLLAND AND LEO LEE
Department of Chemistry, Essex College, University of Windsor, Windsor, Ontario
Received October 3, 1962

ABSTRACT

The reaction between di-2-thienylketoxime and the palladium (II) ion has been studied. The compounds prepared were the complexes dichlorobis(di-2-thienylketoxime-N,N′)palladium (II), biaquobis(di-2-thienylketoxime-N,N′)palladium (II) half hydrate, and polymeric forms of the chelate bis(di-2-thienylketoxime)palladium (II).

INTRODUCTION

A recent investigation of complex formation between bivalent palladium and 2-thienyl-*trans*-aldoxime has illustrated the utility of a thiophene derivative as an analytical reagent (1). The purpose of the present work was to investigate complex formation between bivalent palladium and di-2-thienylketoxime.

A survey of the literature reveals a surprising lack of information regarding thiophene derivatives in complex formation with the transition metals. Although thenyltrifluoroacetone has been used for the separation of zirconium and hafnium (2) and the stability constants of metal complexes of 2-thiophenecarboxylic acid have been measured (3) no other thiophene derivatives seem to have been studied.

Oximes in general form stable complexes with metals, particularly with those of the transition triads of the Periodic Table, and are widely used for the detection and estimation of those metals. Examples are salicylaldoxime (4) and benzylmethylglyoxime (5).

EXPERIMENTAL

Di-2-thienylketoxime

A solution of 11.2 g of di-2-thienylketone (6), 11.2 g of hydroxylamine hydrochloride, and 44 g of potassium hydroxide in 500 ml of alcohol was refluxed for 2 hours. The reaction mixture was poured into 1000 ml of water and made acid to litmus by the addition of hydrochloric acid. The precipitate was filtered under suction and dissolved in alcohol. Water was added until the solution became turbid. On cooling, colorless needles separated which were filtered under suction and air-dried. There was obtained 10.3 g, 86% yield, of white needles, m.p. 134–136°. Anal. Calc. for $C_9H_7NOS_2$: C, 51.63; H, 3.37; N, 6.69. Found: C, 51.56; H, 3.46; N, 6.55.

Dichlorobis(di-2-thienylketoxime-N,N′)palladium (II)—Compound I

To a 400-ml beaker was added 1.0 g of di-2-thienylketoxime, 50 ml of alcohol, and 4.2 ml of concentrated hydrochloric acid. A solution of 0.40 g of anhydrous palladium (II) chloride in 5 ml of concentrated hydrochloric acid was prepared in a 100-ml beaker by warming on a hot plate. To the palladium (II) chloride solution was added 50 ml of water and the pH was adjusted to zero by dropwise addition of a concentrated potassium hydroxide solution. The palladium (II) chloride solution and 100 ml of 1 *N* hydrochloric acid were added with stirring to the oxime solution. After standing the solution for 1 hour the yellow precipitate was filtered under suction and air dried. There was obtained 1.30 g, 93% yield, of yellow crystals, m.p. 212–214° with decomp. Anal. Calc. for $PdC_{18}H_{14}Cl_2N_2O_2S_4$: Pd, 17.85; N, 4.70; Cl, 11.87. Found: Pd, 17.85; N, 4.58; Cl, 11.83.

On dissolving a few milligrams of I in 10 ml of alcohol and adding alcoholic silver nitrate, a clear solution was obtained which on standing for 3 hours became opalescent.

Regeneration of Di-2-thienylketoxime from I

To a 250-ml separatory funnel was added 0.3 g of I, 50 ml of acetone, 50 ml of chloroform, and 50 ml of concentrated hydrochloric acid. On shaking the mixture for 3 minutes, the solid went into solution and the chloroform layer became colored a pale yellow. The chloroform layer was withdrawn, washed first with a solution of 50 ml of acetone and 50 ml of concentrated hydrochloric acid, then four times with 50-ml portions of water, dried over anhydrous sodium sulphate, and filtered. On evaporation of the chloroform there was obtained a colorless, crystalline residue amounting to 0.22 g, 100% yield, m.p. 133–136°. A mixture melting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

point determination with an authentic sample of di-2-thienylketoxime showed no depression; mixture m.p. 133–136°.

Biaquobis(di-2-thienylketoxime-N,N')palladium (II) Half Hydrate—Compound II

To a 250-ml separatory funnel was added 1.33 g of I, 50 ml of benzene, 50 ml of acetone, and 50 ml of water. The mixture was shaken for 10 minutes, at the end of which time all the solid had gone into solution to give a dark red-brown benzene layer. The benzene layer was washed with seventeen 50-ml portions of water and allowed to stand overnight. The yellow crystalline precipitate was filtered under suction and dried *in vacuo* over anhydrous calcium sulphate. The residue amounted to 0.80 g, 63% yield, m.p. 185–188° with decomp. Anal. Calc. for $PdC_{18}H_{14}N_2O_2S_4.2\frac{1}{2}\ H_2O$: Pd, 18.73; H_2O, 7.93. Found: Pd, 18.77; H_2O, 8.06.

The above procedure was repeated with 0.7221 g of I. The combined water washings were titrated with 0.102 *N* NaOH using phenolphthalein as indicator. Calc. for $PdC_{18}H_{14}Cl_2N_2O_2S_4$: HCl, 12.18. Found: HCl, 12.14.

Regeneration of Di-2-thienylketoxime from II

The procedure used for the regeneration of the ketoxime from I was followed with 0.15 g of II. There was obtained 0.11 g, 93% yield, of a crystalline residue, m.p. 133–136°. A mixture melting point determination with an authentic sample of di-2-thienylketoxime showed no depression; mixture m.p. 133–136°.

Bis(di-2-thienylketoxime)palladium (II) High Polymer—Compound III

On heating II at 120° for 3 hours, there was obtained a yellow-brown residue, m.p. 187–190° with decomp. Anal. Calc. for $PdC_{18}H_{12}N_2O_2S_4$: Pd, 20.35; N, 5.36. Found: Pd, 20.38; N, 5.46.

Ultraviolet absorption measurements in chloroform gave for III λ_{max} 288 mμ; $E^{1\%}_{1\ cm}$ 547.

On dissolving III in boiling benzene and allowing the solvent to evaporate at 50° a brown residue was obtained. This material in chloroform gave an ultraviolet absorption spectrum identical with that obtained with IV; λ_{max} 284 mμ; $E^{1\%}_{1\ cm}$ 507.

A cyroscopic molecular weight of III in nitrobenzene gave a value of 533. The calculated value for the monomer of IV is 523. Evaporation of the nitrobenzene on a steam bath under an air current gave a dark brown solid residue of IV.

A dipole moment measurement of III in carbon tetrachloride solution gave μ = 1.86 D.

Regeneration of Di-2-thienylketoxime from III

The procedure used for the regeneration of the ketoxime from I was followed with 0.15 g of III. There was obtained 0.12 g, 100% yield, of a crystalline residue, m.p. 133–136°. A mixture melting point determination with an authentic sample of di-2-thienylketoxime showed no depression; mixture m.p. 133–136°.

Bis(di-2-thienylketoxime)palladium (II) Low Polymer—Compound IV

To a 1-liter beaker was added 1.1 g of di-2-thienylketoxime, 5 ml of a saturated solution of potassium hydroxide, and 1500 ml of water. The pH of the solution was adjusted to 6.9 by the addition of hydrochloric acid. A solution of 0.4 g of palladium (II) chloride was prepared in 5 ml of concentrated hydrochloric acid with warming and diluted to 75 ml with water. The pH of the palladium (II) chloride solution was adjusted to 6.2 by the addition of potassium hydroxide solution and the solution diluted to 100 ml. To the boiling ketoxime solution was added alternately 2.0 ml of the palladium (II) chloride solution and 0.70 ml of 0.1024 *N* sodium hydroxide with vigorous stirring. When all the palladium (II) chloride had been added and a total of 35.0 ml of the sodium hydroxide solution, the reaction mixture was cooled to room temperature. The dark brown precipitate was filtered under suction and air dried. The dried residue was dissolved in benzene and filtered from a small amount of palladium (II) oxide. After evaporation of the benzene the residue was suspended in alcohol overnight to remove any unreacted ketoxime. The suspended chelate was filtered under suction and air dried. There was obtained 0.75 g of IV, m.p. 175–185° with decomp. Anal. Calc. for $PdC_{18}H_{12}N_2O_2S_4$: Pd, 20.35; N, 5.36. Found: Pd, 20.39; N, 5.44.

Ultraviolet absorption measurements of IV in chloroform gave λ_{max} 284 mμ; $E^{1\%}_{1\ cm}$ 509.

A dipole moment measurement of IV in carbon tetrachloride gave μ = 2.60 D.

A cyroscopic molecular weight determination of IV in nitrobenzene gave a value of 519. The calculated value for the monomer is 523. A similar determination in benzene gave a value of 1290. On standing, the cold benzene solution deposited yellow-brown crystals of III, m.p. 185–190° with decomp. The value 1290 corresponds to an average degree of polymerization of 2.5 for IV.

Regeneration of Di-2-thienylketoxime from IV

The procedure used for the regeneration of the ketoxime from I was followed with 0.15 g of IV. There was obtained 0.07 g, 60% yield, of a crystalline residue, m.p. 133–136°. A mixture melting point determination with an authentic sample of di-2-thienylketoxime showed no depression, mixture m.p. 133–136°.

DISCUSSION

In the present work di-2-thienylketoxime was found to form either a complex or a chelate with bivalent palladium, depending on the pH of the reaction medium. In 2 *N*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hydrochloric acid a small amount of the complex (I) formed and the major part of the reagent was recovered. In 1 *N* acid solution an almost quantitative yield of the complex (I) was obtained, while in neutral or slightly basic solution there was a good yield of the chelate (IV). In moderately acid solution in the pH range 1 to 6, mixtures of I and IV formed.

The complex (I) is a pale yellow crystalline solid insoluble in water and slightly soluble in benzene and chloroform, while the chelate (IV) is a dark brown solid insoluble in water and very soluble in benzene and chloroform, giving dark red-brown solutions.

When the complex (I) was treated with a mixture of benzene and water, hydrogen chloride was eliminated quantitatively as was shown by titration of the water layer with standard base. On standing, the benzene layer deposited a yellow crystalline solid which at 120° lost $2\frac{1}{2}$ moles of water to give a light brown solid (III) insoluble in water and slightly soluble in benzene and chloroform.

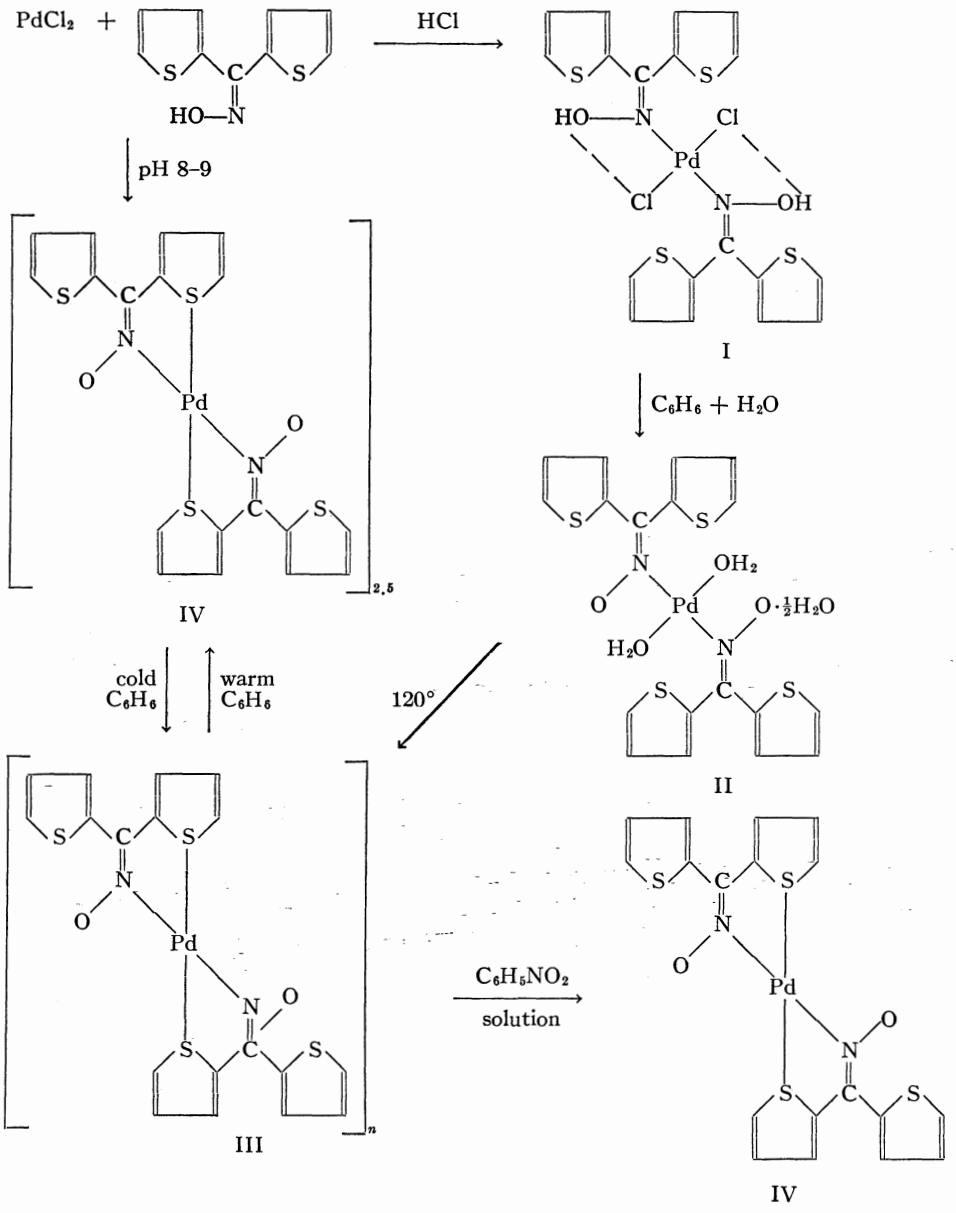
In alcoholic silver nitrate solution I gave no immediate precipitate, but on standing, the solution became turbid and silver chloride began to precipitate. This indicates that the chlorine atoms are bound covalently to the palladium. Analysis of I showed that two molecules of the ketoxime and two atoms of chlorine are associated with each palladium atom. Palladium therefore has a coordination number of four. This is to be expected since the existence of palladium (II) compounds with a coordination number greater than four has never been convincingly demonstrated (7). Although there is no experimental evidence to indicate whether coordination is with the nitrogen of the oxime group rather than with the sulphur of the thiophene ring, nevertheless the coordinating ability of the oxime group and the very strong donor properties of the oxime nitrogen are very well known (8). Further, one would expect the donor ability of the sulphur to be decreased because of resonance with the unsaturated ring.

Magnetic susceptibility measurements showed I and II to be diamagnetic. The complex (I) therefore is considered to be planar rather than tetrahedral. This is in accord with the fact that no tetrahedral structure for palladium (II) complexes has yet been identified positively, unless, of course, it is sterically impossible for the compound to assume a planar configuration. Also coordination theory predicts a planar configuration for ions such as bivalent palladium which have one *d*-orbital available for bond formation. In such a situation dsp^2 hybridization occurs and a square planar structure results.

The postulated hydrogen bonding for I eliminates the possibility of cis–trans isomerism. Such bonding would give rise to a more stable structure, since it has been long observed that an increase in the number of rings within a particular complex structure results in greater stability (9). Such a postulated bonding has precedent in the literature. For example, Brady and Meurs (10) proposed such bonding in their study of the nickel derivatives of biacetyl dioxime. That the complex (I) exists in the trans form is borne out by the facile elimination of hydrogen chloride. The ease of such elimination indicates that the hydrogen and chlorine atoms are adjacent to each other, whereas a cis configuration would place them on opposite sides of the molecule. Further molecular models reveal that a cis configuration would be more strained than a trans configuration. Infrared spectra of I indicate hydrogen bonding. Such spectra reveal no hydroxyl band present in the region 3400–3700 cm^{-1}, but do show a very broad band at 3100 cm^{-1}. Thus, the hydroxyl group band has been shifted considerably to a lower frequency. Such a shift is considered evidence for strong intramolecular bonding.

The structure shown for the hydrate (II) is based on the analysis and the course of the reaction used in its preparation. Thus, on shaking I in a mixture of benzene and water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



the benzene layer becomes colored a dark red-brown and hydrogen chloride is produced in the water layer. The color of the benzene layer indicates that a chelate has formed. On standing, the color disappears and a yellow crystalline precipitate forms. This is interpreted as being due to a displacement of the palladium–sulphur bond in the chelate with formation of a complex in which water molecules are coordinately bonded to palladium. Molecular models reveal that the two water molecules must be trans since a cis configuration would impart a large strain. The remaining one-half water molecule is considered to be involved in crystal formation.

For personal use only.

The structure assigned to III is based on the analysis and on molecular weight determinations of III and IV. Thus IV in freezing benzene gave a molecular weight corresponding to that of a low polymer of IV, the average degree of polymerization being 2.5. On standing, the cold benzene solution deposited a yellow-brown solid with the same melting point as III. Thus IV is converted to III from cold benzene solution. This indicates that III is a polymer of IV. No direct molecular weight determination of III could be carried out in benzene owing to its insolubility in this solvent. On suspending III in boiling benzene and allowing the solvent to evaporate at 50° IV was obtained. Thus in hot benzene III is reconverted to IV. In freezing nitrobenzene III gave a molecular weight corresponding to that of a monomer of IV. On evaporation of the nitrobenzene a dark brown residue of IV was obtained. Substance III is thus converted to a low polymer of IV from warm nitrobenzene.

The analyses of III and IV showed these substances to be isomeric. That III and IV are not simply dimorphic is borne out by an examination of their ultraviolet absorption spectra in chloroform solution. Small, but definite, differences in their spectra were found.

The possibility of III and IV being cis–trans isomers was eliminated by dipole moment measurements in carbon tetrachloride solution. The moments of III and IV were 1.8 and 2.6 D respectively. If IV were a cis isomer the dipole moment would be expected to be much higher. Also a cis configuration for IV would mean that the two negatively charged oxygens of the nitrone groups would be adjacent to one another. It is highly unlikely that such a separation of like charges would take place since the resulting compound would be highly unstable.

The assignment of the chelate structure to IV is based on the analysis and on its solubility in benzene or chloroform to give highly colored solutions. Molecular weight determination in benzene indicates that IV is a low polymer of the structure shown. Similar determination in nitrobenzene reveals IV as the monomer in this solvent. That the structure contains two nitrone groups is inferred by reference to the studies made by Pfeiffer (11) on the nickel dimethylglyoxime chelate. In this case the author showed that a covalent linkage exists between nitrogen and the metal rather than between oxygen and the metal.

Finally, that the ketoxime reagent undergoes no change in structure is shown by the fact that it could be readily regenerated in high yield from each of I, II, III, and IV by treatment with strong hydrochloric acid solution.

THE DECOMPOSITION OF 2-METHYL-Δ^2-OXAZOLINE IN AQUEOUS SOLUTION[1]

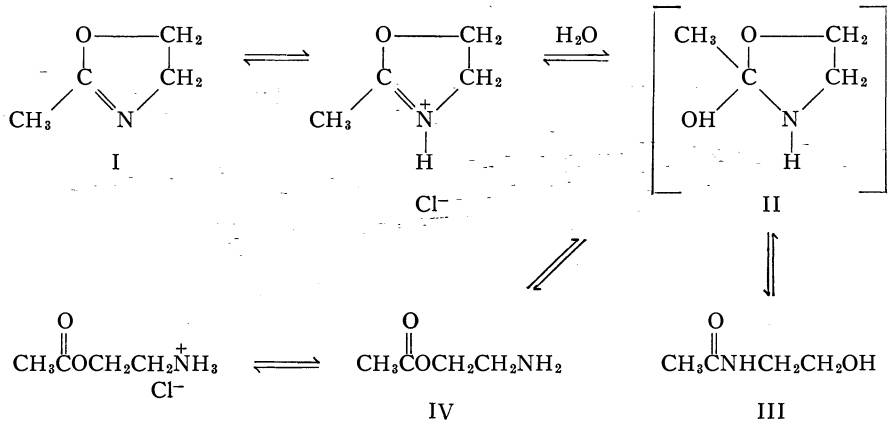
R. GREENHALGH, R. M. HEGGIE, AND M. A. WEINBERGER
Defence Research Chemical Laboratories, Ottawa, Canada

Received January 3, 1963

ABSTRACT

Nuclear magnetic resonance has been used to follow the decomposition of aqueous solutions of 2-methyl-Δ^2-oxazoline (0.29 *M*) at constant pH values in the range −1 to 14. The decomposition is first order with respect to total oxazoline at any specific pH, but deviates from the simple reaction of water with the protonated species above pH 5. At neutral pH values this is shown to be partially due to a second reaction involving 2-methyl-Δ^2-oxazoline and O-acetylethanolamine which yields N-2-acetoxyethyl N′-2-hydroxyethyl acetamidate. The decrease in rate constant at pH < 2 is accounted for by variation in the water concentration, which is related to the acidity function. A kinetic expression is derived for the decomposition over the whole pH range studied. The decomposition of the amidate is also discussed.

One of the more interesting properties of 2-methyl-Δ^2-oxazoline (I) is its decomposition in aqueous solution to give either O-acetylethanolamine (IV) or N-acetylethanolamine (III), both the rate of reaction and the product varying with pH. This decomposition has been examined kinetically in neutral and acid solutions by other workers (1, 2) and, except for pH < 2, the variation in the rate of decomposition was shown to be dependent on the concentration of the protonated species. Martin and Parcell suggested the following mechanism, which involves 2-hydroxy-2-methyloxazolidine (II) as a labile intermediate:



Earlier work in these laboratories (3) on the reaction of I in more concentrated solutions showed that this scheme did not account for the results at pH 7 and 8. Consequently, a study of the decomposition of I in aqueous solutions of pH −1 to 14 was undertaken.

Examination of the n.m.r. spectra of I and its known decomposition products, III and IV, in this pH range showed that they could be readily differentiated by the field position of the methyl protons. The minimum separation observed in these experiments was at pH 7 between I and III; however, since III is not a significant hydrolysis product of I at this pH, it did not produce any difficulties. At pH 7 the methyl triplet in I (4) is centered

at 2.728 p.p.m. upfield from water, whilst III and IV give single methyl proton peaks at 2.709 and 2.571 p.p.m. respectively. Since n.m.r. can also be used under certain conditions to determine the relative amounts present (5), it appears to be a suitable method for following the decomposition of oxazoline.

Over the pH range studied, the decomposition of I at any specific pH was found to follow first-order kinetics. Typical first-order plots are shown in Fig. 1.

The pH dependence of the observed first-order rate constants (k_{obs}) is shown in Fig. 2.

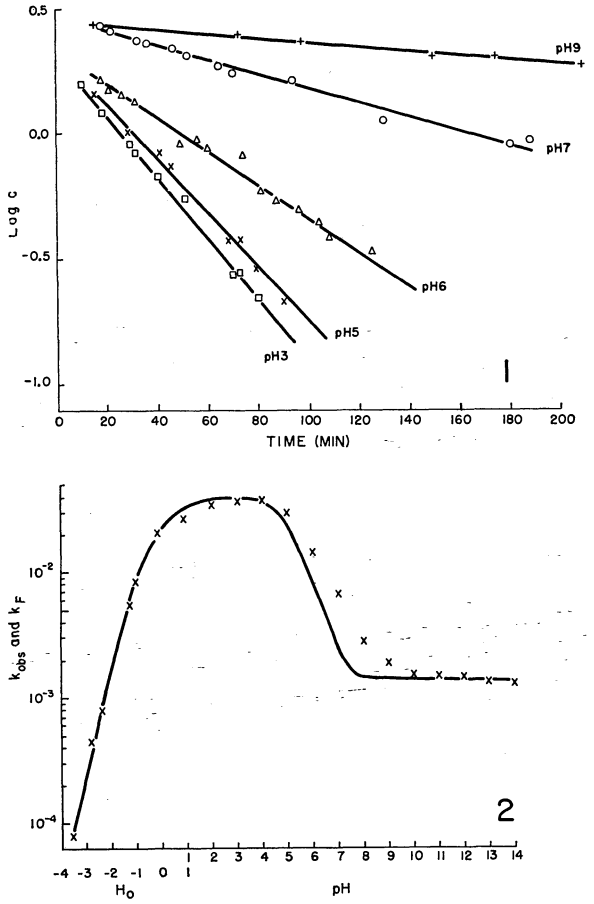

FIG. 1. Decomposition of I at 30° and constant pH. Concentration is expressed as the ratio of peak height of I to that of external standard.

FIG. 2. Variation with pH and H_0 of the observed first-order rate constant (points). The curve represents the values calculated from equation (F) with $k_1 = 4.58\times10^{-9}$ mole l^{-1} min^{-1}, $k_2 = 3.06\times10^{-2}$ min^{-1}, and $K_a = 3.16\times10^{-6}$ mole l^{-1}.

Examination of Fig. 2 reveals that the observed rate constants are virtually pH independent in alkaline solution. Therefore the decomposition of oxazoline above pH 10 is compatible with one or both of the following mechanisms, where B and BH^+ represent I and its protonated form:

$$BH^+ + OH^- \rightarrow \text{products}$$

$$B + H_2O \rightarrow \text{products.}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The former mechanism is preferred; however, our data do not allow us to differentiate between specific and general base catalysis. Both mechanisms lead to an expression for the first-order constant with respect to total oxazoline,

$$k_A = \frac{k_1}{K_a + [OH_3^+]}, \tag{A}$$

which is constant when $[OH_3^+] \ll K_a$, the ionization constant for the equilibrium $BH^+ \rightleftharpoons B + H^+$; k_1 is a composite constant, and k_A represents the theoretical approximation to k_{obs} given by equation (A). This nomenclature is used throughout to differentiate the theoretical first-order constants applicable to the various pH ranges.

In addition to the above mechanism the general shape of the k_{obs}/pH curve for the remaining pH region can, with some reservation at pH 6, 7, and 8, be accounted for by a mechanism proposed by Edward and Meacock (6(*a*), 6(*b*)) to explain the hydrolysis of benzamide and methyl benzimidate.

$$B + OH_3^+ \overset{1/K_1}{\rightleftharpoons} \overset{+}{B}H + H_2O \overset{K_2}{\rightleftharpoons} M^+ \overset{k}{\rightarrow} \text{products}$$

M^+ is the transition state for the hydrolysis, k a velocity constant, $1/K_1$ and K_2 are equilibrium constants. This mechanism leads to the expression

$$k_B = \frac{kK_2K_a}{K_1} \cdot \frac{[OH_3^+]}{K_a + h_0} \cdot \frac{f_B f_{OH_3^+}}{f_{M^+}}, \tag{B}$$

where h_0 is the non-logarithmic acidity function. The activity coefficient term is assumed not to vary and an overall constant (k_2) can therefore be defined:

$$k_2 = \frac{kK_2K_a}{K_1} \cdot \frac{f_B f_{OH_3^+}}{f_{M^+}}.$$

At any pH, then, the observed rate constant will be the sum of $k_A + k_B$. In the pH region around the pK_a, i.e. 5.5, this sum reduces to expression (C) since $h_0 \simeq [OH_3^+]$:

$$k_C = \frac{k_2[OH_3^+] + k_1}{K_a + [OH_3^+]}. \tag{C}$$

This describes the shape of the k_{obs}/pH curve in this region, apart from deviations which will be considered later.

For the range pH 2–4, since $K_a \ll h_0 = [OH_3^+]$ and the contribution from equation (A) is now negligible, equation (C) reduces to

$$k_D = k_2. \tag{D}$$

Finally, at high acid concentrations, where $h_0 \neq [OH_3^+]$, equation (B) becomes

$$k_E = k_2 \frac{[OH_3^+]}{h_0}. \tag{E}$$

The complete expression for the variation of the first-order constant with pH in the range -1 to 14 is therefore

$$k_F = \frac{k_2[OH_3^+] + k_1}{K_a + h_0}, \tag{F}$$

where $h_0 = [OH_3^+]$ at high pH's. The curve representing this expression is shown in Fig. 2 and, as can be seen, the observed rate constant at low pH is in good agreement with that

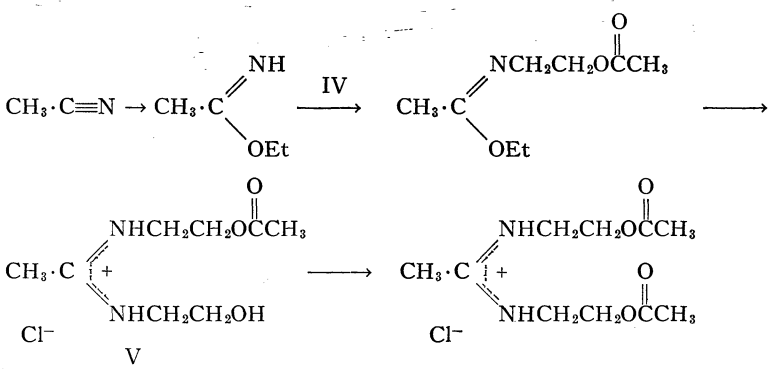
derived from equation (E). The decrease in k_{obs} is thus adequately described by the decrease in water concentration, which is proportional to $[OH_3^+]/h_0$. The treatment at high acid concentrations is equivalent to that of Bunnett (7(*c*)) for a base strong enough to be virtually completely protonated at the acid concentrations involved and with $\omega^* = 0$. The slope (ω^*) of the Bunnett plot (log k_{obs} − log [HCl] − H_0 vs. log a_{H_2O}) applicable in this case (7(*a*)) was found to be very close to zero. This implies that water is acting as a proton transfer agent in the rate-determining step (7(*b*)) and further that there is no change in hydration between the transition state and the reactants (7(*c*)). Martin and Parcell (2) have proposed an alternative expression which accounts for the falloff in k_{obs} with decrease in pH in terms of an equilibrium between BH^+ and 2-hydroxy-2-methyloxazolidine (II) which is reversed by high hydrogen ion concentration. This latter treatment has been applied to both I and 2-methyl-Δ^2-thiazoline, although very recently Martin has expressed some reservations about the applicability of his mechanism to the hydrolysis of I (8).

From Fig. 2 it is evident that agreement between the theoretical curve and the experimental points is poor in the range pH 5–9. This is due to a second reaction involving I that yields an amidate which at pH 7 is the primary product (9). This compound has been isolated, and spectral and analytical data showed it to be N-2-acetoxyethyl N′-2-hydroxyethyl acetamidate hydrochloride (V). The infrared spectrum showed peaks at 3325, 1060; 1660; 1740, and 1230 cm^{-1}, which were assigned to hydroxyl, imino, and ester groups. The presence of the hydroxyl group was confirmed by acetylation, which gave a crystalline derivative whose infrared spectrum showed an increase in intensity at 1740 cm^{-1} together with a new peak at 1245 cm^{-1}, whilst the peaks assigned to the hydroxyl group were missing. In order of appearance with increasing field, the n.m.r. spectrum of this acetyl derivative showed a triplet, a poorly resolved multiplet, and two single peaks at τ 7.544 and 7.917. The areas of the combined low-field multiplets and the single peaks were in the ratio 8.00:2.96:6.04, confirming that these peaks are due to the methylene protons, the methyl protons of the acetamidate group, and the methyl protons of the ester groups respectively. More recently the material and its acetyl derivative have been synthesized by the following scheme, thus confirming the structural assignment:



If we consider I as a cyclic imidate the formation of V is not unexpected since amidates are known to be formed from the reaction of imidates with primary or secondary amines (10). There are two possibilities for the amine component of this reaction, IV, and II, which has been postulated as an intermediate in the decomposition of I. To determine if IV was the reactant, the reaction of equimolar aqueous solutions of this amine and I was studied at pH 6, 7, and 8. At all three pH values the rates of both decomposition of I and appearance of V were greater when the amine was added. At pH 7, the disappearance of I could

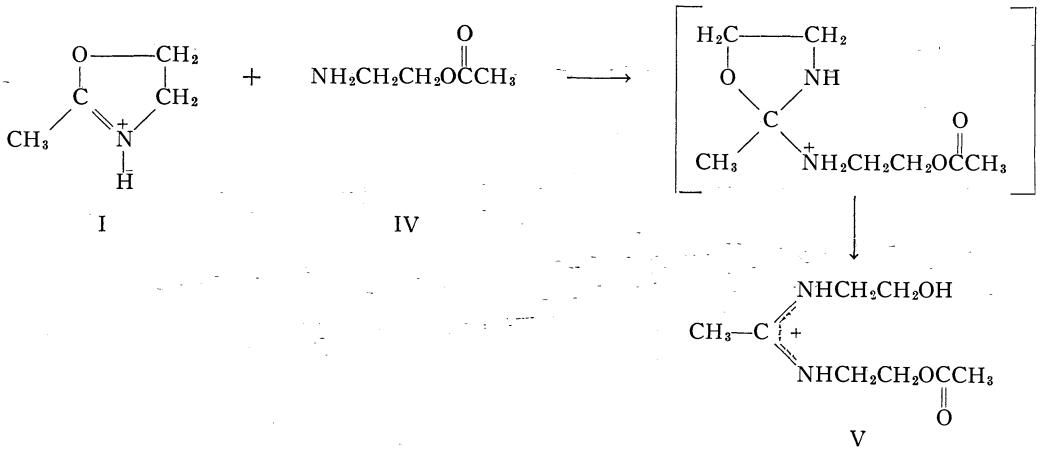
be described by second-order kinetics (Fig. 3) with a rate constant of 2.8×10^{-1} l. mole^{-1} min^{-1}.

At pH 6 the first-order decomposition of I and at pH 8 the transformation of IV to III become significant competing reactions for the formation of V. The limitations of the method and the narrow pH range available for study make it impossible to determine the formation of V with sufficient accuracy for kinetic purposes.

Since V is formed by a second-order reaction it is surprising that the decomposition of I is apparently first order over the whole pH range studied. This can be explained at pH 6 and 8 by the fact that V is not the major reaction product. At pH 7, where V is the main product, the first-order treatment is still applicable since the concentration of IV rapidly reaches a low steady value. It is possible to calculate a value for the second-order rate constant (k_3) for amidate formation at this pH by use of equation (G), where k_C is the first-order rate constant derived from equation (C) and k_{obs} is the experimental value:

$$k_{obs} = k_C + k_3[IV]. \qquad (G)$$

The value of the second-order constant, 2.4×10^{-1} l. mole^{-1} min^{-1}, is found to be in good agreement with that obtained directly from the equimolar experiments at pH 7. All the above evidence supports the postulate that the amidate (IV) arises from the reaction of I with IV:



I IV V

Although I is stable in anhydrous methanol, if it is mixed with IV in this solvent it reacts to give V. When concentrations of reactants are used which are similar to those employed in the experiments in water, the reaction proceeds at about a quarter of the rate at pH 7. Since the absence of water would prevent the formation of II, it is felt that this evidence lends support to the mechanism derived from the kinetic data.

The properties of V were briefly examined, particularly its decomposition at various pH values. It was found to be stable at pH 4 and to decompose rapidly in alkaline solution. The formation of V and its subsequent decomposition at pH 7 are outlined in Fig. 4.

The persistence of IV long after I has disappeared indicates it to be a decomposition product of V, since it normally undergoes rapid transformation at this pH to III (see Table I). Thus at pH 7 the primary products of the decomposition of V are III and IV and a little acetate ion, with IV transforming to III as the ultimate product. At pH 10, however, the product ratio of III and acetate ion is reversed since acetate ion is now formed

For personal use only.

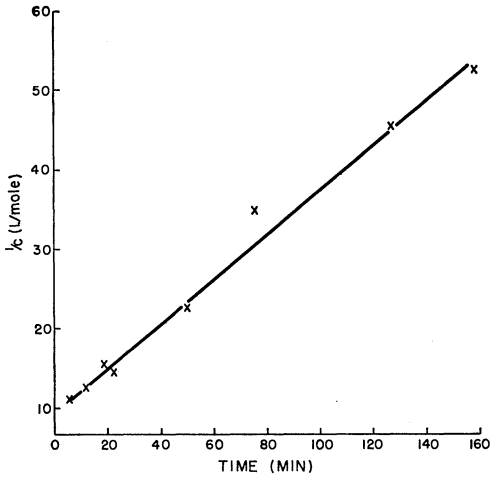

FIG. 3. The disappearance of I (0.14 *M*) at pH 7, 30°, in the presence of an equimolar amount of IV; $k_3 = 2.86 \times 10^{-1}$ l. mole^{-1} min^{-1}.

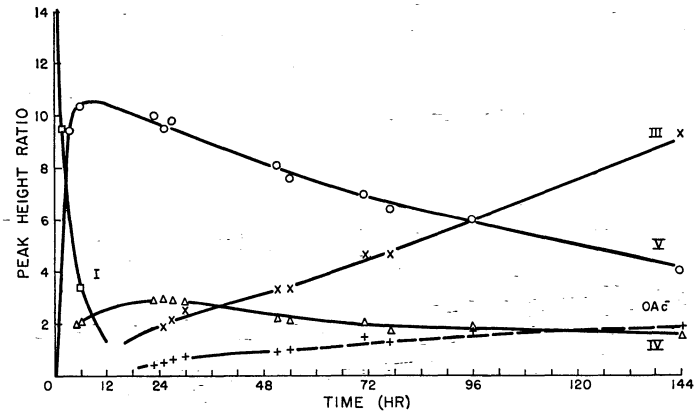

FIG. 4. The formation and decomposition of N-2-acetoxyethyl N′-2-hydroxyethyl acetamidate at pH 7 and 30°. Concentration is expressed as the peak height ratio of the particular methyl protons to the external standard. The conversion factor to moles/l. varies slightly between compounds.

very rapidly. By n.m.r. it is possible to show that the formation of the acetate ion is equivalent to the loss of the acetoxy group in V, and that the formation of III is equivalent to the loss of the methyl group of the amidate moiety. Thus two simultaneous reactions appear to be involved in the decomposition of V. Assuming that the k_{obs} for the decomposition of V is made up of the sum of the rate constants for these reactions, the ratio of these rate constants can be determined by product analysis. Comparison of the results at pH 7 and 10 indicates that the rate of formation of acetate ion increases by a factor of 10^3, whilst the rate for the reaction involving the amidate moiety increases at the most by a factor of 10. An intermediate, N,N′-bis-2-hydroxyethyl acetamidate, is postulated as being formed following cleavage of the acetoxy group. The two reactions are shown below, where with increasing pH the mechanism on the right-hand side predominates.

Reverting to the decomposition of I, it is found that the formation of V takes place only in the range pH 5 to 9, although V is found to be stable at pH values outside this range.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For pH < 5, this might be explained by the fact that both I and IV will be protonated, whereas amidate formation in general requires one or both reactants to be in the unprotonated form (10, 11). At pH 9 and above, any IV that is formed from I might be expected to transform preferentially into III. The fact that neither V nor its decomposition products were detected at pH 10 and above is in accord with this. The rates of transformation of IV to III are shown in Table I. As was noted above, when I and IV were mixed at pH 7

TABLE I

Rate constants for the transformation of O- to N-acetylethanolamine (30°)

pH	Rate constant, min^{-1}
6	1.2×10^{-3}
7	4.7×10^{-3}
8	3.8×10^{-2}
9	$>1.4\times10^{-1}$

III was not a significant early product. However, at pH 8 a substantial quantity of III was rapidly formed, apparently from isomerization of IV. This lends support to the above explanation.

In an attempt to determine the mode of ring opening of I, the n.m.r. spectra obtained during its decomposition were examined. The compounds of most interest in this respect are III and IV. Below pH 7, IV is found to the exclusion of III and above pH 9 the opposite is true; between these values signals due to both are observed. Two mechanisms have been postulated to explain these results. The first involves the decomposition of a transition complex of I and water to give IV, which at high pH is rapidly transformed to III. The second proposes hydration of the C=N bond to give II as a labile intermediate which yields III or IV depending on the pH. As no IV was detected above pH 8.5, and no signal was obtained in the experiments with I, I and IV, or IV which could be assigned to II, we are unable to differentiate between these two possibilities. The natural assumption that equation (A) also represents the direct formation of III was shown to be incorrect. At pH 7, equation (A) should account for approximately 40% of the decomposition of I, but as can be seen in Fig. 4, III is not present in significant amounts until after I has decomposed.

It has previously been suggested that 2-substituted Δ²-oxazolines behave like imidates in some of their reactions (3, 12). In the two reactions of I studied here, namely hydrolysis and amidate formation, the results are found to be in agreement with this hypothesis.

EXPERIMENTAL

Aqueous solutions of 2-methyl-Δ²-oxazoline (0.29 *M*) were held at 30° and maintained at the required pH by a Beckman automatic titrimeter. The n.m.r. spectra of aliquots were recorded at regular intervals using a Varian 4300C spectrometer at 60 Mc/s, with cyclohexane as an external reference. At least two spectra in the same sweep direction were recorded for each aliquot. The spectra were calibrated by the side-band technique using an electronic counter. Identification of peaks was checked by comparison of the field position of each compound separately at the appropriate pH and concentration. The reactions of O-acetylethanolamine hydrochloride (0.3 *M*) and O-acetylethanolamine hydrochloride (0.14 *M*) with 2-methyl-Δ²-oxazoline (0.14 *M*) were similarly studied.

For the sake of convenience, concentration was expressed as a ratio of the peak height of the methyl protons of the compound to that of the external standard. For O-acetylethanolamine, N-acetylethanolamine, and N-2-acetoxyethyl N′-2-hydroxyethyl acetamidate the peak height was used directly, whilst for 2-methyl-Δ²-oxazoline the height of the center peak of the triplet was doubled in order to determine the peak height ratio. The maximum deviation from linearity of the peak height to concentration relationship for 2-methyl-Δ²-oxazoline was found to be ±7% over the range 0.3 *M* to 0.03 *M*. It was necessary to reduce the peak height ratios of 2-methyl-Δ²-oxazoline by a factor of 0.71 to enable correlation with those obtained from O-acetylethanolamine.

Infrared spectra were recorded on a Perkin–Elmer 221 spectrophotometer. *2-Methyl-Δ²-oxazoline* was prepared by the method of Wenker (13), b.p. 109–111°. *O-Acetylethanolamine hydrochloride* was prepared from 2-methyl-Δ²-oxazoline by adjusting a 20% aqueous solution to pH 3 and allowing it to stand overnight at room temperature. The product was isolated after evaporation of the water under vacuum, and recrystallized from methanol/ether, m.p. 130–131° (lit. 128–130° (14)).

Isolation and Characterization of N-2-Hydroxyethyl N′-2-Acetoxyethyl Acetamidate Hydrochloride

A solution of oxazoline (1.25 g) in water (50 ml) which had been maintained at pH 7 and 30° overnight was taken to dryness under vacuum. The resulting oil (1.61 g) was chromatographed on Woelm acid alumina grade IV but was recovered unchanged on elution with 1:75 methanol:chloroform. Calc. for $C_8H_{17}O_3N_2Cl$: C, 42.81; H, 7.57; N, 12.50; Cl, 15.80%. Found: C, 41.06; H, 7.71; N, 11.26; Cl, 14.97%. Infrared (film): 3325 cm^{-1}, O—H; 3215 cm^{-1}, N—H; 3080 cm^{-1}, N—H; 1740 cm^{-1}, C=O (ester); 1660 cm^{-1}, C=N; 1230 cm^{-1}, C—OC (ester); 1060 cm^{-1} (sh), C—OH; 1050 cm^{-1}, C—C. The n.m.r. and infrared data are identical with those of the synthetic product, and with the analytical data support the assignment of the structure N-2-acetoxyethyl N′-2-hydroxyethyl acetamidate hydrochloride to this compound.

Some of the oil was warmed on a steam bath with acetic anhydride for 1/2 hour, and on evaporation a yellow oil resulted. Chromatography of this oil (600 mg) on Woelm acid alumina grade IV gave two fractions. The first fraction (79 mg) was eluted with chloroform and identified by its infrared spectrum and analysis as N,O-diacetylethanolamine. Elution with 1:75 methanol:chloroform gave a colorless oil (505 mg) which crystallized on standing. Recrystallization from acetone gave thick white needles, m.p. 106–108°. Calc. for $C_{10}H_{19}O_4N_2Cl$: C, 45.03; H, 7.13; N, 10.51; Cl, 13.30%. Mol. wt. 266. Found: C, 45.31; H, 7.21; N, 10.46; Cl, 13.01%. Mol. wt. 254 ($CHCl_3$), 145 (H_2O). Infrared (KBr): 3205 cm^{-1}, N—H; 3170 cm^{-1}, N—H; 3060 cm^{-1}; 3020 cm^{-1}; 1740 cm^{-1}, (C=O) ester; 1650 cm^{-1}, C=N; 1245 cm^{-1}, C—OC (ester); 1230 cm^{-1}, C—OC (ester); 1062 cm^{-1}, C—C. The relative intensities of the n.m.r. signal using a Varian electronic integrator were (CH_2), 8.00±0.12; (CH_3), 2.96±0.10; (CH_3, ester), 6.04±0.09. Comparison by mixed melting point and infrared spectrum indicated it to be identical with a synthetic sample of N,N′-bis-2-acetoxyethyl acetamidate hydrochloride.

Preparation of N-2-Acetoxyethyl Ethyl Acetimidate Hydrochloride

The procedure of Cornforth (15) was used; ethyl acetimidate hydrochloride (3 g) (16) was suspended in ether and stirred together with a solution of potassium carbonate (3.6 g) in water (10 ml). The ethereal solution containing the free base was decanted and to it O-acetylethanolamine hydrochloride (4.2 g) in water (10 ml) was added with cooling, and the mixture was stirred for 3/4 hour. The ether was again decanted, dried over sodium sulphate, and gave a yellow oil (1.53 g) on evaporation of the solvent. The oil was purified by distillation at 50° at 0.1 mm. Yield 25%. Calc. for $C_8H_{15}O_3N$: C, 55.5; H, 8.68; N, 8.09%. Found: C, 55.60; H, 8.80; N, 8.17%. Infrared (film): 1740 cm^{-1}, C=O (ester); 1628 cm^{-1}, C=N; 1465 cm^{-1}, C—CH_3; 1240 cm^{-1}, C—OC; 1048 cm^{-1}, C—C. pK_a (H_2O) 6.75.

Preparation of N-2-Acetoxyethyl N′-2-Hydroxyethyl Acetamidate Hydrochloride and its Acetyl Derivative

N-2-Acetoxyethyl ethyl acetimidate (1 g) was dissolved with cooling in anhydrous ether (10 ml) containing hydrogen chloride (208 mg). After the solvent was removed, the product was dissolved in absolute ethanol (10 ml), and ethanolamine (370 mg) in absolute ethanol (5 ml) was slowly added whilst the temperature

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

was maintained below 5°. The reaction mixture was stirred for 3 hours, after which the solvent was evaporated, leaving a yellow oil (940 mg). Although the oil was chromatographed on Woelm acid alumina grade IV its infrared spectrum remained unchanged, and the oil could not be induced to crystallize. Yield 72%. Calc. for $C_8H_{17}O_3N_2Cl$: C, 42.81; H, 7.57; N, 12.50; Cl, 15.80%. Found: C, 43.06; H, 7.71; N, 11.26; Cl, 15.4%. Ultraviolet: λ_{max} 207 mμ, ϵ 13,400 (0.3 mg/10 ml H_2O). pK_a 10.91 (H_2O).

The amidate hydrochloride (840 mg) was acetylated with acetic anhydride, giving a product (717 mg) which crystallized from acetone in the form of thick needles, m.p. 109–110°. Yield 71%. Calc. for $C_{10}H_{19}O_4N_2Cl$: C, 45.03; H, 7.13; N, 10.51; Cl, 13.30%. Found: C, 45.10; H, 7.39; N, 10.5; Cl, 13.00%. Ultraviolet: λ_{max} 207 mμ, ϵ 14,500 (0.28 mg/10 ml H_2O). pK_a 10.78 (H_2O). The spectral and analytical data are consistent with the structure of N,N′-bis-2-acetoxyethyl acetamidate hydrochloride.

ACKNOWLEDGMENTS

The authors would like to thank K. Oikawa for the n.m.r. spectra and J. Legari for technical assistance. Analytical determinations by J. Helie and infrared spectra by R. Gravelle are also gratefully acknowledged.

THE USE OF ENZYMES IN STRUCTURAL STUDIES ON POLYSACCHARIDES

I. THE MODE OF ATTACK OF A β-D-(1 → 3)-GLUCANASE ON LAMINARIN[1]

T. E. NELSON, J. V. SCALETTI, F. SMITH, AND S. KIRKWOOD

Departments of Agricultural Biochemistry and Animal Husbandry, University of Minnesota, St. Paul, Minnesota, U.S.A.

Received October 19, 1962

ABSTRACT

A β-D-(1 → 3)-glucanase from the Basidiomycete sp. QM 806 of Reese and Mandels has been purified and shown to hydrolyze insoluble laminarin by removing glucose residues one at a time from the non-reducing end of the polysaccharide. The enzyme will also hydrolyze simple oligosaccharides and its mode of attack on these is similar to its action on laminarin. The products produced by the action of this preparation on laminarin are consistent with recent information on the structure of this polysaccharide.

Reese and Mandels (1), in a survey of the occurrence of β-D-(1 → 3)-glucanases in fungi, observed that an unidentified species of basidiomycete produced a very high level of β-D-(1 → 3)-glucanase activity when grown on a starch medium. The organism was designated Basidiomycete sp. QM 806. The criterion for activity was the extent of attack on the seaweed polysaccharide laminarin. The enzyme brought about the complete hydrolysis of laminarin, as judged by reducing value calculated as glucose. The hydrolysis products produced by the action of this enzyme were investigated (paper chromatography) and glucose was the only product observed. Reese and Mandels point out that this observation, coupled with the fact that the enzyme had a very slow rate of attack on a mixture of oligosaccharides produced from laminarin by the action of a glucanase from *Rhizopus arrhizus*, leads to the conclusion that the basidiomycete enzyme attacks laminarin in an exo or endwise splitting fashion.

Insoluble laminarin, a cold water insoluble polysaccharide from the brown algae *Laminaria cloustoni*, has been shown to contain mannitol (2) to which are attached chains composed of glucose residues. Furthermore, the glucose chains in laminarin are linked by both β-(1 → 6)and β-(1 → 3) bonds (3, 4). Recent investigations have shown that laminarin is heterogeneous and is composed of at least two components. One is a reducing substance, termed laminarose, which consists of glucose residues linked by both β-(1 → 6) and β-(1 → 3) bonds. The other component is a non-reducing substance, termed laminaritol, which appears to be two chains similar to laminarose, both terminating in the same mannitol residue (5). In view of these structural findings it is surprising that the basidiomycete enzyme produces only glucose from laminarin and one must assume that either the preparation is a mixture of enzymes or a single enzyme with a very low order of specificity. In either case the preparation should produce either mannitol or some fragment containing mannitol from that portion of the laminarin structure containing this substance.

In order to investigate these matters further, we have undertaken a study of the action pattern of a purified preparation of this enzyme with the view of using it in structural studies on laminarin and other polysaccharides of similar structure.

Action of the Purified Enzyme on Laminarin

The action of our purified preparation on laminarin[2] was investigated and compared with the results reported by Reese and Mandels. The enzyme was incubated with laminarin and the increase in reducing power with time followed by the Nelson–Somogyi method (6). Companion determinations of the glucose liberated were carried out by a procedure involving the use of glucose oxidase (7). The results of the experiment (Fig. 1)

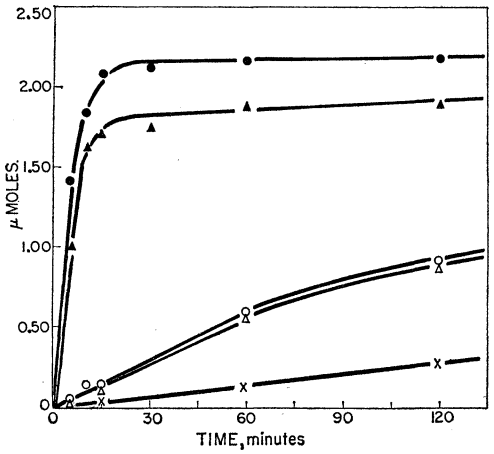

FIG. 1. Action of the enzyme at high concentration on laminarin, on periodate-oxidized and reduced laminarin. The concentration of enzyme used was fivefold that used in the laminarin experiment, the results of which are shown in Table I. The release of reducing power, as glucose and glyceritol, was negligible in the absence of enzyme. ● release of glucose equivalent from laminarin as determined by the Nelson–Somogyi procedure; ▲ release of glucose from laminarin as determined by glucose oxidase; ○ release of glucose equivalent from periodate-oxidized and reduced laminarin as determined by the Nelson–Somogyi procedure; △ release of glucose from periodate-oxidized and reduced laminarin as determined by glucose oxidase; × release of glyceritol from periodate-oxidized and reduced laminarin.

essentially confirm the observations of Reese and Mandels that the increase in reducing power upon enzymatic hydrolysis is due largely to the production of glucose. A further implication of these data is that contamination of this preparation with an endo-type glucanase must be small since the presence of such an enzyme would result in a large difference in the values obtained by the two methods. It should be pointed out also that the fact that the two determinations do not coincide indicates that the enzyme is producing significant amounts of reducing substances other than glucose. Such a result is to be expected on the basis of what is known of the structure of laminarin.

In order to make a more definite estimation of the extent of contamination by an endo-type enzyme, the preparation was incubated with purified undergraded samples of oat and barley gums at five times the enzyme level used in the laminarin experiment, the results of which are given in Table I. No increase in reducing capacity was observed (Table I). Since both oat and barley gums are known to contain both β-(1 → 3) and β-(1 → 4) linkages (8–11), the β-(1 → 3) linkages occurring both singly and together (12), it is reasonable to assume that an endo-type enzyme would attack these polysaccharides. In fact recent work by Parrish, Perlin, and Reese (13) has shown that the endo-glucanase from *R. arrhizus* does indeed produce extensive degradation of both of these polysaccharides. The conclusion may therefore be drawn that our preparation has little or no contamination with an endo-type enzyme. In addition, since cellulase has

[2]*The term "laminarin" is used throughout this paper to denote a preparation of L. cloustoni laminarin obtained from the Liverpool Borax Co., St. Paul's Square, Liverpool 3, England.*

TABLE I

Comparison of the rate of attack on laminarin with that on derivatives of laminarin and on oat and barley gum

Substrate	Enzyme units added	Increase in reducing capacity ΔOD_{660}/15 min
Laminarin	0.047	1.43
Periodate-oxidized and reduced laminarin	0.047	0.014
Periodate-oxidized, reduced, and mild acid hydrolyzed laminarin	0.047	1.07
Air-oxidized laminarin	0.047	1.03
Reduced laminarin	0.047	1.01
Oat poly-β-D-glucan	0.235	0.000
Barley poly-β-D-glucan	0.235	0.000

NOTE: All final substrate concentrations were at 0.05%. Determinations were made by adding to 0.50 ml substrate in 0.05 *M* acetate, pH 4.8, 0.50 ml enzyme solution in the same buffer and incubating for 15 minutes at 37°. The hydrolysis was stopped by the addition of 1.0 ml of Nelson–Somogyi alkaline copper reagent.

been shown to degrade oat and barley gums (13), it can be concluded that the cellulase contamination is negligible.

Action of the Enzyme on Chemically Modified Laminarins

In order to establish the mode of attack of the glucanase on laminarin, various derivatives of this polysaccharide were prepared in which the reducing and/or non-reducing ends had been altered. By comparing the rate of action of the enzyme on each of these with its rate of attack on unaltered laminarin, it has been possible to reach certain conclusions concerning its mode of attack.

Samples of laminarin in which the reducing end of the laminarose component had been altered were prepared by air oxidation in the presence of dilute alkali and by sodium borohydride reduction. The former procedure converts the reducing ends to acid residues, the latter procedure converts them to glucitol residues. In addition, a sample of laminarin that had been partially purified by dialysis and reprecipitation from water was oxidized with dilute sodium metaperiodate for several days in the dark at 4° and then reduced with sodium borohydride. This procedure alters both the reducing and non-reducing ends of laminarose (see Fig. 2) and laminaritol. The remaining 1 → 3-linked residues are, however, left intact (12, 14). A portion of this periodate-oxidized and reduced material was subjected to mild acid hydrolysis at room temperature. The hydrolysis regenerates the non-reducing ends by removing the altered residues and freeing the adjacent intact glucose moieties. It should be noted that this regenerated laminarin resembles the original material only at the non-reducing terminals, the other end of the molecule is probably terminated by an arabitol residue in the case of laminarose and a glyceritol residue in the case of laminaritol.

The action of the purified enzyme on these substrates is shown in Table I. An enzyme concentration was used such that the rate of attack on unaltered laminarin was at the maximum value that could be measured with any accuracy. This was done so that very low rates of attack on the modified substrates could be detected and compared with the rate on the unaltered material.

As can be seen in Table I, laminarin modified only at the reducing end of the molecule by air oxidation or sodium borohydride reduction is attacked at a rate only slightly less than that characteristic of untreated laminarin. Periodate-oxidized and reduced laminarin, in which both the reducing and non-reducing ends have been altered, is attacked at 1/100

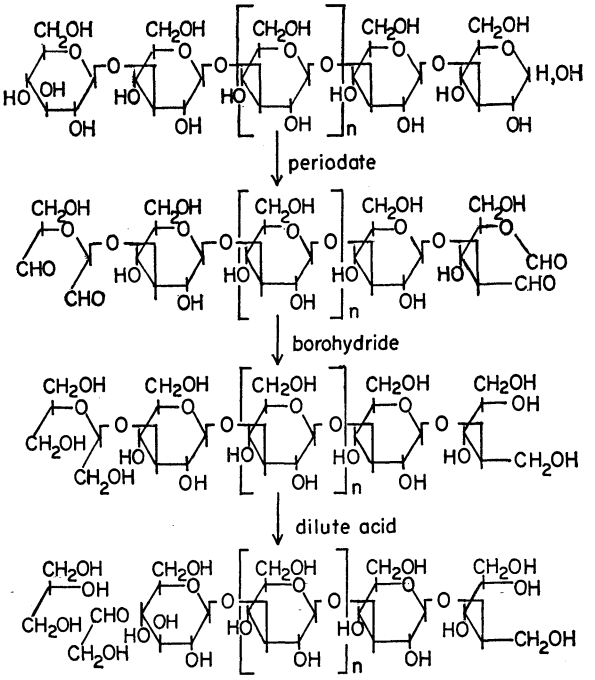

FIG. 2. Structural representation of periodate oxidation, reduction, and mild acid hydrolyses on the laminarose component of laminarin. The branching known to occur in this molecule is ignored for purposes of illustration. The ends of all branches will react in the same fashion as the non-reducing terminal illustrated in the drawing.

or less of this rate. The increase in reducing value was so low that it borders on experimental error. The rate of enzyme attack on the periodate-oxidized polysaccharide (tested prior to reduction) was also very low. However, in this case the high reducing value given by the substrate makes the rate of attack measurement much less accurate. Mild acid hydrolysis of the periodate-oxidized and reduced laminarin, which removes the blockage at the non-reducing end, resulted in a product that was almost as susceptible to enzymatic attack as the original laminarin. This is highly significant since it rules out the possibility that the failure of the enzyme to attack the periodate-oxidized and reduced molecule was due to a structural modification at a point other than the non-reducing terminal. Thus it can be stated conclusively that this glucanase preparation from Basidiomycete sp. QM 806 acts upon laminarin from the non-reducing end of the molecule, removing one residue at a time.

Modified laminarin is slowly degraded by the enzyme (Fig. 1). This may be attributed to a limited ability of the glucanase to attack the modified non-reducing end unit, to a slight endo-glucanase contamination, or to spontaneous hydrolysis of the non-reducing ends, allowing enzymatic attack on the exposed glucose residues. These possibilities can be differentiated readily by the fact that hydrolytic cleavage of the altered end unit liberates glyceritol, whereas this polyol would not be formed by attack along the interior of the chain. The data (Fig. 1) show a steady release of glyceritol as well as glucose, and since the modified polysaccharide does not decompose spontaneously at the pH of the enzymatic reaction, the glucanase preparation must have a limited ability to attack the altered non-reducing end unit.

Products of the Action of the Enzyme on Laminarin

Aliquots removed at various periods during the hydrolysis of laminarin by the glucanase were examined by paper chromatography. Glucose was the major observable product in all hydrolyses, and in those which were virtually complete it accounted for about 70% of the carbohydrate as measured by the phenol – sulphuric acid method (15). In addition, laminaribiose, gentiobiose, laminaritriose, and several higher oligosaccharides appeared. It was shown by elution of the material from the chromatogram, followed by acid hydrolysis and paper electrophoresis in borate, that at least two of the higher oligosaccharides contained mannitol. As the course of the hydrolysis proceeded, laminaritriose and most of the higher oligosaccharides gradually disappeared while gentiobiose remained constant and laminaribiose increased.

This pattern of the appearance and disappearance of products during the course of hydrolysis is consistent with recent work on the structure of laminarin (3, 16, 17, 18). The origin of the laminaribiose and laminaritriose is explicable on the basis that they result from the reducing ends of the laminarose component of laminarin. The enzyme apparently has the capacity to attack laminaritriose, since this substance gradually disappears, but it does not attack laminaribiose, which persists to the end of the hydrolysis. Gentiobiose (the β-(1 $\rightarrow$ 6)-linked disaccharide) arises from the 1 $\rightarrow$ 6 linkages that have been shown to occur in both laminarose and laminaritol. The enzyme is apparently incapable of hydrolyzing a 1 $\rightarrow$ 6 linkage but can bypass it, thus leaving gentiobiose from this structural feature. The mannitol-containing oligosaccharides result from the enzyme failing to totally hydrolyze the laminaritol chains. The action of the enzyme apparently ceases at some distance from the terminal mannitol unit.

Action of the Glucanase on Simple Oligosaccharides of Known Structure

The pattern of products produced by the action of the enzyme on laminarin suggests that it is incapable of attacking disaccharides but is capable of attacking a trisaccharide of the proper structure at a rate somewhat less than that characteristic of a longer-chain material. In order to confirm this, the action of the enzyme on laminaribiose, gentiobiose, and laminaritriose was investigated using the same conditions as those for laminarin (Table I). It was found that the two disaccharides were not attacked at all, while laminaritriose was acted on at about 1/10 the rate observed with laminarin. These results reinforce the conclusion that the glucanase attacks a β-(1 $\rightarrow$ 3)-linked chain of D-glucose residues from the non-reducing terminal and rapidly removes glucose residues one at a time, bypassing 1 $\rightarrow$ 6 linkages, until it approaches the reducing terminal. When the residue from the chain reaches the trisaccharide level, the action of the enzyme is slowed and then ceases after one more residue is removed. The final stages of this process are not established by the data since an attack on either glycoside bond in laminaritriose will yield the same products, namely glucose and laminaribiose. However, the accumulation of mannitol-containing oligosaccharides would indicate that the attack is stepwise, ceasing as the terminal is approached, even if the last residue is not glucose.

To establish the terminal process with more certainty, the action of the enzyme on laminaribiosyl-erythritol and laminaritriitol[3] was determined. If the attack is as predicted,

[3]*Common names have been used throughout to describe the oligosaccharides mentioned in this paper; their more formal designations are: laminaribiosyl-erythritol, O-β-D-glucopyranosyl-(1 → 3)-O-β-D-glucopyranosyl-(1 → 2)-D-erythritol; laminaritriitol, O-β-D-glucopyranosyl-(1 → 3)-O-β-D-glucopyranosyl-(1 → 3)-D-glucitol; laminaritriose, O-β-D-glucopyranosyl-(1 → 3)-O-β-D-glucopyranosyl-(1 → 3)-D-glucopyranose; laminaribiose, 3-O-β-D-glucopyranosyl-D-glucopyranose; gentiobiose, 6-O-β-D-glucopyranosyl-D-glucopyranose; laminaribiitol, 3-O-β-D-glucopyranosyl-D-glucitol; glucosyl-erythritol, 2-O-β-D-glucopyranosyl-D-erythritol.*

For personal use only.

namely a single cleavage of the bond connecting the non-reducing terminal in the trisaccharide, then the former should give only glucose and glucosyl-erythritol, the latter only glucose and laminaribiitol. Both substrates were incubated with the enzyme and it was found, by paper chromatography and paper electrophoresis, that only the expected products were produced (Figs. 3 and 4). No erythritol or glucitol were produced even with very high concentrations of enzyme and long periods of incubation. These would be the products produced by any action of the enzyme on the "reducing" end of the chain.

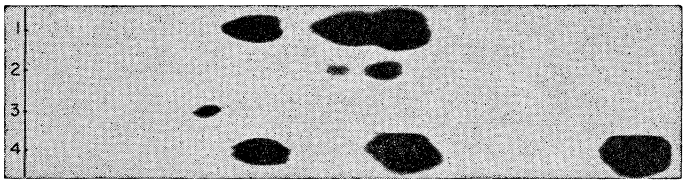

FIG. 3. Products of the action of the glucanase on laminaribiosyl-erythritol as shown by paper chromatography. All spots are named in order proceeding from the origin. Lane 1: laminaribiose, glucosyl-erythritol, and glucose standards; lane 2: the enzymatic hydrolyzate; lane 3: laminaribiosyl-erythritol standard; lane 4: laminaribiose, glucose, and erythritol standards. The enzyme concentration used in this experiment was 350-fold that used in the laminarin experiment reported in Table I, the substrate concentration was 0.2% and the incubation time 6 hours.

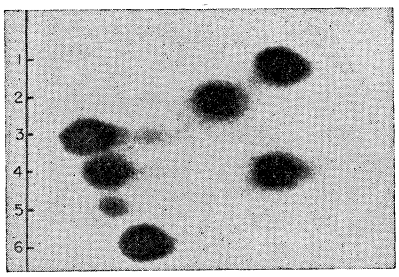

FIG. 4. Products of the action of the glucanase on laminaribiosyl-glucitol as shown by paper electrophoresis. All spots are named in order proceeding from the origin. Lane 1: glucose standard; lane 2: glucitol standard; lane 3: laminaritriitol standard; lane 4: enzymatic hydrolyzate; lane 5: laminaribiitol standard; lane 6: laminaribiose standard. The enzyme concentration used in this experiment was 350-fold that used in the laminarin experiment reported in Table I, the substrate concentration was 0.5% and the time of incubation was 18 hours.

EXPERIMENTAL

Preparation and Purification of the Enzyme

Basidiomycete sp. QM806 was grown on the 0.5% starch medium of Reese and Mandels (1). The crude culture filtrate was evaporated *in vacuo* at 37°, dialyzed, and then fractionated with ammonium sulphate. The ammonium sulphate precipitate was taken up in buffer, dialyzed, and refractionated on a diethylaminoethylcellulose column. The resulting preparation had a specific activity of 163 units per milligram of protein, which represents a 100-fold increase in specific activity over that of the crude culture filtrate. The full details of this and the further purification of this enzyme will be the subject of a separate publication.

Enzyme Assay and Unitage

To 0.5 ml of substrate solution (0.1% laminarin in 0.05 *M* acetate buffer, pH 4.8) was added 0.5 ml of an appropriate dilution of the enzyme preparation in the same acetate buffer. The mixture was incubated for 15 minutes at 37° and the reaction stopped by the addition of 1.0 ml of the alkaline copper reagent used in the Nelson–Somogyi reducing sugar estimation (6). The rate of reaction under these conditions is first order with respect to enzyme if the extent of hydrolysis does not proceed beyond 60%. One unit of enzyme is defined as that amount which will liberate 1 μmole of glucose equivalent per minute under the above conditions of incubation.

Other Incubation Procedures

Incubations carried out for purposes other than enzyme assay, such as investigation of the nature of products of hydrolysis etc., were done under the same general conditions as used for assay purposes. If the glucose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was to be estimated by the glucose oxidase procedure, the reaction was stopped by immersing the mixture in a boiling water bath for 5 minutes. In all cases where quantitative determinations were carried out, standards were included in the procedure and both reagent and substrate blanks used. In experiments involving the action of the enzyme on substrates other than laminarin, the latter was always run as a check on enzyme activity.

In the case of laminaribiosyl-erythritol and laminaritriitol, a micromethod of incubation was used. Ten microliters of buffered substrate and 5 μl of enzyme were incubated in a sealed capillary tube, heat-denatured in a boiling-water bath, and then spotted directly onto paper. This method permitted extreme economy in the use of valuable substrates.

Glyceritol Determination

The usual method (19, 20) was modified by carrying out the periodate oxidation in 0.05 *M* acetate buffer at pH 4.8 rather than in 1 *N* H_2SO_4. Under these conditions the altered non-reducing ends of the periodate-oxidized and reduced laminarin were not affected and only free glyceritol was determined. The excess periodate was destroyed by arsenious oxide. The glycerol values were corrected for the formaldehyde released by the action of periodate on the glycollic aldehyde produced during enzyme hydrolysis.

Paper Chromatography and Electrophoresis

All chromatography was done on Whatman No. 1 paper in the solvent system 1-propanol, ethyl acetate, water in the proportions 7:1:2 (21). The usual irrigation period was 36 hours. Paper electrophoresis was carried out with 0.1 *M* sodium borate in a potential gradient of 50 v/cm. The paper was dried and dipped through 10% HF in acetone to remove borate prior to developing the spots (22). The carbohydrate spots were developed by the Trevelyan modification of the Tollen's method (23).

Substrates

The "laminarin" used in these experiments was a preparation from *L. cloustoni* obtained from the Liverpool Borax Co., St. Paul's Square, Liverpool 3, England.

Air-oxidized laminarin.—Air-oxidized laminarin was obtained by passing a stream of air through a 0.5% solution of laminarin in 1.0% NaOH at reflux temperature. The reaction was discontinued when the reducing power of the solution had fallen to a negligible value. The solution was then neutralized with HCl, dialyzed in the cold against 0.05 *M*, pH 4.8 acetate buffer to remove salts, and used as the acetate buffer solution.

Reduced laminarin.—Reduced laminarin was prepared by reducing an aqueous solution of laminarin with excess sodium borohydride overnight at room temperature. The excess borohydride was destroyed by acidifying with acetic acid, the solution dialyzed in the cold against buffer as described above and used as the substrate solution. It should be noted that laminarin is partially dialyzable so that all dialyses were carried out in the cold, on a rocking dialyzer, for no more than 6 hours with two changes of dialyzing medium. All substrates that had been dialyzed were used on the basis of their total carbohydrate content as determined by the phenol – sulphuric acid method (15).

Periodate-oxidized and reduced laminarin.—Periodate-oxidized and reduced laminarin was prepared by Dr. B. Lewis of this laboratory and was dialyzed prior to use. The purified undegraded oat gum and the laminaribiosyl-erythritol used in this work were prepared by Dr. Lewis. The purified barley gum was prepared by Dr. G. Hay.

Laminaritriitol.—Laminaritriitol was prepared from chromatographically pure laminaritriose by sodium borohydride reduction. In this case the borate was removed by deionization with resin followed by evaporation to dryness several times in the presence of anhydrous methanol.

Laminaritriose, laminaribiose, and gentiobiose.—The first two substances were available in this laboratory, the last was obtained from the Pfanstiehl Co.

Other materials.—The glucose oxidase used was the "pure" grade supplied by Nutritional Biochemicals Corp. All glucose oxidase preparations that we have examined have been contaminated with a small amount of β-(1 → 3)-glucosidase activity. All determinations involving glucose oxidase reported in this paper were carried out with control procedures that eliminated this source of error. The peroxidase was a horseradish preparation from the Worthington Biochemical Corp.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to Dr. B. Lewis and Dr. G. Hay of this laboratory for their generous gifts of substrates and to Dr. E. T. Reese of the Quartermaster Research Laboratories, Natick, Mass., for supplying us with the culture of Basidiomycete sp. QM 806.

SULPHONIUM SALT SOLVOLYSIS

PART IV. SOLVENT EFFECTS

J. B. HYNE AND J. H. JENSEN
Department of Chemistry, University of Alberta, Calgary, Alberta
Received March 11, 1963

ABSTRACT

The variation of rate of solvolysis of dimethyl-*t*-butyl sulphonium iodide as a function of solvent composition is reported for various binary mixtures of water with ethanol, N,N-dimethylformamide, N-methylformamide, dioxane, and ethylene glycol. The inadequacy of solvent bulk dielectric constant as a correlating parameter is demonstrated and solvent *Y* and *Z* parameters are compared in this respect. The importance of the specific microscopic role of the solvent in the activation process is demonstrated and a possible important nucleophilic role for the amides suggested. Deviations in dioxane and ethylene glycol systems are discussed.

INTRODUCTION

The solvolysis of alkyl sulphonium salts has been repeatedly cited as a typical example of the class of reactions showing rate enhancement as dielectric constant of the solvolytic medium is reduced. This behavior follows from the fact that the mechanism commonly accepted for the solvolysis involves dispersal of the formal sulphonium ion charge in passing from the initial to the transition state of the rate-determing step (1 and references cited therein). In lower dielectric solvent media elimination becomes increasingly important, yielding olefins rather than the solvolysis product. The observation that the extent of elimination does not appear to be critically dependent on the nature of the leaving group (2) has been considered evidence in support of an E1 mechanism. Consequently, even in solvents where elimination is significant, the rate-determining step remains the same as in solvolysis, namely cleavage of the sulphonium salt to a neutral dialkyl sulphide leaving group and a carbonium ion entity.

Although the qualitative nature of the solvent dependence of sulphonium salt solvolysis rates is generally understood there has been little work done on the quantitative aspects of this problem. As part of our continuing study of the mechanism of sulphonium salt solvolysis (1, 3, 4) we report here the results of a study of the rates of solvolysis of dimethyl-*t*-butyl sulphonium iodide in a series of organic solvent mixtures with water. Among the organic solvents chosen was N-methylformamide, a liquid having a dielectric constant very much greater than water and one which would be expected to *reduce* the rate of solvolysis below that observed in water as the mole fraction in water mixtures is increased. The fact that no such result is observed, together with other conclusions that may be drawn from attempts to analyze the observed solvent effects quantitatively, lends further strong support to the growing volume of kinetic evidence which argues in favor of the critical role of specific solute–solvent interaction in kinetic processes and against the dominant role of bulk solvent medium effects.

EXPERIMENTAL

Reagents

N-Methylformamide was refluxed over calcium oxide and distilled, $n_{25}^{D} = 1.4303$, lit. $n_{25}^{D} = 1.4310$ (5), 1.4300 (6). N,N-Dimethylformamide was refluxed over calcium oxide and distilled, $n_{25}^{D} = 1.4285$, lit. $n_{25}^{D} = 1.4299$ (7). *p*-Dioxan, Matheson, Coleman and Bell spectroscopic grade, was used without further purification. Ethanol, reagent dry grade absolute, was used without further purification. Karl Fisher titration showed *less than* 0.14% water. Attempts to dry the ethanol further resulted in contamination as revealed

by its ultraviolet spectrum. Ethylene glycol, Fisher reagent grade, was used without further purification. Karl Fisher titration showed *less than* 0.2% water. The water used was doubly distilled, with conductance less than 1×10^{-7} mhos. Pyridine-1-oxide was purified by distillation. Fraction used: b.p. = 150–151° (15 mm), lit. b.p. = 146–147° (13 mm) (8). C^{14}-Dimethyl-*t*-butyl sulphonium iodide was prepared by the method of Hyne and Wolfgang (9), m.p. 159–160°.

Rate Determinations

Rate constants in all solvents except ethanol–water were determined by the radiochemical flow counting technique described previously (9). Rate constants in ethanol–water solvent mixtures were measured conductimetrically using an a-c. bridge at 1000 c.p.s. as described by Robertson (10).

Determination of Z′ Values

Solvent mixtures as recorded in Table II were prepared by weight from a stock solution to give final concentrations of pyridine-1-oxide of 5×10^{-5} *M*. The λ_{max} for each solvent in the ultraviolet was measured on a Beckman DK-1 recording ultraviolet spectrometer using 1-cm cells. At a chart scale of 5 mμ/inch λ_{max} values reproducible to ±0.2 mμ were obtained. *Z′* values were calculated from λ_{max} values using the Kosower equation (8).

RESULTS

The first-order rate constants for the solvolysis of dimethyl-*t*-butyl sulphonium iodide in a variety of organic solvent mixtures with water are recorded in Table I. The solvent mixtures were all chosen so as to maintain the bulk dielectric constant above 30. This restriction is necessary in view of the previously established onset of an alternative mechanism involving sulphonium salt ion pairs in media of dielectric constant less than 25 (3). The effect of onset of such a mechanism is illustrated in the dioxane–water solvent system where media of very low dielectric constant are possible. Below a dielectric constant value of 20 the rate increases rapidly due to the role played by the ion-pair mechanism.

Dielectric constant values in Table I were obtained from the literature as follows: ethanol–water (11); ethylene glycol – water (11); dioxane–water (12); N-methylformamide–water (5) and N,N-dimethylformamide–water (5). In the two latter cases interpolation was necessary to obtain the values required.

Although neither the dielectric constant nor *Z′* values were determined at the same temperature as the rate measurements the temperature dependence of both of these solvent parameters is such that using values at the same temperature as the rate determinations would not significantly alter the form of the plots in either Fig. 1 or Fig. 2.

DISCUSSION

In the attempt to analyze the observed rate dependence on solvent composition in a quantitative manner three different parameters characteristic of the solvent medium were considered: the bulk dielectric constant; the polarity of the solvent as measured by the *Y* value of the Winstein, Grunwald, and Jones relationship; and the *Z′* parameter suggested by Kosower and obtainable from the ultraviolet spectral shift effect of the various solvents on a reference solute. These three approaches are considered separately.

Bulk Dielectric Constant

In the many previous attempts to correlate rate with solvent bulk dielectric constant a variety of terms involving *D* have been suggested. The simplest model based upon the assumption that the solvent is a structureless dielectric continuum leads to a linear relationship between log *k* and $1/D$ (13). While the application of this relationship to kinetic systems has met with some qualitative success quantitative agreement cannot be expected since there are no grounds for the assumption, inherent in the derivation, that the microscopic behavior of the dielectric in the vicinity of the reacting species will be related to the macroscopic bulk dielectric constant *D*. A similar criticism applies to the other common rate versus bulk dielectric constant relationships such as log *k* versus $(D-1)/(2D+1)$ derived for reactions between ions and polar molecules (14), and log *k* vs. *D*, proposed by Tommila and Hella (15). None of these relationships satisfactorily accounts for the rate variations with solvent shown in Table I. An adequate relationship

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

should produce a straight-line plot accommodating all of the rates irrespective of the molecular composition of the solvent. For illustrative purposes the simple log k versus D plot is shown in Fig. 1. Even the qualitative relationship, however, breaks down in the

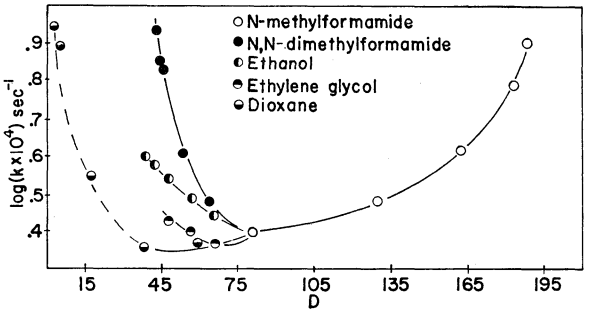

FIG. 1. Dependence of rate of solvolysis of dimethyl-*t*-butyl sulphonium iodide on the dielectric constant of various organic solvent – water mixtures.

case of N-methylformamide. As the bulk dielectric constant of the solvent medium increases with higher N-methylformamide mole fraction the qualitative prediction would be that the rate should decrease. Figure 1 clearly establishes the opposite behavior, leaving little doubt that the bulk dielectric constant of the solvent medium bears little if any relationship to the kinetic behavior of the sulphonium system. It is interesting to note that Ross and Labes (7) found a similar discrepancy in the bulk dielectric effect of N-methylpropionamide ($D^{30} = 164$) on the rate of solvolysis of *t*-butyl bromide. The rate of solvolysis in the propionamide is several powers of 10 *slower* than in water ($D^{30} = 80$) while the qualitative prediction would be the opposite.

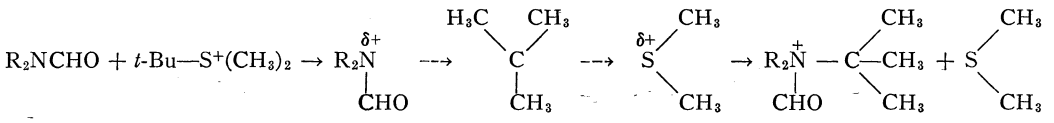
Solvent Y Values

From the data in Table I for the rates of solvolysis of dimethyl-*t*-butyl sulphonium iodide in ethanol–water mixtures a value for the reactant constant $m = -0.062$ in the relationship $\log k/k_0 = mY$ (16) may be evaluated for the sulphonium salt using the known values of Y for ethanol–water mixtures (17). The negative sign of this m value compared with positive values close to unity for most alkyl halides is indicative of the charge dispersal character of the activation process in the sulphonium salt solvolysis compared with the charge creation character of the alkyl halide solvolysis. Using this m value, Y values for the N-methylformamide and N,N-dimethylformamide solvent mixtures may be calculated. The highest N-methylformamide composition used, 0.936 mole fraction, has a $Y = -4.7$ while 0.65 mole fraction N,N-dimethylformamide has a $Y = -5.2$. Ross and Labes (7) obtained a pure N,N-dimethylformamide value for various alkyl halide solvolyses which varied between -2.46 and -3.72. Our value for a much lower formamide concentration is considerably more negative. Ross and Labes did not use N-methylformamide as a solvent but their value for N-methylpropionamide, a similarly high dielectric solvent, was also variable between -2.60 and -3.14 depending on the alkyl halide used. It is clear, therefore, that the mY type relationship will not account for the solvent dependence of the rate of solvolysis of the sulphonium salts. The lack of agreement between Y values computed for the amide solvents using different reacting solutes and the high negative values obtained in the sulphonium case indicate that the solvent is playing a role other than one based solely on its polarity or solvating power. Solvents with large negative Y values in the Winstein, Grunwald, and Jones treatment are among

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

those to which Swain and co-workers attribute an important nucleophilic role in the four-parameter type relationship (18). As a typical example 97.5% acetic anhydride – 2.5% acetic acid mixtures have $Y = -3.29$ in the mY type relationship but the magnitude of the coefficient describing the nucleophilic role of this solvent in the Swain four-parameter equation is greater than the coefficient for the electrophilic role. Since the electrophilic role of the solvent in such solvolysis is largely a measure of the ability of the solvent to "solvate" the leaving group in the rate-determining step it is hardly surprising that this role is minimized in the sulphonium salt case where the leaving group (dialkyl sulphide) is neutral. Comparing the Y values obtained for the amides in this work with those obtained by Ross and Labes for alkyl halide solvolysis, it is seen that the larger negative values for the sulphonium cases reflect a proportionately larger nucleophilic role for the amides as a result of the reduced electrophilic role in a rate step involving a neutral leaving group. Although the nucleophilic role in the alkyl halide case is important the leaving halide anion has a greater solvation demand, which requires a significant electrophilic contribution from the solvent.

The apparently important nucleophilic role of the formamide solvents suggests that there may be a significant contribution in the rate-determining step for the solvolysis from covalent type bond formation leading to a quaternized ammonium intermediate. A similar solvent role was proposed by Ross and Labes. Subsequent decomposition of the



quaternary ammonium intermediate by either solvolysis or elimination would be rapid. It is interesting to note that this mechanism presumes transalkylation from sulphonium sulphur to nitrogen, a sulphonium salt role of considerable importance in biochemical transmethylations.

Correlation with Solvent Z′ Values

A test of the mY type relationship as applied to the solvent systems used in this work is limited to the comparison of Y values with those obtained for comparable amides by Ross and Labes since Y values are not available for the whole range of amide–water mixtures. Kosower has shown (8) that the energies associated with the charge-transfer band of pyridinium salts and related solutes in a wide variety of solvent mixtures (Z values) are linearly related to Y values where these parameters are available for comparison. The greater ease of measurement of the Z value, however, makes this solvent parameter a much more attractive one for use in rate–solvent correlation. Kosower has also illustrated (8) the quantitative correlation of rate variation with solvent using the Z parameter for several types of reaction. Z' values (using pyridine-1-oxide as solute) for all solvent systems used in this work were determined as described in the Experimental Section and are recorded in Table II.

In Fig. 2 the sulphonium salt solvolysis rate variation with solvent is correlated by using the Z' parameters for ethanol–water, N,N-dimethylformamide–water, and N-methylformamide–water mixtures. While there are deviations from both linearity and a single-curve representation, these deviations are minor compared with the inadequacy of the bulk dielectric constant type relationship illustrated in Fig. 1. In particular the kinetic role of the high dielectric constant N-methylformamide appears to be much more accurately described by the Z' value. The apparent success of the Z' value correlation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

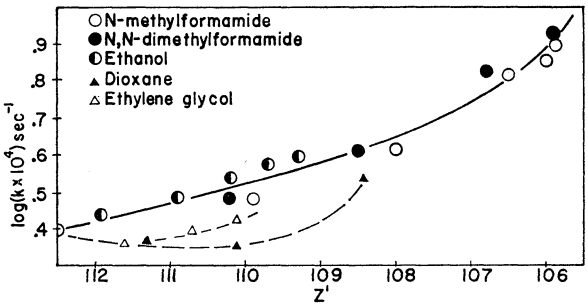


FIG. 2. Dependence of rate of solvolysis of dimethyl-*t*-butyl sulphonium iodide on Z' values.

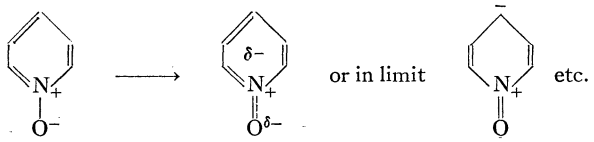
is again a reflection of the importance of the microscopic solvent role in the activation process. The Z' value measures the specific effect of the solvent on a charge delocalization



Charge transfer complex

process in passing from pyridine-1-oxide to the charge-transfer complex. This process has formal similarity to the activation process in the sulphonium salt solvolysis where a formal positive charge on sulphur is delocalized in the activation process.

Notwithstanding the apparent success of the Z' correlation in accounting for solvent effects in the ethanol and amide solvent mixtures it is clear from Fig. 2 that considerable deviations are still observed in the cases of ethylene glycol – water and dioxane–water solvent mixtures, especially in highly aqueous mixtures. While the specific role of solvent species in the activation process of the rate-determining step is still too imperfectly understood to warrant even a speculative interpretation of these observations it should be noted that in both these cases the non-aqueous component of the solvent mixture is a "bifunctional" molecule. Similar anomalies in the solvation behavior of dioxane have been noted previously (19) and solvent species of the general type X—CH_2—CH_2—Y, having the potential of existing in trans or gauche rotamer forms, have also been reported as exhibiting anomalous solvent behavior (20). The failure of the Z' correlation in these cases indicates that whatever the specific role of these "bifunctional" solvent molecules may be in the kinetic process it is not operative as a specific solvent effect in the charge-transfer process measured by Z'. Such anomalous observations, however, may be the key to the next stage in the refinement of the understanding of specific solute–solvent interactions.

THE ANODIC OXIDATION OF AMMONIA AT PLATINUM BLACK ELECTRODES IN AQUEOUS KOH ELECTROLYTE

H. G. Oswin and M. Salomon[1]

Leesona Moos Laboratories, Lake Success, Long Island, N.Y., U.S.A.

Received February 19, 1963

ABSTRACT

Electrochemical kinetic studies are reported on the anodic oxidation of ammonia in aqueous potassium hydroxide solutions at platinum black electrodes. A kinetic scheme of consecutive reactions is proposed; Tafel slopes are deduced for various rate-determining mechanisms and compared with the experimental behavior. The reaction pathway is correlated with that involved in the analogous catalyzed ammonia vapor decomposition. The exchange currents obtained, compared with those for hydrogen oxidation, render the system unfavorable for fuel cell applications.

INTRODUCTION

Recently, ammonia has been considered as a possible fuel for use in fuel cell applications; it has the advantage of being a relatively cheap liquid fuel, and it appears to oxidize completely to nitrogen and water. It has, therefore, been considered a possible successor to hydrogen, but investigations that we have carried out with ammonia show that it is a far less reversible electrode than hydrogen over the temperature range 0° C to 200° C. Thus, although considerable current densities can be obtained from noble metal electrodes and ammonia, the polarization of these electrodes is excessively high and would preclude the use of ammonia where high thermal efficiency is required. It has been the object of this investigation to determine the rate-limiting steps in the overall mechanism of the anodic oxidation of ammonia which are responsible for the observed polarization levels.

A preliminary investigation of noble metal blacks indicated that platinum black appeared to be the most reversible of electrode systems and was chosen as the electrode for a detailed investigation of mechanisms. It was not possible to conduct these studies on a bright platinum surface because, under the experimental conditions, such surfaces exhibited very poor stability and reproducibility. This is considered to be a result of the low exchange current of the NH_3/Pt electrode relative to electrolyte impurity currents.

EXPERIMENTAL TECHNIQUE

The experimental cell used is shown in Fig. 1 and consists of four compartments. Compartments A and D contain the electrodes for pre-electrolysis, which was conducted for 24 hours at a current density of approximately 1 ma/cm^2. The study electrode and pre-electrolysis electrodes were prepared by electroplating platinum black onto platinum foil by the method described by Janz and Ives (1). High-purity nitrogen was bubbled through the pre-electrolysis compartments during the period of pre-electrolysis. The reference electrode was Hg/HgO/KOH. Electrolyte concentrations of 1, 5, and 10 molal KOH were prepared from analytical grade KOH and water triply distilled from alkaline permanganate solution.

The current–potential relationships were obtained by the galvanostatic method using a square-wave current generator. The potential transients were displayed on a Tektronix 545A oscilloscope and recorded photographically. The magnitude of the activation overpotential was measured at the point where $dV/dt = 0$.

The molal activity coefficients (2) for KOH solutions were used to calculate the reversible potential of the ammonia electrode. The activity of ammonia at 25° C was calculated from the experimental values of the solubility of ammonia in KOH and was estimated to be 0.0352. From the Nernst equation, E_0 was calculated to be −0.787 v versus the standard hydrogen electrode (S.H.E.). All potentials shown are referred to the standard hydrogen electrode (S.H.E.).

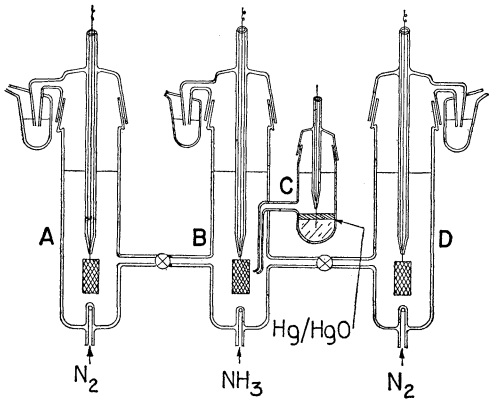

FIG. 1.

EXPERIMENTAL DATA

Experimental data are shown in Figs. 2–4. Table I lists the recorded open-circuit voltages (O.C.V.) and calculated exchange currents. The Tafel plots demonstrate two

TABLE I

Open-circuit voltages and exchange currents

Figure No.	Temperature (°C)	O.C.V. vs. S.H.E. (mv)	Current density, i_0 (amp/app. cm²)
1	27	−385	$\sim 10^{-8}$
2	32	−550	$\sim 10^{-8}$
3	70	−615	$\sim 10^{-8}$

distinct regions: a low-current linear region having a slope of (approximately) $2RT/3F$, and a high-current region where the slope approaches infinity. Visible gas evolution was observed in both regions, and the gas has been identified as pure nitrogen. The overall reaction appears to be

$$NH_3 + 3OH^- \rightarrow \tfrac{1}{2}N_2 + 3H_2O + 3e^- \qquad [A]$$

and the reaction appears to proceed with 100% coulombic efficiency. It might be noted that oxides of nitrogen would only be expected at potentials positive to S.H.E. All of the experiments reported herein were conducted in the potential region negative to S.H.E. It can be reasonably assumed, therefore, that over the whole current range observed, the currents correspond to the anodic oxidation of ammonia; also, the two different regions observed in the Tafel plots each have corresponding rate-limiting processes.

DISCUSSION OF RESULTS

An overall sequence of reactions must first be proposed. Considering the postulated mechanism of the vapor phase decomposition of ammonia to form nitrogen and hydrogen, it is presently believed that ammonia chemisorbs on the transition-metal surfaces, followed by dissociation to an amine radical which further dissociates to an imine radical (3–10). This can be represented by the following scheme, where (a) represents an adsorbed species.

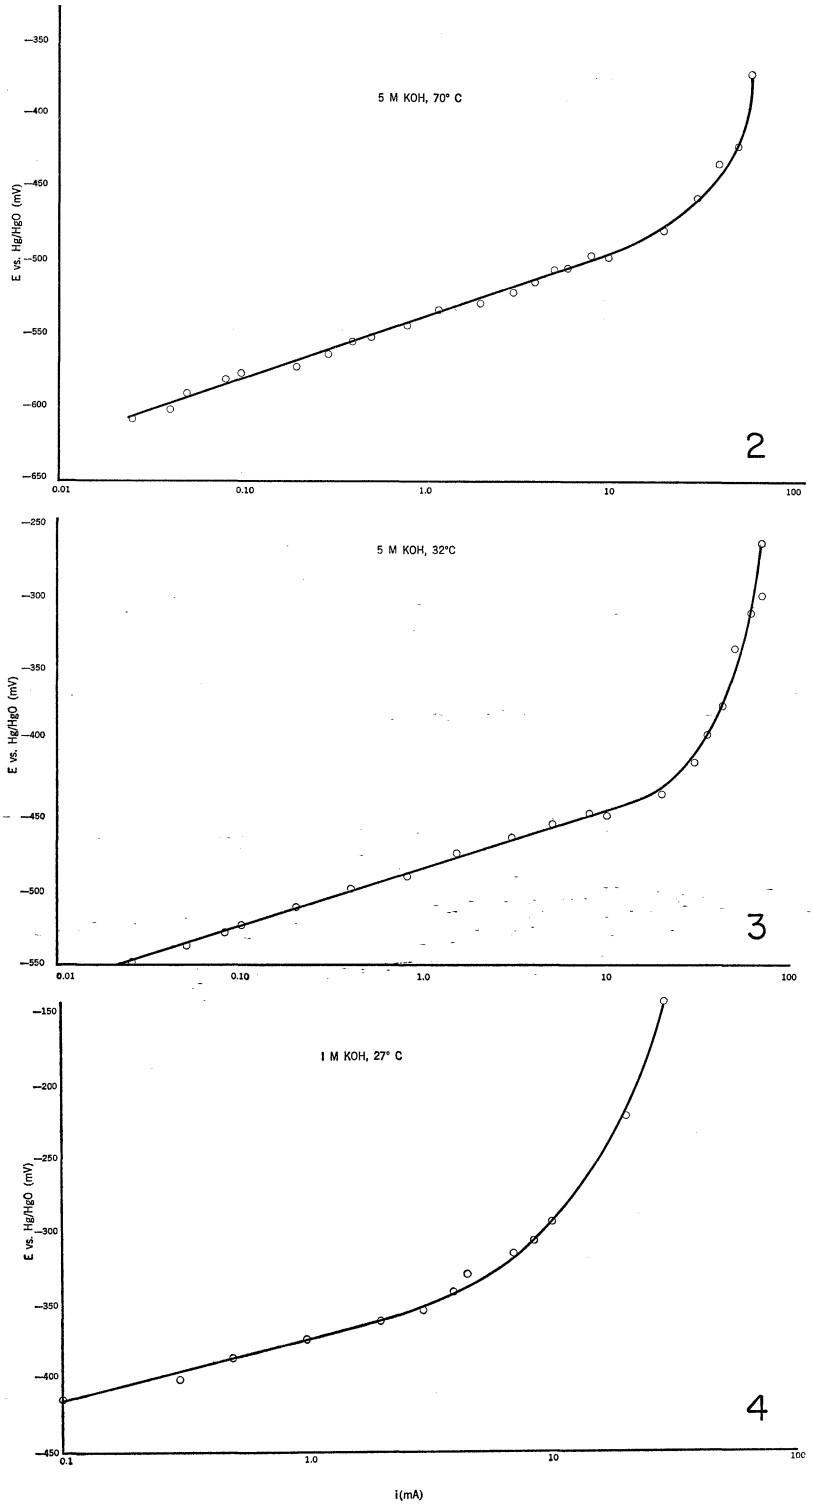

FIGS. 2–4.

$$NH_3 \rightarrow NH_2(a) + H(a) \quad [B]$$

$$NH_2(a) \rightarrow NH(a) + H(a) \quad [C]$$

$$NH(a) \rightarrow N(a) + H(a) \quad [D]$$

$$2H(a) \rightarrow H_2 \quad [E]$$

$$2N(a) \rightarrow N_2 \quad [F]$$

The overall gas phase equilibrium is

$$2NH_3 \rightleftharpoons 3H_2 + N_2.$$

Brunauer, Love, and Keenon (3) found that the energy of activation of adsorption increases linearly with coverage according to

$$\Delta E^{\ddagger} = \Delta E_0^{\ddagger} + r\theta, \quad [1]$$

where $\Delta E^{\ddagger}$ is the energy of activation at some finite coverage and $\Delta E_0^{\ddagger}$ is the energy of activation at zero coverage, r is a constant and has the dimensions of energy, and θ is the surface coverage. Similarly, for desorption, the energy of activation varies with coverage according to

$$\Delta E'^{\ddagger} = \Delta E_0'^{\ddagger} + r\theta.$$

From these experimental studies (3–5), it is concluded that reaction [F] (nitrogen recombination) is rate determining. Horiuti *et al.* (6–10) have proposed that the rate-determining step is one of the reactions [B], [C], or [D], although they favor reaction [D] (10). The conclusion that reaction [B], [C], or [D] is rate determining is based on the experimentally determined stoichiometric number of 2; that is, the number of times the rate-determining step has to occur for every complete reaction is two. The stoichiometric number is 2 for reactions [B], [C], and [D], 3 for reaction [E], and 1 for reaction [F]. These results for the vapor phase decomposition are important since we propose that two similar mechanisms occur during the anodic oxidation of ammonia in KOH solutions.

In strong acid electrolytes, the anodic oxidation of ammonia appears to be extremely slow. It is, therefore, proposed that the NH_3 molecule is the reacting species rather than the ammonium ion. It does not seem likely that the NH_4^+ ion can be chemisorbed without prior dissociation to NH_3 and H_3O^+, since the nitrogen does not have any electrons available to form a surface bond when in the NH_4^+ form. Therefore, we propose that the anodic oxidation of ammonia proceeds via the dissociation of an ammonia molecule in a manner similar to that believed to occur in the gas phase dissociation. Four sequential steps for the anodic oxidation of ammonia are proposed:

$$NH_3 + M + OH^- \rightarrow M{-}NH_2 + H_2O + e_m \quad [i]$$

$$M{-}NH_2 + OH^- \rightarrow M{=}NH + H_2O + e_m \quad [ii]$$

$$M{=}NH + OH^- \rightarrow M{=}N + H_2O + e_m \quad [iii]$$

$$M{\equiv}N + N{\equiv}M \rightarrow 2M + N_2. \quad [iv]$$

Three single electron-exchange steps are involved, followed by a non-electrochemical recombination of nitrogen atoms and the desorption of nitrogen molecules. The surface, therefore, would be covered with the chemisorbed species —NH_2, —NH, and —N. Since the potential region studied is greater than 200 mv positive to the reversible hydrogen potential in the electrolyte, it must be assumed that surface coverage of M—H species is very low and that θ_{MH} is negligible.

A comprehensive derivation of the kinetic parameters is treated for two cases. The first

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

case is where surface coverage is either low or high, i.e., $0.2 > \theta > 0.8$, which are the necessary conditions for applying the Langmuir isotherm. The second case is for intermediate coverages where the heat of chemisorption varies linearly as a function of θ and adsorption can be described by the Temkin isotherm (11).

Case I—Application of Langmuir Isotherm

When the initial stage [i] is the slow and rate-determining step, the rate of the reaction is given by the relation

$$V_1 = k_1 \cdot a_{NH_3} \cdot a_{OH^-}(1-\theta_t)e^{\beta VF/RT}, \qquad [2]$$

where k_1 is the electrochemical rate constant, β is the relative slope factor for the energy curves of the initial and final states at their point of intersection, θ_t is the total surface coverage, and all the other terms have their usual significance. Differentiation of eq. [2] yields a Tafel slope of $dV/d \ln i = RT/\beta F$ (noting that $i = zFV$). If $\beta = 0.5$, then the slope is 118 mv at 25° C.

When stage [ii] is rate determining, then [i] can be considered in quasi-equilibrium, and the reverse rate is

$$V_{-1} = k_{-1} \cdot a_{H_2O} \cdot \theta_{MNH_2} \cdot e^{-(1-\beta)VF/RT}. \qquad [3]$$

Since this step is regarded as being in equilibrium, the forward and reverse rates can be equated and the value of θ_{MNH_2} determined. Hence,

$$\theta_{MNH_2}/(1-\theta_t) = K_1 \cdot e^{VF/RT}, \qquad [3a]$$

where K_1 is the equilibrium constant. For low surface coverages

$$\theta_{MNH_2} = K_1 \cdot e^{VF/RT}. \qquad [4]$$

The velocity of the rate-determining mechanism is given by

$$V_2 = k_2 \cdot a_{OH^-} \cdot \theta_{MNH_2} \cdot e^{\beta VF/RT}. \qquad [5]$$

Substituting for θ_{MNH_2} from [4] and differentiating, we obtain

$$dV/d \ln i = 2RT/3F = 39 \text{ mv}. \qquad [6]$$

If step [iii] is rate determining, then [i] and [ii] can be considered to be in quasi-equilibrium. The reverse rate of step [ii] is

$$V_{-2} = k_{-2} \cdot a_{H_2O} \cdot \theta_{MNH} \cdot e^{-(1-\beta)VF/RT}. \qquad [7]$$

By equating eqs. [5] and [7]

$$\theta_{MNH} = K_2 \cdot \theta_{MNH_2} \cdot e^{VF/RT}.$$

Substituting for θ_{MNH_2} from eq. [4]

$$\theta_{MNH} = K_1 K_2 e^{2VF/RT} \qquad [8]$$

The velocity of step [iii] is

$$V_3 = k_3 \cdot a_{OH^-} \cdot \theta_{MNH} \cdot e^{\beta VF/RT}. \qquad [9]$$

Combining eqs. [8] and [9] and differentiating yields a Tafel slope of $2RT/5F$ or 24 mv. Similarly, where step [iv] is the rate-determining process

$$\theta_{MN} = K_1 K_2 K_3 e^{3VF/RT} \qquad [10]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and the rate is

$$V_4 = k_4 \cdot \theta_{MN}^2. \quad [11]$$

Equating [10] and [11]

$$V_4 = k_4[K_1K_2K_3]^2 \cdot e^{6VF/RT} \quad [12]$$

and differentiating, we obtain a Tafel slope of $RT/6F$ or 10 mv.

For the case of high coverages, i.e., as $\theta \rightarrow 1$, the coverage is no longer a function of potential. A Tafel slope of $RT/\beta F$ is predicted for all cases except the last, where the slope is infinite. Thus, when the nitrogen recombination stage is rate determining and surface coverage is high, a limiting-current condition is achieved (12).

It should be noted that application of Langmuir isotherm results in a decreasing Tafel slope when the assumed rate-determining step changes from the initial to the final step for the case of small surface coverages. It is quite possible, however, that intermediate surface coverages are involved and that the Langmuir isotherm is no longer applicable (see below).

Case II—Application of Temkin Isotherm

Recently, Thomas (13) has shown that linear Tafel lines can arise from the hydrogen evolution reaction in the region of intermediate coverage, i.e., $0.2 < \theta < 0.8$. Conway and Gileadi (14) have extended this treatment for a series of consecutive electrochemical reactions and have shown that the lowest Tafel slope obtainable for a terminal recombination step is $RT/2F$. This treatment for intermediate coverages is based upon the Temkin isotherm when there is a linear relation between heat of adsorption and coverage. This dependence can be represented by a form of eq. [1]. The exact form of eq. [1], which is applicable in the case of consecutive reactions, will depend upon the model used (14). The model which seems most probable is that of Boudart, which is based on the surface induction effect (15). This model is preferable to the one based on intrinsic heterogeneity of surface sites, since experimental investigations of the vapor phase decomposition of NH_3 on metals indicate that surface interactions not due to heterogeneity are involved (16, 17).

The r term in eq. [1] thus arises from dipole double-layer (surface potential) contributions from MNH_2, MNH, and MN. Hence, we can write equations analogous to [1] for the three species as

$$\begin{aligned}
\Delta H_A &= \Delta H_A^0 - r_A\theta_A - r_B\theta_B - r_C\theta_C \\
\Delta H_B &= \Delta H_B^0 - r_A\theta_A - r_B\theta_B - r_C\theta_C \\
\Delta H_C &= \Delta H_C^0 - r_A\theta_A - r_B\theta_B - r_C\theta_C,
\end{aligned}$$

where ΔH is the heat of adsorption. Replacing $r_A\theta_A + r_B\theta_B + r_C\theta_C$ by $f(\theta)$,

$$\begin{aligned}
\Delta H_A &= \Delta H_A^0 - f(\theta) \\
\Delta H_B &= \Delta H_B^0 - f(\theta) \\
\Delta H_C &= \Delta H_C^0 - f(\theta).
\end{aligned} \quad [13]$$

Since the heat of adsorption decreases linearly with the coverage, the free energy of activation is decreased by some fraction $1-\gamma$ of $f(\theta)$ (13, 14). The forward rate of step [i] can be written as

$$V_1 = k_1 \cdot a_{NH_3} \cdot a_{OH^-} \cdot (1-\theta_t) \cdot \exp\, -[\Delta G_{0_1}^{\ddagger} + \gamma f\theta - \beta VF]/RT. \quad [14]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Similarly, for the reverse reaction, the free energy of activation is increased by some fraction $1-\gamma$ of $f(\theta)$, and the reverse rate of step [i] is, therefore,

$$V_{-1} = k_{-1}\cdot\theta_{MNH_2}\cdot a_{H_2O}\cdot\exp\ -[\Delta G^{\ddagger}_{0_{-1}}-(1-\gamma)f\theta+(1-\beta)VF]/RT. \qquad [15]$$

If [i] is rate determining then θ_{MNH_2} is small and the simple discharge slope of $2RT/F$ can be derived. If [i] is fast (another step being slow), then it is assumed that [i] is in quasi-equilibrium. Equating [14] and [15]

$$f(\theta) = VF+K_1. \qquad [16]$$

Reactions [ii] and [iii] are radical–ion recombinations which involve charge transfer and production of a new surface species. Thus, the rate of [ii] is

$$V_2 = k_2\cdot\theta_{MNH_2}\cdot a_{OH^-}\cdot\exp\ -[\Delta G^{\ddagger}_{0_2}+\gamma f(\theta)-(1-\gamma)f(\theta)-\beta VF]/RT. \qquad [17]$$

Assuming that γ equals $1/2$

$$V_2 = K_2\cdot\theta_{MNH_2}\cdot a_{OH^-}\cdot\exp\ -[\Delta G^{\ddagger}_{0_2}-\beta VF]/RT. \qquad [17a]$$

For intermediate coverages, it follows that the pre-exponential terms in θ can be neglected compared to the exponential term in θ (13, 14). Using logs and differentiating [17*a*] yields a Tafel slope of $2RT/F$. Since mechanism [iii] is identical in form with mechanism [ii], it yields a Tafel slope of $2RT/F$.

The rate of terminal recombination step [iv] for non-activated chemisorption of nitrogen is

$$V_4 = k_4\cdot\theta^2_{MN}\cdot\exp\ -[\Delta G^{\ddagger}_{0_4}-2f(\theta)]/RT \qquad [18]$$

and for the activated adsorption of nitrogen is

$$V_4 = k_4\cdot\theta^2_{MN}\cdot\exp\ -[\Delta G^{\ddagger}_{0_4}-2\delta f(\theta)]/RT. \qquad [18a]$$

Here, δ is the symmetry factor of the energy barrier associated with activated chemisorption of nitrogen.

From equations [16] and [18] for non-activated adsorption

$$V_4 = k_4'\cdot\theta^2_{MN}\cdot\exp\ -[\Delta G^{\ddagger}_{0_4}-2VF]/RT. \qquad [19]$$

From eqs. [16] and [18*a*] and activated adsorption

$$V_4 = k_4'\cdot\theta^2_{MN}\cdot\exp\ -[\Delta G^{\ddagger}_{0_4}-2\delta VF]/RT. \qquad [20]$$

Therefore, the Tafel slopes corresponding to equations [19] and [20] are $RT/2F$ and $RT/2\delta F$, respectively.

Table II is a summary of the calculations performed and contains the derived Tafel slopes, assuming different rate-controlling mechanisms and either Langmuir or Temkin isotherms. In addition to the slopes for the Temkin isotherm (refer to Table II), other slopes can appear depending on the ratio of the coverages by intermediate species (14). Thus, if reaction [iii] is rate determining, both θ_{MNH_2} and θ_{MNH} can be significant depending upon the equilibrium constant for reaction [ii], i.e.,

$$\theta_{MNH}/\theta_{MNH_2} = K_2e^{VF/RT}. \qquad [21]$$

If step [iv] is rate determining, then there are three surface intermediates whose coverages are a function of the equilibrium constant for reaction [iii], i.e.,

$$\theta_{MN}/\theta_{MNH} = K_3e^{VF/RT} \qquad [22]$$

TABLE II
Tafel slopes

Mechanism	Langmuir case	Temkin case
(*a*) Calculated		
[i]	$2RT/F$	—
[ii]	$2RT/3F$	$2RT/F$
[iii]	$2RT/5F$	$2RT/F$
[iv]	RT/6F or ∞ ($\theta \rightarrow 1$)	RT/F (activated adsorption) or $RT/2F$ (non-activated)
(*b*) Observed		
	$2RT/3F$ $\rightarrow \infty$	Low-current region High-current region

and the equilibrium given above. Considering reaction [iii] to be rate determining and K_2 in eq. [21] $\ll 1$, then θ_{MNH} is small and exponentially dependent on potential. In addition, substitution for θ_{MNH} in the rate equation must be made. If the rate is

$$V_3 = k_3 \cdot a_{OH^-} \cdot \theta_{MNH} \cdot \exp -[\Delta G^{\ddagger}_{0_3} - \gamma f(\theta) + (1-\gamma) f(\theta) - \beta VF]/RT \qquad [23]$$

then substitution for θ_{MNH} yields

$$V_3 = k_3' \theta_{MNH_2} \cdot \exp VF/RT \cdot \exp \beta VF/RT. \qquad [24]$$

Since θ_{MNH_2} can be considered to be constant compared to the exponential term in θ, the Tafel slope is $2RT/3F$ or 39 mv.

Considering step [iv] to be rate determining and K_3 in eq. [22] $\ll 1$, then θ_{MN} is small and exponentially dependent upon potential. For activated nitrogen chemisorption,

$$V_4 = k_4'' \cdot \theta^2_{MNH} \cdot \exp 2VF/RT \cdot \exp 2\delta VF/RT \qquad [25]$$

is obtained from eqs. [20] and [22]. Assuming $\delta = 1/2$, the derived Tafel slope is $RT/3F$.

If both K_2 and K_3 are $\ll 1$, substitution must be made for θ^2_{MNH} in eq. [25]. The potential-dependent form for θ^2_{MNH} is obtained from eq. [21]. Substitution for θ^2_{MNH} yields

$$V_4 = K_4^* \cdot \theta^2_{MNH_2} \cdot \exp 4VF/RT \cdot \exp 2\delta VF/RT.$$

For $\delta = 1/2$

$$V_4 = k_4^* \cdot \theta^2_{MNH_2} \cdot \exp 5VF/RT \qquad [26]$$

and the Tafel slope is $RT/5F$.

Therefore, it is seen that a variety of slopes can be predicted which depend on equilibrium constants K_2 and K_3 in eqs. [21] and [22]. These constants are dependent on the relative bond strengths of the surface species involved. For example, K_2 will be closer to unity if the bond strength M=N > M—N. It is reasonable to assume that the bond strength will increase in the order M≡N > M=N > M—N. This is analogous to the case of carbon–nitrogen bonds (17). Therefore, slopes predicted by equations [21–26] can be rejected.

Comparison of Case I and II

The experimental values of $dV/d \ln i$ obtained from Figs. 2, 3, and 4 correspond to $2RT/3F$ in the low-current region and to infinity in the high-current region. Within the limitations and assumptions inherent in eqs. [2–26], it would seem that these experimental values can be interpreted in terms of the Langmuir isotherm. Thus, at low-current densities, the rate-controlling step would be the oxidation of the surface amine,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

as shown in step [ii], while at high-current densities, the rate-determining process is nitrogen recombination and evolution (refer to step [iv]).

There appears to be some justification, therefore, for stating that there are similarities between the mechanisms of vapor phase decomposition and anodic oxidation of ammonia on a platinum electrode. However, there appears to be a significant difference between the two systems. In the anodic oxidation, the kinetic treatment using the Langmuir isotherm indicates both limiting low and high surface coverages. In the vapor phase decomposition, apparently the data can be explained on the basis of the Temkin isotherm, which requires that surface coverage be intermediate.

This difference might be expected in the case of the recombination step for the following reasons. During the vapor phase decomposition of ammonia, the overall nitrogen desorption rate would be influenced by surface coverage with chemisorbed hydrogen, which acts as a "poison" (3, 4). Thus, the rate of nitrogen recombination is reduced by the presence of chemisorbed hydrogen.

However, during the anodic oxidation of ammonia, the coverage with respect to chemisorbed hydrogen at potentials several hundred millivolts positive to the reversible hydrogen potential will be insignificant. This is clearly indicated from the approximate exchange current density values for the ammonia electrode, which are lower than that reported for hydrogen evolution (19) by a factor of about 10^5.

Therefore, it is suggested that in the anodic oxidation case no "poisoning" or blocking of surface sites by hydrogen ad-atoms occurs. In addition, nitrogen recombination can be rapid at low current densities. This is consistent with Horiuti *et al.* (6–10), except we conclude that step [ii] is rate determining at low-current densities; in the vapor phase, step [iii] is thought to be rate determining.

ACKNOWLEDGMENT

The authors would like to acknowledge the very helpful discussions with Professor B. E. Conway and Mr. E. Gileadi.

THE POLAROGRAPHY OF THE MAGNESIUM–ALIZARIN SYSTEM

D. G. Brewer[1] and John A. Page
Department of Chemistry, University of Toronto, Toronto, Ontario
Received March 13, 1963

ABSTRACT

The polarography of alizarin alone, and alizarin in the presence of magnesium, has been studied in an ammonia–ammonium chloride electrolyte. Alizarin was found to give a reduction wave with $E_{1/2} = -(0.14+0.059\ \text{pH})$ volts vs. S.C.E. and a polarographic diffusion coefficient D, equal to 1.20×10^{-6} cm^2 sec^{-1} over a range of pH from 7.4 to 10.0 in aqueous solution at 25° C. The slope of the wave corresponded to a two-electron reversible process. The addition of magnesium caused a decrease in the polarographic wave for alizarin, but the combining ratio of magnesium to alizarin was a function of pH, ranging from 1.02 at pH 9.0 to 1.28 at pH 10.1. The combining ratio greater than unity could be attributed to alizarin adsorbed on a 1:1 (MgAlz) precipitate. The removal of alizarin from the solution was not quantitative in the presence of excess magnesium, and there is evidence of the formation of soluble complex species. The reaction is potentially useful for the indirect polarographic determination of magnesium.

INTRODUCTION

The direct polarographic determination of magnesium has proved unsatisfactory, with hydrogen evolution accompanying the reduction of the magnesium at the dropping mercury electrode (1). In basic supporting electrolytes of tetraalkyl ammonium salts the polarographic wave for magnesium is irregular and abnormally large, with a half-wave potential of −2.2 volts vs. S.C.E. (2, 3, 4). However, magnesium has been determined polarographically utilizing a streaming mercury electrode in a tetramethyl ammonium chloride electrolyte of pH 5.4 to 6.8 (5).

A number of indirect polarographic procedures for magnesium have been reported in the literature. One method measures the amount of 8-hydroxyquinoline unused in the precipitation of magnesium (6), while a variation dissolves the magnesium precipitate in acid for a polarographic determination of the 8-hydroxyquinoline equivalent to the magnesium (7). Another indirect method involves the precipitation of the hexamine complex of either magnesium iodide or calcium–magnesium ferrocyanide (8). The precipitate is filtered, washed, dissolved in a potassium nitrate solution, and then the iodide is determined polarographically or the ferrocyanide is titrated amperometrically with a lead nitrate solution. Two methods employing ethylenediaminetetraacetic acid (EDTA) have also been reported. In one (9), magnesium is added to a buffered ammonia – ammonium chloride solution containing the zinc–EDTA complex. Zinc, equivalent to the magnesium, is liberated and determined polarographically. A second method (10) depends on the decrease in the anodic wave of EDTA caused by the presence of magnesium. All of these indirect methods are subject to numerous interferences.

A literature survey of reagents for the qualitative and quantitative determination of magnesium has revealed no reagent outstanding in specificity. However, the alizarin reagent family (Fig. 1(*a*)) is most prominent in magnesium spot tests and colorimetric procedures (11, 12, 13). Furman and Stone (14) have carried out a systematic polarographic study of these reagents in various aqueous buffer solutions containing 1% ethanol. In alkaline solutions they found that most of the alizarin reagents gave a single polarographic reduction wave with slopes close to that for a reversible two-electron process, indicating reduction to a hydroquinone form. However, some specific buffer effects were

observed. In some cases, two polarographic waves, each with a one-electron slope, were obtained. This was taken as an indication of intermediate semiquinone formation. In the pH region of 4 to 8 a number of cases were found of single waves with slopes close to that for a one-electron process.

EXPERIMENTAL

Polarograms were recorded on a Leeds and Northrup Type E Electrochemograph with damping set at the No. 1 position. A conventional H-type cell with a saturated calomel reference electrode was used; the polarography was carried out at 25.0°. The dropping mercury electrode was used with a 50.0-cm head of mercury; the flow rate, m, was 1.178 mg sec^{-1}. Diffusion currents were measured at −1.00 volts vs. S.C.E. and corrected for residual current by graphical means; the drop time, t, was 5.25 sec at this potential in the supporting electrolyte. The capillary constant was equal to 3.11 $mg^{2/3}$ $sec^{-1/2}$.

Prepurified nitrogen (less than 20 p.p.m. nitrogen) was used to displace the oxygen from solutions for polarography. The pH measurements were made with a Beckman Model G meter employing external electrodes. The meter was standardized at 25.0° using Beckman 3501 pH 7.00 buffer. Most absorbance measurements were made on a Bausch and Lomb Spectronic 505 using matched quartz cells of 1-cm path length. One series of solutions (Table IV) was run on a Beckman DU spectrophotometer. Absorbances measured on both instruments differed appreciably, apparently due to a difference in the optical systems.

The alizarin used was supplied by the Fisher Scientific Company as a reagent grade material. It was recrystallized from carbon tetrachloride and dried at 110°. The purified reagent was confirmed by both infrared and n.m.r. spectra; it had a melting point of 280–283°. Standard stock solutions were prepared by dissolving known weights of the reagent in 25 ml of 0.1 M NaOH solution and then diluting to 500 ml with water. A number of preliminary experiments were carried out with a stock solution prepared by dissolving alizarin in 300 ml of ethanol and then diluting to 500 ml with stock NH_3–NH_4Cl buffer solution.

The stock NH_3–NH_4Cl buffer solution was prepared by dissolving 300 g of reagent NH_4Cl and 400 ml of concentrated aqueous NH_3 in water and diluting to 2000 ml. A 15-ml aliquot of this stock solution was used for each 100 ml of final solution, giving a system that was 0.45 M with respect to both NH_3 and NH_4Cl. Adjustment of the solution to the final pH was accomplished by addition of HCl or NH_3 before the final dilution. The standard magnesium solution was prepared by dissolving reagent grade MgO in a minimal amount of hydrochloric acid and then diluting. The solution was standardized by an EDTA titration employing Eriochrome Black T as indicator (15).

Determination of Alizarin

A method of analysis for alizarin in the presence of a large excess of magnesium or ammonium salts was developed. The procedure involves the dilution of an aqueous alizarin solution with concentrated H_2SO_4 to give a final solution 9 M in the acid. The final solution was yellow with an absorbance maximum at 428 mμ. A calibration curve prepared from weighed amounts of pure alizarin was found to obey Beer's law up to 5×10^{-5} M with a molar absorptivity, E, of 5.70×10^{-3} liter $mole^{-1}$ cm^{-1} at the absorbance maximum. Aliquots of the final buffered NH_3–NH_4Cl solutions containing known amounts of alizarin both alone and in the presence of large excess of magnesium gave results in agreement with the calibration curve.

Polarography of Alizarin

Alizarin was found to give a well-defined reduction wave with a regular diffusion current plateau in the buffer system. The stock solution of alizarin in NaOH was found to be stable for weeks, but the polarographic wave obtained from the buffered solutions deteriorated on several days' standing.

The diffusion current was found to be relatively independent of pH over the range from 8.8 to 10.8 with a mean diffusion coefficient of 4.13 μa $mmole^{-1}$ l^{-1} (Table I). Below pH 8, a buffered solution of alizarin containing 10% ethanol was found to give a precipitate with an accompanying decrease in the observed diffusion current (Fig. 2). The half-wave potential for the alizarin wave was found to shift with pH. Two

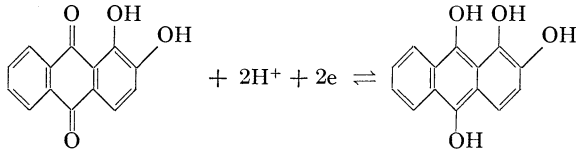
series of experiments using each of the stock solutions of alizarin in NaOH and ethanol gave similar shifts of -0.059 volts per pH unit but the presence of ethanol was found to shift the half-wave potentials to more negative values at a given measured pH (Fig. 3). Plots of log $(i/(i_d-i))$ vs. E_{dme} gave straight lines with slopes in close agreement with a 2 faraday per mole reduction (Table II). Thus the polarographic reduction presumably results in the formation of a hydroquinone species according to the equation



On the basis of the 2 faraday per mole reduction, a polarographic diffusion coefficient, D, equal to 1.20×10^{-6} cm^2 sec^{-1} can be calculated from the unmodified Ilkovic equation. Attempts to verify the 2 faraday per mole reduction by controlled potential coulometric reduction at a large isolated mercury cathode were not successful. Electrolysis in the buffered NH_3–NH_4Cl solution at -0.85 volts vs. S.C.E. was incomplete even after the passage of quantities of electricity several times larger than that predicted from the polarographic data.

Polarography of the Magnesium–Alizarin System

The effect of magnesium on the polarographic behavior of alizarin was studied by additions of magnesium to the buffered alizarin solutions before making up to final volume. Polarograms, taken at intervals, showed that approximately 3 hours at 25.0° were required to reach equilibrium (Fig. 4). A precipitate was observed to settle out of the solution over this period. The diffusion current at equilibrium in the presence of a fixed added amount of magnesium was found to be a function of pH (Fig. 2). The half-wave potential of the residual alizarin wave was not significantly shifted by added magnesium (Fig. 3), and plots of log $(i/(i_d-i))$ vs. E_{dme} again gave straight lines, in agreement with a 2 faraday per mole reduction (Table II).

The addition of a large excess of magnesium and subsequent filtration after equilibrium had been established left a residual polarographic wave with the same half-wave potential as free alizarin. The wavelength of maximum absorbance of the solution, however, was found to be shifted. The alizarin left in solution was determined spectrophotometrically in 9 M H_2SO_4 (Table I), and a mean polarographic diffusion coefficient of 4.50 μa mmole^{-1} l^{-1} was calculated.

The overall combining ratio of magnesium to alizarin was also determined. A series of solutions were prepared of fixed pH, fixed alizarin concentration, but varying concentrations of added magnesium. In each

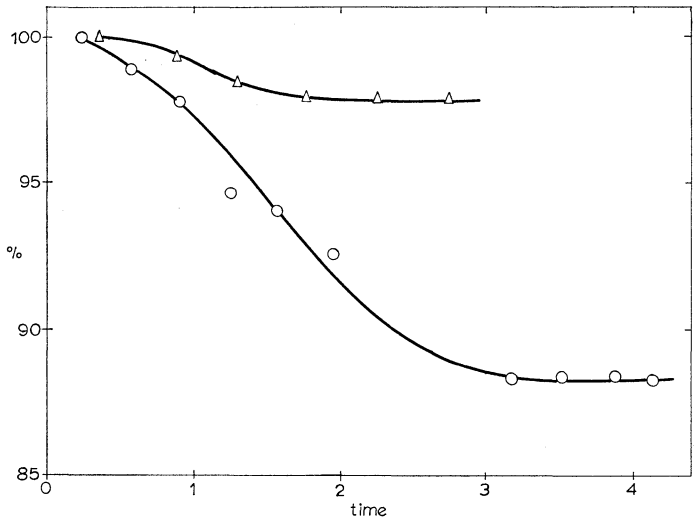

FIG. 4. Effect of standing at 25.0°. Diffusion current of alizarin (%) vs. time (hr). Upper line: 0.416 mmolar alizarin plus 0.231 mmolar Mg, pH 9.49; lower line: 1.002 mmolar alizarin plus 0.499 mmolar Mg, pH 9.71.

case investigated there was obtained an initial linear region in which the diffusion current decreased linearly with added magnesium, but also in each case the diffusion current approached zero only slowly on the addition of excess magnesium (Fig. 5). The initial linear region was extrapolated to zero diffusion current and the concentration of added magnesium corresponding to complete removal of the alizarin was determined. The overall combining ratio was found to be a function of pH (Table III), and the results have been confirmed by parallel absorbance measurements on each series of solutions (Table IV).

DISCUSSION

The acid dissociation constants for alizarin have been determined by Hüttig from solubility and absorption measurements (16). The values of K_1^H and K_2^H were found to be 6.61×10^{-9} and 1.07×10^{-12} at 18°. This would result in a distribution of the species H_2Alz, $HAlz^-$, and Alz^{2-} such that the predominant form over the range of pH studied would be $HAlz^-$.

Since the extrapolation of the linear region indicates a combining ratio near unity, the formula MgAlz may be assigned to the precipitate. A structure (Fig. 1(*b*)) can be postulated on the basis of a study of the reactions of other hydroxyanthraquinones. The reagents were relatively insoluble where there was the possibility of hydrogen bonding of all the hydroxyl groups to adjacent quinone oxygens; the solubility appeared to depend upon free hydroxyl groups. Of the reagents tested (Fig. 1(*a*)) only alizarin and quinalizarin precipitated with magnesium; the only reaction site consistent with insolubility

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

is across the 1- and 2-hydroxyl groups. Anthrapurpurin also provides this reaction site, but here the 7-hydroxyl group is available to give a soluble complex. Many other metals react with these anthraquinone reagents to form colored products. Some of these are the so-called "lakes" which are generally considered to be adsorbed dye on an insoluble hydroxide and are non-stoichiometric. However, some of the products are nearly stoichiometric and the two types may grade into each other. Sandell (13) has reviewed the chemistry of these anthraquinone products but could not establish if the bonding involved two adjacent hydroxyl groups or a quinone oxygen and its adjacent hydroxyl group.

In the present study, the combining ratio of alizarin to magnesium was close to that of a 1:1 precipitate at pH 9.00, but at a higher pH the ratio was significantly larger. These results could be explained by the formation of a mixed 1:1 and 1:2 magnesium–alizarin precipitate, the adsorption of alizarin on the 1:1 precipitate, or "lake" formation in which alizarin is adsorbed on a magnesium hydroxide precipitate in a ratio greater than 1:1. If the reaction between the alizarin and magnesium is quantitative, it would be expected that the measured diffusion current would decrease to zero in a linear fashion with added magnesium and this is not the case. The actual diffusion currents were found to approach zero slowly after an abrupt transition from the linear combining region. This behavior could not be explained on the basis of impurities in the alizarin reagent, for while the excess of magnesium did produce a spectral shift, the spectrum obtained on acidification of the solution to 9 M with H_2SO_4 was identical with that of pure alizarin.

Simple "lake" formation can also be rejected as an explanation of the behavior, for even in this case an excess of magnesium would cause the diffusion current to approach zero rapidly. Calculations based on the solubility product of $Mg(OH)_2$ (5.5×10^{-12} (17)) indicate the possibility of precipitation of the hydroxide, with the resultant buffering of the magnesium ion concentration at some maximum value. The concentration of unreacted alizarin and the diffusion current would then be expected to approach some limiting value with added magnesium, but the limiting value would increase with increasing pH; no such simple relationship was found.

The spectral shift obtained with a large excess of added magnesium may be taken as a positive indication of complex ion formation. If it is assumed that there is only one complex species in solution under these conditions, then the data of Table I can be used to calculate a mean extinction coefficient for the complex at the two wavelengths. The data of Table IV can then be resolved (18) in terms of the concentration of free and complexed alizarin using extinction coefficients for the free alizarin calculated from the absorption of the initial solution at each pH containing no added magnesium. The analysis shows significant concentrations of the complex species even at small additions of magnesium. The complex is evidently polarographically active with a half-wave potential close to that of free alizarin, and the complexation probably does not involve the quinone oxygens.

The formation of a 1:2 complex:

$$MgAlz + HAlz^- \rightleftharpoons MgAlz_2^{2-} + H^+,$$

is not in agreement with the experimental data, for the concentration of such a complex in equilibrium with the 1:1 precipitate would be a definite fraction of the free alizarin concentration at any pH. To fit the experimental results the complex must contain more magnesium than alizarin, e.g., 2:1:

$$MgAlz + Mg^{2+} \rightleftharpoons Mg_2Alz^{2+}.$$

The concentration of such a complex in equilibrium with the 1:1 precipitate would depend on the magnesium ion concentration in the solution; the concentrations calculated by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

resolution of the spectra were found to decrease to a limiting value, indicating a maximum value of the free magnesium ion concentration.

If the primary reaction for the removal of alizarin from the solution is assumed to be the formation of a 1:1 precipitate:

$$Mg^{2+} + HAlz^{-} \rightleftharpoons MgAlz + H^{+},$$

then values of the equilibrium constant, K, can be calculated (Table IV). The concentration H^+ is known from the pH, and the concentration of $HAlz^-$ can then be calculated from the spectrally resolved free alizarin concentration and the known K^H values. The concentration of Mg^{2+} removed from the solution can be calculated if it is assumed that the combining ratio determined by extrapolation of the initial linear region holds over the whole range of added magnesium. The concentration of free Mg^{2+} can then be calculated if an allowance is made for the magnesium bound up in the known concentration of complexed alizarin (2 Mg:1 alizarin). The calculation is valid only in the intermediate range of added magnesium, for with small additions the free Mg^{2+} concentration is indeterminate, and with large additions the free alizarin concentration is indeterminate. A mean value of 2.6×10^{-2} mole^{-1} liter was obtained for the equilibrium constant.

It appears that the experimental data is not capable of further analysis as regards the nature of the reaction; none the less the initial linear decrease of diffusion current with added magnesium can be used as the basis of an indirect polarographic determination of magnesium (19).

STRESSES AND STRAINS IN ADSORBENT–ADSORBATE SYSTEMS

V. THERMODYNAMIC THEORY OF ADSORPTION-EXTENSION PHENOMENA[1]

E. A. FLOOD AND F. M. FARHAN[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received February 25, 1963

ABSTRACT

The extensive thermodynamic variables of solids having large surface–volume ratios are usually not homogeneous functions of first degree in one another. In such systems mutual thermodynamic field potentials usually exist as between surface and interior regions. In general, mutual Helmholtz field potentials are not additive. When the lack of additivity of the Helmholtz potentials in adsorbate–adsorbent systems is independent of the quantity adsorbed, the changes in potentials of adsorbent and of adsorbate, due to adsorption, are additive and the equilibrium resembles the equilibrium of purely mechanical stresses. In such cases the adsorption potential is measured largely by the partial reversible relaxation of compressive and shear self-strain potentials of the solid adsorbent.

INTRODUCTION

Properties of porous materials such as their permeabilities, mechanical strengths, weather resistances, etc. are in many cases largely determined by their pore structures. Accordingly it is of considerable importance to obtain a description of these structures adequate to predict behaviors under various conditions.

In case of materials having considerable adsorptive capacities these pore structures are often very complex, very fine grained, and far from uniform. Such structures are usually not directly observable and we must resort to indirect measurements which yield various average quantities. Thus we must resort to describing these structures in terms of suitable distribution functions or in terms of a "statistical geometry".

With a view toward obtaining statistical descriptions of the structure of some activated carbons we have been studying their X-ray diffraction patterns, their permeabilities, densities, etc. We have been studying particularly the dimensional changes which these carbons undergo when subjected to mechanical stresses of various kinds, including such changes as accompany the immersion of the sample in fluids having various pressures. When the fluids are appreciably adsorbed the carbons usually expand as a result of the immersion, the phenomena being commonly referred to as adsorption-swelling or adsorption-extension.

Ideally, adsorption-extension measurements can provide a great deal of information concerning micropore structures that is difficult to obtain in almost any other way. The validity of this information depends, of course, on the validity of the theory assumed applicable to the adsorption-extension phenomena. Accordingly it is of considerable importance to obtain some notion of the validities of the various theories associated with this interesting phenomenon.

Adsorption-extension measurements have been carried out by a number of investigators using a variety of adsorbents and a variety of adsorbable gases and liquids. Notable

among these investigators are Bangham (1–3), McIntosh (4, 5), Yates (7, 8), Ambert (6), Dacey (9), Sereda (10, 11).*

In previous papers of this series (12–15) we have presented a theoretical description of adsorption extension based largely on the following assumptions:

Assumption A: The change in thermodynamic state of an adsorbent arising from physical adsorption is wholly equivalent to a change in its volumetric mean state of stress.

Assumption B: The thermodynamic conditions for equilibria of systems in hydrostatic states of stress and in scalar potential fields are adequate to describe physical adsorption equilibria.

Practically all of the existing theoretical equations describing adsorption-extension are based directly or indirectly on assumptions A and B. While a change in solid surface tension, if interpreted literally, is necessarily a change in volumetric mean state of stress, the converse statement does not hold.

While in many cases the theoretical equations based on A and B are in excellent agreement with experiment, the theory is difficult to reconcile with the "anomalous contractions" sometimes observed, i.e. with cases where adsorption leads initially to isotropic contractions instead of the predicted expansions.†

Assumption A is practically equivalent to describing the physical adsorption reaction as a purely mechanical interaction, i.e. as an interaction where forces associated with potential fields may be neglected in spite of the fact that it is just these forces which give rise to the whole adsorption phenomenon.

In what follows it is shown that assumption A is equivalent to assuming that the lack of additivity of the Helmholtz potentials of the adsorbent–adsorbate system is independent of the quantity adsorbed and that this will probably be the case when adsorption potentials are small compared with the lack of additivity of the Helmholtz potentials of the pure adsorbent, i.e. small compared with solid surface potentials.

It is also shown that the anomalous contractions cannot be strictly consistent with assumptions A and B but that if the thermodynamic conditions for equilibria include non-isotropic states of stress, thus modifying assumption B, contractions can be consistent with assumption A and are to be expected in some cases.

THERMODYNAMIC THEORY

Basic Postulates

In previous papers of this series it has been assumed that in cases of physical adsorption assemblies of volumes of adsorbate and of adsorbent can both exist separately in equilibrium with externally applied forces in states which are thermodynamically identical with their corresponding parts in the combined adsorbate–adsorbent systems; in these states the sums of the Gibbs potentials, Helmholtz potentials, volumes, etc. of the separate systems are assumed equal to the Gibbs potential, Helmholtz potential, volume, etc. of the combined system. Thus if v_a and v_c are the volumes of the adsorbate and adsorbent

**Maximum expansions of solid active adsorbents are of the order of 1 or 2% (i.e. $\delta V/V \simeq 0.015$), and are observed on immersion in liquids which "wet" the adsorbent and also on exposure to saturated vapors or to higher pressures of adsorbable gases. These expansions are more or less isotropic and show little specificity either with respect to the adsorbent or adsorbate and appear to be largely dependent on the net δG of the adsorption reaction. Expansions of this order are observed in H_2O, CCl_4, butane, alcohols, etc., also in some silicone oils, krypton, and methane at higher pressures, etc. The anomalous contractions seldom exceed 1/20 of the magnitude of maximum expansion.*

†They are normally observed only at low relative pressures and at coverages varying from small to large. They appear to be specific, depending both on the adsorbent and adsorbate. CCl_4 gives the largest contraction we have observed. Anomalous contractions are usually negligible in the case of the carbons having large micropores. Twisted rope-like adsorbents usually expand radially and contract axially—quite a different type of phenomena.

respectively and p_a, p_c the volumetric mean of the principal stresses of adsorbate and adsorbent respectively, and P is the hydrostatic pressure of the whole adsorbent–adsorbate system, then

$$[1] \qquad v_a p_a + v_c p_c = (v_a + v_c)P,$$

where $p_c = \sum \delta v_{ci}(p_{xi}+p_{yi}+p_{zi})/3v_c$ and $\sum \delta v_{ci} = v_c$; also p_{xi}, p_{yi}, p_{zi} are the principal stresses of the ith element of volume in the adsorbent; p_a is similarly defined.

Equation [1] will apply to any purely mechanical equilibrium where no "body forces" cross the surfaces over which p_a and p_c are summed.* Obviously the assumption that the two parts of the system can each exist separately in equilibrium with externally applied forces etc. applies literally to any purely mechanical interaction of two bodies. In the case of "physical" adsorption the assumption is that any mutual fields, stresses, etc. produce only such changes in the adsorbate and adsorbent as could be produced in bulk material by the application of suitable external forces, mechanical and other. While this would seem a more or less obvious definition of purely physical interaction, the assumption that in these states the potentials are additive imposes limits on the nature of the "externally applied forces". If these "forces" include forces associated with scalar field potentials (i.e. body forces, gravitational, electrostatic, van der Waals) as well as mechanical stresses, the potentials will not in general be additive unless the effect of the field on at least one of these two parts is thermodynamically equivalent to a change in state of stress only.

When we derive by "balancing mechanical forces" the relation $\Delta p = 2\gamma/r$ for the effect of surface tension on the pressure difference between the outside and inside of a spherical drop of water we assume that all "body forces" are contained within the thin spherical shell of the surface regions and that the Gibbs potentials, Helmholtz potentials, etc. of the spherical shell and the remaining spherical mass are additive. Theoretically, at least, both the water within the shell and the remainder can exist in equilibrium with externally applied stresses and suitable fields in states that are identical with those in the whole spherical mass and hence equation [1] is applicable. If, however, we consider a large self-gravitating spherical mass of water and suppose the sphere divided into two parts, which undoubtedly constitute a "physically" interacting system, body forces will pass the dividing surface and although each part separately can exist in equilibrium with externally applied forces and fields in states which are "identical" with those in the whole mass, the potentials will not be additive since the mutual field potential must be supplied by the external fields twice to the separate bodies and hence equation [1] will not hold.

Evidently assumption A and equation [1] are equivalent.

Hydrostatic States of Stress. Potentials Additive

In the first paper of this series the physical content of assumptions A and B was presented thermodynamically more or less as follows:

In order that the two separate bodies of adsorbate and adsorbent be reversibly convertible into the combined system, their natures and states remaining constant (i.e. the temperature, the pressures of the three systems, their positions in any fields, etc.) during the conversion, we must have

**The notions of stress, body force, etc. are quite sophisticated. In limiting cases the two types of force become indistinguishable. Some crude definitions are: Stress, force per unit area acting only on the surface of a volume. Principal stresses are normal stresses, i.e. p_x is the force per unit area normal to the plane yz, no shear stress being operative in the plane yz. Body force is the force per unit mass associated with a scalar potential field and may be thought of as operating at a point contained within a volume. Thus ideally we can change the shape of the surface, the volume contained by the surface, and the position of the "point" (within the surface or volume) on which the body forces operate—all independently.*

[2] $$G_a+G_c = G_{ac},$$

where G_a and G_c are respectively the Gibbs potentials of the separate assemblies of adsorbate and adsorbent; G_{ac} is the Gibbs potential of the combined systems.

In order that the systems to which G_a and G_c refer and the system to which G_{ac} refers remain reversibly interconvertible as any of the variables are changed, we must have

[3] $$dG_a+dG_c = dG_{ac}.$$

In the case of the gas remote from the surface forces, if the only changes are a change in hydrostatic pressure and the corresponding change in mass concerned (i.e. adsorbed), then

[4] $$dG_a = v_g\,dp_g+\mu_a dm_a = \frac{m_a}{\rho_g}\,dp_g+\mu_a dm_a.$$

If the combined system to which G_{ac} refers has the volume v and is immersed in the gas of pressure p_g, then

[5] $$dG_{ac} = v dp_g+\mu_a dm_a.$$

It is assumed that the solid and any reaction "products" are all contained within the volume v; i.e. they are insoluble in the gas. Hence we can write

[6] $$\delta G_c = \int_0^P v dp_g - \int_0^P \frac{m_a}{\rho_g}\,dp_g.$$

Equation [6] is applicable to any kind of reversible reaction between a gas and a solid (liquid) of zero vapor pressure, when the solid and all reaction products remain insoluble in the gas as the gas pressure changes from 0 to P.*

The volume v must include the volume of any residual pure solid as well as the volumes of any reaction products. While the volume of the solid component in its chemical compounds has no very definite meaning and cannot normally be treated as a thermodynamic entity, in the case of physical adsorption it is assumed that the volume of the pure solid remains distinct from that of the adsorbate so that the solid volume is a definite quantity, v_c. Thus v contains v_c and also the volume of all gas (adsorbate) under the influence of the surface field as well as any more or less arbitrary volume of normal gas. The total volume is thus the sum of v_c and v_a, where v_a must contain all of the gas under the influence of the field and also must contain the same mass of gas as the v_g of equation [4]. In the case of porous adsorbents it is convenient to take v as the total volume of the porous body; in this case v_a is the void volume.

Thus in the case of physical adsorption reactions we can write

[7] $$\delta G_c = \int_0^P (v_a+v_c)dp_g - \int_0^P \frac{m_a}{\rho_g}\,dp_g = \bar{v}_c \cdot P - \int_0^P \frac{v_a(\rho_a-\rho_g)}{\rho_g}\,dp_g,$$

An alternative expression for the δG_c accompanying the immersion of the solid in a large excess of gas at constant pressure and temperature is given by

$$G_a(p_g,m_a)+G_c(p_c = 0,\ m_c) = G_{ac}(p_g,m_a,m_c)+\delta G_c$$
$$\mu_a m_a+\mu_{c0}m_c = \mu_a m_a+\mu_c m_c+\delta G$$

since μ_a does not change.

$$\delta G = (\mu_{c0}-\mu_c)m_c = -\delta G_c.$$

If the rate of transfer of matter within the solid (i.e. its self-diffusion rate etc.) be negligible it is not necessary that μ_c be the same everywhere within the solid nor that $d\mu_c$ be the same everywhere. Thus δG_c is $(\bar{\mu}_c-\bar{\mu}_{c0})m_c$, where the bars represent the average quantities.

For personal use only.

where $\bar{v}_c P$ is written for $\int_0^P v_c dp_g$* and ρ_a is the apparent mean density of the adsorbate. Evidently $v_a(\rho_a - \rho_g)$ is the mass adsorbed.

If assumptions A and B are valid,

$$[8] \qquad \delta G_c = \int_0^{p_c} v_c \cdot dp_c = \bar{v}_c \cdot \delta p_c$$

and equation [7] becomes

$$[9] \qquad \delta G_c = \bar{v}_c \cdot \delta p_c = \overline{v_a + v_c} \cdot P - \int_0^P \frac{m_a}{\rho_g} dp_g.$$

Since v_c and v_a are nearly constant we can obtain δp_c from experimental data, all the quantities on the right-hand side of equation [9] being measurable. In previous papers equation [9] was written in the form

$$[10] \qquad \delta p_c = \left[1 + \frac{v_a}{v_c}(1-\alpha)\right] P,$$

where $\int_0^P (\rho_a/\rho_g) dp_g = \alpha P$, defining α. If the solid is reasonably isotropic we can write

$$[11] \qquad \frac{\delta v_c}{v_c} = \frac{3\delta l}{l} = -A\delta p_c(1 - B\delta p_c),$$

where A is the compressibility and B measures the variation of the compressibility with compression. If δp_c were a uniform change in hydrostatic stress, $\delta v_c/v_c$ would be equal to $\delta v_a/v_a$ and hence to $\delta v/v$. Normally we cannot measure $\delta v_c/v_c$ directly but only $\delta v/v$.

In an assembly of solid spheres packed in some regular manner, if the spheres have markedly different radii, a uniform decrease in surface tension of the spheres would lead to different changes in their hydrostatic pressures. The resulting dilation of the whole assembly would be greater than the sum of the dilations of the solid spheres.

To provide for such geometric or "statistical" correlations we have written

$$[12] \qquad \frac{\delta v}{v} = -A\delta \bar{p}_c{}^L (1 - B\delta \bar{p}_c{}^L),$$

where

$$[13] \qquad \delta \bar{p}_c{}^L = \left[1 + f(p) \cdot K \cdot \frac{v_a}{v_c}(1-\alpha)\right] P,$$

where K is a characteristic constant for a particular solid structure and is a measure of the variation in cross-sectional area of representative solid filaments. Thus K measures what we have referred to as "persistence of configuration" in statistical geometric systems (13). Normally K will be greater than unity. The term $f(p)$ is a specific pressure-dependent factor measuring correlation of "surface potentials" and pore structure. The implication is that these terms are of the order of unity. As we shall see, if assumptions A and B are interpreted strictly, $f(p) \cdot K$ must be unity. Thus where $\delta v/v \neq \delta v_c/v_c$ shearing and similar stresses must be involved if assumption A is retained.

Turning our attention to the adsorbate and assuming with Polanyi that in the combined system the adsorbate behaves thermodynamically as a single substance in a scalar potential field and that only hydrostatic states of stress are involved, we can write

**In Lewis notation $\bar{X}$ represents a partial molar quantity. Throughout this paper $\bar{X}$ will represent a mean quantity.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[14] $$\begin{aligned} dG_a &= v_g dp_g + \mu_a dm_a \\ &= \sum \delta v_{g\,i} dp_g + \mu_{a\,i} \sum dm_{a\,i} \\ &= \sum \delta v_{a\,i} dp_{a\,i} + \mu_{a\,i} \sum dm_{a\,i} \\ &= v_a dp_a + \mu_a dm_a, \end{aligned}$$

where $\sum \delta v_{a\,i} = v_a$ and $p_a = \sum \delta v_{a\,i} \cdot p_{a\,i}/v_a$, i.e. p_a is the volumetric mean hydrostatic pressure of the adsorbate. If p_a is not a uniform hydrostatic pressure equal to p_g it implies that scalar potential fields, say ϵ_i, exist between each element of volume of adsorbate, $\delta v_{a\,i}$, and the gas remote from the surface.

Assuming that dG_c is measured by its change in state of hydrostatic stress only we can write equation [3] in the form

[15] $$v_a dp_a + v_c dp_c = (v_a + v_c) dp_g,$$

where $v_a dp_a$ refers to assemblies of adsorbate volumes in the fields implied by equations [14], while $v_c dp_c$ refers to a separate adsorbent assembly, no field being explicitly involved. Thus the pure adsorbate is separated from the combined system, the pure adsorbent, and from the adsorbable gas by the field potentials implied by equations [14]. Evidently, equation [15] is implied by assumptions A and B.

Integrating equation [15] along a path where p_g increases from zero, i.e. along $0 \leqslant p_g \leqslant P$, gives

[16] $$\bar{v}_a \cdot p_a + \bar{v}_c \cdot p_c = \overline{v_a + v_c} \cdot P,$$

where $\bar{v}_a \cdot p_a$ is written for the integral $\int_0^{p_a} v_a \cdot dp_a$ etc.

It will be noted that equations [1], [15], and [16] cannot be mutually self-consistent when p_a or p_c differ from P unless $\delta v_c/v_c = \delta v/v$, $\bar{v}_c/v_c = \overline{v_a + v_c}/v_a + v_c$, etc., i.e. there can be no change in shape.

Thus in equation [13], $f(p) \cdot K$ must be unity and since δG_c is negative when adsorption occurs, $\delta v/v$ must be positive. Thus the "anomalous contractions" cannot be strictly consistent with assumptions A and B.

Non-isotropic States. Potentials Additive

The basic thermodynamic equation underlying equations [14] is

$$dE = TdS - pdv + fdx + \mu dm,$$

where f is the force function of a scalar potential field (i.e. a "body" force) and x is a suitable positional coordinate: the other symbols have their usual significance. If the system can increase in extent, i.e. grow in mass, volume, etc., its nature and state remaining constant, i.e. T, p, x, μ, then we can write for the corresponding increments

$$E = TS - pv + \mu m$$

and

$$G = E - TS + pv = \mu m.$$

Hence

$$dG = -SdT + vdp + fdx + \mu dm.$$

If shear stresses, polarization energies, etc. are included we must write the basic equation

[17] $$dE = TdS - pdv + \phi dq + fdx + \mu dm,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where ϕdq measures the work done on the system at constant S, v, x, and m; p is the effective mean principal stress. For reversible dilation $p = \frac{1}{3}(p_x+p_y+p_z)$.

In equation [17] only the independent variables, S, v and m, are "extensive" variables. Hence when the system grows reversibly (from a suitable source), its nature and state remaining constant (i.e. T, p, q, x, μ), the corresponding increment in the energy is $E = TS-pv+\mu m$ as before.* But for given values of p, μ will normally be greater when the principal stresses are not equal. Thus when non-isotropic forces are included we have

$$dG = -SdT+vdp+\phi dq+fdx+\mu dm. \qquad [18]$$

Applying this basic equation, equations [9], [15], [16] become respectively

$$\delta G_c = \bar{v}_c\cdot\delta p_c+\Phi_c = \overline{v_c+v_a}\cdot P - \int_0^P \frac{m_a}{\rho_g}\,dp_g \qquad [19]$$

$$v_a dp_a+\phi_a dq_a+v_c dp_c+\phi_c dq_c = (v_a+v_c)dp_g \qquad [20]$$

$$\bar{v}_a p_a+\Phi_a+\bar{v}_c p_c+\Phi_c = \overline{v_c+v_a}\cdot P, \qquad [21]$$

where $\Phi = \int_0^q \phi dq$ etc.

The potentials of the parts still being assumed additive, equation [1] holds, but now it is evident that in general $\delta v/v$ will not be equal to $\delta v_c/v_c$. Hence $f(p)K$ in equation [13] will differ from unity.

In an assembly of distinguishable volumes of matter, each of which is capable of having definable thermodynamic properties as in an assembly of solid granules, if the granules exert only mechanical forces upon one another, no body forces, no scalar potential fields being involved, the potentials are obviously additive. Hence the general thermodynamic equations for mechanical equilibrium can be written

$$\sum v_i p_i = vP \qquad [22]$$

and

$$\sum v_i dp_i + \sum \phi_i dq_i = vdp+\phi dq, \qquad [23]$$

where $\sum v_i = v$ and $p_i = \frac{1}{3}(p_{xi}+p_{yi}+p_{zi})$. Since $p_{xi}+p_{yi}+p_{zi}$ is invariant toward orthogonal transformation of coordinates, the directions of the principal stresses are largely immaterial in purely thermodynamic considerations. If the external pressure is a purely hydrostatic pressure the external work term ϕdq is zero, but this does not mean that $\sum \phi_i dq_i$ is necessarily zero by any means. Presumably $\phi_i dq_i$ will be expressible as a function of $(p_{xi}-p_{yi})^2$, $(p_{yi}-p_{zi})^2$, etc. as in elasticity theory. In any case these potentials, being scalar quantities, are independent of the choice of coordinating axes.

Evidently equations [22] and [23] are analogous to the equations of equilibrium for purely mechanical interaction,

$$\frac{\partial X_x}{\partial x}+\frac{\partial X_y}{\partial y}+\frac{\partial X_z}{\partial z} = 0, \qquad \frac{\partial Y_x}{\partial x}+\frac{\partial Y_y}{\partial y}+\frac{\partial Y_z}{\partial z} = 0, \text{ etc.}$$

When applicable to any reaction the equations virtually state that the "reaction potential" arises from a partial reversible relaxation of the mechanical self-strain potential of the solid. Since reversible compressive strain potentials can be very large, while reversible shear strain potentials are limited by shear strengths, large values of δG_c will be dominated

*The growth must take place in a definite manner in order that $\int_{v_0}^{v_0+\Delta v} pdv$ should have a definite value. When p_x, p_y, and p_z are not equal, Δv must be a pure dilation, i.e. $\Delta x/x = \Delta y/y = \Delta z/z$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by $\bar{v}_c\delta p_c$ terms. Also, since most rigid solids have very limited compressibilities, $\bar{v}_c \approx v_c$, i.e. $\int_{p_{c0}}^{p_c} vdp = \bar{v}_c\delta p_c \approx v_c\delta p_c$, and we can write $\bar{v}_c = v_c + K_c\delta v_c$, $\bar{v}_a = v_a + K_a\delta v_a$, where K_c and K_a are of the order of $\pm\frac{1}{2}$. Hence equations [1] and [21] lead to

$$[24] \qquad K_a\frac{\delta v_a}{v_a} - K_c\frac{\delta v_c}{v_c} = \frac{\Phi_a + \Phi_c}{v_a(p_a - P)},$$

where $K_a\delta v_a/v_a$ and $K_c\delta v_c/v_c$ are small quantities. Hence if either ϕ_a or ϕ_c is comparable in magnitude with $v_a(p_a - P)$, ϕ_a and ϕ_c must be of comparable magnitudes but of opposite signs.

When the volume of the surface region is small compared with the solid volume, i.e. when the volume of solid and adsorbate under the influence of surface forces is small, equation [9] may be expressed in terms of the Gibbs adsorption equation if desired. Thus in the case of the spherical drop the change in Gibbs potential due to a change in surface tension is $\delta G = v\delta p = \frac{2}{3}\sigma d\gamma$, where σ is the surface area and γ the surface tension. The assumption that dimensional changes of an adsorbent are proportional to δG_c, the proportionality constant being directly related to the compressibility, is equivalent to assumption A whether we follow Bangham and measure δG_c via the change in "surface tension" and the Gibbs adsorption equation or by the more general equation [19]. The experimental evidence gives considerable support for assumption A. Thus in spite of the fact that the physical adsorption phenomenon is undoubtedly the result of mutual field potentials the systems appear to behave as mechanical systems, i.e., as systems in which the potentials of the adsorbent as a whole and that of the adsorbate as a whole are additive (equation [1] or [22]).

Referring again to the spherical drop of liquid of visible size, the volume of the surface region is so small compared to the whole that any changes in volume of the surface region are quite negligible and hence the change in volume of the drop as a whole due to changes in surface tension will be given by

$$\frac{\delta v}{v} = -A\delta p = -A\left(\frac{2\sigma}{3v}\right)\delta\gamma.$$

Thus lowering of the surface tension will cause an increase in volume of the whole drop. But since a reduction in tension is equivalent to an increase in pressure, other things being equal, the small surface volume should decrease when the surface tension is lowered. It must be emphasized that when adsorbents have "surface areas" of the order of $10^3\ m^2/g$ the volume of the surface region cannot be small compared to the whole solid volume. In this case a decrease in solid "surface tension", if construed at all literally, should lead to a net contraction. Further, in systems of such large surface areas the lack of additivity of potentials of the solid itself must be large and, paradoxically, one might conclude that there can be little or no correlation between dimensional changes and the corresponding changes in Gibbs potential. Evidently there is some special feature involved in physical adsorption reactions which must be brought out to resolve this apparent "paradox".

Any State of Stress. Potentials not Additive

Potentials which are inherent in the state of a body as distinct from any field potentials are commonly referred to as "intrinsic" potentials (16). Thus in an assembly of granules, the intrinsic potentials of the granules are necessarily additive, but if mutual field potentials exist these potentials are not strictly properties of any particular granule alone and are not normally additive. Thus if A_i is the Helmholtz potential of a granule and $A_i =$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$A_i^0 - \omega_i$, where ω_i is the Helmholtz potential of the field, then while $A^0 = \sum A_i^0$, A is not in general equal to $\sum A_i^0 - \sum \omega_i$ if the field potentials are "mutual" potentials.

While in any condensed system intermolecular "mutual potential fields" exist, usually these mutual "potential fields" only contribute to the "intrinsic" potentials and are thus not strictly thermodynamic field potentials. In the case of mobile fluids the time-average property of any small volume of the fluid (remote from surface regions) is the same as that of any other equal volume, while in the case of solids the "potentials" are periodic properties of position. In either case, if within any homogeneous phase a reasonably sized volume be interchanged with any other equal volume, temperature, pressure, etc., remaining constant during the interchange, no appreciable change in any thermodynamic property occurs. Thus in the case of solids for reasonably large volumes $\int_{x_0}^{x} \partial G/\partial x \cdot dx$ is virtually independent of the distance moved, any variation δG or δA with δx is negligible in comparison with G or A. For small volumes $\partial G/\partial x$ is a periodic function of x. In the case of mobile fluids remote from surface regions, $\partial G/\partial x = 0$. In such systems the thermodynamic properties are additive in the sense that no change in external systems accompanies the reversible combining of two identical systems. Thus it is possible for such systems to grow reversibly in "extent", i.e. in mass, volume, etc., from a suitable source, while the temperature, pressure, and thermodynamic potentials, etc., remain virtually constant during the process. Mathematically the extensive variables are homogeneous functions of first degree in one another (17, cf. also Butler's article in ref. 18).

Thus we can write

$$dG = \partial G/\partial m \cdot dm = \mu dm$$

and

$$G_i' = \partial G/\partial m \cdot m_i = \mu_i m_i$$

and

$$G = \sum G_i = \sum G_i' = \sum \mu_i m_i .$$

If $\sum G_i'$ refers to n separate identical bodies the combining of these separate bodies, the principal stresses, temperature, etc. remaining constant, involves no change in any thermodynamic property of any external body. If $\sum G_i'$ refers to n separate bodies which are different and have different principal stresses etc. and $\sum G_i$ refers to the n corresponding parts in the assembly, again no net change in any thermodynamic property of any external body accompanies the reversible combining of the separate parts. If, however, the parts exert forces upon one another and the separate bodies are placed in suitable fields so that $G_i' \equiv G_i$, then while $G = \sum \mu_i m_i = \sum G_i'$ work must be done during the combining of the separate systems, i.e. the process resembles a phase change or a reversible displacement in a field and $\sum G_i' \not\equiv G$.*

It is quite possible for a heterogeneous system, i.e., one of many phases, to grow in extent while T, p, μ_i, etc. remain constant. It is also possible for such a system to grow in extent in a field, say, along equipotential surfaces in the earth's field, while p (or rather $\bar{p}$ in this case), T, μ_i, etc. remain constant, and hence the potentials can be—and in fact on a laboratory scale they usually are—homogeneous functions of first degree in the mass or volume regardless of whether the systems are physically uniform and homogeneous or not. In such systems the potentials are additive in the sense that $\sum G_i' \equiv G$. However, if *mutual* potential fields exist between the parts of a system, then in general the potentials will not be additive and they will usually not be homogeneous functions of first degree in

*Not identical, $\not\equiv$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the masses. While on a laboratory scale for n indentical parts, $\sum G_i' \equiv G$ to a high degree of accuracy, if the separate masses are too large or too numerous mutual gravitational potentials become large and $\sum G_i' \neq G$, $\sum A_i' \neq A$. Similarly when the volumes of the separate parts are too small or have too high a surface–volume ratio, again $\sum G_i' \neq G$, $\sum A_i' \neq A$. In both cases $\sum G_i' > G$ and the mutual potentials appear as "attractive" potentials.*

Active adsorbents have very high surface–volume ratios and hence are systems where large mutual surface potentials normally exist and where $\sum A_i' \neq A$. In addition these self-strained, highly porous bodies will not in general be in equilibrium everywhere with respect to "diffusive" interchange of material, i.e. the thermodynamic potential of the carbon will not be the same in regions relatively remote from one another (>20 atomic diameters when the transport is through the solid; > 2–3 atomic diameters if the transport involves evaporation and condensation, i.e. transport across a void space). However, in general these porous adsorbents will be in equilibrium with respect to mechanical and "body" forces and can undergo small elastic or reversible mechanical deformations. We cannot hope to describe in any detail the thermodynamics of such complex systems, but we can perhaps bring out the special "feature" by virtue of which these systems behave as mechanical systems in physical adsorption reactions.

As before we shall regard the solid body as made up of a number of granules. When no field potential exists, equations [22], [23] are applicable. When "intergranular" mutual field forces exist within the volume v, we can still write $G = A+pv$ as the Gibbs or displacement potential of the whole assembly, but in this case the Helmholtz potentials will not be additive. Thus $A = \sum A_i^0 - \sum\omega_i + \pi$, where π is the overlap potential, i.e. π measures the lack of additivity of the mutual Helmholtz field potentials ω_i. If each granule separately is in a field ω_i due to an external body, so that each granule is thermodynamically identical with the corresponding granule in the assembly, whose pressure is p_i and volume v_i, we can write for this system $\sum(A_i^0 - \omega_i + A_i^0 x) + \sum p_i v_i$, where $A_i^0 x$ is the intrinsic potential of an external body providing the field ω_i. We form the system $(\sum A_i^0 - \sum\omega_i + \pi + pv) + \sum A_i^0 x$, i.e. we form the assembly and the external bodies with their intrinsic potentials only. If this transformation can be carried out reversibly by a displacement or growth process where the pressures p_i and p remain constant, so that the net work done is $\sum p_i v_i - pv$ while the Helmholtz potentials of all the bodies concerned have increased by π, then $\sum p_i v_i - pv = \pi$. The relation between the various potentials, the stresses, etc. apart from any phase changes or chemical reaction, may be brought out perhaps more clearly by regarding each granule as a different substance or component. We assume that initially the system is a homogeneous function of first degree in the masses of its parts and write

$$dE = TdS - pdv + \phi dq + \sum \mu_i^0 dm_i,$$

where μ_i^0 is the intrinsic chemical or thermodynamic potential of each granule. We assume that the system is capable of growing reversibly from suitable sources of m_i, while T, p, q, the "composition", etc. remain constant. Accordingly we write as usual, $A+pv = \sum \mu_i^0 m_i = G$ where A, pv, etc. are the increments corresponding to the increments m_i, the ratios $m_i/\sum m_i$ remaining constant. However, if mutual attractive potentials develop

*This is the type of case referred to as "an apparent paradox" by Lewis and Randall (19). If by "molal free energy" we mean $\partial G/\partial m$, then when G is not a homogeneous function of first degree, $\partial G/\partial m$ is a function of m. Of course if $\partial G/\partial m$ refers not to all the variables other than m being held constant, but only to some of the m, the coefficient will be a function of the remaining variables. In the case discussed by Lewis and Randall, it would appear that $\partial A/\partial m$ was meant by "molal free energy".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

during the growth we must write $G = A + pv = \sum \bar{\mu}_i m_i$, where in general $\bar{\mu}_i < \mu_i^0$, i.e., the system is not a homogeneous function of first degree in the masses. At this stage in the growth we assume that a small additional increment in the masses may occur without changing materially any of the various mutual fields, stresses, etc. that may have developed within the granular assembly, and we write for this small additional increment $\delta G = \delta A + p\delta v = \sum \bar{\mu}_i' dm_i$.

Focusing our attention on the individual granules during this increment we can write

$$[25] \quad dE = TdS - \sum p_i dv_i + \sum f_i \frac{\partial x_i}{\partial v_i} dv_i + \sum \phi_i dq_i + \sum f_i \frac{\partial x_i}{\partial q_i} dq_i + \sum \mu_i dm_i,$$

where $f_i \cdot dx_i/\partial v_i \cdot dv_i$, $f_i \cdot \partial x_i/\partial q_i \cdot dq_i$ are work terms against the mutual or internal field forces f_i.

Integrating over the increment $\sum \delta m_i$ with T, p_i, f_i, q_i and the "composition" constant,

$$dE = TdS - \sum p_i \delta v_i + \sum f_i \frac{\partial x_i}{\partial v_i} dv_i + \sum \bar{\mu}_i' dm_i,$$

and putting $d\pi = \sum f_i \cdot \partial x_i/\partial v_i \cdot dv_i$, we get

$$\delta G = \delta A + \sum p_i \delta v_i - \delta \pi = \delta A + p\delta v$$

and

$$\delta A = \sum (\delta A_i^0 - \delta \omega_i) + \delta \pi.$$

Evidently we can write

$$[26] \quad \sum p_i v_i - \pi = pv$$

and

$$[27] \quad dG = vdp + \phi dq = \sum v_i dp_i + \sum \phi_i dq_i + \sum \frac{\partial \pi}{\partial q_i} dq_i$$

as the thermodynamic equations describing the isothermal equilibrium between the mechanical and field forces within an assembly of solid particles and the stresses applied to the whole assembly.

Within the assembly the usual condition for equilibrium with respect to heat transfer will apply, i.e., the temperature must be uniform. If all of the "granules" are of the same kind of matter which may "interchange" by diffusive processes, independently of the other variables, the thermodynamic or chemical potentials must be the same everywhere. In the latter case $v_i dp_i + \phi_i dq_i + d\pi_i$ must be the same everywhere. If the granules are of the same kind of matter but diffusive interchange over appreciable distances is negligible, the system would be capable of elastic or reversible deformations where the μ_i and $d\mu_i$ of the parts were not the same everywhere.

Equations [26], [27] will apply to any system whose parts are capable of having individual thermodynamic properties, and we shall assume that we can apply these equations to solid adsorbents, when the elements of volume, v_i, are suitably chosen, i.e. we assume that such elements of volume exist. In these equations π is a measure of the lack of additivity of the potentials and is not the same in general as the "surface potential" although it can be a direct measure of it. When no mutual potentials exist anywhere π and any "surface potential" must both be zero.* For small elastic deformations of the

*While π is a function of the net internal Helmholtz field potential, π also depends on the distribution of these potentials and their influence on one another.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

assembly the change in mutual field potentials would be small, so that if π were relatively large compared with $\sum p_i v_i$, $d\pi$ would be small compared with either $\sum v_i dp_i$ or $\sum \phi_i dq_i$ for relatively rigid and nearly incompressible systems.

Equations [26], [27] indicate that other things being equal the introduction of attractive mutual field potentials tends to increase the volumetric mean stresses and thus for the same external stresses these mutual potentials should lead to contractions. If no mutual field potentials exist within a solid and it is immersed in a liquid which is attracted toward the solid while the liquid pressure remote from solid is kept constant, then for the whole system after immersion

$$\sum p_i v_i - \pi = pv,$$

or distinguishing between the solid volume v_c and the volume of liquid v_a under the influence of the field,

$$p_c v_c + p_a v_a - \pi = P(v_a + v_c),$$

i.e. equation [1] will not hold.

If initially $\sum p_{ci0} v_{ci0} = p_{c0} v_{c0} \approx 0$, and after immersion $P(v_a + v_c) \approx 0$, the volumetric mean stress of the whole system must increase as a result of the immersion. If the equation of state of the liquid is not materially changed by the field, the density of the liquid must increase, while the density of solid may either increase or decrease depending on the shape of the dividing surface, the range and nature of the fields, etc. If a large fraction of the solid volume is directly under the influence of the field, the solid volume will almost certainly decrease. However, if the solid in its initial state has a large mutual attractive potential so that π is large,

$$\sum p_{ci0} v_{ci0} - \pi = p_{c0} v_{c0} \approx 0.$$

If these mutual potentials are largely confined to the surface regions, the outer surface being attracted toward the interior, then when immersed in a fluid which exerts attractive forces on these outer surface regions the interaction will reduce the potential gradients in the surface region and thus effectively reduce the mutual field forces within the solid. Thus we should have after immersion

$$\sum p_{ci}' v_{ci}' - \pi + \delta\pi_{ads}' = p_c' v_c' \quad [28]$$

while within the fluid we will now have potential gradients, and

$$\sum p_{ai} v_{ai} - \delta\pi_{ads}'' = p_a v_a. \quad [29]$$

Hence assuming $\delta\pi' = \delta\pi''$ we get

$$\sum p_{ci}' v_{ci}' - \pi + \sum p_{ai} v_{ai} = P(v_a + v_c) \quad [30]$$

and

$$\sum p_{ci}' v_{ci}' - \sum p_{ci0} v_{ci0} + \sum p_{ai} v_{ai} = P(v_a + v_c) - p_{c0} v_{c0}. \quad [31]$$

Thus the changes in volumetric mean states of stress are additive and the changes in Helmholtz potentials are additive. Thus in terms of the Helmholtz potentials we first suppose each element of volume of the solid and of the fluid placed in suitable fields of external bodies so that each element is identical with the corresponding element in the combined system, i.e., we have for the separate parts,

$$\sum A_{ci}^0 - \sum \omega_{ci} - \sum \omega_{cai} + \sum A_{cix}^0 + \sum A_{aj}^0 - \sum \omega_{acj} + \sum A_{ajx}^0, \quad [32]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

which if removed from the external bodies to which A_{cix}, A_{ajx} refer, and combined, we get

[33] $$(\sum A_{ci}^0 - \sum \omega_{ci} + \pi - \delta\pi' + \sum A_{aj}^0 - \sum \omega_{acj}) + \sum A_{cix}^0 + \sum A_{ajx}^0.$$

The change in Helmholtz potential is $\delta A = \pi - \delta\pi' + \sum \omega_{cai}$ and when $\delta\pi' = \sum \omega_{cai}$, $\delta A = \pi$ and the additivity has not changed. If this can be carried out reversibly by a displacement process corresponding to

[34] $$\sum p_{ci}'v_{ci}' + \sum p_{aj}v_{aj} - P(v_a + v_c)$$

this work must be equal to π. Thus $\delta A_c + \delta A_a = \delta A_{ac}$ or

[35] $$A_c - A_{c0} + A_a = A_{ac} - A_{ac0} = A_{ac} - A_{c0}.$$

When adsorbent–adsorbate systems behave in this way they are special cases of systems where mutual field potentials exist but where the lack of additivity of the potentials π is independent of the quantity adsorbed. Accordingly the Gibbs potential changes which accompany the immersion of the adsorbent in an excess of fluid, whose pressure and temperature are kept constant, will be measured by the change in volumetric mean state of stress of the solid, i.e., assumption A will hold. In these cases,

[36] $$dG_c = \sum v_{ci}dp_{ci} + \sum \phi_{ci}dq_{ci} = v_c dp_c + \phi_c dq_c - d\pi = (v_a + v_c)dp_g - \frac{m_a}{\rho_g}dp_g$$

and

[37] $$\delta G_c = \bar{v}_c(\bar{p}_c - \bar{p}_{c0}) + \bar{\Phi}_c = \overline{v_a + v_c}\, p_g - \int_0^P \frac{m_a}{\rho_g}dp_g.$$

Note that while $\phi_c dq_c$ as applied to the outer surface of the solid volume is necessarily positive, $\sum \phi_{ci}dq_{ci}$ can be either positive or negative.

We would not expect the model systems and hence equations [36], [37] to be applicable if any solution or chemical reaction occurs, or if any material passes the dividing surface between solid and fluid or if for any reason the dividing surface largely ceases to exist.

When the model is applicable the additivity of the potentials should be independent of the quantity adsorbed when the adsorption potentials are much less than the initial solid surface potentials and when no adsorbent–adsorbate field forces of appreciable magnitude extend into the solid beyond the region where mutual solid potentials exist. When these conditions are met and adsorption potentials or energies are small compared with solid sublimation energies the equation of state of the solid should be substantially unchanged by the adsorption reaction, i.e. the compressibility should vary with compression very nearly as does the solid alone. Hence equation [13] should be reasonably valid and we should conclude that the "anomalous contractions" referred to above are mainly due to non-isotropic forces, i.e. to terms of the type $\sum \phi_{ci}dq_{ci}$. In the case of carbons of exceptionally high surface areas terms of the type $d\pi$ (i.e. variation in additivity or net internal field potential) might contribute to the anomalous contraction and would be very difficult to distinguish from $\sum \phi_{ci}dq_{ci}$ terms and other factors. However, if a given carbon physically adsorbs two different adsorbates with about equal δG_c values and the different adsorbate molecules are chemically similar and are of comparable sizes, but in one case the porous body expands more or less as predicted while in the other an "anomalous contraction" is observed, the implication is strong that the difference is due to terms of the type Φ_c and Φ_a, i.e. to rather highly specific "bridging" and similar mechanisms that might be associated with the mismatching field periodicities of the adsorbate and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

periodicities (20) of two or more adjacent surfaces with which it is in "contact" or with mechanisms associated with pore size and shape distributions and their compatibility with condensed adsorbate molecular configurations, etc. If for any reason the adsorbate tends to draw two adjacent surfaces together while tending to increase the area of the two surfaces, terms of the type Φ_c will be involved.

Gibbs Adsorption Equation

Finally a few remarks may be made concerning the Gibbs adsorption equation.

If we suppose a flat surface region capable of growth in extent in two dimensions only (i.e. constant thickness, h) and following Gibbs, we assume this region capable of thermodynamic properties and write

$$[38] \qquad dE = TdS - \bar{p}dv + \phi dq + \mu_1 dm_1 + \mu_2 dm_2,$$

where $\bar{p} = \frac{1}{2}(\bar{p}_x + \bar{p}_y)$, and $\bar{p}_x$, $\bar{p}_y$ are the principal surface or tangential stresses averaged over the thickness h, and $dv = hd\sigma$, where h is perpendicular to the interface (of area σ) and large enough to include all of the region under the influence of the surface fields, then this surface region can grow in area or extent while $\bar{p}$, T, q, μ_1 and μ_2 remain constant, i.e., although mutual potentials exist the potentials are homogeneous functions of first degree in the area, and masses. Hence, $G_s = \mu_1 m_1 + \mu_2 m_2$ or putting

$$\bar{\gamma} = -h\tfrac{1}{2}(\bar{p}_x + \bar{p}_y)$$

we get

$$[39] \qquad m_1 d\mu_1 + m_2 d\mu_2 = -\sigma d\gamma + \phi dq$$

and for μ_2 constant and $d\mu_1 = dp_g/\rho_g$, putting

$$m_1 = \sigma h(\rho_a - \rho_g) + \rho_g \sigma h = \sigma\Gamma + \rho_g \sigma h$$

we get the Gibbs equation in the form

$$[40] \qquad d\gamma - \phi_s dq = -\int_0^P \frac{\Gamma}{\rho_g} dp_g - h dp_g.$$

If we associate tangential surface tractions or surface tensions with such self-strained bodies as active carbons, it seems hardly possible that the principal surface tensions, i.e. the components of γ, can be equal everywhere. Thus it seems almost certain that terms of the type $\phi_s dq$ must be involved in adsorption reactions on the majority of solid surfaces.

The fact that in many cases dimensional changes can be correlated quite well ignoring terms of this type is probably due to the fact that strain potentials of the vdp type are generally much larger than those of the ϕdq type (cf. refs. 21–24).

SYNTHESIS OF SOME PEPTIDES OF ε-N-ACETYL-L-LYSINE

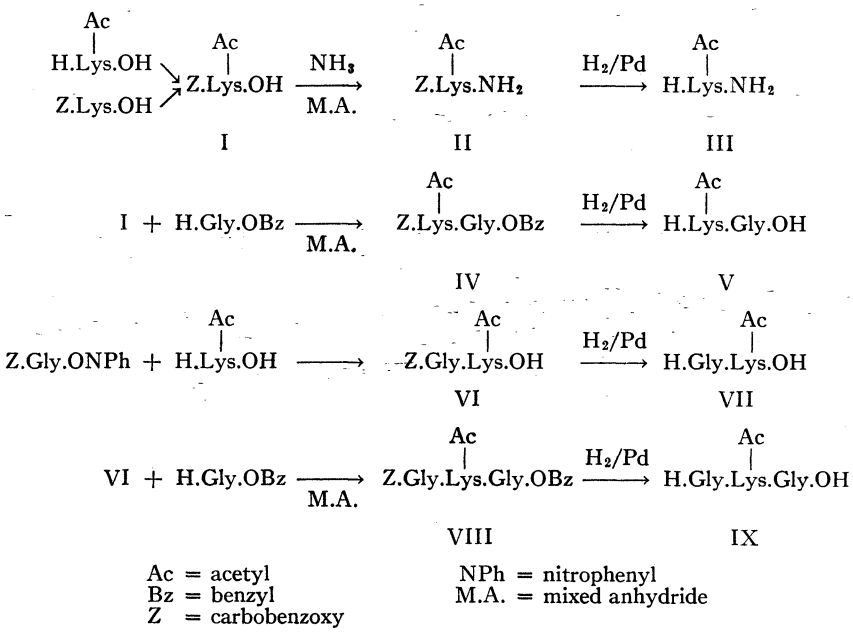
LEO BENOITON
Department of Biochemistry, Faculty of Medicine, University of Ottawa, Ottawa, Ontario
Received February 8, 1963

ABSTRACT

ε-*N*-Acetyl-L-lysinamide, α-*N*-glycyl-ε-*N*-acetyl-L-lysine, ε-*N*-acetyl-L-lysylglycine, α-*N*-glycyl-ε-*N*-acetyl-L-lysylglycine, and ε-*N*-acetylglycyl-L-lysine have been synthesized for testing as substrates for the enzyme ε-lysine acylase.

Several years ago, the enzyme ε-lysine acylase was identified and partially purified from rat kidney (1). We have now purified ε-lysine acylase from a much more convenient source, hog kidney, and have tested its hydrolytic action on several derivatives of lysine including some peptides of ε-*N*-acetyl-L-lysine (2). This paper describes the synthesis of the peptides.

The compounds III, V, VII, and IX, and the synthetic routes employed, are illustrated in the accompanying scheme. In addition, the isomeric peptide ε-*N*-acetylglycyl-L-lysine was also prepared.



ε-*N*-Acetyl-L-lysine, prepared by acetylation of the copper salt of lysine (3), was carbobenzoxylated to the disubstituted derivative I, which was crystallized as the dicyclohexylammonium salt. I was also prepared by acetylation of α-*N*-carbobenzoxy-L-lysine, obtained through the ε-*N*-benzylidene derivative (4); however, our inability to obtain the reported yields for α-*N*-carbobenzoxy-L-lysine rendered this route less attractive. The mixed anhydride (5) of I, by treatment with anhydrous ammonia or glycine benzyl ester, gave the protected amide II and dipeptide IV respectively. Catalytic hydrogenolysis of these provided the ε-*N*-acetyl-L-lysine amide III and the ε-*N*-acetyl-L-lysine dipeptide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

V. The isomeric glycyl dipeptide VII was made by hydrogenation of the protected intermediate VI, obtained in one step by the coupling of carbobenzoxyglycine *p*-nitrophenyl ester with ε-*N*-acetyl-L-lysine in hot acetic acid (6). The mixed anhydride (5) of VI plus glycine benzyl ester yielded the protected tripeptide VIII, which gave the free ε-*N*-acetyl tripeptide IX on hydrogenation. ε-*N*-Acetylglycyl-L-lysine was prepared directly by using a general procedure for the synthesis of ε-*N*-lysine peptides (7), namely, the coupling of the mixed anhydride of acetylglycine with the copper salt of lysine in aqueous solution.

Several of the optical rotations observed were extremely low, with one (for VII) actually being equal to zero. However, this was not due to racemization. If racemization had occurred, it would have been during the synthesis of VI by the nitrophenyl ester method. The optical purity of VI was established by measuring the optical rotation of a sample after hydrolysis in 5 *N* hydrochloric acid. The observed rotation was identical with that of a solution of lysine of corresponding concentration.

Enzymatic studies (2) have shown that the peptides are cleaved by ε-lysine acylase at rates of 85, 24, 109, and 70 for III, V, VII, and IX respectively, relative to a rate of 100 for ε-*N*-acetyl-L-lysine.

EXPERIMENTAL

General

Melting points were determined by the capillary method, using a thermometer calibrated against standard substances. Optical rotations were determined with a Rudolph Model 62 polarimeter using a 2-dm tube. Compounds were dried at 60° before analysis. Acetonitrile and chloroform were purified and distilled before use. The R_f values recorded are for the following solvents: R_f^B, *n*-butanol – acetic acid – water (4:1:5); R_f^F, *tert*-butanol – formic acid – water (70:15:15).

Starting Materials

ε-*N*-acetyl-L-lysine, $[\alpha]_D^{25}$ +22.7° (1, 5 *N* HCl), was prepared by acetylation of the copper salt of lysine with acetic anhydride (3) using two equivalents of lithium hydroxide as base (8). Yields of recrystallized, chromatographically pure material averaged 45%. Yields of 60%, obtained when using only one equivalent of base, have been reported (8). In our hands this procedure gave a product which was too highly contaminated with lysine to be purified by recrystallization. The original procedure (3) calls for two equivalents of base.

Carbobenzoxyglycine *p*-nitrophenyl ester (9) was prepared by the action of dicyclohexylcarbodiimide (10) on carbobenzoxyglycine (11) and *p*-nitrophenol in pyridine. After 12 hours, the mixture was filtered into ice water, and the precipitate which formed was washed by trituration with 1 *N* hydrochloric acid, water, and aq. sodium bicarbonate, and finally recrystallized from ethanol. Yield: 81%, m.p. 128°.

Glycine benzyl ester hydrochloride (12) was prepared from the corresponding *p*-toluenesulphonate (13) as described (14) except that the product was recrystallized from benzyl alcohol–ether. Yield: 80%.

Acetylglycine (15) was prepared by adding acetic anhydride to a hot solution of glycine in acetic acid.

α-N-Carbobenzoxy-ε-N-acetyl-L-lysine (Dicyclohexylammonium Salt (I))

(*a*) To a vigorously stirred cold solution of ε-*N*-acetyl-L-lysine (7.52 g; 0.04 mole) containing sodium bicarbonate (10 g) was added carbobenzoxy chloride (7 g) in four portions. After 3 hours, the solution was acidified (HCl) and extracted with ethyl acetate, the extract dried (Na_2SO_4) and evaporated to dryness. The residue was dissolved in ethyl acetate, and excess dicyclohexylamine was added. Crystals appeared immediately. After cooling, the product was filtered, recrystallized from acetonitrile, and washed with ether. Yield: 5.54 g (55%), m.p. 132–133°, $[\alpha]_D^{25}$ +8.6° (2, ethanol). Found: C, 66.7; H, 9.0; N, 8.3. $C_{28}H_{47}N_3O_5$ (503.7) requires: C, 66.8; H, 9.0; N, 8.3%.

(*b*) To a vigorously stirred solution of α-*N*-carbobenzoxy-L-lysine (4) (5.6 g; 0.02 mole) and sodium bicarbonate (3.78 g) in water (5°) was added, dropwise, acetic anhydride (2.3 g; 0.022 mole) during 30 minutes. Stirring was continued an additional hour at 25°, then the solution was acidified and the compound crystallized as described above. Yield: 5.54 g (55%), m.p. 132–133°.

α-N-Carbobenzoxy-ε-N-acetyl-L-lysinamide (II)

To I (3.02 g; 0.006 mole) suspended in chloroform was added 1 *N* sulphuric acid (6 ml). After shaking, the organic layer was taken and washed twice with water, dried overnight (Na_2SO_4), and concentrated down. The solution was cooled (0°), and triethylamine (0.83 ml; 0.006 mole) followed by ethyl chloroformate (0.54 ml; 0.006 mole) was added. After 30 minutes, anhydrous ammonia was bubbled through for 15 minutes,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

the mixture being stirred by a magnetic stirrer. The mixture was kept an additional 15 minutes at 25°, then cooled and filtered. The product was washed with cold chloroform, and recrystallized from acetonitrile. Yield: 1.1 g (60%), m.p. 179°, $[\alpha]_D^{25}$ +3.4° (1, dimethylformamide). Found: C, 59.8; H, 7.1; N, 13.0. $C_{16}H_{23}N_3O_4$ (321.4) requires: C, 59.8; H, 7.2; N, 13.1%.

ε-N-Acetyl-L-lysinamide Hydrochloride (III)

A solution of II (0.96 g) in ethanol (25 ml) containing 1 *N* hydrochloric acid (3 ml) was hydrogenated over palladium black. The catalyst was filtered off, the solution evaporated to dryness, and the residue crystallized from ethanol containing a few drops of water. Ether was then added. Yield: 0.53 g (80%), m.p. 243°, $[\alpha]_D^{25}$ +17.9° (1, water), R_f^B 0.32, R_f^F 0.41. Found for a sample recrystallized from water–ethanol: C, 43.2; H, 8.1; N, 18.2. $C_8H_{18}ClN_3O_2$ (223.7) requires: C, 43.0; H, 8.1; N, 18.8%.

α-N-Carbobenzoxy-ε-N-acetyl-L-lysylglycine Benzyl Ester (IV)

The mixed anhydride of *α-N*-carbobenzoxy-*ε-N*-acetyl-L-lysine was prepared from I (4.02 g; 0.008 mole) as described for the synthesis of the amide (II). After 30 minutes, a cold chloroform solution of glycine benzyl ester hydrochloride (1.61 g; 0.008 mole) and triethylamine (1.11 ml; 0.008 mole) was added. The solution was kept at 0° for 1 hour, and at 25° overnight. The solution was then washed successively with 1 *N* hydrochloric acid, water, aq. sodium bicarbonate, and finally water, dried (Na_2SO_4), and evaporated to dryness. The residue, which solidified on trituration with ether, was collected and recrystallized from chloroform–ether. Yield: 2.85 g (80%), m.p. 113–114°. A sample recrystallized for analysis had m.p. 115–116°, $[\alpha]_D^{25}$ −6.3° (1, dimethylformamide). Found: C, 63.8; H, 6.8; N, 8.9. $C_{25}H_{31}N_3O_6$ (469.5) requires: C, 63.95; H, 6.65; N, 8.95%.

ε-N-Acetyl-L-lysylglycine (V)

A solution of IV (1.41 g) in ethanol (35 ml) containing water (5 ml) and acetic acid (2 ml) was hydrogenated over palladium black. After removal of the catalyst, the solution was evaporated down and the residue was crystallized from water–ethanol–ether. Yield: 0.59 g (80%). Recrystallization from water–ethanol gave 0.41 g (56%), m.p. 225–226°, $[\alpha]_D^{25}$ +74.3° (1, water), R_f^B 0.32, R_f^F 0.49. Found: C, 48.8; H, 8.0; N, 16.9. $C_{10}H_{19}N_3O_4$ (245.3) requires: C, 49.0; H, 7.8; N, 17.1%.

α-N-Carbobenzoxyglycyl-ε-N-acetyl-L-lysine (VI)

A mixture of *ε-N*-acetyl-L-lysine (3.76 g; 0.02 mole) and carbobenzoxyglycine *p*-nitrophenyl ester (7.2 g; 0.021 mole) in dry acetic acid was refluxed for 3 hours. The solvent was distilled off, and the residue was distributed between ethyl acetate and aq. sodium bicarbonate. The aqueous layer was acidified and extracted with ethyl acetate, the extract was dried (Na_2SO_4) and then evaporated to a white solid. The product was filtered with the aid of ether and recrystallized from acetonitrile. Yield: 4.4 g (58.7%), m.p. 126°, $[\alpha]_D^{25}$ −3.6° (1, dimethylformamide). Found: C, 56.9; H, 6.8; N, 11.2. $C_{18}H_{25}N_3O_6$ (379.4) requires: C, 57.0; H, 6.6; N, 11.1%. After hydrolysis of a sample (129.6 mg) in 5 ml of 5 N hydrochloric acid, α was +0.52° corresponding to $[\alpha]_D^{25}$ +26.0° when calculated for a lysine content of 49.9 mg. A solution of lysine had $[\alpha]_D^{25}$ +26.4° (1, 5 *N* HCl).

α-N-Glycyl-ε-N-acetyl-L-lysine (VII)

A solution of VI (1.54 g) in ethanol (50 ml) containing water (10 ml) and acetic acid (2 ml) was hydrogenated over palladium black. After removal of the catalyst by filtration, and solvent by evaporation, the residue was crystallized from water–ethanol. Yield: 0.7 g (72%), m.p. 220–221°, $[\alpha]_D^{25}$ 0 (water, or 5 *N* HCl), R_f^B 0.31, R_f^F 0.46. Found: C, 48.8; H, 7.9; N, 17.2. $C_{10}H_{19}N_3O_4$ (245.3) requires: C, 49.0; H, 7.8; N, 17.1%.

α-N-Carbobenzoxyglycyl-ε-N-acetyl-L-lysylglycine Benzyl Ester (VIII)

To VI (1.89 g; 0.005 mole) and triethylamine (0.70 ml; 0.005 mole) in dry chloroform at 0° was added ethyl chloroformate (0.45 ml; 0.005 mole). After 30 minutes, a cold chloroform solution of glycine benzyl ester hydrochloride (1.01 g; 0.005 mole) and triethylamine (0.70 ml; 0.005 mole) was added. After 1 hour at 0°, and 12 hours at 25°, the solution was successively washed with 1 *N* hydrochloric acid, water, aq. sodium bicarbonate, water, and then dried. The chloroform was evaporated off and the white residue was crystallized twice from acetonitrile. Yield: 1.2 g (46%), m.p. 170–171°, $[\alpha]_D^{25}$ −7.2° (1, dimethylformamide) Found: C, 61.4; H, 6.6; N, 10.7. $C_{27}H_{34}N_4O_7$ (526.6) requires: C, 61.6; H, 6.5; N, 10.6%.

α-N-Glycyl-ε-N-acetyl-L-lysylglycine (IX)

A solution of VIII (1.25 g) was hydrogenated as described for the preparation of VII. The product was crystallized twice from water–ethanol. Yield: 0.53 g (74%), m.p. 245–246°, $[\alpha]_D^{25}$ +1.5° (1, water), R_f^B 0.28, R_f^B 0.36. Found: C, 47.45; H, 7.4; N, 18.3. $C_{12}H_{22}N_4O_5$ (302.3) requires: C, 47.7; H, 7.3; N, 18.5%.

ε-N-Acetylglycyl-L-lysine

The mixed anhydride prepared from acetylglycine (1.17 g; 0.01 mole) in tetrahydrofuran was added quickly to a cold aqueous solution of the copper salt of lysine (1.83 g; 0.01 mole) containing 5 ml of 2 *N* lithium hydroxide. The mixture was kept cold and stirred for 2 hours. Next morning, the blue precipitate was collected, washed with water, then dissolved in hot water, and hydrogen sulphide was bubbled through

For personal use only.

the solution. After subsequent charcoal treatment, the remaining solution was evaporated down and the residue crystallized twice from water–ethanol. Yield: 1.23 g (50%), m.p. 245–247°, $[\alpha]_D^{25}$ +17.1° (1, 5 *N* HCl), R_f^B 0.28, R_f^F 0.52. Found: C, 48.8; H, 7.9; N, 16.9. $C_{10}H_{19}N_3O_4$ (245.3) requires: C, 49.0; H, 7.8; N, 17.1%.

Reçu le 8 mars 1963

RÉSUMÉ

La synthèse de dérivés hydroxylés en positions 3 et 4 de 1′ α-phtalimidoglutarimide et de ses produits d'hydrolyse est décrite.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

D'après les essais effectués dans nos laboratoires sur la thalidomide il semble que l'agent chimique responsable des malformations congénitales observées par Wiedemann (syndrome de Wiedemann) (1) ne soit pas la thalidomide elle-même, mais un produit de son métabolisme, vraisemblablement un dérivé hydroxylé dans les positions 3 ou 4 du groupe phtalyle. Williams et ses collaborateurs (2) pensent aussi que l'un des métabolites qu'ils ont isolés récemment est un dérivé hydroxylé en position 3. Dans le but d'obtenir des composés de référence connus pour l'identification et la détermination des activités biologiques de ces métabolites, la synthèse des hydroxy-3 et -4 phthalimidoglutarimides (hydroxy-3 et -4 thalidomides) et de leurs analogues à chaine ouverte, les hydroxy-3 et -4 phtalylglutamines fut entreprise et est décrite ici.

Les hydroxy-3 et -4 phtalylglutamines, V*a* et V*b*, s'obtiennent difficilement par réaction directe des anhydrides II*a* et II*b* avec la glutamine à cause de la facilité avec laquelle celle-ci se cyclise en acide pyrrolidone-2 carboxylique-4. Il s'est avéré profitable de protéger les fonctions hydroxylées des groupes phtalyles et de procéder par l'intermédiaire des anhydrides benzyloxyphtalimidoglutariques IV*c* et IV*d*. L'ouverture de ces anhydrides par l'ammoniac dans l'éthanol (3) donne les glutamines substituées V*c* et V*d* de préférence aux dérivés de l'isoglutamine; l'hydrazinolyse de V*c* et V*d*, par la phénylhydrazine suivant la méthode de Ujejski et Gaver (3), fournit uniquement la *dl*-glutamine. Les glutarimides VI*a* et VI*b* sont alors obtenues par cyclisation de V*c* et V*d* dans l'anhydride acétique et hydrogénolyse des groupes benzyles. L'hydroxy-4 phtalimidoglutarimide VI*a* peut aussi être preparée à partir de l'anhydride IV*a* et de l'urée mais il est préférable de passer par les intermédiaires III*c*, IV*c*, V*c* et VI*c*. Les produits obtenus sont optiquement inactifs.

Les essais biochimiques seront publiés bientôt.

PARTIE EXPÉRIMENTALE[2]

Acide benzyloxy-4 phtalique (Ic)

L'acide hydroxy-4 phtalique (4) (18.2 g, 0.1 mole) est dissous dans une solution de 17 g (0.3 mole) d'hydroxyde de potassium dans 46 ml d'eau; 13.9 g (0.11 mole) de chlorure de benzyle sont alors ajoutés en une fois et le mélange est vivement agité et reflué pendant 16 heures. Une solution de 8.5 g d'hydroxyde de potassium dans 46 ml d'eau est ajoutée et le tout chauffé à reflux jusqu'à l'obtention d'une solution limpide (3 heures). La solution est alors refroidie, lavée à l'éther et acidifiée au rouge congo par l'acide chlorhydrique concentré. Le précipité est filtré et recristallisé dans l'acide acétique pour donner 16 g (59%) du diacide fondant à 182–183°. Calculé pour $C_{15}H_{12}O_5$: C, 66.17; H, 4.44%. Trouvé: C, 66.11; H, 4.44%. Spectre

[1]α-*Phtalimidoglutarimide.*

[2]*Les points de fusion ont été déterminés en tubes capillaires et ne sont pas corrigés. Les spectres infrarouges ont été déterminés à l'aide d'un spectromètre Perkin–Elmer, modèle 237: des suspensions dans le nujol ont été employées là où le solvant n'est pas spécifié. Les spectres ultraviolets ont été déterminés au moyen d'un spectrophotomètre Beckman, modèle DK2. Les microanalyses sont du Dr. Claude Daesslé, 5757 Decelles, Montréal.*

infrarouge: —OH (acide), 3200 à 2100; =CO, 1675; aromatique, 1598 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 252 mμ, log ϵ = 4.106.

Acide benzyloxy-3 phtalique (Id)

Préparé à partir de l'acide hydroxy-3 phtalique (5) suivant le procédé décrit plus haut. Rendement: 62%. P.f. 163–165° (eau). Calculé pour $C_{15}H_{12}O_5$: C, 66.17; H, 4.44%. Trouvé: C, 66.04; H, 4.33%. Spectre infrarouge: —OH (acide), 3400 à 2500; =CO, 1715 et 1665; aromatique, 1595 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 293 mμ, log ϵ = 3.47.

Anhydride benzyloxy-4 phtalique (IIc)

Une mélange de 14 g (50 mmole) de I*c* et de 50 ml d'anhydride acétique est chauffé à reflux jusqu'à l'obtention d'une solution limpide (5–15 minutes). Celle-ci est évaporée sous vide au bain-marie et le résidu solide est recristallisé dans l'acétate d'éthyle – éther de pétrole pour donner 9 g (69%) de l'anhydride, p.f. 128–129°. Calculé pour $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%. Trouvé: C, 70.81; H, 4.26%. Spectre infrarouge ($CHCl_3$): =CO, 1845 et 1775; aromatique, 1615 et 1600; —O— (éther), 1255 cm^{-1}. Spectre ultraviolet ($CHCl_3$): λ_{max} 311 et 277 mμ, log ϵ = 3.73 et 3.76.

Anhydride benzyloxy-3 phtalique (IId)

Preparé comme II*c*. Recristallisé dans le benzène – éther de pétrole après filtration d'une petite quantité de produit secondaire insoluble dans le benzène. P.f. 158–160°. Rendement: 75%. Calculé pour $C_{15}H_{10}O_4$: C, 70.86; H, 3.96%. Trouvé: C, 70.53; H, 3.72%. Spectre infrarouge: =CO, 1840 et 1770; aromatique, 1615 et 1595; —O— (éther), 1255 cm^{-1}. Spectre ultraviolet ($CHCl_3$): λ_{max} 331 mμ, log ϵ = 3.71.

Acide dl-(benzyloxy-4 phtalimido)-2 glutarique (IIIc)

On chauffe sous vide pendant une heure à 165–185° un mélange intime de II*c* (5 g, 19.7 mmole) et d'acide L-(+)-glutamique (3 g, 20.4 mmole). Après refroidissement, la masse vitreuse est triturée avec de l'eau et le solide ainsi obtenu est filtré et recristallisé dans l'acide acétique. Rendement: 5.5 g (73%). P.f. 235–240°. Calculé pour $C_{20}H_{17}O_7N$: C, 62.66; H, 4.47; N, 3.65%. Trouvé: C, 62.79; H, 4.36; N, 3.86%. Spectre infrarouge: —OH (acide), 3400 à 2200; =CO, 1770 et 1705; aromatique, 1610 et 1595; —O— (éther), 1250 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 321 mμ, log ϵ = 3.35.

Acide dl-(hydroxy-4 phtalimido)-2 glutarique (IIIa)

(*a*) Un mélange d'anhydride hydroxy-4 phtalique (4) (12.5 g, 76 mmole) et d'acide L-(+)-glutamique (12.5 g, 85 mmole) dans 100 ml de pyridine est chauffé à reflux pendant 2 heures. L'excès d'acide glutamique est enlevé par filtration et la solution est évaporée sous vide au bain-marie. La trituration de l'huile résiduelle avec un excès d'acide chlorhydrique froid à 10% amène la formation d'un volumineux précipité blanc qui, après recristallisation dans l'eau, donne 14.3 g (64%) du diacide, p.f. 249–250°. Calculé pour $C_{13}H_{11}O_7N$: C, 53.24; H, 3.78; N, 4.78%. Trouvé: C, 53.33; H, 3.79; N, 4.87%. Spectre infrarouge: —OH, 3500 à 2300, sommet à 3285; =CO, 1775 et 1700; aromatique, 1615 et 1603; —O— (éther), 1255 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 325 mμ, log ϵ = 3.16.

(*b*) III*c* (1 g) hydrogéné dans l'éthanol en présence de palladium à 10% sur charbon (0.5 g) donne 0.3 g (40%) de III*a*, p.f. 240–250°.

For personal use only.

Anhydride dl-(acétyloxy-4 phtalimido)-2 glutarique (IVe)

Le produit brut, provenant de la réaction de 3 g d'acide L-(+)-glutamique avec 3 g de II*a* telle que décrite plus haut, est dissous dans un excès d'anhydride acétique sur le bain-marie. La solution est évaporée à sec sous vide et le résidu cristalisé par trituration avec de l'éther. P.f. 162–163° (acide acétique). Rendement: 2.6 g (50%). Calculé pour $C_{15}H_{11}O_7N$: C, 56.78; H, 3.50; N, 4.42%. Trouvé: C, 56.45; H, 3.64; N, 4.22%. Spectre infrarouge: =CO, 1815, 1760 et 1715; aromatique, 1610 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 292 mμ, log ϵ = 3.19.

Anhydride dl-(benzyloxy-4 phtalimido)-2 glutarique (IVc)

IIIc (3.6 g) est chauffé à reflux avec un excès d'anhydride acétique (25 ml) jusqu'à dissolution complète (20 minutes). La solution est évaporée sous vide au bain-marie et le résidu est recristallisé dans l'acétate d'éthyle. Rendement: 2.7 g (80%). P.f. 164–165°. Calculé pour $C_{20}H_{15}O_6N$: C, 65.75; H, 4.14; N, 3.83%. Trouvé: C, 66.16; H, 4.18; N, 3.99%. Spectre infrarouge ($CHCl_3$): =CO, 1815, 1770 et 1715; aromatique, 1615 et 1603; —O— (éther), 1250 cm^{-1}. Spectre ultraviolet ($CHCl_3$): λ_{max} 325 mμ, log ϵ = 3.28.

Anhydride dl-(benzyloxy-3 phtalimido)-2 glutarique (IVd)

Obtenu en traitant le produit brut de la réaction de II*d* avec l'acide glutamique par l'anhydride acétique. Rendement: 80%. P.f. 194–197°. Calculé pour $C_{20}H_{15}O_6N$: C, 65.75; H, 4.14; N, 3.83%. Trouvé: C, 65.64; H, 3.85; N, 4.30%. Spectre infrarouge: =CO, 1815, 1770 et 1715; aromatique, 1615 cm^{-1}. Spectre ultraviolet ($CHCl_3$): λ_{max} 336 mμ, log ϵ = 3.93.

Benzyloxy-4 phtalyl glutamine (Vc)

A une solution refroidie d'ammoniac 1 *N* dans l'éthanol absolu (30 ml) on ajoute IV*c* (3 g) par portions successives. Après évaporation du solvant le résidu est émulsionné dans l'eau et acidié par l'acide chlorhydrique à 10% jusqu'au rouge congo. Les solvants sont décantés et la masse semi-solide est lavée à l'eau froide et recristallisée dans l'éthanol. Rendement: 2 g (47%). P.f. 165–168°. Calculé pour $C_{20}H_{18}O_6N_2$: C, 62.82; H, 4.74; N, 7.33%. Trouvé: C, 62.67; H, 4.54; N, 7.48%. Spectre infrarouge: —NH, —OH, 3500 à 2400, sommets à 3465 et 3320; =CO, 1775, 1700 et 1650; aromatique, 1610; —O— (éther), 1250 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 322 mμ, log ϵ = 3.23.

L'hydrolyse de V*c* par la phénylhydrazine suivant la méthode décrite par Ujejski et Gaver (3) donne un produit identique (point de fusion mixte et spectres infrarouges) à la *dl*-glutamine preparée d'après ces auteurs.

Benzyloxy-3 phtalyl glutamine (Vd)

Preparé comme V*c*. Rendement: 72%. P.f. 196–197° (*n*-butanol). Calculé pour $C_{20}H_{18}O_6N_2$: C, 62.82; H, 4.74; N, 7.33%. Trouvé: C, 62.88; H, 4.92; N, 7.55%. Spectre infrarouge: —OH, —NH, 3500 à 2500, sommet à 3410; =CO, 1760, 1700 et 1640; —O— (éther), 1250 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 332 mμ, log ϵ = 3.66.

Hydroxy-4 phtalyl glutamine (Va)

L'hydrogénolyse de V*c* (1 g) dans l'acide acétique (40 ml) en présence de palladium à 10% sur charbon (0.5 g) est complète en 30 minutes. Après filtration et évaporation du solvant le produit est obtenu sous forme solide par cristallisation dans l'eau. Rendement: 0.6 g (80%). P.f. 210–212°. Calculé pour $C_{13}H_{12}O_6N_2$: C, 53.42; H, 4.14; N, 9.59%. Trouvé: C, 53.14; H, 4.00; N, 9.66%. Spectre infrarouge: —OH, —NH, 3630 à 2300, sommets à 3600 et 3430; =CO, 1700 et 1650; aromatique, 1605 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 326 mμ, log ϵ = 3.16.

Hydroxy-3 phtalyl glutamine (Vb)

Preparé comme V*a*. Rendement: 78%. P.f. 198–200° (eau). Calculé pour $C_{13}H_{12}O_6N_2$: C, 53.42; H, 4.14; N, 9.59%. Trouvé: C, 53.30; H, 4.30; N, 9.65%. Spectre infrarouge: —OH, —NH, 3500 à 2300, sommets à 3460 et 3350; =CO, 1735, 1695 et 1635; aromatique, 1610 et 1595 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 335 mμ, log ϵ = 3.66.

α-(Benzyloxy-4 phtalimido)glutarimide (VIc)

V*c* (3 g) est chauffé au bain-marie pendant une heure avec un excès d'anhydride acétique (50 ml). Après évaporation du solvant le résidu est recristallisé dans le toluène. Rendement: 2.4 g (84%). P.f. 172–176°. Calculé pour $C_{20}H_{16}O_5N_2$: C, 65.93; H, 4.43; N, 7.69%. Trouvé: C, 65.93; H, 4.76; N, 7.64%. Spectre infrarouge: —NH, 3200 à 2550; =CO, 1765 et 1700; aromatique, 1605; —O— (éther), 1245 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 321 mμ, log ϵ = 3.37.

α-(Benzyloxy-3 phtalimido)glutarimide (VId)

Preparé comme VI*c*. P.f. 230–234°. Calculé pour $C_{20}H_{16}O_5N_2$: C, 65.93; H, 4.43; N, 7.69. Trouvé: C, 66.07; H, 4.28; N, 8.06%. Spectre infrarouge: —NH, 3200; =CO, 1770 et 1705; aromatique, 1610 cm^{-1}. Spectre ultraviolet (CH_3OH): λ_{max} 335 mμ, log ϵ = 3.68.

COLUMN AND GAS CHROMATOGRAPHIC ANALYSIS OF OIL OF WILD GINGER

IDENTIFICATION AND ESTIMATION OF SOME NEW CONSTITUENTS

ISHWAR C. NIGAM[1] AND LEO LEVI
Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Canada

Received February 1, 1963

ABSTRACT

Oil of wild ginger was found to contain the following as yet unreported constituents: β-pinene, Δ^3-carene, β-caryophyllene, *ar*-curcumene, linalool, borneol, and α-terpineol. The presence of three ketones, one of them readily generated during gas chromatographic analysis from a non-ketonic sesquiterpenoid, was also demonstrated. Formation of a sesquiterpene alcohol as a compositional artefact of the oil occurred during column chromatography over alumina.

Oil of wild ginger, *Zingiber zerumbet* Smith, has been the subject of a number of chemical investigations (1–4). These established—though not unanimously—the presence of the following constituents: α-pinene, camphene, dipentene containing some limonene, α-humulene, humulene monoxide, humulene dioxide, cineole, camphor, zerumbone, and an unidentified alcohol. It is the purpose of this paper to describe the detection of hitherto unreported compounds in a genuine product. The oil from which the major portion of zerumbone had been removed by cooling to 5° C was fractionated by column chromatography and the various fractions were subjected to gas chromatographic analysis using Reoplex 400 and sucrose diacetate hexaisobutyrate (SAIB), respectively, as liquid phase. Constituents were identified by comparison of retention times on both columns as well as infrared characteristics with those of authenticated reference standards and determined by the sigma method developed in this laboratory (5, 6).

EXPERIMENTAL

I. Column Chromatography of Analytical Sample

The oil (1.433 g) was passed over alumina (Woelm Grade 1; 15 g) using as eluants petroleum ether (b.p. 40–60° C), benzene, and ether. Eight fractions were collected (see Table I) and, following removal of solvent in a rotating vacuum evaporator, examined by gas chromatography.

TABLE I

Column chromatography of oil of wild ginger

Fraction No.	Eluant	Volume of eluant (ml)	Weight of oil (%)

II. Gas Chromatography of Essential Oil and Isolated Fractions

Apparatus and experimental procedures have been described (7, 8). Constituents were characterized by the serial dilution technique (9) and infrared examination of effluents collected following repeated sample injections and rechromatographed under optimal conditions of temperature and carrier gas flow rate (10). Rigorous comparison of retention times and infrared spectra with those of authentic specimens examined under the same experimental conditions was made for compound identification. Constituents detected for the first time are shown in the illustrations above the corresponding gas chromatographic peaks observed.

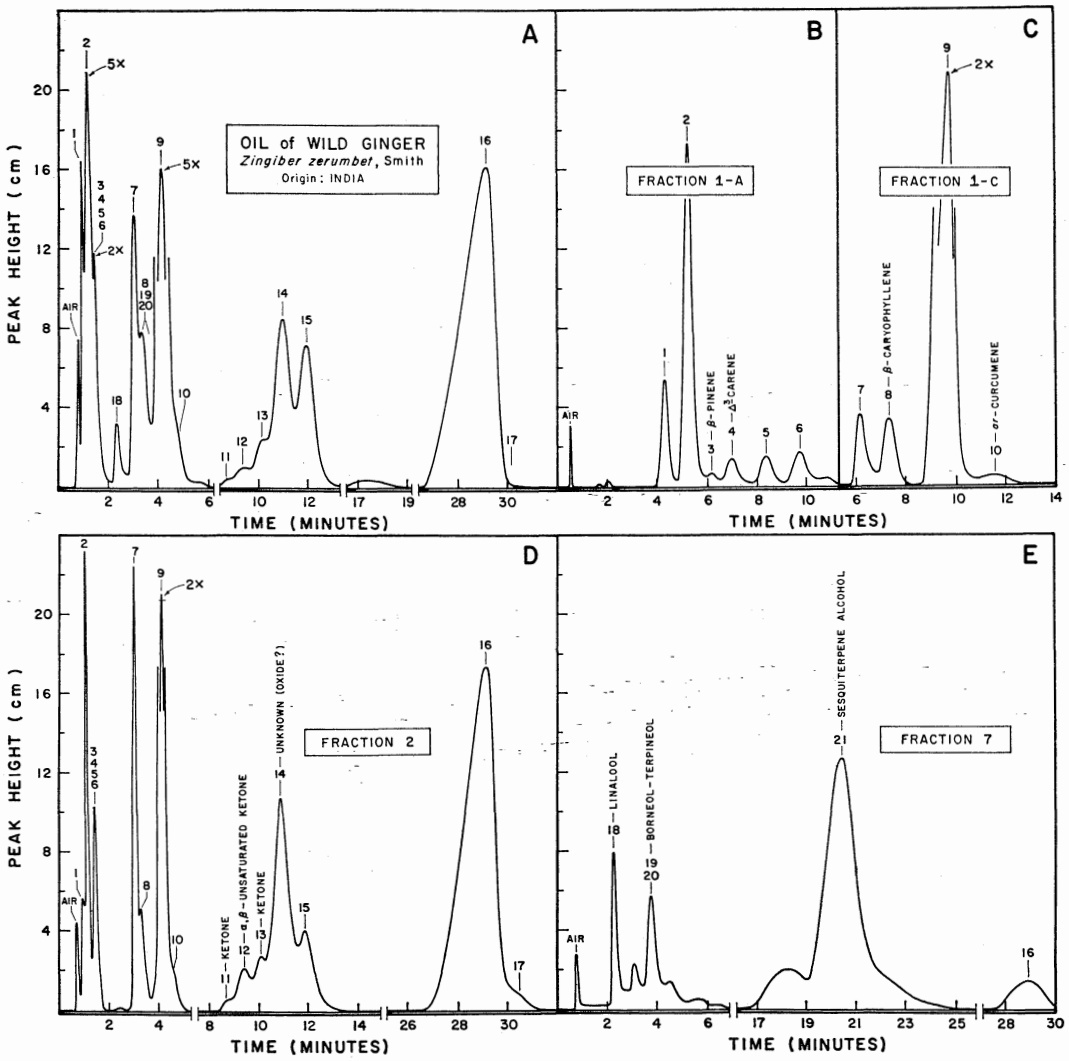

FIG. 1. Gas chromatographic examination of oil of wild ginger. Experimental conditions: A, D, E: column: Reoplex 400 (10%) on Chromosorb W (acid-washed); temp.: 200° C; helium: 25 ml/20 sec; sample vol.: 5 λ (A), 3 λ (D), 2 λ (E). B: column: SAIB (20%) on Chromosorb W (acid-washed); temp.: 130° C; helium: 25 ml/20 sec; sample vol.: 1 λ. C: column: Reoplex 400 (10%) on Chromosorb W (acid-washed); temp.: 170° C; helium: 25 ml/25 sec; sample vol.: 3 λ.

The chromatogram of the specimen prior to analytical treatment is reproduced in Fig. 1A. Monoterpenoids were not well resolved under the experimental conditions and in order to improve their separation from sesquiterpene compounds, fraction 1 was distilled at atmospheric pressure as illustrated in Table II.

TABLE II
Fractionation of petroleum ether eluate of oil of wild ginger

Fraction	Bath temp. (°C)	Weight of fraction (%)	Nature of isolate
1A	185–195	8.6	Monoterpenes
1B	195–210	12.8	Monoterpenes plus trace amounts of sesquiterpenes
1C	210–225	37.5	Sesquiterpenes plus trace amounts of monoterpenes
Residue		35.7	
		Recovery 94.6%	

RESULTS AND DISCUSSION

The following constituents were identified by means of the techniques described.

α-Pinene, β-Pinene, Δ³-Carene

These terpenes were readily detected in fraction 1A (see Fig. 1B) and trace amounts were found to be present in fraction 1B and 1C, respectively.

Camphor, β-Caryophyllene, ar-Curcumene

These compounds made up the major portion of fraction 1C (Fig. 1C). In addition to identification by infrared spectroscopy *ar*-curcumene was also characterized by its ultraviolet absorption (λ_{max}^{EtOH} 273, 267, 264, and 258 mμ).

Zerumbone, Humulene Monoxide

Both constituents were found to be present in fractions 2 and 3 (see Fig. 1D), with zerumbone occurring also in succeeding fractions.

Humulene Dioxide

Small amounts of this compound were detected in fraction 4.

Linalool, Borneol, α-Terpineol

These compounds were found to be present in fractions 7 and 8. Borneol and α-terpineol emerged together under the experimental conditions and were identified by comparison of the infrared spectrum of the effluent with that of a binary mixture of genuine reference specimens. Coupled gas liquid – thin layer chromatographic data served to confirm the identifications (11).

Unidentified Sesquiterpene Ketones

Infrared examination of carefully rechromatographed effluents of fraction 2 emerging within the 8- to 13-minute time interval (see Fig. 1D) indicated the presence of three ketones (peaks No. 11, 12, and 13), the latter of which displayed marked absorption at 1716 cm^{-1}; 1630 and 882 cm^{-1} (terminal methylene); and 802 cm^{-1} (trisubstituted double bond).

Treatment of fraction 2 with Girard-T reagent (12) followed by column chromatography of isolated carbonyls over alumina and gas chromatography through a Reoplex 400 column at 200° C led to recovery of the three ketones already detected but showed, moreover, that peak No. 12 was considerably enhanced. Comparable analyses of the ether eluate of the non-ketonic fraction revealed a closely related phenomenon—marked diminution of peak No. 14 accompanied by distinct enhancement of peak No. 12. Evidently, constituent No. 14 is an oxygenated, non-ketonic sesquiterpene—possibly an isomeric humulene oxide—rearranging partially to the carbonyl compound, constituent No. 12, during the course of the analysis. The infrared spectrum of the ketone, collected for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

examination following column and gas chromatographic purification, displayed intense absorption at 1668 cm^{-1} and ultraviolet analysis demonstrated likewise the presence of α,β-unsaturation (maxima at 316 and 236 mμ, respectively).

Sesquiterpene Alcohol

Infrared examination of the main constituent occurring in fractions 7 and 8, peak No. 21, established that it was an alcohol. Yet the presence of this terpenoid was not detected in the original product. Correlation of these findings with the observation that the intensity of the humulene monoxide peak decreased following column chromatographic treatment of the essential oil (see Figs. 1A and 1D, respectively) suggested that significant amounts of the monoxide were apparently degraded and converted to the alcohol. Further experimental evidence for the observation was secured by chromatographing 20 mg of humulene monoxide over 1 g of grade 1 alumina (eluant diethyl ether). Infrared analysis of the isolate both prior to and following gas chromatographic examination proved that the major portion of material thus obtained was identical with the alcohol found as chief constituent of fraction 7 as well as fraction 8.

The findings illustrate that column chromatography of natural products may lead to the formation of artefacts and that the process of separation cannot always be considered entirely safe for the resolution of essential oils and the characterization of their constituents. Similar phenomena have also been observed in our laboratory during column chromatography of caryophyllene oxide. The nature of the alcohols thus produced will be described in a forthcoming publication.

Composition of Essential Oil

Quantitative results were obtained from the gas chromatographic data by determining peak areas in accordance with the sigma method previously reported (5, 6). The composition thus deduced for the essential oil is shown in Table III.

TABLE III

Composition of oil of wild ginger*

Peak No.	Constituents	Percent
1	α-Pinene	3.4
2	Camphene	21.9
3	β-Pinene	0.6

REACTIONS WITH SUBSTITUTED XANTHENONES

V. MANNICH REACTION ON HYDROXY-9-XANTHENONES AND HYDROXY-10-THIAXANTHENONES

AHMED MUSTAFA, MAHMOUD M. SIDKY, AND FOUAD M. SOLIMAN

Chemistry Department, Faculty of Science, Cairo University, and the Laboratory of Synthetic Chemotherapy, National Research Centre, Cairo, Egypt

Received September 24, 1962

ABSTRACT

The application of the Mannich reaction to hydroxy-9-xanthenones and hydroxy-10-thiaxanthenones, which gives rise to the corresponding aminomethyl derivatives, is described. Experimental proof of the position taken by the aminomethyl group is given.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

In continuation of our previous work (1), the behavior of hydroxy-9-xanthenones and hydroxy-10-thiaxanthenones towards the Mannich reaction has been investigated.[1]

Perusal of the literature reveals that hardly any work has been done on the application of the Mannich reaction to 9-xanthenone derivatives, though de Diesbach (2) has claimed the isolation of 2-trichloroacetylaminomethyl-9-xanthenone (IV*a*) via the action of N-hydroxymethyltrichloroacetamide on 9-xanthenone in the presence of concentrated sulphuric acid.

We have found that hydroxy-9-xanthenones as well as hydroxy-10-thiaxanthenones undergo the Mannich reaction. This seems to be of interest in view of the difference in behavior of the isomeric hydroxy-9-xanthenones. Thus, whereas 1-hydroxy-9-xanthenone (I*i*) shows reactions typical of phenols (3) by undergoing, for example, the Friedel–Crafts reaction and the Fries rearrangement (1, 4), 2-hydroxy-9-xanthenone (II*h*) fails to react with these reagents (5). 2-Hydroxy-10-thiaxanthenone (II*k*) was found in the present investigation to be similarly stable towards acetylation under the conditions of the Fries and Friedel–Crafts reactions.

The hydroxy-9-xanthenones (I*i*, I*j*, and II*h*) and hydroxy-10-thiaxanthenones (II*k* and III*d*) were allowed to undergo the Mannich reaction in the presence of formaldehyde. A number of secondary bases were used, namely, dimethyl-, diethyl-, and diethanolamine, piperidine, and morpholine.

When 1-hydroxy-9-xanthenone (I*i*) was allowed to condense with paraformaldehyde and a secondary base, in acetic acid, the corresponding aminomethyl derivative of I*i* was obtained in good yield. When ethanol and formaldehyde were used instead of acetic acid and paraformaldehyde, the yield of the respective Mannich bases was considerably reduced.

In I*i* substitution may occur in more than one way. In every case only one of the isomeric bases which can theoretically be formed was isolated. That substitution took place mainly at the ortho position finds confirmation from the following:

(*a*) Whenever an ortho position of a phenolic compound is free, monosubstitution via the Mannich reaction occurs preferentially at this position (6).

(*b*) The obtained Mannich bases reacted positively with 2,6-dichlorobenzoquinone chloroimide (Gibbs reagent). This shows that the position para to the hydroxyl group was unsubstituted (7).

[1]*The biological activity of these compounds is now under investigation.*

(*c*) The phenolic bases did not respond to Millon's test (8), demonstrating that the ortho position to the hydroxyl group was substituted (9).

(*d*) Chloromethylation of I*i* yielded 4-chloromethyl-1-hydroxy-9-xanthenone, I*f*. The corresponding morpholino derivative I*g* was obtained by the action of morpholine on I*f*. The product (I*g*) reacted positively (9) with the Millon and negatively with the Gibbs reagent. It proved also to be different from that obtained by the action of morpholine and formaldehyde on I*i* (mixed m.p.).

(*e*) The behavior of I*i* towards the Mannich reaction finds analogy with its behavior towards the Friedel–Crafts reaction (1, 4) and the Claisen rearrangement (10).

We have also studied the behavior of 2-hydroxy-9-xanthenone, II*h*, and 2-hydroxy-10-thiaxanthenone, II*k*, towards the Mannich reaction.

The proposed structure for the Mannich base, e.g., II*a*, is based upon the fact that it could be converted into the corresponding 1-formyl-2-hydroxy-9-xanthenone, II*g*, by boiling with acetic acid in the presence of hexamine. The 1-aldehydo derivative II*g* was identical with that obtained from II*h* by the Duff reaction (11).

2-Hydroxy-9-xanthenone was chloromethylated to give 1-chloromethyl-2-hydroxy-9-xanthenone, II*f*. The position of the chloromethyl group was ascertained from the fact that upon treatment of II*f* with dimethylamine II*a* was obtained. The latter was identical with that obtained by the action of formaldehyde and dimethylamine on 2-hydroxy-9-xanthenone, II*h* (mixed m.p.), and was also converted to the known II*g*. Similarly, treatment of II*f* with morpholine gave the morpholinomethyl derivative II*e*.

By carrying out the Mannich reaction on 4-hydroxyl-1-methyl-10-thiaxanthenone, III*d*, the aminomethyl derivatives III*a*–III*c* were similarly obtained (cf. Table I).

With regard to the amine exchange reaction (12), the aminomethyl derivatives I*a*, II*a*, and II*i* behave in a manner similar to that of the phenolic Mannich bases (13). Thus, it was possible to substitute a secondary base such as morpholine for the dimethylamino group in each case.

EXPERIMENTAL

All melting points are uncorrected. The 1-hydroxy-9-xanthenone (14), 1-hydroxy-3-methyl-9-xanthenone (15), 2-hydroxy-9-xanthenone (11), 2-hydroxy-10-thiaxanthenone (16), and 4-hydroxyl-1-methy-10-thiaxanthenone (17) were prepared according to the published procedures.

Attempted Friedel–Crafts Acetylation

A mixture of 2-hydroxy-10-thiaxanthenone (2.2 g) and powdered anhydrous aluminum chloride (4.0 g) in nitrobenzene (20 ml) was treated under stirring with a solution of acetyl chloride (or acetic anhydride) (2.0 g) in nitrobenzene (5 ml). The reaction mixture was kept at room temperature for 5 days. After treatment with 2 N hydrochloric acid, followed by steam distillation to remove the nitrobenzene, only the starting material was obtained (mixed m.p.).

‡Crystallizing solvent was ethanol/ether.
§Ethanol was used as solvent for crystallization.
‖Crystallized from dilute ethanol.

Attempted Fries Rearrangement of 2-Acetoxy-10-thiaxanthenone

2-Acetoxy-10-thiaxanthenone (see below) (2.7 g) in nitrobenzene (25 ml) was treated with anhydrous aluminum chloride (3.5 g) and the mixture was left at room temperature for 4 days; only 2-hydroxy-10-thiaxanthenone was obtained almost in quantitative yield.

2-Acetoxy-10-thiaxanthenone, IV*b*, was obtained as colorless crystals by boiling II*k* in acetic anhydride – pyridine mixture for 2 hours. Crystallization from ethanol yielded IV*b*, m.p. 137–138°. Calc. for $C_{15}H_{10}O_3S$: C, 66.64; H, 3.72. Found: C, 66.43; H, 3.81.

Mannich Reaction on Hydroxy-9-xanthenones and Hydroxy-10-thiaxanthenones (General Procedure)

Method A

To a cooled suspension of the hydroxy-9-xanthenone (0.01 mole) in glacial acetic acid (30 ml) was added the secondary base (0.011 mole), followed by paraformaldehyde (0.011 mole). The reaction mixture was then heated under reflux for 4 hours and left overnight at room temperature. After the acetic acid was removed, in a vacuum, the residue was treated with dilute hydrochloric acid to dissolve the Mannich base formed. The reaction mixture was filtered and the cooled filtrate was made alkaline with ammonium hydroxide. The product was isolated either in the form of the solid free base or its hydrochloride (cf. Table I). The hydrochloride was formed by saturating the dry ethereal solution of the base with dry hydrogen chloride gas.

Method B

An aqueous solution of 40% formaldehyde (0.011 mole) was added dropwise to a mixture of the hydroxy-9-xanthenone (or hydroxy-10-thiaxanthenone) (0.01 mole) and the secondary amine (0.011 mole) in about 40 ml of ethanol. The temperature was kept below 10° and the solution was effectively stirred. The reaction mixture was then refluxed for 5 hours and left overnight at room temperature. After the volatile materials were removed, under reduced pressure, the residue was worked up as described in method A. Yields, physical data, and analytical data of the compounds are shown in Table I.

4-Chloromethyl-1-hydroxy-9-xanthenone

A mixture of 1-hydroxy-9-xanthenone (2.12 g), 20 ml of concentrated hydrochloric acid (sp. gr. 1.17), 1 ml of concentrated sulphuric acid (sp. gr. 1.84), and methylal (2.28 g) was stirred at 70° for 5 hours. During this time, dry hydrogen chloride gas was passed into the reaction mixture. After the mixture was cooled, the precipitate was collected, washed with cold water, and air-dried. Yield 2 g, m.p. 118–120°. Recrystallization from absolute ethanol gave an analytical sample, m.p. 120–122°. Anal. Calc. for $C_{14}H_{19}O_3Cl$: Cl, 13.6. Found: Cl, 13.4.

4-Morpholinomethyl-1-hydroxy-9-xanthenone

A mixture of 4-chloromethyl-1-hydroxy-9-xanthenone (2.5 g), morpholine (1 g), and dry benzene (50 ml) was refluxed for 5 hours. 4-Morpholinomethyl-1-hydroxy-9-xanthenone was isolated as its hydrochloride. Recrystallization from absolute ethanol gave the analytical sample, m.p. 258–260° (depressed when admixed with a sample of I*e*). Yield 70%. Anal. Calc. for $C_{18}H_{17}NO_4HCl$: N, 4.03. Found: N, 3.91.

1-Chloromethyl-2-hydroxy-9-xanthenone

This compound was obtained from II*h* using the above-described procedure for the preparation of 4-chloromethyl-1-hydroxy-9-xanthenone. An attempt to crystallize it resulted in its decomposition; the uncrystallized sample melts at 210–212°. It was directly converted into the corresponding aminomethyl compound II*a* (see below).

1-Dimethylaminomethyl-2-hydroxy-9-xanthenone

Dimethylamine gas was allowed to pass into a solution of 1-chloromethyl-2-hydroxy-9-xanthenone (2.5 g) in boiling benzene (70 ml) for 3 hours. After removal of the volatile materials under reduced pressure, the residue was treated with dilute hydrochloric acid to dissolve the aminomethyl compound formed. The reaction mixture was filtered and the cooled filtrate was made alkaline with ammonium hydroxide. The resulted solid was collected, washed with cold water, and crystallized from dilute ethanol to give II*a*, m.p. 120–122°. Admixture with a sample obtained by the Mannich reaction on II*h* as described above did not depress the melting point. Yield 55%.

Similarly the action of morpholine on 1-chloromethyl-2-hydroxy-9-xanthenone in boiling benzene gave II*e*. Recrystallization from ethanol gave the product melting at 168–169°. Its melting point was not depressed on admixture with a sample prepared from the reaction of 2-hydroxy-9-xanthenone with formaldehyde and morpholine in ethanol.

1-Formyl-2-hydroxy-9-xanthenone

A mixture of 1-dimethylaminomethyl-2-hydroxy-9-xanthenone (1 g), hexamine (1 g), and glacial acetic acid (20 ml) was refluxed for 1 hour. The reaction mixture was poured into dilute hydrochloric acid and left to stand overnight in the ice chest. The resulting yellow solid was collected, washed with water, dried, and crystallized from light petroleum (b.p. 100–120°) to give II*g*, m.p. 161–162°. Yield 45%. A mixed melting point with authentic 1-formyl-2-hydroxy-9-xanthenone (prepared by the Duff reaction) (11) was not depressed.

Amine Exchange Reaction of Hydroxyxanthenones Mannich Bases

A mixture of 2-dimethylaminomethyl-1-hydroxy-9-xanthenone (1.3 g) and morpholine (0.9 g) was heated in a nitrogen atmosphere at 130° for 2 hours. The oily product, thus obtained, was poured into cold water (10 ml) and then extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulphate. Saturation with dry hydrogen chloride gas gave the hydrochloride of I*e*. Admixture with a sample obtained by the Mannich reaction on I*i* using formaldehyde and morpholine in ethanol did not depress the melting point. Yield 60%.

Similarly, 1-morpholinomethyl-2-hydroxy-9-xanthenone, II*e*, and 1-morpholinomethyl-2-hydroxy-10-thiaxanthenone, II*j*, were obtained in 45% and 40% yield respectively.

GAS–LIQUID CHROMATOGRAPHY OF TERPENES

PART VIII. THE VOLATILE OIL OF TANACETUM VULGARE L.[1, 2]

E. VON RUDLOFF

National Research Council of Canada, Prairie Regional Laboratory, Saskatoon, Saskatchewan

Received February 21, 1963

ABSTRACT

The chemical composition of the commercial oil of tansy and of that obtained from a local tansy species was determined by means of gas–liquid chromatography. Both oils contained *d*-isothujone as the major component (68.5%, 58%). The commercial oil contained fairly large amounts of *l*-camphor (13.9%), whereas that from local plants had only traces of camphor and 19.8% of *l*-thujone. The minor components isolated and identified in both oils were *l*-α-pinene, *l*-camphene, *d*-sabinene, *d*-limonene, 1:8-cineole, γ-terpinene, *p*-cymene, *d*-terpinen-4-ol, *l*-carvotanacetone, and *l*-borneol. Small amounts of α-thujene, β-pinene, α-terpinene, terpinolene, neoisothujyl and isothujyl alcohols, and dihydrocarvone were identified by retention characteristics only. Car-4-ene, isomeric alloocimenes, and carvomenthone may also be present. An unknown, crystalline monoterpene alcohol with a terminal methylene group was isolated in small amounts. A sesquiterpene (3.7%) was obtained from the oil of local plants.

Prefractionation of these oils by fractional distillation resulted in extensive isomerization of isothujone to *dl*-carvotanacetone. Such a rearrangement was not encountered during prefractionation by preparative gas–liquid chromatography.

An accurate qualitative and quantitative analysis of the volatile oil of the common tansy (*Tanacetum vulgare* L., fam. Compositae) was required for a biochemical study. Several early investigations have been reported (1), but no analysis with more modern techniques appears to have been published. Only two recent papers deal with this oil, Schenk and Heim (2) reporting that the highest oil content is found in the flowers shortly after opening (up to 1.42% of the dry weight of the plant) and Ionescu *et al.* (3) finding it to contain *d*-isothujone (60%, $[\alpha]_D$ +68.3°), a mixture of terpenes (10%), and a camphor (20%, n_D^{15} 1.4570, $[\alpha]_D$ +24°, oxime m.p. 141° C) which was not further characterized.

Semmler (4) was the first to recognize that the major constituent of the oil of tansy is thujone and Wallach (5) showed this to be dextrorotatory β-thujone (*d*-isothujone (6)). Persoz (7, cf. ref. 1) and Vohl (8, cf. ref. 1) found camphor which was later shown to be the rare *l*-form (9, cf. ref. 1). Small amounts of borneol appear to be present (9) and Bruylants (10) thought it likely that thujyl alcohol was a constituent of this oil. None of the terpene hydrocarbons have been isolated and identified.

In previous papers of this series (11, 12) the analysis of other thujone-containing oils by means of gas–liquid chromatography (GLC) has been reported. When this technique was applied to the analysis of the oil of tansy considerable difficulty was encountered in the complete separation and identification of the minor oxygenated monoterpenes. Since some of these components may have biochemical significance an attempt was made to improve the present technique, using temperature-programmed GLC, to a point where complete analysis may become possible. Two samples of the oil of tansy were investigated, one being of commercial origin, the other being obtained by steam distillation of local wild tansy plants.

EXPERIMENTAL

Isothermal GLC chromatograms were obtained as described previously (11–13). Temperature-programmed experiments were carried out with an Aerograph Autoprep model A-700 chromatograph (Wilkins

Instrument and Research Inc., Walnut Creek, Calif., U.S.A.). This instrument is equipped with an automatic injector (0.03- to 2-ml capacity) and an automatic collector. Temperature programming was non-linear and the single-column technique was used. Fractions were automatically collected in 5-ml glass traps (ice-cooled) by a trip-switch which was actuated by the recording pen and which may be set for any particular peak height. Analytical runs were carried out on 4 mm I.D. (1/4 in. O.D.) coiled copper or stainless steel columns, and preparative runs on similar ones of 6-mm I.D. (3/8-in. O.D.).

Melting points were determined with a Leitz hot-stage microscope. Optical rotations were measured at 22–25° C in chloroform (1–5% solution) or, in case of the derived oximes and semicarbazones, in ethanol. The rotation of each oil sample was obtained with the undiluted material. Infrared spectra were recorded with a Perkin–Elmer model 21 double-beam spectrophotometer, liquid samples being mounted as films between sodium chloride plates and solid ones by the KBr-disk method.

Materials

The commercial oil (Fritzsche Bros. Inc., New York) had n_D^{24} 1.4590, $[\alpha]_D$ +39.7°. Steam distillation of the leaves and flowers of locally growing wild tansy plants (11.7 kg fresh weight), harvested near Saskatoon during September 1962, gave a light yellow oil (24.3 g) with n_D^{24} 1.4615, $[\alpha]_D$ +19.3°. Reference compounds were either commercial samples (purified by GLC where necessary) or those obtained from other plant sources (11–13). The four isomeric thujyl alcohols were prepared by reduction of *l*-thujone or *d*-isothujone with lithium aluminum hydride. Dihydrocarvone, carvotanacetone, and carvomenthone were obtained by reduction of *l*-carvone (14–17). A detailed description of these reductions and of the isolation of the individual products will be reported elsewhere.

The liquid phases used in the GLC columns were commercial products, except for adipate and azelate polyethylene glycol polyesters, which were kindly donated by Dr. B. M. Craig. The solid support was Chromosorb W (60–80 mesh) in the analytical columns, and Gas Chrom P (60–80 mesh) in most of the preparative columns. The ratio of liquid phase to solid support was 1 to 6, except in the 20-ft preparative polyethylene glycol column supplied with the Aerograph instrument (3/8 in. O.D. aluminum), which had 30% PEG 20 M on Chromosorb W.

Analytical Chromatograms

Aliquots (3 μl) of the two oils were analyzed on a 6-ft SE-30 column (at 65–180° C in 25 minutes in temperature-programmed runs; at 160° C in isothermal runs) to determine whether significant amounts of sesquiterpenes were present. In the commercial oil three peaks were recorded in trace amounts in the cedrene–cadinene range, but the oil from local plants had two minor and one fairly large component (approx. 4% of the oil) in this range. The latter was correlated with peak 26 of the PEG 20 M chromatogram (see Fig. 1(*b*)).

The oils were then systematically analyzed (isothermal runs) on all the analytical columns. The relative retention times (RRT) of monoterpene hydrocarbons (limonene = 1.00) on PEG 20 M (at 65° C; 64 ml helium/min); NGA polyester (18) (65° C; 160 ml); and ethylene glycol bis(propionitrile) (EGPN) (65° C;

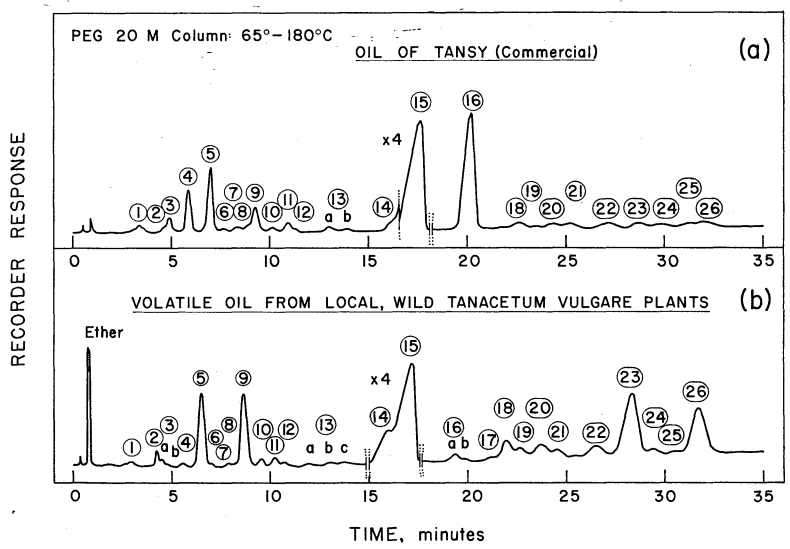

FIG. 1. Gas chromatograms of oil of tansy on a 6-ft polyethylene glycol column (temperature-programmed from 65° to 180° C). (*a*) Commercial oil; (*b*) oil from local tansy plants.

†Commercial oil.
‡Oil from local tansy plants.

trans–trans-alloocimene were RRT 4.14, 4.85 and 3.32, 3.90 on PEG 20 M and EGPN respectively. The data of known monoterpenes as determined on the other analytical columns have been reported previously (11, 12, 13, 20). When the retention times of a particular peak agreed with that of a known compound on every column, the peak was considered as tentatively identified.

Some higher-boiling trace components which were recorded in temperature-programmed runs (PEG 20 M and NGA, 65–180° C; see Fig. 1(*a* and *b*)) were absent on the charts from isothermal runs. Only after prefractionation were the concentrations of these trace components high enough to be clearly recorded by the latter technique. For this reason the quantitative composition was calculated (triangulation method) from the areas under the peaks as recorded in the temperature-programmed runs. The calculated data was reproducible within the errors of the method (11, 12, 13, 21) in repeat runs on the same, as well as on different columns. Use of internal standards (known amounts of *n*-decane, limonene, 1:8-cineole, camphor, 4-terpineol, carvone, and/or *n*-decanol added to a known weight of oil) showed that 98±2% of the oils could be accounted for, provided the trace components were included. Since isothujone (peak 15) was present in such large

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

amounts, it could not be recorded at the same attenuation as the other peaks when the aliquot of oil was large enough (5 to 10 μl) to permit recording of the trace components (see Fig. 1(*a* and *b*)). The use of a different attenuation and the skewing of the isothujone peak caused by the relatively large samples introduced fairly large errors (up to 5%) and it was found advantageous to calculate the quantitative data from runs with smaller aliquots (1–3 μl) and to add to this the respective amounts of trace components as recorded in runs with 5- to 10-μl samples.

Prefractionation

The commercial oil (100 ml) was fractionally distilled *in vacuo* (50 mm Hg) through a 1-mm×8-mm spinning band column (Podbielniak Inc., Chicago), using takeoff ratios from 1:60 to 1:100. Five fractions were collected and GLC analysis showed the following composition:

I (5 ml, b.p. 50–75° C) mainly monoterpene hydrocarbons;
II (10 ml, b.p. 75–100° C) hydrocarbons and isothujone;
III (55 ml, b.p. 100–108° C) mainly isothujone and some camphor;
IV (15 ml, b.p. 108–112° C) isothujone and midrange oxygenated monoterpenes;
V (10 ml, b.p. 112–120° C) mainly higher-boiling terpenes, including carvotanacetone and carvone, and sesquiterpenes.

The distillation residue showed extensive decomposition and polymerization and was not further investigated.

The oil from local plants was prefractionated in 0.2-ml aliquots on a 6-ft×3/8-in. SE-30 column at 90–180° C (in 15 minutes). Cuts similar to those obtained in the fractional distillation were collected, the collecting mechanism of the Autoprep being operated by hand. Recovery of the hydrocarbons varied between 40 and 80%, losses due to aerosol formation being highest for the minor constituents. No decomposition peaks were recorded on reinjection of each fraction on analytical columns. Overlaps of compounds between adjacent fractions were not as marked as in the distillation.

Hydrocarbons

Fractions I and II from distilled commercial oil were injected repeatedly (30- to 50-μl aliquots) onto a 6-ft×3/8-in. PEG 20 M column, which was temperature-programmed from 65° to 90° C during 12 minutes. The components which were isolated in sufficient amount and purity to permit recording of infrared spectra and physical data were identified by comparison with the corresponding data of authentic monoterpene hydrocarbons as: peak 3*a*, *l*-α-pinene (n_D^{24} 1.4606, $[\alpha]_D$ −21.6°) contaminated with a compound which had the same retention time as α-thujene (peak 3*b*, see Table I); peak 4, *l*-camphene (m.p. 30–42° C, $[\alpha]_D$ −111.1°); peak 5*b*, *d*-sabinene (n_D^{24} 1.4678, $[\alpha]_D$ +43.4°); peak 8, impure *d*-limonene (positive rotation); peak 9, 1:8-cineole (n_D^{23} 1.4584, $[\alpha]_D$ ±0); peak 10, γ-terpinene (n_D^{23} 1.4712, $[\alpha]_D$ ±0); peak 11, *p*-cymene (n_D^{24} 1.4800, $[\alpha]_D$ ±0). *p*-Cymene was further identified by its ultraviolet spectrum. The data of these components as isolated from fractions I and II of the oil from the local plants were in good agreement with those reported above.

Peaks 1 (mixture of at least 3 components) and 2 could not be identified, whereas peaks 3*b*, 5*a*, 6, and 7 were tentatively identified by relative retention times (cf. Table I). Peaks 13*a*, *b*, and *c* had retention times in the alloocimene range (see above) but none could be isolated pure as some decomposition was encountered.

Thujones

Fraction III from distilled commercial oil was fractionated on the same GLC column using a temperature range of 90–140° C. Essentially pure *d*-isothujone (peak 15) was obtained; n_D^{24} 1.4503, $[\alpha]_D$ +65.9° (*c*, 2.3, $CHCl_3$). The derived semicarbazone had m.p. 174–175° C, $[\alpha]_D$ +216.8° (*c*, 2.0, EtOH) after recrystallization from aqueous ethanol. Found: C, 63.38; H, 9.18; N, 20.22%. Calculated for $C_{11}H_{19}N_3O$: C, 63.12; H, 9.15; N, 20.08%.

Just ahead of the isothujone peak (peak 15), a shoulder (peak 14) was also recorded in preparative runs. This material was collected in small amounts. The infrared spectrum was similar to that of thujone and the optical rotation was negative; n_D^{24} 1.4500. GLC analysis showed contamination with about 10% isothujone.

In the oil from local plants peak 14 was a major constituent which was partially resolved from isothujone. By collecting the early portions of peak 14 and late ones of peak 15, both components were isolated fairly pure; n_D^{24} 1.4498 and 1.4501 and $[\alpha]_D$ −10° and +67° respectively. These data, as well as the infrared spectra, were in good agreement with those of *l*-thujone and *d*-isothujone respectively.

l-Camphor

Fraction III of the commercial oil also contained fairly large amounts of peak 16, which was isolated chromatographically pure in the above runs. The collected material had m.p. 150–170° C, $[\alpha]_D$ −39.8° (*c*, 2.2, $CHCl_3$). Further purification by recrystallization proved difficult and the material was converted to the oxime, m.p. 115.5–116.5° C, $[\alpha]_D$ +50.4° (*c*, 2.2, EtOH), after recrystallization from aqueous ethanol. Found: C, 72.08; H, 10.25; N, 8.57%. Calculated for $C_{10}H_{17}NO$: C, 71.81; H, 10.25; N, 8.38%.

In the oil from local plants peak 16 was only a trace component and analytical chromatograms showed an overlap with a second component (peak 16*b*). In the preparative runs these components were collected as one fraction. The infrared spectrum showed as characteristic absorption only a strong carbonyl band (1735–1715 cm^{-1}), indicating that both components are ketones.

Higher-Boiling Minor Components

The individual components from fraction IV could not be obtained pure by preparative GLC. All fractions collected, except peak 18, were subsequently shown to be mixtures of two or more components. Peak 18, as collected from the 6-ft×3/8-in. PEG column (120–190° C), had n_D^{24} 1.4754, $[\alpha]_D$ +17.0° (*c*, 1.3, $CHCl_3$) and its infrared spectrum was similar in all respects with that of terpinen-4-ol.

In analytical runs it was found that QF-1 polymer retained ketones and esters strongly with respect to alcohols and hydrocarbons (see Table I). A 6-ft×3/8-in. preparative column was made up and fraction IV was fractionated on a 0.03-g scale into alcohols and ketones. GLC analysis on the PEG 20 M column of the alcohol fractions showed the presence of six components with RRT 1.40, 1.68, 1.89, 2.28, 3.26, and 3.58 (peaks 18, 19, 20, 22, 25, and 26 respectively). Of these, peak 18 (RRT 1.40) was readily identified as *d*-terpinen-4-ol. Peaks 19 and 20 had RRT values corresponding with those of neoisothujyl and isothujyl alcohols respectively. However, neither component could be obtained pure in sufficient amount to confirm their identities. Peak 22 (RRT 2.28) was obtained crystalline (m.p. 120–180° C, $[\alpha]_D$ −23°) and its infrared spectrum agreed in all respects with that of borneol. α-Terpineol (RRT 2.24) could be a contaminant, but this was not confirmed by the infrared spectrum. Peak 25 (RRT 3.26) was also obtained crystalline (m.p. 45–60° C, $[\alpha]_D$ −43°). The infrared spectrum had strong bands at 3300, 2960–2860, 1655, 1465–1455, 1360, 1332, 1150, 1050, 975, and 882–877 cm^{-1} and well-defined weak bands at 3070, 850, and 765 cm^{-1}.

Of the ketonic components only carvotanacetone (peak 21, RRT 2.06) and carvone (peak 23, RRT 2.66) were positively identified (see below). A component of RRT 1.68, i.e. the same peak as 19, was isolated fairly pure and its infrared spectrum corresponded with that of dihydrocarvone. Because of paucity of material no crystalline derivative was obtained.

Carvotanacetone and Carvone

Fraction V of the commercial oil was composed of about 85% of peak 21 and smaller amounts of peaks 22, 23, 24, and 26. Peak 25 was not recorded and may have been lost in the distillation. Preparative GLC (using the QF-1 column first and then the PEG 20 M column) gave peak 21 practically pure; n_D^{24} 1.4808, $[\alpha]_D$ ±0. The infrared spectrum was similar to that of carvotanacetone. The oxime, m.p. 92.5–93.5° C, $[\alpha]_D$ +0.5°, after recrystallization from aqueous ethanol was obtained directly from fraction V. Found: C, 72.22; H, 10.32; N, 8.46%. Calculated for $C_{10}H_{17}NO$: C, 71.81; H, 10.25; N, 8.38%.

Peak 23 was isolated fairly pure in small amounts; n_D^{24} 1.4855, $[\alpha]_D$ −10.8°. The infrared spectrum was similar to that of *l*-carvone. During attempts to isolate peaks 24, 25, and 26 decomposition was encountered and these fractions from the commercial oil were not further investigated.

Peaks 21 and 23 were obtained fairly pure in small amounts from fraction IV of the oil from local plants. The infrared spectra agreed with those of carvotanacetone and carvone respectively and the optical rotations were negative (−45° and −11°).

Sesquiterpenes

In the oil from local plants peak 26 was recorded in fairly high amounts (about 3.7%). By using the SE-30 preparative column small amounts of this material were isolated fairly pure. The infrared spectrum resembled that of cadinene (strong infrared bands in the 2940–2860 cm^{-1} range, weak bands at 1645–1605 cm^{-1}, medium bands at 875 and 825 cm^{-1}), but the retention time on the PEG 20 M (41.5 min) and NGA column (71.0 min) at 120° C differed from that of cadinene (38.7 and 60.3 min respectively).

RESULTS AND DISCUSSION

Typical temperature-programmed chromatograms (as obtained on the PEG 20 M column) of the commercial oil of tansy and that obtained from local wild tansy plants are shown in Fig. 1(*a* and *b*). Nearly 30 different peaks were recorded and on comparison with chromatograms obtained in isothermal GLC runs the better detection of the higher-boiling minor components (peaks 18 to 26) in the temperature-programmed runs was evident. Therefore, it is likely that the values reported earlier for corresponding components in the volatile oils of the leaves of *Thuja occidentalis* L. (11), *Thuja plicata* D. Don (12), and black, white, and Colorado spruce (13) as determined by isothermal GLC require an upward correction. That the calculated values for oxygenated higher-boiling monoterpenes tended to be low in comparison with those of the lower-boiling hydrocarbons was already pointed out (20), but the error was thought to be mainly due to tailing. The use of internal standards in this study showed that 98±2% of the components of each oil were accounted for provided that all peaks were recorded at the same attenuation and trace components were included. The presence of a single component in excess of 50% caused inaccuracies in calculating quantitative data since fairly large aliquots (5–10 μl) of the oil had to be injected to record the trace components adequately. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

required a change of attenuation and resulted in considerable skewing of the large peaks (cf. Fig. 1). Both factors increased the error in quantitative calculations.

The preliminary runs on the SE-30 column showed that the commercial oil contained only traces of sesquiterpenes in the cedrene–cadinene range, and no oxygenated sesquiterpenes were recorded. The oil from the local plants, however, contained appreciable amounts of sesquiterpenes (peaks 24 to 26). Of these one (peak 26) was isolated fairly pure. The infrared spectrum showed it to be similar to cadinene but it was more strongly retained on GLC columns.

The average quantitative composition of the two oils as determined on a variety of columns in temperature-programmed runs is shown in Table I. All the major and several of the minor components were identified after isolation by preparative GLC. The results obtained confirm that *d*-isothujone (peak 15) is the major component in both oils. In the commercial oil the second largest component was *l*-camphor (peak 16), but this was only present in trace amounts in the oil from local tansy plants. Instead, *l*-thujone (peak 14) was a major constituent. The latter oil also contained fairly large amounts of *d*-sabinene (peak 5*b*), 1:8-cineole (peak 9), *l*-carvone (peak 23), and the unsaturated sesquiterpene (peak 26). In the commercial oil, the latter two components were only minor constituents and somewhat more *l*-α-pinene (peak 3*a*) and *l*-camphene (peak 4) were recorded. The presence of minor amounts of *l*-borneol (peak 21) was confirmed but no camphor having an oxime of m.p. 141° C, as reported by Ionescu *et al.* (3), was isolated. Of the other minor peaks *d*-limonene (peak 8), γ-terpinene (peak 10), *p*-cymene (peak 11), *d*-terpinen-4-ol (peak 18), and *l*-carvotanacetone (peak 21) were identified positively. Peaks 3*b*, 5*b*, 6, 7, 12, 19*a*, 19*b*, and 20 were identified tentatively by retention data (and to some extent by infrared spectra) as α-thujene, β-pinene, car-4-ene, α-terpinene, terpinolene, neoisothujyl alcohol, dihydrocarvone, and isothujyl alcohol respectively. Peaks 13*a* to *c* were recorded in the alloocimene range and the retention times of peaks 13*b* and *c* agreed fairly well with those of *trans–cis-* and *trans–trans*-alloocimene (see also ref. 22). By analogy, peak 13*a* could be *cis–cis*-alloocimene. Peak 25 appears to be a mixture of a sesquiterpene (trace amounts) and the unidentified crystalline alcohol of melting point 45–60° C, $[\alpha]_D$ −43°. The infrared spectrum of the latter indicated the presence of a terminal methylene group (sharp, medium strong bands at 1655 and 880 cm^{-1}). No reports of a crystalline monoterpene alcohol with such characteristics could be found in the literature.

Examination of the amount of carvotanacetone in the commercial oil as recorded by GLC and that present in fractions IV and V from the fractional distillation showed a considerable increase of this compound during distillation. Since the thujones have been isomerized to carvotanacetone at 280° C (23) it is likely that this rearrangement has occurred during distillation even though the pot temperature did not exceed 160° C. Disproportionation of carvone to carvacrol and more saturated ketones, including carvotanacetone (24, 25), may also have taken place. The fact that the compound isolated from the distilled fraction was optically inactive lends strong support that rearrangement from isothujone to carvotanacetone has occurred preferentially. When this compound was isolated by GLC from the oil of local plants a negative rotation was recorded. Also, when pure thujone, isothujone, and carvone were injected onto analytical GLC columns the relative amounts recorded were the same as those injected (within ±2%) and no sign of decomposition could be detected. Thus, the use of preparative GLC for the prefractionation of essential oils is to be preferred over fractional distillation. However, the poor recovery of some components (due to aerosol formation) is as yet a disadvantage.

Most of the oxygenated compounds found in the oil of tansy are substituted at C-2. This suggests a biogenetic relationship and it may be that a sequence in the formation of these compounds similar to the one described by Reitsema (26) for mint oils is operative. This aspect, as well as the effect of environmental changes on the composition of the oil, is being studied in this laboratory.

ACKNOWLEDGMENTS

The author wishes to thank Mr. M. Granat for technical assistance, Mr. M. Mazurek for the microanalyses, and Mr. W. C. Haid for recording the infrared spectra.

THE INHIBITED AUTOXIDATION OF STYRENE

PART II. THE RELATIVE INHIBITING EFFICIENCIES OF META- AND PARA-SUBSTITUTED PHENOLS[1]

J. A. HOWARD[2] AND K. U. INGOLD
Division of Applied Chemistry, National Research Council, Ottawa, Canada

Received January 7, 1963

ABSTRACT

The relative rates of reaction of 11 meta- and para-substituted phenols with styrylperoxy radicals have been measured at 65° C and have been shown to give an excellent correlation with electrophilic substituent constants. The reaction is compared with a number of similar hydrogen abstraction reactions.

INTRODUCTION

In Part I of this series (1) it was shown by means of the deuterium isotope effect that the reaction of styrylperoxy radicals with 2,6-di-*tert*-butyl-4-methylphenol (BMP) involved a straightforward abstraction of the phenolic hydrogen by the radicals. That is,

$$RO_2\cdot + AH \rightarrow ROOH + A\cdot , \qquad [6]$$

where AH represents the phenol. In order to obtain further information about this reaction a number of meta- and para-substituted phenols have now been examined at 65° C in the same system, i.e., as inhibitors of the α,α'-azo-bis-isobutyronitrile (AIBN) initiated oxidation of styrene. The relative inhibiting efficiencies, i.e. the relative k_6 values, have been measured and have been found to give an excellent correlation with Brown's electrophilic substituent constants (σ^+ constants) (2). The implication of this correlation on the nature of the transition state of reaction [6] is discussed and the reaction is compared with a number of similar hydrogen abstraction reactions.

RESULTS

The experimental techniques and the kinetic treatment of the data have been described in Part I (1). In the present work, the inhibited rate was generally kept between 1% and 10% of the uninhibited rate in order to avoid the kinetic complexities associated with the self-termination reaction,

$$RO_2\cdot + RO_2\cdot \rightarrow \text{inactive products.} \qquad [5]$$

Under these conditions, theory predicts (1) that,

$$P = \rho - (2e-1)k_1[I_2] = \frac{ek_1k_3[RH][I_2]}{k_6[AH]},$$

where ρ is the measured inhibited rate, e is the efficiency of radical production by the initiator I_2, k_1 is its rate constant for decomposition, k_3 is the propagation rate constant, and RH represents the styrene. Although this equation fits the data for inhibition by BMP fairly well (1) it does not fit the data for any of the simple, unhindered phenols studied in the present work. Instead, the measured value of k_6 appears to decrease as the phenol concentration is increased. That is, although $P/[I_2]$ is independent of $[I_2]$ at constant [AH], when experiments are performed at constant $[I_2]$ then P[AH] increases as

[1]*Issued as N.R.C. No. 7348.*
[2]*N.R.C. Postdoctoral Fellow 1961–1963.*

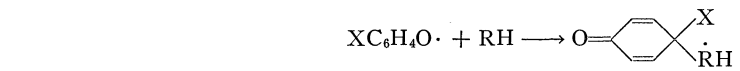
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

[AH] is increased. A plot of P against $[I_2]/[AH]$ therefore shows a rather bad scatter of the experimental points since both $[I_2]$ and [AH] are generally varied from experiment to experiment. The points tend to be concave towards the $[I_2]/[AH]$ axis since $[I_2]/[AH]$ will, in part, be increased by decreasing [AH]. Over a limited range of conditions the rate law could appear to have the form $P \propto [I_2]/[AH]^{\frac{1}{2}}$ (or even $P \propto ([I_2]/[AH])^{\frac{1}{2}}$ if $[I_2]$ were not varied appreciably) but neither of these expressions fit the data over a large range in [AH].* It is therefore dangerous to attempt to draw conclusions as to the mechanism of the inhibition reaction on the basis of inadequate kinetic data involving only comparatively small changes in the concentrations of I_2 and AH.

Since reaction [5] is unimportant under the present experimental conditions the apparent decrease in k_6 as the inhibitor concentration is increased may be due either to intermolecular hydrogen bonding of the phenol (which would decrease the availability of free phenol for the inhibition reaction) or to chain transfer reactions of the type

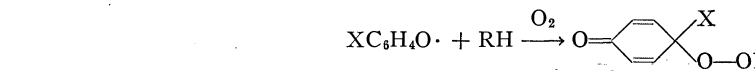
$$XC_6H_4O\cdot + RH \longrightarrow XC_6H_4\dot{O}RH \qquad [9a]$$

or



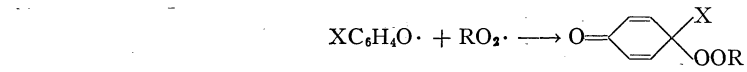
[9b]

or



[9c]

That is, at high inhibitor concentrations these reactions will become of greater importance relative to the normal combination reaction



[7]

since, at constant $[I_2]$, the concentration of peroxy radicals will be decreased and the concentration of phenoxy radicals will be increased as [AH] increases. However, the destruction of phenol by direct oxidation or by reaction with an oxidation product is unlikely to account for this effect since the oxygen uptake curves would then show a fairly pronounced curvature whereas they are actually fairly good straight lines up to a phenol consumption of at least 20%. Whatever the causes of the apparent decrease in k_6 with increasing [AH] its true value can very easily be obtained from the measured values at different inhibitor concentrations by extrapolation to zero inhibitor concentration. A typical extrapolation is shown in Fig. 1, where the measured value of $1/k_6$ for phenol is plotted against the phenol concentration. Since a good straight line is obtained the limiting value of k_6 is found fairly accurately.† These k_6 values for a number of meta- and para-substituted phenols are given in Table I together with the slope of the line from which k_6 was obtained, i.e. slope $= [(1/k_6)_{[AH]} - (1/k_6)_{[AH]=0}]/[AH]$ in seconds. It can be seen that electron-releasing groups increase k_6 and decrease the slope. Rather high concentrations of 4-cyanophenol, the least active phenol studied, were required to reduce the rate to a reasonable fraction of its uninhibited value. For this reason, compounds such as 4-nitrophenol, which would be expected to be even less active, were not examined.

**It is interesting that similar equations are obtained under conditions where self-termination becomes of significant importance compared with reaction [6] (1).*

†k_6 values were calculated on the basis of the k_6 value obtained in Part I for BMP, *i.e. on the assumption $k_5 = 10^7$ liter/mole sec; then, for high concentrations of* BMP, *$k_6 = 7.95 \times 10^3$ liter/mole sec at 65°.*

4-CN	0.659	0.29	4.3×10^{-1}

[a] σ^+constants estimated by the method outlined in reference 10 for E_s constants.

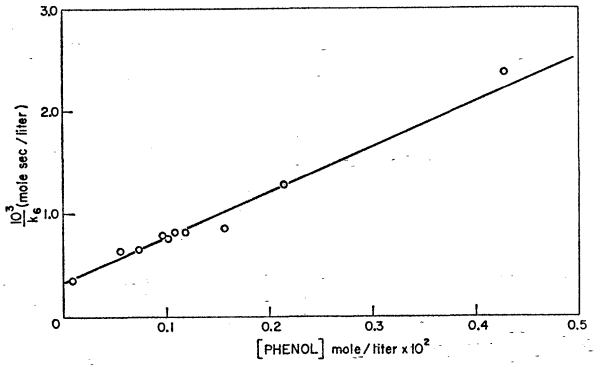

FIG. 1

The deuterium isotope effect on k_6 was examined for 4-*t*-amylphenol and phenol by the technique in which the phenol is maintained in its fully deuterated condition throughout the oxidation by the addition of heavy water (1). The results obtained with 4-*t*-amylphenol are rather more accurate than those obtained with phenol probably because of its lower solubility in water. For this phenol the limiting value of $(k_6)_D = 6.89\times10^2$ liter/mole sec, giving an isotope effect $(k_6)_H/(k_6)_D = 10.6$, in excellent agreement with the isotope effect found previously for BMP (1). Water has a negligible effect on $(k_6)_H$ and the slope for the light phenol; for the deuterated 4-*t*-amylphenol in the presence of D_2O the slope is 1.6×10^{-2} sec. In contrast, H_2O reduces the extrapolated value of k_6 for phenol to 2.1×10^3 liter/mole sec and reduces the slope to 3.2×10^{-3} sec. For deuterated phenol in the presence of D_2O the slope is 2.1×10^{-2} sec and $(k_6)_D = 1.4\times10^2$ liter/mole sec, giving an apparent isotope effect of 15. This rather large isotope effect may be due, in part, to experimental error arising from the high solubility of phenol in water.

An attempt to measure inhibitor stoichiometry (i.e. the number, n, of peroxy radicals destroyed by each inhibitor molecule) by the induction period method (1, 3) was frustrated by the discovery that n varied with inhibitor concentration. This is not too surprising since the apparent k_6 is a function of inhibitor concentration. However, it appears that a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

second factor relating to the absolute magnitude of the true limiting k_6 may be even more important in determining apparent inhibitor stoichiometry. That is, the efficiency of radical production from AIBN, e, was found to be 0.74 at 65° with BMP as the inhibitor. As the concentration of BMP is decreased e at first stays constant but then also starts to decrease since self-termination by reaction [5] becomes important right from the start of the reaction. Therefore, to determine n for a less efficient inhibitor than BMP one must increase the concentration of this inhibitor to a point where reaction [5] is completely suppressed, i.e. to a point where the initial rate for a given AIBN concentration is at least as small as is found with the minimum concentration of BMP which gives a constant e. However, at 65° the uninhibited oxygen uptake curves are only linear for about 13,000 seconds owing to consumption of the AIBN. It is therefore impossible to suppress completely reaction [5] with a very weak inhibitor without adding so much that the inhibitor is not, itself, totally consumed before 13,000 seconds. For this reason measured values of n for inhibitors significantly weaker than BMP tend to be greater than the expected value of 2.0. This difficulty may well account for some of the non-integral stoichiometries greater than 2.0 reported by various authors (3, 4). It could probably be overcome by working at lower temperatures, where the half-life of the AIBN would be increased.

DISCUSSION

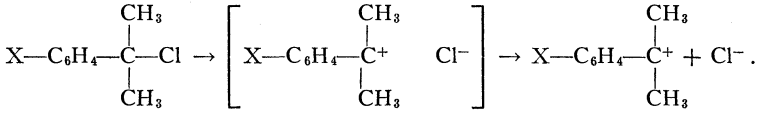
The limiting k_6 values given in Table I have, with the exception of hydroquinone, been plotted against the σ^+ substituent constants in Fig. 2. In the case of hydroquinone, k_6 has been halved to allow for the two hydroxyl groups. Both meta- and para-substituted phenols fall on a single line the equation for which is

$$\log_{10} k/k_0 = -0.010 - 1.49\sigma^+.$$

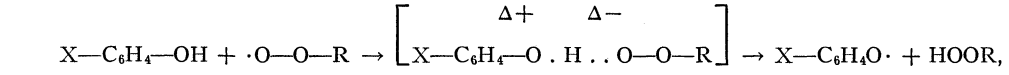
However, there seems to be some doubt as to the correct σ^+ constant for the 4-OH group (5). If the result for hydroquinone is excluded a rather better line of steeper slope is obtained which is given by

$$\log_{10} k/k_0 = 0.002 - 1.58_5\sigma^+.$$

Since σ^+ constants were mainly derived from the rates of hydrolysis of *tert*-cumyl chlorides (2) they give a measure of the effect of an aromatic nuclear substituent on the ease of formation of the transition state presumed to be involved in first-order solvolysis, i.e.,



By analogy a similar transition state should be applicable to the reaction under study. That is, reaction [6] can be written



with the O—H bond becoming polarized to give at least a partial positive charge on the oxygen ($\Delta+$) and the electron being at least partially transferred to the attacking peroxy radical ($\Delta-$). However, in view of the very large deuterium isotope effect the rate-determining step cannot be an electron-transfer process, but it is not possible on the basis of kinetic evidence alone to decide whether electron transfer occurs prior to or during the

For personal use only.

stretching of the O—H bond (6, 7). The excellent correlation by a single line of both meta- and para-substituted phenols, in particular 3-methyoxyphenol (8), indicates that there is no significant enhancement of resonance effects by meta substituents in this reaction (8).

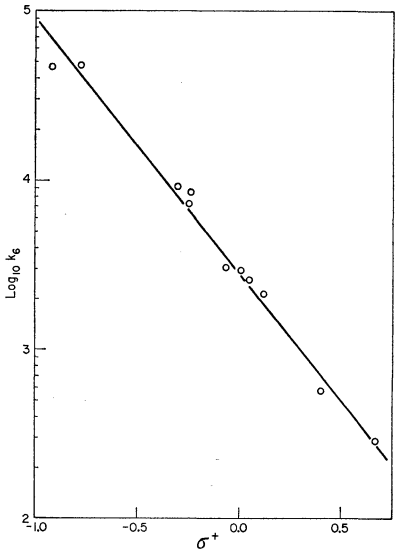

FIG. 2

The slopes of the lines from which limiting k_6 values are obtained very roughly obey the Hammett equation with $\rho \approx 2.2$ but with 3-chlorophenol showing a large positive deviation and 4-chlorophenol showing a large negative deviation (σ for 4-cyanophenol was taken as 1.00, and the other σ values were taken from McDaniel and Brown's compilation (9)). The positive sign of ρ is not unreasonable since the more acidic phenols may be expected to form stronger intermolecular hydrogen bonds. Alternatively, if the apparent decrease in k_6 with increasing inhibitor concentration is due chiefly to chain transfer it implies that the radical becomes more reactive the stronger the electron-withdrawing power of the substituents.

In some earlier work from this laboratory it was shown that the induction periods produced by 4-substituted-2,6-di-*tert*-butylphenols in a naphthenic hydrocarbon oil at 160° and at 140° C could be correlated extremely well by the Hammett σ constants and Taft steric substituent constants (E_s) of the group in the 4-position (10). The correlation with σ implies that under these conditions the transition state did not involve the formation of a phenoxy cation or partial phenoxy cation. It should, however, be added that owing to the apparent instability of 4-methoxy-2,6-di-*tert*-butylphenol at these reaction temperatures a highly polar transition state cannot be completely ruled out (11). Possible reasons for the differences in the two transition states are discussed below. The correlation with E_s, that is, the decreasing induction period associated with increasing size of the 4-alkyl substituents, was ascribed to a decrease in the rate of reaction [7] as the 4-position became sterically better protected. This effect appears to be of negligible importance in the present system probably both because of the smaller size of the peroxy radicals (i.e., they are secondary rather than tertiary as in the oil) and because of the unprotected nature of the ortho positions in these phenols.

The present data are compared in Table II with the available data for similar radical hydrogen abstraction reactions from compounds of the type XC_6H_4YH. This table includes the reactions, reaction temperatures, solvents, and the number of compounds used in the calculations. With the exception of reaction [2], compounds containing one or two ortho substituents have not been included in the determination of ρ. The original data have been recalculated in most cases* and the best correlation, i.e., that giving the smallest standard deviation (root mean square in $\log_{10}$ units), is given in heavy type. It can be seen that in aromatic solvents and in CCl_4 only reactions [7] and [14] are better represented by σ than by σ^+ and that for reactions [4] and [13] no distinction can properly be made.

There are several factors that might be expected to influence ρ, such as solvent (reactions [5] and [6]), temperature (reactions [10] and [11]), the nature of the attacking radical and the reactant, etc. Some of these effects are clearly brought out in this table but others still remain to be elucidated.

A change in ρ produced by a change in solvent might be due either to a change in the polarizability of the solvent or to a complexing of the radicals with the solvent, particularly if it is aromatic (27). It is difficult to evaluate the importance of the first factor from reactions [5] and [6] since benzene and CCl_4 have very similar polarizabilities. However, it would seem reasonable that an increase in the polarizability or dielectric constant of the solvent would tend to stabilize a charged transition state and thereby increase ρ, particularly for a reaction following σ^+ constants. Moreover, it is possible that a reaction following σ^+ constants in an aromatic system might follow σ constants in a less polarizable medium (cf. reactions [1] and [2] as a possible example of this phenomenon). If the radical complexes with the solvent one might expect a decreased sensitivity to polar effects, i.e., a decreased ρ, since polarization in the same direction will be involved in the complex as in the transition state. The overall reactivity of the radical will, of course, also be decreased by complexing. However, solvent effects must also depend on the nature of the attacking radical and reactant since, for reaction [12], ρ is the same in benzene as in CCl_4 even though chlorine atoms are known to complex with aromatic solvents (27). The possible importance of solvent effects suggests that ρ values obtained by competitive experiments in mixed reactants are less valuable than those obtained in a pure solvent since the polarizability of the medium will change as the reactants are changed.

The increase in ρ with decreasing temperature exemplified by reactions [10] and [11] appears to be a fairly general phenomena (28).

In addition to solvent effects, the magnitude of ρ for a given reactant may be expected to increase with increasing electron affinity of the attacking radical as originally proposed by van Helden and Kooyman (22). There is little or no evidence available at present to support this conclusion owing, in part, to the variety of solvents employed by different workers. However, it seems likely that this factor could become important in a series of reactions following σ^+ constants. Moreover, radicals with a very low electron affinity might follow σ rather than σ^+ constants. Reaction [7] may possibly be an example of this phenomenon. Similarly, the fact that reaction [15] definitely follows σ^+ constants whereas reactions [13] and [14] tend more to favor σ constants would also be in line with this suggestion.

For a given radical it seems probable that, in reaction series following σ^+ constants, ρ will increase with increasing polarizability of the YH bond, that is with increasing ease of formation of the $XC_6H_4Y^+H$ cation. Some evidence in favor of this is provided by a

**The difference in many of the ρ values listed in Table II and the values given in the original papers indicates that the method of least squares is "a custom more honour'd in the breach than the observance".*

NOTE: The σ^+ constants have been taken from reference 2 and the σ constants from reference 9.

[a]With hydroquinone.

[b]Without hydroquinone.

[c]Of the 4-alkyl phenols, only 4-Me-2,6-Bu_2^t phenol was used in the calculations. 4-NO_2-2,6-Bu_2^t was not included and σ(4-CH_3O) was taken as −0.16 (10). ρ has been corrected for the observed 2/3 reaction order.

[d]The data are not in a form suitable to permit recalculation.

[e]Data not plotted by authors. Calculations based on 4-NO_2, 4-C_6H_5, 4-MeO, and 4-OH phenols and phenol. The reported efficiency for hydroquinone was not divided by 2.0.

[f]σ^+(4-CH_3CO) taken to equal σ(4-CH_3CO).

[g]σ(4-NO_2) taken as 1.00. 2,3-Benzo group not included in calculations.

[h]This data supersedes earlier data (18) for $RO_2\cdot$ + cumene, and $RO_2\cdot$ + toluene at 90° both in the reactants. The former gives σ correlation $\rho = -0.445 \pm 0.015$ and σ^+ correlation $\rho = -0.410 \pm 0.015$ and the latter gives a σ correlation $\rho = -0.756 \pm 0.035$ and $\sigma+$ correlation $\rho = -0.705 \pm 0.023$.

[i]This data supersedes the earlier work of Kooyman, van Helden, and Bickel (21) on Br· + toluene at 80° in CCl_4, and it is shown that virtually identical ρ values are obtained with Br_2, N-bromosuccinimide, N-bromotetrafluorosuccinimide, and N-bromotetramethylsuccinimide. van Helden and Kooyman's data give for Br_2 σ correlation $\rho = -1.33 \pm 0.062$, σ^+ correlation $\rho = -1.05 \pm 0.021$ and for N-bromosuccinimide σ correlation $\rho = -1.80 \pm 0.045$ and σ^+ correlation $\rho = -1.41 \pm 0.023$.

[j]This data supersedes the earlier work of van Helden and Kooyman (22) and Walling and Miller (23) on Cl· + toluene at 80° and 70°, in benzene and the reactants, respectively. The former workers' results give σ correlation $\rho = -1.32 \pm 0.043$, σ^+ correlation $\rho = -1.27 \pm 0.052$ and the latter workers' results give a σ correlation $\rho = -0.845 \pm 0.0196$ and a σ^+ correlation $\rho = -0.741 \pm 0.0203$.

[k]β-Picoline and γ-picoline were not included in the calculations. The value given for the 4-CH_3 group was not included either since it was derived from a comparison of cumene and *p*-cymene. In these two compounds the *tert*-hydrogen is abstracted and this hydrogen has a different local environment to that of a hydrogen atom in toluene (see text). The value given for the 4-CH_3 group is therefore not directly comparable with values given for the other substituted toluenes.

comparison of reaction [1] with reaction [8] since the OH bond is presumably more polarizable than the CH bond. Unfortunately the solvents are not identical but since they are both aromatic the comparison is probably justifiable.

The data given for $RO_2\cdot$ + toluene and $RO_2\cdot$ + cumene in footnote *h* to Table II suggests that there could be yet another factor influencing ρ since ρ is smaller for cumene than for toluene. This difference might be due to a smaller activation energy for hydrogen abstraction from cumene compared with toluene. However, it is also possible that this type of solvent effect arises from the local environment around the abstracted hydrogen. That is, in cumene the local environment will be more aliphatic in character than in toluene and will therefore be less polarizable and will presumably tend to give a smaller ρ. Some of our more recent work has shown that there is a similar decrease in ρ for reaction [1] when the phenols contain two ortho-alkyl groups. Such local environmental effects are known to be very important in determining the fundamental O—H stretching frequencies and intensities of sterically hindered phenols (29).

It is clear from the foregoing discussion that a great deal of further work on hydrogen abstraction reactions under carefully controlled conditions is required to elucidate the precise role of solvents in determining ρ. Further work is also needed to correlate ρ with radical electron affinities, with the ease of formation of the $XC_6H_4Y^+H$ cation, with the activation energies, and with the various steric and local environmental factors that may all play a part in the reaction mechanism and its transition state.

ACKNOWLEDGMENT

The authors wish to thank Dr. I. E. Puddington for his continuing interest and advice throughout the course of this work.

AROMATIC SUBSTITUTION

PART II. THE REACTION OF VARIOUS 3-SUBSTITUTED PYRIDINE DERIVATIVES AND OF QUINOLINE WITH PHENYLLITHIUM[1]

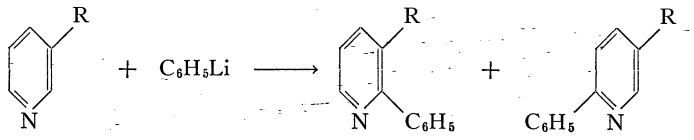
R. A. ABRAMOVITCH, K. S. AHMED, AND CHOO-SENG GIAM
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received March 7, 1963

ABSTRACT

Phenyllithium and pyridine-3-*N*,*N*-diethylsulphonamide gave the expected 2-phenyl derivative exclusively. Contrary to a previous report some 2,3-diphenylpyridine is formed with 3-phenylpyridine. No pyridyne intermediate seems to be formed in the reaction of phenyllithium with 3-bromopyridine. The reactions of phenyllithium with quinoline and with *N*-benzylpyridinium chloride have also been studied and are discussed.

In previous papers in this series (1, 2, 3) the reaction of phenyllithium with a number of 3-substituted pyridines was examined. With a 3-alkylpyridine (I) the main product was the 3-alkyl-2-phenylpyridine (II) when the alkyl group was methyl, ethyl, or isopropyl, but it was the 5-alkyl-2-phenylpyridine when the substituent was *t*-butyl. With nicotine (I; R = 2-*N*-methylpyrrolidyl) the isomer ratio was approximately 1:1. Two further examples were studied: R = NH_2 and R = OCH_3. In both cases the only isomer detected was the 2,3-disubstituted pyridine. It was suggested (2) that in these last two cases the exclusive substitution at the 2-position might be explained by assuming some coordination of the lithium atom with a pair of electrons on the 3-substituent such that the phenyl group would be suitably oriented for attack at the 2-position. No 4-phenylpyridine could be detected gas chromatographically in the reaction of phenyllithium with pyridine. A number of possible explanations were considered (3) to account for the observed orientation with 3-alkylpyridines.



I II III

All the 3-substituents mentioned above are electron donating. The only reported example of such a reaction being carried out with a 3-substituted pyridine in which the 3-substituent may be considered to be electron attracting is that in which 3-phenylpyridine (I; R = C_6H_5) was the substrate used (4). In this case, and contrary to the expected electrical effect of a phenyl substituent group ($-I > +M$), it was reported that only 2,5-diphenylpyridine (III; R = C_6H_5) was isolated. It was postulated (1) that this might be attributed to steric inhibition of coplanarity in the transition state leading to the formation of the 2,3-isomer, whereas no such inhibition exists in the transition state for the 2,5-isomer. It seemed rather strange, though, that *no* 2,3-diphenylpyridine had been formed at all in this reaction. This has been reinvestigated. It was also important that the reaction of phenyllithium with 3-substituted pyridines in which the 3-substituent was electron attracting be studied: on the basis of simple electronic considerations (which fail to predict the correct behavior when R = CH_3, Et, or *i*-Pr (3)) it might be predicted that

[1]*Part I. Can. J. Chem.* **40**, *213 (1962).*

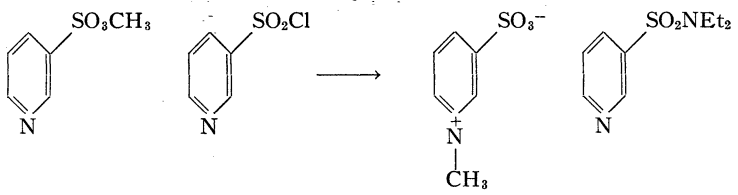
the 2,3-isomer should be formed predominantly in these cases. The choice of such a substituent was made difficult by the fact that most of the common electron-attracting groups (e.g. NO_2, CO_2R) themselves react with the organolithium reagent. It was decided to examine the reactions when R = SO_3CH_3 and Br, and also to try and determine whether coordination of the organolithium reagent at the pyridine nitrogen atom was important in determining the preferential orientation of the entering nucleophile, as had been suggested (5). The latter seemed unlikely since it has been reported that the reaction of benzylmagnesium chloride with 3,4-lutidine methiodide (where further coordination at nitrogen is not possible) gives the 1,2-dihydro-2-benzyl derivative (6). Other examples of such reactions are known (7). To this end it was decided to study the reaction of phenyllithium with *N*-benzylpyridinium chloride and with 3-methyl-*N*-benzylpyridinium chloride. Finally, it was suggested by Brown and Harcourt (8) that a "strong" nucleophilic reagent would attack the quinoline ring preferentially at $C_{(2)}$, whereas a "weak" one would attack it at the position of lowest nucleophilic atom localization energy, namely $C_{(4)}$. Phenyllithium is considered to be a strong nucleophile and it was, consequently, of interest to determine the orientation of the entering phenyl group with greater certainty than had been done before. Ziegler and Zeiser (9) carried out this reaction and obtained 2-phenylquinoline together with a small amount of a lower-melting compound which, they suggested but did not prove, was 4-phenylquinoline. Gilman and Gainer (10) repeated the reaction and obtained 2-phenylquinoline and 2,2-diphenyl-1,2-dihydroquinoline, but no 4-phenylquinoline. It was decided to re-examine this reaction and to attempt to detect by gas chromatographic analysis any 4-phenylquinoline formed.

Methyl 3-pyridinesulphonate (IV) could not be prepared by any of the standard reactions. Pyridine-3-sulphonic acid was recovered unchanged on treatment with diazomethane. When the acid chloride (V) was treated with methanolic sodium methoxide the betaine (VI) was obtained, identical with that prepared from potassium pyridine-3-sulphonate and methyl iodide in the presence of aqueous sodium hydroxide (11). It is conceivable that the required ester may have been formed in this reaction but that it underwent self-alkylation in the working-up process. Pyridine-3-*N*,*N*-diethylsulphonamide (VII) was used instead of the ester in the reaction with phenyllithium. When VII



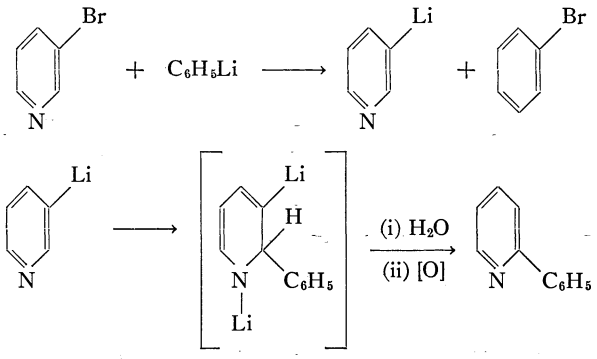
IV V VI VII

in excess was treated with phenyllithium and the product worked up by column chromatography only one product other than starting material was isolated, in low yield (20% based on phenyllithium). On the basis of its analysis and infrared spectrum (bands at 1578, 778, and 730 cm^{-1} (12, 13)) this is thought to be 2-phenylpyridine-3-*N*,*N*-diethylsulphonamide (II; R = SO_2NEt_2). No 2,5-isomer could be detected among the reaction products. The orientation observed is thus in accord with that expected on the basis of the electron-attracting character of the substituent.

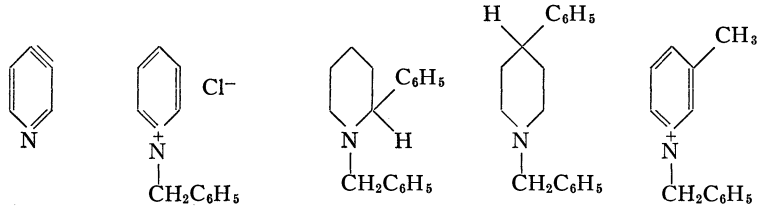
The reaction of phenyllithium with 3-bromopyridine gave a mixture of neutral and basic products. Each of these fractions was analyzed by gas-phase chromatography. The neutral fraction was found to contain bromobenzene (43.4% of neutral components) together

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

with some biphenyl (some of which arises in the preparation of phenyllithium from bromobenzene) and an unknown product. No unreacted bromobenzene was present in the initial phenyllithium solution, however. The ether-soluble basic products were found to contain a small amount (1.8%) of 2-phenylpyridine together with a product which was different from 3-bromo-2-phenylpyridine (II; R = Br). A small amount of this substance was collected; its analysis was different from that expected for a bromophenylpyridine. Insufficient quantities were available to permit its structure to be investigated further at this time. Authentic 3-bromo-2-phenylpyridine could be prepared in low yield from 3-amino-2-phenylpyridine via the Sandmeyer reaction. A somewhat better yield (25.9%) was obtained by the use of Craig's perbromide hydrobromide method (14). Gilman and Spatz (15) similarly report (with L. Tolman) the isolation of 2-*p*-dimethylaminophenylquinoline from 3-bromoquinoline and *p*-dimethylaminophenyllithium. The reaction of 3-bromopyridine with butyllithium was shown (15) to give rise to a complex mixture of products. The 2-phenylpyridine and bromobenzene formed in the present reaction may arise as follows:



It is interesting to note that not only were no bromophenylpyridines isolated but neither was any 3- or 4-phenylpyridine detected gas chromatographically. This seems to rule out the formation of a 2- or 3-pyridyne intermediate in this case. In a recent report, Kauffmann and Boettcher (16) showed that the reaction of 3-chloro- or 3-bromo-pyridine with lithium piperidide and piperidine in ether involves the formation of a 3-pyridyne intermediate, with the resulting production of 3- (48%) and 4-piperidinopyridine (52%). Again, the formation of 4-phenacylpyridine and of 4-aminopyridine has been reported (17) in the reaction of 3-bromopyridine with sodioacetophenone and sodium in liquid ammonia, respectively, which has been postulated to take place by way of a pyridyne intermediate (VIII). Similarly, had a 2-pyridyne intermediate been formed one might have expected



VIII IX X XI XII

some 3-phenylpyridine to be formed, particularly in view of the −I effect of the pyridine ring nitrogen atom (which would direct the entering nucelophile mainly to $C_{(3)}$ (see, for example, reference 18)).

The procedure reported (4) for the reaction of phenyllithium with 3-phenylpyridine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(I; R = C_6H_5) was modified somewhat in that a larger proportion of I (R = C_6H_5) compared with phenyllithium was used. Column chromatographic separation of the mixture of products formed confirmed that 2,5-diphenylpyridine (III; R = C_6H_5) was the main product formed (29% yield). A second product, m.p. 216–216.5° (5.7% yield), was also isolated which analyzed for a diphenylpyridine. That this was the expected 2,3-diphenylpyridine was established by a study of its n.m.r. spectrum in carbon disulphide solution. It exhibited a single proton doublet ($J_{\alpha\beta}$ 5 c.p.s.) centered at 534 c.p.s. (relative to tetramethylsilane as internal standard and using an oscillator frequency of 60 Mc/s) corresponding to H_α (1, 19), and another single proton doublet centered at 461 c.p.s. due to H_γ ($J_{\beta\gamma}$ 5 c.p.s.), which is only consistent with a 2,3-disubstituted pyridine derivative (the resolution was not high enough to separate the bands due to splitting between the α- and γ-protons). The n.m.r. spectrum of 2,5-diphenylpyridine was more complex because of the overlap of some of the phenyl proton peaks with the H_γ peak. The H_α proton peak consisted of a singlet at 530 c.p.s. whose intensity corresponded to that expected for one proton. A third fraction was isolated from the column chromatographic separation but this could neither be purified properly for analysis nor characterized at this time.

An ethereal suspension of *N*-benzylpyridinium chloride (IX) was treated with phenyllithium and the reaction products reduced catalytically (to change any dihydropyridines to the corresponding piperidine derivatives) and analyzed by gas chromatography. Most of the reaction products were high-boiling polymeric tars, which is not unexpected since the 1,2-dihydropyridine adduct is essentially a *cis*-butadiene system, which in this case, cannot aromatize under the conditions of the reaction and is formed in the presence of an efficient Zielger-type polymerization catalyst. The gas chromatogram consisted of four minor peaks followed by a fifth larger one. The latter was found to be due to *N*-benzyl-2-phenylpiperidine (X) (5.2% yield based on total reduction products). No peak corresponding to *N*-benzyl-4-phenylpiperidine (XI) or to either of the debenzylated products was detected. This is in contrast with the reaction of cyclopentadienyllithium with IX, which is reported to give the 4-substituted derivative (20) (it should be noted that in this case aromatization of the adduct to give the zwitterion is favored). When the phenyllithium reaction was carried out with *N*-benzyl-3-picolinium chloride (XII) only high-boiling tars were obtained. The preparation of authentic samples of *N*-benzyl-2- and -4-phenylpiperidine and of *N*-benzyl-3-methyl-2-phenylpiperidine is described in the Experimental section.

The reaction of phenyllithium with an excess of quinoline was examined next. Two products were detected by gas chromatography. The major product was, as expected, 2-phenylquinoline. The first, and very minor, peak corresponded to a compound whose retention time was different from that of authentic 4-phenylquinoline (21). A very small amount could be collected: its infrared spectrum and melting point (84–85° as compared with 61–62° for 4-phenylquinoline) were different from those of 4-phenylquinoline, whose presence was not detected among the reaction products. Similarly, no 2,2-diphenyl-1,2-dihydroquinoline appeared to be formed under these conditions. Unfortunately, insufficient quantities of the unknown component were obtained to permit any further structural work to be carried out. Though the possibility of an addition across the —C(H)=N— cannot be ruled out to explain the lack of formation of 4-phenylquinoline, with acridine, in which such an addition is not possible, phenyllithium gives 9,10-dihydro-9-phenylacridine readily (22).

EXPERIMENTAL

Melting points are uncorrected. Infrared spectra were measured on a Perkin–Elmer Model 21 spectrometer equipped with sodium chloride optics (only the main peaks are reported), and n.m.r. spectra on a Varian

For personal use only.

A60 instrument, using carbon disulphide solutions of the compounds and tetramethylsilane as the internal standard. The oscillator frequency was 60 Mc/s.

Pyridine-3-*N,N*-diethylsulphonamide, m.p. 49–50°, was prepared according to the method of Zienty (23). 4-Phenylquinoline was prepared from β-chloropropiophenone as described by Kenner and Statham (21). 2-Phenylpyridine was prepared from pyridine and phenyllithium (24). 3-Phenylpyridine was obtained from the reaction of 3-pyridyllithium with cyclohexanone followed by dehydration and dehydrogenation (25). 2,2-Diphenyl-1,2-dihydroquinoline was prepared from 2-phenylquinoline and phenyllithium (10). 3-Amino-2-phenylpyridine was obtained by the reaction of phenyllithium on 3-aminopyridine (2). Treatment of dry pyridine with benzyl chloride gave *N*-benzylpyridinium chloride as a highly hygroscopic solid (26).

N-Methyl Betaine of Pyridine 3-Sulphonic Acid

(*a*) A solution of pyridine 3-sulphonyl chloride (4.54 g) in dry methanol (10.5 ml) containing sodium methoxide (from 0.60 g of sodium) was boiled under gentle reflux for 1 hour and then treated with water. The mixture was extracted repeatedly with ether, the ether layer washed with aqueous sodium bicarbonate and then with water, and the solvent evaporated to give the betaine as a pale yellow solid (0.6 g) which did not melt below 330° and was sparingly soluble in ether. (Calc. for $C_6H_7NO_3S$: C, 41.62; H, 4.08. Found: C, 41.79; H, 4.18.)

(*b*) Cf. Meyer (11). Potassium pyridine-3-sulphonate (0.8 g), 10% aqueous sodium hydroxide (1 ml), and methyl iodide (2 ml) were heated under reflux for 12 hours. The solution was evaporated to dryness and the residue recrystallized from hot water to give the betaine, m.p. > 330°, whose infrared spectrum was identical with that of the sample prepared above. Infrared spectrum (Nujol mull): 1646 (s), 1505 (s), 1235 (vs), 1215 (vs), 1135 (s), 1045 (vs), 1032 (vs), 820 (m), 720 (s), and 675 cm^{-1} (s).

Reaction of Phenyllithium with Pyridine-3-N,N-diethylsulphonamide

To a well-stirred solution of pyridine-3-*N,N*-diethylsulphonamide (18.2 g, 0.1 mole) in anhydrous ether (50 ml) and under nitrogen was added a solution of phenyllithium (0.05 mole, prepared from lithium and bromobenzene (3)) in dry ether (68 ml) at such a rate that the mixture boiled gently under reflux. At the end of the addition the ether was distilled off and simultaneously replaced with dry toluene. The solution was then boiled under reflux for 7.5 hours, cooled, treated with water, and extracted repeatedly with ether. The ether layer was extracted several times with hydrochloric acid, the acidic solution made strongly alkaline and extracted with several portions of ether. The dried (KOH) ether extract was evaporated and the residue chromatographed on a column of alumina (100 g). Elution with methanol (after preliminary elution with benzene and ether to remove unchanged VII) gave *2-phenylpyridine-3-N,N-diethylsulphonamide* as a waxy solid (2.8 g) which, after recrystallization from methanol, had m.p. 77–77.5°. (Calc. for $C_{15}H_{18}N_2O_2S$: C, 62.05; H, 6.25. Found: C, 62.12; H, 6.42.) Infrared spectrum (Nujol mull): 1578 (m), 1338 (s), 1155 (s), 778 (m), 730 (s), 700 (m), 690 (m), and 662 cm^{-1} (w).

3-Bromo-2-phenylpyridine

A solution of 3-amino-2-phenylpyridine (0.566 g) in 48% hydrobromic acid (2 ml) was cooled in an ice–salt mixture and bromine (0.8 ml) was added to it dropwise with stirring, when the solid orange perbromide separated. Sodium nitrite (1.0 g) in water (3 ml) was added with stirring at such a rate that the temperature remained at 0°. As the last of the sodium nitrite solution was added a vigorous evolution of gas occurred and the temperature rose to 10°. The reaction mixture was made strongly alkaline and steam-distilled, the distillate was extracted with ether, the ether extract dried (Na_2SO_4) and evaporated. The residue was distilled at 305–307° at 720 mm to give *3-bromo-2-phenylpyridine* (0.202 g) as a pale yellow liquid. (Calc. for $C_{11}H_8NBr$: C, 56.43; H, 3.44. Found: C, 56.74; H, 3.70.) Infrared spectrum (liquid film): 3030 (m), 1573 (s), 1432 (s), 1122 (s), 1088 (s), 1008 (s), 781 (s), 735 (s), and 682 cm^{-1} (s).

Reaction of Phenyllithium with 3-Bromopyridine

An ethereal solution of phenyllithium (28.5 ml, 0.0333 mole of phenyllithium, prepared from lithium and bromobenzene) was added dropwise under nitrogen to a stirred solution of 3-bromopyridine (15.8 g, 0.1 mole) in dry ether (100 ml). The mixture was stirred for another 2 hours, water was added followed by hydrochloric acid, the organic layer separated, and the aqueous layer extracted repeatedly with ether. The combined ether layers (A) containing the neutral products was concentrated and analyzed as described below. The acidic layer was basified with sodium hydroxide and extracted with ether. The ether extracts containing the basic material were evaporated, the residue distilled to remove unreacted 3-bromopyridine, and the residue (B) analyzed.

Fraction (A) was subjected to gas chromatography using a 3 ft×1/4 in. column packed with Apiezon N on Fluoropak (80–100 mesh) (1:10 by weight); the column temperature was 160° and the helium inlet pressure 30 p.s.i. Three peaks were observed, the first (retention time 1 min 20 sec) due to bromobenzene (43.4% of total neutral products), the second to biphenyl (retention time 12 min 40 sec), and the third to an unknown substance (retention time 29 min 20 sec).

Fraction (B) was subjected to gas chromatography on an 8 ft×1/4 in. column packed with ethylene glycol succinate on Chromosorb (1:10 by weight). The column temperature was 160° and helium inlet pressure 40 p.s.i. Two peaks were observed: the first (retention time 21 min 20 sec) was due to 2-phenylpyridine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(characterized by its retention time, infrared and ultraviolet spectra) (1.8% yield based on total amount of basic product); the second (retention time 44 min) was due to a compound of unknown structure. A small amount of the latter product was collected and analyzed: Found: C, 72.27; H, 5.94. Under these conditions the retention time of 3-bromo-2-phenylpyridine was 50 min. No 3- or 4-phenylpyridine could be detected.

Reaction of Phenyllithium with 3-Phenylpyridine

A solution of phenyllithium (0.0182 mole) in dry ether (47 ml) was added dropwise under nitrogen to a well-stirred solution of 3-phenylpyridine (3 g, 0.0193 mole) in ether (150 ml). The mixture was stirred for a further 24 hours and oxygen was then bubbled through the reaction mixture for 30 minutes. An excess of water was added and the mixture extracted exhaustively with ether. The dried (Na_2SO_4) ether extract was evaporated and the residue chromatographed on a column of alumina (110 g). Elution with light petroleum (b.p. 40–60°) – benzene mixture (4:1 v/v) gave 2,5-diphenylpyridine (0.947 g), m.p. 174–175° after recrystallization from alcohol. Wiley *et al.* (25) report m.p. 174–175° for this compound. Elution with light petroleum – benzene (1:1 v/v) gave unreacted 3-phenylpyridine (1.003 g). Elution with benzene – ether (4:1 v/v) brought down *2,3-diphenylpyridine* (0.169 g), which gave a bluish fluorescence in this solvent mixture. It was recrystallized from a benzene – light petroleum (b.p. 40–60°) mixture and had m.p. 216–216.5°. (Calc. for $C_{17}H_{13}N$: C, 88.28; H, 5.60. Found: C, 88.40; H, 5.61.) Infrared spectrum (KBr disk): 3060 (m), 1600 (m), 1538 (m), 1500 (m), 1457 (m), 1428 (m), 1121 (s), 903 (m), 800 (m), 767 (s), 748 (s), 698 (s), 678 cm^{-1} (m). Elution with ether and ethyl acetate gave a yellow powder (0.531 g), m.p. 112–113°, which could not be purified further. Infrared spectrum (KBr disk): 3090 (m), 1684 (s), 1610 (m), 1505 (s), 1465 (s), 758 (s), 698 cm^{-1} (s). The n.m.r. spectrum of this compound exhibited none of the peaks usually associated with pyridine ring protons.

2-Phenylpiperidine (27)

2-Phenylpyridine (1 g) in 1.1 *N* hydrochloric acid (6.6 ml) and 95% ethanol (50 ml) was reduced at atmospheric pressure in the presence of platinic oxide (50 mg). The catalyst was filtered off, the solvent evaporated, and the residue treated with dilute sodium hydroxide solution and extracted with ether. The dried (Na_2SO_4) ether extract was evaporated and the residue distilled to give 2-phenylpiperidine (0.855 g), b.p. 246–248° at 726 mm. Ushakov and Promyslov (27) give b.p. 255–256° at 766 mm for this compound.

4-Phenylpiperidine

This was prepared similarly by the reduction of 4-phenyl-1,2,3,4-tetrahydropyridine (28). The yield of product, b.p. 250–252° at 720 mm, was 74%. It had previously been prepared by the reduction of 4-phenylpyridine (29) and the reported boiling point was 255–257° at 727 mm.

N-Benzyl-2-phenylpiperidine

2-Phenylpiperidine (0.683 g) and benzyl chloride (0.53 g) were heated at 120–160° for 1/2 hour, the mixture was cooled, treated with dilute sodium hydroxide solution, and extracted with ether. The dried (Na_2SO_4) ether extract was evaporated, yielding *N-benzyl-2-phenylpiperidine* (0.728 g), which crystallized from ethanol and had m.p. 93–93.5°. (Calc. for $C_{18}H_{21}N$: C, 86.01; H, 8.42. Found: C, 86.00; H, 8.60.)

N-Benzyl-4-phenylpiperidine

Prepared in the same way as the 2-isomer it was obtained as a yellow oil, b.p. 149–150° at 0.4 mm. Boggiano, Petrov, Stephenson, and Wild (30), who prepared this compound by the reduction of *N*-benzyl-4-phenyl-4-propionoxypiperidine, report its b.p. as 151° at 0.4 mm.

Reaction of Phenyllithium with N-Benzylpyridinium Chloride

To a well-stirred suspension of *N*-benzylpyridinium chloride (15.87 g, 0.154 mole) in dry ether under nitrogen was added an ethereal solution of phenyllithium (0.077 mole) during 1/2 hour. The reaction mixture was stirred for 24 hours under nitrogen, treated with water, and extracted repeatedly with ether. The dried (Na_2SO_4) ether extract was evaporated to give a viscous dark red residue (11.82 g). A portion of this (1.18 g) was dissolved in a mixture of 95% ethanol (60 ml) and 1.1 *N* hydrochloric acid (4.8 ml) and hydrogenated at room temperature and pressure over platinic oxide. Uptake of hydrogen was very slow. The hydrogenated product was subject to gas chromatographic analysis on a 3 ft×1/4 in. Apiezon N on Fluoropak (80–100 mesh) (1:10 w/w) column operated at 220° and with a helium inlet pressure of 30 p.s.i. Five peaks were observed, the last one (retention time 15 min 15 sec) being due to *N*-benzyl-2-phenylpiperidine (5.2% yield based on reduced products) (retention time and infrared spectrum). The retention times and spectra of the compounds giving rise to the first four peaks were quite different from those of 2- and 4-phenylpiperidine and *N*-benzyl-4-phenylpiperidine. These substances were not investigated further.

3-Methyl-2-phenylpiperidine

This was prepared by catalytic reduction of 2-phenyl-3-picoline (1). The *product* (76.2% yield), b.p. 256–257° at 724 mm, was purified for analysis by gas chromatography using a 5 ft×1/4 in. 10% Apiezon N on Fluoropak column, followed by redistillation, but could not be obtained in an analytically pure state. (Calc. for $C_{12}H_{17}N$: C, 82.23; H, 9.78. Found: C, 80.55; H, 9.26.) Infrared spectrum (liquid film) 1497 (m), 1457 (s), 1383 (m), 1277 (m), 1130 (m), 1088 (m), 875 (m), 827 (s), 696 cm^{-1} (s).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

N-Benzyl-3-methyl-2-phenylpiperidine

3-Methyl-2-phenylpiperidine (0.876 g; redistilled) and benzyl chloride at 120–160° for 1 hour gave, in a manner similar to that described for the unmethylated compound, *N-benzyl-3-methyl-2-phenylpiperidine* (0.8 g), b.p. 176–180° at 6 mm, m.p. 69–69.5° (after recrystallization from absolute alcohol). (Calc. for $C_{19}H_{23}N$: C, 85.92; H, 8.75. Found: C, 85.71; H, 8.92.) Infrared spectrum (KBr disk): 1610 (m), 1502 (s), 1462 (s), 1379 (m), 1272 (m), 1230 (m), 1142 (s), 738 (s), and 694 cm^{-1} (s).

Reaction of Phenyllithium with Quinoline

A solution of phenyllithium (0.024 mole) in dry ether (150 ml) was added dropwise under nitrogen to quinoline (9.29 g, 0.072 mole; purified via the zinc chloride complex) in dry ether (20 ml). When the addition was complete the ether was distilled off and simultaneously replaced by dry toluene (60 ml). The mixture was then boiled under reflux for 6 1/2 hours, the solution cooled and treated with water, and the toluene layer separated and extracted with hydrochloric acid. The acid layer was basified, extracted with ether, and the dried (NaOH) ether extract evaporated. The excess quinoline was distilled at 80° at 0.35 mm and the residue (1.434 g) analyzed by gas chromatography. A 3 ft × 1/4 in. 10% Apiezon N on Fluoropak column was used at a temperature of 220° and a helium inlet pressure of 45 p.s.i. Only two peaks, with retention times of 9.9 and 14.4 min, were observed. The latter (major peak) was due to 2-phenylquinoline (retention time and infrared spectrum). The first peak had a retention time and infrared spectrum different from that of 4-phenylquinoline. A small sample was collected and had m.p. 84–85°. Infrared spectrum (KBr disk): 1587 (s), 1494 (s), 1393 (s), 850 (m), 766 (s), and 698 cm^{-1} (s). This substance was not investigated further at this time.

ACKNOWLEDGMENTS

ISOTOPE EFFECT STUDIES ON ELIMINATION REACTIONS

III. NITROGEN ISOTOPE EFFECTS IN THE E2 REACTION OF ETHYLTRIMETHYLAMMONIUM AND 2-PHENYLETHYLTRIMETHYLAMMONIUM IONS[1]

G. AYREY,[2] A. N. BOURNS, AND V. A. VYAS[3]

Department of Chemistry, Hamilton College, McMaster University, Hamilton, Ontario

Received February 14, 1963

ABSTRACT

Nitrogen isotope effects have been determined for the E2 reaction of two quaternary ammonium salts with ethoxide ion in ethanol. Ethyltrimethylammonium iodide gave k^{14}/k^{15} values of 1.017 at 60° and 1.015 at 95°, while 2-phenylethyltrimethylammonium bromide gave 1.012 at 40° and 1.009 at 60°. These results and the β-deuterium isotope effects reported by others have been interpreted in terms of the relative extent of C_α—N^+ and C_β—H bond weakening in the transition states of the two reactions.

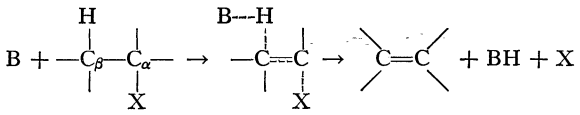
INTRODUCTION

Although it was recognized by Ingold as early as 1927 (1) that bimolecular β-elimination reactions need not be fully synchronous processes, it has only been in recent years that the concept of a continuous spectrum of E2 reactions differing in the relative extent of C_α—X and C_β—H bond rupture in the transition state has been invoked to account for observed phenomena (2–13). The various factors, structural and environmental, which



can be expected to influence the nature of the transition state have been discussed very recently by Bunnett (14), who, along with others (15, 16), has critically examined the limited number of tests now available for assessing the position of any particular elimination in the spectrum of E2 mechanisms.

Possibly the most definitive test is that based on the effect of isotopic mass of H and of X on reaction rate, i.e., the kinetic isotope effect. Although isotope effect theory has not been developed to the point that the magnitude of the isotope effect observed in an individual reaction can be used as any more than a semiquantitative measure of bond weakening in the transition state, a *comparison* of the isotope effects observed in a reaction series can allow certain conclusions to be drawn with respect to the influence of structural changes on the relative extent of bond rupture as one proceeds from reactant to reactant within the series. A complication arises, however, in the case of hydrogen isotope effects as a consequence of the fact that theory predicts (17, 18) a maximum effect when the proton is half transferred to the base at the transition state. If, then, for each of two related reactions, the proton is less than half transferred, that reaction showing the larger isotope effect will have the greater C_β—H bond weakening in the transition state. On the other hand, if the proton is more than half transferred at the transition state the relationship between the magnitude of the isotope effect and the extent of C_β—H bond rupture will be the reverse of this. Indeed, it is possible for two reactions to give rise to similar

[1]*Part II: G. Ayrey, E. Buncel, and A. N. Bourns. Proc. Chem. Soc. 458 (1961).*

[3]*Present address: Rajkot, Bombay State, India.*

hydrogen isotope effects and yet differ markedly in the extent of C_β—H bond weakening at the transition state since this state for one reaction may be reached before the point of half transfer and for the other after half transfer. It is only when other considerations indicate that the transition states for both reactions find themselves on a particular side of the symmetrical situation that isotope effects give an indication of relative extents of C_β—H bond rupture. Alternatively, if it is known on the basis of other measurements, in particular, substituent effects on reaction rates, how C_β—H bond weakening at the transition state changes from reactant to reactant, then the direction of the variation in isotope effects will show the extent of proton transfer to base (14).

No such complication arises with respect to the isotope effect associated with the atom of the leaving group X which is attached to the α-carbon since this atom, unlike hydrogen, is not undergoing a three-center displacement. The magnitude of the isotope effect will therefore depend on the extent to which the composite force constant of the C—X bond is decreased in going from initial to the transition state (19). In other words, the X-isotope effect can be expected to increase regularly in a reaction series with the extent of bond weakening in the transition state. In spite of this straightforward relationship, few studies of X-isotope effects in elimination reactions have been reported. The reason for this is obvious. The effects are very small, amounting to never more than a few percent, and they require for their measurement very high precision mass spectrometry. When the necessary precision is achieved, however, the results can contribute in a significant way to our understanding of the nature of the transition state.

The first investigation of this kind was made by Saunders (20), who reported for the reaction of 2-phenylethyldimethylsulphonium ion with hydroxide ion in aqueous solution the extremely small sulphur isotope effect, k^{32}/k^{34}, of 1.0015, a value which may be compared to 1.018 in the S_N1 reaction of *t*-butyldimethylsulphonium ion. This result clearly indicates that the force constant of the C—S bond in the sulphonium salt elimination is essentially unchanged at the transition state and, together with the observed hydrogen isotope effect of 5.9 at 30° C (5) and a Hammett rho of +2.21 (21) for a series of phenyl-substituted sulphonium salts, it establishes that the transition state for the reaction possesses carbanionic character.

A similar study has been carried out in our laboratories on the $E_{CO}2$ elimination reaction of benzyl nitrate to benzaldehyde (15). The combination of a normal nitrogen isotope effect, k^{14}/k^{15}, of 1.020 and a hydrogen isotope effect of 5.0 at 60° indicates that both C_β—H and C_α—N bond rupture are well advanced at the transition state, although the large Hammett rho value of +3.4 (22) for the reaction shows that the former bond change is running ahead of the second.

We have now undertaken a study of the nitrogen isotope effect in the Hofmann elimination reaction of quaternary ammonium salts. This system has an advantage over the sulphonium salt studied by Saunders (20) since N^{14}:N^{15} isotope effects can be expected to be about twice as large as S^{32}:S^{34} effects (19) for the same extent of bond weakening at the transition state and can readily be measured with a precision of better than ±0.1%. The present paper reports the results obtained for the E2 reaction of ethyltrimethylammonium ion and 2-phenylethyltrimethylammonium ion with ethoxide ion in ethanol. The latter is the nitrogen analogue of the sulphonium salt studied by Saunders (20). Since the β-hydrogen isotope effects for the elimination reaction of both ammonium salts have already been reported (4, 5) the results of the present study make it possible to test the predictions of Bunnett (14) on the effect of a β-aryl group on the relative timing of the two bond changes.

EXPERIMENTAL

Materials

Ethyltrimethylammonium iodide.—The product formed by reaction at room temperature of equimolar quantities of trimethylamine and ethyl iodide in ethanol was repeatedly recrystallized from ethanol; m.p. 336° decomp.

2-Phenylethyltrimethylammonium bromide.—2-Phenylethyldimethylamine, prepared by the method of Icke *et al.* (23), was reacted with methyl bromide in benzene solution and the product was recrystallized several times from a methanol–water mixture; m.p. 251–252°.

Nitrogen Isotope Effect Measurements

The nitrogen isotope effects were obtained by comparing the nitrogen isotopic abundance in the trimethylamine formed in reactions carried to some small known extent of completion (7–20%) with the isotopic abundance in the starting compound. Isotopic analyses were performed mass spectrometrically on nitrogen gas samples prepared by oxidation of ammonia formed by Kjeldahl digestion of the quaternary salts and of the trimethylamine product. Compounds containing the natural abundance of the nitrogen isotopes were used throughout.

(a) Preparation of Nitrogen Samples from the Quaternary Ammonium Salts

Quaternary ammonium salt (ca. 0.2 mmole) was weighed into a 25-ml Kjeldahl flask, water (1.0 ml), 30% AnalaR hydrogen peroxide (0.5 ml), and sulphuric acid (0.5 ml) were added, and the mixture was boiled to expel the liberated iodine. After removal of most of the water by distillation, potassium sulphate (1.5 g), mercuric oxide (0.1 g), and sulphuric acid (2.5 ml) were added and the mixture digested in the usual way for 8 to 9 hours. Ammonia was liberated by addition of sodium hydroxide and distilled into excess standard sulphuric acid (average yield 97%).

The ammonium sulphate solution was concentrated to about 3 ml and then transferred to a high-vacuum system (Fig. 1) where, after thrice degassing in A, it was oxidized to nitrogen gas using degassed aqueous

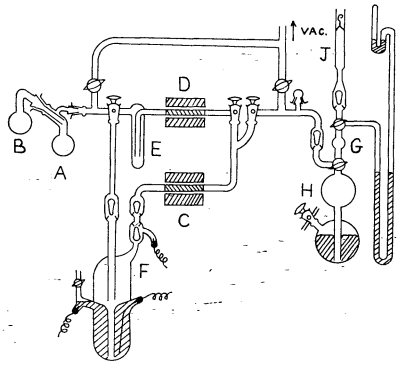

FIG. 1. Apparatus for preparation of nitrogen samples for mass spectrometric analysis.

sodium hypobromite (24, 25) transferred from B. The nitrogen was purified by repeated cycling by means of an automatic Urry Toepler pump (26), F, over copper (reduced oxide wire), C, and copper oxide wire, D, both at 750°, and through a trap, E, cooled in liquid nitrogen. After purification the gas was transferred to a standard volume, G, by means of the manual Toepler pump, H, where the yield (>95%) was determined. Finally, the nitrogen was pumped into the breakseal tube, J, which was then sealed. The need for such purification of nitrogen for precise mass spectrometry has been stressed by Hoering (27), and we can confirm that, in addition to the obvious interference by carbon monoxide at mass 28, the presence of oxygen has a deleterious effect upon the stability of the mass spectrometer.

(b) Partial Reactions and Preparation of Nitrogen Samples from Trimethylamine

Quaternary ammonium salt (ca. 2 mmole) was weighed into flask K (Fig. 2(*a*)) which was then restricted as shown. The required amount of alcoholic base (KOH in 95% ethanol or C_2H_5ONa in absolute ethanol) was added and the flask quickly attached to a vacuum manifold and cooled in liquid nitrogen. After triple degassing, the vessel was sealed and placed in a thermostatted bath for a predetermined time. The flask was then removed from the bath, cooled, opened, and the trimethylamine distilled into a liquid nitrogen cooled trap, L, (Fig. 2(*b*)) at below 0.1 mm pressure and 0° during 15–20 minutes. From time to time ethanol was added from the funnel, M, to avoid undue concentration of reactants. This distillation procedure was rigorously tested and it was shown that removal of trimethylamine was quantitative and no significant further reaction occurred during the time required. Trap L was then disconnected, stoppered at P, and the

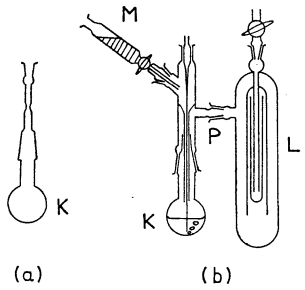

FIG. 2. (*a*) Apparatus for partial reactions.
(*b*) Apparatus for recovery of product.

trimethylamine and ethanol were distilled *in vacuo* into excess standard sulphuric acid, which was back titrated with standard alkali. The trimethylammonium sulphate solution was treated with sulphuric acid (1.0 ml), evaporated to a volume of about 1 ml, and transferred to a Kjeldahl flask for digestion. Nitrogen gas was prepared from the resulting ammonia by the method already described.

Mass Spectrometry and Evaluation of the Isotope Effect

The mass spectrometric analyses were carried out using a 90° sector-type instrument similar to one described by Wanless and Thode (28). It was capable of measuring *relative* isotopic abundance ratios, $N^{14}N^{14}/N^{14}N^{15}$, to ±0.02%. Twice the mass 28/29 ratio is equal to the N^{14}/N^{15} ratio in the compound degraded.

The kinetic isotope effect was calculated from the expression (29)

$$k^{14}/k^{15} = \frac{\ln (1-f)}{\ln (1-rf)},$$

where

$$r = \frac{(N^{14}/N^{15})_{\text{reactant}}}{(N^{14}/N^{15})_{\text{amine}}} = \frac{(N^{14}N^{14}/N^{14}N^{15})_{\text{reactant}}}{(N^{14}N^{14}/N^{14}N^{15})_{\text{amine}}}$$

and f is the fractional extent of reaction as determined by the trimethylamine yield.

RESULTS

The nitrogen kinetic isotope effect results for the Hofmann elimination reaction of 2-phenylethyltrimethylammonium ion and ethyltrimethylammonium ion are given in Table I. In the calculation of the individual k^{14}/k^{15} values, the $N^{14}N^{14}/N^{14}N^{15}$ ratios found for the nitrogen gas formed from a quaternary salt were averaged and the resulting value was combined in the above equation with the individual $N^{14}N^{14}/N^{14}N^{15}$ ratios for the nitrogen gas produced from the trimethylamine formed in each partial reaction of that salt. Although most partial reactions were carried out using as base sodium ethoxide in absolute ethanol, a few experiments were done using potassium hydroxide in 95% ethanol. A comparison of the results of experiments 14 and 15 with those of 16, 17, and 18 shows that, within the limits of measurement, the isotope effect is the same under the two reaction conditions. As a consequence no distinction is made between the two in the subsequent discussion.

DISCUSSION

Comparison of the E2 Reactions of 2-Phenylethyltrimethylammonium and 2-Phenylethyldimethylsulphonium Ions

In Table II are listed the nitrogen isotope effect found in the present study for the E2 reaction of 2-phenylethyltrimethylammonium ion in ethanol at 60° C, the sulphur isotope effect reported by Saunders (20) for reaction of the corresponding sulphonium ion in

aqueous medium at the same temperature, the deuterium isotope effects for the two reactions, also previously reported by Saunders (5), and the Hammett rho values found in the reaction of a series of meta- and para-substituted 2-phenylethyltrimethylammonium and 2-phenylethyldimethylsulphonium salts (14, 21).

In contrast to the very low sulphur isotope effect found by Saunders (20) for the sulphonium salt, an effect of 0.9% is found for the reaction of the corresponding ammonium salt. This value is a little less than one-third the theoretical maximum effect of 3.2% calculated by the method of Bigeleisen and Wolfsberg (reference 19, equation II.30) using for the C—N^+ bond a value of 5.50×10^5 dynes cm^{-1} for the diagonal force constant (30) and 955 cm^{-1} for the stretching frequency (31). It is also only about one-half the isotope effect found in the E2 reaction of ethyltrimethylammonium ion (Table II). Nevertheless there is clearly a significant decrease in the composite force constant of the C—N^+ bond

in passing from the initial to the transition state. Even after taking into account that, for the same percentage decrease in the C—X^+ force constant at the transition state, a sulphur isotope effect can be expected to be little more than half a nitrogen isotope effect, it is clear that C—N^+ bond rupture must be more fully advanced in the transition state of the 2-phenylethyltrimethylammonium ion reaction than is C—S^+ bond rupture for the corresponding sulphonium salt. This is so despite the fact that $-N^+(CH_3)_3$ is presumably the poorer leaving group (5, 14).

Interpretation of the relative magnitude of the deuterium isotope effects found in the reactions of the two salts requires a knowledge of the extent to which the proton is transferred from carbon to the oxygen base at the transition state. If for both salts it is more than half transferred, then that reaction in which C—H bond weakening is the greater will give the smaller deuterium isotope effect. If, on the other hand, the proton is less than half transferred the opposite will be the case. Light is shed on this matter by relating the observed isotope effects and the Hammett rho values found in the two reactions.

In a concerted process the negative charge released by the partial transfer of the hydrogen to the base at the transition state will reside in part on the β-carbon and its attached aryl group and in part on the leaving group X. A measure of the former is provided by the Hammett rho value for the reaction; the larger the rho the more charge is accommodated on the β-aryl group. A measure of the latter is provided by the magnitude of the isotope effect associated with X. Now it has already been shown from a comparison of nitrogen and sulphur isotope effects that C—N^+ bond weakening is more fully advanced in the transition state of the ammonium salt reaction than C—S^+ bond weakening for the sulphonium salt. Furthermore, the Hammett rho is considerably greater in the ammonium salt reaction (Table II). It therefore must be concluded that more electron charge is being accommodated *both* on the β-aryl group *and* on the leaving atom X in the reaction of the ammonium ion. This is only possible if there is more electron charge to be accommodated, that is, if C_β—H bond weakening is considerably more advanced in the transition state of the E2 reaction of the ammonium salt than in that of the sulphonium salt. Now reference to Table II reveals that the β-deterium isotope effect for the former reaction is considerably smaller than that for the latter and, furthermore, both effects are smaller than would be expected for a reaction in which the partial bonds of hydrogen to carbon and to oxygen are of equal strength at the transition state. Since,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

then, it is the reaction with the greater C_β—H weakening which gives rise to the smaller isotope effect, it must be concluded that for the ammonium salt reaction, and very likely for the sulphonium salt reaction as well, the proton is more than half transferred to the base at the transition state. A similar conclusion has been reached by Bunnett (14) from a comparison of the deuterium isotope effects and Hammett rho values for the reaction of 2-phenylethyl tosylates, halides, and onium compounds. However, knowledge of the relative extent of C—X^+ weakening, which is provided in the present study from a comparison of the isotope effects associated with X, places this conclusion on a firmer basis.

It is somewhat surprising to find that both C_β—H and C_α—X bond rupture have made greater progress in the transition state for the 2-phenylethylammonium compound than for the corresponding sulphonium salt. More than one factor may be responsible for this. Firstly, the ammonium salt is less reactive, its free energy of activation being considerably greater than that of the sulphonium salt (32). One, therefore, might expect that the overall bond changes involved in the reaction might be more fully advanced in the transition state for the ammonium salt (33). Secondly, the nature of the medium may have an important influence on the extent to which bond rupture has progressed at the transition state. Saunders' (20) measurements on the sulphonium salt were carried out in aqueous solution while ethanol was the solvent in the present study on the ammonium salt reaction. It is possible that in this less polar medium the sulphonium salt reaction also might show a significant isotope effect with respect to the leaving group.

That the nature of the medium can influence to some degree the extent of bond weakening in the transition state is apparent from the deuterium isotope effect results obtained by Saunders (5) for the sulphonium salt (see Table II). In aqueous medium at 30°, k^H/k^D was found to have a value of 5.93. In ethanol the isotope effect was considerably lower, 5.07, which, since the proton is more than half transferred to base, means greater C_β—H bond weakening in the transition state for the reaction in the less polar solvent.

The foregoing explanation of the differences in the transition states for the two reactions is undoubtedly an oversimplification. Other factors, such as the ability of sulphur, but not of nitrogen, to use *d* orbitals in forming bonds with other atoms, may be more important than medium or transition state energy effects. Indeed, at this stage of our knowledge it is probably more fruitful to compare the isotope effects associated with reactants of the same reaction type than to attempt to account for the relative magnitude of the effects associated with two quite different leaving groups. A comparison of the former kind is to be found in E2 reaction of ethyltrimethylammonium and 2-phenylethyltrimethylammonium ions, which is discussed in the following section.

Comparison of the E2 Reactions of Ethyltrimethylammonium and 2-Phenylethyltrimethylammonium Ions

The relative magnitude of the isotope effects in the reaction of the two ammonium salts provides the first direct test for the hypothesis that, for reactants of the same type, any structural factor which facilitates the departure of one atom (H or X) will cause the bond to that atom to be weakened more and the bond to the other atom to be weakened less in the transition state than would be the case in the absence of this factor. A β-phenyl group, through its ability to conjugate with a developing carbanionic center on the β-carbon, can be expected to make proton transfer energetically easier. The pathway of lowest energy, therefore, should be that in which at the transition state C_β—H bond rupture has made greater progress and C_α—N^+ bond rupture less progress than in the case of the unsubstituted compound. The results given in Table II bear out this prediction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The k^H/k^D ratio for 2-phenylethyltrimethylammonium ion is 3.0 at 50° C. For ethyltrimethylammonium ion the experimentally observed effect is 3.9 at 137°, which corresponds to an effect of between 5.5 and 6.5 at 50°. This value is twice the effect found for the phenyl-substituted compound and corresponds closely to the maximum expected for reaction in which the proton is half transferred to base at the transition state. It has been already shown (*vide supra*) that for the β-phenyl compound the proton is more than half transferred. The much smaller isotope effect observed for this compound must therefore mean a much greater C_β—H bond weakening at the transition state, which is in accordance with prediction.

The relative values of the nitrogen isotope effects for the two reactants bear out the prediction that the two bond changes are complementary; that is, the more C_β—H bond rupture the less C_α—N^+ bond rupture at the transition state. In contrast to an effect of 0.9% for the β-phenylethyl compound, the nitrogen isotope effect for the unsubstituted compound is 1.7%. This value is one of the highest nitrogen isotope effects observed in a rate process and is about one-half the maximum predicted from the Bigeleisen–Wolfsberg equation (*vide supra*).

It would appear then that the E2 reaction of ethyltrimethylammonium ion is a highly synchronous process with the two bond rupture processes having progressed to about the same extent at the transition state. The transition state for the reaction of the β-phenylethyl compound, on the other hand, has considerable carbanionic character.

The results of the present study demonstrate clearly how so-called heavy element isotope effects, when measured with sufficient precision, can be of great value in shedding light on the relative timing of concerted bond changes in elimination and related processes.

TWO-PHASE FLOW OF ADSORBED VAPORS

R. M. BARRER
Physical Chemistry Laboratories, Chemistry Department, Imperial College, London, England
Received March 8, 1963

ABSTRACT

Through a microporous medium, transport of a vapor may occur in an adsorbed film and in the gas phase. The formulation of this two-phase transport has been given in terms of forces and associated phenomenological coefficients, and the resultant expression for the total flux has then been related to the complex Darcy law and Fick law coefficients of flow and diffusion respectively. It is suggested how the various coefficients may be determined as functions of gas pressure or surface concentration of sorbate. The diffusive and hydrodynamic models of transport are considered as two limiting cases of the transport phenomenon, the former of increasing importance for decreasing sorption below monolayer coverage and the latter dominant above monolayer coverage. Steady state total concentration gradients are considered in presence and absence of blockage of gas phase flow by capillary condensate and multilayers, and when there is and is not interconversion between surface and gas phase fluxes along the direction of flow. Finally, the fluxes of each component in a two-phase two-component flow are derived. This problem is of major importance in the separation of mixtures by flow through microporous barriers.

1. INTRODUCTION

There are three ways in which one may attempt to formulate flow through a microporous medium, in which both surface and gas phase components of flux arise. These are, in terms of Fick's equation, Darcy's equation, and by means of irreversible thermodynamic procedures. The first two methods can be shown to be formally equivalent as will be seen from the following development of two-phase flow, although one emphasizes diffusion and the other hydrodynamic transport. The most fundamental procedure (see Section 4) seems to be that based on the thermodynamics of irreversible processes, which will be the method primarily developed here. It will then be the purpose of this paper to give some properties of the two-phase flow process and to indicate the conclusions which may be drawn from its measurement.

2. USEFUL THERMODYNAMIC PROPERTIES OF THE FLOWING COMPONENT

Consider the flow through unit cross section, in the x-direction. The flow occurs simultaneously in the adsorbed phase and the gaseous phase. In any plane $x = x$, normal to the direction of flow, it is assumed that the elements of each fluid are in thermodynamic equilibrium with each other, i.e.

$$\mu_s = \mu_g \quad [1]$$

$$d\mu_s = d\mu_g, \quad [2]$$

where μ_s and μ_g are the chemical potentials of the flowing component in the adsorbed film and the gaseous phase respectively. Also, for a single-component phase at constant temperature

$$d\mu_s = V_s dP_s \quad [3]$$

$$d\mu_g = V_g dP_g.$$

Equations [2] and [3] may be combined to give

[4] $$dP_s = \frac{V_g}{V_s} dP_g$$

and the total pressure drop between $x = 0$ and $x = l$ in the adsorbed film is then

[4a] $$\int dP_s = [P_s]_{x=0} - [P_s]_{x=l} = \Delta P_s = \int_{(P_g)_{x=l}}^{(P_g)_{x=0}} \frac{V_g}{V_s} dP_g.$$

If the concentration in the adsorbed film at $x = l$ (the outgoing face of the membrane) is very much smaller than at $x = 0$, we may write

$$\Delta P_s \sim [P_s]_{x=0} \sim \int_0^{(P_g)_{x=0}} \frac{V_g}{V_s} dP_g$$

and since $V_g \gg V_s$ it follows that $\Delta P_s \gg \Delta P_g$. Thus, the pressure drop in the adsorbed film, between $x = 0$ and $x = l$, is much larger than that in the gas phase, as noted for example by Flood (1).

3. FORMULATION OF FLOW

We now consider a porous medium with adsorbed and gaseous phases of sorbate, both phases diffusing (or flowing). Through any unit cross section normal to the direction of flow (the x-direction)

[5] $$J = J_s + J_g$$

where J_s is the flux of sorbed phase and J_g of gaseous phase.

Let ϵ and A denote pore volume and area per cm³ of porous medium. Let the degree of filling of pores with adsorbed phase be S at a given plane x, normal to the flow direction. Then the volume of adsorbed phase per unit volume of porous medium is $S\epsilon$, and the gaseous volume is $(1-S)\epsilon$. Unit cross section normal to x then contains an area equal to $S\epsilon$ of sorbed phase and $(1-S)\epsilon$ of gaseous phase. The total flux is then defined in terms of phenomenological coefficients λ_s and λ_g per unit cross-section of sorbed and gaseous phases respectively, and the total forces X_s and X_g acting respectively on sorbed and gaseous molecules through unit area of the sorbed phase and the gas phase:

[6] $$J = S\epsilon\lambda_s X_s + (1-S)\epsilon\lambda_g X_g$$

where the forces, X, are

[7] $$X_s = -\frac{C_s}{S\epsilon}\frac{d\mu_s}{dx}; \qquad X_g = -\frac{C_g}{(1-S)\epsilon}\frac{d\mu_g}{dx}.$$

C_s and C_g denote the total numbers of molecules per cm³ of porous medium on surface and in gas phase. If C_g' is the number of molecules per unit volume of gas phase, then

[8] $$(1-S)\epsilon C_g' = C_g$$
$$p_g = C_g' kT.$$

Then, using eq. [2]

[9] $$J = -\left[\lambda_s C_s \frac{d\mu_s}{dx} + \lambda_g C_g \frac{d\mu_g}{dx}\right]$$
$$= -[\lambda_s C_s + \lambda_g C_g]\frac{d\mu_g}{dx}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Since

$$d\mu_g = RTd \ln C_g' = RTd \ln p_g$$

eq. [9] reduces, with the aid of eq. [8], to

$$[10] \qquad J = -\left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right] RT \frac{dC_g'}{dx}.$$

If, then, we define a diffusion coefficient, D, by Fick's law

$$[11] \qquad J = -D \frac{dC_g'}{dx}$$

we obtain

$$[12] \qquad D = \left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right] RT.$$

We may also use eq. [8] with eq. [10] to obtain Darcy's law:

$$[13] \qquad J = -\left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right] N_0 \frac{dp_g}{dx}$$

in which N_0 is Avogadro's number. The Darcy's law coefficient, K_D, defined by

$$[14] \qquad J = -K_D \frac{dp_g}{dx}$$

is then

$$[15] \qquad K_D = \left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right] N_0.$$

Darcy's and Fick's laws are thus seen to be equivalent.

4. PROPERTIES OF THE FLUX EQUATION

From eq. [13], by integration between $x = 0$ and $x = l$, we obtain

$$[16] \qquad Jl = \int_{p_1}^{p_0} \left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right] N_0 dp_g$$

so that

$$[17] \qquad l \frac{dJ}{d[p_g]_{x=0}} = \left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right]_{x=0} N_0 = [K_D]_{x=0}.$$

Similarly

$$[18] \qquad l \frac{dJ}{d[C_g']_{x=0}} = \left[\lambda_s \frac{C_s}{C_g'} + (1-S)\epsilon\lambda_g\right]_{x=0} RT = [D]_{x=0}.$$

Equations [17] and [18] give the differential concentration dependences of K_D or D for the medium at $x = 0$. The relation between $S\epsilon$ and C_s needs further consideration.

In the region of small sorption, before any multilayers or capillary condensate appear, perhaps up to sorptions approaching monolayer coverage, we will write for the effective sorption volume

$$[19] \qquad S\epsilon = Ad$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where d is approximately the molecular diameter of the sorbate. Any molecule with its center within this distance from the surface is regarded as adsorbed. If its center is more than d from the surface the molecule is regarded as being in the gas phase. With this simplification, up to near the monolayer,

[20] $$\rho_s = \frac{C_s m}{S\epsilon} = \frac{C_s m}{Ad}$$

so that the film density ρ_s is proportional to C_s; m is the molecular weight of the sorbate.

After the monolayer region, $S\epsilon$ increases through the formation of multilayers and of capillary condensate, but the density will now be approximated as being close to that of the liquid sorbate:

[21] $$\rho_s \sim \rho_l.$$

In this event

[22] $$S\epsilon = \frac{C_s m}{\rho_l}$$

and so the degree of filling after monolayer coverage becomes proportional to C_s. This is the region in which a hydrodynamic mechanism of transport has largely replaced the diffusive, or random walk, mechanism appropriate for small values of C_s. The diffusive mechanism is dominant in the dilute Henry's law range of sorption. The two regions will in reality probably merge continuously into one another as in Fig. 1, curve iii. We will, however, assume that eq. [20] is valid up to the monolayer coverage, and eq. [22] thereafter (Fig. 1, curves i and ii).

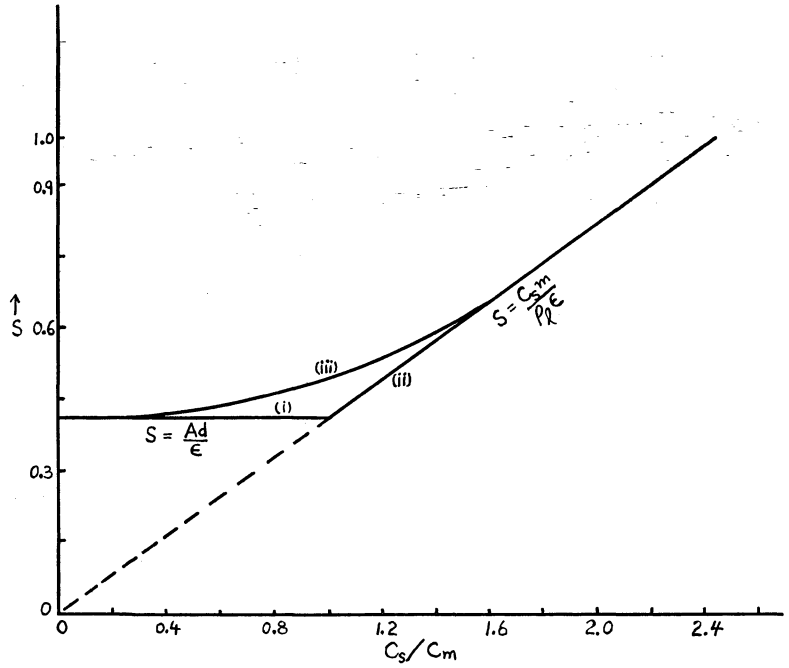

FIG. 1. The assumed variations of the fraction of saturation of the pore space below monolayer coverage (line (i)) and above monolayer coverage (line (ii)). Curve (iii) may represent behavior such as would be actually encountered.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

In the region of applicability of eq. [20] $S\epsilon = Ad$ is a constant in eqs. [17] and [18]. When eq. [22] is valid, however, its substitution in eqs. [17] and [18] gives

$$[23] \qquad l\frac{dJ}{d[p_g]_{x=0}} = \left[\lambda_s \frac{C_s}{C_g'} + \left(\epsilon - \frac{C_s m}{\rho_l}\right)\lambda_g\right]_{x=0} N_0 = [K_D]_{x=0}$$

$$[24] \qquad l\frac{dJ}{d[C_g']_{x=0}} = \left[\lambda_s \frac{C_s}{C_g'} + \left(\epsilon - \frac{C_s m}{\rho_l}\right)\lambda_g\right]_{x=0} RT = [D]_{x=0}.$$

As the pore space fills, $(\epsilon - (C_s m)/\rho_l)$ approaches zero, and finally

$$[25] \qquad l\frac{dJ}{d[p_g]_{x=0}} \rightarrow \left[\frac{C_s}{C_g'}\lambda_s\right]_{x=0} N_0 = \left[\frac{S\epsilon\rho_l}{mC_g'}\lambda_s\right]_{x=0} N_0 = \left[K_D\right]_{x=0}.$$

This behavior further identifies the hydrodynamic term.

In their expression for transport Gilliland, Baddour, and Russell (2) followed Babbit (3) in that the driving force was regarded as the negative of the gradient of surface pressure rather than of chemical potential. In terms of adsorption thermodynamics (Hill (4); Everett (5))

$$[25a] \qquad d\mu_s = -S_s dT + V_s dp_g + A_s d\phi$$

so that in an isothermal system

$$[25b] \qquad \frac{d\mu_s}{dx} = V_s \frac{dp_g}{dx} + A_s \frac{d\phi}{dx}$$

where S_s, V_s, and A_s are the molar entropy, volume, and surface area of the adsorbate regarded as a single pure component phase. Flood (1) on the other hand considered the driving force to be proportional to $-dP_s/dx$ where the pressure, P_s, is defined by eq. [3]. However, in these expressions, V_s and A_s may be and usually are functions of p_g (or of amount sorbed). Moreover a limitation of these approaches is seen further when the temperature is not constant. The forces in the irreversible thermodynamic formulation are still clearly defined (De Groot (6)) as $-T\{d(\mu/T)/dx\}$ and $-(1/T)(dT/dx)$ in the flux equations such as

$$[25c] \qquad J_g = -\left\{\lambda_{11}{}^g C_g \cdot T\frac{d}{dx}(\mu_g/T) + \lambda_{12}{}^g C_g \frac{1}{T}\frac{dT}{dx}\right\}$$

where $\lambda_{12}{}^g$ is the cross-coefficient and $\lambda_{11}{}^g$ is the same as λ^g.

Blockage of the gas phase flux is also involved through the term $(\epsilon - C_s m/\rho)$. So long as there is any pore space unfilled there will be some vapor transport across it. This blockage will not in general be that measured by using an indicator gas non-sorbed and insoluble in the sorbate film, as was done by Ash, Barrer, and Pope (7), because towards such an indicator gas the pore system can become sealed by capillary condensate in bottle-necks while there still remains some pore volume unfilled by condensate. The present formulation is for the total flux in the gas phase (per cm² normal to the direction of flow) and for the reason given in the previous sentence is greater than that measured by the use of an indicator gas. The use either of a non-sorbed calibrating gas flowing through the sorbate-free medium (e.g. Barrer and Gabor (8)), or of the non-sorbed indicator gas (Ash, Barrer, and Pope (7)), leads to coefficients K_D and D for the combined or two-phase flow differently related to the terms of eqs. [12] or [15] (Barrer and Gabor (9)).

In the very dilute region of adsorption where Henry's law is valid, C_s/C_g' has its maximum value of $(Ak_s+S\epsilon)$, where k_s is the Henry's law constant. C_s denotes the total number of molecules in the adsorbed layer; this number exceeds that normally measured in a sorption experiment by $S\epsilon C_g'$. Accordingly $C_s/C_g' = AC_s'/C_g' + S\epsilon$ where C_s' is the measured surface excess in molecules per cm² of surface. In the Henry's law region, $k_s = C_s'/C_g'$. Above the monolayer coverage, from eq. [22],

$$[26] \qquad A\frac{C_s'}{C_g'}\frac{\rho_1}{(\rho_1-\rho_g)} = \frac{C_s}{C_g'}$$

where ρ_g is the density of the gas phase in equilibrium. In many cases $A(C_s'/C_g') \gg S\epsilon$ and the distinction between the surface excess per unit area and the *total* number of molecules in the sorbed phase per unit area is negligible. In microporous media of high area and low porosity one may find that $S\epsilon = Ad$ represents nearly all the pore space. This implies that there is little gas phase flow, and is a state which is approached by some active carbons well compacted into plugs and which is reached for the internal porosity of molecular sieve zeolites.

The rate of decline of $(\epsilon - C_s m/\rho_1)$ towards zero in eqs. [23] and [24], as p_g increases, is determined by the isotherm type in Brunauer's classification (Fig. 2). Equally interesting

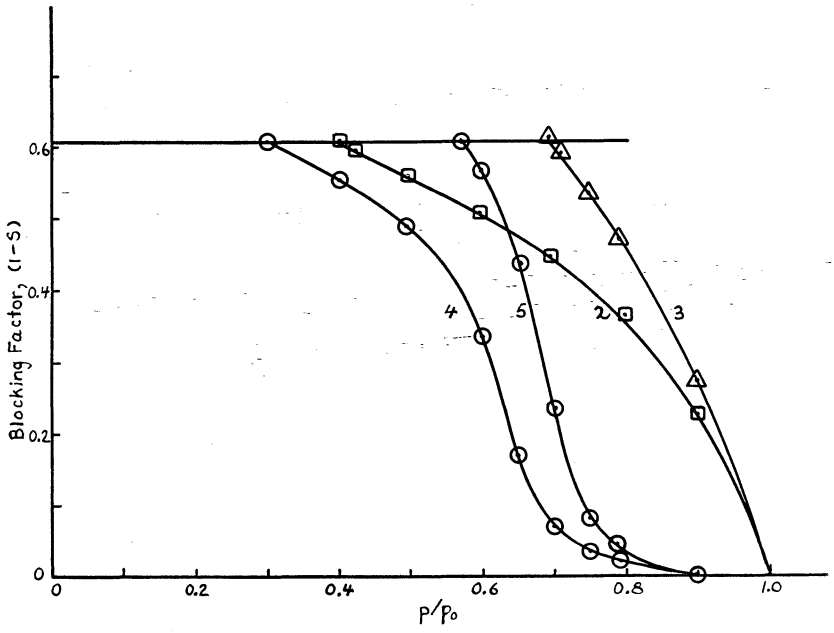

FIG. 2. The blockage factor $(\epsilon - C_s m/\rho_1)$ above monolayer coverage for isotherms of Types 2, 3, 4, and 5 in Brunauer's classification. Curves 2, 3, 4, and 5 correspond respectively to the isotherms 2, 3, 4, and 5 of Fig. 3. Monolayer coverage is taken as 78 cm³ at s.t.p. per cm³ of porous medium for isotherms 2 and 3 and as 70 cm³ at s.t.p. per cm³ for isotherms 4 and 5.

is the change in C_s/C_g' for various types of isotherm. This change is illustrated in Fig. 3. For Type I isotherms C_s/C_g' decreases continually, but for Type II isotherms this ratio may pass through a minimum, and for those of Type IV, may go through a minimum and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

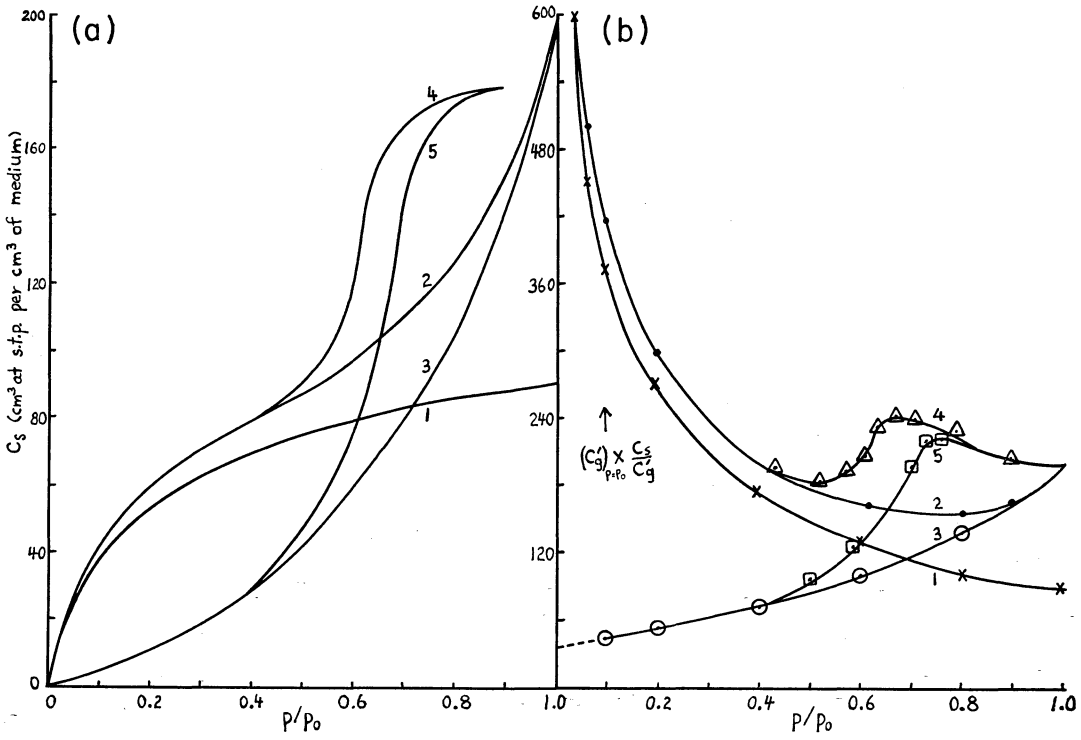

FIG. 3. (*a*) The isotherms of Types 1 to 5 in Brunauer's classification used to calculate the blockage factors of Fig. 2, and the ratios $(C_s/C_g')\times(C_g')_{p=p_0}$ in Fig. 3(*b*).
(*b*) The concentration dependence of the ratios $(C_s/C_g')\times(C_g')_{p=p_0}$ for the isotherms 1 to 5 in Fig. 3(*a*).

a maximum. In the case of Type III isotherms, C_s/C_g' increases continuously, and with those of Type V this quotient increases to a maximum and then decreases.

5. STEADY STATE DISTRIBUTION FOR DILUTE ADSORBED FILMS ($S\epsilon$ = CONSTANT)

For the purposes of Sections 5 and 6 it is convenient to transcribe the flux equations into the notation of Fick's law. Eq. [10] can be rewritten as

$$[27] \qquad J = -\left[\lambda_s RT \frac{d \ln C_g'}{d \ln C_s}\frac{dC_s}{dx} + (1-S)\epsilon RT\lambda_g \frac{dC_g'}{dx}\right]$$
$$= -\left[D_s \frac{dC_s}{dx} + (1-S)\epsilon D_g \frac{dC_g'}{dx}\right]$$

where the surface diffusion coefficient $D_s = \lambda_s RT(d \ln C_g'/d \ln C_s)$ and the gas phase diffusion coefficient $D_g = \lambda_g RT$. If there is no blockage and slip flow is occurring, $D_g = D_g^0(1+(D_p/D_g^0)C_g')$, where D_g^0 is the Knudsen flow diffusion coefficient and D_p is the coefficient appropriate for Poiseuille flow. Then

$$[28] \qquad Jx = -\int D_s dC_s - \int (1-S)\epsilon D_g dC_g' + B$$

where B is a constant. Also, we may set

$$[29] \qquad D_s = D_0(1+f(C_s))$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

so that provided we are in the dilute range of the adsorption (below monolayer coverage), in absence of blocking, and for slip-flow

$$[30] \qquad Jx = -\left\{D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right\}+B$$

where $F(C_s) = \int f(C_s)dC_s$. When $x = l$, since C_s and C_g' are both very small at $x = l$, Henry's law should be valid, $f(C_s) \to 0$, and the Poiseuille term becomes negligible, giving

$$[31] \qquad Jl = -[D_0C_s+(1-S)\epsilon D_g^{\,0}C_g']_{x=l}+B.$$

When $x = 0$, $Jx = 0$ and so B is evaluated as

$$[32] \qquad B = \left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=0}.$$

Thus, finally,

$$[33] \qquad \frac{x}{l} = \left\{\left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=0} - \left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=x}\right\}$$
$$\div\left\{\left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=0} - [D_0C_s+(1-S)\epsilon D_g^{\,0}C_g']_{x=l}\right\}.$$

If, at $x = l$, C_s and C_g' are negligible compared with their values at $x = 0$, then eq. [33] reduces to

$$[34] \qquad 1-\frac{x}{l} = \frac{\left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=x}}{\left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=0}}.$$

6. RELATION BETWEEN THE STEADY STATE DISTRIBUTION FOR DILUTE FILMS, AND $D_s = D_0(1+f(C_s))$

If we differentiate eq. [34] with respect to x we obtain

$$[35] \qquad J = \frac{\left[D_0(C_s+F(C_s))+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{2D_g^{\,0}}C_g'\right)C_g'\right]_{x=0}}{l}$$
$$= -\left[D_0(1+f(C_s))\frac{dC_s}{dC_g'}+(1-S)\epsilon D_g^{\,0}\left(1+\frac{D_p}{D_g^{\,0}}C_g'\right)\right]\frac{dC_g'}{dx}$$

while, at $x = l$, if Henry's law obtains, and molecular streaming is occurring in the gas phase,

$$[36] \qquad J = -\left\{\left[D_0(Ak_s+S\epsilon)+(1-S)\epsilon D_g^{\,0}\right]\frac{dC_g'}{dx}\right\}_{x=l}.$$

Two possibilities now arise:

(i) J_s and J_g are each constant between $0 < x < l$.
(ii) There is interconversion of fluxes J_s and J_g in this range.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

When J_g is measured using a non-sorbed calibrating gas then condition (i) must necessarily be met, in an unblocked medium. This condition is also satisfied when J_g is measured using the calibrating gas as an indicator admixed with the sorbable gas, which partially blocks the medium. However, J_s (derived from J and J_g) is in both circumstances partly in the gas phase (Barrer and Gabor (9)) so that as noted previously D_s and D_g have here meanings different from those in eqs. [27] to [36].

If J_s and J_g are each constant over all x, we find

$$[37] \qquad \left(\frac{dC_g'}{dx}\right)_{x=l} \Big/ \left(\frac{dC_g'}{dx}\right)_{x=0} = \left(1 + \frac{D_p}{D_g^0} C_g'\right)_{x=0}$$

and by equating the terms for J_s in [35] and [36] we obtain (cf. Barrer (10))

$$[38] \qquad D_s = D_0(1+f(C_s))_{x=0} = D_0(Ak_s+S\epsilon)\left[\left(1 + \frac{D_p}{D_g^0} C_g'\right)\frac{dC_g'}{dC_s}\right]_{x=0}$$

$$= D_0(Ak_s+S\epsilon)\left[\left(1 + \frac{D_p}{D_g^0} C_g'\right)\frac{1}{A\dfrac{dC_s'}{dC_g'} + S\epsilon}\right]_{x=0}$$

where C_s' is the number of molecules adsorbed per cm^2 of surface. If there is only Knudsen flow in the gas phase then D_p in eq. [38] is zero.

When interconversion of fluxes occurs the theorem embodied in eq. [38] must be reformulated as follows. $(dC_g'/dx)_{x=l}$ can be evaluated from eq. [36], since J is known, and since D_g^0, D_0, and Ak_s can be evaluated from low-pressure flow and sorption data (Section 9). The ratio

$$[39] \qquad \left(\frac{dC_g'}{dx}\right)_{x=0} \Big/ \left(\frac{dC_g'}{dx}\right)_{x=l} = \phi = \frac{[D_0(Ak_s+S\epsilon)+(1-S)\epsilon D_g^0]_{x=l}}{\left[D_0(1+f(C_s))\dfrac{dC_s}{dC_g'} + (1-S)\epsilon D_g^0\left(1 + \dfrac{D_p}{D_g^0} C_g'\right)\right]_{x=0}}.$$

By rearrangement this equation gives

$$[40] \qquad \left\{D_0(1+f(C_s))\frac{dC_s}{dC_g'}\right\}_{x=0} = \left[\frac{D_0(Ak_s+S\epsilon)+(1-S)\epsilon D_g^0}{\phi}\right]_{x=l} - \left[(1-S)\epsilon D_g^0\left(1 + \frac{D_p}{D_g^0} C_g'\right)\right]_{x=0}.$$

7. STEADY STATE DISTRIBUTION WITH C_s ABOVE MONOLAYER VALUE AT $x = 0$

We may start with eq. [28], and proceed as previously, but recall that $S\epsilon$ is now proportional to C_s at $x = 0$ and also for other intermediate values of x. This leads to the steady state distribution

$$[41] \qquad \frac{x}{l} = \left\{\left[D_0(C_s+F(C_s))_{x=x} + \int_0^{(C_g')_{x=x}} (1-S)\epsilon D_g dC_g'\right] - \left[D_0(C_s+F(C_s))_{x=0} + \int_0^{(C_g')_{x=0}} (1-S)\epsilon D_g dC_g'\right]\right\} \div \left\{\left[D_0C_s+(1-S)\epsilon D_g^0 C_g'\right]_{x=l} - \left[D_0(C_s+F(C_s))_{x=0} + \int_0^{(C_g')_{x=0}} (1-S)\epsilon D_g dC_g'\right]\right\}$$

where, in the slip-flow region, $D_g = D_g^0(1+(D_p/D_g^0)C_g')$. Again, where C_s, C_g' are small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

enough at $x = l$, the first term in the denominator is negligible compared with the second, and so

$$[42] \qquad 1 - \frac{x}{l} = \frac{D_0(C_s + r'(C_s))_{x=x} + \int_0^{(C_g')_{x=x}} (1-S)\epsilon D_g dC_g'}{D_0(C_s + F(C_s))_{x=0} + \int_0^{(C_g')_{x=0}} (1-S)\epsilon D_g dC_g'}.$$

Alternatively eq. [42] may be written

$$[43] \qquad \left(1 - \frac{x}{l}\right) = \frac{\int_0^{(C_g')_{x=x}} \left[\nu_0(1+f(C_s))\frac{dC_s}{dC_g'} + (1-S)\epsilon D_g{}^0\left(1 + \frac{D_p}{D_g{}^0} C_g'\right)\right] dC_g'}{\int_0^{(C_g')_{x=0}} \left[D_0(1+f(C_s))\frac{dC_s}{dC_g'} + (1-S)\epsilon D_g{}^0\left(1 + \frac{D_p}{D_g{}^0} C_g'\right)\right] dC_g'}.$$

Differentiating with respect to x gives

$$[44] \qquad J = \frac{1}{l}\int_0^{(C_g')_{x=0}} \left[D_0(1+f(C_s))\frac{dC_s}{dC_g'} + (1-S)\epsilon D_g{}^0\left(1 + \frac{D_p}{D_g{}^0} C_g'\right)\right] dC_g'$$

$$= -\left[D_0(1+f(C_s))\frac{dC_s}{dC_g'} + (1-S)\epsilon D_g{}^0\left(1 + \frac{D_p}{D_g{}^0} C_g'\right)\right]\frac{dC_g'}{dx}.$$

Also, at $x = l$, assuming Henry's law and Knudsen flow at this point, and that $f(C_s)$ here consequently tends to zero, one recovers eq. [36]:

$$[36] \qquad J = -\left[\{D_0(Ak_s + S\epsilon) + (1-S)\epsilon D_g{}^0\}\frac{dC_g'}{dx}\right]_{x=l}.$$

With $(dC_g'/dx)_{x=0}/(dC_g'/dx)_{x=l} = \phi$, as before, one obtains as the expression for the concentration dependence of D_s:

$$[45] \qquad \left[D_0(1+f(C_s))\frac{dC_s}{dC_g'}\right]_{x=0} = \frac{1}{\phi}[D_0(Ak_s + S\epsilon) + (1-S)\epsilon D_g{}^0]_{x=l}$$

$$-\left[\left(\epsilon - \frac{C_s m}{\rho_1}\right) D_g{}^0\left(1 + \frac{D_p}{D_g{}^0} C_g'\right)\right]_{x=0}.$$

8. FLUX INTERCONVERSION

It has been observed that, in a medium in which, according to helium flow measurements, only Knudsen flow was taking place in the gas phase, the permeability K for adsorbed vapors may increase with p_g (Ash, Barrer, and Logan (11)). The permeability K is defined as $K = Jl/[p_g]_{x=0}$ where J refers to unit cross section of the porous medium. On the basis of these experiments it was observed that

$$[46] \qquad \frac{Jl}{[p_g]_{x=0}} = K_0\{1 + \beta[p_g]_{x=0}\}$$

so that multiplying by p_g and differentiating with respect to p_g one has

$$[47] \qquad l\frac{dJ}{d[p_g]_{x=0}} = K_0\{1 + 2\beta[p_g]_{x=0}\}.$$

$l\{dJ/d[p_g]_{x=0}\}$ is, however, given by eq. [17], and combining this with eq. [13] leads to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[48] \qquad \left[\frac{dp_g}{dx}\right]_{x=0} = -\frac{J}{l}\frac{d[p_g]_{x=0}}{dJ} = -\frac{1}{l}\frac{d[p_g]_{x=0}}{d\ln J}$$

so that from a plot of p_g vs. $\ln J$ we can easily find $[dp_g/dx]_{x=0}$ as a function of $[p_g]_{x=0}$. Thus, in the systems considered,

$$[49] \qquad -\left[\frac{dp_g}{dx}\right]_{x=0} = \frac{[p_g]_{x=0}}{l}\left\{\frac{1+\beta[p_g]_{x=0}}{1+2\beta[p_g]_{x=0}}\right\}.$$

When surface flux is progressively transformed into gas phase flux as x increases we expect $-[dp_g/dx]_{x=0}$ to fall below and $-[dp_g/dx]_{x=l}$ to rise above the 'ideal' gradient $[p_g]_{x=0}/l$ for Knudsen flow. That is, in the absence of such interconversion, β should become zero, giving the 'ideal' gradient. The results expressed in eq. [49] therefore indicate interconversion of flows. Evidence obtained in these laboratories has shown flux interconversion for hydrocarbons in cracking catalyst plugs (Ash, Barrer, and Logan (11)) and for sulphur dioxide in carbon plugs (Ash, Barrer, and Pope (7)). There is no flux interconversion when Henry's law expresses the adsorption isotherm, nor in the region of still dilute adsorbed films outside the Henry's law range (Barrer and Strachan (12); Aylmore and Barrer (13), for various gases in carbon plugs).

9. ESTIMATION OF λ_s AND λ_g

The determination of λ_s and λ_g is not simple, because, as noted in Section 4, there are limitations in the use of helium as a non-sorbed calibrating gas to measure λ_g. In Section 8 it was also pointed out that according to our experiments $dJ/d[p_g]_{x=0}$ remains constant over a range of values of C_s appreciably outside the Henry's law range, and that then there is no interconversion of the fluxes J_s and J_g as x increases. In absence of flux interconversion and in the region of Knudsen flow in the gas phase, the relation of eq. [38] between D_s and isotherm curvature becomes

$$[38a] \qquad D_s = D_0(Ak_s+S\epsilon)\frac{dC_g'}{dC_s}.$$

The relation $D_s = \lambda_s RT(d\ln C_g'/d\ln C_s)$ can then be combined with eq. [38a] to give

$$[50] \qquad \lambda_s\frac{C_s}{C_g'} = \frac{D_0(Ak_s+S\epsilon)}{RT}$$

so that under these conditions the quotient $\lambda_s(C_s/C_g')$ is a constant. Accordingly in absence of flux interconversion each term in the relation

$$\frac{l}{N_0}\frac{dJ}{d[p_g]_{x=0}} = \left[\lambda_s\frac{C_s}{C_g'} + \lambda_g(1-S)\epsilon\right]_{x=0}$$

is separately constant. The intrinsic concentration dependence of λ_s is then that of the ratio C_g'/C_s, but the absolute value of λ_s (or of λ_g) cannot be obtained from the above argument. Two possible procedures are indicated below.

(a) λ_s in the Henry's Law Range

In this range the treatment of Barrer and Gabor (9) may lead to an estimate of λ_s. In their notation

$$[51] \qquad D_{ss}^* = \frac{D_{ss}}{(1-X)-X(J_s/J_g)_{\text{He method}}}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

where $(J_s/J_g)_{\text{He method}}$ is the ratio of the surface flux to gas flux as found by the use of a non-sorbed indicator gas (Section 4) together with the flowing adsorbed gas (Ash, Pope, and Barrer (7)). X is the fraction of the plug length, or of the cross section A_c, along which or through which respectively the molecules comprising J_s are in the gas phase. Accordingly $(1-X)$ can be taken as a measure of the ratio J_s'/J_s where J_s' is now the flux which is only in the surface and J_s is the "surface" flux measured by means of the indicator gas and which is partly in the gas phase as noted above. D_{ss} is the steady state "surface" diffusion coefficient corresponding to J_s, and D_{ss}^* is this coefficient for an unbroken surface in which molecules comprising J_s are not involved in evaporative flights across cracks and blind pores. The physics of this situation has been described by Barrer and Gabor (9).

Different values of X are then tried in the eq. [51], and values of D_{ss}^* to correspond evaluated. For a given X, log D_{ss}^* is then plotted against $1/T$ to determine the Arrhenius energy of activation, E. The correct value of X is taken to be that for which $E/\Delta E$ lies between about 0.25 and 0.5. The ratio $E/\Delta E$ approaches the critical range of $E/\Delta E$ very sharply, i.e. over a narrow range of values of X, which is thus obtainable within a reasonable margin. Accordingly from $(1-X) = J_s'/J_s$ one may estimate J_s', and hence λ_s from

$$J_s' = \lambda_s \frac{C_s}{C_g'} N_0 \frac{[p_g]_{x=0}}{l} \qquad [52]$$

since $[p_g]_{x=l} \to 0$. The above expression is valid if unblocked Knudsen flow occurs in the gas phase.

(b) λ_g in the Absence of Flux Interconversion

If helium (or hydrogen) is used as a non-sorbed indicator gas along with the flowing adsorbed gas we may approximate to λ_g for not too large adsorptions. For the two gases we have, at any cross section

$$J_g = -\lambda_g(1-S)\epsilon RT\frac{dC_g'}{dx} = -D_g'\frac{dC_g'}{dx} \qquad [53]$$

$$J_g^{He} = -\lambda_g^{He}(1-S\theta)\epsilon RT\left(\frac{dC_g'}{dx}\right)^{He} = -(D_g^{He})'\left(\frac{dC_g'}{dx}\right)^{He}$$

where θ denotes the fraction of a monolayer covered by the adsorbed gas. The linear decrease in the product $\lambda_g^{He}(1-S\theta)$ corresponds quite well with the reduction in permeability of hydrogen as an indicator gas in admixture with SO_2 in carbon plugs (Ash, Barrer, and Pope (7)) in the pre-monolayer adsorption range. On the other hand the adsorption volume $S\epsilon = Ad$ is constant for the adsorbed gas in this range (eq. [19]). Then

$$\frac{D_g'}{(D_g^{He})'} = \frac{\lambda_g(1-S)}{\lambda_g^{He}(1-S\theta)}. \qquad [54]$$

As $\theta \to 0$

$$\frac{D_g'}{(D_g^{He})'} = \frac{\lambda_g(1-S)}{\lambda_g^{He}} = \sqrt{(M_{He}/M)}\cdot(1-S) \qquad [55]$$

and as $\theta \to 1$

$$\frac{D_g'}{(D_g^{He})'} = \frac{\lambda_g}{\lambda_g^{He}} \sim \sqrt{(M_{He}/M)}. \qquad [56]$$

This latter relation may serve to derive λ_g, but only provided that the pore geometry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

plays the same role for the indicator gas at $\theta = 1$ as for the adsorbed gas. The relation as $\theta \rightarrow 0$ may be the more useful. Once λ_g is known, λ_s follows from the relation

$$\frac{l}{N_0}\frac{dJ}{d[p_g]_{x=0}} = \left(\lambda_s\frac{C_s}{C_g} + \lambda_g(1-S)\epsilon\right)_{x=0}.$$

10. TWO-PHASE FLOW OF TWO ADSORBED COMPONENTS IN A MIXTURE

This important problem relates directly to the separations possible for binary (or more complex) mixtures by flow through micropore systems. Such separations are attracting increasing attention, and can be remarkably effective (Kammermeyer and Wyrick (14); Ash, Barrer, and Pope (7)). Both components are present in each phase (vapor and adsorbed). The nomenclature is modified for convenience, 1 and 2 as subscripts denoting quantities related to species 1 and 2 respectively, while the superscripts s and g denote surface and gaseous phases. In the plane at x, normal to flow, equilibrium is assumed for distribution of the components between each phase:

$$[57] \qquad \begin{aligned} \mu_1^s &= \mu_1^g; & \mu_2^s &= \mu_2^g \\ d\mu_1^s &= d\mu_1^g & d\mu_2^s &= d\mu_2^g. \end{aligned}$$

In the steady state of flow

$$[58] \qquad \begin{aligned} J_1 &= J_1^s + J_1^g \\ J_2 &= J_2^s + J_2^g \end{aligned}$$

where J_1 and J_2 are independent of x. For these flows

$$[59] \qquad \begin{aligned} J_1^s &= S\epsilon(\lambda_{11}^s X_1^s + \lambda_{12}^s X_{21}^s) \\ J_2^s &= S\epsilon(\lambda_{22}^s X_2^s + \lambda_{12}^s X_{12}^s) \\ J_1^g &= (1-S)\epsilon(\lambda_{11}^g X_1^g + \lambda_{12}^g X_{21}^g) \\ J_2^g &= (1-S)\epsilon(\lambda_{22}^g X_2^g + \lambda_{12}^g X_{12}^g) \end{aligned}$$

where the X's denote forces and the λ's are the relevant phenomenological coefficients. The λ_{12} are the cross-coefficients, and in the formulation, although this is not essential, Onsager's reciprocal relations have been assumed. For the forces X we now have:

$$[60] \qquad \begin{aligned} X_1^s &= -\frac{C_1^s}{S\epsilon}\frac{d\mu_1^s}{dx}; & X_{21}^s &= -\frac{C_1^s}{S\epsilon}\frac{d\mu_2^s}{dx} \\ X_2^s &= -\frac{C_2^s}{S\epsilon}\frac{d\mu_2^s}{dx}; & X_{12}^s &= -\frac{C_2^s}{S\epsilon}\frac{d\mu_1^s}{dx} \\ X_1^g &= -\frac{C_1^g}{(1-S)\epsilon}\frac{d\mu_1^g}{dx}; & X_{21}^g &= -\frac{C_1^g}{(1-S)\epsilon}\frac{d\mu_2^g}{dx} \\ X_2^g &= -\frac{C_2^g}{(1-S)\epsilon}\frac{d\mu_2^g}{dx}; & X_{12}^g &= -\frac{C_2^g}{(1-S)\epsilon}\frac{d\mu_1^g}{dx}. \end{aligned}$$

Then, taking the flow of species 1 as an example

$$[61] \qquad J_1 = S\epsilon(\lambda_{11}^s X_1^s + \lambda_{12}^s X_{21}^s) + (1-S)\epsilon(\lambda_{11}^g X_1^g + \lambda_{12}^g X_{21}^g)$$

so that, substituting for the forces from eq. [60], utilizing eq. [57], and integrating from $x = 0$ to $x = l$, one obtains

$$[62] \qquad J_1 l = \int_{\mu_l^g}^{\mu_0^g} \left\{(\lambda_{11}^s C_1^s + \lambda_{11}^g C_1^g) + (\lambda_{12}^s C_1^s + \lambda_{12}^g C_1^g)\frac{\partial\mu_2^g/\partial x}{\partial\mu_1^g/\partial x}\right\} d\mu_1^g.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

On differentiating with respect to μ_1^g, and recalling that $(1-S)\epsilon(C_1^g)' = C_1^g$ (where $(C_1^g)'$ denotes the number of molecules of species 1 per cm³ of gas phase), one finds from eq. [62] that

$$[63] \qquad \frac{l}{N_0}\frac{dJ_1}{d[p_1^g]_{x=0}} = \left\{\left(\lambda_{11}\frac{C_1^s}{(C_1^g)'} + (1-S)\epsilon\lambda_{11}^g\right) + \left(\lambda_{12}^s\frac{C_1^s}{(C_1^g)'} + (1-S)\epsilon\lambda_{12}^g\right)\frac{\partial\mu_2^g/\partial x}{\partial\mu_1^g/\partial x}\right\}_{x=0}.$$

In the region of pressures where Knudsen flow occurs in the gas phase, and when there is no interconversion of fluxes

$$-\frac{d(C_1^g)'}{dx} = \frac{(C_1^g)'_{x=0}}{l}; \qquad -\frac{d(C_2^g)'}{dx} = \frac{(C_2^g)'_{x=0}}{l}$$

and so $(\partial\mu_2^g/\partial x)/(\partial\mu_1^g/\partial x) = 1$. Then

$$[64] \qquad \frac{l}{N_0}\frac{dJ_1}{d[p_1^g]_{x=0}} = \left\{(\lambda_{11}^s+\lambda_{12}^s)\frac{C_1^s}{(C_1^g)'} + (1-S)\epsilon(\lambda_{11}^g+\lambda_{12}^g)\right\}_{x=0}.$$

Expressions similar to eqs. [63] and [64] may be written for $(l/N_0)(dJ_2/dp_2^g)_{x=0}$, and all these may be further simplified if in addition Henry's law is valid for each constituent. Moreover, since molecule–molecule collisions are negligible when Knudsen flow occurs, λ_{12}^g may vanish. Then

$$[65] \qquad \frac{l}{N_0}\frac{dJ_1}{d[p_1^g]_{x=0}} = \{(\lambda_{11}^s+\lambda_{12}^s)(Ak_s+S\epsilon)+(1-S)\epsilon\lambda_{11}^g\}_{x=0}.$$

I wish to acknowledge various helpful discussions with Dr. L. A. G. Sylmore, now of the University of Perth, W. Australia, and with Mr. R. Ash, of this department.

INTERDIFFUSION IN THALLIUM AMALGAMS

W. T. FOLEY AND L. E. REID[1]
Department of Chemistry, St. Francis Xavier University, Antigonish, Nova Scotia
Received January 25, 1963

ABSTRACT

The interdiffusion coefficient of thallium in thallium amalgams was measured by the capillary reservoir technique. At 25° C the values of 10^5D in cm^2 sec^{-1} at 0.00365, 0.0536, 0.0895, 0.148, 0.188, 0.283, 0.323, and 0.404 mole fraction thallium were 1.08, 1.37, 1.50, 1.37, 1.14, 0.83, 0.95, and 1.11 respectively with standard deviations in 10^{-5}(cm^2 sec^{-1}) of 0.03, 0.06, 0.09, 0.10, 0.09, 0.08, 0.08, and 0.11 respectively. The minimum in the value of D at 0.288 mole fraction thallium shows that the compound Tl_2Hg_5 plays a significant role in the diffusion process. Values of $\partial \ln a/\partial \ln N$ for the thallium and for the compound were used to explain the dependence of D on the concentration.

This study of diffusion in thallium amalgams was undertaken because this unusual system is liquid at room temperature from 0 to 42 wt% thallium and because accurate thermodynamic data are available from the classic work of Richards and Daniels (1) on thallium amalgam concentration cells. For the concentration range 0.137–0.160 wt% thallium, von Wogau (2) reports that at 11.0–12.0° C the diffusion coefficient of thallium is 1.03×10^{-5} cm^2 sec^{-1}; and, for the concentration range 0.00216 to 0.00287 wt% thallium, Furnam and Cooper (3), from polarographic measurements at 25° C, found that the diffusion coefficient was 0.99×10^{-5} cm^2 sec^{-1}. Stromberg (4), from polarographic measurements on a 10^{-3} wt% amalgam, deduced a value of 1.60×10^{-5} cm^2 sec^{-1}.

The experimental method used was based on that employed by Anderson and Saddington (5) with the modification that a chemical rather than a radiochemical method of analysis was used. Fick's second law of diffusion for a one-dimensional system states that

$$\partial c/\partial t = D\cdot\partial^2 C/\partial x^2, \qquad [1]$$

where c is the concentration of the diffusing species, t is the time, and D is the diffusion coefficient with dimensions of area per unit of time. Consider a capillary of length l, with one end closed, having an initial concentration C_1 uniform throughout. Let the capillary be immersed in so large a volume of solution of composition C_∞ that at infinite time when diffusion is complete and the composition within the capillary and outside the capillary is the same the composition is still C_∞. The solution of equation [1] for time t under these circumstances is

$$\frac{C_{av}-C_\infty}{C_1-C_\infty} = \frac{8}{\pi^2}\sum_{n=0}^{n=\infty}\frac{1}{(2n+1)^2}\exp\left(\frac{2n+1}{2l}\right)^2\pi^2 Dt, \qquad [2]$$

where C_{av} is the average composition of the solution in the capillary at time t. The series on the right side of equation [2] is rapidly convergent.

In the derivation of equation [2] from equation [1] it was assumed that the diffusion coefficient is independent of the concentration. When the difference in concentrations of the two solutions is small, it may be assumed that the diffusion coefficient is constant. In this present work a chemical method of analysis was used to evaluate the terms on the left-hand side of equation [2] with the result that in both the numerator and the denomi-

[1]*Holder of National Research Council Bursary 1961–1962 and holder of National Research Council Studentship 1962–1963.*

nator there are small differences between large numbers. The success of the experiment depended upon having such a difference in concentration of the two solutions that the value for the left side of equation [2] would have accuracy, yet that the difference in concentration would not be so great as to render equation [2] inapplicable. The situation was not a happy one, but the results obtained for the concentration differences chosen are significant.

EXPERIMENTAL

The mercury used was purified by washing for long periods of time with dilute nitric acid while a stream of air was bubbled through it. After this treatment the metal was distilled. Thallium sulphate, which assayed 99.9%, was recrystallized once and the salt thus obtained was used to prepare the amalgams by electrolysis. The electrolyte was made 1 F with respect to sodium hydroxide and it contained hyrazine as an anodic depolarizaer. The metal was plated into the mercury at a controlled cathode potential of −0.53 v with respect to the standard hydrogen electrode. The normal reduction potential for lead in this electrolyte is −0.58 v so that there is no danger of lead being plated.

In a preliminary investigation of the diffusion coefficient, the more concentrated amalgam was placed in a 400-ml beaker and the amalgam was protected against corrosion by making it the cathode in an electrolysis cell. The electrolyte, which covered the amalgam to a depth of 1 inch, was 3% with respect to sodium sulphate and 1% with respect to hydrazine sulphate. A platinum anode, 2 cm^2 in area, dipped into the sulphate solution and the polarizing current of 5 ma was obtained by placing a 40,000-ohm resistor in series with the cell and a 200-v direct-current power supply. The diffusion cells, approximately 3 cm long and 1 mm in internal dimaeter, were made from pyrex capillary tubing of precision bore and the bottoms were made perfectly flat. A travelling microscope was used to measure the lengths of the capillaries. In an experiment, the beaker-reservoir was mounted on a stand in a constant-temperature bath regulated to 25±0.02° C. A capillary was filled with the less concentrated amalgam, and under a protecting atmosphere of carbon dioxide, this capillary was lowered into the reservoir until the top of the capillary was almost submerged into the amalgam. When it was felt that thermal equilibrium was reached, the capillary was lowered under the surface of the amalgam in the beaker and the time was noted. A stirrer, which rotated the capillary four times an hour in a circle with a radius of 1 inch, was attached to the capillary holder. An effort was made to have the average concentration of the amalgam in the capillary at the conclusion of a run about equal to the average of the initial concentration of the amalgam in the capillary and of the concentration of the amalgam in the reservoir; and, to that end, the diffusion was allowed to proceed for a period of from 20 to 60 hours. At the end of the run, the capillary was withdrawn, weighed, and its contents were removed with the aid of a centrifuge. The capillary was rinsed with dilute nitric acid which was then used to dissolve the amalgam. This solution was analyzed for thallium, and this result, along with a knowledge of the concentration of thallium in the two initial amalgams, the time t, and the capillary length l, was used in equation [2] to evaluate D.

The method used to analyze the amalgam was that described by Foley and Osyany (6), which method depends on the removal of mercury through the use of formic acid followed by the estimation of thallium by means of an iodate titration to an iodine monochloride end point. If the sample were micro or semi-micro, the thallium was estimated by coulometric titration with electrogenerated bromine in the manner described by Buck, Farrington, and Swift (7).

The procedure outlined above worked well only when mercury was used in the capillary. The apparatus shown in Fig. 1 was next adopted. In an experiment, vessel A was charged with the more dilute amalgam

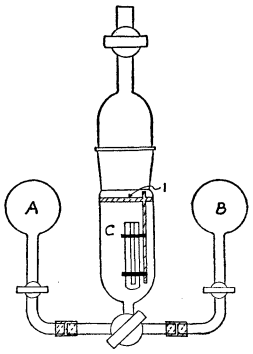

FIG. 1. Apparatus for diffusion measurements.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

under vacuum, and vessel B was charged with the more concentrated amalgam. The reaction vessel C was evacuated and the more dilute amalgam was admitted into C until the solution covered the capillary supported by the holder I. The stopcock joining A and C was closed and purified nitrogen gas was admitted into chamber C until the pressure was 1 atm. The gas was now pumped off and the amalgam, except for that which was in the capillary, was restored to vessel A. The apparatus was now transferred to the constant-temperature bath; and, when it was felt that thermal equilibrium was established, the more concentrated amalgam was admitted to chamber C until the capillary was covered. The stopcock joining B and C was closed and purified nitrogen gas was admitted until the pressure was 1 atm. At the end of the run, the amalgam was restored to vessel B and the capillary was removed and treated as described above.

Even though the reaction vessel was firmly clamped to a sturdy stand while it was in the water bath, the surface of the amalgam was never quiescent. It is important that the amalgam just above the top of the capillary be always of the same concentration as that of the whole reservoir. Some users of the capillary-reservoir technique, for example, Burkell and Spinks (8), have assumed that stirring is unnecessary to maintain this boundary condition. To determine whether a stirrer should be added to the apparatus of Fig. 1, 10 runs were made with mercury in the capillary and with the same concentration of amalgam in the reservoir as was used in the open-beaker method. The average diffusion coefficient and the standard deviation of the diffusion coefficients obtained in the two cases were the same, and it was thus concluded that the boundary conditions were being met.

EXPERIMENTAL RESULTS

The experimental results are given in Table I and they are also displayed in Fig. 2 by the plot of the experimental diffusion coefficient against the mean mole fraction for the concentration interval used.

TABLE I

Interdiffusion of thallium at 25° C

Mole fraction thallium		$D \times 10^5$	Std. Deviation $\times 10^5$	Number
Capillary	Reservoir	(cm^2 sec^{-1})	(cm^2 sec^{-1})	of runs
0	0.00710	1.08	0.028	20

0.388	0.420	1.11	0.110	8

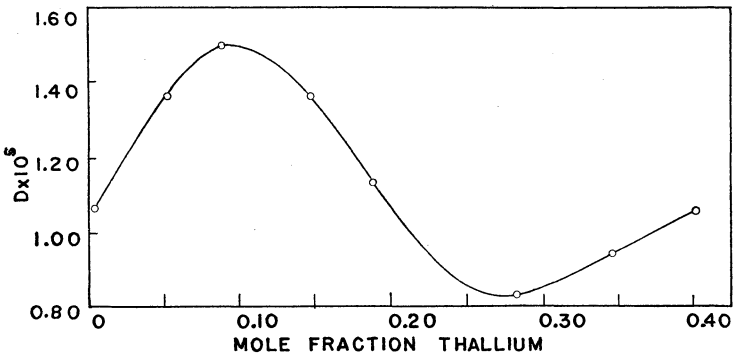

FIG. 2. Variation of D with concentration.

DISCUSSION

An understanding of the factors that determine the diffusion coefficient in a binary system would require a complete theory of the liquid state. With the information presently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

available it is possible to give a qualitative explanation of the experimental results obtained in the thallium mercury system. Jost (9) gives equation [3] below to express the dependence of the rate of change of concentration with time of a diffusing species:

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(\frac{cu}{N}\frac{\partial \mu}{\partial x}\right), \qquad [3]$$

where c = molar concentration, u = mobility of the diffusing particle per unit force, μ = chemical potential, and N = Avogadro's number. Introducing the activity a, we find

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left(D_0 \frac{\partial \ln a}{\partial \ln N_i}\frac{\partial c}{\partial x}\right), \qquad [4]$$

where $D_0 = ukT$ and $\partial \ln c = \partial \ln N_i$ and N_i is the mole fraction.

If we compare equations [1] and [4], we see that for non-ideal mixtures D should be replaced by

$$D = D_0 \frac{\partial \ln a}{\partial \ln N_i}.$$

The coefficient D_0, thus defined, is independent of deviations from ideal behavior, but it may still depend on concentration, since the mobility may depend on concentration.

The phase diagram for thallium and mercury (10) shows that at 28.95% thallium by weight there is a compound whose formula is Tl_2Hg_5. The electromotive force data of Richards and Daniels (1) were extrapolated to 14.9° C, the freezing point of the compound, and the activities of thallium and mercury were calculated from these extrapolated data for 14.9° C. The equilibrium constant for the chemical reaction leading to the formation of the compound is

$$K = (a_{Tl})^2 \times (a_{Hg})^5 / a_{Tl_2Hg_5}.$$

At 14.9° C and at 28.95% Tl the activity of the thallium is 1.92 and the activity of the mercury is 0.566. If we assume that at 14.9° C the activity of the compound is unity, the value of the equilibrium constant is about 0.2. At 25° C the activity of thallium in the amalgam increases very rapidly with increase of thallium content; but the activity of the mercury, on the other hand, more closely obeys the law of ideal solutions. This variation of activity with concentration may be accounted for by the fact that Tl_2Hg_5 removes from the solvent more mercury than thallium. The activity data at 325° C of Hildebrand and Eastman (11) show that the activity of thallium is so high in concentrated amalgams that one must conclude that the compound still exists in the liquid phase at this temperature. Hence, it is felt that the value of the equilibrium constant K will not change much when the temperature is raised from 14.9° C to 25° C and thus K is arbitrarily assigned a value of 0.2.

To account for the experimental curve of Fig. 2 values of $\partial \ln a/\partial \ln N$ were determined for thallium and for the compound Tl_2Hg_5. Richards and Daniels (1) obtained at 20° C and 30° C electromotive force data for concentration cells made up with a wide range of concentrations of thallium amalgams. These electromotive force data were interpolated to yield results valid for 25° C and the activities of mercury and thallium were calculated from these interpolated electromotive force data in the same manner as that described by Lewis and Randall (12). These activities are given in columns two and four of Table II. From a plot of log a_{Tl} against log N_{Tl} values of $\partial \ln a/\partial \ln N$ were obtained by measuring tangents to the curve. The results, shown in column three of Table II, reveal that $\partial \ln a/\partial \ln N$ increases very rapidly between mole fractions 0.005 and 0.10. This rise

TABLE II

Activities of Tl and Tl_2Hg_5 and values of $\partial \ln a/\partial \ln N$ at 25° C

N_1, mole fraction Tl	a_1, activity of thallium	$\frac{\partial \ln a_1}{\partial \ln N_1}$	a_2, activity of mercury	a_{12}, activity of compound	N_{12}, mole fraction Tl_2Hg_5	$\frac{\partial \ln a_{12}}{\partial \ln N_{12}}$
0.005	0.0052	1.06	0.994	1.32×10^{-4}	3.45×10^{-3}	2.60
0.010	0.012	1.10	0.988	6.78×10^{-4}	5.11×10^{-3}	2.60
0.020	0.026	1.21	0.979	3.03×10^{-3}	1.06×10^{-2}	2.50
0.040	0.092	1.41	0.967	3.39×10^{-2}	2.27×10^{-2}	2.40
0.050	0.100	1.50	0.945	3.77×10^{-2}	3.86×10^{-2}	2.35
0.080	0.190	1.65	0.895	1.03×10^{-1}	5.25×10^{-2}	2.25
0.10	0.240	1.70	0.852	1.27×10^{-1}	7.14×10^{-2}	2.00
0.15	0.570	1.85	0.770	5.60×10^{-1}	0.136	1.70
0.20	0.96	1.85	0.692	0.735	0.251	0.80
0.25	1.41	1.70	0.618	0.893	0.500	0.35
0.2875	1.76	1.70	0.572	0.948	1.00	0.00
0.35	2.42	1.65	0.493	0.839	0.590	−0.13
0.40	3.08	1.45	0.440	0.787	0.428	−0.62

accounts for the rapidly increasing values of D for the same concentration range because, as will be explained below, the rate of diffusion of the compound remains quite constant in this concentration interval.

To explain the minimum in the curve it was necessary to calculate the activity of the compound from the equilibrium constant and from the activities of mercury and thallium. These results are given in column five of Table II. In a manner similar to that described above values of $\partial \ln a/\partial \ln N$ were obtained for the compound and they are shown in column seven of Table II. The curve was parabolic so that $\partial \ln a/\partial \ln N$ falls to zero and then becomes negative. Between thallium mole fraction 0.08 and 0.2857 the tendency for the compound to diffuse falls steadily and the rate of diffusion of thallium atoms changes but little and this is reflected in the observed minimum in Fig. 2. For thallium mole fractions beyond 0.2857 the compound diffuses out of the capillary into the reservoir. The compound removes two and one-half times as much mercury as thallium so that the net result is an increase in the diffusion of thallium into the capillary. This is in contrast to the concentration range less than 0.2857 mole fraction because then the diffusion of the compound into the capillary increases the thallium content of the capillary.

Self-diffusion coefficients for thallium–mercury systems will be measured in this laboratory in the hope that further light will be shed on diffusion in these solutions.

ACKNOWLEDGMENT

Grateful acknowledgment is made by one of us, W. T. F., for a grant in aid of this research from the National Research Council of Canada.

ON THE RELATIONSHIP BETWEEN INTERNAL PRESSURE AND ULTRASONIC VELOCITY[1,2]

S. C. SRIVASTAVA[3] AND N. BERKOWITZ
Coal Research Division, Research Council of Alberta, Edmonton, Alberta
Received December 26, 1962

ABSTRACT

Because of the relevance of internal pressure data to sonochemical kinetics, some interest attaches to expressions which permit evaluation of P_i from readily available or easily measured quantities. One such expression is developed in this paper. It relates P_i to the velocity u of ultrasonic waves transmitted through the liquid and takes the form $u\sqrt{D} = K'\sqrt{(R_m)}P_i$, where K' is a constant proportional to $\sqrt{(C_p/C_v)}\sqrt{(1/RT)}$, and D and R_m denote the density and molar refraction of the liquid.

The utility of this expression is tested against some 100 liquids (including a few binary liquid mixtures and aqueous electrolyte solutions), and it is shown that the equation offers an acceptable and quite general method for calculating P_i.

I. INTRODUCTION

Despite a considerable literature, details of sonochemical decomposition reactions remain generally uncertain and often controversial. In the case of *large* molecules (m.w. > ca. 5000) it is, however, at least possible to clearly discern the major variables that affect such reactions: as a rule, their rates depend upon the size of the reacting species, upon the frequency and intensity of the sound waves, and upon the intensity of cavitation in the liquid reaction medium. Decomposition or depolymerization in the absence of cavitation* is now conceded to be minimal (2).

No such view can be taken of sonochemical reactions involving *small* molecules, e.g. partial dehalogenation of $CHCl_3$, CCl_4, or KI. In most, if not in fact all, such instances, sound frequency and intensity are somewhat irrevelant (except insofar as they affect cavitation); and while cavitation is as necessary a prerequisite as in the case of large molecules, cavitation intensities per se, no matter how these might be defined, exert only an indirect control over reaction rates. For example, while *aqueous solutions* of $CHCl_3$ and CCl_4 will liberate Cl_2 at frequencies and intensities as low as 10 kc/s and 2 w/cm^2 and do so at increasing rates as the cavitation intensity is raised, *pure* $CHCl_3$ or CCl_4 will not measurably decompose even when they are made to cavitate with greater intensity than their solution counterparts (3). The same is qualitatively true of dichloro- and diiodo-methane, ethyl chloride, and dichloro- and dibromo-ethane (4), and of CS_2 which *inter alia* yields elemental sulphur (5).

In the light of these findings—which may, however, gain undue prominence from the fact that no serious study has yet been made of non-aqueous solutions—it is tempting to regard sonochemical decompositions of small molecules as in reality initiated and sustained by a peroxide mechanism which, as a first step, involves

$$H_2O \rightleftharpoons OH + H \qquad (a)$$

$$2OH \rightleftharpoons H_2O_2. \qquad (b)$$

[1]*Contribution No. 203 from the Research Council of Alberta, Edmonton.*

**Cavitation can be virtually completely suppressed by thorough outgassing of the liquid reaction medium before exposure of the solution (or suspension) to the action of an ultrasonic field.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(That some such conversion actually occurs when water is exposed to ultrasonic sound seems to be fairly conclusively established; cf. ref. 6.) But two pieces of evidence combine to make this a doubtful contention: (1) there is no indication of *oxidative* breakdown when aqueous suspensions or solutions of polymers are ultrasonically degraded, and (2) experiments in these laboratories indicate that aqueous solutions of, say, CCl_4 will decompose with liberation of Cl_2 at frequencies ($<$20 kc/s) at which water itself forms little H_2O_2.*

A better approach is therefore to suppose that sonochemical decomposition of small molecules will occur whenever the internal pressure (P_i) of the reaction medium exceeds some critical threshold value and to associate effective rate control with energy releases resulting from the collapse of cavitational 'holes'. (Since the internal pressure of water is 3–5 times greater than that of $CHCl_3$, CCl_4, etc., such a view would qualitatively account for the behavior of pure compounds vis-a-vis their aqueous solutions and, at the same time, assign an appropriate role to the cavitation intensity.)

In the prevailing absence of sufficient (and acceptable) sonochemical kinetic data, the mechanism here postulated must, of course, remain purely speculative. But it should be observed that it would, if valid, make P_i a uniquely important parameter in sonochemistry. In 'steady state' cavitation, i.e. when the number of developing 'holes' equals the number of collapsing 'holes', the cavitation intensity can be quite properly expressed in terms of the corresponding liquid volume increment Δv; and since the work entailed in forming the 'holes' may then be put as proportional to $P_i \Delta v$, where

$$P_i \simeq T(\partial P/\partial T)_v \simeq (\partial E/\partial v)_T,$$

it follows that the maximum energy released by 'hole' collapse (and therefore available for sonochemical reaction) should be proportional to $\int_0^{\Delta v} (\partial E/\partial v)_T dv$.

II. THE FUNCTION $u = f(P_i)$

With these considerations in mind, some interest attaches to expressions which permit evaluation of P_i from readily available or easily measured quantities. Such expressions are, of course, perfectly well known in principle. But since they entail the use of frequently unreliable (7) thermal expansion or compressibility coefficients or the direct measurement of $(\partial P/\partial T)_v$, the alternatives developed (and explored) in this paper may be thought to offer a worthwhile simplification.

It should perhaps also be noted here that while the derivation of the final form (equation (ix)) involves a number of approximations that do not enter into other expressions for P_i, the actual errors introduced by them do not exceed the errors normally incurred when estimating P_i by the various alternative methods. It is therefore possible to regard these approximations (and their more obvious shortcomings) with some equanimity.

A convenient starting point for deriving the desired relationship is afforded by Van der Waal's equation of state

$$(P + a/v^2)(v-b) = RT, \qquad \text{(i)}$$

which, when differentiated with respect to v at constant temperature and then multiplied by v, yields

$$-v(\partial P/\partial v)_T + 2a/v^2 = vRT/(v-b)^2 \qquad \text{(ii)}$$

**No hydrogen peroxide could, under these conditions, be detected by methods whose detection limits were of the order of 10^{-4} to 10^{-6} mole/100 cc. The primary reaction step must therefore be assumed to be $CCl_4 \rightarrow CCl_3 + Cl$, followed by $2Cl \rightarrow Cl_2$ and $2CCl_3 \rightarrow C_2Cl_6$. (A solid, white precipitate possibly corresponding to this latter compound has, in fact, been observed.)*

whence

$$-v(\partial P/\partial v)_T + 2a/v^2 = vRT/(v-b) - RTb/(v-b)^2 + RTb/(v-b)^2$$
$$= RT/(v-b) + (b/RT)[R^2T^2/(v-b)^2] \quad \text{(iii)}$$

or, after substitution of terms from (i),

$$-v(\partial P/\partial v)_T = P - a/v^2 + (b/RT)[P+(a/v^2)]^2. \quad \text{(iv)}$$

Replacing $-(1/v)(\partial v/\partial P)_T$ by the isothermal compressibility β_{iso}, and making use of the observation (8, 9, 10) that many liquids obey $a/v^2 = (\partial E/\partial v)_T \simeq P_i$, equation (iv) becomes

$$1/\beta_{iso} \simeq P - P_i + (b/RT)(P+P_i)^2 \quad \text{(v)}$$

or, since $P \ll P_i$,

$$1/\beta_{iso} \simeq (b/RT)P_i^2 - P_i. \quad \text{(vi)}$$

And since $(b/RT)P_i^2 \gg P_i$, $\beta_{iso}/\beta_{adia} = C_p/C_v$, and $1/\beta_{adia} = u^2D$, where β_{adia} and D denote the adiabatic compressibility and density of the liquid, and u the velocity of ultrasonic waves transmitted through it, (vi) may be written as

$$u^2D \simeq (C_p/C_v)(b/RT)P_i^2 \quad \text{(vii)}$$

which, after putting $b = 4M/D$, where M = molecular weight, becomes

$$uD \simeq K\sqrt{(M)}P_i, \quad \text{(viii)}$$

where $K = \sqrt{(C_p/Cv)}\sqrt{(4/RT)}$. Alternatively, remembering that

$$b = f\left(\frac{4}{3}\pi Nr^3\right),$$

where the bracketed term denotes the actual (as opposed to the apparent) molecular volume/mole, and that

$$\frac{n_\infty^2 - 1}{n_\infty^2 + 2}\frac{M}{D} = \frac{4}{3}\pi Nr^3$$

equation (viii) can be written in the form

$$u\sqrt{D} \simeq K'\sqrt{(R_m)}P_i, \quad \text{(ix)}$$

where $K' = \sqrt{(C_p/C_v)}\sqrt{(k_0/RT)}$ and R_m = molar refraction. k_0 (contained in K', is the proportionality constant connecting b with the RHS of the molar refraction equation.

While the Van der Waal's equation is an admittedly poor approximation for liquids—and here only preferred because of its simplicity—equations (viii) and (ix) turn out to be quite useful.

Table I offers a test of (viii) and (ix) by listing values of K and K' for several classes of compounds for which the necessary data (i.e. values of u, D, R_m, and P_i) were available in the literature. The bracketed numbers in column A indicate the number of compounds in each class, while columns B and C list the calculated (weighted arithmetic mean) values of K and K' and the maximum deviations from these. In general, equation (ix) leads to slightly narrower error limits than (viii) and appears therefore to be somewhat more useful. But the intraclass variation of *either* K *or* K' is sufficiently small to permit evaluation of P_i with no greater uncertainty than attaches to its determination by other means.

TABLE I

Class		K		K'	
1. Paraffins	(13)	3.64	$^{+0.24}_{-0.27}$	7.52	$^{+0.17}_{-0.07}$
2. Monoolefins	(8)	3.93	$^{+0.46}_{-0.39}$	7.52	$^{+0.25}_{-0.28}$
3. Aromatic hydrocarbons	(6)	4.00	$^{+0.37}_{-0.19}$	7.13	$^{+0.18}_{-0.17}$
4. Nitro compounds	(4)	3.67	$^{+0.17}_{-0.50}$	6.73	$^{+0.09}_{-0.08}$
5. Aliphatic chlorides	(8)	3.87	$^{+0.19}_{-0.10}$	7.55	$^{+0.31}_{-0.18}$
6. Aromatic chlorides	(8)	3.82	$^{+0.04}_{-0.10}$	6.89	$^{+0.26}_{-0.29}$
7. Aliphatic bromides	(8)	3.58	to 5.02	6.14	to 8.81
8. Aliphatic iodides	(4)	3.76	$^{+0.11}_{-0.07}$	6.88	$^{+0.06}_{-0.16}$
9. Esters	(10)	3.76	$^{+0.20}_{-0.16}$	7.21	$^{+0.68}_{-0.90}$
10. Alcohols (cf. note A)	(13)	3.29	$^{+0.72}_{-1.05}$	6.55	$^{+1.28}_{-1.59}$
11. Monocarboxylic acids (cf. note B)	(6)	3.58	$^{+0.86}_{-0.65}$	6.74	$^{+1.72}_{-0.78}$

NOTE A: If MeOH is omitted because of its abnormalities in other respects (7), K and K' become, respectively, 3.39 (+0.62, −0.55) and 6.89 (+0.96, −0.88), i.e. K' obeys the generalization $K' = 7 \pm 1$.
NOTE B: If C_{17} is omitted and consideration confined to C_3 to C_7, the values of K and K' become, respectively, 3.40 (+0.07, −0.47) and 6.40 (+0.35, −0.44).

On the other hand, both K and K' are distinctly structure dependent (cf. interclass variation of these constants); and in several instances, both constants show a systematic and more or less regular increase when proceeding from one member of a homologous series to the next. For example, for six straight-chain monocarboxylic acids, K' increased from 5.96 for C_3 to 6.75 for C_7 and 8.46 for C_{17}, i.e. $\Delta K'$ decreased progressively as the chain length increased. But among monoolefins, K' increased from 7.23 for C_7 (1-heptene) to 7.77 for C_{16} (1-hexadecene) at $\Delta K' = 0.05$ per incremental carbon atom; and for three *n*-alkyl bromides covering the range from C_2 to C_8, K' increased linearly at $\Delta K' = 0.07$ per incremental C atom. These observations, and the fact that the inclusion of several homologous series in any one class can, as in the case of aliphatic bromides, lead to fairly wide and occasionally seemingly erratic variations in K and K', suggest that both constants may be markedly affected by polarity, association, and (perhaps) molecular packing.

III. THE TEMPERATURE DEPENDENCE OF P_i

If equation (ix) is written in the form

$$u\sqrt{D} \simeq \sqrt{(C_p/C_v)}\sqrt{(k_0/R)}\sqrt{(1/T)}\sqrt{(R_m)}P_i$$

and C_p/C_v assumed to be effectively temperature independent over the range encompassed by liquidity, K' resolves itself into two terms of which one is temperature insensitive and the other equal to $\sqrt{(1/T)}$. By putting $K'' = \sqrt{(k/T)}$, where k is the temperature-insensitive component of K' (and therefore uniquely determined if K' is known at any one temperature), the variation of P_i with temperature can consequently be estimated by means of

$$u\sqrt{D} \simeq K''\sqrt{(R_m)}P_i, \qquad (x)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where u, D, and R_m are the ultrasonic velocity, liquid density, and molar refraction at the particular temperature T at which P_i is to be evaluated.

Table II shows some results calculated from published values of u by means of equation (x); the second and fifth columns list values of P_i and the third and sixth the corresponding values of $(\partial P/\partial T)_v$, i.e. P_i/T_{abs}. While their accuracy cannot be directly checked, Table III (taken from Hildebrand *et al.* (8)) suggests that they are unlikely to be much in error.

TABLE II

Toluene			*p*-Xylene		
Temperature, °C	P_i, atm	$(\partial P/\partial T)_v$	Temperature, °C	P_i, atm	$(\partial P/\partial T)_v$
3.0	3056	11.07	2.3	2448	8.89
10.0	3021	10.67	10.0	2428	8.57
20.0	3000	10.24	18.0	2408	8.27
31.8	2968	9.76			

TABLE III

Values of $(\partial P/\partial T)_v$—after Hildebrand *et al.* (8)

	$(\partial P/\partial T)_v$ at:		
	20° C	25° C	35° C
n-Heptane	8.66	8.41	7.93
Carbon tetrachloride	11.47	11.22	10.33
Benzene	12.58	12.23	11.49
Acetone	11.72	11.22	10.33

IV. LIQUID MIXTURES AND SOLUTIONS

For simple binary mixtures, equations (ix) assumes the form

$$u_{12}\sqrt{D_{12}} \simeq (K_1'x_1+K_2'x_2)\sqrt{(R_m)_{12}}(P_i)_{12}, \qquad \text{(xi)}$$

where x_1 and x_2 denote the mole fractions of the two components and the subscript '12' refers to the mixture.

A test of this expression is contained in Table IV, in which values of P_i (computed from published data and equation (xi)) and of $(\partial P/\partial T)_v$ (calculated via (x)) are compared with corresponding values given by Hildebrand *et al.* (8). The agreement appears to be aceptable.

TABLE IV

Mixture	Mole fraction	From equation (xi)		From Hildebrand (8)	
		P_i, atm	$(\partial P/\partial T)_v$	P_i, atm	$(\partial P/\partial T)_v$
C_6H_6 in CCl_4; 20° C	0	3087	10.53	3360	11.47
	50	3271	11.16	3572	12.19
	100	3410	11.64	3686	12.58
n-C_7H_{16} in CCl_4; 20° C	50	2783	9.49	2836	9.68
	100	2179	7.43	2573	8.66
C_6H_6 in *n*-C_7H_{16}; 20° C	50	2587	8.83	2889	9.86

For *dilute* solutions, $(K_1'x_1+K_2'x_2)$ becomes effectively equal to K_1', i.e. to the value of K' for the solvent, and equation (xi) then reduces to

$$u_{12}\sqrt{D_{12}} \simeq K'\sqrt{(R_m)_{12}}(P_i)_{12}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

or

$$\simeq K'\sqrt{(R_m)_{12}}(P_i+\Delta P_i), \qquad \text{(xii)}$$

where P_i denotes the internal pressure of the solvent and $(P_i)_{12}$ that of the solution.

The major interest attaching to (xii) centers on the observation that for aqueous electrolyte solutions, ΔP_i turns out to be directly proportional to the osmotic pressure of the solution, and that π_{12} and the osmotic coefficient ϕ (the latter via (xiii)) can hence be estimated from a knowledge of u_{12}. Some examples of this proportionality between ΔP_i and π_{12} are shown in Figs. 1, 2, and 3. The values of π_{12} used in constructing these diagrams

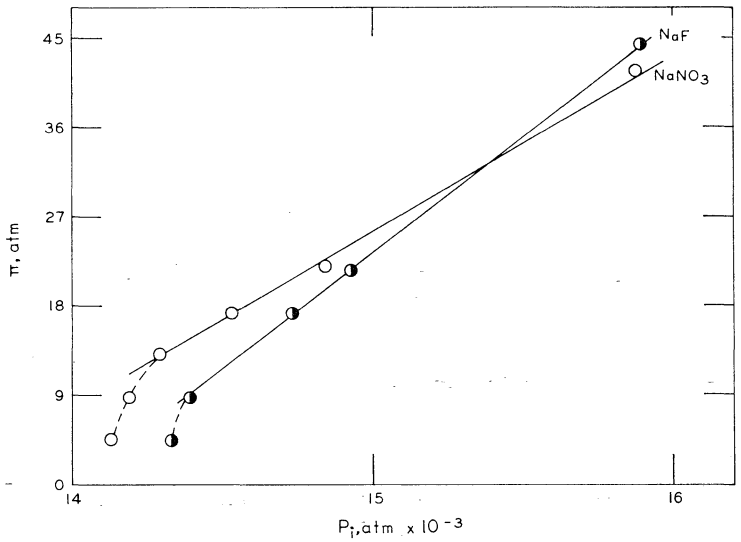

FIG. 1. Variation of osmotic pressure with internal pressure—aqueous solutions of NaF and $NaNO_3$.

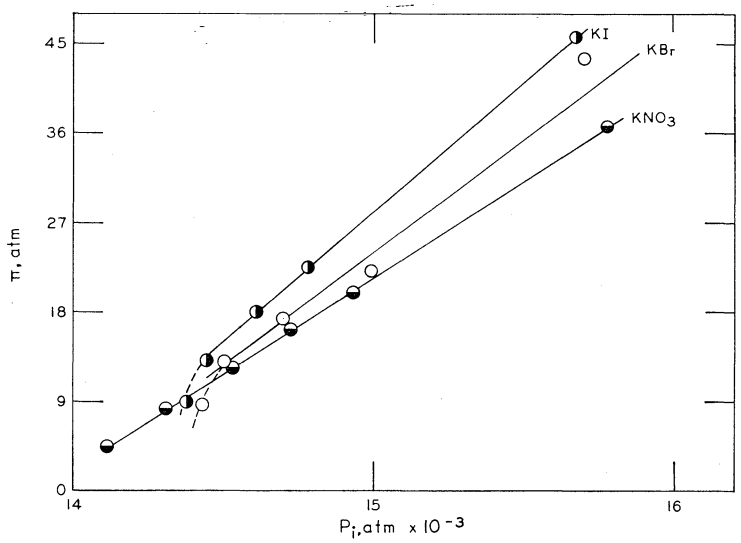

FIG. 2. Variation of osmotic pressure with internal pressure—aqueous solutions of KI, KBr, and KNO_3.

For personal use only.

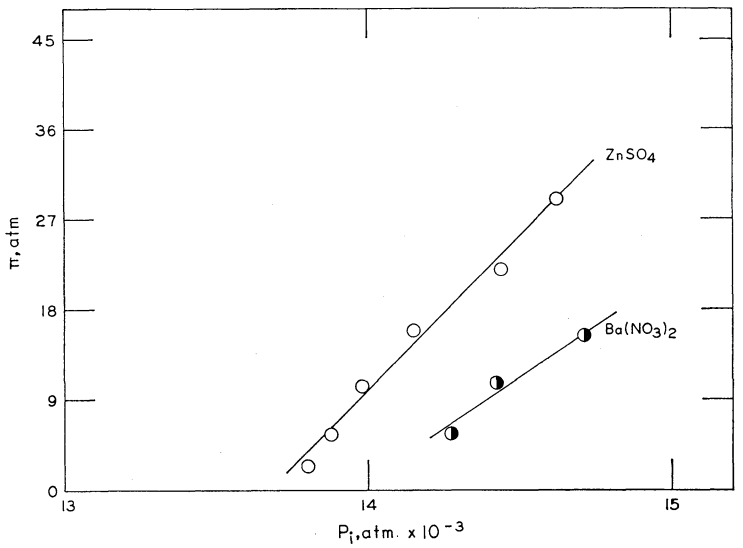

FIG. 3. Variation of osmotic pressure with internal pressure—aqueous solutions of $ZnSO_4$ and $Ba(NO_3)_2$.

were calculated from published values of ϕ by means of the usual relationship

$$\pi_{12} = \frac{RT\bar{n}mW_s}{V_s \cdot 1000}\,\phi, \qquad \text{(xiii)}$$

in which m is the molality of the solution, $\bar{n}$ the number of ions/molecule of electrolyte, and V_s and W_s the partial molal volume and molecular weight of the solvent.

Except at the very lowest concentrations, at which marked departures from linearity are observed in several instances, plots of P_i versus π_{12} are strictly linear with slopes of ca. 0.02 for NaF, 0.016 for $NaNO_3$, 0.02 for KNO_3, 0.025 for KI, 0.023 for KBr, 0.02 for $Ba(NO_3)_2$, and 0.03 for $ZnSO_4$.

DEVIATIONS FROM THE "MIXTURE LAW" IN THE RADIOLYSIS OF HYDROCARBON MIXTURES

II. YIELDS OF LIQUID PRODUCTS IN MIXTURES OF CYCLOHEXANE AND CYCLOPENTANE[1]

P. J. DYNE AND J. DENHARTOG

Research Chemistry Branch, Atomic Energy of Canada Limited, Chalk River, Ontario

Received March 14, 1963

ABSTRACT

The radiolytic yields of olefins and dimers have been measured in mixtures of cyclohexane and cyclopentane. While the dimeric products ($(C_6H_{11})_2$, $C_6H_{11}\cdot C_5H_9$) show a bias towards C_5 groups, the olefins show a bias towards C_6 groups; the yield of cyclohexene at low concentrations of cyclohexane is more than twice the maximum predicted by the "mixture law". These results confirm earlier isotopic work which showed a higher reactivity of cyclohexane-d_{12} in cyclohexane-d_{12} – cyclopentane mixtures relative to that in cyclohexane-d_{12} – cyclohexane. The results also confirm the preferential change of identity of cyclohexyl radicals to cyclopentyl radicals, which leads to a predominance of C_5 groups in the dimer.

INTRODUCTION

An alkane solvent can have a large effect on the radiolytic reactivity of other alkane solutes. This effect was first observed in alkane solutions of cyclohexane-d_{12} (C_6D_{12}) where the changes in reactivity were detected through the variation in the D_2 and HD content of the radiolytic hydrogen (1). For example, the yield of D_2 from a dilute solution of C_6D_{12} in cyclopentane is about five times greater than that from a comparable solution of C_6D_{12} in cyclohexane. We called these variations in reactivity deviations from the "mixture law" and concluded that they could only be explained by a physical mechanism, such as energy transfer or charge transfer from the alkane solvent to the cyclohexane-d_{12}.

One would expect that the high yields of D_2 and HD from solutions of C_6D_{12} in cyclopentane would be associated with high yields of the liquid products, cyclohexane-d_{10}, and the dimers $(C_6D_{11})_2$ and $C_6D_{11}\cdot C_5H_9$. By analogy one would also expect high yields of products containing C_6 groups in mixtures of undeuterated cyclohexane and cyclopentane. This last expectation was not, however, in agreement with the results of Muccini and Schuler (2), who studied the dimeric products formed in the radiolysis of cyclohexane–cyclopentane mixtures and found a greater yield of the dimers containing C_5 groups. The composition of the dimer was a function of the dose rate, the bias towards C_5 groups being more pronounced at low dose rates.

In iodine solutions Muccini and Schuler found that the yields of cyclohexyl iodide and cyclopentyl iodide were linear functions of the composition. From this they concluded that the initial yields of C_5 and C_6 radicals were, respectively, proportional to the electron fractions of cyclopentane and cyclohexane. The high yield of C_5 groups in the dimer was then explained by the change of identity reactions

$$C_6H_{11}\cdot + C_5H_{10} \rightarrow C_6H_{12} + C_5H_9\cdot \quad [1]$$

$$C_5H_9\cdot + C_6H_{12} \rightarrow C_5H_{10} + C_6H_{11}\cdot \quad [2]$$

If the rate constants for these reactions differed, k_1 being greater than k_2, then the steady state radical distribution would contain a greater fraction of $C_5H_9\cdot$ radicals. This would be shown in the composition of the dimers.

[1]*Issued as A.E.C.L. No. 1754.*

The dimer yields measured by Muccini and Schuler are not, in themselves, in conflict with our isotopic experiments since, if C_6 radicals were predominant in the initial decomposition, the change of identity reaction could still lead to a predominance of C_5 radicals if the radical lifetimes were long enough. "Mixture law" deviations should, however, be detectable in liquid products which do not have free-radical precursors. Cyclohexene is such a product; some is formed by the molecular detachment of hydrogen (3):

$$C_6H_{12} \longrightarrow\!\!\!\!\!\sim\!\!\!\!\!\rightarrow C_6H_{10} + H_2 \qquad [3]$$

Accordingly, we measured the yields and isotopic composition of all liquid products, olefins, and dimers in the three binary systems C_6D_{12}–C_6H_{12}, C_6D_{12}–C_5H_{10}, and C_6H_{12}–C_5H_{10}. The results confirm both the "mixture law" deviations predicted from our isotopic experiments and the change of identity reaction postulated by Muccini and Schuler.

In some other studies (4) we have found that "mixture law" deviations which appear in a mixture of two hydrocarbons are changed by the addition of solutes, e.g. benzene, carbon tetrachloride, cyclohexene, and iodine. Specifically, the partial yields of D_2 and HD, G_1(D) and g(HD), for cyclohexane-d_{12} in cyclopentane are 1.6 and 10.0, respectively. In 10^{-2} M iodine solution they are reduced to 1.16 and 6.50, respectively. In our opinion, experiments with additives introduce further complications to the "mixture law" deviations in hydrocarbon mixtures. For this reason, we set aside Muccini and Schuler's measurements on iodine solutions.

EXPERIMENTAL PROCEDURES

Materials

Cyclohexane (Fisher Scientific Spectranalyzed) and cyclohexane-d_{12} (Merck) were used as received. Cyclopentane (Phillips Research Grade) was passed through a column of silica gel, activated by heating to 150° C under vacuum, to remove cyclopentene.

Sample Preparation and Irradiation

The techniques of sample preparation, dosimetry, and gas analysis have been described previously (1). The irradiations were all carried out at a dose rate of $\sim 2\times10^{22}$ ev/l. hr to a total dose of $\sim 4\times10^{22}$ ev/l.

Analysis of Liquid Products

Cyclohexene and cyclohexene-d_{10} in C_6H_{12}–C_6D_{12} mixtures were separated by preparative gas–liquid chromatography. A 400-λ sample of the irradiated mixture was injected onto a 12-ft column packed with 28% ethylene glycol saturated with $AgNO_3$ on firebrick. At 40° C the retention time of the olefins was 40 minutes. The effluent was passed through a magnesium perchlorate trap to remove moisture and the olefin fraction was condensed at liquid nitrogen temperature. The ratio C_6D_{10}/C_6H_{10} was determined from the ratio of peaks at m/e = 92 and 82 measured on a Consolidated 21–130 mass spectrometer.

For the analysis of dimers $(C_6H_{11})_2$ and $C_6H_{11}\cdot C_6D_{11}$ in C_6H_{12}–C_6D_{12} mixtures, 20 ml of irradiated solution was concentrated to 4 ml by distillation. About 2 ml of the concentrate was injected 200 λ at a time onto a column packed with 0.1% Apiezon-L grease on glass beads. The column was initially at room temperature. After all the cyclohexane was eluted, the column temperature was raised slowly; the dimer was eluted at a column temperature of about 120° C, trapped at liquid nitrogen temperature, and analyzed mass spectrometrically. The ratio of peaks at m/e equal to 177 and 166 gave the ratio of $C_6H_{11}\cdot C_6D_{11}$ to $(C_6H_{11})_2$ in the product.

Cyclopentene in cyclohexane–cyclopentane mixtures was analyzed by infrared spectrophotometry on a Perkin–Elmer Model 21 spectrometer using the absorption band at 695 cm^{-1}. The techniques have been described earlier (5). Cyclohexene was measured by gas–liquid chromatography using a 12-ft column packed with 17% 1,2,3-tris(2-cyanoethoxy)propane on acid-washed firebrick. Dimer fractions were separated on a 12-ft column packed with 20% O.S. 124 (a polyphenyl ether) on "Columpack". The relative sensitivities of the hydrogen flame detector to the C_{10}, C_{11}, and C_{12} hydrocarbons were assumed to be in the ratio of their carbon numbers. This assumption was found to be correct experimentally. At low concentrations of cyclohexane the dimers were concentrated by distillation to increase the sensitivity of the analysis.

DISCUSSION

In this discussion we shall be more interested in the initial slope of the plot of a G-value as a function of concentration rather than in the G-value itself. This slope might be called

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

a "partial yield", one which is calculated on the basis of the energy absorbed by one component of a mixture. The partial yield of a product P_A, $g(P_A)$, derived from component A of a mixture is given by:

$$g(P_A) = \text{molecules } P_A/100 \text{ ev absorbed in component A.}$$

In our earlier paper (1) we used the mole fraction as the parameter which determines the partitioning of energy in a mixture. However, recent experiments in the gas phase carried out in this laboratory (6) have convinced us that, for mixtures of alkanes, the electron fraction is a more suitable parameter and we shall use it in this paper. Values of the partial yields, obtained from the initial slopes of yields shown in Figs. 1–4, are given in Table I.

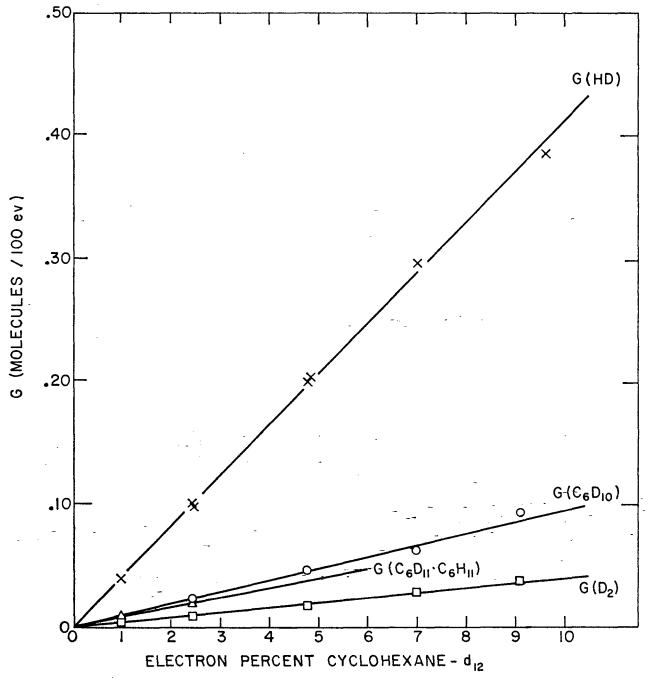

FIG. 1. Yields of deuterated products in mixtures of cyclohexane-d_{12} and cyclohexane.

TABLE I

Partial yields of products* in alkane mixtures

	Cyclohexane–cyclohexane-d_{12}	Cyclopentane–cyclohexane-d_{12}	Cyclopentane–cyclohexane	Pure cyclohexane†
$g(D_2)$‡	0.35	1.6	—	—
g(HD)	4.0	10.0	—	—
$g(C_6D_{10})$	0.9	2.6	—	—
$g(C_6H_{10})$	—	—	8.9	3.3
$g(C_6)$ in dimer	0.8§	1.9	2.5	3.9

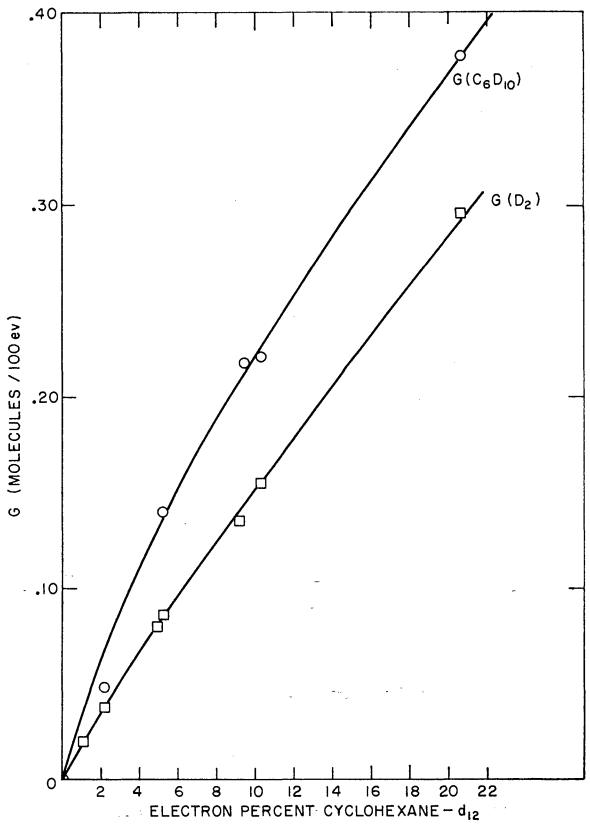

FIG. 4. Yield of deuterated cyclohexene and D_2 in mixtures of cyclohexane-d_{12} and cyclopentane.

The Change of Identity Reaction

The yield of the isotopically substituted bicyclohexyl $C_6H_{11}\cdot C_6D_{11}$ in C_6H_{12}–C_6D_{12} mixtures provides further evidence for the change of identity reactions suggested by Muccini and Schuler. Since every HD molecule is formed together with a C_6D_{11} residue, the expectation, if no disproportionation occurred, is that $g(HD)$ would be equal to $g(C_6H_{11}\cdot C_6D_{11})$. As can be seen from Table I and Fig. 1, $g(HD)$ is more than four times greater than $g(C_6H_{11}\cdot C_6D_{11})$ and is also greater than the sum of $g(C_6H_{11}\cdot C_6D_{11})$ and $g(C_6D_{10})$. The missing C_6D_{11} residues can only be present as $C_6D_{11}H$, which would be formed by the change of identity reaction

$$C_6D_{11}\cdot + C_6H_{12} \rightarrow C_6D_{11}H + C_6H_{11}\cdot$$

We have obtained partial confirmation of this reaction by isotopic analysis of irradiated C_6D_{12}–C_6H_{12} mixtures and found that $C_6D_{11}H$ is detectable. This analysis could, however, only be performed on highly irradiated mixtures, and direct comparison with the yields measured at low doses is not significant.

Analogous results are found in the C_6D_{12}–C_5H_{10} mixtures; $g(HD)$ is, in this system, about five times greater than $g(C_6)$ in the dimer.

"Mixture Law" Deviations

The qualitative expectations outlined in the introduction are borne out in the yields

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

of olefins. In Fig. 2, we see that $g(C_6H_{10})$ in cyclohexane–cyclopentane mixtures is initially much greater than it is in pure cyclohexane. In Fig. 4, we see first that, for cyclohexane-d_{12}–cyclopentane mixtures, the yield of deuterium is matched by the yield of C_6D_{10} and, second, that $g(C_6D_{10})$ is nearly three times greater than $g(C_6D_{10})$ in C_6D_{12}–C_6H_{12} mixtures. In addition, there is a similar difference of a factor greater than 2 for $G(C_6)$ in these two mixtures (Table I).

These simple observations require, however, more detailed discussion. Suppose that mixtures of cyclohexane and cyclopentane obeyed the "mixture law". If cyclohexene were produced only by molecular detachment, its yield would be a linear function of composition such that $g(C_6H_{10})$ would be 3.3, which is the cyclohexene yield in pure cyclohexane (7). If, on the other hand, cyclohexene were formed only by the disproportionation

$$C_6H_{11}\cdot + C_5H_9\cdot \rightarrow C_6H_{10} + C_5H_{10}$$

the initial value of $g(C_6H_{10})$ would be less than 3.3 because some of the disproportionating radicals would give cyclopentene:

$$C_6H_{11}\cdot + C_5H_9\cdot \rightarrow C_6H_{12} + C_5H_8$$

The plot of $G(C_6H_{10})$ vs. C_6H_{12} concentration would be concave upwards due to the increasing probability of the disproportionation of two $C_6H_{11}\cdot$ radicals (necessarily giving cyclohexene) which occurs at high cyclohexane concentrations. The change of identity reaction which removes $C_6H_{11}\cdot$ radicals from the system will also reduce the initial value of $g(C_6H_{10})$ below the limiting value of 3.3. The initial value of $g(C_6H_{10})$ will also be less than 3.3 if cyclohexene is formed by both molecular elimination and disproportionation.

The observed yields of cyclohexene in C_6H_{12}–C_5H_{10} mixtures do not follow either of these predictions. In Fig. 2, we see that $g(C_6H_{10})$ is initially more than twice the "expected" value shown by the broken line which corresponds to $g(C_6H_{10}) = 3.3$. This yield is concave downwards, showing, presumably, that the deviations from the "mixture law" are smaller at higher C_6H_{12} concentrations. By contrast, the yield of C_6 dimers (Fig. 3) is, in agreement with Muccini and Schuler, less than that predicted by the "mixture law".

An observation, of minor importance, which requires comment is the difference between the yields of C_6D_{10} and D_2 in both systems containing cyclohexane-d_{12}. Since $g(C_6D_{10}) > g(D_2)$, it follows that cyclohexene is being formed by some process other than the molecular detachment of deuterium. In cyclopentane solutions $g(C_6D_{10}) - g(D_2) = 1.0$.

This process could be the disproportionation

$$C_6D_{11}\cdot + C_5H_9\cdot \rightarrow C_6D_{10} + C_5H_9D,$$

which would be matched by an approximately equal number of disproportionations giving cyclopentene. The total yield of disproportionating $C_6D_{11}\cdot$ radicals is therefore about 2, which is very close to the number combining to give $C_6D_{11}\cdot C_5H_9$ (1.9). If the disproportionation is forming C_6D_{10} then the probabilities of disproportionation and combination must be approximately equal.

Two other processes which could lead to this extra yield of C_6D_{10} are (1) a dissociation to give deuterium atoms which would react to give HD:

$$C_6D_{12} \rightsquigarrow C_6D_{10} + 2D$$

and (2) molecular detachment of HD from the isotopic impurity $C_6D_{11}H$, which is present in a concentration of about 6%. We have already noted (8) that the yield of HD from 'pure' deuterated cyclohexane is inordinately high. It is possible therefore that, in mixtures, $C_6D_{11}H$ shows a reactivity much in excess of that expected from its electron fraction.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The difference between $g(C_6D_{10})$ in C_6D_{12}–C_5H_{10} mixtures (2.6) and $g(C_6H_{10})$ in C_6H_{12}–C_5H_{10} mixtures establishes the existence of a large isotope effect in the probability of molecular detachment and, possibly, in the process which leads to these "mixture law" deviations. Skurat (9), using our isotopic techniques, found similar large isotope effects in the yields of hydrogen formed by molecular detachment in the radiolysis of polyethylene and deuteropolyethylene.

ACKNOWLEDGMENT

It is a pleasure to acknowledge both the helpful advice on gas chromatographic techniques and the critical comments on this paper that we received from Dr. J. A. Stone.

PREPARATION, THIN LAYER CHROMATOGRAPHY, AND ULTRAVIOLET SPECTRA OF SOME O-BENZYL DERIVATIVES OF D-GLUCOSE[1]

M. E. TATE[2] AND C. T. BISHOP
Division of Applied Biology, National Research Council, Ottawa, Canada
Received January 10, 1963

ABSTRACT

A new method for benzylation of carbohydrates has been developed which facilitated complete substitution of hydroxyl groups in one of the compounds prepared. Thin layer chromatography provides a good criterion of purity and is also a preparative method for separation of identifiable amounts of *O*-benzyl derivatives of carbohydrates. The number of benzyl groups in a compound can be determined by ultraviolet absorption spectroscopy. The following compounds were prepared, some of which have not been reported previously: benzyl-2,3,4,6-tetra-*O*-benzyl-α-D-glucoside; benzyl 2,3,4,6-tetra-*O*-benzyl-β-D-glucoside; methyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside; 2,3,4,6-tetra-*O*-benzyl-α-D-glucose; 1-*O*-(*p*-nitrobenzoyl)-2,3,4,6-tetra-*O*-benzyl-α-D-glucose; octa-*O*-benzyl sucrose; 3,5-di-*O*-benzyl-1,2-*O*-cyclohexylidene-α-D-xylose.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The value of the benzyl group in syntheses of carbohydrate derivatives has been recognized by chemists for many years and the subject has been reviewed by McCloskey (1). More extensive use of poly-*O*-benzyl derivatives of carbohydrates has been somewhat limited undoubtedly because many of them are not crystalline at room temperature and therefore of uncertain purity. Nevertheless, a number of important compounds have been prepared from these amorphous products (2, 3, 4). The success of thin layer chromatography in separating carbohydrate acetates (5) prompted the present study to see if the same method would be useful as a criterion of homogeneity for poly-*O*-benzyl derivatives of carbohydrates. The ultraviolet absorption properties of these *O*-benzyl derivatives were also examined and found to provide a method of analysis for *O*-benzyl groups.

The compounds used in this investigation may be considered as derivatives of 2,3,4,6-tetra-*O*-benzyl-D-glucose in which substituents at the anomeric carbon were α-*O*-benzyl; β-*O*-benzyl; α-*O*-methyl; α-hydroxyl; α-*O*-(*p*-nitrobenzoyl); and α-*O*-(1,3,4,6-tetra-*O*-benzyl-β-D-fructofuranosyl), i.e. octa-*O*-benzyl sucrose.

Separations were obtained on thin layers of silica gel G by development with light petroleum containing 3–5% of methanol. As with the benzene–methanol solvent system used for carbohydrate acetates (5) the mobilities of the various components were strongly dependent upon the concentration of methanol. These two solvent systems are complementary in that they give a wide range of solvent polarity.

Figure 1 shows the separation of the fully benzylated glucoses and the resolution that can be obtained in this series with various substituents at the anomeric carbon atom. The large differences in mobilities between fully substituted derivatives and those containing a free hydroxyl group clearly indicate that thin layer chromatography is an ideal method for following reactions which involve formation of ether, ester, or acetal groups. This feature was emphasized in the attempted benzylation of benzyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucoside by the usual benzyl chloride – powdered potassium hydroxide procedure (1). Thin layer chromatography of the crude reaction mixture showed a yield of only 33% of the expected benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside and some 60% of a product corresponding to a tetra-*O*-benzyl glucose derivative. All attempts to force the benzylation

to completion by raising the temperature or extending the time of reaction were unsuccessful and led to excessive formation of dibenzyl ether. However, the tetra-*O*-benzyl glucose derivative was smoothly benzylated by benzyl chloride and sodium hydride at 130° C to give a 90% yield of crystalline benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside. This method of benzylation, which does not appear to have been applied to carbohydrates before, was based upon an observation by Cristol, Ragsdale, and Meek (6) that benzyl chloride does not react with sodium hydride at temperatures up to 170° C. The use of sodium hydride also prevents the formation of dibenzyl ether, which is a major by-product in other methods of benzylation. The new method forms a useful adjunct to the older procedures (1) and is especially valuable for the benzylation of hindered hydroxyl groups. The preparation of methyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside as described in the experimental section is an example of benzylation by the benzyl chloride – sodium hydride procedure.

The key compound 2,3,4,6-tetra-*O*-benzyl-α-D-glucose was prepared by hydrolysis of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

its methyl glycoside (3) but in much better yield by hydrolysis of the corresponding benzyl glycoside. The acetate of 2,3,4,6-tetra-*O*-benzyl-α-D-glucose was not crystalline; however, a crystalline *p*-nitrobenzoate was obtained. Octa-*O*-benzyl sucrose was prepared by benzylation of sucrose with benzyl bromide, silver oxide, and barium oxide (7), the product being isolated by a procedure previously described (2) and purified for analysis by preparative thin layer chromatography. Benzylation of 1,2-*O*-cyclohexylidene-α-D-xylofuranose to the 3,5-di-*O*-benzyl derivative provided another compound to test the spectrophotometric estimation of *O*-benzyl groups as described below.

It was apparent in this work that some method for determining the number of *O*-benzyl groups in a compound would be very valuable, just as the methoxyl determination has been so useful in the chemistry of methylated carbohydrates. The early work on benzylated carbohydrates utilized the hydriodic acid fission of ethers, as used for methoxyl estimation, for determining benzyl groups (8). However, that method involves isolation of the lachrymatory benzyl iodide and is rendered invalid by the presence of a methoxyl group in the compound being analyzed. The ultraviolet absorption spectrum of the benzyl group has been used as the basis of a spectrophotometric method for the estimation of benzyl penicillin (9). Accordingly, the ultraviolet spectra of a number of crystalline *O*-benzyl derivatives of carbohydrates were examined to see if the method could be used for quantitative estimation of *O*-benzyl broups in these compounds.

With one exception, all the *O*-benzyl derivatives examined so far have shown an $\epsilon_{258.5}$ value per benzyl group of 186±2. The single exception was benzyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucoside, which, in ethanol, gives a spectrum with no clear maximum at 258.5 mμ. In cyclohexane this maximum is revealed but the $\epsilon_{258.5}$ value (245) per benzyl group is much greater than those for the other compounds. Those benzyl derivatives which gave the $\epsilon_{258.5}$ value per benzyl group of 186±2 all exhibited a pronounced minimum in the vicinity of 230–240 mμ; unless this minimum is present estimates of benzyl groups from $\epsilon_{258.5}$ are likely to be in error. The spectra obtained are in agreement with that recorded (10) for benzyl alcohol, which also gives an $\epsilon_{258.5}$ value of 185. The validity of Beer's law was established for benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside over the concentration range 0.02–0.12% and the constancy of the $\epsilon_{258.5}$ value per benzyl group in other compounds with varying degrees of *O*-benzyl substitution indicated its validity for them as well, over the range of concentration used.

The successful application of ultraviolet spectroscopy for estimating *O*-benzyl groups in amorphous compounds is largely dependent on the purity of those compounds. Thin layer chromatography is the method of choice for purification because the samples isolated from a single plate are more than sufficient for spectroscopic analysis. In turn, the ultraviolet spectra provide useful information about the degree of substitution in the compounds isolated and the methods therefore mutually enhance the value of each other.

EXPERIMENTAL

Thin Layer Chromatography

Glass plates (20×20×0.3 cm) were coated with silica gel G* or with silica gel G containing 1% (w/w) of fluorescent zinc silicate.† The plates were prepared and samples were applied to them as previously described (5). The dyes Sudan III and methyl orange were used as markers and plates were developed with light petroleum (b.p. 65–110° C) – methanol mixtures containing 3–5% (v/v) of methanol. As with the carbohydrate acetates (5) the methanol content of the solvent was varied, within the above limits, depending on the compounds being separated. The separation shown in Fig. 1 was obtained with a single

ascending development (solvent front 14.7 cm) in 40 minutes using light petroleum (b.p. 65–110° C) containing 5% (v/v) of methanol. Fresh solvent was made up each day because of gradual depletion of the methanol content by adsorption onto the silicic acid.

Detection

Reaction of the components on the plates with iodine vapor was the most convenient and sensitive method of detection for routine work. A saturated atmosphere of iodine vapor was obtained by keeping 3–5 g of iodine crystals in the bottom of a covered glass jar. The thin layer chromatograms were dried in a current of air from a fan and were then placed in the tank containing the iodine. The compounds on the chromatograms became visible in a few minutes and the spots reached their maximum intensity after 30 minutes. This method will clearly detect 0.4 μg of benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside. The chromatograms can be covered with clean glass plates for ease of handling or tracing. For non-destructive detection the plates were prepared from the fluorescent silica gel G described above; the chromatograms, developed and dried, were then examined under a suitable shortwave source of ultraviolet light (Mineralight S. L. 2537). Factors involved in the selection of fluorescent materials and light sources have been examined by Sease (11); the technique has been applied to thin layer chromatography by Kirchner *et al.* (12). The sensitivity of this method of detection for benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside was 4 μg but obviously the level of detection will vary with the molar extinction coefficient (ϵ) of the compound being detected. In general, the iodine vapor technique was used for analytical work and the ultraviolet method for semimicro preparative plates.

Semimicro Preparative Separation

Plates were prepared as described for the analytical separations and the *O*-benzyl derivatives were applied as contiguous spots to give 30–100 mg per 20-cm plate. Fluorescent silica gel G was used and the plates were developed with light petroleum (b.p. 65–110° C) containing 5% (v/v) of methanol. The developed plates were dried in air and the zones were detected in ultraviolet light as dark areas on a fluorescent yellow background. The zones were outlined with a scalpel and scraped from the plate for elution of the separate components. This technique was described in detail for thin layer chromatography of carbohydrate acetates (5). In the majority of separations elution of the zone scrapings with chloroform yielded analytically pure samples. Products recovered for analysis were dried at 60° C in a high vacuum (0.01 mm of mercury) for 18 hours.

Preparation of O-Benzyl Derivatives

I. Benzyl 2,3,4,6-Tetra-O-benzyl-α-D-glucoside

Benzyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucoside (1.0 g (13, 14); $E^{1\%}_{1\,cm}$ = 4.2 at 258.5 mμ, $\epsilon_{max/benzyl\,group}$ = 184) was benzylated by benzyl chloride (8.0 ml) and powdered potassium hydroxide (3.0 g) (1). The product was a colorless sirup (1.5 g), $[\alpha]_D^{25}$ +66.4 (*c*, 3% in chloroform). Thin layer chromatography of this sirup showed the presence of dibenzyl ether and two other products: A (R_f 0.33) and B (R_f 0.09); Sudan III had R_f 0.51. Pure samples of products A (32.2 mg) and B (48.0 mg) were obtained by preparative thin layer chromatography of a portion of the sirup.

Product A crystallized when triturated with methanol (1 ml). The crystals were filtered and washed with methanol (2×0.5 ml) to give benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside I (17.8 mg) as colorless needles with a melting point of 93.5–94.5° C unchanged on recrystallization from the same solvent. Anal.: Calc. for $C_{41}H_{42}O_6$: C, 78.07%; H, 6.71%. Found: C, 77.84%; H, 6.92%. $[\alpha]_D^{28}$ +55.8° (*c*, 1.63% in chloroform). $E^{1\%}_{1\,cm}$ = 14.8 at 258.5 mμ; $\epsilon_{max/benzyl\,group}$ = 187.

Product B could not be induced to crystallize but analysis showed that it was a tetra-*O*-benzyl derivative of glucose. Anal.: Calc. for $C_{34}H_{36}O_6$: C, 75.53%; H, 6.71%. Found: C, 75.63%; H, 6.81%. $[\alpha]_D^{24}$ +90.8° (*c*, 1.42% in chloroform). Benzylation of this sirupy tetra-*O*-benzyl derivative (50 mg) by sodium hydride and benzyl chloride, as described below for methyl α-D-glucopyranoside, yielded crude benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside, m.p. 91–93° C (53 mg, 91%); one recrystallization from methanol provided a pure product, m.p. 93.5–94.5° C (41 mg, 70%).

Overall yields in the benzylation were 33% of benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside and 60% of the tetra-*O*-benzyl derivative. The unresolved mixture in methanol solution gave a further 270 mg of benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside when seeded with crystals of the pure product obtained by thin layer chromatography.

II. Benzyl 2,3,4,6-Tetra-O-benzyl-β-D-glucoside

Benzyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucoside (0.44 g (13); $E^{1\%}_{1\,cm}$ = 5.6 at 258.5 mμ, $\epsilon_{max/benzyl\,group}$ = 245) was benzylated with powdered potassium hydroxide (1.5 g) and benzyl chloride (5 ml) as described above. The oily product (0.6 g) crystallized partially when triturated with methanol at 0° C. The crystals were washed with methanol (2×0.5 ml) and dried; m.p. 79–81° C, 209 mg, 33%. Thin layer chromatography revealed trace quantities of a slower-moving component. Recrystallization from methanol (5 ml) provided pure benzyl 2,3,4,6-tetra-*O*-benzyl-β-D-glucoside, m.p. 83–84° C, $[\alpha]_D^{25}$ −14.9° (*c*, 1.48% in chloroform); reported (8), m.p. 83.5° C. Anal.: Calc. for $C_{41}H_{42}O_6$: C, 78.07%; H, 6.71%. Found: C, 77.90%; H, 6.50%. $E^{1\%}_{1\,cm}$ at 258.5 mμ = 14.8; $\epsilon_{max/benzyl\,group}$ = 187.

III. Methyl 2,3,4,6-Tetra-O-benzyl-α-D-glucoside

This compound has been reported by Schmidt *et al.* (3), who prepared it by benzylation of methyl α-D-glucopyranoside with powdered potassium hydroxide and benzyl chloride. However, the specific rotation reported is not in agreement with that found in the present work and the only analytical value cited was methoxyl content. In the present study methoxyl analysis of these compounds was found to be unreliable and gave consistently high values, probably due to interference by the *O*-benzyl groups.

A mixture of methyl α-D-glucopyranoside (5 g, finely powdered), benzyl chloride (125 ml), and sodium hydride (11 g) was stirred magnetically under anhydrous conditions for 3 hours at 125–130° C. During the strongly exothermic reaction the mixture became thick and gelatinous and then changed to a thin slurry as the reaction reached completion. The progress of the reaction was followed by thin layer chromatography, which showed that benzylation was virtually complete after 3 hours. The reaction mixture was centrifuged, the supernatant liquor was decanted, and the residue was washed with benzene (4×50 ml) by centrifugation and decantation. The excess of sodium hydride was destroyed by adding the solid residue to a large volume of ethanol. The combined benzene supernatant liquors were steam-distilled until the distillate was clear and the oily residue was extracted with chloroform (4×50 ml). The extract was dried by passage through a wad of cotton and evaporated to give a yellow sirup (22.0 g). This product was sufficiently pure for the preparation of 2,3,4,6-tetra-*O*-benzyl-D-glucose as described below. A small aliquot was purified by preparative thin layer chromatography to give methyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside as a colorless sirup, $[\alpha]_D^{25}$ +18.7° (*c*, 1.5% in chloroform); reported (3), $[\alpha]_D^{25}$ +32.2 (*c*, 5% in chloroform). Anal.: Calc. for $C_{35}H_{38}O_6$: C, 75.79%; H, 6.91%. Found: C, 75.67%; H, 7.00%. λ_{max} 258.5 mμ; calc. $E^{1\%}_{1\,cm}$ = 13.4, found $E^{1\%}_{1\,cm}$ = 13.4; $\epsilon_{max/benzyl\,group}$ = 186.

IV. 2,3,4,6-Tetra-O-benzyl-α-D-glucose

(a) Hydrolysis of methyl 2,3,4,6-tetra-O-benzyl-α-D-glucoside.—The method of Schmidt *et al.* (3) was modified to give an improved overall yield. Crude methyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside (21.7 g) was dissolved in glacial acetic acid (400 ml) and the solution was heated to 90° C on a steam bath. Sulphuric acid (108 ml, 2 *N*) was added and the heating was continued for 2 hours. Thin layer chromatography showed that considerable amounts of starting product were still present. A further portion (84 ml) of 2 *N* sulphuric acid was added and the solution was heated for 18 hours, after which thin layer chromatography showed that none of the initial product remained. The hydrolyzate was poured into water (3.5 l.) whereupon a yellow oil was precipitated which gradually solidified. The solid was isolated by filtration and washed with cold methanol to give colorless crystals of 2,3,4,6-tetra-*O*-benzyl-α-D-glucose (5.0 g, 35%), m.p. 146–149° C. Recrystallization of this product from methanol (160 ml) yielded needles having a melting point of 150–151° C and $[\alpha]_D^{24}$ +20.7 (*c*, 2.47% in chloroform); reported (3), m.p. 148° C, $[\alpha]_D^{20}$ +21.2° (*c*, 3.5% in chloroform). Total yield of pure product recovered from the recrystallization was 4.2 g, 30%.

(b) Hydrolysis of benzyl 2,3,4,6-tetra-O-benzyl-α-D-glucoside.—Compound I (2.0 g) was dissolved in hot, 90% acetic acid (60 ml) and to the solution was added 2 *N* sulphuric acid (16 ml). The solution was heated on a steam bath for 3 hours and then a second portion (12 ml) of 2 *N* sulphuric acid was added. The reaction was heated for a further 3 hours, after which hydrolysis was shown to be complete by thin layer chromatography. The hydrolyzate was poured into boiling water (900 ml) whereupon the product crystallized. The crystals were isolated by filtration and washed with cold methanol (2×4 ml) to give colorless needles (1.0 g), m.p. 142–145° C. Recrystallization from methanol yielded 2,3,4,6-tetra-*O*-benzyl-α-D-glucose (0.81 g, 47%), m.p. 150–151° C, $[\alpha]_D^{24}$ +20.7° (*c*, 2.5% in chloroform). $E^{1\%}_{1\,cm}$ = 13.8 at 258.5 mμ, $\epsilon_{max/benzyl\,group}$ = 186. The 1-*O*-(*p*-nitrobenzoyl)-2,3,4,6-tetra-*O*-benzyl-α-D-glucose (V) was prepared by heating IV with *p*-nitrobenzoyl chloride in anhydrous pyridine and after recrystallization from ethanol had m.p. 126–127° C and $[\alpha]_D^{26}$ +72.3° (*c*, 2.13% in chloroform). Anal.: Calc. for $C_{41}H_{39}O_9N$: C, 71.39%; H, 5.70%. Found: C, 71.43%; H, 5.40%. The high positive rotation of this derivative suggests assignment of the α-D-configuration. Catalytic de-*O*-acylation of V gave a 74% yield of Compound IV, m.p. 147–149° C raised to 150–151° C by two recrystallizations from methanol.

V. 1,3,4,6-Tetra-O-benzyl-β-D-fructosyl-2,3,4,6-tetra-O-benzyl-α-D-glucoside (Octa-O-benzyl Sucrose)

Sucrose (0.5 g) was benzylated in dimethylformamide (5 ml) by benzyl bromide (5 ml), silver oxide (5 g), and barium oxide (2.5 g) (7). Examination of the product (1.2 g) by thin layer chromatography showed the presence of two components, one of which was dibenzyl ether. Preparative thin layer chromatography of a small portion of the crude sirup yielded the second constituent, octa-*O*-benzyl sucrose, as a colorless sirup, $[\alpha]_D^{26}$ +31.6° (*c*, 1.65% in chloroform). Anal.: Calc. for $C_{68}H_{70}O_{11}$: C, 76.81%; H, 6.64%. Found: C, 76.30%; H, 6.67%. λ_{max} 258.5 mμ; calc. $E^{1\%}_{1\,cm}$ = 14.0, found $E^{1\%}_{1\,cm}$ = 14.2; $\epsilon_{max/benzyl\,group}$ = 188. The crude product could be purified on a larger scale by dissolution of the sirup in hot absolute ethanol (25 ml), which was then allowed to cool to room temperature (2). The oily product, precipitated from the cooled solution, was washed by decantation and was then dried to a yellow sirup (0.45 g, 29%).

VI. 3,5-Di-O-benzyl-1,2-O-cyclohexylidene-α-D-xylose

1,2-*O*-Cyclohexylidene-α-D-xylofuranose (6.9 g), m.p. 86–87° C, $[\alpha]_D^{25}$ −6.2° (*c*, 2.0% in methanol) (15), was benzylated by benzyl chloride (75 ml) and powdered potassium hydroxide (22.0 g) (1). The product crystallized when nucleated with seed crystals obtained by trituration of a small portion of the oil with *n*-hexane. Recrystallization from *n*-hexane (30 ml) yielded 3,5-di-*O*-benzyl-1,2-*O*-cyclohexylidene-α-D-xylose

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

as colorless needles (10.7 g, 87%); m.p. 91–92° C, $[\alpha]_D^{27}$ −31.3° (*c*, 1.64% in chloroform). Anal.: Calc. for $C_{25}H_{30}O_5$: C, 73.14%; H, 7.37%. Found: C, 73.13%; H, 7.37%. $E^{1\%}_{1\,cm}$ = 9.1 at 258.5 mμ, $\epsilon_{max/benzyl\,group}$ = 186.

Ultraviolet Spectroscopy

The spectra reported in this work were measured with a Cary recording spectrophotometer Model 11M using 1-cm quartz cells. The solvent used was 95% ethanol except for benzyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucoside, which gave a satisfactory spectrum only in cyclohexane. A spectrum of benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside in cyclohexane showed no significant difference in $\epsilon_{258.5}$ to that obtained in 95% ethanol. The $E^{1\%}_{1\,cm}$ at 258.5 mμ for benzyl 2,3,4,6-tetra-*O*-benzyl-α-D-glucoside in 95% ethanol varied from 15.0–14.8 over the concentration range 0.02–0.12%, indicating the validity of Beer's law within the reproducibility (2–3%) of the method. The $E^{1\%}_{1\,cm}$ values, cited for the compounds prepared, are of importance as a method of characterization (16). The values may be calculated for any benzylated compound from:

$$E^{1\%}_{1\,cm} = \frac{\epsilon \times 10}{\text{Mol. Wt.}}.$$

As shown here $\epsilon_{258.5} = n \times 186 \pm 2$ where n is the number of benzyl groups in the molecule; hence $E^{1\%}_{1\,cm} = 1860n/\text{Mol. Wt.}$ This value for all benzylated compounds should lie between 0 and 18.8 (the value of $E^{1\%}_{1\,cm}$ for dibenzyl ether) if there is no interference from other chromophores.

THE PREPARATION AND REACTIONS OF SOME SIMPLE 2,8-DISUBSTITUTED PURINES AND RELATED DERIVATIVES

ARTHUR F. LEWIS, ALDEN G. BEAMAN, AND ROLAND K. ROBINS
Department of Chemistry, Arizona State University, Tempe, Arizona, U.S.A.
Received February 25, 1963

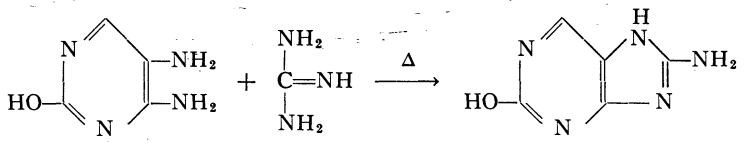
ABSTRACT

Several previously unknown, simple 2,8-disubstituted purines have been prepared. The readily available (see H. Ballweg, Ann. **649**, 114 (1961); and A. G. Beaman and R. K. Robins, J. Appl. Chem. (London), **12**, 432 (1962)) 2,8-dichloropurine proved to be a most valuable synthetic intermediate in this work. The chemical reactivity of 2,8-dichloropurine toward nucleophilic substitution has been studied.

INTRODUCTION

The 2,6-disubstituted purines have long been known and have been thoroughly investigated (1). A systematic study of the chemistry of various 6,8-disubstituted purines has likewise been made (2); however, no such investigation of 2,8-disubstituted purines has been undertaken, although about eighteen 2,8-disubstituted purines* have been described by an almost equally large number of investigators. The purpose of the present investigation was to prepare as many as possible of the remaining unknown 2,8-disubstituted purines having relatively simple substituents.

The method of introducing an 8-amino group by fusion of a 4,5-diaminopyrimidine with guanidine (2) was further investigated in the hope of applying it to the synthesis of the unknown 2-substituted-8-aminopurines. As a consequence of this investigation, 8-amino-6-purinethiol was prepared in large quantity and dethiated with Raney nickel to give an efficient new synthesis of the difficultly accessible 8-aminopurine (4(*a*)). Fusion of guanidine with 4,5-diamino-2-hydroxypyrimidine (I) (4(*b*)) gave 8-amino-2-hydroxypurine (II). Fusion of 4,5-diamino-2-pyrimidinethiol (4(*c*)) with guanidine failed to give



I II

8-amino-2-purinethiol. 2,4,5-Triaminopyrimidine was prepared by dethiation of 6-methylthio-2,4,5-triaminopyrimidine (5) with Raney nickel. This method proved to be superior to the preparation of 2,4,5-triaminopyrimidine from 2,4-diamino-5-nitropyrimidine (6). Fusion of this triamine with guanidine failed to give 2,8-diaminopurine (IV), which was prepared by dethiation of 2,8-diamino-6-purinethiol (III) (7) with Raney nickel. Fusion

**The known 2,8-disubstituted purines are: 2,8-dihydroxypurine (3(a, b)), 2-hydroxy-8-purinethiol (3(c)), 8-hydroxy-2-purinethiol (3(e)), 2,8-purinedithiol (3(f, h)), 2-hydroxy-8-methylthiopurine (3(e)), 8-hydroxy-2-methylthiopurine (3(e)), 2,8-bis(methylthio)purine (3(f)), 2-amino-8-hydroxypurine (3(b, d)), 2-hydroxy-8-methylaminopurine (3(c)), 2-amino-8-phenylpurine (3(g)), 8-hydroxy-2-methylsulphonylpurine (3(f)), 8-hydroxy-2-methylpurine (3(b)), 2,8-dichloropurine (3(i, j)), 2-chloro-8-hydroxypurine (3(j)), 8-chloro-2-methylthiopurine (3(e)), 2,8-dibromopurine (3(h)), 2-bromo-8-hydroxypurine (3(h)), and 2-hydroxy-8-methylpurine (3(k)).*

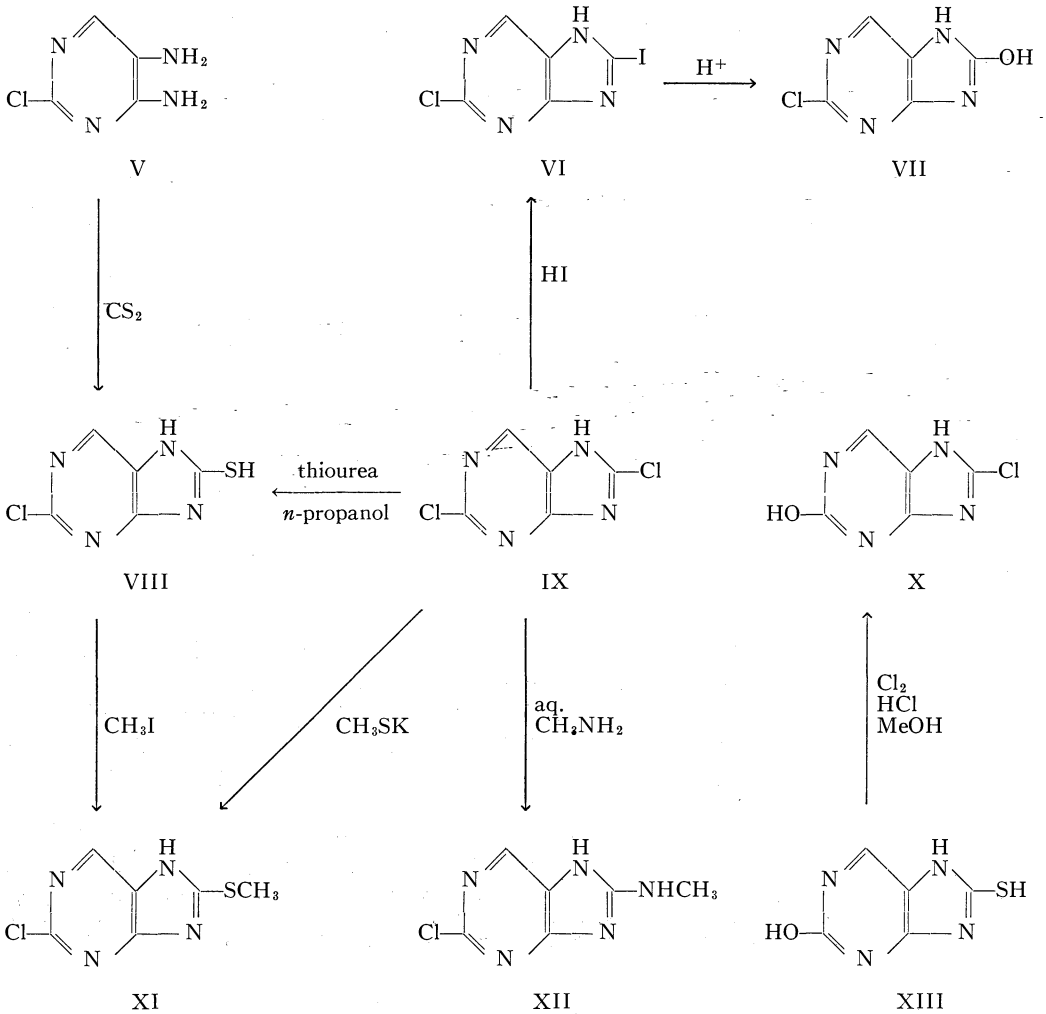
III IV

of 2,4,5-triaminopyrimidine with thiourea was successful and gave 2-amino-8-purinethiol. Treatment of 2,4,5-triaminopyrimidine with phosgene afforded a new route to 2-amino-8-hydroxypurine.

The recently described 2,8-dichloropurine (IX) (3(*i*, *j*)) proved to be a versatile intermediate for the synthesis of several inaccessible 2,8-disubstituted purines. When treated with thiourea in refluxing *n*-propanol, 2,8-dichloropurine (IX) gave a monochloromonothiopurine which was identical with 2-chloro-8-purinethiol (VIII) prepared from 2-chloro-4,5-diaminopyrimidine (V) (8) and carbon disulphide.



V VI VII

VIII IX X

XI XII XIII

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Upon treatment with hydriodic acid, 2,8-dichloropurine (IX) gave 2-chloro-8-iodopurine (VI), the structure of which was proved by acid hydrolysis to the known 2-chloro-8-hydroxypurine (VII) (3(*j*)). With warm aqueous methylamine 2,8-dichloropurine gave 2-chloro-8-methylaminopurine (XII), the structure of which was proved by treatment with palladium-on-charcoal in the presence of hydrogen to give the known 8-methylaminopurine (4).

With potassium methylmercaptide, IX gave a compound which was identical with 2-chloro-8-methylthiopurine (XI) obtained by methylation of 2-chloro-8-purinethiol (VIII). Refluxing 2,8-dichloropurine with an excess of sodium methoxide in methanol gave 2,8-dimethoxypurine.

When 2-hydroxy-8-purinethiol (XIII) (3(*c*)) was treated with chlorine gas in methanol plus aqueous hydrochloric acid, 8-chloro-2-hydroxypurine (X) was formed.

In the cases studied with 2,8-dichloropurine (IX), nucleophilic attack occurred at position 8 before position 2 when preferential nucleophilic displacement could be accomplished. This is interesting since 2,6,8-trichloropurine (9–11) and 6,8-dichloropurine (2) usually exhibit nucleophilic displacement first in the pyrimidine ring (position 6). These experimental observations, however, are in accord with the electron density calculations of Mason (12) and Pullman (13) which predict that nucleophilic attack should occur more readily at positions 8 and 6 than at position 2.

The mechanism for acid hydrolysis of a 2,8-dihalogenated purine has been proposed as involving protonation in the imidazole ring (3(*j*)) and resulting in the 2-halogenated 8-hydroxypurine. This mechanism receives further support from the study of the acid hydrolysis of 2-chloro-8-iodopurine (VI).

The ultraviolet absorption spectra of several of the 2,8-disubstituted purines are given in Table I.

EXPERIMENTAL

2,8-Diaminopurine (IV)

2,8-Diamino-6-purinethiol (III) (7) (36 g) was dissolved in a mixture of 4 liters of water plus 2.7 liters of conc. aqueous ammonia at 70°. With vigorous stirring 175 g of water-wet Raney nickel was added, and the mixture was boiled briskly and stirred for 1.5 hours. The nickel was filtered hot and washed with boiling water, and the combined filtrate was evaporated to 500 ml under reduced pressure. A small amount of slimy residue was removed by filtration, and the filtrate was further evaporated to 100 ml and refrigerated to give 24 g of crude 2,8-diaminopurine. An additional 7 g was obtained by evaporating the filtrate to dryness. The crude product was recrystallized from boiling water (7 parts) with the aid of charcoal to give colorless crystals, m.p. 296°. Calc. for $C_5H_6N_6$: C, 40.0; H, 4.0. Found: C, 39.4; H, 4.1. A sample was recrystallized from boiling 10% sulphuric acid to give a white solid, m.p. 300° decomp. Calc. for $C_5H_6N_6 \cdot H_2SO_4 \cdot \frac{1}{2}H_2O$: C, 23.4; H, 3.5; N, 32.7. Found: C, 23.6; H, 3.6; N, 32.7.

2-Chloro-8-iodopurine (VI)

2,8-Dichloropurine (IX) (3(*j*)) (2 g) was added slowly to 25 ml of 47% hydriodic acid at −10° with stirring. After the mixture was stirred for 1.5 hours at 0°, the solid was filtered, suspended in 30 ml of water, the pH adjusted to 5–6, and the slurry refrigerated. The solid was collected and suspended in hot water, and enough ammonia added to effect solution. The solution was treated with decolorizing charcoal and filtered, and the filtrate was adjusted to pH 5 with acetic acid and cooled. The resulting solid was recrystallized from water and ethanol to give colorless 2-chloro-8-iodopurine (1 g, 34%), m.p. 238–240°. Calc. for C_5H_2ClIN: C, 21.4; H, 0.7; N, 20.0; total halogen, 58.0. Found: C, 21.6; H, 0.8; N, 20.0; total halogen, 58.3.

8-Chloro-2-hydroxypurine (X)

2-Hydroxy-8-purinethiol (XIII) (3(*c*)) (5 g) was added to a mixture of 10 ml of methanol plus 30 ml of conc. aqueous hydrochloric acid at −20°. With stirring, chlorine gas was bubbled through the solution at −10 to −5°. The solid dissolved and another solid precipitated from solution. After about 12 minutes the reaction was complete. The mixture was poured on 150 g of ice with stirring; the pH was adjusted

*Inflection.
†Correction of data previously published, ref. 3(*f*).

to 1.5–2 with conc. aqueous ammonia, and the mixture was refrigerated for an hour. The crude 8-chloro-2-hydroxypurine was collected, washed with ice water, and dried to yield 2.6 g (51%). A sample was recrystallized from water and ethanol. Calc. for $C_5H_3ClN_4O$: C, 35.3; H, 1.8; N, 32.9. Found: C, 35.4; H, 1.5; N, 33.0.

8-Aminopurine

8-Amino-6-purinethiol* (20 g) was dissolved in 1 liter of distilled water plus 200 ml of conc. aqueous ammonia solution. Neutral water-wet Raney nickel (200 g) was added, and the mixture was refluxed with stirring for 2.25 hours. The nickel was filtered and washed with a little hot water, and the filtrate plus wash was boiled until no odor of ammonia could be detected. The light yellow 8-aminopurine, which formed on refrigeration, weighed 8 g. An additional 1 g (total yield 56%) was obtained by concentrating the filtrate to 100 ml. A sample was purified by precipitation from solution in dilute ammonia with acetic acid (pH 7). Calc. for $C_5H_5N_5$: C, 44.4; H, 3.7; N, 51.8. Found: C, 44.6; H, 4.0; N, 52.1.

2,4,5-Triaminopyrimidine Sulphate

A mixture of 33 g of 6-methylthio-2,4,5-triaminopyridine (5), 500 ml of distilled water, 300 ml of conc.

**A much better yield of 8-amino-6-purinethiol was obtained than previously reported (2) by fusion of 4,5-diamino-6-pyrimidinethiol with guanidine for 10 hours at 180–200°.*

aqueous ammonia solution, and 200 g of neutral water-wet Raney nickel was refluxed for 7 hours with vigorous mechanical stirring. The nickel was filtered and washed with hot water. The filtrate plus wash was boiled until there was no longer any ammonia odor (volume about 400 ml). The hot solution was acidified to pH 5 with sulphuric acid and cooled overnight. The yield of light-colored sulphate salt was 29 g (82%). Calc. for $C_4H_7N_5 \cdot \frac{1}{2}H_2SO_4 \cdot \frac{1}{2}H_2O$: C, 26.2; H, 4.9; N, 38.2; H_2O, 4.9. Found: C, 26.3; H, 5.2; N, 38.0; H_2O, 4.9 (Karl Fischer).

2-Amino-8-purinethiol

2,4,5-Triaminopyrimidine sulphate (5 g) and thiourea (15 g) were fused at 160–180° for 30 minutes. The cake was dissolved in 400 ml of hot 1 *N* potassium hydroxide solution and treated with charcoal. The filtrate was acidified (pH 2–3) with sulphuric acid and cooled to give 6 g of crude material. This product was dissolved in hot, dilute ammonia (charcoal) and precipitated with sulphuric acid (pH 7) to give a yellow product. Calc. for $C_5H_5N_5S$: C, 35.9; H, 3.0; N, 41.9. Found: C, 35.9; H, 3.0; N, 41.6.

2-Chloro-8-purinethiol (VIII)

Method (A).—2,8-Dichloropurine (IX) (3(*j*)) (1.0 g) was added to a solution of 0.40 g of thiourea in 30 ml of *n*-propanol. The solution was refluxed for 1 hour, and a yellow precipitate gradually formed. After refrigeration the product was collected, washed with water and acetone, and dried to yield 0.7 g of VIII. The product had an ultraviolet absorption spectrum identical with that of 2-chloro-8-purinethiol (VIII) prepared by method (B).

Method (B).—2-Chloro-4,5-diaminopyrimidine (V) (8) (5 g) was added to a mixture of 85 ml of pyridine and 20 ml of carbon disulphide, and the solution was refluxed for 3 hours. The cold solution was acidified to pH 1 with hydrochloric acid and cooled. The crude 2-chloro-8-purinethiol (VIII) was collected, washed with water and acetone, and dried to yield 2.7 g (42%). This material was further purified by reprecipitation from warm (50°) dilute ammonia with acetic acid (pH 6). Calc. for $C_5H_3ClN_4S$: C, 32.2; H, 1.6; N, 30.0 Found: C, 32.2; H, 1.6; N, 30.3.

2-Chloro-8-methylaminopurine (XII)

2,8-Dichloropurine (IX) (5 g) was dissolved in 150 ml of 40% methylamine solution. The solution was heated on the steam bath for 2 hours. An additional 100 ml of methylamine solution was added and the solution evaporated to dryness on the steam bath. The residue was dissolved in hot, dilute hydrochloric acid, treated with charcoal, and filtered, and the pH of the filtrate was adjusted to 7 with dilute potassium hydroxide. After refrigeration overnight, the light yellow product was filtered, washed with water and ethanol, and dried to yield 0.9 g. Calc. for $C_6H_6ClN_5$: C, 39.4; H, 3.3; N, 38.2. Found: C, 39.4; H, 3.6; N, 38.3.

8-Methylaminopurine

2-Chloro-8-methylaminopurine (XII, 0.5 g) was dissolved in a solution of 0.4 g of sodium hydroxide in 100 ml of water. Then 0.5 g of 10% palladium-on-charcoal was added and the mixture shaken for 3 hours under 45 lb/sq. in. pressure of hydrogen. The catalyst was filtered, and the filtrate was treated with charcoal, neutralized, and concentrated to 50 ml. The ultraviolet absorption spectrum of this solution was identical with that recorded by Albert and Brown (4) for 8-methylaminopurine.

2-Chloro-8-methylthiopurine (XI)

Method (A).—2-Chloro-8-purinethiol (VIII, 0.9 g) was dissolved in 10 ml of 1 *N* potassium hydroxide solution. Methyl iodide (3 ml) was added and the mixture stirred at room temperature for 1.5 hours. The solution was neutralized and cooled overnight to yield a yellow product, which was filtered, washed with water and acetone, and dried. The filtrate was extracted with ethyl ether and the ether evaporated to yield additional product. The total yield was 0.7 g (72%). A sample was recrystallized from methanol and water. Calc. for $C_6H_5ClN_4S$: C, 36.0; H, 2.5; N, 28.0. Found: C, 36.1; H, 2.8; N, 28.0.

Method (B).—2,8-Dichloropurine (IX, 2 g) was dissolved in a solution of 8 g of potassium hydroxide in 50 ml of water containing 10 ml of methanethiol. The solution was heated on a steam bath for 30 minutes and cooled; an additional 10 ml of methanethiol was added and the mixture heated for an additional hour. The solution was neutralized with glacial acetic acid and cooled overnight. The white solid which precipitated was filtered, washed with water and acetone, and dried to yield 0.25 g. The filtrate was extracted with ethyl ether and the ether evaporated to give 0.5 g of additional material. The product had ultraviolet and infrared absorption spectra identical with those of the 2-chloro-8-methylthiopurine (XI) prepared by method (A).

2,8-Dimethoxypurine

2,8-Dichloropurine (IX, 5 g) was added to a solution of 6 g of sodium in 150 ml of methanol. The solution was refluxed for 2.5 hours and evaporated to dryness on the steam bath. The residue was dissolved in water (100 ml), and the solution was neutralized with hydrochloric acid and cooled overnight. The product was filtered, washed with water and acetone, and dried to yield 2.6 g (54%). A sample was further purified by dissolving the product in hot, dilute aqueous ammonia. The solution was then treated with charcoal

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and filtered and the excess ammonia boiled away. The product then crystallized from the solution. Calc. for $C_7H_8N_4O_2$: C, 46.7; H, 4.4; N, 31.1. Found: C, 46.7; H, 4.7; N, 30.7.

2-Amino-8-hydroxypurine

2,4,5-Triaminopyrimidine sulphate (10 g) was dissolved in 100 ml of 2 *N* sodium hydroxide solution. Phosgene was bubbled through the solution, with stirring, for 45 minutes. Small amounts of 6 *N* sodium hydroxide solution were added as needed to maintain a basic solution (pH > 10). After this 45-minute period the phosgene addition was continued until the pH of the solution was approximately 7–8. The solution was then stirred for 0.5 hour without addition of phosgene, neutralized with aqueous hydrochloric acid, and cooled for several hours. The tan-colored solid was filtered, washed with water and acetone, and dried to yield 8 g. The product was dissolved in hot, dilute aqueous ammonia solution and precipitated with conc. hydrochloric acid (pH 6–7) to yield 4.5 g (55%). Calc. for $C_5H_5N_5O$: C, 39.7; H, 3.3. Found: C, 39.6; H, 3.6.

8-Amino-2-hydroxypurine Sulphate (II)

Guanidine hydrochloride (25.6 g) (85%) was converted to guanidine (2). 4,5-Diamino-2-hydroxypyrimidine sulphate (I) (4(*b*)) (10 g) was added, and the mixture was heated in a metal bath at 160–180° for 7.5 hours. The hard, black cake was dissolved in 500 ml of hot 1 *N* potassium hydroxide solution, treated with charcoal, and filtered and the filtrate acidified with acetic acid (pH 5). Upon refrigeration a light-colored product was obtained; it was filtered, washed with water and acetone, and dried to yield 5.5 g. The product was reprecipitated from dilute, aqueous ammonia with conc. sulphuric acid (pH 5–6) and then recrystallized from water to yield 2.0 g. The product was then extracted with methanol to remove a small amount of soluble impurity and finally recrystallized from water containing a little sulphuric acid to give 1.8 g. Calc. for $C_5H_5N_5O \cdot \frac{1}{2}H_2SO_4$: C, 30.0; H, 3.0. Found: C, 29.9; H, 3.8.

2-Chloro-8-hydroxypurine (VII)

2-Chloro-8-iodopurine (VI, 0.1 g) was dissolved in 30 ml of 1 *N* hydrochloric acid. The solution was refluxed for 20 minutes, cooled, neutralized with ammonia, and concentrated to a small volume. Upon refrigeration a white solid formed which possessed an ultraviolet absorption spectrum identical with that of 2-chloro-8-hydroxypurine (3(*j*)). The two compounds possessed the same R_f values in three solvent systems.

BEHAVIOR OF THE HETERO-RING IN γ-PHENYL-$\Delta^{\beta,\gamma}$-BUTENOLIDE DERIVATIVES TOWARD HYDRAZINES. ACID REARRANGEMENT OF 4-PHENYLAZO-2-PHENYLOXAZOLIN-5-ONE

AHMED MUSTAFA, SAMIR A. KHATTAB, AND WAFIA ASKER
Chemistry Department, Faculty of Science, Cairo University, Cairo, Egypt, U.A.R.

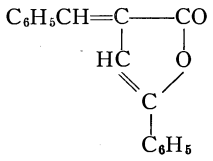
Received October 29, 1963

ABSTRACT

The substituted pyridazinones 3-phenyl- and 1,3-diphenyl-5-benzylidene-1,4,5,6-tetrahydropyridazinone-6 have been prepared from α-phenacylcinnamic acid hydrazide and α-phenacylcinnamic acid phenylhydrazone, respectively. The dipyridazinone 5,5-di(3-phenyl-1,4,5,6-tetrahydro)pyridazinone-6 was prepared from the dilactone IV, isolated as a side product in the synthesis of lactone VI.

Rearrangement of 4-phenylazo-2-phenyloxazolin-5-one now has been found to proceed also in the presence of acidic reagents.

α-Benzylidene-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide* (I) has been reported to undergo ring opening upon treatment with aqueous base, with methanol under both acidic and basic conditions (1, 2) and with benzylamine (1) to form α-phenacylcinnamic acid (II*a*), its methyl ester (II*b*), and its benzylamide derivative (II*e*) respectively.

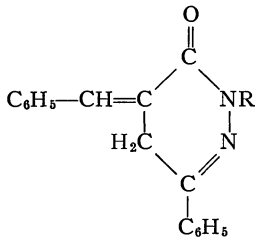


I

$C_6H_5CH{=}C(CH_2{-}COC_6H_5)COR$

II*a*, R = OH
b, R = OCH_3
c, R = $NHNH_2$
d, R = $NHNHC_6H_5$
e, R = $NHCH_2C_6H_5$

This investigation was undertaken with a view to study the behavior of the hetero-ring in compound I toward the action of hydrazines. Treatment of compound I with hydrazine hydrate effected ring opening with the formation of α-phenacylcinnamic acid hydrazide (II*c*). The latter compound underwent ring closure upon treatment with hydrochloric acid – acetic acid mixture or with aqueous sodium hydroxide solution with the formation of 3-phenyl-5-benzylidene-1,4,5,6-tetrahydropyridazinone-6 (III*a*) (or its tautomer).



III*a*, R = H
b, R = C_6H_5

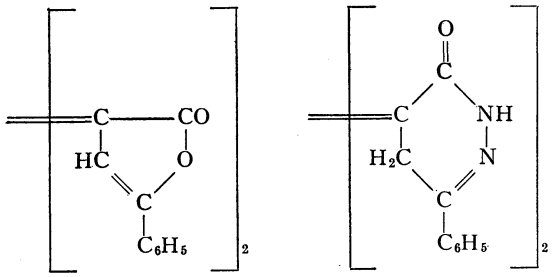
The proposed structure for the hydrazide II*c* finds support from the fact that this compound was readily obtained via treatment of methyl α-phenacylcinnamate (II*b*) with

**This nomenclature is after that used by Filler (1).*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hydrazine hydrate. Compound III*a* was also found to be identical with an authentic specimen prepared after Thiele (2).

When the dilactone IV was treated with hydrazine hydrate, 5,5′-di(3-phenyl-1,4,5,6-tetrahydro)pyridazinone-6 (V) (or its possible tautomer) was isolated, but not the corresponding acyclic hydrazide.

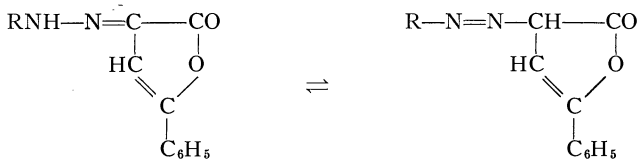


IV V

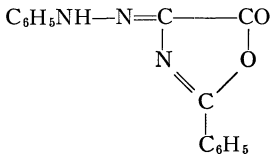
α-Phenacylcinnamic acid (II*a*), upon treatment with phenylhydrazine, gave the corresponding phenylhydrazone derivative. When the latter compound was treated with hot sodium hydroxide solution, it underwent ring closure with the formation of 1,3-diphenyl-5-benzylidene-1,4,5,6-tetrahydropyridazinone-6 (III*b*). The assigned structure for the latter compound finds support from its identity with a sample obtained via the condensation of 1,3-diphenyl-1,4,5,6-tetrahydropyridazinone-6 with benzaldehyde (3).

Phenylhydrazine was found to react with compound I, not to form the phenylhydrazone derivative of α-phenacylcinnamic acid but to give a colorless product believed to be α-phenacylcinnamic acid phenylhydrazide (II*d*).

Dieckmann described the preparation of α-phenylazo-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (VI*a*) by coupling of γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide with benzenediazonium chloride (4). We have succeeded in preparing a number of α-arylazo-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolides, VI*a–d*, after the procedure described by Sawdey (5) for the preparation of 4-phenylazo-2-phenyloxazolin-5-one (VII) using β-benzoylpropionic acid for hippuric acid. Work-up of the filtrate of



VI*a*, R = C_6H_5
b, R = C_6H_4—CH_3 (*p*)
c, R = C_6H_4—Cl (*m*)
d, R = C_6H_4—Cl (*p*)

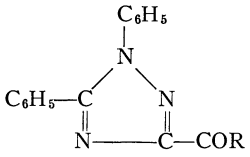


VII

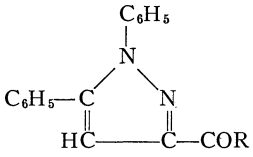
the reaction mixture, after separation of the reaction products VI*a–d*, gave dark red crystals identical with the dilactone IV (6, 7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

While the rearrangement of 4-phenyl-azo-2-phenyloxazolin-5-one (VII) and its carbon analogue α-phenylazo-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (VI*a*) was in progress in this laboratory (8), Browne and Polya (9, 10) reported the rearrangement of compound VII in the presence of basic reagents, a fact which prompts us to record our findings. Results in our hands confirm the findings of the latter authors, but we would like to report that the rearrangement of compound VII to 1,5-diphenyl-1,2,4-triazole-3-carboxylic acid hydrazide (VIII*c*) with hydrazine hydrate can be brought about in the absence of solvent. Hydrolysis of the hydrazide VIII*c* to the corresponding 1,5-diphenyl-1,2,4-triazole-3-carboxylic acid (VIII*a*) is readily effected by the action of hydrochloric acid – acetic acid mixture.



VIII*a*, R = OH
b, R = OCH_3
c, R = $NHNH_2$



IX*a*, R = OH
b, R = OC_2H_5
c, R = $NHNH_2$

We would like also to record that, though the latter authors reported that the rearrangement of compound VII did not occur in solutions acid to litmus, in our hands treatment of this compound with hydrochloric acid – acetic acid mixture yielded the triazole acid VIII*a* in a yield similar to that obtained by alkali rearrangement (5).

The carbon analogue VI*a* underwent rearrangement by action of alcoholic alkali or hydrochloric acid – acetic acid mixture to give the corresponding 1,5-diphenylpyrazole-3-carboxylic acid (IX*a*) (4). The ethyl ester IX*b*, now obtained from the corresponding acid IX*a*, reacts with hydrazine hydrate to give 1,5-diphenylpyrazole-3-carboxylic acid hydrazide (IX*c*).

EXPERIMENTAL

All melting points are uncorrected.

Action of Hydrazine Hydrate

(a) On α-Benzylidene-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (I)

Hydrazine hydrate (4 ml, 80%) was added to compound I (0.5 g) and the reaction mixture was allowed to stand at room temperature for half an hour with occasional shaking. The yellow color of compound I was completely discharged with the formation of a colorless deposit of α-phenacylcinnamic acid hydrazine (II*c*). It was collected, washed thoroughly with water, and upon crystallization from ethanol, gave colorless crystals, m.p. 185° (decomp.). Yield, ca. 53%.

Anal. Calc. for $C_{17}H_{16}N_2O_2$: C, 72.85; H, 5.71; N, 10.00. Found: C, 73.07; H, 5.93; N, 9.95.

It gave a red color with concentrated sulphuric acid and was found insoluble in cold aqueous sodium carbonate solution (1%). The infrared spectrum* showed well-defined absorption bands at 1650 cm^{-1} characteristic of the —CONH— group (11) and at 1700 cm^{-1} characteristic of the $—COC_6H_5$ group.

The hydrazide II*c* could also be obtained from methyl α-phenacylcinnamate (II*b*) and hydrazine hydrate in 80% yield when the reaction mixture was allowed to stand for 48 hours under the experimental conditions described above.

(b) On Dilactone IV

The reaction was carried out as for compound I and the mixture was left for 2 weeks. The product, 5,5′-di(3-phenyl-1,4,5,6-tetrahydro)pyridazinone-6 (V), was crystallized from acetic acid as colorless crystals (65% yield), m.p. >350°.

Anal. Calc. for $C_{20}H_{16}N_4O_2$: C, 69.76; H, 4.65; N, 16.27. Found: C, 69.87; H, 4.85; N, 16.19.

**The infrared spectra were produced on a Perkin–Elmer Infracord model 137B and the samples were examined in Nujol solution.*

Ring Closure of Hydrazide IIc

Method (a)

A mixture of glacial acetic acid (7 ml), hydrochloric acid (3.5 ml), and hydrazide II*c* (0.5 g) was refluxed for 1 hour. The cooled reaction mixture was poured into ice-cold water, and the precipitate so obtained was collected and washed thoroughly with water. It gave colorless crystals of 3-phenyl-5-benzylidene-1,4,5,6-tetrahydropyridazinone-6 (III*a*) from ethanol, m.p. 177°. Yield, ca. 43%.

Anal. Calc. for $C_{17}H_{14}N_2O$: C, 77.86; H, 5.34; N, 10.68. Found: C, 77.56; H, 5.46; N, 10.87.

Compound III*a* was proved to be identical with an authentic specimen prepared after Thiele (2) (mixed m.p. determination and identical infrared spectrum).

Method (b)

Aqueous sodium hydroxide solution (10 ml, 4%) was added to hydrazide II*c* (0.3 g) and the reaction mixture was refluxed for half an hour. It was then allowed to cool, diluted with water, and acidified with hydrochloric acid. The precipitated solid was collected, washed with water, and crystallized from ethanol to give colorless crystals of compound III*a*. Yield, ca. 35%.

Action of Phenylhydrazine

(a) On α-Phenacylcinnamic Acid (IIa)

Freshly distilled phenylhydrazine (3.0 g) was added to a suspension of the acid II*a* (3.0 g) in absolute ethanol (30 ml). The reaction mixture was refluxed for 5 hours. On evaporation of the solvent, an oily residue was obtained which after trituration with hot petroleum ether (b.p. 70–80°) was solidified to a pale yellow solid. Upon two crystallizations from the same solvent, it gave almost colorless crystals, m.p. 101° (slight decomp.); yield, 50%; identified as the phenylhydrazone derivative of the acid II*a*.

Anal. Calc. for $C_{23}H_{20}N_2O_2$: N, 7.86. Found: N, 7.66.

When a mixture of the above phenylhydrazone derivative (0.5 g), sodium hydroxide solution (20 ml, 4%), and ethanol (10 ml) was refluxed for 1 hour, it gave upon cooling a colorless deposit of 1,3-diphenyl-5-benzylidene-1,4,5,6-tetrahydropyridazinone-6 (III*b*). The latter was collected, washed with water, and crystallized from ethanol as colorless crystals, m.p. 124°. Yield, ca. 53%.

Anal. Calc. for $C_{23}H_{18}N_2O$: C, 81.65; H, 5.32; N, 8.28. Found: C, 81.61; H, 5.38; N, 8.28.

The product III*b* was found to be identical (m.p. and mixed m.p. determination, infrared spectral comparison, and color with concentrated sulphuric acid) with a sample obtained via the condensation of 1,3-diphenyl-1,4,5,6-tetrahydropyridazinone-6 with benzaldehyde (3).

(b) On α-Benzylidene-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (I)

Phenylhydrazine (0.4 g) was added to a suspension of compound I (1.0 g) in absolute ethanol (30 ml). The reaction mixture was refluxed for 5 hours and then the solvent was evaporated. The oily product so obtained was solidified on trituration with cold ether or petroleum ether and was crystallized from ethanol to give colorless crystals of α-phenacylcinnamic acid phenylhydrazide (II*d*), m.p. 207° (decomp.). Yield, ca. 28%.

Anal. Calc. for $C_{23}H_{20}N_2O_2$: C, 77.52; H, 5.61; N, 7.86. Found: C, 77.41; H, 5.58; N, 8.01.

It gave a yellowish red color with concentrated sulphuric acid and was found to be insoluble in cold sodium carbonate solution (1%). The infrared spectrum showed well-defined absorption bands at 1650 cm^{-1} characteristic of the —CONH— group (11) and at 1700 cm^{-1} characteristic of the $—COC_6H_5$ group.

Preparation of α-Arylazo-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolides (VIa–d)

The following exemplifies the procedure: To a solution of freshly distilled aniline (3.7 g) in glacial acetic acid (15 ml) was added hydrochloric acid (8 ml), then while the mixture was being cooled in ice and stirred, isoamyl nitrite (8 g) was added dropwise. To the diazonium mixture was added freshly fused sodium acetate (6.0 g). β-Benzoylpropionic acid (10.0 g) was added to acetic anhydride (40 ml) and the mixture was refluxed for 3 hours then allowed to cool to room temperature. This solution was added dropwise, with stirring and cooling in ice, to the diazonium mixture. The reaction mixture was allowed to stand overnight and the precipitated solid was collected, washed with water several times, and crystallized from a large volume of acetic acid.

The arylazo derivatives VI*a–d* (listed in Table I) ranged in color from brownish yellow to deep brown and were found to be sparingly soluble in common organic solvents. They showed an absorption maximum at 350 mμ, which was attributed to the arylhydrazone group (12).

α-Phenylazo-γ-phenyl-$\Delta^{\beta,\gamma}$-butenolide (VI*a*) was proved to be identical with an authentic specimen prepared after Dieckmann (4) (mixed m.p. determination and infrared spectral comparisons).

The mother liquors, after filtration of the products VI*a–d*, gave upon concentration and trituration with ether a dark red solid which was crystallized from xylene or acetic acid as dark red crystals of the dilactone IV in a yield which varied from 5–10%.

Anal. Calc. for $C_{20}H_{12}O_4$: C, 75.94; H, 3.79. Found: C, 75.84; H, 4.02.

The dilactone IV was identical with an authentic specimen prepared after Rogert and Ritter (6).

Formation of 1,5-Diphenyl-,1,2,4-triazole-3-carboxylic Acid Hydrazide (VIIIc)

(a) From 4-Phenylazo-2-phenyloxazolin-5-one (VII)

Hydrazine hydrate (5 ml) was added to a suspension of compound VII (1.0 g) in ethanol (30 ml). On shaking the reaction mixture for 15 minutes at room temperature, the orange color of compound VII disappeared with the formation of a colorless deposit. It was allowed to stand overnight, poured into water, and the precipitated solid was collected, washed with water, and crystallized from ethanol or chlorobenzene as colorless crystals of the hydrazide VIII*c*, m.p. 185°. Yield, ca. 42%.

Anal. Calc. for $C_{15}H_{13}N_5O$: C, 64.51; H, 4.65; N, 25.08. Found: C, 64.33; H, 4.84; N, 25.21.

The hydrazide VIII*c* could also be obtained in an almost quantitative yield when a suspension of compound VII (0.6 g) in hydrazine hydrate (10 ml) was allowed to stand for 6 weeks at room temperature.

(b) From 1,5-Diphenyl-3-carbomethoxy-1,2,4-triazole (VIIIb)

Compound VIII*c* was obtained either by allowing a suspension of the ester VIII*b* (0.3 g) in hydrazine hydrate (3 ml) to stand at room temperature for 4 weeks (yield was ca. 60%) or by heating the same suspension on the direct flame until the ester dissolved in the medium and then continuing the heating on a boiling-water bath for 15 hours. Yield, ca. 33%.

Hydrolysis of 1,5-Diphenyl-1,2,4-triazole-3-carboxylic Acid Hydrazide (VIIIc)

The hydrazide VIII*c* (0.5 g) was treated with a mixture of glacial acetic acid (15 ml) and hydrochloric acid (20 ml). The reaction mixture was refluxed for 3 hours, cooled, and poured into water. The solid so obtained was collected, washed with water, and crystallized from benzene as colorless crystals of 1,5-diphenyl-1,2,4-triazole-3-carboxylic acid (VIII*a*), m.p. 181° (decomp.), not depressed when admixed with an authentic specimen prepared after Sawdey (5). Yield, ca. 63%.

Action of Hydrochloric Acid – Acetic Acid Mixture on 4-Phenylazo-2-phenyloxazolin-5-one (VII)

Compound VII (2.0 g) was treated with a mixture of glacial acetic acid (40 ml) and hydrochloric acid (60 ml) and the reaction mixture was refluxed for 5 hours. Working up of the reaction product as above gave the acid VIII*a*. Yield, ca. 80%.

Preparation of 1,5-Diphenyl-3-carbethoxypyrazole (IXb)

To 1,5-diphenylpyrazole-3-carboxylic acid (IX*a*) (1.0 g) was added absolute ethanol (25 ml) and concentrated sulphuric acid (0.5 ml) and the reaction mixture was refluxed on a boiling-water bath for 5 hours. It was cooled, poured into ice-cold sodium carbonate solution (100 ml, 0.5%) and the solid obtained was collected, washed with water, and crystallized from dilute ethanol (1:1) as colorless crystals of the ethyl ester IX*b*, m.p. 90° not depressed when admixed with an authentic specimen (13, 14). Yield, ca. 77%.

Formation of 1,5-Diphenylpyrazole-3-carboxylic Acid Hydrazide (IXc) from the Ethyl Ester IXb

Method (a)

The ester IX*b* (1.0 g) was heated with hydrazine hydrate (5.5 ml) on a boiling-water bath for half an hour, then absolute ethanol (20 ml) was added to the reaction mixture, which was then refluxed for 3 hours. It was allowed to cool and then poured into water. The hydrazide IX*c* was collected, washed with water, and upon crystallization from ethanol, colorless crystals were obtained, m.p. 174°. Yield, ca. 63%.

Anal. Calc. for $C_{16}H_{14}N_4O$: C, 69.06; H, 5.03; N, 20.14. Found: C, 69.16; H, 5.27; N, 20.25.

Method (b)

The same hydrazide could also be obtained in a similar yield as above when a mixture of the ester IX*b* (1.0 g) and hydrazine hydrate (6 ml) was allowed to stand at room temperature for 1 week.

THE THERMAL DECOMPOSITION OF PERACETIC ACID IN THE VAPOR PHASE[1, 2, 3]

C. SCHMIDT AND A. H. SEHON
Department of Chemistry, McGill University, Montreal, Que.

Received June 28, 1962

ABSTRACT

The thermal decomposition of peracetic acid in a stream of toluene was studied over the temperature range 127–360° C. The main products of the reaction were CO_2, CH_3COOH, C_2H_6, CH_4, HCHO, O_2, and traces of CO. Dibenzyl was also formed.

The overall decomposition of peracetic acid was partly heterogeneous and was represented by the two parallel primary reactions

$$CH_3CO_2—OH \rightarrow CH_3CO_2 + OH \rightarrow CH_3 + CO_2 + OH \quad \text{(i)}$$

$$CH_3CO_2—OH \rightarrow CH_3COOH + \tfrac{1}{2}O_2. \quad \text{(ii)}$$

The dissociation energy of the O—O bond in peracetic acid was estimated to be 30–34 kcal/mole.

INTRODUCTION

The importance of hydroxyl radical reactions in oxidation processes of hydrocarbons is now widely accepted but very few studies have been made on the kinetics of the reactions between these radicals and different hydrocarbons. This is due in part to the lack of a suitable source of hydroxyl radicals. Several methods have been used to produce the radicals, e.g. electric discharge through water vapor (1), electron transfer reactions in aqueous solution (2), and the thermal and photochemical decomposition of hydrogen peroxide (3) and alkyl hydroperoxide (4), but all of these methods have many disadvantages.

It was considered possible that peracetic acid might be a convenient source of hydroxyl radicals both in the gas phase and in solution, the radicals being formed by the sequence of reactions

$$CH_3COOOH \rightarrow CH_3CO_2 + OH \rightarrow CH_3 + CO_2 + OH.$$

If the decomposition took place by this mechanism the rate of formation of hydroxyl radicals could readily be followed by measuring the rate of production of carbon dioxide.

In the present study the mechanism of the decomposition of peracetic acid was investigated in the gas phase using the "toluene-carrier technique" (5). It was also hoped that this study would lead to the evaluation of the O—O bond dissociation energy, $D(CH_3 \cdot CO_2—OH)$.

EXPERIMENTAL

Materials

Peracetic Acid

The primary difficulty in the preparation of peracetic acid is the extremely explosive nature of the compound. This hazard can be minimized by preparing small quantities of about 1 g and by maintaining the compound in solution at all times apart from two stages in its preparation.

The peracetic acid was prepared by the method of Egerton *et al.* (6), which yielded a product free from

acetic acid. The method consisted of perhydrolysis of the mixed anhydride of acetic and boric acid, prepared according to the procedure of Pictet (7), with 98% hydrogen peroxide, which was kindly supplied by the Becco Chemical Div., Buffalo, N.Y. The peracetic acid was separated from solid boric acid by distillation at room temperature and at a pressure of 10–12 mm Hg. The peracetic acid obtained in this manner was only 90% pure. The solution was frozen at −3° C, the crystals were filtered off and were shown to contain 98% peracetic acid. On redistillation of the melted crystals at a pressure of 10–12 mm Hg and at 18° C at least 99% pure peracetic acid was obtained.

The purity of the peracetic acid solution was established by titration of solutions of peracetic acid in 1:1 isopropanol–water solution using potassium hydroxide for the determination of total acid and sodium thiosulphate for the iodometric determination of "free" oxygen (8). If the results obtained with the two methods agreed within 1–2% it was assumed that the peracetic acid was free from acetic acid. Since hydrogen peroxide could have interfered with these methods its absence was always ascertained by titrating the solution at 0° C with permanganate in the presence of sulphuric acid and manganous sulphate, under which conditions peracetic acid is not titrated. The peracetic acid was also shown to be free of diacetyl peroxide.

The peracetic acid prepared by this method was found to be stable for periods of over 1–2 months when kept in the freezing compartment of an ordinary refrigerator. At room temperature pure peracetic acid underwent slow decomposition, e.g. about 9% decomposed during 19 hours. However, solutions of about 4% peracetic acid in toluene were shown to be stable at room temperature for periods of the order of 24 hours.

Toluene

Nitration grade toluene was generously supplied by the Gulf Oil Corporation, Pittsburgh, Pa. It was dried over anhydrous calcium sulphate and then distilled.

Methods

The vapor phase decomposition of peracetic acid was studied using a conventional apparatus as employed in the "toluene-carrier method" (5, 9). A pyrex reaction vessel was used in the temperature range 432–561° K. The total pressure in the reaction vessel was changed from 2.2 to 14 mm Hg and the ratio of toluene to peracetic acid was varied from 50 to 340. The time of reaction was limited to 0.28–0.78 second. The effect of the surface on the reaction was established by packing the reaction vessel with pyrex glass wool, which increased the surface-to-volume ratio by a factor of 20.

In general, 200 to 500 μmoles of peracetic acid was passed in a stream of toluene through the reaction vessel for periods of up to 20 minutes. To establish a mass balance for the reaction at different temperatures and to determine the condensable products which may have been formed in small amounts, special experiments were done under identical conditions using larger amounts of reactants over periods of time up to 4 hours.

The products which were non-condensable at −190° C, i.e. carbon monoxide, methane, and oxygen, were analyzed for carbon monoxide by combustion over copper oxide at 350° C and for methane by combustion over a hot platinum wire in the presence of a known excess of oxygen. The amount of oxygen collected at −190° C was calculated as the difference between the total amount of non-condensable gases and the sum of the amounts of methane and carbon monoxide. The products condensing at −190° C were analyzed for carbon dioxide and ethane as described previously (9). The contents of the trap maintained at −78° C were analyzed for "free oxygen" and total acid by titration with thiosulphate and hydroxide solutions as described above. The amount of undecomposed peracetic acid and the amount of acetic acid formed were calculated from these data. Formaldehyde which condensed also in this trap was determined with chromotropic acid according to the method of Stone (10). No hydrogen peroxide, diacetyl peroxide, methyl alcohol, or phenol were detected amongst the reaction products.

RESULTS

The main products of the reaction were carbon dioxide, acetic acid, ethane, methane, oxygen, and formaldehyde. Small amounts of dibenzyl were produced, the amounts increasing with temperature. The presence of ethylbenzene in the contents of the trap at −78° C was confirmed by vapor phase chromatography.[4] Minute quantities of carbon monoxide were formed, and these only at higher temperatures.

The overall rate of decomposition of peracetic acid was calculated from the amount of peracetic acid recovered, and was found to be first order with respect to peracetic acid. As shown in Table I, the first-order rate constant for the overall decomposition, k_0, was independent of the partial pressures of peracetic acid and toluene at any given temperature. However, as can be seen in Table II, the first-order rate constant k_0 was somewhat time dependent.

[4]*We should like to thank Dr. T. Vrbaski for the chromatographic analyses.*

The effect of the surface of the reaction vessel on k_0 was studied only at 432° K and 516° K. At the lower temperature the rate of decomposition in the packed reaction vessel was about 50% higher than that in the unpacked reaction vessel, as shown in Table III. At 561° K there was an increase in the rate of the reaction but this could not be determined precisely. The results of the analyses obtained for most of the products are given in Table IV, and the ratios of some of these products are given in Table V.

DISCUSSION

The main products of the reaction and the kinetic features of the overall decomposition of peracetic acid in an excess of toluene may be accounted for by the following set of reactions:[5]

$$CH_3COOOH \longrightarrow CH_3CO_2 + OH \quad [i]$$

$$CH_3CO_2 \longrightarrow CH_3 + CO_2 \quad [ii]$$

$$2CH_3 \longrightarrow C_2H_6 \quad [iii]$$

$$CH_3 + \phi CH_3 \longrightarrow CH_4 + \phi CH_2 \quad [iv]$$

$$OH + \phi CH_3 \longrightarrow H_2O + \phi CH_2 \quad [v]$$

$$CH_3 + \phi CH_2 \longrightarrow \phi CH_2CH_3 \quad [vi]$$

$$2\phi CH_2 \longrightarrow \phi CH_2CH_2\phi \quad [vii]$$

$$CH_3COOOH \xrightarrow{\text{wall}} CH_3COOH + \tfrac{1}{2}O_2 \quad [viii]$$

$$CH_3 + O_2 \longrightarrow CH_3O_2 \longrightarrow HCHO + OH. \quad [ix]$$

The results of Table IV demonstrate that the amount of peracetic acid decomposed was almost equal to the sum of carbon dioxide and acetic acid formed. Therefore, steps [i] and [viii] in the above scheme are considered to be simultaneous reactions responsible for the decomposition of peracetic acid. If the methyl radicals produced in reaction [ii] were removed only by reactions [iii], [iv], and [vi] one would expect that the ratio $2(C_2H_6+CH_4)/CO_2$ should be equal to unity. However, the results of Table V indicate that this ratio varied between 0.4 and 0.5, and this would suggest, therefore, that the methyl radicals must have disappeared by reactions leading to products other than methane and ethane. As stated previously, formaldehyde was found amongst the products. The formation of formaldehyde may be explained by the extremely rapid reaction [ix] between methyl radicals and molecular oxygen as postulated by Vanpee and Fally (11). As shown in Table V the amount of formaldehyde formed accounted almost completely for the loss of methyl radicals, i.e. the ratio $[2(C_2H_6+CH_4)+HCHO]/CO_2$ was only slightly smaller than unity.

The absence of hydrogen peroxide, and of methanol and phenol, from the reaction products excludes the possibility that the hydroxyl radicals were removed by the dimerization reaction

$$2OH \rightarrow H_2O_2$$

or by the metathetical reactions

$$\phi CH_3 + OH \rightarrow \phi OH + CH_3$$

$$\phi CH_3 + OH \rightarrow \phi + CH_3OH.$$

[5]*The symbol ϕ represents* C_6H_5.

Therefore, it would appear that most, if not all, hydroxyl radicals formed in reactions [i] and [ix] were removed by reaction [v] with toluene to form water. However, because of the great technical difficulties required to establish a water-free apparatus, no attempt was made to determine the amount of water formed in the decomposition. A similar hydrogen abstraction reaction was postulated by Kirk and Knox (4) to account for the removal of hydroxyl radicals in the presence of benzene. Since $D(\phi CH_2—H)$ is smaller than $D(\phi—H)$, it is reasonable to expect that the reaction of hydroxyl radicals with toluene would occur even more readily than that with benzene. Thus, benzyl radicals would have been produced not only in reaction [iv] but also in reaction [v], and in consequence considerably more methyl radicals could have been removed in reaction [vi] to give ethyl benzene. This may explain the fact that the ratio $[2(C_2H_6+CH_4)+HCHO]/CO_2$ was always smaller than unity. The participation of reaction [vi] was demonstrated also previously in systems leading to the formation of methyl radicals in the presence of toluene (9). The reason for methyl radicals not being removed exclusively by reaction [iv] is that the activation energy of this reaction is greater than 8 kcal/mole (9), and obviously reaction [iv] will be relatively less favorable at the lower temperatures used in these experiments.

The formation of dibenzyl is considered further evidence that the decomposition of peracetic acid involved free radicals. Carbon monoxide was formed in amounts not exceeding 1% of the amount of peracetic acid consumed and hence was ignored in the reaction scheme.

It is evident from the results listed in Table III that the pyrolysis of peracetic acid was heterogeneous. The ratio of acetic acid to carbon dioxide was larger in the packed reaction vessel, which was taken as proof for reaction [viii] occurring primarily on the surface of the reaction vessel.

All the experimental data are, therefore, consistent with the decomposition of peracetic acid proceeding by the two simultaneous reactions [i] and [viii], the first producing free radicals and the latter leading to the formation of acetic acid and oxygen on the walls of the reaction vessel.

In spite of the fact that the overall first-order rate constant k_0 was somewhat dependent on the time of the reaction, it was felt that the rate of decomposition could be represented to a good approximation by the expression

$$-\frac{d[PA]}{dt} = k_0[PA] = (k_1+k_2)[PA], \qquad [1]$$

where k_1 and k_2 represent the rate constants of reactions [i] and [viii] respectively, and [PA] refers to the peracetic acid concentration. The values of the rate constant k_1 were calculated as a function of the carbon dioxide formed, using the equation

$$k_1 = \frac{[CO_2]}{[PA]_0} k_0(1-e^{-k_0 t})^{-1}. \qquad [2]$$

In view of the complicated nature of the decomposition, the values obtained for k_1 were not considered to be sufficiently accurate to justify the calculation of the activation energy of reaction [i] from the temperature dependence of k_1. However, as was shown by Szwarc (12), an approximate value for the activation energy may be computed by assuming a reasonable value for the frequency factor in the Arrhenius equation. From a survey of the literature (3, 4) it would appear that a reasonable value of the frequency factor of reactions involving the dissociation of oxygen–oxygen bonds would be 10^{14} sec^{-1}. Using

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

this frequency factor and the values obtained for k_1 at the higher temperatures, where the contribution of the heterogeneous mode of decomposition was smaller, a value of 30–34 kcal/mole was estimated for the activation energy of reaction [i]. On the basis of the usual assumption that the reverse reaction involving the recombination of free radicals has no activation energy, this activation energy can be identified tentatively with the dissociation energy of the O—O bond in peracetic acid. This value seems reasonable when compared with the values of D(O—O) in hydrogen peroxide and diacetyl peroxide, which are 48.5 kcal/mole and 30 kcal/mole, respectively (13).

THE THERMAL DECOMPOSITION OF PERACETIC ACID IN AROMATIC SOLVENTS[1, 2]

F. W. EVANS[3] AND A. H. SEHON
Department of Chemistry, McGill University, Montreal, Que.

Received December 17, 1962

ABSTRACT

The thermal decomposition of peracetic acid in toluene, benzene, and *p*-xylene was studied over the temperature range 75–95° C. The main products of decomposition were found to be CH_4, CO_2, CH_3COOH; small amounts of methanol, phenols, and polymeric compounds were also detected.

The rate of the overall decomposition was first order with respect to peracetic acid, and the results could be explained by postulating the participation of the two simultaneous reactions:

$$CH_3COOOH \xrightarrow{k_1} CH_3CO_2 + OH \rightarrow CH_3 + CO_2 + OH \qquad (1)$$

$$CH_3COOOH + RH \xrightarrow{k_2} CH_3COOH + \text{"RHO"}. \qquad (2)$$

The rate constant of reaction (1) was independent of the solvent, whereas k_2 was dependent on the solvent. The ratio k_2/k_1 was about 10.

INTRODUCTION

The thermal decomposition of many peroxy compounds in organic solvents has been studied but very little information is available concerning the decompositions of peroxy acids. The reactions of these latter compounds with olefins leading to the formation of epoxides are well understood (1), but reactions involving peracids with other organic compounds are only now receiving attention. The results of these recent studies are, however, confusing, and several different mechanisms have been reported for the decomposition reactions of peracids. Thus, the decomposition of perbenzoic acid in benzene (2) was accounted for by a first-order free-radical reaction involving the dissociation of the O—O bond; however, this decomposition followed a different mechanism in 1-butanol solution.

Similarly, various reaction mechanisms have been postulated for the decomposition of perlauric acid in solution (3, 4). According to Swern *et al.* (3) the decomposition of perlauric acid in benzene involved primarily the formation of oxygen and lauric acid, and possibly a small amount of free radicals. However, Letort *et al.* (4) suggested that the initial step in the decomposition of perlauric acid might involve the dissociation of the O—O bond, and that the subsequent step resulted in the decarboxylation of the corresponding free radical.

The pyrolysis of peracetic acid in the vapor phase had been studied previously in this laboratory (5, 6), and was found to involve two simultaneous reactions: (i) a free-radical homogeneous reaction, and (ii) a heterogeneous reaction. Since the solvation effects in hydrocarbon solution may be expected to be quite small, it was anticipated that the rate of the free-radical reaction in solution should be of the same order of magnitude as that

in the vapor phase. Hence, in the present investigation the thermal decomposition of peracetic acid was studied in some aromatic solvents.

EXPERIMENTAL

Materials

The peracetic acid was prepared essentially according to the method described previously (5, 6), i.e. by the addition of 99% hydrogen peroxide to the mixed anhydride of acetic acid and boric acid. The peracetic acid was separated from the reaction mixture by distillation at room temperature and at 2–5 mm Hg pressure, the middle fraction being collected in a trap at −196° C. This product was then immediately dissolved in six times its volume of toluene and purified by crystallization from this solution in the apparatus shown in Fig. 1. The toluene solution was placed in the left-hand arm, which was equipped with a sintered-glass

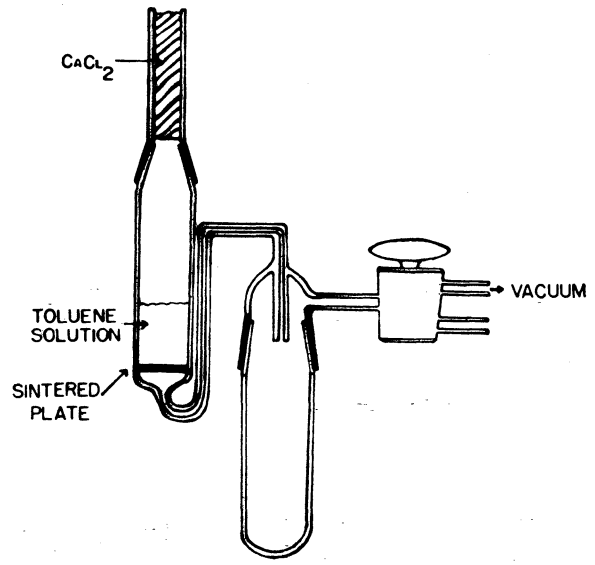

FIG. 1. Apparatus for recrystallization of peracetic acid.

disk, and cooled to −78° C. At this temperature the peracetic acid crystallized out of the solution and the supernatant was drawn off by suction, leaving the peracetic acid on the glass disk. The crystals were dissolved in pure toluene and the crystallization process was repeated. Finally, a stream of dry air was drawn over the crystals to remove the last traces of toluene. The desired solution was then made by the addition of an appropriate solvent onto the glass disk. This method was less dangerous than the method described previously (6), as the peracidic acid was never handled in the pure, solid state, but only in solution.

The purity of the product was determined by iodometric and acidimetric titrations (6); it was shown to be free of acetic acid, hydrogen peroxide, or diacetyl peroxide, and to be at least 98% pure peracetic acid.

The other reagents used in this study were commercial samples. Nitration grade toluene was generously supplied by Gulf Oil Corporation, Pittsburgh, Pa., and was dried over anhydrous calcium sulphate and then distilled. A.R. grade benzene (Mallinckrodt Chemical Works) was dried with sodium wire and distilled. *p*-Xylene (highest purity grade, Eastman Kodak Co.) was dried over sodium and then distilled; a sample of this material was found to be free from other xylenes on analysis by gas chromatography.

Methods

Known amounts of peracetic acid were dissolved in each of the appropriate solvents as described above, and the solutions were transferred into 50-cc glass reaction vessels sealed onto a high-vacuum manifold. Each of the reaction vessels was also equipped with a "break-seal". To remove all of the dissolved air, the solutions in the reaction vessels were degassed and the reaction vessels were then sealed off. The peracetic acid was decomposed by placing the reaction vessels in a thermostated water bath controlled to ±0.05° C. The decomposition was stopped after the desired period of time by removing the reaction vessel from the thermostat and placing it in a "dry-ice" bath. Five to eight solutions could be heated simultaneously and, in general, each reaction vessel was heated for a different period of time. The products of each reaction mixture were determined independently by the methods described below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Each of the reaction vessels was connected through the "break-seal" to an apparatus designed for the analysis of small gas samples. The gaseous products of the reaction were separated and measured on a high-vacuum system by distillation of the reaction mixture through a series of traps maintained at −78° C, −117° C, and −196° C. The gases which were non-condensable at −196° C were collected by means of a Toepler pump into a calibrated volume. They were shown to contain only methane by mass spectrometric analysis. The products condensing at −196° C were measured in the same way as the methane by warming this trap to −78° C; the mass spectrometric analysis of these gases showed that they consisted of only carbon dioxide, i.e. no ethane was found amongst the reaction products.

The remainder of the products, together with the unchanged reactants, was collected in the trap maintained at −117° C. These were always analyzed for peracetic acid and for total acid by titration with sodium thiosulphate and potassium hydroxide solutions, respectively (6). The presence of acetic acid amongst the reaction products was shown by the gas chromatographic analysis of a sample of the products, which had been separated by distillation on a "Nestr" spinning-band column. The identity of the acetic acid so separated was further confirmed by infrared spectrum analysis. The other acidic materials present in the toluene solution were concentrated, tested with Millons reagent (7), and shown to contain small amounts of phenolic materials. One other product of the reaction was a dark polymeric material. This was isolated by carrying out the decomposition of peracetic acid to completion and distilling off the other products and the solvent. This polymeric material was soluble in dilute aqueous alkaline solution and in carbon tetrachloride. The infrared spectrum of this latter solution showed broad peaks at 1166, 1260, 1458, 1497, 1602, 1695, 1726, 2920, 2960, and 3030 cm^{-1}.

RESULTS AND DISCUSSION

The products of the decomposition of peracetic acid in toluene, benzene, or *p*-xylene were found to be methane, carbon dioxide, acetic acid, phenolic compounds, and a polymeric material. In general, only the first three products were determined, in addition to the amount of undecomposed peracetic acid. The results of a typical reaction are shown in Table I.

TABLE I

Reaction time (min)	CH_4 (μmole)	CO_2 (μmole)	$\frac{CH_4}{CO_2}$	Peracetic acid remaining (μmole)	Acetic acid (μmole)	Total acid remaining (μmole)	Total acid remaining plus CO_2 (μmole)
60	1.47	1.86	0.82	140	17	157	159
120	1.77	2.40	0.74	128	29	157	159
180	2.30	3.14	0.73	114	38	152	155
240	3.61	5.50	9.66	99	63	162	167
300	3.50	4.80	0.73	89	70	159	164
360	4.08	4.95	0.83	82	77	159	164

From these data the following rate constants were calculated at 85° C: $k_0 = 3.22\times10^{-5}$ sec^{-1}, $k_1 = 0.21\times10^{-5}$ sec^{-1}, and $k_2 = 3.01\times10^{-5}$ sec^{-1}

NOTE: Each sample contained initially 162 μmoles peracetic acid in 7 ml toluene.

It was found that the rate of the overall decomposition was first order with respect to peracetic acid (Fig. 2), and that the amount of peracetic acid decomposed was equal to

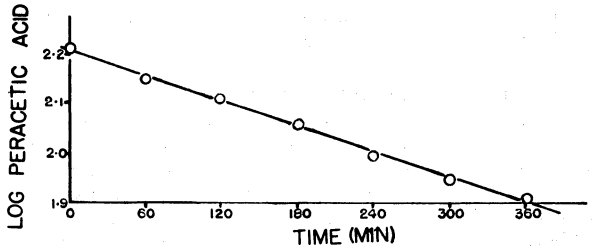

FIG. 2. Kinetics of the overall decomposition of peracetic acid.

the amount of acetic acid plus carbon dioxide formed within the uncertainties of the analytical determinations. With this limitation in mind, these results could be explained by postulating that the decomposition of peracetic acid involved the two simultaneous reactions

$$CH_3COOOH \xrightarrow{k_1} CH_3CO_2 + OH \rightarrow CH_3 + CO_2 + OH \quad [1]$$

$$CH_3COOOH + RH \xrightarrow{k_2} CH_3COOH + \text{"RHO"} \quad [2]$$

and that the rates of these reactions were measured by the rates of formation of carbon dioxide and acetic acid. The rate constants were calculated using the relations

$$k_0 = k_1 + k_2$$

$$k_1 = \frac{[CO_2]}{[PA]_0} k_0(1-e^{-k_0 t})^{-1}$$

$$k_2 = \frac{[HA]}{[PA]_0} k_0(1-e^{-k_0 t})^{-1},$$

where k_0 is the overall rate constant for the decomposition of peracetic acid, $[CO_2]$ and [HA] are the amounts of carbon dioxide and acetic acid formed, respectively, in time t from an initial amount of peracetic acid $[PA]_0$.

As is evident from Fig. 3, the kinetics of the decomposition of peracetic acid could be

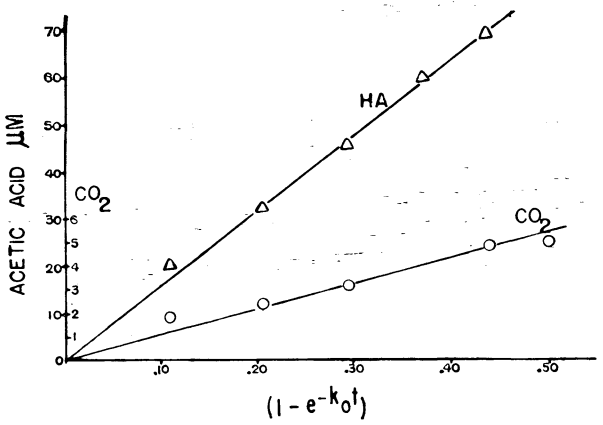

FIG. 3. Kinetics of the formation of acetic acid and carbon dioxide.

represented by this mechanism. The values of k_0, k_1, and k_2 were determined for different reaction mixtures in the three solvents at 85° C, and in the range 75–95° C for toluene solutions. From the results listed in Table II, the following conclusions can be drawn:

(i) the decomposition was first order with respect to peracetic acid,

(ii) the rate constant for reaction [1], i.e. k_1, was independent of the solvent,

(iii) the rate constant k_2 was dependent on the solvent, increasing with increasing methyl substitution of the benzene ring.

Reaction [1] was found to be independent of the solvent. It was assumed to involve the dissociation of the O—O bond and the formation of hydroxyl and acetyl radicals, and that subsequently the latter radicals decomposed to give a methyl radical and a molecule

of carbon dioxide. In accordance with other free radical reactions in solution (8), it was considered that some of the methyl and hydroxyl radicals would combine together before escaping from the solvent cage to form methanol. For this reason a sample of the reaction products was analyzed by gas chromatography and indeed small amounts of methanol were detected.

The hydroxyl and methyl radicals which escape from the solvent would be expected to react with the solvent molecules. Methyl radicals react with aromatic compounds by abstraction of a hydrogen atom to form methane, or by addition onto the benzene ring. If all the methyl radicals react to form methane, then, according to reaction [1], one would expect the ratio of CH_4/CO_2 to be unity. However, from the results listed in Table II, it can be seen that this ratio was only of the order of 0.8 in toluene and *p*-xylene. Therefore, it follows that some of the methyl radicals were removed either by reaction with hydroxyl radicals to give methanol, or by addition to the solvent molecules. It has been demonstrated in the decomposition of diacetyl peroxide in toluene (9) that methyl radicals react with the solvent only by a hydrogen abstraction reaction. Therefore, by analogy, in the decomposition of peracetic acid in toluene and *p*-xylene, the addition of methyl radicals to the solvent may be excluded, and it is concluded that about 20% of the methyl radicals formed in these solvents react with hydroxyl radicals to form methanol. The presence of methanol amongst the products of the reaction was proved, but because of the small amounts of methanol formed, these were not determined quantitatively. From the results of Table II, it is evident that the ratio of CH_4/CO_2 in benzene was very much lower than in the other two solvents and this might be accounted for by the disappearance of a large proportion of the methyl radicals by addition onto the benzene molecules. This explanation is supported by similar results obtained in the decomposition of diacetyl peroxide in benzene (9).

Some of the hydroxyl radicals produced in reaction [1] react with methyl radicals to form methanol. The others would be expected to react with the solvent to form water or phenols. Because of technical difficulties, the small amounts of water which might have been produced were not determined. On the other hand, phenols were detected amongst the products of the reaction and were determined spectrophotometrically in a few experiments as the corresponding nitrosophenol derivatives (10). From these analyses it was estimated that the amounts of phenols formed were in excess of the amounts of hydroxyl radicals produced in reaction [1], and hence it is concluded that some, if not all, of the phenols were produced in reaction [2].

The decomposition of peracetic acid leading to the formation of acetic acid necessitates

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the loss of oxygen from the reactant. In the study of the pyrolysis of peracetic acid in the vapor phase (6), it was shown that molecular oxygen was formed primarily by a heterogeneous reaction and that it was almost completely removed by reaction with methyl radicals to give formaldehyde. By contrast, in solution no detectable amounts of oxygen or of formaldehyde were produced, and it is concluded that no molecular oxygen was formed. The rate of reaction [2] was found to depend on the solvent, which indicates that peracetic acid reacted directly with the solvent molecules to form some intermediate "oxygenated" compound, denoted here as "RHO", which led to formation of phenols and polymeric materials. It is interesting to note that these products are very similar to those obtained by Cvetanović *et al.* (11) in the direct oxidation of these compounds by oxygen atoms.

The rate of reaction [2] was measured by the rate of formation of acetic acid. A comparison of the rate constants k_1 and k_2 given in Table II indicates that reaction [2] was about 10 times as fast as reaction [1] under the experimental conditions used. It is of interest to compare the decomposition of peracetic acid with that of perlauric acid (3) under similar conditions. In both cases the decomposition proceeds by two simultaneous reactions, i.e. a free-radical reaction of only secondary importance, and the main reaction leading to the formation of either acetic or lauric acid, respectively. The mechanisms of these latter reactions are, however, quite different: no oxygen was formed in the decomposition of peracetic acid and it was concluded that this peracid reacted with solvent; by contrast, the main products of the decomposition of perlauric acid were lauric acid and oxygen.

The rate of reaction [1], i.e. of the free-radical reaction, was measured in toluene at three temperatures, and in benzene and *p*-xylene at one temperature, 85° C. The concentration of peracetic acid in toluene was varied within the range 0.007–0.023 M and the time of the reaction was varied from 20 to 420 minutes. From the values of k_1, the activation energy of reaction [1] was calculated as 31.5–33.0 kcal/mole, on the assumption that the frequency factor in the Arrhenius equation was 10^{14} sec^{-1} (6). This value agrees with the value of 30–34 kcal/mole calculated for the activation energy of the same reaction in the gas phase and may be identified with the O—O bond dissociation energy in peracetic acid, i.e. $D(CH_3COO—OH)$. This value is slightly higher than the oxygen–oxygen bond dissociation energy in diacetyl peroxide of 29.5 kcal/mole (12), and lower than that for the same bond in hydrogen peroxide, i.e. $D(HO—OH) = 48$ kcal/mole (13).

NOTES

OCCURRENCE OF THE ρ PHASE AMONG CHALKOGENIDES

OSVALD KNOP

In a previous communication (1) the existence of a number of π phases of the type Co_8MS_8 has been reported and attention drawn to the relative paucity of occurrence of the π phase. This is noteworthy, as the somewhat analogous spinels, which are also based on a cubic close-packed structure of oxygen or sulphur with the metal atoms in tetrahedral or octahedral coordination, are much more widely distributed.

In an attempt to extend the number of known π phases several sulphides of the overall composition M_9S_8 (M = Ru, Rh, Pd, Ir; Ag) were prepared by dry synthesis from very pure elements. Although a cubic phase of the alleged composition Rh_9S_8 had been reported previously and its symmetry described as primitive rather than face-centered cubic (2, 3), its preparation was repeated in view of the unsatisfactory past experience with other chalkogenides of unusual stoichiometries whose formulae and structures had been assigned by analogy with better-studied compounds. Seven compositions were prepared in all, but none of them contained a π phase. Instead, the primitive cubic symmetry of "Rh_9S_8" has been confirmed and another, presumably isostructural, phase has been found in a preparation containing Rh and Pd. These phases will be referred to as ρ phases for brevity. In the following, the intended formulae (in square brackets) and the results of a phase analysis are given. Filtered Cu K radiation was used throughout ($\lambda\alpha_1$ = 1.54050 Å).

[Ru_9S_8]: A mixture of Ru and RuS_2, the latter with $a_0 = 5.6100\pm7$ Å. This value corresponds to the $C2$ phase saturated with Ru and is, to our knowledge, the most accurate value so far reported for a well-defined RuS_2.

[Rh_9S_8]: Pure cubic pattern with no systematic absences and no foreign lines present. The same phase, ρ(Rh,S), as described previously must thus have been obtained; $a_0 = 9.9103\pm23$ Å.

[Pd_9S_8]: Although the existence of an intermediate body-centered cubic phase $Pd_{2.2}S$ has been described (4), a mixture of Pd_4S and PdS was found in this preparation, presumably because of the relatively short annealing time or too high annealing temperature. The identification of PdS was not completely certain because of the poor quality of the diffraction lines.

[Ir_9S_8]: Ir + ?; the unidentified phase was neither π nor ρ.

[Rh_8PdS_8]: Pattern of a homogeneous ρ phase was found with $a_0 = 9.9301\pm21$ Å.

[Rh_8AgS_8]: ρ + ?; $a_0 = 9.9115\pm19$ Å. It is doubtful that silver was accommodated in the ρ structure to any extent. The second phase was presumably a Ag_2S polymorph, but the quality of the lines made it difficult to establish its identity.

[$Ru_{4.5}Pd_{4.5}S_8$]: Ru + $C2$ + ? The $C2$ phase had $a_0 = 5.6100\pm11$ Å and must have been RuS_2, possibly with some Pd substitution.

The ρ phase has thus been found only in three preparations, and it is likely that only *two* distinct phases were present, ρ(Rh,S) and $\rho(Rh_8PdS_8)$. In addition to these there exists ρ(Pd,Se) (4, 5). As for the true composition and structure of ρ(Rh,S), Stubbles (2) concluded from his equilibration studies that its composition was nearer Rh_8S_7 than Rh_9S_8,

and that the phase had a narrow homogeneity range and only a small degree of intrinsic disorder. The difficulty concerning the correct formula seems to have been resolved recently by Geller (6), who obtained the crystal structure of the phase and found by crystallographic argument that the true primitive formula should be $Rh_{17}S_{15}$. Since our experimental work was done before the publication of Geller's results, we had been unaware of the correct formula and therefore selected the compositions Rh_8PdS_8 and Rh_8AgS_8 on the assumption that the coordination situation in ρ(Rh,S) was similar to that in π(Co,S). Since this now has been shown not to be the case, nothing can be said at present about the nature of the Pd substitution in the ρ(Rh,S) structure, apart perhaps from a speculation that the palladium atoms would tend to prefer square planar coordination and thus might locate in the 3(*d*) sites of the *Pm3m* structure proposed by Geller. Ibrahim (7) prepared, in this laboratory, as early as 1957 a number of compositions of the type π(Co,Rh,S) and these are now being examined in the light of the tetrahedral, octahedral, and square planar coordination preferences.

MONOFLUOROSUCCINIC ACID[1]

F. H. DEAN AND F. L. M. PATTISON

Monofluorosuccinic acid, $HOOCCH_2CHFCOOH$, is an interesting compound from a biochemical standpoint, because it is one of the few remaining monofluorinated members of the tricarboxylic acid cycle which has not yet been authenticated; as such, its action on the enzymes of the cycle would be significant in the general study of poisoning by organic fluorine compounds.

Mention has been made of this acid on several occasions. Martius (2), in 1949, reported experiments using monofluorosuccinic acid; he thanked Professor Theilacker for a gift of the acid, but no details of its preparation have appeared in the literature. In 1953, Gitter, Blank, and Bergmann (3) stated that the sodium salt is non-toxic, but gave no indication of the source nor of the method of preparation of the material tested. In 1956, Bergmann and Szinai (4) reported the preparation of an impure sample of diethyl monofluorosuccinate by reaction of the enolate of ethyl fluoroacetate with ethyl bromoacetate;

[1]*First reported at the Second International Symposium on Fluorine Chemistry, Estes Park, Colorado, July 17–20, 1962 (1).*

and that the phase had a narrow homogeneity range and only a small degree of intrinsic disorder. The difficulty concerning the correct formula seems to have been resolved recently by Geller (6), who obtained the crystal structure of the phase and found by crystallographic argument that the true primitive formula should be $Rh_{17}S_{15}$. Since our experimental work was done before the publication of Geller's results, we had been unaware of the correct formula and therefore selected the compositions Rh_8PdS_8 and Rh_8AgS_8 on the assumption that the coordination situation in ρ(Rh,S) was similar to that in π(Co,S). Since this now has been shown not to be the case, nothing can be said at present about the nature of the Pd substitution in the ρ(Rh,S) structure, apart perhaps from a speculation that the palladium atoms would tend to prefer square planar coordination and thus might locate in the 3(*d*) sites of the *Pm3m* structure proposed by Geller. MONOFLUOROSUCCINIC ACID[1]

F. H. DEAN AND F. L. M. PATTISON

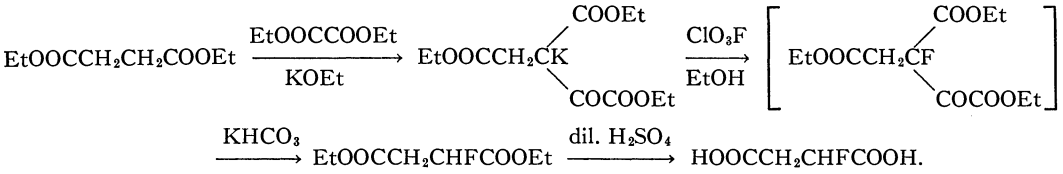
Monofluorosuccinic acid, $HOOCCH_2CHFCOOH$, is an interesting compound from a biochemical standpoint, because it is one of the few remaining monofluorinated members of the tricarboxylic acid cycle which has not yet been authenticated; as such, its action on the enzymes of the cycle would be significant in the general study of poisoning by organic fluorine compounds.

Mention has been made of this acid on several occasions. Martius (2), in 1949, reported experiments using monofluorosuccinic acid; he thanked Professor Theilacker for a gift of the acid, but no details of its preparation have appeared in the literature. In 1953, Gitter, Blank, and Bergmann (3) stated that the sodium salt is non-toxic, but gave no indication of the source nor of the method of preparation of the material tested. In 1956, Bergmann and Szinai (4) reported the preparation of an impure sample of diethyl monofluorosuccinate by reaction of the enolate of ethyl fluoroacetate with ethyl bromoacetate;

[1]*First reported at the Second International Symposium on Fluorine Chemistry, Estes Park, Colorado, July 17–20, 1962 (1).*

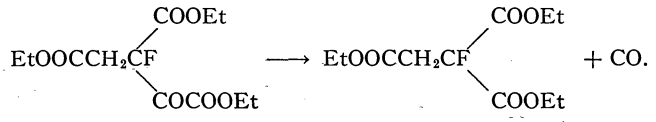
the analysis was in error, and the authors stated that the ester could not be obtained in a pure condition. Hydrolysis of this crude material did not yield the free acid by the procedures used. Finally, Peters (5), a year later, called attention to the unconfirmed results of Martius and questioned the identity of the test sample, "as several others (personal communication) have not been successful in preparing monofluorosuccinic acid".

We now wish to report the preparation of this acid from diethyl succinate by the following route:



The method involves the addition of the ethoxalyl grouping, which in turn promotes fluorination (6) by perchloryl fluoride. The strongly electronegative character of the fluorine atom thus introduced greatly facilitates the alkaline cleavage of the resulting non-enolizable β-keto-ester. Under the very mild reaction conditions, beta-elimination of hydrogen fluoride becomes negligible. In short, the activating ethoxalyl grouping is preferentially removed. The overall yield of diethyl monofluorosuccinate, based on the potassium enolate of triethyl oxalylsuccinate, was 73%; the acid hydrolysis of this ester to monofluorosuccinic acid proceeded in 67% yield.

The intermediate ester, triethyl α-fluoro-α-oxalylsuccinate, could not be purified by distillation, even at 0.05 mm pressure, because of ready decarbonylation. Under these conditions, diethyl α-fluoro-α-carbethoxysuccinate was formed in 77.5% yield:



Monofluorosuccinic acid and its diethyl ester were found to be non-toxic to mice by intraperitoneal injection in propylene glycol ($LD_{50} > 107$ mg/kg). The acid is being examined in other laboratories for its biochemical properties.

EXPERIMENTAL

Melting points (uncorrected) were determined on a Kofler hot stage, and densities with a Fisher–Davidson gravitometer. The nuclear magnetic resonance spectrum was obtained with a Varian DP-60 spectrometer. Infrared spectra were obtained with a Beckman IR-7 infrared spectrophotometer (in the case of diethyl monofluorosuccinate) or with an IR-5 (in the case of monofluorosuccinic acid and diethyl α-fluoro-α-carbethoxysuccinate). The perchloryl fluoride was purchased from the Technical Division of Pennsalt Chemicals Corporation, Philadelphia 18, Pa.

Potassium Enolate of Triethyl Oxalylsuccinate

The potassium enolate was prepared by the standard procedure (7) with two modifications: (*a*) the work was carried out in a nitrogen atmosphere; and (*b*) the freshly cut potassium was not washed with ether. By this means, the formation of potassium hydroxide and carbonate was reduced. Diethyl succinate was freshly redistilled through a 23-plate spinning band column (b.p. 97° at 8 mm, n_D^{25} 1.4185, d_4^{20} 1.035). Diethyl oxalate was similarly purified (b.p. 76° at 10 mm, n_D^{25} 1.4090, d_4^{20} 1.075). The super-dry ethanol was stored over Linde molecular sieves, Type 5A. The enolate was washed with dry ether and placed in a P_2O_5 vacuum desiccator for 15 hours at 0.5 mm. Yield: 91–97%, as a light yellow, friable solid.

Diethyl Monofluorosuccinate

A 500-ml three-necked flask was equipped with a stirring magnet, a gas-inlet tube with a fritted-glass gas disperser, a drying tube filled with indicating Drierite, and a −50° to +50° thermometer secured by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

gum-rubber tubing to a ground-glass holder. After the flask had been flushed with dry nitrogen, dry potassium enolate (23.6 g, 75.5 mmoles) was introduced, followed by super-dry ethanol (300 ml). To the mixture was added 2 ml of bromthymol blue (0.05% in absolute ethanol) and dry reagent-grade potassium bicarbonate (1.75 g, 17.5 mmoles). Dry nitrogen was passed through the mixture, which was stirred and cooled in an ice bath. When the temperature was steady at 4°, the perchloryl fluoride cylinder was attached to the gas disperser by gum-rubber tubing[2] and wired on securely. Perchloryl fluoride gas was then introduced until the temperature had risen to 8–10°. The gas flow was then stopped until the temperature had again fallen to 4°, when it was resumed. In this manner, 10.7 g (104.3 mmoles) of perchloryl fluoride were added over a 1-hour period, the actual duration of gas inflow being 21 minutes. As the perchloryl fluoride is being added, the original deep-green color lightens due to the formation of potassium chlorate; the end of the reaction is readily determined by a color change from green to yellow and by a fall in temperature on the addition of more perchloryl fluoride. The gas cylinder was then detached, an additional quantity (10.2 g, 102 mmoles) of potassium bicarbonate was added, the ice bath was removed, and the mixture was stirred at room temperature (20 hours). The flask was flushed with nitrogen to remove any unreacted perchloryl fluoride, water (800 ml) was added, and the solution was thoroughly extracted with ether. The combined ether extracts were washed with water and dried over magnesium sulphate. The ether was removed on a water bath and the alcohol at aspirator pressure. The residue was then distilled through a 6-in. Vigreux column under oil-pump pressure. Two main fractions were obtained: (*a*) diethyl oxalate (4.15 g), b.p. 72° at 9 mm to 62° at 2.75 mm, n_D^{25} 1.4092–1.4090; and (*b*) diethyl monofluorosuccinate (15.0 g), b.p. 75° at 2.75 mm to 72° at 0.25 mm, n_D^{25} 1.4135–1.4133. The first fraction, on redistillation through a spinning-band column, gave 3.23 g of pure diethyl oxalate, b.p. 72° at 8 mm, n_D^{25} 1.4087, d_4^{20} 1.076, the infrared spectrum of which was identical in all respects with that of a sample of the pure ester.[3] Redistillation of the second fraction, which contained about 8% of diethyl maleate (ultraviolet analysis), through the spinning-band column gave pure diethyl monofluorosuccinate (10.6 g, 73%) as a stable, colorless liquid, b.p. 72° at 1 mm, n_D^{25} 1.4125, d_4^{20} 1.142, MR_D 41.98 cc/mole; estimated 42.19 cc/mole. (Gitter, Blank, and Bergmann (3) report b.p. 70–71° at 0.8 mm, n_D^{23} 1.4240, d_4^{23} 1.1090, MR_D 44.23 cc/mole.) *Principal infrared bands* (3% solution in CCl_4), cm^{-1}: 1769.5 (C═O) s, 1746.5 (C═O) s, 1372.8 (CH_3) s, 1286.0 (C—O) s, 1264.0 m, 1179.5 (C—O) s, 1097.0 (C—F) s, 1051.2 m, 1028.5 s. *Nuclear magnetic resonance spectrum* (27.7% w/v in CCl_4 using tetramethylsilane as internal standard): chemical shifts (τ), coupling constants (c/s). Two CH_3CH_2O: 8.69 τ, 8.73 τ (*t*); 5.78 τ, 5.85 τ (*q*); J_{HH} 7.0 c/s. CH_2: 7.17 τ; J_{HH} 5.9 c/s; J_{HF} 23.3 c/s. CHF: 4.85 τ; J_{HH} 5.9 c/s; J_{HF} 47.6 c/s. The ester showed only weak end-absorption in the *ultraviolet*, ϵ_{220} 100.5 in 95% ethanol, indicating the absence of diethyl maleate (ϵ_{220} 6380); cf. diethyl succinate, ϵ_{220} 118. Anal. Calc. for $C_8H_{13}FO_4$: C, 49.99; H, 6.82; F, 9.89. Found: C, 50.16; H, 6.75; F, 9.77.

Monofluorosuccinic Acid

Pure diethyl monofluorosuccinate (3.3 g, 17.1 mmoles) and 5% sulphuric acid (20 ml) were heated under reflux at 110° for 30 minutes, that is, until the mixture appeared to be homogeneous. The cooled solution was extracted once with 35–60° petroleum ether, to remove any unchanged ester, and then was subjected to continuous ether extraction for 38 hours; no further acid was obtained after a further 24 hours of extraction. The extract was dried (magnesium sulphate), filtered, and concentrated using a Rinco rotary evaporator. The addition of benzene (5 ml) and removal of residual ether by boiling induced the acid to crystallize (1.33 g), m.p. 140–147°. Concentration of the mother liquors gave a further quantity (193 mg) of the crude acid. The petroleum ether extract gave 90 mg of unchanged ester. Yield of crude acid (1.523 g) based on ester consumed: 67%. It is important that any residual ester be removed and that the ether solution be dry to avoid difficulties in the initial crystallization of the acid. The acid may be recrystallized from benzene–ether, or, better, from hot ethyl acetate. An analytical sample is conveniently obtained by sublimation at 105° (0.3 mm) as a colorless, crystalline solid, m.p. 144–145°; positive fluorine test. The infrared spectrum in acetonitrile showed a band at 1747 cm^{-1} (C═O) with a shoulder on the high-frequency side; cf. succinic acid, 1744 cm^{-1}. Ultraviolet absorption spectrum in 95% ethanol (1-mm cells): λ_{max} 198 mμ, ϵ_{max} 130 (cf. maleic acid: λ_{max} 203 mμ, ϵ_{max} 14,900). Anal. Calc. for $C_4H_5FO_4$: C, 35.30; H, 3.70. Found: C, 35.48; H, 3.72.

Diethyl α-Fluoro-α-carbethoxysuccinate

Attempted distillation of the crude intermediate triethyl α-fluoro-α-oxalylsuccinate at 160–200° (0.05 mm) yielded the decarbonylated ester (77.5%). Redistillation gave a colorless liquid, b.p. 107–109° at 0.55 mm, n_D^{25} 1.4264. The infrared spectrum in CCl_4 showed bands at 1745 (C═O) and 1095 (C—F) cm^{-1}. Anal. Calc. for $C_{11}H_{17}FO_6$: C, 49.99; H, 6.49. Found: C, 50.13; H, 6.64.

ACKNOWLEDGMENTS

We wish to express our indebtedness to Canadian Industries Limited, Montreal, for the award of a Fellowship (F. H. D.); to the National Research Council for financial

THE RATIO OF THE INDEPENDENT FORMATION CROSS SECTIONS OF THE ISOMERIC STATES OF Cs^{134} IN THE PROTON-INDUCED FISSION OF URANIUM[1]

J. H. DAVIES[2] AND L. YAFFE

Both Cs^{134m} (2.9 hr) and Cs^{134g} (2.1 yr) are formed in the proton-induced fission of uranium. The 2.9-hr metastable state is a primary product shielded by stable Xe^{134} and Ba^{134}. The 2.1-yr ground state is formed both as a primary product and from the decay of the metastable state by isomeric transition.

This nuclide provides one of the rare instances where the independent formation cross sections of a pair of isomers produced in fission can be conveniently measured.

In the course of work on the nuclear charge dispersion in the fission of natural uranium by high-energy protons (1), data were collected on the independent yields of cesium isotopes. This enabled us to calculate the ratio of the formation cross sections of the Cs^{134} isomers at a number of incident proton energies. Details of the separations and measurements are provided in the former work (1).

The β-activity of the cesium fraction, purified radiochemically, was measured by means of an end-window gas-flow proportional counter. The decay curves were resolved cleanly into three components, 32-min Cs^{138}, 2.9-hr Cs^{134}, and 12.9-day Cs^{136}, with a long-lived, low-activity tail. The γ-spectrum of this sample revealed two photopeaks attributable to Cs^{134} (2.1 yr) and Cs^{137} (30 yr) after the decay of Cs^{136}. Both the Cs^{134m} and the Cs^{134} activities were measured relative to that of Cs^{136} from the β- and γ-ray measurements respectively. The independent yield of Cs^{134g} was obtained by difference between the two measurements. The method of calculation of the formation cross sections and the correction factors used are given in the charge dispersion paper (1).

The ratio of the isomeric cross sections as a function of incident proton energy is shown in Fig. 1. It is apparent that the high-spin metastable state (8−) is always favored in this

energy range, and is formed almost exclusively at the lower energies. However, the low-spin ground state (4+) becomes increasingly favored with increasing excitation energy. This is not in agreement with the conclusions of Bailey (2), who reasoned that, since high-energy fission is a high angular momentum process, the low-spin isomer ought to be less favored at higher energies.

6-O-METHANESULPHONYL-D-GALACTOSE

D. L. MITCHELL

Acid hydrolysis of the *O*-isopropylidene groups of 1,2:3,4-di-*O*-isopropylidene-6-*O*-toluene-*p*-sulphonyl-D-galactose with retention of the 6-*O*-toluene-*p*-sulphonyl ester offers little difficulty and the product, 6-*O*-toluene-*p*-sulphonyl-D-galactose, has been described as a crystalline solid (1). Because the methanesulphonyl ester of a primary alcohol is more easily hydrolyzed by acid than the corresponding toluene-*p*-sulphonyl ester, and because the liberated methanesulphonic acid renders the reaction autocatalytic, selective removal of the *O*-isopropylidene groups of 1,2:3,4-di-*O*-isopropylidene-6-*O*-methanesulphonyl-D-galactose has offered greater difficulty and the product, 6-*O*-methanesulphonyl-D-galactose, has hitherto been obtained only as a syrup although two crystalline thioacetal derivatives have been reported (2).

Hydrolysis conditions are now described for the preparation of 6-*O*-methanesulphonyl-D-galactose as a crystalline compound. The product was the α-anomer since an aqueous solution mutarotated to a less positive equilibrium value. Chromatographic examination of the equilibrium solution revealed the absence of possible dehydration products, thus confirming that the rotational change originated from a mutarotation and not from the formation of 3,6-*O*-anhydro-D-galactose or other products. Acetonation of the crystalline

energy range, and is formed almost exclusively at the lower energies. However, the low-spin ground state (4+) becomes increasingly favored with increasing excitation energy. This is not in agreement with the conclusions of Bailey (2), who reasoned that, since high-energy fission is a high angular momentum process, the low-spin isomer ought to be less favored at higher energies.

6-O-METHANESULPHONYL-D-GALACTOSE

D. L. MITCHELL

Acid hydrolysis of the *O*-isopropylidene groups of 1,2:3,4-di-*O*-isopropylidene-6-*O*-toluene-*p*-sulphonyl-D-galactose with retention of the 6-*O*-toluene-*p*-sulphonyl ester offers little difficulty and the product, 6-*O*-toluene-*p*-sulphonyl-D-galactose, has been described as a crystalline solid (1). Because the methanesulphonyl ester of a primary alcohol is more easily hydrolyzed by acid than the corresponding toluene-*p*-sulphonyl ester, and because the liberated methanesulphonic acid renders the reaction autocatalytic, selective removal of the *O*-isopropylidene groups of 1,2:3,4-di-*O*-isopropylidene-6-*O*-methanesulphonyl-D-galactose has offered greater difficulty and the product, 6-*O*-methanesulphonyl-D-galactose, has hitherto been obtained only as a syrup although two crystalline thioacetal derivatives have been reported (2).

Hydrolysis conditions are now described for the preparation of 6-*O*-methanesulphonyl-D-galactose as a crystalline compound. The product was the α-anomer since an aqueous solution mutarotated to a less positive equilibrium value. Chromatographic examination of the equilibrium solution revealed the absence of possible dehydration products, thus confirming that the rotational change originated from a mutarotation and not from the formation of 3,6-*O*-anhydro-D-galactose or other products. Acetonation of the crystalline

mono-*O*-methanesulphonyl-D-galactose regenerated the starting material, 1,2:3,4-di-*O*-isopropylidene-6-*O*-methanesulphonyl-D-galactose, and the location of the methanesulphonyl ester at the primary alcohol (carbon 6) was therefore confirmed. Quantitative periodate oxidation of the crystalline ester also gave data consistent with that expected for an aldohexopyranose substituted at the primary alcohol. Similar results were also obtained for the periodate oxidation of crystalline 6-*O*-toluene-*p*-sulphonyl-D-galactose.

Attempts to form the 2,5-dichlorophenylhydrazone and the *N*-benzylphenylhydrazone derivatives by the usual method of gentle warming of an alcoholic solution of the substituted hydrazine and 6-*O*-methanesulphonyl-D-galactose gave crystalline products that contained no sulphur. Analyses corresponded to those of anhydrohexose phenylhydrazones and the products have been tentatively identified as 3,6-*O*-anhydro-D-galactose 2,5-dichlorophenylhydrazone and 3,6-*O*-anhydro-D-galactose *N*-benzylphenylhydrazone respectively. Under refluxing conditions during the attempted formation of the phenylosazone, loss of the 6-*O*-methanesulphonyl group occurred and an anhydrohexose phenylosazone was isolated, which was most likely 3,6-*O*-anhydro-D-*lyxo*-hexose phenylosazone.

When a lower reaction temperature was employed (i.e. reaction at room temperature for several days), the expected hydrazone derivatives were obtained without the anhydro compound being simultaneously formed. Several new substituted hydrazone derivatives of 6-*O*-(methanesulphonyl- and toluene-*p*-sulphonyl-)D-galactose have been described in Table III.

EXPERIMENTAL

For paper chromatographic examination, the following solvent system was used (v:v): ethyl acetate – acetic acid – water (9:2:2). 1,2:3,4-Di-*O*-isopropylidene-D-galactose was prepared in 66% yield by a procedure adapted from the preparation of 1,2:5,6-di-*O*-isopropylidene-D-glucose (3). $[\alpha]_D^{20}$ −54.1° (*c*, 1.0, chloroform) (lit. $[\alpha]_D^{24}$ −54.7° (4)).

The above compound was methanesulphonated in 85% yield, by the usual method employing methanesulphonyl chloride and pyridine. The product, obtained as a solid when the reaction mixture was poured into ice-cold water, had m.p. 122–123° C and $[\alpha]_D^{24}$ −63.4° (*c*, 1.7, chloroform) after several recrystallizations from methanol (lit. m.p. 122° C and $[\alpha]_D^{20}$ −62° (chloroform) (5)).

6-O-Methanesulphonyl-D-galactose

1,2:3,4-Di-*O*-isopropylidene-6-*O*-methanesulphonyl-D-galactose (46.2 g) was dissolved in ethanol (200 ml), water (200 ml), and 2 *N* sulphuric acid (20 ml) and the solution was heated to 80° C for 3 hours. The cooled solution (0° C) was neutralized on columns of Amberlite IR-45 (acetate) and IR-120 (H) ion exchange resins and the eluate was concentrated under reduced pressure to a small volume (50 ml). Some of the starting material (ca. 1 g) separated and was recovered. The mother liquors were concentrated to a syrup which was repeatedly dissolved in a small volume of ethanol and reconcentrated to remove traces of water. The syrup was dissolved in acetone (50 ml), warmed slightly, and light petroleum (b.p. 60–80° C) was added to incipient turbidity. Storage at 4° C for 4 days induced crystallization (rosettes, 14.6 g, 42%). Recrystallization from ethanol–water (25:1) gave fine needles of m.p. 124–125° C, $[\alpha]_D^{23}$ 83.9° (13 minutes) → 55.2° (3.5 hours) → 52.8° (constant value) (*c*, 0.9, water), and a R_f 0.45 and R_{Rh} 1.06. Anal. Calc. for $C_7H_{14}O_8S$: C, 32.7; H, 5.5; S, 12.4. Found: C, 32.6; H, 5.5; S, 12.4. Syrupy 6-*O*-methanesulphonyl-D-galactose, obtained by using the hydrolysis conditions (dilute acetic acid) described by Stacey (2), crystallized after nucleation with the above crystalline specimen.

The above hydrolysis conditions were found to be too mild for the preparation of the corresponding 6-*O*-toluene-*p*-sulphonyl-D-galactose and a modified procedure was adopted. A solution of 1,2:3,4-di-*O*-isopropylidene-6-*O*-toluene-*p*-sulphonyl-D-galactose (20 g) in ethanol (140 ml), water (60 ml), and dilute sulphuric acid (2 *N*, 25 ml) was heated to 80° C for 4 hours. Using the above isolation procedure, 31% yield of 6-*O*-toluene-*p*-sulphonyl-D-galactose was obtained, m.p. 133–134° C and $[\alpha]_D^{23}$ 32.8° → 46.7° (24 hours) (*c*, 1.22, water).

Periodate Oxidation Experiments

Periodate oxidation at room temperature of samples (38.7 mg, 1.5×10^{-4} mole) with sodium metaperiodate solution (12×10^{-4} mole in 25 ml) under unbuffered and buffered conditions is described in Tables I and II.

sulphuric acid (1 drop) was stored for 24 hours at room temperature. After neutralization (barium carbonate) and filtration from the inorganic salts, the solution was concentrated to a crystalline mass. This material was recrystallized from methanol and had a melting point of 121–122° C which was not depressed upon admixture with an authentic specimen of 1,2:3,4-di-*O*-isopropylidene-6-*O*-methanesulphonyl-D-galactose. The derived product possessed an infrared absorption spectrum identical with that of the authentic specimen. Both comparisons using solid material (potassium bromide disk) and chloroform solutions were employed.

6-O-Methanesulphonyl-D-galactose 2,5-Dichlorophenylhydrazone

A suspension of 6-*O*-methanesulphonyl-D-galactose (0.20 g) and 2,5-dichlorophenylhydrazine (0.17 g) in dry methanol was stored in a stoppered flask at room temperature. After 24 hours, the reactants formed a solution, which was stored for a further 24 hours. Concentration under reduced pressure afforded a solid which was recrystallized from a small volume of ethanol, m.p. 143–145° C, $[\alpha]_D^{23}$ +30° (*c*, 0.53, pyridine) (Table III).

The preparations of 6-*O*-methanesulphonyl-D-galactose *N*-benzylphenylhydrazone, and 6-*O*-toluene-*p*-sulphonyl-D-galactose 2,5-dichlorophenylhydrazone were also carried out by the above method (Table III) (6).

6-O-Methanesulphonyl-D-galactose 2,4-Dinitrophenylhydrazone

The 2,4-dinitrophenylhydrazones were prepared by mixing a warm alcoholic solution of the D-galactose sulphonyl ester with an excess of Brady's reagent. After 30 minutes' reaction, the precipitate was collected by centrifugation and repeatedly washed with ether. The physical constants are reported in Table III.

(?) 3,6-O-Anhydro-D-galactose N-Benzylphenylhydrazone

A solution of 6-*O*-methanesulphonyl-D-galactose (0.24 g) and *N*-benzylphenylhydrazine (0.50 g) in methanol (5 ml) was cautiously warmed to ca. 45–50° C intermittently for 1 hour and stored for a further 48 hours. Concentration to dryness afforded a crystalline solid that was repeatedly triturated with cold (−10° C) ether followed by hexane–ether solutions. A portion was recrystallized from ethanol to give white needles of m.p. 155–156° and $[\alpha]_D^{23}$ −22° (12 hours) (*c*, 1.2, pyridine). Anal. DETERMINATION OF RELATIVE SIGNS OF COUPLING CONSTANTS IN QUINOLINE BY NUCLEAR MAGNETIC DOUBLE RESONANCE

W. G. Paterson* and G. Bigam

A great deal of interest has been generated recently by the discovery (1–3) that the relative signs of n.m.r. coupling constants could be determined by double-irradiation experiments. The present note describes double-resonance measurements on quinoline which yield the relative signs of the coupling constants in the heterocyclic ring. In a recent paper (4) on 2-amino-3-picoline, it was claimed that the single-resonance spectrum indicated that J_{AX} and J_{BX} were of the same sign, although details of the calculations were not given. Assuming that both coupling constants were positive, it was then shown

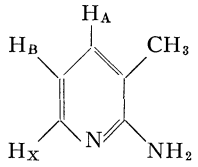
DETERMINATION OF RELATIVE SIGNS OF COUPLING CONSTANTS IN QUINOLINE BY NUCLEAR MAGNETIC DOUBLE RESONANCE

W. G. Paterson* and G. Bigam

A great deal of interest has been generated recently by the discovery (1–3) that the relative signs of n.m.r. coupling constants could be determined by double-irradiation experiments. The present note describes double-resonance measurements on quinoline which yield the relative signs of the coupling constants in the heterocyclic ring. In a recent paper (4) on 2-amino-3-picoline, it was claimed that the single-resonance spectrum indicated that J_{AX} and J_{BX} were of the same sign, although details of the calculations were not given. Assuming that both coupling constants were positive, it was then shown



2-Amino-3-picoline

**Present address: Central Research Laboratories, Minnesota Mining and Manufacturing Co., St. Paul, Minn., U.S.A.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

by nuclear magnetic double resonance that J_{AB} was also positive. The fact that the chemical shifts in 2-amino-3-picoline are quite large compared to the coupling constants renders the intensities of the transitions quite insensitive to the relative signs of J_{AX} and J_{BX}. Furthermore, since proton A is also coupled to the methyl protons, 2-amino-3-picoline is a rather unsuitable compound, and it is therefore desirable that the relative signs of the coupling constants in pyridine derivatives be verified by a different approach.

The n.m.r. spectrum of the protons in the heterocyclic ring of quinoline at 100 Mc/s is almost first order, and the relative signs of the coupling constants may be determined by the method of Freeman (3). The single-resonance spectrum of the protons in the heterocyclic ring of quinoline at 100 Mc/s is shown in Fig. 1 along with a calculated spectrum

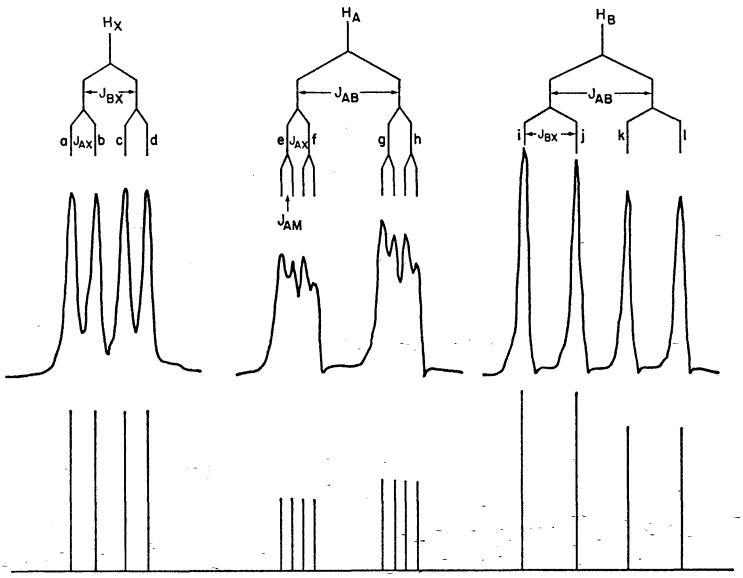


FIG. 1. The observed and calculated n.m.r. spectrum of quinoline at 100 Mc/s. The small inter-ring coupling J_{AM} was treated as a first-order perturbation. All coupling constants are assumed to be positive. The magnetic field increases from left to right.

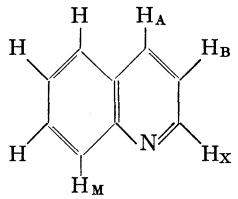
for the heterocyclic ring based on an ABX approximation (5, Chap. 6). The n.m.r. parameters are listed in Table I. The nuclei are labeled as shown below. The calculated intensities for (i) all J's positive and (ii) with J_{AX} negative were identical within experimental error.



Irradiation with a moderately weak r.f. field at a frequency $\frac{1}{2}(a+c)$ in the X spectrum should collapse lines i and j in the B spectrum to a single line if J_{AB} and J_{AX} are of the same sign, or collapse lines k and l if they are of opposite sign. Analogous arguments apply to irradiation at a frequency $\frac{1}{2}(b+d)$. The possibilities are summarized in Table II. Typical experimental traces are shown in Fig. 2. It is clear that collapse of the signals is

more complete when a decoupling frequency is used which corresponds to like signs for J_{AB} and J_{AX}.

Similarly, irradiation at a frequency $\frac{1}{2}(a+b)$ in the X spectrum should collapse lines e and f in the A spectrum (leaving a closely spaced doublet due to J_{AM}) if J_{AB} and J_{BX} are of like sign or collapse lines g and h if they are of opposite sign. Analogous considerations apply to irradiation at a frequency $\frac{1}{2}(c+d)$. A summary of the possibilities is given in Table III. Experimental spectra are shown in Fig. 3. Optimum collapse of the signals was obtained for the experimental arrangement which corresponded to like signs for J_{AB} and J_{BX}.

FIG. 3. The double-resonance spectra of nucleus A in quinoline observed for different frequencies of the decoupling r.f. field H_2. The separations in c.p.s. between the r.f. fields H_1 and H_2 are shown below the spectra. The magnetic field increases from left to right.

It may be concluded that all three coupling constants in the heterocyclic ring of quinoline have the same sign, in agreement with the results of Rao and Baldeschwieler (4) for 2-amino-3-picoline.

EXPERIMENTAL

The n.m.r. spectra were obtained with a Varian high-resolution spectrometer operating at 100 Mc/s. The spectra were calibrated by the usual side-band method (7), using a Hewlett–Packard Model 200AB audio-oscillator and a Hewlett–Packard Model 521C frequency counter. The double-resonance experiments were carried out as described by Johnson (8). With the center-band signal phased out, the first modulation side band H_1 of the V3521 Integrator is used to record the n.m.r. spectrum while a second, stronger side band, H_2, provided by an audio-oscillator, is applied to the system under investigation such that $|\omega_2-\omega_1|$ is equal to the separation necessary to do the double-resonance experiment. The output of the oscillator is quite critical (3). The ratios of the chemical shifts to the coupling constants in the present instances were sufficiently large that corrections to the modulation frequency were unnecessary (9). The frequency of the first modulation side band of the Integrator varied slightly from day to day and was checked before each experiment. As a check on the method, the results reported by Freeman (3) for *trans*-crotonaldehyde were repeated and duplicated.

Quinoline (synthetic grade) was obtained from Matheson, Coleman, and Bell and degassed by the nitrogen bubbling technique prior to the n.m.r. measurements.

SELF-CONDENSATION OF METHYL PROPIOLATE

ERNEST WENKERT, K. A. H. ADAMS, AND CURTIS L. LEICHT

When during the course of a study of alkaloid synthesis methyl propiolate was observed to undergo a chemical change in the presence of a tertiary amine, this unusual reaction was investigated. Exposure of a benzene solution of the ester to triethylamine, N-methylpyrrolidine, or N-methylpiperidine for a short period of time gave good yields of a dimer. Elemental, infrared, ultraviolet, and proton magnetic resonance analysis of the product

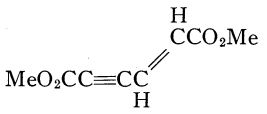
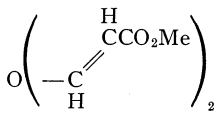
as well as its conversion to dimethyl adipate on catalytic hydrogenation revealed the compound to be dimethyl *trans*-but-1-ene-3-ine-1,4-dicarboxylate (I) (1, 2). In some reactions a side product was formed. Its analyses as well as its transformation to dimethyl β-oxy-bis-propionate (3) on catalytic hydrogenation showed it to be dimethyl *trans*-β-oxy-bis-acrylate (II). Since this product reflected intervention of water in the reaction, its yield was expected, and then shown to increase on deliberate addition of water to the reaction medium.



I



II

Whereas the hydrogen abstraction (4, 5) and the Michael addition (6) processes responsible for the formation of I have known precedents, the present case represents an interesting example of a combination of these reactions of the same propiolyl system and appears to be a high-yielding variation of the dimerization of acetylenes to en-ines under the influence of cuprous salts and acid (2, 7). Unfortunately there seems to be a subtle competition between the dimerization and polymerization of the conjugated ethynylcarbonyl substrate, as an unsuccessful attempt to bring about the dimerization of methyl ethinyl ketone illustrated.

EXPERIMENTAL

All melting points were observed on a Kofler microscope hot stage. Ultraviolet spectra were run on 95% ethanol solutions on a Cary model 12 spectrophotometer, while infrared spectra were obtained on a Perkin–Elmer model 21 spectrophotometer. Proton magnetic resonance spectra were measured on deuterochloroform solutions with tetramethylsilane as internal standard on a Varian A-60 spectrometer.

Dimethyl trans-But-1-ene-3-ine-1,4-dicarboxylate (I)

A cooled solution of 0.5 g of N-methylpiperidine in 5 ml of dry benzene was added over a 20-minute period to a cold solution of 500 mg of methyl propiolate in 5 ml of dry benzene and the mixture was stirred for 1.5 hours over nitrogen while being kept cold. Evaporation of the brown solution left a brown solid, 451 mg. Its extraction with hot hexane, evaporation of the extract, and sublimation of the residue yielded 440 mg (88%) of the diester I, m.p. 53–54° (lit. (1) m.p. 53°; (2) 57°); μ (KBr) C≡C 4.47 (m), C=O 5.81 (s), C=C 6.14 (m); λ_{max} 245 mμ (log ϵ 4.17), 254 mμ (log ϵ 4.22), and 267 mμ (log ϵ 4.08); δ two one-proton doublets 6.87 p.p.m. (J = 16 c.p.s.), 6.46 p.p.m. (J = 16 c.p.s.), two three-proton singlets 3.83 p.p.m., 3.81 p.p.m.

Anal. Calc. for $C_8H_8O_4$: C, 57.14; H, 4.80. Found: C, 57.09; H, 4.70.

Addition of some water to the hot methanol extract of the residue of the above hexane extraction induced the separation of a small quantity of solid whose gas-phase chromatographic retention time was identical with that of II (*vide infra*).

The use of N-methylpyrrolidine led to similar results, while triethylamine gave only 30–40% yields of I accompanied by black polymer, presumably polypropiolate.

Hydrogenation of a methanolic solution of I, 21 mg, and 10 mg of palladium–charcoal at atmospheric pressure and room temperature yielded 20 mg of dimethyl adipate, identified by comparison of the product's infrared and p.m.r. spectra and gas-phase chromatography retention time with those of an authentic sample.

Dimethyl trans-β-Oxy-bis-acrylate (II)

A cooled solution of 0.21 ml of N-methylpyrrolidine in 5 ml of benzene saturated with water was added over a 20-minute interval to a cold solution of 400 mg of methyl propiolate in 6 ml of benzene saturated with water and the mixture was stirred for 1.5 hours over nitrogen while being kept cold. After filtration of the resultant precipitate the mixture was evaporated and the residue extracted repeatedly with hot hexane. Evaporation of the extract and crystallization of the residual solid from ethyl acetate and from aqueous methanol gave 212 mg (45%) of white needles of the diester II, m.p. 158–159°; μ (KBr) C=O 5.82 (s), C=C 6.11 (s); λ_{max} 253 mμ (log ϵ 4.49); δ two two-proton doublets 7.67 p.p.m. (J = 12 c.p.s.), 5.71 p.p.m. (J = 12 c.p.s.), six-proton singlet, 3.79 p.p.m.

Anal. Calc. for $C_8H_{10}O_5$: C, 51.61; H, 5.41. Found: C, 51.81; H, 5.51.

The use of N-methylpiperidine led to higher yields (60–70%). Neither reaction mixture revealed any detectable amounts of ester I.

THE KINETICS OF THE TRIBUTYLAMINE-CATALYZED REACTION OF PHENYL ISOCYANATE WITH 1-BUTANETHIOL IN VARIOUS SOLVENTS

YOSHIO IWAKURA AND HISAO OKADA

In a previous paper (1), we reported the kinetics of the tertiary-amine-catalyzed reaction of organic isocyanate with thiols, and discussed the kinetic scheme of this reaction. In the present work, the kinetics of the tributylamine-catalyzed reaction of phenyl isocyanate with 1-butanethiol was studied in detail in various solvents at 25–45°.

The catalytic coefficients of the tributylamine-catalyzed reaction of phenyl isocyanate with 1-butanethiol in various solvents at 25° are summarized in Table I. The dielectric constants of the solvents are also listed in Table I, and compared with the catalytic coefficients. The reaction rate is found to depend generally upon the dielectric constant of the solvent, but a definite relationship between the dielectric constant of the solvent and the catalytic coefficient cannot be found. If the solvents are classified as aromatic or aliphatic, the aromatic solvents have higher reactivity, e.g., cyclohexane < toluene < benzene; ethyl acetate < ethyl benzoate.

In solvents with high-valued dielectric constants (more than about 10), such as 1,2-dichloroethane, cyclohexanone, acetone, and nitrobenzene, the reaction rate is not applicable to ordinary second-order kinetics, and deviates downwards from the plot of the ordinary second-order reaction rate equation according to the increase of the conversion.* In the case of these highly polar solvents, the rate constant was calculated on the initial reaction, and listed in Table I.

The dependency of the catalytic coefficient upon the reaction temperature was studied

Dyer et al. (2(b)) have reported that the reaction rate of the tertiary-amine-catalyzed reaction between phenyl isocyanate and thiols deviated upwards from the plot of the ordinary second-order kinetics in the solvents examined, e.g. toluene, butyl acetate, nitrobenzene, and acetonitrile. Further, they have suggested the following overall rate equation on the tertiary-amine-catalyzed reaction of phenyl isocyanate with thiols:

$$k_e = k_0 + k_b[\text{base}] + k_p[\text{product}] + k_{bp}[\text{base}][\text{product}], \qquad [1]$$

where k_e is the experimental second-order rate constant, k_b, k_p, and k_{bp} are the catalytic rate constant for the base, product, and base–product catalyzed reaction, respectively.

Hydrogenation of a methanolic solution of 53 mg of II and 20 mg of palladium–charcoal at atmospheric pressure and room temperature yielded 51 mg of dimethyl β-oxy-bis-propionate, identified by comparison of the product's infrared and p.m.r. spectra and gas-phase chromatographic behavior with those of an authentic sample (3).

*Initial concentration of phenyl isocyanate and 1-butanethiol: $[C_6H_5NCO] = [n\text{-}C_4H_9SH] = 0.2500$ mole/liter in toluene, benzene, chlorobenzene, *p*-dioxane, and anisole; 0.1250 mole/liter in the other solvents.
†Quoted from A. Weissberger, Organic Solvents, Interscience Publishers Inc., New York, 1955, pp. 270–274; and Landolt-Börnstein, Zahlenwerte und Funktionen aus Physik, Chemie, Astronomie, Geophysik, Technik, II, Band 6, 1959.
‡Average value of the results in two or three different tributylamine concentrations.
§Value at 20°.

in several solvents at 25°, 35°, and 45°. The apparent energies of activation and log A were calculated by the Arrhenius equation, and are listed in Table II.

TABLE II

The dependency of the catalytic coefficients upon reaction temperature in the tributylamine-catalyzed reaction of phenyl isocyanate with 1-butanethiol in several solvents

Solvent	Catalytic coefficient (liter²/mole² min) 25°	35°	45°	Apparent energies of activation (kcal/mole)	log A (A in liter²/mole² min)
p-Dioxane	77.6	72.0	58.7	−2.6±0.8	−0.02±0.53
Benzene	37.0	34.1	29.1	−2.3±0.5	−0.11±0.34
Toluene	19.1	19.3	16.8	−1.2±0.8	0.04±0.57
Anisole	265	176	199	−2.8±2.8	0.35±2.01
Chlorobenzene	155	145	143	−0.8±0.3	1.62±0.20
Tetrahydrofuran	64.0	57.3	55.6	−1.3±0.4	0.82±0.29
o-Dichlorobenzene	173	155	141	−1.9±0.2	0.81±0.12

In benzene solution, the apparent activation energy of the tributylamine-catalyzed reaction of phenyl isocyanate with 1-butanethiol is −2.3 kcal/mole, as shown in Table II. On the other hand, it is 2.7 kcal/mole for the reaction with 1-butanol (both 0.250 mole/liter) (log A = −0.48, A in liter²/mole² min) (3). Therefore, if the reaction mechanism suggested previously (1) is simplified as shown in equations [2] and [3], and the activation

energy of k_3, and k_4, is expressed as E_3, and E_4, respectively, E_3 is nearly equal to $E_4-5.0$ kcal/mole.

$$R—N=C=O + R_3N \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \left(\begin{matrix} R—N=C=O \\ \vdots \\ NR_3 \end{matrix} \right) \text{(complex)} \qquad [2]$$

$$\text{complex} + R—SH \xrightarrow{k_3} R—NHC(=O)S—R + R_3N \qquad [3]$$

$$\text{complex} + R—OH \xrightarrow{k_4} R—NHC(=O)O—R + R_3N \qquad [4]$$

EXPERIMENTAL

Procedure

The detailed kinetic method has been described previously (1). As shown in Table III, reproducibility of the experiments was good and agreement of duplicate runs was within ±2%.

TABLE III

Materials

The solvents used were purified carefully in the usual manner (4).

Cyclohexane was passed through a 1-m, 20 mm i.d. column packed with silica gel to remove a small amount of benzene contained in the commercial reagent, and distilled from sodium. Tetrahydrofuran was well shaken with a paste of ferrous sulphate and a small amount of concentrated sulphuric acid to remove the peroxide. It was neutralized with sodium hydroxide and dried over calcium chloride, and then boiled under reflux with sodium and distilled from the sodium. Cyclohexanone was shaken with a 5% solution of potassium bichromate in sulphuric acid, and washed with water and fractionally distilled twice under reduced pressure. The main portion of the distillate was dried over sodium sulphate and distilled under reduced pressure. Acetone was thoroughly shaken with a small amount of powdered potassium permanganate and allowed to stand for 4 days. After being distilled, the product was dried over potassium carbonate and distilled. Ethyl benzoate was synthesized from benzoic acid and ethanol, and distilled under reduced pressure.

PRESSURE EFFECT AND MECHANISM IN ACID CATALYSIS XIII. HYDROLYSIS OF METHYL α-D-GLUCOPYRANOSIDE[1]

R. J. WITHEY[2] AND E. WHALLEY

The rate of the acid-catalyzed hydrolysis of methyl α-D-glucopyranoside in concentrated acid (1) has been interpreted to indicate both that the slow step is unimolecular (1) and probably that it is bimolecular (2). There is little doubt now that the Zucker–Hammett hypothesis, on which the first suggestion was based, is invalid, and there are enough exceptions (1, 3) to Bunnett's (2) criterion for it to be unreliable. Because the volume of activation can distinguish between the unimolecular and bimolecular slow steps in acid catalysis (4) we have measured the effect of pressures up to 3 kbar on the rate of hydrolysis.

EXPERIMENTAL METHODS AND RESULTS

The methyl α-D-glucopyranoside was a commercial sample having $[\alpha]_D^{22}$ +157.8°, and this was unchanged after recrystallization three times from ethanol. Reagent grade perchloric acid, 0.518 *M* at room temperature and pressure, was used as catalyst, and about 3 g of the glucoside in 100 cm³ of acid solution was used in each run. The optical rotation, which was measured in a 4-dm 5-cm³ polarimeter tube, changed by about 6° during each run. A Rudolph model 70 polarimeter which was reproducible to 0.01° was used. The pressure techniques have been described previously (5).

About six samples were obtained for each run. Good values of the final rotation could not be obtained at 100° due to slight coloring which occurred during the long times required, but which was inappreciable during the 10 hours or so required for a run. The final rotation was therefore obtained by hydrolyzing the glucoside in 2.6 *M* perchloric acid at 100° C for 3 hours. It agreed within the experimental error with the value calculated from the reported rotation of the products.

The first-order rate constants k_1, and the second-order rate constants k_a for which the concentration of acid was corrected for thermal expansion and compression as if it were pure water (6), are summarized in Table I. The rate constant at ordinary pressure is reasonably consistent with those reported for lower temperatures (1, 7).*

TABLE I

Rate constants for the acid-catalyzed hydrolysis of methyl α-D-glucopyranoside in 0.518 *M* (at room temperature and pressure) perchloric acid at 100.00° C

p/bar	$10^6 k_1$/sec^{-1}	$10^6 k_a$/l. mole^{-1} sec^{-1}
1	166	334
1000	148	286
2000	128	239
2000	129	241
3000	114	207

**A reviewer has suggested that side reactions of D-glucose, such as acid reversion and formation of anhydrides, may affect the apparent rate constants. The maximum extent (S. Peat, W. J. Whelan, T. E. Edwards, and O. Owen, J. Chem. Soc. 586 (1958), and earlier work referred to there) of these reactions under our conditions is less than 1% at atmospheric pressure and it is unlikely to be much greater under pressure. They will therefore have no great effect on our rate constants. The fact that the reaction is accurately first order and that the rotation of the fully hydrolyzed solution agrees within experimental error with that calculated from the initial concentration and rotation of methyl α-D-glucopyranoside and the specific rotation of α-D-glucose confirms this.*

The volume of activation $\Delta V^{\neq}$, calculated from the usual relation

$$\partial \ln k_a/\partial p = -\Delta V^{\neq}/RT,$$

where R is the gas constant and T the temperature, is $5.1 \pm \sim 0.5$ cm^3 mole^{-1} at 100° C.

DISCUSSION

The volume of activation of $5.1 \pm \sim 0.7$ cm^3 mole^{-1} indicates that the mechanism is unimolecular, i.e. if G represents methyl α-D-glucopyranoside, then if the first step is assumed to be

$$H_3O^+ + G \rightleftharpoons H_2O + GH^+, \text{ equilibrium,}$$

the second step is

$$GH^+ \xrightarrow{\text{slow}} \text{products.}$$

Further details of the slow step are uncertain (1). The entropy of activation, which is reported (7) to be 13.8 cal deg^{-1} mole^{-1}, is consistent with the unimolecular mechanism (4).

Bunnett (2) has recently suggested a modification of the Zucker–Hammett hypothesis and from it suggested that methyl α-D-glucopyranoside hydrolyzes by a bimolecular mechanism. The evidence from the volume of activation disagrees with this suggestion.

PROTON RESONANCE SPECTRA OF VINYL-METALLIC COMPOUNDS
PART II. HEXAVINYLDIGERMANE

S. Cawley and S. S. Danyluk

Considerable interest has centered recently on the dependence of cis, trans, and gem coupling constants for vinyl compounds upon the electronegativity of the substituent group. Schaefer (1) has reported a linear correlation of J_{cis}, J_{trans}, J_{gem} and their sum with electronegativities of the substituent group for a wide range of vinyl compounds. Similar correlations have also been observed independently by Waugh and Castellano (2) and Banwell and Sheppard (3). The significance of correlations of this type in sorting out unacceptable values for coupling constants in the analysis of proton resonance spectra is readily apparent. For example, Castellano and Waugh (4) recently utilized the constancy of $J_{cis}+J_{trans}+J_{gem}$ as a criterion for rejection of spectral assignments for tetravinylsilane which yielded spacings whose sum was significantly different from 38.2 c/s.
