Methyl 3,4-Dichloro-3,4-dideoxy-β-D-ribopyranoside 2-Chlorosulfate

Methyl α-L-arabinopyranoside (5 g) was treated with sulfuryl chloride (11 ml) and pyridine (20 ml) in chloroform solution (2). The chloroform-soluble product was isolated as in previous reactions and was a syrup (6 g). To ensure maximum chloro-substitution the syrup was further heated with pyridine hydrochloride in chloroform at 50° for 10 h (3). The chloroform solution was washed with water and saturated sodium bicarbonate solution, dried (anhydrous sodium sulfate), filtered, and concentrated to a syrup which crystallized. Recrystallization from chloroform–*n*-hexane gave large colorless crystals (2.5 g, 30%) of m.p. 74° and $[\alpha]_D$ −102° (*c*, 1.3 in chloroform).

Anal. Calcd. for $C_6H_9Cl_3O_5S$: C, 24.0; H, 3.0; Cl, 35.6; S, 10.7. Found: C, 23.6; H, 2.9; Cl, 35.3; S, 10.6.

Methyl 3,4-Dichloro-3,4-dideoxy-β-D-ribopyranoside

The crystals above (2.5 g) were dechlorosulfated in methanol solution using sodium iodide in the presence of barium carbonate (1). The filtered solution was concentrated to small volume and partitioned between chloroform and water. The chloroform extract was dried (anhydrous sodium sulfate), filtered, and concentrated to a syrup (1.7 g, 100%) which did not crystallize but which was shown to be homogeneous by thin layer chromatography. A small quantity of the syrup was distilled under reduced pressure and had $[\alpha]_D$ −55° (*c*, 0.8 in methanol).

Anal. Calcd. for $C_6H_{10}Cl_2O_3$: C, 35.8; H, 5.0. Found: C, 35.7; H, 5.0.

3,4-Dichloro-3,4-dideoxy-β-D-ribopyranose

The syrup above (1.5 g) was refluxed in a *N* sulfuric acid solution of dioxane–water and the hydrolysis was followed by thin layer chromatography. The hydrolysis was extremely slow and was stopped after 3 days, when not completely hydrolyzed, because substantial decomposition had taken place. The solution was neutralized with barium carbonate, filtered, and the filtrate was deionized by passage through Amberlite 1R120 (H form) and Duolite A4 (OH form) ion exchange resins. The solution was then concentrated to a syrup (1 g) which slowly crystallized. Recrystallization from chloroform–petrol (b.p. 40–60°) gave needles (0.1 g, 7%) of m.p. 107–108° and $[\alpha]_D$ −9.5° (15 min) → −3.2° (24 h equilibrium) (*c*, 0.6 in methanol).

Anal. Calcd. for $C_5H_{10}Cl_2O_3$: C, 31.8; H, 5.3; Cl, 37.6. Found, C, 31.9; H, 5.3; Cl, 37.9.

Paper electrophoretograms of the crystals run in 0.05 *M* borate solution (3) and sprayed with alkaline silver nitrate (11) indicated one component at M_g = 0.68.

3,4-Dichloro-3,4-dideoxy-1,2-O-isopropylidene-α-D-ribopyranose

The mother liquors from the recrystallization from above were concentrated to a syrup (0.9 g). The syrup (0.9 g) was shaken with anhydrous acetone (40 ml), concentrated sulfuric acid (0.3 ml), and anhydrous copper sulfate (4 g) for 4 days. The solution was neutralized with concentrated ammonia solution, filtered, and concentrated to a syrup which rapidly crystallized. Recrystallization from chloroform–petrol (b.p. 40–60°) gave colorless needles (0.3 g) of m.p. 171° and $[\alpha]_D$ −52° (*c*, 0.7 in chloroform).

Anal. Calcd. for $C_8H_{12}Cl_2O_3$: C, 42.3; H, 5.3; Cl, 31.3. Found: C, 42.4; H, 5.4; Cl, 31.2.

1,2-O-Isopropylidene-3,4,6-trichloro-3,4,6-trideoxy-α-D-allopyranose

3,4,6-Trichloro-3,4,6-trideoxy-D-allose (0.5 g) (3) was shaken for 6 days with anhydrous acetone, concentrated sulfuric acid, and anhydrous copper sulfate and the product isolated as described previously. The product was a syrup which partially crystallized. Recrystallization from chloroform gave needles (0.15 g) of m.p. 170° undepressed on admixture with the starting compound. The mother liquors were washed with water (×3) and the chloroform solution was concentrated to a syrup (0.3 g, 51%) which was shown to be homogeneous except for a small quantity of the starting compound (t.l.c.). The syrup was purified by distillation under reduced pressure and had $[\alpha]_D$ −25° (*c*, 0.6 in chloroform).

Anal. Calcd. for $C_9H_{13}Cl_3O_3$: C, 39.2; H, 4.7. Found: C, 39.4; H, 4.7.

Methyl 4-Deoxy-3,4-dichloro-β-D-glycero-pent-2-enopyranoside

Crystalline methyl 3,4-dichloro-3,4-dideoxy-β-D-ribopyranoside 2-chlorosulfate (1.2 g) obtained previously was dissolved in pyridine (6 ml) and the reaction mixture was allowed to stand for 24 h. The reaction mixture was then partitioned between chloroform and water and the chloroform extract, after treatment with charcoal, was filtered and concentrated to a syrup (0.52 g, 71%) which crystallized. The crystalline product was purified by sublimation to give colorless plates of m.p. 70–71° and $[\alpha]_D$ +52° (*c*, 1.0 in methanol).

Anal. Calcd. for $C_6H_8Cl_2O_2$: C, 39.4; H, 4.4; Cl, 38.8. Found: C, 39.9; H, 4.8; Cl, 38.7.

The infrared spectrum of the crystals indicated no hydroxyl absorption and the presence of an unconjugated ethylenic bond (1 657 cm^{-1})

Methyl 3,4,6-Trichloro-3,4,6-trideoxy-α-D-allopyranoside 2-Chlorosulfate

Methyl 3,4,6-trichloro-3,4,6-trideoxy-α-D-allopyranoside (3) (2 g) was treated with sulfuryl chloride (6.5 ml) and pyridine (10 ml) in chloroform solution (2). The chloroform-soluble product was a syrup which rapidly crystallized. Recrystallization from chloroform–petrol (b.p. 40–60°) gave crystals (2.4 g, 90%) of m.p. 95° and $[\alpha]_D$ +81° (*c*, 1.1 in chloroform).

Anal. Calcd. for $C_7H_{10}Cl_4O_5S$: C, 24.2; H, 2.9; Cl, 40.8; S, 9.2. Found: C, 24.4; H, 2.8; Cl, 41.0; S, 9.2.

The crystals above (2 g) were treated with pyridine as in the previous reaction with methyl 3,4-dichloro-β-D-ribopyranoside 2-chlorosulfate and after 48 h the only isolable chloroform-soluble product was crystalline methyl 3,4,6-trichloro-3,4,6-trideoxy-α-D-allopyranoside as confirmed by a mixed melting point with the authentic compound (3).

SEMIEMPIRICAL SCF CALCULATIONS ON AZULENE AND ITS SINGLY CHARGED IONS[1]

J. E. BLOOR[2]
Chemistry Division, Franklin Institute Research Laboratories, Philadelphia, Pennsylvania
Received May 18, 1965

ABSTRACT

SCF MOs for azulene have been obtained by the semiempirical Pariser, Parr, Pople procedure using the Nishimoto–Mataga method of calculating repulsion integrals and the assumption that nearest neighbor resonance integrals are independent of interatomic distance. Excited states calculated from these MOs by a CI calculation are in very good agreement with experiment. Ground state charge densities, bond orders, and the dipole moment are similar to other SCFMO calculations and reveal no disadvantage in adopting a constant resonance integral for all bonds. It is shown that estimates of the π-electron charge density by n.m.r. methods are not compatible with direct dipole moment measurements and it is suggested that the interpretation of the n.m.r. measurements suffers from inaccuracies in estimating ring currents. Doubt is also thrown on the use of simple relationships between calculated π-bond orders and bond lengths obtained by X-ray crystallographic measurements on the solid state, particularly since all the bond lengths in azulene are predicted to be longer than in benzene whereas experiment shows some to be shorter. Calculations on spin densities and charge densities of the singly charged azulene anion and cation have been performed by a restricted Hartree–Fock perturbation method in which the matrix elements for the interaction between singly excited states and the ground state are calculated using the closed shell SCFMOs of azulene as the basis set. Agreement with experiment for the anion is fairly good. For the cation our results are in severe disagreement with recent VB calculations, but there are no experimental results available to decide between the two methods.

I. INTRODUCTION

The assumptions usually employed in semiempirical self-consistent field (SCF) calculations of the type associated with the names of Pariser (4), Parr, and Pople (1–3) are so sweeping that, although they can be justified to some extent theoretically (1, 4), their adoption can only ultimately be condoned by their success, as has been achieved in the case of many polycyclic alternant hydrocarbons (1–7), in explaining experimental work, in predicting new effects, and as a guide to the design of new experiments.

However, the polycyclic alternant hydrocarbons are not the ideal class of molecules for parameter evaluation. As has been shown by Ruedenberg (4) the results of calculations on this class of molecule are more strongly dependent on their topological matrix than on the choice of repulsion or resonance integrals.

Two classes of conjugated hydrocarbons which are more sensitive to parameter choice are (*a*) the alternant hydrocarbons such as styrene, stilbene, and diphenyl, which possess one or more bonds with lengths considerably different from the bond length of benzene and (*l*) non-alternant hydrocarbons such as azulene. In a companion paper (7) to the present one we will present results of semiempirical calculations of styrene, stilbene, and diphenyl in which we demonstrate that the assumption that the nearest neighbor resonance integral β_{pq} is independent of the band distance r_{pq} is quite a good assumption to be used in calculating excited state ionization potentials and electron affinities (7).

In the present paper we examine the suitability of this assumption in calculating the excited states, ionization potential, electron affinity, charge densities, bond orders, and dipole moment of a typical non-alternant hydrocarbon, azulene. Since it is well known

[1]*Presented at the Symposium for Molecular Structure and Spectroscopy held at the Ohio State University, Columbus, Ohio, June 14–18, 1964.*

that the 9:10 bond (numbering system in Fig. 1) is considerably longer than the other bonds in azulene we would expect any weakness in our assumption of a distant independent β_{pq} to be revealed by calculations on such a molecule.

In addition to the results for azulene we have extended the calculations to the calculation of the charge densities and spin densities of the azulene singly charged positive and negative ions.

The computation of pi electron spin densities and their relationship to experimental hyperfine splitting constants is of very great interest and importance. At the present time it has not been clearly established whether any of several ways of calculating spin densities gives any better agreement with experiment than any other.

For the azulene negative ion several experimental determinations of hyperfine splitting constants have been made (33, 34) and the results of calculations using unrestricted Hartree–Fock (UHF) techniques (33, 36) and the valence bond (VB) method (35) have recently been reported for both the negative ion and the positive ion of azulene.

For the purpose of comparison with these earlier results we have carried out calculations of the spin and charge densities of these two ions using a restricted Hartree–Fock (RHF) perturbation method which uses the semiempirical self-consistent field molecular orbitals (SCFMOs) as the basis set for carrying out a configuration interaction (CI) calculation. The CI calculation is carried out by allowing the singly excited states to interact with the ground state (10). We have previously used this method (10) for a number of ions of alternant hydrocarbons and found it to be very satisfactory.

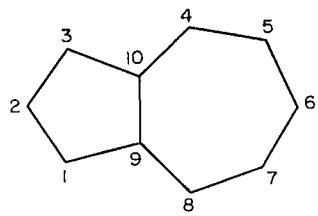

FIG. 1. Carbon skeleton of azulene.

II. METHOD OF CALCULATION

For the azulene molecule, we have used the standard SCF MO method described previously (8). In calculating the repulsion integrals, we have used the method proposed by Nishimoto and Mataga (9) i.e. for the one-center integrals we use $\gamma_{11} = 10.85$ eV and for the two-center integrals between two atoms p and q a distance r_{pq} Å apart we use the formula

$$\gamma_{pq} = \frac{14.397}{a_{cc} + r_{pq}} \text{ eV},$$

where $a_{cc} = 1.328$.

We have used one value $\beta_{pq} = -2.39$ eV for the resonance integral between neighboring atoms. All non-nearest neighbor β_{pq} are put equal to zero. By contrast to this present assumption it has, in recent years, become the custom to assume a very strong distance dependence of β_{pq} on r_{pq} e.g. by assuming β_{pq} is proportional to the overlap S_{pq} or is an exponential function of r_{pq}. However, our previous theoretical work on styrene and similar molecules (7) shows that such assumptions underestimate the interaction of vinyl and ethynyl groups with aromatic rings, because, in choosing β_{pq} from a curve of β_{pq} against r_{pq}, the steep slope of the curve gives very high values for β_{pq} at short r_{pq} distances and

low values for long bonds—both factors leading to small interactions between the separate fragments joined by the bonds in question. The calculations in the present paper are carried out with the same assumption to verify or disprove whether it is applicable to non-alternant hydrocarbons. For the MOs used to obtain the excited states of col. 4 (Table I) we diagonalized the F matrix (Table III, method 1, ref. 15) reported by Brown and Heffernan as being the final result of a variable electronegativity self-consistent field (VESCF) MO calculation (8).

In obtaining the excited states from our SCFMOs (Table I col. 3) and from the VESCFMOs (Table I col. 4) we carried out CI calculations (8) for both singlet and triplet states using the six lowest A-type and the six lowest B-type configurations. For the VESCF CI calculation we used repulsion integrals taken from ref. 15. The spin densities were calculated by a restricted Hartree–Fock LCAO perturbation procedure, the details of which have been described elsewhere (10). In this procedure, the correct expressions (10) for a radical ion with one unpaired electron are used to calculate the energies of the excited configuration and the matrix elements for the interaction of the excited configuration with the ground configuration, but the actual MOs used in the calculation are the SCF MOs of the neutral molecule. In the present work we used our closed-shell SCF MOs for azulene in the perturbation calculations for the azulene anion and cation.

III. AZULENE MOLECULE

1. Excited States

The existence of five singlet excited states with transition energies below 55 000 cm^{-1} has been established experimentally (5, 11) although the symmetry of only one of these (ν_{00} = 28 400 cm^{-1}) has been established by vibrational analysis (12). In Table I we have compared the calculated frequency values with experimental values for ν_{max} measured in cyclohexane solution. These may differ from the true values of the isolated molecule by up to 500 cm^{-1} because of solute–solvent interactions. For comparison, we have also included in Table I the results of three other calculations (13, 14) besides the new results reported in cols. 3 and 4.

Comparison of the MO calculations of Table I shows that they all predict the first transition to be a $^1A_1 \rightarrow {}^1B_1$ transition (short axis polarized) and the second one to be a $^1A_1 \rightarrow {}^1A_1$ transition. However, whereas our SCF result and the non-iterative antisymmetrical molecular orbitals with configuration interaction (ASMOCI) procedures* of Pariser (13), of Simmons (16), and of Koutecky (17) agree quite well with experiment. The method of Brown and Heffernan (15) and the non-iterative ASMO CI calculation of Hummel and Ruedenberg (14) yield very low values for the first transition. The reason for this, in the latter case (14), is probably because, even though they used topological MOs rather than SCFMOs, they did not include interaction of the singly excited configurations with the ground configuration. Similar calculations (13, 16, 17) show that such interactions are very important for azulene since they lower the ground configuration energy by 0.2–0.3 eV. The reason for the lack of agreement in the case of Brown and Hefferman's VESCF calculation is not clear since in other systems the method has apparently worked well (18). In another SCF calculation (19) Julg, using his LCAO "improved method", which includes the variation of parameters with the effective

**The calculations on azulene described in refs. 17 and 18 are substantially the same as those of Pariser, ref. 13, and so are not reported in Table I. The ASMOCI work of ref. 18 uses the same repulsion integrals as those employed in the present paper. The good agreement between our work and that of ref. 18 shows that, at least for azulene, the inclusion of interactions of only singly excited states with the ground state is sufficient CI to make up for not using SCF MOs.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

nuclear charge in a different way than the VESCF method of ref. 15, reaches good agreement between experiment and theory for the first excited state although no CI was included. In our calculation, the first transition was lowered 0.14 eV (1 130 cm^{-1}) by CI with the other five B-type configurations.

For the second transition, our calculation is in better agreement with experiment than the non-iterative ASMOCI calculations of Pariser (13) or Simmons (16) and of Koutekcy *et al.* (17), as is also the VESCF calculation of Brown and Heffernan (15). The oscillator strength of this ^1A excited state is predicted to be lower than for the first transition for all the calculations although experimentally it is found to be much higher:

$$(f_{II}/f_I)_{expt} = 9.0$$

However, it has recently been shown (20) that the band origin of this second transition is weak, and that it is quite possible for 80% of the total intensity of the band envelope to be due to intensity stealing brought about by vibrations in higher A-type transitions.

It has recently been established experimentally that there is a weak transition at 36 100 cm^{-1} almost overlapped by a strong broad transition at 36 470 cm^{-1}. All the theoretical calculations summarized in Table I except the VESCF method predict two bands in this region. Our SCFMO calculation predicts a weak transition to ^1B state at 36 230 cm^{-1} in excellent agreement with experiment. The ASMOCI calculations predict this transition 3 000 cm^{-1} lower than the observed one.

Both our SCFMOCI calculation and the ASMOCI calculation of Pariser are in good agreement with experiment in predicting two fairly strong transitions in the 36 000 to 45 000 cm^{-1} region. No transition is predicted in this region in the VESCF CI calculation while the transition energies of the Ruedenberg calculation are all, as expected, lower by about 3 000 cm^{-1} than the observed spectra.

There is no experimental information on the triplets of azulene. However, it is interesting to note that our calculation and those of Pariser (13) and of Simmons (16) agree in predicting the lowest triplet to be of ^3A symmetry and to be in the 12 000 cm^{-1} region. The VESCF method, however, predicts it to be very low at 2 600 cm^{-1} due to a large depression of the first triplet ($5 \rightarrow 6$) by the configuration ($3 \rightarrow 6$). (The MOs are numbered in order of ascending energy.) In our calculation the latter configuration interacts very little with the former configuration.

2. Ionization Potential and Electron Affinity

The ionization potential of azulene has not been measured directly, but recently (21) an indirect estimate of 7.4–7.5 eV has been obtained from the study of the spectra of charge-transfer complexes of azulene with different acceptors. We have shown elsewhere (7) that the ionization potentials of a number of hydrocarbons are given by

$$I = -(E_{HO}^{SCF} + 1.33)\ eV$$

where E_{HO}^{SCF} is the orbital energy of the highest occupied MO.

Using this equation, we obtain 7.43 eV in good agreement with experiment. Our previous contention (7) that Koopman's theorem, with a correction term, is a satisfactory way of calculating ionization potentials without carrying out separate corrective calculations for the molecule and its positive ion (22) is supported by the fact that our parameters give orbital energies which, when used together with *one* correction factor of 1.33 eV, predict successfully the ionization potentials of alternant polycyclic hydrocarbons, hydrocarbons such as stilbene and biphenyl, and also a non-alternant hydrocarbon, azulene.

**R. Pariser, ASMO CI method, ref. 13.
††Huckel LCAO method assuming $\beta_{9,10} = 0.8\beta$. E. Heilbronner, ref. 5.

For the electron affinity as measured by $\epsilon_{1/2}$, the halfwave reduction potential measured in 75% aqueous dioxane, we have found for alternant hydrocarbons (7) that we can write

$$\epsilon_{1/2} = -(E_{LO}^{SCF} + 4.77)\ \text{eV}$$

where E_{LU}^{SCF} is the energy of the lowest unoccupied MO in eV. For azulene, our calculation gives an orbital energy E_L^{SCF} of -3.15 eV giving $\epsilon_{1/2} = -1.62$ eV, in good agreement with the experimental value of -1.64 eV. It is interesting to note that, if the energy values obtained from Huckel LCAO calculations are used to establish a linear relationship between E_{LU}^{H} and $\epsilon_{1/2}$, then the point for azulene is considerably off the least-squares correlation line (23); whereas, using SCF energy values, E_{LU}^{SCF} for azulene fits the line for alternant hydrocarbons (7).

3. Bond Orders and Bond Distances

The bond distances for azulene in the solid state have been measured in a thorough X-ray crystallographic study (24) and have been reported to be in the order of decreasing distance (Table II, column 2)

$$9\text{–}10 > 1\text{–}9 > 4\text{–}5 > 1.397\ \text{Å} > 1\text{–}2 > 5\text{–}6 > 4\text{–}10.$$

Most of the MO calculations summarized in Table II give this order except for the 4–10 bond, which is predicted to be one of the longer bonds rather than the shortest, as is observed. However, a much more serious discrepancy between experiment and theory is that whereas the measurements show the presence of three bonds shorter than the bond length of benzene (1.397 Å), the MO calculations, with only one exception, predict that all the bonds in azulene should have π-bond orders less than the π-bond order of benzene (0.667) and hence should have longer lengths than those of benzene. This discrepancy is clearly brought out in Table II where we compare experimental bond orders p_{pq} calculated from the experimental bond distance R_{pq} using the equation, calculated for polycyclic alternant hydrocarbons (6)

$$R_{pq} = (1.52 - 0.184p_{pq})\ \text{Å} \qquad [1]$$

with theoretical bond orders calculated by Coulson's definition of the π-bond order

$$p_{pq} = 2 \sum_{\substack{i \\ \text{doubly occupied orbitals}}}^{\text{Nocc}} C_{ip}\, C_{iq}$$

where C_{ip} is the AO coefficient for atom p in the ith MO and Nocc is the number of occupied MOs. The one calculation which predicts a bond order greater than 0.667 is the VESCF calculation of Hoyland and Goodman (22). However, in this case, only the 4–5 bond is predicted to be shorter than the one in benzene and then the difference is slight, i.e. $R_{4,5} = 1.396$ Å. The discovery of this difference between experiment and theory raises doubts on whether we are justified in using simple relationships between π-bond order and bond length, and whether we should use measurements on the solid state to test out theoretical calculations carried out on an isolated molecule. Measurements on the bond lengths of isolated molecules in the vapor phase by techniques such as electron diffraction on substances, chosen because considerable deviations from the standard aromatic bond length might be expected, are badly needed. For azulene it has been stated (5) that measurements of this type yielded a distance of 1.45 Å for the 9–10 bond, i.e. considerably shorter than that found by X-ray crystallographic measurements. However, no experimental details were given.

We might expect our bond order for the long 9–10 bond to be considerably higher than that calculated by methods in which the resonance integral $\beta_{9,10}$ was allowed to be lower than the other resonance integrals. The results of Table II show that this is not so and that except for the VESCF study of Brown and Heffernan (15), the other MO calculations gave a bond order similar to ours. Using our value of 0.3101 in eq. [1] gives a bond length for the 9–10 bond of 1.46 Å, in good agreement with the electron diffraction measurement reported by Heilbronner (5), but significantly lower than the X-ray value of 1.483 ± 0.004 Å (24). Examination of MO calculations for other molecules containing long bonds shows that this tendency to predict distances shorter than the observed is widespread. For example, when use is made of Coulson and Golebiewski's (25) technique of allowing the resonance integral to be a function of the bond order and iterating until the resulting bond orders do not change, then for the long bonds in tetracene and pentacene, Hutchison (26) found that the calculated values are 1.434 Å and 1.436 Å respectively, compared to experimental values of 1.46 Å and 1.45 Å. For biphenylene, Ali and Coulson (27) using a similar method calculated 1.467 Å for the longest bond, whereas the experimental value is 1.52 Å. In a recent SCF calculation (28), this same bond was predicted to be 1.48 Å, the extra .04 Å being attributed to hybridization changes.

On the basis of these findings we conclude that, in the case of azulene, the use of a constant resonance integral does not lead to predicted bond distances that are any less reliable than those for other MO calculations. However, the validity of the whole procedure of relating π-bond order to bond distances determined by X-ray analysis, especially for molecules with bond distances differing considerably from the standard benzene C—C length, is questionable, because of the results of all the calculations reported in Table II and the other examples cited above.

4. Dipole Moment

The dipole moment of azulene determined by conventional methods is 1.0 D (5). This is much lower than that calculated by the simple Huckel method; i.e., 6.4 D (5). SCF methods and the ASMOCI method, however, give lower values, and our SCF result is compatible with other calculations (Table III last row) in giving a value of 3.18 D.

This high value, compared to the experimental value, is not unexpected, since we have found, in SCF calculations on polar molecules (8), that, by choosing parameters giving agreement with ionization potentials, electron affinities, and electronic excited states,

the π dipole moment is calculated to be too high compared to the normal experimental result. At present, we cannot state whether the high value is due to a deficiency in our model, e.g., in neglecting effects such as CI of the ground state with doubly excited states, or in neglecting penetration integrals, or is due to a contribution to the dipole moment from polarization of the core electrons in the opposite direction to the π-electron dipole moment.

A possible way to arrive at the dipole moment of the π electrons, which does not appear to have been explored previously, is to use the π-electron charge density estimates obtained from n.m.r. studies (29, 30, 31). Using the bond distances and angles suggested by Brown and Heffernan (15), we have calculated μ_π values using the experimental charge densities reported in Table III. Extremely low μ_π values of 0.18 D for the C^{13} results (29), and of 0.02 D for Schaeffer and Schneider's proton chemical shift results were obtained (30). For Dailey's (31) estimate using proton chemical shifts we arrived at the quite reasonable value of 1.47 D; however, this value is in the opposite direction to that usually assumed for the azulene molecule (5) and supported by studies on the effect of solvents on the excited states (32); i.e., Dailey's results predict the negative end of the dipole to lie in the seven-membered ring. This reversal of sign in the dipole moment is due to Dailey's (31) estimate of quite large excess charge densities at the 5, 7, and 6 positions. The estimates of Schneider (29, 30) assign a deficiency of charge ($q < 1$) at the 6-position. The main difference between Dailey's and Schneider's interpretations of the measured azulene proton chemical shifts is in the method of estimating the magnitude of the ring current. Schneider's estimate of the ring-current corrections for the atoms in the five-membered ring are larger than Dailey's, but for those in the seven-membered ring, they are smaller. This difference is sufficient to lead to the charge reversal of the dipole moment for Dailey's charge density distribution. Thus, until more reliable procedures for the calculation of ring-current effects have been developed, the estimation of charge densities from proton magnetic resonance spectra is a very uncertain procedure, full of ambiguities in sign and uncertainties of magnitude—a conclusion reached by Dailey on other grounds.

5. Charge Densities

In view of our comments in the last section, conclusions obtained by comparison of theoretical π-electron densities with estimates from n.m.r. data must be regarded with caution. We have compiled, in Table III, charge densities from n.m.r. measurements and from the more recent MO calculations including our SCF calculation. The general similarity of the results of Table III calculated by different MO techniques shows that the charge density is rather insensitive to parameter variation. In general, the theoretical calculations give better rough qualitative agreement with Schneider's (29, 30) experimental estimates than with Dailey's (31). For example, the MO calculations predict excess charge density ($q > 1$) at the 6-position in agreement with Schneider whereas Dailey favors an electron density less than one for this position.

IV. CALCULATIONS ON THE IONS

1. Azulene Anion Spin Densities

Experimental measurements on the hyperfine splitting constants of the azulene anion have been reported by several workers (33, 34, 35), and these have recently been compared with calculations carried out by both valence bond (VB) calculations (35) and unrestricted Hartree–Fock calculations (36). However, in comparing the results of

previous MO calculations (36, 37) with his own VB calculations, Brown (35) used the wrong sign for the calculated spin densities at the 1-position (designated *B* in Table II of ref. 35). For comparison we have summarized the results of other calculations and those of our RHF perturbation calculations in Table IV together with the effective $(Q_{CH})_p$ values defined by

$$[2] \qquad (Q_{CH})_p = \frac{a_H(\text{expt.})_p}{\rho_H(\text{calcd.})_p}$$

for atom p. The experimental values Q_{CH} (expt.) were obtained by Brown (35) from the nuclear magnetic resonance coupling constants ($J_{^{13}C-H}$) of azulene (36).

The results of Table IV show that two of the MO calculations which include electron correlation (columns 3, 6) yield negative spin densities in the 1, 3, 5, and 7 positions. By contrast the VB method of Brown (35) (Table IV col. 4) gives negative spin densities only in the 5 and 7 positions with a substantial positive spin density in the 1 and 3 positions. Considering the fact that the VB results were calibrated by varying three parameters to give the best overall fit for the three largest hyperfine splitting constants corresponding to positions 2, 4, and 6, and the MO calculations in cols. 4, 6, and 7 were not scaled in any way to fit e.s.r. data, the more sophisticated MO treatments must be regarded as preferable to use for the interpretation of e.s.r. results rather than the VB method.

None of the results of the calculations can be claimed to be completely satisfactory as is shown by the large variation in the Q_{CH} values (Table IV). It is noteworthy that the Q_{CH} values obtained using our SCF calculation (cols. 3 and 4) are much improved by carrying out the CI, and it would be of very great interest to know whether the use of open-shell MOs would improve the agreement still further especially for the 1-position. Calculations of this type raise the problem of whether the variation of the empirical parameters with the charge should be taken into account, as was done for positive ions by Hoyland and Goodman (22), and, if so, what is the best method to do this. Such calculations are in progress for a number of hydrocarbon ions.

2. Azulene Negative Ion Charge Densities

There are no experimental estimates of the charge densities for the azulene anion. We have compared our calculations of these quantities with those of others in Table V. Comparison between columns 2 and 3 show that the effect of CI is to transfer a considerable amount of electronic charge from the five-membered ring into the seven-membered ring. The results of the unrestricted Hartree–Fock calculation of Amos (36) are quite similar to our charge densities after CI. The VB calculation of Brown (35) predicts

quite a different charge distribution from those indicated by any of the MO calculations, particularly in the prediction of a very high charge density at the 2-position and a very low one at the 6-position. It is unfortunate that at the moment we have no direct method of distinguishing between these different predictions by experiment.

3. Azulene Positive Ion Spin Densities

There are at present no experimental results available for the hyperfine splitting constants of the azulene positive ion. However, our theoretical results for spin and charge densities are compared with other recorded theoretical calculations in Table VI. It is found that there are substantial differences between the VB method and the MO methods. This is particularly evident for position 1 for which both our work and that of Amos (36) predict a large positive spin density whereas the VB method (35) predicts a sizable negative spin density at this position. The fairly large differences in predictions by the various methods evident in Table V make it very important that a serious attempt be made to obtain the experimental hyperfine splitting constants for the azulene positive ion.

4. Azulene Positive Ion Charge Densities

A comparison of the charge densities of the positive ion calculated by different methods is made in Table VI. Columns 6 and 7 show that CI has a considerable effect on the charge densities in our SCFMO calculation. In col. 8 we report charge densities obtained for the azulene positive ion by an open-shell VESCF technique (22). The results of this calculation, and the UHF calculation of Amos (35) (col. 9), and our SCF + CI calculation are very similar. They differ from our calculation in positions 5 and 7, for which we predict a much lower charge density than the other methods. As we found for the spin densities there is also considerable difference between the HF and the VB calculations. At the present time, there are no experimental results to compare with the theoretical predictions.

V. CONCLUSIONS

Our SCF calculations on azulene, using the Mataga and Nishimoto (9) approximation for two-center integrals and a constant resonance integral for all nearest neighbors, are justified by the very good agreement we obtain with experiment for transition energies, the ionization potential, and the electron affinity. For ground-state properties, such as the bond lengths, the charge density, and the dipole moment, our method gives very similar results to other methods, all of which are in only poor agreement with experiment. Whether this disagreement is because of deficiencies in MO techniques, or in interpreting the experimental data directly in terms of such theoretical concepts as π-bond orders and π-charge densities, is not clear at present.

Our SCFMO calculations on the singly charged ions of azulene are in considerable disagreement with similar calculations using the VB technique. In the case of the negative ion, the spin densities are in fair agreement with experiment. Corresponding experimental data on the positive ion would help resolve the question of whether MO calculations are superior to the VB method for calculating spin densities. We believe that the SCFMO + CI procedure used in the present paper are to be preferred to other methods such as the VB and the unrestricted Hartree–Fock method because of its capabilities of calculating several unrelated physical properties with the same parameters.

Received May 20, 1965

ABSTRACT

The reaction between 2,2-diphenyl-1-picrylhydrazyl (DPPH) and 2,4,6-tri-*t*-butylphenol in benzene solution has been studied by optical and electron spin resonance methods. In the absence of oxygen, equilibrium is reached with the products 2,2-diphenyl-1-picrylhydrazine and the tri-*t*-butylphenoxy radical. The equilibrium constant for the reaction is 0.10 ± 0.03 at 20 °C and from its variation with temperature the heat of reaction is estimated to be 1.6 ± 0.3 kcal/mole. The entropy change in the reaction is small.

The rate constants for the forward reactions with tri-*t*-butylphenol and deuterated tri-*t*-butylphenol are 0.12 ± 0.02 l/(mole s) and 0.010 ± 0.002 l/(mole s) respectively at 20 °C. The corresponding activation energies are 6.5 ± 0.8 kcal/mole and 7.7 ± 0.7 kcal/mole. The rate constant for the reverse reaction is approximately 2 l/(mole s) at 20 °C and the activation energy is 4.8 ± 1 kcal/mole.

INTRODUCTION

2,2-Diphenyl-1-picrylhydrazyl (DPPH) reacts with a wide range of hydrogen donors including aliphatic thiols (1), aromatic amines (2, 3), hydroaromatic compounds (4, 5), and phenols (6, 7, 8). The major product of these reactions is 2,2-diphenyl-1-picrylhydrazine (DPPH-H) and kinetic studies have shown that in reactions with phenols the rate-determining step involves hydrogen abstraction from the OH group (7, 8). Since DPPH is a free radical and the solvent e.g. benzene, is of low polarity, it is probable that the rate-determining step can be represented by eq. [1].

$$\text{DPPH} + \text{XH} \rightarrow \text{DPPH-H} + \text{X}\cdot \qquad [1]$$

The reactions with phenols are, however, quite sensitive to inductive effects of meta-substituents, and changes in para-substituents can alter the rate constants at 30 °C by factors as great as 20 000. McGowan, Powell, and Raw (6) have compared the effect of substituents on the rate of hydrogen abstraction by DPPH from phenols with their effect on the rates of solvolysis of dimethylbenzyl chlorides and have suggested that DPPH may abstract hydride ions rather than hydrogen atoms from phenols.

The reactions of DPPH with aromatic amines (3), phenols (7), and acetic acid and ethanol (9) are retarded by the product DPPH-H. The retardation of the reactions with amines and phenols has been explained in terms of the reversibility of the rate-determining step [1]. Proll and Sutcliffe (9) argue that the hydrogen abstraction process is not reversible when acetic acid and ethanol act as donors, and state that retardation is due solely to complex formation between DPPH and DPPH-H. If their explanation is correct it should also apply to the reactions of DPPH with amines and phenols.

The radical nature of the reaction between DPPH and phenols and the reversibility of the primary step can be most simply studied if a stable free radical X· is produced in

reaction [1]. This paper describes a study of the reaction between DPPH and 2,4,6-tri-*t*-butylphenol to give DPPH-H and the stable tri-*t*-butylphenoxy radical. The disappearance of DPPH was followed by visible spectrometry and the formation of tri-*t*-butylphenoxyl by electron spin resonance (e.s.r.). Forward and reverse reactions were investigated in addition to equilibria between 20 °C and 60 °C.

EXPERIMENTAL

Materials

DPPH-H was prepared by the reaction of picryl chloride with 1,1-diphenylhydrazine (10, 11). Melting point 170–171 °C. DPPH was prepared by lead dioxide oxidation of DPPH-H and was recrystallized from a benzene–ether mixture. It was heated *in vacuo* to remove complexed benzene (12). Melting point 137.5–138.5 °C. 2,4,6-Tri-*t*-butylphenol was recrystallized from ethanol in an atmosphere of nitrogen. Melting point 131–132 °C. Tri-*t*-butylphenoxyl was prepared by oxidation of tri-*t*-butylphenol using an alkaline ferricyanide solution (13). It was stored in an atmosphere of nitrogen. Deuterated tri-*t*-butylphenol was prepared in benzene solution by shaking a 0.01 *M* solution of the normal phenol with heavy water. Equilibrium is rapidly attained (8) and from the relative amounts of phenol and heavy water used it was estimated that the phenol was approximately 96% deuterated at the OH group.

Procedure

A preliminary spectroscopic study of the reaction was made using a Bausch and Lomb 'Spectronic 20' spectrometer. Solutions containing approximately 5×10^{-4} *M* DPPH and 10^{-3} to 5×10^{-2} *M* tri-*t*-butylphenol were prepared under nitrogen or *in vacuo* and their spectra after various times were compared with those of solutions of DPPH, DPPH-H, and tri-*t*-butylphenoxyl. The reverse reaction between tri-*t*-butylphenoxyl and DPPH-H was investigated using mixtures of approximately 10^{-4} *M* DPPH-H and tri-*t*-butylphenoxyl prepared under nitrogen.

Initial rates of reaction were determined using a modified Fisher electrophotometer, the 1 cm reaction tubes being placed in a jacket through which water at constant temperature was circulated (3). The absorbance at 525 mμ was measured at ½ min intervals and, after correction for the DPPH-H and tri-*t*-butylphenoxyl present, was used as a measure of the DPPH concentration. Initial rates of reaction of DPPH with tri-*t*-butylphenol are almost unaffected by oxygen and most of the early measurements were performed with air present. More accurate rate constants were obtained from data for reactions which proceeded to equilibrium, but these required thoroughly degassed solutions as tri-*t*-butylphenoxyl reacts with oxygen. Solutions of the reactants were preferably degassed separately since a considerable amount of reaction occurs during the degassing of a reaction mixture. Phenol concentrations ranged from 4 to 80×10^{-4} *M* and DPPH concentrations from 2 to 50×10^{-5} *M*. For reactions involving the higher concentrations of DPPH, absorbance measurements were made using a Unicam SP500 spectrophotometer at a wavelength of 700 mμ.

Initial rates of the reverse reaction between 2,4,6-tri-*t*-butylphenoxyl and DPPH-H were determined using the Fisher electrophotometer. The reactant solutions were prepared in an atmosphere of nitrogen and the concentration range of each reactant was approximately 5 to 15×10^{-5} *M*.

Electron spin resonance spectra of reaction mixtures were obtained using a Varian V-4500 EPR spectrometer, operating at 9 400 Mc/s, with a Mullard 10 in. electromagnet (14). It was established that microwave power saturation of the free radicals in benzene solution was negligible. The spectra of the two free radicals overlap but the narrow line spectrum of the tri-*t*-butylphenoxyl was readily observed at low gain and the broad line spectrum of DPPH at high gain. Relative concentrations of tri-*t*-butylphenoxyl during a reaction were obtained from peak heights of the first derivative curves. The ratio of concentrations of DPPH and tri-*t*-butylphenoxyl at equilibrium was obtained by double integration of the first derivative functions to give the areas under the absorption curves; the absolute concentration of each radical was derived on the assumption that the total radical concentration did not change during the establishment of equilibrium. Temperature control (±1 °C) for experiments conducted in the 20 °C to 60 °C temperature range was obtained using a stream of heated nitrogen. The initial concentrations of phenol varied from 8 to 150×10^{-4} *M* and the initial concentration of DPPH was 5×10^{-4} *M*.

RESULTS

When DPPH reacts with 2,4,6-tri-*t*-butylphenol in the presence of air the violet color of the DPPH gives way to the light brown of DPPH-H. In the absence of air an equilibrium is reached and a solution initially containing 5×10^{-4} *M* DPPH and 10^{-2} *M* tri-*t*-butylphenol remains violet because of the presence of DPPH. At higher concentrations (0.1 *M* to 1 *M*) the equilibrium DPPH concentration is reduced to a very low value and the visible spectrum of the equilibrium mixture shows a weak maximum at 625 mμ; on admission of air this maximum disappears. If the absorbance is due primarily to the tri-*t*-butylphenoxy

For personal use only.

radical a rough calculation of its concentration using an extinction coefficient of 400 l/(mole cm) (15) gives a value of $5 \pm 1 \times 10^{-4}$ M, compared with 5×10^{-4} M if 1 mole tri-*t*-butylphenoxyl is formed from 1 mole DPPH.

Stronger evidence for the formation of tri-*t*-butylphenoxyl is obtained from the electron spin resonance spectrum of a reacting solution. At low gain the spectrum consists of a triplet with a peak to peak separation of 1.8 G, characteristic of the 2,4,6-tri-*t*-butylphenoxy radical under conditions when the hyperfine structure due to the *t*-butyl groups remains unresolved (16). At high gain the observed spectrum is principally the broad line spectrum of DPPH except that the central region is obscured by the phenoxy radical. If a g factor of 2.0036 is assumed for DPPH, the g factor of 2,4,6-tri-*t*-butylphenoxyl is estimated to be 2.0045 ± 0.0002 (cf. 2.0052 (17)).

The identification of the tri-*t*-butylphenoxy radical as a major product and the approach to a position of equilibrium are expressed in eq. [2].

[2] 
The reversibility was confirmed by mixing dilute solutions of DPPH-H and tri-*t*-butylphenoxyl in an atmosphere of nitrogen. The solution became violet and the visible spectrum was almost identical with that of DPPH. In separate experiments it was shown that DPPH and tri-*t*-butylphenoxyl do not react at an appreciable rate in benzene solution under the conditions of this work.

The Equilibrium Constant

The results of the equilibrium constant measurements are given in Table I. In optical determinations the equilibrium concentration of DPPH was estimated from absorbance measurements at 525 mμ or 700 mμ. Concentrations of DPPH-H and tri-*t*-butylphenoxyl are derived on the assumption that the reaction proceeds quantitatively according to eq. [2]. The concurrent hydrogen exchange reactions between tri-*t*-butylphenol and tri-*t*-butylphenoxyl (18) and between DPPH-H and DPPH should not affect the validity of this assumption. The mean value of the equilibrium constant from optical measurements is 0.12 ± 0.04, at 20 °C. The electron spin resonance results are probably of slightly higher accuracy because the ratio of the concentrations of the two radicals is obtained from the experimental observations. They yield an average value of 0.10 ± 0.03 for the equilibrium constant at 20 °C, in good agreement with the results of optical measurements.

TABLE I

Equilibrium constants for the reaction between DPPH and tri-*t*-butylphenol at 20 °C

Equilibrium constant	Phenol concentration (M)	Method
0.09	8×10^{-4}	e.s.r.
0.12	1.7×10^{-3}	e.s.r.
0.09	1.8×10^{-3}	e.s.r.
0.10	3.9×10^{-3}	e.s.r.
0.085	3.9×10^{-3}	e.s.r.

When the temperature of an equilibrium mixture was raised from 30 °C to 60 °C there was a decrease in absorbance at 525 mμ due (*a*) to a decrease in density of the solution (*b*) to a movement of the equilibrium in favor of the products; the absorbance slowly regained its former value on cooling to 30 °C. The enthalpy change in the reaction, estimated from the variation of equilibrium constant with temperature, was found to be 1.0 ± 0.5 kcal/mole. Values of the equilibrium constant were also determined from electron spin resonance studies at 30 °C, 40 °C, 50 °C, and 60 °C and these lead to an enthalpy change of 1.6 ± 0.3 kcal/mole. Since the free energy change in the reaction at 20 °C is 1.4 ± 0.2 kcal/mole, the entropy change for the reaction in benzene solution is small.

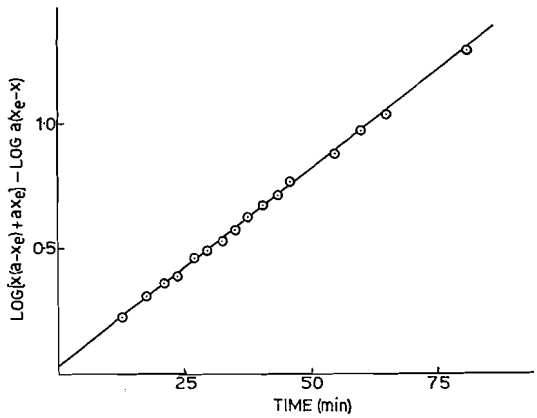

FIG. 1. Plot of kinetic data derived from electron spin resonance measurements at 20 °C.

The Rate Constants

In studies of the forward reaction carried out *in vacuo* the phenol concentration remained almost constant during any single experiment. First order velocity constants were derived using the integrated rate expression for a reaction of the type $A \rightleftharpoons C + D$. Fig. 1 is a plot of $\log [ax_e + x(a - x_e)] - \log a(x_e - x)$ vs. time t, where a, $a - x$, and $a - x_e$ are the concentrations of DPPH at times 0, t, and at equilibrium respectively. In this experiment the initial phenol concentration was 1.5×10^{-3} M, and the DPPH concentration was derived from electron spin resonance measurements of the tri-*t*-butylphenoxyl concentration assuming that the stoichiometry of the reaction is correctly expressed by eq. [2]. Straight lines obtained in the graphical treatment showed that the reaction is of first order with respect to DPPH. On dividing the first order constants by the phenol concentrations, the second order constants for the forward reaction were obtained. These are independent of phenol concentration in the range 1 to 7×10^{-3} M showing that under these conditions the reaction is of first order with respect to the phenol. Rate constants at 20 °C derived from optical measurements of the DPPH concentration and from electron spin resonance measurements of the tri-*t*-butylphenoxyl concentration are given in Table II. The mean value of the rate constant is 0.12 ± 0.02 l/(mole s) at 20 °C. Rate constants have also been derived from initial rates of reaction and the results agree with those in Table II provided that similar concentrations of reactants are used. However, for DPPH concentrations in the range 2 to 6×10^{-5} M and phenol concentrations in the range 2 to 20×10^{-4} M, the order with respect to phenol drops to 0.7–0.8. Initial rates are not significantly affected by degassing so that the change in order is not caused by oxygen in the system. The apparent second order 'rate constant' rises to 0.16–0.19 l/(mole s) at 20 °C.

TABLE II

Rate constants for the reaction between DPPH and tri-*t*-butylphenol at 20 °C

Rate constant (l/(mole s))	Phenol concentration (M)	Method
0.11	8.4×10^{-4}	e.s.r.
0.12	1.5×10^{-3}	e.s.r.
0.125	3.8×10^{-3}	e.s.r.
0.115	7×10^{-3}	e.s.r.
0.13	2.2×10^{-3}	Optical
0.115	3.9×10^{-3}	Optical
0.12	7.6×10^{-3}	Optical

The activation energy for the forward reaction is 6.5 ± 0.8 kcal/mole. With 2,4,6-tri-*t*-butylphenol approximately 96% deuterated at the OH group, the rate constant at 20 °C is 0.010 ± 0.002 l/(mole s) and the activation energy is 7.7 ± 0.7 kcal/mole.

The reverse reaction between DPPH-H and the tri-*t*-butylphenoxy radical is much faster than the forward reaction and reactant concentrations not greater than 1.5×10^{-4} M are required for measurable rates of reaction. Analysis of the initial rates of formation of DPPH shows that, over small concentration ranges, the reverse reaction appears to be of first order with respect to the tri-*t*-butylphenoxyl but only about half order with respect to DPPH-H. The second order 'rate constant' for a DPPH-H concentration of 10^{-4} M is 2.2 ± 0.4 l/(mole s) at 20 °C and the activation energy is 4.8 ± 1 kcal/mole. The difference between the activation energies of the forward and reverse reactions is 1.7 ± 1.3 kcal/mole compared with an enthalpy change derived from equilibrium constants of 1.6 ± 0.3 kcal/mole.

DISCUSSION

The reaction between DPPH and 2,4,6-tri-*t*-butylphenol in benzene solution gives DPPH-H and the stable 2,4,6-tri-*t*-butylphenoxy radical. Deuteration of the phenol at the OH group reduces the rate constant of the forward reaction by a factor of the order of 12, showing that abstraction of hydrogen occurs almost exclusively at the OH group. The equilibrium constant for the reaction of DPPH with the deuterated phenol is 0.11 ± 0.03, i.e. within experimental error it is unaffected by deuteration of the phenol. It may be inferred that the reverse reaction is subject to a primary kinetic isotope effect of comparable magnitude to that observed for the forward reaction.

At relatively high concentrations of DPPH and tri-*t*-butylphenol the reaction is of first order with respect to each reactant but at low concentrations the order with respect to phenol drops to 0.7–0.8. The reason for this divergence from simple kinetic behavior is not understood; a similar dependence of rate constant upon phenol concentration has been observed in reactions of styrylperoxy radicals with unhindered phenols (19). At low concentrations of reactants the reverse reaction is of first order with respect to tri-*t*-butylphenoxyl but of about 0.5 order with respect to DPPH-H. The second order 'rate constant' is therefore a function of concentration under these conditions and the ratio of the rate constants at 20 °C for the forward and reverse reactions, 0.12/2.2 = 0.055, is lower than the value of the equilibrium constant observed directly, 0.10 ± 0.03.

The reaction between DPPH and tri-*t*-butylphenol gives rise to a stable phenoxy radical and experiments in progress show that phenoxy radicals are intermediates when other hindered phenols are attacked by DPPH. While it remains possible that hydride ions are abstracted, to be followed by electron transfer, it appears more likely that hydrogen atoms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

are directly transferred to the DPPH. The very great sensitivity of DPPH–phenol reactions to substituents in the phenol (6, 7) is then ascribed to the importance of polar contributions of the form $\overset{+}{X}OH\ \overset{-}{D}PPH$ to the transition state.

In the reversible reaction between DPPH and tri-*t*-butylphenol the rate constant for the reverse reaction is an order of magnitude greater than that for the forward reaction, and it is probable that addition of DPPH-H causes retardation of the overall reaction with other phenols by reducing the concentrations of reactive phenoxy intermediates. Reversibility of the primary step is likely to be quite general in hydrogen abstraction reactions of DPPH, and retardation of the reactions between DPPH and acetic acid and ethanol (9) may well be caused by this reversibility. DPPH forms complexes with solvents (12) and its reactions may in some cases be influenced by such complex formation, but retardation of DPPH hydrogen abstraction reactions by DPPH-H is not likely to be due to the formation of complexes between DPPH and DPPH-H at the concentrations used in these experiments.

In this work, electron spin resonance has been applied to the measurement of concentrations of the stable 2,4,6-tri-*t*-butylphenoxy radical in benzene solution and the derived rate and equilibrium constants are in excellent agreement with those obtained from optical studies. The success of the method depends upon the phenoxy radical having a narrow line spectrum compared with that of DPPH. In general, reactions of DPPH with phenols and other donors produce reactive intermediates at lower concentrations than those observed here but in many cases their stationary concentrations may be determined by similar methods. The kinetics of the secondary reactions of the reactive intermediates may then be studied directly.

ACKNOWLEDGMENTS

We are grateful to Janet Smith, Queen's University, for making the preliminary optical studies of this problem. This work was supported by an operating grant from the National Research Council. K. E. R.'s visit to the Department of Physical Chemistry, University of Leeds, was supported by grants from the Nuffield Foundation and the National Research Council.

THE ARSENIDES OF TUNGSTEN AND MOLYBDENUM

WAs_2, W_2As_3, $MoAs_2$, Mo_2As_3, AND Mo_5As_4[1]

J. B. TAYLOR, L. D. CALVERT, AND M. R. HUNT[2]

Received June 2, 1965

ABSTRACT

Binary alloys in the systems tungsten–arsenic and molybdenum–arsenic have been annealed at temperatures between 600 and 1 000 °C and, after quenching, examined by X-ray diffraction techniques. The only intermediate phases observed are WAs_2, W_2As_3, $MoAs_2$, Mo_2As_3, and Mo_5As_4. No solid solubility was detected in the elements or the compounds. The diarsenides are monoclinic, $C2$, and have the $NbAs_2$ structure. WAs_2, $a = 9.085 \pm 0.002$ Å, $b = 3.318 \pm 0.002$ Å, $c = 7.690 \pm 0.002$ Å, $\beta = 119° 31' \pm 2'$, $MoAs_2$, $a = 9.07$ Å, $b = 3.30$ Å, $c = 7.73$ Å, $\beta = 119° 20'$. The X_2As_3 compounds are monoclinic, condensed diffraction symbol $C*/*$; W_2As_3, $a = 13.346 \pm 0.002$ Å, $b = 3.278 \pm 0.002$ Å, $c = 9.599 \pm 0.002$ Å, $\beta = 124° 48' \pm 2'$; Mo_2As_3, $a = 13.339 \pm 0.002$ Å, $b = 3.240 \pm 0.002$ Å, $c = 9.628 \pm 0.002$ Å, $\beta = 124° 31' \pm 2'$. Mo_5As_4 is tetragonal, $I4/m$, with the Ti_5Te_4 structure, $a = 9.595 \pm 0.001$ Å, $c = 3.284 \pm 0.002$ Å. Data for $MoAs_2$ and Mo_5As_4 confirm or amplify previous reports. In contrast to other reports, MoAs and W_2As were not observed. W_4As_5 and Mo_4As_5, which have been mentioned briefly elsewhere, are here identified as W_2As_3 and Mo_2As_3.

During an investigation of crystal growth by vapor transport methods the phase relationships in the tungsten–arsenic and molybdenum–arsenic systems were studied over the full range of composition using powder diffraction and single crystal X-ray diffraction methods.

Both $MoAs_2$ and WAs_2 were prepared by Heinerth and Biltz (1). Boller and Nowotny (2) reported WAs_2, W_4As_5, and W_2As as the only phases occurring in the tungsten-arsenic system. W_4As_5 was examined by Weissenberg methods and assigned monoclinic cell parameters $a = 7.99$ Å, $b = 3.28$ Å, $c = 6.88$ Å, $\beta = 99° 12'$. No further information on the other phases was given except that WAs_2 is not stable at high temperatures. The same authors reported the existence of $MoAs_2$, Mo_4As_5, MoAs, and Mo_5As_4. On the basis of diffractometer powder patterns and intensity comparisons they assigned the MnP structure type to MoAs ($a = 5.98_9$ Å, $b = 3.36_8$ Å, $c = 6.41_7$ Å) and the Ti_5Te_4 structure type (3) to Mo_5As_4 ($a = 9.60_0$ Å, $c = 3.27_8$ Å). $MoAs_2$ was claimed to be orthorhombic and Mo_4As_5 to have the same structure as W_4As_5 but no further details were given. Jensen and Kjekshus (4) have concluded that $MoAs_2$ has the $NbAs_2$ structure type, $a = 9.069$ Å, $b = 3.2996$ Å, $c = 7.717$ Å, $\beta = 119.36°$. They reported the existence of $MoAs_{1.4}$ and $MoAs_{0.8}$ but did not stipulate that these are the only additional phases in the molybdenum–arsenic system.

We have been prompted to publish the results of our phase analytical and crystallographic work because of discrepancies which exist between our results and those of Boller and Nowotny.

EXPERIMENTAL

Materials

Tungsten powder (−200 mesh) was supplied by A. D. Mackay. It contained less than 100 p.p.m. Mo; between 5 and 50 p.p.m. each of Mg, Si, Fe, and Ni; and between 1 and 10 p.p.m. each of Cu and Ca. Molybdenum powder (−200 mesh) was donated by the U.S. Fansteel Corporation. It contained between 40 and 100 p.p.m. each of W, Fe, Ni, and Cu; between 5 and 50 p.p.m. each of Mg, Si, Ca, and Cr; and between 1 and 10 p.p.m. of Ag. Arsenic was obtained from Cominco as "high purity arsenic" which was

[1]*Issued as N.R.C. No. 8611.*
[2]*N.R.C. Postdoctorate Fellow.*

claimed to be spectroscopically better than 99.999%. It was fractionally sublimed *in vacuo* at 450 °C to reduce oxide contaminant not accounted for in the analysis.

Phase Analysis

Samples were prepared in the usual way by sealing under vacuum (10^{-5} mm Hg) weighed quantities of arsenic and tungsten or molybdenum in fused silica ampoules. Care was taken to ensure that the ampoules and charges were thoroughly outgassed before sealing. In the tungsten–arsenic system, samples having the following compositions were prepared: WAs_3; WAs_2; $WAs_{1.8}$; $WAs_{1.6}$; $WAs_{1.4}$; $WAs_{1.2}$; WAs; $W_{1.2}As$; $W_{1.4}As$; $W_{1.6}As$; $W_{1.8}As$; W_2As; W_3As; W_4As. In the molybdenum–arsenic system the following samples were prepared: $MoAs_4$; $MoAs_3$; $MoAs_2$; $MoAs_{1.8}$; $MoAs_{1.6}$; $MoAs_{1.4}$; $MoAs_{1.2}$; MoAs; $Mo_{1.2}As$; $Mo_{1.4}As$; $Mo_{1.6}As$; $Mo_{1.8}As$; Mo_2As; Mo_3As; Mo_4As; Mo_5As. Both series of samples were reacted at 850 °C for 40 days and then quenched in water. Each sample was divided into five parts, sealed in fused silica tubes under vacuum, and annealed at 600, 700, 800, 900, and 1 000 °C for periods of not less than 18 days. In addition, samples of composition WAs_6; WAs_5; $WAs_{4.5}$; WAs_4; WAs_3; $WAs_{2.6}$; $WAs_{2.4}$ were sealed in heavy-walled fused silica ampoules and annealed at 850 °C for 30 days.

Another set of samples WAs_2; $WAs_{1.8}$; $WAs_{1.6}$; $WAs_{1.4}$; $WAs_{1.2}$; WAs; $W_{1.2}As$; $W_{1.4}As$; $W_{1.6}As$; $W_{1.8}As$ was prepared by reaction for 20 days at 600 °C instead of 850 °C. Only one molybdenum arsenide, MoAs was prepared at 600 °C. As required, samples were quenched in water and Debye–Sherrer patterns obtained on 11.46 cm Norelco cameras using nickel-filtered copper radiation. Guinier focussing camera patterns were obtained on an 11.46 cm camera with monochromatic Cu K_α radiation ($\lambda = 1.5405$ Å).

The attack on the silica tubes was assessed by visual examination of the used ampoules coupled with spectrographic analysis of the reacted charges. Only in the case of samples richer in arsenic than XAs_2 was there any marked attack of the tubes. In these samples, silicon contents rose to 1 000 p.p.m. In all other samples analyzed, the silicon contaminant remained below 100 p.p.m. and very little attack of the silica was detected by visual examination.

Assignment of a particular molecular formula to a phase was based initially on careful examination of 16 h exposure Guinier photographs of a series of samples covering the composition range in question. The composition of the samples was calculated from the weighed quantities of each component prior to reaction.

Single Crystal Preparation

Single crystals of W_2As_3 were obtained using a bromide vapor transport reaction. The growth tube was fused silica, 9 mm i.d., 12 cms long. About 1 g of WAs_2 was placed at one end. Two sidearms about 8 cm long were attached to the tube and one contained 58 mg $PtBr_2$. The system was evacuated to 10^{-5} mm of mercury and sealed off. Bromine was generated by thermal decomposition of the $PtBr_2$ (about 500 °C) and trapped at liquid nitrogen temperature in the second side limb. The limb which had contained the $PtBr_2$ was sealed off and the bromine transferred by distillation into the growth tube. The growth tube was sealed off and placed in a furnace for 24 h with the end containing WAs_2 maintained at 1 075 °C and the other end at 900 °C. W_2As_3 crystals grew at the cooler end and to a lesser extent on the charge also.

Single crystals of $MoAs_2$ were obtained by chloride vapor transport reaction. The growth tube was of a similar size to that used for W_2As_3. The charge consisted of 0.8455 g of molybdenum and 1.5205 g of arsenic. Chlorine was obtained from a fused chloride electrolytic generator and 0.1025 g metered coulometrically. The tube was heated for 2 days with the charge held at 914 °C and the opposite end at 938 °C. Needles of $MoAs_2$ grew on the substrate at the hotter end of the tube. The relevant parameters are recorded for each case although they may not define unique conditions necessary for crystal growth.

RESULTS

In the tungsten–arsenic system, the only compound observed above 800 °C is W_2As_3 but below this temperature, WAs_2 is also stable. There is no indication of any binary phase richer in tungsten than W_2As_3. Guinier patterns obtained from $WAs_{1.4}$ showed W_2As_3 and tungsten reflections only.

In the molybdenum–arsenic system, the only intermediate phases obtained were $MoAs_2$, Mo_2As_3, and Mo_5As_4. They are all stable between 600 and 1 000 °C. No evidence was found to confirm the existence of MoAs. Thus in patterns obtained from samples of $MoAs_{1.4}$, there were reflections attributable to Mo_5As_4 and Mo_2As_3 only.

The intermediate phases have no detectable range of composition as judged from the constancy of their back reflection Debye–Scherrer patterns. There is little or no solid solubility of arsenic in tungsten or molybdenum. Thus the lattice parameter of tungsten is 3.1650 Å in a sample containing W_2As_3 and W annealed at 600 °C. The molybdenum parameter is 3.1468 Å in a sample containing Mo_5As_4 and Mo annealed at 700 °C. (Both

DISCUSSION

X_2As_3 Phases

The formula assigned to these phases is based initially on a comparison of Guinier patterns of specimens with compositions $XAs_{1.4}$ (58 at. % As) and $XAs_{1.6}$ (62 at. % As). $WAs_{1.4}$ is a mixture of W_2As_3 and W; $WAs_{1.6}$, a mixture of W_2As_3 and WAs_2 when annealed below 800 °C. $MoAs_{1.4}$ is a mixture of Mo_5As_4 and Mo_2As_3; $MoAs_{1.6}$, a mixture of Mo_2As_3 and $MoAs_2$. The observed densities of the powders, within the limits of the accuracy, are consistent with X_2As_3 but the formulae X_8As_{11} and X_8As_{13} are not completely excluded by the density measurements.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

A possible structural classification for these X_2As_3 phases can be derived by considering the alternative body-centered cell for which the cell parameters are simply related to the NiAs (*B*8) structure. Thus $a_{b.c} \approx 2c_{NiAs}$, $b_{b.c} \approx a_{NiAs}$, $c_{b.c} \approx 3a_{NiAs}$. Furthermore the powder patterns of W_2As_3 and Mo_2As_3 have certain specific resemblances to those for Ni_3Se_4 (6), Ni_3Sn_4 (7), Cr_3S_4 (8) which have monoclinic structures based on ordering of vacancies in the NiAs structure. The possibility of vacancies in the structure makes it unwise to place too much reliance on a specific stoichiometry in the absence of a complete structure determination.

The phase of approximate composition W_4As_5 reported by Boller and Nowotny has been assigned the formula W_2As_3 here, because their "monoclinic" cell with $a = 7.99$ Å, $b = 3.28$ Å, $c = 6.88$ Å, $\beta = 99° 12'$ can be transformed to the *c*-face-centered cell used here (transformation matrix $00\bar{2}/010/101$). It should be noted that the smaller cell is not a true unit cell and does not account for all the reflections on our powder patterns or single crystal photographs. Mo_4As_5, reported by Boller and Nowotny to be analogous, is also probably Mo_2As_3.

XAs_2 Phases

WAs_2 and $MoAs_2$ undoubtedly have the $NbAs_2$ structure as is shown by the very close similarity of the three powder patterns. It may be noted that this structure can be derived from the *C*18 marcasite structure in the setting *Pnnm* by the transformation $110/001/1\bar{1}0$ followed by relatively small shifts of the atoms (i.e. the monoclinic *a* and *c* axes are the face-diagonals of the *ab*-face of the *C*18 cell). The other family of diarsenides and related dipnictides typified for example by $CoAs_2$ (9), can also be derived from the *C*18 unit cell by the analogous transformation $\bar{1}01/010/101$ (i.e. the *a* and *c* monoclinic axes are derived from the diagonals of the *ac*-face of the *C*18 cell).

MoAs and W_2As

MoAs and W_2As were not observed in our experiments, contrary to Boller and Nowotny's report. We can offer no positive explanation for this discrepancy but we have given a full statement of our experimental procedures. Patterns from all samples richer in tungsten than W_2As_3 contained only W and W_2As_3 reflections. Similarly patterns obtained from samples richer in molybdenum than Mo_2As_3 contained reflections from Mo_5As_4 and Mo_2As_3.

Addendum

A paper by A. Brown (Nature, 206, 503 (1965)) has come to hand since this manuscript was submitted. His data for $MoAs_2$ independently confirm the data given here and in addition, the structure is determined. A phase of composition $Mo_{0.4}As_2$ is described and reported to have a defect *C*18 structure (*Pnnm*, $a = 5.299$ Å, $b = 5.983$ Å, $c = 2.885$ Å). This compound was not observed in the present work. In the absence of details of the preparative techniques used by Brown, it is not possible to offer any explanations for this discrepancy. Our own techniques are described in full and are based on a reaction temperature of 850 °C and subsequent annealing and quenching. It may be that this is another example of the surprisingly different results obtained from different conditions of sample preparation. A. Kjekshus and W. B. Pearson have recently commented on this (Progr. in Solid State Chem. 1, 83 (1964), pp. 86, 106, and 107) in discussing systems having the NiAs and closely related structures.

ACKNOWLEDGMENTS

The authors are indebted to Mr. G. J. G. Despault, who prepared the samples, and to Miss F. Hui, who obtained the powder patterns.

THE UNIMOLECULAR DECOMPOSITION OF METHYL CHLORIDE

W. FORST AND P. ST. LAURENT[1]
Department of Chemistry, Université Laval, Québec, Québec
Received May 18, 1965

ABSTRACT

The second-order rate constant for the unimolecular decomposition of methyl chloride

$$CH_3Cl \rightarrow CH_3 + Cl$$

has been calculated on a computer by the quantum version of the Marcus–Rice theory assuming no active rotations and using the experimental activation energy. With a harmonic energy level density count the calculated rate constant is 32 times smaller than the experimental value. When correction for anharmonicity is applied, the agreement is somewhat improved but the calculated rate constant is still some 20 times too small. These results are discussed in the light of the assumptions made in the course of the calculations. It is concluded that the quantum statistical collision theory, to which the Marcus–Rice theory reduces at low pressure, is a good deal more successful than Slater's, which is in error by a factor of 10^5–10^6.

RÉSUMÉ

La constante de vitesse de la réaction du deuxième ordre pour la décomposition monomoléculaire du chlorure de méthyle

$$CH_3Cl \rightarrow CH_3 + Cl$$

a été calculée au moyen d'un ordinateur électronique suivant le modèle quantique de la théorie de Marcus–Rice en utilisant la valeur expérimentale de l'énergie d'activation, et dans l'hypothèse qu'aucune rotation n'est active. La constante ainsi calculée est plus petite que la valeur expérimentale d'un facteur 32. On peut augmenter la valeur de la constante calculée de 50% en corrigeant la densité des niveaux de vibrations pour l'anharmonicité. A la lumière des hypothèses posées pour ces calculs, on arrive à la conclusion que la théorie de Marcus–Rice, qui représente à basse pression le modèle quantique de la théorie statistique des collisions moléculaires, reproduit beaucoup mieux les données expérimentales de la vitesse de réaction que la théorie de Slater qui conduit à des valeurs trop faibles d'un facteur de 10^5 à 10^6.

INTRODUCTION

The thermal decomposition of methyl chloride has been studied experimentally by Shilov and Sabirova (1). Holbrook (2) analyzed the Russian workers' data and concluded that the rate of formation of HCl affords a measure of the unimolecular reaction

$$CH_3Cl \rightarrow CH_3 + Cl,$$

and that between 10 to 35 mm Hg this reaction is in its second-order region, the rate constant having the value $k_0 = 1.86 \pm 0.21 \times 10^4$ cc mole^{-1} s^{-1} at 1 116.7 °K. Holbrook then proceeded to compare the experimental value of k_0 with k_0 calculated according to Slater's theory of unimolecular reactions (3). Using the symmetrical C—Cl stretch as the reaction coordinate, he calculated $k_0 = 3.29 \times 10^{-2}$ or 1.03×10^{-1} cc mole^{-1} s^{-1}, depending on the force constant used; for a critical coordinate composed of an equally weighted combination of C—Cl stretching and symmetrical methyl deformation he obtained $k_0 = 3.99 \times 10^{-1}$ cc mole^{-1} s^{-1}. Slater's theory thus predicts a second-order rate constant that is too small by a factor of 10^5–10^6, which Holbrook ascribed (assuming the basic reaction mechanism is valid) to rapid vibrational energy redistribution among the vibrational modes, a redistribution the Slater theory does not permit. It seemed therefore interesting to calculate k_0 according to the quantum version of the theory of

[1]*Abstracted from a B.Sc. Thesis submitted to the Faculty of Science by P. St. Laurent, May 1965.*

Marcus and Rice (4, 5), since this theory is based on the explicit assumption of rapid energy flow among vibrational degrees of freedom, and see if better agreement between theory and experiment could be obtained.

THE METHYL CHLORIDE MOLECULE

The molecule belongs to symmetry C_{3v}; there are three totally symmetric vibrational modes and three doubly degenerate ones, with frequencies (6) in cm^{-1}: $\nu_1 = 2\,879$, $\nu_2 = 1\,355$, $\nu_3 = 732$, $\nu_4 = 3\,048$ (2), $\nu_5 = 1\,460$ (2), $\nu_6 = 1\,020$ (2). For the purpose of the calculations, ν_2 and ν_5 were grouped together and their geometric mean (1 424 cm^{-1}) used to represent the group. The molecular vibrational partition function Q_v in the harmonic oscillator approximation was calculated from the free energy function corresponding to these frequencies, as given in tables (7); $\log_e Q_v = -\sum_1^9 (F^0 - E_0^0)/RT$. In a similar fashion, the mean vibrational energy $\langle E_v \rangle$ was calculated from the enthalpy function; $\langle E_v \rangle = RT \sum_1^9 (H^0 - E_0^0)/RT$. The entropy of methyl chloride has been calculated by Herzberg (8) who showed that the experimental entropy is adequately accounted for by translations, vibrations, and overall rotations, so that there are no internal degrees of freedom of rotation. It will be assumed in the following that there are no rotational degrees of freedom active in intramolecular energy transfer. The collision diameter of methyl chloride has been calculated to be 4.3 Å (9).

THE RATE CONSTANT INTEGRAL

For no active rotations in the molecule, the Marcus–Rice expression for the limiting second-order rate constant k_0 is (5)

$$[I] \qquad k_0 = \frac{k_2 \exp(-E_a/kT)}{Q_v} \int_0^\infty N^*(E_a + E^+) \exp(-E^+/kT)\, dE^+,$$

where k_2 is the collision frequency, E_a is the critical energy and $N^*(E_a + E^+)$ is the number of vibrational energy states per unit energy at the energy $(E_a + E^+)$. It should be noted that the expression does not involve the properties of the activated complex, only those of the active molecule. The experimental low-pressure activation energy is $E_0 = 85.5$ kcal/mole (1) and E_a will be of the same order of magnitude. At such high energies, $N^*(E_a + E^+)$ can be adequately approximated by the semiclassical expression (4)

$$[II] \qquad N^*(E_a + E^+) = \frac{(E_a + E^+ + E_z)^{s-1}}{\Gamma(s) \prod_s h\nu_i}$$

where E_z = zero-point energy, s = number of vibrational degrees of freedom, Γ = gamma function. Substituting [II] in [I] allows the latter to be integrated after binomial expansion. Since by definition $E_0 = kT^2 (d \log k_0/dT)$, it can be shown (10) that for measurements at constant concentration the derivation yields

$$[III] \qquad E_0 = E_a + 3/2kT - \langle E_v \rangle$$

where $\langle E_v \rangle$ is the mean vibrational energy of the molecule. This result is valid for $(E_a + E_z) \gg (s - 1)kT$. For methyl chloride, eq. [III] yields $E_a = 30\,951$ cm^{-1}; furthermore, $E_z = 8\,009$ cm^{-1}, $s = 9$, and RT at 1 116.7 °K is 776 cm^{-1}, so that the inequality is satisfied.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

For the purpose of evaluating the integral in eq. [I], $N^*(E_a + E^+)$ was calculated from an approximation formula of Whitten and Rabinovitch (11)

$$[IV] \qquad \sum_{E_V=0}^{E} P(E_V) = \frac{[E + (1 - \beta w)E_z]^s}{\Gamma(s+1)\prod_s h\nu_i}$$

$\beta = v(s-1)/s$, $\log w = -1.0506(\epsilon)^{0.25}$, $v = \langle \sum_s (h\nu_i)^2 \rangle / \langle \sum_s h\nu_i \rangle^2$, where $\epsilon = E/E_z$ and the other symbols have their usual meaning. $\sum_{E_V=0}^{E_V=E} P(E_V)$ is the total number of vibrational states at the energy E; $N^*(E)$, the number of states per unit energy at E, is then the derivative of $\sum P(E_V)$ with respect to E. At the high energies involved here this formula gives results that are within a few percent of the exact count, and is thus somewhat superior to the semiclassical formula [II], of which it is in fact a modification.

Equation [IV] was programmed on an IBM 1410 computer and the vibrational energy sums computed at 200 cm^{-1} intervals starting at $E = E_a = 31\,000$ cm^{-1} up to $E = 46\,000$ cm^{-1}; a derivative was then computed at each point and the results inserted into a program for the computation of the intergral in eq. [I] by the trapezoidal rule, likewise at 200 cm^{-1} intervals. It was found that at 46 000 cm^{-1} the integral has converged to virtually 100% of its value. The result of the integration is $k_0 = 5.82 \times 10^2$ cc $mole^{-1}$ s^{-1}, which is a considerably better value than the one calculated by Slater's theory but still some 32 times smaller than the experimental value.

ANHARMONICITY

Up to this point, all vibrations have been considered as strictly harmonic. If anharmonicity of vibrations is taken into account, the density of vibrational energy levels is increased, particularly at high energies. Since potential functions for polyatomic molecules other than linear triatomic are not available at present, one way of accounting for anharmonicity of molecular vibrations in cases like methyl chloride is to consider the molecule as a system of independent Morse oscillators. A convenient correction factor has been developed by Haarhoff (12) from considerations of the inverse Laplace transform of the vibrational partition function

$$[V] \qquad \frac{N^*(E)\,(\text{anharmonic})}{N^*(E)\,(\text{harmonic})} = \left\{\left(1 + \frac{2}{\epsilon}\right)^{\frac{\epsilon}{2}\left[1+\frac{\epsilon}{2}\right]} \exp\left[-\frac{v-1}{3(1+\epsilon)}\right]\right\}^{E_z/D} \times \exp\left[\frac{(1+\epsilon)^2}{2(s+1)}\left(\frac{E_z}{D}\right)^2 + \frac{(1+\epsilon)^3}{(s+1)(s+2)}\left(\frac{E_z}{D}\right)^3\right]$$

where $1/D = \langle 1/D_m \rangle$, D_m = dissociation energy of the mth Morse oscillator; the other symbols have their usual significance. Now for a Morse oscillator $D_m = (F_{2m})^3/2(F_{3m})^2$, where F_{2m} and F_{3m} are the quadratic and cubic force constants, respectively, of a stretching vibration. For polyatomic molecules, Herschbach and Laurie (13) have proposed a simple exponential function for the quadratic and higher bond-stretching force constants,

$$(-1)^n F_n = 10^{-(r_e - a_{ij})/b_{ij}} \qquad n = 2, 3$$

where r_e is the equilibrium bond length and a_{ij} and b_{ij} are empirical constants for bonds between atoms from row i and j of the periodic table. Thus for ν_1 and ν_4 (C—H stretch), taking a bond length of 1.09 Å as in methane (8), one obtains D_1 or $D_4 = 83.9$ kcal/mole; for ν_3 (C—Cl stretch), taking a bond length of 1.71 Å (8), one obtains $D_3 = 96.9$ kcal/mole. The assignment of a dissociation energy for ν_2 and ν_5 (CH_3 deformation) is difficult;

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

it was taken from Schneider and Rabinovitch (14) who used as an educated guess a dissociation energy of 500 kcal/mole in the case of CH_3NC. The assignment of D_6 (ν_6, $H_3{\equiv}C{-}Cl$ bending) is equally difficult; a frankly arbitrary assignment of 600 kcal/mole was made, which might be too high but is not very critical since D is only moderately sensitive to any particular D_m. This assignment corresponds to a Morse anharmonic constant of $-1.4\ cm^{-1}$. With the above values of the various D_m, D = 163.3 kcal/mole. Equation [V] was programmed on an IBM 1410 computer and the $N^*(E)$ (harmonic), calculated previously, corrected for anharmonicity, point by point; the $N^*(E)$ (anharmonic) thus obtained was then substituted in eq. [I] and the integration performed as before. The result is $k_0 = 8.4 \times 10^2$ cc mole^{-1} s^{-1}, i.e. some 50% higher than the k_0 calculated previously, but still some 22 times smaller than the experimental result.

CONCLUSIONS

The theoretical value of k_0 calculated on the harmonic model depends a good deal on the experimental activation energy, which affects E_a directly and through it $N^*(E_a+E^+)$, but in an opposite direction. For example, if the activation energy were 3.5 kcal/mole lower (a possible error in a complicated reaction), the factor multiplying the integral in eq. [I] would be 5 times larger; this would be offset somewhat by a decrease in the value of the integral, so that the net increase in k_0 would still be a factor of 3 or 4, leaving only a discrepancy between experiment and theory of about a factor of 10.

Nothing has been said so far about active rotations, beyond stating it as a pure assumption that no rotations are active. If any of the overall rotations were taken as active, the results would be an appreciable increase in k_0, but in the absence of any guiding principle the number of active rotations would merely take the character of an adjustable parameter. Another uncertainty enters into k_2 in the form of the assumption of unit collisional deactivation efficiency; an efficiency of less than unity would decrease the calculated value of k_0. There is also a relatively minor uncertainty in the collision diameter.

The same considerations apply to k_0 calculated on the anharmonic model. In addition, if we assume that eq. [V] is not significantly in error, the anharmonic correction factor used here can be described only as minimal, since an assignment of lower dissociation energies to CH_3 rocking and deformation frequencies would tend to increase the correction factor. This increase, however, would not be very large. For example, using D_2 or D_5 = 300 kcal/mole (three times the dissociation energy of a C—H bond), D_6 = 106 kcal/mole, and the same values as before for the remaining D_m's, calculation gives $k_0 = 9.7 \times 10^2$ cc mole^{-1} s^{-1}. Until the appropriate force constants are available for polyatomic molecules, it will be difficult to make very accurate predictions on the effects of anharmonicity. From the present results it would appear that anharmonicity increases k_0 only moderately, so that CH_3Cl behaves in this respect like a "large" molecule. In any event, considering a molecule as an assembly of independent Morse oscillators is a rather crude assumption. The effect of anharmonicity on the vibrational partition function Q_v has been neglected, since anharmonicity becomes appreciable only at the higher vibrational energies and here the exponential becomes predominant and wipes out most of the increase in the energy level density.

These calculations show that, on the whole, the Marcus–Rice theory is much more successful than Slater's theory in accounting for the low pressure rate of the methyl chloride decomposition, and would probably yield even better quantitative agreement

if a rational criterion could be found for the inclusion of active rotations. Additional work on the experimental aspects of the reaction would also be desirable to provide evidence in support of the mechanism and of the published values of E_0 and k_0.

ACKNOWLEDGMENT

The authors are indebted to Mr. P. Ardouin of the Centre de Traitement de l'Information de l'Université Laval for the programming and execution of the machine computations reported here, and to the National Research Council of Canada for financial assistance.

A STUDY OF TAUTOMERISM IN CYCLIC β-DIKETONES BY PROTON MAGNETIC RESONANCE

NATSUKO CYR AND LEONARD W. REEVES
Chemistry Department, University of British Columbia, Vancouver, British Columbia

Received May 25, 1965

ABSTRACT

The keto–enol equilibrium of cyclohexane-1,3-dione in chloroform is best interpreted from proton resonance measurements as

$$\text{enol dimer} \overset{K_1}{\rightleftharpoons} \text{2-enol monomer} \overset{K_2}{\rightleftharpoons} \text{2-keto monomer.}$$

K_1 and K_2 may be separately determined from chemical shift measurements of the enol-OH proton and intensity measurements of peaks assigned to keto and enol forms. K_1 and K_2 are satisfactorily independent of concentrations except in very dilute solutions where intensity measurements become unreliable. The overall equilibrium constant $K = K_1 \times K_2^2$ can be obtained for the same molecule in acetonitrile solutions where the enol monomer form is in very low concentration. 5,5′-Dimethylcyclohexane-1,3-dione in chloroform has less enol form than the unsubstituted molecule. The enthalpy change associated with 'K' for cyclohexane-1,3-dione in chloroform is 2.05 ± 0.5 kcal mole^{-1}.

INTRODUCTION

It is well known that β-diketones form enol isomers and that the extent of enolization is controlled mainly by the conjugation of C=O and C=C double bonds and the strong intramolecular hydrogen bond formed (1, 2). The equilibrium keto $\rightleftharpoons$ enol is affected by concentration and solvents as well as temperature (3). Proton magnetic resonance studies of such tautomeric systems generally reveal separate peaks for each tautomer thus enabling a simple intensity measurement to give the equilibrium constant (3, 4). There are several interesting features of proton magnetic resonance studies of tautomeric systems (5–13) including spin–spin coupling to the enol-OH proton (11) and multi-site proton exchange processes which can be determined by double resonance methods (14, 15).

The present study is directed towards the six-membered cyclic β-diketones where the formation of an intramolecular hydrogen bond is excluded. Cyclohexane-1,3-dione and 5,5′-dimethylcyclohexane-1,3-dione exist both in the solid state and concentrated solutions mostly as enolic molecules (16–18). A large dimer unit has been suggested (16) to provide the strong hydrogen bond which stabilizes the enol form. The study of the tautomeric equilibrium in these molecules is confined to chloroform and acetonitrile solutions where the solubility is appreciable.

EXPERIMENTAL

Commercially available samples (L. Light and Co. and Eastman Kodak Co.) of cyclohexane-1,3-dione and 5,5′-dimethylcyclohexane-1,3-dione were purified by recrystallization from benzene. Spectroscopic grade chloroform was shaken with concentrated sulfuric acid, washed with distilled water, and fractionally distilled to remove added ethanol. It was stored over calcium chloride in a dark place. Reagent grade acetonitrile was fractionally distilled and kept over calcium chloride. All concentrations were obtained by weighing solute and solution. The solutions were sealed in vacuum in nuclear magnetic resonance (n.m.r.) sample tubes after degassing by successive freeze, pump, thaw procedures. A small amount of magnesium perchlorate for the chloroform solutions and sodium sulfate for the acetonitrile solutions was added to each n.m.r. sample tube to keep solutions dry throughout measurements. A Varian A60 spectrometer was used for measurements with accurate calibrations provided by a Hewlett-Packard Wide Range Audio oscillator standardized at each measurement by a model 522B electronic frequency counter. Higher temperatures in the A60 spectrometer were obtained by using a V6057 variable temperature attachment and temperature measurement achieved with the calibrated separation of methylene and —OH proton resonances in ethylene

glycol. A small amount of tetramethylsilane (TMS) served as an internal reference for chemical shifts. The intensities of respective peaks in enol and keto forms were measured at the slowest sweep rate: 500 s on the narrowest sweep width, 50 c.p.s., and with the spectrum amplitude not exceeding the linear response region of the instrument. The absorption signals were carefully traced onto good quality bond paper and the cutouts weighed.

The signals used for intensity measurements are:

Cyclohexane-1,3-dione in $CHCl_3$

enol-OH (7 in structure I)

keto-CH_2 between the carbonyls (2 in structure II).

Cyclohexane-1,3-dione in CH_3CN

enol-olefinic proton (2 in structure I)

keto-CH_2 between the carbonyls (2 in structure II).

5,5′-Dimethylcyclohexane-1,3-dione

4 and 6 signals for both the keto and the enol.

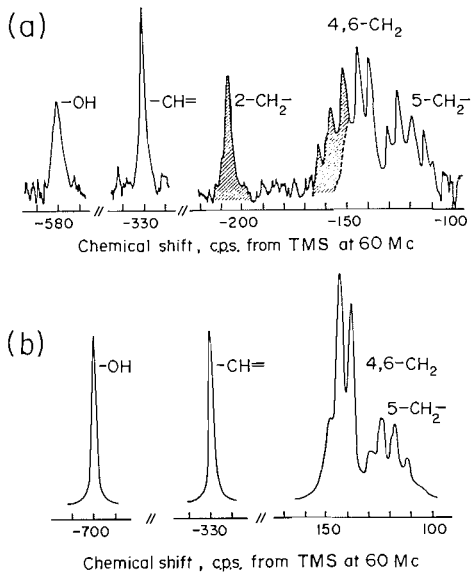

FIG. 1. (*a*) Spectrum of cyclohexane-1,3-dione in chloroform 16.0 mole %. (*b*) Spectrum of cyclohexane-1,3-dione in chloroform 1.05 mole %.

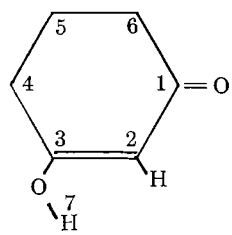
RESULTS AND DISCUSSION

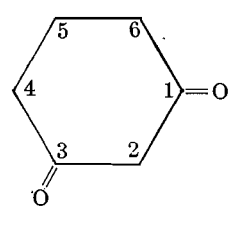
A. Equilibrium Constants

The spectrum of cyclohexane-1,3-dione at the solubility limit of 16.0 mole % in chloroform is shown as Fig. 1*a*. The peaks can all be reliably assigned to the enol form.

As in structure I we have enolic-OH at −700 c.p.s. (−11.67 p.p.m.), olefinic C—H at position C2 −330 c.p.s. (−5.5 p.p.m.), aliphatic —CH_2— protons giving a complex spectrum of which peaks centered at −120 c.p.s. (−2 p.p.m.) can be attributed to 5C



I



II

protons. In Fig. 1*b* at 1.05 mole % in $CHCl_3$ signals due to the keto form (structure II) appear. These have been shaded to make them more distinct in the figure.

Peaks at −207 c.p.s. (−3.45 p.p.m.) are assigned to the C2 methylene protons and the C4, C5, and C6 protons of II are in a region −155 c.p.s. (−2.58 p.p.m.). A noticeable feature of Fig. 1*b* is the change in chemical shift of the enol-OH proton to −580 c.p.s. (−9.66 p.p.m.) from Fig. 1*a*. The large change in chemical shift of the enol-OH proton with concentration is indicative of the rupture of hydrogen bonds (19) as the enol form is diluted. The chemical shift of the enol-OH proton has been measured accurately at all available concentrations and the variation can be described by a linear dependence on $1/\sqrt{C}$. Figure 2 shows a plot of chemical shift from TMS versus the inverse square root of concentration in (moles l)$^{-1/2}$. The chemical shift at infinite concentration is −740 c.p.s. (−12.32 p.p.m.) and must correspond to the completely hydrogen-bonded enol species, most reasonably represented as a dimer. (Structure III.)*

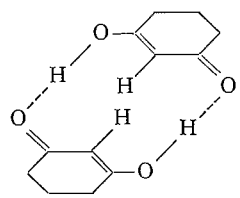
FIG. 3. Dependence of log K for cyclohexane-1,3-dione in chloroform on inverse absolute temperature.



III

This dimer would account for the very low field shift of the —OH proton and is typical of the shifts observed for intramolecular hydrogen-bonded enols (4, 5). The large concentration dependence of the enolic-OH chemical shift must result from dissociation of

**The O—H · · · · O lines are approximately in the plane of the cyclohexane ring because the lone pairs on the oxygen determines the strongest hydrogen bonds in this direction. The olefinic hydrogens at C2 are not close enough to interact with each other.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

these dimers and the appearance of monomeric enol molecules in solution. The equilibria in chloroform solutions can therefore be described by

$$\underset{C_D(1-\alpha)}{\text{enol dimer}} \overset{K_1}{\rightleftharpoons} \underset{2\alpha C_D}{\text{enol monomer}} \overset{K_2}{\rightleftharpoons} \underset{2(C-C_D).}{\text{keto monomer}}$$

Concentrations at equilibirum in terms of initial concentrations of undissociated forms are given below the equation above. C = total concentration of cyclohexane-1,3-dione expressed in units of dimer (moles l^{-1}); C_D = concentration of enol form considered completely as dimeric form (moles l^{-1}); α = degree of dissociation of the enol form into monomers.

Two equilibrium constants can be defined as above in terms of these concentrations.

[1] $$K_1 = 4\alpha^2 C_D/(1-\alpha)$$

[2] $$K_2 = (C - C_D)/\alpha C_D$$

The value of C_D is determined from a knowledge of the signal areas for enol and keto forms

[3] $$C_D = C/(1 + (1/2R))$$

where R = [enol]/[keto].

The degree of dissociation 'α' will be obtained from the observed hydroxyl proton chemical shift

[4] $$\delta_{obs} = X_D\delta_D + X_M\delta_M.$$

X_D and X_M are the respective fractions of enol molecules in dimer and monomer form. δ_D and δ_M are chemical shifts associated with the enol-OH proton in dimer and monomer forms of the enol molecule. δ_{obs} is the observed chemical shift at some arbitrary concentration. From Fig. 2 the value of δ_D may be taken as -740 c.p.s. Thus

[5] $$\alpha = 740 - \delta_{obs}/(740 - \delta_M).$$

The only unknown is 'δ_M' which may be chosen so as to give constant values of K_1 and K_2 at all concentrations. The best value is -300 c.p.s. (-5 p.p.m.) giving a change in chemical shift due to hydrogen bond formation of 7.32 p.p.m. This is in close agreement with previous values suggested for a strong —O—H --- O hydrogen bond (20, 21). The equilibrium constants obtained are listed in columns 8 and 9 of Table I. The values of K_1 are satisfactorily constant for all concentrations but values of K_2 vary between 1.13 and 0.42 over the concentration range studied. There is a reasonably constant value of $K_2 = 0.55 \pm 0.01$ at the higher concentrations of cyclohexane-1,3-dione. The possible factors likely to cause errors are: (*a*) Impurities contained in the chloroform which contain —OH groups and enhance the enol-OH peak intensity at low concentration. (*b*) Low signal to noise and possible saturation of the resonances at low concentrations. This would cause broadening of signals and loss of intensity in the noise. If relaxation times for the resonances chosen for intensity measurements are different there could be a differential factor (22). (*c*) The solubility of magnesium perchlorate in chloroform is small at room temperature. However, in ketonic solvents such as acetone it is quite large. In the presence of a large quantity of cyclohexane-1,3-dione the increase of the solubility of the salt could cause some small error as well.

3.10	4.53	2.79	675	0.217	12.1	6.2	6.76	0.5
3.72	5.86	3.43	679	0.203	13.9	5.8	7.12	0.4
							Average 7.31×10^{-2}	

The purified chloroform was run as a blank sample and no impurities were found at the highest sensitivity of the spectrometer. The effect of (*b*) above would be most serious in measurements of K_2 at low concentration where the ratio 'R' occurs in both numerator and denominator of eq. [2]. It is reasonable thus to neglect values of K_2 below 1.4 moles/l.

The equilibrium constants obtained for acetonitrile solutions of cyclohexane-1,3-dione are obtained from direct measurements of intensities of keto and enol peaks assuming negligible monomer enol form is present. The equilibrium constant 'K' may be defined

$$[6] \qquad K = K_1 \times K_2^2 = 4(C - C_D)^2/(1 - \alpha)C_D \simeq 4(C - C_D)/C_D.$$

The values obtained for K over a threefold increase in concentration are satisfactorily constant as shown in Table II. Corresponding values of $K = K_1 \times K_2^2$ for 5,5′-dimethylcyclohexane in chloroform solutions were necessarily limited to the concentration range 0.67 to 0.87 moles/l by the solubility and spectrometer sensitivity. A constant value of $K = 5.5 \pm 0.4 \times 10^{-2}$ was, however, found in this limited range. This compares with $K = 2.21 \pm 0.2 \times 10^{-2}$ for the cyclohexane-1,3-dione itself in the same solvent from Table I. The keto form is thus favored slightly by the 5,5′-dimethyl substitution.

TABLE II

Overall equilibrium constant K for keto/enol system cyclohexane-1,3-dione in acetonitrile solutions (symbols as defined in the text)

C (× 10)	R	C_M (× 10)	C_D (× 10)	K (× 10)
0.62	0.568	0.29	0.33	1.0
0.95	0.699	0.38	0.57	1.0
1.37	0.951	0.47	0.90	1.0
1.56	0.944	0.54	1.02	1.1
2.11	1.062	0.68	1.43	1.3

B. Temperature Dependence of 'K'

The overall equilibrium constant 'K' for cyclohexane-1,3-dione in chloroform at a concentration of 0.47 mole/l was measured as a function of temperature. At this concentration, dissociation into monomer enol molecules is small and 'K' can be measured from peak intensities alone. The enthalpy change associated with 'K' is derived as 2.05 ±

THE REACTION OF HEXAFLUOROACETONE WITH SOME SILANES

A. F. JANZEN AND C. J. WILLIS
Department of Chemistry, University of Western Ontario, London, Ontario
Received May 7, 1965

ABSTRACT

The reaction of hexafluoroacetone with various methyl- and chloro-silanes has been studied. It has been found that ready addition occurs to give a variety of fluorinated alkoxy-silanes, containing the grouping Si—O—$CH(CF_3)_2$. Some properties of these new compounds are given.

It has been known for some years (1) that ketones will add across the Si—H bond in various silanes, the addition occurring in an "abnormal" direction (as judged by analogous reactions of carbon compounds) to give alkoxy-silanes, rather than silyl alcohols, i.e.

$$R_3SiH + R_2'CO \rightarrow R_3SiOCHR_2'.$$

This reaction, although it proceeds in good yield with a variety of substituted silanes, is of limited synthetic value in conventional silicon chemistry, since the alkoxy-silanes produced are usually available from other routes involving the parent alcohols. In the field of highly fluorinated derivatives, however, the corresponding fluorinated alcohols are not readily available, due in many cases to their lack of stability. The fluorinated ketones are more accessible and very stable, and it would therefore seem that, if the direction of addition of fluorinated ketones across the Si—H bond is also "abnormal", this would represent a useful route to highly fluorinated alkoxides.

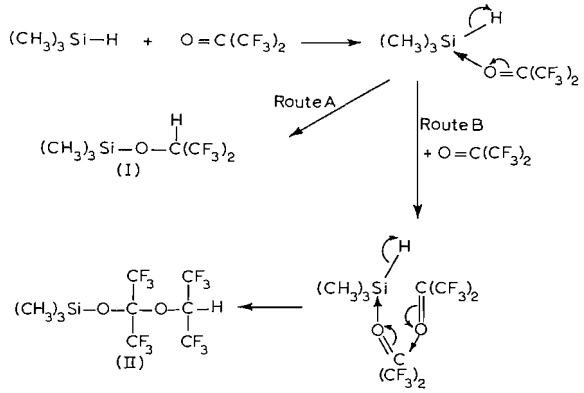
We have therefore investigated the addition of hexafluoroacetone to a variety of methyl-silanes and to trichlorosilane, and find that reaction does occur readily to give a variety of highly fluorinated, stable alkoxy-silanes. In most cases the reaction proceeded under the influence of ultraviolet irradiation in the gas phase. The compounds resulting from the addition of hexafluoroacetone to methyl-, dimethyl-, trimethyl-, and trichloro-silane are summarized in Table I. Yields quoted are based on silane present and are for typical reactions; no attempt was made to establish optimum conditions.

TABLE I
Products of reaction of hexafluoroacetone with silanes

Silane	Moles HFA per mole silane	Irradiation time, h	Products	Yield, based on silane, %
CH_3SiH_3	1.0	9	$CH_3SiH_2OCH(CF_3)_2$ +	52
			$CH_3SiH[OCH(CF_3)_2]_2$	11
CH_3SiH_3	2.5	12	$CH_3SiH[OCH(CF_3)_2]_2$	90
$(CH_3)_2SiH_2$	1.2	9.5	$(CH_3)_2SiHOCH(CF_3)_2$ +	80
			$(CH_3)_2Si[OCH(CF_3)_2]_2$	4
$(CH_3)_2SiH_2$	3.5	23	$(CH_3)_2Si[OCH(CF_3)_2]_2$	77
$(CH_3)_3SiH$	2.6	15	$(CH_3)_3SiOCH(CF_3)_2$†	68
$(CH_3)_3SiH$	1.3	33*	$(CH_3)_3SiOCH(CF_3)_2$ +	80
			$(CH_3)_3SiOC(CF_3)_2OCH(CF_3)_2$	9
Cl_3SiH	1.3	13	$Cl_3SiOCH(CF_3)_2$	68

*Reactants held in dark at −78°, not irradiated.
†NOTE ADDED IN PROOF. Since this work was completed, we have learned of the simultaneous preparation of this compound by other workers. (W. R. Cullen and G. E. Styan. Inorg. Chem. In press.) We thank Dr. Cullen for communication of his results in advance of publication.

The reaction of hexafluoroacetone with trimethylsilane was the only one which proceeded readily in the absence of irradiation. A reasonable intermediate in this reaction would be a molecular adduct involving coordination from oxygen to silicon, which could then rearrange to give the 1:1 product (I) (route A).



Compound (II), formed by the addition of two molecules of hexafluoroacetone to one of trimethylsilane, is presumably the result of attack by hexafluoroacetone on the above intermediate (route B) rather than by further reaction with the product (I), since it was found in a separate experiment that no reaction occurred between hexafluoroacetone and compound (I) under similar conditions.

The ready reaction of hexafluoroacetone with trimethylsilane at $-78°$ is presumably associated with the presence of three methyl groups on the silicon atom. The electron-releasing nature of these groups, as compared with the hydrogen or chlorine atoms present in the other silanes studied, would facilitate the migration of a hydrogen atom in the above schemes. The addition to trimethylsilane of a second molecule of hexafluoroacetone, a feature not found with other silanes studied, is presumably a result of the reaction occurring in the liquid phase in the presence of excess ketone, whereas all other reactions occurred in the gas phase.

Reaction with the remaining silanes in Table I proceeded under the influence of ultraviolet irradiation. It is noticeable that the presence of two hexafluoroisopropoxy groups on a silicon atom prevents addition of a further molecule of ketone. Thus, irradiation of methylsilane with an excess of hexafluoroacetone gave the 1:2 adduct, $CH_3SiH[OCH(CF_3)_2]_2$ in high yield, but no compound corresponding to the 1:3 adduct, $CH_3Si[OCH(CF_3)_2]_3$, could be found. Apart from the obvious steric effect of isopropoxy groups on the silicon atom, this result might be expected from considerations of charge distribution. Since these reactions must all involve at some stage the attachment of oxygen to silicon, they will be favored if the silicon is able to accept electrons. As isopropoxy groups are attached to silicon, there will be p_π–d_π back bonding from oxygen to silicon within the molecule, thus markedly lessening the acceptor tendencies of the silicon towards other species. It is not surprising, therefore, that it did not prove possible to attach more than two hexafluoroisopropoxy groups to the same silicon atom by this method.

Since a tetravalent carbon atom is unable to increase its coordination with the same readiness that silicon does, it would not be possible to invoke intermediates held together by coordination from oxygen to carbon in the analogous reactions of ketones with carbon–hydrogen bonds. This may be one reason why the addition of ketones across silicon–hydrogen bonds occurs in a direction opposite to that across carbon–hydrogen bonds.

The various silicon hexafluoroisopropoxides showed no sign of decomposition when handled in a moist atmosphere (with the exception of the trichloro compound). However, treatment with water at 110° in a sealed tube caused cleavage of the silicon–oxygen bond, giving 1,1,1,3,3,3-hexafluoroisopropanol. When the compounds were treated with concentrated sulfuric acid, the alcohol was evolved immediately at 20°.

Reduction of the hexafluoroisopropoxides with lithium tetrahydridoaluminate proceeded readily, either in absence of solvent or in dioxane. The corresponding methyl-silanes were produced in high yield.

The thermal stability of some of the new compounds produced was briefly investigated, and was found to be very high. No sign of decomposition was found below 400°, at which temperature slight (~ 3%) breakdown occurred in 10–12 h. At higher temperatures, above 500°, complete breakdown to give silicon tetrafluoride, fluoroform, carbon dioxide, etc., occurred in a few minutes.

Nuclear Magnetic Resonance Spectra

Proton nuclear magnetic resonance (n.m.r.) spectra were used extensively to provide confirmation of structure and, in some cases, to distinguish between possible isomers. Essential features of the spectra are given in Fig. 1.

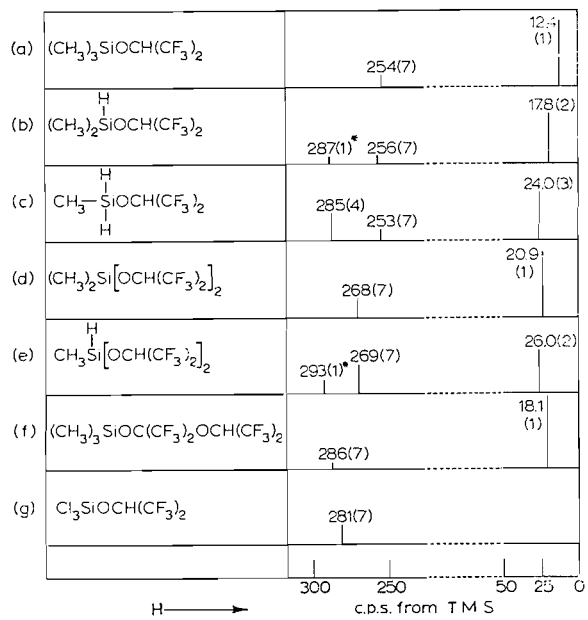

FIG. 1. Nuclear magnetic resonance spectra of hexafluoroisopropoxysilanes. Height proportional to area of peak; numbers in parenthesis indicate multiplicity. (*Peak broad, not clearly resolved.)

All absorption peaks occurred on the low field side of tetramethylsilane. Methyl groups attached to silicon showed small chemical shifts (12–26 c.p.s.) and showed coupling with protons on silicon, where present. Every spectrum contained a septet with chemical shift in the range 253–286 c.p.s. and coupling constant 5.4–5.9 c.p.s.; this is attributed to the proton of the hexafluoroisopropoxy group, which would be coupled equally with the six adjacent fluorine atoms. The only remaining peaks occurred in the range 285–293 c.p.s. in spectra *b*, *c*, and *e*. These are attributed to protons attached to silicon in those compounds,

and showed the expected interaction with the adjacent methyl groups, seen as a quartet in *c* (J = 3.5 c.p.s.) and as unresolved broadening in *b* and *e*.

Fluorine n.m.r. spectra were also recorded for some of these compounds. In all cases except *f*, all fluorine atoms in the molecule are equivalent and, typically, a single doublet was found (chemical shift for *a* is −69.9 c.p.s. from trifluoroacetic acid (TFA)) the splitting being due to the adjacent proton (J = 5.7 c.p.s.). For compound *f*, two fluorine resonances were observed, at −270 and +102 c.p.s. from TFA. Both were broad absorptions, that at −270 c.p.s. being a poorly resolved doublet. The broad doublet is attributed to the fluorine atoms adjacent to the proton of the hexafluoroisopropoxy group, where one would expect a doublet of septets from coupling with the proton and other fluorine atoms in the side chain. The second fluorine resonance is then attributed to the six remaining fluorine atoms, where one would expect a septet which is not resolved due to the considerable separation of the interacting nuclei.

Integration of all proton n.m.r. spectra was carried out, and the relative peak areas were in complete accordance with those expected from the structures in Fig. 1. In particular, the spectra eliminate the possibility that structures *d* or *e* might have been the isomers $(CH_3)_2SiH.OC(CF_3)_2OCH(CF_3)_2$ or $CH_3SiH_2.OC(CF_3)_2OCH(CF_3)_2$ respectively.

EXPERIMENTAL

General

Volatile materials were handled in a conventional vacuum system and separated by fractional condensation. Molecular weights were determined by Regnault's method. Hexafluoroacetone was a redistilled commercial sample* whose purity was checked by molecular weight measurement and infrared examination. Methyl-, dimethyl-, and trimethyl-silane were prepared by reduction of the corresponding chlorosilanes with lithium tetrahydridoaluminate (2). Irradiation was provided by a 400 W G.E. mercury arc lamp at a distance of 60 cm from the reaction tubes (clear silica, 100 ml volume), which were arranged so that only the gaseous phase was irradiated. Microanalyses were performed by Dr. Alfred Bernhardt. Analysis for fluorine was attempted in some cases but the presence of silicon in the molecule made it impossible to obtain reliable results. Nuclear magnetic resonance spectra were recorded on Varian model A-60 and DP-60 instruments, using 60 Mc/s and 56.4 Mc/s for proton and fluorine resonance respectively.

Infrared spectra of all new compounds were recorded, using Beckman IR-5A instruments (NaCl and CsBr), and were fully consistent with the assigned structures, showing absorption around 3 000 cm^{-1} (C—H), 2 200 – 2 300 cm^{-1} (Si—H), 1 150 – 1 400 cm^{-1} (C—F), and 1 100 – 1 120 cm^{-1} (Si—O—C). Essential features of the spectra are shown in Fig. 2.

Reaction of Hexafluoroacetone with Methylsilane

(i) Methylsilane (0.66 g, 14.3 mmoles) and hexafluoroacetone (2.50 g, 15.1 mmoles) in a sealed tube were irradiated for 9 h, the lower 10 cm of the tube being shielded and kept at 20°. Fractionation gave unreacted methylsilane (0.065 g, 1.41 mmoles), a trace of hexafluoroacetone, and 1,1,1,3,3,3-hexafluoroisopropoxymethylsilane (1.44 g, 6.84 mmoles, b.p. 50° at 737 mm).

Anal. Calcd. for $C_4H_6F_6OSi$: C, 22.6; H, 2.85. Found: C, 22.8; H, 2.71.

Also formed was a small amount (0.55 g, 1.45 mmoles) of bis(1,1,1,3,3,3-hexafluoroisopropoxy)methylsilane. The yield of this compound was markedly increased when the tube was not cooled, as in (ii) below, since the purpose of cooling was to remove the less volatile products from the reaction zone.

(ii) Methylsilane (0.454 g, 9.87 mmoles) and hexafluoroacetone (4.00 g, 24.1 mmoles) in a sealed tube were irradiated for 12 h. Fractionation gave bis(1,1,1,3,3,3-hexafluoroisopropoxy)methylsilane (3.37 g, 8.91 mmoles, b.p. 110–111° at 737 mm).

Anal. Calcd. for $C_7H_6F_{12}O_2Si$: C, 22.2; H, 1.60. Found: C, 22.3; H, 1.79.

(iii) In attempts to prepare tris(1,1,1,3,3,3-hexafluoroisopropoxy)methylsilane, the above reaction was repeated several times under various conditions. The molar ratio of hexafluoroacetone to methylsilane was increased up to 4:1 and irradiation was carried out for longer periods with the reaction tube maintained at 130° to keep reactants in the vapor phase, but no evidence of the desired compound was found.

Reaction of Hexafluoroacetone with Dimethylsilane

(i) Dimethylsilane (1.20 g, 20.0 mmoles) and hexafluoroacetone (4.02 g, 24.2 mmoles) in a sealed tube were irradiated for 9.5 h, the lower 10 cm of the tube being shielded and maintained at 20°. Fractionation gave unreacted dimethylsilane (0.084 g, 1.4 mmoles) and hexafluoroacetone (0.23 g, 1.4 mmoles) and 1,1,1,3,3,3-hexafluoroisopropoxydimethylsilane (3.37 g, 14.9 mmole, b.p. 72–73° at 743 mm).

Anal. Calcd. for $C_5H_8F_6OSi$: C, 26.5; H, 3.65. Found: C, 26.5; H, 3.53.

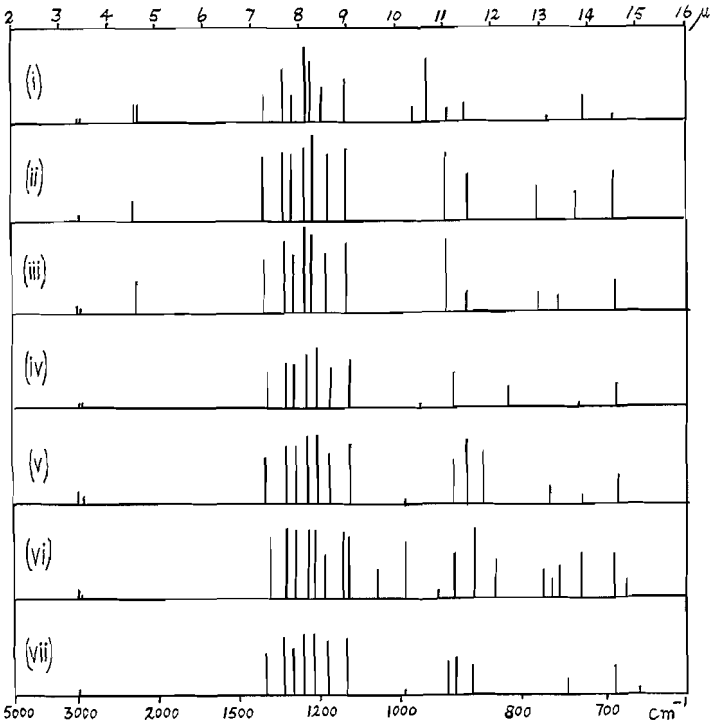

FIG. 2. Infrared spectra of hexafluoroisopropoxysilanes. Liquid films, except (i) and (iii) (gaseous). (i) $CH_3SiH_2OCH(CF_3)_2$, (ii) $CH_3SiH[OCH(CF_3)_2]_2$, (iii) $(CH_3)_2SiHOCH(CF_3)_2$, (iv) $(CH_3)_2Si[OCH(CF_3)_2]_2$, (v) $(CH_3)_3SiOCH(CF_3)_2$, (vi) $(CH_3)_3SiOC(CF_3)_2OCH(CF_3)_2$, (vii) $Cl_3SiOCH(CF_3)_2$.

The 1:2 adduct, bis(1,1,1,3,3,3-hexafluoroisopropoxy)dimethylsilane, was also produced in low yield (0.30 g, 0.8 mmole).

(ii) Dimethylsilane (0.636 g, 10.6 mmoles) and hexafluoroacetone (6.40 g, 38.5 mmoles) in a sealed tube (uncooled) were irradiated for 23 h. Fractionation gave unreacted hexafluoroacetone (0.63 g, 3.79 mmoles) and bis(1,1,1,3,3,3-hexafluoroisopropoxy)dimethylsilane (3.21 g, 8.19 mmoles, b.p. 127–128° at 732 mm).

Anal. Calcd. for $C_8H_8F_{12}O_2Si$: C, 24.5; H, 2.06. Found: C, 24.8; H, 1.99.

Reaction of Hexafluoroacetone with Trimethylsilane

(i) Trimethylsilane (0.65 g, 8.8 mmoles) and hexafluoroacetone (3.8 g, 23 mmoles) in a sealed tube were irradiated for 15 h. Fractionation gave traces of fluoroform and hexafluoroethane, unreacted hexafluoroacetone (1.8 g, 11 mmoles), and 1,1,1,3,3,3-hexafluoroisopropoxytrimethylsilane (1.43 g, 6.0 mmoles, b.p. 90° at 748 mm).

Anal. Calcd. for $C_6H_{10}F_6OSi$: C, 30.0; H, 4.20. Found: C, 29.7; H, 4.24.

(ii) Trimethylsilane (1.47 g, 19.9 mmoles), hexafluoroacetone (4.21 g, 25.4 mmoles) and trimethylchlorosilane (0.2 g) were kept in a sealed tube in the dark at −78° for 33 h. The products were warmed to 20° and subsequently separated by fractionation to give unreacted trimethylsilane (0.13 g, 1.8 mmoles) and hexafluoroacetone (0.25 g, 1.5 mmoles), 1,1,1,3,3,3-hexafluoroisopropoxytrimethylsilane (3.45 g, 14.4 mmoles), and 2-(1,1,1,3,3,3-hexafluoroisopropoxy)-hexafluoroisopropoxytrimethylsilane (0.71 g, 1.8 mmoles, b.p. 135–136°).

Anal. Calcd. for $C_9H_{10}F_{12}O_2Si$: C, 26.6; H, 2.48. Found: C, 27.2; H, 2.58.

Reaction of Hexafluoroacetone with Trichlorosilane

Trichlorosilane (2.99 g, 22.1 mmoles) and hexafluoroacetone (4.65 g, 28.0 mmoles) in a sealed tube were irradiated for 13 h. Fractionation gave traces of fluoroform, hexafluoroethane, some unidentified noncondensable gas (presumably carbon monoxide), unreacted hexafluoroacetone (0.72 g, 4.3 mmoles), and 1,1,1,3,3,3-hexafluoroisopropoxytrichlorosilane (4.52 g, 15.0 mmoles, b.p. 89° (743 mm).

Anal. Calcd. for $C_3HCl_3F_6OSi$: C, 12.0; H, 0.33; Cl, 35.3. Found: C, 12.1; H, 0.53; Cl, 35.1.

Hydrolysis

1,1,1,3,3,3-Hexafluoroisopropoxytrimethylsilane (0.5 g) was heated in a sealed tube with water (2 ml) for 8 days at 110°. Fractionation gave 1,1,1,3,3,3-hexafluoroisopropanol, but it was not possible to separate it

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

completely from water and an accurate estimate of yield could not be made. The alcohol produced in this and subsequent reactions was identified by infrared spectroscopic comparison with a known sample, prepared by the reduction of hexafluoroacetone with lithium tetrahydridoaluminate (3).

Acid Cleavage

1,1,1,3,3,3-Hexafluoroisopropoxytrimethylsilane (0.21 g, 0.88 mmole) was added to concentrated sulfuric acid (2 ml) at 20°. After the solution was mixed, volatile materials were pumped off and found to be solely 1,1,1,3,3,3-hexafluoroisopropanol (0.06 g, 0.36 mmole, 41%). A similar reaction with 1,1,1,3,3,3-hexafluoroisopropoxydimethylsilane gave the same alcohol in 81% yield.

Reduction

The various silanes were condensed onto a 10% molar excess of lithium tetrahydridoaluminate in an evacuated tube, which was sealed and kept at 110° for 2 h (4). Fractionation gave the following results.

Silane	Product	Yield, %
$CH_3SiH[OCH(CF_3)_2]_2$	CH_3SiH_3	81
$(CH_3)_2SiHOCH(CF_3)_2$	$(CH_3)_2SiH_2$	70
$(CH_3)_2Si[OCH(CF_3)_2]_2$	$(CH_3)_2SiH_2$	83
$(CH_3)_3SiOCH(CF_3)_2$	$(CH_3)_3SiH$	1.5
$(CH_3)_3SiOCH(CF_3)_2$	$(CH_3)_3SiH$	74 (with dioxane added)

Upon cautious treatment with sulfuric acid of the solid residues produced in the above reductions, 1,1,1,3,3,3-hexafluoroisopropanol was produced in yields up to 50%.

Thermal Decomposition

1,1,1,3,3,3-Hexafluoroisopropoxytrimethylsilane (0.29 g) in a heavy-walled pyrex tube (8 ml) was heated at 400° for 10 h, by which time a slight yellow coloration was apparent. Fractionation showed that the bulk of the silane was unchanged, with traces ($\sim$ 3%) of more volatile decomposition products.

When a similar reaction tube was heated from 100° to 500° over a period of 2 h, no change was noticed until 450°, when slight darkening began. The darkening rapidly increased above 500°. After the reaction tube was kept at 550° for 13 h, decomposition was complete, and fractionation gave fluoroform, silicon tetrafluoride, carbon dioxide, and other material, with a black residue remaining in the tube.

The decomposition of the silanes $(CH_3)_2Si[OCH(CF_3)_2]_2$ and $(CH_3)_2SiHOCH(CF_3)_2$ followed a very similar course, the presence of the hydrogen atom directly attached to silicon in the last compound apparently making little difference.

THE REACTION OF OZONE WITH DIMETHYLLAURYLAMINE[1]

GARSON P. SHULMAN[2]
Research Laboratories, Archer-Daniels-Midland Co., Minneapolis, Minnesota

Received April 13, 1965

ABSTRACT

In the oxidation of dimethyllaurylamine in chloroform solution by ozone, increase in temperature results in decreased yields of amine oxide and amine hydrochloride and increased yields of amide and carboxylic acid. The reaction is first order in amine and first order in ozone and is not affected by light. These data are consistent with a mechanism involving oxidation of an amine–chloroform charge transfer complex stable at low temperatures.

INTRODUCTION

The reaction of tertiary amines with ozone leads almost exclusively to amine oxides when conducted in chloroform solution below −50° (1, 2, 3). At somewhat higher temperatures (−45° to 0°) or in other polar solvents (specifically in methanol), somewhat lower yields, and isolation of amides, aldehydes, acids, and other products of oxidative attack on the alpha carbon have been reported (4, 5, 6). In nonpolar solvents (pentane, cyclohexane, 1-chlorobutane, carbon tetrachloride), amine oxide yields are very low, regardless of temperature.

Maggiolo and Niegowski (4) suggested a mechanism for the reaction involving electrophilic attack on the amine nitrogen by ozone, followed by decomposition of the intermediate zwitterion (I). This mechanism is postulated by analogy with the Criegee mechanism for reaction of olefins with ozone. No experimental data to support the mechanism are presented. Henbest and Stratford (5, 6) have presented a detailed scheme accounting for production of aldehydes, secondary amines, acids, and amides as a result of oxidation at the alpha carbon atom. This investigation was carried out in an attempt to establish experimentally a mechanism for oxidation at the nitrogen atom.

A systematic study covering a temperature range of −75° to 61° in chloroform solution was selected as the approach most likely to lead to better understanding of the reaction. After the observation that oxidation at the alpha carbon atom was negligible at dry ice temperature, experiments to determine the effects of some other variables were conducted. A preliminary kinetic study was also performed.

EXPERIMENTAL

Reaction at Various Temperatures

Vigorously stirred chloroform solutions of dimethyllaurylamine in a micro-reaction apparatus (7) were maintained at the desired temperature while ozone was introduced at a rate of 65 ± 10 mg/min (in a 0.02 c.f.m. oxygen stream). At intervals, titrations for unreacted ozone were performed. The reaction was terminated when a 10% excess of ozone had been absorbed, as determined from the area under the absorption vs. time graph. Solvent was removed by evaporation under vacuum at room temperature. The product was analyzed by titration for amine oxide, amine, amide, and acid, and qualitatively by infrared spectrometry and thin-layer chromatography. Assignment of acids as carboxylic or trialkyl ammonium chloride was based on presence of characteristic N—H or C=O absorption bands in the infrared spectrum. Details are given in Table I.

Effect of Other Variables

A 500-ml flask was fitted with a Tru-Bore stirrer, a gas inlet tube, and an outlet connected at regular intervals to a potassium iodide trap. After the initial reaction, the flask was wrapped to exclude light. Reaction in a dry ice bath (−75°) was continued until the desired amount of ozone had been introduced. Nearly quantitative uptake was observed. Results are summarized in Table II.

Kinetic Studies

Solutions of 10.0 g of dimethyllaurylamine in 50.0 ml of chloroform were prepared. Using an oxygen flow rate of 0.05 c.f.m., each solution, in a gas-washing tower, cooled to −75° in a dry ice bath, was treated with a different concentration of ozone with vigorous stirring. The rate of the reaction, expressed as mg/min of ozone consumed, was initially constant. A straight line graph of rate vs. ozone concentration was obtained (see Table III).

Solutions of 1.00 to 4.00 g of amine in 50.0 ml of chloroform were prepared. Each was placed in a 100 ml, three-necked flask with ground glass sealed stirrer, cooled to −75°[3] and ozonized with a stream of 0.02 c.f.m. containing 65.4 mg/min of ozone. Figure 1 shows typical curves at low and high amine concentrations. A graph of initial rate (extrapolated linearly at high amine concentrations) vs. initial amine concentration was linear.

Amide Analysis[4]

A weighed sample (1–2 g) was placed in a Florence flask with 25 ml of 6 *N* sodium hydroxide. The mixture was distilled into 10.0 ml of standardized 0.5 *N* hydrochloric acid until most of the water had been removed.[5] The distillate was titrated with base, to a methyl red end point, giving the amount of

[3]*Pure chloroform freezes at −63.5°. The technical grade of chloroform used in these experiments froze when a solution containing only 10 g/l was employed, but the freezing point was lowered enough by higher concentrations of amine that no difficulty was encountered.*

[4]*The amides formed are all secondary products of alpha carbon oxidation to carbinolamine. Therefore, total amide, amine oxide, and amine salt are the significant analyses for determining the mechanism of the primary oxidation step.*

[5]*The decomposition of aliphatic amine oxides in aqueous solution is extremely slow, even in strong base. The analysis is essentially a Kjeldahl determination without a reduction step (8).*

dimethylamine (from dimethyllauramide and dimethylformamide). The residue was extracted three times with 25 ml of chloroform, then the combined extracts were washed twice with 150 ml of water, mixed with toluene – isopropyl alcohol – bromphenol blue solution, and titrated to determine methyllaurylamine (from *N*-methyl-*N*-laurylformamide) and unreacted dimethyllaurylamine.[6] A second sample was titrated without prior treatment, determining the dimethyllaurylamine, which was then subtracted from the sum of the other titrations.

Amine Hydrochloride Analysis

A standard titrimetric method[7] for determination of acids or ammonium salts was employed.

Amine and Amine Oxide Analysis

A nonaqueous acidimetric titration was used for determination of amine and amine oxide (9). Details of the thin-layer chromatography method have also been described previously.

Purification of Dimethyllaurylamine Oxide

The mixture obtained from reaction of 50 g of amine in 1 l of chloroform in the presence of 50 g of calcium carbonate at −75° was recrystallized from benzene, yielding 9 g of white powder, m.p. 108–112°.

Analysis showed that it contained no amine hydrochloride and 89.4% amine oxide. A second recrystallization of a small portion gave anhydrous dimethyllaurylamine oxide, m.p. 117–120° (reported m.p. 117–123°) (10).

Oxidation of Dimethyllaurylammonium Chloride

A solution of 2.0 g, m.p. 190–194°, in 200 ml of methanol was cooled to −30° and treated with 520 mg of ozone, absorbing 211 mg. Solvent was removed under vacuum. The product, m.p. 146°, contained 7.2% of amine oxide.

DISCUSSION

Synthetic Studies

Conversion of dimethyllaurylamine to the oxide increases as the temperature is lowered, while amide formation (Fig. 2) diminishes, until at −75° amide formation is negligible.

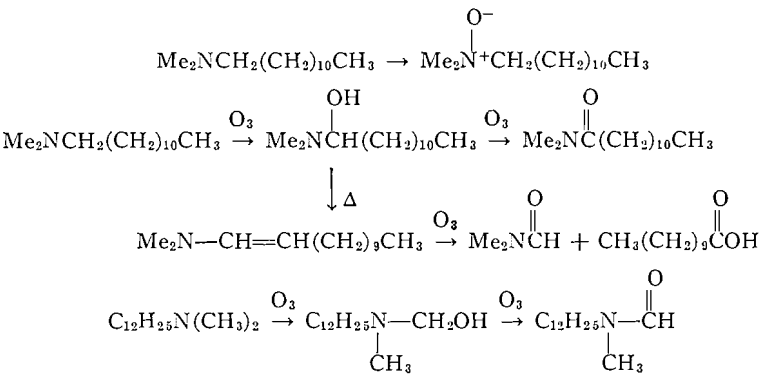

FIG. 2. Reactions of dimethyllaurylamine with ozone.

No improvement can be expected at temperatures below −75°, since conversion to the hydrochloride competes, and dimethyllaurylammonium chloride does not react rapidly with ozone.[8] By adding calcium or sodium carbonate, amine hydrochloride formation is minimized (0–10%), and higher yields (64–82%) of amine oxide are attained. Addition of sodium methoxide resulted in a markedly lower yield of amine oxide and extensive formation of by-products. A large (60%) excess of ozone gave a poorer conversion to amine oxide than either 10% or 35% excess. This is probably the result of oxidation of the amine oxide at the alpha carbon. Use of ethyl acetate and methanol as solvents normally leads to slightly lower yields (44 and 50%) of amine oxide than in chloroform carbonate mixtures (74 ± 10%) but amide formation becomes significant at −75°.

Kinetic Studies

The method employed by Wibaut (11) was used in this investigation. By keeping the oxygen–ozone flow constant and varying discharge voltage, one can measure the dependence of rate on ozone concentration. Absorption of the stream in a potassium iodide trap for 60 s leads to an expression of ozone concentration in mg/min. Similar titration of the off-gas and subtraction from input then gives ozone absorption in mg/min, and is a direct measurement of the rate. Similarly, with constant ozone input and varying concentration of amine, the dependence of rate on amine concentration may be determined. Since the reaction is essentially heterogeneous, no significant rate constants can be obtained.

[8]*Generally, salt formation stabilizes an amine toward ozone. Because of the marked solvent effects on this reaction, it would have been desirable to verify that reaction of the salt is slow in chloroform, but the amine salt is not appreciably soluble at low temperatures.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Oxidation of dimethyllaurylamine to the oxide is first order in ozone and first order in amine at −75°,

$$d[O_3]/dt = K[O_3][R_3N].$$

Mechanism of Reaction

There are four likely mechanisms for amine oxide formation: (A) electrophilic attack of ozone [I] (4); (B) preliminary formation of an amine–solvent complex followed by displacement of solvent [II]; (C) formation and decomposition of a trialkylammonium ozonide [III and IV]; and (D) oxidation by a free radical process. Amine hydrochloride (or hydrogen chloride) formation must result from decomposition of chloroform, either free [V] or in an amine–solvent complex [VI].

[I] $$R_3N + O_3 \rightarrow R_3N^+—O—O—O^- \rightarrow R_3NO + O_2$$

[II] $$R_3N + CHCl_3 \rightleftharpoons R_3N.....CHCl_3 \xrightarrow{O_3} R_3N \rightarrow O + CHCl_3 + O_2$$

[III] $$H_2O + 3R_3N + 2O_3 \rightarrow 2(R_3NH^+O_3^-) + R_3NO$$

[IV] $$2(R_3NH^+O_3^-) \rightarrow R_3NO + H_2O + R_3N + 2O_2$$

[V] $$R_3N + CHCl_3 \xrightarrow{O_3} R_3NH^+Cl^- + COCl_2$$

[VI] $$R_3N.....CHCl_3 \xrightarrow{O_3} R_3NH^+Cl^- + COCl_2$$

While it might be possible to propose stepwise mechanisms for oxidation via free radical or trialkylammonium ozonide intermediates which would obey the observed rate expression, the kinetic data strongly suggest either I or II as the actual mechanism. The parallel decrease in conversion to amine oxide and to amine hydrochloride with increasing temperature is consistent with reaction of a low-temperature stable amine–solvent complex, but not with oxidative degradation of chloroform, which would be favored at higher temperatures. The remarkable ability of chloroform to suppress alpha carbon oxidation could be explained if alpha oxidation involves a free radical mechanism. Chloroform would function better as an inhibitor than the other solvents which have been employed.

Spectral evidence for amine–halomethane interaction has been presented (12). The evidence did not clearly differentiate between charge-transfer complexes and contact charge-transfer spectra, but it was suggested that charge-transfer complexes might be the species involved in photochemical reactions leading to amine hydrohalides or enamines (12). Since exclusion of light from the dimethyllaurylamine–chloroform–ozone system did not suppress amine hydrochloride formation, one must conclude that the reaction of ozone with an amine–chloroform complex is the principal source of hydrogen chloride. It has also been proposed that the superior yields of amine oxide in chloroform and methanol are due to the hydrogen bonding ability of these solvents (5). Additional work to determine the nature of the amine–solvent complex is needed.

SYNTHESIS OF 3-AMINO-2,3-DIDEOXY-D-*lyxo*-HEXOSE

HANS H. BAER AND FRANK KIENZLE
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received June 2, 1965

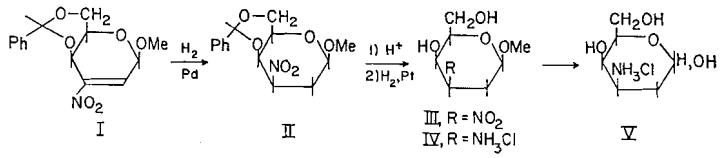
ABSTRACT

Catalytic hydrogenation of methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hexopyranos-2-enide (I) afforded methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*lyxo*-hexopyranoside (II). Acid debenzylidenation and further hydrogenation gave in turn methyl 2,3-dideoxy-3-nitro-β-D-*lyxo*-hexopyranoside (III) and the corresponding amine hydrochloride (IV). Several crystalline derivatives of IV were prepared, and the configuration at C-3 was proved by degradation of the *N*-benzoate (VII) to *N*-benzoyl-D-aspartic acid. The title compound (V) was obtained as a chromatographically homogeneous sirup.

Some methyl 3-deoxy-3-nitro-β-L-hexopyranosides were prepared for potential use as starting materials in analogous syntheses in the L-series.

In the course of work directed at the synthesis of rare amino sugars a route was recently elaborated that led to 3-amino-2,3-dideoxy-D-*arabino*-hexose (1). We have now prepared 3-amino-2,3-dideoxy-D-*lyxo*-hexose in similar fashion. Sugars of this type are of interest as they are related to certain carbohydrate components of anthracycline antibiotics (2), namely to rhodosamine (3-dimethylamino-2,3,6-trideoxy-L-*lyxo*-hexose (3)) and daunosamine (3-amino-2,3,6-trideoxy-L-*lyxo*-hexose (4)). It may be anticipated that the principle presented in this paper can be utilized for the synthesis of these natural products, especially since 3-deoxy-3-nitro-hexopyranosides of the L-series have become accessible (see below).

Methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hexopyranos-2-enide (I) which is available (5) starting from methyl 3-deoxy-3-nitro-β-D-galactopyranoside, was hydrogenated over palladium on charcoal to give in good yield methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*lyxo*-hexopyranoside (II). Debenzylidenation of II readily afforded methyl 2,3-dideoxy-3-nitro-β-D-*lyxo*-hexopyranoside (III) which by catalytic reduction over platinum in the presence of 1 equiv of dilute hydrochloric acid gave the corresponding amine, methyl 3-amino-2,3-dideoxy-β-D-*lyxo*-hexopyranoside hydrochloride (IV). Whereas all compounds up to this point crystallized well, the reducing sugar (V) produced upon acid hydrolysis has thus far failed to do so; it was characterized by paper chromatography.



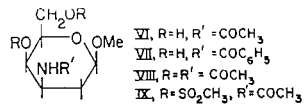
I II III, R = NO_2 IV, R = NH_3Cl V

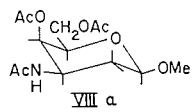
It was presumed that hydrogen addition to the olefinic double bond in I would place the nitro group chiefly into equatorial disposition as has been the case with the analogous β-D-*erythro* nitroolefin (1). To prove this point, i.e., the D-*lyxo* configuration of II and the products derived from it, the *N*-acetate (VI), *N*-benzoate (VII), di-*O*-acetyl-*N*-acetate (VIII), and di-*O*-methanesulfonyl-*N*-acetate (IX) were prepared by standard procedures from the aminoglycoside IV and were dealt with as follows.

The triacetate VIII gave a 60 Mc n.m.r. spectrum[1] exhibiting methyl resonances of

[1]*In deuterochloroform solution with tetramethylsilane as internal standard; a Varian V-4302 high-resolution instrument was used.*

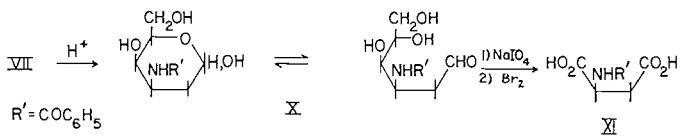
equal intensities at 8.07, 7.96, and 7.86 τ, consistent with one equatorial acetamido group, one equatorial acetoxy group, and one axial acetoxy group (6). The signal at 8.07 τ, in particular, can only be attributed to an equatorial *N*-acetyl (7). The OCH_3 signal appeared at 6.50 τ in line (8) with equatorial orientation of the glycosidic group. The spectrum, therefore, was indicative of the conformational formula VIII*a* (cf. also the data obtained (1) for the isomeric D-*arabino* compound).





It was hoped that solvolysis of the dimesylate IX would provide further evidence as to the geometrical relationship between the C-3 acetamido group and the C-4 acetoxy group, the stereochemistry of the latter being known. This approach had proved fruitful in the D-*arabino* series, although the reaction had taken an unexpected course there (1). In the present case the solvolysis indeed proceeded with much greater difficulty than in the earlier case. Only 1 mole of sodium methanesulfonate was isolated and the solvolyzed product according to its infrared spectrum still contained mesyloxy. This fact suggested that the substituents at C-3 and C-4 were *cis*, i.e., unfavorably disposed for neighboring group participation. However, no crystalline sugar derivative could be elaborated in these experiments, neither directly nor upon acetylation or remesylation, so that the evidence furnished can be regarded only as circumstantial.

Unambiguous chemical proof of the configuration at C-3 came from another experiment, however. When the benzoylamino glycoside VII was partially hydrolyzed (0.1 *N* hydrochloric acid at 98° for 30 min) and the hydrolysate that was presumed to contain the reducing benzoylamino sugar (X) was oxidized, first with periodate and then with bromine water, crystalline levorotatory D-benzoylaspartic acid (XI) was isolated. Its identity was established by comparison with an authentic sample of dextrorotatory L-benzoylaspartic acid (9).[2]



The key starting materials for the syntheses of 3-amino-2,3-dideoxy-D-hexoses as exemplified above and earlier (1) are methyl 3-deoxy-3-nitro-β-D-hexopyranosides from which nitroolefins of type I can be obtained (1, 5). In order that these syntheses may be performed also in the L-hexose series, the preparation of the requisite methyl 3-deoxy-3-nitro-β-L-hexopyranosides was undertaken by use of the nitromethane cyclization method (10). To this end the dialdehyde XII, D'-methoxy-L-hydroxymethyldiglycolic aldehyde, was needed. It is obvious from Jackson and Hudson's work (11) that this compound can be made, theoretically, by periodate oxidation of any methyl β-L-hexopyranoside or of any methyl β-L-pentofuranoside, although those authors did not in fact prepare it. L-Hexoses being difficult to provide, we chose to generate XII from methyl β-L-arabinofuranoside, which can be prepared with a reasonable outlay in time and materials (12). The dialdehyde was then subjected to a nitromethane cyclization according to the directions given (13, 14)

[2]*A similar degradation was employed (4) with daunosamine proving its* C-3 *to possess the opposite configuration.*

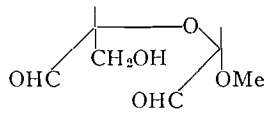
For personal use only.

for its enantiomorph. In this way methyl 3-deoxy-3-nitro-β-L-glucopyranoside (XIII) was obtained, and by benzylidenation of the material contained in the mother liquor there was isolated methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-L-galactopyranoside (XIV) and -mannopyranoside (XV). The L-compounds were identical with their known enantiomorphs in all respects except for an opposite sign of rotation. The conversion in this manner of a pentofuranoside into hexopyranoside derivatives represents another example of lengthening of sugar chains "from within" (15, 13), a principle that has been fruitfully adopted recently in the nucleoside field (16).



XII

EXPERIMENTAL

Methyl 4,6-O-Benzylidene-2,3-dideoxy-3-nitro-β-D-lyxo-hexopyranoside (II)

Methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-nitro-β-D-*threo*-hexopyranos-2-enide (I, 2.70 g) was dissolved in 100 ml of ethyl acetate and hydrogenated at ordinary temperature and pressure in the presence of 300 mg of palladium on charcoal (10%). Within 15 min there was consumed 225 ml (s.t.p.) of hydrogen, corresponding to 1.08 molar equivalents. A very sharp decrease in the rate was noticed after that time. The catalyst was filtered off immediately and the solution was brought to dryness giving a crystalline residue. Recrystallization from ethyl acetate – petroleum ether (30–60°) afforded a first crop of needles (1.03 g; m.p. 169–172° (decomp.)) and a second crop (0.71 g; m.p. 166–168° (decomp.)) upon evaporating the mother liquor and taking up the residue in a small amount of absolute ethanol. Thus, the total yield of (slightly yellowish) crude product was 1.74 g (64%); this material was suitable for use in the next step. An analytical sample was obtained by one recrystallization from ethyl acetate – petroleum ether which raised the m.p. to 176° (decomp.) and by a second recrystallization which caused no further change in the melting point; $[\alpha]_D^{23}$ +15.2° (*c*, 0.8 in dimethylformamide).

Anal. Calcd. for $C_{14}H_{17}NO_6$ (295.3): C, 56.94; H, 5.83; N, 4.74. Found: C, 57.05; H, 6.00; N, 4.62.

Methyl 2,3-Dideoxy-3-nitro-β-D-lyxo-hexopyranoside (III)

Benzylidene compound II (1.9 g) in 50 ml of 70% acetic acid was heated on the steam bath for 30 min (but no longer). The acid was removed *in vacuo* and the residue was thrice evaporated with water. The resulting solid was taken up in 10 ml of water, whereby 30 mg of material remained undissolved and was discarded. The solution was treated with decolorizing carbon, evaporated, and dried by two evaporations with absolute ethanol. The residue was crystallized (at 4°, overnight) from 5 ml of ethanol with the addition of a few drops of petroleum ether. The yield was 720 mg of III melting at 139–140°; another 70 mg was obtained from the mother liquor (m.p. 128–136°), the combined yields being 59.4%. For analysis, a sample was recrystallized from ethyl acetate – petroleum ether; m.p. 141°, $[\alpha]_D^{23}$ +28.8° (*c*, 1 in water).

Anal. Calcd. for $C_7H_{13}NO_6$ (207.2): C, 40.58; H, 6.33; N, 6.76. Found: C, 40.64; H, 6.50; N, 6.80.

Debenzylidenations using the ion-exchange method (1) were also performed and gave the same product, but the yields were generally lower, the best being 39%.

Methyl 3-Amino-2,3-dideoxy-β-D-lyxo-hexopyranoside Hydrochloride (IV)

Nitro glycoside III (880 mg) was hydrogenated at ordinary temperature and pressure in 45 ml *N*/10 hydrochloric acid in the presence of 250 mg of prehydrogenated platinum dioxide catalyst. The hydrogen uptake was quantitative (3 molar equivalents); the time required was found in various similar runs to be 1–2.5 h depending on the efficiency of shaking. The filtrate from the catalyst was evaporated, with two additions of water toward the end. The crystalline residue was taken up in a small amount of ethanol, a few drops of ethyl acetate were added, and crystallization was allowed to take place overnight in a refrigerator. The yield of colorless crystals was 734 mg (81%); $[\alpha]_D^{23}$ −13.0° (*c*, 1 in water). Chromatography (17) showed only one spot (blue-violet with ninhydrin), $R_{glucosamine}$ 1.31. On heating, the compound decomposed slowly without showing a narrow decomposition range.

Anal. Calcd. for $C_7H_{16}ClNO_4$ (213.7): C, 39.35; H, 7.56; N, 6.56. Found: C, 39.26; H, 7.68; N, 6.61.

Methyl 3-Acetamido-2,3-dideoxy-β-D-lyxo-hexopyranoside (VI)

Aminoglycoside hydrochloride IV (500 mg) in 14 ml of water and 1.8 ml of methanol was stirred in an ice bath with 16 ml of Dowex-1-X2 (CO_3^{2-}). Acetic anhydride (0.4 ml) was added and the stirring was continued for 90 min. The resin was removed and the solution was evaporated giving a colorless sirup that was twice evaporated with ethanol. The material was crystallized from ethanol – ethyl acetate (15 h at 4°).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The yield was 465 mg (90.5%) of long prisms with m.p. 213° and $[\alpha]_D^{23}$ +41.8° (*c*, 0.9 in water). In a parallel run the m.p. was 210–212° and was raised to 213° by one recrystallization. The material gave a negative ninhydrin test.

Anal. Calcd. for $C_9H_{17}NO_5$ (219.2): C, 49.30; H, 7.82; N, 6.39. Found: C, 49.38; H, 7.65; N, 6.60.

A sample of *N*-acetate VI (2 mg) was heated in a sealed tube with 1 ml of *N* hydrochloric acid for 1 h at 110°. The acid was then removed by evaporation *in vacuo* with the addition of water. The solution reduced hot Fehling solution, was ninhydrin-positive, and on paper chromatography (17) gave virtually one spot of $R_{glucosamine}$ 1.06, attributed to 3-amino-2,3-dideoxy-D-*lyxo*-hexose hydrochloride (V). A number of larger-scale hydrolyses using VI as well as IV failed to produce V in crystalline condition.

Methyl 3-Acetamido-4,6-di-O-acetyl-2,3-dideoxy-β-D-lyxo-hexopyranoside (VIII)

Acetamido derivative VI (65 mg) was acetylated using pyridine (2.5 ml) and acetic anhydride (0.6 ml) at room temperature (15 h). The reaction mixture was worked up according to standard procedures (ice water; chloroform extraction) giving 52 mg of needles, m.p. 197–198° (from ethyl acetate – petroleum ether, 30–60°), $[\alpha]_D$ +66.0° (*c*, 0.9 in ethanol). The infrared spectrum indicated absence of hydroxyl and presence of *O*-acetyl and *N*-acetyl groups.

Anal. Calcd. for $C_{13}H_{21}NO_7$ (303.3): C, 51.47; H, 6.98; N, 4.62. Found: C, 51.49; H, 7.01; N, 4.43.

Methyl 3-Acetamido-2,3-dideoxy-4,6-di-O-mesyl-β-D-lyxo-hexopyranoside (IX)

Methanesulfonyl chloride (0.28 ml) was added dropwise with stirring to an ice-cold solution of acetamido derivative VI (200 mg) in pyridine (25 ml). The mixture was stirred for 30 min, then left overnight in a refrigerator. Water was added (20 ml) and the mixture stirred for 30 min, whereby a first crop of IX (45 mg) separated. The filtrate thereform was evaporated and the residue treated with 5 ml of water, which afforded a second (main) crop of IX (231 mg). The combined yield was 83%. Recrystallization from methanol–ethanol (1:1) furnished needles (240 mg) of m.p. 175° (decomp.), raised to 176° (decomp.) by a second recrystallization; $[\alpha]_D^{23}$ +13.3° (*c*, 0.6 in dimethylformamide).

Anal. Calcd. for $C_{11}H_{21}NO_9S_2$ (375.4): C, 35.19; H, 5.64; N, 3.73; S, 17.08. Found: C, 35.22; H, 5.98; N, 3.83; S, 16.93.

Methyl 3-Benzamido-2,3-dideoxy-β-D-lyxo-hexopyranoside (VII)

Amino glycoside hydrochloride (IV, 150 mg) and sodium bicarbonate (150 mg) were dissolved in 4 ml of water, and a solution of benzoylchloride (105 mg) in tetrahydrofuran (2 ml) was added dropwise with magnetic stirring. The stirring was continued for 30 min. Tests with indicator paper showed that the solution remained weakly alkaline throughout. The reaction mixture was then diluted with about 20 ml of water, deionized by stirring for 10 min with 2 ml of Dowex-50-X12 (H^+) and 5 ml of Amberlite IR-45 (OH^-) and filtered, the resins being washed well with water. The filtrate (pH about 4) was extracted twice with $\frac{1}{4}$ volume of ether to remove residual benzoic acid, and was then brought to dryness leaving 139 mg (70%) of white crystals of VII, m.p. 185–186°. Recrystallization from about 10 ml of boiling ethyl acetate containing a few drops of ethanol gave fine needles of m.p. 193–194°, raised to 194–195.5° (196–197° in a sealed capillary) by a further recrystallization, $[\alpha]_D^{23}$ +36° (*c*, 2 in water). The infrared spectrum showed hydroxyl, amide-I, and amide-II bands as expected.

Anal. Calcd. for $C_{14}H_{19}NO_5$ (281.3): C, 59.77; H, 6.81; N, 4.98. Found: C, 59.93; H, 6.92; N, 5.18.

Degradation of VII to N-Benzoyl-D-aspartic Acid

N-Benzoyl glycoside VII (145 mg) was hydrolyzed in 7 ml of *N*/10 hydrochloric acid for 1 h on a steam bath. After cooling, the solution was neutralized (to pH 4–5) by treatment with 3 ml of Amberlite IR-45 (OH^-) and concentrated *in vacuo*. Thin-layer chromatography on silica gel with benzene–methanol (4:1) gave only one spot; its rate of movement as compared with VII was 0.67. A ninhydrin test was negative. The product in solution was presumed to be X. Sodium metaperiodate (350 mg) in 4 ml of water was now added and the solution was stored in the dark at room temperature for 20 h. In the course of the oxidation 0.5 ml of a 0.5 *M* sodium bicarbonate solution was added in small portions maintaining the pH at 5–6. The solution was then evaporated nearly to dryness, the residue was triturated with 5 ml of ethanol, and the insoluble, inorganic material was discarded. The ethanol extract was evaporated and the residue again treated with a small amount of ethanol, whereby further inorganic material was removed. Finally, the ethanol was removed by two evaporations with methanol, and the remaining solid was taken up in about 10 ml of water in which it was sparingly soluble. Calcium carbonate (1 g) and an excess of bromine water were added and the mixture was stored in the dark at room temperature for 20 h, with occasional swirling. The solution was filtered, freed from excess bromine by aeration, shaken for 5 min with 1 g of silver carbonate, and filtered again. The filtrate was freed from cations by treatment with 5 ml of Rexyn RG-50 (H^+) and the resulting solution which was acidic and slightly yellow was cleared with activated carbon and evaporated *in vacuo*. *N*-Benzoyl-D-aspartic acid (XI) separated as colorless, small crystals of m.p. 163–164°. Recrystallization from water by slow evaporation in the air gave long needles with m.p. 170–171° (sealed capillary); the yield was 35 mg. The product (XI) showed $[\alpha]_D^{23}$ −22.3° (*c*, 1.03 in water containing 2 equiv of KOH).

A sample of the L-enantiomorph of XI was prepared (9) by *N*-benzoylation of authentic L-aspartic acid. It also was obtained as small crystals (m.p. 163–164°) or as long needles (m.p. 170–171°, sealed capillary),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

depending on the mode of crystallization. The reported (9) m.p. of 180–181° was not observed. The two enantiomorphs moved at the same rate on a thin-layer plate and gave superimposable infrared spectra.

The L-enantiomorph exhibited $[\alpha]_D^{23}$ +34.5° (reported, +33° (4); +37.4° (9); all in water in the presence of 2 equiv of KOH). When a sample was treated in aqueous solution with silver carbonate and recovered by cation exchange and evaporation (as in the work-up procedure of XI), the rotation value decreased to +25.5°.

Solvolysis of Dimesylate IX

Dimesylate IX (190 mg) and anhydrous sodium acetate (230 mg) were refluxed for 48 h in 20 ml of 95% ethanol. Upon cooling, only starting material crystallized out. The solvent was therefore replaced by 20 ml of 95% 2-methoxyethanol, and another 150 mg of sodium acetate was added. After being refluxed for a further 48 h and concentrated *in vacuo* to 15 ml the brownish solution, on standing overnight at 4°, deposited 61 mg of sodium mesylate (calcd. for 1 molar equiv, 59.7 mg) which was identified by its infrared spectrum. Attempts to obtain a crystalline sugar derivative from the mother liquor either directly or by acetylation or remesylation were unsuccessful.

Preparation of the Deoxynitro L-*Hexopyranoside Derivatives XIII, XIV, and XV*

Glycosidation of L-arabinose was performed in 7 g batches using methanol containing 0.036% of hydrogen chloride according to Augestad and Berner's directions (12). The sirupy glycoside mixture was separated in 2 g batches on a column (3.5 × 60 cm) of powdered cellulose with ethylmethylketone saturated with water. The fractions (12 ml) were checked polarimetrically. In one such chromatography, for example, fractions No. 70–90 (levorotatory) were combined, fractions No. 91–99 were returned to a later chromatography, and fractions No. 100–120 (dextrorotatory) were combined. Both the combined levorotatory and the combined dextrorotatory fractions upon evaporation yielded colorless sirups that crystallized without difficulty when triturated with small amounts of ethyl acetate and when allowed to stand in a refrigerator overnight. The glycosides, which were very hygroscopic, had to be filtered and washed quickly and with the least possible exposure to moist air. Recrystallization from ethyl acetate of the dextrorotary material gave *methyl β-*L*-arabinofuranoside*, m.p. 56°, $[\alpha]_D^{23}$ +117° (*c*, 1 in water), in excellent agreement with the literature (12). The levorotatory material, which after one recrystallization showed m.p. 52° and $[\alpha]_D$ −111° (*c*, 1 in water), was methyl α-L-arabinofuranoside although it was, apparently, not quite pure (reported data: m.p. 64–66°; 65–67°; $[\alpha]_D$ −123° (12)).

The periodate oxidation of methyl β-L-arabinofuranoside and the nitromethane condensation of the resulting dialdehyde XII were performed as previously described for the analogous experiments relating to the D-series (13, 14).

*Methyl 3-deoxy-3-nitro-β-*L*-glucopyranoside (XIII).*—The crude product obtained melted at 194 ± 3°. The product recrystallized from ethyl acetate – ethanol showed m.p. 204–205° (decomp.) and $[\alpha]_D^{23}$ +12.1° (*c*, 1 in water). Reported (13) for the D-enantiomorph: m.p. 204–205° (decomp.), $[\alpha]_D$ −12.0°, −12.8° (*c*, 2 in water). The infrared spectra of the D- and L-forms were identical. Benzylidenation of the material that remained in the mother liquor of XIII was done, and the benzylidene derivatives were separated by fractional crystallization, as described (1, 5) for the D-series.

*Methyl 4,6-O-benzylidene-3-deoxy-3-nitro-β-*L*-galactopyranoside (XIV).*—The product showed m.p. 231° (decomp.) and $[\alpha]_D^{23}$ −26.2° (*c*, 1 in dimethylformamide). Reported (5) for the D-enantiomorph: m.p. 230–231° (decomp.); $[\alpha]_D^{23}$ +24.8°. The infrared spectra of the D- and L-compounds were identical.

*Methyl 4,6-O-benzylidene-3-deoxy-3-nitro-β-*L*-mannopyranoside (XV).*—The product had m.p. 197–199°; $[\alpha]_D^{23}$ +101.5° (*c*, 1.8 in dimethylformamide). Reported (5) for the D-enantiomorph: m.p. 198–199°; $[\alpha]_D^{23}$ −105°. The infrared spectra of the D- and L-compounds were identical.

EFFECT OF CHANGING pH UPON THE RATE AND MECHANISM OF DECARBOXYLATION OF SUBSTITUTED ANTHRANILIC ACIDS

G. E. DUNN, P. LEGGATE,[1] AND I. E. SCHEFFLER[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received May 7, 1965

ABSTRACT

The ionization constants of 4-methoxyanthranilic acid have been determined spectrophotometrically in water at 60 °C and ionic strength 0.10. The variation in rate of decarboxylation with varying pH at constant ionic strength has been measured at 90 °C with 4-methylanthranilic acid and at 60 °C with 4-methoxyanthranilic acid. With each acid the maximum rate occurs at a pH about 2 units less than the isoelectric pH. To account for these results it is necessary to postulate an equilibrium between at least two intermediates formed by protonation of the 1-position of the aromatic ring. One of these must be formed from the anion and the other(s) by protonation of neutral acid and (or) zwitterion.

A number of aromatic amino acids have been observed to undergo decarboxylation under relatively mild conditions (1).

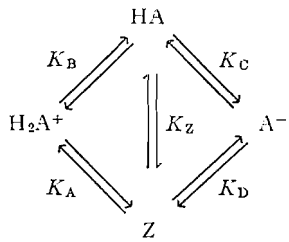
$$NH_2ArCOOH \rightarrow ArNH_2 + CO_2$$

Mechanistic investigations have been concentrated upon anthranilic (2, 3), *p*-aminobenzoic (2, 4), and *p*-aminosalicylic acids (5, 6, 7) in aqueous solution and upon anthranilic acid in the melt (3, 8) or in nitrobenzene solution (9).

Kinetic studies in aqueous solution are complicated by the fact that the amino acid may be present as neutral molecule, zwitterion, cation, or anion, any one or more of which may decarboxylate. Although the ratio of neutral molecule to zwitterion is independent of pH, the proportions of the other species present in solution will vary with the acidity of the solution. Consequently, the rates of decarboxylation of amino acids in solution may vary with the acidity of the solution, and the manner in which they vary may be expected to yield information about the nature of the species undergoing decarboxylation.

In aqueous solutions of an amino acid there are assumed to be four organic species in equilibrium with hydronium ion (10). These may be represented in general by $H_3N^+ArCOOH$ (abbreviated H_2A^+), $H_2NArCOOH$ (HA), $H_3N^+ArCOO^-$ (Z), and $H_2NArCOO^-$ (A^-). These will be referred to hereafter as the Bjerrum species. The equilibria are shown below with the accompanying hydronium ions omitted.

[1]



If the concentrations (or, at high ionic strengths, the activities) of HA and Z are represented by [HA] and [Z], then the concentration of total ampholyte is [N] = [HA] + [Z]. For most purposes N can be treated as a single species, since the ratio [Z]/[HA] = K_Z is independent of pH. The experimental ionization constants K_1 and K_2 define the equilibria

[1]*National Research Council Postdoctorate Fellow, 1960–1962.*
[2]*Holder of a N.R.C. Bursary, 1963–1964.*

$$H_2A^+ \overset{K_1}{\rightleftarrows} H^+ + N$$

$$N \overset{K_2}{\rightleftarrows} H^+ + A^-$$

and are related to the individual ionization constants of eq. [1] as follows.

$$K_1 = K_A + K_B$$

$$1/K_2 = 1/K_C + 1/K_D$$

From these relationships it follows that when the total concentration of amino acid is [C] the concentrations of the individual Bjerrum species are given by the equations below.

$$[H_2A^+] = \frac{[C]}{K_1K_2/[H^+]^2 + K_1/[H^+] + 1} \quad [2]$$

$$[N] = \frac{[C]}{[H^+]/K_1 + 1 + K_2/[H^+]} \quad [3]$$

$$[A^-] = \frac{[C]}{[H^+]^2/K_1K_2 + [H^+]/K_2 + 1} \quad [4]$$

These equations show that $[H_2A^+]$ approaches [C] at high hydronium ion concentrations, $[A^-]$ approaches [C] at low hydronium ion concentrations, and that [N] reaches a maximum when $[H^+]$ lies between K_1 and K_2. By setting $d[N]/d[H^+] = 0$ it is found that [N] reaches a maximum when $[H^+] = \sqrt{K_1K_2}$; that is, at the isoelectric point, where $pH = \frac{1}{2}(pK_1 + pK_2)$. Since [Z] and [HA] are both proportional to [N] and the proportionality is independent of pH it follows that both [HA] and [Z] will also have their maximum values at the isoelectric point. The variations with pH of the concentrations of the various species is shown schematically in Fig. 1.

If the rate-controlling step in the decarboxylation of an amino acid is the first-order or pseudo-first-order decomposition of any of the Bjerrum species, a plot of the rate constant against pH should show the same inflections as the concentration vs. pH plot for the corresponding species in Fig. 1. The same will be true, of course, for any other (non-Bjerrum) species in equilibrium with one of the Bjerrum species, or with one of these and water, so long as the equilibrium does not involve gain or loss of protons.

Furthermore, if the rate of decarboxylation is determined by the rate of formation or decomposition of any intermediate formed by protonation (or deprotonation) of one of the Bjerrum species, the rate constant vs. pH profile should follow the concentration vs. pH profile of the Bjerrum species next to the left (or next to the right) in eq. [1]. For example, suppose A^- can be protonated to give an intermediate AH* (non-Bjerrum) which then decarboxylates.

$$A^- + H^+ \underset{k_2}{\overset{k_1}{\rightleftarrows}} AH^*$$

$$AH^* \overset{k_3}{\rightarrow} CO_2 + P$$

The steady-state concentration of AH* will be given by

$$[AH^*] = \frac{k_1}{k_2 + k_3}[A^-][H^+]$$

and the rate of decarboxylation by

$$\frac{-d[C]}{dt} = k_3[AH^*] = \frac{k_1k_3}{k_2 + k_3}[A^-][H^+] = \frac{k_1k_3K_2}{k_2 + k_3}[N]. \quad [5]$$

Hence the observation of a maximum in the rate of decarboxylation at the pH where no maximum occurs in the concentration vs. pH curves could not be accounted for by first-order decarboxylation of any of the Bjerrum species nor of any other species formed from a Bjerrum species by simple protonation or deprotonation.

The aromatic amino acid for which the effect of pH upon rate of decarboxylation in aqueous solution has been most thoroughly examined is *p*-aminosalicylic acid. Willi and Stocker (5) found that the rate reaches a maximum at the isoelectric point and concluded that the rate-controlling step involves the protonation of *p*-aminosalicylate anion, A^-, at the 1-position of the aromatic ring. However, they found that, although the rate decreases as the pH is decreased below the isoelectric point, it does not decrease as fast as does the calculated value of $[H^+][A^-]$. They concluded, therefore, that the zwitterion is also subject to decarboxylation by proton attack at the 1-carbon, so that the overall rate expression becomes

$$[6] \qquad -\frac{d[C]}{dt} = k'[H^+][A^-] + k''[H^+][N]$$

with k' larger than k'' by a factor of about 10.

Rekker and Nauta (6) also observed a maximum in the rate of decarboxylation of *p*-aminosalicylic acid in aqueous solution at the isoelectric point, but they found no decarboxylation in strong acid where Willi's kinetic expression shows it should be appreciable. They concluded that the reaction is a first-order decarboxylation of the zwitterion.

The decarboxylation of *p*-aminosalicylic acid in aqueous solution was also investigated by Liquori and Ripamonte (7). They too, observed the rate-maximum at the isoelectric point at 25 °C, but concluded that the rate-controlling step is a first-order decomposition of the molecular acid, HA. The most interesting aspect of their work, however, is their observation that as the temperature of the reaction is increased the rate-maximum shifts towards lower pH, until at 97.4 °C the maximum occurs at a pH more than one unit less than the isoelectric pH.

The effect of acidity upon the rate of decarboxylation of anthranilic acid in aqueous solution was investigated briefly by Stevens and co-workers (3) as part of a study in which they showed that there is no carboxyl–carbon isotope effect in the reaction. They studied the rate of decarboxylation in varying concentrations of sulfuric acid at 100 °C without using buffered solutions or constant ionic strength and found a maximum rate at about 0.75 *N* sulfuric acid. Here again the rate-maximum appears to be at lower pH than the isoelectric point (3.5 at 25 °C). However, they concluded that the rate-controlling step is protonation of the zwitterion at the 1-carbon.

The most recent and most careful investigation of the pH dependence of rate of decarboxylation is that by Willi (4) using *p*-aminobenzoic acid. He found that the rate of decarboxylation increases with increasing hydrogen-ion concentration but does not reach a maximum at the isoelectric point (pH = 3) nor even at pH = 1.7, the highest acidity studied. He showed that, as with *p*-aminosalicylic acid, his data can be accommodated by eq. [6] with $k'' = 25k'$. However, since rates were not measured at high acidity this conclusion is open to the same objection raised by Rekker and Nauta regarding *p*-aminosalicylic acid (6).

In summary, there seems to be good reason to believe that the occurrence of a rate-maximum at the isoelectric point of *p*-aminosalicylic acid at temperatures in the vicinity of 20 °C is only a special case, and that for another amino acid and (or) another temperature the maximum rate may occur at a pH other than the isoelectric point. If this is true,

the mechanism of decarboxylation must be considerably more complex than any suggested by previous authors or any of those outlined in the discussion above. It is the purpose of the present investigation to test this hypothesis by determining the effect of changing pH upon the rate of decarboxylation of substituted anthranilic acid in buffered aqueous solutions of constant ionic strength. Decarboxylation of anthranilic acid is inconveniently slow, but 4-methylanthranilic acid decarboxylates at convenient rates at 90 °C and preliminary studies were made with this acid. However, measurement of the ionization constants at 90° proved difficult, so the main investigation used 4-methoxyanthranilic acid, for which both rates and ionization constants can be conveniently measured at 60°.

EXPERIMENTAL

Materials

The preparation and purification of 4-methyl and 4-methoxy anthranilic acids were reported in an earlier paper (11).

Buffer Solutions

Buffer solutions were prepared as suggested by Bates (12) using acetate in the pH region 5.6–5, formate in the region 5–3.5, chloroacetate in the region 3.5–2.5, and hydrochloric acid for pH's less than 2. Each buffer was adjusted to ionic strength 0.10 or 0.50 with potassium chloride.

pH Measurements

All pH measurements were made with a Radiometer model 4C pH meter with shielded glass and calomel electrodes in cells thermostatted to ±0.1 °C. At 25° the electrodes were Radiometer G202B (glass) and K100 (calomel); at 60° they were Radiometer G302BH (glass) and K4016 (calomel). The meter was calibrated against N.B.S. tetroxalate and hydrogen phthalate buffers at the appropriate temperatures. Measured pH's were reproducible to ±0.003 pH unit and are assumed to be accurate to ±0.01 unit.

pH measurements were made at both 25° and 60° on the same series of buffer solutions covering the range of each buffer compound and having the same composition as those used for ionization and rate determinations. By plotting pH at 60° against pH at 25° linear calibration curves were obtained which could be used to calculate from measurements made at 25° the pH of solutions to be used for equilibrium constant or rate determinations at 60°. Differences in pH at the two temperatures were usually less than 0.1 pH unit.

Absorbance

Measurements of absorbance were made in 1 cm cells thermostatted within ±1 °C using a Beckman model DK-1 spectrophotometer and the procedure previously described (11). Measurements were reproducible within ±0.01 unit of absorbance.

Determination of Ionization Constants

Determination of the ionization constants of 4-methyl- and 4-methoxyanthranilic acids at 25° by a spectrophotometric method was reported in an earlier paper (11). Attempts to use the same method at 90° were hampered by instability of the electrodes used for pH measurements at the high temperature and by difficulties encountered in thermostatting the cell compartment of the spectrophotometer at 90°. However, these difficulties were greatly reduced at 60°. The spectrophotometer cell compartment could be thermostatted to ±1° and pH readings on a particular buffer solution were constant and reproducible within ±0.004 unit over a period of 3 to 4 h. Consequently, the previously described method (11) was used to determine the ionization constants of 4-methoxyanthranilic acid at 60°. At pH's less than 2, absorbance readings at 60° decreased slightly with time because of decarboxylation. In these cases the readings were recorded over a period of about 10 min and back-extrapolated to zero time. Absorbance measurements were made at 330 mμ where the absorbance vs. pH curve shows a maximum at the isoelectric point.

Rate Measurements

The change in concentration of substituted anthranilic acid with time was followed spectrophotometrically by measurements made in alkaline solution where all the acid is in the anionic form, and at wavelengths where the absorbance of the reaction product is negligible. These were 322 mμ for 4-methylanthranilic acid and 315 mμ for 4-methoxyanthranilic acid.

A 250 ml round-bottom flask immersed to the neck in an oil bath at 60.0 ± 0.1° or 90.0 ± 0.1° served as the reaction vessel. The flask with 200 ml of buffer solution was allowed to come to the bath temperature, then 130 mg of the substituted anthranilic acid dissolved in 3 ml of 0.25 *N* sodium hydroxide solution were added. The flask was shaken and, after 10 min, 30 ml of solution were withdrawn and cooled to 25° for pH measurement. Two more 30 ml samples were withdrawn for pH measurement, one at the middle and one at the end of the run. The three samples had the same pH within 0.005 unit in all the runs reported below. Some attempted runs with chloroacetate buffers at 90° had to be abandoned because of pH changes during the run

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

caused, probably, by hydrolysis of the halogen. At approximately equal time intervals 2 ml aliquots were withdrawn for absorbance measurement and immediately injected into weighed 25 ml volumetric flasks containing about 15 ml of 0.1 *N* sodium hydroxide solution each. The volumetric flasks were reweighed, then filled to the mark with 0.1 *N* sodium hydroxide and set aside for spectrophotometric measurement at 25°. Absorbances were corrected to correspond to a constant weight of aliquot. First-order plots of the logarithm of absorbance against time gave excellent fits up to more than 90% conversion.

RESULTS

Ionization Constants

Determinations were made on two different samples of 4-methoxyanthranilic acid at 60° and ionic strength 0.10. Table I reports for each sample the resulting K's and pK's with their standard deviations and the two values for the absorbance, D_N, of the ampholyte, N, which are obtained, one in the calculation of K_1 and the other in the calculation of K_2. Details of the calculations are given in ref. 11.

The weighted means for the two samples are $K_1 = (1.15 \pm 0.10) \times 10^{-2}$, $K_2 = (1.97 \pm 0.09) \times 10^{-5}$ and $pK_1 = 1.94 \pm 0.05$, $pK_2 = 4.71 \pm 0.02$. These may be compared with the corresponding values obtained (11) by the same method at 25°: $K_1 = (8.74 \pm 0.94) \times 10^{-3}$, $K_2 = (1.33 \pm 0.07) \times 10^{-5}$ and $pK_1 = 2.06 \pm 0.05$, $pK_2 = 4.88 \pm 0.02$. From these values the pH at the isoelectric point is found to be 3.33 ± 0.03 at 60° and 3.47 ± 0.04 at 25°.

Rates of Decarboxylation

The best values of the specific rate constants, k, and their standard deviations were obtained by fitting the data to the equation $[C] = [C]_0 e^{-kt}$ by the least squares method and assuming a constant experimental uncertainty in [C] and t.

Table II records the rates obtained in some preliminary experiments on the decarboxylation of 4-methylanthranilic acid at 90° in buffered solutions with pH measured at 25°. The data are fragmentary because the difficulty in determining the ionization constants of the acid at 90° forced the discontinuation of experiments with the 4-methyl acid. However, enough data are available to show the reproducibility of the method and that the rate is a maximum at an intermediate pH and decreases at both high and low pH. The pH at the maximum can not be determined precisely because of the lack of data at low pH and because the pH's were measured at 25° instead of 90°. However, the pH's of buffers similar to these were found to increase in pH by less than 0.1 unit on changing temperature from 25° to 60°, so it is safe to say that the maximum rate occurs at a pH less than 1. The pH at the isoelectric point of 4-methylanthranilic acid at 25° is 3.71 (11) and, since the isoelectric pH of 4-methoxyanthranilic acid was shown above to increase by 0.14 unit on changing from 25° to 60°, it is probable that the isoelectric pH of 4-methylanthranilic acid at 90° is slightly greater than 3.7. Hence, it may be concluded that the rate of decarboxylation of 4-methylanthranilic acid is a maximum at a pH nearly three units less than the isoelectric pH.

Table III shows the variation with pH in the rate of decarboxylation of 4-methoxyanthranilic acid at 60° in buffers of ionic strength 0.10. The minimum pH attainable at this ionic strength is about 1.1 but within this limit it is seen that the rate increases as pH decreases.

To reach lower pH values it is necessary to increase the ionic strength of the buffers, and Table IV shows the variation in rate of decarboxylation of 4-methoxyanthranilic acid at 60° in solutions of ionic strength 0.50. The data of both Tables III and IV are plotted in Fig. 1, where a definite peak in the rate is observed in the vicinity of pH = 1.3 at ionic strength 0.50, and it becomes evident that the curve for ionic strength 0.10 must have a maximum at about pH = 1. Since pH = 3.3 at the isoelectric point of this acid at this

temperature and ionic strength, it is clear that the rate vs. pH profile does not fit any of the concentration vs. pH relationships described in the introduction.

Figure 1 also shows that on the high pH side of the peak, where rates were measured at two ionic strengths, the rate of decarboxylation at a given pH is greater at the higher ionic strength. The data do not permit a definite conclusion, but the shape of the curves suggests that the effect of decreasing ionic strength is to shift the position of the rate-maximum toward lower pH, and consequently, that on the low pH side of the peak rates would be greater at the lower ionic strength.

Figure 2 shows the results of an attempt to estimate the importance of general acid catalysis in the decarboxylation. Rate constants obtained in the same pH region using buffers of the same ionic strength but different buffer capacity are plotted against pH. To minimize errors in rate caused by errors in pH, measurements are made in the high pH region where the rate of change of rate constant with respect to pH is small. It is seen that the rate does vary with the nature of the buffering acid and with the concentration of a single buffer. The effect is small, however, and difficult to evaluate quantitatively. It was also demonstrated that general acid catalysis is very small at a pH near the peak in the rate vs. pH curve by measuring the rate of decarboxylation in a buffer made up of 0.05 *N*

[14], at $\mu = 0.50$; ——— rates constants calculated from eq. [14], at $\mu = 0.10$.

FIG. 2. Dependence of rate constant for decarboxylation of 4-methoxyanthranilic acid at 60 °C upon buffer acid and buffer capacity. ○ 0.20 *N* formate buffer; ● 0.04 *N* formate buffer; □ 0.20 *N* chloroacetate buffer; ■ 0.05 *N* chloroacetate buffer.

HCl and 0.05 *N* chloroacetic acid ($\mu = 0.10$, pH = 1.41 at 60°). The rate constant, $(1.77 \pm 0.02) \times 10^{-4}$ s^{-1}, obtained in this buffer may be compared with the value of 1.70×10^{-4} s^{-1} obtained by interpolation in the curve for a HCl buffer of the same pH and ionic strength. The effect of the chloroacetic acid (undissociated at this pH) is seen to be very small.

DISCUSSION

It will be noted that the shape of the rate vs. pH curve is very similar to that of the [N] vs. pH curve. Each has a maximum at intermediate pH and approaches zero at either end of the pH scale, but the rate curve is displaced toward lower pH. There are three obvious possibilities which might account for this discrepancy.

1. The reaction involves simultaneous decarboxylation of two or more Bjerrum species.
2. Decarboxylation results from a reaction between different Bjerrum species.
3. A fifth Bjerrum species is formed by further protonation of the cation.

The first possibility is the one suggested by Willi (4, 5) and requires a rate expression of the form:

$$[6] \qquad \frac{-\mathrm{d[C]}}{\mathrm{d}t} = k[\mathrm{C}] = k_1[\mathrm{H_2A^+}] + k_2[\mathrm{N}]$$

or its kinetic equivalent. Substituting eq. [2] and [3] into this gives:

$$k = \frac{k_1}{1 + K_1/[\mathrm{H^+}] + K_1K_2/[\mathrm{H^+}]^2} + \frac{k_2}{[\mathrm{H^+}]/K_1 + 1 + K_2/[\mathrm{H^+}]}.$$

In the region of the maximum rate $[\mathrm{H^+}] = 0.1$ approximately. Since K_2 is about 2×10^{-5}, the terms involving $K_2/[\mathrm{H^+}]$ are not important in this region and

$$k = \frac{k_1[\mathrm{H^+}] + k_2K_1}{[\mathrm{H^+}] + K_1}.$$

The slope of the plot of k against $[\mathrm{H^+}]$ is given by:

$$\frac{\mathrm{d}k}{\mathrm{d}[\mathrm{H^+}]} = \frac{K_1(k_1 - k_2)}{([\mathrm{H^+}] + K_1)^2}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

That is, the slope is zero only when $k_1 = k_2$, and when this is true the slope is zero at all pH values where the approximation is valid. Hence, the concurrent decarboxylation of two Bjerrum species cannot account for the observed pH at the rate maximum.

The second possibility suggests a rate expression of the form:

$$\frac{-\mathrm{d}[\mathrm{C}]}{\mathrm{d}t} = k[\mathrm{H_2A^+}][\mathrm{N}].$$

Since $[H_2A^+]$ approaches zero at high pH and [N] approaches zero at low pH, this equation predicts a maximum rate at a pH intermediate between those where $[H_2A^+]$ and [N] are maximum, but it also predicts that the rate at a given pH will be second order with respect to [C]. Since the reaction is distinctly first order, a reaction between two Bjerrum species cannot account for the observed kinetics.

The third of the possible interpretations suggests that the species undergoing decarboxylation is the cation, H_2A^+, but that at low pH this is further protonated to a doubly charged cation, H_3A^{2+}, which does not decarboxylate. The concentration of H_2A^+ would then reach a maximum at a pH between pK_1 and the pK of the new protonation. The possible sites for the new protonation are the carboxyl group or the substituent. However, carboxyl groups of aromatic acids are not appreciably protonated in the pH range under consideration here (13). Furthermore, the rate maximum at low pH is observed with 4-methyl as well as with 4-methoxy substituents, and the former is certainly not subject to protonation on the substituent. Hence, the position of the rate maximum cannot be explained by the appearance of a fifth Bjerrum species.

Since the pH at the rate maximum cannot be accounted for by reaction of any combination of Bjerrum species, decarboxylation must take place by way of an intermediate not part of the Bjerrum system. It was shown in the introduction that decarboxylation of a non-Bjerrum intermediate formed by protonation of a Bjerrum species would have a rate profile corresponding to the concentration profile of the next Bjerrum species. However, it will be noted that if either (but not both) of the terms in the denominator of eq. [5] contained $[H^+]$ the rate vs. pH profile would differ from the concentration profile of any of the Bjerrum species. This would require that the decomposition of the non-Bjerrum intermediate, AH*, involve two competing processes, one (but not both) of which must involve attack by proton upon the intermediate. The question then arises whether or not such a mechanism can be accommodated to the other known characteristics of the decarboxylation and structure of anthranilic acids.

The ease of decarboxylation increases in the order anthranilic < 4-methylanthranilic < 4-methoxyanthranilic acid, showing that the reaction is facilitated by a high electron density on the aromatic ring.[3] Decarboxylation involves the breaking of C—C and O—H bonds and the making of a C—H bond at the 1-carbon of the aromatic ring. Of these, only the last is facilitated by a high electron density on the aromatic ring. This suggests that the non-Bjerrum intermediate, HA*, is formed by protonation of a Bjerrum species at the 1-carbon.

After the ring is protonated two competing reactions will be loss of ring-proton and loss of carbon dioxide. One of these, but not both, must be brought about by a second proton attack. Thus, one of the competing reactions involves two successive protonations of a Bjerrum species. Obviously, the species most likely to play this role is the anion, A^-, but in principle either the neutral acid, HA, or the zwitterion, Z, could serve. Equation [7] below

[3]*Another possible interpretation would be that the order of increasing rates reflects an increase or decrease in percent zwitterion. However, eq. [20] of ref. 11 and the ρ values given there may be used to show that the order of increasing percent zwitterion is 4-methyl- > 4-methoxy- > anthranilic acid.*

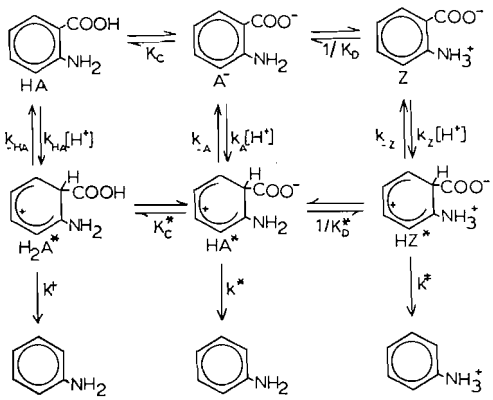
[7]



shows the structures of the non-Bjerrum intermediates, H_2A^*, HA*, and HZ*, which would be formed by ring-protonation of each of the species HA, A^-, and Z, respectively. Obviously the non-Bjerrum species are directly interconvertable by gain or loss of proton from the carboxyl groups of H_2A^* and HA* or the amino groups of HZ* and HA*. This interconversion constitutes the second protonation reaction which was postulated above in order to account for the shift in pH of the rate maximum. It should be rapid compared to the ring protonations, so it has been represented in eq. [7] as a pair of equilibria, K_C^* and K_D^*.

In the most general case we may suppose that all three intermediates decarboxylate. The overall rate expression may then be arrived at by calculating the total concentration of all three intermediates in the steady state.

Let $$[H_2A^*] + [HA^*] + [HZ^*] = [X].$$

Introducing the constants for equilibrium between intermediates from eq. [7] gives

$$[HA^*]\,([H^+]/K_C^* + 1 + [H^+]/K_D^*) = [X].$$

Letting the expression in parentheses $= Q$ leads to

$$[HA^*] = [X]/Q,$$

$$[H_2A^*] = [H^+][X]/K_C^*Q,$$

$$[HZ^*] = [H^+][X]/K_D^*Q.$$

The steady-state assumption for [X] is

$$\frac{d[X]}{dt} = k_{HA}[HA][H^+] + k_A[A^-][H^+] + k_Z[Z][H^+] - (k^+ + k_{-HA})[H_2A^*] - (k^* + k_{-A})[HA^*] - (k^{\mp} + k_{-Z})[HZ^*] = 0$$

which has as its solution

$$[X] = Q \times \frac{k_{HA}[HA][H^+] + k_A[A^-][H^+] + k_Z[Z][H^+]}{(k^+ + k_{-HA})[H^+]/K_C^* + (k^* + k_{-A}) + (k^{\mp} + k_{-Z})[H^+]/K_D^*}$$

$$= Q[N]\frac{k_AK_2 + (k_{HA}K_B/K_1 + k_ZK_A/K_1)[H^+]}{k^* + k_{-A} + \{(k^+ + k_{-HA})/K_C^* + (k^{\mp} + k_{-Z})/K_D^*\}[H^+]}.$$

The rate of decarboxylation is then

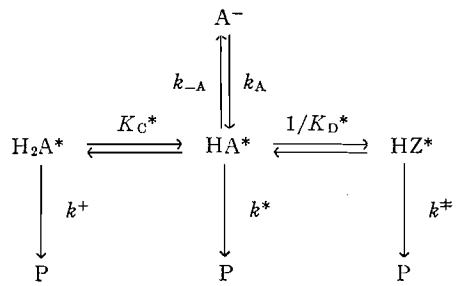
$$[8]\qquad \frac{-d[C]}{dt} = k^*[HA^*] + k^+[H_2A^*] + k^{\mp}[HZ^*]$$

$$= \frac{[X]}{Q}\{k^* + (k^+/K_C^* + k^{\mp}/K_D^*)[H^+]\}$$

$$= [N]\{k_A K_2 + (k_{HA}K_B/K_1 + k_Z K_A/K_1)[H^+]\} \times \frac{k^* + (k^+/K_C^* + k^{\mp}/K_D^*)[H^+]}{k^* + k_{-A} + \{(k^+ + k_{-HA})/K_C^* + (k^{\mp} + k_{-Z})/K_D^*\}[H^+]}.$$

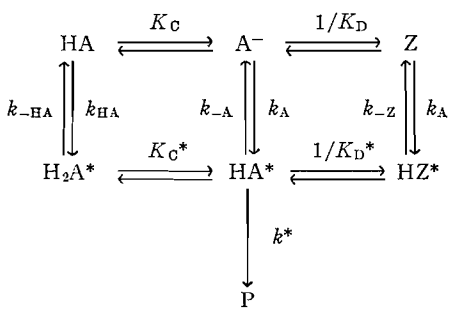
This general expression for the rate of decarboxylation via non-Bjerrum intermediates reduces to the equivalent of eq. [6] in either of two special cases: first, if the rate of decarboxylation greatly exceeds the rate of deprotonation for all three intermediates (i.e. $k^+ \gg k_{-HA}$, $k^* \gg k_{-A}$, $k^{\mp} \gg k_{-Z}$); second, if the rate of deprotonation greatly exceeds the rate of decarboxylation for all three (i.e. $K_C^* k_{HA}/k_{-HA} = K_C k_A/k_{-A}$, $K_D^* k_Z/k_{-Z} = K_D k_A/k_{-A}$). Since eq. [6] does not fit the data, evidently neither of these conditions is met.

As it stands, eq. [8] does not fit the data either, because the $[H^+]^2$ terms of the numerator prevent the rate from becoming small at low pH. For the rate to decrease at low pH will require either that k_{HA} and $K_Z = 0$ or that k^+ and $k^{\mp} = 0$, but not both. That is, in order for eq. [7] to represent the mechanism one or both of H_2A^* and HZ^* must participate, but either they are not formed directly by protonation of HA and Z or they do not decarboxylate. In the former case the mechanism becomes



$$[9]\qquad \frac{-d[C]}{dt} = [N]k_A K_2 \frac{k^* + (k^+/K_C^* + k^{\mp}/K_D^*)[H^+]}{k^* + k_{-A} + \{(k^+ + k_{-HA})/K_C^* + (k^{\mp} + k_{-Z})/K_D^*\}[H^+]}$$

and in the latter case it is



$$[10]\qquad \frac{-d[C]}{dt} = [N]k^* \frac{k_A K_2 + (k_{HA}K_B/K_1 + k_Z K_A/K_1)[H^+]}{k^* + k_{-A} + (k_{-HA}/K_C^* + k_{-Z}/K_D^*)[H^+]}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

It is difficult to decide which is the more likely. H_2A^* should be more stable than HZ^* because the amino group can help to distribute the positive charge in H_2A^* but not in HZ^*. That is, H_2A^* should be more easily formed but less easily decarboxylated, so that the former alternative (eq. [9]) would seem more reasonable for HZ^* but the latter (eq. [10]) would be more likely for H_2A^*. These considerations can be accommodated as special cases of the general mechanism if only one of HZ^* or H_2A^* is formed in significant concentration.

If only HZ^* is involved, eq. [9] reduces to

$$[11] \qquad \frac{-d[C]}{dt} = [N]k_A K_2 \frac{k^* + (k^{\ddagger}/K_D^*)[H^+]}{k^* + k_{-A} + (k^{\ddagger}/K_D^*)[H^+]}$$

and if only H_2A^* participates, eq. [10] becomes

$$[12] \qquad \frac{-d[C]}{dt} = [N]k^* \frac{k_A K_2 + (k_{HA}K_B)/K_1)[H^+]}{k^* + k_{-A} + (k_{-HA}/K_C^*)[H^+]}.$$

All four equations [9–12] are of the general form

$$[13] \qquad \frac{-d[C]}{dt} = [N]\frac{a + b[H^+]}{c + d[H^+]}$$

which, with suitable values of the constants, can be fitted to the data.

In order to estimate a, b, c, and d for 4-methoxyanthranilic acid it is necessary to expand eq. [13]. Substituting into it the value of [N] from eq. [3] gives:

$$\frac{-d[C]}{dt} = k[C] = \frac{a + b[H^+]}{c + d[H^+]} \times \frac{[C]}{[H^+]/K_1 + 1 + K_2/[H^+]}$$

or

$$[14] \qquad k = \frac{b}{d} \times \frac{a/b + [H^+]}{c/d + [H^+]} \times \frac{1}{[H^+]/K_1 + 1 + K_2/[H^+]}.$$

Since $K_2 \cong 2 \times 10^{-5}$, the last term in the denominator will be negligible compared to 1 when $[H^+]$ is larger than 2×10^{-3} M (or pH is less than 2.7) which includes almost the whole pH range over which rates were measured. Equation [14] can therefore be simplified to:

$$[15] \qquad k = \frac{b}{d} \times \frac{a/b + [H^+]}{c/d + [H^+]} \times \frac{K_1}{[H^+] + K_1}.$$

Setting $dk/d[H^+] = 0$ gives:

$$[16] \qquad \frac{a}{b} = \frac{K_1 c/d - [H^+]_{max}^2}{c/d + 2[H^+]_{max} + K_1},$$

where $[H^+]_{max}$ is the hydrogen ion activity at the maximum rate. Since a/b is a ratio of sums of rate constants it can not be negative; therefore, c/d must be larger than $[H^+]_{max}^2/K_1$. From Fig. 1 the pH at the rate-maximum may be estimated to be 1.1 at $\mu = 0.10$, which makes $[H^+]_{max} = 0.794$ M; K_1 at this ionic strength is 1.15×10^{-2}, so that c/d must be larger than 0.548. Since $[H^+]$ is much less than 0.548 over the whole range of rates studied at $\mu = 0.10$, $(c/d + H^+)$ may be set equal to c/d, so that eq. [15] becomes:

$$k = \frac{bK_1}{c} \times \frac{a/b + [H^+]}{K_1 + [H^+]}$$

which can be rearranged to

$$[17] \qquad k\frac{K_1 + [H^+]}{K_1} = \frac{a}{c} + \frac{b}{c}[H^+].$$

Fig. 3 shows a plot of the left-hand side of eq. [17] against $[H^+]$, using the data of Table III, from the slope and intercept of which $b/c = 1.90 \times 10^{-2}$ and $a/c = 2.03 \times 10^{-5}$, respectively. Dividing one by the other gives $a/b = 1.07 \times 10^{-3}$. Substituting this value of a/b

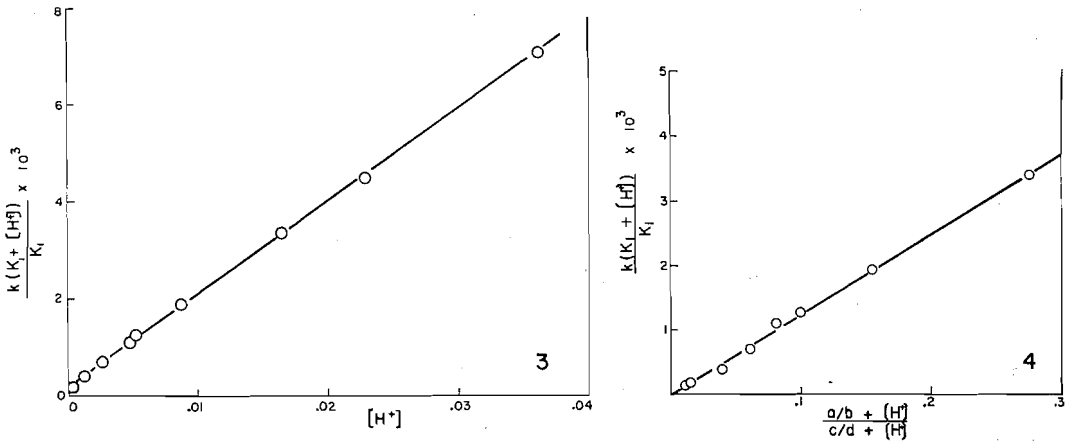


FIG. 3. Test of eq. [17]. Slope = b/c; intercept = a/c.
FIG. 4. Test of eq. [15]. Slope = b/d.

into eq. [16] gives $c/d = 0.622$, and using these values of a/b and c/d in a plot of eq. [15] (Fig. 4) gives a straight line with slope $b/d = 1.23 \times 10^{-2}$. Figure 1 compares the experimental points with the curve k vs. pH calculated from eq. [14] using the above values of a/b, c/d, and b/d. The fit is good but because experimental points are available only on one side of the peak, it is not possible to say whether eq. [14] adequately represents the data.

An adequate test of eq. [14] would require that the above calculations be repeated at $\mu = 0.50$ where rates are available on both sides of the peak. Since K_1 and K_2 were not measured at $\mu = 0.50$, it will be necessary to estimate them by an extrapolation of the Debye–Hückel theory to this range of ionic strengths. If it is assumed that the glass electrode measures hydrogen-ion activity and that ionic strength will have little effect on the activity of the neutral species, HA, then it follows that:

$$(K_1)_{0.5} = (K_1)_{0.1}\frac{(f_{H_2A^+})_{0.5}}{(f_{H_2A^+})_{0.1}} \quad \text{and} \quad (K_2)_{0.5} = (K_2)_{0.1}\frac{(f_{A^-})_{0.1}}{(f_{A^-})_{0.5}}$$

where K represents observed ionization constant, f represents activity coefficient, and the subscripts outside parentheses refer to ionic strengths. Introducing the simple Debye–Hückel relationship for activity coefficient in aqueous solution

$$-\log f = \frac{\sqrt{0.5\mu}}{1 + 1.6\sqrt{\mu}}$$

gives $(K_1)_{0.5} = 1.00 \times 10^{-2}$ and $(K_2)_{0.5} = 2.27 \times 10^{-5}$.

These small changes in equilibrium constant with ionic strength have a very small effect on the calculated values of a/b, c/d, and b/d, but the observed change in the pH at the rate-maximum has a much larger effect. Taking the rate-maximum when $\mu = 0.50$ to lie at pH = 1.38 (from Fig. 1) eq. [16] requires that c/d must be larger than 0.174, which shows that eq. [17] applies at all $[H^+]$ less than 0.01 M. A plot of eq. [17] using the data of Table IV for pH's greater than 2 gives a straight line from which $a/b = 0.9 \times 10^{-3}$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Equation [16] then gives $c/d = 0.200$ and eq. [15] gives $b/d = 5.26 \times 10^{-3}$. Figure 1 shows that the experimental data fit this calculated curve satisfactorily over the whole range of rate measurements. Hence, all of eqs. [9–12] represent variants of the general mechanism which satisfactorily account for the pH dependence of the rate of decarboxylation of 4-methoxyanthranilic acid and probably of other aromatic amino acids as well.

At high pH these rate expressions are greatly simplified. Introducing the values of a/b, c/d, and b/d at $\mu = 0.50$ into eq. [14] gives:

$$[18] \qquad k[C] = \frac{b}{d}\frac{a/b + [H^+]}{c/d + [H^+]}[N] = 0.00506\frac{0.001 + [H^+]}{0.205 + [H^+]}[N].$$

At pH's greater than 4 (i.e. $[H^+]$ less than 0.0001) the $[H^+]$ becomes negligible and the rate expression is

$$[19] \qquad k[C] = \frac{a}{c}[N] = \frac{k^*K_AK_2}{k^* + k_{-A}}[N]$$

for all of eqs. [9–12]. This involves the rate constants for only one non-Bjerrum intermediate, HA*, so that at high pH the main route of decarboxylation is simply

$$H^+ + A^- \underset{k_{-A}}{\overset{k_A}{\rightleftharpoons}} HA^* \xrightarrow{k^*} \text{products.}$$

On the other hand, at pH's less than -0.3 (i.e. $[H^+]$ greater than 2) the fraction containing the sums disappears from eq. [18] and the rate expression becomes

$$k[C] = \frac{b}{d}[N].$$

However, this expression does not correspond to any simple mechanism except in the case of eq. [11] where it reduces to

$$k[C] = k_AK_2[N] = k_A[H^+][A^-]$$

which implies that the rate of decarboxylation at high acidities is determined by the rate of protonation of A^-.

The proposed mechanisms also permit some predictions concerning the possibility of a carboxyl–carbon isotope effect. At pH's greater than 4 all four mechanisms obey eq. [19] which contains k^*, the rate of carbon–carbon bond breaking, so that there will be an isotope effect unless the rate of decarboxylation, k^*, greatly exceeds the rate of deprotonation, k_{-A}. This is possible for eqs. [10] and [12] so that these mechanisms can accommodate an isotope effect or none. However, for eq. [9]

$$\frac{a/b}{c/d} = \frac{k^*}{k^* + k_{-A}}\left(1 + \frac{k_{-HA}K_D^* + k_{-Z}K_C^*}{k^+K_D^* + k^{\mp}K_C^*}\right) = 1.8 \times 10^{-3}.$$

Since the quantity in parentheses cannot be less than 1, k^* must be considerably smaller than k_{-A}. Therefore mechanism [9] and its special case [11] require a carboxyl–carbon isotope effect at pH 4 or greater.

At pH -0.3 or less eq. [9] reduces to

$$\frac{-d[C]}{dt} = [N]k_AK_2\frac{k^+/K_C^* + k^{\mp}/K_D^*}{(k^+ + k_{-HA})/K_C^* + (k^{\mp} + k_{-Z})/K_D^*}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

so that there will be an isotope effect unless $k^+ \gg k_{-HA}$, and $k^{\pm} \gg k_{-Z}$, but if this were the case eq. [9] would become equivalent to eq. [5] which does not fit the data. Equation [10] also requires an isotope effect since k^* cannot be eliminated from the equation in this pH range. In summary, then, eqs. [9] and [11] require an isotope effect at all pH's, but eqs. [10] and [12] need not have one except at very low pH.

Stevens, Pepper, and Lounsbury (3) showed that the carboxyl–carbon isotope effect for the decarboxylation of anthranilic acid is very small in sulfuric acid concentrations up to 1 *N*. There did seem to be a tendency for the isotope effect to increase slightly at the highest acidity studied. Should this observation hold for 4-methoxy as well as for unsubstituted anthranilic acid this would be strong support for a mechanism corresponding to eq. [10] or [12]; that is, one in which HA* and H_2A^* (and (or), less probably, HZ*) are formed but only HA* decarboxylates. Of course, the pH at which the isotope effect should appear depends upon the value of c/d and this may well be different for anthranilic acid than for 4-methoxyanthranilic acid. In fact, we have shown c/d for a single acid to be fairly sensitive to ionic strength, so that the observance or non-observance of an isotope effect may well depend upon the substitutent, the pH, the ionic strength, the temperature and the solvent. Further work is planned to investigate the influence of these factors on the isotope effect.

ACKNOWLEDGMENT

The authors are grateful to Miss Paula Van Buren for assistance with some of the experimental work, and to a referee for valuable suggestions concerning the presentation of the kinetics.

NOTES

DIRECT OBSERVATION OF $A^3\Sigma_u^+$ NITROGEN MOLECULES IN THE N–I_2 FLAME

D. I. WALTON, M. J. MCEWAN, AND L. F. PHILLIPS

Previous studies (1, 2) of the reaction of iodine with active nitrogen have shown that an energetic metastable species is produced by the reaction, and have made it appear very likely that the metastable species is a nitrogen molecule in the A-state. In the present work direct evidence for the presence of this species as a product of the reaction has been obtained by observing absorption of the nitrogen first positive bands by the reaction flame.

From the postulated mechanism (1) one can conclude that a maximum concentration of the excited species should be obtained when the N-atom concentration is large and when the rate of destruction of NI at the walls of the reaction vessel is small. Therefore we have used a condensed discharge as a source of nitrogen atoms, and a reaction vessel of large internal diameter (52 mm).

Up to 10% absorption of the (0,0) and (1,0) first positive bands could be produced by introducing iodine into the reaction vessel with the condensed discharge turned on. No absorption was found (*a*) on addition of the argon carrier gas alone, (*b*) on addition of iodine plus carrier gas with the condensed discharge turned off, (*c*) when argon replaced nitrogen in the microwave discharge which was used as a light source, or (*d*) for bands other than those with $v'' = 0$ (upper limit for other bands, 1% absorption). We have not observed any Vegard–Kaplan bands in emission, using a microwave discharge to produce N atoms, but have yet to try this experiment with the condensed discharge.

Oldenberg, Bills, and Carleton (3) observed 0.9% absorption of the (1,0) band in a 5 ft discharge tube with a calculated A-state molecule concentration of 6.5×10^{10} per cm^3. Assuming that the rotational temperatures in our experiments were not too different from theirs, this would indicate that in our reaction vessel, with a light path of 80 cm, there was a mean concentration of 1.4×10^{12} A-state molecules per cm^3. The maximum concentration, assuming exponential decay, would therefore have been 10^{13}–10^{14} per cm^3, since the lack of blue iodine emission at the exit to the reaction vessel showed that the A-state concentration was zero at this point. This is much less than the maximum N-atom concentration (10^{16} per cm^3 at least). Neglecting NI destruction at the walls, the steady state concentration of A-state molecules is approximately [N]/3, if the A-state is produced every time that N reacts with NI (2). In our experiments the N-atom concentration would have fallen somewhat by the time the steady state was reached; however, the results indicate that the production of an A-state molecule is a rather infrequent occurrence, and so diminish the prospect of using this reaction system as a convenient source of the metastable species.

EXPERIMENTAL

The light from a 100 W microwave discharge in a 14 mm quartz tube was chopped at 80 cycles/s before entering the 16 cm long, 52 mm i.d., reaction vessel. The end windows of the vessel were silvered externally, and the light entered through one small window at one end and left through a diagonally opposite one at the other end. Typically five traverses were used, for a total light path of 80 cm. From the exit window

the light was focussed on the entrance slit of a Hilger D2853 quartz monochromator. A lead sulfide photoconductor (Kodak Ektron, N2, uncooled) was placed at the exit slit of the monochromator, and the signal from this was taken to a Tektronix type 122 low-level preamplifier, a phase-sensitive detector, and a chart recorder. Very careful shielding was necessary to eliminate pickup from the condensed discharge. The nitrogen pressure was in the range 5–10 Torr, and the velocity of flow through the reaction tube was estimated to be about 80 cm/s. Nitrogen, argon, and iodine were as previously described (1). Once the apparatus was turned on an experiment consisted simply of repeatedly opening and closing a stopcock between a heated iodine saturator and the reaction vessel. The stability of the system was such that 1% absorption of the light beam could just be detected with certainty.

AN APPARATUS FOR STUDYING HYDROGEN SULFIDE OXIDATION KINETICS

A. E. Werner

INTRODUCTION

The oxidation of hydrogen sulfide by dissolved oxygen is of importance in some water pollution problems (1). While the half-life of H_2S in sea water was recently found to be of the order of 17 min (2), there are indications that in polluted waters, coexistence of the dissolved gases is possible over prolonged periods.

A study was undertaken to investigate this reaction under a variety of conditions by an apparatus designed for measuring the rate constant involved and the influence on it of temperature, catalysts, and inhibitors. The effects of the latter were compared by a null method.

The oxidation involved is a complicated process because the primary reaction products tend to progressive further oxidation (3, 4, 5). In the gas phase a minimum of $1\frac{1}{2}$ volumes disappear for each volume of hydrogen sulfide oxidized.

[1] $$2H_2S_{(g)} + O_{2(g)} \rightarrow 2H_2O_{(l)} + 2S_{(s)}$$

At room temperature and in the absence of catalysts, oxidation is much faster in solution than in the gas phase. This can be deduced theoretically because at low pressures the specific rate constant in solution ($k_{(l)}$) and its counterpart in the gas phase $k_{(g)}$ are related by

[2] $$k_{(l)} = k_{(g)} \frac{\gamma_{H_2S}\,\gamma_{O_2}}{\gamma_{\neq}}$$

where γ denotes the activity coefficient in solution of the gas given by the subscript and $\gamma_{\neq}$ refers to that of the activated complex (6). In many relations the activity coefficient factor $= (\gamma_1\gamma_2)/\gamma_{\neq}$ has values around 100, although exceptions are known (7).

the light was focussed on the entrance slit of a Hilger D2853 quartz monochromator. A lead sulfide photoconductor (Kodak Ektron, N2, uncooled) was placed at the exit slit of the monochromator, and the signal from this was taken to a Tektronix type 122 low-level preamplifier, a phase-sensitive detector, and a chart recorder. AN APPARATUS FOR STUDYING HYDROGEN SULFIDE OXIDATION KINETICS

A. E. Werner

INTRODUCTION

The oxidation of hydrogen sulfide by dissolved oxygen is of importance in some water pollution problems (1). While the half-life of H_2S in sea water was recently found to be of the order of 17 min (2), there are indications that in polluted waters, coexistence of the dissolved gases is possible over prolonged periods.

A study was undertaken to investigate this reaction under a variety of conditions by an apparatus designed for measuring the rate constant involved and the influence on it of temperature, catalysts, and inhibitors. The effects of the latter were compared by a null method.

The oxidation involved is a complicated process because the primary reaction products tend to progressive further oxidation (3, 4, 5). In the gas phase a minimum of $1\frac{1}{2}$ volumes disappear for each volume of hydrogen sulfide oxidized.

[1] $$2H_2S_{(g)} + O_{2(g)} \rightarrow 2H_2O_{(l)} + 2S_{(s)}$$

At room temperature and in the absence of catalysts, oxidation is much faster in solution than in the gas phase. This can be deduced theoretically because at low pressures the specific rate constant in solution ($k_{(l)}$) and its counterpart in the gas phase $k_{(g)}$ are related by

[2] $$k_{(l)} = k_{(g)} \frac{\gamma_{H_2S}\,\gamma_{O_2}}{\gamma_{\neq}}$$

where γ denotes the activity coefficient in solution of the gas given by the subscript and $\gamma_{\neq}$ refers to that of the activated complex (6). In many relations the activity coefficient factor $= (\gamma_1\gamma_2)/\gamma_{\neq}$ has values around 100, although exceptions are known (7).

In a heterogeneous system consisting of an aqueous and a gaseous phase, the reacting components, H_2S and O_2, are distributed between the phases. The equilibrium condition is characterized by the distribution coefficients α_{H_2S} and α_{O_2}. The latter are expressed by the ratio of the activities of the particular component in the respective phases.

$$[3] \qquad \alpha = \frac{(f_1[C_1])_{(g)}}{(f_2[C_2])_{(l)}}$$

The symbols f_1 and f_2 refer to the activity coefficients and $[C_1]$ and $[C_2]$ represent the concentrations.

When oxidation takes place preferentially in one phase, the concentrations $[H_2S]$ and $[O_2]$ decrease in that phase and the system tends to restore equilibrium by transferring the relevant species from the other phase.

This results (at constant temperature and pressure) in a measurable decrease of the gas volume. Alternatively, a pressure drop is experienced at constant volume. Inasmuch as $\Delta p \ll p$ under prevailing conditions the reaction rate is not noticeably influenced.

METHOD

To water, saturated with oxygen and in contact with a gaseous phase initially consisting of oxygen, a dilute, aqueous solution of hydrogen sulfide is added. The reaction is followed through the pressure change at constant volume (or the volume change at constant pressure) of the gaseous phase in contact with the solution.

In an apparatus of V_T ml capacity, an initial amount of oxygen (expressed as ml at S.T.P.) is present, partly as free gas and partly dissolved in x ml of water. When y ml of hydrogen sulfide solution is added, an equal volume of oxygen gas is vented. The volume of oxygen available for the reaction is therefore

$$[4] \qquad V_0 = V_T - (1 - 0.031)x - y \quad \text{(ml at S.T.P.)}.$$

Two volumes of hydrogen sulfide gas require at least 1 volume of oxygen (cf. eq. [1]) and the solubility of oxygen and hydrogen sulfide in water at 20 °C is 31.1 and 2 160 ml per liter (reduced to S.T.P.), respectively. The volumes of the saturated solutions which are to be mixed can be calculated as follows:

$$[5] \qquad 2(V_T - 0.969x - y) = 2.61y$$

$$[6] \qquad 2.305y + 0.969x = V_T.$$

It would be impossible to determine oxidation kinetics by this method if the rate of transfer across the phase boundary were the rate-determining step. Rapid mechanical agitation proved a suitable way of avoiding restriction at this point because the rate of transfer is proportional *inter alia* to the gas liquid interface A. The shaking not only increases A but it assists absorption by replacing slow diffusion by faster convectional processes (8).

APPARATUS

The assembly was constructed almost entirely of borosilicate glass, but stopcock plugs and leak-preventing "sleeves" between the standard tapers consisted of "Teflon". The temperature was controlled by immersion in a thermostatted water bath. Two almost identical parts which were joined by a differential manometer M (Fig. 1) made up the

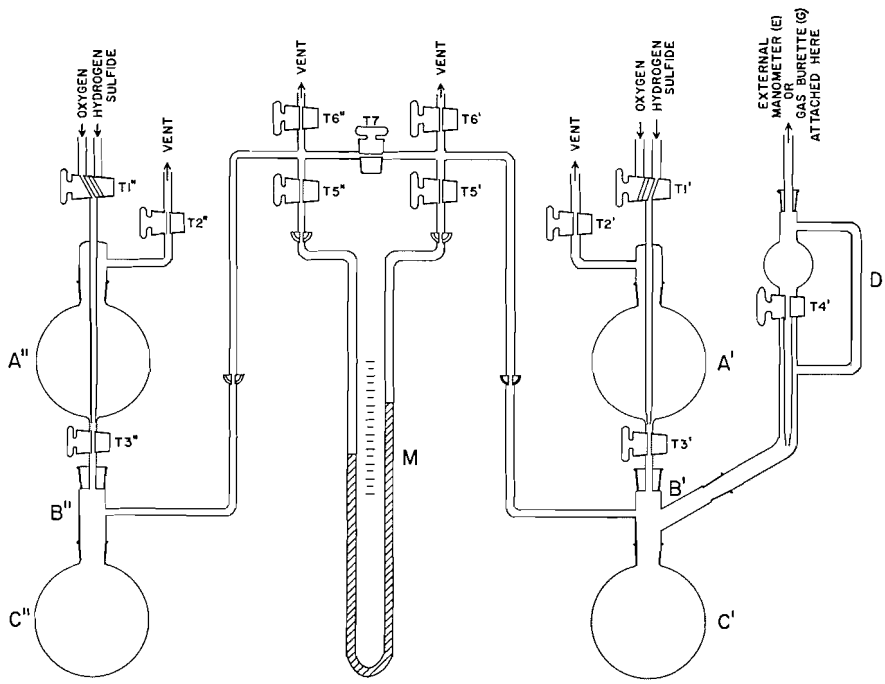

FIG. 1. Apparatus for the study of hydrogen sulfide oxidation kinetics. Legend: (A′, A″) saturators for preparing the solutions; (B′, B″) manifolds; (C′, C″) reaction flasks; (D) dropping funnel for adding catalysts and (or) inhibitors; (E) external manometer (not shown); (G) gas burette (not shown); (M) differential manometer; (T1′, T1″) stopcocks for controlling gas flow to saturators; (T2′, T2″) stopcocks for venting saturators; (T3′, T3″) stopcocks for dropping saturated solutions into reaction flasks; (T4′) stopcock for dropping catalysts or inhibitors into reaction flasks; (T5′, T5″) stopcocks for isolating differential manometer; (T6′, T6″) stopcocks for venting reaction flasks; (T7) stopcock for separating control side of apparatus.

unit. These left and right sides were used separately for finding pressure or volume changes or jointly for measuring relative pressure drops in catalyst or inhibitor studies.

In the volumetric technique the gas burette G was used. The whole apparatus was filled with oxygen at atmospheric pressure, then the sides were separated by closing the appropriate tap. The reaction mixture was prepared in one half of the apparatus and the contraction measured with the gas burette in conjunction with the manometer M.

The null method was applicable whenever it was desirable to compare directly the rates of catalyzed and non-catalyzed reactions. This was possible by letting them proceed side by side simultaneously in the two halves of the apparatus and measuring the time function of the pressure difference. Errors caused by small changes in temperature, illumination, etc. were thus minimized. Tap T7 remained open until the absolutely synchronous descent of the H_2S–water into the reactors was completed. Catalysts or inhibitors were placed into the reactor flasks C′ and (or) C″. In case they had to be added after the start of the reaction, they were put into D′. Duplicate runs were carried out as follows:

	LEFT SIDE	RIGHT SIDE
1st run	Catalyst A	Inhibitor B
2nd run	Inhibitor B	Catalyst A

PERFORMANCE

The two sides were made exactly equal in capacity (169.9 ml) by adding a small piece of glass rod to the larger of them. Leakage was so small that the pressure in the evacuated apparatus rose at the rate of 1.06×10^{-4} mm/min.

(a) Reaction in the Gas Phase

Oxygen (x ml) and hydrogen sulfide ($2x$ ml) were dosed in from the gas burette and a series of pressure readings was taken for calculating average pressure-drop coefficients. At 25 °C they were: (i) at 1 atm initial pressure, 8.99×10^{-2} mm Hg/min; (ii) at 0.5 atm initial pressure, 4.01×10^{-2} mm Hg/min. Their small rate of change with pressure (9.96×10^{-2} mm Hg/atm) justified the statement made above that pressure instead of volume measurement may be made whenever this is convenient.

(b) Transfer Across Phase Boundary

Only the right half of the apparatus was used. The system was filled with oxygen at atmospheric pressure, then a measured volume of degassed water was placed into C′. The shaker was started and manometer readings were taken.

The results are shown in Table I. The measured gas volumes, reduced to S.T.P., are presented as concentrations expressed in ml/l of water per minute. The last column shows the average % of oxygen which is transferred per minute in the particular time interval. It is based on the total average amount of oxygen transferred.

TABLE I

Transfer across phase boundary at 25 °C

Time interval, min	O_2 transported during time interval, ml/l min			Average transport (based on average total oxygen transported), % per min
	1*	2†	3‡	
0–1	7.1	6.6	3.2	47.5
1–2	3.8	3.1	2.1	23.1
2–3	2.6	1.5	1.3	15.4
3–4	0.8	0.5	0.8	5.9
4–6	0.4	0.1	0.5	2.8
6–8	0.1	0.1	0.1	0.8
8–12	0.0	0.0	0.0	0.0

*Total O_2 transferred 15.4 ml/l, total H_2O advanced 85.0 ml, total gas space 85.0 ml.
†Total O_2 transferred 12.1 ml/l, total H_2O advanced 75.0 ml, total gas space 95.0 ml.
‡Total O_2 transferred 8.5 ml/l, total H_2O advanced 50.0 ml, total gas space 120.0 ml.

Table I shows that the half-life constant of the transfer reaction is of the order of 1 min, amply adequate to prevent starvation of the H_2S oxidation reaction in solution.

The heats of solution of sodium chloride, sodium fluoride, sodium methane sulfonate ($MeSO_3Na$), sodium benzene sulfonate (ϕSO_3Na), and sodium *p*-toluenesulfonate (TOSNa) have been determined at several concentrations in light and heavy water at 25 °C.

Baker and Adamson reagent grade NaCl was recrystallized three times from equilibrium water and dried at 100 °C. The NaF was Baker and Adamson reagent grade dried at 120 °C. Eastman Kodak reagent grade TOSNa was recrystallized once from methanol and dried under vacuum at 80 °C. The samples of $MeSO_3Na$ and ϕSO_3Na were kindly supplied by Dr. R. E. Robertson (N.R.C.) and were recrystallized and dried by him. Infrared analyses of samples of the heavy water carried out by Dr. W. H. Stevens (Atomic Energy of Canada Ltd.) indicated a D_2O content of 99.8 weight %. The H_2O employed was equilibrium conductivity water. No attempt was made to remove dissolved gases from either of the solvents.

The sample to be dissolved was contained in a thin-walled glass bulb closed with a Teflon stopper. These bulbs were constructed from precision bore tubing to ensure a uniform fit of the stoppers. The calorimeter vessel (1), the adiabatic shield (2), and the control system (3) have been described previously.

TABLE I

Heats of solution in H_2O

Compound	Mole fraction	Temp. (°C)	ΔH (J mole^{-1})	ΔH (25 °C) (J mole^{-1})
NaCl	0.008927	24.961	4110	4106
	0.008927	24.992	4106	4105
	0.008927	24.941	4108	4102
	0.008927			Mean 4104±2
	0.004483	24.976	4229±7	4226±7
NaF	0.004481	24.999	1484±6	
$MeSO_3Na$	0.002495	24.961	7022±13	
	0.001249	25.058	6920±25	
ϕSO_3Na	0.002494	24.995	7492±13	
	0.001249	24.999	7387±41	
TOSNa	0.002495	25.004	9695±12	
	0.001248	25.004	9534±24	
	0.001249	25.068	9507±24	

Tables I and II report the results obtained for the heats of solution in light and heavy water respectively. The weights of all the components were corrected to *vacuo*. Concentrations are stated as mole fractions of the solute, and ΔH is expressed in joules per mole of solute.

The results for the solution of NaCl in H_2O were corrected to 25 °C by employing temperature coefficients of -102 J mole^{-1} deg^{-1} at $x = 0.0089$ and of -115 J mole^{-1}

[1]*Issued as N.R.C. No. 8613.*

[2]*National Research Council of Canada Postdoctorate Fellow, 1963–1965. Present address: Department of Chemistry, Dalhousie University, Halifax, Nova Scotia.*

deg^{-1} at $x = 0.0045$. These coefficients were calculated from heat capacity data determined for NaCl solutions by Lipsett, Johnson, and Maass (4). The temperature coefficient for the heat of solution of NaCl in D_2O at $x = 0.0045$ was estimated to be -143 ± 7 J $mole^{-1}$ deg^{-1} from the data in Table II. A temperature coefficient of -128 J $mole^{-1}$ deg^{-1} was calculated for the heat of solution of NaCl in D_2O at $x = 0.0089$ by assuming a concentration dependence proportional to that for the NaCl–H_2O system.

TABLE II

Heats of solution in D_2O

Compound	Mole fraction	Temp. (°C)	ΔH (J $mole^{-1}$)	ΔH (25 °C) (J $mole^{-1}$)
NaCl	0.008927	25.007	6297±3	6298±3
	0.004483	24.930	6529	6519
	0.004478	24.985	6509	6507
	0.004480	25.001	6492	6492
	0.004481	23.367	6739	6505
	0.00448		Mean	6506±10
NaF	0.004479	25.001	1484±6	
$MeSO_3Na$	0.002495	25.015	8259±13	
	0.001249	25.051	8163±27	
ϕSO_3Na	0.002495	25.007	8664±14	
	0.002495	24.989	8706±14	
	0.001249	25.002	8554±50	
TOSNa	0.002494	25.011	10904±13	
	0.001249	24.999	10656±26	

On the basis of the reproducibility of the results for the two NaCl systems, it was concluded that the calorimetric technique was precise to ±0.28 J in the total heat measured. This value was used to estimate the precisions indicated for the other systems in Tables I and II.

TABLE III

Isotope effect

NaCl	0.00893	2194±4	
	0.00448	2280±12	
NaF	0.00448	0±8	
$MeSO_3Na$	0.00250	1237±18	1238
	0.00125	1243±37	
ϕSO_3Na	0.00250	1193±19	1191
	0.00125	1167±65	
TOSNa	0.00250	1209±18	1194
	0.00125	1136±35	

Table III reports the values obtained for the isotope effect ($\Delta H_{D_2O} - \Delta H_{H_2O}$). Since within the precision of the measurements at these low concentrations there is no significant dependence of the isotope effect for the sulfonates on concentration, average values were computed by assigning to each result a weight inversely proportional to the square of its precision.

Previous determinations of the heat of solution of NaCl in H_2O carried out in this laboratory (1) yielded values of 4117 ± 4 and 4245 ± 8 J $mole^{-1}$ at mole fractions of 0.0089 and 0.0045 respectively. A redetermination (2) at $x = 0.0089$ using the same

For personal use only.

adiabatic shield assembly employed in the present work produced a value of 4116 J mole^{-1}. The heats of solution of NaCl in H_2O reported in Table I are in reasonable agreement with these earlier results, since the samples used in the previous investigations had been pumped under vacuum at 300 °C for 12 h and sealed in evacuated bulbs. Our results also agree with Lange and Martin's (5) experimental value of 2343 ± 84 J mole^{-1} for the isotope effect with NaCl at a mole fraction of 0.0045 and with their calculated value of 21 ± 84 J mole^{-1} for the isotope effect with NaF.

When an ionic compound is dissolved to form a very dilute solution, the thermodynamic properties for the process can be calculated as the resultant of contributions associated with the steps of an alternative path between the same initial and final states. The first step along this path is the dissociation of the crystal lattice to produce an ionic gas in some standard state. This is followed by the solution of the ionic gas in the solvent. The first step depends only on the solute, whereas the second, which corresponds to the hydration of the ions, is a function of both the solute and the solvent.

Discussions of the hydration of ions generally divide the process into two sub-steps, the creation of a cavity in the solvent and the insertion of the ion into this cavity. In principle the thermodynamic properties for the creation of a cavity can be calculated from the properties for the vaporization of the solvent plus a contribution from the formation of a new liquid surface; the ionic contribution to the solute–solvent interaction can be calculated from the Born equation (6, 7) and, if necessary, a contribution from the dispersion forces can be included. Unfortunately there is a marked lack of unanimity regarding the proper choice of an ionic radius (cavity size) and of an effective value for the dielectric constant in the neighborhood of the solvated ion, and thus the detailed application of the model varies from author to author (5, 7). The isotope effect arises from the difference between the solvation process in light and heavy water, and the thermodynamic properties associated with it are those for the transfer of an ion from light to heavy water.

Swain and Bader (8) have investigated the structures of light and heavy water by treating the librational motion (restricted rotation) of each solvent molecule as a three dimensional harmonic oscillator. They found that the isotope effect could be attributed almost entirely to the change in librational frequency of the water molecules in the first hydration shell of the ions. As the librational frequencies in light and heavy water are related to each other by a constant factor, only one frequency need be considered for each ion. Infrared absorption spectra of solutions of fluoride ions in light water exhibit a fairly well-defined librational band centered at 698 cm^{-1}. Using this value together with an assignment of 667 cm^{-1} for the librational frequency of pure H_2O, they calculated the isotope effect on the heat of hydration of the fluoride ion to be −732 J mole^{-1}. The isotope effects for other ions were obtained by combining this result with experimental heats of solution in light and heavy water. These effects were then used to calculate the librational frequency of the water molecules in the hydration shell, and the results compared with experimental infrared spectra. Unfortunately the librational bands observed were too broad to allow an unequivocal assignment of the frequency; but in all cases a fairly satisfactory correlation was possible.

The isotope effect on the heat capacities of hydration can be calculated (8) from the librational frequencies. For NaCl such a calculation predicts a difference of −2 J mole^{-1} deg^{-1} between the heat capacities of hydration in light and heavy water. This result is obtained whether the frequencies quoted by Swain and Bader or those calculated from our experimental heats are employed. This value is not in agreement with the experimentally determined value of −28 J mole^{-1} deg^{-1} at $x = 0.0045$ since the uncertainty in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the experimental value is only about 10 J mole^{-1} deg^{-1}. However, since the configurational integrals were equated in deriving the formula, this lack of agreement is not unexpected.

If one accepts Swain and Bader's value for the isotope effect on the heat of solution of the fluoride ion, the data in Table III lead to values of +732, +1548, +506, +459, and +462 J mole^{-1} for the Na^+, Cl^-, $MeSO_3^-$, ϕSO_3^-, and TOS^- ions respectively.

The fluoride ion is the only singly charged ion for which a negative contribution to the isotope effect has been observed, and hence is the only such ion for which the librational frequency of the solution is greater than that of pure water. This singular behavior of the fluoride ion does not imply that there is any discontinuity in the properties of the halogens, since plots of the ionic contributions to the thermodynamic properties against the ionic radius or its reciprocal are smooth curves (7).

It is interesting to note that the isotope effect on the heats of hydration of the sulfonates does not vary much with the size of the anion. We have not calculated the corresponding change in librational frequency for the sulfonates since in order to have done so we would have had to introduce further assumptions regarding the extent of coordination. However, it does appear that in all cases these ions tend to decrease the amount of water structure, the disruptive effect being greater in D_2O than in H_2O. This is in line with the positive entropies of transfer (H_2O to D_2O) deduced by Greyson from measurements of the ion exchange membrane potentials for a number of chlorides (9).

Provided that the solute–solvent interaction in the transition state for the solvolysis of alkyl halides and sulfonates in water is proportional to that in the final state, the isotope effects reported in this paper support the hypothesis (10) that it is the initial state solvation shell rather than that in the transition state which is the major factor in determining kinetic solvent isotope effects since the latter do not vary in the same manner as do the enthalpy changes.

ACYLGUANIDINES AS INTERMEDIATES IN PEPTIDE SYNTHESES

Eliahu Hoffmann and Dov Diller

In our investigation of new peptide syntheses we considered the properties of guanidine as a carboxyl-activating group.

Acylguanidines (I), according to the literature (1, 2), can be prepared by the action of guanidine (liberated from its salt by sodium alkoxide) on the esters of carboxylic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

acids. It seemed to us that these compounds should be very prone to proton-catalyzed aminolysis as outlined in eq. [1], since they have, indeed, distinctly basic properties (3).

[1] $$\underset{\text{(I)}}{RCNHCNH_2} \xrightarrow{H^+} \underset{\text{(II)}}{\left[RCNHCNH_2\right]^+} \xrightarrow{NH_2R'} RCNHR' + \left[NH_2CNH_2\right]^+$$

The positively charged intermediate (II) should then suffer nucleophilic attack by amines to yield the expected amide. The reaction could conceivably be carried out in aqueous or mixed aqueous–organic solvents. Furthermore, the trend of the reaction should be towards the formation of the resonance-stabilized guanidinium ion, thus facilitating the formation of the amide bond.

In a preliminary attempt to verify these assumptions we were successful in preparing acylguanidines of hippuric acid, benzyloxycarbonylglycine, benzyloxycarbonyl-DL-alanylglycine, formyl-L-valine, formyl-L-phenylalanine, and tosyl-L-proline from their corresponding ethyl or methyl esters. The yields in these reactions were fair to good and the substances could be obtained in crystalline form.

These guanidine compounds were then caused to react with either ethyl or benzyl glycinate in water or water–dimethylformamide solution at pH 8 to give ethyl hippurylglycinate, benzyl benzyloxycarbonylglycylglycinate, ethyl benzyloxycarbonyl-DL-alanylglycylglycinate, ethyl formyl-L-valylglycinate, ethyl formyl-L-phenylalanylglycinate, and ethyl tosyl-L-prolylglycinate, respectively, with fairly good yields.

It therefore seems that this is a feasible method for the synthesis of peptides and that optical activity can be retained in these reactions. The scope and limitation of this method are at present under investigation.

EXPERIMENTAL

All melting points were taken on a Fisher–Jones apparatus and are uncorrected.

Benzyloxycarbonylglycylguanidine

Methyl benzyloxycarbonylglycinate (6.1 g; 0.0274 mole) was treated with a solution of 0.0435 mole of free guanidine in 20 ml of absolute ethanol. The ester dissolved and the solution was left to stand at room temperature for several hours. After precipitation was complete, the material was filtered off and dried. The yield was 5.5 g (80.4%); the compound could be recrystallized from either nitromethane or ethanol – ethyl acetate and it melted at 152°.

Anal. Calcd. for $C_{11}H_{14}N_4O_3$: C, 52.8; H, 5.6. Found: C, 52.9; H, 5.9.

Similarly prepared were the following.

Hippurylguanidine

This compound was obtained in 87.6% yield. It was recrystallized from dioxane and melted at 182°.

Anal. Calcd. for $C_{10}H_{12}N_4O_2$: C, 54.5; H, 5.4. Found: C, 54.6; H, 5.6.

Benzyloxycarbonyl-DL-alanylglycylguanidine

This compound was obtained in 51% yield. It was recrystallized from ethanol and melted at 175–176°.

Anal. Calcd. for $C_{14}H_{19}N_5O_4$: C, 52.4; H, 5.9. Found: C, 52.6; H, 5.9.

Formyl-L-valylguanidine

This compound was obtained in 74% yield. It was recrystallized from *n*-butanol and melted at 162–164°; $[\alpha]_D^{25}$ +2.8° (*c*, 1.8 in absolute ethanol).

Anal. Calcd. for $C_7H_{14}N_4O_2$: C, 45.1; H, 7.5; N, 30.1. Found: C, 45.3; H, 7.8; N, 29.9.

Formyl-L-phenylalanylguanidine

This compound was obtained in 69% yield. It was recrystallized from *n*-butanol and melted at 153°; $[\alpha]_D^{25}$ +27.2° (*c*, 1.6 in absolute ethanol).

Anal. Calcd. for $C_{11}H_{14}N_4O_2$: C, 56.4; H, 6.0; N, 23.9. Found: C, 56.1; H, 6.3; N, 23.9.

Tosyl-L-prolylguanidine

This compound was obtained in 79% yield. It was recrystallized from absolute ethanol and melted at 187–188°; $[\alpha]_D^{25}$ −174° (*c*, 0.8 in absolute ethanol).

Anal. Calcd. for $C_{13}H_{18}N_4O_3S$: C, 50.4; H, 5.8; N, 18.0. Found: C, 50.5; H, 6.1; N, 18.3.

Ethyl Benzyloxycarbonylglycylglycinate

A solution of 1.25 g (0.005 mole) of benzyloxycarbonylglycylguanidine in 5 ml of dimethylformamide was added to an aqueous solution of 0.7 g (0.005 mole) of ethyl glycinate hydrochloride, the pH of which was adjusted to 8 with alkali. The resultant clear solution was stirred at room temperature overnight and then evaporated on a water bath (40°) under reduced pressure (0.4 mm Hg). The residue was treated with water until crystallization occurred, then filtered, and air dried to yield 1.35 g (90%) of white solid which was recrystallized from ethyl acetate and melted at 80° (lit. m.p. 80° (4)).

Anal. Calcd. for $C_{14}H_{18}N_2O_5$: C, 57.1; H, 6.1. Found: C, 57.0; H, 6.2.

Similarly prepared were the following.

Ethyl Hippurylglycinate

This was obtained in 76% yield. It was recrystallized from water and melted at 117° (lit. m.p. 117° (5)).

Anal. Calcd. for $C_{13}H_{16}N_2O_4$: C, 59.1; H, 6.1. Found: C, 59.0; H, 6.2.

*Ethyl Benzyloxycarbonyl-*DL*-alanylglycylglycinate*

This was obtained in 50% yield. It was recrystallized from ethanol–water and melted at 110° (lit. m.p. 113° (6)).

Anal. Calcd. for $C_{17}H_{23}N_3O_6$: C, 55.9; H, 6.3. Found: C, 56.0; H, 6.4.

*Ethyl Formyl-*L*-valylglycinate*

This was obtained in 71% yield. It was recrystallized from ethyl acetate – petroleum ether and melted at 155° (lit. m.p. 156–157° (7)).

Anal. Calcd. for $C_{10}H_{18}N_2O_4$: C, 52.2; H, 7.8; N, 12.2. Found: C, 52.1; H, 7.9; N, 12.4.

*Ethyl Formyl-*L*-phenylalanylglycinate*

This was obtained in 82% yield. It was recrystallized from water and melted at 132°; $[\alpha]_D^{25}$ +4.6° (*c*, 1.6 in absolute ethanol) (lit. m.p. 131–132°; $[\alpha]_D^{26}$ +4.4° (7)).

Anal. Calcd. for $C_{14}H_{18}N_2O_4$: C, 60.5; H, 6.5; N, 10.1. Found: C, 60.3; H, 6.6; N, 10.6.

*Ethyl Tosyl-*L*-prolylglycinate*

This was obtained in 68% yield. It was recrystallized from hexane – ethyl acetate (2:1) and melted at 84–86°; $[\alpha]_D^{25}$ −115.8° (*c*, 4.5 in absolute ethanol).

Anal. Calcd. for $C_{16}H_{22}N_2O_5S$: C, 54.3; H, 6.2; N, 7.9. Found: C, 54.4; H, 6.1; N, 8.0.

SYNTHESIS OF 5-BENZAMIDO-5-DEOXY-D-XYLOPYRANOSE

M. S. Patel and J. K. N. Jones

The synthesis of the *N*-acetyl (1, 2) (I, R = $COCH_3$) and the *N*-benzyl (3) (I, R = CH_2Ph) derivatives of 5-amino-5-deoxy-D-xylopyranose (4) (I, R = H) and of the corresponding furanose compounds has been described (1–4). Recently we attempted the preparation by reported procedures of the acetobromo derivative of 5-acetamido-5-deoxy-D-xylopyranose (I, R = $COCH_3$) but were unsuccessful. The synthesis of the benzamido derivative of 5-amino-5-deoxy-D-xylopyranose (I, R = COPh) was therefore undertaken in the hope that this would yield, after *O*-benzoylation, a benzoylbromo sugar.

SYNTHESIS OF 5-BENZAMIDO-5-DEOXY-D-XYLOPYRANOSE

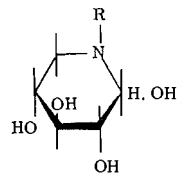
M. S. Patel and J. K. N. Jones

The synthesis of the *N*-acetyl (1, 2) (I, R = $COCH_3$) and the *N*-benzyl (3) (I, R = CH_2Ph) derivatives of 5-amino-5-deoxy-D-xylopyranose (4) (I, R = H) and of the corresponding furanose compounds has been described (1–4). Recently we attempted the preparation by reported procedures of the acetobromo derivative of 5-acetamido-5-deoxy-D-xylopyranose (I, R = $COCH_3$) but were unsuccessful. The synthesis of the benzamido derivative of 5-amino-5-deoxy-D-xylopyranose (I, R = COPh) was therefore undertaken in the hope that this would yield, after *O*-benzoylation, a benzoylbromo sugar.

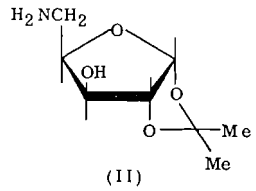
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

Also, it was of interest to compare the effect of the presence of a *N*-benzoyl group in 5-amino-5-deoxy-D-xylopyranose on the ratio of the pyranose and furanose forms of I, R = COPh.

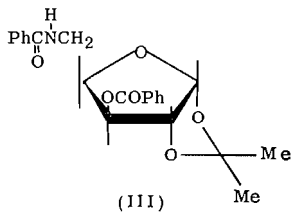
5-Amino-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (II) was prepared from D-xylose by an improved procedure (5). On treatment with an excess of benzoyl chloride in 10% aqueous sodium hydroxide it readily yielded crystalline 5-benzamido-3-*O*-benzoyl-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (III) in 92% yield. The latter, on treatment with a catalytic amount of sodium methoxide in methanol, yielded 5-benzamido-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (IV) in 82.5% yield (based on compound II). On treatment with benzoyl chloride (1.1 moles) in pyridine, compound IV gave III in 25% yield. Hydrolysis of IV with an acidic ion-exchange resin yielded 5-benzamido-5-deoxy-D-xylopyranose (I, R = COPh) (51% yield) as the major product in equilibrium with 5-benzamido-5-deoxy-D-xylofuranose (V). No other product was detected by chromatography (8).



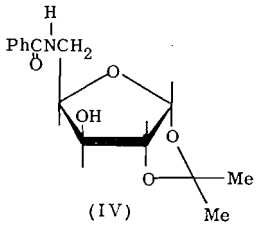
(I)



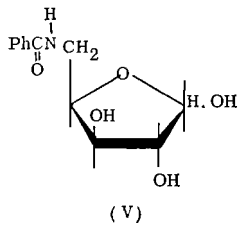
(II)



(III)



(IV)



(V)

Cellulose column chromatography of the above mixture gave compounds V and I, R = COPh. One of these (I, R = COPh) was obtained in a crystalline form, and the other was obtained as a pale yellow chromatographically uniform syrup which could not be crystallized. The infrared spectrum of this syrup showed characteristic absorption caused by the presence of OH, NH, and an aromatic ring. The results of periodate oxidation in unbuffered aqueous solution also indicated that the compound possessed the structure V. The compound was, therefore, 5-benzamido-5-deoxy-D-xylofuranose. The crystalline compound (I, R = COPh) showed no NH band in its infrared spectrum and the results of periodate oxidation in unbuffered aqueous solution were consistent with the pyranose structure.

EXPERIMENTAL

Apparatus, Methods, and Material

Solutions were concentrated under reduced pressure below 40° with a rotatory vacuum-type evaporator. Melting points were determined on a Fisher–Johns melting point apparatus. Optical rotations were measured at 20 ± 3° with a Hilger standard polarimeter. Infrared spectra were measured with a Perkin–Elmer model 21 spectrophotometer. Paper chromatography was performed by the descending method at room temperature on Whatman No. 1 filter paper in the following solvent system (v/v/v): 1-butanol – ethanol – water (3:1:1). Sugars were detected on paper chromatograms by the following spray reagents: (*i*) alkaline silver nitrate (6); (*ii*) *p*-anisidine hydrochloride (7); (*iii*) modified ceric ammonium nitrate reagent (8); (*iv*) orcinol – trichloroacetic acid (ketose spray) (9).

Rates of movement of the sugars on paper chromatograms are given relative to that of L-rhamnose. Thin-layer chromatography was carried out on silica gel G supplied by Research Specialities Company, Richmond, California. Benzene–isopropanol (2:1) was used as eluent. The developed plates were dried in air, sprayed with concentrated sulfuric acid, and then heated in an oven at about 150°. Organic microanalyses were performed by Dr. C. Daessle, Montreal.

Periodate Oxidation

The compound under examination (10–15 mg) was dissolved in water containing 0.3 *M* sodium metaperiodate solution (1 ml). The total volume was made up to 25 ml with additional water. A blank was prepared with 0.3 *M* sodium metaperiodate (1 ml), which was made up to 25 ml with water. The solutions were stored in the dark at room temperature. Aliquots (2 ml) were removed at intervals from each of the two solutions for the determination of periodate uptake (11). Formic acid production was determined by addition of ethylene glycol (3 ml) to an aliquot portion (2 ml), followed by titration after 10 min with 0.01 *N* sodium hydroxide, with phenolphthalein as indicator. The results are summarized in Table I. (No formaldehyde was detected in either *a* or *b* by the chromotropic acid method (12).)

TABLE I

(*a*) 5-Benzamido-5-deoxy-D-xylofuranose (V)						
Time (h)	0.55	1.35	7.0	14.00	28.00	48.00
Periodate (moles/mole)	1.18	1.64	1.68	1.70	1.82	1.88
Formic acid (moles/mole)	0.48	0.96	1.22	1.31	1.5	1.53
(*b*) 5-Benzamido-5-deoxy-D-xylopyranose (I, R = COPh)						
Time (h)	1.00	6.00	8.00	24.00	48.00	
Periodate (moles/mole)	1.50	2.48	2.71	2.81	2.84	
Formic acid (moles/mole)	1.00	1.65	1.85	2.20	2.40	

5-Amino-5-deoxy-1,2-O-isopropylidene-D-xylofuranose (II) (Modified Procedure of Szarek and Jones (5))

Raney nickel (10) (10 g) was added to a solution of 5-azido-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (10.0 g) (3) in methanol (250 ml) and the mixture was shaken overnight. Fresh catalyst (15 g) was then introduced, and after being shaken for an additional 6.0 h the solution was filtered and concentrated to give a crystalline product (5.0 g). This material could be recrystallized readily from ether, yielding crystals of m.p. 102–110°. The substance is highly hygroscopic, and satisfactory analytical results were not obtained. The infrared spectrum in chloroform showed absorption at 3 350 cm^{-1} (OH and NH) and absorption at 1 382 and 1 392 cm^{-1} (the isopropylidene group), but was devoid of azide absorption.

5-Benzamido-3-O-benzoyl-5-deoxy-1,2-O-isopropylidene-D-xylofuranose

To a solution of 5-amino-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (3.5 g) in 10% aqueous sodium hydroxide (50 ml) was added excess benzoyl chloride (7 ml). After a few minutes of vigorous shaking a solid product separated; this was dissolved in chloroform (25 ml) and the solution was washed successively with aqueous sodium hydrogen carbonate and with water, and then dried ($MgSO_4$). Concentration of the filtered solution gave a solid (6.8 g, 92%), which was crystallized from benzene–petrol (b.p. 40–60°) as fine needles of m.p. 148–149° and $[\alpha]_D$ −64° (*c*, 1.2 in chloroform). The infrared spectrum in chloroform showed absorptions at 1 665 cm^{-1} (the amide-I band) and 1 730 cm^{-1} (ester carbonyl stretching), absorptions at 1 460 and 1 495 cm^{-1}, 1 590 and 1 610 cm^{-1} attributable to the aromatic ring, and a doublet at 1 382 and 1 390 cm^{-1} (the isopropylidene group), but was devoid of OH absorption.

Anal. Calcd. for $C_{22}H_{23}NO_6$: C, 66.5; H, 5.8; N, 3.5. Found: C, 66.8; H, 6.0; N, 3.45.

5-Benzamido-5-deoxy-1,2-O-isopropylidene-D-xylose (IV)

To a solution of 5-benzamido-3-*O*-benzoyl-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (0.33 g) in absolute methanol (15 ml) was added a catalytic amount of metallic sodium. The reaction solution was allowed to stand at room temperature for 2 h with occasional shaking. It was then poured onto ice, and after the ice had melted the solution was concentrated to one-half the initial volume and then extracted

with chloroform. The combined chloroform extracts were washed with water, dried ($MgSO_4$), and filtered, and the filtrate was concentrated to a syrup (0.255 g) which crystallized immediately. Recrystallization from benzene–petrol (b.p. 40–60°) gave needles (0.225 g, 98.4%) of m.p. 163–163.5° and $[\alpha]_D$ +15° (*c*, 1.23 in CH_3OH). The infrared spectrum in chloroform showed absorptions at 3 485 cm^{-1} attributable to OH, at 3 400 cm^{-1} attributable to NH, at 1 650 cm^{-1} (the amide-I band), at 1 530 cm^{-1} (the amide-II band), aromatic absorption at 1 610, 1 585, 1 495, and 1 460 cm^{-1}, a doublet at 1 380 and 1 385 cm^{-1} (isopropylidene group, and showed the absence of an ester.

Anal. Calcd. for $C_{15}H_{19}NO_5$: C, 61.4; H, 6.5; N, 4.8. Found: C, 61.4; H, 6.4; N, 5.0.

Benzoylation of IV

5-Benzamido-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (3.4 g) in pyridine (10 ml) was treated with benzoyl chloride (1.1 moles) and the mixture was left at room temperature overnight. Water was then added to the solution and the mixture was extracted with chloroform (3 × 30 ml). The solution was washed successively with dilute sulfuric acid, with sodium bicarbonate solution, and with water. The dried chloroform solution was evaporated and the product recrystallized from benzene–petrol (40–60°). The yield of purified product was 1.95 g. It had m.p. 148°, identical with the product (III) described above.

Hydrolysis of 5-Benzamido-5-deoxy-1,2-O-isopropylidene-D-xylofuranose (IV)

To an aqueous suspension (100 ml) of 5-benzamido-5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (1.345 g) was added Rexyn 50 (H form) (Fisher Scientific Company) (ca. 5.0 g). The reaction mixture was stirred at 75° until all the solid had dissolved (ca. 3 h). Rexyn 50 was removed by filtration and the filtrate was stirred with a small quantity of Duolite A-4 (OH form) to remove acidity. The filtered solution was concentrated to yield a colorless syrup (1.109 g) which was examined on paper chromatograms as well as by thin-layer chromatography. Sprays *i* and *ii* both showed the presence of components on paper chromatograms at R_{rh} 1.4 (I, R = COPh) and 2.0 (V). No unchanged starting material was detected either on paper chromatograms (spray *iii*) or by thin-layer chromatography. The syrup was placed on a cellulose column (54 × 2.5 cm) and irrigated with pure 1-butanol. Fractions (3 ml) were collected automatically. Chromatographic examination of the fractions showed that a partial separation of the two components (0.14 g of V and 0.20 g of I, R = COPh) had been achieved. The unresolved mixture was refractionated using the same experimental conditions. Complete separation was then obtained. The two components (I, R = COPh and V) of the hydrolysate were obtained in a chromatographically pure state.

(a) 5-Benzamido-5-deoxy-D-xylofuranose (V)

This component was obtained from the eluate as a yellow syrup (0.218 g) which could not be crystallized. The compound had $[\alpha]_D^{20}$ +19.2° (*c*, 0.8 in methanol) and R_{rh} 2.0. The infrared spectrum (thin film on KBr) showed characteristic absorption caused by OH at 3 310 cm^{-1}, by NH at 1 557 cm^{-1}, and by the aromatic ring at 1 460, 1 495, 1 590, and 1 610 cm^{-1}.

(b) 5-Benzamido-5-deoxy-D-xylopyranose (I, R = COPh)

This component was obtained from the eluent above as a white crystalline solid (0.6 g, 51.7%). It crystallized from methanol–ether with 1 molecule of methanol as a solvent of crystallization and had an indefinite melting point (m.p. 94–102°), $[\alpha]_D^{20}$ −11.5° (*c*, 0.69 in methanol), and R_{rh} 1.4. The infrared spectrum of this material (0.8% in KBr) showed strong absorption at 3 310 cm^{-1} attributable to OH, strong absorption at 1 625 cm^{-1} caused by *N*-benzoyl (amide-I), aromatic absorption at 1 475, 1 495, and 1 590 cm^{-1}, but no absorption caused by NH.

Anal. Calcd. for $C_{12}H_{15}NO_5 \cdot CH_3OH$: C, 55.7; H, 1.9; N, 5.0. Found: C, 55.6; H, 7.1; N, 5.1.

GLYCOSIDATION OF SUGARS
III. GAS–LIQUID CHROMATOGRAPHY OF THE METHYL GLYCOSIDES OF D-GALACTOSE, D-GLUCOSE, AND D-MANNOSE AS THEIR TRIMETHYLSILYL ETHERS[1]

V. SMIRNYAGIN,[2] C. T. BISHOP, AND F. P. COOPER

The previous paper (1) in this series described a study of the kinetics of methanolysis of the four D-pentoses. As a prelude to extending this work to the hexoses it was necessary to find methods for analyzing the methyl hexosides by gas–liquid chromatography. The present communication describes the gas–liquid chromatographic separation of the four methyl glycosides of each of the three aldohexoses, D-galactose, D-glucose, and D-mannose.

Unsubstituted methyl glycosides are considerably less volatile than many other derivatives in which some of the hydroxyl groups of the sugar ring are substituted by ester or ether groups. Nevertheless, gas–liquid chromatography of a number of unsubstituted methyl glycosides has been described (2, 3). However, the conditions required for these separations were not sufficiently selective to resolve the four isomeric glycosides of a single monosaccharide. In the previous studies in this series (1, 4) the methyl glycosides were *O*-methylated or *O*-acetylated to make them sufficiently volatile for analysis by gas–liquid chromatography. In the present study it was found that the *O*-trimethylsilyl derivatives of the methyl hexosides could be resolved better than either the *O*-acetyl or the *O*-methyl derivatives. The use of *O*-trimethylsilyl derivatives has the advantage of ease of preparation and simple recovery of the original compound by a very mild hydrolysis (5). The separations described here may therefore also be used on a preparative scale to provide pure samples of individual methyl glycosides for spectroscopic examination or studies of kinetics of hydrolysis.

The retention times of the methyl tetra-*O*-trimethylsilyl hexosides and of the trimethylsilyl tetra-*O*-trimethylsilyl hexosides, relative to the fastest moving component in each series, are shown in Table I. Three column packings were used and each required a different column temperature for optimum resolution. The crystalline hexoses each gave only one peak after trimethylsilylation; it is not known whether these single peaks contained more than one anomer or ring form. However, it is likely that the hexoses underwent trimethylsilylation before equilibration in the pyridine solution. If this was so, then the single peaks for each hexose must represent the anomeric species present in the common crystalline form of the sugar. This is in agreement with the results of Sweeley *et al.* (6), who found that "the products obtained from pure single anomers of pentoses and hexoses generally show a single peak on gas chromatography though, in some cases, small amounts of another anomeric form may be apparent. In general, anomerizations occurring in pyridine during preparation of the trimethylsilyl derivative are remarkably minimal."

The four methyl D-mannosides were well resolved on columns *a* or *b*, with the latter providing slightly better separation. Similarly, the four methyl D-glucosides were resolved on columns *b* or *c* but the separation was significantly improved on the latter column. The four methyl D-galactosides could not be completely resolved on a single column. Thus, on columns *a* and *b* methyl α-D-galactopyranoside and methyl α-D-galactofuranoside run together. On column *c* it is the methyl β-D-galactofuranoside and methyl α-D-galactopyranoside that are not separated. Successive separations on columns *a* and *c* or *b* and *c*

TABLE I

Relative retention times of *O*-trimethylsilyl derivatives of methyl D-hexosides and of hexoses

Methyl glycoside and hexose	Column:*		
	a	*b*	*c*
β-D-Galactofuranoside	*1.00*	1.16	*1.00*
D-Galactose	1.10	*1.00*	1.13
α-D-Galactopyranoside	1.22	1.42	1.05
α-D-Galactofuranoside	1.28	1.44	1.16
β-D-Galactopyranoside	1.65	1.80	1.43
β-D-Glucofuranoside	—	*1.00*	*1.00*
α-D-Glucofuranoside	—	1.09	1.10
D-Glucose	—	1.16	1.32
α-D-Glucopyranoside	—	1.79	1.52
β-D-Glucopyranoside	—	1.81	1.71
D-Mannose	*1.00*	*1.00*	—
α-D-Mannopyranoside	1.16	1.41	—
β-D-Mannopyranoside	1.51	1.74	—
α-D-Mannofuranoside	1.89	2.25	—
β-D-Mannofuranoside	2.29	2.69	—

*Carrier gas was argon at a flow rate of 100 ml/min; β-ionization detector. Columns were straight glass tubes (120 × 0.5 cm) and were packed with—*a*: 10% (w/w) of neopentylglycolsebacate polyester on acid-washed Chromosorb W (100–120 mesh) (temp. 150 °C); *b*: 15% (w/w) of polyphenyl ether (*m*-bis-(*m*-phenoxyphenoxy) benzene) on acid-washed Chromosorb W (100–120 mesh) (temp. 175 °C); *c*: 10% (w/w) of Carbowax 6000 on acid-washed Chromosorb W (100–120 mesh) (temp. 140 °C).

are therefore required for the analysis of each component. Figure 1, A–D, shows the separations obtained. Individual glycosides, prepared and characterized as described below, were used to establish the identities of the peaks. There was no evidence of anomerization or change in ring size during trimethylsilylation or during gas–liquid chromatography.

EXPERIMENTAL

A Pye Argon chromatograph was used for gas–liquid chromatography. Methyl glycosides were prepared by standard methods (7) and had physical constants in agreement with the literature values.

(*a*) Methyl α-D-galactofuranoside, m.p. 92–93 °C, $[\alpha]_D^{24}$ +104° (*c*, 2 in water). Reported (8), m.p. 91–92 °C, $[\alpha]_D^{20}$ +104° (*c*, 1 in water).

(*b*) Methyl β-D-galactofuranoside, m.p. 66–67 °C, $[\alpha]_D^{24}$ −113.5° (*c*, 3 in water). Reported (8), m.p. 69 °C, $[\alpha]_D^{20}$ −112° (*c*, 3 in water).

(*c*) Methyl α-D-galactopyranoside, m.p. 115–117 °C, $[\alpha]_D^{24}$ +192° (*c*, 2 in water). Reported (9), m.p. 114–116 °C, $[\alpha]_D^{20}$ +196° (in water).

(*d*) Methyl β-D-galactopyranoside, m.p. 176–179 °C, $[\alpha]_D^{20}$ ±0° (*c*, 2 in water). Reported (9), m.p. 178 °C, $[\alpha]_D^{20}$ ±0° (in water).

(*e*) Methyl α-D-glucofuranoside; this compound was prepared by borohydride reduction of methyl α-D-glucofuranosidurono-6,3-lactone, m.p. 145–147 °C, $[\alpha]_D^{24}$ +145° (*c*, 0.5 in water). Reported (10), m.p. 148 °C, $[\alpha]_D$ +147° (in water). The reduced product, after trimethylsilylation, showed only one peak on gas–liquid chromatography; the single peak had the same retention time as the second fastest peak of the four products obtained by methanolysis of D-glucose.

(*f*) Methyl β-D-glucofuranoside; this compound was prepared by borohydride reduction of methyl β-D-glucofuranosidurono-6,3-lactone, m.p. 138–139 °C, $[\alpha]_D^{24}$ −59° (*c*, 2.4 in water). Reported (10), m.p. 140–141 °C, $[\alpha]_D$ −58° (in water). The reduced, trimethylsilylated product gave a single peak on gas–liquid chromatography; the single peak corresponded to the fastest moving peak of the four components obtained by methanolysis of D-glucose.

(*g*) Methyl α-D-glucopyranoside, m.p. 166–167 °C, $[\alpha]_D^{27}$ +159° (*c*, 2.0 in water). Reported (11), m.p. 165–166 °C, $[\alpha]_D^{20}$ +158° (in water).

(*h*) Methyl β-D-glucopyranoside, m.p. 107–110 °C, $[\alpha]_D^{24}$ −33.7° (*c*, 2.1 in water). Reported (12), m.p. 108–110 °C, $[\alpha]_D^{20}$ −34.2° (in water).

(*i*) Methyl α-D-mannofuranoside, m.p. 120–121 °C, $[\alpha]_D^{24}$ +111° (*c*, 1.3 in water). Reported (13), m.p. 118–119 °C, $[\alpha]_D^{20}$ +113° (*c*, 1 in water).

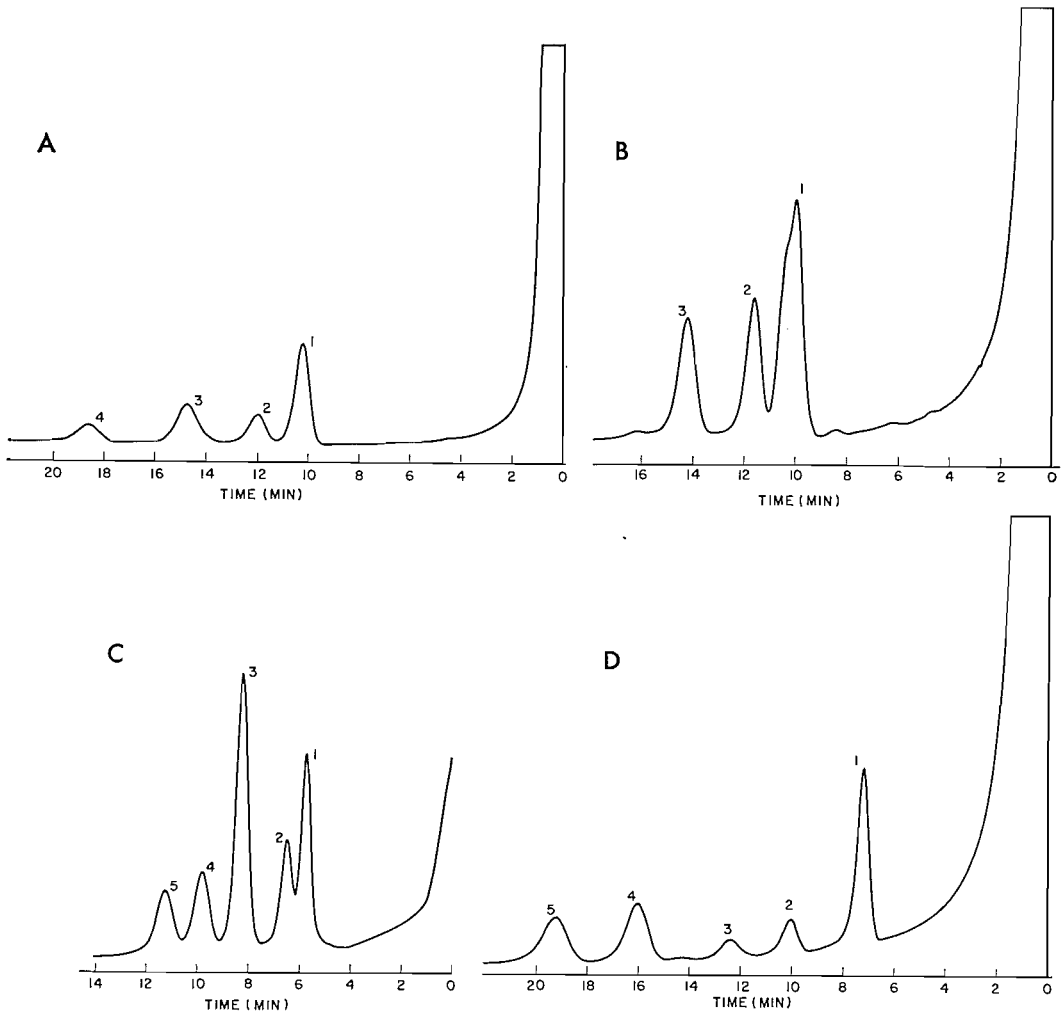

FIG. 1. Gas–liquid chromatograms of methyl tetra-*O*-trimethylsilyl-D-hexosides. A: Methyl D-galactosides and D-galactose on column *b*. Peaks: 1, D-galactose; 2, methyl β-D-galactofuranoside; 3, methyl α-D-galactopyranoside and methyl α-D-galactofuranoside; 4, methyl β-D-galactopyranoside. B: Methyl D-galactosides on column *c*. Peaks: 1, methyl β-D-galactofuranoside and methyl α-D-galactopyranoside; 2, methyl α-D-galactofuranoside; 3, methyl β-D-galactopyranoside. C: Methyl D-glucosides on column *c*. Peaks: 1, methyl β-D-glucofuranoside; 2, methyl α-D-glucofuranoside; 3, D-glucose; 4, methyl α-D-glucopyranoside; 5, methyl β-D-glucopyranoside. D: Methyl D-mannosides on column *b*. Peaks: 1, D-mannose; 2, methyl α-D-mannopyranoside; 3, methyl β-D-mannopyranoside; 4, methyl α-D-mannofuranoside; 5, methyl β-D-mannofuranoside.

(*j*) Methyl β-D-mannofuranoside; this compound could not be obtained in a crystalline form. Gas–liquid chromatography of its trimethylsilyl ether showed the presence of only one component which differed in retention time from the other three methyl D-mannosides; $[\alpha]_D^{24}$ −110° (*c*, 1 in water). Reported (14), m.p. 47°, $[\alpha]_D^{20}$ −107° (in water).

(*k*) Methyl α-D-mannopyranoside, m.p. 192–193 °C, $[\alpha]_D^{24}$ +80° (*c*, 5 in water). Reported (15), m.p. 193–194 °C, $[\alpha]_D^{20}$ +79.2° (in water).

(*l*) Methyl β-D-mannopyranoside isopropyl alcoholate, m.p. 74–76 °C, $[\alpha]_D^{24}$ −60° (*c*, 1.0 in water). Reported (16), m.p. 74–75 °C, $[\alpha]_D^{20}$ −53.3° (*c*, 4 in water).

Trimethylsilyl derivatives were prepared by the method of Sweeley *et al.* (6); reagents (pyridine, 1 ml; hexamethyldisilazane, 0.2 ml; and trimethylchlorosilane, 0.1 ml) were added to the crystalline hexoses (10 mg) successively and with a minimum of delay so that there was little time for anomerization.

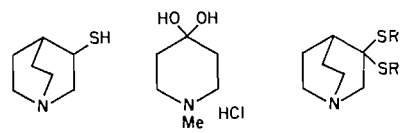
3-MERCAPTOQUINUCLIDINE[1]

K. B. Shaw

This note describes the preparation of 3-mercaptoquinuclidine (I), which was required in connection with another problem. The usual methods (1) for the synthesis of thiols involving the reaction of a halide with a sulfur-containing compound, e.g. potassium thiolacetate, sodium hydrosulfide, or thiourea, failed in the present case, since 3-chloroquinuclidine was quite inert towards nucleophilic substitution by these reagents under a variety of conditions. Inspection of a model of 3-chloroquinuclidine indicated that attainment of the transition state in a S_N2 reaction is sterically improbable (similar to the situation in bicyclo[2.2.2]octane compounds (2)). The failure of reactions under conditions which would be expected to promote a S_N1 reaction can be attributed to the rigid structure of the quinuclidine molecule, which prevents the intermediate carbonium ion that would be formed from becoming planar.



I II III, R = H
IV, R = COMe

Hence a route to I not involving displacement of a substituent in the 3-position of the quinuclidine ring was required, and the method used (3) for the preparation of 1-methyl-4-mercaptopiperidine seemed most promising.

It was shown by Lyle *et al.* (4) that, when 1-methyl-4-piperidone was dissolved in dilute hydrochloric acid and the solution evaporated to dryness, the salt crystallized with 1 molecule of water. The infrared spectrum of the hydrate proved that the structure

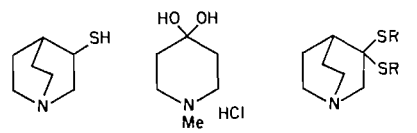
3-MERCAPTOQUINUCLIDINE[1]

K. B. Shaw

This note describes the preparation of 3-mercaptoquinuclidine (I), which was required in connection with another problem. The usual methods (1) for the synthesis of thiols involving the reaction of a halide with a sulfur-containing compound, e.g. potassium thiolacetate, sodium hydrosulfide, or thiourea, failed in the present case, since 3-chloroquinuclidine was quite inert towards nucleophilic substitution by these reagents under a variety of conditions. Inspection of a model of 3-chloroquinuclidine indicated that attainment of the transition state in a S_N2 reaction is sterically improbable (similar to the situation in bicyclo[2.2.2]octane compounds (2)). The failure of reactions under conditions which would be expected to promote a S_N1 reaction can be attributed to the rigid structure of the quinuclidine molecule, which prevents the intermediate carbonium ion that would be formed from becoming planar.



I II III, R = H
IV, R = COMe

Hence a route to I not involving displacement of a substituent in the 3-position of the quinuclidine ring was required, and the method used (3) for the preparation of 1-methyl-4-mercaptopiperidine seemed most promising.

It was shown by Lyle *et al.* (4) that, when 1-methyl-4-piperidone was dissolved in dilute hydrochloric acid and the solution evaporated to dryness, the salt crystallized with 1 molecule of water. The infrared spectrum of the hydrate proved that the structure

[1]*Issued as D.C.B.R.L. Report No. 455A.*

is as shown in II. Similar behavior was observed with 1-methyl-3-piperidone. The formation of the *gem*-diol (II) led Barrera and Lyle (3) to believe that hydrogen sulfide might add similarly to the carbonyl group of 1-methyl-4-piperidone to give a *gem*-dithiol, which could be reduced to the thiol; this was shown to be the case. However, it has been stated more recently by Lyle *et al.* (5) that a similar route to 1-methyl-3-mercaptopiperidine was unsuccessful.

3-Quinuclidinone was not available to us and its preparation from the available 3-quinuclidinol was investigated. Although chromic acid is the preferred reagent for the oxidation of secondary alcohols to ketones, the method proved impracticable in this case, primarily because of difficulties in separating the product from inorganic material; the oxidation was achieved finally with potassium permanganate in acetone solution. It was found that 3-quinuclidinone did not form a stable hydrate under the same conditions that the piperidones did; the salt showed no hydroxyl band in the infrared but did show a strong carbonyl band at 1 748 cm^{-1}. However, hydrogen sulfide did react with 3-quinuclidinone in isopropanol solution to give 3,3-dimercaptoquinuclidine (III). Clearly, the success or failure of a ketone to form a stable dithiol does not depend upon whether or not the ketone forms a stable hydrate by addition of water to the carbonyl group. Other examples of this are available; acetone, 3-pentanone, and cyclohexanone, for instance, form stable dithiols (6) but their hydrates are not isolable.

The reaction of hydrogen sulfide with 3-quinuclidinone in isopropanol solution was much slower than that with 1-methyl-4-piperidone, and it was necessary to increase the reaction time from about 6 h to 40 h to obtain a similar yield (65%) of product. The reaction was not accelerated by variations in solvent or temperature. The dithiol, a white solid which separated from solution as the reaction proceeded, had an onion-like odor (6), liberated hydrogen sulfide in water, and with alcoholic lead acetate solution gave a yellow color which darkened rapidly (6). It was not a hydrate (infrared), as was the case with 1-methyl-4,4-dimercaptopiperidine, and could not be recrystallized; however, the presence of two sulfhydryl groups was shown by reaction with acetic anhydride to give a diacetate (IV) (characterized as the picrate), and the two groups were shown to be on the same carbon atom (6) by reaction with 2,4-dinitrophenylhydrazine in hydrochloric acid to give 3-quinuclidinone 2,4-dinitrophenylhydrazone hydrochloride (identical (infrared) with an authentic sample prepared from 3-quinuclidinone). The free bases of these two derivatives were also identical.

Reduction of 3,3-dimercaptoquinuclidine with sodium borohydride in isopropanol solution, as in the preparation of 1-methyl-4-mercaptopiperidine from 1-methyl-4,4-dimercaptopiperidine (3), gave no identifiable product but, with a modified work-up, 3-mercaptoquinuclidine was obtained in about 50% yield. A by-product of the reaction was probably the corresponding disulfide (but see ref. 7) formed by the oxidation of the thiol in the alkaline medium, although the reaction had been worked up under nitrogen as far as possible.

EXPERIMENTAL

3-Quinuclidinone

Acetone (250 ml) containing finely ground potassium permanganate (110 g) was heated under reflux beneath a thimble containing 3-quinuclidinol (25.4 g). The extraction was complete in ca. 30 min and the mixture was heated under reflux for a further 2 h. The solid was separated (Celite) and the acetone removed *in vacuo*, leaving a white crystalline solid (10–13 g; 40–52%), m.p. 145–147.5° (sealed tube) (lit. 147–148° (8)).

The 2,4-dinitrophenylhydrazone hydrochloride, prepared in 95% ethanol containing concentrated hydrochloric acid, was crystallized several times from aqueous ethanol and was obtained as yellow needles, m.p. >250°, but a satisfactory elemental analysis was not obtained. The hydrochloride was dissolved in hot water and the solution made alkaline with sodium carbonate. The copious precipitate was filtered off,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

dried, and crystallized several times from ethanol to give 3-quinuclidinone 2,4-dinitrophenylhydrazone as orange needles, m.p. 244–245°.

Anal. Calcd. for $C_{13}H_{15}N_5O_4$: C, 51.14; H, 4.95; N, 22.94. Found: C, 51.36; H, 5.04; N, 23.13.

3,3-Dimercaptoquinuclidine

3-Quinuclidinone (36 g) in dry isopropanol (85 ml) was stirred, and hydrogen sulfide was bubbled into the solution for 20 h. The solid was filtered off and dried (23 g), and the filtrate was treated with hydrogen sulfide for a further 20 h to yield an additional 9.3 g (64% total) of white solid, m.p. 94–99° decomp., after reddening from 60° (sealed tube).

3,3-Dimercaptoquinuclidine Diacetate

A solution of the foregoing dithiol (3.5 g) in pyridine (20 ml) containing acetic anhydride (4 ml) was left at room temperature for 6 days and then concentrated to yield a deep red, viscous liquid. This was dissolved in ether (150 ml) and passed twice (air pressure) through a column (4.5 × 1.2 cm) of activated charcoal. Removal of the ether left a pale yellow liquid which soon began to darken. The picrate, after several crystallizations from ethanol, was obtained as yellow plates, m.p. 145–146°.

Anal. Calcd. for $C_{17}H_{20}N_4O_9S_2$: C, 41.80; H, 4.13; N, 11.47; S, 13.13; mol. wt. 488.5. Found: C, 41.76; H, 4.25; N, 11.38; S, 13.29; mol. wt. (ultraviolet) 497.

3-Quinuclidinone 2,4-Dinitrophenylhydrazone from 3,3-Dimercaptoquinuclidine

3,3-Dimercaptoquinuclidine (1.3 g) and 2,4-dinitrophenylhydrazine (1.48 g) in 95% ethanol (100 ml) containing concentrated hydrochloric acid (10 ml) were heated under reflux for 5 h and then left overnight. The yellow crystalline solid was separated, dried (2.28 g; 89%), and after several crystallizations from aqueous ethanol was obtained as yellow needles, m.p. >250°. As was the case with the hydrochloride prepared from 3-quinuclidinone, a satisfactory elemental analysis was not obtained. The free base, prepared from the hydrochloride as described above, was crystallized several times from ethanol and obtained as orange rods, m.p. and mixed m.p. with above sample 244–245°.

Anal. Calcd. for $C_{13}H_{15}N_5O_4$: C, 51.14; H, 4.95; N, 22.94. Found: C, 51.29; H, 5.14; N, 22.44.

3-Mercaptoquinuclidine

(*a*) 3,3-Dimercaptoquinuclidine (30 g) was added in portions to a stirred suspension of sodium borohydride (10 g) in isopropanol (200 ml). When the addition was complete the temperature was raised to 65° and maintained there for 2.5 h. The mixture was cooled, diluted with water (100 ml), acidified with concentrated hydrochloric acid (40 ml), and then taken to dryness, the resulting white solid being finally dried over calcium chloride *in vacuo* to constant weight (56 g). A portion of this solid was stirred at room temperature with absolute ethanol and filtered, and the ethanol removed, leaving a white solid which was then similarly treated with dry chloroform. The resulting white solid was crystallized 3 times from ethanol, giving white prisms of 3-mercaptoquinuclidine hydrochloride, m.p. 242–244.5° (sealed tube, heated from 180°), 97% thiol by iodine titration.

Anal. Calcd. for $C_7H_{14}ClNS$: C, 46.79; H, 7.85; N, 7.80; Cl, 19.73; S, 17.84. Found: C, 46.80; H, 7.63; N, 7.70; Cl, 19.78; S, 17.87.

The rest of the original solid (40 g) in water (100 ml) was stirred under nitrogen, made alkaline with sodium carbonate, and extracted with chloroform (7 × 50 ml). The combined extracts were dried ($MgSO_4$), the chloroform removed, and the residue distilled to give 3-mercaptoquinuclidine (7.1 g, 40% based on 40 g of solid used), b.p. 97–98° at 8 mm, 96% thiol by iodine titration, equiv. wt. 150 (calcd. 143). The picrate was crystallized from ethanol as yellow needles, m.p. 171–174°.

Anal. Calcd. for $C_{13}H_{16}N_4O_7S$: C, 41.93; H, 4.33; N, 15.05. Found: C, 41.80; H, 4.60; N, 15.05.

(*b*) 3,3-Dimercaptoquinuclidine (60 g) was reduced with sodium borohydride (20 g) in isopropanol (350 ml) as described above. After 2 h at 70° the isopropanol was removed, the partially solid residue dissolved in water (200 ml), and the cooled solution acidified with concentrated hydrochloric acid. The solution, under nitrogen, was then adjusted to pH 8.5–9 with sodium carbonate, more water (200 ml) was added to dissolve the solid that was present, and the solution was extracted with chloroform (6 × 100 ml). The combined extracts were dried ($MgSO_4$), the chloroform removed, and the residue distilled to give 3-mercaptoquinuclidine (22.9 g, 47%), b.p. 97–98° at 8 mm, 98% thiol by iodine titration. The product eventually solidified, m.p. 48–50°, thiol titration unchanged.

Anal. Calcd. for $C_7H_{13}NS$: C, 58.72; H, 9.15; N, 9.78; S, 22.35. Found: C, 58.60; H, 9.25; N, 9.74; S, 22.26; equiv. wt. 146.

ACKNOWLEDGMENTS

A gift of 3-quinuclidinol from the U.S. Army Chemical Research and Development Laboratories is gratefully acknowledged. Analyses were performed by Mr. J. G. Helie of these laboratories.

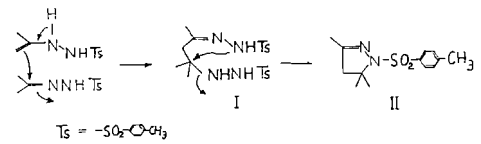
ON THE FORMATION OF A PYRAZOLINE FROM ACETONE TOLUENESULFONYL HYDRAZONE[1]

Y.-C. LIN AND G. JUST

When the tosylhydrazone of acetone, m.p. 136°, was heated to 160°, a vigorous reaction occurred. Chloroform extraction of the reaction product and crystallization gave, in about 10% yield, a crystalline, colorless compound, m.p. 162–163°. Analysis indicated that the elemental composition was $C_{13}H_{18}N_2O_2S$. The infrared spectrum showed absorption at 1 650 cm^{-1} (C=N), 1 605 cm^{-1} (aromatic), and 1 170 cm^{-1} (*p*-toluenesulfonyl group). The nuclear magnetic resonance spectrum[2] showed an A_2B_2 quartet centered at 7.73 p.p.m., and singlets at 2.63 (2H), 2.42 (3H), 1.95 (3H), and 1.45 (6H) p.p.m. The only structure compatible with these data is represented by II.



The same compound was also obtained by heating the *p*-toluenesulfonyl hydrazone of acetone, mesityl oxide, or ethyl acetoacetate in glacial acetic acid containing hydrochloric acid for 3–4 h at 90–100°.

A pyrazoline is known to be formed when the hydrazone of mesityl oxide is refluxed in acetic acid (1).

The reaction is not general. The *p*-toluenesulfonyl hydrazones of cyclopentanone, acetophenone, and acetaldehyde did not undergo the reaction. In the case of cyclohexanone, some pyrazoline was formed, but the yield was very low and the product that was obtained was impure.

SOLVENT DEPENDENCE OF CHEMICAL SHIFT AND COUPLING CONSTANTS IN *p*-NITROANISOLE

H. M. Hutton and T. Schaefer

A solvent dependence of geminal proton coupling constants has been found in a number of compounds (1–5). For example, in the vinyl halides they vary by as much as 100% and are roughly proportional to the reaction field of the medium (5). A 2% variation is found for the vicinal coupling constants in the vinyl halides (5) but a 30% variation is found in 1-chloro-2-ethoxyethylene (6)

For the following reasons, a solvent dependence of the proton coupling constants in substituted benzenes may be observable. Valence bond calculations (7) predict π-contributions of $+0.5$, -0.2, and $+0.2$ c/s to the ortho, meta, and para coupling constants, respectively, in the benzene molecule. If benzene were substituted with a strong electron acceptor, A, and a strong electron donor, D, then the quinoid structure

may contribute substantially to the ground state of the molecule. If so, the π-contribution to J_o (ortho coupling) would increase, and since J_o is probably positive (8), it would increase in magnitude. Similarly, the π-contribution to J_m (meta coupling) would decrease

SOLVENT DEPENDENCE OF CHEMICAL SHIFT AND COUPLING CONSTANTS IN *p*-NITROANISOLE

H. M. Hutton and T. Schaefer

A solvent dependence of geminal proton coupling constants has been found in a number of compounds (1–5). For example, in the vinyl halides they vary by as much as 100% and are roughly proportional to the reaction field of the medium (5). A 2% variation is found for the vicinal coupling constants in the vinyl halides (5) but a 30% variation is found in 1-chloro-2-ethoxyethylene (6)

For the following reasons, a solvent dependence of the proton coupling constants in substituted benzenes may be observable. Valence bond calculations (7) predict π-contributions of $+0.5$, -0.2, and $+0.2$ c/s to the ortho, meta, and para coupling constants, respectively, in the benzene molecule. If benzene were substituted with a strong electron acceptor, A, and a strong electron donor, D, then the quinoid structure

may contribute substantially to the ground state of the molecule. If so, the π-contribution to J_o (ortho coupling) would increase, and since J_o is probably positive (8), it would increase in magnitude. Similarly, the π-contribution to J_m (meta coupling) would decrease

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and J_m, being positive (9), should increase. Finally, J_p (para coupling) will probably decrease.

Now it is true that coupling constants also depend on the energy of excitation to triplet states, which the quinoid structure, or intramolecular charge-transfer state (10), is not. Nevertheless, it is possible that the energy of the triplet states will also be lowered on substitution and that stabilization of the quinoid structure by polar solvents could therefore also lead to a change in coupling constants.*

We chose *p*-nitroanisole (I), which is soluble in nonpolar as well as polar solvents and

I

contains strong acceptor and donor groups (12). The parameter most easily obtained from the loosely coupled A_2B_2 proton resonance spectrum of *p*-nitroanisole is $|J_o + J_p|$, which is equal to the separation of the two intense lines in either half of the symmetrical spectrum (13).† To obtain individual values of all three coupling constants, solution of fourth-order secular equations is necessary. Fitting the calculated and observed spectra introduces an additional error into the values of the individual coupling constants, i.e. while $|J_o + J_p|$ can be determined to an accuracy of, say, 0.05 c/s, the derived values of J_o and J_p will also have an accuracy of 0.05 c/s. $J_p = 0.23 \pm 0.05$ c/s for *p*-nitroanisole in cyclohexane (14). Since any variation of J_o is expected to be larger than that of J_p, we have at this stage determined only $|J_o + J_p|$.

TABLE I

Chemical shifts and coupling constants in c/s at 60 Mc/s of 5 mole % *p*-nitroanisole in various solvents

Solvent	ϵ*	Chemical shifts				$\lvert J_o + J_p \rvert$§
		Ortho†	Meta†	Ortho‡	Meta‡	
Cyclohexane‖	2.0	409.9	485.8	0	0	9.21±0.04

Acetronitrile	37	421.1	489.3	−11.2	−3.5	9.35±0.06 9.37±0.05¶

*Dielectric constant.
†To low field from internal tetramethylsilane.
‡Relative to shift in cyclohexane.
§Standard deviation of a minimum of 10 recordings is given.
‖Saturated solution, less than 5 mole %.
¶At 100 Mc/s.

In Table I are listed $|J_o + J_p|$ and the chemical shift, with respect to internal tetramethylsilane, of the ortho and meta protons of 5 mole % solutions of *p*-nitroanisole in a number of solvents with dielectric constants ranging from 2 to 37.‡ The high-field shift

The quinoid structure of p-nitrotoluene is stabilized by 15 kcal/mole in water as compared with the vapor (11).

†*It is true that the two major peaks in the half spectrum are multiple. In this molecule, however, the two meta couplings are equal (15) and J_p is among the smallest known (14). Under these circumstances it appears that the changes in internal shift with solvent will not account for the observed variation in the splitting. To check this point, the splitting of the major peaks in acetonitrile solution was measured independently at 100 Mc/s. The agreement with the results at 60 Mc/s is excellent (see Table I). We are grateful to a referee for stressing this point, of which we were aware. It may be that there are still grounds for doubt, but we hope that further work will dispel them.*

‡*The very high dielectric constants of some solvents (like hydrogen cyanide) are probably due to the internal arrangement of the solvent molecules and will probably not be reflected in the internal electric fields acting on the solute.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

was taken to be that of the ortho protons. This agrees with the substituent parameters (15) and also with the 0.1 to 0.2 c/s broadening of these resonance peaks, which is attributed to the coupling to the methoxy protons (15).

$|J_o + J_p|$ appears to be larger in acetonitrile and methanol than in cyclohexane. Thus, the difference between cyclohexane and acetonitrile solutions is 0.14 ± 0.10 c/s (0.16 ± 0.09 c/s if the 100 Mc/s result in acetonitrile is accepted). The increase in J_o may be somewhat offset by a smaller decrease in J_p. The larger values of $|J_o + J_p|$ tend to be associated with larger values of the dielectric constant of the medium, but it may well be true that the molecular properties of the solvent are as important as, or more important than, the dielectric constant, which is a bulk property. We are now improving the frequency–field stabilization of our spectrometer and intend to extend the measurements to other substituted benzenes and other solvents.

In Table I, it is seen that the solvent shifts of the protons meta to the nitro group are greater than those of the protons ortho to the nitro group. Since the dipole moment of the molecule is determined mainly by the nitro group (the dipole moment of nitrobenzene is 4.01 D while that of anisole is 1.30 D), the relative solvent shifts can be *qualitatively* understood in terms of the reaction field model (16). However, quantitatively, there are many discrepancies. For example, the solvent shift in acetone is larger than that in acetonitrile, yet the dielectric constant of the former is smaller. The solvent shift in benzene is presumably to be understood as a result of preferred orientations of solvent and solute molecules, such that the ring current effect is to high field. The benzene molecule appears to avoid the electron-rich region of the solute molecule (17). Further measurement of solvent shifts in substituted benzenes is in progress.

ACKNOWLEDGMENTS

PREPARATION OF ANTIDOTES FOR ANTICHOLINESTERASE POISONING III. ESTERS OF 1-ARYLCYCLOALKANECARBOXYLIC ACIDS[1]

J. H. PARKKARI, R. A. B. BANNARD, AND I. W. COLEMAN

In preceding papers of this series (1, 2) the preparation of several analogues of 2′-diethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride (Parpanit) and certain of their quaternary salts was described. These compounds were required for evaluation of their efficacy as substitutes for, or adjuncts to, atropine in the treatment of sarin poisoning (3–5). The preparation of fifteen additional analogues of Parpanit and four N-methyl-4′-piperidyl 1-arylcycloalkanecarboxylate hydrochlorides required for extension of these studies is reported herein. The compounds prepared and their properties are listed in Tables I to VI, and representative preparations are described in the Experimental section.

The majority of the Parpanit analogues (Table IV) was prepared by the interaction of potassium 1-phenylcyclopentanecarboxylate with the appropriate dialkylaminoalkyl chloride, followed by treatment with dry hydrogen chloride (method F) in ethanol (1, 6, 7). This was the most useful synthetic method when the requisite intermediate dialkylaminoalkyl chloride hydrochloride could be readily prepared, or when prepared, could be brought into reaction. 3′-Diethylaminopropyl 1-phenylcyclopentanecarboxylate hydrochloride, for example, was obtained in 62% yield from 3-diethylaminopropyl chloride and potassium 1-phenylcyclopentanecarboxylate, whereas the interaction of 3′-chloropropyl 1-phenylcyclopentanecarboxylate with diethylamine according to the general method of Weston (8) furnished only a 30% yield (method H).

The potassium salt method proved impractical for the synthesis of 3′-quinuclidinyl 1-phenylcyclopentanecarboxylate hydrochloride. 3-Quinuclidinyl chloride hydrochloride is readily prepared by the action of thionyl chloride upon 3-quinuclidinol (9). 3-Quinuclidinyl chloride (10), however, could not be induced to react with potassium 1-phenylcyclopentanecarboxylate, presumably because the rigidity of the ring system prevents the S_N1 reaction by inhibiting carbonium ion formation and also shields the 3-position from S_N2 attack. This compound was therefore prepared by interaction of 1-phenylcyclopentanecarbonyl chloride and 3-quinuclidinol in anhydrous benzene (cf. refs. 1, 8, 11–15; method K), or by transesterification of methyl 1-phenylcyclopentanecarboxylate with 3-quinuclidinol in toluene using a catalytic amount of sodium, followed by treatment with dry hydrogen chloride (cf. refs. 13, 14, 16; method J). Transesterification of 3-quinuclidinol with ethyl 1-phenylcyclopentanecarboxylate (17) was unsuccessful. 2′-*t*-Butylmethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochloride was prepared by the interaction of 2′-*t*-butylaminoethyl 1-phenylcyclopentanecarboxylate with ethyl iodide in benzene, followed by ion exchange (method G).

The N-methyl-4-piperidyl hydrochloride esters of 1-phenylcyclopentanecarboxylic, 1-phenylcyclobutanecarboxylic, 1-*p*-methylphenylcyclobutanecarboxylic, and 1-*p*-methoxyphenylcyclobutanecarboxylic acids were prepared by treatment of the appropriate acid chloride with N-methyl-4-piperidinol in anhydrous benzene (1, 8, 11–15; method K).

The alkylamino- and dialkylamino-ethanols required as intermediates (Table II) were prepared by the interaction of an amine and ethylene oxide (18–20; method B) or 2-chloroethanol (21, 22; method C), by the action of an alkyl halide on a 2-alkylaminoethanol

(1, 23, 24; method D), or by the reductive methylation of 2-ethylaminoethanol with formaldehyde and formic acid (24–26; method E). Salts of these aminoalcohols were prepared by standard methods for characterization purposes (Table III). The alkylamino- and dialkylamino-ethanols were converted into the corresponding chloride hydrochlorides by the action of thionyl chloride in benzene (1), from which the free bases were obtained by neutralization with aqueous potassium hydroxide and extraction (1) with ether.

The 1-arylcycloalkanecarbonyl chlorides (Table I) were prepared from the corresponding acids by treatment with thionyl chloride in anhydrous benzene (1; method A). Methyl and ethyl 1-phenylcyclopentanecarboxylates were prepared by interaction of the appropriate alcohol and 1-phenylcyclopentanecarbonyl chloride.

EXPERIMENTAL[2,3]

Method A: 1-Phenylcyclobutanecarbonyl Chloride

A solution of thionyl chloride (8 ml, 13.1 g, 0.11 mole) in sodium-dried benzene (15 ml) was added dropwise, with stirring, to a slurry of 1-phenylcyclobutanecarboxylic acid (7.05 g, 0.04 mole) in sodium-dried benzene (40 ml). The reaction mixture was heated under reflux, with stirring, for 4 h. Benzene and thionyl chloride were removed by distillation and the residue was fractionated, yielding 1-phenylcyclobutanecarbonyl chloride as a colorless, mobile oil; b.p. 66° at 0.15 mm; n_D^{25} 1.5395; 6.48 g (83%).

Preparation of 2-Alkylamino- and 2-Dialkylamino-ethanols

Method B: 2-t-Butylaminoethanol

2-*t*-Butylaminoethanol (b.p. 80° at 12 mm) was prepared in 78% yield by the method of Bortnick *et al.* (18).

Method C: 2-Diisobutylaminoethanol

A mixture of diisobutylamine (64.6 g, 0.50 mole) and 2-chloroethanol (40.3 g, 0.50 mole) was heated in a stainless steel bomb for 8 h at 110°. The cooled reaction mixture was dissolved in water, basified with 20% sodium hydroxide, and extracted with ether (3 × 100 ml). The extract was dried over anhydrous magnesium sulfate, and the ether was removed by distillation. Fractionation yielded a forerun consisting of unreacted starting materials, b.p. 51–57° at 28 mm, and 2-diisobutylaminoethanol, b.p. 100–101° at 18 mm; n_D^{25} 1.4334. Yield, 46.0 g (53%, 75% based upon reacted starting material).

Method D: 2-t-Butylethylaminoethanol

A solution of 2-*t*-butylaminoethanol (11.7 g, 0.10 mole) and ethyl iodide (46.8 g, 0.30 mole) in benzene (40 ml) was heated under reflux with stirring for 20 h. Massive precipitation occurred within the first hour. The precipitate was collected by filtration, washed with anhydrous ether, and dried *in vacuo*. Recrystallization from absolute ethanol – ether furnished N-*t*-butylethylaminoethanol hydriodide as colorless prisms, m.p. 162.5–163°. Yield, 23.1 g (85%). The hydriodide (20 g, 0.073 mole) was dissolved in water (100 ml), neutralized with solid sodium carbonate (to pH 9), and extracted with ether (1 × 50 ml; 3 × 25 ml). The

					Found	66.86	8.24	4.31	10.74

*All compounds were prepared by method K.

extract was concentrated, and dried over anhydrous magnesium sulfate, and the ether was removed by distillation. Fractionation of the residue gave 2-*t*-butylethylaminoethanol; b.p. 75–76° at 13 mm; n_D^{25} 1.4441. Yield, 6.40 g (60%).

Method E: 2-Ethylmethylaminoethanol

2-Ethylaminoethanol (35.7 g, 0.40 mole) was added dropwise, with stirring, to 88% formic acid (51.2 g, 1.00 mole) at 0°. Formaldehyde solution (37%; 45 ml, 0.60 mole) was added dropwise at room temperature and the solution was heated to 90° when vigorous ebullition occurred. Heating was discontinued until the reaction subsided and was then resumed at 95–98° for 8 h. Hydrochloric acid (4 *N*, 100 ml) was added to the cooled solution, which was then evaporated to dryness *in vacuo*. The viscous residue was dissolved in water (60 ml), basified with sodium hydroxide (18 *N*, 50 ml), and extracted with benzene (4 × 30 ml). The extract was dried over anhydrous potassium carbonate, then heated under reflux with acetic anhydride (75 ml), poured into 5% hydrochloric acid (500 ml), and extracted with ether (1 × 100 ml; 3 × 50 ml) to remove the unreacted secondary amine as the N-acetyl derivative. The aqueous layer was basified by careful addition of solid sodium carbonate in portions and extracted with ether (1 × 100 ml; 3 × 50 ml). The ether was removed *in vacuo* and the residue was heated under reflux with 25% sodium hydroxide (200 ml) for 18 h. The two layers were separated and the aqueous layer was extracted with ether (4 × 50 ml). After the solution had been dried over anhydrous magnesium sulfate, the ether was removed *in vacuo* and the residue was fractionated, yielding 8.2 g (20%) of 2-ethylmethylaminoethanol as a heavy, colorless oil; b.p. 49° at 13 mm; n_D^{25} 1.4357 (cf. Leonard and Simet (25), Icke and Wisegarver (26), and Wright *et al.* (24)).

Alkylamino- and Dialkylamino-alkyl Chloride Hydrochlorides

The compounds shown in Table IV were prepared by treatment of the appropriate freshly distilled amino-alcohol with a good grade of thionyl chloride in chloroform, using the general method described by Bannard and co-workers (1). The thionyl chloride solution should be added as quickly as possible, without allowing the reaction temperature to rise above −10°. The reaction mixture is brought to room temperature and then heated under reflux with stirring until the mixture begins to darken, usually from 1½ to 4 h. Excessive heating frequently complicates the purification of the product, and should be avoided.

Alkylamino- and Dialkylamino-alkyl Chlorides

These compounds were prepared from the corresponding alkylaminoalkyl chloride hydrochlorides (Table IV) by neutralization and extraction, using the method previously described (1). Yields were generally over 90%. These compounds were not characterized, but were used immediately in reaction with potassium 1-phenylcyclopentanecarboxylate.

Preparation of Alkylamino- and Dialkylamino-alkyl 1-Phenylcyclopentanecarboxylate Hydrochlorides

Modifications to the method of interaction between potassium 1-phenylcyclopentanecarboxylate and a dialkylaminoalkyl chloride, which was described previously (1), have been made. The preparations of 2′-*t*-butylaminoethyl and 2′-*t*-butylmethylaminoethyl 1-phenylcyclopentanecarboxylate hydrochlorides are typical and are described below.

Method F: 2′-t-Butylaminoethyl 1-Phenylcyclopentanecarboxylate Hydrochloride

2-*t*-Butylaminoethyl chloride (4.39 g, 0.032 mole) in absolute ethanol (20 ml) was added dropwise to a warm, stirred solution of potassium 1-phenylcyclopentanecarboxylate (6.84 g, 0.03 mole) (1) in absolute ethanol (30 ml) and the resultant mixture was heated under reflux, with stirring, for 16 h. The reaction mixture was taken to dryness *in vacuo*, shaken with water (50 ml), and extracted with ether (4 × 50 ml). The extract was dried, filtered, and taken to dryness *in vacuo*. The residue, a colorless, mobile oil, was dissolved in methanol (60 ml), saturated with dry hydrogen chloride, and again taken to dryness *in vacuo*. Two recrystallizations from absolute methanol – ether yielded colorless needles, m.p. 198–199°. Yield, 7.37 g (75%).

Method G: 2′-t-Butylmethylaminoethyl 1-Phenylcyclopentanecarboxylate Hydrochloride

A warm, stirred solution of 1-phenylcyclopentanecarboxylic acid (11.4 g, 0.06 mole) in ethanol (50 ml) was neutralized with 10% ethanolic potassium hydroxide, with phenolphthalein as the external indicator. The reaction mixture was taken to dryness *in vacuo*, dissolved in absolute ethanol (100 ml), and added dropwise, with stirring, to 2-*t*-butylaminoethyl chloride, which was obtained by neutralization of 2-*t*-butylaminoethyl chloride hydrochloride (17.2 g, 0.10 mole). The mixture was heated under reflux, with stirring, for 18 h, and was taken to dryness *in vacuo*. The residue was shaken with water (100 ml) and ether (100 ml) for 2 h. The layers were separated and the ether layer was dried over anhydrous magnesium sulfate and taken to dryness *in vacuo*. The residue was dissolved in benzene (50 ml), methyl iodide (25 ml) was added dropwise, with stirring, and the reaction mixture was heated under reflux, with stirring, for 1 h. Ether (200 ml) was added and the precipitate was collected, washed with ether, and dried. Yield, 18.1 g (66% as the hydriodide). This compound was dissolved in 25% ethanol (900 ml) and passed through Amberlite IRA-400 resin in the chloride form, followed by 25% ethanol (1 000 ml). The eluate was taken to dryness *in vacuo* and recrystallized from absolute methanol – ether, yielding 4.42 g (32%) of the hydrochloride as colorless needles, m.p. 146–147°.

Method H: 3′-Diethylaminopropyl 1-Phenylcyclopentanecarboxylate Hydrochloride

(a) 3′-Chloropropyl 1-phenylcyclopentanecarboxylate.—A solution of 1-phenylcyclopentanecarbonyl chloride (4.17 g, 0.02 mole) in sodium-dried benzene (20 ml) was added dropwise, with stirring, to a solution of freshly distilled 3-chloropropanol (4.73 g, 0.05 mole) in dry benzene (25 ml). The reaction mixture was heated under gentle reflux, with stirring, for 1 h, and evaporated to dryness *in vacuo*. The residue was dissolved in ether and the solution was dried over anhydrous magnesium sulfate. After removal of the ether by distillation, the residue was fractionated *in vacuo*, yielding 3.98 g (76%) of 3′-chloropropyl 1-phenylcyclopentanecarboxylate; b.p. 178–180° at 10 mm; n_D^{25} 1.5218.

Anal. Calcd. for $C_{15}H_{19}O_2Cl$: C, 67.53; H, 7.18; Cl, 13.29. Found: C, 67.61; H, 7.12; Cl, 13.22.

(b) 3′-Diethylaminopropyl 1-phenylcyclopentanecarboxylate hydrochloride.—3′-Chloropropyl 1-phenylcyclopentanecarboxylate (2.27 g, 0.01 mole) was dissolved in freshly distilled diethylamine (20 ml) and heated in a stainless steel bomb at 110° for 16 h. The dark reaction mixture was decanted and the reaction vessel was washed several times with small portions of methanol. The combined reaction mixture and washings were heated with charcoal, filtered through a pad of Celite, and taken to dryness *in vacuo*. The residue was basified with 10% aqueous potassium hydroxide, and diluted with water (40 ml), and the dark, cloudy mixture was extracted with ether (4 × 15 ml). The extract was dried over anhydrous magnesium sulfate, and taken to dryness *in vacuo*. The dark, heavy residue was dissolved in ethanol (20 ml), saturated with dry hydrogen chloride, and again taken to dryness *in vacuo*. Recrystallization from absolute ethanol – ether gave colorless needles, m.p. 139.5–140°. Yield, 1.03 g (30%).

Method J: 3′-Quinuclidinyl 1-Phenylcyclopentanecarboxylate Hydrochloride

(a) Ethyl 1-phenylcyclopentanecarboxylate.—1-Phenylcyclopentanecarbonyl chloride (4.17 g, 0.02 mole) (1) dissolved in sodium-dried benzene (20 ml) was added dropwise, with stirring, to absolute ethanol (50 ml). The reaction mixture was heated under reflux for 2 h. Excess ethanol and benzene were removed by distillation, and the residue was fractionated. Ethyl 1-phenylcyclopentanecarboxylate, a heavy colorless liquid, was collected; b.p. 138–139° at 9 mm; n_D^{25} 1.5116. Yield, 3.66 g (84%). Laüger *et al.* (17) report b.p. 142–144° at 10 mm; n_D^{20} 1.5145.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.32. Found: C, 76.97; H, 8.24.

(b) Methyl 1-phenylcyclopentanecarboxylate.—1-Phenylcyclopentanecarbonyl chloride (8.34 g, 0.04 mole) in anhydrous methanol (50 ml) was heated at 40°, with stirring, for 16 h. After the excess methanol had been removed by distillation, the residue was shaken with water (20 ml) and extracted with ether (2 × 15 ml). The extract was dried over anhydrous magnesium sulfate, the ether was removed, and fractionation gave methyl 1-phenylcyclopentanecarboxylate; b.p. 131–133° at 9 mm; n_D^{25} 1.5216. Yield, 7.26 g (90%).

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.89. Found: C, 76.22; H, 7.97.

(c) 3′-Quinuclidinyl 1-phenylcyclopentanecarboxylate hydrochloride.—A mixture of methyl 1-phenylcyclopentanecarboxylate (6.06 g, 0.30 mole), 3-quinuclidinol (4.45 g, 0.035 mole), and sodium (0.12 g, 0.005 mole) in toluene (100 ml) was heated under reflux, with stirring, for 20 h, during which massive precipitation occurred. The solid was collected, washed with benzene, dried, and dissolved in water. The filtrate was acidified with 10% hydrochloric acid (100 ml) and the layers were separated. The aqueous layer was basified by addition of sodium carbonate in portions, then combined with the aqueous solution of the precipitate, and extracted with ether (4 × 25 ml). The extract was dried over anhydrous magnesium sulfate and taken to dryness *in vacuo*. The residue was dissolved in ethanol (20 ml), saturated with dry hydrogen chloride, and again taken to dryness *in vacuo*. Recrystallization from ethanol–ether yielded colorless flakes, m.p. 206–207°. Yield, 2.80 g (28%).

N-Methyl-4′-piperidyl 1-Arylcycloalkanecarboxylate Hydrochlorides

Method K: N-Methyl-4′-piperidyl 1-p-Methoxyphenylcyclobutanecarboxylate Hydrochloride

A solution of 1-*p*-methoxyphenylcyclobutanecarbonyl chloride (2.25 g, 0.01 mole) in sodium-dried benzene (15 ml) was added dropwise, with stirring, to 4-hydroxy-N-methylpiperidine (2.90 g, 0.025 mole) in sodium-dried benzene (40 ml). The reaction mixture was heated under reflux, with vigorous stirring, for 2 h, and then chilled. Anhydrous ether was added and the precipitate was collected. The filtrate was taken to dryness *in vacuo*, shaken with water (50 ml), and extracted with ether (2 × 25 ml). The extract was dried over anhydrous magnesium sulfate and taken to dryness *in vacuo*, yielding 2.89 g (95%) of dark yellow oil. This material was dissolved in methanol (25 ml), and saturated with anhydrous hydrogen chloride, and the solution was evaporated to dryness *in vacuo*. Methanol (20 ml) was added, and the solution was boiled with charcoal, filtered through Celite, and again taken to dryness *in vacuo*. Recrystallization from methanol–ether gave N-methyl-4′-piperidyl 1-*p*-methoxyphenylcyclobutanecarboxylate hydrochloride as colorless flakes, m.p. 191.5–192.5°. Yield, 2.55 g (75%).

ADDENDUM: THE CHROMIC ACID OXIDATION OF ARYL TRIFLUOROMETHYL ALCOHOLS: ISOTOPE AND SUBSTITUENT EFFECTS

ROSS STEWART AND DONALD G. LEE

(Ref. Can. J. Chem. 42, 439 (1964))

The unidentified compound (m.p. 70–71°) (see page 445) has been shown to be 2,4-dinitrobromobenzene. This compound is formed by the nitration of bromobenzene, an impurity (21%) in the α,α,α-trifluoroacetophenone used in the preparation of 3,5-dinitrophenyltrifluoromethyl ketone. (We thank Mr. J. M. McAndless for this work.)

HIGH ENERGY MODIFICATIONS OF THE HYDRATES OF ZINC SULFATE

J. W. S. JAMIESON, R. A. LAMONTAGNE, BARBARA A. PATTERN, AND G. R. BROWN

Department of Chemistry, St. John's College, University of Manitoba, Winnipeg, Manitoba

Received May 31, 1965

ABSTRACT

Much higher heats of solution than have previously been observed for hydrates of zinc sulfate have been measured for various new vacuum dehydration products. It is suggested that the maximum heat of transition to normal crystalline form of 82.8 cal/g, 23.8 kcal per mole of heptahydrate, or 8.3×10^3 cm^{-1} is a satisfactory measure of the ligand field splitting energy for the hexaaquozinc(II) ion.

INTRODUCTION

Recently it has been postulated (1) that high energy vacuum dehydration products can be obtained for any salt hydrate for which the heat of solution of the normal anhydride is higher than would be expected from extrapolation of the data for higher normal crystalline hydrates.

For several hydrated salts, linear relations similar to those shown in Fig. 1 have been obtained by plotting the heats of solution in cal/g of solute against the % water in various samples. Maximum possible heats of solution for the vacuum dehydration products of a hydrated salt have then been estimated (1) by constructing a line CE through the point C for the heptahydrate and parallel to the line AB between the normal anhydride and the crystalline monohydrate.

Such maxima, however, are not always attained since lower heats of solution may result if the method of dehydration allows formation of one of the lower crystalline hydrates before high energy modifications are produced. This apparently was the case in the previous study of the hydrates of zinc sulfate by Frost, Moon, and Tompkins (2) who measured heats of solution for various crystalline hydrates and vacuum dehydration products. Similar results have been obtained (1) by vacuum dehydration of $CoSO_4.7H_2O$, although points on a maximum line such as CE were obtained when barium oxide was present as desiccant during the vacuum dehydration.

The possibility that modifications of lower hydrates of zinc sulfate having maximum heats of solution (on the line CE of Fig. 1) could also be obtained by alteration of the method of vacuum dehydration initiated the present investigation.

EXPERIMENTAL

Samples of $ZnSO_4.7H_2O$, 'Baker Analyzed' reagent, which was obtained from Canadian Laboratory Supplies Limited, were ground in a mortar and dehydrated under vacuum for sufficient time to give products of approximately the composition desired. An ordinary vacuum line with a mechanical pump, a liquid

nitrogen trap, and a McLeod gauge was used in all experiments. Each sample to be dehydrated was placed in a porcelain boat in either a Pyrex tube, 28 mm o.d. and about 30 cm long, or a vacuum oven of about 12 l volume, both of which were connected to the vacuum line. In most experiments a second porcelain boat containing barium oxide was present in the vessel containing the sample being dehydrated.

Heats of solution were measured at 29 °C, as cal/g of solute, in a simple calorimeter which has previously been described (1). After solution of a sample the concentration was 0.02 *m* or less.

RESULTS AND DISCUSSION

In accordance with the method used in a recent investigation in this laboratory of the hydrates of the divalent sulfates of manganese, iron, cobalt, and nickel (1) the data of Frost, Moon, and Tompkins (2) have been recalculated. In Fig. 1, the line BI with the equation

$$y = -2.06x + 82.6$$

represents their results for the normal crystalline hydrates of zinc sulfate. In this and the other linear equations given x is the % water in the sample and y is the heat of solution in cal/g of solute. The line FG denotes the data of Frost, Moon, and Tompkins (2) for the modifications obtained by vacuum dehydration, and has the equation

$$y = -4.51x + 148.5.$$

The heat of solution of the heptahydrate (−7.86 cal/g) obtained by extrapolation of the line BI to the point C (at 43.86% water) is thought to be more exact than the value (about −8 cal/g) estimated by direct measurement in the present calorimeter, since it is difficult to determine values close to zero accurately with this apparatus.

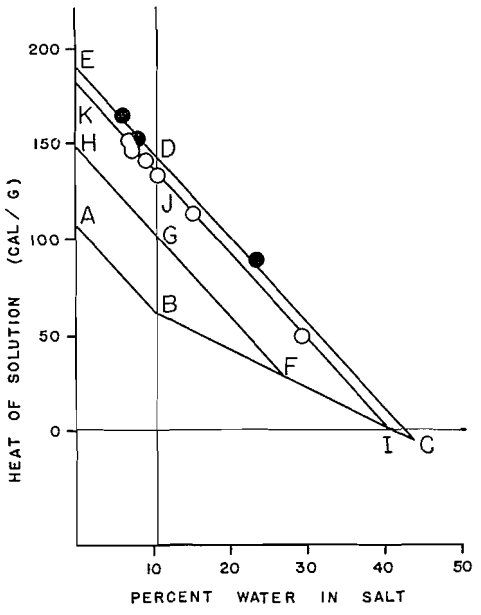

FIG. 1. Heats of solution for the hydrates of zinc(II) sulfate.

It appears that the line CE, passing through the point C for the heptahydrate and having the same slope as the line FG, which has the equation

$$y = -4.51x + 190.0,$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

represents the maximum possible heats of solution for high energy modifications of the hydrates of zinc sulfate.

Preliminary experiments in which the vacuum dehydration was done in the Pyrex tube without barium oxide have given results on the line FG in agreement with the work of Frost, Moon, and Tompkins (2). When barium oxide was present during vacuum dehydration in the Pyrex vessel, the results plotted in Fig. 1 along the line IK were obtained. This line has essentially the same slope as the lines FG and CE and passes through the point I at the hexahydrate composition (40.10% water). Furthermore, as shown in Fig. 1, dehydration in the vacuum oven gave results on the predicted maximum line CE, whether or not barium oxide was present. Data for the present results on the lines IK and CE are also given in Table I.

TABLE I

Heat of solution data

% water in sample	Heat of solution (cal/g)	Method of dehydration
6.96	151.9	Pyrex tube with BaO*
7.44	146.0	
9.22	140.8	
10.66	133.1	
15.31	112.5	
29.39	48.2	
6.08	164.4	Vacuum oven with BaO†
8.11	152.1	Vacuum oven, no BaO
23.35	88.4	Vacuum oven, no BaO

*This set of results falls on the line IK which meets the line BC for normal crystalline hydrates at the hexahydrate composition.
†This set of results falls on the maximum possible line CE which extrapolates to the point for the normal crystalline heptahydrate.

It appears that the different sets of results are due to differences in pressure, particularly at the start of dehydration. It is known (3, 4) that a liquid nitrogen trap is a better desiccant than barium oxide, while dehydration in a vacuum oven would surely begin long before the oven was fully evacuated. Thus it seems that dehydration at higher pressures gives products of higher energy. Dependence of rate of dehydration on water vapor pressure has been observed by Topley and Smith (5), Volmer and Seydel (6), and Frost and Campbell (7), all of whom found, as the pressure increased from zero, that the rate fell rapidly to a minimum, then rose to pass through a maximum, and finally decreased slowly at higher pressures. An apparent dependence of formation of energy-rich product on water vapor pressure, during the dehydration of $CuSO_4.5H_2O$ and $ZnSO_4.6H_2O$, has also been reported by Frost, Moon, and Tompkins (2). It may be that the present results on the maximum line CE were obtained because the initial pressure of water vapor was at or higher than the Topley–Smith minimum (5) for zinc sulfate. Unfortunately a McLeod gauge, as used in the present investigation, is unsuitable for the measurement of water vapor pressure.

The maximum heat of solution of the monohydrate (shown in Fig. 1 as a vertical line at 10.04% water) at the point D is found from the equation of the line CE to be

$$y_D = 144.7 \text{ cal/g}$$

while the heat of solution of the normal crystalline monohydrate at point B, calculated from the line BI is

$$y_B = 61.9 \text{ cal/g}.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The difference DB gives a maximum heat of transition of 82.8 cal/g or 23.8 kcal/mole of $ZnSO_4.7H_2O$.

Since it has recently been observed empirically (1) that the maximum heats of transition in kcal/mole of $MnSO_4.7H_2O$, $FeSO_4.7H_2O$, $CoSO_4.7H_2O$, and $NiSO_4.7H_2O$ are equal to the ligand field splitting energies for the hexaaquo divalent cations of manganese, iron, cobalt, and nickel, it is probable that the ligand field splitting energy for $[Zn(H_2O)_6]^{2+}$ is 23.8 kcal or 8.3×10^3 cm^{-1}, although it appears that a spectroscopic value for comparison is not available.

STRUCTURE VIBRATIONNELLE DES SPECTRES D'ABSORPTION DANS L'ULTRAVIOLET DE QUELQUES DÉRIVÉS HALOGÉNÉS DU BENZÈNE

P. PESTEIL, H. F. SHURVELL[1] ET L. PESTEIL
Laboratoire de Physique P.C.B. 1, Faculté des Sciences, Marseille, France

Reçu le 11 mai 1965

SOMMAIRE

Les spectres d'absorption dans l'ultraviolet des cristaux purs suivants ont été étudiés à basse température: hexachlorobenzène, *o*, *m* et *p*-dichlorobenzènes, *o*, *m* et *p*-dibromobenzènes, trichloro 1,2,3-benzène et tétrachloro 1,2,4,5-benzène. Il s'agit, dans tous les cas, des premières bandes d'absorption correspondant à la transition $^1B_{2u}$–$^1A_{1g}$ du benzène. Pour six de ces composés, la résolution des spectres était suffisante pour permettre des analyses complètes de la structure vibrationnelle des bandes électroniques. Les résultats montrent que les vibrations totalement symétriques sont seules à apparaître dans le cas des transitions électroniques observées. Nous en concluons que quelques changements doivent être apportés à de précédentes attributions vibrationnelles.

ABSTRACT

Ultraviolet absorption spectra have been recorded, at low temperatures, for pure crystals of the following compounds: hexachlorobenzene, *o*, *m*, and *p*-dichlorobenzenes, *o*, *m*, and *p*-dibromobenzenes, 1,2,3-trichlorobenzene, and 1,2,4,5-tetrachlorobenzene. In all cases, the first electronic transition corresponding to the $^1B_{2u}$–$^1A_{1g}$ transition of benzene has been studied. For six of these compounds the spectra were sufficiently well resolved to permit complete analyses of the vibrational fine structure of the electronic bands. The results indicate that only totally symmetrical vibrations appear in conjunction with the observed electronic transitions. Several changes in published vibrational assignments are proposed, in the light of present results.

INTRODUCTION

Après l'étude des vibrations du benzène sur lesquelles la plupart des auteurs semblent maintenant d'accord (1, 2, 3), l'intérêt des chercheurs s'est porté sur les dérivés substitués. Ces recherches, basées généralement sur les résultats de spectroscopie Raman ou infrarouge, concernent la substance soit à l'état de vapeur, soit à l'état liquide, soit à l'état cristallisé. Il est possible de déterminer sur les spectres obtenus les différents types de vibrations et de confronter ces résultats avec les prévisions théoriques. L'adoption de constantes de force de tension et de flexion permet également de calculer les vibrations. On trouve enfin, dans de nombreux articles, des tableaux de vibrations classées en types de symétrie (4, 5, 6).

La structure des spectres électroniques en absorption ou en émission permet également de déterminer les différents types de vibrations. Les spectres d'absorption, obtenus lors du passage de l'électron du niveau fondamental à un niveau excité, fournissent les vibrations de la molécule à l'état excité, c'est-à-dire, en ce qui concerne notamment le benzène et ses dérivés, de la molécule dilatée par rapport à son état fondamental; les fréquences obtenues seront donc plus faibles que celles données par la diffusion Raman et l'absorption infrarouge. Les spectres de fluorescence, correspondant au passage de l'électron du niveau excité au niveau fondamental, permettent d'obtenir les vibrations de la molécule à l'état fondamental et de retrouver certaines vibrations Raman ou infrarouge.

Cette méthode expérimentale peut donc servir de complément utile pour vérifier des attributions; elle ne permet cependant pas de retrouver toutes les vibrations, mais seulement celles qui sont permises ou favorisées par le passage de la molécule d'un état à un autre. Lorsque la transition est permise par les règles de sélection, il est plus probable de

[1]*Adresse actuelle: Department of Chemistry, Queen's University, Kingston, Ontario.*

voir apparaître les vibrations totalement symétriques par rapport au groupe de point de la molécule (7); mais, dans certains cas, une vibration peut rendre la transition électronique permise en lui conférant la même symétrie que celle d'une translation: ainsi, pour le benzène, une vibration E_{2g} transforme la transition électronique interdite B_{2u} en symétrie E_{1u} de même type de symétrie que les translations T_x et T_y; la transition devient donc permise.

D'autre part, parmi les vibrations permises, certaines apparaissent avec une intensité accrue; ce sont les vibrations qui font passer la molécule de sa forme normale à sa configuration dans l'état électronique excité. Par exemple, la vibration 613 cm^{-1} de la molécule d'acétylène étudiée par Ingold et King (8) amène la molécule linéaire dans son état fondamental à une forme quasi-éthylénique *trans* dans l'état excité et donne naissance à des groupes de bandes que l'on observe dans le spectre d'absorption ultraviolet.

Cette méthode d'analyse a déjà été utilisée dans ce laboratoire; l'étude de la structure vibrationnelle des spectres d'absorption et de luminescence a permis de dresser des tableaux de vibrations totalement symétriques à l'état excité ou à l'état fondamental pour de nombreuses molécules aromatiques: naphtalène, acénaphtène, phénanthrène, fluoranthène, acénaphtylène et dérivés du naphtalène (9–15). L'étude simultanée des spectres d'absorption et de fluorescence permet même d'établir des correspondances entre vibrations des états fondamental et excité. On trouve généralement un nombre de vibrations actives en bon accord avec celui prévu par le dénombrement théorique, mais la complexité des molécules étudiés précédemment rend difficile l'attribution d'une vibration donnée à un type de mouvement prévu en utilisant les coordonnées de symétrie. C'est pourquoi il nous a paru préférable d'étudier des molécules plus simples et en particulier les dérivés halogénés du benzène, afin de baser nos recherches sur les résultats universellement admis pour le benzène.

On peut étudier, soit la vapeur, soit, à basse température, une solution ou un cristal pur; ces méthodes ont chacune des avantages et des inconvénients.

Les spectres d'absorption ou de luminescence des vapeurs de dérivés aromatiques sont généralement bien résolus en raies fines, mais leur étude se faisant à température élevée, leur complexité est extrême; on trouve, sur le même spectre, des vibrations de l'état fondamental et des vibrations de l'état excité. Cette méthode a cependant permis à Ingold d'expliquer la structure vibrationnelle du benzène.

L'état condensé peut être étudié, soit sur des solutions dans les paraffines (Shpol'skii a montré que, dans ce cas, les spectres sont remarquablement bien résolus (16, 9–15)), soit sur des échantillons de substances pures qui donnent également de bons résultats. Dans ces deux derniers cas, les spectres d'absorption ne fournissent que les vibrations de l'état excité, les spectres de luminescence, les vibrations de l'état fondamental; d'où une simplification notable par rapport aux spectres des vapeurs. En contrepartie, les interactions entre molécules de solvant et de soluté jouent un rôle non négligeable pour compliquer la structure des spectres par apparition des phénomènes excitoniques dont on trouvera l'étude dans les références suivantes (17, 18).

Le présent article rend compte des résultats obtenus à basse température sur les substances pures cristallisées suivantes: *o*, *m* et *p*-dichlorobenzènes, *o*, *m* et *p*-dibromobenzènes, trichloro 1,2,3-benzène, tétrachloro 1,2,4,5-benzène et hexachlorobenzène. Ces substances, faciles à obtenir dans le commerce, présentent un intérêt théorique certain et leur étude, aussi limitée soit-elle, peut apporter de nouveaux éléments à la connaissance des vibrations des dérivés halogénés du benzène.

Toutes les molécules étudiées ici ont donné lieu à de nombreuses publications tant en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Raman qu'en infrarouge; on trouvera dans l'article de Scherer et Evans (5) des tableaux très complets où les auteurs établissent des listes de vibrations classées en types de symétrie pour tous les dérivés chlorés étudiés dans le présent article; le *p*-dibromobenzène a été étudié par Whiffen (6). Ce sont principalement ces deux articles qui nous ont servi de base pour la discussion de nos résultats expérimentaux.

Certains de ces dérivés ont également donné lieu à des études dans l'ultraviolet, c'est le cas des *o* et *p*-dichlorobenzènes (19), du tétrachlorobenzène (20) et de l'hexachlorobenzène (21).

MÉTHODE EXPÉRIMENTALE

Les produits ont été trouvés dans le commerce à l'état purum ou purissimum; nous avons recristallisé les purum dans l'alcool; les *p*-dichlorobenzène, *p*-dibromobenzène et tétrachloro 1, 2,4,5-benzène ont été purifiés par fusion de zone (40 à 80 passages selon les cas); mais aucune modification du spectre n'a été observée entre les produits purissimum et les produits purifiés par fusion de zone. Les résultats expérimentaux montreront d'ailleurs que les spectres peuvent être expliqués en ne faisant intervenir que des vibrations de la substance étudiée, ce qui élimine l'influence des impuretés.

Les échantillons sont obtenus cristallisés par refroidissement lent de la substance entre deux disques de silice et l'épaisseur contrôlée au microscope polarissant; l'épaisseur convenable correspondant pour la plupart des substances à des couleurs vives entre nicols croisés. Dans le cas des liquides, le contrôle n'est plus possible; une goutte est alors déposée entre les deux disques de silice et l'ensemble plongé directement dans le cryostat; on recommence l'opération jusqu'à ce que la lame soit d'épaisseur convenable et sans trou.

Le cryostat utilisé est le même que celui qui a été décrit à plusieurs reprises (22, 9–15); le système dispersif est un spectrographe ultraviolet 120 de Huet (60 cm^{-1}/mm vers 2 700 Å); la source une lampe à xenon Osram de 500 W et les plaques des Superfulgur de Guilleminot; le temps de pose varie de quelques secondes à quelques minutes, selon l'épaisseur des lames. Le rayonnement infrarouge important de la lampe est arrêté au moyen d'une solution diluée de sulfate de nickel et de sulfate de cobalt; l'absorption de cette solution dans le proche ultraviolet ne nous a jamais gênés, car les spectres étudiés se situent toujours plus loin dans l'ultraviolet. Les fréquences ont été déterminées au microscope de mesure Beaudouin et au microphotomètre de Chalonge et Laffineur.

DÉNOMBREMENT DES VIBRATIONS ACTIVES

Pour le choix des axes de symétrie des différentes molécules, nous nous sommes conformés à la standardisation proposée en 1955 (23). Nous avons conservé les mêmes axes pour le benzène (symétrie D_{6h}) et pour les dérivés para et tétra halogénés (symétrie D_{2h}): l'axe z est perpendiculaire au plan de la molécule, l'axe y passe par un atome de carbone et l'axe x est perpendiculaire à une liaison C—C. Pour les autres dérivés, la molécule est dans le plan yz, l'axe z étant toujours l'axe binaire de symétrie.

Nous pensons qu'il n'y a pas lieu de s'étendre sur le dénombrement des vibrations de chaque molécule, puisque cela a été fait à maintes reprises et ne présente aucune difficulté. Nous avons résumé les résultats dans le Tableau I.

En tête du tableau, on trouvera le nom de la molécule, son schéma avec indication des axes et l'orientation du dipole d, correspondant à la transition électronique permise (issue de la transition interdite $^1B_{2u}$–$^1A_{1g}$ du benzène), ainsi que le groupe de symétrie (notation de Schoenflies) auquel appartient la molécule.

On trouvera dans les colonnes les types de symétrie des vibrations correspondant à des mouvements totalement symétriques ou qui sont susceptibles de faire tourner le dipole de $\pi/2$ dans le plan de la molécule (mouvements correspondant à une rotation autour de l'axe perpendiculaire à la molécule); les premières sont notées A_g ou A_1, les secondes B_{1g} ou B_2, selon le groupe de symétrie. Nous pensons que le Tableau I est suffisamment clair pour faire ressortir la correspondance entre les vibrations du benzène et les vibrations de ses dérivés. Dans chaque cas, nous avons également indiqué le nombre de vibrations attendues. Enfin au bas du tableau, nous avons fait la somme des vibrations totalement symétriques d'une part et des vibrations qui donnent une autre orientation au dipole, d'autre part. Il

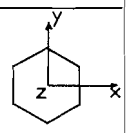
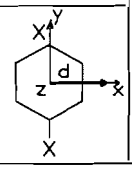
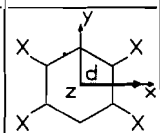
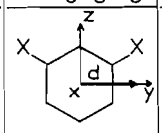
TABLEAU I

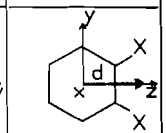
Dénombrement des vibrations utilés dans le présent travail

C_6H_6		$p.C_6H_4Cl_2$ $p.C_6H_4Br_2$		$1,2,4,5.C_6H_2Cl_4$	$m.C_6H_4Cl_2$ $m.C_6H_4Br_2$ $1,2,3.C_6H_3Cl_3$		$O.C_6H_4Cl_2$ $O.C_6H_4Br_2$	
								










D6h		D2h			C2v		C2v*	
A_{1g}	2	A_g	2		A_1	2	A_1	2
A_{2g}	1	B_{1g}	1		B_2	1	B_2	1
B_{1u}	2				A_1	2	B_2	2
B_{2u}	2	B_{3u}			B_2	2	A_1	2
E_{1u}	3				A_1	3	B_2	3
					B_2	3	A_1	3
E_{2g}	4	A_g	4		A_1	4	A_1	4
		B_{1g}	4		B_2	4	B_2	4
Total		A_g	6		A_1	11	A_1	11
		B_{1g}	5		B_2	10	B_2	10

est évident que l'hexachlorobenzène, qui ne figure pas nommément dans le tableau, a les mêmes propriétés que le benzène. Ajoutons enfin que ce tableau n'a de valeur que si les molécules conservent dans le cristal la même symétrie qu'à l'état libre.

La correspondance entre symétries du benzène et de ses dérivés est également encore valable pour la symétrie de chacune des transitions électroniques; le Tableau I donne également l'orientation du dipole correspondant à la transition électronique; elle est permise dans tous les cas, puisque $B_{2u}(D_{6h})$ devient: $B_{3u}(D_{2h})$, $B_2(C_{2v})$ et $A_1(C_{2v}{}^*)$; les groupes C_{2v} et $C_{2v}{}^*$ diffèrent par la position de leur axe de symétrie z.

Les spectres des dérivés halogénés (sauf celui de l'hexachlorobenzène) seront donc en principe assez différents de celui du benzène, puisque dans ce dernier cas, la transition interdite était rendue permise, comme nous l'avons déjà dit, par une vibration de symétrie E_{2g} (520 cm^{-1}) qui servait d'origine à une série de raies fortes dont les fréquences étaient données par une relation de la forme: $\nu' = (0''\text{–}0') + 520 + n.923$. Dans le cristal, à cause des interactions moléculaires, une autre série de raies plus faibles apparait cependant (24): $\nu' = (0''\text{–}0') + p.923$.

L'objet principal du présent article est de vérifier si la structure des spectres d'absorption peut s'expliquer avec les seules vibrations totalement symétriques; c'est pour cela qu'il est nécessaire de dresser maintenant un tableau des résultats obtenus en Raman et en infrarouge (Tableau II).

RÉSULTATS EXPÉRIMENTAUX ET ANALYSE VIBRATIONNELLE

Dans l'exposé qui suit, nous étudierons successivement les molécules précédemment citées dans l'ordre suivant: C_6Cl_6, p-$C_6H_4Cl_2$, p-$C_6H_4Br_2$, 1,2,4,5-$C_6H_2Cl_4$, 1,2,3-$C_6H_3Cl_3$, o-$C_6H_4Cl_2$, o-$C_6H_4Br_2$, m-$C_6H_4Cl_2$, m-$C_6H_4Br_2$.

On trouvera, pour chaque substance, une photographie du spectre d'absorption à 20 °K (Figs. 1, *a*, *b*, *c*, ...) et un microphotogramme (Figs. 2, *a*, *b*, *c*, ...).

Précisions que l'objet du présent article est l'étude de la structure vibrationnelle; nous ne chercherons donc pas à expliquer la structure de la transition électronique (0″–0′) (exciton), même si nous sommes souvent amenés à tenir compte de cette structure qui sert d'origine aux vibrations. Nous rappellerons simplement, pour mémoire, qu'il existe actuellement deux méthodes concurrentes pour expliquer, cette structure excitonique; la première, proposée par Davydov en 1948 (25), est admise par la plupart des chercheurs; elle considère que la structure provient de la séparation du niveau en composantes polarisées parallèlement aux axes ou plans de symétrie du cristal. L'autre a été proposée plus récemment par l'un de nous (17), puis développée par Benarroche (18); elle fait intervenir une structure quasi-hydrogénoïde qui rappelle l'exciton de Wannier (26); cette structure a été également trouvée dans les solutions cristallisées (27); elle semble avoir été confirmée récemment par la découverte d'un effet photoélectrique (28).

(a) Hexachlorobenzène, $C_6Cl_6(D_{6h})$

Ce cristal a déjà donné lieu à une étude extrèment soignée de Schnepp et Kopelman (21) à 4 °K; la structure étant suffisamment fine à 20 °K, nous n'avons pas jugé nécessaire d'utiliser l'hélium liquide.

Le spectre est reproduit sur la Fig. 1*a*; le microphotogramme correspondant se trouve sur la Fig. 2*a*; la Fig. 2*a*′ est le microphotogramme de la transition (0″–0′); on notera son extrême complexité. Enfin, dans le Tableau III, nous avons indiqué la position des raies d'absorption que l'on peut également reconnaître sur la Fig. 2*a*.

Ces fréquences, précisons le bien, résultent de notre présentation du spectre avec une seule origine et non d'une séparation des vibrations en plusieurs composantes. Chacune des X_i, par exemple, est distante de 309 cm^{-1} d'une raie située dans la bande (0''–0'). Nous donnons, dans le Tableau IV, la liste des différences de fréquences calculées en utilisant les formules α et β.

TABLEAU IV

309	333	365	423	471	573	$(n = 0)$	
682	706	738	796	844	946	$(n = 1)$	(α)
1 055	1 079	1 111	(1 169)	1 217	1 319	$(n = 2)$	
1 428	1 452	1 484	1 542	1 590	1 692	$(n = 3)$	
373	746	1 119	1 492			$(q = 0)$	(β)
487	860	1 233	1 606			$(q = 1)$	

Si l'on compare les fréquences données par le Tableau IV et les $D\nu'$ du Tableau III et de la Fig. 2*a*, on voit que l'accord est très satisfaisant; on retrouve en effet toutes les raies du spectre d'absorption, exception faite des deux raies fortes 1 151 et 1 181.

Pour les expliquer, remarquons que la deuxième vibration A_{1g} doit également intervenir pour donner un motif de bandes analogue aux motifs α et β. Or, la fréquence de cette vibration à l'état électronique fondamental étant 1 210 cm^{-1} (voir sur le Tableau II), on doit la trouver vers 1 150 cm^{-1} dans l'état excité. Nous proposons donc de la situer à 1 169 cm^{-1} où elle serait en résonance de Fermi avec la fréquence de même symétrie située à la même place, pour donner les deux raies trouvées expérimentalement à 1 151 et à 1 181 cm^{-1}.

En conclusion de cette étude, on voit que tout le spectre peut être expliqué en n'utilisant que 3 vibrations qui sont, dans l'état électronique excité, de fréquence: 309 cm^{-1}, de symétrie E_{2g} (520 pour le benzène); 373 cm^{-1}, de symétrie A_{1g}; vibration C—Cl de tension (3 130 pour le benzène); 1 169 cm^{-1}, de symétrie A_{1g}; vibration C—C (923 pour le benzène).

Ces résultats sont conformes aux propositions du Tableau II et aux prévisions théoriques si l'on suppose que la molécule conserve sa symétrie D_{6h} dans le cristal. Un essai d'interprétation de la structure excitonique sera publié ultérieurement.

(b) Paradichlorobenzène, $C_6H_4Cl_2(D_{2h}$ ou $V_h)$

La substitution des halogènes en para supprime l'axe d'ordre 6 normal au plan de la molécule, mais lui conserve 3 axes binaires. La symétrie relativement élevée de la molécule explique le nombre réduit de vibrations A_{1g} (six) et de vibrations B_{1g} (cinq) susceptibles de faire tourner le dipole de $\pi/2$ (Tableau I).

La transition interdite, B_{2u}, du benzène devient B_{3u}, permise, avec un moment dipolaire vibrant parallèlement à l'axe x. L'aspect du spectre doit être très différent de celui du benzène (ou de C_6Cl_6) et sa structure vibrationnelle constituée par un seul motif de bandes. On peut cependant se demander si les deux vibrations de symétries A_g et B_{1g} issues de la vibration E_{2g} (521 cm^{-1}) du benzène n'interviennent pas ensemble pour donner deux transitions de polarisations différentes dans le plan de la molécule. C'est une possibilité dont il nous faudra tenir compte dans notre analyse.

L'utilisation des coordonnées de symétrie permet d'avoir une représentation simple des mouvements correspondant aux 6 vibrations A_g issues des 2 vibrations A_{1g} (923 et 3 130) et des 4 vibrations E_{2g} (521, 1 130, 1 470 et 3 080) du benzène.

Nous proposons, dans le Tableau V, une telle représentation qui a l'avantage de séparer nettement les vibrations C—H des vibrations C—Cl (ou C—Br). Nous nous sommes servis, pour le dresser, du tableau de vibrations reproduit par Brodersen et Langseth (3) et nous

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

avons conservé la numérotation des vibrations adoptée par ces auteurs. Il ne s'agit là, évidemment, que d'une représentation qualitative des mouvements des atomes.

Il n'y a aucune difficulté pour les vibrations 8 et 9 pour lesquelles les mouvements des atomes sont les mêmes que pour le benzène; pour les 4 autres vibrations, elles doivent être couplées deux à deux, en phase ou en opposition de phase, pour obtenir les schémas (1, 6)′ et (1, 6)″ d'une part et (2, 7)′ et (2, 7)″ d'autre part. (2, 7)′ est une vibration de tension purement C—H, alors que (2, 7)″ est une vibration de tension purement C—Cl.

Nous avons également porté sur ce tableau les résultats relatifs au *p*-$C_6H_4Br_2$ et au 1,2,4,5-$C_6H_2Cl_4$ que nous étudierons ensuite.

TABLEAU V

Schémas et fréquences des vibrations totalement symétriques des molécules appartenant au groupe de symétrie D_{2h}

Le spectre d'absorption du *p*-dichlorobenzène a fait l'objet d'une étude à l'état de vapeur (19); Anno et Matubara ont expliqué sa structure par les fréquences de vibrations suivantes de l'état excité: 331, 528, 725, 1 051, 1 061, 1 089, 1 461 et 3 081 cm^{-1}, c'est-à-dire

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

par 8 vibrations alors qu'il n'y a que 6 vibrations totalement symétriques; mais, selon ces auteurs, la vibration 528 cm^{-1} serait la composante B_{1g} issue de la vibration 521 cm^{-1} (E_{2g}) du benzène, la fréquence 330 en étant la composante A_g. Cela évidemment est possible, mais on ne saurait plus où situer la vibration de tension C—Cl qui doit être voisine de 300 cm^{-1}.

On trouvera dans le Tableau II, les vibrations proposées par Scherer et Evans (5) et par Stojiljkovic et Whiffen (6). On constate que la vibration de fréquence 626 (528 à l'état excité) est proposée avec une symétrie B_{1g}; cette classification concorde donc avec les résultats d'Anno, tout au moins en ce qui concerne cette vibration.

Le spectre d'absorption à 20 °K est représenté sur la Fig. 1*b*; le microphotogramme du spectre est reproduit en Fig. 2*b*.

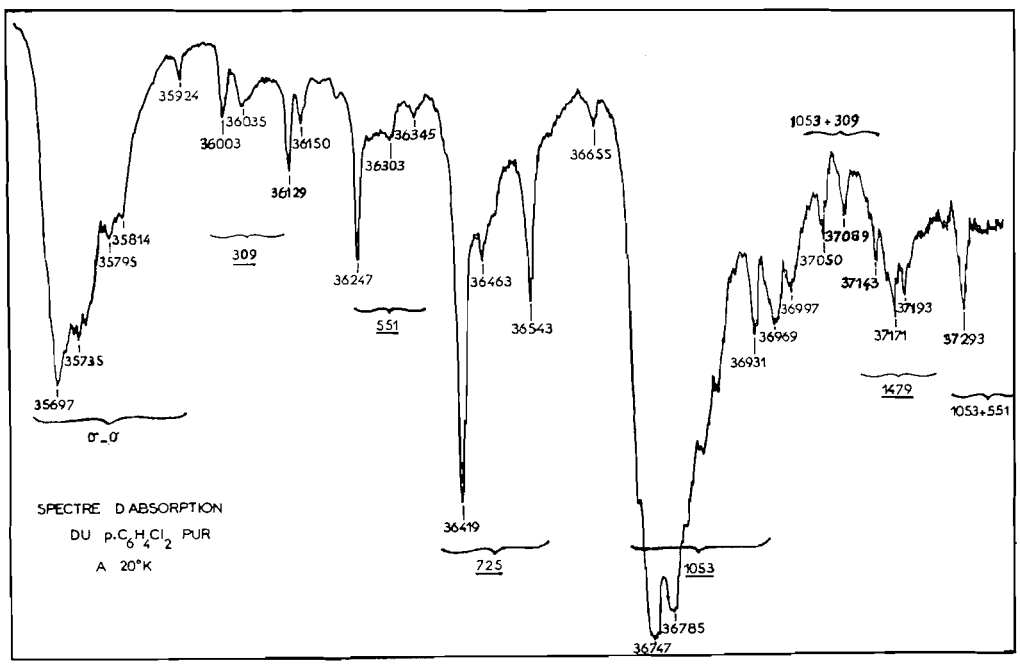

FIG. 2*b*.

Afin de trouver d'éventuelles variations d'orientation du dipole, nous avons étudié la polarisation du spectre et séparé les deux composantes vibrant suivant les lignes neutres de la lame cristalline. On peut voir, sur la Fig. 1*b*, que la vibration 551 cm^{-1}, repérée par un point (nous n'avons pas retrouvé la fréquence 528 proposé par Anno) a la même polarisation que l'ensemble du spectre. On peut interpréter ce résultat de deux manières; soit parce que la vibration 551 est totalement symétrique (ce que nous pensons), soit par une orientation convenable des molécules par rapport aux lignes neutres.

La fréquence des principales bandes a été indiquée sur la Fig. 2*b*; nous utiliserons cette figure pour étudier la structure vibrationnelle du spectre. L'étude détaillée, faite au microscope de mesure, montre que tout le spectre peut être expliqué en ne faisant intervenir que les 6 vibrations suivantes: 309, 551, 725, 1 053, 1 479 et 3 171 cm^{-1} (cette dernière vibration n'apparait pas sur la Fig. 2*b* qui ne va pas au delà de 37 500 cm^{-1}; la raie d'absorption correspondante se trouve à 38 868 cm^{-1}).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Ces résultats sont conformes aux prévisions théoriques qui nous donnaient 6 vibrations totalement symétriques (Tableau I); les fréquences des vibrations correspondantes de l'état fondamental sont incontestablement les suivantes, d'après le Tableau II: 330, 626, 747, 1 096, 1 574 et 3 070 cm^{-1}, alors que les vibrations A_g admises par Evans se situent à: 330, 747, 1 096, 1 169, 1 574 et 3 070 cm^{-1}.

La différence porte sur deux vibrations: 626, classée parmi les B_{1g}, et 1 169, sans équivalent dans notre spectre.

Nous avons porté, sur le Tableau V, à côté du schéma de chaque vibration, la fréquence que nous proposons pour l'état excité et, entre parenthèses, pour l'état fondamental.

(c) Paradibromobenzène, $C_6H_4Br_2(D_{2h})$

Afin de contrôler les résultats qui viennent d'être exposés, nous avons entrepris l'étude du *p*-$C_6H_4Br_2$ dont les fréquences de vibration sont connues également (6); par contre, nous n'avons trouvé aucune référence sur une éventuelle tentative d'analyse du spectre d'absorption ultraviolet.

Il est évident que les modes de vibrations proposés sur le Tableau V pour le dérivé chloré sont encore valables pour le paradibromobenzène.

Le spectre est reproduit sur la Fig. 1*c*; les Figs. 2*c* et 2*c'* représentent respectivement les microphotogrammes d'une portion étendue du spectre et de la structure de la transition électronique (0''–0'); cette structure est compliquée et fera l'objet d'une étude ultérieure.

Sur la Fig. 2*c*, nous avons indiqué les fréquences des principales raies d'absorption ainsi que les fréquences des vibrations responsables de la structure.

Nous avons trouvé les fréquences suivantes: 217, 542, 693, 1 010, 1 476 et 3 170 cm^{-1}; nous leur proposons les correspondantes suivantes dans l'état fondamental (6) (Tableau II): 218, 623, 708, 1 067, 1 570 et 3 068 cm^{-1}.

Le dérivé bromé nous donne donc des résultats comparables à ceux du dérivé chloré: la vibration 623 est classée parmi les B_{1g} par Whiffen et nous ne retrouvons pas la vibration de l'état excité correspondant à 1 170 cm^{-1}.

Notons encore, pour terminer, qu'il y a concordance parfaite entre le nombre de vibrations totalement symétriques prévues et le nombre de fréquences qui composent le motif vibrationnel.

(d) Tetrachloro 1,2,4,5-benzène, $C_6H_2Cl_4(D_{2h})$

L'intérêt de cette molécule vient de ce qu'elle a même symétrie que les deux précédentes et qu'elle est, en quelque sorte, le complément du *p*-$C_6H_4Cl_2$, les vibrations C—H de l'une étant remplacées par des vibrations C—Cl de l'autre (Tableau V).

Le spectre d'absorption ultraviolet à l'état de vapeur a été étudié par Anno (20) qui propose une structure expliquée par des vibrations de fréquences: 85, 155, 636 et 1 134 cm^{-1}; il est difficile de trouver leurs correspondantes dans l'état fondamental dont les vibrations totalement symétriques sont de fréquences: 190, 352, 684, 1 165, 1 549 et 3 070 cm^{-1} (Tableau II).

Nous avons reproduit, sur la Fig. 1*d*, la photographie du spectre à 4 °K et sur la Fig. 2*d*, le microphotogramme correspondant.

On notera d'abord que la résolution des bandes est moins bonne que dans le cas des molécules précédentes; les bandes sont cependant suffisamment fines pour permettre un pointé convenable. Tout le spectre peut être expliqué par la combinaison des fréquences suivantes de vibrations de l'état excité: 195, 330, 645, 1 135, 1 455 et 3 085 cm^{-1} qui correspondent aux vibrations totalement symétriques de l'état fondamental qui viennent d'être énumérées.

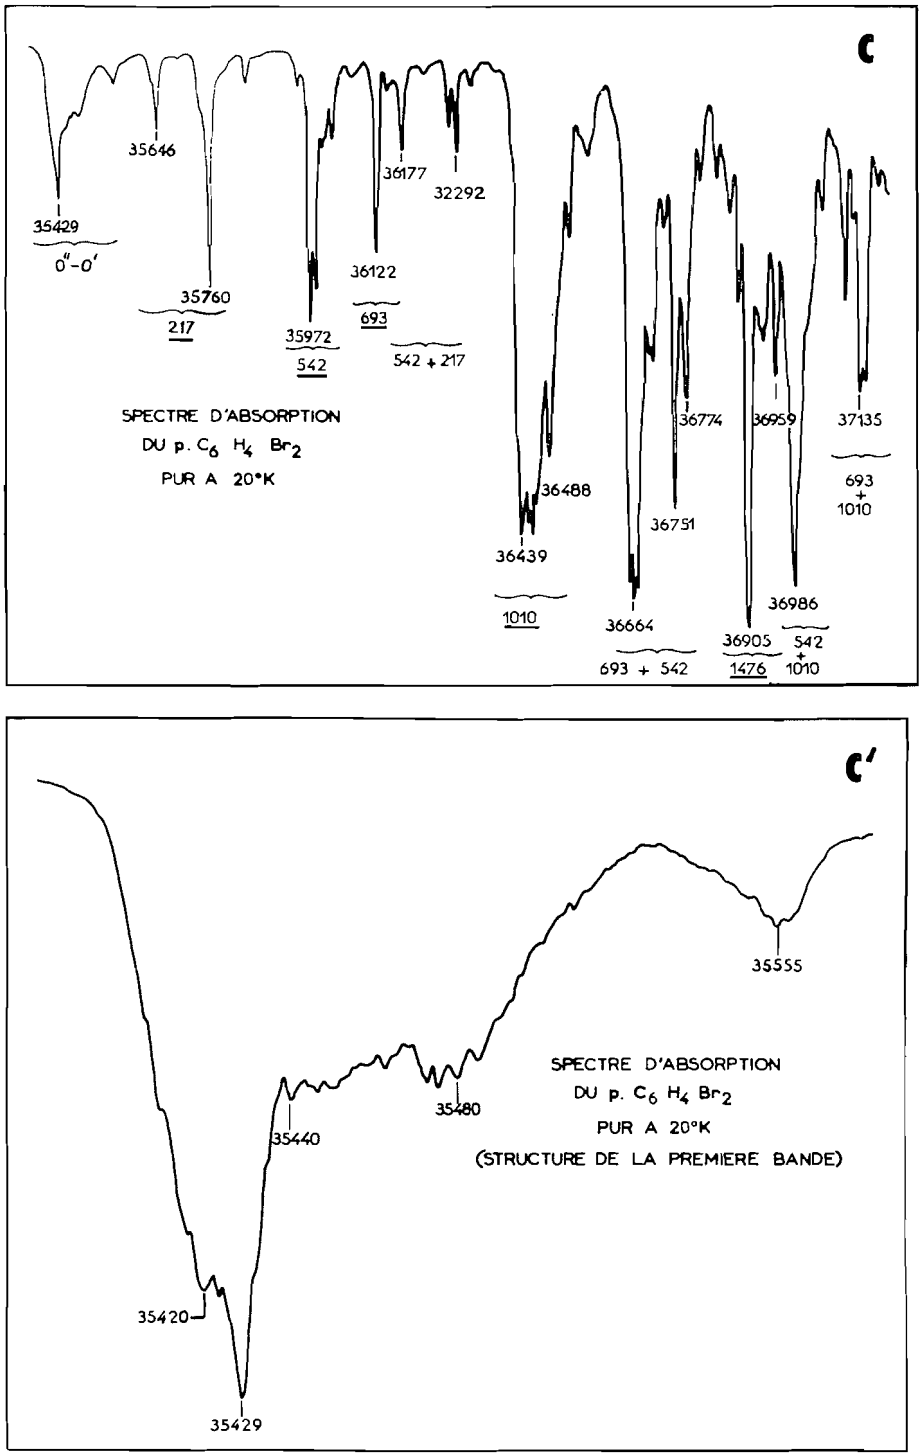

FIGS. 2*c* and 2*c'*.

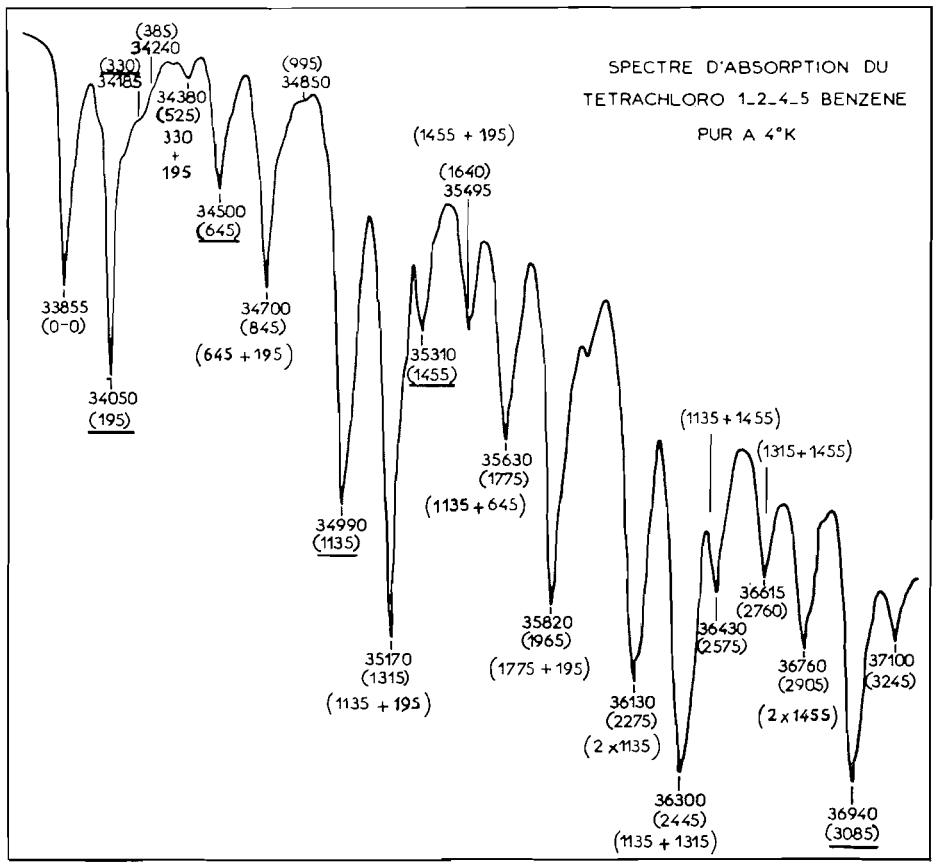

FIG. 2*d*.

Il y a donc, encore ici, une bonne concordance entre les prévisions théoriques et nos résultats expérimentaux.

(e) Trichloro 1,2,3-benzène, $C_6H_3Cl_3(C_{2v})$

Cette molécule n'a plus qu'un axe binaire et deux plans de symétrie; elle appartient donc au groupe C_{2v}; les vibrations A_1 et les vibrations B_2 sont en plus grand nombre que dans les cas précédents (11 A_1 et 10 B_2 dont on trouvera les fréquences de l'état fondamental dans le Tableau II).

Le spectre d'absorption à 20 °K est mieux résolu que celui du tétrachlorobenzène et permet un pointé plus précis des fréquences.

La Fig 1*e*, reproduit la photographie du spectre; le microphotogramme correspondant se trouve en 2*e*. Sur ce microphotogramme est indiquée la fréquence de chaque bande ainsi que l'attribution vibrationnelle que nous proposons. On voit que tout le spectre visible sur la figure peut être expliqué en tenant compte des vibrations suivantes: 215, 326, 383, 460, 502, 714, 1 126, 1 374, 1 490, 3 081 et 3 101 cm^{-1}, soit en tout 11 vibrations comme prévu si l'on suppose que seules les vibrations totalement symétriques interviennent.

La comparaison de ces fréquences avec celles du Tableau II permet de faire correspondre à ces vibrations de l'état excité, respectivement, les 11 fréquences suivantes de l'état fondamental: 212, 352, 400, 492, 516, 738, 1 161, 1 416, 1 566, 3 072 et 3 072 cm^{-1}.

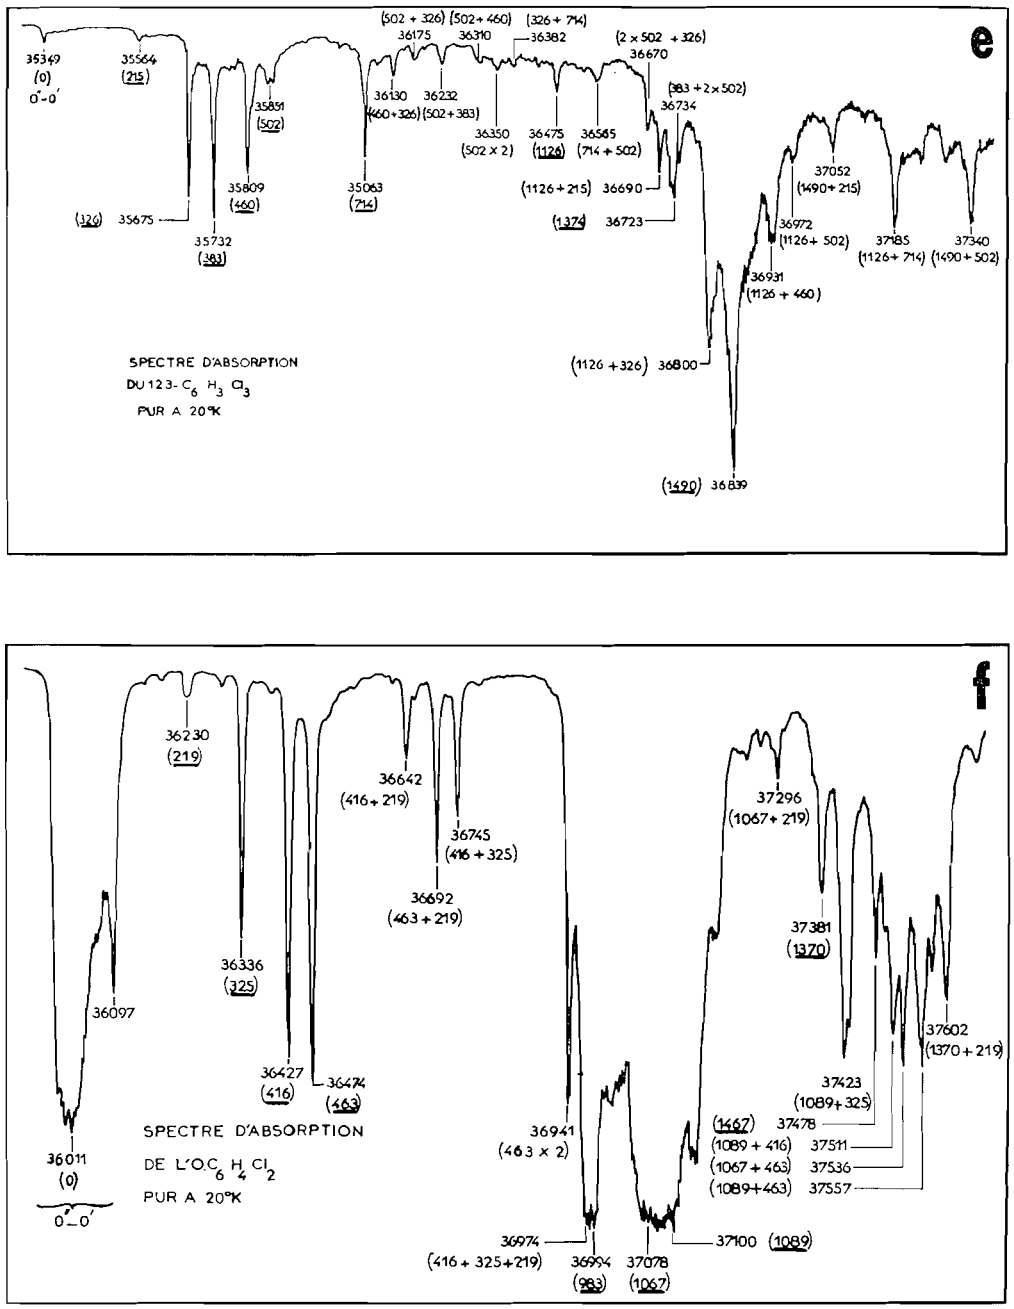

FIGS. 2*e* and 2*f*.

Deux de ces vibrations (400 et 492) sont classées par Evans parmi les B_2; toutes les autres sont données comme A_1.

Il est difficile de trancher définitivement cette question, mais nous pensons que le fait de trouver le même nombre de vibrations actives et de vibrations totalement symétriques

soit un argument en faveur de l'attribution de la symétrie A_1 aux fréquences 400 et 492 de l'état fondamental (383 et 460 à l'état excité).

Ajoutons enfin qu'il est difficile de proposer pour cette molécule des schémas de vibrations comme il a été fait pour les dérivés para et tétra substitués pour lesquels nous avions pu séparer nettement les vibrations C—Cl des vibrations C—H.

(f) Orthodichlorobenzène, $C_6H_4Cl_2(C_{2v}*)$

L'*o*-dichlorobenzène appartient également au groupe de symétrie C_{2v}; l'astérisque qui suit le symbole du groupe indique seulement que l'axe de symétrie est différent (ici, cet axe est perpendiculaire à une liaison C—C du benzène, alors qu'il passe par un atome de carbone dans le cas des dérivés méta et 1,2,3-$C_6H_3Cl_3$).

Le spectre d'absorption à l'état de vapeur a été également étudié par Anno (19) qui propose une structure vibrationnelle faisant intervenir les fréquences de vibrations suivantes: 151, 307, 437, 610, 1 089 et 1 486 cm^{-1}; il est difficile de trouver sur le Tableau II les fréquences correspondantes de l'état fondamental.

Le spectre est bien résolu à 20 °K, comme on peut le constater sur la Fig. 1*f*; le microphotogramme (Fig. 2*f*) permet également d'effectuer un pointé convenable des raies d'absorption.

Nous avons relevé les fréquences suivantes qui permettent d'expliquer la structure vibrationnelle: 219, 325, 416, 463, 983, 1 067, 1 089, 1 370, 1 467, 3 130 et 3 130 cm^{-1}.

D'après le Tableau II, les fréquences correspondantes dans l'état fondamental seraient, respectivement: 203, 334, 429, 480, 1 041, 1 130, 1 162, 1 468, 1 575, 3 070 et 3 070 cm^{-1}.

Toutes ces vibrations ont été classées dans le type A_1, sauf 334 et 429 que Evans pense être de symétrie B_2.

TABLEAU VI

Tableau des vibrations actives dans le spectre d'absorption (à l'état excité) d'aprés le présent travail et des vibrations correspondantes de l'état fondamental

C_6Cl_6		p-$C_6H_4Cl_2$		p-$C_6H_4Br_2$		1,2,4,5-$C_6H_2Cl_4$		1,2,3-$C_6H_3Cl_3$		o-$C_6H_4Cl_2$	
Exc.	Fond.	Exc.	Fond.	Exc.	Fond.	Exc.	Fond.	Exc.	Fond.	Exc.	Fond.
309	323	309	330	217	218	195	190	215	212	219	203
373	372	551	626*	542	623*	330	352	326	352	325	334*
1 169	1 210	725	747	693	708	645	684	383	400*	416	429*
		1 053	1 096	1 010	1 067	1 135	1 165	460	492*	463	480
		1 479	1 573	1 476	1 570	1 455	1 549	502	516	983	1 041
		3 171	3 072	3 170	3 068	3 085	3 070	714	738	1 067	1 130
								1 126	1 161	1 089	1 162
								1 374	1 416	1 370	1 468
								1 490	1 566	1 467	1 575
								3 081	3 072	3 130	3 070
								3 101	3 072	3 130	3 070

En ce qui nous concerne, nous proposons de classer toutes ces vibrations dans le type A_1, puisque leur nombre correspond exactement à celui des vibrations totalement symétriques.

(g) Orthodibromobenzène, $C_6H_4Br_2(C_{2v}*)$, métadibromobenzène, $C_6H_4Br_2(C_{2v})$ et métadichlorobenzène, $C_6H_4Cl_2(C_{2v})$

Ces 3 dernières substances ont été également étudiées à 20 °K mais, pour des raisons qui nous échappent, leurs spectres sont très mal résolus; les bandes sont trop larges pour permettre un pointé précis et une analyse vibrationnelle fructueuse.

Nous nous contenterons donc de reproduire, sans commentaires inutiles, les photographies des spectres sur les Figs. 1*g*, 1*h*, 1*i*, et les microphotogrammes correspondants sur les Figs. 2*g*, 2*h*, 2*i*.

CONCLUSION

Tous les résultats obtenus ont été résumés dans le Tableau VI; dans ce tableau, nous avons donné la liste des vibrations actives dans les spectres d'absorption, ainsi que les vibrations de l'état fondamental qui leur correspondent d'après les travaux antérieurs en diffusion Raman et en absorption infrarouge (5, 6).

Lorsque la transition est permise, le nombre de vibrations trouvées est rigoureusement égal à celui des vibrations totalement symétriques; cela nous conduit naturellement à la conclusion suivante: les vibrations totalement symétriques sont les seules actives en absorption ultraviolet. Cette conclusion nous oblige à corriger des résultats, obtenus en Raman et en infrarouge, qui attribuaient à certaines des vibrations reconnues sur nos spectres des mouvements non totalement symétriques. Ces vibrations sont suivies d'un astérisque sur le Tableau VI.

THE ULTRAVIOLET SPECTRA OF RIBONUCLEIC ACIDS IN SOLID STATE AND IN SOLUTION[1]

MICHAEL FALK
Atlantic Regional Laboratory, National Research Council, Halifax, Nova Scotia
Received July 14, 1965

ABSTRACT

The ultraviolet absorption spectra of nine samples of soluble, ribosomal, and viral ribonucleic acid (RNA) were studied over the range 3 500 to 1 830 Å. The spectra and the spectral changes which occur upon denaturation were the same for all types of RNA examined, which suggests that their secondary structure is comparable. Dehydration of solid films of RNA at room temperature caused spectral changes resembling those which occur when RNA is heated in aqueous solution. This indicates that the dehydration of RNA, like the dehydration of deoxyribonucleic acid (DNA), causes some loss of the regular stacking and pairing of the nucleotide bases in the helical regions. In contrast to DNA, the rehydration of RNA was not always complete at 98% relative humidity. The decrease of absorbance in the 2 900 Å region upon denaturation, previously reported by Rich and Kasha, was not confirmed with any of the RNA samples studied.

INTRODUCTION

Because of the great sensitivity of the ultraviolet spectra to conformational changes of nucleic acids, ultraviolet spectroscopy continues to be one of the most commonly employed techniques in the study of these compounds. Ultraviolet spectra of various types of ribonucleic acid (RNA) have been frequently measured in the past. However, the previous measurements have been limited to the spectra of solutions, mainly in the region of 2 600 Å. The purpose of the present study was to examine systematically the spectra of various types of RNA (soluble, ribosomal, viral), in solid films as well as in solution, throughout the spectral range of 3 500 to 1 830 Å and under a variety of experimental conditions. In addition, the effect of drying on the spectrum and structure of RNA was investigated.

EXPERIMENTAL

Ten samples of RNA were used. The following samples of soluble RNA from yeast were obtained: (i) one from Professor R. W. Holley, Cornell University; (ii) two from Dr. G. L. Brown, King's College, London; (iii) one from the Sigma Chemical Company, St. Louis; and (iv) one from the Nutritional Biochemicals Corporation, Cleveland. Samples of ribosomal RNA, (v) one from *Escherichia coli* and (vi) one from rat liver, were obtained respectively from Dr. R. A. Cox, Mill Hill Hospital, London, and Dr. S. L. Liu, Chester Beatty Institute, London. Three samples (vii) from tobacco mosaic virus were supplied by Professor H. Fraenkel-Conrat, University of California, Berkeley. The samples designated i, ii, v, vi, and vii were prepared by published methods in the order shown (1, 2, 3, 4, 5). All of the samples were in the form of the sodium salt. The spectra were recorded on a Beckman DK-2 far-ultraviolet spectrophotometer (6). The necessary precautions were observed in flushing the instrument and the sample and reference cells with purified nitrogen, and in rejecting that part of each spectrum at short wavelengths in which the proportion of stray light was above 0.5%. The experimental procedures used in previous work (7) were followed with only a few modifications.

Solutions of approximately 0.001% RNA were prepared in H_2O or D_2O containing 0.15 mole of sodium fluoride per liter. Fluoride rather than chloride was used because it does not have measurable far-ultraviolet absorption above 1 800 Å and does not shift the absorption of water (8). The solutions were stored at 1 °C and their pH was about 6.0.

Solid films of RNA were prepared by the slow evaporation at room temperature of a drop of concentrated aqueous solution spread on the inside surface of a standard 1-cm fused silica cell. The first spectrum was usually recorded before the film had dried completely. A small reservoir, which contained either a drying agent or a saturated solution of an appropriate salt in H_2O or in D_2O, was fitted into the cell. The sample could thus be exposed to a particular vapor pressure of H_2O or D_2O even while the spectrum was being

[1]*Issued as N.R.C. No. 8659.*

recorded. Overnight equilibration was found to be sufficient to bring the specimen to equilibrium at any selected value of relative humidity, as indicated by the lack of further spectral changes. The highest relative humidity which could be reproducibly attained was 98%. Higher humidities caused swelling and distortion of the RNA films.

RESULTS

Comparison of Spectra of the Three Types of RNA

Table I shows the wavelengths of the absorption maximum (λ_{max}) near 2 580 Å, and of the absorption minimum (λ_{min}) near 2 300 Å, averaged from a large number of spectra recorded under various experimental conditions. The centers of these broad maxima and minima can be reproducibly estimated to about 2 Å, but the absolute accuracy is only about ±4 Å. The values of λ_{max} and λ_{min}, the values of the wavelength maximum near 1 830 Å, and the values of several ratios of absorbances at different wavelengths, which together characterize the shape of the absorption spectrum, showed no systematic differences between the three types of RNA under study or between the various specimens of one type of RNA.

Spectra of RNA in Solution and the Effect of Heating

The spectra of RNA dissolved in H_2O and in D_2O were found to be identical. The spectral changes which occurred when the solutions were heated were also found to be identical in H_2O and in D_2O, in agreement with the findings of Mahler, Dutton, and Mehrotra (9). The spectra in D_2O are presented here, as they extend down to about 1 880 Å, some 30 Å further than the spectra in H_2O (7). A typical spectrum of a solution of approximately 0.001% of soluble RNA in D_2O containing 0.15 *M* sodium fluoride is shown in Fig. 1. It can be seen that, in the wavelength region studied, the absorption spectrum consists of the well-known band with a maximum near 2 570 Å and of a second, more intense band, with a maximum below 1 900 Å at room temperature. The shape of these RNA bands is essentially the same as that of the DNA bands (7), and, as in the spectrum of DNA, it can be seen that there are very weak shoulders at about 2 820 Å, 2 120 Å, and possibly also at about 1 950 Å.

The effect of heating to 95° on the spectrum of RNA in solution is also shown in Fig. 1. Thermal denaturation* caused an increase of the absorbance of RNA throughout the accessible region of the spectrum. The average increase of absorbance at 2 570 Å for the 10 RNA samples investigated was 26 ±3%, with allowance for the increase of the volume of solution by nearly 3% in the temperature interval studied. Thermal denaturation also caused an upward shift of the lower wavelength band of RNA by at least 50 Å. At 90° the maximum of this band is at about 1 915 Å, just within the region of spectrum observed at this temperature in aqueous solution. A similar shift has been observed for DNA (7). The changes of absorbance of this band upon denaturation of RNA are somewhat uncertain, because only about a half of the band is accessible to the present observations. The integrated intensity of this band may either increase or decrease upon denaturation. The spectra of native and denatured RNA suggest a crossing point just below the observable region, as for DNA.

The ultraviolet spectra of RNA in solution, recorded in the present work, and the spectral changes observed on heating, agree with the spectrum at 25° and 90° of a solution of soluble RNA reported by Voet *et al.* (10).

**The terms "native" and "denatured", applied here to RNA by analogy with DNA, denote simply the presence or absence of ordered double-helical regions and do not imply any relation to the actual structure of various types of RNA in vivo. "Denaturation" denotes the total or partial disappearance of such ordered regions.*

	λ_{min}	2311±3	2327±2	2308±3	2315±8	2310±5

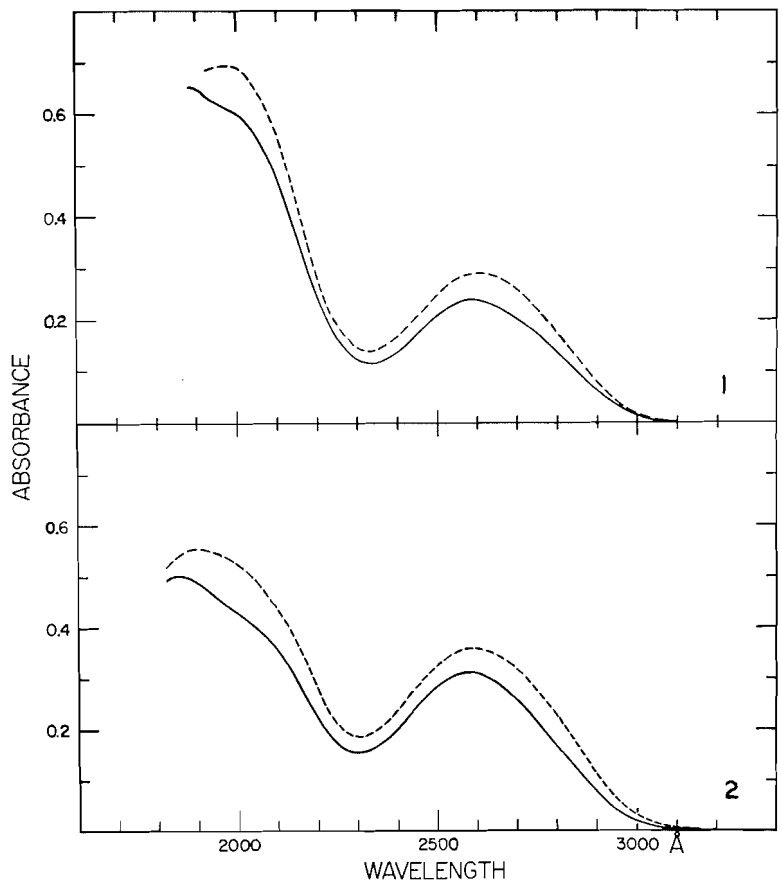

FIG. 1. Full line: spectrum of a solution of 0.001% RNA in D_2O containing 0.15 *M* NaF at 15° in a 1 cm cell. Broken line: spectrum of the same solution at 99°, uncorrected for the decrease in density with temperature.

FIG. 2. Full line: spectrum of a solid film of RNA exposed to 98% relative humidity (D_2O). Broken line: spectrum of the same film at 0% relative humidity (both at 22°).

Spectra of Solid Films and the Effect of Drying

The spectra of solid films of RNA hydrated by H_2O or D_2O were found to be nearly identical. Figure 2 shows a typical spectrum of a solid film of RNA in both the anhydrous and hydrated state. It is shown that the spectra of *highly hydrated* films of RNA differ only slightly from those of RNA in solution; for example the band maximum at 2 570 Å in solution is shifted to about 2 581 Å in the hydrated film. A similar upward shift of about 10 Å has been observed for DNA (Table I). Drying (Fig. 2) caused an absorbance increase throughout the spectral region investigated, similar to that which occurs upon thermal denaturation (Fig. 1). Drying and thermal denaturation also caused similar minor changes in the shape of the RNA absorption bands. The spectral changes which occurred when solid films of RNA were dried were largely but not completely reversible when the films were rehydrated. The initial increase of absorbance in the first drying cycle equalled 20–25% for most RNA samples. This approaches the absorbance increase of 26 ±3% which occurred upon heating of the RNA in solution. Subsequent rehydration at 98% relative humidity caused an absorbance decrease which occasionally equalled the original

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

decrease, but often fell considerably short of it. In a typical series of 17 consecutive hydration–dehydration cycles a film of soluble RNA showed the following percentage increases in absorbance: 21.2, 16.0, 12.0, 14.7, 6.4, 8.0, 8.8, 9.6, 10.8, 14.5, 13.8, 27.0, 21.8, 26.0, 26.8, 16.5, 17.5. The lack of reproducibility indicates failure of the RNA films to return to their original state of hydration when exposed to 98% relative humidity. This behavior of RNA contrasts with the complete rehydration of DNA at relative humidity as low as 92% (7, 11). Unlike the rather sharp spectral changes in DNA, which occur largely in the relative humidity range of 59 to 75%, the corresponding spectral changes in RNA appear to occur much more gradually, over the whole relative humidity range of 0 to 100%.

The absorption maximum of RNA at lower wavelengths is seen more clearly in the spectra of solid films, as these are observable down to 1 830 Å, which is about 70 Å farther than the spectra of solutions. Denaturation of RNA by drying clearly shifts the band maximum to higher wavelengths as it does for DNA. Because they extend to somewhat lower wavelengths, spectra of the solid films suggest more strongly than do those of solutions that the absorbances of native and denatured RNA cross just below 1 830 Å.

Effect of Temperature on Spectrum of Dry RNA

The effect of temperature on the spectrum of a typical dry film of RNA is shown in Fig. 3. It is shown that the spectral changes corresponding to an increase of temperature of 148°C are very slight, and consist of a very small broadening of the bands and of a shift of the band at 2 580 Å to higher wavelengths by about 5 Å. There is almost no change in the absorbance at 2 580 Å. It is shown in Fig. 4 that the effect of temperature on the spectrum of a mixture of nucleosides in aqueous solution is also very slight, especially if a correction for the 3% expansion in volume is applied, and that it is similar to the effect of temperature on the spectrum of the dry RNA films.

Light Scattering in Spectra of Films

The contribution of light scattering to the absorption spectrum of the solid samples was probably small and was neglected. The agreement between the spectra of solid films of varying thickness was good. The films were optically clear and generally showed no transmittance changes above 3 100 Å, that is, outside of the region of RNA absorption. Any contribution of increased scattering to the spectrum at shorter wavelengths would be expected to be largely independent of temperature and degree of hydration, and thus would not affect the present results.

DISCUSSION

Comparison of Various Types of RNA

The similarity of the ultraviolet absorption spectra and of spectral changes on denaturation of soluble, ribosomal, and viral RNA, which differ widely in molecular weight, suggests that the secondary structure of various types of RNA is comparable. This is in agreement with conclusions from X-ray diffraction studies summarized by Fuller (12), and from a variety of other investigations (13). The ultraviolet spectrum of RNA resembles closely that of DNA (cf. Table I) and previous discussion on this subject (7) largely applies also to RNA.

Thermal Denaturation of RNA

The spectral changes that occur during thermal denaturation of RNA are qualitatively similar to those for DNA. However, the increase of absorbance near 2 600 Å is about 42%

for DNA (7), and only about 26% for RNA. The smaller increase for RNA *may* be partly due to its incomplete helical structure. However, the structure of the helical parts of RNA has not been established and may differ from the DNA helix. Since hypochromism of polynucleotides (that is, a decrease of ultraviolet absorption intensity that accompanies transition from a disordered form to a helix) can be expected to be highly sensitive to the exact geometry of the helix (14), the hypochromism of helical RNA may be different from that of DNA. The increase of absorbance at 2 600 Å for fully double-stranded viral RNA has recently been measured by Gomatos and Tamm and found to be 27 to 36% for wound tumor virus RNA (15) and 30% for reovirus RNA (16), significantly lower than the value of about 39% for DNA under similar conditions.

A tacit assumption has often been made that the spectral changes which occur when RNA or other polynucleotides are heated in solution are *entirely* due to thermal denaturation. This assumption has now been tested by the study of the effect of heating on dry films of RNA. The negligible effect of temperature on the absorbance of dry RNA (Fig. 3)

or on the absorbance of a mixture of nucleotides in solution (Fig. 4), *under conditions where no structural changes occur*, shows that the large spectral changes which occur upon heating RNA in solution *are* in fact due almost entirely to thermal denaturation.

Comparison of the Effect of Drying on DNA and RNA

The reversible changes in the structure of the DNA helix, which are caused by the variation of relative humidity, are now known in considerable detail (17). At high values of relative humidity, DNA exists in either the B or the A configuration. The B configuration, usually stable at 92% relative humidity, is stabilized by hydrophobic forces between the nucleotide base pairs, which are stacked 3.4 Å apart with their planes normal to the axis of the helix. At a somewhat lower relative humidity (about 75%), most samples of the sodium salt of DNA transform to the A configuration, in which the base pairs are inclined by about 20° from normal to the axis of the helix. This results in somewhat looser base-stacking than in the B configuration and a slight increase in the ultraviolet absorbance at 2 600 Å (7). At relative humidities below about 65%, DNA undergoes a transition to a disordered form, characterized by a broadening or disappearance of the X-ray diffraction pattern (18), a broadening of the infrared absorption bands (19–21), almost complete loss of infrared and ultraviolet dichroism (11), and an increase of the ultraviolet absorbance at 2 600 Å identical with that which occurs upon thermal denaturation (7, 11). These observations imply that the "dry configuration" involves an irregular collapse of the DNA helix and loss of the stacking and of the pairing of the nucleotide bases. The transition at low relative humidity occurs because the hydrophobic forces disappear in the absence of water and the stacking of the base pairs is no longer energetically advantageous. The helix is then free to adopt the new configuration of minimum energy, which does not involve the stacking of bases. The A configuration, which is stable at an intermediate degree of hydration, may correspond to a state when the hydrophobic forces between the base pairs have decreased somewhat but have not disappeared.

The spectral changes observed in the present work prove that the dehydration of RNA causes reversible structural changes similar, at least qualitatively, to those that occur in DNA. The increase of absorbance near 2 600 Å indicates that these structural changes must involve a loss of stacking and of pairing of the nucleotide bases.* Heating of the dehydrated films to temperatures above 100° has no further effect on the structure. Additional evidence that drying produces structural changes in RNA similar to those produced in DNA is provided by infrared spectra of RNA (20, 22), which upon drying show changes similar to those observed for DNA (19–21). The infrared spectral changes indicate the complete or partial disappearance of the specific base pairing (23) and a diminution of the degree of molecular order (21). The diminution of order upon drying agrees with the observed broadening of the X-ray diffraction patterns of RNA upon drying (24, 25). Some samples of RNA, including RNA of intact ribosomes and viruses, show complete disappearance of the diffraction pattern upon drying (25–27), which is indicative of collapse of order. Such disappearance of the nucleic acid diffraction pattern is also characteristic of DNA–protein complexes (28, 29). On the other hand, recent studies of highly oriented and nearly 100% double-stranded RNA from reovirus (30), from wound tumor virus (31), and of crystalline RNA of low molecular weight (32, 33) indicate only minor changes in the X-ray diffraction pattern on drying. The present finding that rehydration of RNA is not always complete at 98% relative humidity may

**The present discussion is independent of whether base-pairing or base-stacking is the main cause of the hypochromism in polynucleotides, since in the solid films of nucleic acids any loss of pairing is likely to be accompanied by a loss of stacking, and vice versa (11).*

have some bearing on the behavior of these exceptional RNA samples. It would be of interest to study more thoroughly the effect of hydration on the structure of these samples in the difficult region above 98% relative humidity. This might also help to establish whether at high relative humidity (and thus also in vivo) RNA occurs in a form corresponding to the A or B configuration of DNA. The X-ray diffraction studies so far are divided on this point (25, 26, 30–32) and molecular model building shows that RNA helix can be accommodated in either form (12). The present optical study cannot clearly distinguish between the A- or the B-type configuration at high relative humidity, since all attempts at the preparation of highly oriented RNA films have so far failed and thus the ultraviolet (or infrared) dichroism could not be measured, as had been done earlier for DNA (11). However, the spectral changes which are occurring near 98% relative humidity in RNA could be analogous to those which occur near 85% relative humidity in DNA and which accompany the A $\rightleftarrows$ B transition.

The $n \rightarrow \pi^*$ Transitions

It may be expected that the $n \rightarrow \pi^*$ transitions of the nucleotide bases will contribute to the absorption spectrum of nucleic acids (34). Some evidence for such a contribution in the 2 900 Å region has been presented (34–39). Since the $n \rightarrow \pi^*$ transitions may exhibit *hyperchromism* (that is, an *increase* of their absorption intensity with transition from a disordered form to a helix) at long wavelengths, they should be distinguishable from the $\pi \rightarrow \pi^*$ transitions of the nucleotide bases, which are responsible for the bulk of the ultraviolet absorption of nucleic acids and which are known to be *hypochromic* (35, 40). Careful examination of the RNA spectra recorded in the present work shows that thermal denaturation as well as drying causes, invariably, an *absorbance increase* throughout the 2 570 Å band. The *decrease* of absorbance near 2 900 Å when RNA is heated to 90°, as reported by Rich and Kasha (34, 35), was not confirmed with any of the RNA samples studied. In fact the increase of absorbance in this region was somewhat greater than near the maximum at 2 570 Å. Thus, if the $n \rightarrow \pi^*$ transitions are assumed to be hyperchromic, they cannot contribute more than a small fraction of the absorption in the region of 2 900 Å of either DNA or RNA with the usual nucleotide content. Hyperchromism above 2 800 Å has been observed for the double-stranded helix of polyadenylic + polyuridylic acid (10, 35, 41), and nucleic acids that are particularly rich in adenine-uracil pairs may also be hyperchromic in that region (41). There is still some doubt, however, whether such hyperchromism is due to the contribution from $n \rightarrow \pi^*$ transitions (42).

A treatment of RNA with hot aqueous alkali or with ribonuclease does cause a decrease of absorbance in the 2 900 Å region (43, 44). Such treatment, however, results in the breakdown of the primary as well as of secondary structure of RNA; hence more complex spectral changes may be expected than those which occur upon simple denaturation.

ACKNOWLEDGMENTS

I thank Miss P. J. Baird for her skillful technical assistance throughout most of this work, and Drs. R. W. Holley, G. L. Brown, R. A. Cox, S. L. Liu, and H. Fraenkel–Conrat for their kindness in supplying samples of RNA. Dr. W. B. Gratzer offered several helpful comments on the manuscript.

OCCURRENCE IN SEED OILS OF SOME FATTY ACIDS WITH CONJUGATED UNSATURATION[1]

C. Y. Hopkins and Mary J. Chisholm
Division of Pure Chemistry, National Research Council, Ottawa, Canada

Received July 23, 1965

ABSTRACT

The following fatty acids were identified in the respective seed oils; α-eleostearic in *Kentranthus macrosiphon*; *trans*-8,*trans*-10,*cis*-12-octadecatrienoic in *Osteospermum hyoseroides*; 9-hydroxy-10,12- and 13-hydroxy-9,11-octadecadienoic in *Tagetes erecta*. Dimorphecolic acid was obtained from *Osteospermum ecklonis* in pure crystalline form. It gave 9-D-hydroxystearic acid on hydrogenation, thus establishing the D-configuration of the parent acid. Dehydration of dimorphecolic acid gave a mixture of all-*trans*-8,10,12- and all-*trans*-9,11,13-octadecatrienoic acids.

INTRODUCTION

Fatty acids with conjugated unsaturation were not known to occur in seed oils of species of Compositae until 1956, when McLean and Clark found a large amount of conjugated trienoic acid in the oil of the common calendula (1). Since then, the family Compositae has been shown to produce, in its seed oils, a surprising number of unusual fatty acids with such components as hydroxy and epoxy groups, *trans* double bonds, and conjugated olefinic and acetylenic linkages.

The present work consists of a study of three species of Compositae containing four different fatty acids with conjugated olefinic unsaturation, and one species of the related family Valerianaceae. The species and their distinctive acids are listed in Table I.

TABLE I

Identification of conjugated fatty acids

Family and species	Oil content of seed, % (air-dry basis)	Conjugated acid	
		Identity	Amount in total acids, %
Valerianaceae			
Kentranthus macrosiphon Boiss.	26.2	α-Eleostearic	50.4
Compositae			
Osteospermum hyoseroides (DC.) Norlindh	15.4	*trans*-8,*trans*-10,*cis*-12-octadecatrienoic	36.3
Osteospermum ecklonis (DC.) Norlindh	16.4	Dimorphecolic (9-hydroxy-*trans*-10, *trans*-12-octadecadienoic)	54.1
Tagetes erecta L.	18.5	9-Hydroxy-10,12-octadecadienoic\ 13-Hydroxy-9,11-octadecadienoic/	8.9

The acids were examined by spectrometric methods to show the number of double bonds in conjugation and to determine whether they were all-*trans* or mixed *cis* and *trans*. Chemical methods were employed to determine the chain length, the position of the double bonds, and their configuration.

RESULTS AND DISCUSSION

Seed oil of *Kentranthus macrosiphon* was examined. The fatty acids contained 50.4% of a conjugated trienoic acid which was isolated and identified as α-eleostearic acid. The

[1]*Issued as N.R.C. No. 8658.*

content of α-eleostearic acid compares with 43% in the related species *K. ruber* (2). The plant is an annual and can be grown in north temperate regions so that it is a potential source of eleostearic-type oil in northern countries. These two species of *Kentranthus* are the only members of the Valerianaceae family from which a conjugated fatty acid has been isolated.

The seed oil of *Osteospermum hyoseroides* was reported by Earle and co-workers to contain a conjugated triene component (3). In the present study, the acid was isolated and identified as *trans*-8,*trans*-10,*cis*-12-octadecatrienoic acid by its melting point and by mixed melting point of its maleic anhydride adduct with an authentic sample. The tetracyanoethylene adduct was also prepared. The acid has been shown previously to be a constituent of *Calendula officinalis* (1, 4).

Osteospermum ecklonis

The oil of *O. ecklonis* (syn. *Dimorphotheca ecklonis*) showed strong ultraviolet absorption at 233 mμ, corresponding to 54.1% of conjugated dienoic acid. Earle and co-workers reported a somewhat higher diene absorption in this species (3), and Smith and co-workers identified the substance as dimorphecolic acid by converting it to 10,12-octadecadiene-1,9-diol (5). The acid was isolated and characterized in the present work as follows.

The mixed acids were partitioned between methanol and petroleum ether. The methanol-soluble portion yielded, on fractional crystallization, a small amount of crystalline acid, m.p. 66.5–67.5° and a larger amount with m.p. 36–37°. The 36–37° acid showed by its infrared spectrum the presence of an OH group (3 600 cm^{-1}) and of *trans* double bonds (983 cm^{-1} but no maximum near 943 cm^{-1}). The intensity at 983 cm^{-1} was twice that of methyl elaidate; thus the acid had two *trans* linkages. Its optical rotation was positive.

The ultraviolet spectrum verified the presence of two double bonds in conjugation (λ_{max} 231 mμ). There was no absorption in the region of 275 mμ. Hydrogenation gave 9-hydroxystearic acid, m.p. 82.5–83.5°, that was not depressed in admixture with an authentic sample of the D-form of the acid of m.p. 83–84° (6*a*). Thus the hydrogenated acid is judged to have the D-configuration. (The racemic form of 9-hydroxystearic acid melts at 75.5° (6).) The original unsaturated acid must have a straight chain of 18 carbon atoms with an OH group at the 9-position. It is also judged to have the D-configuration since catalytic hydrogenation does not cause inversion.

The location of the OH group in the hydrogenated acid was confirmed by cleavage with solid potassium permanganate in acetic acid, which gave the expected fragments (nonanoic, decanoic, suberic, and azelaic acids). There were no fragments corresponding to 13-hydroxystearic acid.

The original dienoic acid was oxidized by von Rudloff's procedure, giving hexanoic acid, thus placing the conjugated double bonds at Δ^{10} and Δ^{12}. The acid was therefore (+)-9-D-hydroxy-*trans*-10,*trans*-12-octadecadienoic (dimorphecolic) acid.

Properties of Dimorphecolic Acid

The nuclear magnetic resonance (n.m.r.) spectrum confirmed the structure of the acid (Table II). The hydroxyl and carboxyl protons gave a combined peak as in other hydroxy acids (7), and it was extinguished by the addition of deuterium oxide. The peak for protons adjacent to double-bonded carbons had an area equivalent to two protons only, showing that the OH substituent was attached to the other allylic carbon. Furthermore, the —CHO— proton gave a band at 5.85 τ, instead of the usual 6.4 τ, because of the de-shielding effect of the adjacent double-bond linkage.

The acid has not been reported previously in crystalline form, although Lohmar and

TABLE II

Nuclear magnetic resonance spectral data for dimorphecolic acid

Chemical shift, τ	Multiplicity	No. protons	Assignment
	$CH_3(CH_2)_4CH{=}CHCH{=}CHCH(CH_2)_7COOH$		
		OH	
3.25	Broad singlet	2	OH + COOH
3.6–4.6	Multiplet	4	$(CH{=}CH)_2$
5.85	Apparent doublet	1	CH—OH
7.65–7.75	—	2	CH_2COO
7.85–7.95	Multiplet	2	$CH_2CH{=}$
8.65	Broad peak	18	Isolated $(CH_2)_n$
9.1	Irregular triplet	3	CH_3
		32	

co-workers (8) isolated a sample that was semisolid. The present sample had m.p. 36–37°, $E_{1\ cm}^{1\%}$ 1 170 at 231 mμ (in MeOH), ϵ = 34 700. Binder and co-workers (9) reported ϵ = 33 600 although the melting point and other properties were not given. The present sample had $[\alpha]_D^{25}$ +15.2° (*c* 5.2, MeOH). The optical properties of the acid have not been recorded previously, but Diamond and co-workers (10) found $[\alpha]_D^{25}$ +14.0° for the methyl ester.

The small fraction of melting point 66.5–67.5°, obtained during the fractional crystallization, may have been an isomorphic crystalline form of the same acid. Its n.m.r. spectrum was identical and its infrared spectrum virtually identical with the spectra of dimorphecolic acid of m.p. 36–37°.

Dehydration of Dimorphecolic Acid

Dimorphecolic acid is dehydrated by heating with acetic acid to give a product having conjugated triene absorption, as observed by Smith and co-workers (11). The product (not characterized by Smith) was found in our experiments to consist only partly of the expected $\Delta^{8,10,12}$ trienoic acid. The infrared spectrum showed that the double bonds were all *trans*. Hydrogenation gave stearic acid. However, the melting point of the substance could not be raised above 58–61° by recrystallization (all-*trans*-8,10,12-octadecatrienoic acid melts at 77–78° (1)). Oxidative cleavage gave approximately equal amounts of valeric and hexanoic acids, and of suberic and azelaic acids. Thus the dehydration product was a mixture of all-*trans*-8,10,12- and all-*trans*-9,11,13-octadecatrienoic acids. Possibly dehydration is preceded by rearrangement of a portion of the dienoic acid to 13-hydroxy-9,11-octadecadienoic acid.

The occurrence of a hydroxy-dienoic acid and a conjugated trienoic acid in different species of the same genus (*O. ecklonis* and *O. hyoseroides*) suggests that there is a biogenetic relationship between the two acids. They may arise from the same precursor. It is unlikely that the trienoic acid (*trans*-8,*trans*-10,*cis*-12-) is formed from the hydroxy acid since the Δ^{12} double bond is *trans* in the hydroxy acid of *O. ecklonis* but *cis* in the trienoic acid of *O. hyoseroides*. It is more likely that the trienoic acid arises from 9-hydroxy-*trans*-10,*cis*-12-octadecadienoic acid, which is considered to be one of the isomers present in some species of Compositae (12).

Tagetes erecta

Two samples of seed of *Tagetes erecta* were examined, but only one gave an oil with an

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

appreciable amount of conjugated diene absorption in the ultraviolet. Earle and co-workers (13) found only 2% of conjugated diene in their sample of this species. The present sample yielded an oil containing 8.9% of conjugated dienoic acid.

The total fatty acids were partitioned between methanol and petroleum ether. The methanol-soluble portion was purified by crystallization from acetone at low temperature, followed by a second partitioning. The product was a concentrate consisting mainly of conjugated dienoic acid (λ_{max} 233 mμ). It had infrared absorption at 3 620 cm^{-1}, indicating an OH group, and two peaks of nearly equal intensity at 945 and 980 cm^{-1}, characteristic of a conjugated *cis,trans* or *trans,cis* diene. The substance was identified by oxidative cleavage, before and after hydrogenation, as a mixture of 9-hydroxy-10,12- and 13-hydroxy-9,11-octadecadienoic acids. The procedure and results were similar to those described previously for the identification of these two acids in the oil of another species of the Compositae, *Tragopogon porrifolius* (4). The ratio of 9-hydroxy- to 13-hydroxy-acid was estimated to be about 60:40.

Occurrence of such acids in some but not all samples of a species indicates that they are probably intermediates and not end-products in fatty acid biosynthesis. On the basis of the theory recently advanced by Gunstone (14) it is likely that they are intermediates in the formation of conjugated trienoic acids in the seed. However, the possibility that they are secondary products formed under special climatic or cultural conditions is not excluded.

EXPERIMENTAL

Methods

Seeds were purchased from reliable commercial sources.

Infrared spectra were obtained in carbon disulfide solution; ultraviolet measurements were made in cyclohexane unless otherwise noted; n.m.r. spectra were obtained in deuterochloroform with tetramethylsilane as internal reference. Petroleum ether refers to the fraction of b.p. 30–60°. Hydrolysis of the oils was carried out at 25° for 16 hours in ethanolic 1 *N* potassium hydroxide.

Kentranthus macrosiphon

The oil had λ_{max} 262, 272, 283 and $E_{1\ cm}^{1\%}$ 891 at 272 mμ. There was little absorption and no peak in the region of 233 mμ. The mixed acids (6.1 g) were crystallized fractionally from 54 ml of acetone. Crystals collected at −15° (2.0 g) and −28° (1.3 g) contained 75% and 78% of conjugated trienoic acid respectively. Crystallization of the second fraction from acetone at −20° gave α-eleostearic acid, m.p. 48–49°. Its adduct with maleic anhydride, prepared by the usual method (15), had m.p. and mixed m.p. 63–64°.

Osteospermum hyoseroides

The oil had λ_{max} 263, 272, 283.5 mμ and $E_{1\ cm}^{1\%}$ 642 at 272 mμ. There was no peak in the region of 233 mμ. The infrared spectrum had ν_{max} 957 (w) and 987 (vs) cm^{-1}. There was a trace of absorption at 3 620 cm^{-1}.

The fatty acids were crystallized from acetone at low temperatures. Saturated acids were removed at −20°. The crystals obtained at −30° were recrystallized, first from pentane and then from acetone, yielding the trienoic acid, m.p. 38–39°. Its melting point was not depressed in admixture with *trans*-8,*trans*-10,*cis*-12-octadecatrienoic acid (m.p. 40–40.5°) prepared from calendula seed oil (4). The acid gave an adduct with maleic anhydride which melted at 72–73°, alone and in admixture with the authentic adduct prepared from the calendula acid.

The trienoic acid was treated with tetracyanoethylene in benzene solution by the method described previously (15). The adduct, 3–6′-carboxyhexyl-4,4,5,5-tetracyano-6-*cis*-1′-heptenylcyclohexene, was crystallized from ether – petroleum ether. It melted at 112.5–113.5°.

Anal. Calcd. for $C_{24}H_{30}N_4O_2$: N, 13.8. Found: N, 13.8.

Osteospermum ecklonis

The oil had $E_{1\ cm}^{1\%}$ 595 at 233 mμ (conjugated diene). There was weak absorption at 270 mμ, equivalent to 1.7% of conjugated trienoic acid. The infrared spectrum had ν_{max} 983 (vs) (*trans* double bonds in conjugation) and 3 600 (m) (OH) but no peak in the region 900–975 cm^{-1}.

The oil (12 g) was hydrolyzed for 16 h at 25°, unsaponifiable matter was removed, and the mixed acids were partitioned between petroleum ether and methanol–water (4:1). The methanolic portion yielded 6.8 g of solid acids. Two grams of this product was crystallized from acetone at −20°. The crystals, 0.2 g, m.p. 66.5–67.5°, were removed. When the filtrate was cooled to −50° crystals of dimorphecolic acid formed (1.6 g, m.p. 36–37°, λ_{max} 231 mμ, $E_{1\ cm}^{1\%}$ 1 170, ϵ 34 700).

Anal. Calcd. for $C_{18}H_{32}O_3$: C, 72.92; H, 10.88. Found: C, 72.71; H, 11.01.

A portion (0.15 g) was oxidized by permanganate–periodate (16). The fragments were identified by gas–liquid chromatography (g.l.c.) as hexanoic and azelaic acids.

A portion of the acid (0.7 g, m.p. 36–37°) was hydrogenated in ethanol with Adams' catalyst. The product, after crystallization from ethanol at 0°, had m.p. 82.5–83.5 °C, alone and mixed with 9-D-hydroxystearic acid. The hydroxy acid was oxidized by solid potassium permanganate in glacial acetic acid and the fragments were identified by g.l.c. as nonanoic, decanoic, suberic, and azelaic acids. There were minor amounts of octanoic and pimelic but no valeric or hexanoic acids.

A portion of the dienoic acid was dehydrated by being heated under reflux for 2 h in glacial acetic acid. The product, after crystallization from acetone, had m.p. 58–61° and infrared maximum 990 cm^{-1}, but no peaks in the region 945–975 cm^{-1}. Ultraviolet maxima were at 260, 269, 280 mμ. The substance was treated with iodine in pentane solution but there was no change in melting point or ultraviolet absorption. It was oxidized by permanganate–periodate and the resulting products were identified by g.l.c. as valeric, hexanoic, suberic, and azelaic acids.

Tagetes erecta

Two samples of seed from different sources yielded 22.5% and 18.5% of oil respectively. The first oil had negligible ultraviolet absorption in the regions of conjugated unsaturation. The second had n_D^{25} 1.4760, acid value 4.1, and $E_{1\ cm}^{1\%}$ 98 at 234 mμ. There was no appreciable absorption in the conjugated triene region. The infrared spectrum had ν_{max} 943, 975 (conjugated *cis,trans* diene) and 3 570 (OH), all of low intensity.

The mixed acids (20 g) were partitioned between petroleum ether and methanol–water ($4CH_3OH:1H_2O$). The methanolic fraction (3.1 g) had ultraviolet absorption at 233 mμ equivalent to 48% of conjugated dienoic acid. It was concentrated further by crystallization from acetone at −45° and then by solvent partition as before. The concentrate had ν_{max} 3 620 (OH) and 945 (m), 980 (m) cm^{-1} (*cis,trans* or *trans,cis* conjugated double bonds). A portion (0.7 g) was hydrogenated, giving a product of m.p. 57–59°. It was oxidized by solid potassium permanganate in acetic acid and the main products were identified by g.l.c. as valeric, hexanoic, nonanoic, decanoic, suberic, azelaic, dodecanedioic, and tridecanedioic acids.

ACKNOWLEDGMENTS

The authors are indebted to Dr. F. D. Gunstone for comparing the 9-hydroxystearic acid with his synthetic sample, to Mr. H. Seguin for n.m.r. spectra, and to Mr. R. Lauzon for infrared spectra.

INFRARED STUDY OF THE PHOTOCHEMISTRY OF TETRAMETHYLCYCLOBUTAN-1,3-DIONE

IVAN HALLER AND R. SRINIVASAN
IBM Watson Research Center, Yorktown Heights, New York

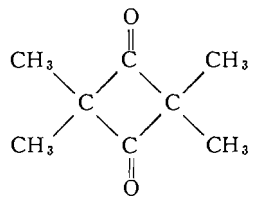
Received June 14, 1965

ABSTRACT

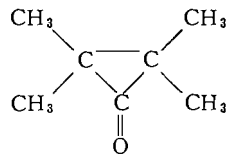
The photolysis of tetramethylcyclobutan-1,3-dione was investigated in a nitrogen matrix at 4 °K and in solution in cyclohexane at room temperature. Infrared spectra of the reactant after irradiation showed the formation of carbon monoxide, dimethylketene, tetramethylethylene, and a compound with an intense absorption at 1 840 cm^{-1} which has been identified as tetramethylcyclopropanone. Since the dimethylketene that was formed was also capable of undergoing secondary photolysis, the effect of light (mainly 2 537 Å) on dimethylketene in solution or in a nitrogen matrix, was also studied. It has been found that in solution 0.2 of the molecules of tetramethylcyclobutandione which decompose, do so to give two molecules of dimethylketene, while approximately the same number of molecules decompose to tetramethylcyclopropanone and carbon monoxide. The remainder of the molecules seem to give tetramethylethylene and carbon monoxide in a concerted process.

INTRODUCTION

The photochemical decomposition of tetramethylcyclobutan-1,3-dione (I) in solution has been the subject of three recent reports (1–3). In benzene solution at 3 660 Å the



I



II

products that were observed were dimethylketene, $(CH_3)_2C{=}C{=}O$, carbon monoxide, tetramethylethylene, and an unstable material which was identified as tetramethylcyclopropanone (II) on the basis of its decomposition products. In hydroxylic solvents, a hemiketal of tetramethylcyclopropanone was isolated which also seemed to lend support to the idea that a primary photoproduct of tetramethylcyclobutandione is tetramethylcyclopropanone.

The present study[1] was undertaken to establish the formation of tetramethylcyclopropanone in this system by direct infrared observation of its presence. The use of infrared spectral analysis to look for transient intermediates in photochemical systems is by no means new (4). Fortunately, in this instance it has been possible to use infrared analysis not only for the purpose of identification, but also for a kinetic study so that a fairly detailed understanding of the photochemistry has been developed.

EXPERIMENTAL

Materials

Tetramethylcyclobutandione (Eastman practical grade), cyclohexane (Eastman spectrograde), ether (Mallinckrodt analytical reagent), and nitrogen (Linde, assayed reagent grade) for the matrix experiments were used as obtained. Dimethylketene was prepared by the pyrolysis of its dimer (5), purified by several bulb-to-bulb distillations *in vacuo*, and stored under its own vapor pressure at −78 °C.

[1] *A preliminary account of this work has appeared in J. Am. Chem. Soc. 87, 1144 (1965).*

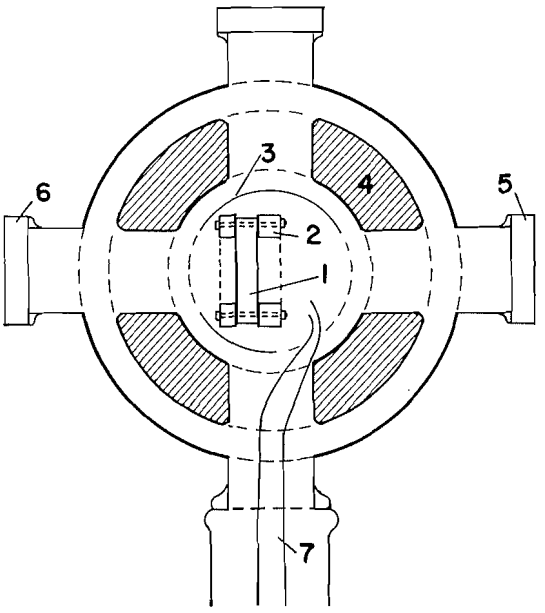


FIG. 1. Section of the low temperature cell. 1, CsBr plate; 2, copper cold finger; 3, copper radiation shield connected to liquid helium container; 4, liquid nitrogen container; 5 and 6, KBr windows; 7, gas inlet tube. The irradiation was affected through window 5.

Apparatus

The optical cell that was used in the matrix experiments was a modified, all-glass double dewar (H. S. Martin Co.) as shown in Fig. 1. Photolyses in solution were carried out in infrared cells with KBr windows which were 1 mm apart.

The light source was a medium pressure mercury arc (Hanovia type 73A10 or type SH) which was used in conjunction with a filter which consisted of a 2 cm layer of water to remove much of the infrared radiation. In some experiments a chlorine gas filter (3.2 cm long, $p = 1$ atm) or a grating monochromator (Bausch & Lomb type ZB3104) was also used to isolate the 2 537 Å radiation.

Infrared spectra were recorded on a Cary-White Model 90 spectrophotometer. The frequency accuracy is ± 3 cm^{-1} in survey spectra and ± 1 cm^{-1} in the regions that were observed in detail. Spectral slit-widths are indicated in the reproductions of the spectra.

Procedure

The mixture of nitrogen and tetramethylcyclobutandione vapor was prepared continuously during deposition by passing the former at a pressure of 20 mm through a glass coil which contained crystals of the latter. The vapor pressure of the diketone at room temperature is of the order of 0.2 mm. Mixtures of dimethylketene and nitrogen were prepared by standard methods (6).

Solutions of dimethylketene in hexane, which were used for the measurement of absorption coefficients, were prepared with particular care to exclude oxygen from the solvent (before the addition of dimethylketene) and from the solution (during transfer or measurements).

RESULTS

Matrix Studies

Tetramethylcyclobutandione was photolyzed in a nitrogen matrix in two separate experiments for 20 min and 2 h, respectively. The infrared spectra that were obtained in the second experiment are shown in Fig. 2. Absorption peaks belonging to the products of photolysis were observed at 2 138, 2 124, 2 103, 1 843, 1 824, 1 675, 1 414, 1 009, 972, 902 (?), 793, and 728 cm^{-1}. In addition, the band at 1 176 cm^{-1} in the spectrum of tetramethylcyclobutandione increased slightly after photolysis and shifted to lower frequencies, probably by the superposition of a product peak.

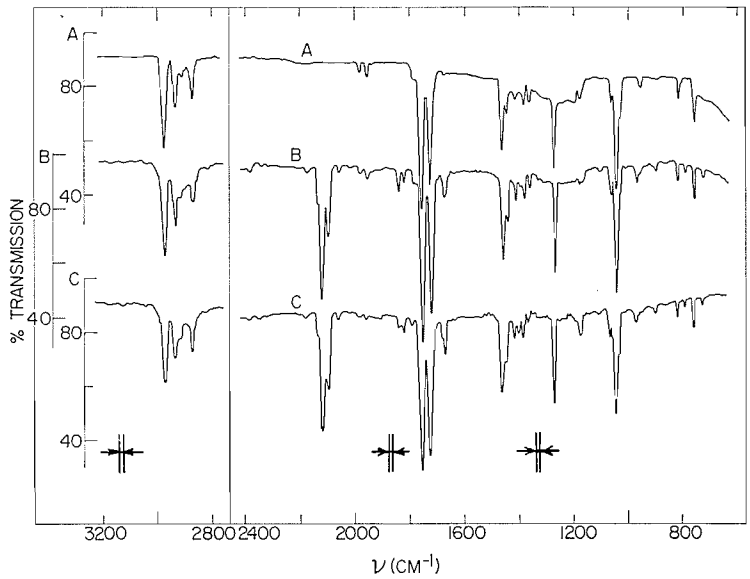

FIG. 2. Infrared spectra of tetramethylcyclobutandione in nitrogen matrix. A, before irradiation; B, after 120 min irradiation; C, after a warm-up cool-down cycle.

The intensity behavior of the stronger absorption peaks, due to the products, is shown in the first three colums of Table I. The spectra, from which these numbers were obtained, were recorded with a spectral slit-width which was less than the half-widths. Allowing the sample to warm to 35 °K, followed by recooling to 4 °K, did not result in the loss of any of the product bands or in the formation of new ones, even though extensive diffusion was indicated by the broadening and shifts in the maxima. When the CsBr plate in the cell was slowly warmed to 77 °K, a substantial part of the products remained as a solid deposit which gave rise to broad absorption bands corresponding to each of the bands observed in the matrix, with the exception of the one at 2 138 cm^{-1}.

Dimethylketene was deposited in a nitrogen matrix at a mole ratio of 1:80, in an amount comparable to that found in the previous experiments. Infrared bands were observed at 2 985, 2 944, 2 921, 2 899, 2 885, 2 866, 2 123.6, 2 104.0, 2 067, 2 061 (?), 1 911 (?), 1 905 (?), 1 450, 1 417, 1 401, 1 388, 1 332, 1 012, 913, and 729 cm^{-1}. None of these peaks changed in intensity, nor did any new peaks appear upon irradiation for 1 h under conditions that were identical to the photolysis of tetramethylcyclobutandione.

Solution Studies

A solution of tetramethylcyclobutandione in cyclohexane (1.22 mole %) was photolyzed at room temperature at 2 537 Å. Infrared bands of the photoproducts appeared at approximately the same frequencies as in the matrix isolation experiments. Figures 3A and 3B show the part of the spectrum from 2 200 cm^{-1} to 1 790 cm^{-1} before and after photolysis. Figure 3C shows the changes in the spectrum on bubbling a few milliliters of oxygen gas through the solution after photolysis.

In a different set of experiments a solution was photolyzed with 3 130 Å radiation. Infrared spectra were recorded after 8, 16, 32, 64, and 128 min of photolysis and after allowing the irradiated solution to stand in the dark for 38 h. Figures 3D and 3E present the regions of interest in the last two spectra. The observed intensities of the product bands are summarized in Table I.

*Not a continuation of the preceding experiment.
†Intensity is reported as both optical density (o.d.) at the maximum, A, and integrated area (o.d. times half-width), B. "sh" refers to shoulder so that integration of the area under the absorption peak was not possible.

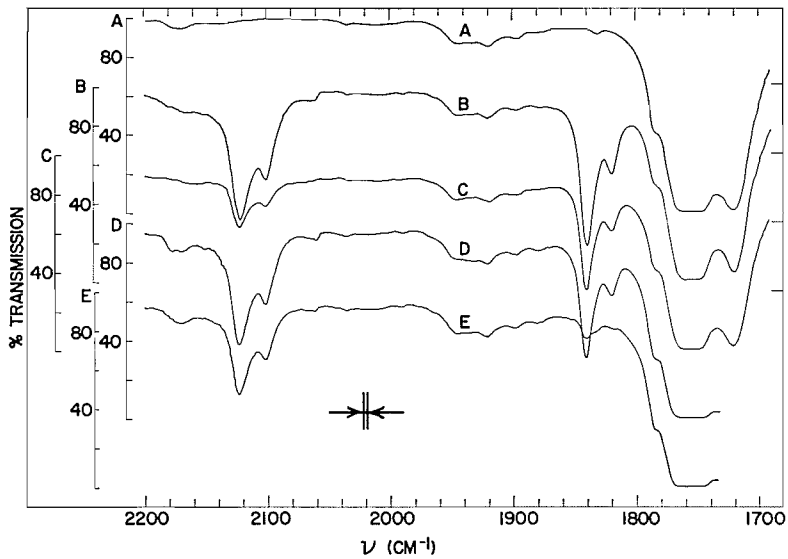

FIG. 3. Tetramethylcyclobutandione in cyclohexane solution. A, before photolysis; B, 20 min irradiation at 2 537 Å; C, after oxygenation; D, after 128 min irradiation at 3 130 Å (new sample); E, after 38 h standing in dark.

In the spectral regions in which the interference from the absorption due to the solvent was not a serious problem, weak bands due to products were observed at 1 415 cm^{-1} and 962 cm^{-1}. On allowing the solution to stand in the dark, and on oxygenation, the former band behaved similarly to the band at 2 123 cm^{-1}, the latter to the band at 1 840 cm^{-1}. A weak product band also appeared at 2 336 cm^{-1}. It underwent tremendous intensification upon oxygenation and was identified as due to carbon dioxide by comparison with the spectrum of a solution of dry ice in cyclohexane.

DISCUSSION

Interpretation of the Spectra

The behavior of the product bands in the warm-up cool-down cycle in the matrix experiments, and the fact that the similar absorption frequencies are observed in the cyclohexane solutions, lead to the conclusion that none of the observed bands belong to an unstable species such as a free radical. The effect of oxygenation and standing at room temperature in the dark indicates the presence of at least two compounds which have different chemical properties.

By direct comparison with the spectrum of dimethylketene the product bands at 2 124, 2 103, 1 414, 1 009, and 728 cm^{-1} were assigned to this compound. The two remaining strong bands, at 1 840 and 1 820 cm^{-1}, apparently belong to one compound as their intensities vary in a similar fashion. An assignment to tetramethylcyclopropanone is strongly favored by the near coincidence with the $\rangle$CO stretching frequency of cyclopropanone in a nitrogen matrix (7), and by the observed chemical behavior. The weak band at 2 138 cm^{-1} was obviously due to carbon monoxide (8).

The formation of dimethylketene as a product had already been shown by earlier work, (1, 3) but the production of tetramethylcyclopropanone was deduced indirectly from the formation of carbon monoxide. The present work thus offers the most direct evidence for the decarbonylation reaction [1].

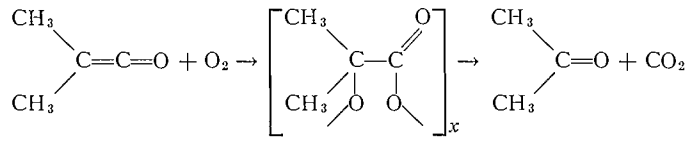
[1] 
Early work had also shown that tetramethylethylene was an important product of photolysis. In this study efforts were made to look for this product in the infrared spectra. The increase in absorption at 1 176 cm^{-1} in the matrix experiments may be due to this product (9). However, it was best to look for this compound in the ultraviolet spectrum where it shows very intense end absorption rather than in the infrared spectrum where its absorption coefficient is low.

The ultraviolet spectrum of a solution of tetramethylcyclobutandione in cyclohexane did show an intense increase in absorption in the region from 2 400 to 2 000 Å on photolysis to low conversion in a quartz cell. This increased absorption could not be accounted for by the presence of dimethylketene or tetramethylcyclopropanone, an upper limit for the concentrations of these two species being available from the $n \rightarrow \pi^*$ absorption. In a typical photolysis, in which the extinction coefficient of the absorption due to the dione decreased from 0.22 to 0.21 at 3 075 Å, the optical density at 2 160 Å increased by more than 0.8. The contribution due to dimethylketene could not have been more than 0.01 at this wavelength, while the contribution due to tetramethylcyclopropanone can be estimated to be even less.



It was also found that bubbling oxygen through a solution of dimethylketene in cyclohexane resulted in no infrared bands belonging to the ketene peroxide (10, 11), only bands at 2 336 cm^{-1} and 1 720 cm^{-1} assignable to its decomposition products, namely, carbon dioxide and acetone. Isobutyric acid anhydride, formed by reacting small quantities of water with dimethylketene, exhibits infrared bands of equal intensity at 1 820 and 1 760 cm^{-1}.

$$H_2O + 2(CH_3)_2C{=}C{=}O \rightarrow [(CH_3)_2CHCO]_2O$$

Photochemical Primary Processes

Since discussions of the photochemistry of tetramethylcyclobutandione have already been published, (1, 3)[1] it is adequate to consider here the modifications which are suggested by the infrared spectral data that were obtained in the present study.

In addition to the photochemical primary process [1] there is undoubtedly a second primary process which gives rise to dimethylketene.

[2] 
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Direct measurement of the concentration of dimethylketene in both the ultraviolet and the infrared spectra of the solution has indicated that at least 2/10 of the molecules of tetramethylcyclobutandione that decompose follow reaction [2]. Whether all of the remaining molecules follow reaction [1] is one of the important questions that can be answered by the present studies. Since tetramethylcyclopropanone appears to be stable enough (half-life of several hours) to build up in solution during photolysis, its concentration can be estimated from the intensity of its carbonyl absorption provided that photolysis is not taken to conversions over a few per cent. The fact that the intensity of the carbonyl absorption due to tetramethylcyclopropanone is considerably less than the carbonyl absorption due to dimethylketene suggests that reaction [1] probably accounts for a smaller fraction of the dione than reaction [2].[2] Since one molecule of the dione gives rise to two molecules of dimethylketene but only one molecule of tetramethylcyclopropanone, an upper limit for the fraction of molecules of the reactant that take part in reaction [1] appears to be 0.4.[3]

The formation of tetramethylethylene was accounted for by the earlier workers (1, 3) through the formation and subsequent decomposition of tetramethylcyclopropanone. While this may be true if the reaction is carried to a point at which secondary photolysis does occur, the presence of tetramethylethylene from the early stages of the photolysis requires a third primary process. This process may very well account for the remaining

[3] 
$$(CH_3)_2C(CO)C(CH_3)_2 + h\nu \rightarrow (CH_3)_2C{=}C(CH_3)_2 + 2CO$$

4/10 of the dione molecules which undergo decomposition. It is known (15) that tetramethylcyclobutandione in its $n \rightarrow \pi^*$ excited state showed an interaction and weak bonding between the carbonyl groups.[4] The effect of such an interaction would be to decrease the distance between the remaining two carbon atoms in the cyclobutane ring so that a concerted process such as that required in reaction [3] may well be possible.

[2]*The integrated intensities of the carbonyl bands of cyclic ketones fall between 1.6 and 2.9 in units of 10^4 moles^{-1} l cm^{-2}, smaller rings being at the higher end of this range (12, 13). For tetramethylcyclopropanone 2.0 may then be taken as a lower limit. The measured integrated intensity for the 2 123 cm^{-1} band of dimethylketene in cyclohexane is 1.9 ± 0.3 in the same units.*

[3]*In earlier work (1, 3), the importance of primary process [1] has been estimated from the scavenging action of oxygen on the system. These estimates assume that tetramethylcyclopropanone reacts rapidly with oxygen, an assumption which is not borne out by the present work. It is wholly possible that an excited state which is the precursor for tetramethylcyclopropanone does react with oxygen, but the same excited state may lead to other products as well. Hence, the estimate is probably too high. The recent report that tetramethylcyclopropanone reacts with oxygen (14) points out the need for careful rate studies on this reaction.*

[4]*Reference 15 also presents data to show that in polar solvents the ultraviolet spectrum of tetramethylcyclobutandione shows marked shifts which are indicative of an interaction between the excited states of the dione and the solvent. As a result it is not possible to draw any conclusions regarding primary process [3] from data that were obtained during photolysis in a polar solvent.*

A NEW SYNTHESIS OF ALKYL FLUORIDES

THE PYROLYSIS OF 2-ALKYLPSEUDOURONIUM FLUORIDES AND FLUOROBORATES[1]

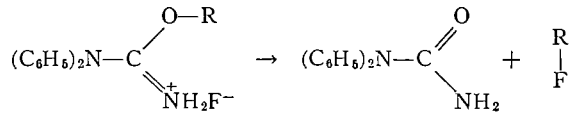
J. H. AMIN, J. NEWTON,[2] AND F. L. M. PATTISON
Department of Chemistry, University of Western Ontario, London, Ontario

Received August 16, 1965

ABSTRACT

The pyrolysis of 2-alkylpseudouronium fluorides and fluoroborates at approximately 185° gave alkyl fluorides in yields of up to 77%. The method is most useful for the preparation of primary alkyl fluorides; attempts to prepare secondary fluorides, such as cyclohexyl fluoride, gave the corresponding alkenes.

In the general investigation of new methods of forming the C—F bond, we have examined the pyrolysis of 2-alkylpseudouronium fluorides and fluoroborates. The reaction is analogous to the decomposition of 2-alkylpseudouronium chlorides (1).



The pseudouronium salts were most conveniently prepared from diphenylcyanamide and the appropriate alcohols in the presence of potassium *tert*-butoxide (1–3). The reaction is readily followed by infrared spectroscopy: the C≡N stretching band at 2 250 cm^{-1} gives way to the new C=N band at 1 640 cm^{-1}. Maximum yields are obtained when the alcohols are freshly distilled and when moisture is rigorously excluded. The fluoride salts were prepared by mixing a dried ethereal solution of the resultant free base with an ethereal solution of hydrogen fluoride; the fluoroborates were obtained with 48% aqueous fluoroboric acid. The fluorides usually had the approximate composition $B \cdot 3HF$ whereas the fluoroborates had the expected stoichiometrical composition $B \cdot HBF_4$. (These ratios were used in the calculation of yields.) Occasionally other methods of preparation were used (3), but were generally less satisfactory. Some yields of pseudouronium salts are shown in Table I.

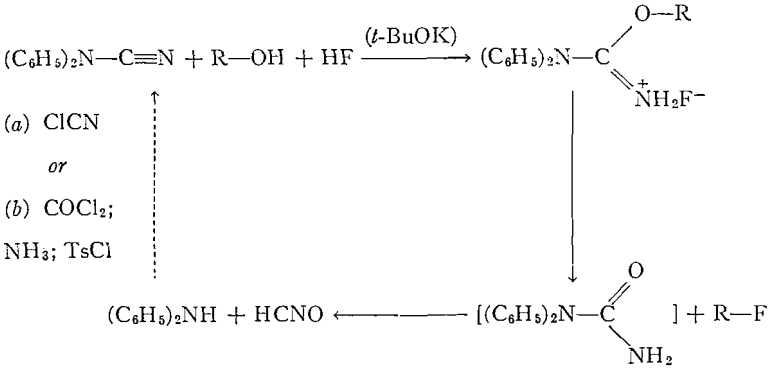
[1]*This paper was presented in part at the Third International Symposium on Fluorine Chemistry, Munich, Germany, August 30 – September 2, 1965.*

[2]*Present address: Chemical Abstracts Service, The Ohio State University, Columbus 10, Ohio 43210, U.S.A.*

The best yields of alkyl fluorides were obtained when the pyrolysis of the salts was carried out at a temperature of about 185°. The residue contained diphenylamine (92% yield); this product is consistent with the well-known decomposition of 1,1-diphenylurea to diphenylamine and cyanic acid. The amine can readily be reconverted into diphenylcyanamide by common synthetic procedures in 90% yield or better. The overall reaction may thus be considered as the reaction of an alcohol with hydrogen fluoride to give an alkyl fluoride; the diphenylcyanamide is alternately consumed and reformed.



The pyrolysis may be carried out with or without solvents (Table II). The following high-boiling solvents were examined: mesitylene, octadecane, paraffin wax, diethylene glycol, and triethylene glycol, but in no case was the yield improved. The nonpolar solvents gave results comparable with those obtained by straight pyrolysis, whereas the

polar solvents were usually less effective. Some yields were improved by adding potassium bifluoride to the pseudouronium salt before pyrolysis; this is necessary, in the case of the fluoroborates, to suppress alkene formation. Isolation and purification of the alkyl fluorides followed standard patterns.

Some variations in the procedure were examined briefly. Free 2-alkylpseudourea bases, on pyrolysis with an excess of potassium bifluoride, gave no alkyl fluorides. 2-Alkylpseudouronium fluorides, on pyrolysis with an excess of ammonium chloride, gave a mixture of alkyl chlorides and alkyl fluorides (RCl:RF = 3:1). 2-Alkylpseudouronium chlorides, on pyrolysis with an excess of potassium bifluoride, gave only alkyl chlorides.

As the work proceeded, it became apparent that, for two reasons, the method is mainly of value in the preparation of *primary* alkyl fluorides. Firstly, primary alcohols form the pseudouronium salts far more readily than do secondary and tertiary alcohols. Secondly, secondary and tertiary alkyl groups, under the conditions of pyrolysis, tend to form the corresponding alkene rather than the alkyl fluoride; thus, 2-cyclohexyl-3,3-diphenylpseudouronium fluoride gave cyclohexene exclusively (56%).

It was hoped that the method could be simplified by using imidate hydrofluorides or fluoroborates in place of the pseudouronium salts. So far, however, we have not been successful in forming the necessary salts, although we have examined a number of routes and techniques. Another alternative, involving the pyrolysis of a mixture of a carbamate and potassium bifluoride, was also unsuccessful.

It is probable that the mechanism of pyrolysis parallels that of the decomposition of imidate hydrochlorides. Kinetic results (4) in chloroform or *tert*-butyl alcohol at 60° (first-order disappearance of halide ion) were consistent with two routes, which, when applied to the pseudouronium fluorides, may be represented as follows:

[i] Intramolecular: $(C_6H_5)_2N-C(=O-R)(=NH_2\cdots F^-) \rightarrow (C_6H_5)_2N-C(=O)-NH_2 + R-F$

[ii] S_N2: $(C_6H_5)_2N-C(=O-R)(=NH_2F^-) \rightarrow (C_6H_5)_2N-C(=O-R\ F^-)(=NH_2) \rightarrow (C_6H_5)_2N-C(=O)-NH_2 + R-F$

For compounds in which R is optically active, the first of these would be expected to result in retention of configuration (S_Ni), and the second in inversion (S_N2). The fact that Walden inversion, in the pyrolysis of crystalline *sec*-butyl acetimidate hydrochloride, has now been observed (5) and that the rates of decomposition of imidate salts are of the same order as those of other recognized S_N2 reactions (4) makes *ii* the mechanism of choice. It is uncertain (but likely) that this conclusion can be applied to the pyrolysis of pseudouronium salts in the solid phase; studies involving optically active pseudouronium salts derived from RCHDOH (6) would clarify this point.

EXPERIMENTAL

The preparations described below represent a typical example of each procedure; obvious variations for obtaining different members have not been included. Melting points (uncorrected) were determined on a Kofler hot stage, and infrared spectra with Beckman IR-7 and IR-5 infrared spectrophotometers. Analyses were performed by the Schwarzkopf Microanalytical Laboratory, Woodside, New York 77. Fractionations were carried out with a 23-plate platinum-plated spinning-band column.

2-Decyl-3,3-diphenylpseudouronium Fluoride

Freshly distilled 1-decanol (150 g), diphenylcyanamide (38.8 g, 0.2 mole), and potassium *tert*-butoxide (0.5 g) were heated under reflux overnight on a steam bath with mechanical stirring. The infrared spectrum of an aliquot in chloroform indicated the complete disappearance of the C≡N band at 2 250 cm^{-1} and the presence of a C=N band at 1 640 cm^{-1}. The unreacted excess of 1-decanol was recovered by distillation under reduced pressure (b.p. 73–74° at 0.4 mm) and the viscous residue was dissolved in anhydrous ether (250 ml). Anhydrous hydrogen fluoride (15 g) (NOTE: *Use rubber gloves*) in cold ether (100 ml) was then added to the ethereal solution of the pseudourea base, which was contained in a polythene beaker. The mixture was stirred and cooled to −50°. The resultant salt was filtered off, washed several times with cold ether, and dried in a desiccator over potassium hydroxide pellets; yield: 73.0 g, 89%. Recrystallization from chloroform – petroleum ether (35–60°) gave colorless needles, m.p. 123–125°.

Titrimetric analysis, using 0.01 *N* sodium hydroxide, indicated that the product usually contained the elements of 3HF, but some variation in fluorine content was observed. This is consistent with the well-known tendency of hydrogen fluoride to form double molecules, complexes, and hydrofluorides of crystallization (7); with weak bases, for example, the molar ratio of HF to base varies between 1 and 4. For purposes of calculation in this work, the composition was taken to be B·3HF.

Melting points of the fluoride salts are listed in Table I. Two analyses follow.

2-Pentyl-3,3-diphenylpseudouronium Fluoride

Anal. Calcd. for $C_{18}H_{25}F_3N_2O$: C, 63.16; H, 7.36; N, 8.18; F, 16.64. Found: C, 62.90; H, 7.25; N, 8.29; F, 16.85.

2-Octyl-3,3-diphenylpseudouronium Fluoride

Anal. Calcd. for $C_{21}H_{31}F_3N_2O$: C, 65.60; H, 8.13; N, 7.29; F, 14.83. Found: C, 65.97; H, 7.76; N, 7.30; F, 15.37.

2-Decyl-3,3-diphenylpseudouronium Fluoroborate

The free pseudourea base was prepared as in the above procedure, with diphenylcyanamide (29.1 g, 0.15 mole), freshly distilled 1-decanol (100 g), and potassium *tert*-butoxide (0.5 g). After recovery of the excess 1-decanol by distillation under reduced pressure, the residue was dissolved in ether (200 ml) and to it was added 48% aqueous fluoroboric acid (50 ml). The ether was allowed to evaporate overnight at room temperature. The oily residue was dissolved in chloroform (250 ml), and the resultant solution was washed with water, dried over anhydrous sodium sulfate, and concentrated to about 100 ml. On careful dilution with petroleum ether (35–60°), the fluoroborate salt crystallized as colorless needles (49.5 g, 75%), m.p. 86–87°. It may be recrystallized from chloroform – petroleum ether (35–60°) and should be stored in a desiccator over potassium hydroxide pellets.

Titrimetric analysis, using 0.01 *N* sodium hydroxide, indicated the composition B·HBF_4. Two analyses follow.

2-Pentyl-3,3-diphenylpseudouronium Fluoroborate

Anal. Calcd. for $C_{18}H_{23}BF_4N_2O$: C, 58.41; H, 6.26; N, 7.57; F, 20.52. Found: C, 58.35; H, 6.44; N, 7.73; F, 20.37.

2-Octyl-3,3-diphenylpseudouronium Fluoroborate

Anal. Calcd. for $C_{21}H_{29}BF_4N_2O$: C, 61.18; H, 7.09; N, 6.79; F, 18.43. Found: C, 61.37; H, 7.24; N, 6.71; F, 18.60.

1-Fluorodecane (from Fluoride Salt)

A 500 ml round-bottomed flask, fitted with an 8 inch vertical air condenser carrying a Claisen-type distillation head leading to appropriate condensers and traps, was charged with a finely ground mixture of 2-decyl-3,3-diphenylpseudouronium fluoride (41.2 g, 0.1 mole) and potassium bifluoride (15.6 g, 0.2 mole). The flask was gradually heated in an air bath until decomposition started (ca. 185°). The temperature was then maintained at about 250° until distillation ceased; thereafter, the temperature was raised to about 300° and the pressure was reduced to ensure complete isolation of the product (15.3 g). The distillate was dissolved in ether (50 ml), and the ethereal solution was washed with 2% aqueous sodium bicarbonate and with water. After this solution was dried over anhydrous sodium sulfate and after removal of the ether, fractionation of the residue gave 1-fluorodecane (12.3 g, 77%), b.p. 187–190°, n_D^{25} 1.4087 (lit. (8) b.p. 74–75° at 13 mm, n_D^{25} 1.4080). The identity of the product was further confirmed by gas–liquid chromatographic analysis and infrared spectroscopy.

The residue, after pyrolysis, was treated with hot water (200 ml) and transferred to a beaker. The oily suspension solidified on the addition of aqueous sodium hydroxide, and cooling. The product was filtered, washed with water, dried in a desiccator, and recrystallized from aqueous methanol; yield: 15.6 g, 92%. It was proved to be identical with diphenylamine by the usual physical and chemical methods.

1-Fluorodecane (from Fluoroborate Salt)

The pyrolysis was carried out in the same equipment and by the same method as in the previous procedure, with 2-decyl-3,3-diphenylpseudouronium fluoroborate (44.0 g, 0.1 mole) and potassium bifluoride (31.2 g, 0.4 mole) in octadecane (100 g). The decomposition started at 225° and the temperature was maintained at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

300° until distillation had ceased. The distillate (12 g) was washed, dried, and purified as before, yielding pure 1-fluorodecane (8.8 g, 55%), b.p. 184–187°, n_D^{25} 1.4084 (lit. (8) b.p. 74–75° at 13 mm, n_D^{25} 1.4080). The identity of the product was further confirmed by the usual methods.

1-Chloro-6-fluorohexane and *1,6-difluorohexane* were prepared by the above procedures (Table II); their identities were confirmed by reference to authentic samples (9).

ORTHO PARTICIPATION IN THE CONVERSION OF *syn*-BENZALDOXIME ESTERS TO NITRILES

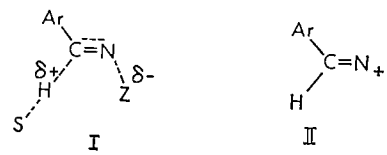
ROBERT J. CRAWFORD AND CHARLES WOO
Department of Chemistry, University of Alberta, Edmonton, Alberta
Received June 11, 1965

ABSTRACT

Substituted *syn*-benzaldoxime esters are transformed, in an alcoholic solution, to the corresponding nitriles according to first-order kinetics. All ortho substituents were observed to accelerate the rate of nitrile formation relative to the corresponding para derivative. While the k_o/k_p ratios for the bromo, chloro, fluoro, methoxy, and methyl substituents fall within the range of 2 to 9, the iodo and methylthio substituents are 119 and 11 000 respectively. Isotopic replacement of the aldoximino hydrogen by deuterium gives rise to a kinetic isotope effect, k_H/k_D being 5.21 for *syn*-*o*-chlorobenzaldoxime *p*-toluenesulfonate, 1.22 for *syn*-*o*-iodobenzaldoxime *p*-toluenesulfonate, and 1.23 for *syn*-*o*-methylthiobenzaldoxime *o*-iodobenzoate. The marked enhancement of rate and the absence of an appreciable isotope effect are considered to be associated with sulfur and iodine participation in the rate-determining step. A mechanism which is capable of explaining the results observed is suggested.

INTRODUCTION

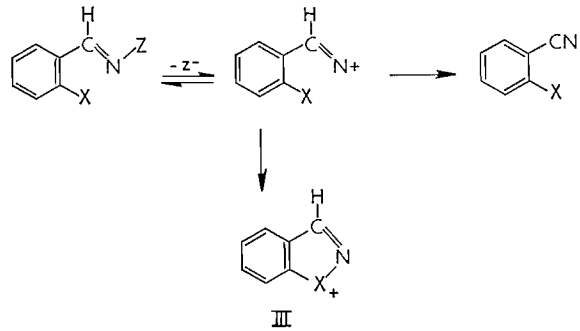
In a recent study of the conversion of *syn*-aldoxime arenesulfonates to nitriles we found that the reaction could be characterized as a concerted elimination (1) having a transition state resembling I. However the possibility that the rate-determining step was proton loss to the solvent from an imidonium species II could not be dismissed. We have undertaken the work reported herein in an attempt to resolve this problem.



I II

We decided to approach this by trying to use an "internal trap" in the ortho position, i.e. if the imidonium species II is formed then a suitable substituent X in the ortho position may trap this species faster than the return to starting material or conversion to product may occur, as per Scheme I. The results from a study of the ortho substituted aromatic ketoximes by von Auwers and co-workers (2) suggests that the ortho substituted acetophenone oximes undergo the Beckmann rearrangement at a faster rate than the similarly substituted para derivatives. This point was confirmed by Pearson and Cole (3), by comparison of the rates of rearrangement of ortho and para acetophenone oximes in sulfuric acid. The acceleration was attributed to a steric force whereby the ortho substituent displaces the α-oximinoethyl group out of the plane of the benzene ring. The rates in concentrated sulfuric acid are complicated by the fact the protonation may occur on oxygen and nitrogen (4); thus we have used arenesulfonate leaving groups.

Some ortho substituents, particularly those in which the substituent can function as a nucleophile, have been observed to anchimerically accelerate the reaction rate. Thus the ionization of *o*-methoxyneophyl *p*-toluenesulfonate and *o*-iodophenylethyl *p*-bromobenzenesulfonate is assisted by the *o*-methoxy and *o*-iodo substituents respectively (5).



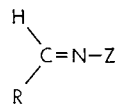
III

SCHEME I.

RESULTS AND DISCUSSION

Configuration of Aldoximes

In order that we may be confident of the configuration of the oximes the nuclear magnetic resonance (n.m.r.) spectrum of known oximes are compared in Table I with those not yet assigned, the *o*-iodo and *o*-thiomethylbenzaldoximes. The configurations of phenylhydrazones, semicarbazones, and thiosemicarbazones of the general structure IV



IV

have been determined by Karabatsos *et al.* (6) by n.m.r. Aldoximes are observed to follow a similar pattern (7). The OH and CH protons in the *syn* configuration appear as two singlets in the region τ 0.0 to 2.0 and are usually well separated. This is well distinguished from the corresponding protons in the *anti* isomer which appear at higher fields and closer together. The fact that these protons in the *o*-iodobenzaldoxime melting at 110° appear at τ 1.27 and 1.54 indicates that it has the *syn* configuration. The same is true for the *o*-methylthiobenzaldoxime melting at 88–90°.

Rate Comparisons

The rate constants were obtained as described in the previous paper (1). A comparison of reaction rates of para and ortho substituted *syn*-benzaldoxime *p*-toluenesulfonates is

listed in Table II. The *p*-toluenesulfonate of *syn-o*-methylthiobenzaldoxime is very reactive and unstable; it cannot be isolated. Thus a slower leaving group was used. Table III presents, for comparison, the extrapolated value at 92° of the rate constants of *syn-o*-methylthiobenzaldoxime *o*-iodobenzoate in 50% dioxane. The reaction of *syn-p*-methylthiobenzaldoxime *o*-iodobenzoate was so slow at 92° that the rate was measured to only 40% completion.

An examination of the ortho and para (k_o/k_p) rate constants from Tables II and III clearly shows that all ortho substituents, irrespective of their resonance or inductive effect, increase the rate of nitrile formation when compared with their para isomer (3). However, it is interesting to note that in the seven pairs of isomeric structures studied, the k_o/k_p ratio of the bromo, chloro, fluoro, methoxy, and methyl substituents fall within the range of 2 to 9, while that for the iodo and methylthio substituents is 119 and 11 000, respectively. Thus substantial rate enhancements are involved in the latter two cases.

*Extrapolated rate constant.

The mechanism of the thermal conversion of substituted *syn*-benzaldoxime esters to nitriles in methanol has been proposed (1) to involve a concerted *cis* elimination, as represented by I. The increase in rate by ortho substituents can be attributed to an increase in potential energy of the reactant in the ground state by virtue of steric inhibition

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of resonance. This steric acceleration has been suggested by Pearson and Cole (3) to be one of the factors responsible for the enhanced rearrangement rate of the ortho substituted acetophenone oximes in sulfuric acid. While steric facilitation may contribute appreciably to the enhancement of rate by a factor up to 9 in the bromo, chloro, fluoro, methoxy, and methyl series, it does not as readily account for the factor of 119 in the iodo, and particularly, 11 000 in the methylthio substituents. The exceptional reactivity of the *o*-iodo and *o*-methylthio substituents is too great to be attributed to resonance, inductive, or steric effects, but suggests that the reaction may proceed through a heterocyclic "onium" ion III, where the *o*-iodo and *o*-methylthio groups contribute to the transition state by release of electrons to the nitrogen atom, thus producing an intermediate wherein the stereochemistry is favorable for the more rapid *trans* elimination to form the nitrile.

The activation parameters in Table IV indicate that the large enhancement of rate by the *o*-iodo substituent is associated with a lowering in $\Delta H^{\ddagger}$ of approximately 2 kcal mole^{-1} when compared with the other ortho substituents. From the rate constants of *syn-o-* and *syn-p*-methylthiobenzaldoxime *o*-iodobenzoates, an estimation of the change of free energy of activation can be made by the following relation.

$$\Delta\Delta F^{\ddagger} = -RT \ln \frac{k_o}{k_p}$$

This gives rise to a decrease in $\Delta F^{\ddagger}$ of 6.7 kcal mole^{-1} for the *o*-methylthio substituent when compared with the corresponding *p*-isomer.

TABLE IV

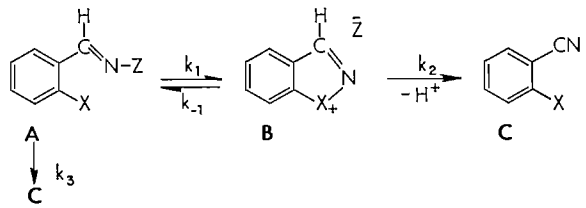
Isotope Effects

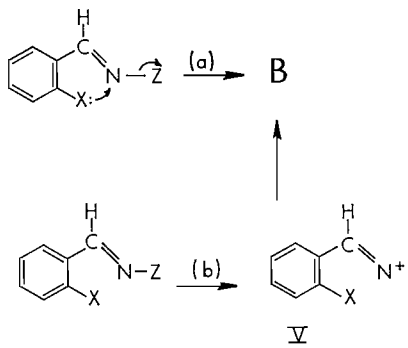
Such an intermediate as III would be ideally set up for the elimination process and one would expect the second step, k_2 in Scheme II, to be very rapid. This point can be tested experimentally. It has been shown (1) that a k_H/k_D value of 4.51 was observed in the elimination of the para substituted compounds. With ortho participation, however, k_2 may be faster than k_{-1}, and k_H/k_D would approach unity. Table V shows that *syn-o*-chlorobenzaldoxime *p*-toluenesulfonate, which is not expected to participate, has a k_H/k_D value of 5.21. The k_H/k_D values for *syn-o*-methoxybenzaldoxime *p*-toluenesulfonate is 2.51, *syn-o*-iodobenzaldoxime *p*-toluenesulfonate is 1.22, and *syn-o*-methylthiobenzaldoxime *o*-iodobenzoate is 1.23. Thus the large enhancement in rate and the absence of appreciable kinetic isotope effect in the latter two cases suggest strongly that ortho participation is a major contributing factor, and that the reaction proceeds by at least a two step process.

The evidence does not, however, indicate how the participation occurs and two possibilities readily come to mind.



SCHEME II.

The ortho substituent may be affecting a nucleophilic displacement on the oximino nitrogen as in (*a*), or the participating group may act as an internal trap for the imidonium species V as in (*b*).

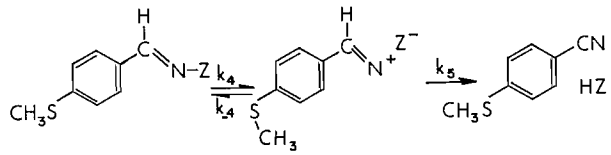


Route (*a*) implies a nucleophilic displacement by the participating group on sp^2 nitrogen, a process which is not well documented, whereas route (*b*) involves an ionic intermediate. By analogy with known properties of internal return from ^{18}O labeling of *p*-nitrobenzoate esters (8) as well as the rearrangement of sulfinates to sulfones (9) and and thiobenzoates to thiolbenzoates (10), one would expect the enhancement of k_1 due to the prevention of the step k_{-1} in Scheme II to be less than a factor of 5.

If the formation of the "onium" species B proceeds by route (*b*) then k_{-1} in Scheme II would approach zero for the *o*-methylthio substituent based on the assumption that it is an efficient trapping agent. From the relative rates of the ortho and para isomers, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

assuming a value of $k_{obs}^{o} = 8k_4$ (i.e. approximately the magnitude for the methyl substituent), the amount of ion-pair return, k_{-4} for the para isomer can be estimated from



VI

SCHEME II

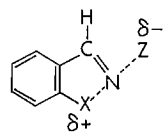
the observed rate constant for the ortho (k_{obs}^{o}) and para (k_{obs}^{p}) isomers. Then from the steady-state treatment for the para isomer we obtain, from Scheme II,

$$k_{obs}^{p} = \frac{k_5}{(k_4 + k_5)} k_4.$$

Thus

$$\frac{k_{obs}^{o}}{k_{obs}^{p}} = \frac{8k_4}{\left(\frac{k_5}{k_{-4} + k_5}\right)k_4} = 11\,000, \text{ and } k_{-4} \simeq 1\,400\, k_5.$$

This implies that if the electronic factors for ortho and para positions are the same and if the para species is going by the imidonium ion VI, then for every time that it formed it must return to starting material 1 400 times more frequently than it went on to product. Such a scheme would imply a much higher degree of internal return of the initially formed ion-pair than has been previously observed (8–10) and indeed what we conclude is that the *o*-thiomethyl group is not acting as an efficient trap, but must be bringing about reactions as per route (*a*), and that the transition state for the *o*-thiomethyl (and *o*-iodo) derivative may be best represented by VII. On this basis we may also rule out the deprotonation of the imidonium species II as the rate-determining step in the previously observed elimination (1).



VII

syn-o-Methoxybenzaldoxime *p*-toluenesulfonate presents an interesting case. Its small k_o/k_p value of 4.06 shows no indication of anchimeric assistance, but the kinetic isotope effect of 2.51 is about half of that expected for a concerted *cis* elimination. However, it has been pointed out (5) that *syn-p*-methoxybenzaldoxime *p*-toluenesulfonate reacts unusually fast because of direct resonance interaction of the methoxy group with the reaction center, thus resulting in a smaller k_o/k_p value. The intermediate value of k_H/k_D of 2.51 may arise in two ways (*a*) that k_{-1} in Scheme II has become competitive with k_2 or (*b*) that k_3 is competitive with the participation route. If one assumes that k_{2H}/k_{2D} has a value of 5.2 (that of *o*-chlorobenzaldoxime), one finds that a ratio of $k_{-1}/k_2 = 0.56$ for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

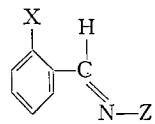
the *o*-methoxy compound would give rise to an isotope effect of 2.5. Using the steady-state treatment or B in Scheme II then

$$\frac{k_H}{k_D} = \frac{k_{2H}k_1(k_{-1} + k_{2D})}{k_{2D}k_1(k_{-1} + k_{2H})} = \frac{k_{2H}\left(\frac{k_{-1}}{k_{2H}} + \frac{k_{2D}}{k_{2H}}\right)}{k_{2D}\left(\frac{k_{-1}}{k_{2H}} + \frac{k_{2H}}{k_{2H}}\right)}$$

and making the appropriate substitution one can solve for k_{-1}/k_2. Similarly if k_{-1} is small and k_3 is competitive with k_1 then a value of $k_1/k_3 = 0.47$ would give rise to an isotope effect of 2.5.

The rate constant of *syn*-2,4,6-trimethylbenzaldoxime *o*-iodobenzoate at 92° in 50% dioxane shown in Table III is about 100 times that of *syn-p*-methylthiobenzaldoxime *o*-iodobenzoate under the same conditions. From Table II, the rate constant of *syn-p*-methylbenzaldoxime *p*-toluenesulfonate is about the same as that of *syn-p*-methylthiobenzaldoxime *p*-toluenesulfonate. Then the *syn*-2,4,6-trimethylbenzaldoxime derivative reacts about 100 times faster than the corresponding *p*-methylbenzaldoxime derivative. Since *syn-o*-methylbenzaldoxime *p*-toluenesulfonate reacts 8.4 times faster than its para isomer, therefore the *syn*-2,4,6-trimethylbenzaldoxime derivative reacts 12 times faster than the corresponding *syn-o*-methylbenzaldoxime derivative.

A factor of 12 between the rate constants of the *syn*-2,4,6-trimethylbenzaldoxime derivative and the *syn-o*-methylbenzaldoxime derivative is not surprising because a single ortho group will still allow some resonance in a confirmation such as VIII, whereas two



VIII

ortho substituents would remove this possibility and give rise to an even greater rate enhancement. Furthermore, the inductive effect of the two additional methyl groups in the trimethyl compound would also tend to increase the reaction rate relative to the *o*-methyl compound.

EXPERIMENTAL

A. Preparation of Materials

Aldehydes

The following substituted benzaldehydes were prepared in this laboratory. All the other aldehydes were obtained commercially.

o-Iodobenzaldehyde

The compound was prepared by the method of Sonn and Muller (11). *o*-Iodobenzanilide was converted to an imido chloride by reaction with phosphorus pentachloride, the imido chloride was reduced with stannous chloride, and the anil so formed was hydrolyzed to the aldehyde, m.p. 37°, in a yield of 50%. Reported m.p. 37° (12).

o-Methylbenzaldehyde

The compound was prepared by the Sonn and Muller method. *o*-Toluanilide was reacted with phosphorus pentachloride. Reduction of the imido chloride with anhydrous stannous chloride and dry hydrogen chloride in ether followed by acid hydrolysis and steam distillation gave the aldehyde, b.p. 94° at 16 mm, in a yield of 60%. Reported b.p. 90–93° at 16 mm (12).

o-Methylthiobenzaldehyde

The compound was prepared by essentially the method of Weygand and co-workers (13). A solution of thiosalicylic acid (58 g, 0.38 moles) and sodium hydroxide (32 g, 0.40 moles) in 200 ml of water was cooled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

to 10°, and dimethyl sulfate (19 g, 0.20 moles) was added slowly with stirring. The mixture was refluxed for 3 h, cooled, and acidified with hydrochloric acid. The precipitate was filtered, washed with water, and recrystallized from hot water. The yield of *o*-methylthiobenzoic acid, m.p. 169–171°, was almost quantitative (reported 169–171°) (12).

A mixture of *o*-methylthiobenzoic acid (30 g, 0.18 moles) and thionyl chloride (30 g, 0.25 moles) was heated gently for 2 h, whereupon 80 ml of benzene was added. The mixture was cooled, and a solution of *N*-methylaniline (30 g, 0.28 moles) in 200 ml of benzene was added slowly with stirring. The mixture was then heated on a steam bath for 30 min, cooled, and washed with water, 5% hydrochloric acid, 5% sodium hydroxide, and water, respectively. The solution was dried and the solvent evaporated. The *N*-methyl *o*-methylthiobenzanilide was recrystallized from Skelly B. The yield was 42 g (91%) m.p. 103°.

Anal. Calcd. for $C_{15}H_{15}NOS$: C, 70.0; H, 5.84; N, 5.45. Found: C, 69.9; H, 5.98; N, 5.15.

A solution of the anilide (39 g, 0.15 moles) in 240 ml of redistilled tetrahydrofuran was cooled to 0° and lithium aluminium hydride (3.0 g, 0.08 moles) was added. The mixture was kept at 0° with stirring overnight, then 500 ml of 10% hydrochloric acid was added. The solvent was evaporated and the residue steam-distilled. The distillate was extracted with ether, the ethereal solution dried, the solvent removed, and the residue distilled under reduced pressure. *o*-Methylthiobenzaldehyde (13 g, 57%) b.p. 89–91° at 0.4 mm was isolated.

Anal. Calcd. for C_8H_8OS: C, 63.1; H, 5.26. Found: C, 63.2; H, 5.58.

Deuterated Aldehydes

The deuterated benzaldehydes were made by the same procedure as described for the synthesis of *o*-methylthiobenzaldehyde. Lithium aluminium deuteride reduction of the corresponding *N*-methyl benzanilides in tetrahydrofuran followed by acid hydrolysis and steam distillation gave rise to the isotopic compounds. They are characterized by the shift in the vibrational frequency of the C—H bond at 2 837 cm^{-1} to the C—D bond at 2 112 cm^{-1} in the infrared spectra in chloroform solution. Further, their n.m.r. spectra in carbon tetrachloride show that the deuterated isomers have no signal about τ 0.44 attributable to aldehydic C—H proton.

N-Methyl o-iodobenzanilide.—M.p. 69–71°, yield 84%. Anal. Calcd. for $C_{14}H_{12}INO$: C, 49.8; H, 3.56; N, 4.16. Found: C, 49.5; H, 3.82; N, 3.92.

o-Iodobenzaldehyde-d.—M.p. 37°, yield 21%.

N-Methyl o-chlorobenzanilide.—M.p. 55°, yield 92%. Anal. Calcd. for $C_{14}H_{12}ClNO$: C, 68.5; H, 4.89; N, 5.71. Found: C, 68.1; H, 4.88; N, 5.45.

o-Chlorobenzaldehyde-d.—B.p. 202°, yield 45%.

o-Methylthiobenzaldehyde.—B.p. 90–93° at 0.4 mm, yield 59%.

N-Methyl o-methoxybenzanilide.—M.p. 76–78°, yield 87%. Anal. Calcd. for $C_{15}H_{15}NO_2$: C, 74.6; H, 6.22; N, 5.81. Found: C, 74.8; H, 6.13; N, 5.71.

o-Methoxybenzaldehyde-d.—B.p. 196°, yield 34%.

Substituted Benzaldoximes

syn-Aldoximes

The substituted *syn*-benzaldoximes were prepared as described previously (1). Reaction of hydroxylamine hydrochloride with the aldehyde in dilute sodium hydroxide solution produces the *syn*-aldoximes in yields between 75 and 90%. The melting point of the *syn*-aldoximes together with that reported (12) are: *syn-o*-iodobenzaldoxime m.p. 110 (reported 107–108); *syn-o*-iodobenzaldoxime-*d* m.p. 108; *syn-p*-iodobenzaldoxime m.p. 123 (reported 122); *syn-o*-bromobenzaldoxime m.p. 103 (reported 102); *syn-p*-bromobenzaldoxime m.p. 110–111 (reported 110–111); *syn-o*-chlorobenzaldoxime m.p. 75 (reported 75–76); *syn-o*-chlorobenzaldoxime-*d* m.p. 74–75; *syn-o*-fluorobenzaldoxime m.p. 63 (reported 63); *syn-o*-methoxybenzaldoxime m.p. 93–95 (reported 92); *syn-o*-methoxybenzaldoxime-*d* m.p. 94–96; *syn-o*-methylthiobenzaldoxime m.p. 88–89.

Anal. Calcd. for C_8H_9NOS: C, 57.5; H, 5.39; N, 8.39. Found: C, 57.4; H, 5.37; N, 8.22;

syn-o-Methylthiobenzaldoxime-*d* m.p. 93; *syn-p*-methylthiobenzaldoxime m.p. 111 (reported 111); *syn-o*-methylbenzaldoxime m.p. 49 (reported 49); *syn*-2,4,6-trimethylbenzaldoxime m.p. 129 (reported 124).

anti-Aldoximes

The substituted *anti*-benzaldoximes were prepared as before (1). They were obtained by conversion of the corresponding *syn* isomers through the hydrochloride. The melting point together with that reported (12) are: *anti-p*-chlorobenzaldoxime m.p. 151 (reported 146); *anti-p*-methylbenzaldoxime m.p. 122–124 (reported 108–111); *anti-p*-methoxybenzaldoxime m.p. 132–133 (reported 133); *anti*-2,4,6-trimethylbenzaldoxime m.p. 179–180 (reported 178–180).

syn-Aldoxime Esters

The *syn*-aldoxime esters were prepared as described previously (1), by reacting the sodium salt of the aldoxime with the acid chloride in absolute ether. The aldoxime *p*-toluenesulfonates of *syn-p*-chloro-, *syn-p*-methoxy-, *syn-p*-fluoro-, and *syn*-benzaldoxime were the same samples used before (1). The data for the new esters are tabulated in Table VI.

*Melted with decomposition.

B. Product Analysis

A mixture of the ester (0.50 g) and 10 ml of 95% ethanol was refluxed overnight. The solvent was evaporated at reduced pressure and 10 ml of 5% sodium hydroxide was added to the residue. The mixture was then extracted with 10 ml of ether and the ethereal solution washed with water, dried, and the solvent evaporated. The nitrile was recrystallized from Skelly B. Thus *o*-iodobenzonitrile, m.p. 53°, reported m.p. 54–55° (12), was obtained from *syn*-*o*-iodobenzaldoxime *p*-toluenesulfonate in 78% yield; *o*-chlorobenzonitrile, m.p. 43°, reported m.p. 42–43° (12), was isolated from *syn*-*o*-chlorobenzaldoxime *p*-toluenesulfonate in 83% yield; and 2,4,6-trimethylbenzonitrile, m.p. 55°, reported m.p. 55° (12), was obtained from *syn*-2,4,6-trimethylbenzaldoxime *o*-iodobenzoate in a yield of 80%.

C. Kinetic Measurements

Kinetic measurements were carried out as described in the previous paper (1). The reaction was studied by following the disappearance of the band at the wavelength of maximum absorption of the corresponding *syn*-aldoxime ester. The small absorption due to the products at this wavelength was corrected for in the rate equation.

A LINEAR CORRELATION OF PROTON CHEMICAL SHIFTS IN SOME ALKYL CHLORIDES AND HYDROCARBONS WITH THE OCCUPATION NUMBER OF THE HYDROGEN ORBITALS

F. HRUSKA,[1] G. KOTOWYCZ,[1] AND T. SCHAEFER[2]
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba
Received July 16, 1965

ABSTRACT

A linear correlation exists between the proton shifts of some alkyl chlorides and some hydrocarbons and the occupation numbers of the hydrogen 1s orbitals in the C—H bonds. The occupation numbers are those given by the self-consistent group orbital and bond electronegativity method. The application of this correlation to the prediction of starting values for occupation numbers, to the derivation of bond anisotropies in ethylene and acetylene, and to the prediction of hydrogen-bonded shifts of C—H protons is discussed.

INTRODUCTION

It was originally hoped that the proton chemical shift in a molecule would be a direct measure of the electron density at the hydrogen atom. The paramagnetic term in Ramsey's equation (1), evaluated for electrons centered on the proton, is small because of the large electronic excitation energies for hydrogen, leaving the diamagnetic term to represent the effect of the electron density on the chemical shift. Experimentally, the protons in methyl compounds are indeed less shielded as the electronegativity of the substituent increases (2) and some success has been obtained in relating proton shifts in aromatic systems to π-electron densities on bonded carbon atoms (3; 4 and references therein).

However, there are many discrepancies in correlations of this sort (2; 4 and references therein) and they have been variously attributed to the magnetic anisotropies of neighboring bonds or atoms (5, 6), to electric fields arising from bond dipoles (7), to reaction fields from the solvent (8), and to intramolecular dispersion interactions (9).

Conversely, some attempts have been made to derive the anisotropies of bonds and substituents from the experimental shifts (10–13). One method is to use the coupling constant and the proton shift in the ^{13}C—H bond to determine irregularities in the shifts, which are then attributed to anisotropy effects (10). The underlying assumption that the ^{13}C—H coupling constant is a direct measure of the s-character of the bonding carbon orbital (14) has been questioned (15).

Recently, the self-consistent group orbital and bond electronegativity method has been employed to calculate the orbital charge distributions in some hydrocarbons and aliphatic chlorides (16). This method defines an effective occupation number, designated charge, of an atomic orbital. In particular, the occupation number or charge of the hydrogen 1s orbitals is given (16). In this paper we note a linear correlation between the proton shifts and the occupation numbers of the hydrogen orbitals and discuss briefly its application to some current topics in proton resonance. A linear correlation between the charge on the carbon atom and the ^{13}C shift in the chloromethanes has already been pointed out (16).

DISCUSSION

1. General

In Table I the occupation numbers, n, of the hydrogen orbitals in a number of hydrocarbons and aliphatic chlorides are presented, as are the proton shifts relative to internal tetramethylsilane for 5% solutions in carbon tetrachloride and cyclohexane. In a few cases the solvent was chloroform or tetramethylsilane. Ideally, the proton shifts in the gas phase are required to eliminate solvent effects (8) but these are not available for most of the compounds in Table I. The most extensive data are for carbon tetrachloride solutions although cyclohexane is preferable as a solvent.

2. Correlation of Proton Shift and Occupation Number

In Fig. 1 the proton shifts in carbon tetrachloride are plotted versus n. For the alkyl chlorides there is a linear correlation and the shielding decreases with the occupation number of the hydrogen 1s orbital. The proportionality constant is 46 ± 1 p.p.m. per electron, as compared to 27 p.p.m. calculated for the shielding in the hydrogen molecule (17). In the alkyl chlorides the hydrogen orbital is probably much less diffuse and this would lead to a higher value for the proportionality constant. However, the matter may be more complex.

TABLE I

Hydrogen orbital occupation numbers and proton shifts for some hydrocarbons and alkyl chlorides

Compound*	n†	Chemical shift in: CCl_4‡	Chemical shift in: C_6H_{12}‡	Hydrogen bond shift‡ at 27 °C

The shifts of the methyl protons in propane and neopentane also fall very near the correlation line in Fig. 1. Reliable data for methane and ethane are not yet available but it would appear that the former deviates considerably from this line. In the absence of further data on occupation numbers and (or) proton shifts we postpone to a later paper the question of separate correlation lines for various classes of compounds (but see below).

In Fig. 2, the proton shifts in cyclohexane are plotted versus n. Again a linear correlation is noted for the alkyl chlorides. The slope of the line is nearly the same as that in Fig. 1, but is slightly displaced to high field. Here the methane shift (measured in tetramethylsilane) deviates strongly to high field from the extended correlation line. If the correlation line held it would indicate $n = 0.996$ for the hydrogen orbital in methane and $n = 1.002$ for the hydrogen orbital in tetramethylsilane.

3. Application of the Linear Correlation

(a) Prediction of n from Proton Shift

For three chlorinated ethanes in Table I the occupation numbers are not yet calculated but they can be obtained from Figs. 1 and 2. The predicted n values from the two plots agree to within 0.001 units and are $n(CHCl_2—CH_2Cl) = 0.916$; $n(CHCl_2CH_2Cl) = 0.876$; $n(CCl_3CH_2Cl) = 0.909$; $n(CCl_3CHCl_2) = 0.868$. The calculation of charge distributions (16) begins with a chemically reasonable value of n for one of the orbitals and then

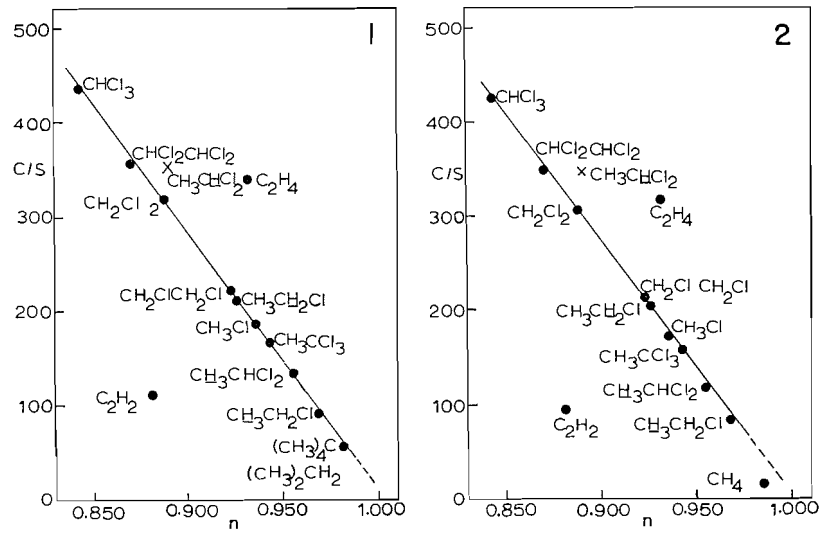

FIG. 1. The proton shifts in c/s at 60 Mc/s of some alkyl chlorides and hydrocarbons in carbon tetrachloride solution are plotted versus the occupation number of the hydrogen 1s orbital. The point marked as a cross is discussed in the text.

FIG. 2. As in Fig. 1 with cyclohexane as solvent.

iterates to a self-consistent charge distribution. The proton shift would seem to present a reasonable value for n and also serves as a check on the calculation. As an example, the proton shift of the methane proton in 1,1-dichloroethane indicates $n = 0.871$ instead of the calculated $n = 0.890$. The latter is marked as a cross in Figs. 1 and 2 and is the only 1 out of 10 that deviates significantly from the correlation line.

(b) Estimates of Bond Anisotropies

In view of the considerable anisotropies attributed to the C—C and C—Cl bonds in the literature (12, 18) the linear correlation in Figs. 1 and 2 is perhaps unexpected, unless they happen to be equivalent to C—H bonds in this respect. Whatever the explanation of this apparent contradiction, it is instructive to consider the ethylene and acetylene proton shifts. On the assumption that the deviations of these shifts from the lines in Figs. 1 and 2 are a measure of the anisotropy contribution of the double and triple bonds, one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

calculates $\Delta\chi = 3.8$ p.p.m. for acetylene and $\Delta\chi = -2.1$ p.p.m. for ethylene. These contributions are of the right sign and compare with $\Delta\chi = 4.0 \pm 0.5$ p.p.m. for acetylene derived by the method discussed in the introduction (19). The ratio of the $\Delta\chi$ values for the two compounds is -1.9, in rough agreement with that calculated from molecular orbital theory (5).

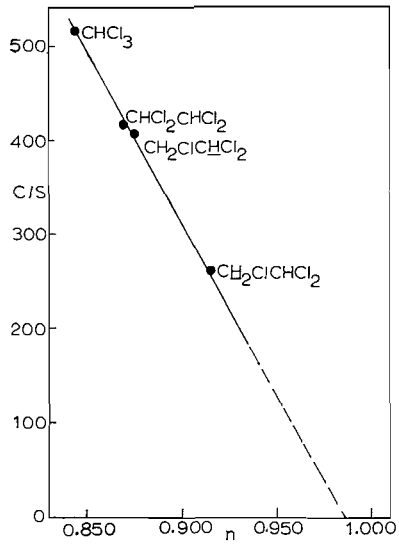

FIG. 3. The hydrogen-bonded shifts of four alkyl chlorides in dimethylsulfoxide are plotted versus the occupation number of the hydrogen 1s orbital.

(c) Hydrogen Bond Shifts

As n decreases the C—H bond becomes more polar and is expected to hydrogen bond more strongly with a proton acceptor. In Fig. 3 the four known hydrogen-bonded proton shifts (20) in dimethyl sulfoxide are plotted versus the occupation number of the hydrogen orbital in the C—H bond. The shifts were obtained by the method of Huggins, Pimentel, and Shoolery (21). There appears to be a linear correlation for this restricted number of values. For two of the points in Fig. 3 the n values were obtained from the plots in Figs. 1 and 2. The extended correlation line predicts a zero hydrogen-bonded shift for methane and this suggests that correlations of this sort will be useful in hydrogen bond studies by proton resonance.

CONCLUSIONS

The linear correlation between the proton shift in alkyl chlorides and some saturated hydrocarbons and the occupation number of the hydrogen orbital in C—H bond suggests its application in predicting starting values for occupation numbers in the iterative process for the calculation of charge distributions in molecules; in deriving bond anisotropies in some cases while, at the same time, casting doubt on some current values for others; and in predicting hydrogen-bonded shifts in equilibrium studies by proton magnetic resonance. There is a need for further data on both shifts and occupation numbers and such data are being gathered.

ABSTRACT

The infrared spectra of some tetramethyl-, tetraethyl-, and triethylmethyl-arsonium salts, and that of tetramethylstibonium triiodomercurate(II) have been recorded in the region 4 000 to 200 cm^{-1}. Vibrational assignments are given for the quarternary 'onium cations, and comparisons are made with the spectra of alkylorganometallic compounds of germanium and tin.

The Raman spectra of aqueous solutions of tetramethylarsonium chloride and of tetramethylstibonium chloride have been measured and assigned (1), but infrared data on these and other alkylarsonium salts are lacking. In the present work, the infrared spectra of a number of tetramethyl-, tetraethyl-, and triethylmethyl-arsonium salts, and of tetramethylstibonium triiodomercurate(II) have been recorded in the range 4 000 to 200 cm^{-1} and assignments made for the fundamental frequencies.

RESULTS AND DISCUSSION

Tetramethylarsonium and Tetramethylstibonium Salts

The observed frequencies are given in Table I, together with the present assignments and the reported Raman frequencies (1). The fundamentals are numbered as by Shimizu and Murata (2). The 45 fundamentals of a tetrahedral $(CH_3)_4M$ molecule comprise $3a_1 + 4e + 7f_2 + a_2 + 4f_1$, the last two species being Raman and infrared inactive. All the remaining modes are Raman active, the a_1 class being polarized, but only the f_2 modes are infrared active. The active fundamental frequencies are compared with these of the isoelectronic group IV molecules in Table II. The frequencies of the infrared active modes of $(CH_3)_4As^+$ listed in Table II are average values for the compounds in Table I: where the observed bands are split, either the value of the most intense component or that of the band center has been used in averaging.

The results are in general accord with the expected tetrahedral symmetry of the 'onium cations, although the a_1 methyl symmetric deformation is observed as a weak or very weak band in the infrared spectra of two arsonium salts, and the a_1 skeletal stretch as a very weak absorption for the stibonium salt. As with the group IV tetramethyls (4), the position of the e methyl rocking mode (ν_6) cannot be located with certainty. Although there are weak Raman lines available as possibilities, it seems most likely that ν_6 is coincident with ν_{13}. The e and f_2 skeletal deformation modes are probably close together but not coincident, the latter being at higher frequencies than the former, as with $(CH_3)_4Ge$ and $(CH_3)_4Sn$ (3, 4). The infrared active mode is not observed above 220 cm^{-1},

and, owing to the rising background absorption, no band could be established in the spectra of the arsonium compounds between 220 and 200 cm^{-1}. Probably the Raman lines of $(CH_3)_4AsCl$ and $(CH_3)_4SbCl$ at 217 and 178 cm^{-1}, respectively, are due to the f_2 mode.

The spectra of the two isoelectronic pairs $(CH_3)_4As^+$ and $(CH_3)_4Ge$, and $(CH_3)_4Sb^+$ and $(CH_3)_4Sn$ may be compared with those of trimethylarsine and trimethylstibine respectively. For trimethylarsine, the Raman data (5) have been assigned and the carbon–arsenic stretching frequencies are at 572 (a_1) and 584 cm^{-1} (e). (These are both infrared active and have apparently been observed, but the values for the frequenices are not given (6).) The CH_3 rocking modes are probably both very close to the Raman line at 884 cm^{-1}; the infrared values are not available. The methyl symmetric and antisymmetric deformation modes are at 1 263 (a_1), 1 242 (e), and 1 417 cm^{-1} (a_1 and e) respectively. For trimethylstibine both Raman (7) and infrared data (8) are available, and we assign the carbon–antimony stretch to 510 cm^{-1} (a_1 and e), CH_3 rocking to the strong infrared band at 813 cm^{-1}, the CH_3 symmetric deformations to 1 210 (a_1) and 1 193 (e), and the antisymmetric deformations to 1 380 cm^{-1} (a_1 and e). (An assignment (9) of the carbon–antimony stretch to 591 cm^{-1} must be in error, since there is no absorption band in that region (8).) Assignments for these modes have also been given (9) for trimethylantimony dihalides.

From these facts and the data in Table II, it follows that the carbon–metal stretching frequencies increase $(CH_3)_4Ge \sim (CH_3)_3As < (CH_3)_4As^+$ and $(CH_3)_4Sn \sim (CH_3)_3Sb < (CH_3)_4Sb^+$. The carbon–metal stretching force constants are approximately the same (1) for the first two compounds of each series. Evidently the charge on or higher oxidation state of the group V atoms in the ions gives stronger carbon–metal bonding. The methyl rocking frequencies (and therefore probably the H—C—M deformation force constant (1)) increase along each series. The changes in the methyl deformation frequencies are smaller, but certainly for the symmetric frequencies $(CH_3)_4Ge \sim (CH_3)_3As < (CH_3)_4As^+$ and $(CH_3)_4Sn \sim (CH_3)_3Sb < (CH_3)_4Sb^+$. The f_2 antisymmetric deformation is significantly higher for the group IV compounds than for the corresponding group V ions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and the *e* mode slightly lower; calculations (1) based on Raman data alone suggests the H—C—H deformation force constant is lower for the ions. The stronger carbon–metal bonding in the 'onium cations leads to stronger carbon–hydrogen bonding in the ions than in the corresponding group IV compounds. This is shown by the frequencies of the C—H stretching modes and, further, a calculation of the C—H stretching force constants from the data of Table I gives values 2–3% higher for $(CH_3)_4As^+$ and $(CH_3)_4Sb^+$ than those (1) for the corresponding group IV compounds.

Tetraethylarsonium Salts

The observed frequencies and assignments are shown in Table III together with those for the isoelectronic tetraethylgermane, assigned by one of us (10) from the literature data (11). Assignments for the ethyl group frequencies are based on those (12) for several ethyl compounds, and only a few points require comment.

The spectra are consistent with tetrahedral symmetry of the C_4As skeleton, although the a_1 skeletal stretching mode appears very weakly for one salt. The position of the C—C—As skeletal bending mode is clear since there is no corresponding absorption in the spectra of the tetramethyl compounds. The CH_2 twisting mode is assigned to the bands at 1 169 to 1 177 cm^{-1}, which are not readily explained as overtone or combination bands. In tetraethylgermane such alternatives do exist, as indicated in Table III, and there are observed Raman lines at 1 299 and 1 328 cm^{-1} which have no ready alternative explanation and may be due to the CH_2 twisting vibration. However, calculations place this at a lower frequency than the wagging mode (12, 13), the position of which is clear. The methylene wagging and rocking modes of the arsonium compounds are at higher frequencies than in tetraethylgermane, paralleling the methyl rocking modes of the corresponding tetramethyl compounds, and probably again reflect a greater H—C—M bending force constant in the cation.

The basis for assignments of the carbon–hydrogen stretching frequencies to methylene and methyl groups is provided by considerations of the spectra of tetraethylmethane, tetraethylsilane, and related compounds (10, 14). For the present molecules it shows that while the methyl frequencies are almost unchanged from those of *n*-butane (2 878 (sym.) and 2 939, 2 956 cm^{-1} (asym.)), the methylene frequencies are markedly higher than those in *n*-butane (2 861 (sym.) and 2 910 cm^{-1} (asym.), Raman values throughout). Again the ν(C—M) frequencies are higher in the arsonium compounds than in tetraethylgermane, reflecting stronger carbon–metal bonding in the cation. Further, the carbon–hydrogen stretching frequencies suggest that the stronger carbon–metal bonding in the cation may again lead to stronger carbon–hydrogen bonding in the cation.

Triethylmethylarsonium Salts

The observed frequencies and assignments are given in Table IV together with the data (11) and assignments (10) for triethylmethylgermane. The skeletal symmetry is effectively C_{3v} with the carbon-metal stretching modes comprising $2a_1 + e$ modes, all infrared active, though the a_1 mode derived from the a_1 mode of $(C_2H_5)_4M$ may be weak. The results are in agreement with this. The $\nu(CH_3—As)$ frequency corresponds closely to $\nu(CH_3—As)$ asym. of $(CH_3)_4As^+$, and all carbon–arsenic stretching frequencies are higher than the corresponding carbon–germanium frequencies.

Additional absorptions in the triethylmethylarsonium salts, compared with the tetraethylarsonium salts, are clear at ca. 880 cm^{-1}, ca. 1 290 cm^{-1}, and ca. 3 000 cm^{-1}, and, from the data for $(CH_3)_4As^+$, must be methyl rocking, methyl symmetric deformation, and ν(CH) asym. modes of Me(—As), respectively. (In triethymethylgermane the

Raman line at 1 239 cm^{-1} appears additionally compared with $(C_2H_5)_4Ge$ and the infrared absorption at this frequency is evidently slightly stronger in the former than in the latter compound, so that CH_2 wagging and CH_3(—Ge) symmetric deformation modes are probably virtually coincident.) The assignments for the carbon–hydrogen stretching modes are based on those for $(CH_3)_4As^+$ and $(C_2H_5)_4As^+$ and are consistent with them; again the evidence indicates stronger C—H bonding in the arsonium compounds than in the germanium derivative.

EXPERIMENTAL

The compounds investigated were obtained during previous studies (15–19) of the reactions of arsines and related compounds, and the preparations have been reported as follows: $(CH_3)_4AsI$ (15), $(CH_3)_4AsI_3$ (16), $(CH_3)_4AsHgI_3$ (17), $(CH_3)_4SbHgI_3$ (18), $(C_2H_5)_4AsI$ (17), $[(C_2H_5)_4As]_2HgI_4$ (17), $(C_2H_5)_3CH_3AsI$ (19), $(C_2H_5)_3CH_3AsHgI_3$ (19), and $[(C_2H_5)_3CH_3As]_2HgI_4$ (19).

Infrared Spectra

The compounds were examined as mulls (Nujol and hexachlorobutadiene) or in KCl discs, using Unicam SP100/130 and Grubb-Parsons DM2 instruments for 4 000 to 400 cm^{-1} and 400 to 200 cm^{-1} respectively. Some compounds were examined both as mulls and discs, and good agreement was observed, though the disc spectra sometimes showed more splitting.

THE INFRARED SPECTRA OF SOME TITANIUM(IV) COMPLEXES WITH PRIMARY DIAMINES

D. HORLEY[1] AND E. G. TORRIBLE
Chemistry Department, Queen's University, Kingston, Ontario
Received July 5, 1965

ABSTRACT

A series of titanium(IV) halide – diamine complexes have been prepared and their infrared spectra measured in the solid state between 4 000 and 300 cm^{-1}. The configuration of the ligand and extent of aminolysis of the titanium–halide bond are discussed in relation to the spectra. Some assignments are proposed in the 600–300 cm^{-1} region for the ethylenediamine complexes.

INTRODUCTION

An extensive study of the reaction between titanium(IV) halides and primary monoamines has shown that the primary amines solvolyze the metal—halogen bond (1). By comparison, little is known of the reaction with primary diamines. Fowles and McGregor (2) reported an ethylenediamine (en) complex, $TiCl_2[HN(CH_2)_2NH_2]_2(en)_2$, and suggested that the ligands were chelated to the metal. More recently Sumarokova and Sakenova (3, 4) claimed no aminolysis of the Ti—Cl bond occurred in the complexes $TiCl_4.2en$, $TiCl_4.3en$, and $TiCl_4.4en$. However, there was evidence for aminolysis in the reaction with hexamethylenediamine (HMD), and the compounds $TiCl_3[HN(CH_2)_6NH_2].n$HMD, where n = 1, 2, and 3, were reported (4). No spectroscopic examination of these compounds has been offered to date. In this paper we describe the preparation of a number of titanium(IV) halide – diamine complexes including a series of 1:1 adducts. The infrared data for these compounds in the range 4 000 to 300 cm^{-1} is given in Table I.

EXPERIMENTAL

Materials and Manipulation

Special precautions were taken to exclude water from the apparatus and chemicals, and all reactions were conducted in an atmosphere of dry nitrogen. The amines and solvents were dried by refluxing over sodium and then fractionally distilled. The titanium halides were distilled or sublimed into the reaction vessels immediately before use.

The complexes were all prepared by the same general method. Solutions of the reactants in benzene were mixed in known molar ratios. Reaction was generally immediate and heat was evolved. The resulting mixture was stirred and occasionally heated for a period of time. The products, which were all insoluble, were filtered, washed with hot benzene, and dried *in vacuo*. All the products reacted vigorously with water and were hydrolyzed rapidly in air. The complexes were nonvolatile and insoluble in any solvent with which they did not react.

The infrared spectra were all determined as mulls in Nujol and hexachlorobutadiene-1,3 between NaCl or KRS-5 plates on a Beckman I.R. 10 grating instrument.

Analyses were obtained as previously described (5) and the data is presented in Table II.

RESULTS AND DISCUSSION

A number of questions remain to be answered with regard to the titanium(IV) halide – diamine complexes so far reported in the literature: (*a*) the extent to which aminolysis of the Ti—X bond (X = Cl, Br, or I) occurs; (*b*) whether the diamine is acting as a chelate or as a *trans* bridging unit between two different metal atoms thus forming polymeric chains; and (*c*) at what value of n in the chain $H_2N(CH_2)_nNH_2$ would there be a possible change from a chelate to a bridged system?

The infrared spectra of ethylenediamine complexes have been reviewed (6), and the spectra of some tris-ethylenediamine complexes of ruthenium(II) have been analyzed in detail (7). The data indicates that ethylenediamine has the *gauche* configuration when acting as a chelating ligand. When the ligand acts as a bridging unit between two metal atoms its configuration must be *trans*. Powell *et al.* (8, 9, 10) have concluded, on the basis of infrared spectra, that a number of mono-ethylenediamine complexes are long chain polymers with the ligand in the *trans* configuration. Brodersen (11) arrived at a similar conclusion and confirmed it by an X-ray study. Generally the chelate structure shows 14–16 peaks in 1 600 to 600 cm^{-1} region, e.g. the $Co(en)_3Cl_3$ complex exhibits 15 peaks. The bridged complexes, because of their higher symmetry, show only 6–9 peaks. The $Ti(en)X_4$ complexes show 15 and 14 peaks for the chloride and bromide respectively. Thus we assume that in the mono-ethylenediamine titanium(IV) complexes the ligand will be chelated and in the *gauche* form. However, the doublet near 840 cm^{-1} which is generally typical of chelated ethylenediamine complexes (10) is absent from the spectra of the $Ti(en)X_4$ complexes. The ruthenium complexes reported by Allen show the doublet very clearly (7).

*Butdiam = 1,4-butanediamine.

If aminolysis has occurred then absorption associated with the $-NH_3^+$ group is to be expected, i.e. a very strong broad band ranging approximately from 3 300 cm^{-1} to 2 500 cm^{-1} and in the process overlapping the $-CH_2-$ stretching bands (12). The spectra of the 1:1 ethylenediamine adducts did not show this type of absorption indicating the absence of aminolysis in the mono-complexes.

With the titanium(IV) halide – hexamethylenediamine complexes there are fewer data available for comparison. If a chelate is formed the chelate ring would contain nine members. Chelate rings of this size are rare but Pfeiffer (13) concluded that the compound $Cu(HMD)_2.(ClO_4)_2$ contained the diamine chelated to the metal. More recently Caglioti *et al.* (14) prepared a series of copper(II)–diamine complexes and suggested that the mono-complexes of the long chain ligands are polymeric. We have prepared the complexes $Cu(HMD)_2.Cl_2$ and $Cu(HMD).Cl_2.2H_2O$, both from ethanol. The analytical and infrared data (4 000 to 300 cm^{-1}) are given in Table III. By analogy with the argument used by Powell and Sheppard (8), the complexes in which the hexamethylenediamine is chelated should exhibit more complex spectra than those in which the ligand is *trans* and

TABLE II

*Butdiam = 1,4-butanediamine.

bridging between two metal atoms. If the spectra in the range 1 600 to 600 cm^{-1} are considered, the bis complex is seen to exhibit 24 peaks as opposed to 16 for the mono-complex. Also, in this region at least two bands of the mono-complex can be assigned to vibrational modes of the coordinated water (15). Thus we conclude that the infrared spectra support the structures originally postulated for these copper(II) complexes. By comparison, the spectra of the mono-hexamethylenediamine titanium(IV) chloride and bromide in the region 1 600 to 600 cm^{-1} show 11 and 14 peaks respectively (Table I). Hence it is probable that these complexes are long chain polymers with the ligand in the *trans* form and bridging between two titanium atoms. Such a structure gives titanium its expected coordination number of six. The spectra between 3 500 to 2 200 cm^{-1} give no indication that aminolysis has occurred.

No clear-cut decision could be made about the configuration of the ligand in the mono-1,4-butanediamine titanium(IV) chloride. The infrared spectrum in the 1 600 to 600 cm^{-1} region showed 12 absorption peaks but no other data was available for comparison. Also the absorption in the 3 300 to 2 500 cm^{-1} region could be interpreted as indicating the presence of the $—NH_3^+$ group. This was unexpected since no evidence for

aminolysis was obtained for the mono-ethylenediamine and mono-hexamethylenediamine complexes.

The complexes of the type Ti(diamine)$_n$.X_4 where n = 2, 3, 4, all showed spectral evidence of aminolysis. This result is in accord with the results reported by Fowles *et al.* (16) for the analogous primary monoamine complexes. The extent of solvolysis could not be determined since it was not possible to separate the amine hydrochloride from the titanium complex. Attempts to wash out the amine hydrochloride with either the parent amine or a solution of the amine in benzene (16) were not successful, and in general there was further reaction between amine and the titanium complex. However, complete solvolysis of the titanium–halogen bond did not occur, at least in the chlorides, as an absorption band in the region 360–390 cm^{-1} could be assigned to the Ti—Cl stretching mode (5).

Thus the products shown as multiple addition complexes are more probably mixtures of the type $TiCl_2[(CH_2)_n(NH)_2].(CH_2)_n(NH_3)_2^{2+}$ or, $[(CH_2)_n(NH_3)_2]^{2+}.[TiCl_4(CH_2)_2(NH)_2]^{2-}$. A similar conclusion has been reached for the products of the reaction between hydrazines and titanium(IV) halides (17). Because of the presence of the amine hydrochloride it is not possible to arrive at any decision regarding the configuration of the ligand bound to the titanium.

The 600–300 cm^{-1} regions of the spectra are interesting. We have found that liquid ethylenediamine between KBr discs shows peaks at 500 and 465 cm^{-1}, and these can be attributed to N—C—C—N bending modes of the free amine possibly in the *gauche* configuration (18). If, as is probable, the amine is *gauche* in the mono-complexes of titanium(IV) then it seems reasonable that the bands at 520 and 442 cm^{-1} and 515 and 435 cm^{-1} for the chloride and bromide respectively (Table I) can be assigned to the N—C—C—N bending modes. We have found that the complex $Cu(en)_2Cl_2$ also shows peaks at 520 and 455 cm^{-1}.

On complex formation the Ti—X stretching frequency is expected to decrease. In a series of complexes of titanium(IV) halides with cyclic ethers and thioethers the Ti—Cl stretching frequency is decreased to 360–385 cm^{-1}, and the Ti—Br stretching frequency to 300 cm^{-1} or less (5). Hence the peak at 372 cm^{-1} in the chloride complex could be assigned to the Ti—Cl stretching mode. The corresponding Ti—Br frequency is beyond the limit of our instrument. The remaining bands are probably associated with metal–nitrogen vibrational modes. A recent review (19) shows that most assignments for the M—N stretching frequency are in the range 300–500 cm^{-1}. No data for the Ti—N bond were included although Fowles *et al.* (16) have made a tentative assignment of 540 cm^{-1} for the stretching frequency. This seems rather high in view of the other M—N assignments; also Fowles *et al.* were restricted to a lower limit of 400 cm^{-1} by their KBr prism. We are tentatively suggesting that the bands at 390 and 350 cm^{-1} in the chloride complex and at 365 and 330 cm^{-1} in the bromide are the Ti—N stretching frequencies. The band at 315 cm^{-1} in the chloride could be assigned to the N—M—N bending mode (19); the bending frequency in the bromide would be displaced to lower than 300 cm^{-1}. The Ti—N stretching frequencies in the mono-butanediamine and mono-hexamethylenediamine chloride complexes would be 365 cm^{-1} and 310 cm^{-1} respectively. Further work is in progress which it is hoped will confirm these assignments.

FRACTIONATION OF PECTINS FROM SUNFLOWERS, SUGAR BEETS, APPLES, AND CITRUS FRUITS[1]

V. ZITKO[2] AND C. T. BISHOP
Division of Biosciences, National Research Council, Ottawa, Canada
Received July 28, 1965

ABSTRACT

Pectins from sunflower heads, sugar beet, apple, and citrus fruits were separated into acid-insoluble pectic acids and acid-soluble polysaccharides. The acid-soluble polysaccharides were shown by moving-boundary electrophoresis to be complex mixtures of four or five polysaccharides. The pectic acids were fractionated by precipitation with sodium acetate from aqueous solution. The fractions were examined for galacturonic acid content, specific rotation, limiting viscosity number, behavior on moving-boundary electrophoresis, and presence of neutral sugars. The results showed that each of the pectic acids contained two acidic components, one a galacturonan free of neutral sugars, the other a galacturonan to which neutral sugars were attached, probably as side chains.

The composition and constitution of pectic substances have been studied extensively and the early literature on the subject has been reviewed by Hirst and Jones (1). Pectins from all sources contain D-galacturonic acid, D-galactose, L-arabinose, and L-rhamnose but it has not been clear whether these components are joined together in a single polysaccharide or whether a group of polysaccharides is present. Early evidence (1) indicated that the pectic substances were mixtures of three polysaccharides, a galacturonan, a galactan, and an araban. However, subsequent attempts to isolate homoglycans by fractionation of various pectins have not confirmed this interpretation (2–8). For example, chromatography on diethylaminoethyl cellulose resolved pectin into a neutral fraction and several acidic fractions (7, 8), but each of these fractions still contained units of the same monosaccharides that were present in the original preparation. It has been known for some time that the predominant structural feature of pectin is a chain of $1 \rightarrow 4$ linked α-D-galacturonic acid residues (9, 10). There is chemical evidence that in some pectic acids neutral monosaccharides are linked to the basic chain of D-galacturonic acid units (3–6, 11, 12), but the homogeneity of those pectic acids was not established. There have been only two reports of the isolation of homoglycans from pectins. Both were galacturonans which yielded only D-galacturonic acid on hydrolysis; one was isolated from sunflower heads (13), the other from the bark of amabilis fir (12). The galacturonan from sunflower heads was obtained by extraction with ammonium oxalate:oxalic acid and reprecipitation in 60% ethanol. The galacturonan from the bark of amabilis fir was separated from another polysaccharide which contained D-galacturonic acid, D-galactose, and L-arabinose by ultracentrifugation of an acidified aqueous solution of the pectin.

Precipitation of acidic polysaccharides by electrolytes has been studied extensively with varying results in the fractionations obtained. Fractional precipitation of alginic acid with solutions of potassium chloride and manganous sulphate yielded fractions with different ratios of D-mannuronic and L-guluronic acids (14, 15). Most studies of the fractionation of pectins by this method have involved the use of electrolytes with polyvalent cations (2, 16, 17). Good separations of neutral from acidic polysaccharides were obtained in this

way, but there was no fractionation of acidic polysaccharides, probably because of the high precipitating power of the polyvalent ions.

In connection with a project to obtain an analytically pure galacturonan for structural studies (18) it was found that pectic acids could be fractionated by precipitation from aqueous solution with sodium acetate. In view of the varying results described above for the composition of pectic substances it was of interest to try this fractionation procedure on pectins from a number of sources. The present paper describes the fractionation of pectins from sunflower heads, sugar beets, apples, and citrus fruits. While this work was in progress it was reported that a galacturonan from amabilis fir pectin could be precipitated from aqueous solution by sodium chloride (12); however, in contrast to the present work, ultracentrifugation was required to separate the galacturonan.

The properties of the crude pectins are shown in Table I. Apple pectin was much higher than the others in galacturonic acid content and the sunflower pectin had a much lower

†Degree of esterification.

degree of esterification. The highest specific rotation ($[\alpha]_D$) was associated with the highest galacturonic acid content. The sunflower and sugar beet pectins showed considerably lower limiting viscosity numbers ($[\eta]$) than the pectins from apple and citrus fruits. Each pectin showed a very broad diffuse peak on moving boundary electrophoresis, indicative of heterogeneity; the electrophoretic mobilities (μ) were in the same order of magnitude and decreased with increasing degree of esterification. Obviously, those molecules with a lower degree of esterification had a higher charge:mass ratio because of free carboxyl groups and hence had a greater mobility on electrophoresis. The pectic acids, precipitated from the deesterified pectins by acid (19) were not analyzed before the sodium acetate fractionation described below. After removal of the pectic acids, polysaccharides which remained in solution were precipitated by ethanol. Table II shows some of the properties of these fractions. Each fraction still contained a considerable amount of galacturonic acid and made up only a small percentage of the crude pectin. A number of components were revealed by electrophoresis, as many as five being detected in this fraction from apple pectin. The ratios of neutral sugars were not determined but from visual examination of paper chromatograms of hydrolyzates the relative amounts of rhamnose, arabinose, and galactose were the same in each fraction. In addition to those three monosaccharides the fraction from sunflower pectin contained glucose, and the one from apple pectin contained glucose and xylose. The results showed that the acid-soluble polysaccharides from each of the four pectins were very similar and were extremely complex mixtures of a number of polysaccharides. The degree of complexity of this material is shown by the electrophoresis pattern given by the acid-soluble polysaccharides from citrus pectin (Fig. 1). As shown below in the results of the sodium acetate fractionation, a galacturonan was responsible for the peak of greatest mobility ($\mu = (11 - 13) \times 10^{-5}$).

FIG. 2. Electrophoretic pattern of sunflower pectic acid; fraction precipitated by 0.14 *N* sodium acetate (94.2% galacturonic acid). Buffer, 0.05 *M* sodium tetraborate; 750 V, 10 mA, 157 min.
FIG. 3. Electrophoretic pattern of sunflower pectic acid; fraction precipitated by 0.14 *N* sodium acetate (92.6% galacturonic acid). Buffer, 0.05 *M* sodium tetraborate; 750 V, 10 mA, 199 min.
FIG. 4. Electrophoretic pattern of sunflower pectic acid; fraction precipitated by 0.22 *N* sodium acetate (87.7% galacturonic acid). Buffer, 0.05 *M* sodium tetraborate; 750 V, 10 mA, 205 min.
FIG. 5. Electrophoretic pattern of sugar beet pectic acid, fraction precipitated by 0.18 *N* sodium acetate (76.5% galacturonic acid). Buffer, 0.05 *M* sodium tetraborate; 750 V, 10 mA, 174 min.
FIG. 6. Electrophoretic pattern of sugar beet pectic acid; fraction soluble in sodium acetate, precipitated by ethanol (62.3% galacturonic acid). Buffer, 0.05 *M* sodium tetraborate; 750 V, 10 mA, 167 min.

Pectic acids, isolated from crude deesterified pectins by precipitation with acid, were fractionally precipitated from 1% aqueous solutions by addition of 2 *M* aqueous sodium acetate. Polysaccharide material not precipitated by this procedure was recovered by precipitation with ethanol. The results are shown in Table III. The fractions obtained at sodium acetate concentrations shown in column 1 were refractionated giving precipitates at the sodium acetate concentrations shown in column 2. Each fraction was then examined for galacturonic acid content, specific rotation ($[\alpha]_D$), limiting viscosity number ($[\eta]$), peaks on electrophoresis, presence of neutral sugars, and yield. The fractions that precipitated earliest contained the most galacturonic acid, which amounted to more than 90% in all except the pectic acid from sugar beet. The galacturonic acid contents decreased with increasing sodium acetate concentration and were markedly lower in the fractions precipitated by ethanol. The specific rotations were directly related to galacturonic acid content and, in the purest fractions, were considerably higher than those which have been reported for pectins or pectic acids (2, 12, 16). The limiting viscosity numbers increased with increasing sodium acetate concentration except for apple pectic acid, in which the first fraction had the highest limiting viscosity number and subsequent fractions a lower and nearly constant value. Except for citrus pectic acid, plots of η_{sp}/c (η_{sp} is specific viscosity, c is concentration) against c were linear for all fractions in the range 0.07–0.20 g/100 ml. The slopes of these plots were nearly the same for the fractions from sugar beet pectic acids. However, with the fractions from apple and from sunflower pectic acids the slopes of η_{sp}/c against c increased with increasing sodium acetate concentrations required for

‡Galacturonic acid.

precipitation. The values for this increase in slope, calculated as k_1 in the Huggins equation (20), were 0.042, 0.107, 0.500, 0.657, and 0.513 (100 ml/g) for the fractions from sunflower pectic acid in order of precipitation. It has been claimed that k_1 increases with an increase in degree of branching in a polymer (21) and the present data may therefore indicate structural differences between the various fractions from a single pectic acid. Certainly, if the pectic acids were linear polymers, it would be expected that the larger molecules would be precipitated first and have the higher viscosities. The reverse trend, increasing viscosities in order of precipitation (Table III), may therefore indicate that the fractions obtained at low sodium acetate concentrations were linear and those precipitated by higher concentrations of sodium acetate were branched. Further structural studies are required to confirm this interpretation.

The electrophoretic patterns gave some idea of the homogeneity of the pectic acid fractions. In all pectic acids except that from sugar beet the fractions precipitated at low sodium acetate concentrations showed a single symmetrical peak on electrophoresis. Figure 2 shows an electrophoretic pattern that was typical of these fractions. The broad peak at the origin in all electrophoretic patterns shown is a false boundary caused by salt gradients. Since these early fractions were very high in galacturonic acid and contained only traces of neutral sugars (apple and citrus) or none at all (sunflower), this single peak of $\mu = (12\text{–}13) \times 10^{-5}$ cm^2 V^{-1} s^{-1} must have represented a galacturonan. It may be noted that every fraction described in Table III contains a component with this electrophoretic mobility and the same component was present in the acid-soluble polysaccharide (Table II). It seems likely that every fraction from the pectins contains the same galacturonan, and the failure to resolve it completely from the other components was probably caused by a broad molecular weight distribution. The sugar beet pectin may be an exception as far as the presence of a galacturonan is concerned. The fractions from sugar beet pectic acid (Table III) had lower specific rotations and contained more than trace amounts of neutral sugars. The first two fractions from sugar beet pectic acid were not obtained in sufficient quantities to permit examination of them by electrophoresis.

Fractions of pectic acids with lower amounts of galacturonic acid showed a second component which appeared first as a shoulder on the main peak and then as a second peak in the electrophoretic patterns. Thus Fig. 3 shows the electrophoretic pattern given by the sunflower pectic acid fraction, which contained 92.6% galacturonic acid. The shoulder on the trailing edge of the peak is readily apparent when compared with the peak in Fig. 2. Figure 4 shows the electrophoretic pattern given by the next succeeding fraction from sunflower pectic acid. This fraction contained 87.7% of galacturonic acid and the appearance of a second component, $\mu = 10.6 \times 10^{-5}$ cm^2 V^{-1} s^{-1}, is quite distinct.

The difference between fractions precipitated by sodium acetate and those which were soluble in sodium acetate is shown by comparison of Figs. 5 and 6. Figure 5 shows the electrophoretic pattern of the last fraction precipitated from sugar beet pectic acid by sodium acetate. Figure 6 shows the electrophoretic pattern of the fraction from sugar beet pectic acid that was soluble in sodium acetate and had to be recovered by precipitation with ethanol. The same two components were present in each fraction but in different amounts; the major component in Fig. 5 was the one with greater mobility, the major component in Fig. 6 being the one with lower mobility. Thus, the addition of sodium acetate raised the ionic strength of the solution and diminished the repulsive forces between galacturonan chains. A linear galacturonan with the greater mobility would therefore aggregate first; and a galacturonan with side chains of neutral sugars and hence a lower charge:mass ratio and lower mobility, would tend to stay in solution.

It is apparent that sodium acetate preferentially precipitates the component of greater electrophoretic mobility in all of the fractionations shown in Table III. It is also clear that the pectic acids contained two components, all other polysaccharides in the crude pectins remaining in solution when the pectic acids were precipitated by acid. From the evidence presented in Table III and discussed above it is very likely that the two components in pectic acids are a linear galacturonan free of neutral sugars and a linear galacturonan to which neutral sugars are attached as side chains. This conclusion fully confirms the results of a study of pectin from the bark of amabilis fir (12) and supports the conclusion, based on a study of sisal pectic acid (3), that the pectic acid consisted of "a mixture of acidic polysaccharides, one composed solely of D-galacturonic acid residues and the other or others containing both neutral sugar and D-galacturonic acid residues". Barrett and Northcote (22) have shown that apple pectin is degraded when heated in buffer at pH 6.8 to give a galacturonan and an acidic polysaccharide which contains neutral sugars. It is possible that such a degradation, by β-elimination, occurred in the present work during the deesterification procedure. However, this is considered unlikely because the products were still of high molecular weight (38 000–49 000) and showed no absorption that was due to unsaturation in their ultraviolet spectra.

EXPERIMENTAL

Analyses

Galacturonic acid contents were determined by potentiometric titration with 0.1 *N* sodium hydroxide. Solutions of pectins and pectic acids in 0.155 *M* sodium chloride at pH 6.0 and 25 °C in the concentration range 0.07–0.2 g/100 ml were used for viscosity measurements; a Cannon-Fenske viscometer with a flow time for water of 52.52 s was used. Specific rotations were measured on 0.45–0.50% solutions at pH 6.0 in a 0.5-dm tube. A Tiselius-type, spinco Model H apparatus was used for moving-boundary electrophoresis, with 0.05 *M* sodium tetraborate as the buffer solution (23). Samples were hydrolyzed by 1 *N* sulphuric acid in sealed tubes at 100 °C for 15 h. Paper chromatograms were run by the descending method with ethyl acetate:pyridine:water in the proportions 10:4:3 (v/v), and sugars were detected on the papers by the *p*-anisidine hydrochloride spray reagent (24). All analytical results are expressed on a dry weight basis determined by drying samples at 105 °C for 12 h.

Pectins

Sunflower pectin was prepared by extraction of sunflower seed heads with a solution of ammonium oxalate:oxalic acid (13). Dr. R. M. McCready kindly supplied the sugar beet pectin, which had been prepared by extraction of sugar beet pulp with 0.5% calgon solution at pH 2.2. Apple pectin was a commercial preparation obtained from the Mann Research Laboratories. Citrus pectin was a commercial preparation from oranges and lemons obtained from Eastman Kodak. All pectins were washed with acidified 60% ethanol to yield the pectinic acids (2). Pectic acids were prepared as described previously (19).

Fractionation

One example of a typical fractionation procedure is given.

Sunflower pectinic acid (20 g) was dissolved in water (1 000 ml) containing 80 ml of 1 *N* sodium hydroxide. The solution was allowed to stand at room temperature for 2 h and was then centrifuged at 20 000 × *g*. Hydrochloric acid (18%) was then added dropwise to the clear solution with vigorous stirring. When precipitation was complete the gel of pectic acid was squeezed through a linen cloth and was washed thoroughly, twice with 60% acidified ethanol (5 ml of concentrated hydrochloric acid per liter), then successively with 60% ethanol, ethanol, and ether. The air-dried product was obtained in a yield of 15.7 g, 78.5% of the pectinic acids. The acid-soluble polysaccharides in the filtrate from the pectic acid precipitation were recovered by complete precipitation with ethanol, yield 0.6 g, 3% of pectinic acids.

The pectic acid (15 g) was dissolved in water (1 500 ml) containing 60 ml of 1 *N* sodium hydroxide to give a solution of pH 6.5. This solution was filtered through medium porosity sintered glass, 2.0 *M* sodium acetate (90 ml) was added with vigorous stirring, and the solution was kept at 5 °C for 18 h. The precipitate was then centrifuged off and dried by solvent exchange; yield, 2.75 g. A second fraction (11.7 g) was obtained by addition of a further 15 ml of 2.0 *M* sodium acetate to the mother liquors from the first fraction. No further precipitates were obtained by the addition of more sodium acetate. The residual polysaccharides in solution were recovered by precipitation with ethanol. The two fractions precipitated by sodium acetate were then refractionated separately by the same procedure. Concentrations of sodium acetate at which precipitates were obtained are shown in Table III, which also includes a record of the analyses of the various fractions.

ACKNOWLEDGMENTS

We are grateful to Dr. R. M. McCready, Western Regional Research Laboratory, U.S. Department of Agriculture, Albany, Calif., U.S.A., for a generous sample of sugar beet pectin.

PHOTOLYSIS OF HEXAFLUOROAZOMETHANE NEAR ROOM TEMPERATURE

J. R. DACEY, R. F. MANN, AND G. O. PRITCHARD[1]
Department of Chemistry and Chemical Engineering, Royal Military College, Kingston, Ontario
Received June 15, 1965

ABSTRACT

The mechanism for the formation of perfluorohexamethyl tetrazine in the photolysis of the title compound is found to occur via dimerization of two perfluorotrimethyl hydrazo radicals. Quantum yield data at 3 660 Å are presented, and compared with the azoethane system.

INTRODUCTION

Our previous work (1, 2, 3) on the photolysis of hexafluoroazomethane in the spectral regions at 2 537 Å and 3 660 Å has demonstrated that the primary step is

$$CF_3N_2CF_3 \xrightarrow{h\nu} N_2 + 2CF_3.$$

The CF_3 radicals either recombine

[1] $$2CF_3 \rightarrow C_2F_6$$

or add easily to the —N=N— double bond

[2] $$CF_3 + CF_3N{=}NCF_3 \rightarrow (CF_3)_2N{-}NCF_3$$

producing hydrazo radicals, with the eventual production of perfluorotetramethyl hydrazine (I) and perfluorohexamethyl tetrazine (II). Product I is formed by the radical–radical interaction

[3] $$CF_3 + (CF_3)_2N{-}NCF_3 \rightarrow (CF_3)_2N_2(CF_3)_2$$

but it is not certain (2) whether product II is formed predominantly by dimerization of two hydrazo radicals

[4] $$2(CF_3)_2N{-}NCF_3 \rightarrow (CF_3)_6N_4$$

or by hydrazo radical addition to hexafluoroazomethane

[5] $$(CF_3)_2N{-}NCF_3 + CF_3NN{=}CF_3 \rightarrow (CF_3)_5N_4$$

followed by the tetrazo radical combining with a CF_3 radical

[6] $$(CF_3)_5N_4 + CF_3 \rightarrow (CF_3)_6N_4.$$

This investigation attempts to distinguish between the two possible mechanisms; also some quantum yield determinations at 3 660 Å are reported.

EXPERIMENTAL

The cylindrical pyrex reaction cell (5 cm diam., 10 cm long, volume 192 cc) was part of a closed loop of total volume = 622 cc. The reacting gas was continually circulated by a magnetically operated all-glass pump. A trap was also included in the loop to freeze out condensables. Pressures were recorded on a constant volume Hg manometer. The light source was a high pressure Hg arc, and the incident light on the reaction space was 5.4×10^{16} quanta/s in the 3 660 Å spectral region, fully illuminating the cell. Conventional solution filters and actinometry were employed.

The circulating system was connected to a calibrated volume equipped with a manometer, which could be

[1]*Department of Chemistry, University of California, Santa Barbara, California.*

included in the carrier gas line to a chromatograph (Perkin–Elmer Model 154). Analysis was carried out in the majority of the experiments for N_2, C_2F_6, and unreacted hexafluoroazomethane, using a 50 cm silica-gel column, maintained at 55 °C with a carrier gas (H_2) flow rate of 18 cc/min. Respective retention times were $1\frac{3}{4}$, $3\frac{1}{2}$, and 17 min. As the reaction products are well established (1, 2, 3), the heavy products (I and II) were obtained by mass balance. Usually three analyses were performed on the products of each run and the results averaged.

Denoting the overall reactions by

$$A \rightarrow N_2 + C_2F_6$$

$$2A \rightarrow N_2 + \text{product I}$$

$$3A \rightarrow N_2 + \text{product II}$$

we have

$$C_2F_6 + I + II = N_2$$

$$\text{product I} = 3N_2 - A \text{ consumed} - 2C_2F_6$$

$$\text{product II} = A \text{ consumed} + C_2F_6 - 2N_2.$$

In some experiments products I and II were identified chromatographically. They did not pass through the silica-gel column in a finite time, but they were resolved and identified on a Dow Corning 200 silicone oil column. The only other substance in the reaction mixtures detectable by chromatography was CF_3I; this occurs as an impurity in the preparation of hexafluoroazomethane (3) and was not removed completely (4).

RESULTS AND DISCUSSION

Mechanism

Experiments were carried out at 5, 25, and 37 °C, and some results for the rates of formation of N_2, C_2F_6, and products I and II are recorded in Table I. If product II is formed via the reaction sequence [5] and [6], and reaction [5] is rate determining in the formation of product II (all the tetrazo radicals formed are rapidly consumed by CF_3 radicals) we may write $R_{II} = k_5$[Hyd.][A], where R is the mean rate of formation, [Hyd.] is the hydrazo radical concentration, and [A] is the hexafluoroazomethane concentration. As hydrazo radicals are consumed only in reactions [3] and [5], for the steady state, we have $R_{(I+II)} = k_2$[CF_3][A], and $R_I = k_3$[CF_3][Hyd.], so that

$$\frac{R_{(I+II)}R_{II}}{R_I} = \frac{k_2k_5[A]^2}{k_3}.$$

Plots of this function versus $[A]^2$ should be linear, passing through the origin. Although the experimental data is scattered at low pressures, distinct curvature is obtained at higher pressures.

Alternatively, if reaction [4] predominates in the formation of product II, we have

$$\frac{R_I}{R_{C_2F_6}^{1/2}R_{II}^{1/2}} = \frac{k_3}{k_1^{1/2}k_4^{1/2}}.$$

The values for this function are recorded in Table I. The data is again scattered, but the average value for the 17 experiments is 1.8. Similar cross-combination values for a great variety of alkyl radicals are reported in the literature (5). According to the simple collision theory of chemical kinetics the ratio should be 2 for reactions with no activation energy and steric factors close to unity, conditions which are assumed to prevail in many radical–radical interactions. Deviations may be expected when one of the radicals involved is strongly polar (6), but if both radicals are of similar polarity (conditions which may well apply in perfluororadical interactions), a value for the cross-combination ratio close to 2 is to be expected. In our previous study (7) of the system $CF_3 + C_3F_7$, a ratio equal to 1.77 ± 0.1 over a 107° temperature range was obtained. Gordon (8) has recently found the ratio 2.07 ± 0.08 for $CF_3 + C_2F_5$ from 50–300 °C. Although we cannot assume that

	12.4	30.6	3.2	9.4	18.0	0.7	0.86	241

*The lack of precision in the cross-combination ratios is due to the fact that small errors in the measurements of the initial and final hexafluoroazomethane concentrations can reflect a large error in the hexafluoroazomethane consumed (10–15% conversion), leading to a large error in the rates of formation of products I and II, as determined by mass balance.

CF_3 and $(CF_3)_2NNCF_3$ are of equal polarity, the cross combination ratio obtained indicates that reaction [4] is the predominant mode of formation of product II, rather than reaction [5], followed by [6].

In some present studies (9) on the photolysis of $C_2F_5N{=}NC_2F_5$, ratios of $C_4F_{10}/N_2 \simeq 0.7$ were obtained at 100, 140 and 200 °C, at about 5 cm pressure. For a similar pressure of $CF_3N{=}NCF_3$ at room temperature and comparable intensity (1) $C_2F_6/N_2 = 0.2$. Assuming similar activation energies for the $R_fN{=}NR_f$ addition by the respective radicals, it is seen that the C_2F_5 radical addition process is less favored sterically (assuming that the perfluoro groups (R_f) attached to the N atoms are not rate controlling, sterically). This represents some corroborative evidence that the hydrazo radical addition in reaction [5] will be unlikely from steric considerations.

A few experiments were carried out with CO_2 added to the system, using 10 mm initial pressure of hexafluoroazomethane at 5 °C, and from 0–21 mm pressure of CO_2. The C_2F_6 yield was found to be independent of diluent gas pressure, indicating the homogeneous second-order recombination of CF_3 radicals. In experiments on the photolysis of CF_3CHO it has been shown that CF_3 radical combination only approaches the third-body dependence region at pressures <0.5 mm (10).

Quantum Yields

Quantum yields of the products arising from radical interactions are given in Fig. 1. (The data are not necessarily derived from those presented in Table I.) The quantum yield of product I increases with temperature as would be expected from the known temperature dependence (3) of reaction [2].

The quantum yield data on N_2 give a value of $\Phi_{N_2} = 1$ at low pressures ($\sim$ 5 mm), dropping to a value of $\Phi_{N_2} \simeq 0.75$ at $\sim$ 30 mm pressure. Although the quantum yield of N_2 does not fall below unity at pressures under 1 atm in the photolysis of azomethane (11), the substitution of fluorine for hydrogen increases the number of effective normal modes of vibration (12) so that we should expect collisional deactivation processes to be more evident at lower pressures with hexafluoroazomethane. Similarly the importance of collisional deactivation has been shown in the photolysis of azoethane because of the

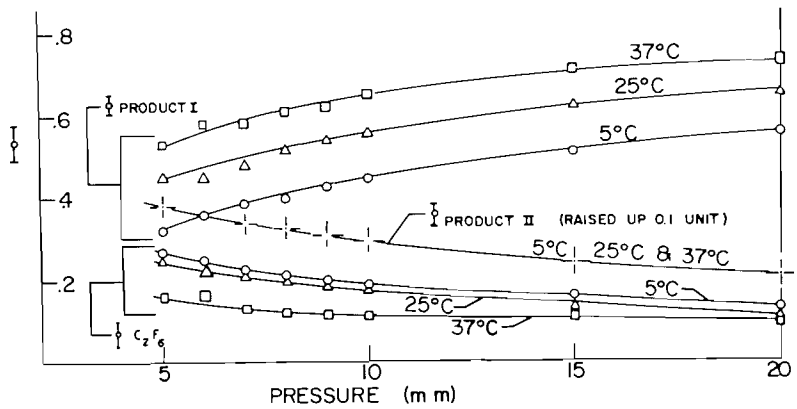

FIG. 1. Overall quantum yield, Φ, for hexafluoroethane (C_2F_6), perfluorotetramethyl hydrazine (product I), and perfluorohexamethyl tetrazine (product II) plotted against temperature and pressure.

larger number of degrees of vibrational freedom (13). At 28 °C and 3 660 Å values of Φ_{N_2} decrease from 0.85 to 0.59 in the pressure range 12 to 134 mm (13). A large pressure effect on Φ_{N_2} is also evident in the photolysis of $C_2F_5N_2C_2F_5$ (9).

From the simple deactivation mechanism

$$A + h\nu \rightarrow A^*$$

$$A^* \xrightarrow{k_a} \text{products}$$

$$A + A^* \xrightarrow{k_b} 2A$$

where A* represents an excited $CF_3N_2CF_3$ with sufficient energy to decompose, we have, in the steady state

$$1/\Phi = 1 + (k_b/k_a)[A].$$

A plot of our data in this form ($1/\Phi$ versus [A]) showed some scatter, but a least-squares treatment gave an intercept of 0.98, which is close to the theoretical value of unity. Similar intercepts were found in the azoethane system (13), in the temperature range 28 to 150 °C, although they were slightly high at lower temperatures (1.1 at 28 °C), probably due to internal conversion to an electronic state which is incapable of dissociation, or to a wall reaction (13). A flash photolysis study of azoethane (14) over the pressure range 20 to 80 mm also gave a unity intercept (for Φ_{N_2} measured at room temperature).

A value of $k_b = 1.6 \times 10^{14}$ mole^{-1} cc s^{-1} may be calculated at 25 °C from collision theory, assuming that $E_b = 0$, a collision efficiency factor of unity, and collision diameters of A and A* = 6.0 Å (based on (15) $(CF_3)_2CO$ = 6.0 Å). Taking this value in conjunction with the experimental slope ($k_b/k_a = 2.3 \times 10^5$ cc mole^{-1}) we obtain $k_a = 0.8 \times 10^9$ s^{-1}. The value for $k_b = 3.6 \times 10^{14}$ mole^{-1} cc s^{-1} for azoethane (assuming collision diameters for A and A* of 7.0 Å (13)); taking an average value for $k_b/k_a = 0.9 \times 10^5$ cc mole^{-1}, calculated from values of 0.81×10^5 and 1.04×10^5 cc mole^{-1} (13, 14), we find that $k_a = 4.0 \times 10^9$ s^{-1} for azoethane, indicating a factor of about 5 in the decomposition rates of the excited states at room temperature.[2] The ratios of k_b/k_a in the two systems indicate a factor of

[2]*Cerfontain and Kutschke (13) give $k_b = 1.8 \times 10^{14}$ mole^{-1} cc s^{-1} which is presumably obtained by dividing the collision number by 2. We have regarded A and A* as unlike species in both calculations. It is also assumed that the translational energy of A* is the same as that for A.*

2.5 in the respective rates, and with allowance for the differences in the reduced masses, the factor becomes 3.6. The remainder of the calculation then depends upon the values assigned to the collision diameters.

It is interesting to note that the rate of thermal decomposition of azoethane is appreciably faster than the rate for hexafluoroazomethane, which is attributable to a difference of ~ 7 kcal mole^{-1} in the respective activation energies for pyrolysis (12). (Using the Arrhenius parameters given (12) we may compute that azoethane decomposes 5 times faster than hexafluoroazomethane at 1 220 °K.)

In proposing the simple deactivation mechanism for azoethane Weininger and Rice (16) emphasized that although some of the excitation energy in photochemical decomposition is initially electronic, conversion into vibrational energy occurs, leading to cleavage of a critical bond(s) if sufficient energy is available. This picture has been retained by subsequent workers (11, 13) and by us. Most recent work (17) places an upper limit of about 30 kcal/mole for the quantum of vibrational energy that is transferred per collision, a figure which is consistent with the simple deactivation mechanism of Weininger and Rice (16), and the initial photochemical energy involved. It is difficult to explain the pressure dependence of the quantum yields in any other way. The energy taken up at 3 660 Å is equivalent to ~ 80 kcal mole^{-1}, which is well above the activation energies required for C—N bond fission[3] in the two compounds: 55.2 and 48.5 kcal mole^{-1} in hexafluoroazomethane and azoethane respectively (12). Although the differences in activation energy are in the right direction, as 10–20 kcal mole^{-1} of excess vibrational energy is transferred at each collision (17), the determining factor in the decomposition rate of the photochemically activated species is dependent upon the probability of it attaining the critical configuration which leads to decomposition, while deactivating collisions are occurring. This probability is a function of the number of available degrees of freedom in the molecule throughout which the excess energy can be distributed, decreasing with increasing degrees of freedom. In terms of the Kassel model the number of effective oscillators, S, is ~ 23 in hexafluoroazomethane (12), while $S = 18$ for azoethane (18), which is in accord with the differences in the decomposition rates and the pressure dependencies of the quantum yields that we have observed.

Implicit in the preceding comparison is the assumption that the collision efficiency factors (Q) are identical for the two systems at room temperature. Since relative deactivating efficiencies vary according to the species being deactivated, a direct comparison is difficult, but we have presumed that they are not markedly different.

In the azoethane photolysis Cerfontain and Kutschke (13) further observed decreasing slopes (k_b/k_a) with increasing temperature, from which they calculated increasing values of k_a. Although the increased vibrational energy content of A*, caused by raising the temperature, cannot be ignored, we may suggest that as energy transfer is less efficient at higher temperatures, the collision efficiency factor (Q) decreases, so that smaller values of k_b should be employed, yielding smaller values of k_a[4]. The increased quantum yields found with increasing temperature may then be largely correlated with a decreasing rate in energy transfer, an identical picture to that which accounts for the pressure dependence of the quantum yield. We are conducting (9) additional experiments with perfluoroazoethane to investigate this possibility.

[3]*The second* C—N *bond cleavage is spontaneous, requiring very little energy, see M. Page, H. O. Pritchard, and A. F. Trotman-Dickenson. J. Chem. Soc. 3878 (1953).*

[4]*If* $Q = 1.0$ *at 28° and 0.3 at 152°C,* k_a *has the same value at both temperatures.*

ORGANIC SULFUR COMPOUNDS

PART I. BENZOTHIAZINE HYDROXAMIC ACIDS AND RELATED COMPOUNDS

R. T. COUTTS, H. W. PEEL, AND ELIZABETH M. SMITH
College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan

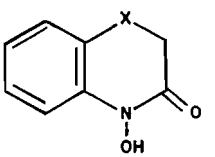
Received June 18, 1965

ABSTRACT

2*H*-1,4-Benzothiazine hydroxamic acids of type V (see Table I) are readily prepared by reducing suitably substituted (*o*-nitrophenylthio)acetates (II, R″ = Me or Et) by means of sodium borohydride and palladium–charcoal. The ester precursors can be prepared by the interaction of *o*-nitrothiophenols and α-bromoesters, but such a method is limited in scope. Diethyl bromomalonate, for example, reacts atypically with *o*-nitrothiophenol. The ester precursors are better prepared by Fischer–Speier esterification of the corresponding acids (II, R″ = H) which, in turn, are the products of nucleophilic attack by α-mercaptoacids on suitable *o*-chloro- (or bromo-) nitrobenzenes. This general preparative method failed in two instances. When *o*-chloronitrobenzene or 4-chloro-3-nitrotoluene was reacted with α-mercaptoisobutyric acid, the only acidic product obtained was α,α′-dithiodiisobutyric acid.

Reduction of methyl 2-(*o*-nitrophenylthio)benzoate (VI) with sodium borohydride and palladium–charcoal gave an azoxy compound, namely 2,2′-bis((*o*-methoxycarbonyl)phenylthio)azoxybenzene (VII).

When suitably substituted aromatic *o*-nitroesters are reduced with sodium borohydride and palladium–charcoal, the nitro group is converted into a hydroxylamino group which then cyclizes with the ester group, and cyclic hydroxamic acids are the result. Using this method of reduction, we have prepared a variety of such compounds (1, 2) including 3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazine (I*a*), the related sulfone (I*b*) and the corresponding benzoxazine (I*c*). Many cyclic hydroxamic acids possess antibacterial properties (2, 3, 4); Dimboa (3,4-dihydro-2,4-dihydroxy-7-methoxy-3-oxo-2*H*-1,4-benzoxazine) exhibits antimetabolic activity (5) and benzothiazines related to I have been shown to possess anthelmintic properties (6, 7). For these reasons, it was of interest to prepare simple derivatives of I*a* and test them initially for antibacterial activity and for their

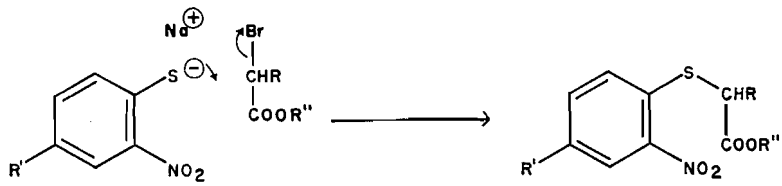


I

(*a*) X = S
(*b*) X = SO_2
(*c*) X = O

action on selected enzymes. This investigation also offered an opportunity to study further the reducing properties of sodium borohydride in the presence of palladium–charcoal.

For the preparation of the precursors (II) required for reduction to 2-substituted 3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazines, the initial method chosen was to condense the appropriate sodium *o*-nitrothiophenolate with suitable α-bromoesters (Scheme 1). This reaction, however, proved to be unsatisfactory. In the first place, the yields of pure *o*-nitrothiophenol obtained by mild reduction of bis(*o*-nitrophenyl) disulfide (III*a*) according to the methods of Claass (8, 9) and Mills and Whitworth (10) were poor, as were the yields of products; in addition, the scope of the reaction was limited by the



SCHEME 1.

nature of the substituent R on the α-carbon of the bromoester. Using this method, 2-(*o*-nitrophenylthio)propionic acid, its ethyl ester (II*a*), ethyl 2-(*o*-nitrophenylthio)butyrate (II*b*), and methyl (2,4-dinitrophenylthio)acetate (II*c*) were prepared from either the disulfides (III*a* or III*b*) or from sodium *o*-nitrothiophenolate. An unsuccessful attempt to extend this reaction to the preparation of the compound in which R was an ethoxycarbonyl group (II*d*) is described in detail later in this paper.

Numerous attempts were made to prepare (4-trifluoromethyl-2-nitrophenylthio)acetic acid (II*e*) from bis(4-trifluoromethyl-2-nitrophenyl) disulfide (III*c*). Using Claass' method of converting disulfides to thiophenols, the disulfide (III*c*) was reduced to 4-trifluoromethyl-2-nitrothiophenol, which was not isolated before being reacted with chloroacetic acid. By this method, very poor yields of II*e* were obtained. The presence of the trifluoromethyl group and its effect on the solubility in water of the product contributed to the poor yield (11). An attempt to isolate 4-trifluoromethyl-2-nitrothiophenol in pure form, prior to condensing with chloroacetic acid, was unsuccessful.

o-Chloronitrobenzene is an alternative starting material for the preparation of compounds of type II. This substance and its simple derivatives are known to react with thioglycollic acid and give (*o*-nitrophenylthio)acetic acids in good yields (12, 13, 14). Using this method, (4-trifluoromethyl-2-nitrophenylthio)acetic acid (II*e*) was prepared from 4-chloro-α,α,α-trifluoro-3-nitrotoluene and was isolated in a yield vastly superior to that obtained as described above. The related 4-bromo and 4-methyl derivatives of (*o*-nitrophenylthio)acetic acid (II*f* and II*g*) were also obtained by this method from 2,5-dibromonitrobenzene and 4-chloro-3-nitrotoluene respectively. This approach to the syntheses of precursors of benzothiazine hydroxamic acids is capable of extension to give the starting materials necessary for the preparation of products substituted in the 2-position of the benzothiazine ring. These starting materials were readily obtained by reacting various *o*-chloro- (or bromo-) nitrobenzenes with α-mercapto acids in the presence of sodium bicarbonate (Scheme 2). Generally, longer reaction times were necessary than when thioglycollic acid was employed in the reaction. Thus, when α-mercaptosuccinic acid and α-mercaptopropionic acid were each condensed with *o*-chloronitrobenzene, 4-chloro-α,α,α-trifluoro-3-nitrotoluene, 2,5-dibromonitrobenzene, and 4-chloro-3-nitrotoluene, a further selection of compounds of type II (II*h*–II*o*) were obtained, usually in good yield. The deactivating effect of the methyl group on the reactivity of 4-chloro-3-nitrotoluene to nucleophilic substitution was clearly illustrated by the fact that the yields of products obtained using this compound were appreciably lower than when the other *o*-nitrochloro (or bromo) compounds were employed in the reactions with α-mercapto acids. The major limitation, however, to this preparative method would seem to be the availability of α-mercapto acids, although the nature of the other substituents on the α-carbon of the mercapto acid and their effect on the reactivity of the thiol group also limits its scope. When, for example, α-mercaptoisobutyric acid is condensed with 4-chloro-α,α,α-trifluoro-3-nitrotoluene or with 2,5-dibromonitrobenzene, the nucleophilic reaction is typical and

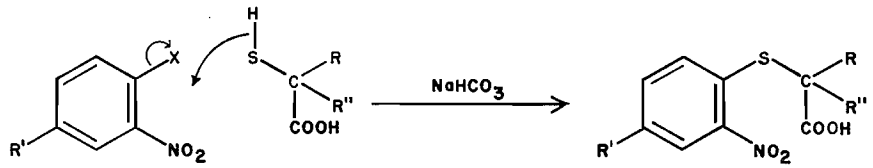

SCHEME 2.

α-(4-trifluoromethyl-2-nitrophenylthio)isobutyric acid (II*p*) and α-(4-bromo-2-nitrophenylthio)isobutyric acid (II*q*) are readily obtained in good yield. No α-(*o*-nitrophenylthio)isobutyric acids were obtained, however, when *o*-chloronitrobenzene and 4-chloro-3-nitrotoluene were reacted with α-mercaptoisobutyric acid. Under the conditions used, neither the thiol group of the α-mercapto acid nor the ortho-chlorine atom of the nitrobenzene employed in the reaction were sufficiently activated to promote a nucleophilic substitution reaction, and, in both cases, the same product, α,α′-dithiodiisobutyric acid, was the only acidic material isolable.

The acids II*e*–II*q* were readily esterified using Fischer–Speier conditions, before being reduced. Reductive cyclization of the esters of type II by means of sodium borohydride and palladium–charcoal produced good yields of cyclic hydroxamic acids (Table I) in most cases. Two attempts to reduce methyl (4-methyl-2-nitrophenylthio)acetate, however, resulted in poor yields of the expected hydroxamic acid (V*g*); the main product of this atypical reaction was the acid (II*g*) of the starting material. Reduction of methyl (2,4-dinitrophenylthio)acetate (II*c*) was also unsatisfactory. A dark brown amphoteric oil was obtained in an amount insufficient for characterization. It gave the color tests expected of

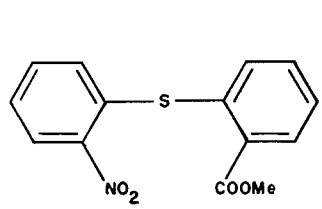
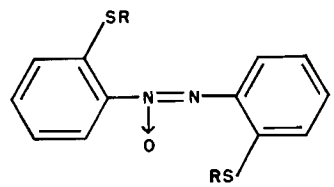
For personal use only.

both a primary aromatic amine and a hydroxamic acid which suggested that the isolated nitro group (R′ in formula II) had, as expected, reduced beyond the hydroxylamino stage (15).

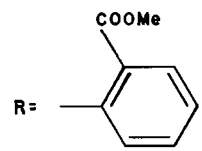
Condensation of methyl *o*-mercaptobenzoate with *o*-chloronitrobenzene produced methyl 2-(*o*-nitrophenylthio)benzoate (VI). This compound was reduced with sodium borohydride and palladium–charcoal in an attempt to prepare a cyclic hydroxamic acid with a seven-membered ring system. Hitherto, reduction of nitro groups with this reagent has produced either primary amines (15) or, as a result of cyclization at the hydroxylamino stage of reduction, cyclic *N*-oxy or *N*-hydroxy compounds (1, 2). In the present case, reduction did occur but the product was neither a primary amine nor a cyclic hydroxamic acid. Instead, an azoxy compound (VII) was obtained. In a different series of reactions, we have found that the yield and the nature of the product obtained in sodium borohydride/palladium–charcoal reductions is greatly influenced by the choice of solvent and the rate of addition of the nitro compound to the reducing medium (16). This is also true in the reduction of VI. When dioxane was employed as solvent and the rate of addition of the



VI



VII



nitro compound was extended to 1 h, a good yield of azoxy compound resulted. A more rapid reduction of VI using ethanol as solvent gave the same product (VII) in much poorer yield. Reduction of the ester (VI) with zinc and ammonium chloride also gave the same azoxy compound, again in poor yield. The structure of the azoxy compound was inferred from its elemental analysis, its color, and the fact that such compounds can be prepared by reducing nitro compounds with zinc and ammonium chloride. Corroboration was obtained from infrared studies. The infrared spectrum of the starting material (VI) showed typical strong absorption in the nitro group regions which was absent in the reduced compound (VII), having been replaced by a strong absorption peak at 1 474 cm^{-1}. This absorption may be attributed to the azoxy group for the reasons which follow. The infrared spectra of 4,4′-dichloroazobenzene, 4,4′-diphenylazobenzene, and 4-chloro-4′-phenylazobenzene were compared with 4,4′-dichloroazoxybenzene, 4,4′-diphenylazoxybenzene, and 4-chloro-4′-phenylazoxybenzene (mixture of isomers) respectively, in the 1 450 – 1 500 cm^{-1} region (17). In the case of each pair of azo and azoxy compounds, the azoxy compound possessed a strong additional absorption peak at 1 473 cm^{-1} (4,4′-dichloroazoxybenzene), 1 469 cm^{-1} (4,4′-diphenylazoxybenzene), and 1 475 cm^{-1} (4-chloro-4′-phenylazoxybenzene mixture). One of the two strong peaks at 1 255 and 1 270 cm^{-1} in the infrared spectrum of compound VII may also be attributed to N—O stretching of an azoxy group (18).

*SO_2 replaces S in structure V.

One example of a substituted benzothiazine-1,1-dioxide was also prepared during this study. 3,4-Dihydro-4-hydroxy-2-methyl-3-oxo-2*H*-1,4-benzothiazine-1,1-dioxide (V*t*) was readily obtained by sodium borohydride/palladium–charcoal reduction of methyl 2-(*o*-nitrophenylsulfonyl)propionate (II*t*) which was, in turn, the product of oxidizing the related sulfide (II*u*) with potassium permanganate. Presumably the sulfones of the benzothiazines listed in Table I could be prepared in a similar manner.

Reduction by means of hydrazine hydrate and palladium–charcoal is also a suitable method of preparing cyclic hydroxamic acids (19) but when this method was applied to methyl (*o*-nitrophenylthio)acetate, no reduction occurred and the only product isolated was the hydrazide of the starting material. This preparative method was therefore not investigated further.

All the hydroxamic acids listed in Table I gave the expected violet color when ethanolic ferric chloride solution was added to an ethanolic solution of the acid. Addition of water to this solution usually resulted in the precipitation of a brown colored ferric chelate.

As previously mentioned, condensation of sodium *o*-nitrothiophenolate with diethyl bromomalonate gave no diethyl (*o*-nitrophenylthio)malonate (II*d*). Instead, a very good yield of bis(*o*-nitrophenyl) disulfide (III*a*) immediately resulted on the addition of the bromomalonate to an aqueous ethanolic solution of sodium *o*-nitrothiophenolate. The filtrate from this reaction, on concentration and standing, deposited a small amount of diethyl bis(*o*-nitrophenylthio)malonate (IV). Such a structure is suggested by elemental analysis, infrared spectrum, and the fact that the same compound is obtained when diethyl dibromomalonate is reacted with sodium *o*-nitrothiophenolate. The isolation of IV, however, is not due to the presence of diethyl dibromomalonate as an impurity in the monobromomalonate. When the dibromomalonate was condensed with sodium *o*-nitrothiophenolate in aqueous ethanol, a yield in excess of 80% of bis(*o*-nitrophenyl) disulfide was immediately formed and only a small quantity of IV was isolated. This reaction requires further investigation and will be the subject of a later communication. The formation of IV is reminiscent of the findings of Honkanen and Virtanen (20) who interacted sodium *o*-nitrophenolate and diethyl bromomalonate and obtained as a minor product of the reaction, a substance which was apparently diethyl bis(*o*-nitrophenoxy)malonate (IV, O replacing S).

A selection of the compounds of types I and II are at present being tested for antibacterial activity and for their action on selected enzymes. Preliminary results in the latter case are encouraging and will be reported elsewhere.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Equivalent weights were determined in aqueous ethanol by direct titration with standard alkali. Infrared spectra were recorded on a Beckmann I.R. 8 spectrophotometer except where stated otherwise, and microanalyses were carried out by Dr. F. Pascher and E. Pascher, Bonn, who determined the molecular weight values by measurement of vapor pressure. Palladium–charcoal refers to 10% palladium-on-charcoal. Ether solutions were dried over Na_2SO_4.

o-Nitrothiophenol

Using Claass' method (8) except that aqueous acetic acid was employed instead of mineral acid to finally liberate the phenol, apparently good yields of *o*-nitrothiophenol (20–24 g) are obtained from bis(*o*-nitrophenyl) disulfide (30 g). The green precipitate, m.p. 48–52°, is impure, however, only approximately half of it being soluble in light petroleum from which the thiophenol is obtained as yellow crystals, m.p. 59–60°, lit. (10) m.p. 61°.

Ethyl 2-(o-Nitrophenylthio)propionate (IIa)

Bis(*o*-nitrophenyl) disulfide (10 g) was converted to sodium *o*-nitrothiophenolate using Claass' method (9), and to the aqueous solution of the salt was added ethyl 2-bromopropionate (8.8 ml). The mixture was stirred until the red solution became much lighter in color, and the oil which separated was extracted into ether.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The dried ether solution was distilled, and the fraction boiling at 184–188° at 10–15 mm Hg (4.41 g) was collected. The oil solidified when triturated with a little methanol and gave ethyl 2-(*o*-nitrophenylthio)propionate (3.71 g) as yellow crystals, m.p. 47–48°.

Anal. Calcd. for $C_{11}H_{13}NO_4S$: C, 51.71; H, 5.13; N, 5.52; S, 12.55. Found: C, 51.82; H, 4.86; N, 5.67; S, 12.38.

Methyl (2,4-Dinitrophenylthio)acetate (IIc)

This was prepared by the method used for II*a*, from the disulfide (20 g) and methyl bromoacetate (10 ml). The compound was a yellow solid (11.2 g), m.p. 92–93°, lit. (12) m.p. 93–94°.

Ethyl 2-(o-Nitrophenylthio)butyrate (IIb)

o-Nitrothiophenol (3.88 g) was dissolved in a solution of sodium hydroxide (1 g) in water, (4 ml) and ethanol (80 ml). To the red solution was added ethyl 2-bromobutyrate (5.09 g). A precipitate of crude disulfide (III*a*, 0.71 g) was removed and the filtrate was evaporated to 20 ml, flooded with water, and extracted with ether. The washed and dried ether layer was distilled. The yellow oil, b.p. 200–205° at 23 mm Hg, (2.49 g) was ethyl 2-(*o*-nitrophenylthio)butyrate.

Anal. Calcd. for $C_{12}H_{15}NO_4S$: C, 53.51; H, 5.61; N, 5.20; S, 11.91. Found: C, 53.21; H, 5.89; N, 4.96; S, 12.07.

(4-Trifluoromethyl-2-nitrophenylthio)acetic Acid (IIe)

Method (a)

Bis(4-trifluoromethyl-2-nitrophenyl) disulfide (25 g) was heated under reflux with ethanol (200 ml). To the refluxing solution was added successive small portions of a concentrated aqueous solution of sodium sulfide nonahydrate (11.7 g) and sodium hydroxide (6.7 g). The dark red solution of the mercaptide was diluted with water (500 ml), cooled, and filtered. To the filtrate was added a solution of chloracetic acid (16.7 g) and anhydrous sodium carbonate (10 g) in water (100 ml) and the whole was heated gently for 2 h. The cooled solution was then extracted with ether, and the aqueous layer was acidified with dilute hydrochloric acid and yielded an almost black solid (10.3 g), m.p. 90–95°. The crude product was purified by repeated dissolution in sodium bicarbonate solution, followed by reprecipitation with acetic acid and crystallization from benzene. This gave 3.22 g of yellow acid (II*e*), m.p. 158°, lit. (14) m.p. 154–155°.

Method (b)

The acid (II*e*) was obtained in 68% yield from 4-chloro-α,α,α-trifluoro-3-nitrotoluene and thioglycollic acid using the general method of preparing 2-(*o*-nitrophenylthio) acids, which is described below. Reflux time time was 5 h. Crystallization from benzene gave yellow crystals, m.p. 158°.

Anal. Calcd. for $C_9H_6F_3NO_4S$: C, 38.44; H, 2.15; N, 4.98; S, 11.40. Found: C, 38.48; H, 2.04; N, 5.17; S, 11.57.

General Method of Preparing 2-(o-Nitrophenylthio) Acids and Esters of Type II

The substituted *o*-nitrochloro or *o*-nitrobromobenzene (0.05 mole) and the α-mercaptoacid (0.05 mole) were refluxed for the stated time in 50% aqueous ethanol (100 ml), in which was suspended a slight excess of sodium bicarbonate (0.11 or 0.16 mole, for monobasic or dibasic acids respectively). The solution was then concentrated to approximately 50 ml, diluted with water, and extracted with ether. The ether layer was rejected. The *o*-nitrophenylthio acid was obtained in the stated yield from the aqueous solution by acidifying with dilute hydrochloric acid.

The acids listed in Table II were obtained by this method. All were yellow solids, except II*i* and II*p* which were pale brown in color, and all had characteristic infrared spectra (KBr discs) which showed the expected carbonyl, hydroxyl, and nitro group absorption peaks. The corresponding methyl esters were prepared in excellent yield by refluxing the acid (5 g) in methanol (50 ml) containing concentrated sulfuric acid (5 ml) for 18–24 h, and the products were isolated in the normal way. The esters were not analyzed before reduction but were characterized by infrared spectrum and m.p. only (see Table II).

Attempted Preparation of α-(2-Nitrophenylthio)isobutyric Acid (IIr)

o-Chloronitrobenzene (3.15 g), α-mercaptoisobutyric acid (2.48 g) and sodium bicarbonate (7.51 g) were refluxed in 50% aqueous ethanol (50 ml) for 48 h. The resulting pale yellow solution was diluted with water and extracted with ether. The ether layer was rejected. The aqueous solution was acidified and extracted with ether which was washed, dried, and evaporated to give an oily solid. Trituration with benzene gave a nitrogen-free cream solid (0.857 g), m.p. 195–197°. Lit. (21) m.p. of α,α'-dithiodiisobutyric acid is 196°.

Attempted Preparation of α-(4-Methyl-2-nitrophenylthio)isobutyric acid (IIs)

By a similar method to that reported immediately above, the interaction of 4-chloro-3-nitrotoluene (3.456 g) and α-mercaptoisobutyric acid (2.425 g) yielded α,α'-dithiodiisobutyric acid (0.905 g), the infrared spectrum and m.p. of which were identical to those of the compound reported above.

General Method of Preparing Cyclic Hydroxamic Acids by Reducing Esters of Type II with Sodium Borohydride and Palladium–Charcoal

Sodium borohydride (0.8 g) was dissolved in water (5 ml) or in some cases 2% aqueous sodium hydroxide (5 ml), and palladium–charcoal (0.1 g) suspended in water (3 ml) was carefully added. The suspension was

diluted with dioxane (10 ml) and nitrogen was passed through the mixture while the ester (2 g) in dioxane (10–20 ml) was added dropwise over a period of 30 min. The passage of nitrogen was continued for 15 min after the ester had been added. The mixture was then filtered, acidified with dilute hydrochloric acid, and diluted with water. In some cases the hydroxamic acid precipitated and was filtered off. In other cases, the solution was concentrated and extracted with ether. Extraction of the ether solution with sodium carbonate solution or sodium hydroxide solution, acidification of the aqueous layer with dilute hydrochloric acid, reextraction with ether, and evaporation of the ether gave the hydroxamic acid.

Using this general method of reduction, compounds II*a* and II*b*, the methyl esters of compounds II*e* to II*k*, and the methyl esters of compounds II*m* to II*q* gave rise respectively to 3,4-dihydro-4-hydroxy-2-methyl-3-oxo-2*H*-1,4-benzothiazine (V*a*), the corresponding 2-ethyl derivative (V*b*); 6-trifluoromethyl-3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazine (V*e*), the corresponding 6-bromo derivative (V*f*), the corresponding 6-methyl derivative (V*g*); methyl 2-(3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazinyl)acetate (V*h*); methyl 2-(6-trifluoromethyl-3,4-dihydro-4-hydroxy-3-oxo-2*H*-1,4-benzothiazinyl)acetate (V*i*), the corresponding 6-bromo derivative (V*j*), the corresponding 6-methyl derivative (V*k*); 6-trifluoromethyl-3,4-dihydro-4-hydroxy-2-methyl-3-oxo-2*H*-1,4-benzothiazine (V*m*), the corresponding 6-bromo derivative (V*n*); 3,4-dihydro-4-hydroxy-2,6-dimethyl-3-oxo-2*H*-1,4-benzothiazine (V*o*); 6-trifluoromethyl-3,4-dihydro-4-hydroxy-2,2-dimethyl-3-oxo-2*H*-1,4-benzothiazine (V*p*) and the corresponding 6-bromo derivative (V*q*), in the yields stated (see Table I).

All the hydroxamic acids listed in Table I were white solids and, with the exception of compound V*t* for which ethyl acetate was employed, all were crystallized from ethanol or aqueous ethanol. A solution of each hydroxamic acid in ethanol turned deep violet on the addition of ethanolic ferric chloride solution. The infrared spectrum of each compound in KBr showed typical broad hydroxyl absorption in the 3 000 – 3 400 cm^{-1} region, the position of the peak varying from 3 090 to 3 280 cm^{-1}. Carbonyl absorption within the range 1 635 to 1 655 cm^{-1} was observed in all cases except compounds V*h*, V*i*, V*j*, and V*k* which had two carbonyl peaks, one in the 1 640 to 1 665 cm^{-1} region (hydroxamate carbonyl) and a second within the range 1 720 to 1 730 cm^{-1} (ester carbonyl).

Reduction of Methyl (4-Methyl-2-nitrophenylthio)acetate

This ester (2.408 g) was reduced by the general method. An ether extraction of the acidified filtrate yielded a yellow solid (1.562 g) which was dissolved in sodium carbonate solution (5%) and extracted with ether. The ether extract was rejected. The aqueous layer was again acidified (dilute hydrochloric acid) and (4-methyl-2-nitrophenylthio)acetic acid (II*g*) (0.948 g) was obtained (m.p. and infrared spectrum were identical to those of an authentic sample). The filtrate was extracted with ether which, on drying and evaporation, yielded 3,4-dihydro-4-hydroxy-6-methyl-3-oxo-2*H*-1,4-benzothiazine (V*g*) (0.229 g), m.p. 98–102°, raised to 105–107° on recrystallizing from ethanol.

In a repeat reduction, the ester (1.641 g) yielded II*g* (0.766 g) and V*g* (0.282 g).

Reduction of Methyl (2,4-Dinitrophenylthio)acetate

This acetate (2 g) was reduced by the general method except that methanol was used as solvent, and 2 g of sodium borohydride and 0.2 g of catalyst were employed in the reaction. The acidified filtrate was made slightly basic with ammonia solution, the excess ammonia was boiled off, and the resulting solution was diluted with water and extracted with ether. From the ether solution, a brown oil (0.25 g) was obtained on evaporation. It gave a violet color with alcoholic ferric chloride solution; it could also be diazotized and coupled with β-naphthol and thus gave an orange-red dye.

Methyl o-Mercaptobenzoate

o-Mercaptobenzoic acid (18.4 g) was refluxed for 15 h in methanol (150 ml) containing concentrated sulfuric acid (15 ml) and the ester was isolated as an oil in the usual way. The oil was distilled and the fraction boiling at 154° at 24 mm Hg (15.8 g) was collected and used in the following reaction. Lit. (22) b.p. 252°.

Methyl 2-(Nitrophenylthio)benzoate (VI)

Methyl *o*-mercaptobenzoate (4.21 g) was dissolved in a solution of sodium hydroxide (1 g) in water (2 ml) and methanol (50 ml). To the resulting red solution was added *o*-chloronitrobenzene (4.75 g) dissolved in methanol (20 ml). The mixture was allowed to stand for 4 days at room temperature then it was concentrated to half volume and flooded with water. A yellow precipitate (5.1 g, m.p. 89–93°) was obtained. After crystallizing from ethanol, the m.p. was 93°, lit. (23) m.p. 92–93°. Infrared spectrum (KBr disc): 1 725 (s) (C=O); 1 560 (s), 1 330 (s), 850 (m) (NO_2) cm^{-1}.

Reduction of Methyl 2-(o-Nitrophenylthio)benzoate

Method (a)

Methyl 2-(*o*-nitrophenylthio)benzoate (1.1 g) in dioxane (15 ml) was reduced by the general method described for the preparation of cyclic hydroxamic acids, except that the solution of the benzoate was added over a longer period (1 h) to the sodium borohydride (0.4 g) and palladium–charcoal (0.05 g) in aqueous dioxane. The filtrate was acidified with dilute hydrochloric acid, concentrated, flooded with water, and finally

extracted with ether. The ether extract was shaken with 5% sodium hydroxide solution, shaken with water, dried, and then evaporated to give a yellow neutral oil (1.01 g). This oil solidified when triturated with methanol and yielded, after recrystallization from ethanol, yellow crystals (0.71 g), m.p. 148–149° of 2,2′-bis((*o*-methoxycarbonyl)phenylthio)azoxybenzene (VII). Infrared spectrum (KBr disc): 1 710 (s) (C=O), 1 474 (s), 1 270 (s) or 1 255 (s) (azoxy) cm^{-1} (determined on a Perkin-Elmer model 21 spectrophotometer).

Anal. Calcd. for $C_{28}H_{22}N_2O_5S_2$: C, 63.38; H, 4.18; N, 5.28; S, 12.09; mol. wt. 530.6. Found: C, 63.12; H, 4.24; N, 5.23; S, 12.16; mol. wt. 511.

Method (b)

The ester (2 g) dissolved in a mixture of ethanol:methanol (3:1) (40 ml) was reduced as described in the general method for the preparation of cyclic hydroxamic acids, except that dioxane was replaced with the mixed solvent. The acidified filtrate yielded a viscous orange neutral oil (1.3 g) when treated as described in the experiment immediately above. On standing, followed by trituration with ethanol, the azoxybenzene (VII) was isolated from this oil as orange crystals (0.19 g), m.p. 145–149°.

Method (c)

A solution of ammonium chloride (2 g) in water (20 ml) was added to a solution of methyl 2-(*o*-nitrophenylthio)benzoate (2 g) in ethanol (50 ml). The mixture was stirred, zinc dust (2 g) was added in small portions over 15 min, and stirring was continued for a further 2 h at room temperature. The colorless filtrate was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was shaken successively with 5% sodium carbonate solution and water, dried, and evaporated to give a neutral viscous red oil (1.62 g) which, on standing, gave a yellow solid (0.15 g), m.p. 145–148°; the infrared spectrum of this solid was superimposable on that of the product obtained by methods (*a*) and (*b*).

Anal. Found: C, 63.79; H, 3.87; N, 4.90; S, 11.60.

Methyl α-(o-Nitrophenylthio)propionate (IIu)

Bis(*o*-nitrophenyl) disulfide (30 g) was converted to sodium *o*-nitrothiophenolate using Claass' method (9). The resulting red solution was filtered, and to the filtrate was added a solution of α-chloropropionic acid (18.8 ml) and anhydrous sodium carbonate (12 g) in water (100 ml). The solution was heated for 2 h, cooled, acidified, and extracted with ether. Re-extraction of the ether layer with sodium carbonate solution, followed by acidification (dilute hydrochloric acid) of the aqueous layer gave α-(*o*-nitrophenylthio)propionic acid (III) (22.2 g) as a brown solid; m.p. 76–81°, raised to 106–108° on crystallization from aqueous ethanol. (Compare yield of III by alternative method of preparation—see Table II). Fischer–Speier esterification of the acid gave an almost quantitative yield of the ester (II*u*) as an orange oil which quickly solidified. On crystallization from methanol, a yellow solid, m.p. 54°, was obtained which was not analyzed before oxidation.

Methyl α-(o-Nitrophenylsulfonyl)propionate (IIt)

The sulfide (II*u*) (3.25 g) was dissolved in glacial acetic acid (50 ml). To this solution, a 5% aqueous solution of potassium permanganate (90 ml) was added in small quantities, with stirring, over 1 h; stirring was then continued for an additional hour. Hydrogen peroxide solution was added dropwise to decolorize the solution and the pale brown sulfone crystals which had separated during the reaction (3.09 g, m.p. 77–81°) were filtered off. Crystallization from ethanol gave white rods, m.p. 87–88°.

Anal. Calcd. for $C_{10}H_{11}NO_6S$: C, 43.95; H, 4.06; N, 5.13; S, 11.73. Found: C, 43.79; H, 3.88; N, 5.09; S, 11.68.

3,4-Dihydro-4-hydroxy-2-methyl-3-oxo-2H-1,4-benzothiazine-1,1-dioxide (Vt)

This hydroxamic acid was prepared by reducing methyl α-(*o*-nitrophenylsulfonyl)propionate with sodium borohydride and palladium–charcoal, using the general method previously described. The yield, m.p., and analytical data are recorded in Table I.

Attempted Reduction of Methyl (o-Nitrophenylthio)acetate with Hydrazine Hydrate and Palladium–Charcoal

The ester (prepared in excellent yield by Fischer–Speier esterification of the corresponding acid, ref. 8) (1.923 g) was dissolved in methanol (25 ml), and palladium–charcoal (0.1 g) was added followed by hydrazine hydrate (2 ml). The mixture was refluxed for ½ h, a further 2 ml of hydrazine hydrate were added, and refluxing was continued for another ½ h. The solution was filtered and the filtrate was evaporated to dryness giving a brown oil which was dissolved in hot methanol. On cooling, yellow crystals of (*o*-nitrophenylthio)-acetic acid hydrazide separated (0.625 g), m.p. 164°. Infrared spectrum (KBr disc): 1 646 (s) (C=O); 1 536 (s), 1 342 (s), 856 (m) (NO_2) cm^{-1} when determined on a Perkin-Elmer model 21 spectrophotometer.

Anal. Calcd. for $C_8H_9N_3O_3S$: C, 42.28; H, 3.99. Found: C, 42.08; H, 3.97.

Treatment of o-Nitrothiophenol with Diethyl Bromomalonate

A solution of *o*-nitrothiophenol (3.89 g) was prepared as before (see II*b*). On the addition of diethyl bromomalonate (4.3 ml) with stirring, an immediate precipitate of bis(*o*-nitrophenyl) disulfide (2.703 g, m.p. 196°) resulted. The infrared spectrum was identical with that of an authentic sample. The red colored filtrate was cooled overnight and a second product, diethyl bis(*o*-nitrophenylthio)malonate (IV), separated (0.591 g, m.p. 98–101°). Crystallization from methanol gave yellow needles, m.p. 101–102°; the infrared spectrum displayed the expected bands at 1 775 (C=O); 1 555, 1 355, 855 (NO_2) cm^{-1}.

Treatment of o-Nitrothiophenol with Diethyl Dibromomalonate

Using the method described in the preparation immediately above, *o*-nitrothiophenol (3.88 g) and diethyl dibromomalonate (3.975 g) gave the disulfide (III*a*, 3.526 g, m.p. 192–196°), and from the concentrated and cooled filtrate, diethyl bis(*o*-nitrophenylthio)malonate (0.165 g) precipitated, m.p. 94–97°, raised to 101–102° on crystallizing from methanol.

ACKNOWLEDGMENTS

We are indebted to Dr. R. A. Abramovitch of the Chemistry Department for helpful discussion and for his and Mr. B. A. Davis's permission to quote their unpublished findings. The technical assistance of Mr. D. Barton is also acknowledged, as is the generosity of the National Research Council of Canada whose financial assistance is greatly appreciated.

SALTING-IN BY QUATERNARY AMMONIUM SALTS

J. E. Desnoyers, G. E. Pelletier, and C. Jolicoeur
Département de Chimie, Université de Sherbrooke, Sherbrooke, Québec
Received July 2, 1965

ABSTRACT

The solubility of benzene in substituted quaternary ammonium bromide solutions has been measured by ultraviolet absorption. The solubility is found to increase in the presence of such salts as $R_{4-n}H_nN^+Br^-$ where R is an alkyl group and n varies between 0 and 3; a smooth transition in behavior is observed when passing from simple salts to long-chained micellar salts. This salting-in can be explained in terms of an association between the nonelectrolyte and the quaternary ammonium ion, which is induced by the increase in the structure of water near large nonpolar groups of the organic ions.

INTRODUCTION

Much interest has been shown recently in the physicochemical properties of tetraalkyl ammonium salt solutions. From the size and the symmetry of these large cations, very little primary hydration would be expected; this hypothesis was used by Robinson and Stokes (1) and by Nightingale (2) in attempts to correct Stokes radii in order to obtain radii of hydrated ions from mobility data. Also, since many of the limitations of the interionic theories do not apply in the case of these large ions, the dependance on concentration of their thermodynamic and electrochemical properties would also be expected to be normal. However, a close examination of these properties indicate numerous anomalies: the entropy of hydration (3), the partial molal heat capacities (4), the variation with concentration of the viscosity (5), osmotic coefficient (6), and partial molal volume (7) are all peculiar. Frank (3, 4) has offered an explanation for these unexpected behaviors in terms of an increase in the structure of water near these large ions. Water is known to be a largely associated liquid. The presence of nonelectrolytes or large organic ions tends to strengthen the hydrogen bonds between the water molecules near the large solute, and a cage or "iceberg" is effectively formed around them. Strong evidence for the correctness of this model was given by Jeffrey (8) when he succeeded in determining the structure of a clathrate hydrate of the salt $(Bu)_4NBr$ containing on the average 32.8 molecules of water.

Another property of these salts which requires further investigation is their ability to salt-in nonelectrolytes in water. While the presence of most salts tends to decrease the solubility of nonelectrolytes, tetraalkyl ammonium salts cause a significant increase in the solubility of nonelectrolytes (9, 10, 11).

The relation between the solubility of the nonelectrolyte and salt concentration can be expressed in two ways;

$$\ln (S_0/S) = k_{so}c \qquad [1a]$$

or

$$(S_0 - S)/S_0 = k_{so}'c \qquad [1b]$$

where S_0 and S are the solubilities of the nonelectrolyte in water and in the salt solution of concentration c. It can be shown by expansion of the logarithm into a power series that the two salting-out constants k_{so} and k_{so}', are identical at low concentration provided natural logarithms are used in [1*a*].

It has been shown recently (12) that salting-out arises from: (i) hydration of ions and (ii) the difference in polarization of the water and the nonelectrolyte molecules. Both these effects cause salting-out of nonpolar nonelectrolytes and cannot be responsible for the salting-in observed with large ions. A tentative explanation of salting-in was put forward by Bockris, Bowler-Reed, and Kitchener (10) in terms of van der Waals attractive forces between large ions and large nonelectrolytes. It will be shown later that these forces could be involved in salting-in but not in the sense implied by these authors, since salting-in occurs even with very small nonelectrolytes such as rare gases (13).

McDevit and Long (14) have derived a general theory based on the internal pressure concept where k_{so} is related to the extent of electrostriction of the salt in solution ($V_s - \bar{V}_s^0$) and to the partial molal volume of the nonelectrolyte, $\bar{V}_n$, by the relation,

$$[2] \qquad k_{so} = \frac{\bar{V}_n(V_s - \bar{V}_s^0)}{\beta_0 RT}$$

where V_s is the intrinsic or actual volume occupied by the salt in solution, $\bar{V}_s^0$ is the partial molal volume at infinite dilution, and β_0 is the compressibility of pure water. Deno and Spink (11) have shown that eq. [2] can account for the salting-in by quaternary ammonium salts since they find a negative electrostriction with these salts. They, however, offer no explanation as to the origin of this negative electrostriction. Both of these theories are therefore incomplete, and it was felt that more experimental data was required for a better understanding of the nature of this salting-in.

EXPERIMENTAL

In this work benzene was chosen as the nonelectrolyte because of the large amount of data already in existence in the literature on this system, and because of the ease of measurement of its solubility by ultraviolet absorption. The benzene used was purified by fractional distillation.

The five salts NH_4Br, $(Me)_4NBr$, $(Et)_4NBr$, $(n\text{-}Pr)_4NBr$, and $(n\text{-}Bu)_4NBr$ were purchased from Eastman Organic Chemicals and, with the exception of $(n\text{-}Bu)_4NBr$, were used without further purification. $(n\text{-}Bu)_4NBr$ was dissolved in CCl_4 and precipitated by addition of an excess of diethyl ether.

All other quaternary salts were prepared by bubbling pure HBr gas in a solution of the corresponding amine (Fisher's Highest Purity) in ethanol. When the salts produced were sufficiently pure, they were not recrystallized but thoroughly washed with diethyl ether. Otherwise they were dissolved in a minimum of ethanol and precipitated by addition of an excess of diethyl ether.

Solubility Measurements

The salt solutions were saturated with benzene at 25 °C by vigorously agitating these solutions for 20 h with an excess of benzene in a constant temperature bath (±0.1 °C) using an automatic shaker. After equilibrium had been reached, the agitation was stopped, and the saturated solutions were left in the bath for at least another 4 h to allow complete separation of the excess benzene and saturated solution. Aliquots (10 ml) of the saturated solutions were then transferred to 250 ml volumetric flasks containing approximately 225 ml of cold water (5 to 10 °C), care being taken to submerge the tip of the pipette under the surface of water during the delivery and maintaining minimum liquid surface exposure in all operations. These precautions were taken to prevent loss of benzene by evaporation during the dilution. The solutions were then warmed to 25 °C before completing the 1:25 dilution. Samples of these well-mixed dilute solutions were transferred to 50 mm stoppered cylindrical cells, and analyzed by ultraviolet absorption using a Perkin–Elmer Spectracord model 4,000. Check runs were also made on a Cary 14 Spectrometer. Water was used in the reference cell except with the larger quaternary salts where it was found necessary to use a salt solution of the same concentration as that containing the benzene. With the other salts absorption was negligible at the concentrations used.

The relative solubility of benzene in the salt solution and in water was obtained from the ratio of maximum absorption at 254 mμ. We have verified that the Beer–Lambert law holds at these low concentrations of benzene in water. The solubility of benzene in pure water was obtained by interpolation on a graph giving the absorbance of benzene as a function of the known concentration of the solutions. By this method, a value of 1.80 ± 0.02 g/l was obtained, which is in excellent agreement with the values obtained by other workers (15–19).

The salting-out of benzene by KCl and by NaCl was determined as a further check; the salting-out constants k_{so} obtained, 0.37 with KCl and 0.44 ± 0.01 with NaCl, agree within experimental error with the values of Saylor *et al.* (20), 0.38 and 0.45, and with those of Long and McDevit (9), 0.39 and 0.46.

RESULTS AND DISCUSSION

The salting-in results obtained are summarized in Table I, where the salting-in constant is defined as the negative salting-out constant.

$$k_{si} = \lim_{c \to 0} \frac{1}{c} \ln \frac{S}{S_0}$$

Each salting-in constant is based on an average of 8 to 12 solubility measurements in the concentration range 0.1 to 1.4 *M*. The values of k_{si} were compared with those of Deno and Spink (11) whenever possible, and good agreement was obtained.

TABLE I

Salting-in of benzene by quaternary ammonium bromides at 25 °C

Salt	k_{si} (l mole^{-1})	Salt	k_{si} (l mole^{-1})
NH_4Br	−0.115	*n*-$PrNH_3Br$	0.065
$(Me)_4NBr$	0.35 (0.35)*	*n*-$BuNH_3Br$	0.13
$(Et)_4NBr$	0.56 (0.58)	*n*-$PeNH_3Br$	0.20
$(n\text{-}Pr)_4NBr$	0.91 (0.94)	*n*-$HeNH_3Br$	0.27
$(n\text{-}Bu)_4NBr$	1.23	$(n\text{-}Pr)_2NH_2Br$	0.135
$(EtOH)_3NH\ Br$	0.25	$(n\text{-}Pr)_3NHBr$	0.50

*Values in parenthesis are those of Deno and Spink.

The dependance of salting-in on the number and size of the alkyl groups is shown in Fig. 1, where k_{si} is plotted as a function of the total number of carbon atoms in the different salts. With the symmetrical quaternary ammonium salts, the salting-in appears to be a linear function of the number of carbon atoms of the cations, while with the salts containing less than four alkyl groups, k_{si} depends also on the symmetry of the large ion. The difference between these two behaviors can be explained by the possibility of a certain amount of salting-out near the charge-bearing nitrogen atom when the large ions are not symmetrical. This would then indicate that the salting-in is caused principally by the organic part of the ion. Further evidence for this is given in Fig. 2 where $\ln(S/S_0)$ is plotted as a function of concentration of the RNH_3Br salts, and where the alkyl group R is varied in length. The limiting slopes are all regular and increase by about 0.07 l mole^{-1} for each additional methylene group (see Table I). However, while $\ln(S/S_0)$ increases linearly with concentration for the lower members of this homologous series, for the higher members, the solubility increases very rapidly with concentration. The same kind of behavior has also been observed by Durand (21) in his study of the solubility of benzene in carboxylic acid salts.

This abnormal dependance of solubility on concentration can be explained through micelle formation of these long-chain salts. The solubility of benzene inside a micelle is large (23), and the critical micelle concentration decreases with increasing length of the organic chain. On this basis, *n*-hexyl ammonium bromide probably forms a micellar complex with benzene at a concentration near 1 *M*. If the extreme case of salting-in, which is often called hydrotropism, can readily be understood through micelle formation, the normal salting-in could well be due to some similar effect since there is no sudden transition between these different cases of salting-in.

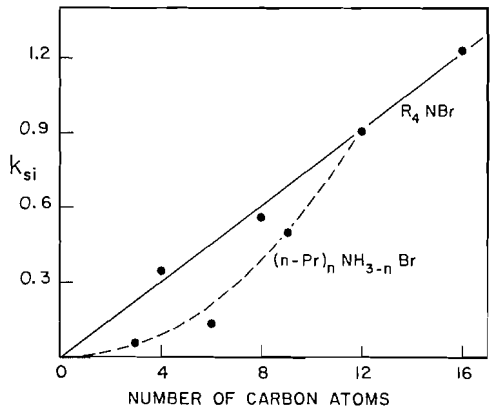

FIG. 1. Salting-in constants of benzene at 25 °C as a function of the number of carbon atoms in the quarternary ammonium bromides.

Diamond (6) has suggested that salting-in may be caused by the formation of an association complex between the large ion and the nonelectrolyte induced by the structure of water. The present work tends to confirm this explanation. In the Frank and Wen (4) model, liquid water consists of hydrogen-bonded ice-like clusters of H_2O molecules in equilibrium with non-hydrogen-bonded molecules. These clusters are unstable and melt by local energy fluctuation. Nemethy and Scheraga (22) have shown that such a model can account quantitatively for most of the physical properties of liquid water. The presence of a neutral molecule or the nonpolar part of a molecule protects the cluster from local attack, and consequently lengthens the average life of the clusters in the immediate vicinity of the neutral molecule. Therefore the presence of neutral molecules increases the ice-like structure of water. This corresponds to a decrease in entropy or increase in the free energy of water. In a system of tetraalkyl ammonium ions, benzene, and water, both the benzene and the large ion will tend to increase the water structure. The system will therefore tend to minimize the increase in free energy through association, the surface area of this association complex being smaller than that of the two particles separately. As the length of the organic chain increases the number of molecules forming the association complex probably increases, and at the limit, micelles containing benzene molecules in their center are formed. The solubility of a nonelectrolyte in water is limited to a large extent by the increase in structure of water. The presence of structure-inducing ions will therefore facilitate the dissolution of the neutral molecule since less work needs to be done by the nonelectrolyte against the structure of water.

The role of van der Waals forces in salting-in is now clearer. The structure of water forces two structure-enhancing particles to associate, and the strength of this association will depend to some extent on the van der Waals forces between the large ion and the nonelectrolyte. Therefore, as the size of either particle increases, both the structure of water and van der Waals interactions will increase, and the larger will be the salting-in. Specific interactions may also affect the strength of this association complex. For example, it is known that tetraethanol ammonium bromide has little influence on the structure of water (24). Similarly, triethanolamine hydrobromide should have little effect on water since the hydroxy groups can fit into the water structure. However, this salt also causes salting-in as seen from Table I. This behavior could possibly be explained by assuming

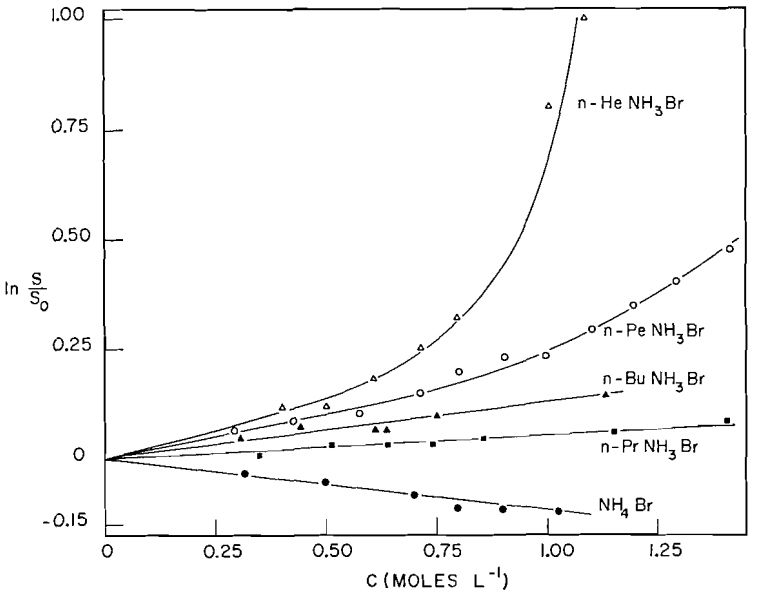

FIG. 2. Salting-in of benzene at 25 °C by monoalkyl quaternary ammonium bromides.

that an association complex is formed in this case as a result of specific interactions between the π bonds of benzene and the hydroxy groups of the salt.

The above explanation of salting-in, proposing association between the nonelectrolyte and the large ion due to the increase in the structure of water, can also account for the success of the McDevit and Long equation in predicting salting-in. Deno and Spink (11) found excellent agreement with the experimental salting-in or salting-out constants of benzene if the McDevit and Long relation, eq. [2], was multiplied by an empirical factor 0.3. On this basis, the negative electrostriction required to explain the observed salting-in of $(Bu)_4NBr$ would be 52.6 ml. Wen (25) and McMullan and Jeffrey (8) have found that this salt forms a polyhedral clathrate hydrate containing on the average 32.8 water molecules. From partial molal volume considerations, Wen and Saito (7) suggested that this same hydrate also exists on a time-average basis in solution. Since it is reasonable to assume that the volume of these large ions changes little upon dissolution (26), most of the electrostriction would result from changes in volume of water molecules surrounding the ions. The molar volume of water in a polyhedral cluster has been estimated by Nemethy and Scheraga (22) as 19.66 ml at 25 °C. The corresponding volume of ordinary water is 18.07 ml. Therefore the total electrostriction would be

$$\Delta V = n(v_w - v_{cl}) = 32.8(18.07 - 19.66) = 52.2 \text{ ml}$$

which is in excellent agreement with that estimated from salting-in data. Although the agreement between the negative electrostriction predicted from the increase in structure of water around the large ions and that obtained from salting-in is probably fortuitous to some extent, it can still be considered as supporting evidence for the dependance of salting-in on the increase in water structure near large ions.

CONCLUSION

The solubility of benzene in quaternary ammonium bromide solutions was studied systematically; the salting-in is shown to be a function of both the length of the alkyl chain and the number of alkyl groups on the nitrogen atom. These results indicate that the increase in structure of water in the vicinity of the large ions plays an important role in salting-in by promoting the formation of an association complex between the non-electrolyte and the organic ion as previously suggested by Diamond. This explanation can account for the partial success of the theories of Bockris, Bowler-Reed, and Kitchener and of McDevit and Long in predicting salting-in. It therefore appears that any successful theory of salting-in will have to consider, at least implicitly, the influence of large ions on the structure of water.

IODINE-CATALYZED RECOMBINATION OF ATOMIC NITROGEN

ROBERT A. YOUNG

Stanford Research Institute, Menlo Park, California

Received April 2, 1965

ABSTRACT

Recent conclusions of Phillips on the excitation of I_2 by $N_2(A^3\Sigma_u^+)$ formed as a product of iodine-catalyzed atomic nitrogen recombination are criticized. Spectroscopic experiments are performed which indicate that $[N_2(A^3\Sigma_u^+)] < 10^9$ molecules/cm^3 which is $\approx 10^{-5}$ of that implied by Phillips.

INTRODUCTION

Recently measurements of the decay of I_2 radiation excited by active nitrogen were interpreted by Phillips (1) to yield the radiative lifetime of the $N_2(A^3\Sigma_u^+)$ state. He supposes that

[1*a*] $$N + I_2 \rightarrow NI + N$$

[1*b*] $$NI + N \rightarrow N_2(A^3\Sigma_u^+) + I$$

produce $N_2(A^3\Sigma_u^+)$ and that

[2] $$N_2(A^3\Sigma_u^+) + I_2 \rightarrow N_2 + I_2^*$$

is followed by emission from I_2.

In this note we wish to point out errors in the interpretation of Phillips' data and present spectroscopic evidence that $N_2(A^3\Sigma_u^+)$ is much lower in the N, I_2 system than is consistent with Phillips' conclusions.

ANALYSIS

The differential equations determining the evolution of the N, I_2 system based on the assumption that only reactions [1*a*], [1*b*], and [2] are important and that [1*a*] controls the decay of [N], are

[3] $$\frac{d[N]}{dt} = -2k_1[N][I_2]$$

[4] $$\frac{d[N_2^*]}{dt} = k_1[N][I_2] - k_2[I_2][N_2^*]$$

[5] $$\frac{d[I_2^*]}{dt} = k_2[I_2][N_2^*] - \frac{1}{\tau}[I_2^*]$$

which have the following solutions:

[6] $$[N] = [N]_0 \exp -2k_1[I_2]t$$

[7] $$[N_2^*] = \frac{k_1}{k_2 - 2k_1}[N]_0 \exp -2k_1[I_2]t + \left([N_2^*]_0 - \frac{k_1[N]_0}{k_2 - 2k_1}\right) \exp -k_2[I_2]t$$

[8] $$[I_2^*] = \tau k_2[I_2][N_2^*]$$

where $1/\tau$ has been assumed so large that I_2 has reached a pseudo-steady-state with N_2^*, and that $[N_2^*]_0$ and $[N]_0$ are the initial concentrations of these species.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The data presented by Phillips for the exponential decay of the nitrogen 1st positive bands (his Table I—$d(\log_{10}I)/dt$) if plotted on his Fig. 3 coincide with the data representing the decay of I_2 emission for different amounts of I_2 added to discharged nitrogen. To convert this plot from $d(\log_{10}I)/dt$ to $k_1[I_2]$, the ordinate must be multiplied by $\log_{10} e = 2.3$ and divided by 2, since the intensity of the first positive bands of N_2 is proportional to $[N]^2$. These factors approximately cancel. Hence the rate at which I_2^* decays is essentially the same as the rate at which N decays and no measurement of k_2 has been made. There is also no evidence in Phillips' data to support the assumed reaction sequence although Rayleigh (2) did find that no compound of iodine and nitrogen was formed that could be collected in a liquid nitrogen trap. This old observation does strongly support the supposed general reaction sequence [1] and [2] without regard to the excited state of N_2.

If in eqs. [3], [4], and [5] k_1I_2 and k_2I_2 are replaced by $k_1I_2 + k_0$ and $k_2I_2 + k_0'$ where k_0 and k_0' represent a unimolecular loss of N and N_2^* then the exponentials in eqs. [6] and [7] become similarly modified. The observed values of k_0 from Fig. 3 of Phillips' paper are $\simeq 1\ s^{-1}$. If this is due to wall loss of N, then γ (the catalytic efficiency) is $\simeq 10^{-5}$ which is quite reasonable. Although no observed change in k_0 was found by Phillips when the surface to volume ratio was altered by $\simeq 2$ (by inserting a central glass rod in the flow stream) only a few measurements were made. If the added surface was less catalytic than the older tube walls, such an effect could occur.

In short, the data presented by Phillips do not indicate anything about the decay or the state of N_2^* formed in reaction [1*b*].

If process [2] is slow there should be an *increase* in the emission from I_2 with distance unless $[N_2^*]$ is large leaving the discharge. Dunford *et al.* (3) could not detect any emission from $N_2(A^3\Sigma_u^+)$ as pure nitrogen leaves the discharge, nor have we, with even more sensitive tests. Thus using the data in Phillips (4) earlier paper (with $[I_2]$ increased by 4 (1)), assuming $[N_2^*]_0$ is negligible, setting the first derivative of eq. [7] with respect to time to zero, and substituting $y = 2k_1/k_2$, one finds the condition for a maximum to be

$$y = \exp -k_2(1 - y)[I_2]t \text{ for } y \neq 1.$$

Upon substituting $t = 0.03$ s (the travel time from the discharge to the I_2 intensity max.) and $[I_2] \simeq 10^{14}/cm^3$ (the smallest value recorded by Phillips) one finds that $k_2 \simeq 10^{-13}$ cm^3/molecule s, using $k_1 = 3 \times 10^{-14}$ cm^3/molecule s (after correcting Phillips' calculation).

Because of the rapidity of process [2], N_2^* is probably in a pseudo-steady-state, i.e.,

$$[9] \qquad k_1[N][I_2] = k_2[I_2][N_2^*]$$

or

$$[10] \qquad [N_2^*] = k_1[N]/k_2 \simeq 0.3\,[N].$$

If $[N] \simeq 10^{15}$ cm^{-3}, $[N_2^*] \simeq 3 \times 10^{14}$ cm^{-3} and emission from the Vegard–Kaplan bands should be at least 10^{14} photons/cm^3 s which would be easily detectable.

EXPERIMENT AND RESULTS

A flow system composed of a 10 cm diameter × 100 cm long quartz observation tube (5) was set up and nitrogen discharged in a 10 mm quartz tube which flared into a 25 mm tube running parallel with the observation tube. The distance from the discharge to the observation tube including two right angle bends with light trap was $\simeq 1$ m (equivalent

to ≈ 0.5 s travel time). Prepurified nitrogen was discharged at ≈ 2 mm Hg and I_2 was added in an N_2 carrier from a trap-type saturator at 0 °C.

Two spectrographs were used to detect the Vegard–Kaplan bands ($A^3\Sigma_u^+ - X^1\Sigma_g^+$) of F 1.0 aperture but having dispersions (in the 2 500 to 3 000 Å region) of 44 Å/mm and 6 Å/mm. (The highest dispersion was obtained with a crossed grating echelle spectrograph having a concentric all reflective camera; the lower dispersion spectrograph used a 2 160 line/mm grating and a Muksutov camera with a LiF corrector lens.)

The strongest Vegard–Kaplan band (6) is the (0,5) at 2 603.8 Å where the overlapping I_2 continuum is weak. No structured band was observed at this location for $[I_2]$ concentrations from 4×10^{13} molecules/cm^3 to 4×10^{14} molecules/cm^3 and $[N] = 4 \times 10^{15}$ atoms/cm^3 with exposures of up to 1.2×10^3 min (20 h). Easily identifiable spectra of the NO bands (in particular the $\gamma(0,3)$ band with double heads at 2 595.7 Å and 2 587.5 Å (6)) were obtained in 1 min for $[N] = [O] = 2 \times 10^{15}$/cm^3. These bands are excited by atomic association

$$N + O + (M) \rightarrow NO + (M) + h\nu.$$

With previous measurements (7) of the rate coefficients of this reaction it was found that the emission rate of the $\gamma(0,3)$ band was 4×10^{11} photons/cm^3.

DISCUSSION

If reciprocity failure of the photographic emulsion (Kodak 103 a-O) did not occur, the (0,5) Vegard–Kaplan band emission rate must be less than 3×10^8 photons/cm^3 or, if the lifetime of this state is ≈ 1 s, the density of $N_2(A^3\Sigma_u^+)$ is less than 3×10^8 molecules/cm^3. Reciprocity effects increase this lower bound to $\approx 10^9$ molecules/cm^3. These results are incompatible with Phillips' analysis of his experiments and with our modifications to this analysis. This conclusion is consistent with Rayleigh's (8) early results.

THE PREPARATION OF L-LYXURONIC ACID, L-LYXOSE, AND 5-DEOXY-L-LYXOSE[1]

R. K. HULYALKAR[2] AND M. B. PERRY
Division of Biosciences, National Research Council, Ottawa, Canada

Received June 23, 1965

ABSTRACT

D-Galactono-1,4-lactone (I) was oxidized by 1 mole of periodate to give L-lyxuronic acid isolated as methyl L-lyxuronate (II). The methyl L-lyxuronate was converted into methyl (methyl α-L-lyxofuranosid)uronate (III) which on reduction by borohydride afforded methyl α-L-lyxofuranoside (IV) from which L-lyxose (V) was obtained by mild acid hydrolysis.

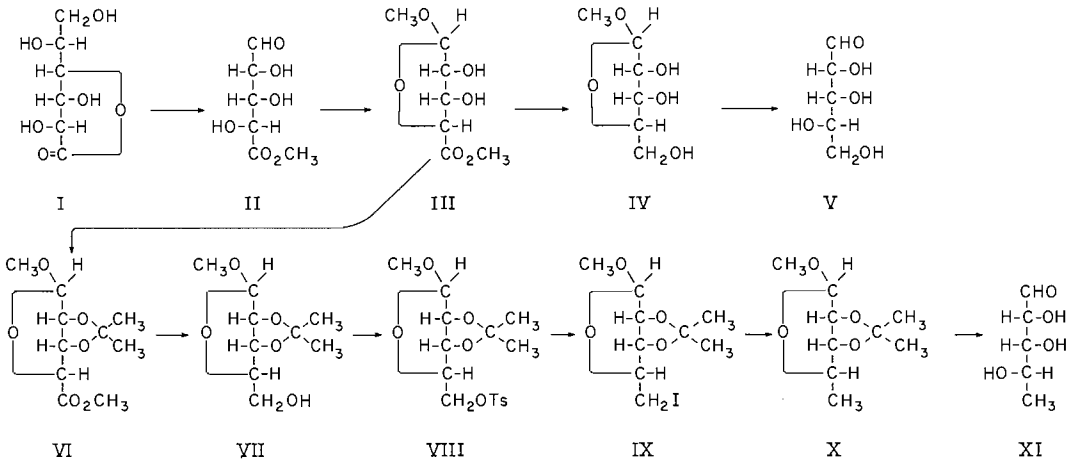
5-Deoxy-L-lyxose was prepared from the methyl (methyl α-L-lyxofuranosid)uronate (III) by the following sequence of reactions: (III) → methyl (methyl 2,3-*O*-isopropylidene-α-L-lyxofuranosid)uronate (VI) → methyl 2,3-*O*-isopropylidene-α-L-lyxofuranoside (VII) → methyl 2,3-*O*-isopropylidene-5-*O*-(*p*-tolylsulfonyl)-α-L-lyxofuranoside (VIII) → methyl 5-deoxy-5-iodo-2,3-*O*-isopropylidene-α-L-lyxofuranoside (IX) → methyl 5-deoxy-2,3-*O*-isopropylidene-α-L-lyxofuranoside (X) → 5-deoxy-L-lyxose (XI).

DISCUSSION

Glycol-cleaving reagents have proved particulary useful in synthetic carbohydrate chemistry for the preparation of sugars from both substituted and unsubstituted sugar precursors. Perlin (1, 2) has shown that lead tetraacetate is especially suitable for differentiating between various kinds of glycol groups and has successfully used the reagent for the synthesis of a wide variety of sugars using this selective property. Periodate is less specific in its glycol-cleaving properties than lead tetraacetate and, in general, its use in synthetic work (3) has been limited to its action on suitably protected carbohydrates in which the cleavage of the glycol systems can be predicted. Some exceptions are found in the selective oxidation with one molar portion of periodate of the exocyclic glycol systems (C_5—C_6) in methyl D-gluco- and D-galacto-furanosides to give methyl D-xylo- and L-arabino-furanosides respectively after reduction of the products (4) and similarly the cleavage of the exocyclic glycol system (C_6—C_7) of methyl D-*glycero*-D-*gulo*-heptopyranoside in the synthesis of D-gulose (5). In the present work the selective cleavage of the exocyclic glycol system (C_5—C_6) in D-galactono-1,4-lactone by 1 mole of periodate to yield L-lyxuronic acid has been used as the first step in the synthesis of the acid which was subsequently used in the synthesis of the rare sugars L-lyxose and 5-deoxy-L-lyxose.[3]

Trial experiments showed that D-galactono-1,4-lactone was oxidized by 1 mole of periodate with the release of 0.98 moles of formaldehyde indicating that the glycol cleavage occurred almost exclusively at the C_5—C_6 bond. An aqueous solution of D-galactono-1,4-lactone (I) was oxidized by the addition of one molar portion of periodic acid, and after removal of the inorganic ions, the resulting solution of L-lyxuronic acid was converted into crystalline methyl L-lyxuronate (II) by repeated evaporation with dry methanol. The methyl L-lyxuronate had equivalent weight, molecular weight, and elemental analysis in agreement with the theoretically expected values, and on borohydride reduction (6) it was converted into L-arabinitol. Treatment of the methyl L-lyxuronate

[1]*Issued as N.R.C. No. 8640.*
[2]*National Research Council Postdoctorate Fellow, 1963–1965.*
[3]*Dr. A. S. Perlin has independently studied the periodate oxidation of D-galactono-1,4-lactone and has prepared L-lyxuronic acid and related derivatives. The results of this work together with structural studies will be published by Dr. Perlin in due course.*



with 1 equiv of sodium hydroxide gave sodium L-lyxuronate. On borohydride reduction the sodium L-lyxuronate gave the expected L-arabonic acid which was identified by gas chromatography as its 2,3,5-tri-*O*-trimethylsilyl-aldono-1,4-lactone derivative (7). Removal of the sodium ions from the sodium L-lyxuronate by ion-exchange resin afforded L-lyxuronic acid as a syrup, which is probably a mixture of the free acid and its lactone.

Treatment of the methyl L-lyxuronate (II) with methanolic hydrogen chloride afforded crystalline methyl (methyl α-L-lyxofuranosid)uronate (III). Gas chromatographic analysis of the methanolysate indicated the presence of about 15% of the β-methyl glycoside; successive treatment with methanolic hydrogen chloride of the residues remaining after the removal of the crystalline α-anomer re-equilibrated the mixture and allowed increased yields of the methyl (methyl α-L-lyxofuranosid)uronate (total yield, 61%) to be obtained. Reduction of the methyl (methyl α-L-lyxofuranosid)uronate by sodium borohydride (6) in ethanol solution afforded crystalline methyl α-L-lyxofuranoside (IV). On mild acid hydrolysis compound IV gave crystalline α-L-lyxose (V), whose physical and chromatographic properties agreed with those recorded in the literature. The 2,4-dinitrophenylhydrazone and toluene-*p*-sulfonylhydrazone derivatives of the synthesized L-lyxose had melting points and infrared spectra identical with those of the corresponding derivatives prepared from authentic D-lyxose.

The above sequence of reactions, repeated without purification of the intermediates, showed that L-lyxose could be prepared from D-galactono-1,4-lactone in 87% overall yield.

5-Deoxy-L-lyxose was prepared in the following manner. On treatment with acetone in the presence of anhydrous copper sulfate catalyst, the methyl (methyl α-L-lyxofuranosid)uronate (III) afforded methyl (methyl 2,3-*O*-isopropylidene-α-L-lyxofuranosid)uronate (VI) which, on reduction with lithium aluminium hydride (8), was converted into methyl 2,3-*O*-isopropylidene-α-L-lyxofuranoside (VII). Treatment of this compound with *p*-toluenesulfonyl chloride in pyridine solution afforded crystalline methyl 2,3-*O*-isopropylidene-5-*O*-(*p*-tolylsulfonyl)-α-L-lyxofuranoside (VIII) which, on heating with sodium iodide in acetone solution, gave methyl 5-deoxy-5-iodo-2,3-*O*-isopropylidene-α-L-lyxofuranoside (IX). Reduction of IX with hydrogen in the presence of Raney nickel afforded methyl 5-deoxy-2,3-*O*-isopropylidene-α-L-lyxofuranoside (X) which on mild acid hydrolysis gave 5-deoxy-L-lyxose (XI). At all stages in the above sequence of reactions the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

purity of the products was established by gas chromatographic analysis of the compounds or their *O*-trimethylsilyl derivatives.

The 5-deoxy-L-lyxose, obtained as a syrup, had the physical and chromatographic properties expected from those recorded in the literature for 5-deoxy-D-lyxose (9). The *p*-bromophenylosazone and 2,5-dichlorophenylhydrazone derivatives of the 5-deoxy-L-lyxose were obtained in a crystalline form.

L-Lyxose is reported to occur in the hydrolysis products of yeast nucleic acid (10) and of curamycin, an antibiotic produced by *Streptomyces curacoi* (11). L-Lyxose has been prepared from calcium L-galactonate using the Ruff degradation procedure (40% yield) (9, 12), and by the periodate oxidation of 2,3,4-tri-*O*-benzyl-D-galactitol prepared from allyl 6-*O*-allyl-2,3,4-tri-*O*-benzyl-α-D-galactopyranoside (13).

L-Lyxuronic acid has not been found in nature but D-lyxuronic acid is reported to be produced from D-glucose by *Acetobacter melanogenum* (14). 5-Deoxy-L-lyxose has not been found in nature but the related compounds 5-deoxy-3-*C*-formyl-L-lyxose (streptose) and 4-*O*-methyl-5,5-dimethyl-L-lyxose (noviose) are of considerable interest.

EXPERIMENTAL

Paper chromatography was performed by the descending method (15) on Whatman No. 1 filter paper using the following solvent systems: (A) butan-1-ol – acetic acid – water (4:1:5 v/v, top layer), and (B) pyridine – ethyl acetate – water (2:5:5 v/v, top layer). Detection of the sugars was made using the spray reagents: (*a*) 1% silver nitrate in acetone followed by 2% sodium hydroxide in ethanol (16), and (*b*) 2% *p*-anisidine hydrochloride in butan-1-ol (17). The rates of movement of the sugars on the chromatograms are quoted relative to D-galactose (R_{gal} = 1.0).

Gas–liquid chromatography was carried out using a Pye argon chromatograph fitted with an ionization detector (^{90}Sr 20 μcuries) and employing a straight glass column (120 × 0.5 cm. i.d.) packed with 10% (w/w) neopentylglycol sebacate polyester on 100–120 mesh acid washed Chromosorb W. The column was maintained at 170° and development was made with dry argon at a flow rate of 120 ml/min. Chloroform solutions of the sugars were analyzed directly or were converted to their *O*-trimethylsilyl derivatives by treatment with hexamethyldisilazane and trimethylchlorosilane in pyridine solution (18). The retention times of the compounds are quoted relative to methyl 2,3,4,6-tetra-*O*-methyl-α-D-glucoside (T_g = 1.00).

Melting points were determined on a hot stage and are corrected. Optical rotations were measured at 22°. Solutions were concentrated in a rotary evaporator under reduced pressure below 50°.

1. *Preparation of* L-*Lyxuronic Acid*

(*a*) *Methyl* L-*Lyxuronate*

A solution of D-galactono-1,4-lactone (89 g) in water (600 ml) was cooled to 5° and a solution of periodic acid (H_5IO_6, 114 g) in water (600 ml) was added dropwise with stirring over 1 h. After keeping the reaction mixture for a further 4 h at room temperature, barium acetate (64 g) in water (200 ml) was added and the insoluble precipitate of barium iodate was removed by filtration. The filtrate was passed down columns of Amberlite IR-120(H^+) and IR-45(OAc^-) ion-exchange resins and the eluate and washings were concentrated to a syrup (68 g, 96%). The product was evaporated to dryness with dry methanol (5 × 500 ml), and the resulting syrup was dissolved in methanol (50 ml) and kept overnight at 5°. The crude crystalline methyl L-lyxuronate (61 g) having m.p. 136–138° was collected and was found after two recrystallizations from methanol to have m.p. 140° and $[\alpha]_D$ −37.7° → −23° (*c*, 1.8 in water) and $[\alpha]_D$ −68° → −45° (*c*, 1.6 in methanol).

Anal. Found: C, 40.32; H, 5.54. $C_6H_{10}O_6$ requires C, 40.45; H, 5.66.

The trimethylsilyl derivative of the methyl L-lyxuronate on gas chromatographic analysis gave a single peak, T_g 1.440.

Methyl L-lyxuronate had a neutralization equivalent, determined by titration with 0.02 *N* sodium hydroxide, of 178 (calcd. equiv. wt. 178) and a molecular weight, determined by hypoiodite oxidation (19), of 176 (calcd. mol. wt. 178). Methyl L-lyxuronate (0.1 g) in water (5 ml) was reduced by the addition of sodium borohydride (58 mg) to give crystalline L-arabinitol (70 mg) having m.p. and mixed m.p. 103° and giving an acetate derivative which had the same gas chromatographic retention time as penta-*O*-acetyl-L-arabinitol (20).

(*b*) *Sodium* L-*Lyxuronate*

Methyl L-lyxuronate (1.78 g) in water (10 ml) was neutralized by the slow addition of *N* sodium hydroxide solution (10 ml); after 1 h ethanol (120 ml) was added to the stirred solution and the precipitated sodium L-lyxuronate (1.8 g) was collected. The product had $[\alpha]_D$ +8.1° (*c*, 3.5 in water).

Anal. Found: C, 32.8; H, 4.0. $C_5H_7O_6Na$ requires C, 32.3; H, 3.78.

Paper chromatographic examination of the sodium L-lyxuronate showed a single spot R_{gal} 0.93 (solvent A) which gave a yellow color with the *p*-anisidine hydrochloride spray. Sodium L-lyxuronate (10 mg) was reduced with sodium borohydride (6 mg) to give L-arabonic acid, which gave an *O*-trimethylsilyl derivative having the same gas chromatographic retention time as authentic 2,3,5-tri-*O*-trimethylsilyl-L-arabono-1,4-lactone (7).

(c) L-Lyxuronic Acid (and Lactone)

Sodium L-lyxuronate (0.93 g) in water (10 ml) was passed down a column of Amberlite IR-120(H^+) ion-exchange resin, and the eluate and washings were concentrated to a syrup (0.78 g) which was dried over phosphorus pentoxide under high vacuum for 3 d. Paper chromatographic examination of the product (solvent A) showed two spots having R_{gal} 0.92 (acid) and R_{gal} 1.61 (lactone) with considerable tailing between them. The preparation had $[\alpha]_D$ −10° (*c*, 2 in water).

Anal. Found: C, 34.8; H, 4.99. $C_5H_8O_6.\frac{1}{2}H_2O$ requires C, 34.7; H, 5.17.

2. Preparation of L-Lyxose

(a) Methyl (Methyl α-L-Lyxofuranosid)uronate

Methyl L-lyxuronate (53 g) was boiled under reflux for 1 h with 1% methanolic hydrogen chloride (1.5 l), and the cooled solution was neutralized with silver carbonate and filtered. After treatment with hydrogen sulfide and refiltration, the filtrate was concentrated to a syrup (58 g). The syrup was dissolved in chloroform and ether was added to incipient turbidity; on keeping at 5°, crystals of methyl (methyl α-L-lyxofuranosid)-uronate (16 g) were collected. The mother liquors were concentrated and again treated with methanolic hydrogen chloride and worked up as described above. The procedure was repeated twice to give a total yield of product of 35 g (61%), m.p. 85°, $[\alpha]_D$ −94° (*c*, 2 in methanol).

Anal. Found: C, 43.72; H, 6.30. $C_7H_{12}O_6$ requires C, 43.75; H, 6.29.

The trimethylsilyl derivative of methyl (methyl α-L-lyxofuranosid)uronate on gas chromatographic analysis gave a single peak, T_g 1.250. The trimethylsilylated product of the original methanolyzate gave two peaks having T_g 1.250 (85%) and T_g 1.781 (15%); the minor peak is probably the β-anomer.

(b) Methyl α-L-Lyxofuranoside

Methyl (methyl α-L-lyxofuranosid)uronate (30 g) in ethanol (400 ml) kept at 0° was reduced by the addition of sodium borohydride (12 g) in ethanol (150 ml). The mixture was kept at 0° for 5 h and then at room temperature for 60 h. The reaction mixture was treated with Amberlite IR-120(H^+) ion-exchange resin to destroy the excess of borohydride and remove sodium ions, and the filtered solution was then evaporated with dry methanol (6 × 250 ml) to remove boric acid. When the product was kept in the presence of a small quantity of methanol it gave crystals (22.8 g, 89%) which were collected after trituration with a chloroform–ether mixture. After recrystallization from ethyl acetate, the methyl α-L-lyxofuranoside had m.p. 93°, $[\alpha]_D$ −125° (*c*, 3 in water) and $[\alpha]_D$ −160° (*c*, 2 in methanol) (lit. $[\alpha]_D$ − 160° (methanol) and m.p. 93° (21)) and had an infrared spectrum identical with authentic methyl α-D-lyxofuranoside.

Anal. Calcd. $C_6H_{12}O_5$: C, 43.90; H, 7.37. Found: C, 43.70; H, 7.34.

Gas chromatographic analysis of the *O*-trimethylsilyl derivative of the methyl α-L-lyxofuranoside gave a single peak T_g 0.582 having the same retention time as the trimethysilyl derivative prepared from authentic methyl α-D-lyxofuranoside. When the methyl α-L-lyxofuranoside (0.1 g) was heated with 0.5 *N* sulfuric acid (10 ml) on a boiling water bath for 20 min, the optical rotation changed from $[\alpha]_D$ −123° to +12.4°.

Paper chromatographic examination of the methyl α-L-lyxofuranoside showed a single red spot with the *p*-anisidine hydrochloride spray having R_{gal} 3.18 (solvent A) and R_{gal} 4.40 (solvent B).

(c) L-Lyxose

Methyl α-L-lyxofuranoside (10 g) in 0.5 *N* sulfuric acid (100 ml) was heated on a boiling water bath for 25 min, and the cooled solution was neutralized ($BaCO_3$) and filtered. The filtrate was passed through small columns of Amberlite IR–120(H^+) and Duolite A4(OH^-) ion-exchange resins, and the eluate was concentrated to a syrup (9 g). The syrup was dissolved in hot ethanol (10 ml); on standing, crystals of α-L-lyxose (7.8 g) were obtained, m.p. 104° and $[\alpha]_D$ +13.9° (*c*, 3 in water, equilibrium value) (lit. m.p. 105° and $[\alpha]_D$ +13.5° (9, 12)).

Anal. Calcd. $C_5H_{10}O_5$: C, 40.00; H, 6.71. Found: C, 40.11; H, 6.64.

On paper chromatograms the L-lyxose gave a red spot with the *p*-anisidine hydrochloride spray having R_{gal} 1.57 (solvent A) and R_{gal} 2.06 (solvent B) corresponding in mobility with authentic D-lyxose. The trimethylsilyl derivative prepared from the crystalline α-L-lyxose on gas chromatographic analysis gave a single peak with T_g 0.41, whereas the product prepared from a sample of the α-L-lyxose equilibrated in aqueous solution showed two peaks, T_g 0.41 and 0.58, which corresponded to the trimethylsilyl derivatives prepared from authentic samples of crystalline α-D-lyxopyranose and β-D-lyxopyranose respectively.

The α-L-lyxose gave a crystalline 2,4-dinitrophenylhydrazone derivative having m.p. 171–172° (lit. m.p. 171–172° for D-lyxose 2,4-dinitrophenylhydrazone (12)) and a toluene-*p*-sulfonylhydrazone derivative having m.p. 142° (lit. m.p. 141° for D-lyxose toluene-*p*-sulfonylhydrazone (22)). The infrared spectra of the two derivatives were identical with the corresponding derivatives of D-lyxose.

3. Preparation of 5-Deoxy-L-lyxose

(a) Methyl (Methyl 2,3-O-Isopropylidene-α-L-lyxofuranosid)uronate

Methyl (methyl α-L-lyxofuranosid)uronate (43 g) and anydrous copper sulfate (95 g) in acetone (800 ml) were boiled under reflux for 16 h. The filtered reaction mixture was concentrated to a syrup which was then extracted with hot light petroleum (b.p. 60–100°), and after concentration of the extract, the methyl (methyl 2,3-*O*-isopropylidene-α-L-lyxofuranosid)uronate (45 g, 87%) was obtained as a syrup. This syrup had $[\alpha]_D$ −47.6° (*c*, 5 in methanol) and $[\alpha]_D$ −2.6 (*c*, 2.6 in chloroform), and on gas chromatography it gave a single peak T_g 0.932.

Anal. Found: C, 51.78; H, 6.88. $C_{10}H_{16}O_6$ requires C, 51.72; H, 6.94.

A distilled sample of the product (bath temperature 130° at 0.4 mm) had the same physical properties as those given above.

(b) Methyl 2,3-O-Isopropylidene-α-L-lyxofuranoside

Methyl (methyl 2,3-*O*-isopropylidene-α-L-lyxofuranosid)uronate (30 g) in dry ether (375 ml) was added dropwise with stirring to a cooled mixture of lithium aluminium hydride (15 g) in ether (600 ml). On completion of the addition, the stirred reaction mixture was heated under reflux for 6 h, and the reduction was then allowed to proceed at room temperature for 16 h. Moist ethyl acetate (220 ml) was added dropwise to the stirred, cooled reaction mixture followed by water (200 ml). The ether layer was separated and combined with the ether washings of the precipitated material, dried (anhyd. Na_2SO_4), and filtered. The filtrate was then concentrated to a syrup (25.5 g, 96%); $[\alpha]_D$ −51° (*c*, 3 in chloroform); η_D^{22} 1.4506; g.l.c. single peak with T_g 0.832.

Anal. Found: C, 53.2; H, 8.1. $C_9H_{16}O_5$ requires C, 52.9; H, 7.9.

(c) Methyl 2,3-O-Isopropylidene-5-O-(p-tolylsulfonyl)-α-L-lyxofuranoside

Methyl 2,3-*O*-isopropylidene-α-L-lyxofuranoside (21.4 g) in dry pyridine (80 ml) was cooled to 0° and treated with *p*-toluenesulfonyl chloride (27.8 g), and after 2 h at ice-bath temperature the mixture was kept at room temperature for 15 h. The reaction mixture was poured onto crushed ice and after 30 min the crude crystalline methyl 2,3-*O*-isopropylidene-5-*O*-(*p*-tolylsulfonyl)-α-L-lyxofuranoside (34.8 g, 92%) m.p. 62–68°, was collected. After recrystallization from aqueous ethanol, the pure product (29 g) was found to have m.p. 76–77° and $[\alpha]_D$ −41.7° (*c*, 3.2 in methanol).

Anal. Found: C, 53.64; H, 6.15. $C_{16}H_{22}O_7S$ requires C, 53.63; H, 6.19.

(d) Methyl 5-Deoxy-5-iodo-2,3-O-isopropylidene-α-L-lyxofuranoside

Methyl 2,3-*O*-isopropylidene-5-*O*-(*p*-tolylsulfonyl)-α-L-lyxofuranoside (26.1 g) and sodium iodide (15 g) dissolved in dry acetone (180 ml) was heated in sealed glass tubes at 115° for 60 h. After cooling, the insoluble sodium *p*-toluenesulfonate was removed by filtration and the filtrate was concentrated to a syrup. The syrup was dissolved in chloroform (250 ml) and the solution was washed with water (2 × 100 ml), dried (anhydrous Na_2SO_4), and concentrated to a syrup (22.9 g, 100%). The product was distilled (80–85° at 0.05 mm) and the methyl 5-deoxy-5-iodo-2,3-*O*-isopropylidene-α-L-lyxofuranoside (21 g) was obtained as a colorless oil, $[\alpha]_D$ −70.4° (*c*, 2 in methanol), η_D^{22} 1.4975.

Anal. Found: C, 34.33; H, 4.69. $C_9H_{15}O_4I$ requires C, 34.4; H, 4.8.

On gas chromatography the product gave a single peak with T_g 1.07.

(e) Methyl 5-Deoxy-2,3-O-isopropylidene-α-L-lyxofuranoside

Methyl 5-deoxy-5-iodo-2,3-*O*-isopropylidene-α-L-lyxofuranoside (14 g) in methanol (200 ml) containing 2.2 *N* methanolic potassium hydroxide (23 ml) and Raney nickel (10 g) was shaken for 5 h at room temperature in a Parr low-pressure shaker-type catalytic apparatus under 50 lb pressure of hydrogen. The nickel catalyst was removed by centrifugation and the supernatant and methanol washings of the catalyst were concentrated to a syrup (6.88 g, 82%) which was distilled (50–55° at 0.05 mm) to yield methyl 5-deoxy-2,3-*O*-isopropylidene-α-L-lyxofuranoside (6.2 g) as a colorless oil. The product on gas chromatographic analysis gave a single peak with T_g 0.128 and had $[\alpha]_D$ −92.7° (*c*, 4.7 in methanol) and η_D^{22} 1.4280.

Anal. Found: C, 57.31; H, 8.50. $C_9H_{16}O_4$ requires C, 57.43; H, 8.57.

(f) 5-Deoxy-L-lyxose

Methyl 5-deoxy-2,3-*O*-isopropylidene-α-L-lyxofuranoside (6 g) was heated for 2 h on a boiling water bath with 0.5 *N* sulfuric acid (50 ml). After cooling, the mixture was neutralized ($BaCO_3$) and filtered. The filtrate was passed through a small column of mixed Amberlite IR-120(H^+) and IR-45(OH^-) ion exchange resins and was concentrated to a syrup (4.05 g, 95%). The 5-deoxy-L-lyxose had $[\alpha]_D$ −30.0° (*c*, 2.5 in water) (lit. $[\alpha]_D$ +32.4° for 5-deoxy-D-lyxose (23)).

Anal. Found: C, 44.54; H, 7.26. $C_5H_{10}O_4$ requires C, 44.77; H, 7.51.

Paper chromatographic examination of the 5-deoxy-L-lyxose showed a single spot R_{gal} 2.74 (solvent A) and R_{gal} 3.33 (solvent B). The trimethylsilyl derivative on gas chromatographic analysis showed two peaks T_g 0.226 (major) and T_g 0.286 (minor).

A portion of the 5-deoxy-L-lyxose (0.1 g) was converted into 5-deoxy-L-lyxose *p*-bromophenylosazone (0.11 g) which had m.p. 153–154° (lit. m.p. 143–144° for 5-deoxy-D-lyxose *p*-bromophenylosazone (23)).

Anal. Found: C, 43.35; H, 3.81; N, 11.7. $C_{17}H_{18}O_2N_4Br_2$ requires C, 43.43; H, 3.86; N, 11.92.

5-Deoxy-L-lyxose (0.22 g) in methanol (15 ml) containing 2,5-dichlorophenylhydrazine (0.28 g) was boiled under reflux for 2 h; the mixture was then concentrated to dryness and the residue was extracted with ethyl acetate. The extract was concentrated and the residue was taken up in hot ether–petroleum mixture (b.p. 40–60°). When this solution cooled, 5-deoxy-L-lyxose 2,5-dichlorophenylhydrazone crystallized, (0.15 g), m.p. 113–114°.

Anal. Found: C, 44.7; H, 4.6. $C_{11}H_{14}O_3N_2Cl_2$ requires C, 45.0; H, 4.8.

HIGHER HOMOLOGUES FROM PYRROLES AND DIPYRRYLMETHENES[1]

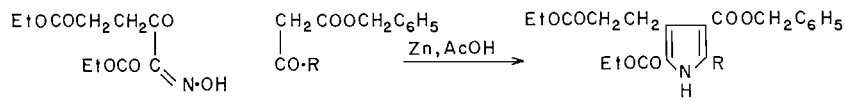
S. F. MacDonald and A. Markovac[2]
Division of Pure Chemistry, National Research Council, Ottawa, Canada
Received July 20, 1965

ABSTRACT

Higher alkyl derivatives were obtained from bromomethyl-pyrroles or -dipyrrylmethenes with the use of Grignard reagents.

INTRODUCTION

The synthesis of pyrro- and δ-phyllo-porphyrins related to the *Chlorobium* chlorophylls (1) required I*a* and its homologues, I*c* and I*d*. These were obtained conventionally as the need for them arose:



followed by

$$COOCH_2C_6H_5 \rightarrow COOH \rightarrow H \rightarrow CHO \rightarrow CH_3$$

The desirability of a general method for conversions such as that of I*a* into I*c* and I*d*, to obtain all three from common intermediates and avoid the use of propionyl- or butyryl-acetic esters, was clear in retrospect. A sequence of established reactions was available for this: 2-$CH_3 \rightarrow$ COOH $\rightarrow$ H $\rightarrow$ CO·R $\rightarrow$ CH_2R, and we have applied it to III*a* (see below). Modifications also reverse the β-substituents: 4-methyl-pyrrole-3-propionic acid (from II*a*), is acylated in the 5-position (2), and a general method follows from the conversion of III*a* into III (CHO for COOEt, R = COOEt) (1).

The well-known reactivity of bromomethyl-pyrroles suggested the shorter sequence now described: $CH_3 \rightarrow CH_2Br$ (+ RMgBr) $\rightarrow CH_2R$. The bromomethyl-pyrroles I*b*, II*b*, and III*b* reacted with methyl- or ethyl-magnesium iodide to form the homologues I (*c* or *d*), II (*c* or *d*), and III (*c* or *d*). By a standardized procedure yields of 55–70% were obtained. We have recorded the preparation of III*b* because, as noted by Fischer (3), earlier references (4) are to its hydrobromide. The less reactive pyrrole V did not react in the desired way, and 30% of it was recovered unchanged. The pyrrole IV*a* (5) (now prepared in double the reported yield) gave IV (*b*, *c*, *d*, and *e*) with the appropriate Grignard reagents. As expected, the pyrroles VI and VII did not react and were recovered in good yield.

Of these homologues, I*c* (1), I*d* (1), IV*b* (6), and IV*c* (5, 7) were known, and II*c* could be hydrolyzed to the known half-ester (free propionic acid) (6, 8). The structures of III*c* and III*d* were confirmed by comparison with the products of the alternative sequence mentioned above, III ($a \rightarrow e \rightarrow f \rightarrow$ (*g* or *h*) $\rightarrow$ (*c* or *d*)). As all these Grignard reactions had taken the expected course, the structures of the remaining products, II*d*, IV*d*, and IV*e*, could be inferred.

Two moles of Grignard reagent were required for 55–70% yields; with 1 mole the yield was less than 30% and the products were difficult to purify. Presumably the Grignard

reagent reacts also with the active hydrogen of the pyrrole. The formally analogous reaction of pyrryl magnesium bromides with III*b* required only 1.3 moles of the former for a >70% yield of dipyrrylmethane (3). Like the acylation of N-ethyl pyrryl magnesium bromide (9), the latter may be condensations rather than Grignard reactions, because pyrroles such as III*b* and even V readily undergo acid-catalyzed condensation with reactive pyrroles to dipyrrylmethanes (10).

Although dipyrrylmethenes without 5-hydroxy groups are amenable to few general reactions, their 5-bromomethyl derivatives, when these can be obtained, are very reactive. Thus the hydrobromides of the dipyrrylmethenes VIII*b* and IX*b* reacted with an excess of methyl magnesium iodide to give VIII*c* and IX*c* respectively, both of which were identified by comparison with the products of conventional syntheses. Nucleophiles, including Grignard reagents (11), frequently attack the bridge of negatively substituted dipyrrylmethenes. No such addition was observed here, and furthermore, VIII*a* and IX*a* were recovered as the free bases but otherwise unchanged after the same treatment.

EXPERIMENTAL

2-Bromomethyl-3-ethyl-4-methyl-5-carbethoxy-pyrrole (IIIb)

Bromine (8 ml) in 50 ml of carbon tetrachloride was slowly dropped into a stirred and water-cooled solution of 16 g of 2,4-dimethyl-3-ethyl-5-carbethoxy-pyrrole (III*a* (12)) in 100 ml of carbon tetrachloride. After 2 h, the yellow crystals of the hydrobromide (22 g, m.p. 128–134°; lit. (4):128–132°) were separated, washed with ether, and dried. This was treated by reflux with benzene (120 ml) until solution was complete and no more HBr was evolved. Colorless needles of the product (16.5 g, 73%, m.p. 144°) were separated from the cooled solution and washed with *n*-hexane.

For analysis it was recrystallized from benzene–*n*-hexane, m.p. 145°.

Calcd. for $C_{11}H_{16}NO_2Br$: C, 48.16; H, 5.87; N, 5.11; Br, 29.16. Found: C, 48.31; H, 5.78; N, 5.31; Br, 29.06.

2,3-Di-ethyl-4-methyl-5-carbethoxy-pyrrole (IIIc)

(a) General Procedure

2-Bromomethyl-3-ethyl-4-methyl-5-carbethoxy-pyrrole (III*b*, 3.4 g, 0.0125 mole) in 70 ml of dry tetrahydrofuran was added dropwise to the Grignard reagent from 0.65 g (0.027 g-atom) of magnesium, 3.54 g (0.025 mole) of methyl iodide and 100 ml of dry ether. The yellow suspension was stirred and heated under reflux for 4 h. Half of the solvent was removed *in vacuo* and ether (50 ml), then aqueous ammonium chloride, were added to the remainder. The aqueous layer was separated off and washed with ether. The combined ether layers were washed with water and dried (Na_2SO_4), and the ether was evaporated *in vacuo*. The crystalline residue was recrystallized from 70% ethanol, and yielded 1.8 g (69%) of colorless prisms, m.p. 68°.

The analytical sample was thrice recrystallized, m.p. 73–74°, which was unchanged when it was mixed with the product of (*b*) below.

Calcd. for $C_{12}H_{19}NO_2$: C, 68.86; H, 9.15; N, 6.69. Found: C, 68.98; H, 9.29; N, 6.83.

(b) The pyrrole III*a* was converted successively into III*e* (13), III*f* (14), and III*g* (8). This last was hydrogenated in ethanol with Raney nickel (1200 p.s.i., 120°, 40 h). The filtrate from the catalyst was concentrated and then cooled to give the crystalline product (90%), m.p. 72°.

The analytical sample was thrice recrystallized from 70% ethanol as colorless prisms, m.p. 73–74°. Found: C, 68.71; H, 9.13; N, 6.83.

2-n-Propyl-3-ethyl-4-methyl-5-carbethoxy-pyrrole (IIId)

(a) By the general procedure, III*b* and ethyl magnesium iodide gave an oily crude product which was distilled (170°, 1×10^{-4} mm). The distillate (58%, m.p. 77°) was recrystallized from 80% ethanol as long colorless prismatic rods, m.p. 82°, which was unchanged when it was mixed with the product of (*b*) below.

Calcd. for $C_{13}H_{21}NO_2$: C, 69.92; H, 9.48; N, 6.27. Found: C, 70.05; H, 9.58; N, 6.48.

(b) 2-Propionyl-3-ethyl-4-methyl-5-carbethoxy-pyrrole (III*h*, see below) was reduced in ethanol over Raney nickel (120°, 1200 p.s.i., 40 h). The filtrate from the catalyst was concentrated and cooled to give the colorless crystalline product (95%), m.p. 80°. When recrystallized from 80% ethanol it formed prismatic rods m.p. 82°.

2-Propionyl-3-ethyl-4-methyl-5-carbethoxy-pyrrole (IIIh)

The acylation of III*f* with propionyl chloride was analogous to that with acetyl chloride (8). A colorless product (57%), m.p. 78°, was obtained by recrystallizing the crude material from petroleum ether (30–60°).

The analytical sample was thrice recrystallized from petroleum ether as prismatic rods, m.p. 80°.

Calcd. for $C_{13}H_{19}NO_3$: C, 65.80; H, 8.07; N, 5.90. Found: C, 65.80; H, 8.08; N, 5.72.

2-Ethyl-3-methyl-5-carboxy-pyrrole-4-propionic Acid Di-ethyl Ester (Ic)

The oily crude product of the above general Grignard procedure applied to I*b* (15) and methyl magnesium iodide was distilled (140–150°, 1×10^{-4} mm), after which it solidified as colorless crystals (65%), m.p. 76°.

The analytical sample was recrystallized four times from 60% ethanol as colorless needles, m.p. 79–80°, which was undepressed by authentic material of m.p. 81–82° (1).

Calcd. for $C_{15}H_{23}NO_4$: C, 64.03, H, 8.24; N, 4.98. Found: C, 63.91; H, 8.42; N, 5.10.

2-n-Propyl-3-methyl-5-carboxy-pyrrole-4-propionic Acid Di-ethyl Ester (Id)

A reaction between ethyl magnesium iodide and I*b* was carried out in the same way, and the oily crude product was distilled (1×10^{-4} mm). For analysis it (57%, m.p. 74°) was recrystallized four times from 60% ethanol as colorless needles, m.p. 77–78°, which was undepressed when it was mixed with authentic material of m.p. 77–79° (1).

Calcd. for $C_{16}H_{25}NO_4$: C, 65.06; H, 8.53; N, 4.74. Found: C, 65.13; H, 8.69; N, 4.77.

2-Ethyl-4-methyl-5-carboxy-pyrrole-3-propionic Acid Di-ethyl Ester (IIc)

Methyl magnesium iodide and II*b* (15) similarly gave an oily crude product, which was distilled (160–170°, 1×10^{-4} mm). For analysis the colorless distillate (60%, m.p. 49–50°) was thrice recrystallized from petrol (20–40°) as colorless prisms, m.p. 52°.

Calcd. for $C_{15}H_{23}NO_4$: C, 64.03; H, 8.24; N, 4.98. Found: C, 64.12; H, 8.21; N, 5.16.

2-Ethyl-4-methyl-5-carbethoxy-pyrrole-3-propionic Acid

The above di-ester was heated under reflux with 1 equivalent of potassium hydroxide in ethanol, and the solvent was then evaporated. The product was precipitated with acid from a solution of the residue in water, then recrystallized from benzene – petrol ether as colorless prisms, m.p. 140° (lit. (6): 138°).

Calcd. for $C_{13}H_{19}NO_4$: C, 61.64; H, 7.56; N, 5.53. Found: C, 61.54; H, 7.54; N, 5.70.

2-n-Propyl-4-methyl-5-carbethoxy-pyrrole-3-propionic Acid Di-ethyl Ester (IId)

The oily crude product from the reaction between II*b* and ethyl mganesium iodide was distilled (150°, 1×10^{-4} mm) and the product (56%, m.p. 57°) was recrystallized thrice from 80% ethanol as long colorless needles, m.p. 63–64°.

Calcd. for $C_{16}H_{25}NO_4$: C, 65.06; H, 8.53; N, 4.74. Found: C, 64.99; H, 8.57; N, 4.96.

2,4-Dimethyl-3-chloromethyl-5-carbethoxy-pyrrole (IVa) (5)

A slurry of paraformaldehyde (6 g) in 75 ml of acetic acid was cooled in ice and stirred while a rapid current of dry hydrogen chloride was passed through. A solution of 31 g of 2,4-dimethyl-5-carbethoxy-pyrrole in 200 ml of acetic acid was then dropped in over a period of 15 min. Passage of the gas stream was continued for 2 h. The mixture was poured into 1 liter of dry ether and refrigerated overnight. The crude product (30 g, m.p. 160° after washing with ether) was recrystallized from benzene as colorless needles (24 g, 60%), m.p. 164–165° (lit. (5): 164–166°).

2,4-Dimethyl-3-ethyl-5-carbethoxy-pyrrole (IVb)

The crude light yellow product of the reaction between IV*a* and methyl magnesium iodide was recrystallized from 95% ethanol as colorless crystals (72%), m.p. 90°. For analysis it was thrice recrystallized as colorless needles, m.p. 94° (lit. (6): 96°), which was unchanged when it was mixed with authentic material.

Calcd. for $C_{11}H_{17}NO_2$: C, 67.66; H, 8.78; N, 7.17. Found: C, 67.79; H, 8.96; N, 7.33.

2,4-Dimethyl-3-n-propyl-5-carbethoxy-pyrrole (IVc)

The crude product of the reaction between IV*a* and ethyl magnesium iodide was crystallized from 95% ethanol as colorless crystals (67%, m.p. 98°). For analysis it was thrice recrystallized as prisms, m.p. 97.5–98.5° (lit. (7): 98°).

Calcd. for $C_{12}H_{19}NO_2$: C, 68.86; H, 9.15; N, 6.69. Found: C, 68.57; H, 8.96; N, 6.81.

2,4-Dimethyl-3-n-hexyl-5-carbethoxy-pyrrole (IVd)

The oily crude product of the reaction between IV*a* and *n*-pentyl magnesium bromide was distilled (140–150°, 1×10^{-4} mm). The distillate solidified into colorless plates (70%), m.p. 59°. For analysis it was recrystallized thrice from 85% ethanol as colorless plates, m.p. 61–62°.

Calcd. for $C_{15}H_{25}NO_2$: C, 71.67; H, 10.03; N, 5.57. Found: C, 71.73; H, 10.13; N, 5.75.

2,4-Dimethyl-3-n-heptyl-5-carbethoxy-pyrrole (IVe)

The oily crude product of the reaction between IV*a* and *n*-hexyl magnesium bromide was distilled (140–150°, 1×10^{-4} mm). The crystalline distillate was recrystallized from 80% ethanol as colorless plates (61%), m.p. 52°. For analysis, it was thrice recrystallized, m.p. 54–55°.

Calcd. for $C_{16}H_{27}NO_2$: C, 72.41; H, 10.26; N,5.28. Found: C, 72.60; H, 10.41; N, 5.41.

2-Formyl-3-ethyl-4-methyl-5-bromo-pyrrole (16)

The corresponding 5-carboxy pyrrole (17) (1 g) was dissolved in 3 ml of acetic acid, a solution of bromine (0.3 ml) in acetic acid (1 ml) was added, and the mixture was heated for 1 h on a steam bath. The solvent was then removed *in vacuo* and the product extracted from the residue into hot petrol (40–60°), leaving the insoluble by-product. The petrol solution was washed with 5% ammonium hydroxide, then with water, and dried with sodium sulfate. The petrol was evaporated, and the residue was crystallized from petroleum ether as colorless prisms (0.4 g, 33%), m.p. 114–115° (lit. (16): 115°).

2,3-Di-ethyl-4-methyl-pyrrole (8)

The 5-carbethoxy derivative (III*c*, 1.5 g) was heated for 20 h at 180° with 10 ml of 15% sodium hydroxide in a Teflon lined screw-capped brass tube. After it was cooled, the product was extracted with ether and the solution was dried with potassium carbonate. The ether was evaporated, and the product distilled (110°, 15 mm) as a colorless oil (100 mg).

4,5,3'-Tri-ethyl-3,4'-dimethyl-5'-bromo-dipyrrylmethene Hydrobromide (VIIIc)

(a) The dipyrrylmethene hydrobromide (VIII*b*, 481 mg (3)), suspended in 80 ml of tetrahydrofuran, was dropped into a solution of Grignard reagent (4 moles, from 98 mg of magnesium, 567 mg of methyl iodide, and 50 ml of ether). The mixture was stirred under reflux for 2 h, then left for 2 h at 20°. Half the solvent was removed *in vacuo*, fresh ether was added, and the product was hydrolyzed with aqueous ammonium chloride. The ether layer and washings were washed with water, dried with sodium sulfate, and the solvent evaporated. The residue was treated by reflux with 3 ml of ethanol. An insoluble by-product separated out, after which the ethanol was evaporated. The residue was converted into the hydrobromide by dissolving it

For personal use only.

in 32% hydrogen bromide in acetic acid. The latter was evaporated, and a crystalline product was left which was recrystallized from ethanol–ether as brown prisms (200 mg, 48%), m.p. 185° (dec.). The X-ray powder photograph of this product and of that of (*b*) below were identical.

For analysis, it was recrystallized thrice from chloroform–ether as red–brown prisms, m.p. 204–205° (dec.).

Calcd. for $C_{17}H_{24}N_2Br_2$: C, 49.04; H, 5.81; N, 6.73; Br, 38.42. Found: C, 48.87; H, 5.63; N, 6.89; Br, 38.24.

The hydrobromide (50 mg) was dissolved in ethanol, a drop of 5% aqueous sodium hydroxide was added, and the solution was cooled. The free base which separated was recrystallized from ethanol as orange–brown prisms, melting point and mixed melting point with the free base prepared by method (*b*) below, 85°.

(b) 2-Formyl-3-ethyl-4-methyl-5-bromo-pyrrole (55 mg), 2,3-di-ethyl-4-methyl-pyrrole (35 mg), and 0.2 ml of acetic acid were well mixed in a small beaker cooled in an ice bath. Hydrobromic acid (0.2 ml of 48%) was added and the mixture stirred for about 30 min. The crystalline hydrobromide was separated out, washed with ether then with acetic acid, and recrystallized from ethanol–ether as red–brown prisms, m.p. 190° (dec.).

For analysis, it was thrice recrystallized from chloroform–ether as red–brown prisms, m.p. 202–203° dec.). Found: C, 49.13; H, 5.76; N, 6.91.

The free base was obtained as under (*a*) above as orange–brown prisms, m.p. 85–86°.

3,5,3′,5′-Tetramethyl-4,4′-di-ethyl-dipyrrylmethene Hydrobromide (IXa) (18)

As in analogous cases, the 5-carbethoxy derivative is now more easily available than 2,4-dimethyl-3-ethyl-pyrrole itself, and the dipyrrylmethene can be more conveniently prepared directly from the former (19) by a general method devised by Fischer (20).

The hydrobromide was converted to the free base, m.p. 150° (lit. (18): 151°), which was unchanged when it was mixed with authentic material.

3,3′-Dimethyl-4,4′-di-ethyl-5,5′-di-bromomethyl-dipyrrylmethene Hydrobromide (IXb) (21)

The dipyrrylmethene hydrobromide (IX*a*, 3.5 g) was dissolved in 60 ml of acetic acid with warming, 4.5 g of bromine was added, and the mixture was heated for 2 h on a steam bath. After it was cooled, the crystals were separated out, washed with acetic acid, then with ether, and recrystallized from chloroform–ether as red–brown prisms (4 g, 78%).

4,5,4′,5′-Tetra-ethyl-3,3′-dimethyl-dipyrrylmethene Hydrobromide (IXc)

(a) The di-bromomethyl dipyrrylmethene hydrobromide (IX*b*, 496 mg), suspended in 80 ml of tetrahydrofuran, was dropped into a solution of Grignard reagent (4 moles, from 96 mg of magnesium, 567 mg of methyl iodide, and 50 ml of ether). The mixture was stirred under reflux for 1 h, then left for 2 h at 20°. Half the solvent was removed *in vacuo*, 10 ml of cold water was added, and the mixture was stirred for 10 min. Chloroform (50 ml) and hydrobromic acid (10 ml of 10%) were added and the mixture was well shaken. The chloroform layer and washings were washed with water and dried with sodium sulfate. The chloroform was evaporated and the residue crystallized from acetic acid as brown–red rods (150 mg, 41%), m.p. 180–184°, (lit. 180° (dec.) (8); 190° (21)). After it was recrystallized again from acetic acid, this product, m.p. 186°, and that obtained as under (*b*) below gave identical X-ray powder photographs.

The hydrobromide (100 mg) was dissolved in 3 ml of ethanol, a drop of ammonium hydroxide was added, the mixture was cooled, and the free base separated. It was recrystallized from aqueous ethanol as orange–brown needles, m.p. 116° (lit. 116° (8)), which was undepressed when it was mixed with the base obtained as under (*b*) below.

Calcd. for $C_{19}H_{28}N_2$: C, 80.23; H, 9.92; N, 9.85. Found: C, 80.33; H, 10.03; N, 10.09.

(b) 2,3-Di-ethyl-4-methyl-5-carbethoxy-pyrrole (III*c*, 300 mg), 3 ml of 98% formic acid, and 2 ml of 48% hydrobromic acid were heated for 1 h on a steam bath. After the mixture had stood overnight at 20°, the product was separated out and recrystallized from acetic acid as prismatic crystals (180 mg, 88%), m.p. 185–186°.

The free base, obtained as under (*a*) above, was thrice recrystallized from 95% ethanol as orange–brown needles, m.p. 116–117°. Found: C, 80.01; H, 9.74; N, 10.03.

VIIIa and IXa with the Grignard Reagent

The chloroform-insoluble perbromide of VIII*a* was treated under reflux for 10 min with 9 parts of acetone, then the mixture was refrigerated. On the next day orange–red prisms of the hydrobromide, VIII*a* (98%), were separated off and washed with ether, m.p. 215–217° (dec.) (lit. (3): 215°).

The dipyrrylmethene hydrobromides VIII*a* and IX*a*, suspended in tetrahydrofuran, were added to ethereal methyl magnesium iodide (3 and 4 moles respectively), heated under reflux, and worked up as in the preparation of VIII*c* by method *a*. When the ethanol was removed and the residues crystallized from aqueous ethanol, the starting methenes VIII*a* and IX*a* were obtained as the corresponding free bases.

The free base from VIII*a* (75%) had a melting point and mixed melting point with authentic material of 102° (lit. 103° (3)).

Calcd. for $C_{16}H_{21}N_2Br$: Br, 24.90. Found: Br, 25.02.

The free base from IX*a* (60%) had m.p. 152°, 151° when mixed with authentic material (lit. 151° (18)).

DIFFUSENESS IN ELECTRONIC SPECTRA

THE VAPOR SPECTRUM OF ANTHRACENE

J. P. Byrne and I. G. Ross
Chemistry Department, University of Sydney, Sydney, Australia

Received May 12, 1965

ABSTRACT

Approximate calculations of the number of rovibronic transitions per unit wavenumber are given for benzene, naphthalene, anthracene, and tetracene. Primarily because of the density of sequence structure all transitions in tetracene vapor should be irresolvably crowded, and hence apparently diffuse, at practical temperatures. Anthracene, whose spectrum has hitherto been described as wholly diffuse, is predicted to be capable of showing resolvable structure at room temperature. At 60 °C and 40 m path a short region of fine sharp structure has been observed. The origin of the first singlet transition is located at 27 688.3 cm^{-1} (27 757.6 cm^{-1} in anthracene-d_{10}).

INTRODUCTION

Congestion as a Cause of Spectral Diffuseness

The spectra of polyatomic molecules, when studied in the vapor phase under high resolution, are only occasionally found to be sharp and detailed. Most transitions are relatively or wholly diffuse. The reasons for this are not always clear. Predissociation is a recognized cause but implies a photolability which is commonly not observed. A second possible cause is a sufficiently strong interaction between the low vibronic levels of one electronic state with a quasi-continuum of high vibronic levels of a state below (1, 2); this interaction may be connected with radiationless transitions (3)—a point we are trying to establish. A third cause of diffuseness is sheer congestion: the rovibronic transitions may be too numerous to be resolved. This last is obvious, but to our knowledge has not been discussed quantitatively.

SPECTRAL CONGESTION

Table I presents the results of some simple approximate calculations of the density of spectral lines in a series of aromatic hydrocarbons.

TABLE I

Spectral congestion in the electronic spectra of some aromatic molecules (300 °K)

	Benzene	Naphthalene*	Anthracene	Tetracene

*Predictions for the isomeric molecule azulene are closely similar.
†Calculated assuming that all levels with given J are degenerate and located at the center of gravity, e.g., for prolate tops, at $(A + 2B)J(J + 1)/3$; that all such J levels with populations > 3% of the most populated level will give rise to observable lines, and that the number of observable P, Q, and R lines originating from each J level is $8J$. Moments of inertia are assumed to be the same in initial and final states.
‡Given as the number of totally symmetric frequencies plus the number of all other frequencies.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Individual rotational lines, it is clear, will be quite unobservable in any molecules of the series, though analyzable structure is sometimes seen if the inertial constants are such that the lines cluster in dense clumps (4).

Vibrational detail becomes more complex along the series for two reasons. First, increase in the number of totally symmetric modes causes a few long progressions (as in benzene (5)) to be replaced by a more elaborate, and generally more compressed, vibrational structure in which most bands are combination tones. But more important still is the proliferation of sequence structure. That is, associated with every vibronic band originating from the zero point level of the initial state are many others originating from vibrationally excited levels, which quanta are retained after the transition. In spectra observed at or near room temperature vibrational levels up to 800 cm^{-1} are observably populated (6, 7). Table I shows the number of such levels, calculated from assigned vibrational spectra (benzene (8), naphthalene (9), anthracene (10)) or roughly estimated (tetracene). The spread of the sequence structure has been calculated according to the pattern which appears in the best resolved transitions of benzene (5), naphthalene (6), and azulene (7), wherein there is one particularly long sequence due to a low-frequency out-of-plane mode whose frequency decreases drastically on excitation (1, 5, 6). Estimates for anthracene (subsequently confirmed: see below) and tetracene were obtained by extrapolation. It is, of course, not necessary that every transition in the one molecule should have the same spread of sequence structure; the estimates given are probably upper limits and therefore represent lower limits to the average interval between sequence bands.

All spectra become more congested as the temperature is raised; thus even the sharp 2 500 Å system of benzene is structureless at 500 °C (11). The limitations of vapor pressure, cited in the table (12), may make low temperature measurements difficult.

Spectral congestion is also caused by the presence of 1.1% of ^{13}C in natural carbon. The total percentages of molecules other than the pure ^{12}C species are included in Table I. In benzene the impurity is almost entirely a single species $^{12}C_5{}^{13}CH_6$; the expected consequence in the 2 500 Å transition is a weak sharp system slightly blue-shifted with respect to the principal spectrum. These bands have not yet been identified. In the larger hydrocarbons, the most likely consequence is a substantial unresolved contribution to the diffuse background.

From Table I it appears certain that tetracene vapor, even at room temperature, should show a spectrum crowded to the point of unresolvability. Benzene, naphthalene, and azulene are known each to have at least one sharp transition; individual vibrational features are well resolved, with rotational envelopes of characteristic profile. Indeed, azulene even shows a rich array of sharp features within the rotational envelope (13). Anthracene emerges as a marginal case. The figure quoted for the sequence spacing is an average; given a transition in which the bulk of the sequence structure is developed to one side of the origin, the intervals near the origin (the least crowded region) could be observable.

SPECTRUM OF ANTHRACENE

Platt (14) has correlated the lower excited states of conjugated acenes. In benzene and naphthalene the first two transitions, in order, are to states designated ^1L_b (weak sharp) and ^1L_a (stronger, diffuse). In anthracene the order of these states is reversed and ^1L_a is lowest. The diffuseness seen in the smaller molecules was offered as a diagnostic criterion for these ^1L_a bands, but there is no clear reason why diffuseness should be a general characteristic in the way that intensity is. The alternative point of view (1) suggests that the ability of a state to fluoresce is a surer guide to whether or not the corresponding absorption spectrum will be sharp.

For personal use only.

The first transition to ^1L_a in anthracene therefore assumes particular significance in this context, since anthracene fluoresces from the ^1L_a state with high efficiency. If then the temperature is low enough, and the ability to fluoresce (i.e., the absence of rapid radiationless transitions) is relevant, the absorption spectrum might be expected to show structure.

Previous measurements of the vapor spectrum have all been made at temperatures above 125 °C because the vapor pressure of anthracene is so low (Table I). Such spectra are diffuse (15). To search for the expected sharp structure we have now remeasured this spectrum, at a lower vapor temperature and at higher resolution.

RESULTS AND ANALYSIS

Using a multiple reflection cell, we find that the spectrum of anthracene can be measured at 60 °C (70 °C for the perdeuterated compound) at a path length of 40 m. With moderately high resolving power (about 100 000), this spectrum (Fig. 1) shows a short region of very sharp structure. This structured region coincides with the origin band of the solution spectrum. Another region with only hints of structure is found $\sim$ 380 cm^{-1} to the blue, this spacing being a progression interval (399 cm^{-1} in mixed crystals (16)). The rest of the spectrum is wholly diffuse.

The region with structure is a more crowded, but no less sharp, version of the kind of development seen in the 3 200 Å system of naphthalene (6) and the 3 500 Å system of azulene (1, 7). The region starts with a strong band at the high frequency end. This band is the most intense of the system, when background absorption, composed of accumulated rotational wings, is subtracted. This can only occur if the highest energy band of the system is the origin, and if the frequencies of all sequence-active vibrations are lower in the excited state than in the ground state. This is so in azulene also (7). Thus we identify the highest frequency band as the origin. Upon this origin is developed a closely packed sequence structure, initially with an average spacing of 2.5 cm^{-1}, but as the sequences progress and overlap and individual bands become weaker, the structure is no longer resolved. The known polarization (in plane, shorter axis) of this transition might be expected to produce double-headed bands as in similarly polarized transitions of naphthalene (6), but such doubling is not seen at all in perprotonated anthracene. In anthracene-d_{10} all the sequence bands except, probably, the origin occur in pairs spaced at 0.9 $\pm$ 0.2 cm^{-1}, but whether this is accidental or not cannot yet be decided.

Failure to see similar sequence structure in higher vibronic band groups could be due either to overlapping of progression members (there are 9 totally symmetric skeletal bending and stretching and CH in-plane bending vibrations, most of which are likely to be Franck–Condon active), or to mixing with the submerged ^1L_b transition which Pariser's calculations (17) place just above ^1L_a.

Table II lists the sequence members observed in anthracene and anthracene-d_{10}. The sequence interval 26.7 cm^{-1} in anthracene may well, on intensity grounds, be the expected large interval associated with the sensitive, low frequency, out-of-plane mode and which would be presumably responsible for the overall sequence length of $\sim$ 200 cm^{-1}. However, a detailed analysis of the sequence structure is not possible because of the large number of modes which are expected to be active.

DISCUSSION

The observation of structure in anthracene supports the general considerations of congestion, due to sequence structure, as a source of apparent spectral diffuseness. Another series of compounds in which the same considerations are clearly operative are the fluorobenzenes (18) wherein progressive substitution of fluorine for hydrogen systematically

lowers all vibrational frequencies. The hypothesis that rapid radiationless transitions may be associated with spectral diffuseness, though not yet conclusively demonstrated, is supported to the extent that this particular transition, leading to a radiative state, is now found to be intrinsically sharp.

The possibility of testing other apparently diffuse transitions in other molecules, by lowering the temperature to reduce the sequence structure, is obviously limited by vapor pressure considerations. However, noting that the spectrum of anthracene, as an impurity in naphthalene or phenanthrene, is also sharp (16) it now seems likely that such mixed crystal spectra may reliably indicate the intrinsic sharpness or diffuseness of electronic transitions in free molecules.

EXPERIMENTAL

The spectra were photographed in the 4th order of a Jarrell–Ash 3.4 m Ebert spectrograph using a 4½ in., 15 000 line/in. grating blazed for 4 000 Å in the first order. The dispersion was 1.15 Å/mm and the practical resolving power at the critical slit width was estimated at about 100 000. Exposure times with a 120 W xenon arc source and Kodak B4 plates were of the order of 4 h, during which time the temperature of the spectrograph was regulated to ±0.2 °C. Plates were microphotometered with a Joyce–Loebl Mark IIIC instrument. Because of the expected crowding and diffuse rotational background the contrast in the spectrum is not easily shown; at the available instrumental dispersion the microphotometer trace makes the features look less sharp than do the original photographs.

The multiple reflection cell was of glass, 2 m long, with brass end fittings connected by neoprene O-rings; the cell was enclosed in an oven for the high temperature measurements. Between fillings with the two anthracenes it was necessary to boil the end fittings in ether and to replace the O-rings.

THE RATIOS OF STEPWISE STABILITY CONSTANTS

III. THE RARE-EARTH α-HYDROXYMONOCARBOXYLATES

P. G. MANNING
Mines Branch, Department of Mines and Technical Surveys, Ottawa, Canada
Received February 2, 1965

ABSTRACT

The magnitudes of stepwise stability constant ratios indicate that the α-hydroxymonocarboxylic acids, in their association reactions with the rare-earth cations, function as monodentate ligands.

INTRODUCTION

The α-hydroxymonocarboxylic acids (e.g., glycolate, lactate, and α-hydroxyisobutyrate) are normally accepted as being bidentate ligands, since they are stronger acids than acetic and form more stable ion associates with metals. It was shown (1) that the rare-earth acetates are ion pairs in which the acetate ion binds electrostatically to the cation primary hydration sheath, and a direct comparison of the stabilities of the rare-earth acetates and α-hydroxymonocarboxylates offers no proof of bidentate character in these glycolate-type ligands.

The determination of the N-dentate nature of these ligands is of interest because they form 1:4 (rare earth:ligand) species (2–6), and the formation of such complexes is evidence in favor of the contention that rare-earth ions have coordination numbers of eight.

In the present paper, the ratios of stepwise stability constants for some lanthanide – α-hydroxymonocarboxylate complexes have been examined statistically.

DISCUSSION

The stepwise stability constant is defined as

$$b_n = [ML_n]/[ML_{n-1}][L],$$

where M and L are metal and ligand ions respectively. Let $P = b_1:b_2$. The P factor is composed of both statistical and ligand effects, and is a measure of the relative ease with which the first two ligands bind to the central cation (7).

Published data on rare-earth – monocarboxylate complexing are abundant, but, unfortunately, do not pertain to standard aqueous conditions. The range in ionic strength is 0.1–2.0, and in temperature 20–25 °C. The P values are largely unaffected by changes in temperature and ionic strength, since activity and dielectric effects cancel out when two stages of ion association are considered (1). The absolute magnitudes of the stability constants are not important in subsequent discussions.

Let us consider, initially, the factors that can influence the magnitude of P. Bjerrum (7) has shown that P is dependent on three factors, the statistical (S), the ligand repulsion (T), the rest (R) effects. The relationship between these factors is

$$P = S \times T \times R.$$

The statistical factor.—S can be estimated from the number of cation association sites and ligand bonding groups. The α-hydroxymonocarboxylates are potentially bidentate,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

while the number of cation association sites depends on whether the association species is an ion pair or a complex (1, 8). The magnitude of $S > 1$. For example, let us consider a simple monodentate ligand associating with a D-hydrated cation species. Then, if the ligand associates through the displacement of a single coordinated water molecule, it is evident that the first ligand to associate has D coordination sites from which to choose. A second ligand approaching the 1:1 (metal:ligand) species will then have $D - 1$ possible sites for coordination. Since there is twice the probability of a ligand departing from the 1:2 species as there is from the 1:1 species, then $S = 2 \times D/(D - 1)$, i.e., $S > 1$ (more correctly, $S > 2$). If we consider a bidentate ligand associating with a hexahydrated rare-earth ion (1), then the 1:3 species will be octahedral. The first ligand to associate can displace two bound water molecules in 12 different ways, the second can displace two water molecules in 5 ways, and the third in 1 way. Since the relative probabilities of a ligand leaving the 1:1 and 1:2 species is 1:2, then $S = 2 \times 12/5 = 4.8$.

The ligand repulsion effect.—A ligand that is about to associate with a 1:1 or 1:2 species will be repelled electrostatically by the bound ligands, since all ligands are charged or possess dipoles. Of necessity, $T > 1.0$.

The rest effect.—In a 1:2 association species, the two bound ligands will have an equal probability of escape from the cation. It is possible that on the escape of one ligand the remaining ligand in the 1:1 species will be held on more strongly to the cation, i.e. bound ligands can influence the binding power of the metal ion (7). In the case described, $R > 1.0$, but cases are known where $R < 1$. In the α-hydroxymonocarboxylate systems, the rest effect is likely to be small and $R \sim 1$ (7).

For carboxylic acids that associate electrostatically with the primary hydration sheath of a rare-earth ion, a plot of b_1 against Z (the atomic number) has a characteristic sinusoidal shape (5), the significance of which has been explained theoretically (1). Plots of b_1 against Z for the rare-earth α-hydroxymonocarboxylates differ considerably from the analogous acetate curves, indicating that the lanthanide α-hydroxymonocarboxylates are not ion pairs (9). Furthermore, pK values for the parent ligand acids increase in the order glycolate < lactate < α-hydroxyisobutyrate, and this is also the order of stability of the 1:1 metal associates (4, 9). The rare-earth α-hydroxymonocarboxylates are, therefore, complexes.

For complexing between a hexahydrated cation and a bidentate ligand, $S = 4.8$. The P values shown in Figs. 1 and 2 are smaller than 4.8, which suggests that this model is incorrect. Moreover, the T factor will inflate the calculated P value, and from chloride complexing with similarly sized cations (Hg^{2+}, Sn^{2+}) an approximate value of $T = 2.0$ (7).

For monodentate ligands displacing one water molecule from the cation hydration sheath, $S = 2 \times 6/5 = 2.40$. If $T = 1.5$, then the calculated P value is consistent with the experimentally derived P values (Figs. 1 and 2, refs. 2, 3, 5). It is possible that glycolate, for example, is bidentate in the first association stage and monodentate in the second, whence $S = 2 \times 12/4 = 6.0$. This P value is again too large.

If rare-earth ions are eight-hydrated (dodecahedral structure), then for a bidentate ligand $S = 2 \times 12/9 = 3.5$. This S value is in excellent agreement with the experimental P value if $T = 1.0$. If the ligands are monodentate $S = 2.3$ and $T = 1.6$. However, $T = 1.1$ for rare-earth acetate ion pairs. Since the average ligand separation is much greater in the acetate system than in the α-hydroxymonocarboxylate, T(acetate) < T(α-hydroxymonocarboxylate), and from simple Coulombic theory and T(acetate) = 1.1 then T(α-hydroxymonocarboxylate) = 1.3–1.4. This T value would favor a monodentate α-hydroxymonocarboxylate.

Accurate P values have been determined for cupric acetate and glycolate ion association (Tables I and II). Cupric and rare-earth ions are of similar size, and it would be expected that the average ligand separation in 1:2 rare-earth α-hydroxymonocarboxylate complexes and 1:2 cupric acetates and glycolates would be very similar, i.e., the T values would be approximately equal. The b_1 values for the transition metal acetates follow closely the Irving–Williams (15) rule, indicating the cupric acetates are complexes. The greater stability of the cupric glycolate associate relative to the acetate suggests that acetate is monodentate and glycolate bidentate. The cupric ion is six-hydrated, four waters being bound in a square plane and the other two perpendicular to the square plane, i.e., tetragonal configuration. In an analysis of the stepwise stability constants, therefore, the facility with which acetate and glycolate can displace the strongly and loosely bound waters must be considered.

In the cupric acetate system the P value = 13.6 may clearly be rejected (Table I). If we use Chauvenet's criterion of rejection (16) of doubtful data, then P = 6.7 may also be rejected with a 90% confidence limit. Therefore, with 90% confidence P(cupric acetate) = 4.7 ± 0.2. In Table III calculated S and T values for cupric acetates and glycolates and also for 4 and 6 available cation sites are given. Table IV presents the best T values for the rare-earth α-hydroxymonocarboxylates and cupric acetates and glycolates; clearly, for singly-charged ligands that bind to cations of the size of rare earths or Cu^{2+}, $T \sim 1.6$. These T values confirm that the α-hydroxymonocarboxylates associate with rare earths as monodentate ligands and also that a Jahn–Teller effect is operative in cupric acetate and glycolate systems (4 available coordination sites). In the cupric glycolate system, however, the ligand–ligand separation in the 1:2 species is greater than the average ligand separation in the corresponding rare-earth system. The difference in T values for the two systems would be expected to be ~ 0.1. This value is less, however, than the deviations quoted for the individual T values.

TABLE III

P, S, and T values for Cu^{2+} complexes

	Ligand			
	Acetate		Glycolate	
Available sites	6	4	6	4
P	4.7±0.2	4.7±0.2	12.0±2.5	12.0±2.5
S	2.40	2.67	4.8	8.0
T	1.95±0.1	1.75±0.1	2.5±0.5	1.5±0.3

TABLE IV

T values for metal complexes

System	Rare earth	Cu acetate	Cu glycolate
T	1.5±0.25	1.75±0.1	1.5±0.3

We may also calculate $P' = b_2{:}b_3$ for the cupric acetates. Thus $P' = 3/2 \times 3/2 \times 1.75 = 3.9$. The average experimental value is 4.3 (Table I).

Let us consider the mechanism of the reaction

$$M(OH_2)_6 + L = M(OH_2)_5L + H_2O.$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

The major cation species in solution is $M(OH_2)_6$, and concentrations of $M(OH_2)_5$ and $M(OH_2)_4$ are negligible (1, 17, 18). The metal–water bonds will make-and-break, and waters of the primary hydration sheath will exchange with other water molecules of the bulk medium or with ligands. While the (monodentate) α-hydroxymonocarboxylate is coordinated to the cation in the 1:1 complex, there is a probability that an adjacent water molecule will vacate its position in the primary hydration layer, and, because of the favorable orientation of the free OH group, chelation will occur. Therefore, the greater the pK value of the parent ligand acid the greater the time spent by the ligand coordinated to the metal and the greater its bidentate character. It would be expected from such a theory that P(α-hydroxyisobutyrate, pK = 3.76) > P(lactate, pK = 3.63) > P(glycolate, pK = 3.57). The data of Choppin and Chopoorian (4) indicate that P values for rare-earth complexing with three pertinent ligands are equal. Also, Sonesson's P values for the glycolates (2, 3) are of almost equal magnitude to those of Stagg and Powell for the α-hydroxyisobutyrates (5). The P values for the glycolates are also indicative of purely monodentate ligand bonding.

Since each monodentate ligand will have four adjacent water molecules in the 1:1 complex, it is clear that the α-hydroxymonocarboxylate ligand spends little time coordinated to the cation (relative to a water molecule). This suggests that the rare-earth hydration sheath is an extremely strong one. It was suggested, from an analysis of the acetate data (1), that the heavier rare-earth ions were hydrated through true coordination, and that water molecules were oriented beyond the first hydration layer so that the second layer acted as a cage preventing the escape of labile waters of the primary hydration sheath. The α-hydroxymonocarboxylate results would be in keeping with this hypothesis. There is infrared evidence that the water structure around La is highly ordered (19).

If the α-hydroxymonocarboxylates were bidentate ligands, then glyoxylic acid (dihydroxyacetic acid) should be a more powerful chelating agent than any of the three above-mentioned ligands, because of the greater number of possible binding groups (9). However, according to the present hypothesis, the stabilities of the rare-earth glyoxylates will depend on the pK value of the acid (pK = 3.17, ref. 9), and, in theory, the glyoxylates should be weaker complexes than glycolate, and P values should be approximately 4. The experimental results of Powell and Suzuki (9) confirm this.

This paper brings out an interesting point. Because pK(acetic acid) > pK(glycolic acid, e.g.) it would be expected that if glycolate bound directly to the cation then acetate would also do so. It is conceivable that in the rare-earth glycolate system the —COO group binds directly to the metal and that the —OH group binds to a neighboring water molecule of the cation hydration sheath, i.e., chelation occurs. This conclusion would be in agreement with that reached by Grenthe (20) on the basis of ΔH and ΔS data. On the basis of the number of water molecules of the rare-earth primary hydration sheath that are displaced, the α-hydroxymonocarboxylates are monodentate.

A recent study by Larsson and Folkeson (21) of the Zn–mandelate system shows that T = 1.5 and that mandelate is monodentate. These conclusions are similar to ours for the rare-earth α-hydroxymonocarboxylates.

We feel that we can justify the value of R = 1.0 used here. For the rare-earth acetates, by definition, R = 1.0 and T = 1.1. Using this latter T value, a T value = 1.3–1.4 was derived for α-hydroxymonocarboxylate complexing. Moreover, the T values listed in Table IV are largely independent of the cation and of the ligand. In the Cu systems, e.g., acetate and glycolate would be expected to give different R values. The T values in Table IV confirm that the R effect must be small.

CONCLUSION

The ratios of stepwise stability constants suggest that the α-hydroxymonocarboxylates are monodentate ligands in their reactions with rare-earth ions. The formation of 1:4 metal:ligand ion associates is not proof of eight-coordination in rare-earth complexes.

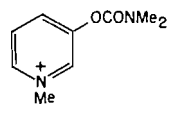
THE INTERACTION OF THE ACETATES AND CARBAMATES OF SOME HETEROCYCLIC ALCOHOLS WITH ACETYLCHOLINESTERASE[1]

K. B. SHAW
Defence Chemical, Biological and Radiation Laboratories, Ottawa, Canada
Received June 24, 1965

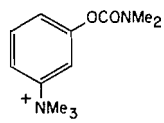
ABSTRACT

The *N,N*-dimethylcarbamates of 3-quinuclidinol, 1-methyl-3-piperidinol, and 1-methyl-4-piperidinol have been prepared and found to be weak inhibitors of acetylcholinesterase. The acetates of the above alcohols were also prepared and found to be moderately good substrates for this enzyme.

The elucidation of the structure (1) of the carbamate physostigmine (eserine), a potent anticholinesterase, led to a search for simpler analogues and a large number of alkyl- and dialkylcarbamates have been prepared and tested for anticholinesterase activity (2). Physostigmine contains a methylcarbamate group attached to an aromatic ring, and perhaps for this reason, the vast majority of the synthetic compounds also contain a carbamate group attached to an aromatic nucleus. An additional structural feature which seems to be necessary for high activity is another nitrogen atom (usually quaternized), which may be incorporated in the aromatic ring as in pyridostigmine (I), or directly attached to it as in neostigmine (II). Since there appears to be very little information in the literature concerning aliphatic carbamates (2), the anticholinesterase activities of the *N,N*-dimethylcarbamates of the saturated alcohols 3-quinuclidinol, 1-methyl-3-piperidinol, and 1-methyl-4-piperidinol have been assessed by measurement of their pI_{50}



I

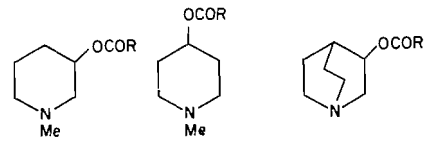


II

values on bovine acetylcholinesterase (the pI_{50} is the negative logarithm of the molar concentration of inhibitor which causes 50% inhibition of the enzyme activity in the system used). In addition, some experiments were performed to investigate the nature of the carbamate inhibition. The acetates of the above alcohols were also prepared and their effectiveness as substrates for acetylcholinesterase determined (by measurement of their Michaelis constants) to provide a comparison with the effectiveness of the carbamates as inhibitors of this enzyme.

1-Methyl-3-piperidyl *N,N*-dimethylcarbamate (III) was prepared from 1-methyl-3-piperidinol and dimethylcarbamyl chloride in pyridine solution (3) and this method proved satisfactory for the preparation of the corresponding 4-isomer (V). Both compounds discolored on storage and were further purified through their picrates, but V still turned slowly brown, even when stored in the freezer. Although some properties of 3-quinuclidinyl *N,N*-dimethylcarbamate (VII) (and its methiodide) have been discussed (4), its preparation does not appear to have been described in the literature. Repetition of the above reaction using 3-quinuclidinol gave a poor yield of impure carbamate and much

[1]*Issued as DCBRL Report No. 455B.*



III R = NMe_2 V R = NMe_2 VII R = NMe_2
IV R = Me VI R = Me VIII R = Me

starting material remained. Separation of the mixture proved to be difficult and after a number of experiments it was apparent that pyridine was not a suitable solvent for this reaction. The required carbamate was eventually obtained in good yield using 2 moles of 3-quinuclidinol and 1.15 moles of dimethylcarbamyl chloride in chloroform solution, either at reflux temperature for 3 h or preferably at room temperature for 20 h. The distilled product showed strong absorption in the infrared at about the expected frequency (1 700 cm^{-1}) for a carbamate carbonyl group (5) and also weaker carbonyl absorption at about 1 760 cm^{-1}, and was conveniently purified, leading to material showing only a single carbonyl peak (1 702 cm^{-1}) through the picrate. The compound absorbing at 1 760 cm^{-1} appeared, albeit in very small yield, in all preparations of the carbamate; the compound was not separable from the carbamate by distillation, although it was separated by chromatography on alumina; it showed two carbonyl peaks in the infrared at 1 760 and 1 705 cm^{-1}, the latter more intense, and the spectrum differed in other respects from that of VII. Titration with hydrochloric acid indicated a pK_a (in aqueous ethanol) very similar to that (8.5) of VII and an equivalent weight of 280, and nitrogen analysis indicated a molecular weight of 288 for three nitrogen atoms. A structure for this compound has not been deduced from the available data.

The acetates (IV, VI, VIII) were prepared from the appropriate alcohol and acetic anhydride (6). Like the corresponding carbamate, 1-methyl-4-acetoxypiperidine (VI) discolored at room temperature, but after two months its infrared spectrum had not changed significantly. Although all three acetates were sufficiently stable at the pH (7.4) at which the kinetic measurements were made, they were unstable in aqueous solution at pH 9–10 and gave erratic equivalent weights on titration with hydrochloric acid. For example VIII (equiv. wt. 169) on rapid titration in 0.1 *N* saline solution gave an apparent equivalent weight of 210 and after standing for 5 h in the same solvent, a value of 338. Satisfactory equivalent weights were obtained in acetonitrile solution.

The pI_{50} values (25°, 2 min incubation time) obtained for the three carbamates, together with the Michaelis constants (K_m) and the V_{max} values, relative to acetylcholine = 1.00, for the corresponding acetates are given in Table I. The acetates are moderately good substrates for acetylcholinesterase, (the K_m for the acetylcholine–acetylcholinesterase system is 4.5×10^{-4} *M* (7)) but the carbamates are poor inhibitors and the pI_{50}

TABLE I

Values of pI_{50} for the inhibitors ($ROCONMe_2$) as well as Michaelis constants and V_{max} (relative to acetylcholine = 1.00) for the substrates (ROCOMe)

R	$ROCONMe_2$ pI_{50}	ROCOMe K_m (*M*)	ROCOMe V_{max}
3-Quinuclidinyl	2.75	$2.52 \pm 0.4 \times 10^{-3}$	0.69
1-Methyl-3-piperidyl	2.51	$2.44 \pm 0.27 \times 10^{-3}$	0.59
1-Methyl-4-piperidyl	2.40	$1.59 \pm 0.27 \times 10^{-3}$	0.42

values are considerably lower than that of physostigmine sulfate, which under the same conditions was found to be 6.26. It has been shown (8) that the inhibition of acetylcholinesterase by carbamates leads to a carbamylated enzyme, but the inhibition produced by the carbamates in the present work is weak enough to suggest that the heterocyclic nitrogen atom and not the carbamate group is almost wholly responsible. Support for this argument was obtained when under the same conditions the pI_{50} of 1-methylpiperidine was found to be 2.50.

In contrast to the physostigmine analogues referred to above, the carbamates described here do not contain a quaternary nitrogen atom. However, since at pH 7.4 these tertiary amine carbamates are predominantly cationic (approximate pK_a values determined by titration in saline were found to be 8.7, 9.1, and 9.5 for III, V, and VII respectively), conversion to the methiodide would not be expected to increase the inhibition (9), hence their weakness as inhibitors cannot be due to this. An example of an aliphatic carbamate with anticholinesterase activity is dimethylcarbamyl choline, but it is less potent than I, and especially II (8). Since the stereochemistry of dimethylcarbamyl choline must be favorable for reaction with the enzyme, its comparatively weak inhibitory power is probably caused by the carbonyl carbon atom being less electrophilic than that in I or II. The carbamates described here also contain a similar weakly electrophilic carbon atom, and in addition their stereochemistry is less favorable than that of dimethylcarbamyl choline since the acetates are weaker substrates than acetylcholine; hence the weakness of the carbamates as inhibitors is perhaps not surprising.

A limited number of experiments was performed with the present carbamates to investigate whether the inhibition was competitive or non-competitive. The rate of hydrolysis of acetylcholine was measured in the absence and presence of carbamate and the results fitted to a Lineweaver and Burk plot (10). Although in every case both the slopes and $1/v$ intercepts of the lines for the uninhibited and inhibited reactions were different, implying non-competitive inhibition, extrapolation of the lines to the $1/S$ axis showed that the K_m of the reaction was changed in the presence of inhibitor, indicating that the inhibition was neither completely competitive nor non-competitive (11).

EXPERIMENTAL

3-Quinuclidinyl N,N-Dimethylcarbamate

Dimethylcarbamyl chloride (24.6 g, 0.23 mole) was added to a solution of 3-quinuclidinol (50.8 g, 0.4 mole) in dry chloroform (250 ml), and the mixture was stirred at room temperature for 20 h. The 3-quinuclidinol hydrochloride was filtered off and dried (32.7 g, 0.2 mole) and the chloroform solution was washed with water (2 × 50 ml) and dried ($MgSO_4$). After removal of the chloroform the product was distilled to give a colorless liquid (27 g, 68%), b.p. 64–67° at 0.003–0.005 mm, n_D^{25} 1.4859. The picrate was prepared from the carbamate (8.6 g) in 50% ethanol–acetone (v/v). After two crystallizations from the same solvent mixture, there were obtained 10.2 g (52%) of yellow prisms, m.p. 174–177°.

Anal. Found: C, 45.13; H, 5.05; N, 16.30. $C_{16}H_{21}N_5O_9$ requires C, 44.97; H, 4.95; N, 16.30.

The picrate (10.5 g) was dissolved in cold saturated lithium hydroxide solution (50 ml) and the solution was extracted with chloroform (5 × 25 ml). The combined extracts were washed with water (50 ml) and dried ($MgSO_4$), the solvent was removed, and the residue was distilled to give 3-quinuclidinyl *N,N*-dimethylcarbamate (2.89 g, 62%) b.p. 75–78° at 0.05 mm, n_D^{25} 1.4481.

Anal. Found: C, 60.72; H, 9.25; N, 14.08; equiv. wt. 201. $C_{10}H_{18}N_2O_2$ requires C, 60.58; H, 9.15; N, 14.13; equiv. wt. 198.

1-Methyl-3-piperidyl N,N-Dimethylcarbamate

The method of Biel *et al.* (3) was used and the product was further purified through the picrate. The picrate was prepared from the carbamate (11.8 g) in 50% ethanol–acetone (v/v) and after one crystallization was obtained as yellow prisms (18.15 g, 69%) m.p. 162–164° (unchanged on recrystallization).

Anal. Found: C, 43.61; H, 5.36; N, 16.88. $C_{15}H_{21}N_5O_9$ requires C, 43.37; H, 5.10; N, 16.86.

The picrate (11.8 g) was converted to the free base as above. The crude product was distilled to give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1-methyl-3-piperidyl *N,N*-dimethylcarbamate (6.75 g, 81%), b.p. 83–84° at 1.1 mm, n_D^{25} 1.4640 (lit. b.p. 101–103 at 3 mm (3)).

Anal. Found: C, 57.99; H, 9.94; N, 15.20; equiv. wt. 191. $C_9H_{18}N_2O_2$ requires C, 58.03; H, 9.74; N, 15.04; equiv. wt. 186.

1-Methyl-4-piperidyl N,N-Dimethylcarbamate

This compound was prepared (65%) from 1-methyl-4-piperidinol and dimethylcarbamyl chloride following Biel *et al.* (3) and was further purified through the picrate. The picrate was prepared from the carbamate (5.6 g) in 50% ethanol–acetone (v/v) and after one crystallization was obtained as yellow needles (7.7 g, 58%), m.p. 198–200°, raised to 201–203° after two recrystallizations.

Anal. Found: C, 43.63; H, 5.19; N, 16.66. $C_{15}H_{21}N_9O_9$ requires C, 43.37; H, 5.10; N, 16.86.

The picrate (7.7 g) was converted to the free base in the usual way. The crude product was distilled to give 1-methyl-4-piperidyl *N,N*-dimethylcarbamate (2.53 g, 73%), b.p. 52–53° at 0.05 mm, n_D^{25} 1.4637.

Anal. Found: C, 57.88; H, 9.67; N, 15.13; equiv. wt. 191. $C_9H_{18}N_2O_2$ requires C, 58.03; H, 9.74; N, 15.04; equiv. wt. 186.

3-Acetoxyquinuclidine

The method of Grob *et al.* (6) was used. The product had b.p. 81–83° at 2.2 mm, n_D^{25} 1.4770 (lit. b.p. 113–115 at 11 mm, n_D^{25} 1.4675 (6)).

Anal. Found: C, 63.56; H, 9.05; N, 8.08; equiv. wt. 175. $C_9H_{15}NO_2$ requires C, 63.88; H, 9.05; N, 8.08, equiv. wt. 169.

1-Methyl-3-acetoxypiperidine

This compound (12, 13) was made by the method of Grob *et al.* (6) from 1-methyl-3-piperidinol and acetic anhydride; b.p. 76–78° at 11 mm; n_D^{25} 1.4470; equiv. wt. 160, calcd. 157 (lit. b.p. 32–40° at 0.2 mm; n_D^{25} 1.4471 (13); b.p. 72° at 11 mm, n_D^{20} 1.4512 (12)).

1-Methyl-4-acetoxypiperidine

The reaction of 1-methyl-4-piperidinol and acetic anhydride, following Grob *et al.* (6) gave the required compound (60%), b.p. 77–79° at 11 mm, n_D^{25} 1.4480.

Anal. Found: C, 61.09; H, 9.71; N, 8.65; equiv. wt. 160. $C_8H_{15}NO_2$ requires C, 61.12; H, 9.62; N, 8.91; equiv. wt. 157.

After several crystallizations from ethanol–acetone, the picrate was obtained as pale yellow needles, m.p. 170–171°.

Anal. Found: C, 43.20; H, 4.65; N, 14.66. $C_{14}H_{18}N_4O_9$ requires C, 43.52; H, 4.70; N, 14.50.

Kinetics

Kinetic measurements were made with a Polarad automatic recording titrator, model AT-2A at pH 7.4 and 25 ± 0.1 °C. The enzyme used was bovine erythrocyte acetylcholinesterase obtained from Winthrop Laboratories, New York. A stock solution, prepared by dissolving in water (5 ml) the material contained in one vial (20 000 units), was suitably diluted as required. The solvent used was water, 0.15 *M* in sodium chloride and 0.04 *M* in magnesium chloride, and the titrant was 0.018 *M* sodium hydroxide.

Determination of Michaelis Constants (K_m)

The acetates, made up in dilute hydrochloric acid and then brought to pH 7.4, were used in the following concentration ranges: IV, 2.0–6.0 × 10^{-3} *M*; VI, 3.0–14.0 × 10^{-3} *M*; VIII, 1.0–10.0 × 10^{-3} *M*. Initial rates of hydrolysis (v) were measured at a number of substrate concentrations (S) using enough dilute enzyme solution to ensure hydrolysis rates of about 0.010–0.015 ml sodium hydroxide/min. The volume of the reaction mixture was 10.2–10.6 ml depending upon the volume of substrate solution used. The Michaelis constant was calculated from a Lineweaver and Burk (10) plot ($1/v$ vs. $1/S$) using the method of least squares to obtain the best line.

Determination of pI_{50} Values

The three carbamates and 1-methylpiperidine were made up in dilute hydrochloric acid, and physostigmine sulfate was made up in water; the solutions were then adjusted to pH 7.4. Concentration ranges for the various inhibitors were: III, 0.95–4.55 × 10^{-3} *M*; V, 1.50–5.30 × 10^{-3} *M*; VII, 0.90–4.0 × 10^{-3} *M*; 1-methylpiperidine, 1.70–6.75 × 10^{-3} *M*; physostigmine sulfate, 4.0–8.0 × 10^{-7} *M*. Acetylcholine bromide (initial concentration approximately 8.3 × 10^{-4} *M*) was used as substrate, and the initial rate of hydrolysis was measured using enough dilute enzyme solution to produce a sodium hydroxide uptake of about 0.05 ml/min. The initial rate of hydrolysis was then measured after incubating the enzyme for 2 min with different concentrations of inhibitor before addition of the substrate. Concentrations of inhibitor and substrate were corrected for the total volume of water in the cell (10–11 ml). Inhibitor concentrations were then plotted against sodium hydroxide uptake and the inhibitor concentration at one half the sodium hydroxide uptake for the uninhibited reaction was read off.

Nature of Carbamate Inhibition

The carbamates were made up in dilute hydrochloric acid as before and the following concentrations were used: III, 1.7 × 10^{-3} *M*; V, 4.3 × 10^{-3} *M*; VII, 1.6 × 10^{-3} *M*. The substrate was acetylcholine bromide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

which was used in the concentration range 2.0–10.0 $\times$ 10^{-4} M. Initial rates of hydrolysis were determined at a number of substrate concentrations, and then determined again after the enzyme had been incubated for 2 min with inhibitor. To determine the nature of the inhibition, $1/v$ was plotted against $1/S$ for both the inhibited and uninhibited reactions.

ACKNOWLEDGMENTS

Thanks are offered to Mr. J. Helie for the microanalyses, Mr. R. Miller for technical assistance, and the U.S. Army Chemical Research and Development Laboratories for a gift of the 3-quinuclidinol used in this work.

ARYLATION OF AROMATIC COMPOUNDS WITH BENZENEDIAZONIUM BOROFLUORIDE

NATURE OF THE ARYLATING SPECIES[1]

R. A. ABRAMOVITCH AND J. G. SAHA
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received May 19, 1965

ABSTRACT

The decomposition of benzenediazonium borofluoride in a number of aromatic solvents has been studied. The main product is fluorobenzene but some substituted biphenyls are formed. The isomer ratios and apparent total rate ratios for these phenylations have been determined. The results are discussed and it is suggested that the reactive intermediate in the arylations is the phenyl diradical cation.

A large body of evidence has been accumulated in support of an S_N1 mechanism for the heterolytic dissociation of diazonium salts, both in aqueous and non-aqueous media. This included kinetic studies indicating that the first-order rate constant is independent of the nature of the anion present (1) and of acidity over a wide range (2), and has very low solvent sensitivity (3). The formation of phenols in aqueous solution and of aryl chlorides in the presence of chloride ions are readily explained on the basis of the formation of aryl cations (4). Evidence has also been presented (4, 5) for the reversibility of the slow heterolysis of the C—N bond.

$$\mathrm{Ar}\text{-}\overset{\text{slow}}{\underset{}{\rightleftharpoons}}\ [\mathrm{Ar^+N_2}] \rightarrow \mathrm{Ar^+} + \mathrm{N_2}$$

$$\mathrm{Ar^+} + \mathrm{H_2O} \xrightarrow{\text{fast}} \mathrm{ArOH} + \mathrm{H^+}$$

$$\mathrm{Ar^+} + \mathrm{Cl^-} \xrightarrow{\text{fast}} \mathrm{ArCl}$$

The formation of onium salts, such as the diphenylbromonium ion from bromobenzene, can also be understood as a reaction of the aryl cation with the lone pair of electrons on bromine (5).

The aryl cation so produced is reported to be highly reactive and unselective (7). The decomposition of benzenediazonium borofluoride in various benzoate esters, in benzotrifluoride and in nitrobenzene, for example, was said to give mainly, if not exclusively, the meta-substituted biphenyls, a result taken to support the intermediacy of phenyl cations as the active species (in some cases a small amount of the para isomer was obtained but the ortho isomer was never isolated) (6). The latter observation would, however, point to a highly selective substituting species. In a preliminary communication (8) the uncatalyzed thermal decomposition of solid benzenediazonium borofluoride in toluene and in nitrobenzene was reported and it was shown that the attacking species was highly reactive *but positionally selective*. Some degree of selectivity was also indicated in the molecular rearrangement of the aryl cation from 1-(*o*-aminophenyl)-1-(substituted aryl)ethanols to give benzophenone derivatives, when a strongly electron-donating substituent in the migrating aryl group increased the yield of ketone appreciably (9).

[1]*The present paper is Part X of the series on aromatic substitution. For Part IX see Can. J. Chem. 43, 940 (1965).*

A systematic study has been undertaken of the thermal decomposition of solid benzenediazonium borofluoride in various aromatic solvents. We now report a quantitative study of the decomposition in toluene, bromobenzene, anisole, and nitrobenzene, including the isomer distributions obtained in these reactions and apparent total rate ratios relative to benzene (obtained from competitive runs).

The gas chromatogram of the reaction mixture obtained from the decomposition of benzenediazonium borofluoride in toluene gave, in addition to peaks corresponding to the isomeric methylbiphenyls, a peak whose retention time was different from those of the latter and from that of bibenzyl. This proved to be due to a mixture of the fluorobiphenyls (microanalysis, infrared, and direct comparison with authentic samples) which is not resolved into the three components under the conditions used. Fluorobiphenyls were also formed in the decomposition in bromobenzene and in anisole, but were absent when nitrobenzene was used as the substrate. (It should be noted that nitrobenzene is the only one of these solvents which dissolves the diazonium borofluoride.) No bibenzyl was detected in the reaction mixture from toluene. The main product formed in all cases (>90%) was fluorobenzene, the normal Schiemann reaction product.

EXPERIMENTAL

Reagents

AnalaR thiophene-free benzene was dried, distilled, and kept over sodium wire. Toluene, bromobenzene, anisole, nitrobenzene, and aniline were purified by standard procedures and had the boiling points reported in the literature.

Reference Compounds

The isomeric methylbiphenyls, bromobiphenyls, nitrobiphenyls, and bibenzyl were obtained from commercial sources and purified by distillation or crystallization; they had the boiling points or melting points reported in the literature. The three isomeric methoxybiphenyls were prepared from the appropriate diazotized anisidine and benzene by the Gomberg–Hey reaction. The products were purified by chromatography on alumina and elution with light petroleum (b.p. 40–60°), when the biaryls were obtained in the first 100 ml of eluent and the by-products remained adsorbed on the column. The chromatographed products were further purified by distillation or recrystallization, as appropriate. The three isomeric fluorobiphenyls were prepared by the thermal decomposition of the corresponding solid diazonium borofluoride (from the appropriate aminobiphenyl) and purified by column chromatography followed by distillation or crystallization. The purity of each of the reference compounds was checked by gas chromatography and only a single peak was observed for each of them.

Benzenediazonium borofluoride was prepared from repurified aniline following the general method described by Roe (10), taking special precautions to avoid the intrusion of metal contaminants. Only freshly prepared and well-dried samples of benzenediazonium borofluoride were used.

All the solvents were degassed by passing oxygen-free nitrogen through them before the addition of the diazonium borofluoride.

General Procedure for the Decomposition

A suspension of benzenediazonium borofluoride (1.6 g, 0.0083 mole) in an excess of the dry solvent was heated with vigorous stirring in a thermostat at 60 ± 0.1°. Stirring was continued for 8 h by which time the evolution of nitrogen and of boron trifluoride had ceased. The reaction mixture was distilled through a 30 cm long fractionating column packed with glass helices to remove most of the solvent and fluorobenzene. The residue (2–5 ml) was analyzed directly by gas chromatography.

Quantitative Analyses

The products formed in the phenylation reactions were resolved gas chromatographically and the compounds corresponding to the individual peaks were identified (i) by comparing their retention times with those of authentic samples, and (ii) by collecting each compound and comparing its infrared spectrum with that of the authentic sample.

The molar thermal response of each compound was determined by the internal standard method of Chang and Karr (11). In those cases where the molar thermal responses of the components of a reaction mixture were found to be identical, the areas of the peaks were taken to be proportional to the relative concentrations of the compounds representing them. Where the thermal responses were found to be different a known amount of the internal standard was introduced into the reaction mixture, and the actual amount of each component was calculated from the areas of the peaks and the weight of the internal standard. The yields of the various products were always determined by introducing the internal standard into the reaction mixture.

Phenylation of Toluene; Isomer Ratios

The benzenediazonium borofluoride:toluene molar ratio was 1:56. The reaction mixtures were best resolved on a 6 ft × 1/4 in. column packed with asphalt (15%) on Chromosorb W (60–80 mesh) operated at 166° and a helium inlet pressure of 40 p.s.i. Under these conditions, the retention times of the three fluorobiphenyls, 2-methylbiphenyl, biphenyl, 3-methylbiphenyl, and 4-methylbiphenyl were 10.2, 11.4, 13.6, 19.6, and 21.3 min, respectively. The compounds corresponding to the first peak, retention time 10.2 min, from the reaction mixture gave the following analytical results.

Anal. Calcd. for $C_{12}H_9F$: C, 83.70; H, 5.26. Found: C, 83.79; H, 5.28.

2-Bromobiphenyl, retention time 17.5 min, was used as the internal standard. No bibenzyl was detected in any of the reaction mixtures, nor was any biphenyl.

Using the above gas–liquid chromatography conditions bibenzyl and 4-methylbiphenyl had identical retention times. However, all three isomeric methylbiphenyls and bibenzyl were well resolved on a 20 ft × 1/4 in. column packed with SE-30 (0.5%) on glass beads, using a column temperature of 162°. Under these conditions 4-methylbiphenyl and bibenzyl had retention times of 41.25 and 46.0 min, respectively.

Phenylation of Bromobenzene; Isomer Ratios

The borofluoride:bromobenzene molar ratio used was 1:35. The analyses were carried out on a 10 ft × 1/4 in. column packed with Apiezon L (25%) on Chromosorb W (45–60 mesh) operated at 215° and a helium inlet pressure of 40 p.s.i. The retention times of fluorobiphenyls, biphenyl, 2-, 3-, and 4-bromobiphenyl were 11.0, 15.3, 31.0, 49.0, and 52.0 min, respectively. Bibenzyl (retention time 26.0 min) was used as the internal standard.

Phenylation of Anisole; Isomer Ratios

The reactions were carried out with a benzenediazonium borofluoride:anisole molar ratio of 1:30. The same column was used as in the bromobenzene runs but was operated at 230°. The retention times of fluorobiphenyls, biphenyl, 2-methoxybiphenyl, 3-methoxybiphenyl, and 4-methoxybiphenyl were 8.5, 13.5, 25.0, 37.0, and 42.0 min, respectively. Bibenzyl (retention time 22.0 min) was used as the internal standard.

Phenylation of Nitrobenzene; Isomer Ratios

The borofluoride:nitrobenzene ratio was 1:50. The reaction mixture turned dark brown immediately upon addition of the benzenediazonium borofluoride to the nitrobenzene and the solid went into solution, while a considerable amount of tar separated during the reaction, unlike what happened in the other three substrates. The concentrated reaction mixture was analyzed on a 5 ft × 1/4 in. column packed with GE-SF-96 silicone fluid (20%) on Gas-Chrom P (60–80 mesh), operated at 182° and a helium inlet pressure of 40 p.s.i. The retention times of biphenyl, 2-, 3-, and 4-nitrobiphenyls were 7.0, 17.0, 25.0, and 29.0 min, respectively. Bibenzyl (retention time 11.6 min) was used as the internal standard. No fluorobiphenyls could be detected in these reactions.

Competitive Reactions

These were carried out with benzenediazonium borofluoride; total substrate ratios of 1:100 to 1:150. Equimolar proportions of the competing aromatic substrates were used for the determination of the total rate ratios for bromobenzene, anisole, and nitrobenzene. Various proportions of toluene:benzene were used in the determination of ${}^{CH_3}_{H}K$.* The latter are summarized in Table V. The reaction mixtures were analyzed gas chromatographically using the same conditions as were used in the determination of the isomer ratios.

Estimation of Total Yields

The overall yields of the various reaction products were determined by gas chromatography using the same conditions as for the isomer ratio determinations, after a known weight of internal standard had been added to the reaction mixture before work-up. The yield of fluorobenzene was determined on a 6 ft × 1/4 in. column packed with asphalt (25%) on Chromosorb W (60–80 mesh) operated at 70° and a helium inlet pressure of 40 p.s.i. Fluorobenzene had a retention time of 7.5 min under these conditions. *n*-Heptane (retention time 10.0 min) was used as internal standard.

DISCUSSION

The relative abundances of the different products obtained in the decomposition of benzenediazonium borofluoride in three of the four substituted benzene derivatives are given in Table I. No fluorobiphenyls were formed with nitrobenzene, and the overall yield of nitrobiphenyls in this case was at most 5% but was not estimated accurately because of the large quantities of tarry materials that were formed.

Products arising from nuclear aromatic substitution account for only about 5% of the total, the main product being the normal Schiemann reaction product, fluorobenzene.

*${}^{X}_{H}K$ *is the ratio of the total rate of attack on* C_6H_5X *compared with the rate of attack on* C_6H_6 *(12).*

TABLE I

Relative yields of products from decomposition of $C_6H_5N_2^+BF_4^-$ in C_6H_5X

	Product (%)		
C_6H_5X	C_6H_5F	r-$C_6H_5C_6H_4F$	r-$C_6H_5C_6H_4X$
$C_6H_5CH_3$	94–95	0.5–0.8	4–5
C_6H_5Br	93–95	0.6–0.8	3–4
$C_6H_5OCH_3$	85–90	0.5–0.8	3–5

The phenyl cation formed can, apparently, react in one of three ways, namely: (i) it can combine with a fluoride ion ($BF_4^- \rightarrow BF_3 + F^-$) to give fluorobenzene; (ii) it can substitute the latter to give fluorobiphenyls; or (iii) it can attack the aromatic substrate to give the substituted biaryls. Reactions (i) and (ii) are most probably taking place within the solid matrix, while the reactive species must diffuse out of the solid matrix to take part in the third mode of reaction. Had the reactive phenyl cations and the fluoride ions diffused out of the solid matrix there would have been much less chance of their recombination (even taking into account relative nucleophilicities of the various substrates) since the aromatic substrate was present in such large excess (30- to 150-fold) and appreciably larger amounts of biaryls would have been formed. Some of the fluorobenzene remains "trapped" in the solid matrix and is attacked by the cationic species to form the fluorobiphenyls and hydrogen fluoride. If reaction (ii) had to occur in the main bulk of the solvent this would require fluorobenzene to be about 1 300 times as reactive as toluene towards the attacking species, which is to be compared with $k_{Cl^-/H_2O} = 2.5$ (7).

It may be seen from Table I that the three products isolated in these reactions account for almost 100% of the phenyl groups present in the benzenediazonium borofluoride used. If any triphenyls are formed, e.g. from the further phenylation of the fluorobiphenyls or of the biphenyls derived from the reactions with the solvent, these will constitute a very minor proportion of the total products and are not likely to have any appreciable significance on the validity of the isomer ratios observed here. If there were any selective removal of one or more of the isomers by triphenyl formation it would have to be taking place to a very small extent only. Thus, less than 0.05% of products would be expected to arise from the attack of the phenyl cations upon the three fluorobiphenyls (ratio of PhF to r-$C_6H_5C_6H_4F$ = 1:120 – 1:180). Similar, and even more powerful, arguments could be raised against the formation of appreciable quantities of triaryls from solvent-derived biaryls since the latter are formed and are present in the bulk of the solvent. In the event, no peaks were observed in the gas chromatograms of the reaction mixtures after the biaryls had appeared.

Table II summarizes the isomer ratios obtained in the phenylation, and compares them with those obtained in the homolytic phenylations when benzoyl peroxide was used as the source of phenyl radicals (12, 13). The salient feature of the data is the non-statistical isomer distribution in the present case together with the formation of an appreciable amount of the meta isomer with toluene, bromobenzene, and anisole and a predominance of the meta isomer with nitrobenzene. The reaction mixtures were analysed directly by gas–liquid chromatography after concentration and no attempt was made to isolate any bromonium salt that might have been formed with bromobenzene, since it would not be eluted from the column. Also, no onium salt formation was reported from a similar reaction with fluorobenzene (14). In the latter case no *m*-fluorobiphenyl was said to have been formed (14), whereas in our experiments the formation of this isomer was proved by

infrared spectroscopy on the mixture of isomers in those cases where this was formed. The isomer ratios obtained in the phenylation of toluene with benzenediazonium borofluoride are not out of line with those obtained, say, in the Friedel–Crafts alkylation of toluene under various conditions (15). The available data for the alkylation of bromobenzene and for some alkylations of toluene as well (15) indicate a much lower ortho/para ratio than is obtained here. No data are available on the isomer ratios obtained in the alkylation of anisole. Nitration, however, gives no meta isomer (16), but it must be appreciated that the nitronium ion is a much weaker electrophile, and hence a more selective one, than the alkyl cation. It should be pointed out, however, that even with very powerful and unselective electrophiles such as $NO_2^+AsF_6^-$ in tetramethylene sulphone or in nitromethane, toluene gives only a small amount (2–3%) of meta substitution product (17). Friedel–Crafts alkylation of nitrobenzene has not been achieved: in fact nitrobenzene may be used as a solvent in such reactions. Contrary to what was reported (6, 18), *m*-nitrobiphenyl is not the only isomer formed in the phenylation of nitrobenzene with benzenediazonium borofluoride, and appreciable amounts of *o*-nitrobiphenyl (but not of the para isomer) are formed ($F_o/F_m = 0.25$).* Such behavior is consistent with an electrophilic attack but not by a "classical" phenyl cation. This point is further emphasized later.

TABLE III

Total rate ratios for the substitution of C_6H_5X

Compound	${}^{C_6H_5X}_{C_6H_6}K$ for substitution using $C_6H_5N_2^+BF_4^-$	${}^{C_6H_5X}_{C_6H_6}K$ for substitution using Nitration (12)	${}^{C_6H_5X}_{C_6H_6}K$ for substitution using $(PhCO_2)_2$ (13, 19)
$C_6H_5CH_3$	0.72	23.0	1.23

The apparent reactivities of substituted benzenes towards the cationic species relative to that of benzene were examined next using the competitive technique. The total rate ratios thus found are given in Table III, which also includes the corresponding values for nitration (12) and homolytic phenylation using benzoyl peroxide (13, 19).

*F_r *is the partial rate factor for substitution at position r in a substituted benzene compared with a position in benzene itself.*

The partial rate factors (the meaningfulness of which will be discussed later), calculated from isomer and total rate ratios, are given in Table IV and compared with the data for nitration and homolytic phenylation.

In an earlier communication (8) the total rate ratio for the phenylation of toluene with benzenediazonium borofluoride was reported to be slightly greater than unity. This may be caused by differences in the experimental procedures used: in the earlier work nitrogen was passed through the reaction mixture while it was kept at 60° and this could well have led to some losses of benzene (which has a higher vapor pressure than toluene) and thus to higher values for ${}^{CH_3}_{H}K$. In the present work the benzene and toluene were first degassed separately and then introduced into the reaction flask, and no nitrogen was bubbled through the mixture during the reaction. The possibility of preferential solvation of the cationic species was examined by carrying out the competitive reactions using different proportions of the competing solvents. The results are presented in Table V from which it can be seen that a fourfold increase in the relative amount of toluene to benzene leaves the total rate ratio unchanged.

4:1	1:100	0.72

*Values of ${}^{CH_3}_{H}K$ calculated after taking into account the ratio of the concentrations of the competing solvents.

The results given in the second column of Table III confirm the relatively indiscriminate character of the reactive entity from the thermal decomposition of benzenediazonium borofluoride. The electrical effects of the bromo, methoxyl, and nitro substituents are evident, the first ($-I > +M$) and the third being electron-attracting and deactivating, and the second ($+M > -I$) being electron-donating. These effects are very small,

however, and it is noteworthy that the bromo and nitro substituents are about equally deactivating. The possibility of some complexing of the cation with the substituent prior to substitution cannot be eliminated at this stage, but this does not seem very likely, particularly when one looks at the isomer ratios obtained: a much higher proportion of ortho isomer might have perhaps resulted from an intramolecular rearrangement of a complexed species. Also, complexing with the substituent by an electrophilic species should have led to values of ${}^{X}_{H}K$ of greater than unity. Unfortunately, no firm statement can be made one way or the other at this stage in view of the heterogeneous character of three of the reactions. In any event, the reactivity of nitrobenzene is much higher than one would expect for an attack by a normal cationic species (I), even a highly reactive one. The results are very reminiscent of those obtained in free radical arylations, particularly with electrophilic radicals. For example, ${}^{NO_2}_{H}K$ in the *o*-nitrophenylation of nitrobenzene is 0.26, ${}^{Cl}_{H}K$ in the *o*-nitrophenylation of chlorobenzene is 0.83 (20). Also ${}^{benz}_{py}K$ for the *o*-nitrophenylation of pyridine was found to be 0.47 (21); interestingly, in this last case, the 3-substituted compound (corresponding to the *m*-isomer) is the main product formed ($F_\beta = 0.71$), as is 3-nitrobiphenyl in the present case (see Table II) (${}^{NO_2}F_m = 0.84$). The results for the phenylation of C_6H_5X (where X = Br, OCH_3, and NO_2) with benzenediazonium borofluoride are then consistent with an attack by a highly electrophilic free radical intermediate. This view is also consistent with the absence of bibenzyl in the products obtained in the phenylation of toluene by benzenediazonium borofluoride. Thus no bibenzyl was obtained in the homolytic phenylation of toluene with *p*-nitrophenyl radical whereas 12.0% of bibenzyl was obtained with the phenyl radical itself (34).

Formation of phenyl radicals according to

$$PhN_2^+BF_4^- \rightarrow Ph + N_2^+ + BF_4^-$$

under the conditions of the reactions can be eliminated as being energetically unlikely (22) and as not being in accord with the results. Expanding a proposal made by Taft (23) it has been suggested (8, 23) that the phenyl cation (I) initially formed in the thermal decomposition of diazonium salts may isomerize to a diradical cation (II) with concerted uncoupling of a pair of π-electrons, one of which falls into the vacant sp^2 σ-orbital. The resulting species would be expected to behave like a highly electrophilic free radical in aromatic substitution reactions. Canonical structure II*a* would give the species some of the properties of a triplet carbene, whereas if a second π-electron fell into the σ-orbital, thus filling it, the species III might behave as a singlet carbene (II*a* and III could well take part in insertions into and hydrogen abstractions from aliphatic C—H groups and account for the demethylations and deaminations, as well as insertions observed in certain attempted Pschorr cyclizations (24, 25). The existence of equilibria I $\rightleftarrows$ II $\rightleftarrows$ III would account for all the reported properties of the phenyl cation. In fact, it might be expected that, provided the intermediate formed from the thermolysis could persist long enough, II and III would be formed. Preliminary M.O. calculations (26) indicate the order of stabilities II > III > I, the triplet diradical cation II being the ground state. Direct evidence for the formation of radicals in these reactions has been obtained from electron spin resonance spectroscopic measurements (8). These radicals are apparently trapped in the solid matrix and, as such, appear to be quite stable. An electron spin resonance spectrum was also observed when benzenediazonium borofluoride in nitrobenzene *solution* was heated at 42° for 10 min (8). *p*-Bromobenzenediazonium borofluoride in aqueous solution at 50° apparently produces free radicals in small concentrations which are sufficient to initiate the polymerization of acrylonitrile, styrene, methyl methacrylate, and methyl acrylate (27). A

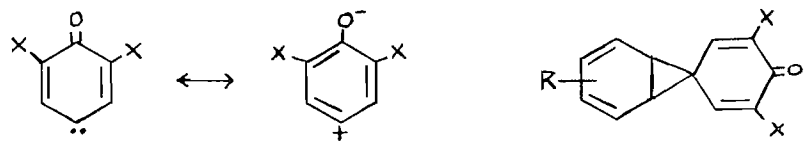
III

study of the copolymerization of styrene and methyl methacrylate by benzenediazonium borofluoride has suggested that a cationic species is the initiator (28). These results can be reconciled if the intermediate is a diradical cation II in equilibrium with I (from which fluorobenzene, and phenol in aqueous solutions, is undoubtedly formed) and perhaps III.

The total rate and isomer ratios for the phenylation of bromobenzene, nitrobenzene, and anisole are readily explained if the attacking entity is the relatively non-discriminating (towards the nucleus as a whole) highly reactive, but apparently positionally selective, electrophilic diradical cation. Very comparable total rate ratios to those obtained here were reported by Dewar and Narayanaswami (29) for the arylation of substituted benzenes using benzene-1,4-diazo oxides. This reaction is thought to involve the carbene (IV) (29, 30) which attacks the aromatic substrate in the rate-determining step of the substitution process to form a π-complex or a spiran (V), the latter opening up to give the biphenyl derivative.



IV V

The formation of appreciable amounts of meta isomer, particularly with toluene and anisole, in the present work rules out a product-determining spiran ring opening and suggests a direct substitution process in our case. The value of ${}^{CH_3}_{H}K < 1$ is, however, disturbing and the effect of the substituent is very difficult to account for on any mechanism, since attack by a nucleophilic reagent must definitely be ruled out. A number of possible explanations were considered. An amount of boron trifluoride equivalent to the fluorobenzene formed is liberated and this could form a π-complex with the aromatic solvent. Toluene forms a complex more readily than does benzene, so that one could visualize more toluene than benzene molecules being complexed in the vicinity of the reactive species; and since the complex should be less susceptible to electrophilic attack

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

than would be the uncomplexed species, this would lead to a statistical advantage of the benzene over the toluene, though the amount of BF_3 formed relative to the amounts of solvent is small. Such a situation might be more likely if the phenylation reaction took place within the solvent cage and if there was a statistical distribution of substrate molecules around the reactive intermediate. If this were so, however, one might expect that increasing the proportion of toluene would then lead to larger values of ${}^{CH_3}_{H}K$, which was not the case (Table V). The most likely explanation at the moment is that the phenylation is a cage process and that the solvent shell around the reactive species does not contain an equivalent number of benzene and toluene molecules (when equimolar quantities of the two substrates are used), but that since toluene is a larger molecule than is benzene a larger number of molecules of the latter will always be present around the diradical cation, irrespective (within certain limits, probably) of the toluene:benzene ratio in the bulk of the system. This non-statistical distribution of solvent molecules in the immediate vicinity of the decomposing diazonium ion would lead to the low values of ${}^{CH_3}_{H}K$ observed and, in fact, would invalidate the use of the product ratios as a measure of the relative reactivities of the various aromatic substrates. A similar low value of ${}^{CH_3}_{H}K$ has been reported for the isopropylation of toluene via the isopropyl cation from isopropyl amine (31). In this case, however, the value of the total rate ratio *decreases* with increasing toluene:benzene molar ratio. The contamination of the cumene fraction by a product with the same retention time on gas chromatography invalidates these results (32).

It is clear, therefore, that too much importance cannot be attached at the moment to the *exact* values of the total rate ratios and hence of the partial rate factors determined in the present work, though these are reproducible from run to run and, apart from those for toluene, are probably of the correct general order of magnitude and in the right direction. This difficulty undoubtedly arises because, *except in the nitrobenzene reaction* (both under competitive and non-competitive conditions), *which is of key importance in the discussion of mechanism*, the reactions are heterogeneous in nature and there is an absence of kinetic control in the substitution process. The limitations of the competitive technique for the determination of relative reactivities in those cases where kinetic control is absent has been discussed recently by Tolgyesi (33). It becomes, therefore, very important to study this process in homogeneous solution with suitable agitation; such work is in progress and will be reported at a later date.

REMARKS ON THE NITRONIUM SALT NITRATION OF TOLUENE AND BENZENE

G. A. OLAH[1] AND N. A. OVERCHUK
The Dow Chemical Company, Eastern Research Laboratory, Wayland, Massachusetts
Received February 22, 1965

ABSTRACT

The nitronium salt nitration of toluene and benzene in tetramethylene sulfone and nitromethane solution was critically reinvestigated.

Stable nitronium salts were introduced as new nitrating agents by Olah *et al.* (1, 2). They were found useful both in preparative nitrations (3) and in the investigation of certain mechanistic aspects of aromatic nitration (4–8). In the course of these investigations the competitive nitration of benzene and toluene, besides other systems, was carried out in tetramethylene sulfone (tetrahydrothiophene-1,1-dioxide) and nitromethane solutions.

Under most conditions toluene reacts about 20 times more rapidly than benzene in the nitration reaction. With stable nitronium salts toluene reacts only about twice as fast as benzene (4). This observation would be readily accommodated in terms of a decreased selectivity of the highly electrophilic nitronium ion. This interpretation is unsatisfactory, however, since the para:meta ratio for substitution in toluene is unaltered. The unusual result is that with reactive nitronium salts the intermolecular (substrate) selectivity is decreased appreciably but the intramolecular (positional) selectivity is not significantly altered (9).

It was pointed out that the low selectivity could have been caused by the very high reactivity of the reagent, reacting indiscriminantly with substrates present. Thus statistical or diffusion controlled reaction conditions and not kinetically controlled competition would be observed with highly reactive electrophilic agents (10).

For the ultimate electrophilic reagent not capable of selecting between two molecules or between available sites in a substituted benzene, like toluene, the relative rate, k(toluene)/k(benzene), k_t/k_b, would be 5/6 and the product ratio would be 40% ortho, 40% meta, and 20% para isomer.

In all of the investigated nitronium salt nitrations of alkylbenzenes (or halobenzenes) the meta:para ratio is extremely low. The amount of meta isomer in the nitration of toluene is generally less than 3%. Thus the observation of high intramolecular (positional) selectivity in reactions showing low intermolecular (substrate) selectivity in itself should invalidate the argument for statistical or diffusion controlled reactivity. For data on statistically controlled isomer distribution in free radical nitration of toluene see subsequent results. The question was however further examined by different methods including changing the ratio of concentration of the aromatic components in competitive experiments from the usual 1:1 to 4:1 and 1:0.25. The results showed that the relative rate ratio remains almost unchanged if a first-order dependence on the aromatic concentration is accepted (Table I).

[1]*Author to whom inquiries should be addressed at the Department of chemistry, Western Reserve University, Cleveland, Ohio.*

TABLE I

Concentration variation of toluene and benzene in competitive nitrations with $NO_2^+BF_4^-$ in tetramethylene sulfone solution at 25°

Toluene:benzene	Observed relative reactivity	k_t/k_b
4:1	6.40	1.60
3:1	5.13	1.71
2:1	3.40	1.70
1:1	1.67	1.67
1:1.5	1.11	1.66
1:2	0.81	1.62
1:3	0.62	1.86
1:4	0.45	1.80
		Av. 1.70

The experimental data obtained pointed to the fact that the observed relative reactivities are due to competition of NO_2^+ with the aromatic substrates, the reactions being first order in aromatic substrates. Statistical distribution which takes place in a fast reaction without any selectivity cannot explain the above data, although it is necessary to state that the reactions are indeed very fast even in high dilutions.

One of the major difficulties in investigating fast reactions is whether complete mixing of the reagents can be achieved before reaction with the reactive reagent takes place. The use of competitive experiments to determine the relative reactivity of substrates helps to overcome the difficulties involved in absolute rate determinations, but nevertheless this method can also have limitations in fast reactions. Should one of the reaction partners (e.g. toluene) in the competitive nitration react much faster than the other competing partner (e.g. benzene), the former would become impoverished in the immediate surroundings of the reagent. This would mean that the competitors appear more closely related in their speed of reaction, without necessarily showing the effects of statistical distribution (12). Our previous experiments carried out to show the effect of mixing on the reaction using various types of conventional stirrers were mostly negative. Nevertheless we continued the investigation of this aspect with more advanced methods, including high-speed flow systems (11, 12).

Reflecting recent interest in the nitronium tetrafluoroborate nitrations, two papers were published reinvestigating the competitive rate data of Olah, Kuhn, and Flood (4). Ritchie and Win carried out competitive nitrations of benzene and toluene (as well as chloro and fluorobenzene) by adding dropwise 0.30 ml of a 0.67 *M* solution of nitronium tetrafluoroborate in tetramethylene sulfone to a solution containing 100 μl of each of the aromatic compounds dissolved in 20 ml of tetramethylene sulfone, while maintaining rapid stirring. These conditions were similar to those used in our previous work concerning the ratio of the reagents and the concentration of the nitronium salt solution, but represented substantially more dilute solutions of the aromatic substrates (about 0.05 *M* solution of each of the aromatics, as compared with about 4.8 *M* solutions used by us). The work of Ritchie and Win fully substantiates our previous data in binary competing systems, even with a nearly 50-fold dilution of the substrate aromatic solution. Quaternary competition using two fast (toluene and benzene) and two slow (chlorobenzene and fluorobenzene) substrates shows some deviation of the relative rate data, but in the same order of magnitude (See Table II). The spread is scattered in both directions; therefore, we feel that these data also support, even if with some limitation, the binary competition data.

TABLE II

Competitive nitrations with nitronium tetrafluoroborate in 0.67 *M* tetramethylene sulfone solution at 25° according to Ritchie and Win (13)

	Rate ratio		
	Binary value* 0.1 *M* aromatic solution	Quaternary value†	Binary value* (Olah *et al.* (4))
Toluene–benzene	1.68 1.74	2.60	1.67
Toluene–fluorobenzene	6.72	3.80	(3.71)‡
Toluene–chlorobenzene	11.2	8.44	(11.8)
Benzene–fluorobenzene	1.89 2.08	1.50	2.22
Benzene–chlorobenzene	7.6	3.32	7.1
Fluorobenzene–chlorobenzene	3.20	2.22	(3.21)
Chlorobenzene–bromobenzene	1.08		(1.17)

*Nitration of a mixture of the two aromatics whose rate ratios are given.
†Nitration of a mixture of benzene, toluene, fluorobenzene, and chlorobenzene.
‡Values in parentheses were calculated from the rates relative to benzene.

Would the nitration indeed be diffusion controlled, changes of such extreme proportion in the reaction condition should have shown substantial changes. This was not the case.

Tolgyesi (14) on the other hand made the claim, that "the relative rates (of toluene/benzene competitive nitrations with nitronium tetrafluoroborate in tetramethylene sulfone) under certain conditions attained a range (25–30) which is considered to represent the range of relative reactivity and it corresponds to the known reactivity of toluene–benzene in nitric acid nitrations. On the basis of these results, there seems to be no reason to suppose that nitronium salt nitration involves a mechanism different from that of nitric acid nitration" (11).

In his work, competitive experiments were carried out by the addition of a solution of the nitronium salt in tetramethylene sulfone to a solution of toluene and benzene in the same solvent. It was found that the efficiency of the stirring, using a magnetic stirrer and expressed in the volt setting of a Powerstat attached to the stirrer, causes only very small differences in the toluene:benzene reactivity ratio, ranging from 1.4 to 2.2. In view of the experimental conditions and analytical method used, this spread is considered well in the limit of previous data. Somewhat larger changes were observed if the used nitronium salt solution was diluted (from 0.74 to 0.15 *M*). Even so, the toluene:benzene ratio showed an average value of 2.5–2.8 (with one extreme value of 5.1 noted) that is in the limit of previous data.

Replacing previously used conventional stirring methods with a claimed new and highly efficient method by the combined use of a vibrator stirrer and syringe addition of the nitrating agent, a spread of 3 to 7 for the toluene:benzene reactivity ratio was reported maintaining conditions otherwise similar to previous experiments. It was found, however, that significant dilution of the solution of the nitronium salt with simultaneous application of the new stirring system causes substantial changes of the toluene:benzene reactivity ratio, ranging from 25 to 30, thus equating it with the known order of nitric acid nitrations. These data were interpreted that having achieved good mixing of the reagents before reaction of a higher substrate selectivity was obtained. This was taken as evidence that previous low substrate selectivity data were obtained under conditions where the competing partners (benzene and toluene) were interacting more through statistical distribution than through real competition.

In view of our continued interest in nitronium salt nitrations and the fact that the claimed equivalence of nitronium salt nitrations with nitric acid nitration is in contradiction to our previous findings and our investigations comparing mixed acid nitrations with nitronium salt nitrations (7), we felt it of interest to report on additional work relating nitronium salt nitrations, including reinvestigation of the conditions used in the quoted paper (14).

RESULTS AND DISCUSSION

A. Substrate (Intermolecular) Selectivity

Comparison of the experimental data of Ritchie and Win (13), with those of Tolgyesi (14) shows that the change in the relative toluene:benzene reactivity ratio was observed only when *the concentration of the solution of the nitronium salt was decreased, but not when the aromatic substrates,* to which the nitrating agent was added, *were diluted.* This finding is extremely surprising. If indeed mixing of the reagents before reaction is the major factor in the differences observed and the higher substrate selectivity data indicate better mixing, then it is difficult to understand that only dilution of the solution of the nitrating agent (A) has any effect, but not dilution of the solution of the competing substrates (B). The two solutions once mixed should give the same overall concentration, regardless whether A or B were first diluted (assuming that the same amount of diluent is used).

The effect of dilution on the relative reactivity ratio can be interpreted in terms that in more dilute solution the number of active, reaction-producing collisions decrease. Having used this argument in one respect (e.g. dilution of the solution of the nitrating agent), Tolgyesi claims on the other hand, that dilute solutions of the substrates effectively show lower reactivity ratios, than those of more concentrated solutions (14). This claim is in direct contradiction with our previous data and our interpretation of the data of Ritchie and Win (13) who found that a nearly 50-fold dilution of the substrate solution had no effect on the toluene:benzene reactivity ratio. The offered explanation (14), e.g. that product ratios decrease with decreasing concentration of the aromatic solution because the extent of the selective depletion of the more reactive competitor in the diffusion layer around the droplet of the entering nitronium reagent is higher when the concentration of the aromatic compound is low, is unacceptable. We should keep in mind, that all the competitive experiments were carried out by adding a solution of the nitrating agent to a substantial (generally 10-fold) excess of the aromatics. The ratios of nitronium salt concentration compared with aromatic concentration are in themselves, however, meaningless, as during the whole reaction the ratios constantly change the nitronium salt is being added into the aromatic solution. The added nitronium reagent encounters in the early stages of the reaction a very large excess of the aromatic substrates and only if all the nitrating agent is added do we reach the 10:1 ratio. Using gas–liquid chromatography (g.l.c.) as the analytical method, 1:100, 1:1000 or an even smaller ratio of the nitronium salt to the aromatics is sufficient to carry out the competitive experiments. Ritchie and Win, having used 50-fold dilution of the substrate as compared to our previous work, maintained at the end of the reaction at least 10-fold excess of aromatics. We, in repeating some of the dilution work, added only 1/10 and 1/100 of the amount of nitronium salt, thus drastically eliminating the possibility of any depletion of the substrate, and still observed practically unchanged substrate reactivity. If we would accept the argument that the bulk concentration of the reaction mixtures is irrelevant since only the concentration in the diffusion layer surrounding the nitronium reagent droplet is important, Tolgyesi's experimental data would be even more inexplicable, since he himself reported

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

with the same stirring method a change in relative reactivity changing from 2.3 *M* to 0.3 *M* aromatic solutions.

The data so far discussed indicate that in the competitive experiments carried out by adding a solution of the nitronium salt to a solution of the competing substrate, only dilution of the nitronium salt solution had major effect on the substrate selectivities, but not the dilution of the aromatic substrate solution. This observation calls attention to the nature of the nitronium salt solution and its fate under dilution. According to the data of Tolgyesi in solutions of highest dilution (0.04 and 0.07 *M* solutions) the observed toluene:benzene reactivities were independent of the speed of stirring. Rechecking these systems under the experimental conditions reported, we found that "conventional" stirring gave the same results. Thus in these high-dilution solutions there is no effect whatsoever of stirring. However, we also found that these solutions *do not contain any more detectable nitronium salt!* Vacuum concentration of the solutions and subsequent spectroscopic (infrared and Raman) investigation revealed no 2 300 or 1 400 cm^{-1} bands, characteristic of nitronium ion. Recovery experiments resulted also in entirely negative results. The solutions, however, are still capable of nitrating. Thus all indications are that the *nitronium salt as such was lost during high dilution in tetramethylene sulfone solution.* The explanation was in our view already found in the experimental part of the quoted paper (14): "The solutions (e.g. NO_2BF_4 in tetramethylene sulfone) had a pale-yellow color probably originating from some impurity of the solvent. In one case a colorless solution was obtained using freshly distilled tetramethylene sulfone." (There was, however, no data given as to the behavior of this specific solution.)

In view of the essential need of high purity of the solvent and strictly anhydrous conditions using increasingly dilute solutions, the experimental techniques used were unsuitable. No vacuum line or dry box technique was used. The handling of highly hygroscopic materials, both during weighing solid nitronium salts on a balance and the treatment of equally hygroscopic tetramethylene sulfone solutions, in the reported experimental conditions seems highly inadequate. The quoted paper (14) further reports that "the purity of the solvent was checked by the freezing point and specific conductivity". The data when compared with those of Arnett (15), Burwell (16), and Olah (3) reported in the literature and summarized in Table III, clearly indicate that the solvent used was impure.

TABLE III

Freezing point and conductivity of tetramethylene sulfone of various purity

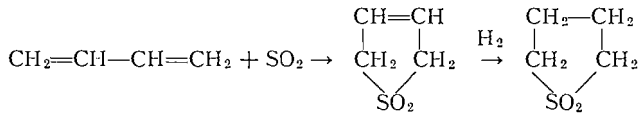
	Ref. 15	Ref. 16	Ref. 3	Ref. 14
Freezing point (°C)	28.4	28.8	27.6	26.7
Specific conductivity (mho/cm)		2×10^{-8}	1.35×10^{-7}	6.5×10^{-6}

Comparison of the purification methods described in the literature and particularly that of E. M. Arnett and C. F. Douty (15) with the purification via a simple distillation described by Tolgyesi makes it highly improbable that the latter used tetramethylene sulfone of sufficient purity. However, in view of the claims made in dilute tetramethylene sulfone solutions, we felt it necessary to reinvestigate the nature of impurities and their effects.

The effect of water present in tetramethylene sulfone could be followed by depression of the freezing point and increase of conductivity. Tetramethylene sulfone is extremely hygroscopic, and picks up water readily as shown by the freezing point depression and by increase of its conductivity. Triple distilled tetramethylene sulfone (from sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

hydroxide pellets) when redistilled from calcium hydride to remove traces of water which it holds tenaciously had a freezing point of 28.35°. After venting the solvent to air the freezing point was depressed to 28.16° within 30 min. If purified tetramethylene sulfone was vented to the air while stirred with a vibrator mixer, the freezing point depressed to 27.21° in 15 min. (The thermometer used could be estimated at 0.01°). The specific conductivity of the solvent changed at the same time from 1.52×10^{-8} to 9.6×10^{-6} mho/cm. The Karl Fischer water determination in tetramethylene sulfone was found unreliable and irreproducible when checked on samples to which known amounts of water was added. One of the reasons for this behavior may be the presence of other impurities in the solvent. Tetramethylene sulfone is made commercially from the Diels–Alder reaction of 1,3-butadiene with sulfur dioxide, giving 2,5-dihydrothiophene-1, 1-dioxide which is then hydrogenated.



Commercial tetramethylene sulfone contains, according to our observations, besides varying amounts of water and some unidentified impurities, up to 2% 2,5-dihydrothiophene-1,1-dioxide (isolated by gas chromatography and identified by its infrared and n.m.r. spectra). Tetramethylene sulfone cannot be separated by a simple vacuum distillation from dihydrothiophene-1,1-dioxide or its cleavage products. Its presence is responsible for the formation of SO_2 during distillation or heating the solvent, thus reversing the Diels–Alder addition of butadiene and sulfur dioxide. Strong acids, like sulfuric acid, give coloration with tetramethylene sulfone containing the olefinic sulfone and a similar coloration indicating complex formation with the nitronium salts! It was indeed found suitable to purify tetramethylene sulfone for nitration experiments by distillation from nitronium tetrafluoroborate.

The effect of impurity moisture on nitronium tetrafluoroborate is not entirely yet clarified. Nitronium tetrafluoroborate reacts in all probability with water to give a more selective nitrating agent, e.g. nitracidium tetrafluoroborate (protonated nitric acid).

$$NO_2^+BF_4^- + H_2O \rightleftharpoons H_2NO_3^+BF_4^-$$

With excess water nitric acid formation takes place.

$$H_2NO_3^+BF_4^- + H_2O \rightarrow HNO_3 + HBF_4 \cdot H_2O$$

In our view nitronium tetrafluoroborate is not identical with nitric acid, even in the presence of small amounts of water. However, the "activity" of nitronium tetrafluoroborate is substantially affected by the presence of water.

We determined the effect of water and 2,5-dihydrothiophene-1,1-dioxide on the nitronium tetrafluoroborate nitrations by adding (in separate experiments) known amounts of them to a 0.5 *M* tetramethylene sulfone solution of nitronium tetrafluoroborate. In these experiments it was possible to reproduce what happens when the impurities are present in concentrations approximating those used in highly diluted solutions. Data obtained are summarized in Tables IV and V.

The experimental facts need little explanation. Using dilute solutions the impurity (in all probability both 2,5-dihydrothiophene-1,1-dioxide and water) can easily reach levels approximating the amount of $NO_2^+BF_4^-$ claimed to be present. A 0.04 *M* solution of the nitronium salt used in ref. 14 means that an equivalent of 0.72 g H_2O in 1 000 ml (1 261 g)

tetramethylene sulfone thus a <0.06 wt. % amount of impurity moisture will completely bind all nitronium salt. In view of the demonstrated effect of water on the relative rate even a much smaller amount can have substantial influence. Similarly a 0.38% dihydrothiophene-1,1-dioxide impurity means a 0.04 *M* solution.

We must conclude based on our experimental data that the nitrations observed in increasing dilutions (14) were *not* pure nitronium salt solutions. In high dilutions it is even questionable that there was any free nitronium salt present. Mixing itself thus had no major effect on the competitive reactions besides distributing the nitrating agent better in the solution of the substrates before reaction, thus making it more susceptible to the effect of all impurities in the system.

Next we turned our attention to the problem of obtaining relative reactivity data of toluene:benzene in competitive nitration experiments using nitronium tetrafluoroborate in highly purified tetramethylene sulfone solution (see Experimental) and using the described new vibrator stirrer – syringe injection system (14). It must be emphasized that otherwise the reaction conditions were not suited to claim absolute anhydrous conditions, as no vacuum line technique was used. Data obtained in nitrating 0.5 *M* benzene and 0.5 *M* toluene solution with 0.67, 0.4, and 0.2 *M* nitronium tetrafluoroborate in tetramethylene sulfone solutions are shown in Table VI. Voltage of the vibrator motor was kept constant at 115 V. An all-glass vibrating stirrer was used instead of a metal one (used in the ref. 14) to avoid any interaction with or surface catalysis on the metal.

It was observed in our experiments too, that with decreasing concentration of the used nitronium salt solution the substrate selectivity increased. In the concentration range investigated the variation of the toluene:benzene reactivity ratio was, however, definitely

in a different order of magnitude than that of nitric acid nitration in the same solvent, and the spread of the experimental data is considerable and the reproducibility poor. All this indicates a mixed nitration system involving more than one nitrating agent. It would also seem that many factors not defined previously have an effect (position of injection, size, material, etc. of vibrator disc, its position in the reaction vessel).

In view of the difficulty of purification of tetramethylene sulfone and its hygroscopic nature, we felt it useful to extend the investigation of the vibrator stirrer – syringe injection system to another solvent system. Nitromethane was selected, the purification of which was previously described (17). Carrying out competitive nitration of toluene and benzene with 0.5 *M* and 0.2 *M* nitronium hexafluorophosphate (nitroniumtetrafluoroborate is not sufficiently soluble) solutions under conditions identical with those used previously, the change of the reactivity ratio with dilution of the solution of the nitrating agent and the use of the new stirring method was found very small (Table VII).

To compare the behavior of the toluene:benzene competitive nitrations with reaction

conditions where, due to an extremely reactive substituting agent, predominantly statistical factors determine both substrate and positional selectivity, we carried out free radical type nitration of the substrates. Toluene and benzene (under competitive reaction conditions in 1:1 ratio) were reacted at the reflux temperature of the mixture with nitrogen dioxide in the presence of benzoyl peroxide catalyst while irradiating the reaction mixture with ultraviolet light (the reaction being carried out in a fused quartz reaction vessel).

TABLE VIII

Competitive nitration of benzene and toluene with nitrogen dioxide at reflux temperature of the mixture in ultraviolet light

		% nitrotoluene		
	$k_t:k_b$	ortho	meta	para
Benzene	1.0			
Toluene	2.6	37.2	38.1	24.7

Data obtained are summarized in Table VIII. From the data of Table VIII it is evident that low substrate selectivity is obtained with simultaneous low positional selectivity, approximating the statistical 40% ortho, 40% meta, 20% para isomer distribution. The high positional selectivity observed in nitronium salt and other electrophilic aromatic nitrations is in sharp contrast with the low positional selectivity observed under free radical nitration conditions.

The possible effect of diffusion control or incomplete mixing was also further investigated by the use of high-speed flow systems. The reaction time in these experiments was cut to 0.01 s. Solutions of the nitronium salt and the competing aromatics were sent through a capillary mixing chamber in concentration similar to those used in previous dropwise addition procedure (~0.7 *M* nitronium salt and also in dilution till 0.25 *M* solution). The reactor was a modified and improved version (with controlled-speed syringe-type addition system) of that used by H. C. Brown and H. Jungk (18) in Friedel–Crafts type reactions. Data of competitive nitration of toluene and benzene in the flow system are summarized in Table IX.

TABLE IX

Competitive nitration of benzene and methylbenzenes in flow reactor (average reaction time 0.01 s)

Aromatic	Nitrating agent	Solvent	$k_{aromatic}:k_{benzene}$
Benzene	$NO_2^+BF_4^-$	Tetramethylene sulfone	1.0
Toluene			2.07
m-Xylene			2.68
Mesitylene			3.50
Benzene	$NO_2^+PF_6^-$	Nitromethane	1.0
Toluene			2.56
m-Xylene			6.54
Mesitylene			10.38

Attempts were also made to measure the absolute rates of the nitration of toluene and benzene respectively in flow systems. Using an internal standard method to enable analysis after quenching of the reaction mixtures by the previously detailed g.l.c. method, measurements were carried out, but no reliable data could be obtained because of the fact that the reactions are fast enough that quenching could become the limiting factor. There was also

For personal use only.

no evidence to prove complete mixing of the reagents as no ideal turbulent flow conditions with suitable Reynolds' numbers were obtainable in tetramethylene sulfone solutions. Using the less viscous nitromethane as solvent, turbulent flow conditions were easily obtained.

The high-speed flow system in competitive experiments gave only a slight increase in the relative reactivity ratio values compared with the previous dropwise addition method. The fact that there is any change in the relative rate indicates that mixing does have some effect on the reactions. Imperfect mixing is also demonstrated by the fact that high-temperature gas-chromatographic methods indicate the formation of small amounts (generally substantially less than 1%) of dinitro products in the nitration of alkylbenzenes (19). Dinitro products could not be formed in the kinetically controlled nitration of alkylbenzenes (in the presence of a large excess of the alkylbenzene), but originate from the fact that the mononitro product is not uniformly distributed in the nitration media and that some dinitration takes place in the immediate surroundings of the nitrating agent. The very small amount of dinitration, however, again indicates that in competitive experiments the effect of imperfect mixing is only a minor one.

The question of mixed acid nitration of benzene and toluene in tetramethylene sulfone and nitromethane solution was previously discussed by Olah, Kuhn, Flood, and Evans (7). It was shown that the concentration of nitronium ion (as monitored by infrared and Raman spectroscopy) decreases with increasing dilution of the acid in the solvent. In dilute solution (not containing spectroscopically detectable amounts of NO_2^+ concentration) the toluene:benzene reactivity ratio was found to be 28, whereas with more concentrated solutions (containing substantial NO_2^+ concentration) it was 1.6.

Nitric acid in organic solutions (acetic anhydride, acetic acid, nitromethane tetramethylene sulfone) shows substantial substrate selectivity ($k_t:k_b = >25$). These solutions according to spectroscopic evidence do not contain detectable amounts of NO_2^+. The observation (14), that using neat nitric acid as nitrating agent and adding it to a dilute tetramethylene sulfone solution of the aromatics gives a toluene:benzene ratio of 3.4 is in our view in accordance with the fact that neat nitric acid according to Raman spectroscopic data is about 0.2 *M* in $NO_2^+NO_3^-$. Thus its use represents the use of a dilute nitronium nitrate solution as nitrating agent. In our hands the competitive nitration of toluene and benzene with dilute (1 *M*) solution of nitric acid in tetramethylene sulfone gave $k_t:k_b = 37$ (% ortho 64.9, % meta 5.6, % para-nitrotoluene 29.5). In contrast neat nitric acid as nitrating agent gave $k_t:k_b = 1.65$ (% ortho 57.5, % meta 4.6, % para 37.9 nitrotoluene).

We are in disagreement with conclusions concerning the supposed equivalence of nitronium tetrafluoroborate nitration with nitric acid nitration (14). Similarly nitric acid in dilute organic (or aqueous) solution cannot be equated with strong proton acid solutions or the neat acid. Nitric acid itself is not an electrophilic nitrating agent. It must first form according to Ingold an electrophile and the formation of this species can be rate determining.

$$HNO_3^+ + H^+ \rightleftharpoons H_2NO_3^+$$

$$H_2NO_3^+ \rightleftharpoons NO_2^+ + H_2O$$

In contrast if we use prepared NO_2^+ salts the formation step is excluded and therefore the rate-determining step can be nothing else than interaction with the substrate. However, we agree that the reported nitronium fluoroborate nitrations in high dilutions (14) indeed do approximate nitric acid nitrations. This in all probability was due to the fact that in

high dilutions it was impossible to keep the system pure enough to carry out any more nitronium salt nitrations and the impure systems resulted in mixed nitrations indicated by the fact that practically any toluene:benzene reactivity value between 1.4 and 40 could be obtained.

B. Positional (Intramolecular) Selectivity

The classical nitration of toluene shows a remarkable constancy of the mononitrotoluene isomer distribution, regardless of the reagents employed. The many references relating to the nitration of toluene report only slight variation in the ortho:para ratio (from 1.41 to 1.66). In all the systems investigated, the *m*-nitrotoluene content also remained relatively constant fluctuating between 1.6 and 5%.

The constancy of the isomer distribution in the nitration of toluene remained unchallenged until our work on nitronium salt nitrations (4), which showed that the ortho:para ratio can be substantially increased (Table X).

Increasing solvation in nitronium salt and related electrophilic nitrations generally decreases the ortho:para ratio without, however, altering the meta isomer content. Mixed acid ($HNO_3 + H_2SO_4$) at $-15°$ gives an ortho:para ratio of 0.92 (4). Neopentyl nitrate in polyphosphoric acid gave a ratio of 0.49, amyl nitrate under similar conditions 0.64, and absolute nitric acid in polyphosphoric acid 0.86 (20).

The amount of meta isomer is generally so small (2–3%) that the analytical methods used do not allow significant differentiation. The ortho:para isomer ratio however is more easy to follow. It is observed that the low substrate selectivity nitrations show generally a higher ortho:para ratio than the higher selectivity reactions, indicating at least a partial change in the nature of the nitrating agent (NO_2^+ versus a bulkier precursor).

Mechanical factors, like efficiency of stirring, should have no effect on the isomer distributions. It was, however, reported (14) that the isomer distributions show changes depending on the efficiency of stirring used. Although the changes were relatively small, it must be remembered, as discussed previously, that the electrophilic nitration of toluene is remarkably insensitive to the nature of the nitrating agent employed.

It is our view that simultaneous changes in *both* substrate and positional selectivity indicate some change in the nature of the nitrating agent, because mechanical factors (efficiency of mixing) could not account for isomer distribution changes. Only if a statistically controlled indiscriminate nitration (giving a distribution of 40% ortho, 40% meta, and 20% para isomer) were superimposed onto a selective nitration (with high ortho:para ratio) could stirring (e.g. better distribution of the reagent before reaction) affect the isomer distribution. There are, however, no data available to substantiate this latter case as the amount of meta-nitrotoluene shows no significant variation.

The isomer distribution data of the nitration of toluene fully substantiate the view that stable nitronium salt nitrations in organic media are different from nitric acid nitrations. The nitronium salt nitrations gave the highest reported ortho:para ratios with the lowest meta isomer content. The isomer distributions are constant under purely mechanical changes in the nitration systems, but vary if the nature of the nitrating agent is affected.

In conclusion it is our belief that the competitive rate determination method for determination of the relative reactivity of toluene and benzene can be applied for the nitronium salt nitrations in tetramethylene sulfone and nitromethane solution. The data indicate low substrate (intermolecular) but high positional (intramolecular) selectivity. It was indicated by us from the very first publication on the topic (4) that the high reactivity of

the nitronium salt may cause experimental problems, but we think we have sufficiently proven that these are only minor ones under conditions of competitive rate determinations using large excess of the substrates. No selective depletion of the more reactive reaction partner (toluene) was observed, neither was evidence obtained indicating statistically (diffusion) controlled reaction conditions.

The claimed variation of the toluene:benzene reactivity ratio with the efficiency of stirring (14) was shown to a large degree to be a consequence of simultaneous high dilution of the system containing impurities affecting the reactivity of the nitrating agent. The final answer as to the possible effect of non-kinetic factors on competitive rate determinations should come from absolute rate determination of toluene and benzene in separate systems. Although attempts were made to this effect the reactions were found so far too fast for reliable measuring even in fast flow systems. We are, however, continuing our efforts to achieve this goal.

EXPERIMENTAL

Due to the extremely hygroscopic nature of nitronium salts and anhydrous tetramethylene sulfone, the preparation and handling of the reagents and their solutions was carried out in a good dry box (Kewaunee Co., Adrian, Michigan) purged with dry nitrogen and desiccated by phosphorus pentoxide. No claim for absolutely anhydrous conditions can, however, be made as no vacuumline techniques were employed in present investigations.

Reagents

Aromatic hydrocarbons (benzene, toluene, *m*-xylene, mesitylene) were highest purity materials dried and distilled from calcium hydride.

Nitronium tetrafluoroborate was prepared as described previously (3, 21). It should be emphasized that the preparation of Kuhn and Olah (3) which is extremely well suited to obtain nitronium tetrafluoroborate of 90–95% purity, applicable to most purposes, does not provide the quality of reagent needed for high dilution work. For this purpose the preparation of Cook, Kuhn, and Olah (21) from nitryl fluoride and boron trifluoride in a vacuum system was found necessary.

Tetramethylene sulfone, commercial material (Phillips Petroleum Company, Bartlesville, Oklahoma or Shell Development Co., Emeryville, California), was purified essentially as described by Arnett and Douty (15). The purification consisted of repeated vacuum distillation from sodium hydroxide pellets until a 1-ml sample in a small test tube did not show development of visible color within 5 min after the addition of an equal volume of 100% sulfuric acid. This usually required two or three distillations. It was then distilled again from calcium hydride to remove traces of water, which it holds extremely tenaciously. Storing the material under vacuum or nitrogen for brief periods of time was possible. It was, however, observed that tetramethylene sulfone is sufficiently hygroscopic to pick up moisture under prolonged storage even under careful conditions and much more so when vented to the atmosphere, even for brief periods of time. Purified tetramethylene sulfone had a freezing point of $28.5 \pm 0.1°$ and a specific conductivity 1×10^{-8} mho/cm. Fresh solutions of pure nitronium tetrafluoroborate in tetramethylene sulfone purified by described procedure were colorless. Coloration was observed when exposed to moisture or on prolonged standing. It was necessary to make up the solutions, to carry out the weighing of the nitronium salt and dilutions in the dry box.

Nitromethane was purified as reported previously (17).

Competitive Nitrations

Magnetic stirrer.—Nitrations using conventional magnetic stirrer were carried out as described (4). Addition of the nitronium salt solution was, however, carried out by running the solution below the level of the substrate solution stirred in the reaction vessel or by addition of the solution of the nitrating agent from a hypodermic syringe. In the concentrations reported in previous work (4), data were well reproducible and the mode of addition of the nitrating agent had little effect.

Vibrator stirrer and syringe addition of the nitronium salt solution.—Reactions were carried out under conditions suggested (14) to achieve maximum mixing. The reaction vessel was a jacketed test tube through which water was circulated at $25 \pm 0.1°$. The reaction vessel had a side arm closed with a serum cap. Generally 60 ml of the solution of the competing aromatic hydrocarbons was measured into the vessel which was agitated with a laboratory Vibro mixer using a perforated 23 mm diameter all-glass vibrating disc. Voltage of the vibrator motor was kept constant at 115 V. The solution of the nitrating agent was added from a hypodermic needle through the serum cap of the side arm of the reaction vessel. If not stated otherwise, the overall amount of nitronium salt was less than 1/100 mole equivalent of that of the combined aromatic substrates.

For personal use only.

The addition of the nitronium salt was generally carried out in 3–4 min. The mixture was stirred for another 5 min. It was then poured into 150 ml water, extracted three times with ether using 50 ml each time, dried, and analyzed by capillary gas chromatography.

Flow Reactor

The reactor used was a modified and improved version of the flow system used by Brown and Jungk (18) in the investigation of Friedel–Crafts type reactions. Glass capillary mixing chambers of 1 mm diameter with volumes of 0.21, 0.12, and 0.07 ml were used. The solutions of the reagents (benzene, toluene, as well as the nitronium salt) were added from syringes, whose plungers were driven by synchronized motors. The quenching of the reaction mixture was effected with aqueous methanol. The work-up of the quenched mixture was effected by extraction with ether. Analyses were carried out under identical conditions as previous reaction mixtures.

Using tetramethylene sulfone as solvent, maximum flow rates of 3.30 ml/s were achieved. The critical velocity for turbulent flow, u_c, as given by the Reynolds' formula for tetramethylene sulfone (d^{30} 1.2615 g/s, viscosity at 30° 0.0987 g/cm s)

$$u_c = \frac{1\,000 \times \eta(\text{viscosity in poises})}{\rho(\text{density}) \times r(\text{radius of tube in cm})}$$

at 30° for a tube of 1 mm bore is 1 656 cm/s. The corresponding volume rate is 13 ml/s. Thus with the fairly viscous tetramethylene sulfone as solvent, no flow rates assuring turbulent flow conditions were possible. In the case of the substantially less viscous nitromethane (viscosity at 25° 0.00627 g/cm s, d^{25} 1.13149 g/s) the critical velocity for turbulent flow is only about 110 cm/s, the corresponding volume rate is 0.86 ml/s. With nitromethane solutions, flow rates of 8.1 ml/s could be obtained, and thus the Reynolds' number was high enough to assure turbulent flow conditions.

Analysis

All analyses were carried out on a Perkin–Elmer model 226 gas chromatograph equipped with flame ionization detector, 150 ft R-column (polypropylene glycol coated Golay column). Resolution of nitrobenzene and the three isomeric nitrotoluenes is seen in Fig. 1 of a representative analysis. Relative peak areas were determined by the use of a fast electronic integrator (Infatronics model CRS-1).

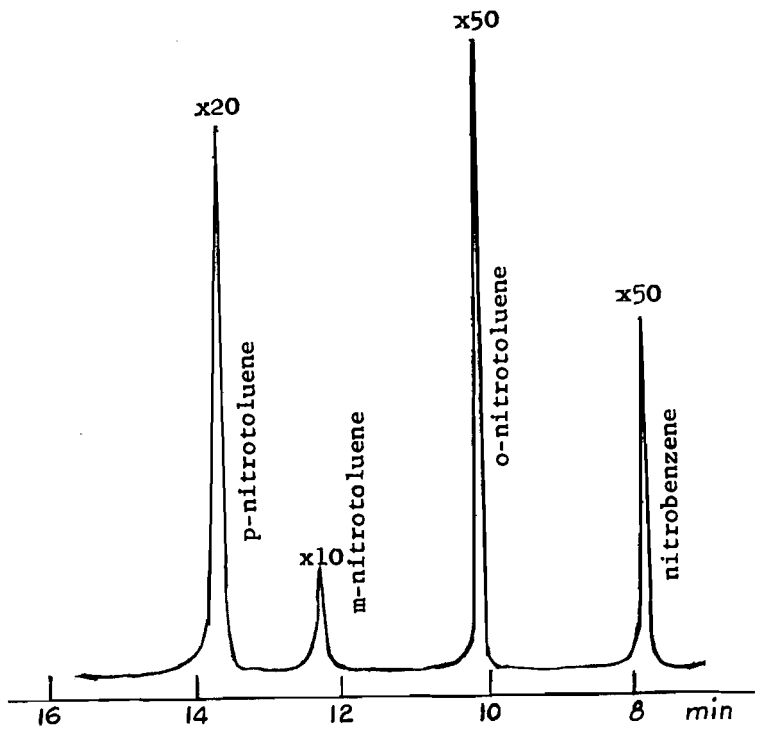

FIG. 1. Analysis of nitrobenzene–nitrotoluene reaction mixture on Perkin–Elmer model 226 gas chromatograph (150 ft R-column, 125°, 30 p.s.i.g. He pressure): k_t/k_b = 3.08; 65% ortho, 2.8% meta, 31% para nitrotoluene.

ALICYCLIC KETYLS

II. TEMPERATURE DEPENDENCE OF THE CONFORMATIONAL MOBILITY OF MEDIUM-SIZED RINGS[1]

J. W. Lown

Department of Chemistry, University of Alberta, Edmonton, Alberta

Received July 28, 1965

ABSTRACT

The electron paramagnetic resonance spectra of ketyls derived from alicyclic ketones containing from 6 to 12 carbons have been recorded in 1,2-dimethoxyethane or dimethoxymethane at temperatures from −96 to +87 °C. At −96° individual conformers of the cyclohexyl ketyl are observed with hyperfine couplings in close agreement with that of the conformationally 'frozen' 4-*tert*-butyl analogue at room temperature. The cycloheptyl ketyl conformational equilibrium between forms which have a plane of symmetry through the C—O bond axis is 'frozen' with respect to the spectrometer frequency at temperatures from −40 to +88 °C. Cyclooctyl ketyl equilibrates at ordinary temperatures between two conformers lacking a plane of symmetry through the C—O bond axis. The electron paramagnetic resonance spectra of the ketyls derived from 10- and 12-membered rings show dramatic temperature dependence, which is interpreted in terms of two or more simultaneous conformational equilibria. Values for the dihedral angles of the alpha protons and for the spin density on the sp^2 carbon are derived.

We recently demonstrated (1) that a study of the electron paramagnetic resonance (e.p.r.) spectra of alicyclic ketyls in 1,2-dimethoxyethane can give valuable information about the conformations adopted by these radical anions in solution. It was found that the predicted (2) angular dependence of hyperfine coupling from protons alpha to the carbonyl group was confirmed and that it could be used to deduce dihedral angles. Within a given ring system, A values (conformational free energy differences) determined from neutral molecules were found to have validity when applied to the conformational analysis of such ketyls. In view of increasing interest in the shapes of medium-sized rings (7 to 12 carbons (3–8)) it was decided to examine the e.p.r. of the corresponding ketyls. A study of the temperature dependence of the e.p.r. spectra afforded valuable information concerning the individual conformers in each case.

Six-Membered Rings

Cyclohexyl ketyl had been shown (1) to give a sharp quintet of lines (1:4:6:4:1; a_H = 10.4 oersteds (Oe)) when generated from the ketone by potassium in dimethoxyethane at room temperature.

The conformationally 'frozen' 4-*tert*-butylcyclohexyl ketyl gave a seven-line spectrum ($a_{H_{ax}}$ = 14.4 and $a_{H_{eq}}$ = 7.2 Oe). Because of the conformational freedom of the unsubstituted six-membered ring, one would anticipate very little change in the e.p.r. spectrum except at low temperatures. A solution of the ketyl in dimethoxymethane (m.p. −104°) gave a quintet at room temperature, but as the temperature was lowered broadening of alternate lines occurred as the rate of inversion became comparable with the difference in the hyperfine frequencies between the two conformers, in accordance with prediction (9), until at −96° seven distinct lines were observed (Fig. 1B). At this temperature the lines are still broad, and accurate intensity computation is not possible. If it were possible to achieve lower temperatures with another solvent, presumably the lines would become

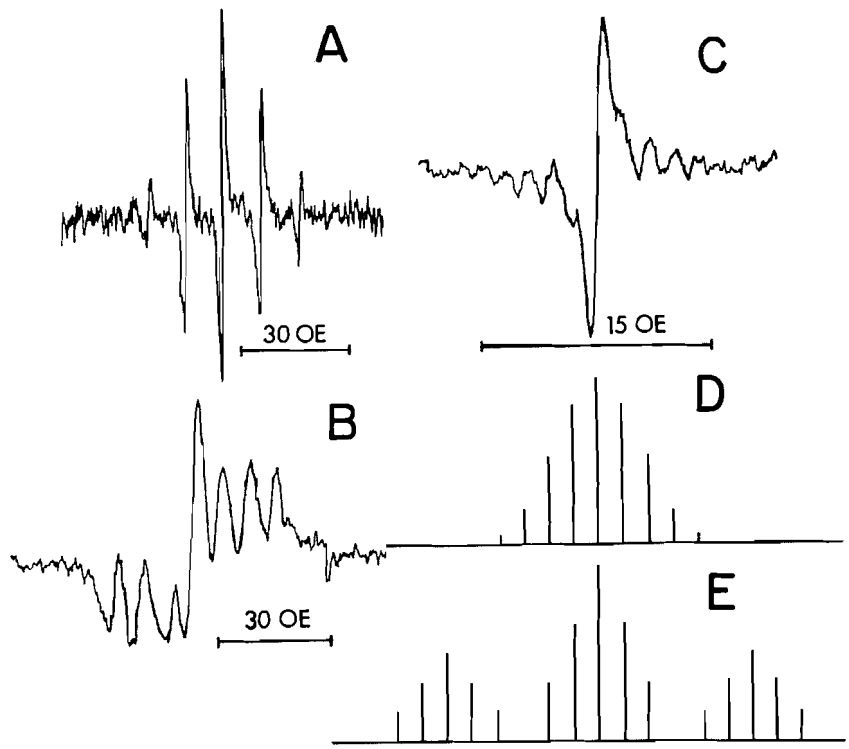

FIG. 1. First derivative e.p.r. spectra. LEGEND: A, cyclohexyl ketyl in 1,2-dimethoxyethane at +20°; B, cyclohexyl ketyl in dimethoxymethane at −96°; C, 2,2,6,6-tetradeuteriocyclohexyl ketyl in 1,2-dimethoxymethane at +20°; D, spectrum of C reconstructed from four equivalent deuterons (a_D = 1.6 Oe); E, spectrum of C reconstructed from one pair of equivalent deuterons (a_D = 1.6 Oe) and a pair of equivalent protons (a_H = 10.4 Oe).

sharp. However, the complete reversibility of the spectrum when the temperature is raised and lowered gives one confidence in assigning the seven-line spectrum to the conformationally 'frozen' ketyl. The fair agreement of the coupling constants 14.20 and 6.90 Oe with those of the 4-*tert*-butyl analogue is gratifying and confirms our previous prediction that distortion of the chair in the latter molecule is not serious (1).

Introduction of a ring substituent might be expected to slow down the rate of interconversion to the point where some temperature dependence could be observed at moderate temperatures. The e.p.r. spectra of the 3-methyl- and 4-methyl-cyclohexyl ketyls reported previously, while being well resolved, had lines appreciably broader than those of the unsubstituted ketyl, indicating some uncertainty broadening. Raising the temperature moderately (+60°) resulted in well-resolved spectra with accurate intensity distribution (Fig. 2A), whereas at temperatures of −35° extensive uncertainty broadening occurred.

The spectra retained their appearance up to +85°, a temperature approaching the boiling point of the solvent. This is consistent with our previous interpretation that inversion is rapid but that the equilibrium population favors the conformer which places the CH_3 group equatorial, so that complete averaging of the hyperfine couplings does not take place.

The increased resolution thus obtained allowed a more accurate determination of the coupling constants for these ketyls.

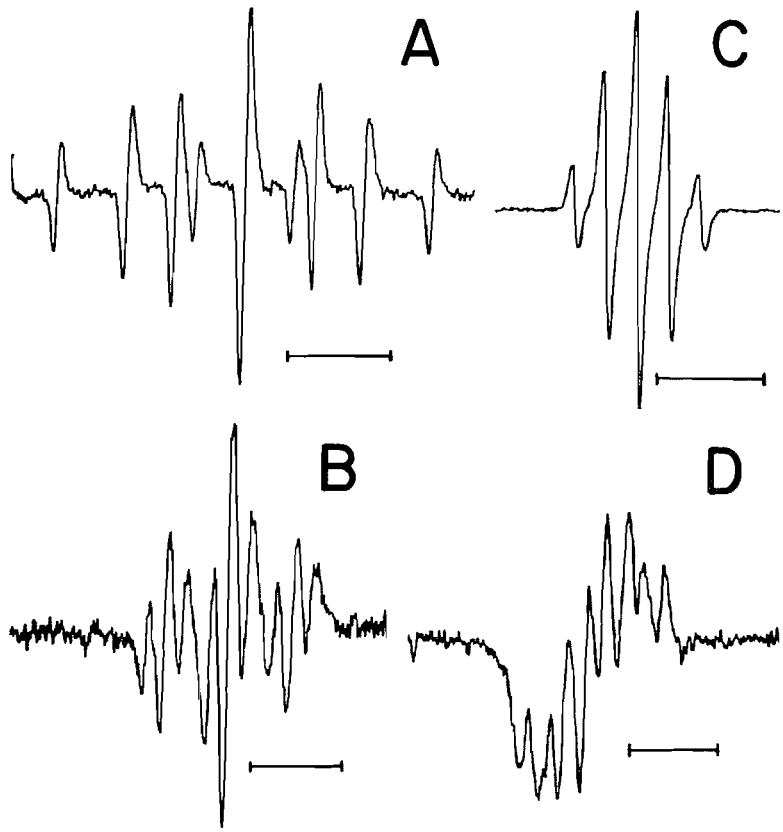

FIG. 2. First derivative e.p.r. spectra in 1,2-dimethoxyethane. LEGEND: A, 4-methylcyclohexyl ketyl at +61°; B, cycloheptyl ketyl at +72°; C, cyclooctyl ketyl at +24°; D, cyclooctyl ketyl at −35°. The bar in each case represents 10 Oe.

Care was taken to use excess potassium in the preparation of the samples to effect complete conversion of the ketone into the ketyl, so as to prevent broadening of the lines resulting from the electron exchange between ketyl and ketone (10). This more pronounced temperature dependence of the e.p.r. spectra of the substituted cyclohexyl ketyls indicates an appreciably larger energy barrier to inversion than exists in cyclohexyl ketyl itself.

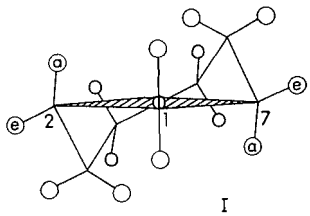
Seven-Membered Ring

Cycloheptyl ketyl gives a well-resolved spectrum consisting of 1:2:1 triplets of 1:2:1 triplets at room temperature with a_H = 7.02 and 2.08 Oe (Fig. 2B). This shows that the conformation of the radical ion is 'frozen' with respect to the difference in the hyperfine frequencies between the two conformers and indicates a lower frequency of conformational inversion than that which obtains in analogues having six-membered rings. The shape of the spectrum is unaltered when the temperature is lowered to −40°, showing that a conformational equilibration between only two forms is involved (see later discussion on 10- and 12-membered rings). The spectrum is unchanged up to +86°, at which temperature decomposition appears to take place. Clearly, the cycloheptyl ketyl interconverts between two conformational forms which have a plane of symmetry through the C—O

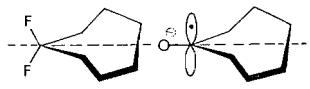
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

bond axis at a rate much slower than that corresponding to the frequency difference of the two couplings (approximately 6×10^7 s^{-1}) up to a temperature of $+86°$.

The most detailed calculation of the conformational energies of cycloheptane yet reported (3) predicts the 'chair' form to be more stable than the 'boat' form. (These conformers are analogues to the cyclohexane forms.) A particular arrangement of the cycloheptane chair, the 'twist-chair' (I), was considerably preferred over other alternatives.



I



II

III

The most comfortable positions for the carbonyl group in cycloheptanone have been predicted to be at C-1, C-2, or C-7 (11) of the 'twist-chair' form of cycloheptanone (I). Since placing the $C—O^{\ominus}$ group only at the C-1 position in I yields a molecular form with a plane of symmetry, we may speculate that III is the preferred conformation of the ketyl. Coupling from two pairs of equivalent protons at the C-2 and C-7 positions would be expected to give rise to couplings of the order of those observed, since the dihedral angles are substantially different. It is interesting to note that recent nuclear magnetic resonance studies (12) of 1,1-difluorocycloheptane (II) show that this molecule interconverts between two 'twist-chair' conformations which have a similar plane of symmetry through the C-1 position.

Eight-Membered Rings

In rings of more than seven carbons transannular interactions become increasingly important in conformational considerations until one reaches rings which are large enough to approximate open chain compounds. At room temperature the spectrum of cyclooctyl ketyl consists of five lines (1:4:6:4:1; $a_H = 3.45$ Oe) clearly arising from four equivalent protons (Fig. 2C). This form of the spectrum is retained up to a temperature of $+88°$. At temperatures below $+14°$ an additional fine structure makes its appearance until, at $-35°$, eight clearly resolved lines with an intensity pattern close to 1:1:3:3:3:3:1:1, $a_{H_1} = 4.47$, $a_{H_2} = 2.35$ Oe, are observed (Fig. 2D). This spectrum arises from coupling of the unpaired electron to *three* equivalent protons and a single proton, and represents a 'freezing out' of the conformation, i.e. rate $\ll 3 \times 10^7$ s^{-1}. These interesting observations show that at room temperature the eight-membered ketyl is inverting more rapidly than the seven-membered analogue, that as a result of its marked temperature dependence the energy barrier to inversion is greater than that for the six-membered ring, and that inversion takes place between two conformers which do *not* possess a plane of symmetry through the C—O bond.

These dramatic changes, with temperature, of e.p.r. spectra from common intermediates show that consideration of conformational phenomena should be made in the interpretation of all e.p.r. spectra of cyclic radical species.

Ten- and Twelve-Membered Rings

Larger rings would be expected to show greater conformational freedom than six- or seven-membered rings. Consequently, the simple assumption of interconversion between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

only two conformational forms is no longer valid. The existence of two or more equilibria between different conformational forms, which do not necessarily occur at the same rate, is therefore to be anticipated. Such considerations apply in the cases of the 10- and 12-membered rings.

The room temperature spectrum of cyclododecyl ketyl consists of three lines (a_H = 9.25 Oe), with the central line appreciably broader and less intense than the outer lines (Fig. 3C). Raising the temperature causes a marked sharpening of the central resonance

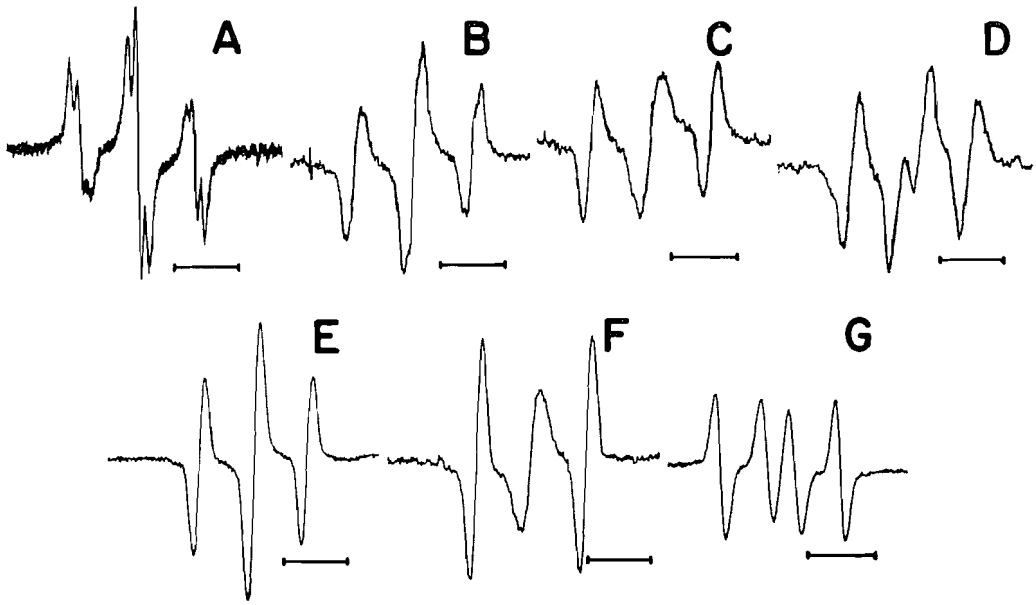


FIG. 3. First derivative e.p.r. spectra in 1,2-dimethoxyethane. LEGEND: A, cyclododecyl ketyl at +83°; B, cyclododecyl ketyl at +62°; C, cyclododecyl ketyl at +20°; D, cyclododecyl ketyl at −35°; E, cyclodecyl ketyl at +90°; F, cyclodecyl ketyl at +20°; G, cyclodecyl ketyl at −32°. The bar in each case represents 10 Oe.

until, at +61°, a 1:2:1 triplet is observed (Fig. 3B). At +83° further splitting of each line can be seen and the spectrum consists of a 1:2:1 triplet of 1:2:1 triplets (a_{H_1} = 9.02, a_{H_2} = 1.67 Oe) showing coupling to two pairs of equivalent protons (Fig. 3A). As the temperature is lowered below 0° the central line becomes increasingly broad, until at −35° four distinct lines are observed, corresponding to coupling to *two* non-equivalent protons, a_H = 11.0 and 7.3 Oe, respectively (Fig. 3D). It is noteworthy that the overall splitting remains constant at ~18.3 Oe and that these dramatic changes are completely reversible, confirming that we are dealing with conformational forms. We interpreted these observations in terms of simultaneous conformational equilibria.

At −35° interconversion occurs between pairs of conformers (which have no plane of symmetry through the C—O bond axis) at a rate much slower than that corresponding to the difference in the hyperfine frequencies. At this temperature in these equivalent conformations, coupling of 11.0 and 7.3 Oe occurs with two protons at the C-2 and (or) C-12 positions, the remaining two protons having couplings close to 0. At room temperature the interconversion between these conformers takes place at a rate now comparable with the hyperfine frequency difference, thus accounting for the broadening of the central line of the triplet. The appearance of the spectrum under these conditions (~+20°) can

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

be explained by an argument similar to that used by Dixon and Norman (13) to interpret the e.p.r. spectra of radicals derived from hydrogen abstraction from dioxane, cyclohexanol, and cyclohexylamine at room temperature.

TABLE I

Nuclear spin orientations in conformer A		Total spin interaction in:			
x	y	Conformer A	Conformer B	Difference	Average
+	+	$x+y$	$x+y$	0	$x+y$
+	−	$x-y$	$-x+y$	$+2x-2y$	0
−	+	$-x+y$	$x-y$	$-2x+2y$	0
−	−	$-x-y$	$-x-y$	0	$-x-y$

Since two of the protons at the C-2 and C-12 positions have 0 hyperfine couplings under these conditions, one need not consider their spin orientations in this discussion. x and y represent the positions adopted by the remaining (coupled) protons, analogous to axial and equatorial protons in cyclohexane. If an x proton changes places with a y proton of different spin in the conformational equilibria, a change in total nuclear spin interaction will result. Table I shows the difference and average spin interactions which result from the equilibration. The 'difference' column predicts that the two outer lines are not subject to change and therefore remain sharp, whereas there are two ways in which the central resonance will be changed, so that a broadened line equal to twice the intensity of the flanking lines is predicted. Examination of Fig. 3C shows that these predictions are confirmed.

As the temperature is raised to $\sim+62°$, interconversion is sufficiently rapid to produce an accurate 1:2:1 triplet (a_H = 9.25 Oe), indicating complete averaging of the two coupling constants 11.0 and 7.30 Oe. At this temperature the individual lines of the triplet are still broad enough to prevent resolution of the additional hyperfine splitting observed at +83°, thus revealing the presence of another conformational equilibration. At +62° this latter equilibration clearly takes place at a rate comparable with the hyperfine frequency difference, but at +83° is sufficiently rapid for clear resolution of the two hyperfine couplings of 9.02 and 1.67 Oe from two pairs of protons at the C-2 and C-12 positions in a conformer of cyclododecyl ketyl which possesses a plane of symmetry through the C—O bond axis. This latter conformational equilibrium does not make a significant contribution at −35°, as shown by the fact that couplings of 9.02 and 1.67 Oe are not involved at this temperature. This type of 'locking out' of a particular conformational equilibrium at low temperatures for energetic reasons has been postulated to account for the temperature variation of the nuclear magnetic resonance spectra of fluorinated cyclooctanes (12).

The spectrum at +87° resembles that of cycloheptyl ketyl, and presumably at a still higher temperature (provided the radical did not decompose) complete averaging of the couplings of the four equivalent protons would produce a 1:4:6:4:1 spectrum. In practice, the radical begins to disappear at $\sim+98°$.

Cyclodecyl ketyl exhibits similar behavior (cf. Fig. 3). The room temperature spectrum consists of three lines spacing 8.52 Oe, with the central line much broader and less intense than the outer lines (Fig. 3F). At lower temperatures the broadening of the central line increases until at −32° four lines (1:1:1:1; a_{H_1} = 10.77, a_{H_2} = 6.50 Oe) are observed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

arising from coupling to *two* non-equivalent protons (Fig. 3G). As the temperature is raised above +20° the central line is seen to sharpen, until at +61° an accurate 1:2:1 triplet is obtained (a_H = 8.52 Oe) consistent with the rapid conformational averaging of the two couplings observed at lower temperatures. The lines are still noticeably broad, however, up to +89°, at which temperature the radical is unstable (Fig. 3E). Consequently, further splitting, which was anticipated in view of the results obtained with cyclododecanone, could not be obtained.

These phenomena can be explained in a similar way in terms of the existence of two or more simultaneous conformational equilibria.

Angular Dependence of Hyperfine Couplings in Medium-Sized Ketyls

The coupling of protons attached to a carbon atom adjacent to a carbon bearing a free electron has been predicted (2) to satisfy an equation of the type

$$a_H = B\rho \cos^2 \theta, \quad [1]$$

where θ is the dihedral angle between the H—C_α—C_π and the C_α—C_π—$2p_\pi$ orbital planes, and ρ is the spin density on C_π.

Refinements of eq. [1] have been attempted by including a second parameter (13–15)

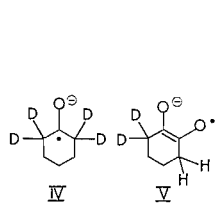
$$a_H = B_0 + B\rho \cos^2 \theta. \quad [2]$$

We derived (1) an equation of the form shown in eq. [2] which satisfactorily interpreted the observed couplings and conformational averaging for six-membered rings. It was found, not unexpectedly, that the derived equation could not be applied indiscriminately to different ring systems, because of substantial differences in unpaired spin density at the ketyl carbon in different rings.

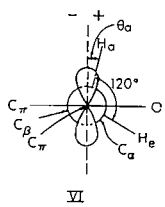
In the discussion of the geometry of the wide range of ring sizes examined here it is preferable to use the simpler original McConnell equation because of uncertainty in the magnitude and signs (15) of the parameters required by eq. [2]. This approach, requiring the minimum of assumptions, has been employed recently in a discussion of the geometry of alicyclic semiquinones (16).

A value of B = 58.5 Oe derived from the $CH_3CH_2\cdot$ radical is used, and substitution in two equations of the type shown in eq. [1] for the two observed couplings (related by $\theta_{equat.\ H} = \theta_{axial\ H} + 120°$ for tetrahedral alpha carbon) allows derivation of the values for the angles and spin density shown in Table II.

The solution of equations of the type shown in eq. [2] lead to two values of $B\rho$ and of θ (except where $\cos^2 \theta_{equat.\ H} = 0$). In accordance with previous practice (16), unrealistic solutions ($B\rho > 58.5/2$) have not been listed.



IV V



VI

The relationship of the dihedral angles considered is illustrated in VI. This type of analysis could not be carried out on the cyclodecyl ketyl at −35°, or the cyclododecyl ketyl at −32°, since coupling from only two protons was observed in both these cases. Therefore it is impossible to decide if these couplings arise from protons on the same carbon or not, and the relationship $\theta_{equat.\ H} = \theta_{axial\ H} + 120°$ cannot be applied in these cases.

‖Solvent was dimethoxymethane.
¶Angles cannot be assigned; see text.

However, since further resolution is obtained at higher temperatures, as has been noted, values for dihedral angles and parameters $B\rho$ and ρ could be obtained.

The results obtained are in good general agreement with the studies reported on the cycloalkyldione radical anions (16), which were, however, restricted to observations at room temperature. The close parallel with these latter results, also tabulated in Table II for comparison, necessitates a proof of the structure of our cycloalkyl ketyls to eliminate the possibility that our method of generation inadvertently has produced the cycloalkyldione radical anions. 2,2,6,6-Tetradeuteriocyclohexanone was prepared and treated with potassium in 1,2-dimethoxyethane, and the e.p.r. spectrum is shown in Fig. 1C. If oxidation to the radical anion V accounted for the signal, one would anticipate a nine-line spectrum similar to that shown in Fig. 1E. The much closer resemblance to that predicted for IV in Fig. 1D confirms the structure of the ketyls.

Some exchange of the deuterium is to be anticipated under the strongly basic conditions used to generate the ketyl, thereby accounting for the weak outer lines caused by traces of partially exchanged ketyl. The reduction in hyperfine coupling on deuteration equals the theoretically predicted value of 6.5.

In view of the complexity of the possible conformational forms of the medium-sized ring (3–5), it is idle to speculate about the actual shapes at this stage. An examination of the behavior of suitably substituted ketyls could, however, be expected to yield more precise information about ring geometry. Work along these lines is continuing.

In principle, it is possible to deduce conformational energy barriers from a consideration of line broadening of the e.p.r. spectra of the ketyls at different temperatures. This is very similar to problems encountered in the theory of nuclear resonance line widths when the environment of the nucleus is undergoing rapid fluctuations which change the resonance frequency. Such treatments based on the Bloch equations are commonly used (17–20). The same principles apply to e.p.r. line-width phenomena, and a theory accounting for the alternation in line widths as a result of rapid isomerization effects in the e.p.r. of radicals has been described (9). It is hoped that a computer program based on this theory will allow the derivation of energy barrier values by a comparison of observed and predicted e.p.r. line shapes.

EXPERIMENTAL

Materials

All liquid ketones, which were commercially available, were fractionated and gave single peaks on gas–liquid chromatographic analysis. The solvents used, 1,2-dimethoxyethane, dimethoxymethane, and bis-(2-methoxyethyl) ether, were refluxed over sodium metal for 12 h and fractionated.

The procedures used for the generation of the ketyls, and the recording and calibration of their e.p.r. spectra, have been described previously (1).

Temperature Control and Measurements

The temperature of the samples in the V-4532 dual cavity was controlled by passing cold dry nitrogen gas through the temperature variable unit of the Varian V-2503 spectrometer. The temperature inside the sample cavity was measured with a copper constantan thermocouple with the reference junction cooled to 0 °C. Temperature readings are estimated to have an accuracy of ±2°.

2,2,6,6-Tetradeuteriocyclohexanone

A solution of 5.06 g of cyclohexanone and 0.333 g of anhydrous potassium carbonate in 7 ml of 99.7% deuterium oxide and 10 ml of sodium-dried dioxane was refluxed for 12 h, cooled, and extracted with light petroleum (b.p. 30–60°). The extract was evaporated to a small volume *in vacuo* and the residual oil subjected to a second similar exchange. The 2,2,6,6-tetradeuteriocyclohexanone was isolated by extraction with light petroleum and fractionation *in vacuo* (b.p. 55° at 20 mm), yield 4.3 g. The nuclear magnetic resonance spectrum of the product showed removal of a band at 7.5 to 7.9 τ characteristic of the four protons alpha to the carbonyl group, with the required reduction in intensity.

The corresponding ketyl was generated with clean potassium and freshly dried, distilled 1,2-dimethoxyethane, and the e.p.r. spectrum was examined as rapidly as possible to minimize exchange.

THE DEPENDENCE OF CONCENTRATION GRADIENT ON CURRENT DENSITY AT WORKING ELECTRODES

R. N. O'Brien,[1] C. A. Rosenfield,[2] K. Kinoshita,[3] W. F. Yakymyshyn,[4] and J. Leja[5]
Inorganic Materials Research Division, University of California, Berkeley, California
Received May 11, 1965

ABSTRACT

An interferometric study of working electrodes in a cell holding less than 1 ml of solution enabled the effects of cell depth, orientation, electrolyte concentration, and temperature on the concentration gradient to be evaluated. The concentration gradient (obtained from the perturbations of a parallel fringe pattern) is an error function of current density, but every factor studied produced deviation from this relationship. The electrodeposition of the following ions has been studied: Cu^{++}, Zn^{++}, Ni^{++}, Ag^{+}, in a wide variety of electrolytes.

INTRODUCTION

There are two optical techniques which give *directly* the concentration gradient in the electrolyte at working electrodes, with no disturbing perturbation. Schlieren optical techniques (1) give a solution density contour which depends in a complicated way on the local refractive index gradient; however, it must be noted that the density of the photographic image used in the evaluation of concentration gradient is also dependent on the photographic technique.

The other technique is interferometry for which the mathematical treatment giving the location of fringes as a function of path length difference, wavelength, and refractive index is well established. The quantitative method of conversion of fringe shift to concentration change, with some examples, has been published (2, 3). An attempt to calculate complete concentration contours has also been made (4).

When electrolysis conditions are ideal, the concentration change (encountered perpendicular to the faces of parallel horizontal electrodes in the cathode-over-anode orientation) follows the expression found by integrating the differential equation $\partial c/\partial x = D(\partial^2 c/\partial x^2)$ (Fick's second law of diffusion) between appropriate boundary conditions. The expression

$$\Delta C(x, t) = \frac{2\sqrt{(Dt/l^2)}\, Ilt_-}{nFD}\ \text{ierfc}\ \frac{(1-x)/l}{2\sqrt{(Dt/l^2)}}$$

is the solution of this equation and has been found to fit recorded interferograms (4). In this expression ΔC is the change in concentration at any point at any time, D is the molar diffusion coefficient, t is time in seconds, l is 1/2 the distance between the two electrodes, I is the current density, t_- is the anion transference number (since the electroactive species is the cation in these cases) and ierfc is the complement of the integrated error function (4). Every variable considered here influences the fringes (which are concentration contours) so that the above expression does not predict the concentration gradient under normal, nonideal conditions.

EXPERIMENTAL

Figure 1 gives an exploded view of one modification of a microcell formed by the parallel faces of the metallic half-discs (electrodes), which in turn are contained between two optical flats, clamped in a holder to give a slight wedge with its axis parallel to the length of the cell. The concentration polarization was always recorded photographically, either by still or motion picture camera, as perturbations to a system of parallel, equi-spaced, wedge-type fringes oriented at 90° to the working faces of the electrodes.

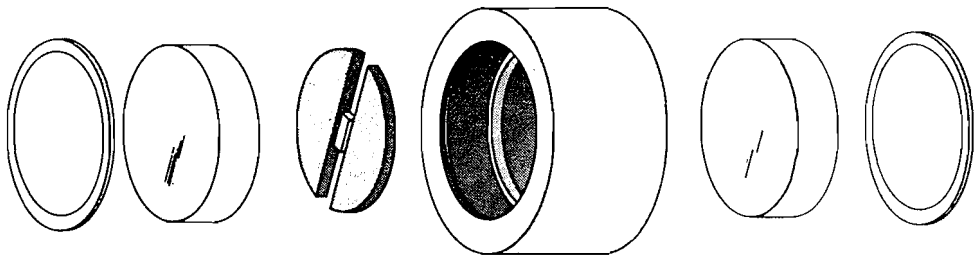

FIG. 1. The cell, exploded view, without the thermostating clamp.

When the cell is oriented in such a way that the working face of the electrode is vertical, natural convection always sets in once a certain current density (c.d.) (about 0.3 mA/cm²) is exceeded; about 15 s after the start of electrolysis its effects become noticeable. Since a quasi-steady-state is established in about 1 min, 3 min or more of electrolysis was allowed before recording any interferogram with a still camera. The concentration polarization was evaluated in two ways. In the first, a value of the concentration gradient which should be very little affected by convection was found by taking the slope of the fringes as close to the electrode as the optical resolution of the instrument would allow and converting this to $\partial c/\partial x$ (where x is the distance in cm measured perpendicularly to the electrode and c is concentration in moles/l). In the second, the total concentration change at an electrode may be found by noting the total displacement of any typical individual fringe (at vertical electrodes, except when they are closer than about 0.75 mm, there always remains a central portion uneffected by concentration changes which may be used as a reference). A knowledge of refractive index change with concentration of the electroactive species and of some cell parameters is required for this method (2).

When the electrode working faces are *horizontal* two distinctly different modes of transport of charge exist. If the anode is above the cathode, although there is always a diffusion layer, convection is the main transport mechanism; moreover it is turbulent convection with consequent unpredictably deep penetrations into the diffusion layer. Although the process is an interesting one and has been investigated it will be mentioned only briefly when the effect of orientation is discussed.

When the cathode is over the anode, diffusion is the principal transport mechanism and no steady-state develops until the gradient extends completely across the cell, but the gradient $\partial c/\partial x$ does not change appreciably during the process and this has been used as a usefully accurate parameter in comparison with vertical electrodes. Interferograms in this orientation were usually recorded with a motion picture camera.

Monochromatic collimated light (either the Na_D line or a continuous, uniphase output C.W. gas laser giving a wavelength of 6 328 Å) is passed through the cell. The coatings on the flats split the amplitude forming two beams (Fig. 2), one passing through, the other reflected back and forth until coherent, parallel, superimposed beams emerge and interfere to produce wedge fringes or fringes of equal thickness. Fringes, light or dark, appear at those places on the wedge where the thickness of the wedge is an integral number of half wavelengths; or, if the refractive index of a solution is varying, at $n\lambda = 2\mu l \cos\phi$. λ is the wavelength,

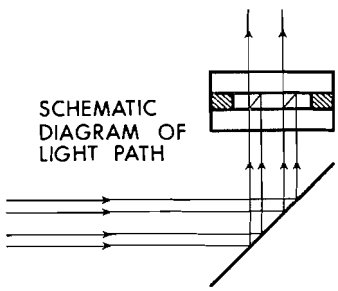

FIG. 2. Schematic diagram of the light path showing how the coated flats split the amplitude of the collimated light into two beams that interfere. No further optics are needed except a recording camera.

n is an integer known as the order of interference, μ the refractive index, t the thickness, ϕ the angle of incidence of the light with $\cos\phi = 1$ usually. The necessary wedge angle was produced by tightening screws in a massive brass clamp. The clamp was drilled appropriately to act as a thermostat and achieved a constant temperature to ± 0.1 °C. The principal cell used was $Cu/CuSO_4/Cu$ and all data reported pertain to it except where noted. The metals Cu, Zn, Ag, and Ni were of highest purity and polycrystalline. Electrodes were first cut out as discs polished flat on 400 or finer emery paper; then the discs were halved and the edges polished. The halved discs were washed in distilled water, immersed in an appropriate acid until the grain boundaries were visible, then washed again in distilled water, dried, and quickly assembled into the cell with a minimum of handling. When precautions were taken to eliminate contamination, no noticeable differences were observed; a trial run, in which all parts of the cell and all auxiliary vessels (which the electrolyte comes in contact with) were refluxed in a soxlet extractor with acetone and handled only with rubber gloves, showed no variation in specific conductivity. It is thought that this lack of sensitivity to purification procedures is due to the high electrode surface – electrolyte volume ratio, about 2 cm^2 and 0.2 ml (compared to 10 cm^2 and 200 ml in the usual cells, i.e. a ratio about 200 times greater).

A variety of cameras have been used. The basic requirement is that the lens opening be of a diameter 2 to 3 times greater than the distance between the electrodes. It is also desirable to have the best optics and the possibility of taking several pictures in quick succession. A 16 mm motion picture camera has been used successfully (4, 5).

All electrolyte solutions were made with highest purity reagents and conductivity water, and their concentrations were checked by appropriate titrations.

A large body of auxiliary information (6) such as refractive indices, (for a variety of ions in water at various pH's, concentrations, and temperatures) trial runs in different solvents (alcohols) and with different anions, etc. has been collected. Some work has also been done on the dependence of refractive index on frequency.

The interferograms (several thousands of them) have been measured using a variety of devices, such as a mm graticule, photographic prints, and a light box; then by draughting instruments after projection onto a ground-glass-topped table. A travelling photosensitive cell has been used but found to be unsatisfactory. A digitalized measuring microscope which produces five significant figure measurements on computer cards is the most recent system used.

RESULTS

The Effect of Current Density and Concentration

Figures 3 and 4 show total concentration change in the diffusion layer at various current densities and concentrations in the cell $Cu/CuSO_4/Cu$ with shallow (1.92 mm) vertical electrodes for the anode and the cathode. A wide range of concentrations of electrolyte was used. Precipitation of copper sulfate crystals was observed in the saturated solution at the anode; in Fig. 4 the vertical straight line at 1 g/l concentration change for the 1 g/l solution shows that no secondary reaction is occurring. No bubbles were observed in this solution at the cathode but some optical effects interpreted as increased convection velocity were noted.

The Effect of Depth of Cell with Vertical Electrodes

Since Ibl (7) has shown that the velocity of the electrolyte in a convective whorl is proportional to the 3/5 power of the height of the electrode and the 2/5 power of the current density, one would expect that both the depth of the cell and the current density would have some effect on the maximum concentration polarization attained for a set of given conditions.

Figure 5 shows the effect of depth (height) of electrodes. The best-fit curve to all points is drawn but the shallower electrodes have the least total concentration change per unit current density (c.d.). This slight influence of depth of solution will again be pointed out when plots of $\partial c/\partial x$ vs c.d. are considered. It has been shown that it is the height of the electrode not the depth of the electrolyte that controls the convective effects (8).

Effect of Temperature

Figure 6 shows the effect of temperature on concentration change at constant current density. The total concentration developed according to Keulegan (9) and others is

$$\frac{\partial n_j}{\partial t} = AD_j \frac{\partial c_j}{\partial x} + AU_j C_j Z_j e \frac{\partial v}{\partial x}$$

where $\partial n_j/\partial t$ is the number of ions of the jth kind passing a cross-sectional reference frame per second, A is the reference frame area, D is the Fick diffusion constant, C the concentration, U the mobility of the ion, Z its valence, V the applied potential, and X the distance perpendicular to the electrode. The second term describes the effect of electromigration.

Only the diffusion constant and the mobility should be affected by temperature. The mobility and the diffusivity are connected through the Einstein relation $D = UkT$ where k is Boltzmann's constant and T is the absolute temperature. Thus only the diffusion coefficient need be considered. If the Einstein–Stokes equation is valid for the system then $D = kT/6\pi\eta r$ where η is the viscosity and r the effective radius of the hydrated ion. Both η and r should be affected by temperature exponentially; r in an unpredictable, exponential way.

The curves obtained are obviously a family of curves but they are not simple exponentials.

The Effect of Electrode Orientation

The orientation of the electrodes in the earth's gravitational field determines the dominant transport (3) process type. In all orientations electromigration occurs, but in the a/c (horizontal, anode above cathode) position only a small amount of transport of charge occurs by diffusion, whereas convection of a turbulent nature accounts for most, as illustrated in the interferogram in Fig. 7*a*. In the cathode over anode (c/a) position convection is absent and diffusion is the dominant process (Fig. 7*b*).

Hydrodynamic theory postulates a stationary film at the electrode surface of sufficient thickness to be observed interferometrically. On the strength of this, it is generally assumed that convection-perturbed systems should have a film next to the electrode where the

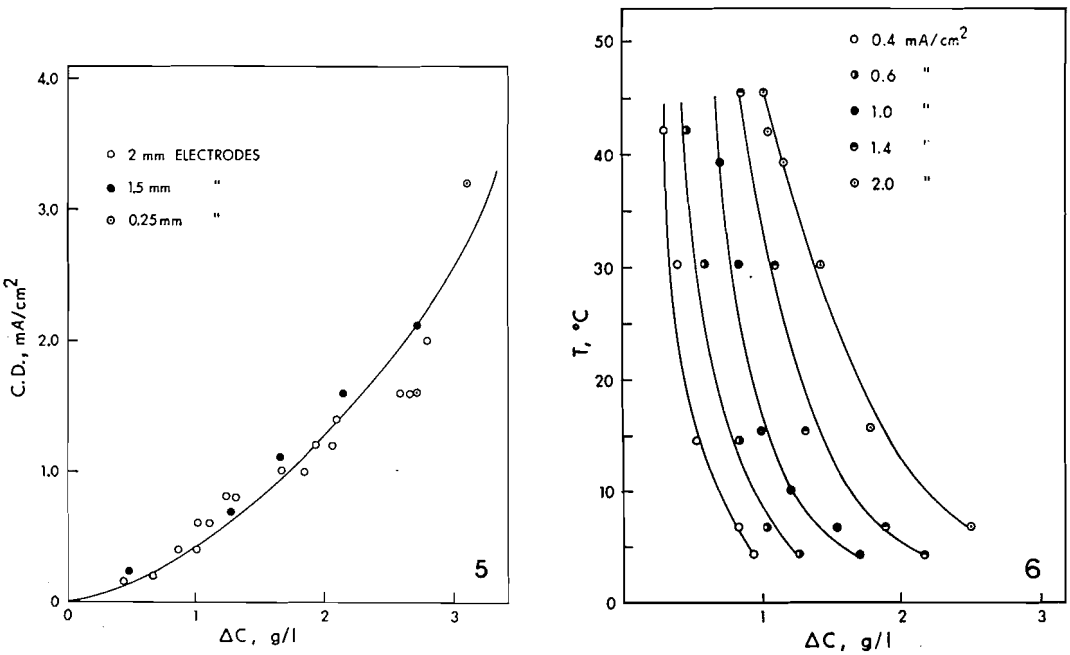

FIG. 5. The effect of depth in shallow vertical electrodes on total concentration change ($Cu/CuSO_4/Cu$ system) at 7.5 °C at the anode.

FIG. 6. The effect of temperature on total concentration change at constant current density ($Cu/CuSO_4/Cu$).

concentration gradient $(\partial c/\partial x)_{x=0}$ should approximate that of a convectionless system, and hence the gradient at $x = 0$ should be independent of electrode orientation. Figure 7 shows that this is not true. Thermodynamically, since $\partial \Delta G/\partial x$ (in each orientation at the same current density) is different for $x = 0$, the concentration gradient at $x = 0$ should also be different. This effect and others which occur close to electrodes has been extensively studied (13).

Figure 8 shows $\partial c/\partial x$ for various c.d.'s in 0.1 N $CuSO_4$, anode and cathode. The relationships are shown for two vertical electrode depths 2 mm (s.v.), shallow vertical, and 38 mm (d.v.), deep vertical, and also for the cathode over anode position. The nearly straight line of the 38 mm deep vertical electrodes suggests that considerable depth of electrode makes for less complicated concentration contour slopes. It also prevents large pH changes at the electrodes as the c.d. and time of electrolysis are increased.

Cell Geometry

A proper design of the cell ensures minimum pH change between the two electrodes (10). It has been observed in this laboratory that when the electrodes are separated by a distance which is more than about 1/3 of the height of the electrode, two convective whorls (with overflow and underflow) (3) tend to form; this appears to be the most efficient configuration to minimize pH gradients at the electrodes. Significantly, such a configuration does not yield the highest c.d. per applied voltage (11). A systematic investigation now underway suggests that whenever there is no chemical reaction either in solution or at the electrode, pH changes do not affect the dependence of concentration change on c.d. (12). Similarly the addition of inert salt as supporting electrolyte has little effect (6).

Concentration Change with Current Density in Other Electrolyte Systems

Exploratory work in Fe^{3+}/Fe^{2+} solution, Ag^+, Ni^{2+}, and Zn^{2+} suggests that the same general dependence of concentration polarization on current density obtains in other systems.

In the case of the $Zn/ZnSO_4/Zn$ system (3*a*) the deep vertical electrodes gave $\partial c/\partial x$ values nearly identical with the c/a values, whereas the values for the shallow vertical electrodes coincided with those for $Cu/CuSO_4/Cu$ (Fig. 8).

Some exploratory work, carried out in buffered and chelated solutions, suggests that there are no general qualitative variations in results.

CONCLUSIONS

Although the results show that the concentration gradient at an electrode is proportional to the c.d., the proportionality factor depends on practically every conceivable variable; accordingly, if $\partial c/\partial x$ or just ΔC is to be used as a measure of the c.d., a calibration curve must first be obtained. When all variables are kept constant except for the electrochemical activity of the various portions of the electrode surface, then, from the average c.d., the true local c.d. can be obtained.

DESERT PLANT CONSTITUENTS

II.[1] OCOTILLOL: AN INTERMEDIATE IN THE OXIDATION OF HYDROXY ISOÖCTENYL SIDE CHAINS[1]

E. W. WARNHOFF[2] AND C. M. M. HALLS
Department of Chemistry, University of Western Ontario, London, Ontario
Received July 20, 1965

ABSTRACT

Ocotillol, $C_{30}H_{52}O_3$, a triterpene isolated from *Fouquieria splendens* Engelm., has been found to have structure I containing a new side chain modification. Confirmation was provided by a partial synthesis from dammarenediol-II monoacetate VII*a*. Ocotillol has been found to be an intermediate in one path for the chromic acid oxidation of the hydroxy isoöctenyl side chain XVI, a common feature of several triterpenes, to the tris nor γ-lactone XIX.

In parts of the Sonoran Desert of southwestern North America the most conspicuous form of vegetation is the ocotillo (2).[3] This singular plant (*Fouquieria splendens* Engelm.) (Fig. 1) belongs to a small family (Fouquieriaceae) which has not previously been investigated chemically.[4] Its long branches are covered with a resinous bark and formidable spines. During the wet season the branches also bear leaves (Fig. 1*a*, 1*b*) which drop off at the onset of dry periods (Fig. 1*c*). However, even after the leaves have fallen, the plant is apparently able to synthesize food, for underneath the tough laminated bark there is a chlorophyll layer. Light which reaches this layer could only do so by passing through the translucent bark. Any organic compounds in this resinous bark have thus been subjected to intense desert sunlight for many years, and it would be suprising if some photochemical transformation products had not been formed during this long irradiation period. With the hope of finding such products, a chemical investigation of the plant was initiated.

Isolation and Determination of Structure

Continuous ether extraction of ocotillo bark gave 10% of clear amber resin which was a mixture of 10 or more compounds. Attempts to separate this mixture by alumina chromatography afforded small amounts of two crystalline compounds, m.p. 260.5° and m.p. 200°. Greater success was attained when the resin was first saponified with methanolic potassium hydroxide. When the base-insoluble saponification fraction (60% of the resin weight) was chromatographed on alumina, thin-layer chromatography (t.l.c.) indicated the presence of three major components. One of these (16% of the unsaponified resin) could be purified by recrystallization to give a new compound, ocotillol, $C_{30}H_{52}O_3$, m.p. 198–200°, $[\alpha]_D$ +28°, which was identical with the compound of m.p. 200° that was obtained from the unsaponified resin. However, ocotillol was more conveniently isolated by direct crystallization of its high-melting monoacetate from the acetylation product of the base-insoluble saponification fraction. The infrared spectrum of ocotillol showed the presence of hydroxyl absorption at 3 622 cm^{-1} (secondary OH) and 3 580 cm^{-1} (intramolecularly hydrogen-bonded OH) (5), but no carbonyl peaks. The ultraviolet spectrum

[1]*Part I is considered to be reference 1 in which a preliminary account of some of this work appeared. Presented in part at the 47th Annual Conference of the Chemical Institute of Canada, Kingston, June 1964.*
[2]*Fellow of the Alfred P. Sloan Foundation.*
[3]*Spanish diminutive derivative of the Nahuatl word ocotl, a certain species of pine tree.*
[4]*The results of two earlier general examinations are given in references 3 and 4.*

revealed a complete absence of double bonds, an uncommon feature which temporarily encouraged thoughts of a photochemically transformed triterpene. In agreement, the nuclear magnetic resonance (n.m.r.) spectrum had no vinyl hydrogen peaks, but did have two multiplets (1H each) at δ 3.73 and 3.18 p.p.m. from protons bonded to carbon atoms bearing oxygen functions. Of the eight methyl groups visible in the spectrum, three were at appreciably lower field (δ 1.12–1.21 p.p.m.) than the others. The only structural feature present that could be capable of such deshielding action was oxygen substitution on the carbon atoms bearing these methyl groups.

Reaction with acetic anhydride – pyridine at room temperature gave as the only product a monoacetate, $C_{32}H_{54}O_4$, m.p. 260–261.5°, which proved to be identical with the second crystalline compound from chromatography of the unsaponified resin. The infrared spectrum had an ester carbonyl peak at 1 734 cm^{-1} and only one hydroxyl peak at 3 580 cm^{-1} (intramolecularly hydrogen-bonded OH) (5). An acetate methyl peak appeared at δ 2.03 p.p.m. in the n.m.r. spectrum, and the H—C—O multiplet formerly at δ 3.18 p.p.m. was now shifted to δ 4.50 p.p.m., as expected of the hydrogen on a carbon atom bearing a secondary hydroxyl group (6). More vigorous reaction of the monoacetate with acetic anhydride – pyridine at reflux furnished a diacetate, $C_{34}H_{56}O_5$, which had no hydroxyl infrared absorption. Its n.m.r. spectrum had two acetate methyl peaks at δ 1.96 and 2.03 p.p.m. However, the H—C—O multiplet at δ 3.73 p.p.m. in ocotillol and ocotillol monoacetate had moved only to δ 3.95 p.p.m. Saponification of both acetates regenerated ocotillol. From the facts just presented, ocotillol must be a saturated tetracarbocyclic triterpene with a secondary hydroxyl group, an intramolecularly hydrogen-bonded tertiary hydroxyl group, and an oxide ring with a single hydrogen atom on an α-carbon.[5] The hydroxyl groups were not vicinal since ocotillol was unaffected by sodium metaperiodate.

Oxidation of ocotillol by chromium trioxide in acetic acid at room temperature produced acetone, isolated as the 2,4-dinitrophenylhydrazone, and a keto γ-lactone, $C_{27}H_{42}O_3$, m.p. 182.5–184.5°, $[\alpha]_D$ +71°, as the only products. In like manner ocotillol monoacetate was rapidly oxidized at room temperature with the consumption of 1.37 moles of chromium trioxide per mole of acetate. The only non-volatile product formed in almost quantitative yield was an acetate γ-lactone, $C_{29}H_{46}O_4$. These facile oxidations with loss of three carbon atoms were reminiscent of the oxidation of the dammarenediols VII*b* (7), dipterocarpol VI (8), folientriol (9), and methyl dammarenolate (10). In fact the physical constants for the keto lactone were the same as those reported, m.p. 183–185°, $[\alpha]_D$ +69° to +71°, by three different groups (7, 8, 11) for the keto lactone IV from dammarenediol-II (VII*b*). The methyl peaks in the n.m.r. spectra of the keto γ-lactone and the acetate γ-lactone also corresponded to those reported (12) for IV and V*a*. A direct comparison of the two pairs of compounds revealed them to be identical, thus establishing the structure of the fused ring system of ocotillol. The oxide ring and the other hydroxyl group of the molecule were therefore restricted to the side chain.

Of the four conceivable side chain formulations A, B, C, and D with oxygen at some or all of carbon atoms C-20, C-24, and C-25 as required by the chromic acid oxidation products, three of these can be eliminated. While there are reasonable mechanisms by

[5]*A triol formula, $C_{30}H_{54}O_3$, for ocotillol is not excluded by the analytical data, but it is excluded by the absence of hydroxyl absorption in the infrared spectrum of the diacetate as well as by the amount of chromium VI consumed on oxidation of the monoacetate to the acetate lactone; a triol would have required 2.00 moles of chromium trioxide per mole of monoacetate as compared with the 1.37 moles actually found. After this work was concluded, the mass spectrum of ocotillol was taken by Dr. G. Snatzke in connection with his work on gratiogenin. The molecular ion at m/e 460 confirmed the molecular formula.*

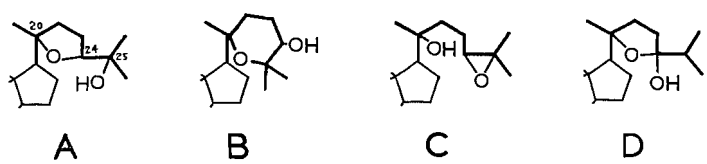
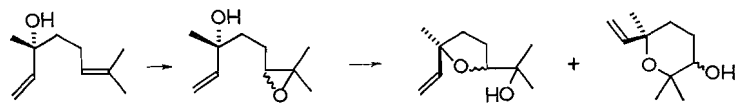
which each could be oxidized in acid solution to a γ-lactone and acetone with the consumption of 1.33 moles of chromium^{VI} per mole of compound, only A is consistent with *all* of the following observations: ocotillol (*a*) forms only a monoacetate at room temperature, (*b*) has three CH_3—C—O and two H—C—O groups, (*c*) is unchanged by anhydrous hydrogen chloride at room temperature, (*d*) is not affected by boiling methanolic potassium hydroxide, (*e*) is recovered from reflux with lithium aluminium hydride in ether or dioxane, and (*f*) is not oxidized by the chromium trioxide – pyridine reagent after monoacetylation. If ocotillol had a tetrahydropyran side chain B, (i) it would have formed the diacetate at room temperature, (ii) *both* H—C—O groups would have been strongly shifted to lower field in the n.m.r. spectrum of the diacetate, and (iii) ocotillol acetate would have been oxidized to a keto acetate by the chromic acid – pyridine reagent since the closely related linalool derivative XV is oxidized to a ketone by this reagent (13, 14).



Therefore, ocotillol has the structure I, its monoacetate formula II, and the diacetate formula III. When this structure was originally proposed (1), the hydroxy tetrahydrofuran appendage was a new terpenoid side chain modification. At about the same time it was recognized in gratiogenin X (15).[6]

Partial Synthesis

The structure I banished consideration of a photochemical origin for ocotillol and suggested that it was probably formed in the plant from a dammarenediol derivative by the biogenetic equivalent of 1,2-epoxidation at C_{24}=C_{25} with subsequent oxide opening at C-24 by the C-20 hydroxyl group. This possibility was later rendered more likely by the discovery in Thailand of a closely related naturally occurring C_{24}—C_{25} oxide, aglaiol XI (16). Although oxide ring opening might occur at C-25, particularly in acid medium, five-membered rings are usually formed more rapidly than six-membered rings. Moreover, there is an excellent analogy for this course of events in the careful work on the so-called linalool oxide (13). Oxidation of R(—) linalool XII with one equivalent of monoperphthalic acid gives as the *primary* product a pair of very sensitive diastereoisomeric 1,2-epoxides XIII and not a mixture of two pairs of diastereoisomeric 1,4- and 1,5-oxides XIV and XV as previously claimed (17). The 1,2-epoxides XIII are very easily converted by acid or heat into a mixture of XIV and XV in the ratio of about 9:1, respectively, the five-membered ring being formed more rapidly even in acidic medium. Consequently, a partial synthesis of ocotillol monoacetate from dammarenediol-II monoacetate VII*a* was undertaken to confirm the structure I.



XII XIII XIV XV

Oxidation of VII*a* under the conditions that produced the true linalool oxide XIII did not permit isolation of the C_{24}—C_{25} epoxides VIII, which are apparently even more easily opened than XIII. Attempts to prepare VIII at lower temperatures or in solution buffered with triethylamine oxide were also unsuccessful. The presence of some 1,2-epoxide could be detected by t.l.c. and was further corroborated by dividing one oxidation product into two fractions, one of which was heated to 100° and the other reduced with lithium aluminium hydride. The thin-layer spot presumed to be epoxides VIII had disappeared in the heated portion with intensification of the spot corresponding to ocotillol monoacetate II, whereas the hydride reduction product contained a new component much more polar than dammarenediol-II (VII*b*) or ocotillol I, which could reasonably be only the triol IX. However, if the epoxidation of VII*a* was allowed to go to completion and worked up as usual, the product gave a single spot corresponding to II on t.l.c. Ocotillol monoacetate was crystallized directly from this product in 35% yield and shown to be identical with the natural material.

The optical rotation and n.m.r. spectrum of the residue from the filtrate betrayed the presence of a second component as well as of II in about equal amounts. From the n.m.r. spectrum and the single t.l.c. spot, the second compound is most probably the C-24 epimer of ocotillol monoacetate, but attempts to crystallize or separate it by chromatography were unsuccessful.

[6]*Dr. Snatzke has informed us that both gratiogenin and ocotillol have as the base peak in their mass spectra the ion m/e 143,* $C_8H_{15}O_2$, *from cleavage of the side chain to XX.*

Stereochemistry

The absolute configurations on the fused ring system of ocotillol at C-3, C-5, C-8, C-9, C-10, and C-14 are fixed by relation to the dammarane skeleton (8, 18), which has in turn been related (18) to *iso*euphol and *iso*tirucallol (19). The β-orientation of the C-13 hydrogen atom follows from the demonstration that the C-13 configuration of the dammarane system is the less stable one. Dammarane derivatives with a carbonyl group at C-17 (20) or at C-12 (21) are epimerized almost completely to the 13-*iso* compounds. The less stable C-13 configuration is β (rings C and D *trans* fused), and molecular rotation differences and conformational analysis support this assignment (20). On the other hand, C-17 has the more stable β-arrangement as witnessed by the stability to base of several C-20 keto derivatives (9, 18, 20). In agreement the coupling constant (10 c.p.s.) between the C-13 and C-17 protons in derivatives with a C-12 keto group is that expected for a *trans* relationship with a dihedral angle of ca. 150° (12). Of the two asymmetric centers in the side chain, the β-configuration of the C-20 hydroxyl has been assigned (21) to folientriol, folientetrol, and the II-series of dammarane compounds, but the grounds on which the assignment was made are erroneous.[7] Thus the stereochemistry at C-20 and C-24 is as yet unknown.

Hydroxy Isoöctenyl Side Chain Oxidation

The quantitative oxidation of the ocotillol side chain to a γ-lactone is merely a special case of the general oxidation of mono ethers of 1,2-diols which Chang and Westheimer (22) have studied with pinacol monomethyl ether. The rapidity of the oxidation suggested that the ocotillol side chain might be an intermediate in the earlier mentioned chromic acid oxidation of the hydroxy *iso*öctenyl side chain XVI of various triterpenes to tris nor γ-lactones XIX. This possibility was tested by oxidation of dammarenediol-II monoacetate (VII*a*) with just the amount of chromium trioxide stoichiometrically required for oxidation to II. From the reaction mixture there was isolated, in addition to lactone V*a* and recovered VII*a*, 6–13% of ocotillol monoacetate II. In view of this result, ocotillol must be an intermediate in one path for the oxidation of VII*a* to V*a*. The hydroxy *iso*öctenyl side chain XVI could produce the hydroxy tetrahydrofuran either by oxidation first to the 1,2-epoxides VIII followed by the rapid oxide opening previously noted, or by oxidation of the double bond to some such cationic intermediate as XVII which is then attacked at C-24 by the C-20 hydroxyl group (XVII → XVIII). Alternatively, the oxidation of the double bond might be an intramolecular process involving a chromate ester of the tertiary C-20 hydroxyl group. The details of this side chain oxidation are being examined further.

EXPERIMENTAL

General

Melting points: Reichert microscope hot stage, corrected.

Optical rotations: Schmidt–Haensch polarimeter, chloroform solutions, 1-dm tube.

Infrared spectra: Beckman IR-5 or IR-7 spectrometer.

Ultraviolet spectra: Bausch and Lomb Spectronic 505 or a Beckman DK spectrometer.

Nuclear magnetic resonance spectra: Varian HR-60 or A-60 spectrometer, 10–20% (g/ml) concentration in deuterochloroform with tetramethylsilane (=O) as internal reference. Integrations by the cut-and-weigh method.

Chromatography: Woelm neutral alumina graded according to the Brockman scale.

Thin-layer chromatography: Camag Kieselgel silica gel with calcium sulphate binder, methanol:chloroform (1.5:98.5) for development, sulphuric acid (33%) for charring. Reported R_f values are taken from one plate on which all compounds were present.

Microanalyses: Dr. A. Bernhardt and associates, Mülheim, Germany.

Petroleum ether refers to the fraction boiling at 60–80°.

[7]*The assignment was based on a molecular rotation difference between a 20-hydroxydammarane (C-13α?) of unknown C-20 configuration and a dammarane also of unknown C-20 configuration, which had been crystallized from a mixture of dammarane isomers.*

Isolation of Ocotillo Resin

Ocotillo bark was collected in Borrego Valley, California, in January, 1962. The loose sandy soil of the region and the shallow root system of the plant make the ocotillo vulnerable to toppling by wind or rain. Since the bark of the fallen and partially dried plants was more easily stripped than that of a freshly cut branch of a living plant, most of the bark was gathered from fallen specimens. The highly resinous bark could not be ground in a Wiley or a hand mill, and instead was cut into small bits with a pair of shears. These pieces, in batches of 20–40 g, were extracted exhaustively with ether in a Soxhlet apparatus. The yield of ether-soluble material per batch varied from 10% to 15% of the weight of the bark. The resin is concentrated in the inner bark, because extraction of the yellow translucent laminated inner bark after separation from the darker outer bark gave 15% of ether-soluble resin, whereas extraction of the whole bark with ether gave only 10–11% of ether-soluble resin. From 6.15 kg of whole bark a total of 618 g (10%) of clear amber resin was obtained. Further extraction of ~~the root~~ bark with methanol gave a small amount of a dark gummy material which was not investigated further. The resin had λ_{max} 269 mμ ($E_{1cm}^{1\%}$ 34), 329 mμ ($E_{1cm}^{1\%}$ 30); $\nu_{max}^{CHCl_3}$ 3 600 and 3 400 cm^{-1} (OH), and 1 725 cm^{-1} (broad, C=O).

The absence of alkaloids in the resin was demonstrated by extraction of an ethyl acetate – chloroform solution of it with dilute hydrochloric acid. The aqueous acid solution gave no precipitate with silicotungstic acid. Basification with sodium hydroxide and extraction with chloroform gave only a trace of residue on evaporation of the dried chloroform solution.

Isolation of Ocotillol Acetate II from Unsaponified Resin (with Mr. J. F. Sollors)

A sample (889 mg) of the unsaponified resin was chromatographed on 30 g of activity I Merck alumina. Only the fractions (58 mg, 6.5%) eluted with ether:benzene (1:3 and 1:1) could be induced to crystallize. These were recrystallized five times from ethyl acetate to give colorless blades, m.p. 260–260.5°, ϵ_{204} 0, ν_{max}^{KBr} 1 724 cm^{-1} (C=O), and 1 250 cm^{-1} (C—O—C). The compound gave a single t.l.c. spot, R_f 0.63, corresponding to ocotillol acetate. The melting point of a mixture with a specimen of the compound from acetylation of ocotillol (see below) (m.p. 257.5–260°) was 257.5–260°, undepressed. There was enough material for only one analysis.

Anal. Calcd. for $C_{32}H_{54}O_4$ (502.75): C, 76.44; H, 10.83. Found: C, 74.99; H, 11.30. Mol. wt. (osmometer, chloroform solution), 513, 517.

A 10-mg sample of the compound was treated under reflux overnight with methanolic potassium hydroxide. Dilution of the reaction mixture with water precipitated a white solid which was recrystallized from 95% ethanol to yield colorless prisms, m.p. 199° (m.p. of ocotillol 198–200°). The infrared spectrum no longer showed carbonyl absorption.

From chromatography of 2.33 g of a different lot of resin there was isolated a few milligrams of I, m.p. 197–200°.

Isolation of Ocotillol I from Saponified Resin

A solution of 10.46 g of ocotillo resin in 350 ml of methanol was heated under reflux with 8 g of potassium hydroxide for 5 h. The reaction mixture was diluted with 1 liter of water and extracted with several portions of ether. The combined ethereal solutions were washed with saturated sodium chloride solution, dried over magnesium sulphate, and filtered. Evaporation of solvents left 6.119 g (ca. 60%) of amber-colored neutral saponification product. Examination by thin-layer chromatography indicated the presence of at least seven compounds of which three were present in considerable amount. Attempts to crystallize the saponification product failed.

The neutral fraction in benzene was poured onto a column of 180 g of grade II alumina, and chromatographed. Benzene:ether (75:25) eluted two fractions weighing 928 mg (15% of the neutral fraction), which crystallized spontaneously and were essentially pure (t.l.c.). Two other fractions weighing 843 mg (13% of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the neutral fraction) crystallized on trituration with ether; these contained a small amount of two contaminants. The total yield of almost pure ocotillol was about 28% of the neutral fraction or approximately 16% of the unsaponified resin. Several recrystallizations of the 928-mg fraction from benzene – petroleum ether or ethyl acetate – petroleum ether gave colorless thin prisms of pure ocotillol I, m.p. 198–200°, $[\alpha]_D^{25}$ +28.3° (*c*, 2.42), $[\alpha]_D^{25}$ +25.7° (*c*, 2.29), R_f 0.36, ϵ_{205}^{EtOH} 228, $\nu_{max}^{CCl_4}$ (IR-7) 3 622 cm^{-1} and 3 580 cm^{-1} (OH) (conc. 0.005 *M*).[8] Integration of the n.m.r. spectrum gave a total of 52–54 hydrogen atoms.

Anal. Calcd. for $C_{30}H_{52}O_3$ (460.72): C, 78.20; H, 11.38; O, 10.42. Found: C, 78.17; H, 11.02; O, 10.90. Mol. wt. (mass spectrum), 460.

From the following experiments ocotillol was recovered almost quantitatively. In each case t.l.c. examination showed I to be the only product.

(*a*) A solution of 19 mg of I and 19 mg of sodium metaperiodate in 3.25 ml of water:dioxane (5:8) was allowed to stand for 140 min at room temperature.

(*b*) A solution of 10 mg of I in 3 ml of chloroform was saturated with anhydrous hydrogen chloride and allowed to stand overnight at room temperature.

(*c*) A solution of 11.2 mg of I in 8 ml of ether was treated by reflux with 87 mg of lithium aluminium hydride for 3.5 h.

(*d*) A solution of 11.4 mg of II in 20 ml of dioxane was treated by reflux with 191 mg of lithium aluminium hydride for 8 h (yield: 6 mg of I).

Ocotillol Monoacetate II

From Pure Ocotillol

A solution of 286 mg (0.62 mmole) of ocotillol in 3 ml of dry pyridine and 0.2 ml of acetic anhydride was allowed to stand for 24 h at room temperature. The reaction mixture was diluted with water and extracted with chloroform and ether. The combined chloroform–ether extracts were washed successively with dilute sulphuric acid, water, sodium bicarbonate solution, and water. The dried (sodium sulphate) and filtered solution was evaporated, to leave 284 mg (91%) of crystalline residue, which t.l.c. showed to be almost pure monoacetate. Four recrystallizations from ethyl acetate – petroleum ether or chloroform – petroleum ether gave colorless prisms of ocotillol monoacetate II, m.p. 260–261.5°, $[\alpha]_D^{25}$ +41° (*c*, 1.13), $[\alpha]_D^{22}$ +39.5° (*c*, 2.52) and +40.5° (*c*, 2.55), R_f 0.63; $\nu_{max}^{CCl_4}$ (IR-7) 3 580 cm^{-1} (OH), 1 734 cm^{-1} (ester C=O) (conc. 0.005 *M*); $\nu_{max}^{CHCl_3}$ 3 546 cm^{-1} (OH), 1 718 cm^{-1} (ester C=O), and 1 256 cm^{-1} (C—O—C).

Anal. Calcd. for $C_{32}H_{54}O_4$ (502.74): C, 76.44; H, 10.83. Found: C, 76.85; H, 10.99.

From Neutral Saponification Product

A solution of 10 g of the neutral fraction of the resin saponification product in 80 ml of dry pyridine and 8 ml of acetic anhydride was allowed to stand for 24 h at room temperature. The reaction mixture was worked up as in the preparation of the monoacetate from pure ocotillol, except that 10% potassium hydroxide solution was used in place of sodium bicarbonate solution. The acetylated product (9.7 g) was dissolved in ethyl acetate – petroleum ether, concentrated to about 200 ml, and seeded with pure II. After several days of slow crystallization first at room temperature and then at 3°, filtration gave 953 mg (ca. 8.7%) of colorless thin prisms (almost pure II), m.p. 222–243°, in three crops. Two recrystallizations from ethyl acetate – petroleum ether gave pure ocotillol monoacetate identical with that prepared as above from pure ocotillol.

Saponification

A solution of 71 mg of ocotillol monoacetate II and 0.4 g of potassium hydroxide in 20 ml of methanol was heated under reflux for 27.5 h. Dilution with water and extraction with ether gave 51 mg (78%) of ocotillol, m.p. 193.5–197°, which gave a single t.l.c. spot. One recrystallization from benzene – petroleum ether raised the melting point to 198–198.5°, undepressed on admixture with authentic ocotillol. The infrared spectrum was identical with that of ocotillol.

Ocotillol Diacetate III

Preparation

Ocotillol monoacetate (252 mg, 0.50 mmole) was treated by reflux for 48 h in 5 ml of pyridine with 0.5 ml of acetic anhydride. The reaction mixture was diluted with water, extracted with ether, and worked up as for the monoacetylation of pure ocotillol. The crude dark brown product (278 mg) was chromatographed on 10 g of activity II alumina. Benzene – petroleum ether (50:50) eluted 193 mg (70%) of colorless crystals which gave a single t.l.c. spot, R_f 0.74. Three recrystallizations from methanol – methylene chloride gave colorless flakes of ocotillol diacetate III, m.p. 199–202°, $[\alpha]_D^{21}$ +38° (*c*, 2.60), $\nu_{max}^{CCl_4}$ 1 736 (ester C=O) and 1 250 cm^{-1} (C—O—C).

Anal. Calcd. for $C_{34}H_{56}O_5$ (544.79): C, 74.95; H, 10.36. Found: C, 75.23; H, 10.49.

An attempted acetylation in pyridine – acetic anhydride at 90° for 24 h (conditions used for diacetylation of gratiogenin X (15)) gave back monoacetate containing only a small amount of diacetate.

Saponification

A 22-mg sample of the diacetate was treated by reflux for 48 h with 88 mg of potassium hydroxide in 15 ml of methanol. Dilution with water and extraction with ether gave 19 mg of a solid, which was recrystallized

[8]*For comparison, a 0.005 M solution of 3β-cholestanol had* $\nu_{max}^{CCl_4}$ *(IR-7) 3 620* cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

from benzene – petroleum ether to yield 12.4 mg of ocotillol, m.p. 197–198°, undepressed on admixture with an authentic specimen.

Oxidation of Ocotillol Monoacetate II

Chromic Acid – Acetic Acid

A solution of 303 mg (0.61 mmole) of II in 41 ml of glacial acetic acid was added to 91 mg (0.91 mmole) of chromium trioxide in 5 drops of water and 2 ml of glacial acetic acid. The reaction mixture was almost green after 1 h. After 24 h the emerald-green solution was treated with potassium iodide. Titration of the iodine liberated by excess chromium trioxide required 2.39 ml of 0.100 *N* sodium thiosulphate (corresponding to 7.9 mg of chromium trioxide). The 83.1 mg (0.83 mmole of chromium ^{VI} consumed in the oxidation was 102% of the theoretical amount required for oxidation of II to the lactone V*a* and acetone.

The titrated reaction mixture was diluted with water and extracted with ether. The ether extracts were washed with thiosulphate solution, water, sodium bicarbonate solution, saturated sodium chloride solution, and then dried over sodium sulphate. Evaporation of the filtered solution left 347 mg of crystalline product, which retained some solvent and gave a single t.l.c. spot, R_f 0.71. One recrystallization from methanol – methylene chloride gave 211 mg (75%) of prisms of acetate lactone V*a* (3β-hydroxy tris nor dammarane 24:20 ξ_2-olide acetate), m.p. 242–245.5° unchanged on further recrystallization, $[\alpha]_D$ +42° (*c*, 2.24); $\nu_{max}^{CHCl_3}$ 1 761 cm^{-1} (γ-lactone C=O), 1 721 cm^{-1} (ester C=O), and 1 253 cm^{-1} (C—O—C) (lit. (8): m.p. 237–238°, $[\alpha]_D$ +50°). The melting point was undepressed on admixture with V*a* from dipterocarpol (8).

Anal. Calcd. for $C_{29}H_{46}O_4$ (458.66): C, 75.94; H, 10.11. Found: C, 75.66; H, 10.04.

From another reaction in which 150 mg of II was oxidized the yield of crude acetate lactone (one t.l.c. spot) was 136 mg (99%).

A solution of 136 mg of acetate lactone in 30 ml of methanol was saponified by reflux with 564 mg of potassium hydroxide. Acidification with dilute sulphuric acid and extraction with ether gave 123 mg of hydroxy lactone V*b* (single t.l.c. spot), which after four recrystallizations from methanol–water had m.p. 208.5–210°, $[\alpha]_D$ +25° (*c*, 1.42, chloroform containing 5% of 95% ethanol) (lit. (8): m.p. 205–206°, $[\alpha]_D$ +39°).

Chromium Trioxide – Pyridine

To the oxidizing agent prepared from 14.3 mg (0.143 mmole) of chromium trioxide and 0.5 ml of pyridine was added a solution of 100 mg (0.207 mmole) of II in 9 ml of pyridine. After 4.7 h at room temperature the reaction mixture was diluted with 40 ml of methylene chloride and poured onto a column of 3 g of activity III alumina. Further elution with 160 ml of methylene chloride gave a colorless eluate which was washed successively with dilute sulphuric acid, water, sodium bicarbonate solution, water, and saturated sodium chloride solution. The dried solution (sodium sulphate) was concentrated, and left 99 mg (99%) of recovered ocotillol monoacetate, m.p. 250.5–254°, $[\alpha]_D^{25}$ +36° (*c*, 2.50), which gave a single t.l.c. spot. The melting point was undepressed on admixture with the starting material, and the n.m.r. spectrum was identical with that of the starting material.

Oxidation of Ocotillol I

A mixture of 202 mg (0.44 mmole) of I, 98 mg (0.98 mmole) of chromium trioxide, and 7 drops of water in 17 ml of glacial acetic acid was allowed to react at room temperature for 24 h. Then a solution of 11 mg of sodium bisulphite in 50 ml of water was added and the reaction mixture was steam distilled. The distillate (25 ml) was treated with acidic 2,4-dinitrophenylhydrazine solution and the resulting orange precipitate (30 mg, 28%) was collected on a filter. Two recrystallizations from ethanol gave 14 mg of prisms of acetone 2,4-dinitrophenylhydrazone, m.p. 125–126°. On admixture with an authentic sample, m.p. 125–126.5°, the melting point was 124.5–125.5°. The infrared spectra of both samples in chloroform were identical.

The residue from the steam distillation was extracted with three portions of ether. The combined ethereal solutions were washed in sequence with water, sodium bicarbonate solution, water, and saturated sodium chloride solution before being dried over anhydrous sodium sulphate. Evaporation of the ether left 181 mg (99%) of crystalline residue, m.p. 173.5–181.5°, which gave a single t.l.c. spot. Three recrystallizations from absolute ethanol – petroleum ether gave 101 mg of colorless prisms of the keto lactone IV, m.p. 182.5–184.5°, $[\alpha]_D^{25}$ +71° (*c*, 2.51), ϵ_{210}^{EtOH} 55; $\nu_{max}^{CHCl_3}$ 1 757 cm^{-1} (γ-lactone), 1 698 cm^{-1} (6-ring C=O), 1 421 cm^{-1} (CH_2 C=O); $\nu_{max}^{CCl_4}$ 1 775 cm^{-1} (γ-lactone) and 1 706 cm^{-1} (6-ring C=O). On admixture with a sample of the tris nor lactone from dipterocarpol VI (≡tris nor keto lactone from dammarenediol-II), the melting point was undepressed. The infrared spectra in chloroform solution were identical. Both samples had the same R_f 0.67 on t.l.c.

Anal. Calcd. for $C_{27}H_{42}O_3$ (414.61): C, 78.21; H, 10.21; O, 11.58. Found: C, 77.84; H, 10.13; O, 11.76. Mol. wt. (mass spectrum), 414.

A blank oxidation with the same reagents but with the omission of I, followed by distillation and addition of 2,4-dinitrophenylhydrazine gave no precipitate. However, extraction of the treated distillate and chromatography on silica gel did give 12 mg of a mixture of dinitrophenylhydrazones of which the acetone derivative constituted about 6 mg. Since this is much less than the *precipitate* collected in the ocotillol oxidation, acetone is one of the products of oxidation of ocotillol.

Dammarenediol-II Monoacetate VIIa from Dipterocarpol VI

A solution of 727 mg of sodium borohydride in 40 ml of dioxane–water (1:1) was added to a solution of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1.781 g of dipterocarpol VI (≡20-hydroxydammarenone-II), R_f 0.73, m.p. 124–134°, $[\alpha]_D^{25}$ +62° (*c*, 3.47) (lit. (8): m.p. 127° and 135–136°, $[\alpha]_D$ +65°) in 60 ml of dioxane. Work-up gave 1.732 g of crude product, which was recrystallized from methanol. There was obtained 1.482 g (85%) of colorless flakes of dammarenediol-II (VII*b*), m.p. 78.5–82° (lit. (7): m.p. 131–133°), R_f 0.44, which were either solvated or polymorphic.

Acetic anhydride (1.2 ml) was added to a solution of 1.48 g of VII*b* in 12 ml of pyridine, and the reaction mixture was allowed to stand at room temperature for 26 h. Work-up as for the monoacetylation of ocotillol gave 1.571 g of yellow resin. Recrystallization from methanol yielded 1.351 g (83%) of dammarenediol-II monoacetate VII*a*, m.p. 130–134°, $[\alpha]_D^{25}$ +38° (*c*, 2.68) (lit. (7): m.p. 135–137°, $[\alpha]_D$ +37°), R_f 0.73.

Epoxidation of Dammarenediol-II Monoacetate VIIa

To a solution of 299 mg (0.615 mmole) of VII*a* in 15 ml of ether chilled in a bath of Dry Ice and acetone, 1.5 ml of an ethereal solution of monoperphthalic acid (0.687 mmole) was added. The reaction mixture was stored at −10° for 210 h, then diluted with chloroform and washed successively with sodium bicarbonate solution, water, and saturated sodium chloride solution. Evaporation of the dried ether solution (water bath temperature = 90°) left 263 mg of colorless solid, which was recrystallized from ethyl acetate – petroleum ether. Seeding with a crystal of ocotillol acetate produced 110 mg (35%) of prisms, m.p. 247–248°, $[\alpha]_D^{25}$ +37° (*c*, 2.46). Three more recrystallizations from the same solvent gave 65 mg of pure ocotillol monoacetate (II), m.p. 260–260.5°, $[\alpha]_D^{25}$ +40° (*c*, 2.50), R_f 0.63. The melting point was undepressed on admixture with an authentic sample prepared as described above. The infrared and n.m.r. spectra were identical with those of authentic II.

Anal. Calcd. for $C_{32}H_{54}O_4$ (502.74): C, 76.44; H, 10.83. Found: C, 76.58; H, 10.95.

In an attempt to isolate the C-24 epimer of ocotillol monoacetate, the mother liquors from the first crop of crystals were combined with those from another reaction and chromatographed on activity II alumina. Various fractions which gave a single t.l.c. spot corresponding in R_f to II had optical rotations ranging from $[\alpha]_D$ +31° to $[\alpha]_D$ +34°, significantly lower than II or VII*a*. The n.m.r. spectrum of this material differed from that of ocotillol monoacetate in that there were two short methyl peaks at 1.11 and 1.13 p.p.m. instead of one tall methyl peak at ~1.12 p.p.m. The material was apparently a mixture of II and its C-24 epimer in about equal amounts; however, the C-24 epimer could not be crystallized from the mixture. A calculation based on the optical rotations of pure II and the estimated composition of the mixture gives a value of $[\alpha]_D$ ca. +24° for the C-24 epimer of ocotillol monoacetate.

Chromic Acid Oxidation of Dammarenediol-II Monoacetate VIIa

Dammarenediol-II monoacetate (249 mg, 0.51 mmole) shown by t.l.c. to be free of I and II in 6 ml of glacial acetic acid containing 10 drops of water was oxidized with 33.5 mg (0.33 mmole, the theoretical amount for oxidation of VII*a* to II) of chromium trioxide at room temperature. After 14 h the reaction mixture was diluted with water and worked up as for the oxidation of ocotillol monoacetate. Thin-layer chromatography of the 237 mg of crude product indicated the presence of the acetate lactone and ocotillol monoacetate as well as unreacted starting material. To remove the lactone the product was treated by reflux in a mixture of 15 ml of methanol, 5 ml of water, and 175 mg of potassium hydroxide for about 4 h. Dilution with water and extraction of the basic solution with chloroform and ether gave 159 mg of neutral material, which was mainly a mixture of I and VII*b*. Acidification of the basic aqueous layer with dilute sulphuric acid and extraction with ether yielded 46 mg (21%) of hydroxy lactone V*b*. Acetylation of this with pyridine – acetic anhydride at room temperature gave 50 mg of acetate lactone V*a* which after two recrystallizations from methylene chloride – methanol had m.p. 241–244.5°, undepressed on admixture with an authentic sample.

The 159 mg of neutral product was dissolved in benzene – petroleum ether and chromatographed on 5 g of grade III alumina. Benzene and benzene:ether (98:2) eluted 55 mg (24%) of dammarenediol-II (VII*b*), which was identified by t.l.c. and conversion to the acetate VII*a*. Benzene:ether (98:2 to 90:10) eluted 58 mg, which t.l.c. showed to be about half II (~13% yield). Five recrystallizations from benzene – petroleum ether gave ocotillol of m.p. 195–196°, undepressed on admixture with authentic I. Acetylation of the recrystallization mother liquors gave 53 mg, which was estimated by t.l.c. to contain ca. 14 mg (~6% yield from VII*a*) of II. Three recrystallizations from ethyl acetate – petroleum ether gave 4 mg of pure II, m.p. 254–255°, undepressed on admixture with an authentic sample.

Dammarenediol-II monoacetate gave little or no ocotillol monoacetate II on oxidation with the chromic acid – pyridine reagent.

ACKNOWLEDGMENTS

The authors would like to thank the National Research Council for support, Professor G. Ourisson for the authentic specimens of IV and V*a*, and Dr. G. Snatzke, Bonn, for the mass spectra and a copy of his manuscript in advance of publication. They are also indebted to Mr. J. F. Sollors for the experiment indicated.

THE STRUCTURE OF AMINOPYRINE SALTS

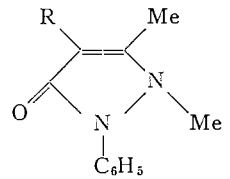
DENYS COOK
Department of National Health and Welfare, Food and Drug Directorate, Ottawa, Canada
Received June 28, 1965

ABSTRACT

The infrared spectra of aminopyrine salts can be interpreted on the basis of protonation of the 4-dimethylamino group nitrogen atom. In the hydrohalides the normal N^+—H···Y^- hydrogen bond occurs, but in salts with complex anions an intramolecular N^+—H···O=C hydrogen bond is probable, though an intermolecular one between the same partners cannot be ruled out.

INTRODUCTION

Salts of antipyrine, a substituted pyrazolone having analgesic and antipyretic properties, have recently been studied (1) to determine the site of protonation. Satisfactory evidence was presented to demonstrate unequivocally that the carbonyl group was the basic site. In aminopyrine, a chemical differing only in the addition of a 4-dimethylamino group, the possibility of protonation at the substituent nitrogen atom arises.



R = H for antipyrine

R = NH_2 for 4-aminoantipyrine

R = $N(CH_3)_2$ for aminopyrine

R = $N(CH_3)CH_2SO_3Na$ for dipyrone

The configuration of the $N(CH_3)_2$ group in the free base is not known. However, the basicity of such nitrogen atoms is much reduced when they are attached to aromatic ring systems: aniline for example has a pK_a of 4.58 while cytosine ($pK_a \sim 4.6$) protonates at the unsubstituted heterocyclic nitrogen (2), not the 4-amino group. The determination of protonation site is of intrinsic interest, and of possible metabolic application. It may also have some bearing on a problem associated with 4-amino substituted antipyrines (aminopyrine, dipyrone, and 4-aminoantipyrine) namely the generation of blood dyscrasias such as agranulocytosis (3).

RESULTS

Tables I and II list the complete frequencies found in the spectra of the salts. Those due to the protonated group are summarized in Table III.

DISCUSSION

Site of Protonation

The protonation site in organic bases has been determined from the deformation frequency, δ_{XH}, of the salt (4). Tertiary (sp^3) amine salts have δ_{NH} near 1 402 cm^{-1}, while protonated carbonyl groups absorb near 1 257 cm^{-1}. The prominent band near 1 400 cm^{-1} in aminopyrine salts, shifting to ~980 cm^{-1} in the deuterated salts, at once suggests that a tertiary (sp^3) nitrogen atom is protonated, and not a carbonyl group. Since no case of N protonation of an amide group has been proved* it is most unlikely that N_1 is protonated. The carbonyl frequency at ~ 1 660 cm^{-1} is also incompatible with N_1 protonation,

**2,2-Dimethylquinuclid-6-one, which protonates at the nitrogen atom (6), contains the amide grouping but not the planar amide configuration.*

since the value of $\sim 1\,800$ cm^{-1} is usually associated with a positively charged nitrogen atom adjacent to a carbonyl group (5–7). There is in fact a small lowering of ν_{CO} on salt formation which will be examined in greater detail later; but in the present context it indicates the unlikelihood of N_2 protonation. Where such N_2 protonation does occur, as in N-methylphthalazone, which has a similar O=C—N—N— grouping, there is a rise of $\sim$38 cm^{-1} in ν_{CO} on protonation. Such an increase in ν_{CO} is quite common for heterocyclic compounds having one atom between the C=O group and the protonation site (8).

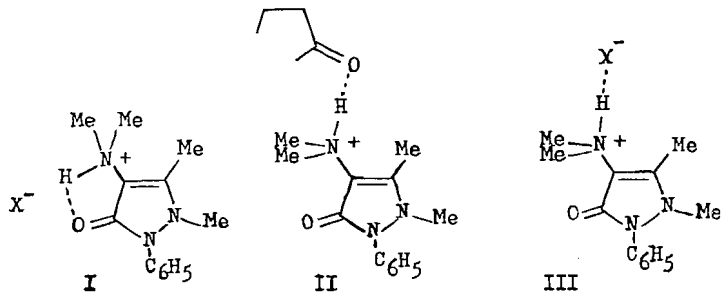
Stereochemical Arrangement at the Protonation Site

In the absence of other functional donor groups, a hydrogen-bonded NH group in a salt will usually involve the anion X^- of the acid HX used to make the salt. When another good donor atom D is present, two factors are involved in determining whether $N^+—H\cdots D$ or $N^+—H\cdots X^-$ hydrogen bonding will occur. These are the relative basicities of D and X^- and the steric requirements of the salt. Three principal configurations can be considered for aminopyrine salts. These are depicted in I, intramolecular hydrogen bond; II, inter-



molecular hydrogen bond to a carbonyl group; and III, the conventional $N^+—H\cdots X^-$ hydrogen bond.

It will be obvious from the structural arrangements in I, II, and III that the position of the NH stretching frequency should be useful in deciding which structure is correct. One would expect III to show an increase in ν_{NH} as the anionic size increased and the effect of its force field decreased, i.e. an increase in the series $Cl^- < I^- < ClO_4^-$ etc. In II, where the structure consists of chains of protonated bases with repeated $N^+—H\cdots O$ hydrogen bonds, the anion not being intimately associated with them, there should be a reasonably constant value of ν_{NH} in different salts, unless a large difference in anionic size forced a changeover to a new lattice with an abrupt change in $N^+—H\cdots O$ distance. Structure I should show a remarkably constant value of ν_{NH} since the 5-membered ring would be almost insensitive to the influence of X^-.

The value of ν_{NH} in the hydrohalides show an increase from 2 290 cm^{-1} to 2 672 cm^{-1} from the HCl salt to the HI salt. Apart from the $N^+—H\cdots X^-$ stretching vibration absorption band, the spectra are all very similar. Structure III is therefore assigned to them, and is determined by the strong $N^+—H\cdots X^-$ hydrogen bonds usually associated

For personal use only.

with halide ions. When the anionic size reaches a certain value, however, and the peripheral force gets weaker, a marked change takes place in the spectrum. Normally, in the sequence $Cl^- < Br^- < I^- < ClO_4^-$, the NH stretching frequency would still increase after the iodide. In aminopyrine perchlorate, however, ν_{NH} is 222 cm^{-1} lower than the iodide showing a change in the crystallographic arrangement. Moreover, salts of HBF_4, $HAsF_6$, and HPF_6 etc., show a value of ν_{NH} very similar to the perchlorate. This constancy in ν_{NH} means a similarity in environment, and points to either the structure I or II. At the same time distinct changes take place in the absorption band due to the carbonyl stretching vibration. From a position near 1 665 cm^{-1} in the hydrohalides it moves to near 1 620 cm^{-1} in the other salts. This is quite consistent with a change in structural type from III to I or II and the lowering in frequency ($\sim$40 cm^{-1}) is quite acceptable for either situation. These changes would not be consistent with a change in protonation site, for example, to the carbonyl group, since then the new carbonyl band (1) would be near 1 500 cm^{-1}, and the OH in-plane deformation mode (4) near 1 260 cm^{-1}.

These salts of complex monovalent acids have a higher deformation frequency, δ_{NH}, near 1 425 cm^{-1}, compared with salts of type III, where it is near 1 400 cm^{-1}. The higher frequency is compatible with the lowered stretching frequency, ν_{NH}, in the salts, and consistent with the view expressed previously that there is an inverse relationship between ν_{XH} and δ_{XH} in strong hydrogen bonds (1, 9).

In salts with complex divalent anions the behavior again reverts to that shown by the hydrohalides. The NH stretching frequency appears near 3 000 cm^{-1} in the hexafluorotitanate and hexafluorosilicate but otherwise the spectra of these salts are quite similar to the spectra of the hydrohalides. In particular, the carbonyl frequency is at its characteristic value near 1 665 cm^{-1}. There are two factors operating in this reversion to the hydrohalide structure. These are the slightly enhanced basicity of the divalent hexafluoro anions compared to the monovalent ones, and the altered stoichiometry. The size factor is of lesser importance since the SiF_6^{2-} and PF_6^- ions have similar dimensions.

X-Ray Powder Diffraction Patterns

While conclusions based on melting point variations may be misleading, a constant value throughout a series such as the $HClO_4$, HBF_4, $HAsF_6$, and HPF_6 salts of aminopyrine in the range 218 to 247° seems informative. It strengthens the conclusion that the organic portion of the salt determines the structure and the anion fits into a conveniently shaped hole of constant influence on lattice energy and melting point. This conclusion is reinforced by X-ray powder diffraction photographs showing that although the pattern of the hexafluorosilicate is unlike any of the others, the perchlorate and the tetrafluoroborate are isomorphous, and the hexafluoroarsenate and the hexafluorophosphate are isomorphous. The last two groups however are not isomorphous. This was unexpected, as the spectra suggest that all the salts shown in Table II would be isomorphous, although small changes in crystallographic arrangement could give rise to different powder diffraction patterns without altering the infrared spectrum appreciably.

The anionic sizes shown in Table IV reveal the cause of this unexpected situation. The BF_4^- and ClO_4^- anions are quite similar in size, effective radius 2.15 and 2.20 Å respectively (arbitrarily using the covalent radius of the peripheral atom) while the PF_6^- and AsF_6^- ions are a good deal larger, though comparable between themselves. In keeping with these differences in powder diffraction pattern, and anionic size, it is possible to detect slight differences in the spectra of these two groups. Table III shows the NH stretching band to be made up of two distinct groups of peaks: the first group contains

TABLE IV
Anionic dimensions (Å)

Anion	d_{MX}	r_X	$(d_{MX}+r_X)$	$(d_{MX}+r_X)^3$
BF_4^-	1.43	0.72	2.15	9.91
ClO_4^-	1.46	0.74	2.20	10.65
PF_6^-	1.73	0.72	2.45	14.70
AsF_6^-	1.85	0.72	2.57	16.96
SiF_6^{2-}	1.71	0.72	2.43	14.25

the broad band near 2 505 cm^{-1}, quite constant in position; the second group has its main band near 2 580 cm^{-1} in the HBF_4 and $HClO_4$ salts and at a slightly higher frequency, $\sim$ 2 640 cm^{-1}, in the HPF_6 and $HAsF_6$ salts. The precise assignment of these bands remains shrouded in the general uncertainty surrounding the breadth and structure of absorption bands due to hydrogen bonds. But it may be, if the salts of the monoacidic fluoro acids are in the internally hydrogen-bonded form, that some slight interaction between X^- and the protonating hydrogen atom exists and causes the spectroscopic differences referred to between the two groups.

The evidence given above slightly favors the structural type I with the internal hydrogen bond, since this would have the required small interaction with the environment. The hydrogen-bonded chain structure II might show more sign of perturbation of the hydrogen bond and therefore of ν_{NH} for small changes in crystallographic arrangement.

Finally, on steric grounds the intermolecular hydrogen bond II seems less favorable than I because of the hindering effects of the 1-phenyl group and the methyl groups of the 4-dimethylamino group. Rotation of the phenyl group might ease this, at the expense of some resonance energy, but even large rotations fo the NMe_2 group would not lessen the hindrance.

EXPERIMENTAL

Spectra

These were recorded as previously described (1).

Materials

Aminopyrine was obtained from the Aldrich Chemical Co. and was used without further purification. The salts were made in the following ways.

HCl

An ether solution of the base deposited a white precipitate of the salt on treatment with dry HCl m.p. 144–145°.

HI

Base (1.16 g) in 25 ml H_2O was mixed with 1.12 g aq. (57%) acid giving a white solid; m.p. 208–209°.

HBF_4

Base (2.31 g) in 83 ml H_2O and 1.76 g HBF_4 gave long needles on standing; m.p. 223–224°.

Anal. Calcd. $C_{13}H_{17}N_3O.HBF_4$: C, 48.92; H, 5.69; N, 13.17. Found: C, 49.25; H, 5.76; N, 13.11.

$HClO_4$

Addition of aq. (70%) $HClO_4$ to an aqueous solution of the base gave needles on standing; m.p. 228–229°.

Anal. Calcd. $C_{13}H_{17}N_3O.HClO_4$: C, 47.06; H, 5.47; N, 12.67. Found: C, 47.22; H, 5.54; N, 12.90.

HPF_6

Mixing concentrated aqueous solutions of acid and base gave a white solid after evaporation of excess water; m.p. 218–220°.

Anal. Calcd. $C_{13}H_{17}N_3O.HPF_6$: C, 41.38; H, 4.81; N, 11.14. Found: C, 40.36; H, 4.43; N, 11.04.

$HAsF_6$

Mixing of aqueous solutions of each component gave a white solid; m.p. 246–247°.

Anal. Calcd. $C_{13}H_{17}N_3O.HAsF_6$: C, 37.07; H, 4.31; N, 9.98. Found: C, 37.34; H, 4.38; N, 9.88.

H_2TiF_6

A solution of TiF_4 in aq. HF was added to the base dissolved in water, precipitating a white solid; m.p. 197–199°.

Anal. Calcd. $(C_{13}H_{17}N_3O)_2.H_2TiF_6$: C, 49.84; H, 5.79; N, 13.42. Found: C, 50.03; H, 5.60; N, 13.37.

REACTIONS OF NITRO SUGARS

II.[1] THE CONVERSION OF METHYL 6-DEOXY-6-NITRO-HEXOPYRANOSIDES INTO DEOXYNITROINOSITOLS BY ALKALINE GLYCOSIDE CLEAVAGE

HANS H. BAER AND WERNER RANK
Department of Chemistry, University of Ottawa, Ottawa, Canada
Received July 2, 1965

ABSTRACT

Methyl 6-deoxy-6-nitro-D-glucopyranoside and methyl 6-deoxy-6-nitro-L-idopyranoside under mild alkaline conditions undergo fission of the pyranoside ring followed by loss of the aglycon and cyclization of the resulting nitro sugars to a mixture of *scyllo* and *myo-1* deoxynitroinositols. A mechanism for the alkaline glycoside cleavage is proposed in which a 5,6-dideoxy-6-nitro-aldos-5-ene is an intermediate. The susceptibility to attack by base of such nitroolefins has been studied using 3-*O*-acetyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-α-D-*xylo*-hexofuranos-5-ene. It has been shown that this compound, when treated with methanolic sodium hydroxide, is methoxylated in position 5 and that this methoxylation occurs more rapidly than de-*O*-acetylation. The significance of this reaction with regard to alkaline acetal and ketal cleavages in the nitro sugar series is discussed.

INTRODUCTION

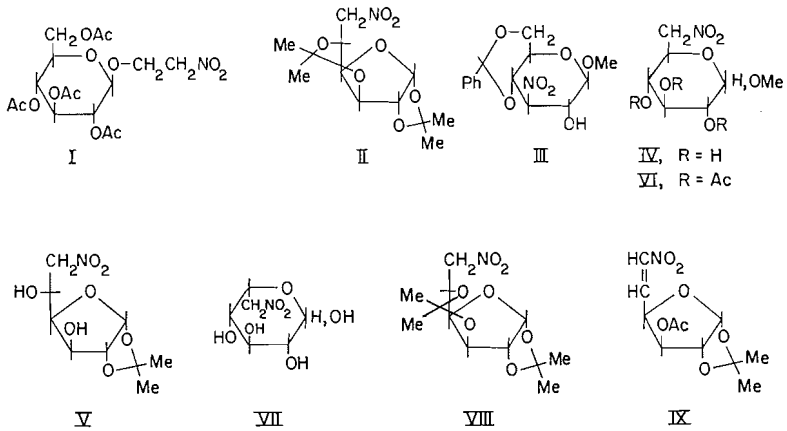
Lability towards alkali of acetals and ketals that bear a primary or secondary nitro group in the β-position has been observed on several occasions. Thus, Helferich and Hase (1) found that the base-catalyzed deacetylation of 2-nitroethyl β-D-glucopyranoside tetraacetate (I) was attended by fission of the glycosidic linkage; Fischer and Baer (2) observed a facile, alkaline removal of the 3,5-*O*-isopropylidene group in 6-deoxy-1,2:3,5-di-*O*-isopropylidene-6-nitro-α-D-glucofuranose (II)[2]; similarly, methyl 4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside (III) readily loses benzaldehyde upon treatment with alkali (4); and finally, bis(2-nitrobutoxy)methane is cleaved by aqueous sodium hydroxide at 38° to 2-nitro-1-butanol and formaldehyde (5).

In view of these facts it appeared conceivable that alkyl hexopyranosides bearing a nitro group in the 6-position, e.g. IV, might represent a novel class of alkali-sensitive glycosides (cf. ref. 6), which would differ from Helferich and Hase's labile glycoside in that the activating substituent is located in the sugar moiety rather than the aglycon. If fission occurs it would be expected to take place between the ring oxygen and C-5 rather than between the lactol oxygen and aglycon. Compounds of this type were therefore prepared, and their predicted alkali cleavage was verified.

MATERIALS

Heating of 6-deoxy-1,2-*O*-isopropylidene-6-nitro-α-D-glucofuranose (V) under reflux in methanol containing 1% of hydrogen chloride produced a syrupy α,β mixture of methyl 6-deoxy-6-nitro-D-glucopyranosides (IV). Acetylation of this material produced a crystalline mixture of the 2,3,4-tri-*O*-acetates (VI) from which the pure α-anomer was obtained after lengthy recrystallizations. Since the anomeric configuration was not regarded as being of prime relevance to an initial study of the present problem, the mixtures IV and

[1] *For Part I, see ref. 8.*
[2] *Under the conditions employed (action of dilute methanolic sodium hydroxide for 30 min at room temperature) the 5-epimeric, L-idose analog of II (VIII) appeared more stable. However, recent investigations have shown that in this case complete loss of the 3,5 acetone group occurs within 3 h at 50° (3).*



Formula VII should have OMe instead of OH at position 1.

VI were used in the subsequent work. Similarly, α,β mixtures of methyl 6-deoxy-6-nitro-L-idopyranoside (VII) were prepared. This was done best by methanolysis of crystalline 6-deoxy-1,2:3,5-di-*O*-isopropylidene-6-nitro-β-L-idofuranose (VIII). Glycosidation of free 6-deoxy-6-nitro-L-idose was also possible although some difficulty arose here because of an interesting instability of that sugar, which will be dealt with in an accompanying communication. Finally, it was convenient to subject to methanolysis the readily available, crystalline mixture of V and its 5-epimer, 6-deoxy-1,2-*O*-isopropylidene-6-nitro-β-L-idofuranose. The D-*gluco*-L-*ido* glycoside mixture so obtained (IV + VII) consumed 2 moles of periodate as required for hexopyranosides.

In the course of the studies described below it became desirable to prepare, as a model compound, 3-*O*-acetyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-α-D-*xylo*-hexofuranos-5-ene (IX). Acetylation of V gave a syrup that was considered to be largely the 3,5-di-*O*-acetate. The infrared spectrum revealed, however, that the acetylation was accompanied to some extent by the generation of a nitroolefin grouping. Since the nitroolefin (IX) rather than a pure diacetate of V was the goal, the crude acetylation product was subjected to a Schmidt–Rutz reaction which produced crystalline IX in 56% yield.[3]

RESULTS AND DISCUSSION

The Alkaline Conversion of the Nitro Glycosides into Nitro Inositols

When the *gluco-ido* glycoside mixture IV + VII was heated for 20 min at 98° in 1.1 equivalents of aqueous $N/100$ sodium hydroxide, the methoxyl content decreased by 90%. Paper chromatography revealed the disappearance of the fast-traveling methyl glycosides and the formation of two slow-moving products. These products also appeared, in the course of several days, when a similar reaction was run at 20°. Treatment of the L-idosides (VII) and of the D-glucoside triacetates (VI) with 1 and 4 equivalents, respectively, of $N/100$ sodium hydroxide for 7 h at 60° resulted in their complete conversion into the same slow-moving products whose chromatographic spot intensities were all approximately equal.

The two reaction products were identified, by co-chromatography with authentic samples, as *scyllo*-deoxynitroinositol (X) (R_{rh} 0.70) and D,L-*myo*-1-deoxynitroinositol (XI) (R_{rh} 0.65). The *scyllo* isomer was isolated in crystalline form.

[3]*The analogous 1,2-O-cyclohexylidene derivative has recently been obtained in amorphous condition (7). Partial olefin formation in the acetylation step is not surprising in view of what has been found in similar systems (cf. ref. 8).*

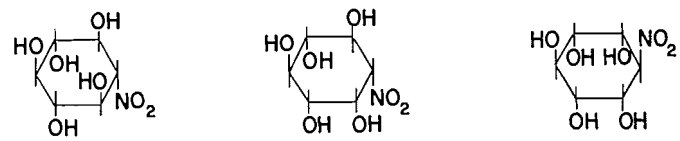
The conversion of methyl 6-deoxy-6-nitro-α,β-D-glucopyranoside (IV) into deoxynitroinositols at 25° was followed by ultraviolet spectroscopy. This was possible by virtue of a change in absorbance of the nitronate peak that is associated with the reaction. The nitro glycoside (IV), in a buffer solution of pH 10,[4] has an initial ϵ value of 10 000 at λ_{max} 242.5 mμ, whereas nitro inositol (X) shows ϵ 3 000 at λ_{max} 250 mμ under the same conditions and attains an extinction comparable to that of IV only at increased pH (with λ_{max} shifting to 248 mμ) (Fig. 1). This difference evidently reflects a lower acidity of X as compared to IV, which causes a smaller proportion of the absorbing species, the nitronate ion, to exist in equilibrium with undissociated nitro compound at pH 10. In Fig. 2 is depicted the decrease in absorbance that occurred in a 0.004 *M* solution of IV at pH 10 in the course of 11 days, after which time ϵ had reached a value (4 000) close to that of X-nitronate. As with the latter, addition thereafter of sodium hydroxide to pH 12 produced a peak of λ_{max} 247 mμ and ϵ 10 000. The half-life of IV under the conditions employed was about 28 h.

When a similar reaction was carried out at pH 12.6 the picture was similar in the early stages (Fig. 3). Later on a broad, relatively weak absorption developed gradually in the near ultraviolet, which must have arisen from the formation of products other than nitro inositols.[5]

It has been demonstrated by Grosheintz and Fischer (9) that 6-deoxy-6-nitro-D-glucose and -L-idose undergo base-catalyzed cyclizations in which both yield three stereoisomeric deoxynitroinositols later shown (10, 11) to possess *scyllo* (X), D,L-*myo-1* (XI), and *muco-3*



X XI XII

(XII) configurations. Lichtenthaler's (11) detailed studies established that the *muco* isomer arises by kinetic control; when allowed to remain in an alkaline medium it epimerizes to a thermodynamically more stable equilibrium mixture of the *scyllo* and *myo* compounds. It is obvious from our findings, therefore, that the methyl pyranosides of 6-deoxy-6-nitro hexoses readily undergo base-catalyzed deglycosidation to the free sugars, which do not accumulate but cyclize rapidly to inositol derivatives. The process is visualized to proceed via a nitroolefin hemiacetal (XIII) which instantly loses methoxide ion to furnish a nitroolefin aldose (XIV). The latter is attacked by hydroxyl ion, giving hexose nitronate (XV) predisposed to Fischer cyclization.

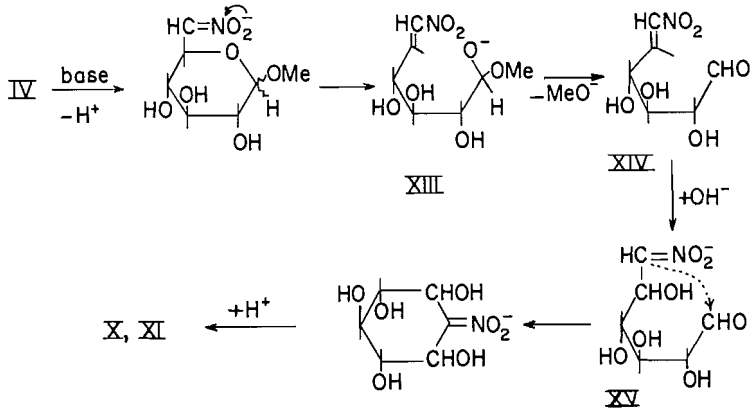
As far as the β-elimination of an acetal oxygen and the formation of a nitroolefin intermediate are concerned, the mechanism suggested here is the same as that proposed (2) in the alkaline removal of the 3,5-*O*-isopropylidene group from 6-deoxy-1,2:3,5-di-*O*-isopropylidene-6-nitro-α-D-glucofuranose (II). In this latter case the nitroolefin presumed to be primarily engendered was the 1,2-acetone derivative of XIV; it evidently added methoxide ion producing two stable, stereoisomeric methyl ethers.[6]

To assess the susceptibility of the hypothetical nitroolefin intermediates to nucleophile

[4]*The actual pH of an unbuffered M/10 sodium IV-nitronate solution was found to be 9.8.*

[5]*The spectral measurements were taken at pH 10 to ensure comparability with the reaction illustrated in Fig. 2. After 11 days no peak in the 247 mμ region was brought forth by measuring at pH 12, but only a slight intensity increase in the long wavelength area.*

[6]*The reaction was carried out in methanol solution (2). Cyclization of the products to inositol derivatives was, of course, prevented by the 1,2-acetone group that is alkali-stable under the conditions employed.*



attack, the behavior toward methanolic sodium hydroxide of crystalline 3-*O*-acetyl-5,6-dideoxy-1,2-isopropylidene-6-nitro-α-D-*xylo*-hexofuranos-5-ene (IX) was studied. These experiments, which are described in the next section, clearly proved the extreme ease with which such olefins are liable to add base. As will be seen, the results are in full accord with the mechanism discussed above and earlier (2), and they suggest in addition that in the sequence IV → XIV → XV the ring cleavage is the rate-determining step.

The Action of Base upon Nitroolefin IX

3-*O*-Acetyl-5,6-dideoxy-1,2-*O*-isopropylidene-6-nitro-α-D-*xylo*-hexofuranos-5-ene (IX), owing to its nitroolefin structure, exhibits high-intensity absorption in neutral and acidic solution: λ_{max} 230 mμ (ε 10 500) in cyclohexane; and λ_{max} 234 mμ (ε 11 500) in methanol with and without addition of sulfuric acid. The addition of *excess* sodium hydroxide to a 10^{-4} *M*, methanolic solution caused an instantaneous bathochromic shift to 244–245 mμ (Fig. 4). When the amount of alkali added was limited to two equivalents,[7] however, the 234 mμ peak disappeared in the course of 90 min with a half-life of ca. 12 min (at 26°). Addition of excess hydroxide after 90 min then produced a new peak at 245 mμ (ε 9 500) (Fig. 5). Now the experiment was repeated over an extended period of time with aliquots being withdrawn at intervals. When the reaction was arrested in the aliquots by acidification with acetic acid or by cation exchange the absorption ceased to decrease, thus providing a measure for the amount of remnant nitroolefin. Thin-layer chromatography revealed the nature of the reaction (Fig. 6). Paralleling the decrease in ultraviolet absorbance, the spot of starting material IX (R_f 0.73) disappeared with concomitant appearance of a spot (R_f 0.65) attributable to 3-*O*-acetyl-6-deoxy-1,2-*O*-isopropylidene-5-*O*-methyl-6-nitro-D-glucofuranose (XVI) and -L-idofuranose (XVII), which were not separated. As the reaction continued the new spot gave way to one of R_f 0.53 that could be resolved into two spots by use of a different solvent system. These spots were indistinguishable from those given by 6-deoxy-1,2-*O*-isopropylidene-5-*O*-methyl-6-nitro-D-glucofuranose (XVIII) and -L-idofuranose (XIX) that had been obtained (2) by treatment with methanolic alkali of the diacetone compound II, and the ratio of XVIII and XIX, roughly estimated at 4:1, was found to be the same in both cases. This can be regarded as proof for the nitroolefin structure being an intermediate in the ketal fission and methoxylation of II as earlier proposed.

From an inspection of Figs. 5 and 6 it follows, moreover, that methoxylation of the

[7]*One equivalent to be consumed by saponification of the acetyl group.*

XVI, R = Ac, R′ = H, R″ = OMe
XVII, R = Ac, R′ = OMe, R″ = H
XVIII, R = R′ = H, R″ = OMe
XIX, R = R″ = H, R′ = OMe

olefinic bond in IX occurred at a rate markedly faster than the de-*O*-acetylation which was quite incomplete when, after 1 h, virtually all of IX had reacted. This conclusion was supported by the results of infrared spectroscopy, confirming the ultraviolet and chromatographic data. When the reaction was done at a higher initial concentration of IX (3.65×10^{-2} *M*), the ultraviolet and thin-layer patterns were fully analogous to those in Figs. 5 and 6, although the speed of reaction was considerably greater: after only 20 and 90 s, respectively, the 234 mμ-peak had decreased by 45 and 90%, while on the chromatograms (Fig. 7) a slow spot corresponding to deacetylated material was already visible after 90 s and became the sole spot within 1 h. The infrared spectra also indicate the rapid conversion of the nitroolefin IX into the nitroalkane acetates (XVI + XVII) and the deacetylation of the latter to XVIII and XIX. Figure 7*b* (20 s) shows a reduction by about half, of the (weak) C=C absorption at 1 680 cm^{-1} and, more significantly, the emergence of a nitroalkane peak (1 555 cm^{-1}) in addition to the olefinic nitro peak (1 530 cm^{-1}). Figure 7*c* (90 s) indicates a far-reaching though incomplete replacement of IX by XVI + XVII, since the C=C frequency has now vanished and the originally strong olefinic NO_2 peak is reduced to a shoulder of the newly generated nitroalkane peak. The change in the intensity ratio of the carbonyl and nitro absorptions and the occurrence of a (yet small) hydroxyl band in Fig. 7*c* bears out the beginning of the deacetylation which progresses (Fig. 7*d*,*e*), and after 1 h (Fig. 7*f*) appears to be complete.

EXPERIMENTAL

Paper Chromatography

Paper chromatography was performed using the descending technique on Whatman No. 1 paper with 1-butanol – acetic acid – water (4:1:5 (v/v), upper layer; the lower layer was placed in the bottom of the tank). The spots were made visible by spraying the chromatogram with ammoniacal silver reagent (0.1 *N* $AgNO_3$, 5 *N* NH_3, 2 *N* NaOH, 1:1:2) and heating it over steam. L-Rhamnose served as a reference standard (R_{rh} = 1). Authentic deoxynitroinositols X (R_{rh} 0.70), XI (R_{rh} 0.65), and XII (R_{rh} 1.04) were prepared according to Lichtenthaler (11; cf. also ref. 13).

Thin-Layer Chromatography

Thin-layer chromatography was done on Silica Gel G (E. Merck AG, Darmstadt) activated for 1 h at 110°, with cyclohexane – ether (1:6) (solvent A) and chloroform – acetone (4:1) (solvent B) as irrigating systems. The spots were detected with 1% ceric sulfate in 10% sulfuric acid.

Spectroscopy

Infrared spectra were taken using a Perkin–Elmer Infracord instrument.

Ultraviolet spectra were recorded with a Perkin–Elmer spectrophotometer Model 202.

Methyl 6-Deoxy-6-nitro-α,β-D-glucopyranosides (IV)

A solution of 500 mg of 6-deoxy-1,2-*O*-isopropylidene-6-nitro-α-D-glucofuranose (V) (12) in 50 ml of methanol containing 1% by weight of hydrogen chloride was refluxed for 4 h. Upon cooling of the solution to 25° the hydrogen chloride was removed by anion exchange with Dowex-1-X8 resin (carbonate form) and the filtrate was evaporated *in vacuo*, with 2 portions of methanol being added near the end. There was obtained 425 mg of a colorless syrup (IV) which, on paper chromatography, showed two spots (R_{rh} 1.48 and 1.62) and was free from starting material (R_{rh} 1.88).

Methyl 6-Deoxy-6-nitro-2,3,4-tri-O-acetyl-α,β-D-glucopyranosides (VI)

Glycoside mixture IV (340 mg) and anhydrous sodium acetate (340 mg) in 7 ml of acetic anhydride were heated for 1 h on a steam bath. The mixture was allowed to cool and then stirred into 70 ml of ice water, whereby an ochra-colored, crystalline product separated out. The crude product was exhaustively washed with water and dried; yield 448 mg. After one recrystallization from ethanol the acetate mixture (VI) was obtained as colorless needles melting at 148–151° and giving a correct elemental analysis.

Anal. Calcd. for $C_{13}H_{19}NO_{10}$ (349.3): C, 44.70; H, 5.48; N, 4.01. Found: C, 44.87; H, 5.62; N, 4.20.

A part of the acetate mixture VI (200 mg) was recrystallized eight more times. The melting point was 173–175° ($[\alpha]_D^{23}$ + 103.6° in chloroform) after the fifth, and 179–180° after the eighth and ninth recrystallizations. The final rotation was $[\alpha]_D^{23}$ +145° (*c*, 1 in chloroform). This product (21 mg) was considered to be the pure α-anomer. Its infrared spectrum was in agreement with the assigned structure: no hydroxyl absorption; 1 740 cm^{-1} (acetyl C=O); 1 550 and 1 370 cm^{-1} (asym. and sym. C—NO_2).

Methyl 6-Deoxy-6-nitro-α,β-L-idopyranosides (VII)

A solution of 200 mg of 6-deoxy-1,2:3,5-di-*O*-isopropylidene-6-nitro-β-L-idofuranose (VIII) (12) in 20 ml of methanol containing 1% by weight of hydrogen chloride was heated under reflux for 5 h. The reaction mixture was worked up as described above for IV. A colorless syrup of VII (150 mg; 97%) was obtained which gave two chromatographic spots (R_{rh} 1.50 and 1.65); no starting material and no slow-moving by-products (deoxynitroinositols, cf. ref. 13) were detectable. The product (VII) had a methoxyl content of 13.0% (calcd. 13.9).

Mixture of IV and VII

A crystalline mixture (2 g) of monoacetone compound V and its β-L-*ido* isomer (12) was methanolyzed for 4 h under reflux with 200 ml of 1% methanolic hydrogen chloride. Work-up as described above for IV afforded 1.7 g (95%) of a colorless syrup showing a methoxyl content of 13.15% (calcd. 13.9). Paper chromatography gave the same pattern as the glycosides IV and the glycosides VII.

A sample of the mixture IV + VII (22.3 mg; 0.1 mmole) was oxidized with sodium periodate, and the consumption of oxidant was followed by titration (14). The consumption, in molar equivalents of $NaIO_4$, was 0.93 (5 min) → 1.32 (10 min) → 1.48 (30 min) → 1.75 (70 min) → 2.02 (130 min), and did not increase further.

3-O-Acetyl-5,6-dideoxy-1,2-O-isopropylidene-6-nitro-α-D-xylo-hexofuranos-5-ene (IX)

To a suspension in anhydrous ether (15 ml) of 400 mg of monoacetone compound V (12) was added pyridine (2.4 ml) and acetic anhydride (0.9 ml). The reaction mixture was kept in a refrigerator for 18 h and then extracted three times with 3 ml of water, twice with 2 ml of 10% acetic acid, and twice with 2 ml of water. Finally, the solution was dried over anhydrous sodium sulfate and evaporated with several additions of xylene to give a colorless syrup (390 mg). The infrared spectrum of this syrup exhibited in addition to the expected characteristics of a V-diacetate (acetyl C=O at 1 755 cm^{-1}; C—NO_2 at 1 560 cm^{-1}), bands attributable to the olefin IX (olefinic NO_2 at 1 535 cm^{-1} and C=C at 1 670 cm^{-1}).

The above syrup was dissolved in 6 ml of dry benzene and the solution was heated under reflux for 5 h in the presence of sodium bicarbonate (600 mg). After it had been cooled and filtered the solution was evaporated, leaving a yellow syrup in which according to an infrared spectrum the nitroolefin predominated, but some nitroalkane was still present. The syrup was extracted twice with 10 ml of hot cyclohexane which upon evaporation gave a partly crystalline residue. This residue was taken up in a small amount of ether from which on standing IX crystallized in long prisms, and these were isolated and washed with ice-cold ether. The yield was 179 mg (56%); m.p. 106–107°. The melting point was raised to 109–110° by one recrystallization from ether and then remained constant. $[\alpha]_D^{23}$ +6.5° (*c*, 1 in chloroform). Ultraviolet absorption: λ_{max} 230 mμ (ε 10 500) in cyclohexane; 234 mμ (ε 11 500) in methanol, unchanged on addition of *N*/10 sulfuric acid (1 drop per milliliter). A 60-Mc nuclear magnetic resonance spectrum in deuterochloroform exhibited peaks corresponding to 3 protons each at 8.65 τ and 8.46τ (the two isopropylidene methyls) and at 7.95τ (acetoxy). A signal at 2.79τ that corresponded to two protons was assigned to the olefinic H-5 and H-6. The H-1, H-2, H-3, and H-4 protons gave doublets in the 4–5.3τ region.

Anal. Calcd. for $C_{11}H_{15}NO_7$ (273.3): C, 48.35; H, 5.53; N, 5.13. Found: C, 48.60; H, 5.63; N, 5.15.

Action of Base upon the Nitro Glycosides

An accurately weighed sample (4.70 mg) of the glycoside mixture IV + VII was introduced in the disconnected reaction flask of a micro methoxyl determination apparatus. *N*/100 sodium hydroxide (2.32 ml, 1.1 molar equivalent) was added and the loosely stoppered flask was heated in a steam bath for 20 min. Upon cooling of the solution, carbon dioxide was passed through the inlet tube for 10 min, and the solution was then freeze-dried. Water (1 ml) was added and the freeze-drying was repeated. Methoxyl determination gave 1.34% of OCH_3 corresponding to 9.65% of the theoretical value (and to 10.4% of the value found) for the starting glycoside.

In a similar experiment 12 mg of glycoside was heated for 20 min at 98° in an equivalent amount of *N*/100 sodium hydroxide; the solution was then deionized with Rexyn RG-50 (H^+), concentrated *in vacuo*, and chromatographed. It gave strong spots at R_{rh} 0.66 and R_{rh} 0.71, but no spots in the glycoside area of R_{rh} 1.5–1.65.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

A sample of methyl L-idosides VII was dissolved in 1 molar equivalent of $N/100$ sodium hydroxide and heated in a closed vessel for 7 h at 60°. After deionization, chromatography gave spots of approximately equal intensity of X and XI; the glycoside spots had disappeared.

A 10-mg sample of the methyl D-glucoside triacetates VI was treated in the same way but with 4 molar equivalents of base. The material, which was difficultly soluble in the cold, dissolved within a few minutes at 60° as deacetylation proceeded. The results of chromatography were the same as with VII. From a 100-mg sample of VI that was treated analogously a syrup was obtained upon deionization and repeated evaporation with water and then with ethanol. When allowed to stand at 4°, a concentrated solution of the syrup in ethanol deposited crystals of *scyllo* deoxynitroinositol (X). The identity of the product was supported by paper chromatography and infrared spectrum. The melting point was 210–220°; reported: 215° decomp. (9); 224–225° for recrystallized product (11).

Ultraviolet Spectroscopic Observations

Nitroglycoside IV (4.46 mg, 0.02 mmole) was dissolved in 5.0 ml of buffer (pH 10) giving a 4×10^{-3} M

solution which was allowed to stand at room temperature. The buffer was composed of boric acid, potassium chloride, and sodium hydroxide according to Clark and Lubs (15). For the measurements recorded in Fig. 2, 0.08-ml aliquots of the solution were mixed in the photometer cell with 3 ml of buffer, the concentration in nitro compound thus becoming close to 10^{-4} *M*. The reference cell contained blank buffer. To record also the extinction at pH 12, 0.1 ml of *N* sodium hydroxide was added to the above, 3 ml of buffer. (The pH thus attained was found potentiometrically.)

The data shown in Fig. 3 were obtained analogously, except that IV was dissolved in *N*/10 sodium hydroxide. Again, pH 10 buffer was used as diluent for the measurements.

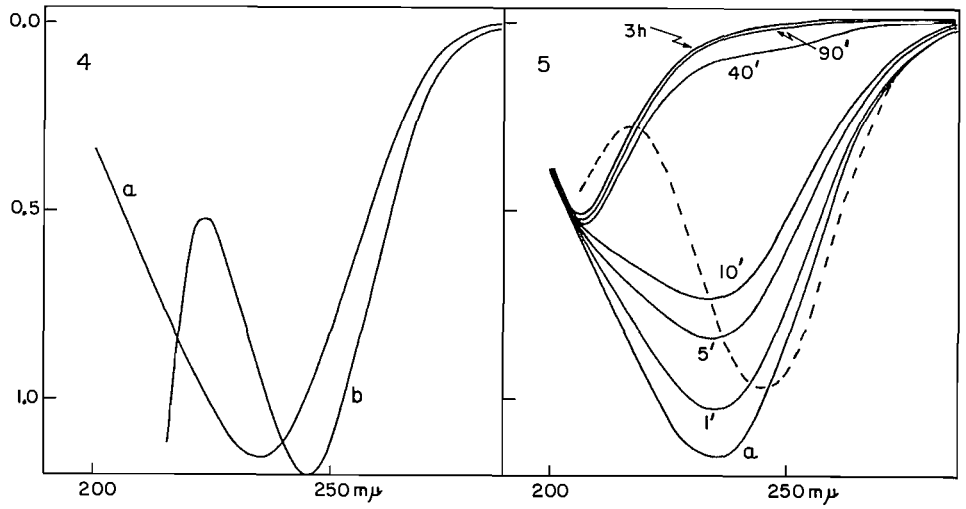

FIG. 4. Nitroolefin IX, 10^{-4} *M* solution in methanol (curve *a*; unchanged upon addition of sulfuric acid); curve *b*, the same after addition of excess sodium hydroxide (0.1 ml *N* NaOH per 3 ml of solution).

FIG. 5. Decrease in absorbance in a 10^{-4} *M* methanolic solution of nitroolefin IX in the presence of 2 equivalents of sodium hydroxide. Curve *a*, IX before the addition of alkali. Broken curve, reaction product at 3 h upon addition of excess alkali (0.1 ml of *N* NaOH per 3 ml of solution).

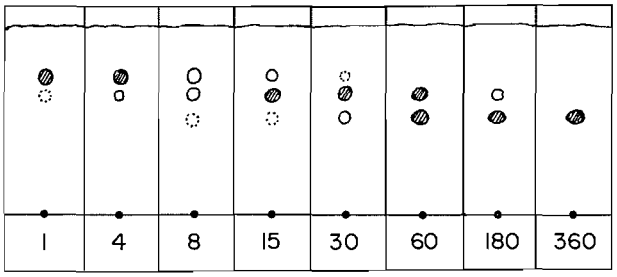

FIG. 6. Thin-layer chromatograms showing the conversion of IX via XVI + XVII into XVIII + XIX (solvent system A). The numbers indicate reaction time in minutes. Strong spots are shaded, medium spots are given as solid circles, trace spots as broken circles.

Action of Base upon Nitroolefin IX

To a 10^{-4} *M* solution of IX in methanol (50 ml) was added 0.1 ml *N*/10 sodium hydroxide solution (2 molar equivalents) and the changes in the ultraviolet spectrum were followed (Fig. 5).

The experiment was repeated with aliquots of 5 ml being withdrawn periodically. The aliquots were deionized by shaking them briefly with a small quantity of Rexyn RG-50 (H^+) that had been washed with methanol and dried in a desiccator. The spectra of the deionized aliquots indicated that the decrease in absorption was arrested. The solutions were then evaporated *in vacuo* and the residues (approximately 0.1 mg) taken up in a few drops of chloroform and applied to thin-layer plates (2.5 × 7.5 cm). Development with solvent A gave the patterns depicted in Fig. 6. The slow-moving spot (R_f 0.53) that occurred as the end product of the reaction was resolved into two spots of R_f 0.46 and 0.39 when larger plates (5 × 20 cm) and solvent B were employed. The following reference compounds were used: XVIII (2) with R_f 0.46 (solvent B)

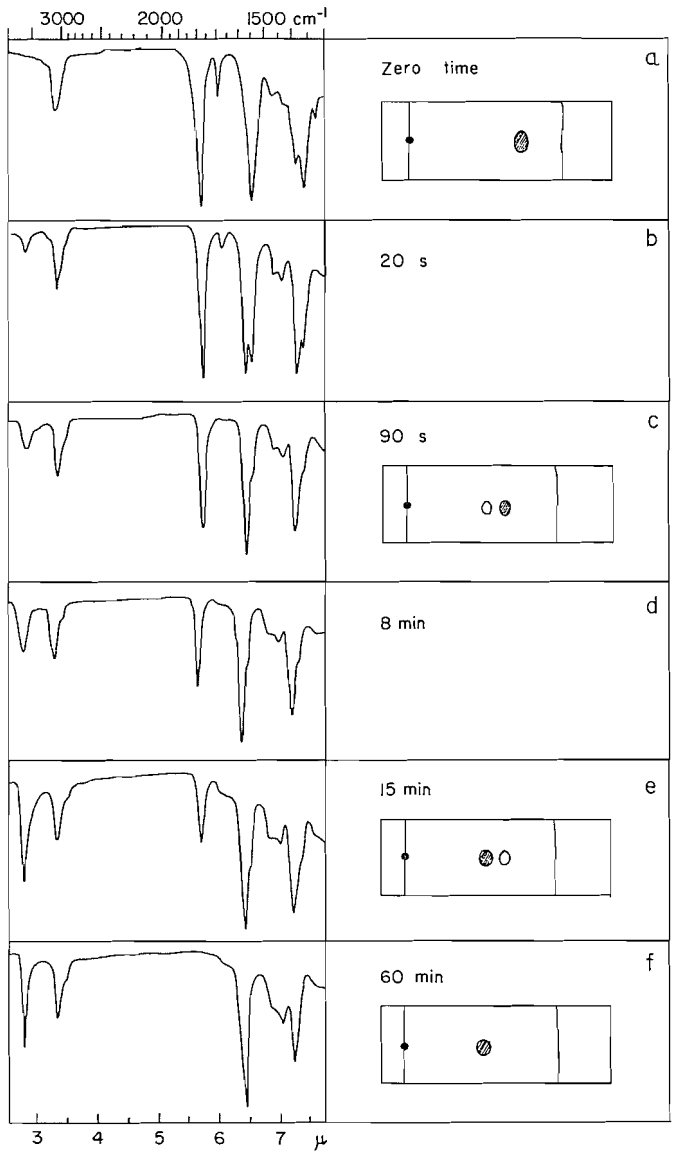

FIG. 7. Infrared spectra and thin-layer chromatograms (solvent A) showing the action of methanolic alkali upon nitroolefin IX.

and 0.53 (solvent A); XIX (2) with R_f 0.39 (solvent B) and 0.53 (solvent A); the product (R_f 0.65 in solvent A) that was obtained by acetylation of XIX (sodium acetate – acetic anhydride; 3 min at 130°).

For the experiments represented by Fig. 7, a solution was made of IX (20 mg) in methanol (20 ml) to which 0.15 ml of *N* NaOH was added. This corresponded to an initial concentration of 3.65×10^{-2} *M* in IX. Aliquots of 2 ml were taken at given intervals and neutralized using *N*/10 hydrochloric acid. From the aliquots withdrawn after 20 s to 60 min ultraviolet spectra were obtained, 0.1 ml of each aliquot having been diluted with 3 ml of methanol. The optical densities at 234 mμ were 55% (20 s), 10% (90 s) and almost 0% (60 min) of that given by a sample of IX of equal concentration but free of alkali. The aliquots were then evaporated to dryness *in vacuo* and the residues were taken up in dry chloroform. Thin-layer chromatograms (solvent A) were obtained (Fig. 7) and infrared spectra were taken of films produced by evaporation of the solvent chloroform on warmed sodium chloride plates (Fig. 7).

NUCLEAR MAGNETIC RESONANCE AND INFRARED STUDIES OF ACYLATED IMIDAZOLIDINONES AND IMIDAZOLIDINETHIONES[1,2]

R. GREENHALGH AND M. A. WEINBERGER
Defence Chemical Biological and Radiation Laboratories, Ottawa, Canada

Received July 2, 1965

ABSTRACT

The infrared and nuclear magnetic resonance spectra of 1-acyl and 1,3-diacyl derivatives of 2-imidazolidinones and 2-imidazolidinethiones were determined, where the acyl groups were acetyl, benzoyl, or trifluoroacetyl. The frequency of the ring carbonyl stretching vibration increases with the degree of acylation and the electron-withdrawing power of the acyl group. The methylene protons of the diacylated derivatives show a single peak, the paramagnetic shift of which is similarly dependent on these parameters when the ring current effects are allowed for. This correlation between the $\nu_{C=O}$ and τ_{CH_2} favors the conclusion that the anisotropy of the acyl carbonyl group does not affect the relative methylene proton shift in these compounds and hence they all have the same preferred configuration. This was deduced to be the planar *trans,trans* structure with respect to the carbonyls. In the unsymmetrical 1,3-diacyl compounds the methylene protons are also nearly equivalent, the τ-value being the average of those for the symmetrical diacyl derivatives. This, together with the changes in the $\nu_{C=O}$ (acyl), is explained by mesomeric equalization of the electronic environment of nitrogen atoms 1 and 3. The C=S bond is found to have a strong deshielding influence on all protons.

INTRODUCTION

The potentialities of nuclear magnetic resonance (n.m.r.) spectroscopy for assigning structures and conformations in acylated 2-oxo-, 2-thio-, and 2-imino-imidazolidines have not in the past been fully exploited. We have used it to differentiate between the several structures suggested for triacetyl-2-imino-imidazolidine on the basis of its infrared spectrum (1). More recently Roberts (2) has also used n.m.r. to assign a symmetrical structure to diacetyl-2-imidazolidinone. Further aspects of the n.m.r. and infrared spectra of acylated 2-oxo- and 2-thio-imidazolidines will now be discussed.

Mecke *et al.* (3) have examined the infrared spectra of 1,3-dihetero-2-oxo-(or 2-thio-)-cyclopentanes and, in particular, investigated the ring carbonyl stretching vibration. They found that the carbonyl frequency is dependent on the nature of the adjacent atoms by virtue of their mass and their inductive and mesomeric effects, as well as on the ring angle at the carbonyl group. The mesomeric effect leads to an increase in the contribution of the canonical dipolar form $\overset{+}{C}—O^-$ and an increase in the angle, which favor a decrease in the carbonyl frequency. In the present work with compounds where the adjacent atoms are nitrogen, their nature is changed by acylation, thus complementing the work with compounds in which the atoms themselves were varied.

EXPERIMENTAL

The n.m.r. spectra were recorded with a Varian 4300–C spectrometer operating at 60 mc/s. Calibrations were made by the standard side band procedure. Chemical shifts with respect to tetramethylsilane are accurate to better than ±.01 p.p.m. The concentration of the compounds was normally 10% w/v.

A Perkin–Elmer Model 221 spectrophotometer was used to determine the infrared spectra. Solutions were 2% w/v in both chloroform and acetonitrile.

The compounds were prepared as specified below. All commercial samples were purified before use. Melting points are corrected.

2-Imidazolidinone

A commercial sample obtained from du Pont de Nemour, U.S.A., was recrystallized from alcohol, m.p. 129–131°.

1-Acetyl-2-imidazolidinone

This compound was prepared by warming 2-imidazolidinone with acetic anhydride, m.p. 173–175° (lit. (4) 171.5–173°). The n.m.r. spectrum (D_2O) was analyzed as an A_2B_2 system and gave approximate τ-values of 6.6 and 6.2 for the 4- and 5-methylene protons respectively.

1,3-Diacetyl-2-imidazolidinone

1-Acetyl-2-imidazolidinone was refluxed for 1 h with acetic anhydride to give the diacetyl derivative, m.p. 126–127° (lit.(5) 126.7–127.5°).

1-Trifluoroacetyl-2-imidazolidinone

2-Imidazolidinone (400 mg) was heated under reflux with trifluoroacetic anhydride (2 ml) for 1 h, taken to dryness, and recrystallized from acetone in the form of white prisms, m.p. 166–168°, in 74% yield.

Anal. Calcd. for $C_5H_5O_2N_2F_3$: C, 32.96; H, 2.75; N, 15.38. Found: C, 33.13; H, 2.65; N, 15.46.

1,3-Ditrifluoroacetyl-2-imidazolidinone

2-Imidazolidinone (500 mg) was heated under reflux with trifluoroacetic anhydride (3 ml) for 24 h. Evaporation to dryness and recrystallization from chloroform/acetone gave white prisms, m.p. 123–124°, in 67% yield.

Anal. Calcd. for $C_7H_6O_3N_2F_6$: C, 29.10; H, 1.30; N, 9.72. Found: C, 29.29; H, 1.25; N, 10.03.

1-Acetyl-3-trifluoroacetyl-2-imidazolidinone

1-Acetyl-2-imidazolidinone (350 mg) was heated under reflux for 24 h with trifluoroacetic anhydride (1 ml). After the solution was concentrated, recrystallization of the product twice from ether gave white plates, m.p. 88–89°, in 81% yield.

Anal. Calcd. for $C_7H_7O_3N_2F_3$: C, 37.50; H, 3.12; N, 12.50. Found: C, 37.79; H, 3.15; N, 12.62 (Kjeldahl).

1,3-Dibenzoyl-2-imidazolidinone

2-Imidazolidinone (500 mg) and benzoyl chloride (2.5 ml) were dissolved in pyridine (5 ml) and heated on a steam bath for 30 min. The solid residue from evaporation was extracted with benzene, and removal of the benzene gave a crystalline residue. The product was finally recrystallized from chloroform to give white needles, m.p. 238–239°, in 42% yield.

Anal. Calcd. for $C_{17}H_{14}O_3N_2$: C, 69.40; H, 4.76; N, 9.52. Found: C, 69.80; H, 4.84; N, 9.57.

1-Acetyl-3-benzoyl-2-imidazolidinone

1-Acetyl-2-imidazolidinone (750 mg) and benzoyl chloride (2 ml) were dissolved in pyridine (5 ml) and heated for 45 min on a steam bath. The material that was left after evaporation to dryness was extracted with hot benzene, which was then removed, and the product was recrystallized from ethanol as white needles (61% yield) m.p. 182–184°.

Anal. Calcd. for $C_{12}H_{12}O_3N_2$: C, 62.00; H, 5.17; N, 12.05. Found: C, 62.20; H, 5.16; N, 11.97.

2-Imidazolidinethione

This material was obtained from the Matheson, Coleman, and Bell Co. U.S.A., and was recrystallized from alcohol, m.p. 202–203°.

1-Acetyl-2-imidazolidinethione

This substance was prepared by treating 2-imidazolidinethione with acetyl chloride in glacial acetic acid, m.p. 165–167° (lit. (6) 161–163°). The n.m.r. spectrum ($CHCl_3$) was analyzed as an A_2B_2 system and gave approximate τ values of 6.4 and 5.8 for the 4- and 5-methylene protons respectively.

1,3-Diacetyl-2-imidazolidinethione

2-Imidazolidinethione was refluxed with acetic anhydride, m.p. 87–89° (lit. (6) 85–87°).

1,3-Ditrifluoroacetyl-2-imidazolidinethione

2-Imidazolidinethione (500 mg) was heated under reflux for 5 h with trifluoroacetic anhydride (10 ml). When the solution was cooled crystals appeared, which were recrystallized from benzene to give red prisms, m.p. 142–144°, in 53% yield.

Anal. Calcd. for $C_7H_4O_2N_2SF_6$: C, 28.55; H, 1.36; N, 9.54; S, 10.88. Found: C, 28.68; H, 1.43; N, 9.58; S, 10.63.

RESULTS AND DISCUSSION

A list of the compounds studied in this investigation together with the main absorption bands in the 1 850–1 600 cm^{-1} region of the infrared is given in Table I.

The values found for 2-imidazolidinone and its acylated derivatives differ from those

1-Acetyl-3-benzoyl-2-imidazolidinone	1 765 (S)	1 695 (Sh)	1 685 (VS)			
2-Imidazolidinethione	—	—	—	—	—	—
1-Acetyl-2-imidazolidinethione			1 677			1 681
1,3-Diacetyl-2-imidazolidinethione			1 695			1 692
1,3-Ditrifluoroacetyl-2-imidazolidinethione	1 780 (W)		1 740 (S)			1 720

quoted by Mecke *et al.* (3) and Roberts (2). This is attributed to the fact that the present values were obtained from solution spectra, whereas the other workers used potassium bromide pellets. A similar effect has been noted in this series by Hall and Zbinden (7).

The assignment of the acyl carbonyl vibration, by comparison of the acylated 2-imidazolidinethiones with the acylated 2-imidazolidinones (2), to the lower frequency band is confirmed by the fact that the relative intensity of this band with respect to the one at higher frequency is greater for diacyl than for monoacyl 2-imidazolidinone. The similarity in the frequency of the acyl carbonyl vibration for the acylated imidazolidinones and imidazolidinethiones also excludes the interpretation that the two carbonyl bands in the series of acylated imidazolidinones are due to coupled vibrations, as was suggested for N,N-diacylamines (8) and anhydrides (9). It may be seen from Table I that the frequency of the ring carbonyl is always higher than that of the acyl carbonyl, which agrees with the results obtained from a study of solid phase spectra.

The infrared spectra of 1-acetyl-3-trifluoroacetyl-2-imidazolidinone and 1-acetyl-3-benzoyl-2-imidazolidinone show three carbonyl peaks, which are attributed to the ring carbonyl and the two different acyl carbonyl bonds. It can be seen that the carbonyl frequency of the acetyl group in 1,3-diacetyl-2-imidazolidinone is 1 698 cm^{-1}, and that of the trifluoroacetyl group in 1,3-ditrifluoroacetyl-2-imidazolidinone is 1 739 cm^{-1}. In the mixed derivative, 1-acetyl-3-trifluoroacetyl-2-imidazolidinone, the two acyl carbonyls appear at 1 710 cm^{-1} and 1 722 cm^{-1}. The decrease in the difference between the acetyl and the trifluoroacetyl carbonyl absorption in going from the symmetrical to the mixed diacyl compounds indicates some form of mutual interaction in which there is an equalization of the electron densities on the nitrogen atoms by mesomerism through the ring.

The frequency assigned to the ring carbonyl is seen to increase with the degree of acylation of the molecule and with the electron-withdrawing power of the acyl group. Acylation reduces the availability of the electrons on the nitrogen atom, thus decreasing the mesomeric effect with the ring carbonyl, which results in a higher carbonyl frequency. This is in accord with the conclusions of Mecke *et al.*, who found that as the hetero-atoms in the series of 1,3-dihetero-2-cyclopentanones are changed from oxygen to nitrogen to sulphur, the frequency decreases with increasing mesomeric effect.

These considerations involving electronic effects may be applied to the interpretation of the n.m.r. results which are shown in Table II.

TABLE II

The τ-values of the methylene and acetyl protons in 2-imidazolidinone, 2-imidazolidinethione, and some of their acyl derivatives

Compound	Solvent	τ —CH_2—	τ —CH_3
2-Imidazolidinone	D_2O	6.50	
1,3-Diacetyl-2-imidazolidinone	D_2O	6.26	7.62
	$CHCl_3$	6.17	7.47
1-Acetyl-3-trifluoroacetyl-2-imidazolidinone	$CHCl_3$	6.05	7.32
	CCl_4	6.10	7.51
1,3-Ditrifluoroacetyl-2-imidazolidinone	$CHCl_3$	5.93	
1-Acetyl-3-benzoyl-2-imidazolidinone	$CHCl_3$	6.05	7.55
1,3-Dibenzoyl-2-imidazolidinone	$CHCl_3$	5.93	
2-Imidazolidinethione	D_2O	6.32	
1,3-Diacetyl-2-imidazolidinethione	$CHCl_3$	6.00	7.18
1,3-Ditrifluoroacetyl-2-imidazolidinethione	$CHCl_3$	5.74

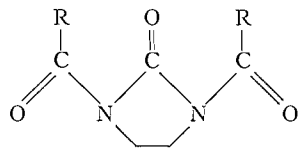
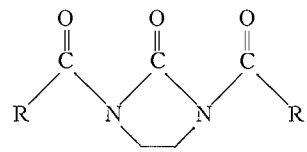
The spectra of the methylene protons in the series of diacylated-2-imidazolidinones are singlets, and this is consistent with acylation of the nitrogens. The τ-values decrease in the order, unacylated >1,3-diacetyl > 1,3-dibenzoyl = 1,3-ditrifluoroacetyl. The similarity of the last two compounds was unexpected, since the τ-value for the benzoyl derivative would be expected to be nearer that of the acetyl because of the relative strengths of the respective acids. Other factors, however, notably the magnetic anisotropy of the C=O group and the aromatic ring current, affect these τ-values. Following the method of calculation and the suggested values of the anisotropies given by Narasimhan and Rogers (10) for the carbonyl bond, and using interatomic distances from related compounds (11), we calculated that, for the planar configuration I, the side-chain carbonyls decrease the screening of the methylenic protons by about 0.24 p.p.m., and that for configuration II the decrease is 0.10 p.p.m. The ring carbonyl further descreens by 0.04 p.p.m. Because of the partial double bond character of the exocyclic C—N bond,



I



II

only configurations I and II would be expected to make significant contributions. As the π-electron distribution varies in the series there will, no doubt, be a concomitant variation of the location of the equivalent C=O dipole, but the resultant changes in anisotropy are very likely small. If it is assumed that the compounds in the above series have similar configurations, the carbonyl anisotropy is not then a factor in determining the relative shifts of the methylene protons. For the benzoyl derivatives, however, the contribution from the ring current must also be considered. This was calculated from the unsubstituted benzene model by the method of Johnson and Bovey (12) to be −0.29 p.p.m. for configuration I, a value which may produce an overcorrection, but the amended τ-values are now more as expected from electronic effects. Some evidence in support of these assumptions is provided by a correlation which is seen to exist between the τ-value of the methylene protons and the ring carbonyl frequency, which is shown in Table III. This

TABLE III

Correlation between τ of methylene protons and ring carbonyl frequency in 2-imidazolidinones

	τ	ν (cm^{-1})
2-Imidazolidinone	6.50	1 703
1,3-Diacetyl-2-imidazolidinone	6.17	1 759
1,3-Dibenzoyl-2-imidazolidinone	6.22*	1 768
1-Acetyl-3-trifluoroacetyl-2-imidazolidinone	6.05	1 781
1,3-Ditrifluoroacetyl-2-imidazolidinone	5.93	1 810

*Corrected for ring current effects from aromatic rings.

correlation would be expected only if the carbonyl anisotropic contributions are constant and τ and $\nu_{C=O}$ are similarly dependent on electronegativity.

For 1,3-dibenzoyl-2-imidazolidinone it is possible to utilize the ring current calculations to determine the preferred configuration. In configuration II, the ring current effect (−0.7 p.p.m.), when deducted, would increase the τ of the methylenes to a value higher

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

than that for 2-imidazolidinone. On the other hand, in configuration I the maximum correction (all rings coplanar) is only 0.29 p.p.m., and thus 1,3-dibenzoyl-2-imidazolidinone is mainly in this configuration.

The mixed 1,3-diacyl compounds give methylene proton spectra which are, surprisingly, almost A_4 ($J/\delta \sim 10$) and have τ-values which are the means of those of the respective unmixed diacyl compounds. Assuming certain configurations in the unmixed derivatives, the approximation to A_4 character can be calculated for a number of configurations of the mixed derivatives. The averaging of the τ-values indicates, however, that the overriding effect operating here is the equalization of the electron densities on the nitrogens via the urea moiety of the ring. Evidence for this effect has already been mentioned in connection with the infrared results. This equalization of the electron density allows an independent means of deducing the configuration of the acyl groups. If it is assumed that there is complete equalization of the shift contribution from the electron density, then, because the methylene protons are virtually an A_4 system, it follows that the anisotropy contributions are also equal, and that consequently the acyl groups have the same configuration.

A residual inequality of 0.12 p.p.m. (from the ring current effect) in the shift of the methylene protons is calculated for 1-acetyl-3-benzoyl-2-imidazolidinone when the simple model is used. This model treats the carbonyl and the benzene ring as independent systems and assumes a planar molecule. Although this is probably incorrect in the present case, these crude ring current calculations show that the benzoyl group has a preference for the *trans*- rather than the *cis*-configuration with respect to the ring carbonyl, since in the *cis*-structure the calculated methylenic proton non-equivalence is 0.3 p.p.m., which is unlikely to disappear even in an improved model. In addition the planar *trans*-configuration I exhibits some steric interaction between the ring carbonyl oxygen and an ortho aromatic proton.* This will most likely result in a twisting of the benzene ring out of the plane of the imidazolidine ring. Hence the ring current effect and the residual inequality will now be decreased. The preference of the *trans*-configuration might be expected, since in the *cis*-configuration there would be considerable carbonyl dipole–dipole interaction, which is virtually absent in the *trans*-form. This argument, which supports the conclusions from the dibenzoyl derivative, implies that all the other diacyl compounds will assume preferentially the *trans*-configuration since no steric factors are involved.

A striking result, which is apparent from Table II, is that in all the 2-imidazolidinethiones the methylene protons are deshielded by approximately the same amount, 0.18 p.p.m., from their counterparts in the 2-imidazolidinones. The acetyl protons are also quite strongly deshielded. This would not be expected on the basis of electronegativity considerations although similar descreening effects have been observed before when C=S replaces C=O (13). The reason for this behavior probably lies in the utilization of the sulphur d-orbitals in the C=S bond. This would markedly change the pattern and values of the magnetic anisotropy from that of the C=O bond. Since the ring carbonyl anisotropy only descreens the methylene protons by 0.04 p.p.m.,† a quite large effect is necessary to explain 0.18 p.p.m. The even larger effect on the methyl protons may be considered as supporting evidence for the supposition that the acetyl C=O group is located in the *trans*-configuration relative to the ring C=O or C=S, as this would reduce the distance of the methyl group from the anisotropic center.

In conclusion it may be pointed out that unlike the diacylated imidazolidinones, the

*The authors thank the referees for drawing this point to their attention.

†*This value may be different if the magnetic anisotropies given in the recent paper by Hooper and Kaiser (14) are used. However, the argument remains unaffected.*

monoacyl-imidazolidinones and imidazolidinethiones give well pronounced but not quite symmetrical A_2B_2-like spectra for the methylene protons. Although this is in agreement with the N-acyl structure, it is not conclusive evidence for it.

ACKNOWLEDGMENTS

The authors thank Mr. K. Oikawa for running some of the n.m.r. spectra and Mr. R. A. Gravelle for determining the infrared spectra. We are also grateful to Mr. J. G. Helie for the analytical work, and to Dr. R. M. Heggie for helpful discussion.

STRUCTURES OF CHLOROBIUM CHLOROPHYLLS (650)[1]

J. W. PURDIE[2] AND A. S. HOLT
Division of Biosciences, National Research Council, Ottawa, Canada

Received June 2, 1965

ABSTRACT

The structures of six *Chlorobium* chlorophylls (650) have been determined. The pheophorbides are derivatives of 2-desvinyl-2-α-hydroxyethyl pyropheophorbide *a*. Variation of the substituents at C_4 (isobutyl, *n*-propyl, or ethyl) and C_5 (ethyl or methyl) accounts for the six different compounds.

DISCUSSION

It was concluded on the basis of an earlier investigation that the pheophorbides of *Chlorobium* chlorophylls (650) were homologues of 2-desvinyl-2-α-hydroxyethyl pyropheophorbide *a* (1) ("homologues" in this case means compounds with different alkyl side chains). Hughes and Holt (2) separated the pheophorbides by liquid–liquid partition chromatography between ether and hydrochloric acid. The six fractions obtained, which were numbered 1 to 6 in order of decreasing acid numbers (order of elution), had almost identical visible absorption spectra. Each fraction was oxidized with chromic acid and the imides obtained were identified by comparison with synthetic imides, except for the neutral imide from fraction 1.

The pheophorbides (650) used in the present work were obtained from *Chlorobium thiosulfatophilum* (strain L) grown and harvested as described by Hughes and Holt (2) and stored at -10 °C. The chlorophylls were extracted and hydrolyzed, and the pheophorbides separated as described previously (2). Each fraction had to be re-chromatographed several times to obtain chromatographically pure pigment. Fraction 3, so obtained, when oxidized with chromic acid, yielded the same neutral imide as fraction 1 and not methyl-*n*-propylmaleimide as found previously. The neutral imide from fractions 1 and 3 has now been identified as methylisobutylmaleimide (3). It was first thought that it might be ethyl-*n*-propylmaleimide; ethyl and propyl groups could possibly arise more readily from uroporphyrin III, an intermediate in the biosynthesis of chlorophyll *a* (4). Also, the retention time of the imide on gas–liquid partition chromatography on polyphenyl ether (2) was greater than that of methyl-*n*-propylmaleimide but less than that which would be expected for methyl-*n*-butylmaleimide. Ethyl-*n*-propylmaleimide was synthesized and compared with the neutral imide from fractions 1 and 3; the retention times were identical on a polyphenyl ether column but differed significantly on a butanediol succinate column.

The nuclear magnetic resonance spectra of the methyl esters of the pheophorbides were measured in $CDCl_3$. Fractions 1 and 3 both showed peaks at $\tau = 8.85$ and 8.95 characteristic of a terminal isopropyl group. Thus these fractions possessed a pyrrole ring with either ethyl and isopropyl groups or methyl and isobutyl groups as substituents. The ratio of the intensities of the peaks at $\tau = 8.85$ and 8.95 was 1.31:1 for fraction 1 and 1.44:1 for fraction 3. This indicated that the substituent was an isobutyl group, since the methyl groups of isopropyl substituents in a similar environment give rise to signals which have

For personal use only.

intensity ratios of about 1.2:1 (5). Methylisobutylmaleimide was synthesized, and examined by gas–liquid partition chromatography. It had exactly the same retention time as the neutral imide from fractions 1 and 3 when run on columns with different characteristics, namely, polyphenyl ether, Carbowax, and butanediol succinate. The neutral imide from *Chlorobium* chlorophylls (660), fractions 1 and 2, also matched methylisobutylmaleimide (6, 7). The nuclear magnetic resonance spectrum of methylisobutylmaleimide, which is described in more detail below, had peaks at $\tau = 9.02$ and 9.12 (ratio of intensities 1.35:1), in good agreement with the spectra of fractions 1 and 3. Rapoport and co-workers (8) also obtained evidence for the presence of a butyl side chain in *Chlorobium* chlorophylls but did not show that it was an isobutyl group.

The pheophorbides were converted into "meso" derivatives by dehydrating the hydroxyethyl group to a vinyl group and hydrogenating the latter to give an ethyl substituent as described below. The "meso" derivatives of fractions 1 to 4 were converted into pyrroporphyrins, i.e. ring V was removed by oxidation and decarboxylation. Pyrroporphyrin XV, prepared from mesopyropheophorbide *a* by the same method, was oxidized with chromic acid in sulfuric acid and found to yield only methylethylmaleimide in the neutral fraction. However, milder oxidation, chromium trioxide in acetic acid, yielded a small amount of citraconimide from ring III in addition to methylethylmaleimide, and this method was used to oxidize the pyrrophorphyrins derived from the (650) pheophorbides. The products were examined by gas–liquid partition chromatography with a column of polyphenyl ether; this was the only column which was found to separate ethylmaleimide and methylethylmaleimide efficiently.

Each pyrroporphyrin yielded the neutral imide that was obtained previously from the corresponding pheophorbide. In addition, fractions 1 to 3 yielded methylethylmaleimide, which confirmed that these fractions all possessed a hydroxyethyl group. Since fraction 4 pyrroporphyrin, in which ring II would give methylethylmaleimide, did not give rise to a larger imide, it must have had a hydroxyethyl group also. Ethylmaleimide was obtained from the pyrroporphyrins of fractions 1, 2, and 4, indicating that each of these fractions had a C_5 ethyl substituent. Citraconimide was not obtained from the pyrroporphyrin of fraction 3, because insufficient material was used for the oxidation (yields from ring III were always very small) and paucity of sample prevented repetition of the oxidation. However, the acid number and the chromatographic properties of fraction 3 indicated that it was smaller than fraction 1 by a CH_2 unit. The results of the oxidative degradation of the pheophorbides and derivatives are summarized in Table I.

The data contained in Table I enabled all the β substituents to be determined, except those on ring I of fraction 6 and ring III of fractions 3, 5, and 6. However, the rate of elution during liquid–liquid partition chromatography of these fractions and their vinyl and meso derivatives indicated that they probably had methyl substituents on ring III. The visible absorption spectra indicated that all fractions were homologues of 2-desvinyl-2-α-hydroxyethyl pyropheophorbide *a* as follows. (*i*) After the hydroxyethyl group was converted into a vinyl group, all fractions had the same spectrum as pyropheophorbide *a*. (*ii*) After the vinyl group was reduced to an ethyl group, the spectrum of each fraction was identical with that of mesopyropheophorbide *a*. (*iii*) When the hydroxyethyl group of fraction 2* was oxidized to an acetyl group, the spectrum was the same as that of 2-desvinyl-2-acetyl pheophorbide *a* but differed from that of pheophorbide *b* (1). Therefore, the hydroxyethyl group had been on ring I, if one assumes that the cyclopentanone

ring was attached to ring III. Hence, if one assumes that the arrangement of the β substituents on the rings was analogous to that of chlorophyll *a*, it was possible to write the structures as illustrated in Fig. 1.

On the basis of these structures it appeared that fraction 6 should be related closely to pyropheophorbide *a*. Consequently, fraction 6 was dehydrated to the 2-vinyl derivative, and this compound was found to co-chromatograph exactly with pyropheophorbide *a* by using the liquid–liquid partition technique which had been used to separate the pheophorbides (650) (2). The 2-vinyl derivative of fraction 5, on the other hand, separated readily from pyropheophorbide *a* when chromatographed similarly. The "meso" derivative of fraction 6 (2-ethyl compound) co-chromatographed with mesopyropheophorbide *a*. The X-ray powder photograph of fraction 6 (2-vinyl derivative) was identical with that of pyropheophorbide *a*; the methyl ester had melting point 222–225 °C alone and 220–225 °C in admixture with pyropheophorbide *a* methyl ester (m.p. 222–225 °C). Fraction 6 was therefore 2-desvinyl-2-α-hydroxyethyl pyropheophorbide *a*. This confirmed the nature of the substituents at C_2 and C_5. Furthermore, it established that the cyclopentanone ring was present as illustrated and showed that the configuration of the substituents on ring IV was the same as that in pyropheophorbide *a*. According to Linstead and co-workers (10), the hydrogen atoms on ring IV of chlorophyll *a* are in the

FIG. 1. Structures of the pheophorbides from *Chlorobium* chlorophylls (650).

trans positions. The structures of the other fractions were subsequently confirmed by comparing porphyrin derivatives with synthetic porphyrins.

Fractions 1 to 4 were confirmed by comparing the pyrroporphyrin derivatives with synthetic pyrroporphyrins prepared by MacDonald and co-workers (11, 12). Thus, the methyl ester of fraction 1 pyrroporphyrin was identical with synthetic 1,3,8-trimethyl-2,5-diethyl-4-isobutylporphin-7-propionic acid methyl ester. Similarly, fraction 2 pyrroporphyrin methyl ester was identical with synthetic 1,3,8-trimethyl-2,5-diethyl-4-*n*-propylporphin-7-propionic acid methyl ester. Fraction 3 pyrroporphyrin methyl ester was identical with synthetic 1,3,5,8-tetramethyl-2-ethyl-4-isobutylporphin-7-propionic acid methyl ester. As previously reported by Archibald *et al.* (12), fraction 4 pyrroporphyrin methyl ester was identical with synthetic 1,3,8-trimethyl-2,4,5-triethylporphin-7-propionic acid methyl ester. The structure of fraction 5 was confirmed by MacDonald and co-workers (11, 12) as follows. The "meso" derivative was converted into the desoxo-phylloerythrin derivative, the methyl ester of which was identical with synthetic 4-*n*-propyl-4-desethyl-desoxo-phylloerythrin methyl ester.

The pheophorbides were obtained from *Chlorobium* chlorophylls (650) by alkaline hydrolysis. Only one alcohol resulted from this hydrolysis, and it was found to be farnesol (9, 13). Rapoport and Hamlow (13) concluded that it was *trans,trans*-farnesol on the basis of its proton magnetic resonance spectrum. Thus the *Chlorobium* chlorophylls (650) are farnesol esters of the magnesium complexes of the pheophorbides illustrated in Fig. 1.

It is now of interest to comment on the method which was used to separate the pheophorbides (650), i.e. liquid–liquid partition chromatography with hydrochloric acid on Celite as the stationary phase and ether as the mobile phase (2). In the initial separation of the mixture of pheophorbides, four bands were usually obtained on the column. Band I, which was eluted first from the column, contained fraction 1; band II contained fractions 2 and 3; band III contained fractions 4 and 5; and band IV contained fraction 6. Thus the compounds in each band differed from the compounds in the adjacent bands by one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

CH_2. Bands II and III occasionally split into component fractions on the initial column but were normally resolved by further chromatography with hydrochloric acid of a slightly higher concentration.

The initial bands I to IV probably correspond to the four fractions obtained by countercurrent distribution between hydrochloric acid and ether (2).

EXPERIMENTAL

Synthesis of Imides

Ethylmaleimide

This imide was obtained by oxidation of 2-methyl-4-ethylpyrrole with chromium trioxide in sulfuric acid as described by Fischer *et al.* (14, 15). The ethyl propionylacetate used to prepare the pyrrole was kindly supplied by Dr. S. F. MacDonald. The imide was purified by sublimation in a vacuum at 80 °C, gas–liquid partition chromatography, and re-sublimation. The white crystalline product had m.p. 80 °C.

Anal. Found: C, 57.62; H, 5.84; N, 11.32. $C_6H_7O_2N$ requires C, 57.59; H, 5.64; N, 11.20.

Methylisobutylmaleimide

The general method followed was that used by Küster for the preparation of methylethylmaleimide (16). Ethyl isobutylacetoacetate was prepared in 55% yield from ethyl acetoacetate and isobutylbromide (1-bromo-2-methylpropane) as described by Renfrow (17). The product was purified by vacuum distillation with a 10 cm fractionating column; b.p. 105–110 °C at 20 mm. The ester (31 g) was dissolved in 100 ml ether and potassium cyanide (21 g) added. The mixture was cooled to −5 °C and concentrated HCl (3 ml) added. The flask was stoppered, shaken for 1 h, and cooled to −5 °C for 30 min, and then a further 3 ml of HCl added. The shaking, cooling, and addition procedure was repeated until 25 ml of HCl had been added. When the addition was complete the mixture was shaken for 12 h and the ether evaporated off. Concentrated HCl (100 ml) was added and the solution was refluxed for 8 h. The solution was concentrated by distillation and then heated slowly on a "Woods metal" bath. Between 174 and 230 °C (bath temperature) water distilled out, and at 260 to 270 °C the product distilled out; methylisobutylmaleic anhydride, b.p. 230–238 °C, pale yellow liquid, yield 4.44 g (16%).

The anhydride was converted into the imide as follows: 1 g was dissolved in anhydrous ethanol (8 ml) saturated with ammonia at 0 °C and heated at 140 °C for 3 h in a Teflon-lined brass bomb. After the ethanol had been evaporated off the product crystallized. Sublimation in a vacuum at 95 °C yielded a white product; yield 1.0 g from 3 g of anhydride (33%). The imide crystallized from petroleum ether as flat needles and plates, m.p. 92–93 °C.

Anal. Found: C, 64.40; H, 7.65; N, 8.51. $C_9H_{13}NO_2$ requires C, 64.65; H, 7.89; N, 8.38.

The infrared spectrum resembled that of methylethylmaleimide; in particular, it had peaks at 3 410 cm^{-1}, 1 770 cm^{-1}, and 1 720 cm^{-1}. The nuclear magnetic resonance spectrum of the imide was measured in $CDCl_3$ on a Varian A-60 high-resolution spectrometer. The spectrum had sharp peaks at $\tau = 9.02$ and 9.12 which were assigned to the methyl groups in the isobutyl chain, and a peak at $\tau = 8.05$ which was attributed to the other methyl group. Peaks at $\tau = 7.68$ and $\tau = 7.78$ (two protons) were assigned to the isobutyl CH_2 protons. The isobutyl CH proton showed up as a band centered approximately at $\tau = 8.3$ but split many times. The remaining proton attached to the nitrogen atom gave a broad band at $\tau = 1.8$.

Ethyl-n-propylmaleimide

This compound was prepared from ethyl *n*-propylpropionylacetate by the same general method as was used to prepare methylisobutylmaleimide. Ethyl *n*-propylpropionylacetate was prepared from commercial ethyl propionylacetate by a procedure analogous to that described for the preparation of ethyl ethylacetoacetate (18).

Ethyl *n*-propylpropionylacetate (30 g) was treated with HCN and hydrolyzed with HCl, and the crude product, ethyl-*n*-propylmaleic acid, extracted with ethyl acetate. This product was heated slowly on a "Woods metal" bath. At a bath temperature of 150 to 240 °C a clear distillate was obtained (mainly water); at a bath temperature of 255 °C ethyl-*n*-propylmaleic anhydride distilled out as a pale yellow oil with a boiling range of 220–230 °C, yield 4 g (15%). Ethyl-*n*-propylmaleimide was obtained by heating the anhydride in ethanol containing ammonia. After evaporation of the ethanol the crude product was purified by gas–liquid partition chromatography, yielding a colorless syrup which did not crystallize even on standing.

Anal. Found: C, 64.22; H, 7.56; N, 8.40. $C_9H_{13}NO_2$ requires C, 64.65; H, 7.87; N, 8.38.

Examination of the Neutral Imide from Fractions 1 and 3

For gas–liquid partition chromatography, a Pye argon chromatograph and columns (0.4 × 117 cm) of polyphenyl ether (17%), Carbowax (10%), or butanediol succinate polymer (10%) on Celite were used. The column temperature was 175 °C in each case. The neutral imides from pheophorbide (650) fractions 1 and 3 and pheophorbide (660) fractions 1 and 2 all had a retention time of 1.76 relative to that of quinoline on the polyphenyl ether column. Methylisobutylmaleimide had exactly the same retention time when run under identical conditions. The neutral imide from pheophorbide (650) fraction 1 also had the same retention

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

times as methylisobutylmaleimide: on the Carbowax column, 1.10 relative to methyl-*n*-propylmaleimide; on the butanediol succinate column, 3.74 relative to quinoline. The ethyl-*n*-propylmaleimide had retention times of 1.76 relative to quinoline on the polyphenyl ether column, 3.50 relative to quinoline on the butanediol succinate column, and 1.07 relative to methyl-*n*-propylmaleimide on the Carbowax column.

Preparation of "Meso" Derivatives of Pheophorbides (650)

General Procedure

The pheophorbide (50 mg) was dissolved in 100% phosphoric acid (20 ml) and maintained at 60 °C for 30 min with vigorous stirring. The pigment was extracted with ether and separated by partition chromatography between ether and hydrochloric acid on Celite. This separated the vinyl derivative, lower band, from the unchanged material, which could again be treated with phosphoric acid to produce more of the vinyl derivative. The vinyl derivatives of bands 1 to 6 were purified with 15.5, 15, 15, 14.5, 14.5, and 14% hydrochloric acid solutions, respectively. The vinyl derivative was hydrogenated (H_2 – palladium black) in acetone and the "meso" derivative that was obtained was purified by partition chromatography with hydrochloric acid which was 0.5% weaker than that required for the corresponding vinyl derivative.

Preparation of Pyrroporphyrins

Mesopyropheophorbide *a* (100 mg) was oxidized by oxygen in dimethylformamide (100 ml solution saturated with oxygen, plus 3 ml aqueous KOH) to a dicarbonyl compound (10-oxo-mesopyropheophorbide *a*) (19). It was immediately oxidized further by adding hydrogen peroxide (30%, 3 ml) to the dimethylformamide solution, shaking for 1 min, and extracting the product (mesochlorin p_6) with ether. The ether solution was washed well with water and evaporated to dryness. The mesochlorin p_6 was dissolved in glacial acetic acid (2–3 ml) and transferred to four Carius tubes. Hydrochloric acid (1%) was added to each tube and the mixture frozen at −80 °C. The tubes were sealed under vacuum and heated at 185 °C for 4 h. In some experiments stronger hydrochloric acid or more acetic acid was used, in an amount sufficient to keep the chlorin in solution after addition of the hydrochloric acid. This was better, as there was less black residue after the solution was heated. The solutions from the tubes were filtered and the pyrroporphyrin was extracted with ether and then crystallized from ether; yield 45 mg (50%). The methyl ester crystallized from tetrahydrofuran–methanol as needles, m.p. 238–241 °C. The mesochlorin p_6 and the pyrroporphyrin had visible absorption spectra identical with those in the literature (20, 21).

The pyrroporphyrins of the pheophorbides (650), fractions 1 to 4, were prepared from the pure "meso" derivatives in the same way, except that smaller quantities were used. The pyrroporphyrins were purified by crystallization from ether or by liquid–liquid partition chromatography (ether – hydrochloric acid on acid-washed Celite) (2). The samples for comparison with the synthetic pyrroporphyrins were chromatographed with 5.0, 4.5, 4.0, and 3.5% hydrochloric acid for fractions 1, 2, 3, and 4, respectively. The pure porphyrins were methylated by diazomethane in ether, crystallized, and examined: fraction 1 pyrroporphyrin methyl ester—fine needles from ether, m.p. 229.5–231 °C; fraction 2 pyrroporphyrin methyl ester—needles from ether or chloroform–methanol, m.p. 207–210 °C; fraction 4 pyrroporphyrin methyl ester—small plates from chloroform–methanol, m.p. 210–215 °C (phase change at 180 °C; plates melted and needles formed); fraction 3 pyrroporphyrin methyl ester—needles from ether, m.p. 220–222 °C (a different crystalline form was obtained from chloroform-methanol).

Anal. Found: C, 76.38; H, 7.67. $C_{34}H_{40}O_2N_4$ requires C, 76.09; H, 7.51.

The pyrroporphyrins all had visible absorption spectra identical with that of the pyrroporphyrin from mesopyropheophorbide *a*.

TABLE II

Gas–liquid partition chromatography of the neutral imides from the oxidation of the pyrroporphyrins (polyphenyl ether column; 175 °C; 100 ml per min)

Source of pyrroporphyrin	Retention times relative to methylethylmaleimide
Mesopyropheophorbide *a*	0.535, 1.00
(650) fraction 1	0.81, 1.00, 1.68
(650) fraction 2	0.81, 1.00, 1.44
(650) fraction 3	1.00, 1.69
(650) fraction 4	0.81, 1.00
Synthetic imides	
Citraconimide	0.53
Ethylmaleimide	0.81
Methylethylmaleimide	1.00
Methyl-*n*-propylmaleimide	1.44
Methylisobutylmaleimide	1.69

Oxidation of Pyrroporphins and Examination of Products

The pyrroporphin to be oxidized (5 mg) was dissolved in glacial acetic acid (2 ml) and the solution was cooled to 0 °C. Aqueous chromium trioxide solution (0.25 ml, 6.7% w/v) was added with stirring and the reaction mixture was allowed to warm up to room temperature. When the chromic acid had been used up (green solution) the pH was raised to 10 with sodium carbonate and the neutral imides were extracted with ethyl acetate in the usual way (2).

By this method the pyrroporphins were oxidized, and the neutral imides were examined by gas–liquid partition chromatography; the results are shown in Table II. It was found that all fractions yielded methylethylmaleimide; thus it was used as an internal reference compound.

ACKNOWLEDGMENTS

The authors are grateful to Dr. S. F. MacDonald of the Division of Pure Chemistry for generous assistance and cooperation throughout. Thanks are also due to Dr. H. J. Bernstein for assistance in nuclear magnetic resonance spectroscopy, and to Dr. Maria Przybylska for X-ray powder photographs and critical interpretation. We also thank Dr. M. Kates and Mr. F. P. Cooper of the Division of Biosciences for advice on gas–liquid partition chromatography.

THE TRANSMISSION OF POLAR EFFECTS

PART II.[1] THE KINETICS OF ESTERIFICATION WITH DIAZODIPHENYLMETHANE AND THE IONIZATION OF 3-SUBSTITUTED ACRYLIC ACIDS

KEITH BOWDEN[2]

Department of Pure and Applied Chemistry, Royal College of Advanced Technology, Salford, Lancashire, England

Received July 20, 1965

ABSTRACT

The rate coefficients for the reaction with diazodiphenylmethane in ethanol, *t*-butyl alcohol, and ethyl acetate at 30° and the pK_a values in water at 25° of fourteen 3-substituted acrylic acids have been determined. The effect of substitution is assessed by use of linear free energy relations. A definite incremental acid-strengthening effect solely due to *cis*-substitution is confirmed. This is not a "bulk" steric effect and is due solely to the orientation of substitution. The polar effect of a substituent is found to be approximately the same from the *cis*- or *trans*-position. An attempt is made to test the suggested mechanisms for the transmission of the polar effect. In the reactions studied the transmission of the polar effect in 3-substituted acrylic acid and ortho-substituted benzoic acids is approximately twice that of the meta- or para-substituted benzoic acids. This appears to be reasonably accommodated by a significant field effect.

INTRODUCTION

In Part I (1), a review of the available data concerning the transmission of polar effects through various systems was given. The present studies have been undertaken to assess suitable models of known geometry. Previously, Hine and Bailey (2) had studied the reaction of certain *trans*-3-substituted acrylic acids with diazodiphenylmethane in ethanol at 30°. Charton and Meislich (3) have also assessed the efficiency of the transmission by the ethylenic system. Both these groups report good correlations with Hammett para σ values. A study of the reactivity of both *cis*- and *trans*-3-substituted acrylic acids in their reaction with diazodiphenylmethane in three solvents and their ionization in water has been undertaken in the present studies and is reported here.

EXPERIMENTAL

Materials

Acrylic, *trans*-crotonic, and 3,3-dimethylacrylic acids were obtained commercially. *cis*-Crotonic acid was prepared by the method of Rappe (4) and stored below 0°. The *trans*- and *cis*-3-halogenoacrylic acids were prepared by the addition of the hydrogen halide to propiolic acid (5, 6, 7). The *trans*- and *cis*-3-chlorocrotonic acids were synthesized by the reaction of phosphorous pentachloride with ethyl acetoacetate (8, 9). *trans*-3-Nitroacrylic (10) and *trans*-3-methoxyacrylic acids (11) were prepared by the known procedures. Acrylic acid was freshly distilled before use (12). The other acids were recrystallized to constant melting point and had melting points identical or very close to those in the literature (4–11). Neutralization equivalents were determined for all acids and were within 1% of the theoretical values. Proton magnetic resonance measurements also showed no evidence of impurities.

The stereochemistry of the 3-substituted acrylic acids was confirmed or determined by the proton magnetic resonance spectra (13). The results were definite in terms of stereochemistry (e.g. *trans*-coupling constants of the vicinal hydrogens greater than *cis*), but showed some interesting features (14). The stereochemical nature of the 3-chlorocrotonic acids has been recently confirmed (15).

Diazodiphenylmethane was prepared as before (16). Solutions were stored in a refrigerator. Pure ethanol, b.p. 78.5° (lit. 78.3°) (17), was prepared by Smith's method (18). *t*-Butyl alcohol, b.p. 82.5° (lit. 82.4°), was dried by fractional distillation from sodium and then by crystallization from its own melt (17). Ethyl acetate, b.p. 77.0° (lit. 77.1°) (17), was dried over freshly ignited potassium carbonate, filtered, and fractionally distilled (17). Karl Fischer titrations (19) showed water contents of $< 0.02\%$ by weight. The solvents were stored with careful exclusion of atmospheric moisture.

Measurements

Rate Coefficients for Diazodiphenylmethane Reaction

These have been determined, at 30 (± 0.05)°, spectrophotometrically as described previously (20, 21), using a Unicam S.P. 600 spectrophotometer. An approximately 10-fold excess of the acid was used (0.03 *M*) and the reaction was studied as a first-order process, using the following equation

[i] $$k = k_1/[HA]$$

where k is the observed second-order rate coefficient, k_1 is the observed first-order rate coefficient and [HA] is the acid concentration. In accord with recent mechanistic studies (22), the observed second-order rate coefficient in alcoholic solvents is not corrected to give the "true" rate coefficient for esterification, which is accompanied by a competing etherification. Diazodiphenylmethane is stable in the alcoholic solvents at 30°. In ethyl acetate, the diazodiphenylmethane appears to be less stable. The decreased precision of the slower rate coefficients in ethyl acetate is probably due to this fact, though the rate of disappearance of the diazodiphenylmethane in ethyl acetate at 30° in the absence of acid is much slower than the first-order rate coefficients observed. The rate coefficients, k, are shown in Table I.

TABLE I

Esterification of the carboxylic acids

*The rate coefficients, k (l mole^{-1} min^{-1}), are reproducible to ±2% or better and are the mean of at least two determinations.

†Hine and Bailey (2) found k for acrylic (1.27), *trans*-crotonic (0.61), *trans*-3-chloroacrylic (2.48), *trans*-3-nitroacrylic (21.8), and benzoic acids (1.00).

‡Rate coefficients are ±5%.

pK_a Values of the Carboxylic Acids

These were determined, at 25 (± 0.1)°, by potentiometric titration of the acids (0.01 *M*) in water with aqueous sodium hydroxide (0.1 *M*), using a direct-reading pH-meter (Electronic Instruments Limited, model 23A) and glass and calomel electrodes. The instrument was calibrated by using phthalate (pH, 4.01) and phosphate (pH, 6.96) buffers (23).

Values of pK_a were calculated in a similar manner to that of Albert and Serjeant (24) from the following equation

[ii] $$pK_a = pH + \log ([HA] - [H^+])/([A^-] + [H^+]) + 0.51I^{1/2}$$

in which [HA] is the concentration of the acid, [A^-] is the concentration of the salt, [H^+] is the concentration of the hydrogen ion, and I is the ionic strength. A stream of nitrogen was played on the solution (50.0 ml) in the thermostatted vessel and carbon-dioxide-free reagents were used, solutions being protected with sode-lime tubes. The pK_a values are shown in Table II.

DISCUSSION

Effect of Substitution on the Esterification Reaction

The effect of the substituents, shown in Table I, is in the usual order for the esterification of the acids with diazodiphenylmethane. However, a striking aspect is that the rate coefficients for the *cis*- and *trans*-isomers are almost the same. This effect is also *independent* of the solvent. The transmission of the polar effect from these substituents to the reactive group must be nearly independent of the *cis*- and *trans*-nature of the substitution. Primary steric effects appear to be unimportant in this reaction (20) and the substituents studied are all of moderate steric bulk.

‡Substituents are Me, Cl, Br, and I.

The substituent effect can be analyzed by use of linear free energy relations. The Hammett equation (eq. [iii]) (27)

[iii] $$\log (k/k_0) = \rho\sigma$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

can be applied to either the *cis*- or the *trans*-substituents, using the known σ values for substituents in the para-position. In Table III, the results are shown. The values used are those suggested by McDaniel and Brown (28), except for the para-iodo substituent. The latter value has been taken as 0.270 (29). The use of σ^n values (30) does not effect any significant improvement in the correlation and, in any case, their application can not be justified in this case. The transmission of the polar effect from the *cis*- or from the *trans*-position is, within the uncertainty of the relations, the same. However, the ρ value for the *cis*-position is, in all cases, slightly greater than that of the *trans*-position. Charton (3*b*) has found a similar effect. The reaction constants, ρ, for the *cis*- or *trans*-substituents show a linear response to the reciprocal of the dielectric constant, as shown in Fig. 1. This relation is given below.

[iv] $$\rho = \rho_c + \rho_s/D.$$

The reaction constant is composed of two parts. The first expresses transmission independent of the medium, ρ_c equal to 1.24 for the *trans*- and 1.34 for the *cis*-substituents; the second expresses transmission controlled by the medium, ρ_s equal to 10.3 for the *trans*- and 10.2 for the *cis*-substituents. However, although it seems likely that the mechanistic path remains the same, this correlation must be treated with reserve.

A treatment similar to that of Dewar and Grisdale (31, see also ref. 32) can be used to analyze the results. If exalted resonance effects are not important in the reaction under study, the relative rates can be assessed in terms of a field effect (F) and a π-inductive-resonance effect (M) such that,

[v] $$\log (k/k_0) = \rho_D(F/r_{ij} + Mq_{ij}),$$

where r_{ij} is the distance between the carbon atom bonded to the reactive group (measured in units of the benzene carbon–carbon bond distance) and q_{ij} is the formal charge at the site produced by the substituent. Only r_{ij} can be calculated, for our systems, and is assumed to be equal to unity. ρ_D and q_{ij} are thus disposable parameters and are given on finding the best fit of the correlation. The important factor is that in the case of the *cis*- and *trans*-3-substituted acrylic acids it would predict, in the absence of steric effect on the conjugation between the carboxyl and ethylenic groups, the *same* effect caused by *cis*- or *trans*-substituents. This is in fact the pattern of reactivity found in the diazodiphenylmethane reaction. The results of the analysis are given in Table IV and result in a very satisfactory

TABLE IV

Dewar–Grisdale analysis*

Reaction	ρ_D	q_{12}	Log k_0	n	r
1. Esterification with DDM at 30.0° in ethanol

2. Aqueous pK_a values at 25.0°					
trans-Acids	1.120	0.270	−4.295	7	1.000
	1.135	0.289	−4.286	5†	1.000

*ρ_D is the reaction constant obtained from the Dewar–Grisdale analysis. r_{12} is taken as 1 (see text). q_{12} is the formal charge term. n is the number of substituents. r is the correlation coefficient.
†Substituents are H, Me, Cl, Br, and I.

correlation. However, it will be realized that as the Hammett para-substituent constants correlate the system satisfactorily, the Dewar and Grisdale treatment must correlate the

system with the field and π-inductive-resonance effects having the same *relative* importance as existing at the para-position in substituted benzene derivatives.

The reaction constant, ρ_D, will be the same as that for the Hammett equation correlation for meta- or para-substituted benzene derivatives. For other systems, ρ_D should remain the same while the effect of change of substitution should be accommodation by r_{ij} and q_{ij}. In this case the reaction constant found, ρ_D equal to 0.85, is in reasonable agreement with the Hammett equation value of 0.94.

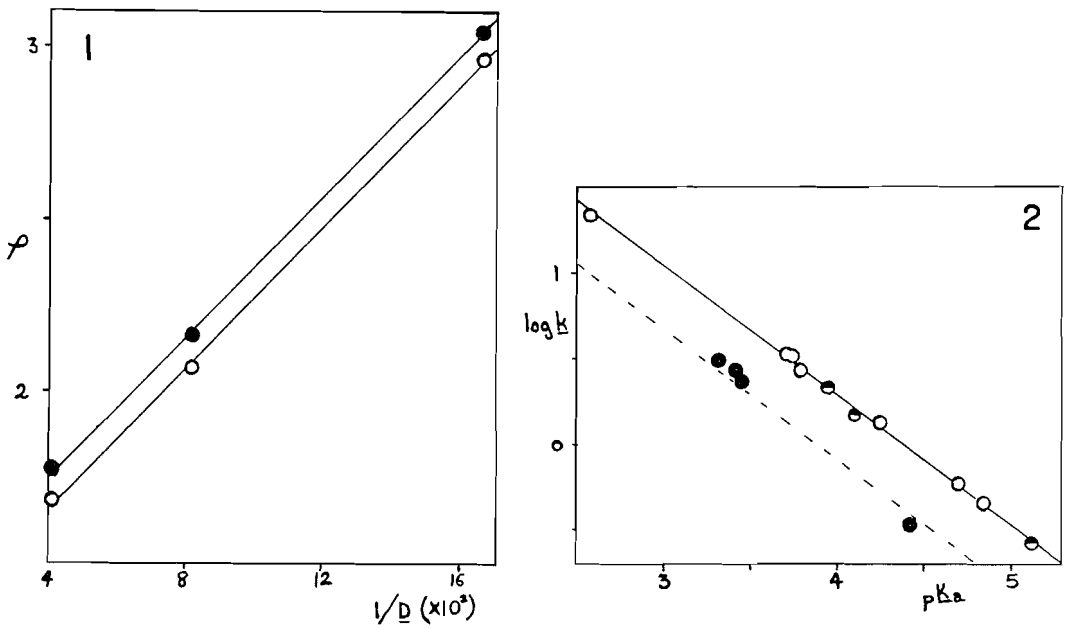

FIG. 1. Relation between the Hammett reaction constants, ρ, and the reciprocal of the dielectric constant of the medium (○, *trans*-; ●, *cis*-acids).

FIG. 2. Relation between the aqueous pK_a values of the acids and the rates of esterification with diazodiphenylmethane in ethanol (○, *trans*-; ●, *cis*-; ◓, di-3-substituted acids).

Relation between the Rate of Esterification with Diazodiphenylmethane and the Aqueous pK_a Values

The relation between the rate of esterification in ethanol and the aqueous pK_a values is shown in Fig. 2. A linear relation is shown by the *trans*-substituents and also includes the three disubstituted acids. The *cis*-substituents form a less delineated regression which can be regarded as parallel. The difference is equivalent to about 0.3 pK_a units. A similar relation has been previously found for benzoic acids (33). The *cis*-substituents correspond to ortho-substituted benzoic acids; while the *trans*-substituents correspond to meta- and para-substituted benzoic acids. The *cis*-substituents of moderate steric bulk (i.e. as large as the methyl or iodo groups) have this acid-strengthening effect due *solely* to their position. This effect is not due to a secondary steric effect causing de-conjugation of the carboxyl group. The cause of this effect has been tentatively suggested as being due to a specific water-bridge solvation effect (33). This is possible but the effect of a definite increment caused by the proximate substituent seems a more general phenomenon (34–36). This effect is difficult to understand in terms of the present evidence and an explanation must await the full analysis of a number of related systems. The correlation of the disubstituted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

acids by the *trans*-acid regression line is thus quite unexpected and does not appear to be fortuitous. It would have been expected that these 3,3-disubstituted acids would respond in a similar manner to the *cis*-acids and no simple explanation for both facts appears obvious.

The application of the Hammett and the Dewar and Grisdale equations to the aqueous pK_a values are shown in Tables III and IV. The correlations are very good and the conclusions drawn are the same as those in the previous section. The *cis*-acids demonstrate in fact almost the same transmission of the substituent polar effect as the *trans*-acids.

The Transmission of the Polar Effects

This model system, like most others (37), is not completely ideal as a means of testing the likelihood of the various suggested modes of transmission of the polar effect. However, it is possible to make a number of tests and come to certain useful conclusions.

A purely inductive transmission could satisfy this system. The similarity of the effect of a substituent at either the *cis*- or the *trans*-position is thus simply accommodated, as no difference would be theoretically expected (1, 37). However, the dependence of the reaction constant on the medium is difficult to explain. It is possible that the susceptibility of the reaction constant to changes in the medium is controlled by the solvating power of the medium (38), which parallels to some extent the dielectric constant of the medium (39). Previously, this dependence has been mainly attributed to that portion of the polar effect transmitted by the medium itself.[2] Nevertheless, the objections previously raised to purely inductive transmission are still valid (37).

Recently, further studies (40, 41) have been made using the field effect calculations based on the method of Kirkwood and Westheimer (42). The application of these calculations to our system is made difficult by the conjugated π-electron system present, i.e. the possible occurrence of resonance and π-inductive effects. Westheimer applied his theoretical model to para-substituted benzoic acids (43). Sarmousakis (44) showed that the theory can be applied with reasonable success to meta-substituted benzoic acids, though the same model was not similarly successful for the para-substituted isomers due to the resonance effect at the latter position. However, it remains useful to attempt to compare the relative transmission by a field effect. Any absolute value of ΔpK_a, obtained from the known dipole moment, will not be a useful estimate.

The field effect model has been treated in two ways; by considering the molecular cavity as a sphere (42*a*) or as a prolate ellipsoid (42*b*). The second model seems more realistic for our system. The dipolar substituent can be treated as a point dipole or two point charges. Kirkwood and Westheimer have presented equations which allow both models to be tested for the *trans*-acrylic acids. In the case of the *cis*-acrylic acids, where the dipolar substituent is not situated on the main molecular axis, it is only possible to use the spherical model with the substituent as two point charges.

$$\log K/K_0 = \frac{e\mu \cos\theta}{2.303kTD_eR^2} \quad \text{for point dipolar substituents} \qquad [vi]$$

$$\log K/K_0 = \frac{e}{2.303kTD_eR} \quad \text{for charged substituents} \qquad [vii]$$

The eqs. [vi] and [vii] have been proposed by Kirkwood and Westheimer (42) to calculate the electrostatic field effect of a substituent group on ionization constants and the

[2]*A model system to test these points is under consideration.*

For personal use only.

relative rates of reaction, where μ is the dipole moment, e the electronic charge, k the Boltzmann constant, T the absolute temperature, and R the distance between the dipole or charge and the reaction center, and D_e the effective dielectric constant. θ is the angle between the line joining the reaction center and the center of the dipole and the axis of the dipole. The molecule is considered to be a low dielectric cavity ($D = 2.0$) embedded in the solvent medium, water ($D = 78.5$) or ethanol ($D = 24.3$). The relative transmission, ϕ, is thus governed by the calculable factors as in equation [viii], for a point dipole substituent.

[viii] $$\phi = \rho/\rho_0 = (R_0^2 D_{e0} \cos\theta)/(R^2 D_e \cos\theta_0)$$

The reaction center is sited as before (1) and the molecular dimensions were calculated from the known molecular geometries (45). The important distance is that from the center of the dipole to the surface of the molecular cavity. This is taken as 1.5 Å in accordance with the suggestion of Tanford (46).

*Calcd. $\phi = [\cos\theta(R \times D_e)^{-1}]_{\text{acrylic}} / [\cos\theta(R \times D_e)^{-1}]_{p\text{-benzoic}}$.

In Table V, the results for a point dipole substituent approximation and in Table VI, the results for a two point charge dipole substituent approximation are shown. The ratio of the reaction constants, ϕ, for the *trans*-acrylic acid to the para-substituted benzoic acids is given as 2.7 (point dipole approx.) or 2.4 (two point charges dipole approx.) for spherical model molecules in water. The ratio is 3.7 (point dipole approx.) or 3.3 (two point charges dipole approx.) for ellipsoidal model molecules in water. The two point charges model is less of an approximation than the point dipole. The calculated ratio, ϕ, falls to 2.6 in ethanol from 2.7 in water. The model also predicts a linear relation between the reaction constant for a particular system, e.g. the reaction of *trans*-substituted acrylic acids and diazodiphenylmethane, and the reciprocal of the dielectric constant.

The experimentally found ratio, ϕ, for this system is 2.2 (ionization in water). This is in

*H_1 or H_2 are simple functions of the reciprocal of dielectric and distance (see eq. [17] of ref. 42*a*).
†Calcd. $\phi = (H_1 - H_2)_{\text{acrylic}}/(H_1 - H_2)_{p\text{-benzoic}}$.
‡Calcd. $\phi = [(D_{e1} \times R_1)^{-1} - (D_{e2} \times R_2)^{-1}]_{t\text{-acrylic}}/[(D_{e1} \times R_1)^{-1} - (D_{e2} \times R_1)^{-1}]_{p\text{-benzoic}}$.

good agreement with the first results, considering the uncertainties. The ratio found in ethanol is 1.8 (diazodiphenylmethane reaction) compared to ratio for water of 2.2 (ionization in water). Thus, the correct qualitative decrease is shown. If the factors determining ρ_c and ρ_s (see eq. [iv]), which are dependent on the type of reaction studied, are the same, the ratio ρ_s/ρ_c should be constant for a given system, e.g. *trans*-acrylic acids. The ratio found experimentally is 8.3 for esterification reaction. Though no data exist to check its constancy, the calculated ratio for a two point charges / spherical model is about 8.0 (see Table VI).

Unfortunately the calculated values found for the *cis*-acids in Table VI, are quite unacceptable with regard to the experimental results (see Tables I and II). The "distant" end of the dipole has a large "neutralizing" effect on the field of the "proximate" end. The lack of reality of this model is probably significantly at fault here. The transmitting cavities are similar for the *cis*- and *trans*-acrylic acids and yet the "distant" end of the dipole has such a dissimilar effect. It seems likely that a reasonable transmitting cavity will enclose the whole molecule, whether or not *cis*- or *trans*-substituted, and the "distant" poles will have a comparable effect.

It seems that the Kirkwood–Westheimer models are not completely satisfactory. The best model indicated is one in which we consider the dipole to be embedded in the low dielectric molecular cavity such that the important influence is the "proximate" end of the dipole attached to the molecule. The polar effect is then transmitted by a field effect from the effectively "mono-pole" substituent through both the low dielectric cavity of the molecule and the solvent sheath. The latter effect is accompanied by, in this case, a π-inductive-resonance effect. This is essentially the model proposed by Dewar (31).

As in a previous study (21), the ρ/ρ_0 interpretation offered can be applied in a similar

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

manner. The value of ρ/ρ_0 for "unconjugated" benzoic acids, i.e. exclusion of π-electron effect, can be estimated to be 0.70. The π-electron effects contribute a factor of 0.30. Thus for the 3-substituted acrylic acids the field effect calculations allows us to calculate the "unconjugated" transmission as ρ/ρ_0 equal to 2.22 ("mono-pole" – ellipsoidal model) or 1.61 ("mono-pole" – spherical model) (see Table VI). The effect of using a dipole model for the *trans*-isomers gives similar results. The π-electron effect contribution can be calculated by assuming the effect to vary inversely with distance, as 0.48 or, by using the relative q_{ij} factors, as 0.57. The calculated values for ϕ are thus 2.70 or 2.79 (ellipsoidal model) and 2.09 or 2.18 (spherical model). The experimental ϕ is 2.2 in water.

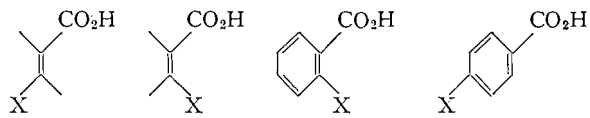
The Value of the Reaction Constants

The values of the reaction constants for a number of systems are shown in Table VII. These were obtained using the para σ values, except for meta-substituted benzoic acids. The reaction constants for the ortho-substituted benzoic acids were obtained by studying only those substituents of moderate steric bulk, i.e. absence of secondary steric effect causing de-conjugation of carboxyl and aromatic ring. The latter values are *very* similar to those obtained for the *cis*- or *trans*-3-substituted acrylic acids. The reaction constants for meta- and para-substituted benzoic acids are considerably smaller. It is very important to point out that 3-substituted acrylic acids (I and II) and ortho-substituted benzoic acids (III) in the reactions shown have a susceptibility to the polar effects of substituents of about twice that of meta- and para-substituted benzoic acids (IV). The cited examples



I II III IV

are two particular cases of a more complex situation which we intend to investigate in subsequent publications.

SYNTHESES WITH 5-DIBROMOMETHYL- AND 5-FORMYL-PYRROMETHENES[1]

A. MARKOVAC[2] AND S. F. MACDONALD
Division of Pure Chemistry, National Research Council, Ottawa, Canada

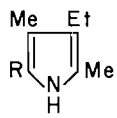
Received July 20, 1965

ABSTRACT

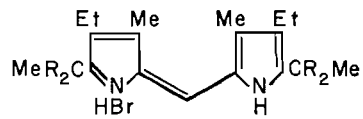
With many 5,5′-dimethyl- and 5-bromo-5′-methyl-pyrromethenes the sequence $CH_3 \rightarrow CH_2Br \rightarrow CH_2OMe$ had been possible. With two such pyrromethenes the following new sequences have been developed: (1) $CH_3 \rightarrow CHBr_2 \rightarrow CH(OMe)_2$ or CHO (cf. III*e* and IV*e*), (2) $CH(OMe)_2$, CHO, or $CH_2OMe \rightarrow Br$ (cf. III*f* and IV*f*), (3) (dimethoxy-methyl-)pyrromethene → formyl-dipyrrylmethane (cf. IX and VII). These provide new intermediates for new porphyrin syntheses and alternative or improved routes to established intermediates.

INTRODUCTION

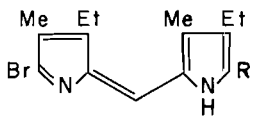
The pyrrole I*a* is readily converted to III*a* by bromine in acetic acid, or to IV*a* by formic and hydrobromic acids, and its analogues behave likewise. The halogenation of



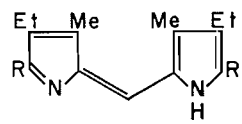
I a ; R = H
I b ; R = COOEt



II a ; $R_2 = H_2$
II b ; $R_2 = HBr$
II c ; $R_2 = Br_2$



III



IV

(a) R = CH_3
(b) R = CH_2Br
(c) R = $CHBr_2$
(d) R = CHO
(e) R = $CH(OMe)_2$
(f) R = Br
(g) R = CH_2OMe

such 5,5′-dimethyl- and 5-bromo-5′-methyl-pyrromethenes to the corresponding bromomethyl derivatives is quite general when the other substituents are purely alkyl, and a 5-carbethoxy-5′-methyl-pyrromethene behaved likewise (1). Further, the bromomethyl-derivatives are readily converted into methoxymethyl-pyrromethenes. When, however, there are other halogen substituents or when the alkyl substituents are carboxylated, the halogenation frequently fails; therefore dihalomethyl- or trihalomethyl-pyrromethenes were unknown. In particular, we have not been able to halogenate 5-bromo-5′-methyl-pyrromethenes with acetic acid and propionic acid residues in the 3(3′) and 4(4′) positions to obtain desired intermediates.

[1]*Issued as N.R.C. No. 8682.*
[2]*National Research Council of Canada Postdoctorate Fellow, 1963–65.*

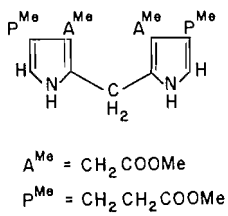
Hans Fischer had reported that an excess of undiluted bromine converted II*a* to a product containing five atoms of bromine but no perbromide (2, 3*a*). It seemed reasonable to assume that his product was not II*b* as provisionally formulated, but II*c*, and that this method of bromination might lead to hitherto unaccessible halogenated pyrromethenes.

This halogenation was also interesting in another connection. Pyrromethenes with acyl groups (formyl or keto) in the 3(3′) and 4(4′) positions were known (3*b*) but 5-acyl-pyrromethenes were only known as their 5′-hydroxy-derivatives (3*c*). This would be expected from the low reactivity of 2-free-5-acyl pyrroles and the exceptional reactivity of 5-free-5′-hydroxy-pyrromethenes. Further, we have failed to convert 5-bromomethyl- to 5-formyl-pyrromethenes in trials with 2-nitropropane, dimethyl–sulfoxide, or selenium dioxide. Recently, however, 4,3′,5′-trimethyl-3,4′-diacetyl-5-formyl-pyrromethene has been obtained from the corresponding 5-free-dipyrrylmethane by reaction with zinc cyanide and hydrogen chloride (4).

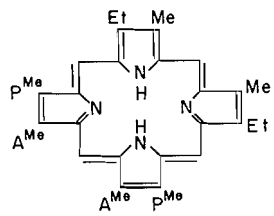
We first studied the bromination of the hydrobromides of III*b* and IV*b*. These were presumably favorable cases because the hydrobromides of III*a* and IV*a* are readily halogenated (to those of III*b* and IV*b*) by bromine in acetic acid. An excess of undiluted bromine at room temperature converted the hydrobromides of III*b* and IV*b* into those of III*c* and IV*c*. Later these were obtained directly under more vigorous conditions from the hydrobromides of III*a* and IV*a* but in equally good yield.

Treatment with methanol followed by alkali converted III*c* and IV*c* into the acetals III*e* and IV*e*. Here the 5-bromo group in the acetal III*e* remained intact, whereas that in 5-*bromo*-4,4′-dimethyl-5′-*carbethoxy*-pyrromethene-3,3′-dipropionic acid hydrobromide is reportedly converted into hydroxyl by cold methanolic hydrogen chloride (5). Although the aldehyde III*d* was obtained from III*c* by treatment with sodium acetate, this reaction failed with IV*c*. Possibly 5,5′-diformyl-, like 5,5′-dicarbethoxy-pyrromethenes (6), exist as carbinols rather than as pyrromethene bases, and unprotected 5,5′-diacyl-pyrromethenes may be generally less stable than the corresponding dipyrrylmethanes.

In the same way as 5,5′-diformyl-dipyrrylmethanes condense with 5,5′-free-dipyrrylmethanes at room temperature to form porphyrins (7), the pyrromethene IV*e* condensed with V to form the porphyrin VI (see also below). The yield was low (17%), perhaps because of the rigidity of an open-chain intermediate, and this new method has no obvious advantage over that using analogues of IV*b* (7) at 100°.



V



VI

Bromine in acetic acid converted the aldehyde III*d* or its acetal III*e* into the new unsymmetrical 5,5′-dibromo-pyrromethene III*f*. The two previously known unsymmetrical 5,5′-dibromo-pyromethenes had been obtained from dipyrrylmethanes (8, 9). Bromine also converted IV*e* into the symmetrical IV*f*. The full sequence now permits the conversion of a 5-methyl- to a 5-bromo-pyrromethene. A more convenient equivalent was later found

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

in the bromination of the methoxymethyl derivatives, III*g* and IV*g* also being converted to III*f* and IV*f*.

Fischer's methods permitted a single pyrrole (e.g. I*a* or I*b*) to be converted unambiguously into pyrromethenes leading to porphyrins (e.g. etioporphyrins) of types 1 and 4. The synthesis of pyrromethenes leading to type 2 and 3 porphyrins required, in addition, the isomeric pyrrole (e.g. 2,3-dimethyl-4-ethyl-pyrrole) (10), which might be much less accessible. However, when extended by the above sequence replacing methyl by bromine, the same methods would also give types 2 and 3 porphyrins from the one pyrrole (Chart I).

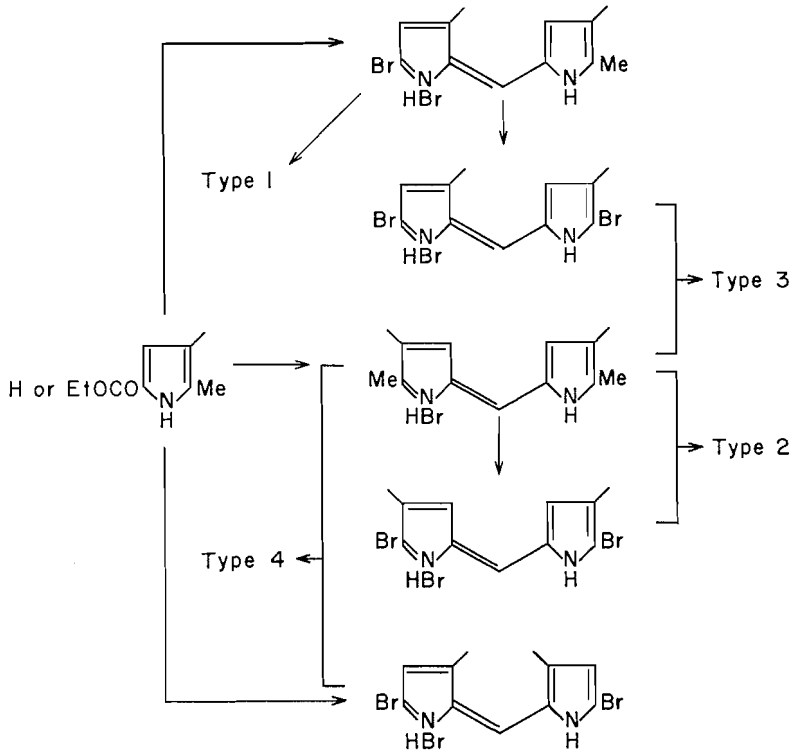


CHART I.

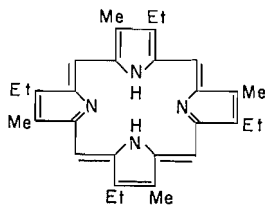
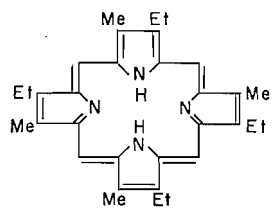
To illustrate this, etioporphyrin 3 (XI) was prepared from III*f* and IV*b*, which required a total of 8 steps compared to the 16 of Fischer's unmodified methods. There are less direct methods by which four isomeric porphyrins could be obtained unambiguously from one pyrrole: one pyrrole could be converted into its isomer (11), or types 2 (7, 12) and 3 (12) porphyrins could be obtained by unrelated methods.



X



XI

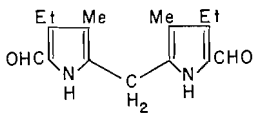
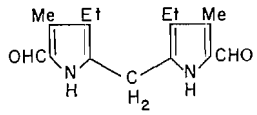
The pyrromethene acetal IV*e* was reduced to the diformyl-dipyrrylmethane VII. This sequence, too, complements an established one, which proceeds over inherently less stable dipyrrylmethanes to convert, for example, *Ib* into VIII (13), the symmetrical isomer of VII. The condensation of VII with V led to the same porphyrin (VI) that was obtained from IV*e* and V (above), but the yield was better (36%). This porphyrin was further identified by degradation to the known mesoporphyrin 4.

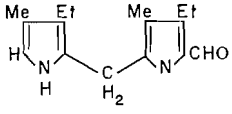
This synthesis of porphyrins from a 5,5′-free- and a 5,5′-diformyl-dipyrrylmethane, like that from a 5,5′-dibromo- and a 5,5′-dimethyl-pyrromethene, requires that one component be symmetrically substituted to avoid an inseparable mixture of two isomers (7). It is thus not applicable to type 1 porphyrins. It suggests, however, a second porphyrin synthesis from two identical or different 5-free-5′-formyl-dipyrrylmethanes which, like the synthesis from two 5-bromo-5′-methyl-pyrromethenes (3*d*, 14), has different symmetry requirements. Accordingly III*d* was reduced but the unstable product, evidently IX, has not been isolated. However, this product did condense to etioporphyrin 1 (X, 44%), which was identified by comparison with authentic material.



VII



VIII



IX

It will be noted that the methoxymethyl- and formyl-pyrromethenes are for some purposes equivalent. However, we have assumed that the reduction of the latter would lead to more stable dipyrrylmethanes. A 5-carboxy-5′-formyl-dipyrrylmethane is reported elsewhere (15).

The nuclear magnetic resonance spectra of all the pyrromethenes and of the diformyl-dipyrrylmethane (Table I) were unambiguous and confirmed the structures assigned.

EXPERIMENTAL

5-Bromo-4,3′-dimethyl-3,4′-di-ethyl-5′-bromomethyl-pyrromethene Hydrobromide (Hydrobromide of IIIb) (3e)

The corresponding 5′-methyl-pyrromethene hydrobromide (III*a*, 2 g (3*f*, 16)) was dissolved in 50 ml of hot acetic acid, bromine (1.2 g) in acetic acid (15 ml) was added, and the solution was heated for 4 h on a steam bath. After the mixture had stood overnight at 20°, the crystalline product was separated out and treated under reflux with acetone for 10 min. The product which separated from the cooled solution was recrystallized from chloroform–hexane as red prismatic crystals (1.8 g, 75%) that decomposed above 250°.

5-Bromo-4,3′-dimethyl-3,4′-di-ethyl-5′-methoxymethyl-pyrromethene (IIIg) (3e)

The corresponding 5′-bromomethyl-pyrromethene hydrobromide (III*b*, 500 mg, prepared as above or, if prepared according to Fischer (3*e*), recrystallized twice from chloroform–hexane) was dissolved in 10 ml of methanol and boiled under reflux for 2 min. Then the solution was cooled and neutralized with 10% sodium hydroxide. The product was recrystallized from methanol as orange–brown needles (290 mg, 79%), m.p. 92–94°.

Unless precautions are taken to ensure that the starting material contains no 5′-methyl-pyrromethene (III*a*), the product has the lower melting point (84°) that has been previously recorded (3*e*).

5-Bromo-4,3′-dimethyl-3,4′-di-ethyl-5′-(dibromomethyl)-pyrromethene Hydrobromide (Hydrobromide of IIIc)

(*a*) The corresponding 5′-bromomethyl-pyrromethene hydrobromide (III*b* (3*e*), 500 mg, twice recrystallized from chloroform–petrol) in 3 ml of bromine was stirred at 20° for 1 h. Excess bromine was then completely removed *in vacuo* and the residue was treated under reflux for 30 min with 10 ml of acetone to dissociate any perbromide. After it had cooled the crystalline product was separated off and recrystallized from chloroform as red-brown prisms (450 mg, 77%) that decomposed above 200°, λ_{max} mμ (ϵ) in chloroform: 504 (112 000). The analytical sample was recrystallized once.

Calcd. for $C_{16}H_{20}N_2Br_4$: C, 34.31; H, 3.60; N, 5.00; Br, 57.09. Found: C, 34.49; H, 3.78; N, 5.24; Br, 56.89.

(*b*) The corresponding 5′-methyl-pyrromethene hydrobromide (III*a* (3*f*), 300 mg) and 3 ml of bromine were held under reflux for 1 h on a steam bath, then left at 20° for 1 h. The product was isolated as above. It formed red-brown prisms from chloroform (310 mg, 74%) that decomposed above 200°.

Its identity with the product of (*a*) above was established from their conversion to the same 5′-formyl-pyrromethene (see below).

5-Bromo-4,3′-dimethyl-3,4′-di-ethyl-5′-formyl-pyrromethene (IIId)

The corresponding 5′-(dibromo-methyl)-pyrromethene hydrobromide (III*c*, 560 mg, prepared by method (*a*) above) in 20 ml of chloroform, and saturated aqueous sodium acetate (10 ml, warmed to 60°) were stirred together for 1 h. The chloroform layer was washed with water, dried, and the solvent removed *in vacuo*. The residue was recrystallized from methanol as brown prisms (300 mg, 89%), m.p. 135–138° (dec.). Recrystallized for analysis, it melted at 138–140° (dec.), λ_{max} mμ (ϵ) in 95% ethanol: 270 (9 800); 434 (30 500).

Calcd. for $C_{16}H_{19}N_2OBr$: C, 57.32; H, 5.71; N, 8.36; Br, 23.84. Found: C, 57.16; H, 5.67; N, 8.21; Br, 24.00.

When the starting material was prepared by method (*b*) above, the product (84%) had m.p. 136–139° (dec.), and mixed melting point unchanged.

5-Bromo-4,3′-dimethyl-3,4′-di-ethyl-5′-formyl-pyrromethene Dimethyl Acetal (IIIe)

The corresponding 5′-(dibromo-methyl)-pyrromethene hydrobromide III*c* (200 mg) was treated under reflux with 2.5 ml of methanol for 5 min, cooled, and neutralized with 5% sodium hydroxide. The product, which crystallized after the container was scratched and refrigerated, was recrystallized from methanol as brown needles (100 mg, 84%), m.p. 99–100°, 100–101° after recrystallization for analysis. λ_{max} mμ (ϵ) in 95% ethanol: 271 (7 600); 432 (25 000).

Calcd. for $C_{18}H_{25}N_2O_2Br$: C, 56.70; H, 6.61; N, 7.35; Br, 20.95. Found: C, 56.72; H, 6.45; N, 7.52; Br, 21.08.

5,5′-Dibromo-4,3′-dimethyl-3,4′-di-ethyl-pyrromethene Hydrobromide (Hydrobromide of IIIf)

(*a*) Bromine (0.1 ml in 1 ml of acetic acid) was added to a solution of the aldehyde III*d* (100 mg) in 2 ml of acetic acid. The solution was stirred at 20° for 30 min; then the solvent was removed *in vacuo*. The residue was treated under reflux for 10 min with 5 ml of acetone. The crystalline product (100 mg, 71%) separated from the refrigerated solution. For analysis, it was recrystallized from chloroform–ether as red prisms that decomposed above 140°, λ_{max} mμ (ϵ) in 95% ethanol: 230 (22 000); 452 (76 000).

Calcd. for $C_{15}H_{19}N_2Br_3$: C, 38.57; H, 4.10; N, 6.00; Br, 51.33. Found: C, 38.73; H, 4.22; N, 5.89; Br, 51.08.

(*b*) The acetal III*e* was treated as in (*a*) above to give the product (69%) as red prisms that decomposed above 140°. Found: Br, 51.20.

(*c*) The 5′-methoxymethyl-pyrromethene (III*g*, m.p. 92–94°, 200 mg) dissolved in 4 ml of acetic acid was treated with bromine (0.2 ml) in acetic acid (4 ml). The mixture was heated for 2 h on a steam bath, the product was isolated as in (*a*) above, and washed with ether before it was recrystallized from chloroform–ether. It formed red prisms (160 mg, 61%) that decomposed above 140°.

The nuclear magnetic resonance spectra of the product obtained as under (*a*), (*b*), and (*c*) were identical.

Etioporphyrin 1 (X)

(*a*) The aldehyde III*d* (50 mg) was hydrogenated (6 h, 20°, 1 atmosphere) in 10 ml of 95% ethanol containing 0.2 ml of triethylamine, over 20 mg of palladium black (uptake 6.9 ml, calcd. for $2H_2$:7.2 ml). The catalyst was separated by decantation and the solvent was evaporated *in vacuo* from the initially pale yellow solution. The residue, evidently IX, was dissolved in 10 ml of acetic acid containing 0.2 ml of hydroiodic acid (56%, decolorized with hypophosphorous acid). After 1 h, 1 g of anhydrous sodium acetate in 15 ml of acetic acid was added, and air was passed through for 24 h while the mixture was kept in the dark. The crude product was precipitated with 25 ml of water, separated out, treated under reflux with 5 ml of methanol, separated out again, and crystallized from chloroform–methanol (yield: 15.5 mg, 44%). For analysis it was recrystallized as well-formed red prisms that decomposed above 380° (17) (evacuated capillary), λ_{max} mμ (relative density) in chloroform: 497 (1); 533 (0.73); 567 (0.49); 620 (0.36).

Calcd. for $C_{32}H_{38}N_4$: C, 80.29; H, 8.00. Found: C, 80.50; H, 8.28.

Both the aldehyde III*d* and its acetal III*e* were reduced as above to nearly colorless solutions (dark red in the absence of triethylamine) but they darkened rapidly, and the product has not been isolated.

(*b*) Authentic etioporphyrin 1 was prepared from the mixed hydrobromides (3*e*) of III*a* and III*b* in formic acid (3 *g*), in the form of red prisms (from chloroform–methanol) that decomposed above 380°.

X-ray powder photographs indicated the identity of the two specimens and showed that both existed in two forms. The analytical specimen obtained as under (*a*) was the first form, which was converted by one recrystallization into a mixture of the first and second forms. The specimen obtained as under (*b*) was the second form, and it was converted by one recrystallization into the first form. The X-ray powder photographs of the first forms were identical.

Etioporphyrin 3 (XI)

The hydrobromides of the pyrromethenes III*f* (40 mg) and IV*b* (40 mg) were heated for 1 h with 400 mg of succinic acid, and the product was isolated as in an analogous synthesis (3 *h*). From chloroform–methanol it separated as elongated prisms (4.8 mg, 12%) that decomposed above 355° (17) (evacuated capillary), λ_{max} mμ (relative density) in chloroform: 500 (1); 535 (0.72); 569 (0.49); 623 (0.36).

For personal use only.

5,5′-Di-(dibromo-methyl)-3,3′-dimethyl-4,4′-di-ethyl-pyrromethene Hydrobromide (Hydrobromide of IVc)

(*a*) The corresponding 5,5′-di-(bromomethyl)-pyrromethene hydrobromide (IV*b* (16, 18), 1.5 g) was stirred for 1 h at 20° with 10 ml of bromine, the bromine was then removed *in vacuo*, and the residue was boiled under reflux for 30 min with 20 ml of acetone. The crystals were separated from the cooled mixture, washed with cold acetone, and recrystallized from chloroform as orange–red needles (1.2 g, 61%) that decomposed above 200°, λ_{max} mμ (ϵ) in chloroform: 252 (12 100); 519 (126 000). The analytical sample was recrystallized once.

Calcd. for $C_{17}H_{21}N_2Br_5$: C, 31.27; H, 3.25; N, 4.29; Br, 61.19. Found: C, 31.42; H, 3.37; N, 4.27; Br, 61.02.

(*b*) The 5,5′-dimethyl-pyrromethene hydrobromide (IV*a*, 300 mg) was brominated on a steam bath, and the product was isolated exactly as in the direct conversion of III*a* to III*c* (see above). The product crystallized from chloroform as orange-red needles (340 mg, 59%) that decomposed above 200°.

The identity of the products as obtained under (*a*) and (*b*) was established by the identity of their nuclear magnetic resonance spectra and by their conversion to the same acetal (see below).

5,5′-Diformyl-3,3′-dimethyl-4,4′-di-ethyl-pyrromethene Tetramethyl Acetal (IVe)

The corresponding 5,5′-di-(dibromo-methyl)-pyrromethene hydrobromide (IV*c*, 1 g, prepared by method (*a*) above) was boiled under reflux for 5 min in 10 ml of methanol. The solution was neutralized with 5% sodium hydroxide and refrigerated. The crystalline product was separated out and recrystallized from methanol as brown needles (450 mg, 77%), m.p. 63–64°. The analytical sample had been recrystallized as orange–brown needles, m.p. 65°, λ_{max} mμ (ϵ) in chloroform: 443 (24 700).

Calcd. for $C_{21}H_{32}N_2O_4$: C, 66.99; H, 8.57; N, 7.44. Found: C, 66.83; H, 8.45; N, 7.61.

When the starting material was prepared by method (*b*), above, the product (71%) had a melting point of 64–65°, and mixed melting point unchanged.

When IV*c* in chloroform was stirred with aqueous sodium acetate, the black product showed no bands in its visible spectrum.

5,5′-Dibromo-3,3′-dimethyl-4,4′-di-ethyl-pyrromethene Hydrobromide (Hydrobromide of IVf)

(*a*) Bromine (0.2 ml) in 2 ml of acetic acid was added to the acetal IV*e* (100 mg) dissolved in 2 ml of acetic acid. The solution was stirred for 30 min, then concentrated to one-half volume *in vacuo*. The crystalline product which separated out was treated under reflux with 2 ml of acetone for 5 min. The product (80 mg, 65%) was separated as red crystals that decomposed at 200°. The analytical sample was recrystallized from chloroform–ether as red prisms that decomposed at 200° (lit. (3*i*): dec. at 200°, as prepared from 2,3-dimethyl-4-ethyl-5-carbethoxy-pyrrole, the isomer of I*b*), λ_{max} mμ (ϵ) in 95% ethanol: 271 (20 600); 443 (79 000).

Calcd. for $C_{15}H_{19}N_2Br_3$: C, 38.57; H, 4.10; N, 6.00; Br, 51.33. Found: C, 38.54; H, 3.94; N, 5.88; Br, 51.21.

(*b*) The 5,5′-di-(methoxymethyl)-pyrromethene (IV*g* (3*j*), free base, m.p. 85°, 200 mg) dissolved in 4 ml of acetic acid was treated with 0.2 ml of bromine in 2 ml of acetic acid, the solution was heated in a steam bath for 2 h, then concentrated *in vacuo* to one-half volume. The crystals which separated were treated by reflux with 3 ml of acetone for 5 min. When the solution cooled, red prisms separated (160 mg, 54%) that decomposed above 200°. The product was recrystallized from chloroform–ether.

The identity of the products obtained as under (*a*) and (*b*) was established by comparing their free bases: 100 mg of the hydrobromides were dissolved in 2 ml of ethanol, the solutions were neutralized with 5% sodium hydroxide, and then refrigerated. The products which separated were recrystallized from 95% ethanol as orange needles (60 mg, 72%) m.p. 176°, mixed melting point unchanged (lit. (3*i*): 175–176°). Their nuclear magnetic resonance spectra were identical.

5,5′-Diformyl-3,3′-dimethyl-4,4′-di-ethyl-dipyrrylmethane (VII)

The acetal IV*e* (250 mg) was hydrogenated (20°, 1 atmosphere) in 15 ml of 95% ethanol over 70 mg of palladium black for 16 h (uptake 15.6 ml, calcd. for 1 mole:16.1 ml). After the catalyst was removed the solvent was evaporated *in vacuo*, and the crystalline residue was recrystallized from tetrahydrofuran-*n*-hexane as pale yellow prisms (170 mg, 89%), m.p. 245–247°. Recrystallization gave the colorless analytical sample, m.p. 250°, λ_{max} mμ (ϵ) in chloroform 301 (29 100); 320 (27 800).

Calcd. for $C_{17}H_{22}N_2O_2$: C, 71.30; H, 7.74; N, 9.78. Found: C, 71.42; H, 7.91; N, 9.95.

The hydrogenation (16 h) was prolonged to allow complete hydrolysis of the acetal; otherwise the product contained methoxy.

2,3-Dimethyl-1,4-di-ethyl-porphin-6,7-di-acetic acid-5,8-dipropionic acid Tetramethyl Ester VI

(*a*) The diformyl-dipyrrylmethane VII (14 mg) and dipyrrylmethane-3,3′-di-acetic acid-4,4′-dipropionic acid tetramethyl ester (V (7), 23 mg) were separately dissolved in warm acetic acid. The cooled solutions were combined, diluted to 10 ml with acetic acid, and 5 ml of acetic acid containing 0.2 ml of 56% hydroiodic acid was added. After 1 h, 1 g of anhydrous sodium acetate in 15 ml of acetic acid was put in, and the solution was aerated in the dark for 24 h. The precipitate was separated out, washed with acetic acid then with methanol, and left overnight in 5% methanolic hydrogen chloride. The solution was mixed with chloroform and ice water. The chloroform layer was well washed with water, dried with sodium sulfate, then passed through Grade IV alumina, which was eluted with 5% methanol in chloroform. The eluate was filtered and concentrated, and the chloroform finally displaced with methanol. The product (13 mg, 36%) separated as curly hairlike needles, m.p. 219–220°. For analysis it was recrystallized as above from chloroform–methanol as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

red-brown hairlike needles, m.p. 220–222°, λ_{max} mμ (relative density) in chloroform: 501 (1); 537.5 (0.66); 572 (0.46); 626.5 (0.30).

Calcd. for $C_{40}H_{46}N_4O_8$: C, 67.59; H, 6.52; N, 7.88. Found: C, 67.78; H, 6.70; N, 7.71.

It was tested for scrambled products (etioporphyrins) by shaking an ethereal solution of the porphyrin-free acid with aqueous sodium hydroxide; the ether layer then showed no visible absorption. Further, the diformyldipyrrylmethane (VII) under the conditions of the synthesis but in the absence of V gave no porphyrin.

(*b*) The diformyl-pyrromethene tetramethyl acetal (IV*e*) was condensed with V as in (*a*) above to give a product (17%) with m.p. 218–220°, from chloroform–methanol. It was recrystallized as red-brown hairlike needles, m.p. 220–222°, which was unchanged when it was mixed with the product of (*a*) above. The X-ray powder photographs of the products of (*a*) and (*b*) were identical.

The porphyrin as obtained by method (*a*) above was degraded at 190° to mesoporphyrin 4, (VI, Me for A^{Me}) by the method used to degrade uroporphyrin 2 to coproporphyrin 2 (7). The methyl ester of the product (69%) crystallized from chloroform–methanol as prisms, m.p. 235° (lit. (3*k*): 233°; 238° corr.), λ_{max} mμ (relative density) in chloroform: 502 (1); 536.5 (0.72); 569 (0.48); 623 (0.35).

ACKNOWLEDGMENT

The authors thank Dr. R. E. Reavill for helpful discussions of the nuclear magnetic resonance spectra.

ESSENTIAL OILS AND THEIR CONSTITUENTS

XXIX.[1] THE ESSENTIAL OIL OF MARIHUANA: COMPOSITION OF GENUINE INDIAN CANNABIS SATIVA L.

M. C. NIGAM,[2,4] K. L. HANDA,[3,4] I. C. NIGAM, AND LEO LEVI
Pharmaceutical Chemistry Division, Food and Drug Directorate, Ottawa, Canada
Received July 2, 1965

ABSTRACT

The essential oil obtained by hydrodistillation of freshly harvested Indian *Cannabis sativa* L. was found to contain the following constituents that have not previously been reported: α-pinene, camphene, β-pinene, α-terpinene, β-phellandrene, γ-terpinene, linalool, *trans*-linalool oxide, sabinene hydrate, α-bergamotene, terpinene-4-ol, β-farnesene, α-terpineol, α-selinene, curcumene, and caryophyllene oxide. The presence of trace amounts of two alcohols and of an α,β-unsaturated ketone, for which gas chromatographic and spectral characteristics are recorded, was also detected.

INTRODUCTION

Marihuana, *Cannabis sativa* Linn., is, like opium, an important drug-bearing plant that grows wild and is also cultivated in many parts of the world. In 1896 Wood, Spivey, and Easterfield (1) examined volatile fractions obtained from plants grown in India, and reported the isolation of a terpene ($C_{10}H_{16}$, b.p. 170–175 °C) and a sesquiterpene ($C_{15}H_{24}$, b.p. 258–259 °C). About half a century later Simonsen and Todd (2) studied the essential oil obtained from Egyptian hashish. They found that its lower boiling fraction consisted mainly of *p*-cymene in admixture with small amounts of 1-methyl-4-isopropenyl-benzene and an unidentified optically active material. The higher boiling fraction of the oil was found to be largely composed of humulene. These authors failed to isolate any myrcene, a hydrocarbon that they assumed Wood *et al.* (1) had obtained, suggesting that it was polymerized in their product "prepared years ago from hashish of uncertain age". Dutt (3) subsequently established the presence in Indian *C. sativa* L. of *p*-cymene, myrcene, dipentene (limonene), and caryophyllene, along with unidentified sesquiterpenes and sesquiterpene alcohols. He reported also the presence of a compound designated as *p*-cymedene (b.p. 179–180 °C; 2-bromodibromide, m.p. 187–189 °C). Martin, Smith, and Farmilo (4) have recently confirmed that some of these are constituents of the essential oil distilled from plants that grow wild in Ontario and Quebec, Canada.

This paper presents the results of a more detailed investigation of the composition of the essential oil obtained from male plants of *C. sativa* L.

EXPERIMENTAL

Samples

Male and female plants of authentic wild *C. sativa* L. from the province of Jammu-Tawi, Kashmir State, India, were collected separately during their flowering period in the month of May. Two light yellow oils with similar characteristic odours were obtained from them in yields of 0.1% by hydrodistillation. Some physicochemical constants for the oil from male plants were d_{20}^{20} 0.9012, n_D^{20} 1.495, α_D^{20} −11.8°, acid value 1.24; and for that from female plants, d_{20}^{20} 0.9012, n_D^{20} 1.494, α_D^{20} −11.6°, acid value 1.48. The gas chromatograms that were obtained for both products under the same experimental conditions were almost identical. For this reason only the essential oil from male plants was analyzed in detail.

Fractional Distillation of Crude Isolate

The essential oil obtained by hydrodistillation (60 g) was fractionated under reduced pressure in a Towers column. Five cuts were collected, which are described in Table I.

TABLE I

Fractional distillation of essential oil of *Cannabis sativa* L.

Fraction	Yield (%)	Pressure (mm)	Temp. (°C)	n_D^{20}
1	10.2	23	62–70	1.468
2	6.2	10	82–84	1.484
3	66.0	7	98–104	1.498
4	2.0	7	104–107	1.499
5	10.0	7	107–115	1.501

Chromatography of Fraction 5

On gas chromatographic analysis, fraction 5 appeared to be composed of sesquiterpene hydrocarbons and oxygenated derivatives. It was therefore chromatographed on 120 g of Woelm, neutral grade I alumina, and eluted successively with petroleum ether, benzene, ether, and alcohol. Elution with petroleum ether yielded 3.63 g of product (fraction 5-A) and with benzene led to 1.86 g (fraction 5-B), which were further analyzed. Recoveries from elution with ether and alcohol were negligible.

Examination of Fractions 3, 4, and 5-A

These fractions consisted primarily of sesquiterpene hydrocarbons, and were very similar in composition. They were therefore combined, and a 5 g aliquot of the mixture was subjected to column chromatography over 500 g of Woelm, neutral grade I alumina, with petroleum ether (b.p. 60-80 °C) as eluant. Effluent fractions of 20 ml each were collected, the solvent was evaporated, and the isolation and characterization of the constituents of the products that were thus obtained were accomplished by gas chromatography and physicochemical analyses, respectively.

Gas Chromatographic Techniques

For gas chromatography, the apparatus and general procedures that have been described previously (5) were used.

Identification and Determination of Essential Oil Constituents

Gas chromatographic effluents were identified by the serial dilution technique and by comparison of the infrared spectra of eluates (collected in carbon tetrachloride and purified by re-chromatography under optimal conditions of temperature and flow rate) with those of authentic reference standards available in the authors' collection or with published data (6). Quantitative results were obtained from measurements of peak areas, as previously reported (7, 8).

RESULTS AND DISCUSSION

The complex composition of the essential oil is illustrated in Fig. 1. All materials collected during the course of this study, including crude products, isolates obtained by distillation, and fractions recovered by column chromatography, were subjected to gas chromatographic analysis to determine the composition of the essential oil, which is given in Table II.

α-Pinene, β-pinene, and myrcene.—These monoterpenes were found almost exclusively in fraction 1. Trace amounts only occurred in fraction 2.

Camphene and α-terpinene.—Minute amounts of these hydrocarbons were found in fraction 1.

Limonene, β-phellandrene, γ-terpinene, and p-cymene.—Limonene and β-phellandrene formed the major portion of fraction 1. Small amounts only were found in fraction 2. γ-Terpinene and *p*-cymene were identified as minor constituents of fraction 1, and trace amounts of them were detected in fraction 2. Neither of these fractions contained any 1-methyl-4-*iso*propenylbenzene, a hydrocarbon that Simonsen and Todd (2) reported to

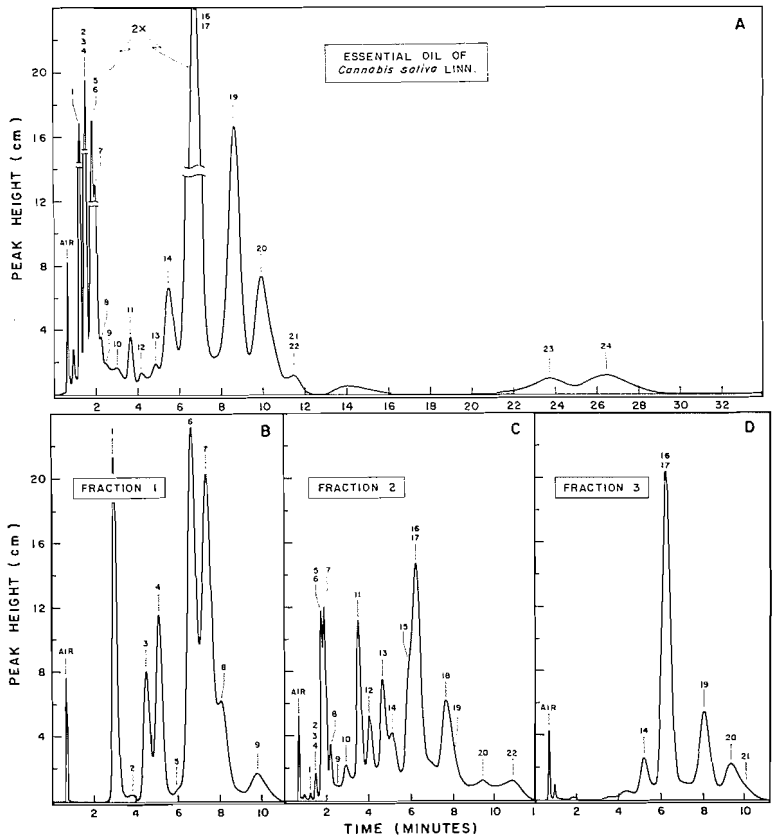

FIG. 1. The result of gas chromatography of oil of *Cannabis sativa* L. Column: Reoplex 400 (20%) on acid-washed chromosorb W. Temperature: A, C, and D,170 °C; B,110 °C. Sample volume: A, 5 λ; B and C, 1.5 λ; D, 1 λ. Helium flow: 75 ml/min.

be a constituent of Egyptian hashish. Its presence in the essential oil was questioned recently by Naves (9).

Linalool and trans-linalool oxide.—These terpenoids were found in fraction 2. *cis*-Linalool oxide, which usually is present with the *trans*-isomer in essential oils, was not detected.

Sabinene hydrate.—This alcohol was identified as a constituent of fraction 2. Its re-chromatography for the purpose of further purification was accompanied by marked decomposition to α- and β-phellandrene and α- and γ-terpinene (10). Hence, some of the β-phellandrene and some α- and γ-terpinene that are reported as constituents of the essential oil (Table II) must be considered as artefacts produced during analysis. Because of the presence of only a small amount of sabinene hydrate (0.4%), no α-phellandrene could be isolated.

Terpinene-4-ol and α-terpineol.—These alcohols were isolated from fraction 2 after repeated gas chromatographic purification.

α-Bergamotene, caryophyllene, β-farnesene, β-humulene, α-selinene, and curcumene.—These sesquiterpenes were identified as components of fraction 3, 4, and 5-A. They also occurred as trace constituents of fraction 2. Caryophyllene and β-farnesene were not resolved by gas

*Partial artefact resulting from degradation of sabinene hydrate under experimental conditions.
†Determined by gas chromatography of essential oil using a column of Reoplex 400 (10%) deposited on acid-base washed Chromosorb W (11).
‡Percentage based on the sabinene hydrate that remained unchanged during gas chromatography.

chromatography under the experimental conditions but they were effectively separated by column chromatography, and cyclic sesquiterpene was eluted more rapidly than the aliphatic hydrocarbon. Gas chromatographic analysis of the column chromatographic fractions permitted quantitative determinations.

Caryophyllene Oxide.—The presence of this terpenoid in *C. sativa* L. was deduced from the characterization of peak No. 24 on the gas chromatograph (see Fig. 1) as that of an aldehyde identical with one that is formed by rearrangement of caryophyllene oxide during gas chromatography (11). Its occurrence in the essential oil was established unequivocally by gas chromatographic analysis of fraction 5-B and of a pure reference standard with a column of Reoplex 400 (10%) on acid-base washed Chromosorb W, from which the epoxide was recovered unchanged.

Unidentified compounds.—These included two alcohols (peak No. 10, alcohol A; peak No. 23, alcohol B) and an α,β-unsaturated ketone (peak No. 22). Alcohol A and the α,β-unsaturated ketone occurred in fraction 2, whereas alcohol B was isolated from fraction 5-B. Alcohol A displayed characteristic infrared absorption at 1 280, 1 252, 1 180, 1 127, 1 070, 933, 930, and 840 cm^{-1}; alcohol B exhibited distinct bands at 1 298, 1 242, 1 162, 1 098, 988, and 918 cm^{-1}; and the unsaturated ketone showed marked absorption at 1 677, 1 645, 1 445, 1 428, 1 370, 1 265, 1 236, 1 180, 1 168, 1 137, 1 110, 1 057, 1 045, 1 018, 930, 891, and 840 cm^{-1}.

Composition of the Essential Oil

Data on the quantitative composition of the essential oil of *C. sativa* L. were obtained by correlating the results of fractional distillation with those of column and gas chromatography. They are summarized in Table II.

Value of the Experimental Findings

Previous work by the authors has shown that the geographical and botanical origin of medicinal plants can be determined with a high degree of accuracy by microanalysis of their essential oils (8, 12–16). Studies that will present such data for oil of marihuana will be the subject of a forthcoming publication.

THE CONDENSATION OF PHOSPHONOTHIOIC AND PHOSPHONIC DICHLORIDES WITH *o*-DIAMINES[1]

RALPH L. DANNLEY AND ARTURS GRAVA
Department of Chemistry, Western Reserve University, Cleveland, Ohio

Received June 8, 1965

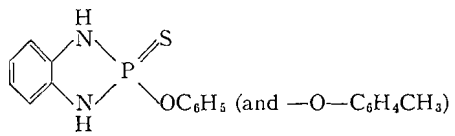
ABSTRACT

A series of 2,3-dihydro-1*H*-1,3,2-benzodiazaphosphole 2-sulfides and 2-oxides have been prepared, most commonly by the condensation of a diamine with a phosphonothioic or phosphonic dichloride in a refluxing inert solvent. The phosphonothioic dichlorides react more slowly than the corresponding phosphonic dichlorides, and phenylenediamines containing electron-donating substituents are more reactive than those containing electron-withdrawing substituents. The diazaphosphole 2-oxides undergo hydrolysis or alcoholysis of only one of the amide groups under mild conditions. The 2-sulfides are much more resistant to hydrolysis than the 2-oxides. The 2-sulfides are converted to the *N*-methyl derivatives by dimethyl sulfate and alkali. The 2-oxides are hydrolyzed under these conditions. The 2-sulfides are invariably lower melting and more soluble in nonpolar solvents than their 2-oxide analogues.

INTRODUCTION

In a previous paper (1) the reaction of phosphonic dichlorides with *o*-diamines has been found to give high yields of 1,3,2-diazaphosphole 2-oxides. The analogous 1,3,2-diazaphosphole 2-sulfides would be of interest as antimetabolites, not only because the sulfur atom would affect the physiological properties but also because the solubility and hydrolytic stability might be more favorable.

The only 1,3,2-diazaphosphole 2-sulfides previously reported were 2,3-dihydro-2-phenoxy-1*H*-1,3,2-benzodiazaphosphole 2-sulfide (2) and its 2-tolyloxy analogue (3) prepared by Autenrieth and his co-workers and the 2-phenyl compound synthesized by Wagner (4).



The present work was therefore undertaken to develop a general method of synthesis of the 1,3,2-benzodiazaphosphole 2-sulfides and by the preparation of a number of representative compounds to establish the factors influencing both their formation and stability.

EXPERIMENTAL

Reagents

Ethylphosphonous dichloride (5) was converted to ethylphosphonothionic dichloride, b.p. 178.6° at 760 mm (lit. b.p. 80–82° at 50 mm (6)). Ethylphosphonic dichloride, b.p. 177–179° (lit. b.p. 171–175° (7)), was prepared by the method of Kinnear and Perren (8).

4,N-Dimethyl-2-nitroaniline

This type of *N*-methyl amine has been conventionally prepared from the corresponding chloronitro compound and methylamine in a sealed tube. The following procedure at atmospheric pressure is more convenient for a larger scale synthesis. A solution of 4-chloro-3-nitrotoluene (34.3 g, 0.2 mole), ethanol (100 ml), 40% aqueous methylamine (40 g), and pyridine (20 ml added to provide a homogeneous reaction) was heated to incipient boiling (4 days). Each day methylamine (20 ml of 20% ethanolic solution) was added to compensate for any losses. After 4 days the excess amine and ethanol were removed by distillation. The oil phase was

[1]*Presented in part at the 139th National Meeting of the American Chemical Society, Chicago, Illinois, September 1961.*

separated from the residue and washed with three 200 ml portions of water; 30 ml of hexane was added to the semisolid mass, and the product was collected by filtration. Recrystallization from hexane gave 4,*N*-dimethyl-2-nitroaniline (15.5 g, 46%), m.p. 84.5–86° (lit. m.p. 84–85° (9)).

o-Phenylenediamines

In addition to the commercially available compounds, a number of diamines were prepared by reduction of the corresponding nitroanilines. The reduction of 4-ethoxy-2-nitroaniline is given as a typical example. Tin was added in small portions to a suspension of 4-ethoxy-2-nitroaniline (46 g, 0.25 mole) in 25% hydrochloric acid (400 ml) kept at 50°. When addition of a drop of the reaction mixture to aqueous sodium hydroxide gave no orange color, the reduction was judged complete (60 g of tin added). The solution was kept below 50° while being made alkaline and then filtered. The filtrate was extracted with seven 200 ml portions of benzene, and the combined extracts after filtration were saturated with dry hydrogen chloride to precipitate 4-ethoxy-*o*-phenylenediamine dihydrochloride. The dihydrochloride darkened above 230° and decomposed completely above 340°. Titration of a sample to the phenolphthalein endpoint gave 223.2 as a molecular weight (calcd. for $C_8H_{14}Cl_2N_2O$, 225.1). When free amines were desired, the benzene solutions were diluted with pentane and cooled to give crystals. If the parent nitro compounds were not commercially available they were synthesized from their chloronitro analogues by the method of Ashton and Suschitzky (10) unless otherwise indicated in Table I.

[b]From methylation of the sulfonamide (14).
[c]This diamine prepared (16) by methylation of *N*,*N*′-di-*p*-toluenesulfonyl-*o*-phenylenediamide (17).

Condensation of a Phosphonothioic Dichloride with an o-Diamine in the Presence of a Tertiary Amine

Phenylphosphonothioic dichloride (5.28 g, 0.025 mole) in toluene (10 ml) was added dropwise with stirring to 4-carbomethoxy-*o*-phenylenediamine (4.15 g, 0.025 mole) in toluene (200 ml). The reaction mixture was maintained at 60° during the addition and for 15 min thereafter. Triethylamine (5.5 g, 0.054 mole) in toluene (10 ml) was added, and the mixture was refluxed for 2 h, cooled, and filtered. A solution of the precipitate in chloroform (15 ml) was poured into 150 ml of boiling toluene. Chloroform was distilled from this mixture while toluene was added to keep the volume at 150 ml. Filtration of the hot toluene solution removed triethylamine hydrochloride, and evaporation of the filtrate to 50 ml and cooling to 5° gave a semisolid precipitate. The decanted mother liquor when evaporated to 25 ml and cooled to −80° gave more product. Recrystallization of these solids from chloroform gave pure 5-carbomethoxy-2,3-dihydro-2-phenyl-1*H*-1,3,2-benzodiazaphosphole 2-sulfide.

Synthesis of Diazaphosphole 2-Sulfides and 2-Oxides in a Refluxing Solvent

The procedure for the reaction of a phosphonic dichloride with a diamine in bromobenzene was described in a previous paper (1). In using phosphonothioic dichlorides, several minor modifications were employed. Passing the exit gases through a cadmium acetate solution permitted measurement of the hydrogen sulfide evolved (max. yield 2%). With reactions which proceeded with difficulty, *o*-dichlorobenzene was often used as a solvent because of its higher boiling point. Some of the diazaphosphole 2-sulfides were quite soluble in aromatic solvents and it was necessary to reduce the volume of the reaction mixture and (or) add pentane to precipitate the product. The details are given in Tables II and III.

The melting point of every diazaphosphole 2-sulfide is lower than that of its 2-oxide analogue. When both amidic nitrogens are replaced by methyl groups a large decrease in melting point is observed for the 2-oxide structure, a small change for the 2-sulfide. These data reflect the weak hydrogen-bonding tendency of sulfur as compared to oxygen. As expected, this also leads to higher solubility in non-polar solvents for the 2-sulfides

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

as compared to the 2-oxides. Also, in both series the *N*-alkyl derivatives are more soluble in non-polar solvents. Both series of compounds are soluble in polar solvents such as methanol and ethanol but as traces of acid or base catalyze solvolysis, these solvents are seldom useful.

Hydrolysis of 2,3-Dihydro-2-phenyl-1H-1,3,2-benzodiazaphosphole 2-Oxide

When this benzodiazaphosphole 2-oxide (4.6 g, 0.02 mole) was added to 1 *N* sodium hydroxide (20 ml) at room temperature, an exothermic reaction occurred (the temperature rising to 38°) and the benzodiazaphosphole dissolved while a sodium salt precipitated. After cooling to 20°, the reaction mixture was filtered and the precipitate washed with absolute alcohol (three 5 ml portions) and dried. Additional product was obtained by partially evaporating the mother liquor and chilling. The sodium salt (2 g) was placed in water (20 ml) and acidification with 1 *N* hydrochloric acid to pH 5 gave 2-aminoanilido-phenylphosphonic acid (1.32 g), m.p. 240–247° decomp.

Anal. Calcd. for $C_{12}H_{13}N_2O_2P$: C, 58.06; H, 5.28; N, 11.29. Found: C, 57.56; H, 5.35; N, 11.38.

This product dissolved in aqueous sodium hydroxide and could be precipitated from the alkaline solution by careful acidification. It also dissolved in aqueous hydrochloric acid but underwent hydrolysis and could not be recovered by addition of alkali. When an aqueous acid solution of the 2-aminoanilidophenylphosphonic acid was boiled to remove most of the liquid, cooling produced the *o*-phenylenediamine salt of phenylphosphonic acid; m.p. 224–228°. This salt has been incorrectly reported as the amide (1).

Anal. Calcd. as 2-aminoanilido-phenylphosphonic acid, $C_{12}H_{13}N_2O_2P$: N, 11.29. Anal. Calcd. as the salt of *o*-phenylenediamine and phenylphosphonic acid, $C_{12}H_{15}N_2O_3P$: N, 11.05. Found (1): N, 11.02.

The salt was synthesized independently by heating to 80° a solution of phenylphosphonic acid (1.58 g, 0.01 mole) and *o*-phenylenediamine (1.08 g, 0.01 mole) in water (10 ml) and then cooling. The precipitate was collected, washed with alcohol, and dried, m.p. 226–230°. Its infrared spectrum was identical to that of the hydrolysis product described above.

Alcoholysis of 2,3-Dihydro-2-phenyl-1H-1,3,2-benzodiazaphosphole 2-Oxide

Dry hydrogen chloride was bubbled into a suspension of 2,3-dihydro-2-phenyl-1*H*-1,3,2-benzodiazaphosphole 2-oxide (1.15 g, 0.005 mole) in 10 ml of methanol until the solid dissolved. The mixture was heated just to boiling, cooled to room temperature, and made slightly alkaline with 1 *N* sodium hydroxide, and water was added to precipitate *O*-methyl-2-aminoanilido-phenylphosphonate (1.0 g, 76%), m.p. 149–150° (from methanol–water).

Anal. Calcd. for $C_{13}H_{15}N_2O_2P$: C, 59.53; H, 5.77; N, 10.68. Found: C, 59.49; H, 5.79; N, 10.59.

The same product was isolated when the diazaphosphole (2.3 g) in methanol (10 ml) was heated with sodium methoxide (0.1 g).

Hydrolysis of 2,3-Dihydro-2-phenyl-1H-1,3,2-benzodiazaphosphole 2-Sulfide

The 2-sulfide apparently does not react with 1 *N* sodium hydroxide at room temperature but slowly dissolves when the mixture is heated to 70°. Hydrogen sulfide is evolved when this solution is made acid.

Hydrolysis of 1,3-Dimethyl-2,3-dihydro-2-phenyl-1H-1,3,2-benzodiazaphosphole 2-Oxides and 2-Sulfides

The 2-oxide was recovered in 60% yield from a solution of 1 *N* sodium hydroxide refluxed for 1 min, but no recovery was possible after 3 min of refluxing. In contrast, the 2-sulfide in 1 *N* sodium hydroxide was recovered in 80% yield after 5 min of refluxing.

Methylation of 1-Methyl-2,3-dihydro-2-phenyl-1H-1,3,2-benzodiazaphosphole 2-Sulfide

Sodium hydroxide (6 ml, 25%) was added to the benzodiazaphosphole 2-sulfide (0.52 g, 0.002 mole) in dimethyl sulfate (1.3 g, 0.001 mole), and the mixture was stirred rapidly for 1 h at room temperature. The viscous liquid which separated from the reaction mixture was recrystallized twice from methanol–water to give a crude product, m.p. 91–92° (4.9 g, 89%). Recrystallization from *n*-hexane gave pure 1,3-dimethyl-2,3-dihydro-2-phenyl-1*H*-1,3,2-benzodiazaphosphole 2-sulfide, m.p. 100.5–101.5°, which did not depress the m.p. of an authentic sample obtained from *N,N'*-dimethyl-*o*-phenylenediamine and phenylphosphonothioic dichloride. The infrared spectra of the two samples were identical.

Methylation of 2,3-Dihydro-2-phenyl-1H-1,3,2-benzodiazaphosphole 2-Sulfide

Using identical quantities of materials to those above except for acetone (5 ml) and solid sodium hydroxide (ca. 0.4 g), this 2-sulfide was converted to the dimethyl derivative in 87% yield. The acetone was removed by distillation, and water (10 ml) was added to isolate the crude product.

Methylation of 2,3-Dihydro-2-ethyl-1H-1,3,2-benzodiazaphosphole 2-Sulfide

By the dimethylation procedure, this diazaphosphole produced 1,3-dimethyl-2,3-dihydro-2-ethyl-1*H*-1,3,2-benzodiazaphosphole 2-sulfide (88%), m.p. 70–71° from methanol–water.

Anal. Calcd. for $C_{10}H_{15}N_2PS$: C, 53.07; H, 6.68; N, 12.38. Found: C, 52.32; H, 6.91; N, 12.42.

Methylation of 1,2-Diphenyl-2,3-dihydro-1H-1,3,2-benzodiazaphosphole 2-Sulfide

By the monomethylation procedure, this diazaphosphole produced 1-methyl-2,3-diphenyl-2,3-dihydro-1*H*-1,3,2-benzodiazaphosphole 2-sulfide (93%), m.p. 115–116° from *n*-hexane.

Anal. Calcd. for $C_9H_{17}N_2PS$: C, 67.83; H, 5.09; N, 8.33. Found: C, 68.00; H, 5.12; N, 8.32.

[a] Crude product suitable for most purposes.
[b] Approximate, for reagents were mixed at room temperature then heated to reflux. Also, the boiling points of the solvents used determine the temperature at which the reaction was run so that all of the figures are not comparable. Where an amine salt is the reagent, the half-life listed is for 50% evolution of hydrogen chloride beyond that calculated for the amine salt decomposition.
[c] In refluxing bromobenzene.
[d] From $CHCl_3$, dried in vacuum.
[e] In refluxing bromobenzene, pentane added to precipitate the product.
[f] From trichloroethylene.
[g] From CCl_4, then heptane.
[h] From a $CHCl_3$ solution passed through alumina.
[i] In refluxing bromobenzene, the reaction mixture reduced in volume, CCl_4 added to precipitate the product.
[j] From $CHCl_3$–CCl_4.
[k] In refluxing toluene containing triethylamine, see experimental section.
[l] In refluxing xylene–dioxane (1:2) containing tri-*n*-propylamine. The solvent was distilled, and the residue was dissolved in C_2H_5OH and poured into H_2O to precipitate the product.
[m] From C_2H_5OH–H_2O, then $CHCl_3$–CCl_4, then C_2H_5OH–H_2O.
[n] Recrystallized from chlorobenzene–CCl_4.
[p] In refluxing *o*-dichlorobenzene.
[q] In refluxing bromobenzene. The entire reaction mixture (0.0125 mole) was chromatographed on alumina (60 g), and eluted with $CHCl_3$; then CCl_4 was added to the eluent to produce crystals.
[r] Chromatographed on alumina from $CHCl_3$ solution, eluted with $CHCl_3$–CCl_4 (1:1).
[s] In refluxing bromobenzene. The product (0.05 mole) was adsorbed on alumina and eluted with CCl_4, then precipitated by adding hexane.
[t] From CCl_4.
[u] Chromatographed on alumina and eluted with $CHCl_3$; CCl_4 added to precipitate the product.
[v] A benzene solution passed through alumina, then cooled to give crystals from $CHCl_3$–CCl_4.
[w] A $CHCl_3$ solution chromatographed on alumina. The product was eluted with CCl_4, the volume of the eluent was reduced, and pentane was added.
[x] A CCl_4 solution chromatographed on alumina. The product was eluted with CCl_4, the eluent was reduced in volume, and hexane was added.
[y] In refluxing CCl_4 containing triethylamine. The product isolation was similar to that given in experimental section except that a $CHCl_3$ solution of the crude product was poured into ether to precipitate triethylamine hydrochloride.
[z] Recrystallized from benzene.
[aa] From $CHCl_3$–CCl_4, then benzene, then again from $CHCl_3$–CCl_4.
[bb] Chromatographed on alumina and eluted with dioxane.
[cc] A $CHCl_3$ solution passed through alumina; the eluent was evaporated and CCl_4 was added.

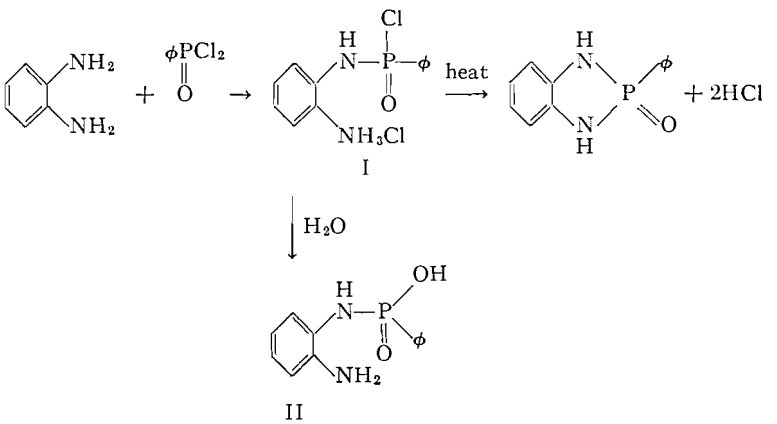
RESULTS AND DISCUSSION

Cyclization Reactions

A series of 1,3,2-benzodiazaphosphole 2-sulfides (Table II) as well as some 2-oxides (Table III) have been prepared, most commonly by the condensation of a diamine with a phosphonothioic or phosphonic dichloride in a refluxing inert solvent. When these reagents are mixed at room temperature a precipitate usually forms immediately. In a previous paper (1), it was suggested that with phenylphosphonic dichloride the initial precipitate consisted of the non-cyclic intermediate I.



I

II

A halogen analysis of the precipitate corresponded very roughly to I and treatment with water produced a white solid thought to be II. In the present work, from the initial precipitate it has been possible to isolate only diazaphosphole 2-oxide and *o*-phenylenediamine hydrochloride. The hydrolysis product, originally thought to be II, now has been proved to be not the amide but instead the salt of *o*-phenylenediamine and phenylphosphonic acid. The inability to isolate a non-cyclic intermediate or its hydrolysis product indicates that the cyclization step proceeds with comparable rapidity, if not with greater rapidity, than the half-amide I formation.

To accomplish the cyclizations the hydrogen chloride formed was either removed physically by its insolubility in a refluxing solvent or removed chemically by combination with a tertiary amine. When a phosphonothioic dichloride reacts with an *o*-diamine in a refluxing solvent some hydrogen sulfide is evolved. Since it is evolved in less than 2% yield, the quantity of diazaphosphole 2-sulfide obtained is not appreciably affected. In the initial phases of the present work the hydrogen sulfide formation was thought to be more significant and, to avoid it, some of the desired heterocycles were obtained at room temperature by adding tertiary amines. However, the reactions in refluxing bromobenzene usually give better yields with greater convenience because the products are much more easily isolated.

In the thermal condensations, as the diazaphosphole is initially formed the hydrogen chloride liberated reacts with unchanged diamine to form a salt. This salt must be decomposed to the free base to permit its utilization in additional diazaphosphole formation. This salt dissociation is not merely the shift of a simple equilibrium process controlled by diffusion of the hydrogen chloride to the surface of the solution, for condensations of both phosphonic and phosphonothioic dichlorides with *o*-phenylenediamine in refluxing bromobenzene were found to proceed more rapidly than the decomposition of *o*-phenylenediamine hydrochloride alone under the same conditions.

For personal use only.

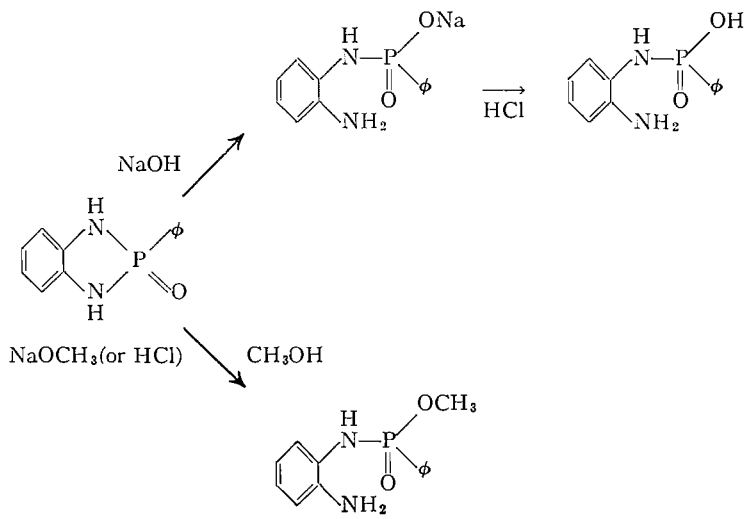
Invariably the condensations of a diamine with a phosphonothioic dichloride required a much longer time than with a phosphonic dichloride. This lower reactivity of the phosphonothioic dichlorides is not unexpected for it has been firmly established in other investigations (18). The course of each reaction was followed by titrating the evolved hydrogen chloride. Despite the lack of temperature control other than that of a refluxing solvent medium, frequently (but not regularly) good first-order rate constants were obtained from these titrations. Thus with *N,N'*-dimethyl-*o*-phenylenediamine in refluxing bromobenzene both phenylphosphonic dichloride ($k = 95 \times 10^{-5}$ s^{-1}) and phenylphosphonothioic dichloride ($k = 2.9 \times 10^{-5}$ s^{-1}) gave first-order constants.

With phosphonothioic dichlorides the condensations with diamines containing electron-withdrawing substituents in the ring were invariably slower than with *o*-phenylenediamine itself. Much faster reactions occurred with amines containing electron-donating substituents. The presence of alkyl groups on the amino-nitrogen facilitated condensation while *N*-phenyl-*o*-phenylenediamine reacted sluggishly. All these data, as well as the lower reactivity of the phosphonothioic dichloride as compared to the phosphonic dichloride, are consistent with the rate-determining step being the nucleophilic displacement on phosphorus.

Using phosphonic dichlorides the condensations do not follow as clear a kinetic pattern. The reactions are so much faster that not only are the observed differences in time less significant but in addition the amine salt decomposition may be a factor in determing the overall rate.

Chemical Properties

The hydrolysis and alcoholysis of the benzodiazaphosphole 2-oxides have been briefly studied. Cleavage of only one amide linkage is possible under mild conditions.



Under more drastic conditions (e.g. refluxing sodium hydroxide) complete hydrolysis to the diamine is obtained. The 2-sulfide analogue was somewhat more resistant to hydrolysis than the 2-oxide compound. The *N,N'*-dimethyl derivatives of the 2-phenyldiazaphosphole 2-oxide and 2-sulfide were much more resistant to hydrolysis than their unsubstituted counterparts. This hydrolytic stability is essential to any potential pharmaceutical use of the heterocycles.

Methylation of the diazaphosphole 2-sulfides was achieved with dimethyl sulfate and sodium hydroxide. These successful methylations offer encouragement for a future attachment of a sugar moiety to the diazaphosphole 2-sulfide to prepare a nucleoside analogue. The diazaphosphole 2-oxides hydrolyzed when subjected to the alkylation procedure and methylated products could not be isolated.

REARRANGEMENT STUDIES WITH ^{14}C

XXIV. SOLVOLYSES OF 2-(α-NAPHTHYL)-1-^{14}C-ETHYL *p*-TOLUENESULFONATE

C. C. LEE AND A. G. FORMAN

Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received June 28, 1965

ABSTRACT

Acetolysis and formolysis of 2-(α-naphthyl)-1-^{14}C-ethyl *p*-toluenesulfonate (I-OTs) were interrupted after 50% completion and the products, 2-(α-naphthyl)ethyl acetate and formate (I-OAc and I-OCHO), and the "unreacted" I-OTs were recovered. Rearrangements of the ^{14}C-label from C-1 to C-2 were found to be about 46% and 50%, respectively, in the I-OAc and I-OCHO. A similar rearrangement amounting to about 38% was observed in the I-OTs recovered from the acetolysis, while the I-OTs recovered from formolysis showed less than 1% ^{14}C rearrangement. Titrimetric rates for these reactions were determined and compared with known rates of solvolyses of 2-phenylethyl and ethyl *p*-toluenesulfonates. Small rate enhancements were indicated. The mechanistic implications of these results in relation to current carbonium ion theory are discussed.

INTRODUCTION

In current discussions on carbonium ion structure, Brown has emphatically suggested that rapidly equilibrating classical carbonium ions may be considered as an alternative to bridged or nonclassical ions (1, 2). Considering only β-phenylethyl systems which could give rise to symmetrical bridged ions, Brown (2) has pointed to the lack of significant enhancement in titrimetric rates for the β-phenyl substituted systems in comparison with the unsubstituted analogs as important evidence against the phenonium ion as a reaction intermediate. On the other hand, Cram (3) has strongly stated the case for the phenonium ion. The present paper reports the results from solvolyses of 2-(α-naphthyl)-1-^{14}C-ethyl *p*-toluenesulfonate (I-OTs) which may be of pertinence to the phenonium ion problem, especially when considered in conjunction with data from solvolyses of 2-phenyl-1-^{14}C-ethyl *p*-toluenesulfonate (II) (4, 5, 6) and 1-^{14}C-ethyl *p*-toluenesulfonate (III) (7).

RESULTS AND DISCUSSION

I-OTs was prepared from 2-(α-naphthyl)-1-^{14}C-ethanol (I-OH) which, in turn, was obtained from carbonation of the Grignard reagent with ^{14}C-carbon dioxide to give α-naphthyl-1-^{14}C-acetic acid, followed by lithium aluminium hydride reduction. Solutions of I-OTs in anhydrous acetic acid (0.350 *M*) and in anhydrous formic acid (0.060 *M*) were heated at 110.6 °C and 56.5 °C, respectively, until the reactions were 50% complete. The products, 2-(α-naphthyl)ethyl acetate or formate (I-OAc or I-OCHO) and the "unreacted" I-OTs were recovered by procedures as used in analogous studies with II (5). The recovered I-OTs was converted to I-OAc by treatment with fused sodium acetate in anhydrous ethanol (8); I-OAc from recovered I-OTs and the product, I-OAc or I-OCHO, were treated with lithium aluminium hydride to give I-OH which was oxidized by alkaline potassium permanganate to α-naphthoic acid (IV) (9). The activity of IV measured the extent of rearrangement of the ^{14}C-label from C-1 to C-2. The results are summarized in Table I. Titrimetric rates for acetolysis and formolysis of I-OTs were determined at convenient temperatures and then extrapolated to 75 °C for comparison with 2-phenylethyl and ethyl *p*-toluenesulfonates (II and III). The data are given in Table II.

Acetolysis	0.772	0.288	0.528
Formolysis	18.9	39.4	169

*From ref. 2.

From Table I, it may be noted that the ^{14}C rearrangement observed in the acetolysis of I-OTs is in complete agreement with the 46% rearrangement reported by Cram and Dalton (10) in their study with 2-(α-naphthyl)-1,1-dideuterioethyl p-toluenesulfonate. Data in Table I also indicate that complete equivalence of C-1 and C-2 has been achieved in the formolysis of I-OTs. These results may be compared with ^{14}C rearrangements of about 5% and 45%, respectively, for acetolysis and formolysis of II (4, 5, 6), and with the total absence of rearrangement in the solvolysis of III (7). The isotopic rearrangement observed in the recovered I-OTs (Table I) may be attributed to the process of return from ionic intermediate to covalent bonding. The extent of return accompanying acetolysis of I-OTs is relatively large ($\sim$38% rearranged), while the rearrangement in the recovered I-OTs from formolysis is almost negligible. These results are consistent with classic concepts regarding the effects of the reaction medium on internal return (11, 12). Returns to isotopically rearranged II have also been observed to accompany solvolyses of II (4, 5, 6); in formolysis such return is chiefly external (6). A decision as to whether the isotopically rearranged I-OTs recorded in Table I arose from intramolecular internal return or from intermolecular external return will require further investigation.

Acetolysis of III is faster than that of II by a factor of 2.7 (1, 2, 3). Cram (3) has attributed this partially to the negative inductive effect of phenyl and also to the unhindered back side of the incipient carbonium ion allowing the solvent to compete successfully with phenyl in this medium, as evidenced by only 5% ^{14}C rearrangement in the acetolysis of II. In the acetolysis of I-OTs, ^{14}C rearrangement rises to 46%, but the titrimetric rate is faster than that for acetolysis of II by only a factor of 1.8 (Table II). If relative rates were to be a true indication of anchimeric assistance, where internal return plays a role, polarimetric rather than titrimetric rates should be used (13). However, in the absence of optical activity for β-arylethyl systems, polarimetric data are not available. Where anchimeric assistance by the β-aryl group is to be considered, at least the basis for comparison should be a reaction involving ethyl cation without assistance. Since acetolysis of II or III entails extensive solvent participation, comparisons of rates of acetolysis among I-OTs, II, and III possibly will reflect only the difference between solvent assistance and aryl assistance rather than the true aryl assistance. Thus besides the influence of inductive effects, a predominance of solvent assistance in the acetolysis of II or III may be an important factor in giving rise to the small overall differences in relative acetolysis rates for I-OTs, II, and III.

Kinetic data (14) and the absence of ^{14}C rearrangement (7) suggest that even in formic acid, a less nucleophilic solvent, solvolysis of III is still not "limiting." The formolysis of II gave about 45% ^{14}C rearrangement and its titrimetric rate is faster than that for the formolysis of III by a factor of 2.1 after overcoming the negative inductive effect of phenyl and possibly also the more favorable solvent assistance for III. In the formolysis of I-OTs, 50% ^{14}C rearrangement is observed, and the titrimetric rate is greater than those for III

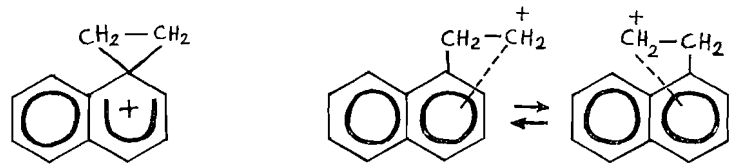
and II, respectively, by factors of 8.9 and 4.3 (Table II). It may also be noted that the negative inductive effect of α-naphthyl is believed to be greater than that of phenyl (15). Thus considering all the factors involved, the data do indicate some enhancement in rate as well as a complete equivalence of C-1 and C-2 in the formolysis of I-OTs. Such results would be consistent with the formulation of an ethylene-α-naphthonium ion (V, drawn by analogy with the structure of phenonium ion recommended by Brown (2)) as an intermediate (3, 10). The results from the formolysis of I-OTs are also analogous to those obtained in the acetolysis and formolysis of 2-(p-anisyl)-1-^{14}C-ethyl p-toluenesulfonate which showed rate enhancement as well as essential equivalence of C-1 and C-2, and for which a bridged ion has been proposed as reaction intermediate (16). On the other hand, where the rate enhancement is small as in the present case, Brown (2, 17) has suggested that the complete scrambling of the ^{14}C in C-1 and C-2 may be the result of rapid equilibration of "π-bridged" ions, VI, involving interaction between the π-cloud of the aromatic ring and the cationic center, instead of the truly bridged "nonclassical" ion V. It is not possible to differentiate V and VI from the present data.



V VI

EXPERIMENTAL

2-(α-Naphthyl)-1-^{14}C-ethyl p-Toluenesulfonate (I-OTs)

Treatment of the Grignard reagent prepared from α-chloromethylnaphthalene with ^{14}C-carbon dioxide gave carboxyl-labeled α-naphthylacetic acid, m.p. 130–131 °C (lit. (18) m.p. 131 °C). Reduction of this acid with lithium aluminium hydride yielded 2-(α-naphthyl)-1-^{14}C-ethanol (I-OH), m.p. 61–62 °C (lit. (9) m.p. 61–62 °C), which was converted to I-OTs by reaction with p-toluenesulfonyl chloride in pyridine (19). Yields of I-OTs, m.p. 59–60 °C (lit. (10) m.p. 56.5–58.0 °C), based on the alcohol, were about 85%.

Anal. Calcd. for $C_{19}H_{18}O_3S$: C, 69.91; H, 5.56; S, 9.82. Found: C, 70.09; H, 5.62; S, 9.64.

Acetolysis of I-OTs

A solution of 5.712 g (0.0175 moles) of I-OTs in 50 ml of anhydrous acetic acid was heated at 110.6 °C for a period of one half-life (740 min). The resulting mixture was poured onto crushed ice and then worked up for "unreacted" I-OTs and for the product, 2-(α-naphthyl)ethyl acetate (I-OAc), by procedures previously described for analogous studies with 2-phenyl-1-^{14}C-ethyl p-toluenesulfonate (II) (5). The recoveries of I-OTs were about 80% of theoretical based on 50% reaction. For duplicate runs, yields of I-OAc, b.p. 144–148 °C at 1 mm, were 1.33 g and 1.73 g (71% and 92% based on 50% reaction).

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.07; H, 6.71.

Formolysis of I-OTs

Because of the lower solubility of I-OTs in formic acid, the reaction was carried out in more dilute solution than in the case of acetolysis. A solution of 4.896 g (0.0150 moles) of I-OTs in 250 ml of anhydrous formic acid was heated at 56.5 °C for one half-life (510 min), poured onto crushed ice, and worked up as before. For duplicate runs, recovered I-OTs amounted to 1.7 g and 1.9 g (70% and 78% based on 50% reaction) and the yields of product, 2-(α-naphthyl)ethyl formate (I-OCHO), b.p. 137–142 °C at 1 mm, were 1.05 g and 1.20 g (67% and 77% based on 50% reaction).

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 77.98; H, 6.04. Found: C, 77.92; H, 6.05.

I-OAc from Recovered I-OTs

Each sample of recovered I-OTs was diluted with inactive carrier to give a total of 5.0 g of starting material and then dissolved in 50 ml of absolute ethanol. Freshly fused sodium acetate (2.9 g) was added and the mixture was refluxed for 24 h. It was then cooled, poured into water, and extracted with petroleum ether. The extract was dried over anhydrous magnesium sulfate and then fractionated to give about 2.0 g of the desired acetate, I-OAc.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Degradation

Each sample of the products, I-OAc and I-OCHO, and of the I-OAc from the recovered I-OTs, was treated with lithium aluminium hydride to give I-OH. The alcohol was oxidized by alkaline potassium permanganate to α-naphthoic acid (9), whose activity measured the extents of rearrangement. As a control experiment, I-OTs, before being subjected to solvolysis, was converted to I-OAc which, in turn, was degraded to give non-radioactive α-naphthoic acid, indicating that the conversion of recovered I-OTs to I-OAc and the degradation procedures would cause no rearrangement.

Kinetic Measurement

The kinetics of acetolysis and formolysis of I-OTs were followed titrimetrically by known methods already mentioned in earlier publications (20, 21). For acetolysis, specific rate constants at 110.6 °C and 100.0 °C, respectively, were found to be 1.37×10^{-5} and 5.53×10^{-6} s^{-1}. For formolysis, k values at 56.5 °C and 40.1 °C were, respectively, 2.18×10^{-5} and 2.90×10^{-6} s^{-1}. Specific rate constants at 75 °C (Table II) were obtained by extrapolation.

ADDITION OF FLUOROACETYLENES TO GROUP V HYDRIDES

W. R. CULLEN, D. S. DAWSON, AND G. E. STYAN
Chemistry Department, University of British Columbia, Vancouver, British Columbia
Received July 19, 1965

ABSTRACT

Compounds of the type R_2EH react readily with $CF_3C{\equiv}CCF_3$ to give $R_2EC(CF_3){=}C(CF_3)H$ (E = N, P, As), and with $CF_3C{\equiv}CH$ to give $R_2ECH{=}CHCF_3$ (E = N, As) and $R_2EC(CF_3){=}CH_2$ (E = As). The isomer distribution of the products is obtained from their n.m.r. spectra and the mechanism of the addition reaction is discussed.

INTRODUCTION

Although it was known that the fluoroacetylenes hexafluorobut-2-yne, $CF_3C{\equiv}CCF_3$ (I) and 1,1,1-trifluoropropyne $CF_3C{\equiv}CH$ (II), react with compounds such as $(C_2H_5)_2NH$ (1) and H_2S (2) to give adducts of the type $HSC(CF_3){=}C(CF_3)H$, very little information was available concerning the isomer distribution of the products. Because of our interest in the reactions of fluoroacetylenes (3, 4) and because little is known about the addition of compounds containing E—H bonds (E = N, P, As) to acetylenes, we have studied the products obtained by reacting hydrides of the type R_2EH (R = CH_3, C_6H_5, CF_3) with I and II.

Recently Stone and co-workers (5, 6) have found that I adds to transition metal hydrides to yield predominantly the *trans*-adduct, e.g.

$$(CO)_5ReH + CF_3C{\equiv}CCF_3 \rightarrow \begin{matrix} (CO)_5Re & & CF_3 \\ & C{=}C & \\ CF_3 & & H \end{matrix}$$

DISCUSSION AND RESULTS

The reactions investigated can be described by the following equations.

$$\begin{matrix} & & CF_3C{\equiv}CCF_3\ (I) & \rightarrow & RR'EC(CF_3){=}C(CF_3)H\ (IV) \\ RR'EH\ (III) & \longrightarrow & & & \\ & & CF_3C{\equiv}CH\ (II) & \rightarrow & RR'ECH{=}C(CF_3)H\ (V) + RR'EC(CF_3){=}CH_2\ (VI) \end{matrix}$$

The products isolated from these reactions will be described first.

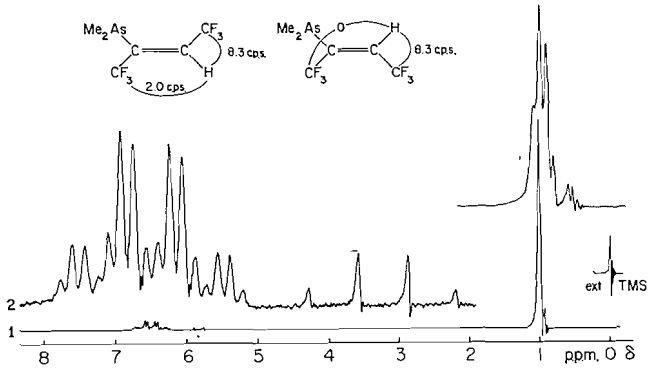

FIG. 1. ^1H n.m.r. spectrum of $(CH_3)_2AsC(CF_3){=}C(CF_3)H$.

Reaction Products

Dimethylarsine (III, R = R′ = CH_3, E = As) and I give the 1:1 adduct IV, a colorless liquid, b.p. 109–110°. The ^1H nuclear magnetic resonance (n.m.r.) spectrum of this product, before distillation, is shown in Fig. 1. The coupling constants indicated in the figure are consistent with the quartet of quartets being associated with the *trans*-isomer and the slightly higher field quartet with the *cis*-compound, the relative abundance of the two isomers being 15:1. In the high field region the areas of the two peaks are also in the ratio 15:1 indicating that they too are associated with the two isomers. These peaks which are due to the methyl groups on the arsenic atoms are split into quartets with J = 1.2 c.p.s. Splittings of this sort have been observed previously for the related compounds $(CH_3)RAsC(CF_3)=C(CF_3)Cl$ (R = CH_3, Br) (3) and $(CH_3)_2AsC(CF_3)=C(CF_3)As(CH_3)_2$. In the latter case the *cis*-compound (4) has an ill-defined quartet at 1.22 p.p.m. ($J \approx 0.5$ c.p.s.) and the *trans*-isomer a similar quartet at 1.18 p.p.m. ($J \approx 1.0$ c.p.s.). It has been suggested (3) that these splittings could be due to "through space" coupling of the arsenic methyl protons with the fluorine atoms of the geminal trifluoromethyl group since arsines of the type $(CH_3)RAsRf$, where Rf is any other type of fluorocarbon group, have only a single sharp methyl peak in their n.m.r. spectra. It is, however, possible to have the $CH_3AsC(CF_3)=$ group present without observing this splitting as in the compound $(CH_3)_2AsC(CF_3)=CHCl$ (7) where the methyl peak is split ($J \approx 1$ c.p.s.) when the arsenic atom is *cis* to the chlorine but is unsplit in the other isomer. Evidently bulky groups are necessary for splitting to occur. The ^{19}F n.m.r. spectrum of a sample of IV (R = R′ = CH_3, E = As) which was at least 90% *trans*-isomer shows two peaks. The downfield peak which consists of a doublet (J = 8.4 c.p.s.) of quartets (J = 1.9 c.p.s.) is assigned to the fluorine atoms of the $=C(CF_3)H$ group. Fig. 1 shows that $J_{CF_3\text{--}H} = 8.4$ c.p.s. and thus the 1.9 c.p.s. splitting must be due to the *trans*-CF_3 groups. These coupling constants are in agreement with those previously reported (6). The high field peak in the ^{19}F spectrum of the arsine is very broad and this is assigned to the fluorine atoms of the $(CH_3)_2AsC(CF_3)=$ group, the broadening being due to the combined effects of the weak CF_3--CF_3, CF_3--CH_3, and *cis*-CF_3--H interactions.

A predominantly *trans*-configuration is also found in the product of the reaction of methylphenylarsine (III, R = CH_3, R′ = C_6H_5, E = As) with I. The mixture of isomers of IV (R = CH_3, R′ = C_6H_5, E = As) obtained after distillation at 54° (10^{-3} mm) contained 92% *trans*-compound. This assignment can be made on the basis of the ^1H n.m.r. spectrum which is very similar to that described for the dimethylarsine adduct (IV, R = R′ = CH_3, E = As). Here again the methyl peak of each isomer has a different chemical shift and is split into a quartet by weak CF_3--CH_3 interactions. Bistrifluoromethylarsine and I give a product IV (R = R′ = CF_3, E = As) b.p. 99–100° which consists only of the *trans*-isomer as characterized by the quartet of quartets in its ^1H n.m.r. spectrum.

The product of the interaction of diphenylphosphine and I is the 1:1 adduct IV (R = R′ = C_6H_5, E = P) b.p. 127° (10^{-3} mm). The ^1H n.m.r. spectrum of this product shows the presence of aromatic and olefinic protons and the relative areas of the peaks indicate that some absorption due to the olefinic protons lies underneath the broad aromatic proton peak. The ^{31}P--H coupling for trivinylphosphine is given as 30 c.p.s. for the *trans*-hydrogen and 14 c.p.s. for the *cis* (8). Thus the diphenylphosphino compound would be expected to show some ^{31}P--H coupling also. Among the peaks associated with the olefinic protons is an isolated quartet (J = 9 c.p.s.) which shows some sign of secondary splitting and which can be assigned to a single proton or to half a proton in the group $=C(CF_3)H$ depending on

whether $J_{^{31}P\text{--}H} \simeq 0$ or $\geqslant 50$ c.p.s. The latter possibility is more likely, but the coupling can not be given more precisely because of overlap of peaks. If the trends found for the arsenic compounds are maintained for phosphorus, then the upfield position and slight secondary splittings of the quartet indicate that it is due to the *cis*-isomer. However, the secondary splitting criterion is not reliable as is seen for the nitrogen compounds described below. The area of this quartet indicates that there is a significant amount of this supposed *cis*-isomer in the mixture (ca. 40% if the ^{31}P--H coupling $\geqslant 50$ c.p.s.).

Dimethylamine and I afford the dimethylaminobutene (IV, R = R′ = CH_3, E = N) b.p. 96–97°. The initial reaction product, undistilled, consists of two isomers in the ratio 6:1 (trans:*cis*, *quod vide*), each isomer having a ^1H n.m.r. spectrum of a downfield quartet (J = 9 c.p.s., showing *slight* secondary splitting) and an upfield singlet which also shows the presence of weak coupling. By analogy with the arsenic compounds the downfield quartet is assigned to the *trans*-isomer and this is substantiated by the ^{19}F n.m.r. spectrum of the pure isomer which contains only two regions of absorption both of which show only very weak F--F coupling resulting in a broadening of the peaks. The ^{19}F spectrum of a mixture of isomers shows a quartet (J = 12.6 c.p.s.) due to the other isomer. It has been found that *trans*-CF_3--CF_3 coupling is much weaker than *cis*-CF_3--CF_3, the former having values of 1.1, 2.3 (5), and 2.5 c.p.s. (6), the latter being of the order of 11.5 c.p.s. (5). Thus in the present example the weak coupling can be assigned to the *trans*-isomer. The ^{19}F spectrum also shows the expected doublet associated with the $=C(CF_3)H$ group but unexpectedly each doublet is split into a septet presumably because of coupling with the methyl groups on the nitrogen. The slight splittings on the methyl peaks in the ^1H spectrum are a further manifestation of this interaction. This long-range coupling (J = 1.7 c.p.s.) is of similar magnitude to the 6-bond H--F coupling in *o*-fluoro-N-cyclohexyl-N-methylbenzamide (9).

Trifluoropropyne (II) and dimethylarsine give a product b.p. 109–110° whose low field n.m.r. spectrum is given in Fig. 2. Analysis of this spectrum resulted in the assignments given in the figure. The assignments were based on the possibility of obtaining three isomers and the expectation that $J_{H\alpha-H\beta}$ for the *cis*-compound would be less than for the *trans*-isomer as is found in related hydrocarbon systems (10). Subsequently the pure *cis*-compound was isolated by vapor phase chromatography (v.p.c.) and converted to the *trans*-form and the n.m.r. spectra of these proved to be identical with those derived (Fig. 2). Confirmation of the *trans*-isomer comes from the infrared spectrum which shows a highly characteristic band of medium intensity at 970 cm^{-1} (11). The *cis*-isomer is transparent in this region. The iso-compound (VI, R = R′ = CH_3, E = As) has an unsplit methyl peak with the same chemical shift found for the *cis*-compound. The ratio of isomers in the original reaction product, after distillation, is *cis*:*trans*:iso = 3:3:2.

Dimethylamine and II give only the *trans*-dimethylamino derivative (V, R = R′ = CH_3, E = N) b.p. 118°. The ^1H n.m.r. spectrum is almost identical with that of the analogous *trans*-dimethylarsino compound. Confirmation of the *trans*-configuration comes from its infrared spectrum which, like the arsenic analogue, contains a strong band in the *trans* —HC=CH— "out-of-plane" bending region at 960 cm^{-1}. The H_α--H_β coupling in the *trans*-amino compound is 13 c.p.s. which is to be compared with 18 and 13 c.p.s. for the *trans*- and *cis*-arsino derivatives respectively.

Isomerization of the Products

A limited amount of information regarding isomerization of the olefinic products has been obtained in the present investigation. Thus the *cis*-isomer of 2-dimethylarsino-1,1,1,4,4,4-hexafluorobutene (IV, R = R′ = CH_3, E = As) is isomerized to the *trans*-compound on heating ($T \geqslant 140°$) although the methylphenylarsinobutene is unaffected at 140°. Isomerization of the dimethylaminobutene (IV, R = R′ = CH_3, E = N) is apparently catalyzed by oxygen since leaving a *trans*-rich mixture exposed to the air at 20° results in an increase in the *cis*-isomer content and distilling the mixture in nitrogen results in an increase in the *trans*-isomer content. (Inevitably some oxygen would be present during the distillation.) However, if a mixture of the isomers is heated in the absence of air then no isomerization takes place below 160° even though other reactions, possibly polymerization, start to become significant at the higher temperatures.

The *cis*-isomer of 1-dimethylarsino-3,3,3-trifluoropropene (V, R = R′ = CH_3, E = As) is converted to the *trans*-isomer both on ultraviolet irradiation and on heating. This provides a convenient method of obtaining the *trans*-compound since the *cis*-isomer can be isolated by v.p.c. The thermal isomerization does not take place in the absence of air below 150°, but at 175° it is almost complete after 12 days.

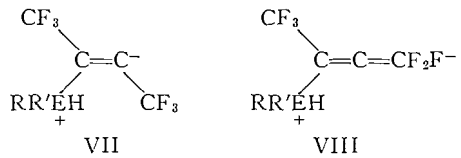
Mechanism of the Addition Reactions

Haszeldine (1) found that nucleophilic attack by alkoxide ion occurs readily on hexafluorobut-2-yne but less readily on 1,1,1-trifluoropropyne. Since his work was reported, a number of studies have been made on the sterochemistry of nucleophilic attack on more commonly available acetylenes which have resulted in the generalization that nucleophilic attack results in *trans*-addition (12), although a few exceptions have been noted (13). More recently *trans*-addition of alkoxide to ethynylsulfur pentafluoride to give predominantly *cis*-$SF_5CH{=}CHOCH_3$ has been found (14). Thus it seems likely that Haszeldines' products $ROC(CF_3){=}C(CF_3)H$ and $ROCH{=}CHCF_3$ will have predominantly the configuration to be expected from *trans*-addition.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

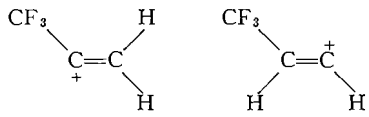
The mechanism of the addition of the compounds R_2EH to the acetylenes is less certain. In the hydrocarbon field it has been found that, in the absence of catalysts, amines add only to activated triple bonds (15, 16). It has been assumed that these additions involve nucleophilic attack by the amine (15, 16), but the geometry of the products has not been investigated.

The addition of arsines to I also appears to involve nucleophilic attack, presumably by the arsenic lone pair, since the ease of reaction of the arsines RR′AsH with I decreases in order $(CH_3)_2AsH > CH_3(C_6H_5)AsH > (CF_3)_2AsH$. This order reflects the decreasing availability of the arsenic lone pair for nucleophilic attack owing to the presence of electron-withdrawing groups on the arsenic atom (17). Similarly the reaction of dimethylamine with I probably involves nucleophilic attack. The nature of the reaction of diphenylphosphine with I is less certain because of the high proportion of what is probably the *cis*-isomer in the product. The transition state leading to *trans*-addition by nucleophilic attack can be represented by VII; hyperconjugation could result in VIII which in turn could result in some *cis*-isomer being produced, but it is difficult to see why VIII should be more stable when E = P.



VII VIII

Haszeldine found that nucleophilic attack by alkoxide on the propyne (II) leads to the formation of only $ROCH{=}CHCF_3$, no $CF_3C(OR){=}CH_2$ being produced. Dimethylamine is now found to add in a similar way to give only *trans*-$(CH_3)_2NCH{=}C(CF_3)H$ but it seems unlikely that the product arises by *cis*-addition and consequently it is believed that *trans*-addition first takes place followed by isomerization. In the corresponding arsenic system it is the *trans*-compound which is more thermodynamically stable. Dimethylarsine and II give the three isomers shown in Fig. 2. The *cis*-compound could arise from nucleophilic attack by the arsine but the amount of the *trans*-compound, which is equal to that of the *cis*, seems to be too much to have resulted from isomerization of the initially formed *cis*-isomer unless the isomerization is catalyzed by unreacted arsine. The mechanism of the formation of the iso-compound VI (R = R′ = CH_3, E = As) is also of interest since electrophilic attack by the hydrogen of the arsine should proceed through intermediates such as IX and X.



IX X

Of the two rather unlikely species X would be expected to be more stable and consequently electrophilic attack should also lead to the *cis*-isomer, Burnelle having recently calculated (18) that a *trans*-distortion of the alkyne is to be expected on the approach of an electrophile. Thus, although Haszeldine (1) found no evidence for nucleophilic attack by alkoxide at the center carbon atom of the propyne it seems likely that this is occurring in the arsine reaction. However, a concurrent free radical addition could be taking place giving rise to all three isomers.

One very important feature of these hydride addition reactions yet to be settled is the question of inter- or intra-molecular hydrogen transfer and it is hoped that competitive experiments with deuterated arsines will provide an answer.

EXPERIMENTAL

All reactions were carried out in sealed thick-walled pyrex tubes. Nuclear magnetic resonance spectra were obtained using Varian A-60 and HR-60 spectrometers and chemical shifts are reported in parts per million (p.p.m.) downfield from external tetramethylsilane (^{1}H spectra) and from external trifluoroacetic acid (^{19}F spectra). Infrared spectra were recorded using a Perkin–Elmer Model 21 instrument. Microanalyses were carried out by Dr. Alfred Bernhardt, Mulheim, Germany.

Reaction of Hexafluorobut-2-yne with Dimethylarsine

The arsine and the acetylene did not react in the gas phase at 20°. However, there was a vigorous reaction when the arsine (3.1 g) and the butyne (10.1 g) were condensed together and allowed to warm slowly to 20°. Trap-to-trap distillation gave 7.4 g of unreacted acetylene and 7.7 g of *2-dimethylarsino-1,1,1,4,4,4-hexafluorobutene* which condensed in a trap cooled to −78°. Vapor phase chromatography (dinonyl phthalate at 100°) showed the fraction to be at least 99% pure. It distilled in nitrogen at 109–110° (Found: C, 26.7; H, 2.8; As, 28.1; F, 42.3. Calcd. for $C_6H_7AsF_6$: C, 26.8; H, 2.7; As, 28.0; F, 42.6). Infrared spectrum (liquid film): 3 020(w), 2 940(w), 2 340(vw), 1 643(w), 1 430(sh,m), 1 424(m), 1 366(w), 1 331(vs), 1 257(vs), 1 160(vs), 1 140 (vs), 940(vw), 900(m), 870(sh,s), 859(s), 850(s), 722(w) cm^{-1}. Spectra (n.m.r.): ^{1}H spectrum (Fig. 1) methyl peaks at 1.03 and 0.94 p.p.m. each split into a multiplet of 4 (J = 1.2 c.p.s.), area ratio = 15.1:1. Two olefinic protons, one consisting of a quartet of quartets centered at 6.5 p.p.m. (J = 8.3 and 2.0 c.p.s.) and the other a quartet centered at 5.83 p.p.m. (J = 8.3 c.p.s.), of relative area 15.1:1. ^{19}F spectrum: two peaks of equal area at 13.6 and 11.1 p.p.m. The low field peak is a doublet (J = 8.4 c.p.s.) each doublet being further split into a quartet (J = 1.9 c.p.s .). The peak at 11.1 p.p.m. is broad being of the order of 8 c.p.s. at half height and is a multiplet of 13.

A sample of the adduct after distillation showed an isomer distribution of 95% *trans*:5% *cis*, and after 36 h at 140° even less of the *cis*-isomer remained. After 36 h at 160° the isomer composition was 98% *trans* and 2% *cis*.

The arsine (*trans*: *cis* = 95:5) and 10 ml of 10% aqueous sodium hydroxide were heated to 100° for 3 days to give 0.043 g (15% yield) of *trans*-1,1,1,4,4,4-hexafluorobutene of known infrared spectrum.

Reaction of Hexafluorobut-2-yne with Methylphenylarsine

The arsine (5.6 g) and the butyne (13.3 g) reacted slowly at 20° to give a single phase after 30 min. The less volatile product which distilled at 54° (10^{-3} mm) was identified as *2-methylphenylarsino-1,1,1,4,4,4-hexafluorobutene* (Found: C, 40.0; H, 2.9; As, 22.6; F, 34.7. Calcd. for $C_{11}H_9AsF_6$: C, 40.0; H, 2.7; As, 22.7; F, 34.6). Infrared spectrum (liquid film): 3 070(w), 2 930(vw), 2 280(vw), 1 641(w), 1 582(w), 1 485(w), 1 438(m), 1 363(w), 1 330(s), 1 283(m), 1 255(vs), 1 143(vs), 1 077(w), 1 069(vw), 1 023(w), 998(w), 870(w), 850(m), 844(m), 737(s), 721(vw), 693(s), 641(s) cm^{-1}. ^{1}H n.m.r. spectrum: two high field peaks at 1.06 and 0.93 p.p.m. of relative area 11:1, the larger one being a distorted quartet ($J \approx$ 1 c.p.s.). In the downfield region are two quartets (J = 8.5 c.p.s.) centered at 6.36 and 5.40 p.p.m. (area ratio = 11:1), each peak of the larger quartet at 6.36 p.p.m. is further split into a quartet (J = 2.0 c.p.s.). The aromatic protons appear as a complex system centered at 6.9 p.p.m. This same n.m.r. spectrum was obtained from a sample that had been heated at 140° for 3 days.

Reaction of Hexafluorobut-2-yne with Bistrifluoromethylarsine

Bistrifluoromethylarsine (2.9 g) and excess acetylene (11.0 g) did not react at 20° (2 days), and after 24 h at 130° only partial reaction had occurred. The reactants and products were then heated to 210° (24 h) to give hexafluorobut-2-yne (8.2 g) containing a little silicon tetrafluoride and fluoroform, and a fraction which condensed at −46° (5.0 g). This last fraction distilled at 99–100° in a nitrogen atmosphere and was identified as *2-bis(trifluoromethyl)arsino-1,1,1,4,4,4-hexafluorobutene*. An analytical sample was obtained by v.p.c. (dinonyl phthalate at 100°) (Found: C, 19.3; H, 0.27; As, 19.9; F, 60.5. Calcd. for C_6HAsF_{12}: C, 19.2; H, 0.27; As, 19.9; F, 60.6). Infrared spectrum (vapor): 3 100(vw), 2 302(vw), 1 793(vw), 1 649(vw), 1 385(m), 1 360(m), 1 331(vs), 1 265(vs), 1 215(s), 1 173(vs), 1 131(s), 1 099(s), 1 067(m), 1 029(m), 1 003(w), 949(vs), 887(m), 855(m), 820(vw), 735(s), 719(s) cm^{-1}. The ^{1}H spectrum consisted of a quartet of quartets centered at 6.93 p.p.m. (J = 7.5 and 1.5 c.p.s.).

Reaction of 1,1,1-Trifluoropropyne with Dimethylarsine

The propyne (6.0 g) and dimethylarsine (4.0 g) were left at 20° for 5 days. The excess alkyne was recovered by trap-to-trap distillation and the less volatile fraction was distilled in a nitrogen atmosphere to give 3.0 g of a product of formula $(CH_3)_2AsC_3F_3H_2$, b.p. 100° (Found: C, 30.2; H, 4.19; As, 37.4, F, 28.7. Calcd. for $C_5H_8AsF_3$: C, 30.0; H, 4.0; As, 37.5; F, 28.5). The ^{1}H n.m.r. spectrum of this product indicated it to be a mixture of isomers, the low field region and the assignments are shown in Fig. 2. The high field spectrum

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

showed peaks at 0.83 p.p.m. (*trans*) and 0.75 p.p.m. (*cis* and iso). The fraction was separated into two components by v.p.c. (dinonyl phthalate at 120°) the first being a mixture of the *trans*- and iso-compounds, the second being the *cis*-isomer. Infrared spectrum of the *cis*-isomer (vapor): 3 000(w), 2 915(w), 1 622(m), 1 424(w), 1 355(s), 1 280(vs), 1 192(vs), 1 146(vs), 1 125(vs), 892(w), 855(m), 714(m) cm^{-1}. The ^1H n.m.r. spectrum was as derived in Fig. 2 except that at high resolution $J_{H\text{--}CF_3}$ is 0.6 c.p.s. A sample of the *cis*-isomer was heated for 3 days at 110°, 3 days at 135°, and 1 day at 150° without change. However, at 175° the *trans*-isomer was slowly formed and after 12 days at this temperature almost complete isomerization had occurred. Infrared spectrum of the *trans*-isomer (vapor): 3 025(w), 2 940(w), 1 642(m), 1 435(w), 1 357(vw), 1 308(vs), 1 283(vs), 1 230(vs), 1 197(vs), 1 145(vs), 970(m), 895(w), 864(m), 722(m) cm^{-1}. The ^1H n.m.r. spectrum was as derived. A sample of the *cis*-isomer was also converted almost completely to the *trans*-compound by ultraviolet irradiation for 1 week (10 cm from 100 watt G.E. lamp).

Comparison of the infrared spectra of the *cis*- and *trans*-compounds with that of the original reaction product showed that the main bands associated with the iso-compound occur at 1 410(m), 1 220(w), 1 170(vs), 1 100(vs), 950(m) cm^{-1}.

Reaction of Hexafluorobut-2-yne with Diphenylphosphine

The phosphine (6.1 g, 32.8 mmoles) reacted immediately at 20° with hexafluorobut-2-yne (8.6 g, 53.0 mmoles) to give a viscous dark-brown material. All the butyne was consumed. The product was extracted with chloroform and distilled at 10^{-3} mm to give *2-diphenylphosphino-1,1,1,4,4,4-hexafluorobutene* b.p. 127° (Found: C, 55.1; H, 2.9; F, 32.9; P, 8.74; mol. wt. (Rast), 353. Calcd. for $C_{16}H_{11}F_6P$: C, 55.2; H, 3.2; F, 32.8; P, 8.91; mol. wt. 348). Infrared spectrum (liquid film): 3 100(w), 1 641(vw), 1 596(vw), 1 488(w), 1 445(m), 1 367(m), 1 334(m), 1 282(sh,s), 1 263(vs), 1 237(vs), 1 202(sh,s), 1 167(vs), 1 137(sh,w), 1 119(sh,w), 1 091(m), 1 072(w), 1 026(w), 1 000(w), 874(w), 841(sh,vw), 742(s), 733(sh,w), 694(s) cm^{-1}. ^1H n.m.r. spectrum: broad peak at 6.86 p.p.m. mainly due to aromatic protons, and a quartet (J = 9 c.p.s.) centered at 5.24 p.p.m. Between these lies a multiplet of 6 peaks (J = 8–9 c.p.s.) centered at 6.2 p.p.m. Both the quartet and the multiplet show secondary splittings (J = 1–2 c.p.s.).

Reaction of Dimethylamine with Hexafluorobut-2-yne

The acetylene (19.3 g) and amine (1.4 g) reacted immediately on melting. The recovered butyne weighed 13.4 g. The reaction product, which condensed in a trap cooled to −78°, distilled at 96–97° in a nitrogen atmosphere. An analytical sample of *2-dimethylamino-1,1,1,4,4,4-hexafluorobutene* was obtained by v.p.c. (dinonyl phthalate at 82°) (Found: C, 34.5; H, 3.5; N, 7.25. Calcd. for $C_6H_7F_6N$: C, 34.8; H, 3.4; N, 6.8). One small impurity was also isolated by v.p.c. from the reaction mixture and it proved to be 1,1,1,4,4,4-hexafluoropropanone (Found: C, 26.8; H, 1.31; F, 63.1. Calcd. for $C_4H_2F_6O$: C, 26.7; H, 1.12; F, 63.3. ^1H n.m.r. spectrum: quartet at 3.04 p.p.m. (J = 9 c.p.s.); infrared spectrum: carbonyl absorption at 1 790 cm^{-1}). When the reaction was done in an n.m.r. tube using excess acetylene as solvent, all the amine was used up immediately on mixing and the ^1H n.m.r. spectrum of the product showed quartets at 4.62 and 4.16 p.p.m. (J = 9.1 and 9.1 c.p.s. respectively) and slightly split methyl peaks at 2.41 and 2.24 p.p.m. The relative area of the downfield quartet to the downfield methyl peak (the *trans*-isomer) was 1:6. The other peaks are associated with the *cis*-isomer (relative area 1:6). The initial reaction product contains both isomers in the ratio of *trans*:*cis* = 6.2:1. Distillation of the isolated product mixture gave a fraction containing predominantly (>98%) the *trans*-isomer. However, if the initial reaction product is left exposed to air at 20° the proportion of *cis*-isomer increases as follows.

Time of exposure to air	*cis*:*trans*
10 min	1:6.5
25 min	1:1.9
2 days	1:1.7
12 days	1:1.6

The 1:1.6 (*cis*:*trans*) mixture was sealed and heated in the absence of air for 1 h at a variety of temperatures up to 140°. Slight darkening occurred at the higher temperatures but no change in isomer distribution was detected even though a second phase began to appear.

The infrared spectrum of the *trans*-isomer (98%) showed the following absorption bands (vapor): 2 915(m), 2 845(m), 1 710(w), 1 660(vs), 1 514(m), 1 476(m), 1 434(s), 1 310(vs), 1 274(vs), 1 239(vs), 1 195(vs), 1 156(vs), 1 127(vs), 1 069(s), 939(m), 859(s), 771(m), 730(w), 696(w), 654(s) cm^{-1}. The ^{19}F spectrum of the same sample showed a doublet (J = 9.4 c.p.s.) of septets (J = 1.7 c.p.s.) at 24.8 p.p.m. and a broad singlet at 11.4 p.p.m. Heteronuclear decoupling experiments showed that the doublet and septet splittings were due to coupling with hydrogen. Removal of hydrogen coupling still left broad fluorine peaks. The ^{19}F spectrum of a *cis–trans* mixture (ca. 1:1.5) showed a complex multiplet at 24.8 p.p.m. due to both isomers, a quartet (J = 12.6 c.p.s.) at 15.3 p.p.m. (*cis*-isomer), and a broad singlet at 11.0 p.p.m. (*trans*-isomer).

Reaction of Dimethylamine with 1,1,1-Trifluoropropyne

The amine (1.2 g) and the propyne (6.0 g) reacted violently well below room temperature. Propyne (4.1 g) was recovered and 2.1 g of a 1:1 adduct was produced. The adduct distilled with decomposition at 118° in a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

nitrogen atmosphere and only 0.5 g of distillate were collected. Analysis indicated that the formula of the distillate was $(CH_3)_2NC_3H_2F_3$ (Found: C, 43.0; H, 5.7; F, 41.0; N, 10.3. Calcd. for $C_5H_8F_3N$: C, 43.2; H, 5.8; F, 41.0, N, 10.1). Infrared spectrum (vapor): 2 915(m), 2 820(w), 1 736(w), 1 660(vs), 1 488(w), 1 447(m), 1 362(s), 1 307(s), 1 258(s), 1 229(s), 1 154(sh,vw), 1 102(w), 1 076(vs), 960(s), 888(s), 845(m), 739(m), 678(s) cm^{-1}. ^1H n.m.r. spectrum peaks at 2.29 (CH_3—), 6.17 (H_α) and 3.66 (H_β) p.p.m. with $J_{CF_3\text{--}H\alpha} = 1.5$ c.p.s., $J_{H\alpha\text{--}H\beta} = 13$ c.p.s., and $J_{CF_3\text{--}H\beta} = 6.5$ c.p.s. $H_\alpha H_\beta$ are defined as in Fig. 2.

ACKNOWLEDGMENTS

The authors are grateful to the National Research Council and Defence Research Board of Canada for financial assistance. They also wish to thank Dr. L. D. Hall for assistance in obtaining the ^{19}F n.m.r. spectra, Mr. Peter Brierley for experimental assistance, and the Ansul Chemical Company for gifts of dimethylarsinic and methylarsonic acids.

THE ELECTRON SPIN RESONANCE SPECTRA OF DINITRONAPHTHALENE ANION RADICALS

P. H. H. FISCHER[1] AND C. A. MCDOWELL
Department of Chemistry, University of British Columbia, Vancouver, British Columbia

Received July 23, 1965

ABSTRACT

The radical anions of 1,4-dinitronaphthalene, 1,5-dinitronaphthalene, and 1,8-dinitronaphthalene have been generated by electrolytic means, and their e.s.r. spectra recorded. The spectra consist of 61, 111, and 85 lines respectively, and can be analyzed in terms of one nitrogen and three proton coupling constants, consistent with the full symmetry of the species giving rise to them. These constants are, for 1,4-dinitronaphthalene: $a_N = 0.97$ G, $a_{H2} = 1.69$ G, $a_{H5} = 0.53$ G, and $a_{H6} = 0.41$ G; for 1,5-dinitronaphthalene: $a_N = 2.30$ G, $a_{H2} = 2.42$ G, $a_{H3} = 0.44$ G, and $a_{H4} = 2.82$ G; for 1,8-dinitronaphthalene: $a_N = 3.03$ G, $a_{H2} = 3.63$ G, $a_{H3} = 0.95$ G, and $a_{H4} = 3.73$ G. Whereas the nitrogen coupling constants can be unambiguously assigned, this, in the absence of deuteration studies say, is not the case for the three sets of equivalent protons. As an aid in the assignment of proton coupling constants, Hückel LCAO calculations and simplified SCFMO calculations by the method of McLachlan have been performed. The first mentioned of the above proton constants could thus be assigned with reasonable certainty, the remaining two a_{Hi} remain ambiguous.

INTRODUCTION

The electron spin resonance (e.s.r.) spectra of paramagnetic species formed by reduction of nitro-substituted aromatic systems have been investigated by several groups of workers. Paramagnetic species have been formed by several processes: by the chemical reduction with alkali metals (1–4), a procedure yielding results which are not without ambiguity, by the more elegant electrolytic method (5–13), and more recently by photolytic methods (14, 15). In the course of our studies of radical anions produced by electrolytic means, we have been able to obtain, amongst many already known ones, the e.s.r. spectra of the anions of the 1,4-, 1,5-, and 1,8-isomers of dinitronaphthalene. Constructed theoretical spectra show good agreement with experimental spectra and it furthermore appears as if no gross anomalies in the linewidths and intensities exist, a search for these being the primary reason for an investigation of the above radical anions. Expecially the 1,8-isomer, also the 1,5-isomer, might be thought to give rise to such anomalies, since the structural arrangement of the nitro groups is similar to the 1,3-dinitrobenzene, where such anomalies have been observed (16, 17), and since no quinonoid structures can be formulated to indicate an inhibition of rotational freedom of the nitro groups. The oxygen atoms of adjacent nitro groups in the 1,8-dinitronaphthalene anion will, however, be in closer proximity than in the 1,3-dinitrobenzene anion, such that a steric effect may prevent free rotation of the nitro groups.

EXPERIMENTAL

Aldrich Chem. Co. 1,4-dinitronaphthalene was recrystallized from chloroform and sublimed under vacuum, to yield pale yellowish crystals of m.p. 130.5–131.5° C (lit. 131–132 °C). 1,5-Dinitronaphthalene was recrystallized from benzene and sublimed to give yellowish plates of m.p. 217–218 °C (lit. 217.5 °C). Flucka AG 80% technical grade 1,8-dinitronaphthalene was repeatedly sublimed and recrystallized until yellowish plates of m.p. 173–175 °C (lit. 173–173.5 °C) were obtained.

Solvents employed were of spectroscopic grade, distilled from P_2O_5 (excepting DMF), and degassed by freezing, pumping, and melting several times. The solvents were stored on a vacuum system and distilled directly into the electrolysis cell described elsewhere (13). Tetra-*n*-propylammonium perchlorate was used as supporting electrolyte and prepared by the method of Geske and Maki (5).

[1]*Present address: Max-Planck Institut f. mediz. Forschung, Institut f. Chemie, Heidelberg/Germany Jahnstrasse 29.*

The spectrometer employed was a Varian X-band spectrometer using 100 kc field modulation. The magnetic field was supplied by a Varian V4012B 12 in. magnet, and monitored using a proton resonance magnetometer.

RESULTS AND DISCUSSION

A. Experimental Results

1,4-Dinitronaphthalene.—When a 10^{-4} *M* solution of 1,4-dinitronaphthalene, with dimethylformamide (DMF) as solvent, was electrolyzed at −0.5 V vs. saturated calomel electrode (s.c.e.), a brown solution resulted exhibiting the hyperfine pattern shown in Fig. 1. The spectrum consists of 61 lines (theoretically 135 lines are possible) and has an overall splitting of only 9.15 G. This is a remarkably small total splitting, as total splittings of nitro-substituted aromatic systems are generally in the range 20 to 30 G. For 1,4-dinitrobenzene anion, the measured overall splitting is, however, also only 10.7 G. Linewidths of perfectly resolved lines towards the edge of the spectrum are 80 mG between points of maximum slope. The spectrum can be quite well reproduced by the following set of coupling constants $a_N = 0.97$ G, $a_{Hx} = 1.69$ G, $a_{Hy} = 0.53$ G, and $a_{Hz} = 0.41$ G, and is also shown in Fig. 1. The overall splitting of this spectrum is 9.14 G, in excellent agreement with the experimentally determined value. In a mixture of 80% dimethoxyethane (DME) and 20% acetonitrile, an identical spectrum was obtained, while in pure acetonitrile a remarkable drop in the degree of resolution occurred.

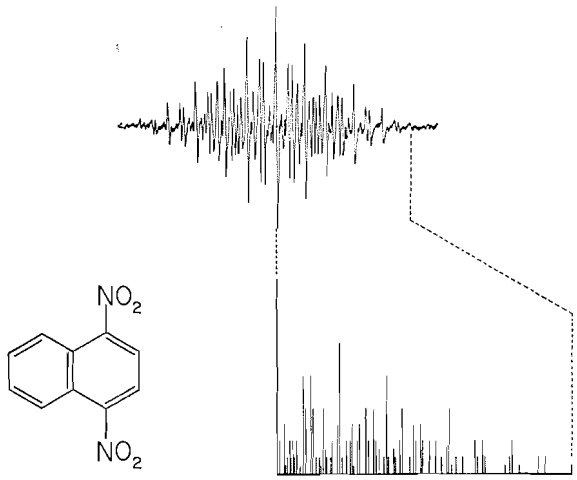

FIG. 1. Electron spin resonance and theoretical spectrum of 1,4-dinitronaphthalene anion radical.

1,5-Dinitronaphthalene.—Electrolysis at −0.62 V vs. s.c.e. of a 10^{-4} *M* solution of 1,5-dinitronaphthalene in DMF resulted in a reddish brown solution, which exhibited the spectrum shown in Fig. 2. This spectrum, under very low modulation and slow scanning conditions, exhibits 111 of the 135 possible lines, and has an overall splitting of 20.70 G. The linewidths of well-resolved hyperfine components are 70 mG, close to the limiting linewidth of the spectrometer employed. The spectrum showed little solvent and temperature dependence and can be analyzed in terms of four coupling constants: $a_N = 2.30$ G, $a_{Hx} = 2.82$ G, $a_{Hy} = 2.42$ G, and $a_{Hz} = 0.44$ G. The theoretical spectrum, of total width 20.56 G, again shows good agreement with the experimental one, and is also given in Fig. 2.

For personal use only.

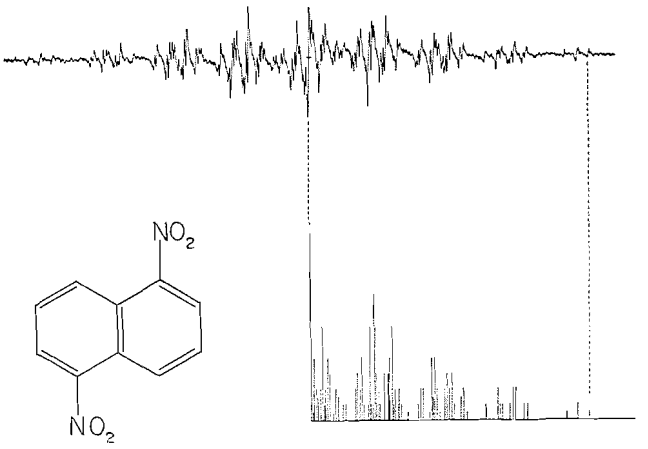

FIG. 2. Electron spin resonance and theoretical spectrum of 1,5-dinitronaphthalene anion radical.

1,8-Dinitronaphthalene.—When a 5×10^{-4} *M* solution of 1,8-dinitronaphthalene in DMF was subjected to reduction at -0.6 V vs s.c.e., a green-yellow solution resulted, showing the hyperfine pattern of Fig. 3. It consists of 85 lines spread over 29.38 G, and linewidths of well-resolved components are 140 mG between points of maximum slope. This is somewhat higher than for the other isomeric species and many other nitroaromatic anions. The spectrum can be reproduced by the following coupling constants: $a_N = 3.03$ G, $a_{Hx} = 3.73$ G, $a_{Hy} = 3.63$ G, and $a_{Hz} = 0.95$ G. The spectrum is shown in Fig. 3.

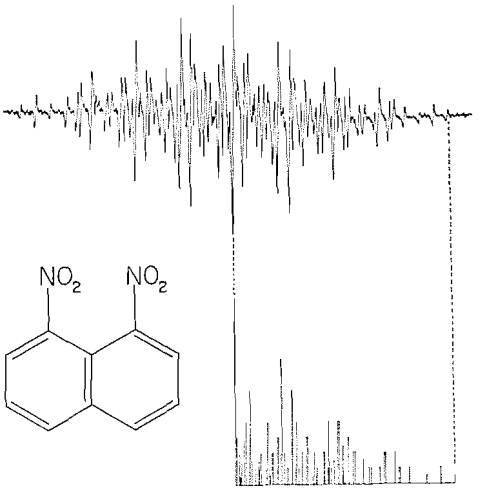

FIG. 3. Electron spin resonance and theoretical spectrum of 1,8-dinitronaphthalene anion radical.

B. Molecular Orbital Calculations

The Hückel LCAO calculations which were performed as an aid in assignment of proton coupling constants employed the Coulomb and exchange parameters suggested by Rieger and Fraenkel (11) namely

$$\alpha_O = \alpha_C + 1.4\beta_{cc},\ \alpha_N = \alpha_C + 2.2\beta_{cc},\ \beta_{CN} = 1.2\beta_{cc},\ \beta_{NO} = 1.67\beta_{cc}$$

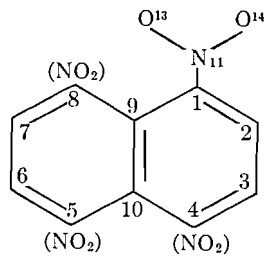
these parameters having been found to give reasonable agreement with a substantial body of experimental results. Introduction of what amounts to an approximation of configuration interaction has been done via McLachlan's (20) method. For the McLachlan-type calculations Hückel orbitals for β-spin electrons were employed, while a set of orbitals for α-spin electrons is calculated with the exchange integrals β_{rs} unchanged, but with the Coulomb integral modified to $\alpha_r = \alpha + 2\lambda|C_{or}|^2\beta$. Here α is the Hückel-type Coulomb integral, C_{or} is the LCAO coefficient of atom r in the Hückel odd electron orbital, and λ is a constant, here taken as 1.2. The spin density ρ_r at atom r is now given by

$$\rho_r = |C_{or}|^2 + \sum_i (|C_{ir}|^2 - |C_{ir}'|^2)$$

where the primed and unprimed coefficients refer to orbitals of β and α spin, respectively. The summation occurs over all filled orbitals. If the dinitronaphthalenes are labelled as follows



then column 3 of Table I reproduces the calculated Hückel spin densities and column 4 the corresponding McLachlan spin densities, while column 5 shows the experimentally determined values using the McConnel equation (18) and a value of $Q_{CH}^{H} = -23.7$ G (19). The experimentally determined coupling constants are given in the last column.

TABLE I

Calculated and experimental spin densities of isomeric dinitronaphthalene anion radicals

Radical anion	Position	Hückel	McLachlan	Expt.	a_i

Some of the above values of the calculated and experimental spin densities correspond quite closely, others show rather large discrepancies. As is usual, the first question to be posed is whether a different value of $Q_{CH}{}^{H}$ might yield better results, but only a rather arbitrary choice of Q_{CH} is possible. Values ranging from -22.5 to -30 G have, of course, been employed. For nitro compounds, many calculations of the Hückel and McLachlan type have been performed by Fraenkel and collaborators, yielding in some cases excellent, in other very poor, agreement. The chief advantage of the McLachlan and more elaborate SCF methods, is that of providing estimates of the negative spin densities at certain nuclei.

For the first mentioned of the anion radicals one set of proton coupling constants is approximately 3 to 4 times larger than the remaining two, as is also the case for the calculated spin densities of one set of carbon atoms contiguous to protons, so that one of the assignments can be made with reasonable certainty. This assignment places the 1.69 G splitting as arising from the 2 and 3 protons, the protons situated on the same ring as the nitro groups. Intuitively this assignment seems correct. The other two calculated coupling constants differ by only 80 mG and remain ambiguous. They are consequently bracketed, as are the spin densities derived from them. For the 1,5-dinitronaphthalene anion, a very similar situation is found, one coupling constant being approximately 1/6 the value of the remaining two. An inspection of Table I shows that this coupling constant must be assigned to position 3 and 7 protons. The McLachlan spin densities show improved agreement with experimentally determined ones. For the last isomeric species, the same considerations apply, placing the 0.95 G splitting as arising from positions 3 and 6 protons. Here agreement between McLachlan and experimental spin density is remarkably good, although the sign of the latter is not a result of our measurements and is bracketed. A further comment is with regard to the zero spin density at carbon atoms 9 and 10 of the last species, this being a consequence of the type of calculation employed. Since the Hückel wave function has a node at the twofold symmetry axis, spin density at C_9 and C_{10} is expected to be zero or very small. Since no protons are attached here, and no splitting can be observed as a consequence, it cannot be as clearly demonstrated, as for the 1,3-dinitrobenzene anion radical say, that negative spin densities occur at these positions. It is a well-known fact, however, that at positions for which a Hückel calculation shows zero or small spin densities, one often finds sites of negative spin when more elaborate calculations are employed. It is hence quite likely that at these positions negative spin densities occur, a statement supported by the considerably larger overall splitting of this isomer. McLachlan-type calculations bear this out. The overall splitting is $\sim$30 G, a value to be compared with the 10–20 G range of the other two isomers and certain other dinitro anion radicals. In the 10–20 G category, the lower value is often found when quinonoid-type structures may be drawn, indicative of greater coplanarity of nitro groups and aromatic ring system.

C. Nitrogen Coupling Constants

The nitrogen coupling constants for the isomeric dinitronaphthalenes show a variation from 0.97 G in the 1,4-isomer to 3.03 G in the 1,8-isomer. This variation in the coupling constants of isomeric species has been observed for other systems. For mononitro aromatic anions, nitrogen coupling constants between 5 and 15 G are generally observed. Comparing the present results with those for the isomeric dinitrobenzenes, we find for the 1,4-isomer a value for an a_N of 1.56 G, for the sterically hindered 1,2-isomer a value of 2.82 G to be compared with 3.03 G of 1,8-dinitronaphthalene, and a value of $\sim$4 G for the 1,3-dinitrobenzene anion. It thus appears in the dinitronaphthalenes, also, that the smallest a_N is observed whenever quinonoid resonance indicates a higher degree of planarity, while

otherwise larger constants are found. The dinitronaphthalene results are qualitatively in agreement with calculations by Rieger and Fraenkel (11), who performed MO calculations, employing a variation of the overlap integral β to indicate variation in the benzene ring/nitro group angle, and whose results indicate a larger splitting constant for nitrogen nuclei of nitro groups rotated out of the carbon skeleton plane.

Rieger and Fraenkel (11) have derived an equation, which defines the nitrogen coupling constant a_N in terms of various parameters S^N and Q_{xy}, and the spin density on the surrounding atoms and N nucleus. Their relation was derived employing McLachlan spin densities and is

$$a_N = K_N\rho_N{}^\pi + 2Q_{ON}{}^N\rho_O{}^\pi + Q_{CN}{}^N\rho_C{}^\pi$$

where all symbols have their usual meaning and the constants have the best values $K_N = (S_N + Q_{NC}{}^N + 2Q_{NO}{}^N) = \pm 99.0$ G, $Q_{ON}{}^N = \mp 35.8$ G, with $Q_{CN}{}^N$ negligibly small. With these values, nitrogen hyperfine coupling constants of 0.86, 1.60, and 1.97 G are calculated for the 1,4-, 1,5-, and 1,8-dinitronaphthalene anion radicals, respectively. These constants will not be of value employing Hückel spin densities, as their magnitude could be quite different. We have as a consequence derived by a least squares method on eight experimental results, a set of constants to be used with Hückel spin densities, so that the above relation takes the form

$$a_N = \pm 179\rho_N{}^\pi \mp 149.2\rho_O{}^\pi \pm 8.06\rho_C{}^\pi$$

that is, the above constants are: $K_N = (S^N + Q_{NC}{}^N + 2Q_{NO}{}^N) = \pm 179$ G, $Q_{ON}{}^N = \mp 74.6$ G, and $Q_{CN}{}^N = \pm 8.06$ G. The ratio of the two constants, as well as the relative sign, is similar to that derived by Rieger and Fraenkel, with $Q_{CN}{}^N$ also quite small. With these constants excellent agreement between calculated and experimented results can be found for some systems, poorer agreement for others. In general the agreement between calculated and experimental nitrogen coupling constants in nitro aromatic radicals is not as good as the remarkable agreement which has been found for nitrile anions (21), even when McLachlan spin densities are employed. For the dinitronaphthalene the agreement is not so impressive.

	a_N (G)	Hückel a_N (calcd.) (G)	McLachlan a_N (calcd.) (G)
1,4-Dinitronaphthalene	0.97	1.08	0.86
1,5-Dinitronaphthalene	2.30	1.96	1.60
1,8-Dinitronaphthalene	3.03	2.50	1.97

Now it has been found that large discrepancies occur when steric factors are operative (as in the 1,8-dinitronaphthalene anion), or when quinonoid resonance is possible (1,4-dinitronaphthalene radical falls into this category.) A more fundamental reason for the not overly impressive agreement is the fact that Hückel spin densities are employed. It is almost certain that these do not represent a true picture of the spin density distribution, as is likewise the case for McLachlan spin densities in such highly substituted aromatic systems. Secondly, it has become apparent that specific effects, such as steric and solvent influences, must be accounted for individually. This is evidenced by a solvent dependence of many observed coupling constants, and it is felt that even comparison of results obtained in the same solvent, need not necessarily be meaningful.

ACKNOWLEDGMENT

We wish to thank the National Research Council of Canada for grants in aid of this work. One of us (P. H. H. F.) thanks the same body for studentships from 1960 to 1963.

THE REACTION OF SULFONYLIMIDO INTERMEDIATES WITH AROMATIC COMPOUNDS[1]

R. A. ABRAMOVITCH, J. ROY,[2] AND V. UMA
Department of Chemistry, University of Saskatchewan, Saskatoon, Saskatchewan

Received June 14, 1965

ABSTRACT

Thermolysis of methanesulfonyl azide in aromatic solvents gives methanesulfonamide and the isomeric methanesulfonanilides. The orientation of the latter and the relative reactivities of the aromatic substrate towards attack by the methylsulfonylimido intermediate have been studied quantitatively. The high reactivity and also great selectivity of the attacking species are interpreted in terms of a rate-determining addition process to give a sulfonylaziridine derivative followed by a product-determining ring opening and rearrangement to the substituted anilides. Partial rate factors are discussed, as are possible mechanisms for the formation of the methanesulfonamide. The methanesulfonylimido intermediate must be abstracting *two* hydrogen atoms synchronously from the aromatic substrate.

The thermal decomposition of sulfonyl azides in aromatic solvents was first studied by Curtius and Schmidt (1). The products obtained from the thermal decomposition of benzenesulfonyl azide in various substituted benzenes were shown to be the corresponding benzenesulfonanilides together with benzenesulfonamide (2, 3). The available evidence points to the intermediacy of a sulfonylimido intermediate (sulfonyl nitrene) (II) in both the thermal and photochemically induced reactions of sulfonyl azides (I), except in those cases where an assisted stepwise addition to olefinic double bonds followed by elimination

$$\underset{\text{I}}{R{-}SO_2N_3} \xrightarrow[\text{or } \Delta]{h\nu} \underset{\text{II}}{RSO_2{-}N} + N_2$$

of nitrogen can take place (4). Thus, the thermal decomposition of benzenesulfonyl azide and *t*-butyl hydroperoxide exhibits mutually induced decomposition of both reagents (5). Whereas sulfonyl azides and dimethyl sulfoxide do not react in the dark, photolysis or thermolysis of the azide gives nitrogen and the sulfonylimido intermediate (II) which is trapped by reaction with dimethyl sulfoxide. Thioethers are even more efficient trapping agents (6). *p*-Toluenesulfonyl azide initiates the copolymerization of mixtures of styrene and methyl methacrylate at 60–120° by a free-radical mechanism, but the activity is extremely low (7), suggesting that the intermediate exists mainly in the singlet electrophilic species (II*b*) rather than in the triplet diradical form (II*a*). More recently, the

$$\underset{\text{II}a}{RSO_2{-}\dot{\ddot{N}}\cdot} \rightleftarrows \underset{\text{II}b}{RSO_2{-}\ddot{\ddot{N}}}$$

thermal decomposition of aliphatic and aromatic sulfonyl azides in cyclohexane under pressure at 175° has been investigated (8). C—H insertion products were mainly obtained; *very little hydrogen abstraction was observed* in all cases. With the aliphatic azides a radical chain process resulting in the evolution of sulfur dioxide was found to compete with the

[1]*The present paper is Part XI of the series on aromatic substitution. Part X: Can. J. Chem. In press. 1965. Part of this work was embodied in a lecture given at the Symposium on Reactive Intermediates held at the Université Laval, Québec, in August 1964.*

[2]*National Research Council Postdoctorate Fellow.*

unimolecular decomposition of the azide, though the radical initiator R· could not be identified.

$$C_5H_{11}SO_2N_3 \rightarrow C_5H_{11}SO_2\dot{\underset{\cdot\cdot}{N}} + N_2$$

$$R\cdot + C_5H_{11}SO_2N_3 \rightarrow C_5H_{11}SO_2\cdot + RN_3$$

$$C_5H_{11}SO_2\cdot \rightarrow C_5H_{11}\cdot + SO_2$$

$$C_5H_{11}\cdot + R{-}H \rightarrow C_5H_{12} + R\cdot$$

The radical chain process could be inhibited to a certain extent by the addition of sulfur or of hydroquinone. Good first-order kinetics were observed in the decomposition of *p*-toluenesulfonyl azide.

The behavior of the imido intermediate after its formation will also depend upon the nature of the solvent used. While in aromatic or aliphatic non-polar solvents sulfonyl azides behave as "rigid" azides i.e. they do not undergo a Curtius-type rearrangement, irradiation of a solution of benzenesulfonyl azide in methanol followed by hydrolysis gave a 28% yield of aniline, presumably formed via $C_6H_5NSO_2$ and $C_6H_5NHSO_2OCH_3$ (9).

The orientation and partial and total rate factors in the substitution of benzene derivatives by the benzenesulfonylimido intermediate produced by thermolysis of the azide have been studied (2, 3). The decompositions were carried out at 105–120° and the products analyzed after preliminary hydrolysis of the anilides formed (2) or as the amides but after appreciable pretreatment (3). Of the aromatic compounds studied, most of those with meta-directing substituents did not react to produce the expected substitution products. With the other substituents, the total rate ratios and partial rate factors were said to be consistent with an attack of the aromatic nucleus by the electrophilic free radical $C_6H_5SO_2\dot{\underset{\cdot\cdot}{N}}\cdot$ (3). The failure of compounds with meta-directing substituents to produce the expected substitution products was attributed to complexing of the radical with the electron-rich substituent group (3). Benzoyl chloride gave a 7% yield of products, 90% of which was benzene-sulfonamide, the rest being exclusively the meta product of substitution. A number of observations remain unexplained by the postulated mechanism (10*a*). (i) The total rate ratios (10*b*) (from competitive reactions between C_6H_6 and C_6H_5X with $C_6H_5SO_2N_3$ at 105–120°) were not much different from unity, as expected for a homolytic substitution. However, the values of the total rate ratios ${}^{CH_3}_{H}K = 1.0$, ${}^{CH_3O}_{H}K = 0.96$, ${}^{OH}_{H}K = 0.80$ are unexpected, since such electron-donating substituents should facilitate attack by an electrophilic free radical (11) and lead to total rate ratios greater than unity. (ii) The partial rate factor calculated for attack at the meta position of toluene is unusually low ($F_m = 0.03$) and it is hard to see why F_m should be less than 1 in toluene, either for a free radical or for an electrophilic substitution process. (iii) Isomer ratios differed somewhat according to whether they were determined under competitive conditions or not.

It was felt that these observations needed careful reinvestigation and that, particularly, a more convenient and reliable analytical technique which would involve a minimum amount of manipulation before the actual analysis was carried out would be desirable. Gas-chromatographic analysis was the obvious choice and, in order to facilitate the elution of the reaction products from the column, it was decided to use methanesulfonyl azide* instead of benzenesulfonyl azide as the source for the imido intermediate. The

**A referee has pointed out that methanesulfonyl azide is, apparently, as sensitive to shock and impact as is nitroglycerine. No trouble was experienced in the present work except in the odd cases where reaction mixtures containing large amounts of undecomposed azide were introduced into the heated injector of the gas chromatograph, when explosions resulted which blew out the Teflon dams. Consequently, caution should be used in the handling of this compound.*

products expected would then be methanesulfonamide $CH_3SO_2NH_2$ (III) and the substituted mesylanilines (IV).

$$CH_3SO_2N_3 \xrightarrow[\text{or } \Delta]{h\nu} CH_3SO_2N$$

$$CH_3SO_2N + RC_6H_5 \rightarrow CH_3SO_2NHC_6H_4R$$

IV

The reaction mixtures were filtered from any tars formed, concentrated, and analyzed directly by gas–liquid chromatography, thus avoiding the possibility of the selective loss of some quantity of one or more of the isomers. All reactions were carried out at 120° under pressure with stirring. Preliminary experiments indicated that similar products were obtained on photolysis of the azides in solution in an excess of the aromatic solvent.

EXPERIMENTAL

Melting points are uncorrected.

Reagents

Reagent thiophene-free benzene and toluene were dried, distilled, and kept over sodium wire. Reagent chlorobenzene and anisole were dried, distilled, and kept over anhydrous sodium sulfate.

Methanesulfonyl Azide

Prepared by the procedure of Horner and Christmann (6), this product was purified by fractional distillation; it had b.p. 71° at 4.5 mm, n_D^{25} 1.4653, and was obtained in 73% yield.

Methanesulfonamide

This was obtained from mesyl chloride and dry ammonia as described by Field and Grunwald (12) and had m.p. 92–93°.

Preparation of Authentic Methanesulfonylanilides

The general procedure described by Marvel, Helfrick, and Belsley (13) was used. A benzene solution of 2 molar equiv of the amine was mixed with 1 equiv of methanesulfonyl chloride in benzene at room temperature. The stirred solution was boiled under reflux from 3 to 12 h. The amine hydrochloride was filtered, the benzene was evaporated *in vacuo*, and the amide was recrystallized from dilute ethanol.

Methanesulphonylanilide had m.p. 101–102°.

o-Methanesulphonyltoluidide had m.p. 106°.

m-Methanesulfonyltoluidide

This compound, prepared by the above method, had m.p. 92–92.5°.

Anal. Calcd. for $C_8H_{11}NO_2S$: C, 51.87; H, 5.99. Found: C, 51.80; H, 6.03.

p-Methanesulfonyltoluidide had m.p. 104.5–105°.

c-Methanesulfonamidochlorobenzene had m.p. 92–93°.

m-Methanesulfonamidochlorobenzene

This compound had m.p. 98–98.5°.

Anal. Calcd. for $C_7H_8ClNO_2S$: C, 40.88; H, 3.92. Found: C, 40.93; H, 4.00.

p-Methanesulfonamidochlorobenzene had m.p. 155–156°.

p-Methanesulfonylanisidide had m.p. 116°.

m-Methanesulfonylanisidide

The compound was obtained as a brown oil which gave a colorless liquid (38%), b.p. 160° at 2.7 mm. The liquid solidified on cooling and could be recrystallized from benzene – light petroleum (b.p. 60–80°) to give colorless crystals, m.p. 67.5°.

Anal. Calcd. for $C_8H_{11}NO_3S$: C, 47.77; H, 5.50. Found: C, 47.90; H, 5.52.

c-Methanesulfonylanisidide, prepared in the usual method, was obtained in 95% yield and had m.p. 69°. Since the reported m.p. is 115.5° (13), the amide was prepared by an alternate method. *o*-Anisidine (3.07 g), dry pyridine (2.23 g), and methanesulfonyl chloride (2.8 g) in benzene (50 ml) were boiled under reflux with stirring for 6 h. A brown gummy solid separated; this was filtered and washed with benzene. The combined filtrates were washed with 15 ml portions of 10% hydrochloric acid and then with water. Evaporation of the solvent gave the amide, which was recrystallized from 95% ethanol (charcoal) and had m.p. 69–69.5°.

Anal. Calcd. for $C_8H_{11}NO_3S$: C, 47.77; H, 5.50. Found: C, 48.05; H, 5.55.

1,2-Diphenoxyethane was prepared by boiling under reflux a mixture of phenol (9.4 g), sodium hydroxide (4 g), and ethylene bromide (9.4 g) for 16 h. The cooled reaction mixture was filtered; the solid was washed with 10% sodium hydroxide solution, washed with water, and recrystallized from 95% ethanol. The product (9.7 g) had m.p. 97.5–98.5°. Simons (14) gives m.p. 97° for this compound.

Methanesulfonylamidation of Aromatic Nuclei Using Methanesulfonyl Azide

General Procedure

Methanesulfonyl azide was dissolved in an excess of the aromatic substrate (molar ratio of azide to aromatic compound 1:25 – 1:50) and the solution was placed in the reaction bottle of a specially designed apparatus which permitted reactions to be carried out under pressure in a glass vessel at constant temperature while being stirred continuously. A description of this apparatus has been published elsewhere (15). The reaction vessels were immersed in a thermostatted oil bath maintained at 120° and stirred for 48 h. The apparatus consisted of three reaction vessels so that all runs could be carried out in triplicate. The cooled glass vessels were opened very carefully to release the nitrogen which had evolved, and the solutions were filtered from small quantities of black precipitate, the amount of which appeared to depend on the nature of the aromatic substrate. The solutions were then transferred quantitatively to a round-bottomed flask, the last traces being washed out with acetone, and concentrated by distillation from a fractionating column.

The products formed were analyzed qualitatively and quantitatively by gas chromatography. Identification was effected by comparing relative retention times with those of authentic samples and then by direct comparison of melting points and infrared spectra of collected material with those of authentic compounds. The internal standard method (16) was adapted for the quantitative analyses and the reliability of the method checked using authentic mixtures of the isomers. The results are accurate to within ±1%.

Methanesulfonylamidation of Benzene

The reaction of methanesulfonyl azide (0.3 g) with a 25 molar excess of benzene was carried out as described above. The reaction products (methanesulfonamide and mesylaniline) were best analyzed on a 6 ft × 1/4 in. column packed with precipitated asphalt on Chromosorb W (60–80 mesh) (25%). (Asphalt, as supplied by the Wilkens Instrument Co., was dissolved in the minimum amount of hot benzene to which was then added *n*-hexane. The precipitated asphalt was filtered and washed with light petroleum (b.p. 60–80°) until the filtrate was colorless). The column temperature was 220° and the helium inlet pressure 50 p.s.i. (flow rate of 55 ml/min). Under these conditions methanesulfonamide had a retention time of 2.3 min, mesylaniline a retention time of 14.1 min, and coumarin (which was used as the internal standard) a retention time of 10.9 min. No biphenyl (retention time 4.6 min) could be detected in the reaction mixtures. The results are summarized in Table I.

TABLE I

Products of reaction of methanesulfonyl azide with benzene

	Methanesulfonamide (%)	Mesylaniline (%)	Total yield (%)

Methanesulfonylamidation of Toluene

The azide:toluene molar ratio was 1:50. The same column as was used above was also used here to resolve the reaction mixture into its components except that it was operated at 230° and a helium inlet pressure of 40 p.s.i. (flow rate 60 ml/min). Five peaks corresponding to methanesulfonamide, dibenzyl, and the *o*-, *m*-, and *p*-methanesulfonyltoluidides having retention times of 2.05, 5.8, 13.6, 16.2, and 18.35 min, respectively, were observed. Coumarin (retention time 10.1 min) was used as the internal standard. The results (mean of three experiments) were as follows. Total yield of methanesulfonyltoluidide (based on methanesulfonyl azide), 76.8%; methanesulphonamide, 22.7%; dibenzyl, 0.5% (assuming that each molecule of methanesulfonylimido intermediate abstracts one proton from each of two toluene molecules). Isomer ratio: *o*, 65.4%; *m*, 2.4%; *p*, 32.2%. Overall amount of azide accounted for: 99.5%.

The reaction was repeated by using a solution of azide in toluene which had been deaerated by passing nitrogen through it and carrying out the reaction under nitrogen. Under these conditions the yield of mesyltoluidides was 72.2% (*o* 65.1%, *m* 3.0%, *p* 31.8%), that of methanesulphonamide was 24.3%, and that of dibenzyl was 0.4%.

Methanesulfonamidation of Chlorobenzene

The azide:chlorobenzene molar ratio used was 1:50. The same column as above was operated at 240° and a helium inlet pressure of 41 p.s.i. (flow rate 68 ml/min). Four peaks corresponding to methanesulfonamide and the *o*-, *m*-, and *p*-methanesulfonylamidochlorobenzenes, having retention times of 1.3, 7.1, 17.8, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

20.15 min, respectively, were observed. *p*-Methanesulfonyltoluidide, retention time 10.15 min, was used as internal standard. The results (mean of three experiments) are summarized below.

Yield of methanesulfonylamido chlorobenzene (%)	Yield of methanesulfonamide (%)	Overall yield based on azide (%)	Yield of isomers (%)		
			o	*m*	*p*
65.1	13.1	78.2	57.4	0.9	41.7

Appreciably more tarry matter appeared to be formed in this reaction compared with the toluene one.

Methanesulfonamidation of Anisole

(*a*) The reaction was carried out as above using methanesulfonylazide (0.15 g) in anisole (6.7 ml) (molar ratio 1:50). Analysis on the same column as before, operated at 225° and 50 p.s.i. inlet pressure of helium (60 ml/min flow rate) gave the following retention times: methanesulfonamide, 1.5 min; coumarin (internal standard), 8.5 min; *o*-methanesulfonylanisidide, 16.5 min; *m*-methanesulfonylanisidide, 28.5 min; *p*-methanesulfonylanisidide, 34.0 min; 1,2-diphenoxyethane, 14.0 min. On a 9 ft × 1/4 in. column of 25% Apiezon N on Chromosorb W at 225°, 1,2-diphenoxyethane had a retention time of 30 min while *p*-methanesulfonylanisidide had a retention time of 25 min. The results of the quantitative analyses are summarized in Table II (expts. 4–6).

‡Average of triplicate determinations.

Some tars were also formed in this reaction and probably account for the balance of the azide. No 1,2-diphenoxyethane could be detected in any of the reaction products.

(*b*) The reaction was carried out as above except that the molar ratio of azide to anisole was 1:25. The results are summarized in Table II (expts. 7–9).

Competitive Reactions

A large excess (100- to 150-fold) of an equimolar mixture of the substituted benzene and benzene over the azide was heated in the sealed glass vessels at 120° as in the case of the non-competitive reactions, and the mixtures were worked up in the same way as before.

Determination of $^{CH_3}_{H}K$

The methanesulfonyl azide to solvent ratios used were 1:100 and 1:150. The gas chromatographic analyses were carried out with an 8 ft × 3/16 in. column packed with 30% Apiezon L on firebrick (60–80 mesh) operated at 220° and a helium inlet pressure of 50 p.s.i. (flow rate 46 ml/min); *o*-, *m*-, and *p*-methanesulfonyltoluidide and mesylaniline had retention times of 10.0, 13.3, 14.9, and 11.7 min, respectively. *o*-Methanesulfonamidochlorobenzene was used as the internal standard and had a retention time of 7.2 min. The results (mean of two experiments each) are summarized below.

Methanesulfonyl azide: solvent molar ratio	$^{CH_3}_{H}K$

Determination of ${}^{Cl}_{H}K$

The methanesulfonyl azide to mixed solvent ratio was 1:100. The reaction products were analyzed on an 8 ft × 3/16 in. column packed with 30% Apiezon L on firebrick operated at 225° and a flow rate of 46 ml/min. *o*-Methanesulfonamidochlorobenzene, methanesulfonylanilide, and an unresolved mixture of *m*- and *p*-methanesulfonamidochlorobenzenes had retention times of 5.6, 8.7, and 22.9 min, respectively. *p*-Methanesulfonyltoluidide (retention time 11.0 min) was used as the internal standard. The calibration factor for the mixed meta and para isomers was obtained by using a standard solution of these isomers in the same proportion as had been found in the non-competitive studies. The total rate ratio thus determined (mean of three experiments) was ${}^{Cl}_{H}K = 0.44$.

Determination of ${}^{CH_3O}_{H}K$

The analyses were carried out as described in the case of the non-competitive reaction with anisole. The azide to mixed solvents molar ratio employed was 1:100, three experiments being carried out. The total rate ratio found was ${}^{CH_3O}_{H}K = 2.54$. Standard mixtures were run to confirm the accuracy of the determinations.

DISCUSSION

The isomer ratios formed in the mesylamidation of the monosubstituted benzene derivatives studied are collected in Table III. These are to be compared with the corresponding results obtained in the benzenesulfonamidations previously reported (3) (Table IV).

The relative reactivities of the substituted benzenes compared with benzene itself were determined using the competitive technique. The total rate ratios are collected in Table V and compared with the total rate ratios reported for benzenesulfonamidation (3). On the basis of these results, apparent partial rate factors can be calculated and are given in Table VI.

The values of the total rate ratios reported here are in accord with the concept of a highly reactive electrophilic species as the reactive attacking reagent. The value for the

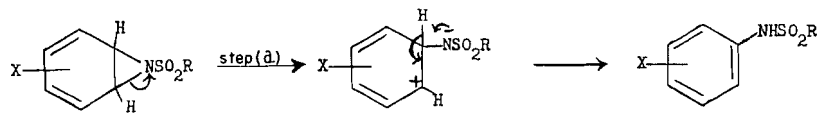
$C_6H_5OCH_3$	4.23	0.09	6.6	2.0	0.06	1.6

total rate ratio for toluene, for example, is somewhat more reasonable than the reported (3) value of ${}^{CH_3}_{H}K = 1.0$ for the corresponding benzenesulfonamidation. Also, it is clear that the methoxyl group is activating, as expected for an electrophilic attack, and that the value of ${}^{CH_3O}_{H}K$ of 0.96 reported for the benzenesulfonamidation is suspect. Again, in accord with the concept of a highly reactive electrophilic attacking reagent, chlorobenzene is somewhat deactivated compared with benzene. The chlorine atom has $-I > +M$, and with the highly reactive reagent the $+E$ effect due to the polarizability of the substituent is not called in play to any appreciable extent. A value of ${}_{C_6H_6}{}^{Xy}K = 2$ has been reported recently for the reactivity of *p*-xylene (8), which is of the correct order of magnitude that would be expected from the results described here.

These values of the total rate ratios would, if taken on their own, suggest that the methanesulfonylimido intermediate was behaving as a highly electrophilic free radical, and hence that it was in the diradical triplet state. The corresponding values of ${}^{X}_{H}K$ for substitution by the electrophilic *o*-nitrophenyl free radical are: ${}^{CH_3}_{H}K = 1.16$, ${}^{Cl}_{H}K = 0.83$ (17), while the apparent values for the phenylation of some C_6H_5X using benzenediazonium borofluoride, a reaction in which the reactive species has been postulated to be the phenyl diradical cation (18), are: ${}^{Br}_{H}K = 0.31$, ${}^{CH_3O}_{H}K = 1.45$ (18). The small amount of side-chain hydrogen abstraction, indicated by the yield of dibenzyl formed in the reaction with toluene (Table III), could also be taken in support of the intervention of an electrophilic free radical (17). On the other hand, application of the Wigner spin conservation rule would suggest that the thermal decomposition of the azides should lead *initially* to a singlet imido intermediate, which could subsequently drop to the triplet ground state (the e.s.r. spectrum of $C_6H_5SO_2N$ obtained by photolysis of the azide at 77 °K in a fluorolube matrix has suggested that the ground state, or a state just above the ground state, is the triplet $C_6H_5SO_2\dot{N}\cdot$ (19)). The small amount of side-chain hydrogen abstraction observed in the decomposition in toluene might also be consistent with a singlet imido intermediate. This minor percentage of hydrogen abstraction by sulfonylimido intermediates has also been commented on in a comparative study of the behaviors of azidoformates and sulfonyl azides (8); similarly, when sulfonyl azides are decomposed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

in cyclohexane, less than 5% of the amide RSO_2NH_2 resulting from hydrogen abstraction is obtained (20). No 1,2-diphenoxyethane, which might have been expected to arise by dimerization of $C_6H_5OCH_2\cdot$ had any been formed by hydrogen abstraction, was detected in the present study. The most convincing evidence against a mechanism involving a straightforward aromatic substitution process by an electrophilic free radical comes from the values of the apparent partial rate factors that can be calculated from the total rate and isomer ratios (Table VI). In all cases, the values calculated for ${}^{x}F_m$ are very low indeed. While values of ${}^{x}F_m$ of slightly less than unity have been reported for the free radical phenylation of toluene and anisole, for example (11, 21), the deactivation observed here cannot be explained at all on the basis of an attack by an electrophilic free radical, nor, indeed, can most of these F values if a direct substitution is taking place. We are clearly dealing here with an attack by a highly *reactive* species, but one that *appears* to be highly selective as well. The values are consistent, however, with a two-step process, the first of which is a rate- (but not product-) determining addition step to form a sulfonylaziridine intermediate (V), and the second of which is the product-determining opening and rearrangement of V to give the substituted sulfonylaniline derivative (VI). The influence of the substituent upon the rate-determining step would be rather minor in view of the high reactivity of attacking sulfonylimidogen; its influence would be large, however, in the determination of the direction of ring opening of the various possible three-membered ring intermediates (V) since this process would involve a separation of charges and give rise to the opportunity for the substituent to stabilize the positive



V VI

charge in the nucleus by delocalization. The direction of the ring-opening process (*a*) would then be governed by the relative stabilities of the various dipolar intermediates formed (Scheme 1).

A likely potential energy diagram for this process would be as illustrated in Fig. 1. Transition state 1 (T.S.1) would be the rate-determining one leading to aziridine formation, shown here as a highly exothermic process with a low energy of activation so that substituents will only exert a minor influence upon this energy of activation. Transition state 2 leading to the opening of the aziridine ring has a lower energy than T.S.1 so that formation of V is still rate controlling, though ring opening has a large activation energy and substituents will exert a large effect upon the *direction* of ring opening. The final proton transfer is expected to be faster than ring opening, hence transition state 3 with the lowest energy of the three. A partly concerted mechanism for the ring opening and hydrogen migration could also be visualized such that appreciable charge separation developed in the transition state. In that case, there would be no third maximum (T.S.3) in Fig. 1. Formation of an aziridine by addition to the benzene "double bond" rather than direct substitution has also been suggested to explain the predominant formation of 1-substituted, rather than 9-substituted, product when benzenesulfonyl azide was boiled under reflux with a solution of anthracene (22). In fact, the formation of four very interesting products of unknown structure when sulfonyl azide was heated with *p*-xylene was thought to involve an addition of NSO_2N to two molecules of *p*-xylene (1). Recently, Dewar and Narayanaswami (23) have suggested a mechanism very similar to the one proposed here

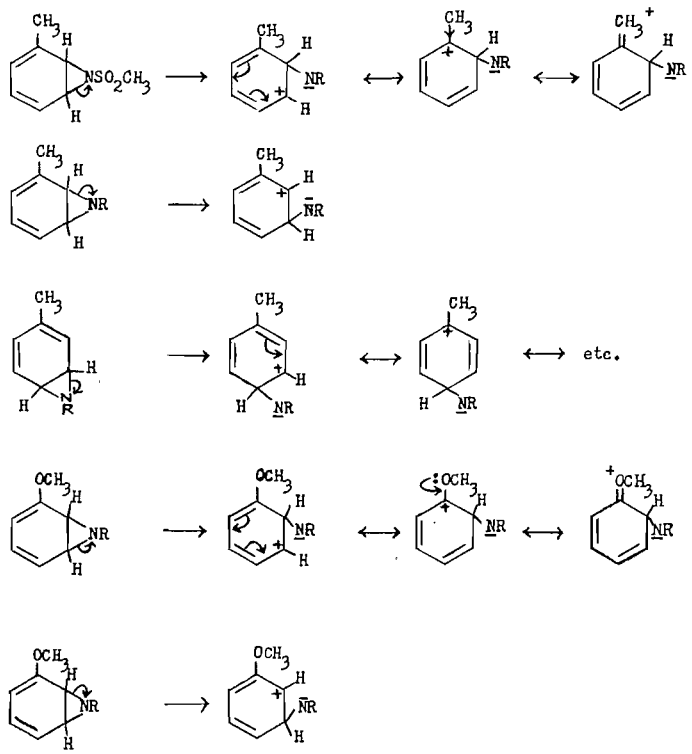

SCHEME I.

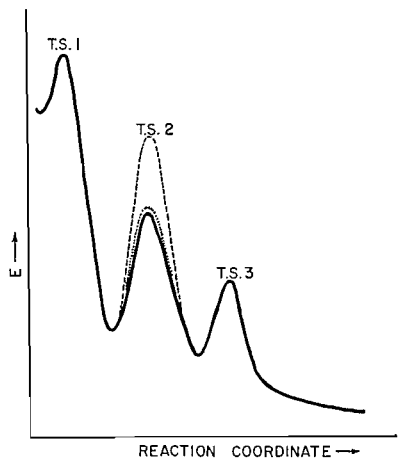

FIG. 1. Potential energy diagram for the reaction of $CH_3SO_2N_3$ with C_6H_5X (where X has a $+M$ effect); (———) opening leading to *p*-isomer, (.....) opening leading to *o*-isomer, (– – –) opening leading to *m*-isomer.

to account for the orientation and relative reactivities observed in the reaction of benzene-1,4-diazooxides with substituted benzenes to give derivatives of 4-hydroxybiphenyl. This behavior of the methanesulfonylimido intermediate is best explained if it is assumed that the thermal decomposition of the azide gives the highly reactive electrophilic singlet species $CH_3SO_2\ddot{N}$ which then reacts as such by adding to an aromatic "double bond".

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

The amount of dibenzyl formation observed with toluene may then be a measure of the amount of triplet diradicals present under these conditions.

An important point to be made at this stage concerns the meaning of partial rate factors in reactions of this type. The usual significance of a partial rate factor as a measure of the reactivity of a given position in a substituted benzene derivative compared with a position in benzene itself does not apply here since the product-determining step is not the rate-determining one and the various nuclear positions in the substituted benzene are not competing with those in benzene for the attacking reagent. This same point has been emphasized by Olah in connection with his studies of various electrophilic substitution reactions (24) using highly reactive electrophiles. Brown's "selectivity rule" (25) does not apply in such cases, the reagent being highly reactive but *apparently* selective. The selectivity here arises because of the relative energies of transition state 2 (Fig. 1) for the ortho, meta, and para positions. The use of partial rate factors is not justified in this case and they have no more meaning than do the isomer ratios; hence, they have been referred to as "apparent" partial rate factors in the preceding discussion.

One very interesting aspect of our results needs to be discussed now, and that is the amount and source of methanesulfonamide formed in these reactions (Table III). Two sets of reactions are particularly revealing, namely the decompositions in benzene and in toluene. In the latter solvent yields of 23–24% of methanesulfonamide were obtained, only 0.5% of which could have arisen by hydrogen abstraction from the alkyl side chain. It is also important to note that in this reaction 97–100% of the azide can be accounted for in the form of methanesulfonamide (III) and of the three mesyltoluidines. These considerations show that III is not formed in any important way according to equations [i] and [ii], or related types of reactions.

[i] $$CH_3SO_2\dot{\ddot{N}}\cdot + C_6H_5CH_3 \rightarrow CH_3SO_2NH\cdot + C_6H_5CH_2\cdot$$
$$CH_3SO_2NH\cdot + C_6H_5CH_3 \rightarrow CH_3SO_2NH_2 + C_6H_5CH_2\cdot$$

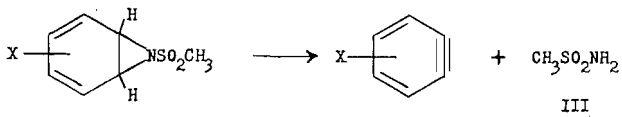
[ii] $$CH_3SO_2\dot{\ddot{N}}\cdot + CH_3C_6H_4NHSO_2CH_3 \rightarrow CH_3SO_2NH\cdot + CH_3C_6H_4\dot{N}SO_2CH_3$$

No biphenyl could be detected in the decomposition of the azide in benzene, though a careful search was made for this compound in the reaction mixture. Nor were any substituted biphenyls detected in the reactions with the other solvents. In benzene and chlorobenzene, the only source of hydrogen atoms (other than from methanesulfonyl azide itself, which has to be eliminated as a source in view of the fact that all the starting azide can be accounted for in the toluene reaction) is the aromatic nucleus. Had the methanesulfonylimido intermediate abstracted a *single* hydrogen atom from the benzene nucleus a phenyl radical would have resulted (see eq. [iii]). This, in the presence of excess benzene, would have given rise to biphenyl according to well known pathways (10*b*). The imidogen must, therefore, be abstracting *two* hydrogen atoms from the aromatic

[iii] $$CH_3SO_2N + C_6H_6 \rightarrow CH_3SO_2NH\cdot + C_6H_5\cdot$$
$$C_6H_5\cdot + C_6H_6 \rightarrow [C_6H_5C_6H_6\cdot] \xrightarrow{CH_3SO_2NH\cdot} (C_6H_5)_2 + CH_3SO_2NH_2$$

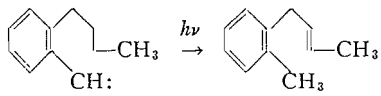
nucleus in a concerted, or very nearly concerted, process so that no aryl free radical is formed at any time. One possibility is that V may give rise directly to III and a benzyne intermediate which then undergoes polymerization. This might account for some of the tars formed in this reaction. No evidence is available at the moment that benzynes are formed under the conditions used here but experiments are under way to try and determine the origin of the methanesulfonamide (III) and to trap a benzyne intermediate if one is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



III

formed. A mechanism involving the simultaneous abstraction of two neighboring hydrogen atoms has been suggested in the carbene field (26).



A very interesting concentration effect was observed in one case, namely the decomposition in anisole (Table III). At the usual azide:substrate molar ratio of 1:50 used with other solvents the overall yield of product was 70.7%, based on the amount of starting azide, and the total yield of mesylanisidines was 66.9%. The balance of azide must have been involved in some by-product and tar formation since no co-distillation of the anisidides with anisole could be detected by gas–liquid chromatography. When a higher azide concentration was used, however, the overall yield of product rose to 90.4% and the yield of mesylanisidides was 81.3%. It is interesting to note that though the yields of III and mesylanisidides both increased, they did so in different proportions so that the increase in the amount of amide (III) is probably not a direct consequence of the greater quantity of anisidides formed. One possible explanation of this observation comes to mind. As mentioned before, aliphatic sulfonyl azides have been shown to undergo a radical chain decomposition to give SO_2 and by-products to a certain extent, this reaction accompanying the more usual dissociation to the sulfonylimido intermediate and nitrogen (8). This might account for some or all of the starting azide not otherwise accounted for by the amounts of III and mesylanisidides formed in the 1:50 molar ratio reaction. At higher azide concentrations the induced decomposition to give the sulfonylimido intermediate at the expense of by-products may well be accelerated (5) leading to the increased yields of products in fact observed.

No products of Curtius-type rearrangements were ever observed under the conditions (aprotic solvents) used here (see also ref. 9). This does not exclude their formation, however, since some of the tars formed in a few cases might arise by the polymerization of $CH_3N{=}SO_2$ in the absence of a solvent capable of trapping the monomer. It seems more likely, however, that hydrogen bonding by a suitable solvent is necessary before the imido intermediate or its precursor will undergo the intramolecular 1,2-shift.

ÉTUDES CONFORMATIONNELLES EN SÉRIE CYCLOPENTANIQUE

I. LA *TERT*-BUTYL-3 CYCLOPENTANONE ET SES DÉRIVÉS

JEAN-CLAUDE RICHER ET CLAUDE GILARDEAU
Département de Chimie, Université de Montréal, Montréal, Qué.

Reçu le 10 juin 1965

RÉSUMÉ

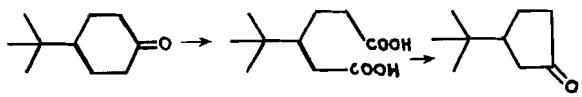
La stéréochimie des réductions de la *tert*-butyl-3 cyclopentanone a été établie. Les alcools épimères qui en dérivent ont été préparés et leur structure déterminée.

INTRODUCTION

La publication du travail original de Winstein et Holness (1) sur l'utilisation du groupe *tert*-butyle pour fixer la conformation des cyclohexanes substitués, a provoqué une avalanche de travaux (2) sur l'analyse conformationnelle des cyclohexanes. Toutefois peu de travaux se rapportant à la série cyclopentanique ont été publiés. Nous rapportons dans le présent travail quelques études conformationnelles effectuées à l'aide des alcools dérivés de la *tert*-butyl-3 cyclopentanone.

RÉSULTATS

La synthèse de la *tert*-butyl-3 cyclopentanone (III) suivant le schéma A a déjà été rapportée par Pines et Ipatieff (3); une modification de cette méthode, décrite récemment (4), a été utilisée pour préparer la cétone III.



I II III

La réduction de III par divers agents réducteurs a été effectuée et les résultats obtenus sont rapportés dans le tableau I; la réduction de III par l'isopropylate d'aluminium dans des conditions équilibrantes est rapportée au tableau II aux côtés des résultats des équilibrations des alcools épimères dérivés de la cétone III.

TABLEAU I

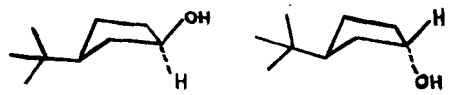
Réduction de la *tert*-butyl-3 cyclopentanone par divers agents réducteurs

	% isomère *cis*
$LiAlH_4$/éther	60
$LiAl(OisoPr)_3H$/THF	66
$NaBH_4$/alcool isopropylique	58
Na/éthanol	56
Na/éther–eau	54
Hydrogénation/PtO_2/acide acétique/H	75
Isopropylate d'aluminium/conditions cinétiques	59

Le produit de l'hydrogénation catalytique de la cétone III peut être transformé en 3,5-dinitrobenzoate (5) qui est cristallisé jusqu'à point de fusion constant de 69–70°. La saponification de ce dérivé livre le *tert*-butyl-3 cyclopentanol cis (IV), $n_D^{21.5}$ 1.4561, chromatographiquement pur.

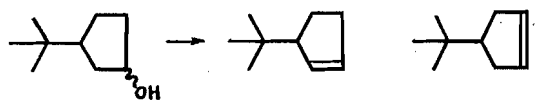
TABLEAU II

Equilibrations	% d'alcool *trans*
tert-Butyl-3 cyclopentanone	53
tert-Butyl-3 cyclopentanol *cis*	52
tert-Butyl-3 cyclopentanol *trans*	52
Moyenne	52

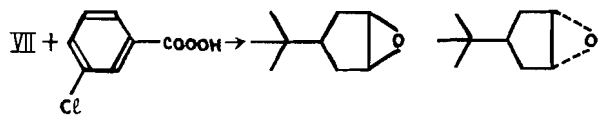


IV V

Le *tert*-butyl-3 cyclopentanol *trans* (V) pur ne peut toutefois pas être obtenu d'une manière aussi directe et l'on doit avoir recours à la méthode proposée dans le schéma B pour y arriver. La déshydratation d'un mélange des *tert*-butyl-3 cyclopentanols épimères (IV et V) à l'aide de sulfate acide de potassium (6) conduit à un mélange 50–50 de *tert*-butyl-3 cyclopentène (VI) et de *tert*-butyl-4 cyclopentène (VII). Ce dernier hydrocarbure (VII) est purifié par chromatographie en phase gazeuse préparative et identifié par un spectre de résonance magnétique nucléaire symétrique avec bandes à 0.85 p.p.m. (9 protons du groupe *tert*-butyle), 2.18 p.p.m. (4 protons allytiques), et 5.67 p.p.m. (2 protons vinyliques). L'hydrocarbure VII réagit avec l'acide méta-chloroperbenzoique (VIII) et conduit à un mélange d'époxydes (IX et X) qui est réduit par l'hydrure double de



IV et V VI VII



VIII IX X

lithium et d'aluminium (7). On obtient ainsi un mélange d'alcools où l'isomère *trans* (V) représente 75% du total. Le *tert*-butyl-3 cyclopentanol *trans*, $n_D^{21.5}$ 1.4550, peut être obtenu chromatographiquement pur par une combinaison de chromatographie en phase gazeuse préparative et de cristallisations fractionnées jusqu'à point fusion constant de 65° du *p*-nitrobenzoate de l'alcool correspondant.

La configuration relative des alcools IV et V est attribuée en partie grâce à une comparaison des spectres infrarouges de ces alcools à ceux des méthyl-3 cyclopentanols (8) et des iso-propyl-3 cyclopentanols correspondants (9). Cette comparaison est résumée dans le tableau III.

Les vitesses d'oxydation chromique du cyclopentanol et des alcools IV et V ont été déterminées et sont résumées au tableau IV. Pour fins de comparaison les vitesses d'oxydation des methyl-3 cyclopentanols correspondants sont aussi rapportées dans le tableau IV.

DISCUSSION

Stéréochimie des réductions de la tert-butyl-3 cyclopentanone

Une cyclopentanone est à toutes fins pratiques planaire. Les hydrogènes qui y sont attachés sont donc distribués d'une manière symétrique au-dessous et au-dessus du plan de la molécule. A l'aide de la théorie complètement stérique proposée récemment (10) pour expliquer la stéréochimie des réductions des cétones cycliques par les hydrures complexes, on peut donc prévoir que l'attaque devrait être favorisée également d'un côté ou de l'autre, du groupement carbonyle. L'introduction d'un groupe *tert*-butyle en position 3 du centre réactionnel aura toutefois comme effet de masquer légèrement une face de la molécule. En se basant sur les concepts stériques proposés, on peut donc prévoir qu'une attaque du groupement carbonyle dans une telle molécule se ferait par la face opposée au groupe *tert*-butyle et conduirait à une formation légèrement prépondérante de l'alcool *cis*. Les résultats rapportés dans le tableau I sont en parfait accord avec cette hypothèse et de ce fait supportent la théorie complètement stérique proposée récemment (10).

Il est à noter que l'environnement stérique du *tert*-butyl-4 cyclopentène (VII) est similaire à celle de la cétone III et que théoriquement l'époxidation de cet hydrocarbure devrait conduire à la formation prépondérante de l'époxyde *trans*. Les résultats expérimentaux rapportés dans le présent travail, ainsi que dans le travail de Henbest (11) sur l'époxidation du méthyl-4 cyclopentène démontrent bien la véracité de cette prédiction.

Stabilité relative des alcools épimères

Les équilibrations directes des *tert*-butyl-3 cyclopentanols à l'aide de l'isopropylate d'aluminium montrent que la différence d'énergie libre entre ces deux alcools est faible, 90 cal/mole; l'isomère *trans* est plus stable que l'isomère *cis*. Les vitesses relatives d'oxydation chromique des alcools IV et V indiqueraient aussi que l'alcool *trans* est le plus stable. En utilisant la relation proposée par Sipos *et al.* (12) il est possible d'évaluer la différence d'énergie libre entre ces deux alcools à 130 cal/mole. Il est intéressant de noter à nouveau que les équilibrations directes et les vitesses relatives d'oxydation chromique conduisent à des conclusions très similaires sur la stabilité relative des alcools épimères.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

La stabilité des alcools épimères telle qu'établie dans le présent travail est en parfait accord avec les valeurs déterminées pour les méthyl-3 cyclopentanols (8); dans les deux cas l'énergie libre semble favoriser l'isomère *trans*. Il est à noter que, par chaleur de combustion, Johnson, Prosen et Rossini (13) ont établi que l'enthalpie du diméthyl-1,3 cyclopentane *cis* est plus faible que celle du dérivé *trans*. Quoique ces deux séries de résultats puissent paraître contradictoires, les différences absolues qui les séparent sont tellement faibles que des facteurs entropiques tels que ceux provenant de la symétrie dans un diméthyl-1,3 cyclopentane, pourraient pratiquement concilier les deux séries de résultats.

Sur l'utilisation du groupe tert-butyle pour fixer la conformation

L'examen des vitesses d'oxydation chromique rapportées dans le tableau IV fait ressortir un fait troublant, à savoir que la vitesse d'oxydation du cyclopentanol n'est pas intermédiaire entre les vitesses d'oxydation des *tert*-butyl-3 cyclopentanols *cis* et *trans*. Une observation semblable peut être faite en examinant les vitesses de solvolyse des tosylates correspondants (14).

Ces résultats indiquent que le groupement *tert*-butyle a des revendications stériques telles qu'il force le cyclopentane à occuper une conformation qui n'est pas favorisée dans le cyclopentanol non substitué.

Cette remarque laisse prévoir que l'introduction d'un groupe *tert*-butyle sur un noyau cyclopentanique ne sera pas d'une très grande utilité dans l'analyse conformationnelle de ces cycles. De plus, sans nous joindre à Kwart et Takeshita (15) dans la critique de l'utilisation du groupe *tert*-butyle comme méthode de "fixer" la conformation d'un cyclohexane mobile, nous suggérons qu'il est possible que l'introduction d'un groupe *tert*-butyle puisse déformer légèrement même un cyclohexane.

PARTIE EXPÉRIMENTALE

Les points de fusion ont été déterminés sur un bloc Kofler et ne sont pas corrigés.

Les spectres infrarouges ont été pris sur un spectrophotomètre Perkin–Elmer modèle 21, à double faisceau, entre deux plaques de chlorure de sodium.

Les chromatographies en phase gazeuses analytiques ont été faites à l'aide d'un appareil Kromo–Tog, modèle K-2, de la compagnie Burrel.

Une colonne de 5 mètres contenant de l'hyprose à 10% sur Kromat FB et maintenue à 120° a été utilisé pour l'analyse des alcools. Une colonne de 2 mètres contenant du nitrate d'argent à 15% sur Kromat FB a été utilisé à la température de la pièce pour l'analyse des hydrocarbures.

Les séparations par chromatographie en phase gazeuse préparative ont été faites à l'aide d'un appareil Fisher Prep–Partitionner en employant 8 colonnes de 50 cm contenant de l'hyprose 10% sur Kromat FB (purification des alcools) ou du β,β'-oxydipropionitrile sur chromosorb P (purification des hydrocarbures).

Les spectres résonances magnétiques nucléaires ont été mesurés sur un appareil A-60 en utilisant le tétraméthylsilane comme standard interne. Les déplacements chimiques (δ) sont exprimés en p.p.m. du champ total.

Des analyses élémentaires satisfaisantes ont été obtenues par C. Daesslé, Organic Microanalysis, Montréal, pour les dérivés des tert-butyl-3 cyclopentanols.

Les vitesses d'oxydation chromiques ont été déterminées de la manière décrite précédemment (16).

REMERCIEMENTS

Les auteurs remercient vivement le Conseil National de Recherches du Canada pour une subvention de recherches qui a permis la réalisation de ce travail, la compagnie C.I.L. pour une bourse d'études à l'un d'entre nous (C.G.), et la compagnie Dow Canada pour un généreux échantillon de tert-butyl-4 cyclohexanone. Les auteurs remercient de plus les Dr. B. Fuchs et R. Haber qui leur ont fourni les méthyl-3 cyclopentanols isomères utilisés pour fins de comparaison.

QUINOXALINE DERIVATIVES

VIII. THE EFFECT OF ELECTRON-DONATING GROUPS ON THE FORMATION OF CERTAIN QUINOXALINECARBOXYANILIDE N-OXIDES AND THEIR REARRANGEMENT[1]

YUSUF AHMAD, M. S. HABIB[2], M. IQBAL, M. IKRAM QURESHI, AND ZIAUDDIN

Chemical Research Division, Central Laboratories, Pakistan Council of Scientific and Industrial Research, Karachi, Pakistan

Received June 28, 1965

ABSTRACT

Introduction of methyl or methoxy groups into the benzene ring of quinoxalinecarboxyanilide (I*d*), makes the resulting anilides less prone to "abnormal" oxidation (1). Normal N-oxides (II*f* and II*j*) were obtained from the anilides I*f* and I*j* in which the cyclic >NH was unprotected. The methyl-substituted anilides I*g* and I*h*, however, on oxidation with peracetic acid gave the hydroxy derivatives (V*g* and V*h*) instead of the N-oxides (II*g* and II*h*). The methoxy-substituted anilides I*k* and I*l* did not give the hydroxy derivatives V*k* and V*l* nor the expected *N*-oxides II*k* and II*l*. All the *N*-oxides (II*e*, II*f*, II*i*, and II*j*) on rearrangement with sulfuric acid yielded the corresponding amines IV*e*, IV*f*, IV*i*, and IV*j*. In spite of the slow rate of rearrangement of these N-oxides, attempts to isolate the intermediate hydroxyaminospirolactams (III) were unsuccessful.

The novel conversion of quinoxalinecarboxyanilide N-oxide (II*a*) in cold sulphuric acid to the amine (IV*a*) has been postulated (2) to proceed by intramolecular electrophilic substitution of the anilide ring by C-2 of the quinoxaline moiety. The N-oxide group intensifies the electrophilic property of C-2 and seems to be necessary for subsequent decarboxylation and dehydration by a cyclic mechanism (2). In the absence of the N-oxide function the anilide (I*a*) has been shown (3) to rearrange to the spirolactam (VI*a*), which unlike the postulated but unstable intermediate (III*a*) in the conversion of II*a* to IV*a*, is quite stable and has been isolated in quantitative yield. These rearrangements are comparatively slower in ethanolic hydrogen chloride than in concentrated sulphuric acid, and it has been possible to isolate (3) the hydroxyamino-spirolactam (VIII*a*) in the rearrangement of the pyrazine N-oxide (VII*a*). The strongly electrophilic character of C-2 in the quinoxaline N-oxide (II*a*) and its derivatives is probably responsible for the marked instability of its hydroxyamino-spirolactam intermediate (III*a*) and the impossibility of isolating this compound.

This is further borne out in the preparation of the N-oxides. It has been observed (1) that if both or either of the cyclic or acyclic NH groups in the anilide (I*d*) are not protected by methyl groups, I*b*, I*c*, and I*d* on oxidation with hydrogen peroxide in acetic acid, instead of giving the corresponding N-oxides (II*b*, II*c*, and II*d*) give the corresponding hydroxy derivatives (V*b*, V*c*, and V*d*), i.e. the anilide side-chain in each case is replaced by an OH group. However, the anilide (I*a*), in which both the NH groups are protected by methyl groups, or I*b* (R″ = Ac), in which the anilide NH is methylated and a mild protection is afforded to the heterocyclic NH, each give the corresponding normal N-oxides II*a* and II*b* (R″ = Ac). In the corresponding pyrazine analogues, the carboxyanilide (VII*b* without oxygen on N_1), which bears no protection on its cyclic amide-nitrogen, on oxidation gives the normal N-oxide (VII*b*). The marked electrophilic nature of the 2-position in 3-hydroxyquinoxaline-2-carboxyanilides has been considered (1) to be

[1]For Part VII see ref. 6.
[2]Present address: Burroughs Wellcome & Co. (Pakistan) Ltd., D/43 S.I.T.E., Karachi.

responsible for these "abnormal" oxidations. This hypothesis is further supported by the fact that in analogous quinoxaline anilide (I*f*), in which two electron-donating methyl groups at position 6 and 7 somewhat decrease the strongly electrophilic nature of C-2, the protection of the cyclic amide-nitrogen became unnecessary, and normal N-oxide (II*f*) could be obtained from the semiprotected anilide (I*f*) with peracetic acid. The fully protected anilide (I*e*), of course, gave the normal N-oxide (II*e*). However, the protection of the anilide NH was still necessary, as both of the anilides (I*g* and I*h*) underwent "abnormal" oxidation with peracetic acid and gave the hydroxy compounds (V*g* and V*h*).

	R	R′	R″	R‴		R	R′	R″	R‴
(*a*)	H	H	Me	Me	(*h*)	Me	Me	H	H

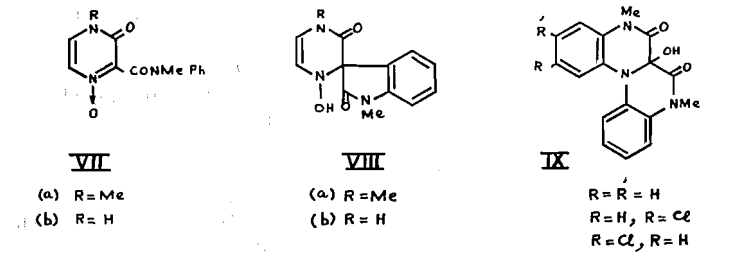
(*g*)	Me	Me	Me	H	(*n*)	Cl	H	Me	Me



Under IX lower right column should be, R′ = Cl, R′ = H.

In place of the methyl groups at positions 6 and 7 in the above quinoxaline anilides, introduction of two methoxy groups, which are even stronger electron donators, would have further reduced the electrophilic nature of the C-2 in the molecule, and this was shown. The anilide (I*k*) in which the acyclic NH group is unprotected, and the anilide (I*l*) in which both the acyclic and cyclic NH groups are unprotected, on oxidation with peracetic acid did not give the corresponding hydroxy derivatives (V*k* and V*l*), which for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

the purpose of comparison were synthesized through an unambiguous route. However, the compounds that were obtained by this oxidation were not even the N-oxides (II*k* and II*l*), since they did not undergo the usual decomposition even in warm concentrated sulphuric acid, and were recovered unchanged. The constitution of these new compounds, which were isolated in poor yields, is under further investigation. The fully protected anilide (I*i*) and the other semiprotected anilide (I*j*), as expected, gave the normal N-oxides (II*i* and II*j*).

The unsubstituted quinoxalinecarboxyanilide N-oxide (II*a*) in concentrated sulphuric acid at 0° has been reported (2, 4, 5) to undergo rearrangement to give the amine (IV*a*) and also an insoluble compound, for which the quinoxalinoquinoxaline structure (IX*a*) has been proposed (4, 5). The derivatives (II*m* and II*n*) of this N-oxide which bear chlorine atoms at positions 6 and 7, undergo this transformation at 0° even faster, and a larger amount of quinoxalinoquinoxaline type of compound (IX*b* or IX*c*) is formed in each case. On the other hand the N-oxides (II*e*, II*f*, II*i*, II*j*) are recovered unchanged from cold concentrated sulphuric acid, and to effect their rearrangement and conversion to the corresponding amines (IV*e*, IV*f*, IV*i*, and IV*j*) it is necessary to heat the mixture at 75° for about an hour, during which process there is virtually no formation of quinoxalino-quinoxaline-type compounds. This can also be attributed to a decrease of the electrophilic character of the C-2 in these quinoxaline N-oxides caused by the introduction of electron-releasing groups in their benzene rings.

Attempts to isolate the intermediate hydroxyamino-spirolactams (III*e*, III*f*, III*i*, and III*j*) by heating the corresponding N-oxides (II*e*, II*f*, II*i*, and II*j*) with ethanolic hydrogen chloride were unsuccessful, because the rearrangement rate of these N-oxides is even slower than that of the pyrazine N-oxide (VII*a*). All four quinoxaline N-oxides were recovered unchanged after they were heated for 8 h with ethanolic hydrogen chloride on a water bath.

EXPERIMENTAL

Infrared spectra were measured in Nujol mull.

General Procedure for the Preparation of N-Oxides

The appropriate quinoxalinecarboxyanilide (1 g), acetic acid (10 ml), and 30% hydrogen peroxide (1 ml) were heated together at 55° and two further quantities of hydrogen peroxide (0.5 ml each) were added after intervals of 24 and 48 h. After a total 72 h of heating (6), the acetic acid was removed under reduced pressure and the residue was crystallized to give the N-oxide.

3-Hydroxy-6,7-dimethyl-2-(N-methyl-N-phenylcarbamoyl) quinoxaline 1-Oxide (II*f*)

3-Hydroxy-6,7-dimethyl-2-(*N*-methyl-*N*-phenylcarbamoyl) quinoxaline (I*f*) (7), when treated with acetic acid and hydrogen peroxide as described above, gave yellow plates (from ethanol) of the *1-oxide* (II*f*), yield 55%, m.p. 266–267° (decomp.).

Anal. Calcd. for $C_{18}H_{17}N_3O_3$: N, 13.0. Found: N, 12.8.

3,4-Dihydro-4,6,7-trimethyl-2-(N-methyl-N-phenylcarbamoyl)-3-oxoquinoxaline 1-Oxide (II*e*)

(*a*) 3,4-Dihydro-4,6,7-trimethyl-2-(*N*-methyl-*N*-phenylcarbamoyl)-3-oxoquinoxaline (I*e*) (7), when similarly treated, gave yellow plates (from ethanol) of the *4-methyl 1-oxide* (II*e*), yield 40%, m.p. 263–264° (decomp.).

Anal. Calcd. for $C_{19}H_{19}N_3O_3$: C, 67.6; H, 5.7; N, 12.5. Found: C, 67.6; H, 5.7; N, 12.2.

(*b*) The 1-oxide (II*f*), when treated with methyl sulphate in the presence of anhydrous potassium carbonate in acetone, gave the 4-methyl 1-oxide (II*e*), m.p. 263° (decomp.), in good yield, identical (mixed melting point and infrared spectrum) with a sample obtained as described in (*a*).

3-Hydroxy-6,7-dimethoxy-2-(N-methyl-N-phenylcarbamoyl) quinoxaline 1-Oxide (II*j*)

3-Hydroxy-6,7-dimethoxy-2-(*N*-methyl-*N*-phenylcarbamoyl) quinoxaline (I*j*) (7), when similarly treated, gave yellow needles (from ethanol) of the *1-oxide* (II*j*), yield 30%, m.p. 272–273° (decomp.).

Anal. Calcd. for $C_{18}H_{17}N_3O_5$: C, 60.8; H, 4.8; N, 11.8. Found: C, 60.5; H, 4.5; N, 11.7.

3,4-Dihydro-6,7-dimethoxy-4-methyl-2-(N-methyl-N-phenylcarbamoyl)-3-oxoquinoxaline 1-Oxide (II*i*)

(*a*) 3,4-Dihydro-6,7-dimethoxy-4-methyl-2-(*N*-methyl-*N*-phenyl-carbamoyl)-3-oxoquinoxaline (I*i*) (7),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

when similarly treated, gave, in 45% yield, yellow needles (from ethanol) of the *4-methyl 1-oxide* (II*i*), m.p. 250–251°.

Anal. Calcd. for $C_{19}H_{19}N_3O_5.H_2O$: C, 58.9; H, 4.9; N, 10.85. Found: C, 59.1; H, 4.9; N, 11.1.

(*b*) The 1-oxide (II*j*) on being treated with methyl sulphate in the presence of anhydrous potassium carbonate in acetone gave in good yield yellow needles (from ethanol) of the 4-methyl 1-oxide (II*i*), m.p. 250–251°, identical (mixed melting point and infrared spectrum) with a sample obtained as described in (*a*).

General Procedure for the Decomposition of N-Oxides in Concentrated Sulphuric Acid

Finely powdered N-oxide (1 g) in concentrated sulphuric acid (5 ml) was vigorously stirred while being heated at 75° till the evolution of CO_2 was complete (about 1 h). The cooled mixture was poured on ice, then neutralized with aqueous sodium hydroxide. The precipitate was collected and crystallized from ethanol as orange needles. Yield 50–80%.

3-Hydroxy-6,7-dimethyl-2-(o-methylaminophenyl) Quinoxaline (IV*f*)

The 1-oxide (II*f*), when treated as above, gave the *amine* (IV*f*), m.p. 238–240°.

Anal. Calcd. for $C_{17}H_{17}N_3O$: N, 15.1. Found: N, 15.1.

3,4-Dihydro-4,6,7-trimethyl-2-(o-methylaminophenyl)-3-oxoquinoxaline (IV*e*)

The 1-oxide (II*e*), when similarly treated, gave the *4-methylamine* (IV*e*), m.p. 163–164°.

Anal. Calcd. for $C_{18}H_{19}N_3O$: C, 73.7; H, 6.5; N, 14.3. Found: C, 73.4; H, 6.4; N, 13.9.

3-Hydroxy-6,7-dimethoxy-2-(o-methylaminophenyl) Quinoxaline (IV*j*)

The 1-oxide (II*j*), when similarly treated, gave the *amine* (IV*j*), m.p. 230–231° (decomp.).

Anal. Calcd. for $C_{17}H_{17}N_3O_3$: C, 65.6; H, 5.5; N, 13.5. Found: C, 65.9; H, 5.7; N, 13.6.

3,4-Dihydro-6,7-dimethoxy-4-methyl-2-(o-methylaminophenyl)-3-oxoquinoxaline (IV*i*)

The 1-oxide (II*i*), when similarly treated, gave the *4-methylamine* (IV*i*), m.p. 159–161°.

Anal. Calcd. for $C_{18}H_{19}N_3O_3$: C, 66.5; H, 5.9; N, 12.9. Found: C, 66.9; H, 6.5; N, 13.0.

3,4-Dihydro-4,6,7-trimethyl-2-(N-phenylcarbamoyl)-3-oxoquinoxaline (I*g*)

3,4-Dihydro-4,6,7-trimethyl-3-oxoquinoxaline-2-carboxylic acid (1.5 g), thionyl chloride (20 ml), and benzene (20 ml) were heated under reflux for 1 h. The solid that was obtained after the thionyl chloride and benzene were removed under reduced pressure, was suspended in dry benzene and a solution of aniline (6 ml) in benzene (10 ml) was added drop by drop. The mixture was shaken for 10 min and washed with dilute hydrochloric acid. The *anilide* (I*g*) that was thus separated was crystallized from ethanol as yellow needles, yield 100%, m.p. 210–212°.

Anal. Calcd. for $C_{18}H_{17}N_3O_2$: C, 70.3; H, 5.6; N, 13.7. Found: C, 70.3; H, 5.5; N, 13.2.

2,3-Dihydroxy-6,7-dimethyl Quinoxaline (V*h*)

(*a*) An attempted preparation of the 1-oxide of 3-hydroxy-6,7-dimethyl-2-(*N*-phenylcarbamoyl) quinoxaline (I*h*) by the general procedure described above for the preparation of N-oxides, led to the formation of *dihydroxyquinoxaline* (V*h*) (colorless needles from acetic acid), yield 80%, m.p. >325°, identical (infrared spectrum) with the synthetic sample obtained as described in (*b*).

(*b*) 4,5-Dimethyl-*o*-phenylenediamine, prepared by the hydrogenation of 4,5-dimethyl-2-nitroaniline (4 g) in ethanol (100 ml) over Pd–C, and without separation from ethanolic solution, was heated with ethyl oxalate (15 g) under reflux for 3 h. When the mixture was cooled a solid separated out, and was crystallized from acetic acid (charcoal) as colorless microneedles of the dihydroxyquinoxaline (V*h*), m.p. >325°.

Anal. Calcd. for $C_{10}H_{10}N_2O_2$: C, 63.2; H, 5.3. Found: C, 62.8; H, 5.1.

3,4-Dihydro-2-hydroxy-4,6,7-trimethyl-3-oxoquinoxaline (V*g*)

In a similar way the attempted preparation of the 1-oxide of the anilide (I*g*) afforded in good yield *4-methyl hydroxyquinoxaline* (V*g*) (colorless needles from ethanol), m.p. >325°.

Anal. Calcd. for $C_{11}H_{12}N_2O_2$: C, 64.7; N, 5.9; N, 13.7. Found: C, 65.4; H, 6.2; N, 13.4.

When this compound (V*g*) was treated with methyl sulphate in the presence of anhydrous potassium carbonate in acetone, it gave, in good yield, colorless needles (from acetone) of *1,2,3,4-tetrahydro-1,4,6,7-tetramethyl-2,3-dioxoquinoxaline* (V*e*), m.p. 305°, identical with the product obtained by methylation of the authentic V*h* described above under (*b*) (infrared spectrum and mixed m.p. 305°).

Anal. Calcd. for $C_{12}H_{14}N_2O_2$: C, 66.0; H, 6.5. Found: C, 66.4; H, 6.4.

Attempted Preparation of the 1-Oxides of 3,4-Dihydro-6,7-dimethoxy-2-(N-phenylcarbamoyl)-3-oxoquinoxaline (I*l*) *and 3,4-Dihydro-6,7-dimethoxy-4-methyl-2-(N-phenylcarbamoyl)-3-oxoquinoxaline* (I*k*)

Both of the anilides (I*l* and I*k*), when they were treated as above (and under various other experimental conditions) with hydrogen peroxide and acetic acid, yielded some unidentifiable compounds. The anilide (I*l*) gave a colorless compound, m.p. 245–247°, which was different (m.p. and infrared spectrum) from the expected *2,3-dihydroxy-6,7-dimethoxy quinoxaline* (V*l*) (colorless needles from acetic acid, m.p. >325°.

Anal. Calcd. for $C_{10}H_{10}N_2O_4$: C, 54.05; H, 4.5; N, 12.6. Found: C, 54.32; H, 4.25; N, 12.6.) prepared by heating together 4,5-dimethoxy-*o*-phenylenediamine and ethyl oxalate under reflux for 3 h. The anilide (I*k*) gave a yellow solid (crystallized from ethanol), m.p. 170° (decomp.), which also did not show the properties of an N-oxide, and was not the other expected compound V*k*.

THE SOLUBILITY OF ALUMINIUM IN $NaF–AlF_3–Al_2O_3$ MELTS

JOMAR THONSTAD

Royal Norwegian Council for Scientific and Industrial Research, Metallurgical Committee, The Technical University of Norway, Trondheim, Norway

Received June 25, 1965

ABSTRACT

The solubility of aluminium in $NaF–AlF_3$ melts saturated with alumina has been investigated by analyzing quenched samples of the melts to determine the contents of metallic sodium and aluminium. The total solubility at 1 000 °C given as wt. % Al decreases with decreasing NaF/AlF_3 molar ratio from 0.33 wt. % Al at $NaF/AlF_3 = 6.70$ to 0.10 wt. % Al in cryolite ($NaF/AlF_3 = 3$) and 0.075 wt. % Al at $NaF/AlF_3 = 1.70$. The change in the solubility is primarily due to a change in the sodium content, while the aluminium content remains almost constant over the range investigated. The solubility in cryolite increases with increasing temperature from 0.10 wt. % Al at 1 000 °C to 0.14 wt. % Al at 1 060 °C. In cryolite at 1 000 °C the dissolved metal was found to consist of 0.065 wt. % Al and 0.090 wt. % Na. The fraction of the dissolved metal represented by sodium increases with increasing temperature.

INTRODUCTION

The solubility of aluminium in $NaF–AlF_3–Al_2O_3$ melts is of interest in relation to the electrolytic production of aluminium, as the loss in current efficiency in that process is caused by oxidation of the dissolved metal by the anode gas. The solubility of aluminium in melts close to the cryolite composition (molar ratio $NaF/AlF_3 = 3$) has been measured by several workers. The results are somewhat controversial, particularly regarding the influence of the NaF/AlF_3 ratio. As will be shown subsequently the dissolved metal consists of sodium as well as aluminium. This fact has been disregarded by most workers and the solubilities are normally given as wt. % Al, which then includes both the sodium and the aluminium contents.

Zhurin (1) found solubilities in the range of 0.10–0.15 wt. % Al at 1 060 °C in cryolite–alumina melts, and 0.21 wt. % Al at $NaF/AlF_3 = 1.67$ and 0.062 wt. % Al at $NaF/AlF_3 = 4$. Pruvot (2) found the solubility in cryolite at 1 000 °C to be 0.02–0.04 wt. % Al. Mashovets and Svoboda (3) measured the solubilities in AlF_3-rich melts where it increased from approximately 0.12 wt. % Al at $NaF/AlF_3 = 2.70$ to 0.40 wt. % Al at $NaF/AlF_3 = 1.80$. Haupin (4) found the solubility at 980 °C to be 0.10 wt. % Al in cryolite, 0.11 wt. % Al at $NaF/AlF_3 = 3.70$, and 0.09 wt. % Al at $NaF/AlF_3 = 2.70$. Haupin also tried to analyze separately the sodium and the aluminium contents of the dissolved metal. In cryolite ($NaF/AlF_3 = 3$) the contents were found to be 0.16 wt. % Na and 0.05 wt. % Al and at $NaF/AlF_3 = 2.6$, 0.10 wt. % Na and 0.05 wt. % Al.

Condensates from $NaF–AlF_3–Al_2O_3$ melts in contact with aluminium contain metallic sodium and aluminium, as well as various fluoride compounds (3, 4). The evaporating species responsible for the metal loss from the melts are probably aluminium monofluoride (AlF) and sodium metal. Sodium has been found spectrographically in the vapor phase (5).

The nature of the dissolved metal in the melt has not been established. It is customary to assume (6) that aluminium occurs as monovalent ions, i.e.

$$[1] \qquad Al^{3+} + 2Al \rightleftarrows 3Al^{+},$$

and that sodium occurs as uncharged metal atoms or ions like Na_2^+, i.e.

$$[2] \qquad 6Na^{+} + Al \rightleftarrows 3Na_2^{+} + Al^{3+}.$$

The ionic nature of the dissolved metal is supported by electrochemical measurements (7).

It is apparent that the available data on the solubility of aluminium in $NaF–AlF_3–Al_2O_3$ melts are partly in conflict and furthermore that the role played by sodium has mostly been neglected. The present investigation has been carried out to determine the excess sodium and aluminium contents in melts having molar ratios from $NaF/AlF_3 = 6.70$ to 1.50.

EXPERIMENTAL

The materials used were Alcan super purity aluminium, hand-picked Greenland cryolite, and reagent grade anhydrous sodium fluoride, aluminium fluoride, and alumina.

The melts were contained in recrystallized alumina crucibles of 20 ml capacity covered by close-fitting lids made of boron nitride or graphite. The composition of the melts was determined from the weighed-in amounts, as the composition changed very little during a run. The melts had to be saturated with alumina to prevent attack on the crucibles. Enough aluminium was added to cover the bottom of the crucible. The equilibration was carried out in a vertical Kanthal furnace where the tube and the radiation shields were made of Inconel. Inert nitrogen gas was passed through the furnace. An equilibration time of 2 h was found to be sufficient. Samples of the melts were taken with a small thick-walled nickel ladle that was lowered from the cold part of the furnace into the melt and then quickly withdrawn. The ladle and the lid of the crucible could be manipulated from the outside by thin rods without admitting air to the furnace.

After cooling the samples were taken to a drybox with inert nitrogen atmosphere. The samples were crushed to −20 mesh, weighed, and transferred to the analyzing apparatus to determine the excess metal content. To this purpose each sample was treated with absolute ethyl alcohol and dilute hydrochloric acid. The metal would react with the alcohol and the hydrochloric acid and evolve hydrogen. The hydrogen was first led through a liquid air trap and then passed over cupric oxide at 350 °C in a tubular furnace, where it was converted to water vapor which was determined gravimetrically by absorption. The carrier gas for this determination was nitrogen.

By the addition of alcohol to the sample a reaction accompanied by gas evolution could be observed. The gas proved to be hydrogen. The reaction would last only for a few minutes, and even prolonged treatment would not produce any more hydrogen. When hydrochloric acid was added the reaction would recommence and normally reach completion after about 20 min.

Blank runs with samples from melts that had not been in contact with aluminium gave no reaction and no weight increase of the absorption tube. These samples were white while samples containing metal had a distinctive grayish tinge.

When the samples were quenched any dissolved metal in the form of subvalent compounds would become unstable. It was assumed that the aluminium was converted to metallic aluminium, e.g., by reversal of reaction [1], while the sodium was converted to metallic sodium. Both sodium and aluminium are expected to react with alcohol giving hydrogen and aluminium and sodium ethoxide respectively. The reaction with aluminium is known to be very slow, however, and the presence of catalyzers like chlorine or mercuric chloride are needed in order to initiate the reaction (8). In order to test this information, a piece of the aluminium used in these experiments was immersed in absolute alcohol and filed to remove the oxide layer. Even after heating no visible reaction occurred. A piece of sodium, on the other hand, reacted readily with the alcohol.

The assumption was then made that alcohol would react only with the sodium in the sample, while it would not react to any measurable extent with the aluminium. Since the metal present in the quenched samples was in a state of fine dispersion and therefore presumably very reactive, the justification of this assumption may be disputed. The shape of the experimental curve (Fig. 1) indicates, however, that the aluminium did not interfere with the determination of sodium.

RESULTS AND DISCUSSION

Figure 1 shows the results obtained at 1 000 °C with melts of varying NaF/AlF_3 ratio, saturated with Al_2O_3. The results at the highest NaF/AlF_3 ratio are somewhat uncertain, because the NaF-rich melts severely attacked the alumina crucibles. The high viscosity of these melts also made sampling difficult. Curve I shows the total solubility given in the customary way as wt. % metallic aluminium. Curve II shows the part of the total solubility found in the alcohol treatment, i.e., the sodium content, given as wt. % metallic sodium. Because the reducing power per mole aluminium is three times greater than that of sodium, the numerical values for the sodium content will for some compositions be higher than the total solubility as given by curve I. Curve III shows the aluminium content of the melt in wt. % Al. Results obtained with cryolite melts at various tem-

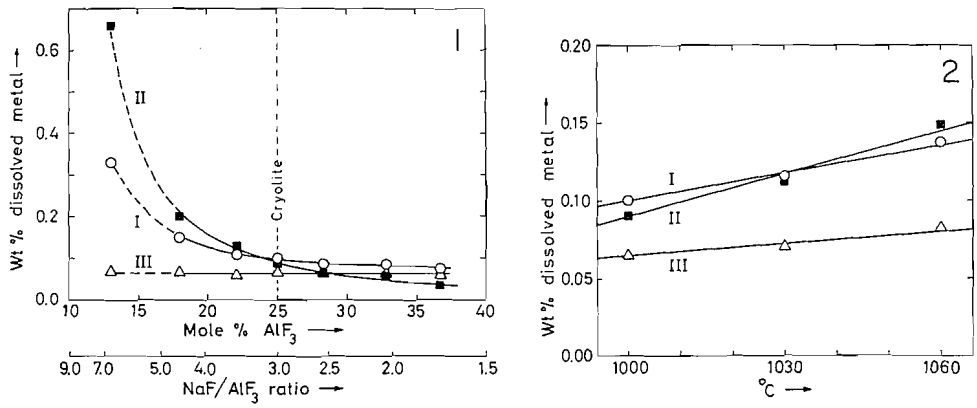

FIG. 1. The solubility of metal in $NaF-AlF_3-Al_2O_3$ melts. Curve I: Total solubility of sodium and aluminium as wt. % Al. Curve II: Sodium content in wt. % Na. Curve III: Aluminium content in wt. % Al.

FIG. 2. The solubility of metal in cryolite–alumina melts versus temperature. Curve I: Total solubility of sodium and aluminium as wt. % Al. Curve II: Sodium content in wt. % Na. Curve III: Aluminium content in wt. % Al.

peratures are presented in Fig. 2. Curves I, II, and III give the total solubility, the sodium content, and the aluminium content respectively.

The precision of the measurements is about ±5% for the total solubility and ±10% for the sodium and aluminium contents. Methods involving slow cooling of the samples gave low and irreproducible results. This was probably due to metal loss by evaporation during sampling. The vapor pressures of sodium over the melts are considerable, e.g., 0.1–0.3 atm in cryolite at 1 000 °C (5, 6, 9). The reproducibility of the results indicate, however, that the rapid quenching that was performed in these experiments permitted effective "freezing" of the existing equilibria in the melts so that possible evaporation losses were negligible.

The total solubility of sodium and aluminium in cryolite at 1 000 °C is 0.10 wt. % Al. The results for melts close to the cryolite composition are in good agreement with the data of Haupin (4). The results for AlF_3-rich melts disagree with those given by Zhurin (1) and by Mashovets and Svoboda (3), as these authors found the solubility to increase with increasing AlF_3 content. The observed total solubility in cryolite at 1 060 °C is slightly lower than that given by Zhurin (1). The results for the sodium content are lower than those found by Haupin (4) for melts with molar ratios $NaF/AlF_3 = 3$ and 2.6. Accordingly the results for the aluminium contents are higher, i.e., 0.065 wt. % Al in the present investigation as against 0.05 wt. % Al found by Haupin for both compositions.

In a previous investigation (10) the reactivity of the dissolved metal versus CO_2 was found to decrease with decreasing NaF/AlF_3 ratio as would be expected from the solubility data presented here. On the other hand, the metal loss due to evaporation (11) increases with decreasing NaF/AlF_3 ratio for melts with $NaF/AlF_3 < 2.7$. This is probably due to kinetic effects governing the evaporation.

The existing equilibrium between the sodium and aluminium contents of the melt may tentatively be described by a reaction as follows

[3] $$Al^{3+} + 2Na_2^+ \rightleftarrows Al^+ + 4Na^+$$

providing the dissolved species are Al^+ and Na_2^+. As long as the activities of the various constituents of these melts are virtually unknown, the Al^+/Na_2^+ ratio cannot be estimated from thermodynamic data. If eqs. [1], [2], and [3] are considered, however, the aluminium

For personal use only.

content would be expected to increase and the sodium content to decrease with decreasing NaF/AlF_3 ratio.

The apparent constancy of the aluminium content as given by curve III in Fig. 1 is therefore somewhat surprising. However, for melts with $NaF/AlF_3 < 3$ saturated with alumina at 1 000 °C, it can be shown that the cation fraction of Al^{3+} (regardless of the structural entities in which it occurs) changes very little with decreasing NaF/AlF_3 ratio, e.g., from 0.36 at $NaF/AlF_3 = 3$ to 0.42 at $NaF/AlF_3 = 1.85$. This is due to the decreasing solubility of alumina in this range. The saturation concentrations of alumina at 1 000 °C are about 13 wt. % Al_2O_3 for melts in the range $NaF/AlF_3 = 3$ to 4.2 and decreases to 7 wt. % Al_2O_3 at $NaF/Alf_3 = 6.4$ (12) and 9.7 wt. % Al_2O_3 at $NaF/AlF_3 = 1.85$ (13).

From the sodium content of pig aluminium, Grjotheim (6) estimated the sodium pressure of a cryolite melt at 1 000 °C to be about 0.1 atm, while Feinleib and Porter (9) from measurements with Pb–Na cathodes found it to be about 0.15 atm. The sodium pressure above the melt has been measured spectroscopically by Stokes and Frank (5) and was found to be 0.3 atm at 1 000 °C, and 0.5 atm at 1 050 °C. Measurements by Jander and Hermann (14) and Grube and Hantelmann (15) indicate that the sodium pressure reaches 1 atm in the range 1–6 mole % AlF_3 in NaF at 1 000 °C.

The sodium content of the melts as given by curve II in Fig. 1 increases rapidly with increasing NaF/AlF_3 ratio as would be expected from the vapor pressure data. This is also in excellent agreement with the data presented by Pearson and Waddington (16) for the sodium content of aluminium in equilibrium with $NaF–AlF_3$ melts at 1 000 °C. The sodium content of the metal thus decreases from 0.031 wt. % Na at $NaF/AlF_3 = 4.25$ to 0.005 wt. % Na at $NaF/AlF_3 = 1.85$, while the sodium content of the melt, as determined in the present work, varies from 0.25 to 0.04 wt. % Na within the same range. It is readily seen that the relative changes in sodium content are the same in the metal and the melt.

The temperature dependence of the sodium solubility shown in Fig. 2 is in agreement with that of the vapor pressures found by Stokes and Frank (5). From Fig. 2 it can also be seen that the fraction of the total solubility represented by sodium increases with increasing temperature. This seems to agree with the fact (9) that the chemical potential of sodium approaches that of aluminium as the temperature increases.

NOTES

DEMJANOV REARRANGEMENT OF 9-XANTHENEMETHYLAMINE

S. N. Alam and D. B. MacLean

The ring expansion of xanthene derivatives to dibenz[*b*,*f*]oxepin is already known. Thus Anet and Bavin (1) have reported the synthesis of dibenz[*b*,*f*]oxepin and 10-methyldibenz[*b*,*f*]oxepin by Wagner–Meerwein rearrangement of 9-xanthenemethanol and 9-hydroxymethyl-9-methylxanthene. More recently, Whitlock (2) has reported the formation of dibenz[*b*,*f*]oxepin in 61% yield when xanthylium perchlorate is treated with ethereal diazomethane. We wish to report on the reaction of 9-xanthenemethylamine under the conditions of the Demjanov rearrangement (3), in which ring expansion has also been observed.

9-Xanthenemethylamine (4, 5) was prepared from 9-xantheneacetic acid (6) in the following manner. The acid was converted into its acid chloride with thionyl chloride and this in turn into the azide, which underwent Curtius rearrangement (7) to the isocyanate. Treatment of the isocyanate with alkali, however, gave N,N′-di(9-xanthenemethyl)urea instead of the amine. The formation of the urea was avoided by conversion of the crude isocyanate into the ethylurethane followed by hydrolysis of the urethane to 9-xanthenemethylamine, which was isolated as the hydrochloride salt, in a yield of 41.5% based on 9-xantheneacetic acid. The yield was improved to 52.5% by treatment of the crude isocyanate with benzyl alcohol followed by reduction of the benzylurethane to the amine.

9-Xanthenemethylamine was treated with nitrous acid in acetate buffer under experimental conditions normally employed in the Demjanov rearrangement. The crude product was worked up as described in the Experimental section and separated into an olefinic and an alcoholic fraction by column chromatography on alumina. The alcoholic fraction, comprising 96% of the product, was shown to be a mixture of 9-xanthenemethanol and 10,11-dihydrodibenz[*b*,*f*]oxepin-10(11,H)-ol in a ratio of 1:4. The ring-expanded alcohol is formed in an overall yield of 65% based on the amine. The composition of the mixture was established by nuclear magnetic resonance (n.m.r.) analysis of the mixture of the two alcohols and by partition chromatography on a silica gel column. To carry out the analysis it was necessary to synthesize the two alcohols by established procedures and to examine their physical properties. 9-Xanthenemethanol was prepared by the method of Anet and Bavin (1) and 10,11-dihydrodibenz[*b*,*f*]oxepin-10(11,H)-ol by borohydride reduction of the corresponding oxepinone, which was prepared by the method of Manske and Ledingham (8). The isomeric tertiary alcohol, 9-methyl-9-xanthenol, a possible product of this reaction, was also prepared (9), but its properties were such that its presence in the alcoholic fraction from the Demjanov reaction is precluded. We found that, when the tertiary alcohol was placed on an alumina column and chloroform applied to the column, the recovered product was not the alcohol. The product showed no hydroxyl absorption in the infrared, and was not further examined.

The foregoing results show that the Demjanov rearrangement may be applied successfully to the synthesis of 10,11-dihydrodibenz[*b*,*f*]oxepin-10(11,H)-ol and of dibenz[*b*,*f*]-oxepin itself. Manske and Ledingham have shown (8), and we have confirmed, that the alcohol may be converted quantitatively into the olefin.

EXPERIMENTAL

Apparatus, Methods, and Materials

Melting points were recorded on a Kofler micro hot stage melting point apparatus and are uncorrected.

The infrared spectra were recorded on a Beckman model IR-5 recording spectrophotometer in Nujol mull unless otherwise stated.

The n.m.r. spectra were measured in deuterochloroform solutions, with tetramethylsilane as an internal standard, on a Varian V-4300B high resolution spectrometer at a frequency of 60 Mc/s.

9-Xantheneacetyl Chloride

Purified thionyl chloride (4 ml) was cooled in an ice bath and 9-xantheneacetic acid (6) (4 g) was added slowly with mechanical stirring, at which time a semisolid green mass formed. Additional thionyl chloride (4 ml) was added and the mixture boiled gently under reflux for 25 min. The excess thionyl chloride was then removed under reduced pressure and the residual green solid crystallized from benzene to give 9-xantheneacetyl chloride (3.5 g, 82%), m.p. 95–96°. The reported melting point for the acid chloride is 98 °C (6).

9-Xantheneacetyl Azide

A solution of sodium azide (1.0 g) in water (2 ml) was added dropwise to a stirred ice-cooled solution of 9-xantheneacetyl chloride (1.0 g) in acetone (15 ml) and the mixture allowed to stand for 15 min. The resulting oily mixture was diluted with water (30 ml) and the crystalline azide filtered and dried at room temperature under reduced pressure. The azide was used in subsequent experiments without further purification. The yield was 0.92 g (90.2%). The infrared spectrum of the azide showed a strong peak at 2 120 cm^{-1} (azide) and 1 730 cm^{-1} ($\rangle C{=}O$).

N,N'-Di(9-xanthenemethyl)urea

The azide prepared above was dissolved in dry benzene (5 ml) and heated under reflux for 2 h (or until nitrogen evolution had ceased). Removal of solvent on a rotary evaporator gave the isocyanate as a brownish solid. The crude isocyanate was dissolved in benzene (10 ml), treated with 10 ml of 50% potassium hydroxide solution, and heated on a steam bath for 1 h. Removal of benzene on a rotary evaporator followed by cooling of the aqueous layer gave a crystalline solid which was separated and washed with water. Crystallization from methanol gave N,N'-di(9-xanthenemethyl)urea which melted at 222–223°. The infrared spectrum showed an absorption peak at 3 330 cm^{-1} (—NH absorption) and a peak at 1 627 cm^{-1} which was attributed to the carbonyl group of the urea linkage.

Anal. Calcd. for $C_{29}H_{24}O_3N_2$: C, 77.90; H, 5.36; N, 6.27. Found: C, 78.31; H, 5.18; N, 6.34.

9-Xanthenemethyl Isocyanate

9-Xantheneacetyl azide (0.9 g) was dissolved in dry benzene (5 ml) and heated under reflux for 2.5 h, at which time the evolution of nitrogen had ceased. Upon evaporation of the benzene a brownish solid (0.8 g) was obtained. The infrared spectrum showed that the azide and the carbonyl peak had disappeared and that a new peak at 2 265 cm^{-1} (—N=C=O) had appeared. The yield of the isocyanate was quantitative.

9-Xanthenemethylamine

Method A

The crude isocyanate (0.6 g) was dissolved in absolute ethanol (20 ml) containing potassium hydroxide (4 g) and boiled under reflux for 15 h, during which time a small amount of a reddish precipitate formed. Additional absolute ethanol (15 ml) was added to dissolve the precipitate and the mixture was boiled under reflux for a further 30 min. The mixture was filtered, and the filtrate acidified with dilute hydrochloric acid and filtered free of potassium chloride. The filtrate was then refluxed for 1 h, cooled, and basified with ammonia, and most of the ethanol removed on a rotary evaporator. Water was added to the residue and the mixture extracted with ether. The ether extract, dried over anhydrous sodium sulfate, was saturated with dry hydrogen chloride gas, whereupon white crystals separated which, after they were dried, weighed 0.26 g (41.5% based on the acid chloride) and melted at 225–230°. Recrystallization from ethanol (95%) gave 9-xanthenemethylamine hydrochloride, which melted at 235–236°. The melting point reported for this compound is 235–236° (5).

Method B

The crude azide (2 g), prepared by the method described previously, was heated under reflux with benzyl alcohol (5 ml) and dry toluene (5 ml) for 3 h. The mixture was poured into a porcelain evaporating dish and the toluene was allowed to evaporate slowly. The crystalline residue was transferred to a Buchner funnel, washed with a little absolute ethanol, and dissolved in a mixture of methanol (15 ml) and glacial acetic acid (5 ml). This solution was hydrogenated at 50 p.s.i.g. in the presence of palladium black catalyst (0.5 g) for 6 h, filtered, concentrated under reduced pressure, and poured into cold water (200 ml). The aqueous solution was treated with 10% hydrochloric acid solution (50 ml) and the mixture was extracted twice with ether to remove non-basic impurities. Basification with ice-cold 10% sodium hydroxide solution gave a white residue, which was extracted with ether. The ether extract, dried over anhydrous sodium sulfate, was saturated with

dry hydrogen chloride gas, after which 1.0 g (53.8% based on acid chloride) of crystalline 9-xanthenemethylamine hydrochloride which melted at 230–231° was obtained. A sample recrystallized from ethanol (95%) melted at 235–237°. The infrared spectrum showed a continuous series of bands between 3 030 cm^{-1} and 2 500 cm^{-1} characteristic of NH_3^+ absorption, and absorption peaks at 1 600 and 1 570 cm^{-1} characteristic of aromatic absorption of xanthene derivatives, but no absorption in the carbonyl region. The mass spectrum of the free base showed a molecular ion peak at m/e 211.

Anal. Calcd. for $C_{14}H_{13}ON \cdot HCl$: C, 68.00; H, 5.65. Found: C, 67.88; H, 5.70.

Demjanov Rearrangement of 9-Xanthenemethylamine

9-Xanthenemethylamine hydrochloride (1.0 g, 0.004 mole) was dissolved in acetic acid – sodium acetate buffer (pH 5.8, 20 ml) and cooled to 0 °C in an ice bath, and the stirred solution was treated with a solution of sodium nitrite (0.4 g) in water (2 ml). When the addition was complete the reaction mixture was allowed to warm up slowly to room temperature and was kept there for 6 h. The mixture was then heated on a steam bath until nitrogen evolution had ceased (approximately 45 min). The cooled reaction mixture was then extracted with ether, and the ether extract washed with water and dried over anhydrous sodium sulfate. Evaporation of the ether gave a yellow oil (0.8 g). This oil was heated under reflux for 1 h with methanolic potassium hydroxide solution (5%, 50 ml) to hydrolyze the acetates to the corresponding alcohols. The reaction mixture was cooled, the methanol removed under reduced pressure, more water added, and the reaction mixture extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. On removal of the ether a yellow oil (0.74 g) which could not be induced to crystallize was obtained.

Vapor phase chromatography on a 2.5% silicone gum rubber on a Celite column showed that approximately 96% of this material was a mixture of isomeric alcohols, the rest being olefin. However, no separation of the alcohol mixture was achieved by vapor phase chromatography. The peak assigned to the alcohol mixture was established by comparison with the peak of a mixture of synthetic alcohols. A mixture of the synthetic primary and secondary alcohols showed a single peak with the same retention time as the alcohol fraction obtained from the Demjanov reaction.

This oil was adsorbed on an alumina column (non-basic alumina, Woelm, Germany) and eluted successively with petroleum ether (b.p. 30–60°), ether, and chloroform. The ether fraction, after evaporation, gave yellow crystals (0.02 g) which melted over a wide range and which were not further investigated.

The chloroform fraction, after removal of solvent, gave a yellow oil (0.71 g). The infrared spectrum showed an absorption of medium intensity at 1 645 cm^{-1} and 1 610 cm^{-1}, a strong peak at 1 570 cm^{-1}, and a strong peak in the OH region at 3 400 cm^{-1}. The ultraviolet spectrum showed absorption at λ_{max} 337, 270, and 260 mμ and continuous absorption beyond 241 mμ. Vapor phase chromatography on the column described above showed only one peak, with a trace of another peak corresponding to that of dibenz[*b,f*]oxepin. The composition of the mixture was estimated from its n.m.r. spectrum by comparison with that of a synthetic mixture of the 9-xanthenemethanol and 10,11-dihydrodibenz[*b,f*]oxepin-10(11,H)-ol. It was found that the ratio of the rearranged alcohol to the unrearranged primary alcohol was approximately 4:1. Thus it may be calculated that the rearranged product is obtained in 65% yield, based on the weight of the free amine.

The alcohol fraction (0.5 g) obtained from alumina chromatography was chromatographed on a silica gel column (12% water) (w/w), elution being performed with ether, benzene–chloroform mixture (1:1), and finally chloroform. There was no material in the ether fraction. The 1:1 benzene fraction, after evaporation, yielded a viscous oil (0.09 g) which would not crystallize but which had an infrared spectrum similar to that of 9-xanthenemethanol. The chloroform fraction gave a viscous oil (0.4 g), the infrared spectrum of which was identical with that of synthetic 10,11-dihydrodibenz[*b,f*]oxepin-10(11,H)-ol.

10,11-Dihydrodibenz[b,f]oxepin-10(11,H)-one

This compound was prepared by the method of Manske and Ledingham (8). It melted at 55–56° (reported m.p. 56° (8)). The infrared spectrum showed carbonyl absorption at 1 675 cm^{-1} and peaks at 1 600 and 1 510 cm^{-1}. The mass spectrum showed a molecular weight of 210.

The n.m.r. spectrum showed a two-proton singlet at $\tau = 6.02$ (methylene protons), a multiplet centered at $\tau = 2.8$ (aromatic protons), and a doublet (one proton) at $\tau = 2.1$ and 1.95. The doublet may be assigned to the aromatic proton adjacent to the carbonyl group. This signal is shifted downfield as a result of diamagnetic anisotropy of the adjacent carbonyl group (10). The splitting into a doublet may be attributed to spin–spin coupling with the adjacent aromatic proton. The other half of the AB system is probably embedded in the general aromatic resonance multiplet.

10,11-Dihydrodibenz[b,f]oxepin-10(11,H)-ol

The oxepinone (1 g) was dissolved in absolute ethanol (15 ml), and sodium borohydride (2 g) was added to it in portions. The mixture was allowed to stand overnight, and the excess borohydride destroyed by adding acetone in portions. The clear solution was then acidified with dilute hydrochloric acid and filtered. The solution was extracted with chloroform, and the extract washed with water and dried over anhydrous sodium sulfate. The removal of solvent gave a viscous oil (0.8 g) which would not crystallize. This oil was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

chromatographed on an alumina column (Woelm, non-basic), elution being performed with ether and chloroform. A small amount of gummy material was eluted with ether. The chloroform fraction, after removal of solvent, gave a viscous oil which would not crystallize. Thin-layer chromatography showed only a single spot. The infrared spectrum showed a peak at 3 400 cm^{-1} (OH) and peaks at 1 605 and 1 575 cm^{-1} (aromatic ring). The mass spectrum of this alcohol showed a molecular weight of 212. The ultraviolet spectrum showed absorption maxima at λ_{max} 300, 270, and 264 mμ, with a shoulder at 275 mμ and intense absorption below 228 mμ.

The n.m.r. spectrum of 10,11-dihydrodibenz[*b*,*f*]oxepin-10(11,H)-ol shows a symmetrical quartet at τ = 5.17 (one proton), a one-proton signal at τ = 7.38 which may be assigned to the hydroxyl proton, and a multiplet of eight signals between τ values 7.26 and 6.62 (two protons). This spectrum is reminiscent of an ABX type (10). Because of the rigidity enforced upon the system by the ether linkage, it can be seen from a Dreiding model of this molecule that the electronic environments around the two methylene protons are not identical. Furthermore, the chemical shift of the proton on the tertiary carbon atom will be different from that of the methylene protons because of the attached hydroxyl group. Consequently, the expected spectrum would be of the ABX type. Thus the quartet may be assigned to the —C*H*OH proton and the multiplet to the methylene protons.

Dibenz[b,f]oxepin

A portion of the alcohol (0.4 g) described above, in toluene (10 ml), was heated under reflux for 15 min with *p*-toluenesulfonic acid (0.5 g). The reaction mixture was poured onto crushed ice, and the toluene layer separated and washed with water. Evaporation of the toluene under reduced pressure yielded dark-colored crystals (0.35 g). The crystals were purified by eluting with ether through an alumina column. The eluted material was crystallized from methanol and melted at 110–111°. The melting point reported in the literature is 111° (8). The infrared spectrum showed two peaks of medium intensity at 1 600 and 1 575 cm^{-1} and a series of strong peaks in the low-frequency region. The mass spectrum showed a molecular weight of 194. The ultraviolet spectrum was identical with that reported by Anet and Bavin (1) for dibenz[*b*,*f*]oxepin. The n.m.r. spectrum of dibenz[*b*,*f*]oxepin is composed of two signals, as expected. There is a two-proton signal at τ = 3.25 (singlet) due to the olefinic protons, and an eight-proton multiplet centered at τ = 2.75 due to the aromatic protons.

9-Xanthenemethanol

This compound was prepared by the method of Anet and Bavin (1). The infrared spectrum showed peaks at 3 600, 3 450, 1 600, 1 570, 1 120, 1 098, and 895 cm^{-1}. The mass spectrum showed a molecular weight of 212. The n.m.r. spectrum of 9-xanthenemethanol shows a one-proton signal at τ = 7.72 (OH proton), a doublet centered at τ = 6.52 (two protons), and a triplet centered at τ = 6.12 (one proton). We have assigned the triplet to the tertiary —C—H proton and the doublet to the methylene protons (10). The coupling constant is found to be 6.6 c.p.s. The line positions and intensities are typical of an AB_2 spectrum with equal AB coupling constants (10), which is expected for such a system.

9-Methyl-9-xanthenol

9-Xanthenone (5 g) was treated with methylmagnesium iodide (2.16 g magnesium plus 11.84 g methyl iodide) in dry ether in a Soxhlet apparatus. A yellow solid separated during the course of the reaction. The whole was boiled under reflux for 1 h, after which the solid was filtered, washed with ether, and decomposed with cold 3% ammonium chloride solution. The mixture was extracted with ether and the ether extract dried over anhydrous sodium sulfate. Removal of the ether gave a crystalline product (3.9 g, 71%) which melted over a wide range. Repeated recrystallizations from a petroleum ether – ether mixture raised the melting point to 95–99° (capillary). The reported melting point for 9-methyl-9-xanthenol is 96–99° (9). The infrared spectrum of 9-methyl-9-xanthenol showed absorption peaks at 3 300, 1 600, 1 570, and 930 cm^{-1}. The mass spectrum did not show the molecular ion peak; instead, the strongest peak in the spectrum was at *m/e* 194 (M-18), which corresponds to a loss of water from the molecular ion.

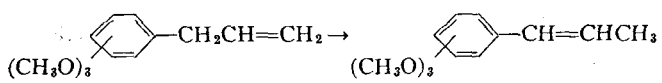
SYNTHESIS OF THE TRIMETHOXYPHENYLPROPENES

ALEXANDER T. SHULGIN

In the reaction shown in eq. [1] eighteen compounds are represented, of which four (elemicin (1), I*a*; isoelemicin (2), III*a*; asarone (3), III*b*; and β-asarone (4), II*b*), as well as an undesignated "calamol" (5), have been observed as constituents of essential oils, and another four have, in addition, been encountered synthetically as chemical intermediates (6). The syntheses and physical properties of these and of the ten remaining



I*a* 3,4,5-Trimethoxy
I*b* 2,4,5-Trimethoxy
I*c* 2,3,4-Trimethoxy
I*d* 2,3,5-Trimethoxy
I*e* 2,3,6-Trimethoxy
I*f* 2,4,6-Trimethoxy

II (*cis*)
III (*trans*)

isomers are described in this note. The methylation of the Claisen rearrangement product of allyl 2,6-dimethoxyphenyl ether yielded elemicin (I*a*) which was identical with that isolated from nutmeg oil (7), and the 2,4,6 counterpart (I*f*) has been synthesized (6*a*) by methylation of the rearrangement product of allyl 3,5-dimethoxyphenyl ether. The synthesis of 2,3,4-trimethoxyallylbenzene (I*c*) was achieved through the corresponding rearrangement of allyl 2,3-dimethoxyphenyl ether (6*b*), but it has been neither isolated nor characterized.

The three remaining isomers, I*b*, I*d*, and I*e*, were obtained by the thermal rearrangement of the appropriate allyl dimethoxyphenyl ethers, followed by methylation of the potassium salts of the resulting phenols with methyl iodide. In the first of these, the rearrangement of allyl 3,4-dimethoxyphenyl ether to the phenolic precursor of I*b*, there are two ortho positions available. Rearrangement occurred preferentially (7:1) to the side nonadjacent to the methoxyl group, as shown by eventual conversion into asarone (III*b*) which was identical with that obtained from parsley oil. In the latter two required rearrangements (those of allyl 2,4-dimethoxyphenyl ether and allyl 2,5-dimethoxyphenyl ether to yield the phenolic precursors to I*d* and I*e* respectively), only a single ortho position is available for the migrating allyl group. The first of these ethers, indeed, rearranged exclusively (>95%) to the available ortho position, but the second underwent appreciable para rearrangement (57% ortho, 43% para) as well as diallylation through some intermolecular phenomenon (see Experimental).

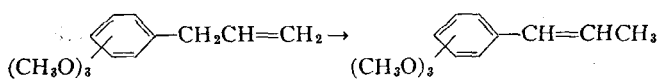
SYNTHESIS OF THE TRIMETHOXYPHENYLPROPENES

ALEXANDER T. SHULGIN

In the reaction shown in eq. [1] eighteen compounds are represented, of which four (elemicin (1), I*a*; isoelemicin (2), III*a*; asarone (3), III*b*; and β-asarone (4), II*b*), as well as an undesignated "calamol" (5), have been observed as constituents of essential oils, and another four have, in addition, been encountered synthetically as chemical intermediates (6). The syntheses and physical properties of these and of the ten remaining



I*a* 3,4,5-Trimethoxy
I*b* 2,4,5-Trimethoxy
I*c* 2,3,4-Trimethoxy
I*d* 2,3,5-Trimethoxy
I*e* 2,3,6-Trimethoxy
I*f* 2,4,6-Trimethoxy

II (*cis*)
III (*trans*)

isomers are described in this note. The methylation of the Claisen rearrangement product of allyl 2,6-dimethoxyphenyl ether yielded elemicin (I*a*) which was identical with that isolated from nutmeg oil (7), and the 2,4,6 counterpart (I*f*) has been synthesized (6*a*) by methylation of the rearrangement product of allyl 3,5-dimethoxyphenyl ether. The synthesis of 2,3,4-trimethoxyallylbenzene (I*c*) was achieved through the corresponding rearrangement of allyl 2,3-dimethoxyphenyl ether (6*b*), but it has been neither isolated nor characterized.

The three remaining isomers, I*b*, I*d*, and I*e*, were obtained by the thermal rearrangement of the appropriate allyl dimethoxyphenyl ethers, followed by methylation of the potassium salts of the resulting phenols with methyl iodide. In the first of these, the rearrangement of allyl 3,4-dimethoxyphenyl ether to the phenolic precursor of I*b*, there are two ortho positions available. Rearrangement occurred preferentially (7:1) to the side nonadjacent to the methoxyl group, as shown by eventual conversion into asarone (III*b*) which was identical with that obtained from parsley oil. In the latter two required rearrangements (those of allyl 2,4-dimethoxyphenyl ether and allyl 2,5-dimethoxyphenyl ether to yield the phenolic precursors to I*d* and I*e* respectively), only a single ortho position is available for the migrating allyl group. The first of these ethers, indeed, rearranged exclusively (>95%) to the available ortho position, but the second underwent appreciable para rearrangement (57% ortho, 43% para) as well as diallylation through some intermolecular phenomenon (see Experimental).

Twelve isomers (II*a*–II*f*; III*a*–III*f*) can result from the base-catalyzed isomerization of the six trimethoxyallylbenzenes, I*a*–I*f*. II*b*, III*a*, and III*b* have been mentioned above as natural products, and both III*c* and III*f* have been prepared synthetically (6). The six allyl isomers described above have each been isomerized in ethanolic potassium hydroxide to mixtures of their *cis*- and *trans*-propenyl counterparts. The ratio of isomers that are formed invariably favored the *trans* form, which further was found to be the slower moving component in gas–liquid chromatography (g.l.c.) separations (8) and to be, in all cases except one, a crystalline solid at or near room temperature. The isomers were purified by preparative g.l.c., and only materials so obtained were utilized for the physical data recorded in Table I.

TABLE I

Physical characteristics of the eighteen trimethoxyphenylpropenes

Methoxy position	Alkyl group	Refractive index*	Melting point (°C)†	Retention time (min)‡	Isomer ratio, *trans*/*cis*§

*All values measured with the sodium D line at 24.5 °C. Solids were supercooled.
†Uncorrected.
‡Determined on a 20M polyethylene glycol column, described in the Experimental. 1,2,3-Trimethoxybenzene was added to the test mixtures, and its retention time taken as 1.00.
§Determined from the areas of the appropriate peaks, as measured by a rolling-disk planimeter.
‖Complete separation is obtained when a SE-30 silicone substrate is employed.

EXPERIMENTAL

The g.l.c. separations were achieved on a Wilkens Instrument Company Autoprep A-700. The principal column employed was an aluminium column, 5 ft by $\frac{3}{8}$ inch diameter, loaded to 10% with 20M polyethylene glycol on 60/80 mesh Chromosorb W. At an air bath temperature of about 180 °C and with a helium flow of about 500 ml/min, the standard internal reference chemical, 1,2,3-trimethoxybenzene, required about 4 min to emerge. The retention times of materials summarized in this report may thus be estimated from the values in Table I. Other substrates employed in the work will be described as they are mentioned. Samples for microanalytical evaluation were obtained from the g.l.c. separation directly in sealable capillaries. The members of this series all carry the empirical formula $C_{12}H_{16}O_3$, and all analyses were acceptable.

All infrared spectra were recorded on a Beckman IR-5A spectrophotometer. With the exception of the three higher melting *trans*-propenyl isomers, all samples were recorded as films between salt plates. These eighteen spectra have been placed in The Depository of Unpublished Data.* The physical data are given in Table I.

All materials described in this report were synthesized by the general sequence of reactions: dimethoxyphenol → allyl dimethoxyphenyl ether → allyldimethoxyphenol → trimethoxyallylbenzene (I) → trimethoxypropenylbenzene (II and III). As it would be unnecessarily repetitious to describe all six parallel processes,

For personal use only.

only one will be presented in detail. Any significant deviations required in the other isomeric syntheses will be mentioned briefly.

2,4-Dimethoxyphenol

A solution of 68 g of 2,4-dimethoxybenzaldehyde (K and K Laboratories) in 250 g glacial acetic acid was brought to 25° and treated dropwise, over 1 h, with 86 g of a 40% solution of peracetic acid in acetic acid. The reaction mixture was diluted with three volumes of water, and then neutralized cautiously with 283 g of anhydrous potassium carbonate. Extensive extraction with ether yielded, after removal of the solvent, 66 g of the formate of 2,4-dimethoxyphenol. This was hydrolyzed with 10% base for 1 h at steam bath temperatures. The resulting solution was extracted once with methylene chloride (discarded), acidified with aqueous hydrochloric acid, and re-extracted several times with methylene chloride. These latter extracts were washed once with an aqueous solution of sodium bicarbonate (which removed much of the color), dried, and concentrated by evaporation on the steam bath. The resulting product, which crystallized when the concentrate was cooled below room temperature, weighed 34.4 g (54% yield) and yielded a benzoate (with benzoyl chloride in pyridine, recrystallized from cyclohexane) which melted at 89–90 °C (literature values: phenol, m.p. 28°; benzoate, m.p. 90° (9)). The 2,3-, 3,4-, and 2,5-dimethoxybenzaldehydes were oxidized similarly to the phenols, in similar yields. 3,5-Dimethoxybenzaldehyde gave no phenolic product with peracetic acid, and the corresponding phenol was synthesized from phloroglucinol (10). 2,6-Dimethoxyphenol was obtained commercially from Eastman Kodak Company.

Allyl 2,4-Dimethoxyphenyl Ether

A solution of 31.0 g of the above crude phenol in 60 ml absolute ethanol was combined with another containing 11.25 g potassium hydroxide in 90 ml anhydrous ethanol. Allyl bromide was immediately added (28 g) and the resulting solution refluxed on the steam bath for 2 h. A precipitate of potassium bromide formed within a minute of heating. At the end of the reaction, the mixture was quenched with several volumes of water, made strongly basic with 10% caustic, and extracted with several volumes of ether. Evaporation of the solvent provided 33.2 g of the desired product (85% yield; b.p. 107–110° at 1.0 mm Hg; $n_D^{22.8}$ 1.5322), which was shown to be free of the starting phenol by analysis on an ethylene glycol succinate g.l.c. column (5% substrate, 10 ft length, $\frac{3}{8}$ inch diameter, 165°*).

2-Allyl-4,6-dimethoxyphenol

The ether (31.0 g) was heated to 215 °C, at which temperature an exothermic reaction ensued that raised the temperature to 270°. The temperature was held at about 260° for an additional 10 min. The rearrangement product thus obtained (n_D^{25} 1.5464) was submitted to methylation without further purification.†

2,3,5-Trimethoxyallylbenzene (Id)

The phenol was methylated directly, in anhydrous ethanol, by treatment with, first, 8.7 g potassium hydroxide dissolved in 75 ml boiling ethanol, and then with 22.4 g methyl iodide. Potassium iodide formed immediately. After 3 h at reflux, the reaction mixture was cooled, quenched with several volumes of water, made strongly basic with 10% caustic, and then extracted with four portions of 100 ml ether. These extracts, after drying and removal of the solvent by evaporation, provided 28 g of an oil. Analysis by g.l.c. showed the presence of about 10% 1,2,4-trimethoxybenzene (from the 2,4-dimethoxyphenol known to be present before methylation) and less than 2% of all other volatile contaminants. The yield of *Id* was thus greater than 80% based on the initial allyl ether. The infrared spectra of the crude reaction product and of the chromatographically isolated specimen were virtually identical; the latter was employed for the refractive index value.

The 2,3,6-trimethoxy isomer obtained similarly from allyl 2,5-dimethoxyphenyl ether was admixed with an almost equal amount of the 2,4,5-isomer. To obtain an adequate amount of the former material both for necessary descriptions and for the subsequent isomerization to the propenyl mixture, it was necessary to repeatedly inject *scores* of 0.15 ml portions into the Wilkins Autoprep machine, utilizing the existing trapping machinery. Trapping efficiency was less than 50%, because of extensive aerosol formation. In this process, a later peak, constituting 12% of the entire crude reaction mixture, was trapped. This trimethoxydiallylbenzene showed a $n_D^{24.5}$ of 1.5228.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12. Found: C, 72.11; H, 7.66.

As one might expect the 1,2,4-substitution of the starting ether to be maintained, and as one might assume that the two allyl groups are located either ortho–ortho or ortho–para to the formed hydroxyl group, then these two allyl groups must bear a meta relationship to one another. Thus this material is assigned the structure 1,3-diallyl-2,4,5-trimethoxybenzene.

**It has been found that the thermally unstable allyl ethers can be analyzed if chromatographed on an ethylene glycol succinate column at temperatures below 180°. Under these conditions there is no detectable rearrangement to the allyl phenols. With a silicone column, even at these temperatures, there is extensive continuous rearrangement on the column, providing a complex and misleading picture of the original composition.*

†*The presence of about 10% of 2,4-dimethoxyphenol in this product (a material specifically shown to be absent in the ether precursor) indicates a side reation involving deallylation. The phenol is best removed as its methyl ether (1,2,4-trimethoxybenzene) in the next step.*

For personal use only.

2,3,5-Trimethoxypropenylbenzene (IId and IIId)

A solution of 26 g of the crude trimethoxyallylbenzene in an equal weight of anhydrous ethanol was treated with 52 g finely flaked potassium hydroxide. Heating on the steam bath for 24 h with occasional agitation effected complete isomerization to the propenyl mixture. The reaction mixture was quenched with much water, and extracted with ether. Removal of the solvent provided 24.6 g of the crude mixture, a yield of about 95%. This crude product provided the isomer ratio data incorporated in Table I. Dilution with an equal volume of pentane, intense cooling, and rapid filtration yielded 9.2 g of an amber-colored crystalline solid. This, upon recrystallization from hexane, provided the pure *trans* isomer, m.p. 44–45°. The mother liquors of the original pentane crystallization were stripped of solvent, and then subjected to g.l.c. purification to provide the sample of the *cis* isomer described in this note. The 2,3,4- and 2,4,6-trimethoxyallylbenzenes required twice the time for isomerization.

DIRECT DISPLACEMENT OF A PRIMARY TOLYL-*p*-SULFONYLOXY GROUP BY THE METHOXIDE ION: A MORE DIRECT ROUTE TO 5-*O*-METHYL-L-ARABINOSE AND 3,5-DI-*O*-METHYL-L-ARABINOSE

S. C. WILLIAMS AND J. K. N. JONES

The direct displacement (S_N2) of a primary tosyloxy group by many other groups has been known for some time. Mitra *et al.* (1) have reported the displacement of a primary mesyloxy (methanesulfonyloxy) group in a hexose derivative by methoxide ion, and we now report the displacement by methoxide of the primary tosyloxy group in a pentose derivative.

Detosylation of 5-*O*-tosyl-L-arabinose derivatives with aqueous methanol and sodium amalgam (2, 3) to give the free hydroxyl on C-5 invariably produced traces of the methylated sugar. It was felt that reaction with sodium methoxide in anhydrous methanol should increase the yield of this methylated sugar by a reaction analogous to that described by Mitra *et al.* (1). Under these conditions 1,2-*O*-isopropylidene-5-*O*-tosyl-L-arabinose (I; R = H, R_1 = tosyl) gave equal amounts of 1,2-*O*-isopropylidene-5-*O*-methyl-L-arabinose (I; R = H, R_1 = CH_3) and 1,2-*O*-isopropylidene-L-arabinose (I; R = R_1 = H), while reaction with 1,2-*O*-isopropylidene-3-*O*-methyl-5-*O*-tosyl-L-arabinose (I; R = CH_3, R_1 = tosyl) gave four times as much 3,5-di-*O*-methyl-L-arabinose derivative (I; R = R_1 = CH_3) as 3-*O*-methyl-L-arabinose derivative (I; R = CH_3, R_1 = H).

The reaction of methyl 3,4-di-*O*-methyl-2-*O*-tosyl-β-L-arabinoside (II; R_2 = tosyl, R_3 = R_4 = CH_3) under the same conditions (sodium methoxide in anhydrous methanol) gave mainly methyl 3,4-di-*O*-methyl-β-L-arabinoside (II; R_2 = H, R_3 = R_4 = CH_3)

2,3,5-Trimethoxypropenylbenzene (IId and IIId)

A solution of 26 g of the crude trimethoxyallylbenzene in an equal weight of anhydrous ethanol was treated with 52 g finely flaked potassium hydroxide. Heating on the steam bath for 24 h with occasional agitation effected complete isomerization to the propenyl mixture. The reaction mixture was quenched with much water, and extracted with ether. DIRECT DISPLACEMENT OF A PRIMARY TOLYL-*p*-SULFONYLOXY GROUP BY THE METHOXIDE ION: A MORE DIRECT ROUTE TO 5-*O*-METHYL-L-ARABINOSE AND 3,5-DI-*O*-METHYL-L-ARABINOSE

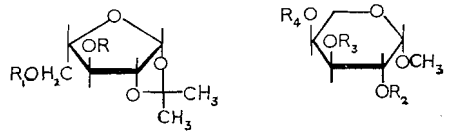
S. C. WILLIAMS AND J. K. N. JONES

The direct displacement (S_N2) of a primary tosyloxy group by many other groups has been known for some time. Mitra *et al.* (1) have reported the displacement of a primary mesyloxy (methanesulfonyloxy) group in a hexose derivative by methoxide ion, and we now report the displacement by methoxide of the primary tosyloxy group in a pentose derivative.

Detosylation of 5-*O*-tosyl-L-arabinose derivatives with aqueous methanol and sodium amalgam (2, 3) to give the free hydroxyl on C-5 invariably produced traces of the methylated sugar. It was felt that reaction with sodium methoxide in anhydrous methanol should increase the yield of this methylated sugar by a reaction analogous to that described by Mitra *et al.* (1). Under these conditions 1,2-*O*-isopropylidene-5-*O*-tosyl-L-arabinose (I; R = H, R_1 = tosyl) gave equal amounts of 1,2-*O*-isopropylidene-5-*O*-methyl-L-arabinose (I; R = H, R_1 = CH_3) and 1,2-*O*-isopropylidene-L-arabinose (I; R = R_1 = H), while reaction with 1,2-*O*-isopropylidene-3-*O*-methyl-5-*O*-tosyl-L-arabinose (I; R = CH_3, R_1 = tosyl) gave four times as much 3,5-di-*O*-methyl-L-arabinose derivative (I; R = R_1 = CH_3) as 3-*O*-methyl-L-arabinose derivative (I; R = CH_3, R_1 = H).

The reaction of methyl 3,4-di-*O*-methyl-2-*O*-tosyl-β-L-arabinoside (II; R_2 = tosyl, R_3 = R_4 = CH_3) under the same conditions (sodium methoxide in anhydrous methanol) gave mainly methyl 3,4-di-*O*-methyl-β-L-arabinoside (II; R_2 = H, R_3 = R_4 = CH_3)



I II

with a small amount of a second material. This material was shown by gas–liquid partition chromatography to be neither methyl 2,3,4-tri-*O*-methyl-β-L-arabinoside (II; $R_2 = R_3 = R_4 = CH_3$) nor methyl 2,3,4-tri-*O*-methyl-β-L-riboside, so that displacement did not occur in this case. This material may possibly contain a double bond between C-1 and C-2 formed by the elimination of *p*-toluenesulfonic acid, as Ball (4) has postulated for a product of a similar type; this is being investigated further.

EXPERIMENTAL

Paper chromatography was carried out in the normal manner with the following solvent systems: (A) butan-1-ol–ethanol–water (3:1:1, v/v/v); (B) butanone saturated with 2% aqueous ammonium hydroxide; (C) butanone–water azeotrope (85:7, v/v). The sugars were located on the paper chromatograms with the following spray reagents: (*i*) alkaline silver nitrate (5); (*ii*) *p*-anisidine hydrochloride (6).

Thin-layer chromatography (t.l.c.) was carried out with silica gel G plates and the following solvent systems: (D) chloroform – 10% methanol; (E) benzene – 1% MeOH. The spots were located by spraying the plate with concentrated sulfuric acid and heating it at 140° for 5–10 min.

Melting points were taken on a Fisher block and are uncorrected. Evaporations were carried out under reduced pressure at 50° or less. Optical rotations were determined at 21° ± 2° on a Hilger standard polarimeter.

1,2-O-Isopropylidene-5-O-methyl-L-arabinose (I; R = H, $R_1 = CH_3$)

A solution of 1,2-*O*-isopropylidene-5-*O*-tosyl-L-arabinose (I; R = H, R_1 = tosyl) (10.0 g) in dry methanol (335 ml) containing sodium methoxide prepared from sodium (11 g) was refluxed under anhydrous conditions until the reaction was complete (26 h) as shown by t.l.c. The solution was cooled and filtered, and the filtrate was concentrated to dryness. The residue was then shaken with a mixture of water (200 ml) and chloroform (100 ml). The water layer was further extracted with chloroform (4 × 50 ml) and these latter extracts were combined, dried over sodium sulfate, and concentrated to a crystalline mass (0.50 g) which, after recrystallization from ether–petrol (100–120°), gave pure 1,2-*O*-isopropylidene-5-*O*-methyl-L-arabinose, m.p. 67–68.5°, $[\alpha]_D$ −9° (*c*, 0.655, in methanol).

Anal. Calcd. for $C_9H_{16}O_5$: C, 52.9; H, 7.9. Found: C, 52.7; H, 7.7.

The water layer yielded 1,2-*O*-isopropylidene-L-arabinose (I; R = R_1 = H) (0.67 g), m.p. 119–120°, $[\alpha]_D$ −28° (*c*, 0.94, in water). Compton and Levene (2) report m.p. 117–118°, $[\alpha]_D$ −29° (*c*, 2, in water). The original chloroform extract was concentrated to a syrup (2.44 g) which crystallized and was a mixture of 1,2-*O*-isopropylidene-5-*O*-methyl-L-arabinose and 1,2-*O*-isopropylidene-L-arabinose. It was separated by partition between chloroform and water. The total yield of pure 1,2-*O*-isopropylidene-5-*O*-methyl-L-arabinose was 1.535 g, i.e. 26%.

5-O-Methyl-L-arabinose

1,2-*O*-Isopropylidene-5-*O*-methyl-L-arabinose (0.49 g) was dissolved in 25% aqueous acetic acid (20 ml) and the solution was refluxed for 3 h. Concentration of the solution then gave syrupy 5-*O*-methyl-L-arabinose (0.39 g) which was chromatographically pure (R_G 0.38 (solvent B) (movement relative to tetramethyl glucose) and R_G 0.39 (solvent C)) and had $[\alpha]_D$ −24° (*c*, 0.86, in water). Siddiqui *et al.* (7) report R_G 0.39 (solvent C) and $[\alpha]_D$ −25° ± 1.5° (*c*, 1, in water). It was further characterized, after oxidation to the lactone, as the crystalline phenylhydrazide, m.p. 176.5–178.5°. The literature gives m.p. 176.5–178° (7).

1,2-O-Isopropylidene-3,5-di-O-methyl-L-arabinose (I; R = $R_1 = CH_3$)

A solution of 1,2-*O*-Isopropylidene-3-*O*-methyl-5-*O*-tosyl-L-arabinose (I; R = CH_3, R_1 = tosyl) (9.3 g) in anhydrous methanol (300 ml) containing sodium methoxide prepared from sodium (9 g) was refluxed, with the exclusion of moisture, for 29 h, at which time t.l.c. showed that no starting material was present. The solution was cooled and filtered, and the filtrate was concentrated to dryness. The product was shaken with water (200 ml) and chloroform (100 ml). The water layer was further extracted with chloroform (3 × 50 ml) and the chloroform extracts were combined, dried, and concentrated to a mobile yellow syrup (5.5 g) which consisted of two components, as shown by t.l.c. (solvents D and E).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3,5-Di-O-methyl-L-arabinose and 3-O-Methyl-L-arabinose

A solution of the above syrup (5.25 g) in 25% aqueous acetic acid (120 ml) was boiled under reflux for 3½ h. The solution was filtered and concentrated to a syrup (4.4 g). This syrup was dissolved in water (40 ml) and the water layer was continuously extracted with chloroform. The chloroform extract yielded chromatographically pure, syrupy 3,5-di-*O*-methyl-L-arabinose (2.6 g), R_G 0.83 (solvent B), R_G 0.82 (solvent C), $[\alpha]_D$ −41.5° (*c*, 1.08, in water). Percival and Zobrist (8) report $[\alpha]_D$ +47° (*c*, 0.76, in water) for the corresponding D-sugar. It was characterized as its crystalline phenylosazone, m.p. 169–170° (lit. m.p. 170° (9)). The aqueous layer, after the continuous chloroform extraction, yielded chromatographically pure syrupy 3-*O*-methyl-L-arabinose (0.6 g), $[\alpha]_D$ +102° (*c*, 0.77, in water), R_G 0.16 (solvent B), R_G 0.12 (solvent C). Hirst *et al.* (3) report $[\alpha]_D$ +96 and +110° (*c*, 3.6, in water). It was characterized as its crystalline phenylosazone, m.p. 163–165° (lit. m.p. 163° (10)).

Detosylation of Methyl 3,4-Di-O-methyl-2-O-tosyl-β-L-arabinoside (II; R_2 = tosyl, $R_3 = R_4 = CH_3$)

Methyl 3,4-di-*O*-methyl-2-*O*-tosyl-β-L-arabinoside (5.0 g) was dissolved in dry methanol (500 ml) containing sodium methoxide prepared from sodium (10 g), and the solution was refluxed under anhydrous conditions for 24 h. The solution was concentrated to dryness, and the residue was then shaken with a mixture of water (250 ml) and chloroform (125 ml). The water layer was further extracted with chloroform (5 × 125 ml), the combined chloroform extracts were dried over magnesium sulfate and filtered, and the filtrate was concentrated to a syrup (2.3 g). This "glycoside mixture" had $[\alpha]_D$ +203° (*c*, 0.96, in chloroform); Honeyman (11) gives $[\alpha]_D$ +210.6° (chloroform) for methyl 3,4-di-*O*-methyl-β-L-arabinoside.

The above syrup (1.9 g) was refluxed for 4 h in 1 *N* H_2SO_4 (50 ml), the solution was neutralized with barium carbonate and filtered, and the filtrate was concentrated to a syrup (1.3 g). Paper chromatography of the hydrolysate in solvent A revealed a main component (X), which moved at a rate equal to that of a dimethyl sugar (R_F 0.51), and a faster second component (Y) of R_F 0.65. These two components were separated by preparative paper chromatography to give 450 mg of the dimethyl sugar (X) and 93 mg of the faster material (Y). The dimethyl sugar (X) had $[\alpha]_D$ +137° (*c*, 0.84, in water); Whistler and McGilvray (12) give $[\alpha]_D$ +125° (water) for 3,4-di-*O*-methyl-L-arabinose.

Demethylation of Y with boron trichloride gave a mixture of arabinose and ribose. Analysis of the "glycoside mixture" by gas–liquid partition chromatography on a column of Apiezon M, 20% on Celite 545 (30–80 mesh), at 149° with a flow rate of 85 ml argon/min, showed that the glycoside of Y was neither methyl 2,3,4-tri-*O*-methyl-β-L-arabinoside nor methyl 2,3,4-tri-*O*-methyl-β-L-riboside (see Table I).

TABLE I

Separation of glycosides with 20% Apiezon M on Celite 545 (30–80 mesh), 149 °C, 85 ml argon/min

Symbol	Compounds	Retention time (min)
A	Methyl 2,3,4-tri-*O*-methyl-α-D-riboside	5.0
B	Methyl 2,3,4-tri-*O*-methyl-β-D-riboside	6.0
	+ methyl 2,3,4-tri-*O*-methyl-β-L-arabinoside	6.2
C	Unknown glycoside of Y	7.7

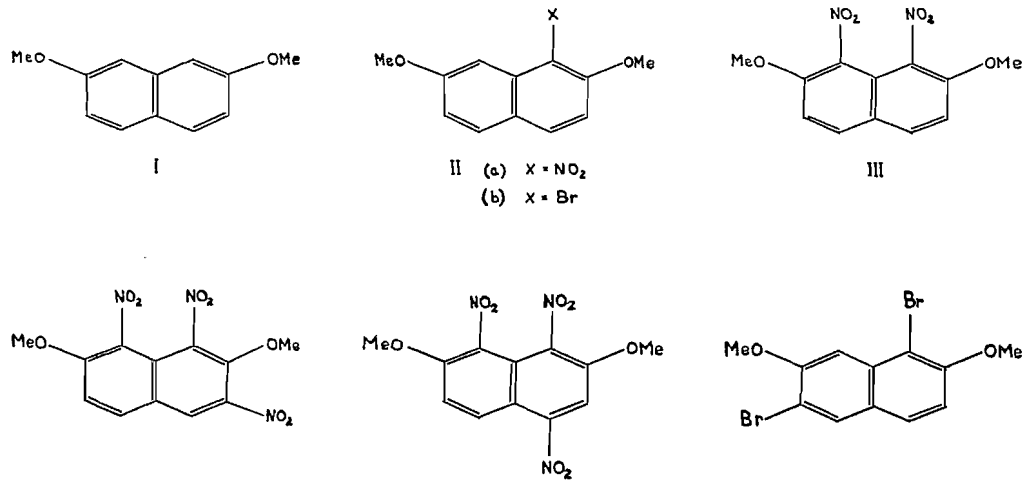
SUBSTITUTIONS EN SERIE NAPHTALENIQUE
II. DERIVES DU DIMETHOXY-2,7 NAPHTALENE

JEAN-CLAUDE RICHER ET YVON PÉPIN

A la suite des résultats quelque peu surprenant qui ont été obtenus au cours d'un travail précédent (1) sur les réactions de substitution du diméthoxy-1,7 naphtalène, nous avons maintenant porté notre attention vers les réactions de nitration et de bromuration du diméthoxy-2,7 naphtalène (I).



I II (a) X = NO_2 (b) X = Br III

IV V VI

VII VIII

Les réactions de nitration de I ont déjà été étudiées (2, 3). La mononitration conduirait au diméthoxy-2,7 nitro-1 naphtalène (II*a*) alors que la dinitration fournirait le diméthoxy-2,7 dinitro-1,8 naphtalène (III). Les nitrations selon Fisher (2) ont été reprises et les spectres de résonance magnétique nucléaire (r.m.n.) des composés obtenus ont confirmé que les structures II*a* et III doivent être attribuées respectivement au dérivé mononitré, p.f. 142° (litt. (2) 141°), et au dérivé dinitré, p.f. 280° (décomp.) (litt. (2) 286°). Aucune structure n'avait été attribué au trinitro diméthoxy-2,7 naphtalène, p.f. 223° (litt. (2) 216°). En appliquant au dérivé dinitré (II*a*) les paramètres d'additivité proposés par Wells et Alcorn (4) il est possible de prédire que le spectre r.m.n. du trinitro-1,3,8 et du trinitro-1,4,8 auraient les caractéristiques suivantes: trinitro-1,3,8 (IV) doublet à 8.02, doublet à 8.91 et singulet à 9.58 p.p.m.; trinitro-1,4,8 (V) doublet à 8.14, singulet à 8.62 et doublet à 9.02 p.p.m. Considérant que le spectre r.m.n. observé pour le dérivé

For personal use only.

trinitré présente un doublet à 8.24, un doublet à 8.94 et un singulet à 9.48 p.p.m., il en est conclu que la structure IV doit être attribuée au dérivé trinitré.

Les réactions de bromuration de I ont été étudiées par plusieurs auteurs et les structures des produits qui en découlent sont des plus controversées (5–11). Les bromurations ont été reprises selon Wilson (9, 11) et les spectres r.m.n. des dérivés bromés obtenus ont été mesurés; les résultats sont résumés au Tableau I. Ces données sont compatibles avec les

*Les spectres r.m.n. ont été déterminés à l'aide d'un appareil Varian A-60 pour des solutions dans la diméthylacétamide. Les déplacements chimiques ont été mesurés par rapport au tétramethylsilane utilisé comme standard interne et sont rapportés en p.p.m. (échelle δ où tétramethylsilane = 0). Les valeurs entre parenthèses indiquent les constantes de couplage entre protons ortho (H_3 vs. H_4 ou H_5 vs. H_6) ou les protons méta (H_6 vs. H_8).

structures II*b*, VI et VII attribuées respectivement aux dérivés monobromé, p.f. 78° (litt (11) 77.5–78°); dibromé, p.f. 128° (litt (9) 129–130°); tribromé, p.f. 171.5–172.5° (litt (9) 172.5°).

Au point de vue mécanistique, il est prévu que les réactions de nitration et de bromuration du diméthoxy-2,7 naphtalène (I) seront orientées principalement vers les positions 1 ou 8 dû au fait que ce sont des positions "α", adjacentes à des groupes méthoxyles qui les activent par des effets inductifs et mésomériques combinés. Toutefois il est connu (12) que les effets stériques présents dans le di-*t*-butyl-2,7 naphtalène (VIII) orientent la réaction de sulfonation de cet hydrocarbure vers la position 4. Il est alors très intéressant de noter que les effets stériques n'influencent aucunement l'introduction d'un premier substituant dans la molécule de diméthoxy-2,7 naphtalène et que les dérivés II (*a* et *b*) sont obtenus. D'autre part la formation du diméthoxy-2,7 dinitro-1,8 naphtalène (III) par opposition à la formation du dibromo-1,6 diméthoxy-2,7 naphtalène (VI) pourrait indiquer soit que les exigences stériques d'un groupe nitro sont plus faibles que celles d'un atome de brome ou que les effets électroniques d'un atome d'halogène par opposition à ceux d'un groupe nitro ont une influence très différente sur l'orientation de la deuxième substitution. Cette dernière hypothèse peut-être toutefois rejetée à la lumière des résultats de Wilson (13), qui rapporte que la dichloruration du diméthoxy-2,7 naphtalène conduit au dichloro-1,8 diméthoxy-2,7 naphtalène. Il peut donc en être conclu que les exigences stériques d'un atome de brome sont plus grandes que celles d'un groupe nitro. A ce point de vue nous rencontrons les opinions exprimées précédemment par Adams (14) dans ses travaux sur l'activité optique des biphényls.

Quant à l'orientation vers des position β (3 et 6) du troisième groupe nitro (position 3) et des deuxième (position 6) et troisième (position 3) atomes de brome, une seule explication semble nécessaire; ces positions β sont d'une part activées par l'effet inductif du groupe méthoxyle voisin alors que d'autre part l'autre groupe méthoxyle en position *amphi* leur oriente ses électrons par effet mésomérique.

En conclusion on peut donc mentionner que les réactions de substitutions sur le diméthoxy-2,7 naphtalène conduisent à des produits dont la formation peut-être rationalisée

CONFIGURATION AND CONFORMATION OF 2,3-DICHLORO-1,4-DIOXANE, M.P. 52°

ROBERT R. FRASER AND C. REYES-ZAMORA

Considerable confusion has arisen recently concerning the configuration and conformation of the higher melting (52°) isomer, A, of 2,3-dichloro-1,4-dioxane. The compound was originally assigned the *cis* configuration by Summerbell and Lunk (1). This conclusion was arrived at after the compound was found to be less stable than the second isomer, B (m.p. 31°), which was proved to be *trans* by the demonstration that it was capable of kinetic resolution into one enantiomer. Subsequently, Altona and co-workers verified the assignment of the *trans* configuration to isomer B and established the configuration to be diaxial (2) through X-ray analysis, infrared spectra, and dipole moment studies. The dipole moment of isomer A was in agreement with the *cis* configuration. More recently, Caspi *et al.* (3) examined the nuclear magnetic resonance spectrum of isomer A and observed a single peak at 4.3 τ for the tertiary protons, and an A_2B_2 pattern for the hydrogens at the 5 and 6 positions. From the appearance of an A_2B_2 pattern they concluded that the dioxane ring possessed a rigid conformation. The single peak at 4.3 τ then led them to deduce the conformation to be an eclipsed boat, with oxygen occupying the "bowsprit" positions. Such conclusions were entirely unwarranted. A pair of rapidly interconverting chair conformations would also give rise to the observed spectrum. Unfortunately their findings were accepted in part by Chen and Le Fèvre (4), who measured the dipole moments, polarization, and polarizability of the two isomeric 2,3-dichloro- and 2,3-diphenyl-1,4-dioxanes. Because they accepted Caspi's conclusion that isomer A possessed a rigid conformation, they were forced, by elimination, to assign the *trans* diequatorial conformation to it. If assignment of either the *cis* boat conformation or the *trans* diequatorial conformation were correct, then some of the fundamental

CONFIGURATION AND CONFORMATION OF 2,3-DICHLORO-1,4-DIOXANE, M.P. 52°

Robert R. Fraser and C. Reyes-Zamora

Considerable confusion has arisen recently concerning the configuration and conformation of the higher melting (52°) isomer, A, of 2,3-dichloro-1,4-dioxane. The compound was originally assigned the *cis* configuration by Summerbell and Lunk (1). This conclusion was arrived at after the compound was found to be less stable than the second isomer, B (m.p. 31°), which was proved to be *trans* by the demonstration that it was capable of kinetic resolution into one enantiomer. Subsequently, Altona and co-workers verified the assignment of the *trans* configuration to isomer B and established the configuration to be diaxial (2) through X-ray analysis, infrared spectra, and dipole moment studies. The dipole moment of isomer A was in agreement with the *cis* configuration. More recently, Caspi *et al.* (3) examined the nuclear magnetic resonance spectrum of isomer A and observed a single peak at 4.3 τ for the tertiary protons, and an A_2B_2 pattern for the hydrogens at the 5 and 6 positions. From the appearance of an A_2B_2 pattern they concluded that the dioxane ring possessed a rigid conformation. The single peak at 4.3 τ then led them to deduce the conformation to be an eclipsed boat, with oxygen occupying the "bowsprit" positions. Such conclusions were entirely unwarranted. A pair of rapidly interconverting chair conformations would also give rise to the observed spectrum. Unfortunately their findings were accepted in part by Chen and Le Fèvre (4), who measured the dipole moments, polarization, and polarizability of the two isomeric 2,3-dichloro- and 2,3-diphenyl-1,4-dioxanes. Because they accepted Caspi's conclusion that isomer A possessed a rigid conformation, they were forced, by elimination, to assign the *trans* diequatorial conformation to it. If assignment of either the *cis* boat conformation or the *trans* diequatorial conformation were correct, then some of the fundamental

energetic concepts in conformational analysis would be invalidated. For this reason we have undertaken a rigorous analysis of the A_2B_2 absorption pattern of isomer A in an attempt to clarify the existing discrepancies.

The nuclear magnetic resonance spectrum of a 15% solution (w/v) of isomer A in chloroform was measured. Figure 1A shows the high-field half of the A_2B_2 absorption.

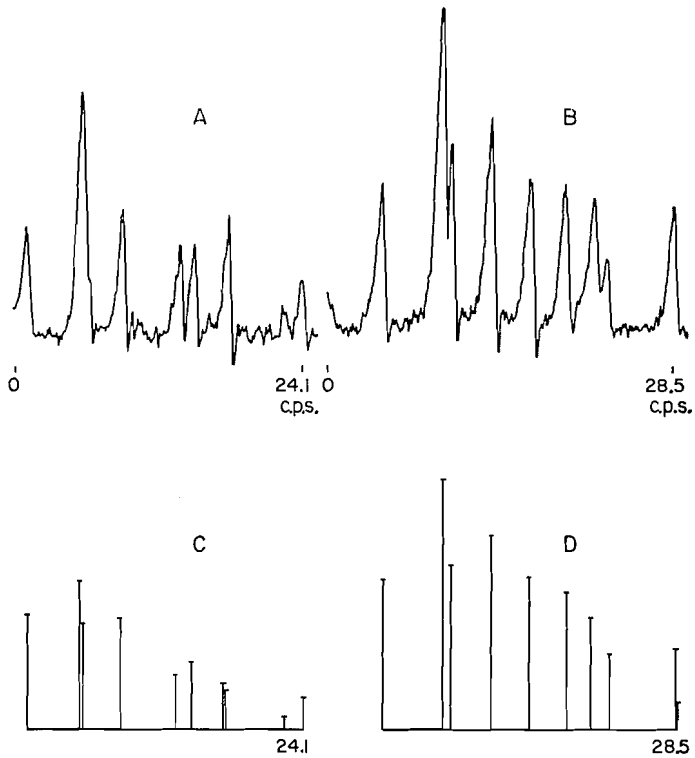

FIG. 1. High-field half of the A_2B_2 absorption of 2,3-dichloro-1,4-dioxane in chloroform (A) and in benzene (B). The spectra calculated from the parameters in the text are shown in C, for chloroform, and in D, for benzene. The points designated 0 refer to the midpoints of the A_2B_2 patterns.

The analysis of this pattern was achieved in the standard manner as recently described by Abraham (5). Assignment of the lines to specific transitions was relatively straightforward, since the spectrum closely resembled that solved by Abraham for 2-methyl-1,3-dioxolane. The parameters K, L, M, N, and δ were adjusted until agreement between calculated and observed line positions was obtained to within 0.15 c.p.s. (Fig. 1C). To check the parameters, we measured the spectrum of a 50% solution (w/v) of isomer A in benzene, and again obtained agreement to within 0.15 c.p.s. between the observed line positions and those calculated from the same values of K, L, M, and N and an adjusted δ. Figure 1 shows the agreement between the observed and calculated spectra in chloroform and in benzene. From the parameters the following coupling constants were found: $J_A = J_B = 3.1$ c.p.s.; $J = -12.25$ c.p.s.; $J' = 6.45$ c.p.s.; $\delta_{CHCl_3} = 22.95$ c.p.s.; $\delta_{benzene} = 31.1$ c.p.s.; where the coupling constants represent the interactions shown below.

$$\begin{array}{l} H_A\text{—}J_A\text{—}H_A \\ \quad | \quad \diagdown \\ \quad J \quad J' \\ \quad | \quad \diagdown \\ H_B\text{—}J_B\text{—}H_B \end{array}$$

For personal use only.

In Fig. 2 all reasonable configurations and conformations for isomer A are shown. If the compound were *cis* and in a rigid chair conformation, we would expect two signals for the protons labelled X and Y in case I. We would also expect an ABCD pattern for the four hydrogens on carbons 5 and 6. Since neither expectation is fulfilled, we can eliminate structure I.

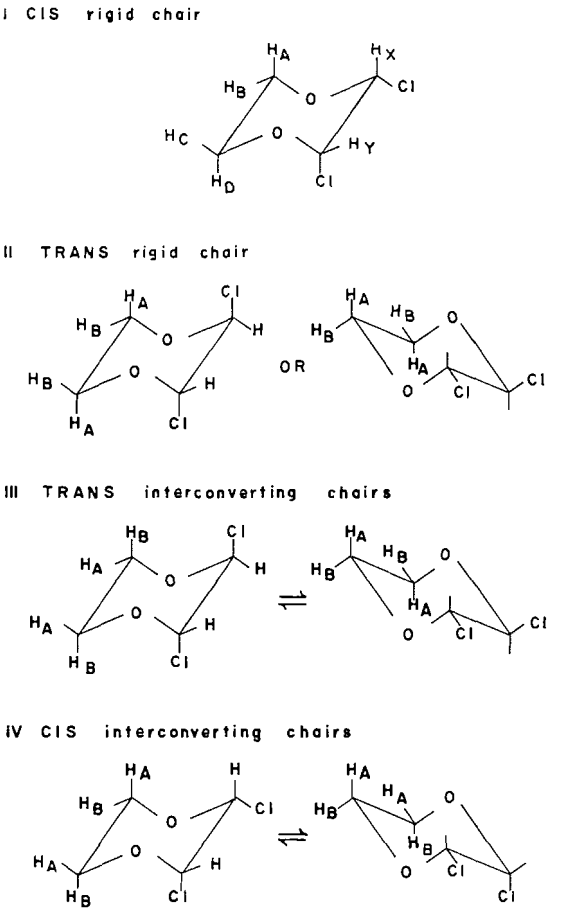

FIG. 2. The four considered representations for 2,3-dichloro-1,4-dioxane, m.p. 52°.

If the compound is *trans* and has its chlorines in either the rigid diaxial or the rigid diequatorial conformation, we would expect an A_2B_2 absorption pattern for the 5 and 6 hydrogens. But in this A_2B_2 system, J_A and J_B should have widely different magnitudes, one typical of diaxial protons and the other typical of diequatorial protons. Since we found $J_A = J_B$, this case is eliminated.

Should the compound possess the *trans* configuration and be rapidly interconverting between the diaxial and diequatorial conformations, there would likely be an unequal population of the two conformations. In this case J_A would not equal J_B, and so this possibility is eliminated. If the two conformations were of equal stability, we would observe coupling constants which are an average of the two contributing structures. This would require $J_A = J_B = (J_{60} + J_{180})/2$ (observed value 3.1 c.p.s.), $J = J_{gem}$, and $J' = J_{60}$ (observed value 6.45 c.p.s.), where the subscripts represent ϕ, the dihedral angle between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the interacting protons. The experimental results would then require that J_{60} be more than twice as large as $(J_{60} + J_{180})/2$. This completely revokes the Karplus relation between J_{vic} and ϕ. Although the relation is far from quantitative, it is completely reliable in predicting $J_{180} > J_{60}$ (6). Thus III is eliminated.

In case IV the observed parameters compare favorably with those encountered in similar six-membered rings. The best model for comparison is the 1,3-dioxane system (Fig. 3), whose analysis gave the following parameters (7): $J_{60} = J_{AB'} = 3.8$ c.p.s.;

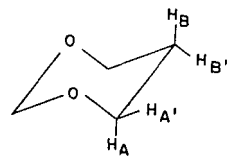

FIG. 3. The chair form of 1,3-dioxane showing the four protons whose coupling constants have been determined (7).

$(J_{60} + J_{180})/2 = (J_{A'B'} + J_{AB})/2 = 6.7$ c.p.s.; $J_{AA'} = -11.0$ c.p.s. (a better model in this case might be $CH_3—\underset{\displaystyle OH}{\underset{|}{CH}}—CH_2OH$, in which $J_{gem} = -11.9$ c.p.s. (8)). In 1,4-dioxane, $J_{60} = 2.7$ c.p.s. and $(J_{60} + J_{180})/2 = 6.1$ c.p.s. (9).

In view of the good agreement between the coupling constants for isomer A and those predicted from the *cis* configuration for interconverting chairs, any consideration of the relatively high energy boat conformations is entirely unwarranted. We therefore conclude that the 52° isomer of 2,3-dichloro-1,4-dioxane has the *cis* configuration and undergoes rapid chair–chair interconversion at room temperature. This is, of course, the original conclusion of Summerbell and Lunk, and is entirely compatible with all other existing physical data.

We are currently examining the isomeric 2,3-diphenyl-1,4-dioxanes, whose original structural assignments have also been questioned by Le Fèvre and Chen.

NOTE ADDED IN PROOF: We have learned of an independent investigation by D. Jung, whose results and conclusions are in complete agreement with our own. Dr. Jung's paper will appear in Chemische Berichte.

EXPERIMENTAL

2,3-Dichloro-1,4-dioxane

This compound was prepared by the procedure of Summerbell and Lunk (1), and after several recrystallizations from pentane–ether melted from 52 to 53 °C.

The nuclear magnetic resonance spectra were recorded on a Varian V-4302 60 Mc spectrometer, and the experimental line positions were obtained from the average of at least six traces, with the standard deviation in all line positions being less than 0.15 c.p.s. Calculations of line positions were carried out on our IBM 1620 computer, using the Frequint IVA program, which was kindly provided by Professor P. C. Lauterbur.

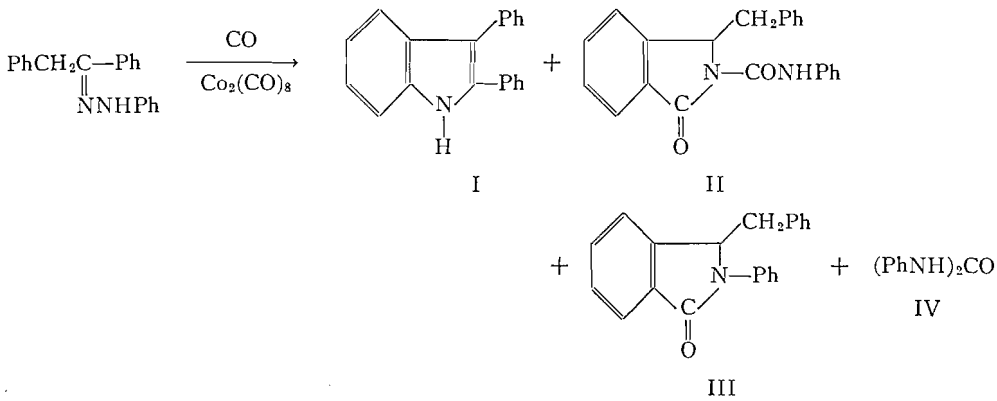
REACTION OF ARALKYL KETONE PHENYLHYDRAZONES WITH CARBON MONOXIDE; THERMAL INDOLIZATION OF ARALKYL KETONE PHENYLHYDRAZONES

ALEX ROSENTHAL AND M. YALPANI

This note summarizes the principal results obtained when aralkyl ketone phenylhydrazones were caused to react with carbon monoxide using dicobalt octacarbonyl as a catalyst. In earlier work (1, 2) it was shown that aromatic ketone and aldehyde phenylhydrazones containing a C=N group which was conjugated to an aromatic ring cyclized with carbon monoxide to yield N-substituted phthalimidines. Under similar conditions, aralkyl ketone phenylhydrazones might be expected to undergo ring closure to afford heterocyclic substances having six or more members.

Reaction of desoxybenzoin phenylhydrazone with carbon monoxide at 3 500 p.s.i. and a temperature of 235° for 3 h in the presence of preformed dicobalt octacarbonyl afforded mainly 2,3-diphenylindole (I), 3-benzylphthalimidine-N-carboxyanilide (II), 3-benzyl-2-phenylphthalimidine (III), and *sym*-diphenylurea (IV) in 20, 22, 11, and 27% yields,



respectively. Separation of these components was achieved by thin-layer chromatography on silica gel G using benzene–methanol (95:5 v:v) as developer or by alumina column chromatography.

Compounds I and IV were identified by direct comparison with authentic samples of 2,3-diphenylindole and *sym*-diphenylurea, respectively. Reaction of 3-benzylphthalimidine with phenylisocyanate afforded an authentic sample of 3-benzylphthalimidine-N-carboxyanilide which was identical (melting point and infrared spectrum) with compound II. Condensation of benzylidene phthalide with aniline afforded 3-benzylidene-2-phenylphthalimidine. Reduction of the latter substance with 1 mole of hydrogen over platinum

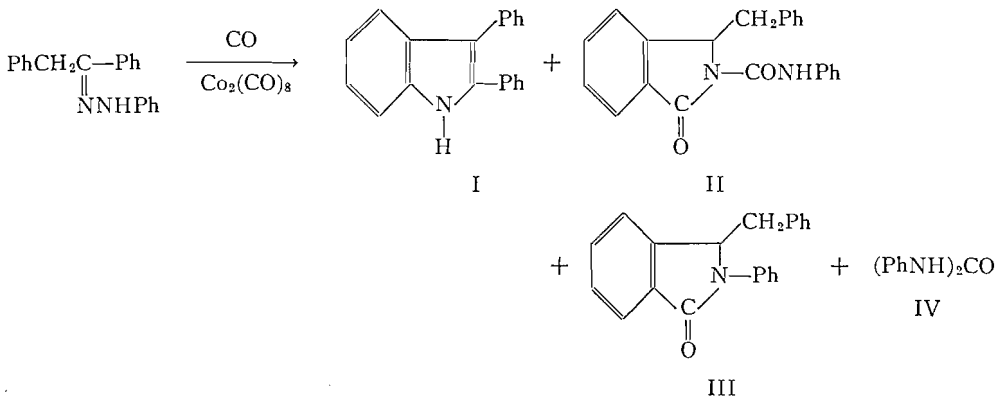
REACTION OF ARALKYL KETONE PHENYLHYDRAZONES WITH CARBON MONOXIDE; THERMAL INDOLIZATION OF ARALKYL KETONE PHENYLHYDRAZONES

ALEX ROSENTHAL AND M. YALPANI

This note summarizes the principal results obtained when aralkyl ketone phenylhydrazones were caused to react with carbon monoxide using dicobalt octacarbonyl as a catalyst. In earlier work (1, 2) it was shown that aromatic ketone and aldehyde phenylhydrazones containing a C=N group which was conjugated to an aromatic ring cyclized with carbon monoxide to yield N-substituted phthalimidines. Under similar conditions, aralkyl ketone phenylhydrazones might be expected to undergo ring closure to afford heterocyclic substances having six or more members.

Reaction of desoxybenzoin phenylhydrazone with carbon monoxide at 3 500 p.s.i. and a temperature of 235° for 3 h in the presence of preformed dicobalt octacarbonyl afforded mainly 2,3-diphenylindole (I), 3-benzylphthalimidine-N-carboxyanilide (II), 3-benzyl-2-phenylphthalimidine (III), and *sym*-diphenylurea (IV) in 20, 22, 11, and 27% yields,



respectively. Separation of these components was achieved by thin-layer chromatography on silica gel G using benzene–methanol (95:5 v:v) as developer or by alumina column chromatography.

Compounds I and IV were identified by direct comparison with authentic samples of 2,3-diphenylindole and *sym*-diphenylurea, respectively. Reaction of 3-benzylphthalimidine with phenylisocyanate afforded an authentic sample of 3-benzylphthalimidine-N-carboxyanilide which was identical (melting point and infrared spectrum) with compound II. Condensation of benzylidene phthalide with aniline afforded 3-benzylidene-2-phenylphthalimidine. Reduction of the latter substance with 1 mole of hydrogen over platinum

oxide as catalyst yielded authentic 3-benzyl-2-phenylphthalimidine having an infrared spectrum which was identical with that of substance III.

Although the high-pressure cyclization reaction of desoxybenzoin phenylhydrazone with carbon monoxide demonstrates the preferential formation of the five-membered ring over the six-membered ring, it did not establish if a six-membered ring could be formed. To ascertain if a six-membered ring could be formed, 1,3-diphenyl-2-propanone phenylhydrazone was treated with carbon monoxide in the presence of dicobalt octacarbonyl. In the latter case no six-membered ring was formed. Interestingly, 2,3-diphenylindole accompanied the product that was obtained from desoxybenzoin phenylhydrazone, and 2-benzyl-3-phenylindole was the major product (65% yield) of the reaction of 1,3-diphenyl-2-propanone phenylhydrazone with carbon monoxide in the presence of dicobalt octacarbonyl.

Because the indoles were formed from the aralkyl ketone phenylhydrazones when the reaction was carried out in the presence of dicobalt octacarbonyl, it was felt that cobalt hydrocarbonyl (which would be formed from the dicobalt octacarbonyl) might be essential for the conversion of the hydrazones into the indoles. This speculation was proved to be incorrect by showing that the same conversion into indoles in higher yield (about 80%) occurred without the presence of the catalyst. A similar thermal indolization of hydrazones has recently been reported by other workers (3).

In the reaction of 2-ethoxy-1-naphthaldehyde phenylhydrazone with carbon monoxide, ring closure to the 8-position was expected, since the 2-position was blocked. However, no cyclization occurred. From these results, as well as those of other workers (4, 5), evidently only five-membered heterocycles can be formed from aromatic compounds containing the C=N group.

EXPERIMENTAL

Melting points are corrected. The alumina used for column chromatography was obtained from British Drug Houses. All molecular weights were determined by mass spectrometry by Mr. F. Bloss of this department on an Atlas CH4 spectrometer. Microanalysis was done in this department.

The high-pressure equipment and general procedure have been described previously (1, 2).

Reaction of Desoxybenzoin Phenylhydrazone with Carbon Monoxide to Yield 2,3-Diphenylindole (I), 3-Benzylphthalimidine-N-carboxyanilide (II), and 3-Benzyl-2-phenylphthalimidine (III)

Desoxybenzoin phenylhydrazone (11 g) was allowed to react with carbon monoxide at 235° and a pressure of 3 500 p.s.i. for 3 h in the presence of dicobalt octacarbonyl (2 g) as described previously (1). After removal of the catalyst, the benzene was evaporated under reduced pressure at 30°. Evaporation of the residual oil under reduced pressure at about 100° afforded aniline (0.5 g, 13%). Crystallization of the residual oil in 50 ml of hot benzene yielded 1.2 g (27%) of *sym*-diphenylurea which was recrystallized from chloroform; m.p. 251–252°; the mixed melting point with an authentic sample of *sym*-diphenylurea was 251–252°.

A 25 ml aliquot of the filtrate was chromatographed on alumina (120 × 71 mm diameter). Benzene (500 ml) eluted 0.23 g of an oil which possessed no carbonyl group.

Substance I (2,3-diphenylindole) was then eluted with 400 ml of benzene; yield 1.1 g (20%). Recrystallization of compound I from cyclohexane gave pure material; m.p. 123–124°; the mixed melting point with an authentic sample of 2,3-diphenylindole (6) was 123–124°. The infrared spectra of both compounds were identical.

Compound II (3-benzylphthalimidine-N-carboxyanilide) was then eluted with 3 000 ml of a 4:1 mixture of benzene–chloroform; yield 1.2 g (22%). Recrystallization of compound II from cyclohexane afforded the pure carboxyanilide; m.p. 146–147°; the mixed melting point with an authentic sample prepared by steps described below was 146–147°. The infrared spectra of both compounds were identical.

Elution of the column with a further 1 500 ml of the benzene–chloroform mixture gave 1.2 g of a mixture of compounds II and III. This mixture was separated by rechromatography on a new alumina column using benzene–ethanol (99.5:0.5) as developer. The yields reported for II and III include the material obtained from the rechromatography of the mixture.

Fraction III (3-benzyl-2-phenylphthalimidine) was then eluted with 1 600 ml of benzene–ethanol (98:2 v:v); yield 1.2 g (11%). Compound III was recrystallized from cyclohexane; m.p. 124–125°; the mixed melting point with a sample prepared by unambiguous steps as described below was 124–125°. The infrared spectra of both compounds were identical.

Thin-layer chromatography of the original product mixture on silica gel G using benzene–methanol (95:5) as developer showed the presence of trace quantities of at least three additional components.

Thermal Indolization of Desoxybenzoin Phenylhydrazone and of 1,3-Diphenylpropanone Phenylhydrazone

Desoxybenzoin phenylhydrazone dissolved in benzene was heated in an autoclave at 235° for 3 h in the absence of catalyst. 2,3-Diphenylindole was obtained in 80% yield. Similarly, 1,3-diphenylpropanone phenylhydrazone was converted thermally in 75% yield into 2-benzyl-3-phenylindole.

Reaction of 2-Ethoxy-1-naphthaldehyde Phenylhydrazone with Carbon Monoxide

2-Ethoxy-1-naphthaldehyde phenylhydrazone (7 g) was allowed to react with 3 500 p.s.i. of carbon monoxide in the presence of dicobalt octacarbonyl (1 g) in 35 ml of benzene at a temperature of 235° for 3 h. The product (freed of catalyst) was chromatographed on alumina using benzene–chloroform (8:1 v:v) as developer, and was shown to contain no cyclic carbonyl group.

Reaction of 1,3-Diphenyl-2-propanone Phenylhydrazone with Carbon Monoxide

1,3-Diphenyl-2-propanone phenylhydrazone was allowed to react with high purity carbon monoxide in the presence of dicobalt octacarbonyl, and the product worked up as described previously. The main component, 2-benzyl-3-phenylindole, m.p. 100–101°, was obtained in 65% yield. The mixed melting point of the main component and an authentic sample of 2-benzyl-3-phenylindole (7) was 100–101°. In addition, *sym*-diphenylurea was produced in about 20% yield. The remaining product, which consisted of traces of different compounds, contained no cyclic carbonyl group.

Synthesis of Authentic 3-Benzylphthalimidine-N-carboxyanilide

3-Benzylphthalimidine (8) was allowed to react with phenylisocyanate as described previously (1) to afford 3-benzylphthalimidine-N-carboxyanilide; m.p. 146–147°. The infrared spectrum of this substance in a KBr pellet was identical with that of compound II and showed strong carbonyl bands at 1 705 and 1 670 cm^{-1}.

Anal. Calcd. for $C_{22}H_{18}N_2O_2$: N, 8.18; mol. wt. 342. Found: N, 8.44; mol. wt. (by mass spectrum) 342.

Synthesis of 3-Benzyl-2-phenylphthalimidine

(a) 3-Benzylidene-2-phenylphthalimidine

Benzylidene phthalide (3 g) (9), aniline (10 g), and ethyl alcohol (15 ml) were refluxed for 5 h. After the alcohol was evaporated, the remaining oil was dissolved in hot acetic acid. The solid which precipitated from the mixture was recrystallized from ethanol to afford 3-benzylidene-2-phenylphthalimidine; m.p. 200–201°.

Anal. Calcd. for $C_{21}H_{15}NO$: C, 84.25; H, 5.02; N, 4.68. Found: C, 84.10; H, 4.91; N, 4.84.

(b) 3-Benzyl-2-phenylphthalimidine

3-Benzylidene-2-phenylphthalimidine (0.1 g) dissolved in 10 ml of chloroform–ethanol (1:1) was hydrogenated over reduced platinum oxide until 1 mole of hydrogen per mole of substrate was absorbed. After the catalyst was removed by filtration, the solvent was evaporated and the product recrystallized from cyclohexane; m.p. 124–125°. Reduction of 3-benzylidene-2-phenylphthalimidine in chloroform – acetic acid with the same catalyst gave a compound that was contaminated with trace quantities of a material having one aromatic ring which was reduced, as shown by its mass spectrum. The infrared spectrum of 3-benzyl-2-phenylphthalimidine showed a strong carbonyl peak at 1 680 cm^{-1}.

Anal. Calcd. for $C_{21}H_{17}NO$: N, 4.68; mol. wt. 299. Found: N, 4.65; mol. wt. (by mass spectrum) 299.

OXIDATION OF SUGARS WITH RUTHENIUM DIOXIDE – SODIUM PERIODATE: A SIMPLE METHOD FOR THE PREPARATION OF SUBSTITUTED KETO SUGARS

V. M. PARIKH AND J. K. N. JONES

The substituted keto sugars have assumed great importance in recent years particularly as intermediates in the synthesis of branched-chain and amino deoxy sugars of antibiotic origin. Beynon *et al.* (1) applied the ruthenium tetroxide oxidation method (2–4) to substituted carbohydrates and reported that the yields by this method were generally better than those obtained when chromium trioxide – pyridine complex (the more usual oxidant) (5–10) is employed. The ruthenium tetroxide oxidation method reported by Beynon *et al.* (1) required two steps, preparation of the oxidant from ruthenium dioxide, and oxidation of the alcohol by at least a molar equivalent of the tetroxide. It has been found that the combination of these two steps has several advantages, some of which are (*a*) nearly quantitative yields of the keto sugars, (*b*) use of only trace quantities of the costly ruthenium dioxide, (*c*) saving of time, and (*d*) destruction of the usual impurities in the starting material, such as unsubstituted or partially substituted sugar derivatives containing vicinal hydroxyl groups.

When this two-step method is used, the carbohydrate derivative is dissolved in carbon tetrachloride or chloroform, trace quantities (20 mg/g of carbohydrate) of ruthenium dioxide* are added, and a 5% aqueous solution of sodium metaperiodate is added dropwise to the mixture, with vigorous stirring, at or below room temperature. The pH of the mixture is meticulously controlled between 6 and 7 (Beckman pH meter Model 72) by the periodic addition of small quantities of dilute sodium bicarbonate solution. Usually about 1.3 molar equivalents of sodium metaperiodate is required, and the end of the reaction, after about 1 to 4 h, is indicated by a change in color from black (ruthenium dioxide) to blackish yellow or yellow (ruthenium tetroxide). The excess of periodate and the ruthenium tetroxide are then destroyed by the addition of *n*-propanol, and ruthenium dioxide is removed by filtration. The carbon tetrachloride is separated from the aqueous layer, washed with water, concentrated, and dried; and this gives the oxidized product in almost quantitative yield.

The oxidations listed in Table I have been achieved with this method.

TABLE I

Oxidation of sugars with ruthenium dioxide – sodium periodate to produce substituted keto sugars

Name of the alcohol	Name of the oxidized product	Yield	Reference
Methyl-2,3-*O*-isopropylidene-α-L-rhamoside	Methyl 6-deoxy-2,3-*O*-isopropylidene-α-L-*glycero*-D-*erythro*-hexos-4-uloside	Quantitative	11
1,3–2,5-Di-*O*-methylene-L-rhamnitol	6-Deoxy-1,3:2,5-Di-*O*-methylene-L-*glycero*-D-*erythro*-4-hexulose	Quantitative	12
1,2–5,6-Di-*O*-isopropylidene-D-glucofuranose	1,2:5,6-Di-*O*-isopropylidene-α-D-*erythro*-D-*glycero*-hexos-3-ribofuranose	85–90%	1
Methyl 3,4-*O*-isopropylidene-β-D-arabinoside	Methyl 3,4-*O*-isopropylidene-β-D-*erythro*-pentos-2-ulopyranose	80%	10
6-*O*-Benzoyl-1,2–4,5-di-*O*-isopropylidene-dulcitol	6-*O*-Benzoyl-1,2:4,5-di-*O*-isopropylidene-*threo*-*glycero*-3-hexulose	Quantitative	6
1,2-*O*-Isopropylidene-L-threose	D-*glycero*-1,2-*O*-Isopropylidene-tetros-3-ulose	70–75%*	New

*The yield is low probably because the product easily sublimes or codistills with the solvent during concentration of the reaction mixture.

**Samples of ruthenium dioxide supplied by a number of manufacturers were tried but only "Ruthenium dioxide 54%" from Engelhard Industries, Inc., 113 Astor Street, Newark 14, New Jersey, was found satisfactory.*

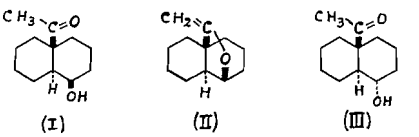
THE USE OF DIMETHYLFORMAMIDE AND OF DIMETHYL SULFOXIDE IN THE PREPARATION OF 2,4-DINITROPHENYLHYDRAZONES

J. Parrick and J. W. Rasburn

Although 2,4-dinitrophenylhydrazine is well known as a reagent for the characterization of carbonyl compounds, its application frequently presents difficulties which may largely be ascribed to the low solubility of the weak base in the usual hydroxylic solvents. Techniques that are employed (1) often seek to overcome these solubility limitations by working with hot solutions, by using fairly high concentrations of a strong acid, or by combining both methods. However, such techniques do not always prevent contamination of the resulting derivative with unchanged reagent and may cause undesirable side reactions with sensitive compounds (see below). In recent years attention has been directed to the use of other solvents, such as diglyme (2) (the dimethyl ether of diethylene glycol) and diethyl phosphonate (3) (diethyl phosphite), in which the reagent as the free base is more soluble and which therefore do not require the high acid concentrations used in earlier procedures. We now report the successful application of dimethylformamide and of dimethyl sulfoxide as solvents of this type.

A particularly suitable example to illustrate the advantage of using a solvent and technique of the abovementioned type is the preparation of the 2,4-dinitrophenylhydrazone of the hydroxy ketone (I).



(I) (II) (III)

All attempts by us and, though not reported, by previous workers (4, 5) to prepare this derivative from the hydroxy ketone (I), or directly from its preparative precursor (II) (4), by applying a wide variety of standard techniques using the reagent in alcoholic or aqueous–alcoholic solution containing the usual concentrations of mineral acid, had been completely unsuccessful, notwithstanding the fact that other carbonyl derivatives of (I), such as its oxime, phenylhydrazone, and semicarbazone, had been prepared (5) quite easily. We have now found, however, that the required derivative, m.p. 159–160°, may be obtained in high yield from the hydroxy ketone (I) and 2,4-dinitrophenylhydrazine in

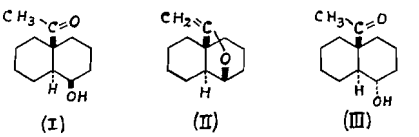
THE USE OF DIMETHYLFORMAMIDE AND OF DIMETHYL SULFOXIDE IN THE PREPARATION OF 2,4-DINITROPHENYLHYDRAZONES

J. Parrick and J. W. Rasburn

Although 2,4-dinitrophenylhydrazine is well known as a reagent for the characterization of carbonyl compounds, its application frequently presents difficulties which may largely be ascribed to the low solubility of the weak base in the usual hydroxylic solvents. Techniques that are employed (1) often seek to overcome these solubility limitations by working with hot solutions, by using fairly high concentrations of a strong acid, or by combining both methods. However, such techniques do not always prevent contamination of the resulting derivative with unchanged reagent and may cause undesirable side reactions with sensitive compounds (see below). In recent years attention has been directed to the use of other solvents, such as diglyme (2) (the dimethyl ether of diethylene glycol) and diethyl phosphonate (3) (diethyl phosphite), in which the reagent as the free base is more soluble and which therefore do not require the high acid concentrations used in earlier procedures. We now report the successful application of dimethylformamide and of dimethyl sulfoxide as solvents of this type.

A particularly suitable example to illustrate the advantage of using a solvent and technique of the abovementioned type is the preparation of the 2,4-dinitrophenylhydrazone of the hydroxy ketone (I).



(I) (II) (III)

All attempts by us and, though not reported, by previous workers (4, 5) to prepare this derivative from the hydroxy ketone (I), or directly from its preparative precursor (II) (4), by applying a wide variety of standard techniques using the reagent in alcoholic or aqueous–alcoholic solution containing the usual concentrations of mineral acid, had been completely unsuccessful, notwithstanding the fact that other carbonyl derivatives of (I), such as its oxime, phenylhydrazone, and semicarbazone, had been prepared (5) quite easily. We have now found, however, that the required derivative, m.p. 159–160°, may be obtained in high yield from the hydroxy ketone (I) and 2,4-dinitrophenylhydrazine in

dimethylformamide containing a trace of concentrated hydrochloric acid as catalyst; after a few hours at room temperature the product was isolated by the addition of dilute hydrochloric acid and was quite pure after one crystallization from ethanol. The use of dimethyl sulfoxide in place of dimethylformamide gave an exactly similar result. The same derivative, i.e. of (I), was obtained also from the vinyl ether (II) by applying this new procedure (using dimethyl sulfoxide), but neither this nor any other procedure has yet afforded any carbonyl derivative from the equatorial hydroxy ketone (III). The low carbonyl reactivity of (III) is as expected from steric considerations, whereas the relatively high reactivity of (I) may be attributed (cf. ref. 5) to the formation of a protonated form of (II) via the intramolecular hemiketal of (I). Under the highly acidic conditions of the older techniques for the preparation of 2,4-dinitrophenylhydrazones it is probable that (I) and (II) undergo not only derivative formation but also other reactions, e.g. the epimerization of (I) to (III) which has already been shown (5) to occur in aqueous acid media. The repeated failure to obtain the derivative, i.e. as a solid, when the older reagents are used may be simply the result of contamination by unreactive by-products, e.g. (III).

The striking success in the above example led us to investigate the possibility of developing a general technique for the preparation of 2,4-dinitrophenylhydrazones with dimethylformamide as solvent. Since the reagent can be dissolved very quickly, and is highly soluble (a 15% solution can be prepared almost instantly by mixing the components at room temperature), there is no need to store a preformed solution, and an excess of the reagent is easily avoided by weighing accurately the required amount and dissolving this immediately before use. All the carbonyl compounds we studied were also readily soluble in the freshly prepared reagent solution but, unlike the hydroxy ketone (I), many of the carbonyl compounds listed below gave derivatives which separated spontaneously usually within 2 h and sometimes within a few seconds. Those derivatives which did not separate spontaneously were isolated by the addition of dilute hydrochloric acid. Satisfactory derivatives were thus obtained from the following: acetophenone, *p*-methyl acetophenone, 2,4-dimethyl acetophenone, 3,4-dimethyl acetophenone, benzil, benzophenone, cyclopentanone, cyclohexanone, 2-methyl cyclohexanone, mesityl oxide, benzaldehyde, vanillin, crotonaldehyde, pyrrol-2-aldehyde, 1,4-naphthoquinone, formaldehyde, acetaldehyde, acetone, *i*-butyl methyl ketone, *n*-hexyl methyl ketone, methyl acetoacetate, ethyl acetoacetate, 4,6-octadien-3-one, and *p*-benzoquinone (those up to, but not including, formaldehyde separated spontaneously within 2 h). The derivatives had melting points in good agreement with literature values; one recrystallization was usually necessary for those derivatives which did not separate spontaneously. A few compounds, including furfural, benzoin, benzal acetophenone, and chloral hydrate, gave products of uncertain purity, but in no case (including those above) was any derivative inferior in quality, as judged by melting point, to that prepared for comparison by using Brady's reagent (1).

The technique does not appear to offer any marked advantage with carbonyl compounds of particularly low reactivity. Thus 2,4,6-trimethyl acetophenone gave only a very small yield of its 2,4-dinitrophenylhydrazone, and even after 1 week the derivative could be isolated only by dilution with hydrochloric acid (2 *N*) and had to be recrystallized several times. The diluted and acidified filtrate gave, after a few more days, a considerable amount of a solid product which was subsequently identified by analysis, and by mixed melting point determination with an authentic sample prepared by orthodox procedures, as the N-formyl derivative, m.p. 182–184°, of 2,4-dinitrophenylhydrazine. Although we obtained no definite evidence that this compound was formed during the reactions with the other carbonyl compounds investigated, its possible presence in very small quantities cannot be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

denied, and it may be partly responsible for the necessity to recrystallize those derivatives which were isolated only by the addition of dilute acid. This possibility discourages the use of prolonged reaction times or of higher reaction temperatures in the case of sluggish reactions.

To avoid any possibility that the 2,4-dinitrophenylhydrazone may be contaminated with this formyl derivative, we investigated the use of dimethyl sulfoxide as an alternative solvent. The reagent base is even more soluble in dimethyl sulfoxide (a 25% solution can be prepared easily at room temperature), and perhaps as a consequence it can be used at a concentration such that some of the more soluble derivatives (e.g. of acetone) separate spontaneously. A preliminary study with about 12 carbonyl compounds of varied types has given excellent results with this solvent, and it is tentatively recommended as being superior to dimethylformamide. Although the reagent appears to be quite stable in dimethyl sulfoxide solution for several weeks if no mineral acid is present, the odor of dimethyl sulfide became apparent in solutions containing a trace of concentrated hydrochloric acid after a few days at room temperature, and more quickly when such solutions were heated.

EXPERIMENTAL

Reagent grade dimethylformamide and dimethyl sulfoxide were used without further purification, since preliminary experiments showed no detectable differences with the results obtained for comparison by using freshly redistilled solvents.

The following procedure was found to be most suitable for the preparation of 2,4-dinitrophenylhydrazones with either of the newer solvents.

The carbonyl compound (0.0025 mole) was added to a solution* of 2,4-dinitrophenylhydrazine (0.5 g) in dimethylformamide (5 ml), or in dimethyl sulfoxide (2.5 ml), and the mixture was swirled gently to obtain a homogeneous solution. Concentrated hydrochloric acid (2 drops) was then added and the mixture was set aside for 2 h unless spontaneous separation of the derivative occurred in a shorter time. The solid product was filtered off, and washed with dilute (2 *N*) hydrochloric acid, then with water, and finally with alcohol or aqueous alcohol depending upon the solubility of the derivative. In those cases in which no solid derivative had separated spontaneously during 2 h† the reaction mixture was diluted with an equal or larger volume of dilute (2 *N*) hydrochloric acid, and the resulting product was collected as soon as possible and washed as described above; scratching with a glass rod was sometimes necessary to induce solidification of an oily initial product. The products were usually dried in a vacuum desiccator. One crystallization from a suitable solvent (generally alcohol, ethyl acetate, or glacial acetic acid) was usually necessary, particularly with those products which did not separate spontaneously, to obtain derivatives with melting points which were in agreement with the literature values. These are listed in most reference works on qualitative organic analysis (see, for example, ref. 1, pp. 138–141); those that are not listed are, with appropriate references, as follows: the 2,4-dinitrophenylhydrazones of 2,4-dimethyl acetophenone (6), 3,4-dimethyl acetophenone (6), 2,4,6-trimethyl acetophenone (7), and 2-formyl pyrrole (8), and the N-formyl derivative of 2,4-dinitrophenylhydrazine (9). Melting points and analytical results are now reported only for the following two derivatives, which have hitherto not been described.

10β-Acetyl-*trans*-decal-1β-ol 2,4-dinitrophenylhydrazone, m.p. 159–160° (ethanol).

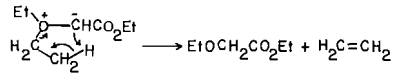
REACTIONS OF ETHYLDIAZOACETATE WITH CYCLOPENTADIENE SYNTHESIS OF THE EPIMERIC ETHYL BICYCLO[3.1.0]HEX-2-ENE-6-CARBOXYLATES

J. WARKENTIN, ELIZABETH SINGLETON, AND JOAN F. EDGAR

There are numerous reports in the literature to the effect that additions of carbenes to conjugated dienes tend to go exclusively 1,2 rather than 1,4 (1, chaps. 2, 6, 8, and 11, and references therein; 2). Although 1,4-addition of methylene to butadiene was postulated by Franzen (3), it now appears likely that the cyclopentene obtained actually arises by isomerization of an activated 1,2-adduct (1, pp. 32 and 231–233, and references therein).

We thought that one of the more promising substrates for 1,4-addition by a carbene might be cyclopentadiene (I), and we now report the results of experiments in which ethyldiazoacetate (II) was decomposed in the presence of I. Our failure to find substituted bicyclo[2.1.1]hex-2-enes among the reaction products indicates that here, also, 1,4-addition is not favored. The products of 1,2-addition, ethyl bicyclo[3.1.0]hex-2-ene-6-*endo*-carboxylate (III) and ethyl bicyclo[3.1.0]hex-2-ene-6-*exo*-carboxylate (VI), were obtained.* Although separation of the isomers proved difficult, carbene additions should provide a more general synthetic route to C_6-substituted bicyclo[3.1.0]hex-2-enes than the method previously described (6).

The esters III and VI were separated by preparative gas–liquid chromatography (g.l.c.). Yields of 30–50%, based on II, were estimated from the gas chromatograms, which also gave the product ratio VI/III. Photolysis of II in a pentane solution of I gave VI/III = 3, while copper-catalyzed decomposition of II in neat I gave VI/III = 5. Higher *exo/endo* ratios of 8.5 and 16 have been reported for the copper-catalyzed reactions of II with 1,3-cyclohexadiene (2) and with cyclohexene (7), respectively. The photolytic procedure gave, in addition to III and VI, a small amount of yellow material which had $\lambda_{max}^{EtOH} = 293$, expected for a 3-carboethoxy-2-pyrazoline (see, for example, ref. 8). Use of ether solvent in the photolysis led to ethyl ethoxyacetate as the principal product, presumably through a ylide mechanism (1, pp. 107–108 and references therein).



The structures III and VI were established by spectroscopic methods and by chemical conversion into known compounds. *Endo* ester III was saponified to the corresponding acid IV (6) and was also converted into the bromolactone V (6, 9). The *exo* ester was

*Others workers (4, 5) have failed to detect III among the products of the copper-catalyzed reaction of I and II and have wrongly concluded that addition is highly stereospecific.

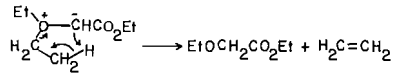
REACTIONS OF ETHYLDIAZOACETATE WITH CYCLOPENTADIENE SYNTHESIS OF THE EPIMERIC ETHYL BICYCLO[3.1.0]HEX-2-ENE-6-CARBOXYLATES

J. WARKENTIN, ELIZABETH SINGLETON, AND JOAN F. EDGAR

There are numerous reports in the literature to the effect that additions of carbenes to conjugated dienes tend to go exclusively 1,2 rather than 1,4 (1, chaps. 2, 6, 8, and 11, and references therein; 2). Although 1,4-addition of methylene to butadiene was postulated by Franzen (3), it now appears likely that the cyclopentene obtained actually arises by isomerization of an activated 1,2-adduct (1, pp. 32 and 231–233, and references therein).

We thought that one of the more promising substrates for 1,4-addition by a carbene might be cyclopentadiene (I), and we now report the results of experiments in which ethyldiazoacetate (II) was decomposed in the presence of I. Our failure to find substituted bicyclo[2.1.1]hex-2-enes among the reaction products indicates that here, also, 1,4-addition is not favored. The products of 1,2-addition, ethyl bicyclo[3.1.0]hex-2-ene-6-*endo*-carboxylate (III) and ethyl bicyclo[3.1.0]hex-2-ene-6-*exo*-carboxylate (VI), were obtained.* Although separation of the isomers proved difficult, carbene additions should provide a more general synthetic route to C_6-substituted bicyclo[3.1.0]hex-2-enes than the method previously described (6).

The esters III and VI were separated by preparative gas–liquid chromatography (g.l.c.). Yields of 30–50%, based on II, were estimated from the gas chromatograms, which also gave the product ratio VI/III. Photolysis of II in a pentane solution of I gave VI/III = 3, while copper-catalyzed decomposition of II in neat I gave VI/III = 5. Higher *exo/endo* ratios of 8.5 and 16 have been reported for the copper-catalyzed reactions of II with 1,3-cyclohexadiene (2) and with cyclohexene (7), respectively. The photolytic procedure gave, in addition to III and VI, a small amount of yellow material which had $\lambda_{max}^{EtOH} = 293$, expected for a 3-carboethoxy-2-pyrazoline (see, for example, ref. 8). Use of ether solvent in the photolysis led to ethyl ethoxyacetate as the principal product, presumably through a ylide mechanism (1, pp. 107–108 and references therein).



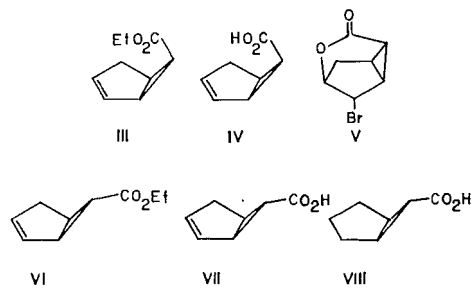
The structures III and VI were established by spectroscopic methods and by chemical conversion into known compounds. *Endo* ester III was saponified to the corresponding acid IV (6) and was also converted into the bromolactone V (6, 9). The *exo* ester was

*Others workers (4, 5) have failed to detect III among the products of the copper-catalyzed reaction of I and II and have wrongly concluded that addition is highly stereospecific.

identified by hydrolysis to the unsaturated acid VII (5) followed by reduction to the saturated acid VIII (6).

Interestingly, III is not readily epimerized by EtO^- in EtOH, a situation which may be fairly general for strained, bicyclic systems (10, 11). Also of interest are some differences in the spectra of the compounds. In the nuclear magnetic resonance (n.m.r.) spectrum of III the vinyl protons give rise to a sharp singlet at 5.64 p.p.m., whereas in the n.m.r. spectrum of VI there are two multiplets centered at 5.52 and 5.92 p.p.m. for those protons. At high field (0.83 p.p.m.) there is a one-proton signal in the spectrum of VI, but not in that of III. This is readily understood in terms of anisotropic shielding of the C_6-*endo* proton of VI by the π-electrons (12). In the ultraviolet spectra, III has an apparent λ_{max}^{EtOH} 286 mμ (ϵ = 160) and end absorption while VI shows only end absorption.

We plan to study the addition of other carbenes to cyclopentadiene and to examine further the effect of geometry and C_6 substituents on the n.m.r. signals of the vinyl protons and on the ultraviolet spectra.



EXPERIMENTAL

Satisfactory elemental analyses were obtained for all new compounds. Melting points and boiling points are uncorrected.

Nuclear magnetic resonance spectra were taken on a Varian A-60 spectrometer with tetramethylsilane as the internal standard. Data are given on the δ-scale, with relative areas in parentheses and with the multiplicity symbols t = triplet, q = quartet, m = multiplet. Ultraviolet spectra were recorded with a Perkin–Elmer Spectrocord model 4000 instrument on ethanol (95%) solutions of rechromatographed samples of the esters. Near infrared spectra were obtained with the same instrument on CCl_4 solutions of the compounds while infrared spectra were done with a Beckman IR5 spectrophotometer. Mass spectra were obtained, through the courtesy of Professor D. B. MacLean, on a Hitachi RMU-6A instrument.

Photolysis Route

A solution of I (13) (238 g, 3.6 moles) and II (Aldrich Chemical Co., Inc., 9.8 g, 0.086 mole) in 400 ml of pure pentane was irradiated for 4 h in a pyrex vessel with the output from the quartz tube of a Westinghouse, 700 W, mercury-arc street lamp. The temperature of the solution was kept at about 30° and an atmosphere of nitrogen was maintained. Cyclopentadiene and pentane were removed by distillation at atmospheric pressure and the dark residue was chromatographed on alumina. Light petroleum eluted most of the dicyclopentadiene and methylene chloride removed the esters, together with a yellow component, from the column. The liquid residue left from distillation of the methylene chloride solution was subjected to preparative g.l.c. in the Aerograph model A-700 gas chromatograph fitted with a 20 ft × $\frac{3}{8}$ in. Argentide* column. At 160° and a helium flow rate of 160 ml min^{-1} the retention times were, in min: dicyclopentadiene, 24; *endo* ester III, 34; *exo* ester VI, 42; pyrazoline, 54.

Copper-Catalyzed Route

To I (13) (171 g, 2.59 moles) and 1.04 g of copper powder in a nitrogen atmosphere was added, dropwise, 30 g (0.26 mole) of II during 1 h. To accelerate the slow evolution of N_2 the flask was gently heated with steam during the addition period and heating was continued for several hours, or overnight. Copper was removed by filtration through Celite before chromatography on alumina and gas chromatography as already described.

**We have coined this name for a packing consisting of deperfumed Tide detergent granules coated with the corresponding silver salt. The packing was prepared by drawing saturated aqueous silver nitrate solution through a bed of the granules.*

Ethyl Bicyclo[3.1.0]hex-2-ene-6-endo-carboxylate (III)

The following spectra were obtained—infrared (CCl_4): 5.77 μ; near infrared (CCl_4): 1.698 μ (6); n.m.r.: 1.20t (3), 1.54–3.11 (5), 4.01q (2), 5.64s (2); mass spectrum: m/e = 152 (molecular ion), strong signals at 79, 78, 77, 66, and 39.

Bromolactone V

To 71.6 mg of III in 1.25 ml of $CHCl_3$ at 0° was added dropwise, with stirring, a 2.57 M solution of Br_2 in $CHCl_3$ until the bromine color persisted for 20 min (9). Distillation and g.l.c. on the distillate gave ethyl bromide (m/e = 108, 110). Crystallization of the distillation residue from pentane gave mixed bromolactones (6); m.p. 84–91°; infrared (CCl_4) 5.73 μ (δ-lactone) and 5.67 μ (γ-lactone). Further crystallization from pentane gave pure δ-lactone, presumably V; m.p. 89–90.5°; n.m.r. 1.79–2.79 (5), 4.28 (1), 4.62 (1); mass spectrum: highest m/e = 204, 202.

Bicyclo[3.1.0]hex-2-ene-6-endo-carboxylic Acid (IV)

Endo ester III was treated with excess sodium ethoxide in ethanol for 46 h at 60°. The n.m.r. spectrum still showed the sharp vinyl singlet of the *endo* ester and lacked the broader vinyl multiplets of the *exo* ester, indicating no detectable epimerization. Dilution with water followed by reflux for 5 h gave, after acidification, the *endo* acid IV; m.p. 91–91.5°; infrared in good agreement with the published spectrum (6).

Ethyl Bicyclo[3.1.0]hex-2-ene-6-exo-carboxylate (VI)

The ester had b.p. (micro) 201°; infrared (CCl_4) 5.80 μ; near infrared (CCl_4) 1.686 μ (6); n.m.r. 0.83t (1), 1.18t (3), 1.93–2.68 (4), 4.03q (2), 5.52m (1), 5.92m (1); mass spectrum: same as that of III, except for differences in relative intensities.

Bicyclo[3.1.0]hex-2-ene-6-exo-carboxylic Acid (VII)

Ester VI (892 mg) was refluxed overnight with NaOH (718 mg) in a solution of H_2O (15 cc) and ethanol (10 cc). The solution was concentrated and acidified to give VII (5); 360 mg (49%); m.p. 79–79.5° (pentane). The n.m.r. spectrum had the high-field signal of the parent ester as well as the two vinyl multiplets; infrared (CCl_4) 5.92 μ.

Bicyclo[3.1.0]hexane-6-exo-carboxylic Acid (VIII)

This acid, m.p. 60.5–61.5°, was obtained from VII by catalytic hydrogenation on prereduced Adams catalyst. The infrared and near infrared spectra matched those described in the literature (6).

Ethyl Ethoxyacetate

This material was purified by preparative g.l.c. and was identified from its spectra: n.m.r. 1.21t (3) overlapping with 1.25t (3), 3.55q (2), 4.02s (2) over 4.19q (2); infrared (neat) 5.70 μ.

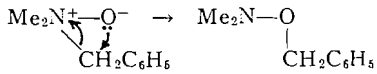
THERMAL REARRANGEMENT OF BENZYLDIMETHYLAMINE OXIDE

GARSON P. SHULMAN,[1] PAUL ELLGEN, AND MARGARET CONNOR

The thermal rearrangement of allyl- or benzyl-dimethylamine oxides to O-allyl- or O-benzyl-N,N-dialkylhydroxylamines had been considered as proceeding by intramolecular migration of the benzyl or allyl group with essentially simultaneous C—N bond breaking and C—O bond formation (1). Free carbonium ion intermediates were excluded from consideration because of a failure to detect allyl or benzyl alcohols. A cyclic intramolecular mechanism involving a three-membered ring was proposed for benzyldimethylamine oxide.



It is now generally accepted that intramolecular electron pair shifts through such small rings are sterically unfavorable. The alternative would be an ion pair mechanism with a transient benzylcarbonium ion.

Recently, a radical mechanism has been suggested (2). The presence of a methylphenylamine oxide radical during the rearrangement of methylphenylbenzylamine oxide was demonstrated by electron spin resonance. Rearrangements of this compound and its allyl analogue occur under milder conditions than those of benzyl- and allyl-dimethylamine oxides (1). Demonstration of a radical intermediate in the one case therefore does not require that a radical intermediate be involved in the other. Kinetic evidence presented by Schöllkopf *et al.* (2) excludes a carbonium ion intermediate, but does not clearly distinguish between radical and anionic mechanisms.

Elimination to olefin and N,N-dialkylhydroxylamine is the principal reaction of aliphatic amine oxides having beta hydrogen atoms. Similarly, alkylbenzyl groups form mainly phenylalkenes. Olefin elimination occurs to a significant extent in benzyldialkylamine oxides having a beta hydrogen. Thus, α-phenethyldimethylamine oxide forms styrene and N,N-dimethylhydroxylamine. Benzyldiethylamine oxide forms 31% of O-benzyl-N,N-diethylhydroxylamine, 34% of N-benzyl-N-ethylhydroxylamine, and 16% of N-ethyl-O,N-dibenzylhydroxylamine, apparently by reaction of the amine oxide with N-benzyl-N-ethylhydroxylamine (3).

Kinetic studies of the pyrolysis to olefin or to amine of a typical aliphatic amine oxide (dimethyllauryl) (4) and of a typical phenethyl type of amine oxide ((3-phenyl-2-butyl) dimethyl) (5) have been reported recently. In beginning a general study of amine oxide pyrolysis, we had hoped that the composition of product mixtures in competitive cases could be predicted from a knowledge of structure and temperature if kinetic data on compounds of typical structures were available. With the observation that a slow dehydration step precedes elimination (4, 5), this approach was abandoned, since the rate of the elimination steps cannot be measured conveniently. Since the rearrangement shows a substituent effect on the rate (2), dehydration must not be rate determining in that reaction. Consideration of the activation parameters which we have determined assists in establishing the proper intermediate for the rearrangement.

EXPERIMENTAL

Preparation of Benzyldimethylamine Oxide

A mixture of 75 ml of isopropyl alcohol and 75 ml (1.1 moles) of 50% hydrogen peroxide was placed in a 50° constant-temperature bath, 135 g (1.0 mole) of benzyldimethylamine[2] was added dropwise, the homogeneous mixture was maintained at 50° for 19 h, and then volatile material was removed under vacuum. Analysis[3] by acidimetric titration (4) indicated a mixture of 12% amine and 79% amine oxide (as hydrate). The mixture was washed 3 times with 100 ml of benzene, then placed in the 50° bath, and stripped of solvent under vacuum. Titration indicated no amine and 96% amine oxide (hydrate). The infrared spectrum was similar to that of benzyldimethylamine except that a strong O—H absorption band was present.

Pyrolysis of Benzyldimethylamine Oxide

An 8.20 g sample of benzyldimethylamine oxide was dropped slowly into a flask which was part of a vacuum micro-distillation apparatus and which had been heated to 150°. The distillate consisted of an aqueous phase (1.63 g) and an organic phase (4.60 g) which was dried over magnesium sulfate. The undistilled "residue" weighed 1.45 g. The dried organic phase contained 96.5% of the principal product and two unidentified lesser components, which were determined to be 2.9% and 0.6% of the total by gas chromatography over 9 ft of ethylene glycol succinate on Chrom P at 150°. The infrared spectrum indicated a trialkylhydroxylamine (presumably O-benzyl-N,N-trimethylhydroxylamine).

Kinetic Studies

A constant-temperature bath was constructed from a 2 l resin kettle fitted with a wooden cover bored to accomodate test tubes and a stirrer, with a thermocouple connected to a Wheelco controller regulating the heating mantle. Weighed samples were placed in the test tubes, left in the silicone oil bath for the required length of time, withdrawn, chilled, and then washed into a beaker with acetic anhydride for titration. Nine to eleven samples were used at each temperature. Runs were carried out to 35–79% of completion. N,N-Diethylhydroxylamine did not interfere with the nonaqueous acidimetric titrations for amine oxides. The results are summarized in Table I. Linear first-order plots (log (percentage of amine oxide) vs. time) and a linear Arrhenius temperature dependence were observed. The energy of activation was calculated from the slope of the Arrhenius plot to be 34.2 ± 1 kcal, and the entropy of activation to be +7.9 ± 2.5 cal deg^{-1}.

TABLE I

Pyrolysis of amine oxides

Amine oxide	Temp. (°C)	Rate constant $\times 10^5$ (s^{-1})
$Me_2NCH_2\phi$	108.2	4.04
$Me_2NCH_2\phi$	119.3	11.1
$Me_2NCH_2\phi$	127.5	31.1
$Me_2NC_{12}H_{25}$	127.5	78*

DISCUSSION

The reaction of benzyldimethylamine oxide was reported to give a 61% yield of O-benzyl-N,N-dimethylhydroxylamine (1). This is in good agreement with the 62% yield which we obtained (if one considers only the organic phase). Other products are formed in small-enough quantity that the rate of amine oxide decomposition is a reasonable measurement of the rate of the rearrangement. There is only an approximate relationship between the composition of the product mixture from benzyldiethylamine oxide and that predicted from kinetic data. If one calculates the elimination to rearrangement ratio of benzyldiethylamine oxide (3) to be $(34 + 16)/31 = 1.6$, the result is only of the same order of magnitude as the ratio one would predict for benzyldilaurylamine oxide from rate constants at 127.5° ($2 \times 78/31.1 = 5.0$). This result is of course not entirely unrelated to the rate measurements, since the critical factors are the relative rates of dehydration (and subsequent elimination) and rearrangement. Since dehydration rates of various amine oxides probably do not differ greatly under equivalent conditions, an agreement of such an order of magnitude might be expected.

Schöllkopf *et al.* attempted to distinguish between carbonium ion, carbanion, and free radical pathways on the basis of a substituent effect (2). Clearly, enhancement of the rate by electron-withdrawing substituents on the benzyl group rules out a carbonium ion intermediate. The distinction between the free radical mechanism which they propose and the carbanion mechanism which is rejected is mainly based on the "anticipated" magnitude of the substituent effect for such a reaction. The positive entropy of activation (+7.9 cal deg^{-1}) is not consistent with an anionic mechanism, since reactions of neutral molecules to form ions generally show negative entropies of activation (6). This evidence, combined with that of Schöllkopf *et al.* (2), thus clearly points to a homolytic mechanism for this reaction.

The energy of activation, 34.2 kcal $mole^{-1}$, is much lower than one would expect for such a reaction, since activation energies are generally close to bond energies for thermal homolytic scission. For example, the energy of the carbon–nitrogen single bond is stated as 69.7 kcal (7), while a value of 59 kcal $mole^{-1}$ has been reported for benzylamine dissociation to benzyl and amino radicals (8). This would imply that the carbon–nitrogen bond in amine oxides is relatively weak, which is certainly consistent with the much lower temperature required for this pyrolysis. In this connection, the agreement between the activation energy for rearrangement and that for elimination to olefin (36 kcal $mole^{-1}$) (4) is of interest, since both appear to involve scission of the carbon–nitrogen bond in the transition state, although by different mechanisms.

REACTIONS OF NITRO SUGARS. III.[1] INSTABILITY OF 6-DEOXY-6-NITRO-ALDOHEXOSES AT INTERMEDIATE pH VALUES

HANS H. BAER AND WERNER RANK

A sample of 6-deoxy-6-nitro-L-idose (I) was required for a study concerning the reactivity of nitro sugar glycosides (1). The compound was obtained by sulfuric acid hydrolysis of its crystalline 1,2:3,5-di-*O*-isopropylidene derivative (II), carefully performed according to the directions by Grosheintz and Fischer (2). The specific rotation of the colorless syrup that was obtained, $[\alpha]_D$ −9.9°, agreed well enough with the reported value of −10.4°. However, paper chromatography revealed the presence of, besides I, a considerable amount of 3-deoxy-3-nitro-*muco*-inositol (III) and of traces of the *myo*-1 (IV) and *scyllo* (V) isomers. These by-products, the formation of which in the absence of alkali was unexpected, obviously escaped detection by the earlier authors (2) who, at the time, had not yet available the tool of paper chromatography. We then examined the deacetonation of II employing a sulfonic acid type resin, Rexyn RG-50 (H^+), at reflux temperature in aqueous ethanol. After 30 min the hydrolysate contained the free sugar I and the *muco* inositol III as main components in addition to traces of the other two nitroinositols, and small amounts of starting material and of what was, presumably, the 1,2-monoacetone derivative of I. Hydrolysis for 2 h produced I and the three inositols, all giving similar spot intensities. After 5 h there was noticed a marked decrease in the amount of free sugar relative to the amount of inositols, and among the latter the *myo* and *scyllo* isomers now predominated (Fig. 1).

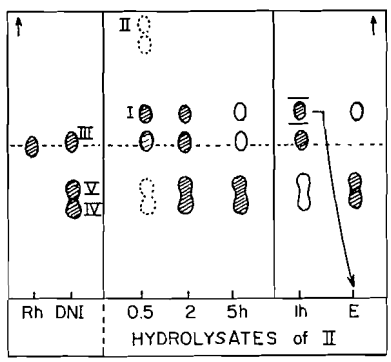

FIG. 1. Paper chromatographic detection of deoxynitroinositols in the hydrolysis of II catalyzed by cation exchange resin. Rh = L-rhamnose; DNI = deoxynitroinositol mixture for comparison; E = zone eluate.

Encouraged by the reasonable differences in the chromatographic mobilities, we then attempted to separate I from the nitroinositols by the zone elution technique. When the zone containing I was cut out and eluted with *distilled water*, the evaporated eluate on rechromatography was found to contain, again, the *myo* and *scyllo* (but no *muco*) inositols, which evidently had arisen during the elution process. This extreme lability of the nitroidose in water was all the more surprising since during the chromatography itself, i.e. in a medium composed of butanol, acetic acid, and water, the compound appeared stable as judged from the absence of trailing on the chromatograms. A chromatographically uniform

[1]*For Part II, see ref. 1.*

syrup of I free from inositols was indeed obtained when the zone elution was done in the presence of acetic acid.

Thus it became of interest to examine the stability of I over varying periods of time at varying pH values. The loss of reducing power, indicated by the anthrone photometric method, was chosen as a measure of the conversion of I into nitroinositols.[2] The results are depicted in Fig. 2. At pH 1.5 and pH 4, no decrease in reducing power occurred within 24 h. At pH 5 there was a slow decrease over 5 days, amounting to 10% within the first 24 h. At pH 6 a fairly rapid reaction was observed, with 90% of the reducing power disappearing in 24 h. A 90% decrease took place within 4 h at pH 7, and within 2.5 h at pH 9.

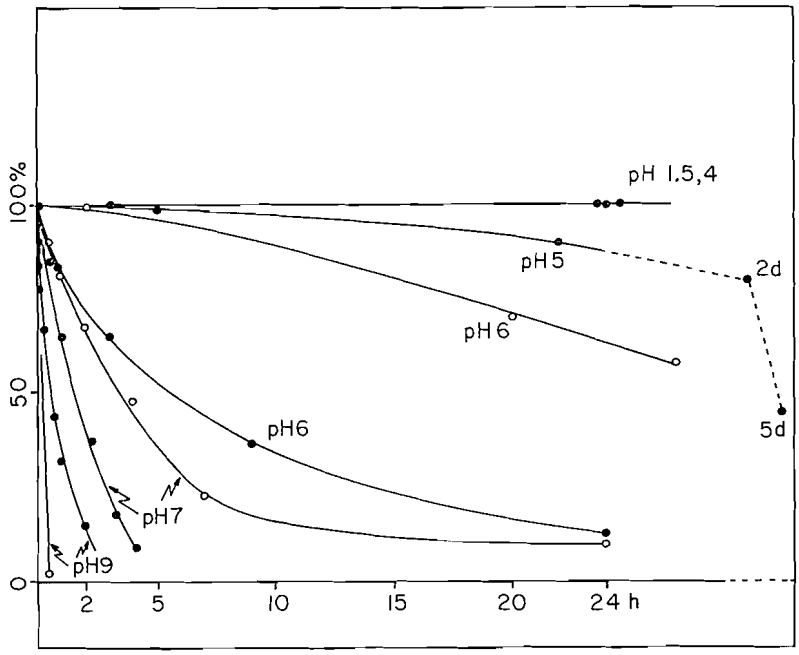

FIG. 2. Decrease in reducing power in 6-deoxy-6-nitro-L-idose (●) and 6-deoxy-6-nitro-D-glucose (○) at various pH values.

6-Deoxy-6-nitro-D-glucose, which differs from I only in the configuration at C-5, exhibited an essentially similar behavior, with gradual differences. It was more stable than in I at pH 6 and 7 but less so at pH 9 (Fig. 2).

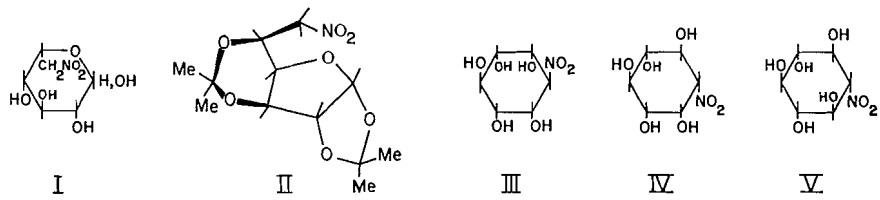
Whereas the rapid cyclization of 6-deoxy-6-nitrohexoses in alkaline medium was, of course, known (2), their lability in neutral to slightly acidic media is remarkable. The results indicating stability in more strongly acidic solution were supported when a sample of I was heated in 0.1 *N* sulfuric acid for 1 h at 80° without a loss of reducing power. Therefore, one has to conclude that the nitroinositols were formed, not during the acid hydrolysis of II, but during the subsequent neutralization and work-up procedures despite the care that was exercised to avoid alkalinity. In hydrolyses with cation exchange resin it appears that in the parts of the solution which are not in immediate contact with the resin surface the acidity is insufficient to prevent cyclization effectively. The observed tendency

[2]*We satisfied ourselves that nitrodeoxyinositols do not interfere with the color production. A simpler, polarimetric study was decided against because of the low specific rotation of I and because of unpredictable dependencies of the rotation on the composition of the buffer solutions that were to be used.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

of the *muco* nitroinositol III to epimerize to thermodynamically more stable isomers (IV and V) is in line with previous findings (3).

The base-catalyzed condensation of nitroalkanes with carbonyl compounds (Henry condensation) normally requires a medium of marked if weak alkalinity. In the 6-deoxy-6-nitro-aldoses the internal Henry condensation appears to be particularly favored, the driving force being the tendency of the molecules to form a stable, six-membered carbocyclic ring. The amount of hydroxyl ion available near neutrality, even on the acid side, is then sufficient for the reaction to be induced although, of course, it proceeds comparatively slowly. The markedly greater reaction speed of the idose derivative as compared to the glucose derivative is reminiscent of the great tendency in idose to form a 1,6-anhydride. The latter fact is attributed to conformational instability by virtue of which the mutual approach of C-6 and C-1 is facilitated. One may perhaps invoke the same conformational factors to explain the faster cyclization of I between pH 5 and 7, but the reversal of the rates at higher pH would remain unexplained.



EXPERIMENTAL

Paper Chromatography

Paper chromatography was performed using the descending technique on Whatman No. 1 paper with 1-butanol – acetic acid – water (4:1:5, v/v) as developing system. The running time was 30–40 h and the temperature about 25°. L-Rhamnose served as a reference standard (R_{rh} = 1). The spots were made visible by spraying the chromatogram with ammoniacal silver reagent (0.1 *N* $AgNO_3$, 5 *N* NH_3, 2 *N* NaOH, 1:1:2) and heating it over steam. Lichtenthaler (3), who used the above system for the chromatography of deoxynitroinositols, reported R_{rh} 1.05 for the *muco* isomer (III), 0.57 for the *myo* isomer (IV), and 0.63 for the *scyllo* isomer (V). We prepared mixtures of III, IV, and V according to his directions and found the pattern of the mobilities essentially as reported, although somewhat higher R_{rh} values for IV and V were usually observed, especially at longer running times. Thus, on a 20-h chromatogram the values were 0.61 (IV) and 0.67 (V); on a 30-h chromatogram, 0.64 (IV) and 0.69 (V); and on a 40-h chromatogram, 0.67 (IV) and 0.72 (V). (The isomer III showed R_{rh} 1.04–1.05 in all cases.) These variations were of little concern in the identification of the compounds, which was based on co-chromatography with authentic materials rather than on R_{rh} values alone.

*Hydrolyses of 6-Deoxy-1,2:3,5-di-O-isopropylidene-6-nitro-*L*-idose (II)*

Compound II was prepared according to reference 2; it melted at 148–150° and was shown by paper chromatography to be free from deoxynitroinositols. (Reported, m.p. 150–151°.)

A sample of II was hydrolyzed with sulfuric acid in aqueous ethanol as specified (2). Paper chromatography of the hydrolysate gave spots of R_{rh} 1.20 (6-deoxy-6-nitro-L-idose (I); main product) and R_{rh} 1.04 (III; strong). There were traces of slow-moving material in the R_{rh} 0.6–0.7 region (IV, V) and a faint, unidentified spot of R_{rh} 1.73 which was probably partially deacetonated II.

Three 100-mg samples of II were dissolved in 10 ml of ethanol each. Water (10 ml) and Rexyn RG-50(H^+) (5 ml) were added to the solutions which were refluxed for 30, 120, and 300 min, respectively. The resin was removed and the solutions were decolorized with alkali-free, activated charcoal. Evaporation yielded colorless syrups that were dried *in vacuo* at room temperature to a glassy consistency. The specific rotations were −13.4°, −12.7°, and −9.9°, respectively (*c*, 0.7, 0.7, and 1.1, in water). The paper chromatograms of the products are represented by Fig. 1.

Another sample of II (200 mg) was heated under reflux for 60 min in 40 ml of ethanol–water (1:1) in the presence of 10 ml of the cation exchange resin. The syrup obtained was chromatographed, on a preparative scale, on four sheets (60 × 18 cm) of paper during 30 h. The zones containing I were located by spraying marginal strips; they were then cut out and eluted with warm water. When the eluate was evaporated *in vacuo* it was shown to contain mainly IV and V; there was very little I (R_{rh} 1.20) and no III. A similar experiment using cold water for the zone elution gave the same results (Fig. 1).

When the preceding experiment was repeated with chromatographic solvent mixture instead of water used

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

for the elution of the zones of I, I was produced as a syrup that was free from any other products detectable by paper chromatography. 6-Deoxy-6-nitro-L-idose (I) so prepared was employed in the experiments relating to the cyclization at various pH values.

As described elsewhere (1), compound II is converted by *methanolysis* into methyl α,β-glycosides. No deoxynitroinositols were detectable in the product.

A sample of impure I containing much IV and V that originated from cation exchange hydrolysis of II for 5 h, was heated under reflux for 5 h in excess methanol containing 1% of hydrogen chloride. The sugar (R_{rh} 1.20) was thereby converted into methyl glycosides (R_{rh} 1.50 and, mainly, R_{rh} 1.66), while the accompanying inositols seemed unaffected by this treatment.

Estimation of the Changes in Reducing Power of 6-Deoxy-6-nitro-L-idose (I) at Various pH Values

Solutions

Samples of chromatographically pure I (2.0 ± 0.1 mg) were dissolved in 10 ml of solvent. From the solutions, which were stored at room temperature, aliquots (1 ml) were withdrawn from time to time and analyzed for reducing power. The following solvents were used: for pH 1.5, $N/10$ sulfuric acid; for pH 4 and 5, $M/10$ acetate buffer; for pH 6, 7, and 9, potassium dihydrogen phosphate – sodium tetraborate buffer according to Kolthoff. The pH values were checked potentiometrically.

Prccedure

The following modification of the anthrone colorimetric method (4) was worked out. In a small test tube the aliquot (1 ml containing about 200 γ of I) was carefully layered over 2 ml of a freshly prepared, 0.2% solution of anthrone in concentrated sulfuric acid. The two layers were cautiously mixed by stirring them with a thin rod for exactly 1 min, whereby the temperature rose to about 90°. The tube was then immersed for 5 min in a water bath of 80° and thereafter quickly cooled to room temperature with running water. A spectral curve in the visible region was recorded using a Perkin–Elmer spectrophotometer (model 202). The reference cell was charged with an identical mixture of anthrone reagent and blank buffer that had been heated in the same fashion. The absorbance, which had λ_{max} at 634 mμ and was constant over several hours, is plotted in Fig. 2 in relation to the value that was obtained with pure I (at pH 1.5 and zero time), the latter value being equated with 100. Hence the ordinate represents percentages of reducing power. At the sugar concentration chosen (200 γ/ml) the optical density corresponding to the 100% value was about 1.0. D-Glucose under identical test conditions also gave an absorption of 634 mμ but with larger extinction; it produced an optical density of 1.0 at 75 γ/ml.[3] No color was given by the mixture of deoxynitroinositols.

Experiments with 6-Deoxy-6-nitro-D-glucose

This sugar was prepared from its 1,2:3,5-di-*O*-isopropylidene derivative essentially according to given directions (2), although on a smaller scale, which necessitated minor modifications. Diacetone compound (100 mg) in 0.5 ml of $N/10$ sulfuric acid and 1 ml of ethanol was kept at 75–80° for 75 min. Thin-layer chromatography on silica gel with benzene–methanol (4:1) revealed that hydrolysis was incomplete. The heating was therefore continued for a further 2 h, with another 0.5 ml of $N/10$ sulfuric acid being added. The reaction was then complete and the product was worked up as described (2). The recrystallized sugar melted at 153–155°, had R_{rh} 1.03, and showed $[\alpha]_D^{23}$ +43° (10 min; *c*, 0.9 in water). The reported values are m.p. 156–157° and $[\alpha]_D^{23}$ +44.6° (10 min; *c*, 2.9 in water).

No evidence was found for formation of inositols IV and V during this hydrolysis. Inositol III, if formed, would have escaped chromatographic detection, as its mobility is too close to that of the nitro glucose. However, a 2-h hydrolysis with cation exchange resin (which in the case of the *ido* isomer II had resulted in considerable conversion of initially formed III into IV and V; cf. Fig. 1) produced only minute traces of IV and V from the *gluco* isomer. It was therefore unlikely that appreciable quantities of III were formed.

The changes in reducing power in 6-deoxy-6-nitro-D-glucose at pH 6, 7, and 9 were followed as described above for I, and the results are included in Fig. 2.

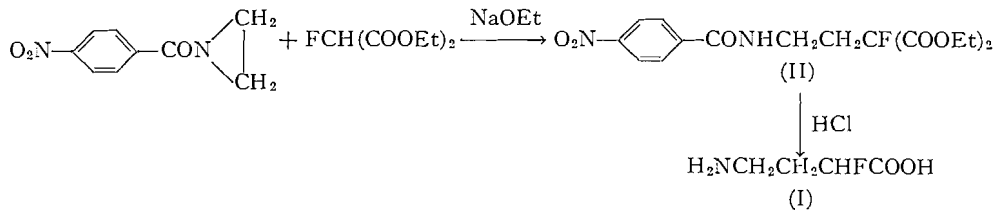
PREPARATION OF α-FLUORO-γ-AMINOACIDS

R. L. BUCHANAN[1] AND F. L. M. PATTISON

Diethyl fluoromalonate has been shown to be a valuable intermediate in the synthesis of α-fluoroalkanoic acids (1), including γ-fluoroglutamic acid (2). We now wish to report two general procedures, based on diethyl fluoromalonate, for obtaining α-fluoro-γ-aminoacids, $RCH(NH_2)CH_2CHFCOOH$.

Of the compounds prepared, the most interesting from a biological standpoint is "fluoro-GABA" (4-amino-2-fluorobutanoic acid) (I). GABA (γ-aminobutyric acid) is known to have an important physiological action upon brain function as well as upon certain peripheral nervous structures (3). In particular, a depletion of GABA in the brain results in hyperexcitability, leading to convulsive states or epilepsy in man. It was thought possible that the fluorinated analogue of this brain component, as an antimetabolite of GABA, might mimic the symptoms associated with GABA deficiency. Moreover, GABA is thought to be concerned with the regulation or transmission of nerve impulses in central grey matter, thus leading to the suggestion that compound I might prove also to be a useful tool in neurophysiological research. Preliminary examination of I in experiments with mice gave no indication of pharmacological activity. Its value in neurophysiology has yet to be determined.

The first method involves the reaction of an *N*-aroylethyleneimine with diethyl fluoromalonate.



Initial work, with *N*-benzoylethyleneimine and a catalytic quantity of sodium ethoxide, gave an insignificant yield of the product. However, by introducing the electron-withdrawing *p*-nitro substituent onto the benzene ring, the aziridine ring becomes more susceptible to nucleophilic attack; the required intermediate II was thus obtained in 47% yield. Acid hydrolysis then gave I as the monohydrate (65%). It is essential that, in the hydrolysis, the refluxing be continued until the reaction is complete; insufficient heating gives an intractable gum, which is hard to purify. Tolman and Vereš (4) have recently reported an unsuccessful attempt to synthesize I, starting from ethyl α-fluorocrotonate.

The second method involves the Michael addition of diethyl fluoromalonate to 2-nitro-1-alkenes (e.g. 2-nitro-1-butene).

Compound III, obtained in 54.5% yield, on being heated under reflux with iron and hydrochloric acid, gave IV, characterized as its *N*-2,4-dinitrophenyl and *N*-benzyloxycarbonyl derivatives. Attempts to decarboxylate IV to VI resulted in decomposition. Compound III was therefore first hydrolyzed and decarboxylated to give V (in 58% yield) as a viscous, yellow oil, which on reduction as before gave VI; this was characterized as its *N*-2,4-dinitrophenyl derivative. The reaction of diethyl fluoromalonate with nitroethylene, in a proposed alternative synthesis of I, afforded only polymeric products and recovered starting materials.

EXPERIMENTAL

4-Amino-2-fluorobutanoic Acid Monohydrate ("Fluoro-GABA") (I)

(a) Diethyl 2-(p-Nitrobenzamido)ethylfluoromalonate (II)

Diethyl fluoromalonate (3.78 g, 21.2 mmoles) and dry dimethylformamide (40 ml) were added to a solution of sodium ethoxide in ethanol, prepared from sodium (50 mg, 2.17 mg-atoms) and dry ethanol (15 ml). The mixture was contained in a 100-ml three-necked flask fitted with a stirrer, a reflux condenser with drying tube, and a gas inlet. The flask was purged with dry nitrogen throughout the reaction. After the mixture had been stirred for 15 min, a solution of *N*-(*p*-nitrobenzoyl)ethyleneimine (3.87 g, 20.1 mmoles) (5) in dry dimethylformamide (15 ml) was added, and this mixture was stirred at 40–45° for 60 h. It was then poured into water, acidified with glacial acetic acid, and extracted twice with ether. The extracts were washed three times with water and dried over anhydrous $MgSO_4$. Removal of the ether gave pale yellow crystals. Benzene was added, followed by an excess of petroleum ether (60–80°), giving II (3.49 g, 47%). Two recrystallizations of a small quantity from benzene – petroleum ether (60–80°) gave the pure product, m.p. 94–95°.

Anal. Calcd. for $C_{16}H_{19}FN_2O_7$: C, 51.89; H, 5.17; N, 7.56. Found: C, 52.07; H, 4.99; N, 7.33.

(b) 4-Amino-2-fluorobutanoic Acid Monohydrate (I)

Compound II (25.0 g, 67.5 mmoles) and concentrated hydrochloric acid (100 ml) were heated under reflux for 75 h. The mixture was allowed to cool and water was added. *p*-Nitrobenzoic acid (10.8 g, 95.5%) was removed by filtration. The filtrate was evaporated to give the syrupy amino acid hydrochloride, which was dissolved in water and stirred with an excess of freshly prepared silver oxide. The mixture was filtered through "Supercel", and the filtrate was treated with excess hydrogen sulfide. The mixture was again filtered through "Supercel". The aqueous filtrate was evaporated, whereupon the product (I) crystallized immediately. After being washed with methanol and dried *in vacuo*, the crystals had m.p. 201–203°. Yield: 5.3 g (65%). Recrystallization from 90% ethanol did not alter the melting point. The infrared spectrum (Nujol mull) had the following bands (cm^{-1}): 1 650($-\overset{+}{N}H_3$ def., m), 1 592 (ionized carboxyl C=O str., s), 1 560 ($-\overset{+}{N}H_3$ def., m), and 1 054 (C—F str., w).

Anal. Calcd. for $C_4H_{10}FNO_3$: C, 34.53; H, 7.25; N, 10.07. Found: C, 34.27; H, 7.11; N, 10.36.

4-Amino-2-fluorohexanoic Acid (VI)

(a) Diethyl (2-Nitrobutyl)fluoromalonate (III)

Diethyl fluoromalonate (10.68 g, 60 mmoles) was added dropwise with stirring to sodium (46 mg, 1.98 mg-atoms) and dry dioxane (8.8 g) in a 50-ml three-necked flask fitted with a stirrer, a reflux condenser with drying tube, and an addition funnel. After all the sodium had reacted, the resultant mixture was cooled in an ice bath, and hydroquinone (10 mg) was added. 2-Nitro-1-butene (4.0 g, 39.6 mmoles) (6) was then added slowly with vigorous stirring over 25 min. Stirring was continued at room temperature for 1 h. The mixture was acidified with glacial acetic acid, poured into water (200 ml), and extracted three times with ether. The ether extract was washed with water and dried over anhydrous $MgSO_4$. The ether was removed and the residue was fractionally distilled through a platinum-plated spinning-band column, giving recovered diethyl fluoromalonate (3.84 g) and the product III (5.84 g, 54.5%), b.p. 90–91.5° at 0.18 mm, n_D^{25} 1.4337, d_4^{20} 1.176, MR_D 61.9 cc/mole (estimated 62.0 cc/mole).

Anal. Calcd. for $C_{11}H_{18}FNO_6$: C, 47.31; H, 6.50; N, 5.02. Found: C, 47.54; H, 6.65; N, 5.23.

(b) (2-Aminobutyl)fluoromalonic Acid (IV)

Diethyl (2-nitrobutyl)fluoromalonate (3.8 g, 13.6 mmoles), powdered iron (5.32 g, 95.2 mg-atoms), concentrated hydrochloric acid (85 ml), water (25 ml), and 95% ethanol (25 ml) were stirred in an atmosphere of nitrogen at room temperature for 20 min. The mixture was then refluxed for 1 h, cooled, made alkaline with 2 *N* sodium hydroxide, and filtered through "Supercel". The filtrate was acidified with concentrated hydrochloric acid and concentrated. The precipitated sodium chloride was filtered off. The silver oxide – hydrogen sulfide treatment (as described above) was carried out. Evaporation and addition of ethanol gave a gummy solid (2.17 g, 83%), which was characterized by the formation of two derivatives.

(1) *N-2,4-Dinitrophenyl derivative,* prepared by the method of Cheronis and Entrikin (7), was obtained as a yellow oil. Chromatography through silica gel (elution with 4:1 benzene–ether) and recrystallization from benzene gave yellow crystals, m.p. 140–141.5°.

Anal. Calcd. for $C_{13}H_{14}FN_3O_8$: C, 43.46; H, 3.93; N, 11.70. Found: C, 43.68; H, 4.07; N, 11.88.

(2) *N-Benzyloxycarbonyl derivative,* prepared by the method of Neuberger and Tait (8), was recrystallized once from benzene – petroleum ether (60–80°) and twice from ethyl acetate – petroleum ether (60–80°) as white crystals, m.p. 136–139°. The infrared spectra of this and of the previous derivative showed an acid carbonyl band at 1 751 cm^{-1}, indicative of an α-fluoromalonic acid (1).

Anal. Calcd. for $C_{15}H_{18}FNO_6$: C, 55.04; H, 5.54. Found: C, 54.92; H, 5.39.

(c) 4-Amino-2-fluorohexanoic Acid (VI)

Diethyl (2-nitrobutyl)fluoromalonate (1.4 g, 5 mmoles) and 6 *N* hydrochloric acid (40 ml) were heated under reflux at 150° for 4.5 h, by which time evolution of carbon dioxide had ceased. Isolation in the usual manner gave the nitro acid as a yellow oil (0.52 g, 58%). This was then reduced directly to the amino acid. Powdered iron (0.84 g, 15 mg-atoms) was added to concentrated hydrochloric acid (5 ml) in an atmosphere of nitrogen. The crude nitro acid (400 mg, 2.2 mmoles) in 50% aqueous ethanol (10 ml) was added. The mixture was stirred at room temperature for 1 h, at 75° for 6 h, and at 50° for 15 h. Isolation of the crude amino acid (VI) hydrochloride (0.4 g, 98%) was carried out as for IV. It was characterized as its *N-2,4-dinitrophenyl derivative* (7), which on chromatography through silica gel and recrystallization from chloroform – petroleum ether (60–80°) was obtained as yellow needles, m.p. 151–155° (decomp.) The infrared spectrum of this derivative showed an acid carbonyl at 1 730 cm^{-1}, indicative of an α-fluoro monobasic acid (1).

Anal. Calcd. for $C_{12}H_{14}FN_3O_6$: C, 45.72; H, 4.48; N, 13.33. Found: C, 45.68; H, 4.28; N, 13.16.

THE REACTION OF SOME TITANIUM AND ZIRCONIUM HALIDES WITH CYCLIC ORGANIC LIGANDS CONTAINING OXYGEN AND SULFUR

E. C. Alyea[1] and E. G. Torrible

Recently a number of complexes of titanium and zirconium halides with cyclic ligands $C_4H_8Y_2$ (Y = O or S) have been reported (1–5). The structure of the 1,4-dioxan (D) complexes have been the subject of some debate. Rolsten and Sisler (1) concluded that the complexes were monomeric and the 1,4-dioxan was acting as a bidentate chelating

[1]*Present address: Chemistry Department, Queen Mary College, University of London, England.*

agent. Hendra and Powell (6) rejected this structure on the grounds that the chelate structure would require the dioxan ring to be in the boat form. Their infrared data showed that the dioxan was in the same configuration as in free dioxan and in $HgCl_2.D$ where it had been proved to have the chair form (7). They concluded that the $TiX_4.D$ structure would be similar to that of $Al_2Br_6.D$, i.e. the chair configuration of the six-membered ring with one oxygen atom only attached to a metal atom. There are two other possible structures; a polymeric chain structure similar to the proved polymeric structure of $HgCl_2.D$ (7), or an ionic structure $[TiCl_2.2D]^{2+}[TiCl_6]^{2-}$ analogous to $[Ga.2D]^+Cl^-$ (8). Molecular weight determination of the complexes in 1,4-dioxan is of no help in elucidating the structure because all four possibilities could be expected to be "monomeric" in solution. Molecular weight determinations in other non-reacting solvents were not possible because of the very low solubility of the complexes.

Conductance measurements in nitrobenzene and nitromethane (Table II) indicate that the compounds are nonelectrolytes and hence the ionic structure must be rejected.

The infrared spectra of the $TiX_4.D$ complexes are very similar above 500 cm^{-1}, and resemble very closely the spectrum of the polymeric $HgCl_2.D$. The spectra show no bands which can be assigned to uncoordinated —C—O—C— asymmetric and symmetric stretching frequencies (1 121 cm^{-1} and 873 cm^{-1} present in the free ligand). This of course rules out a structure similar to $Al_2Br_6.D$ since evidence of uncoordinated oxygen would be expected and is in fact observed for the aluminium complex (6). The proposed polymeric structure for the titanium(IV) complexes is supported by their very low solubility in non-reacting solvents.

The powder diffraction patterns for $TiCl_4.D$, $TiBr_4.D$, and $ZrCl_4.D$ suggest they have similar structures. The pattern obtained for $TiBr_4.D$ exhibits interplanar spacings and intensities which agree with these recorded by Sisler (1). However, Sisler records an extra line at a *d*-value of 2.62 Å which we did not observe. This line was also absent from partially hydrolyzed samples of the complex.

It was hoped to gain evidence to support the proposed polymeric structures for the 1,4-dioxan complexes by studying the complexes of analogous ring systems containing sulfur and of 1,3-dioxan. With 1,3-dioxan ($D^{1,3}$) only titanium(III) chloride yielded a 1:1 complex. The titanium(IV) halides do not appear to form simple addition complexes but yielded products whose analyses closely agreed with the stoichiometry $TiX_2.D^{1,3}$. All the products were insoluble in common solvents. The infrared spectra of these complexes do not lend themselves to clear interpretation. It is possible that the ring has been opened during the reaction.

Recently Fowles *et al.* (2, 3, 4) reported the preparation and characterization of the 1,4-thioxan (T) complexes $TiX_3.T$, $TiX_3.2T$, and $TiX_4.2T$ (X = Cl, Br). From the infrared spectra Fowles concludes that bonding to the metal occurs through the sulfur and not through the oxygen in the bis-complexes. No molecular weights were reported. We have confirmed their findings and in addition found that the $TiBr_4.2T$ complex is monomeric in nitrobenzene. We also report the preparation and characterization of a series of mono-thioxan complexes of the titanium(IV) and zirconium(IV) halides. The mono-complexes all show very similar spectra in the range 1 500 to 500 cm^{-1}; however, certain differences from the spectra given by the bis-complexes are important. The peaks at 1 105 cm^{-1} and 663 cm^{-1} are negligible indicating bonding through both oxygen and sulfur atoms to the metal. The spectra indicate that the ligand is still in the chair form and hence the mono-complexes are probably polymeric. This conclusion is supported by their low solubility in common organic solvents and their low conductivity (Table II).

There is relatively little data in the literature concerning the complexes of 1,4-dithian (Dith). Recently Fowles and Baker (5) reported the preparation of the titanium(IV) halide 1:1 adducts. The free ligand has been reported to have the chair configuration (9). We have found that the spectra of complexes $TiCl_4$.Dith, $TiBr_4$.Dith, and $TiCl_3$.Dith are similar to that of the free ligand implying a polymeric structure. The complexes were not sufficiently soluble for molecular weights to be determined.

All the ligands reported in this note were reacted with titanium(IV) iodide, but in no instance was a simple product obtained. In most of the reactions iodine was displaced and the infrared spectra indicated possible opening of the rings.

The infrared spectra in the 500–300 cm^{-1} range have been recorded (Table III). The absorptions in this region are mainly due to M—X vibrations. Thus the strong band at 360–385 cm^{-1} in the chloride complexes can be assigned to the Ti—Cl stretching mode (485 cm^{-1} in free $TiCl_4$ (10)). Similarly the strong band at 380 cm^{-1} in free titanium(IV)

bromide is lowered to about 300 cm^{-1} in the complexes. The Zr—Cl stretching frequency is lowered from 390 cm^{-1} to 330–345 cm^{-1}, on complex formation. These conclusions are in accord with those recently published by Beattie and Webster (11). For titanium(III) chloride complexes, Fowles *et al.* (12) assigned bands between 400 and 421 cm^{-1} to metal—chlorine stretching modes. We have found that solid titanium(III) chloride shows three absorption bands at 490 cm^{-1} (m), 387 cm^{-1} (s), and 290 cm^{-1} (vs). In the complexes the major absorption bands occur in the range 340–380 cm^{-1} with very little absorption in the 400–420 cm^{-1} region. The spectra recorded by Fowles *et al.* (12) were determined using potassium bromide optics which would not record the absorptions below 400 cm^{-1}.

EXPERIMENTAL

Special precautions were taken to exclude water from the apparatus and chemicals and all reactions were conducted in an atmosphere of dry nitrogen. Reagents and solvents were purified and dried by appropriate methods except 1,4-dithian which was specially prepared by the Aldrich Chemical Co., Inc. and was used as such.

The preparations of the complexes were all done in a similar manner. Either cyclohexane or benzene solutions of the purified reagents were mixed in known molar ratios. Usually a complex was formed on mixing and heat was evolved. However, the reactions involving titanium trichloride required long heating and stirring as the violet trihalide was insoluble in cyclohexane and benzene and reacted only slowly. The products were filtered, washed with suitable solvents to remove the excess of reactants, and dried *in vacuo*.

The infrared spectra were all determined as mulls in Nujol between KRS-5 plates on a Beckman I. R. 10 grating instrument.

Conductivities were measured in a specially adapted cell with a Phillips PR9500 bridge.

Molecular weights were determined cryoscopically using a modified Maier transposed bridge circuit (13). An internal calibration using fluorene was carried out with each determination.

Titanium and halogen were determined by standard gravimetric methods. Carbon, hydrogen, and sulfur were determined commercially.

AN APPROXIMATE DETERMINATION OF THE SECOND-STAGE PROTONATION CONSTANT FOR 2,2′-BIPYRIDYL, 1,10-PHENANTHROLINE, AND DERIVATIVES

W. A. E. McBryde

Although 1,10-phenanthroline has two potentially basic nitrogen atoms per molecule, it is generally regarded as a monoprotic base (1). The related compound 2,2′-bipyridyl, in spite of being a weaker base, shows evidence of the uptake of a second proton (2). The difference in behavior is said to be due to the fused ring system in the former which maintains the two nitrogen atoms at a fixed distance of 2.5 Å; in this circumstance steric or electrostatic factors are thought to preclude the admission of a second proton.

There have been some observations recorded that are consistent with the addition of a second proton to phenanthroline and its analogues. These include a spectral shift in 8 *M*

AN APPROXIMATE DETERMINATION OF THE SECOND-STAGE PROTONATION CONSTANT FOR 2,2′-BIPYRIDYL, 1,10-PHENANTHROLINE, AND DERIVATIVES

W. A. E. McBryde

Although 1,10-phenanthroline has two potentially basic nitrogen atoms per molecule, it is generally regarded as a monoprotic base (1). The related compound 2,2′-bipyridyl, in spite of being a weaker base, shows evidence of the uptake of a second proton (2). The difference in behavior is said to be due to the fused ring system in the former which maintains the two nitrogen atoms at a fixed distance of 2.5 Å; in this circumstance steric or electrostatic factors are thought to preclude the admission of a second proton.

There have been some observations recorded that are consistent with the addition of a second proton to phenanthroline and its analogues. These include a spectral shift in 8 *M*

hydrochloric acid (3), some dependence of the partition coefficient for 5-methylphenanthroline between chloroform and aqueous solutions on the pH of the latter (4), and some unaccountable discrepancies between formation constants of certain metal–phenanthroline complexes determined by pH-titration methods and by other methods (5, and references therein).

METHOD

Efforts to measure the second stage of protonation by extending titrations of various phenanthrolines into moderately acidic solutions failed to yield conclusive results. The degree of protonation, $\bar{n}_H$, the number of moles of hydrogen bound per mole of base, is given by

$$\bar{n}_H = \frac{[H]_T - [OH]_T - [H]}{[L]_T}$$

where $[H]_T$ is the total concentration of strong acid added, $[OH]_T$ is the total concentration of strong alkali added, $[L]_T$ is the total concentration of phenanthroline, and [H] is the concentration of free hydrogen ion. An empirical relationship between H (= antilog (−pH)) and [H] was established by measurements of pH during titrations of strong acids under conditions of relatively constant ionic strength. Unfortunately the relationship observed was such that at lower values of pH small uncertainties in H corresponded to large uncertainties in [H], so much so that the latter became of the same order of magnitude as $[H]_T - [OH]_T - [H]$.

The spectral shift displayed by 1,10-phenanthroline in moderately acidic solutions (3) is also found in several methyl analogues. If the shift is ascribed to the formation of a doubly protonated species, H_2L^{2+}, one may utilize the spectra at various acidities to estimate a second pK_a by means of the Hammett acidity function. This quantity is defined by sets of indicators whose spectral changes in solutions of varying acidity permit estimation of the concentrations of their acidic and basic forms. It incorporates activity coefficients of the acidic and basic forms of the indicators; and when it is used to determine pK_a of an unknown base the important assumption has to be made that the ratio of these activity coefficients responds to changes in acidity in a fashion comparable to that of the indicators used to define the scale.

The majority of the tabulated values of acidity functions apply to indicators whose basic form is uncharged and whose acidic form is of the type HA^+; these values are designated H_0. For use with solutions of phenanthrolinium compounds the acidity function that applies is H_+, defined by

$$H_+ = -\log (a_H + f_{HA^+}/f_{H_2A^{2+}})$$

where HA^+ is some appropriate indicator. Unfortunately, acidity functions of this type have received scant attention, probably because of the lack of sufficient suitable indicators. One study by Brand and co-workers (6) in concentrated sulfuric acid suggests that in this medium values of H_+ parallel those of H_0 but lie about 0.3 unit more negative.

Notwithstanding this limitation, it was decided to apply acidity functions of the type H_0, as determined in hydrochloric acid by Paul and Long (7) and in perchloric acid by Yates and Wai (8), to data recorded for certain phenanthrolines, and to the functionally similar compound 2,2′-bipyridyl, dissolved in various concentrations of one or both of these acids. The procedure used was to plot

$$\log (\epsilon_1 - \epsilon/\epsilon - \epsilon_2)$$

in which ϵ_1 is a molar extinction coefficient for HL^+, ϵ_2 is a molar extinction coefficient for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

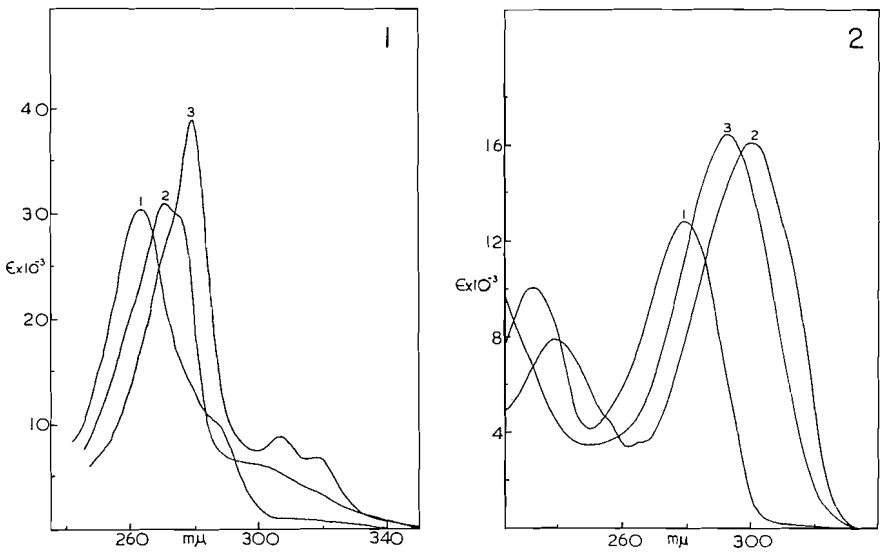

FIG. 1. The spectral shift of 1,10-phenanthroline. (1) L, pH 10.2. (2) HL^+, pH 3.15. (3) H_2L^{2+}, 9.0 *M* HCl.
FIG. 2. The spectral shift of 2,2′-bipyridyl. (1) L, pH 10.2. (2) HL^+, pH 3.0. (3) H_2L^{2+}, 10.0 *M* HCl.

H_2L^{2+}, and ϵ is a molar extinction coefficient for any acidic solution (all values of ϵ applying at the same wavelength) against values of H_0 appropriate to the acid and its concentration in which the base is dissolved. The spectra attributed to L, HL^+, and H_2L^{2+} in the case of 1,10-phenanthroline and of 2,2′-bipyridyl are shown in Figs. 1 and 2 respectively. All of the phenanthrolines showed a shift to longer wavelength in passing from weakly to strongly acidic solutions in contrast with bipyridyl for which, as Krumholtz has noted (2), the shift is in the other direction.

RESULTS AND DISCUSSION

A common difficulty in applying this procedure is the assignment of proper values of ϵ_1 and ϵ_2. Small progressive shifts of the peaks occurred in solutions of changing total acid concentration, so that values of ϵ_1 and ϵ_2 taken respectively from, say, 10^{-3} *M* and 10 *M* solutions of hydrochloric acid could not be assumed to apply exactly in solutions of intermediate concentration of acid. Small lateral displacements of the spectra (5 to 15 Å) were sufficient to bring the characterizing peaks to a common wavelength, and to produce isobestic points. Given this behavior it was possible to take values of ϵ_1 and ϵ_2 from spectra adjusted to correspond to an acid concentration at which $[HL^+] \sim [H_2L^{2+}]$ (9). This practice was followed in the case of 1,10-phenanthroline and 2,2′-bipyridyl, but it was not continued for the substituted phenanthrolines. The direction and extent of the displacement seemed to be approximately symmetrical about the midpoint where $[HL^+] = [H_2L^{2+}]$, and thus the corrective technique did not make much difference to the estimate of p*K*.

A plot of log $([H_2L^{2+}]/[HL^+])$ against H_0 ought to be rectilinear with unit slope if all assumptions applying to acidity functions also apply to the phenanthrolinium ion. In such an event the value of H_0 where $[H_2L^{2+}] = [HL^+]$ may be identified with p*K* for the proton transfer. The results are displayed in Fig. 3. Each point shown represents an average value for three estimates of log $([H_2L^{2+}]/[HL^+])$ made at three wavelengths. The plots

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

are reasonably linear, and the slope is not far from unity in each case. The values of pK taken from these data are regarded as estimates only, bearing in mind the various limitations to the use of H_0 values for the process under study. The true values may lie even more negative than those quoted in Table I in which are also given values of pK for first-stage protonation.

TABLE I

Acidity constants

Compound	pK_{HL}*	pK_{H_2L} (estimated)	Hammett† slope
2,2′-Bipyridyl	4.5	−0.5	0.68
1,10-Phenanthroline	4.98	−1.7 ($HClO_4$)	0.83

†Hammett slope $\Delta H_0/\Delta \log (\epsilon_1 - \epsilon)/(\epsilon - \epsilon_2)$.

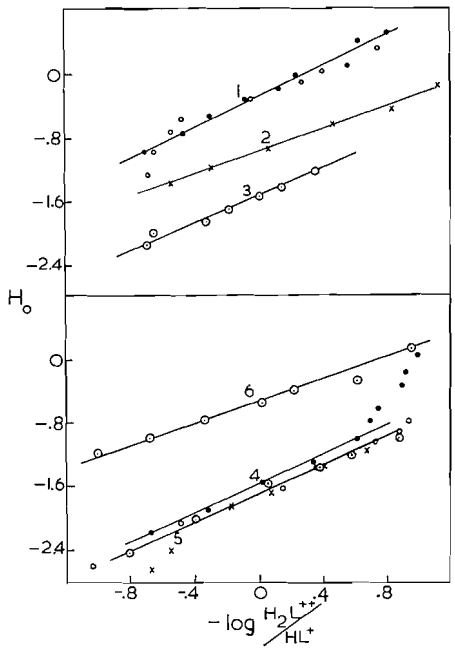

FIG. 3. (1) 2,9-Dimethylphenanthroline (duplicate run). (2) 4,7-Dimethylphenanthroline. (3) 5,6-Dimethylphenanthroline. (4) 5-Methylphenanthroline. (5) 1,10-Phenanthroline: (○) HCl ± 15 Å shift, (×) $HClO_4$, (⊙) HCl. (6) 2,2-Bipyridyl.

It is appropriate to note that these results confirm the greater resistance on the part of phenanthroline toward acceptance of a second proton than shown by 2,2′-bipyridyl. Krumholtz has reported a concentration constant for the latter in 2.2 M (HCl + LiCl) pK_c = −0.18 (2). The species H_2L^{2+} for 5-methylphenanthroline is evidently much too strong an acid to account for the effect of pH on its partition coefficient between chloroform and water mentioned above; this must be due to neglect of activity coefficients.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Furthermore, all values of pK_{H_2L} lie too negative to admit of any significant amount of H_2L^{2+} being formed during pH titrations suitable for determination of stability constants of metal complexes. Therefore, the existence of protonated metal complexes is possibly indicated, and is being investigated by the author. The correlation between pK_{HL} and pK_{H_2L} is not completely satisfactory, but the two sets of values clearly follow the same trend.

EXPERIMENTAL

The phenanthrolines were purchased from the G. F. Smith Chemical Company, the bipyridyl from British Drug Houses, and were all subjected to purification as follows: First, they were recrystallized from warm benzene, then dissolved in dilute hydrochloric acid, and re-precipitated by the addition of sodium hydroxide. This process was repeated, if necessary, until the product obtained melted sharply and at the melting point published for the appropriate compound. Solutions of these compounds were prepared in hydrochloric or perchloric acid of known molarity prepared by the addition of measured volumes of a concentrated analyzed stock acid to a fixed final volume. The perchlorates of these bases are rather insoluble, so that only 1,10-phenanthroline could be measured over a wide range of perchloric acid concentrations. Absorption spectra were measured with a Cary Model 14 spectrophotometer. In some cases, optical densities at single wavelengths were measured in a Beckman Model DU spectrophotometer.

RARE-EARTH ACETATE ION ASSOCIATION

P. G. Manning

Diamond (1) has suggested that the rare-earth acetates are ion pairs that associate according to the "localized hydrolysis" theory of Robinson and Harned (2), in which the acetate ion binds electrostatically to the hydrogen atoms of the cation primary hydration sheath. Each potentially binding acetate has a fixed number of association sites from which to choose, and the magnitudes of the stepwise stability constants will be related statistically. The absolute magnitudes of the stability constant ratios will depend largely on the number of water molecules that comprise the cation hydration sheath, since ligand–ligand interaction should be small (3).

The stepwise stability constant is defined as

$$b_n = [ML_n]/[ML_{n-1}][L],$$

Furthermore, all values of pK_{H_2L} lie too negative to admit of any significant amount of H_2L^{2+} being formed during pH titrations suitable for determination of stability constants of metal complexes. Therefore, the existence of protonated metal complexes is possibly indicated, and is being investigated by the author. The correlation between pK_{HL} and pK_{H_2L} is not completely satisfactory, but the two sets of values clearly follow the same trend.

EXPERIMENTAL

The phenanthrolines were purchased from the G. F. Smith Chemical Company, the bipyridyl from British Drug Houses, and were all subjected to purification as follows: First, they were recrystallized from warm benzene, then dissolved in dilute hydrochloric acid, and re-precipitated by the addition of sodium hydroxide. This process was repeated, if necessary, until the product obtained melted sharply and at the melting point published for the appropriate compound. Solutions of these compounds were prepared in hydrochloric or perchloric acid of known molarity prepared by the addition of measured volumes of a concentrated analyzed stock acid to a fixed final volume. The perchlorates of these bases are rather insoluble, so that only 1,10-phenanthroline could be measured over a wide range of perchloric acid concentrations. Absorption spectra were measured with a Cary Model 14 spectrophotometer. In some cases, optical densities at single wavelengths were measured in a Beckman Model DU spectrophotometer.

RARE-EARTH ACETATE ION ASSOCIATION

P. G. Manning

Diamond (1) has suggested that the rare-earth acetates are ion pairs that associate according to the "localized hydrolysis" theory of Robinson and Harned (2), in which the acetate ion binds electrostatically to the hydrogen atoms of the cation primary hydration sheath. Each potentially binding acetate has a fixed number of association sites from which to choose, and the magnitudes of the stepwise stability constants will be related statistically. The absolute magnitudes of the stability constant ratios will depend largely on the number of water molecules that comprise the cation hydration sheath, since ligand–ligand interaction should be small (3).

The stepwise stability constant is defined as

$$b_n = [ML_n]/[ML_{n-1}][L],$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

where M and L are metal and acetate ions respectively. Also, let $P = b_1:b_2$. Then P is a measure of the relative ease with which the first and second ligands associate, and its magnitude depends on statistical factors and ligand–ligand interactions upon association (3).

Stability constants for rare-earth acetates in water have been determined independently by Sonesson (4) and Kolat and Powell (5). The data of Kolat and Powell (5) pertain to two stages of ion association, and $b_1:b_2$ values only will be analyzed here. When allowance is made for the difference in experimental conditions employed by these workers, their results are in excellent agreement. Thus, plots of b_1 against Z (the atomic number) show identical trends (Fig. 1). A better indication of this agreement is afforded by a comparison of the P values (Fig. 2). Also included in Fig. 2 are P values for cerium and europium acetates as measured by Fronaeus (6) and Grenthe (7). The rare-earth acetates may be divided into three classes according to the magnitudes of the P values. For the lighter rare earths (La–Eu), $P = 5.3 \pm 0.5$, and for the heavier cations (Dy–Lu), $P = 2.5 \pm 0.1$. The P values for Gd and Tb are intermediate, although it is possible that Tb belongs to the heavier cations.

TABLE I

Mobilities of rare-earth ions (8, 9)

M	La	Ce	Pr	Nd	Sm	Eu	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu
Λ_0	69.9	69.8	69.5	69.6	68.6	67.8	67.4		67.4	66.3	65.9	65.4	65.4	64.7

There is evidence in the literature that suggests that the rare-earth ions are hydrated to the same extent. The ion size parameters for rare-earth chlorides and perchlorates, as determined from the activity-coefficient data of Spedding and co-workers (8, 9), lie in the range 5.3–6.0 Å and 6.3–7.2 Å respectively. The limiting ionic mobilities presented in Table I confirm the uniformity in size of the hydrated cations (8). As the cation radius decreases, the water molecules become more firmly bound, but it is sterically unlikely that a greater number of water molecules will coexist in the primary hydration sheath. The smaller ionic mobilities of the heavier metals would therefore seem to be unrelated to cation size.

Bjerrum (3) has shown that

$$P = S \times T,$$

where S is a statistical factor readily calculable from a knowledge of the number of cation binding sites and ligand groups, and T is a "ligand effect", the most important contribution to which arises from the electrostatic repulsion between bound ligands and ligands about to bind. The statistical effect may be explained as follows. Let the cation be n-hydrated, and let the anion be a monodentate ligand that displaces one water molecule from the cation hydration sheath. Then, the first ligand to bind has a choice of n possible association sites, but the second ligand has $n - 1$ possible sites. Since the probability of a ligand leaving the ML_2 species is twice that of leaving the ML species, then $S = 2 \times n/(n - 1)$. Clearly, $S > 1$.

The second ligand to bind will be repelled by the ligand already bound to the cation, and since all ligands are negatively charged or possess negative poles $T > 1$. For the chloride complexes of Sn and Hg (radii approximately equal to rare-earth ions), $T = 2.0$ (3). As the cation radius decreases, T will increase, and, provided the number of cation binding sites remains unchanged, P should also increase. The experimental results show that P is smaller for the smaller rare-earth ions and that there is no trend within the two different series of P values. Clearly, electrostatic repulsion is of secondary importance in

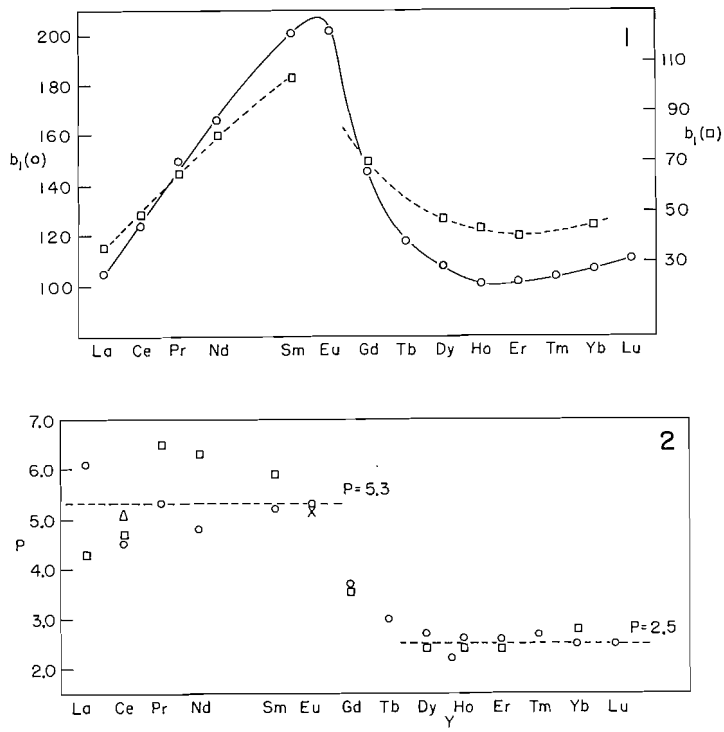

FIG. 1. Plot of b_1 rare-earth acetates against atomic number. ○ Data of Kolat and Powell (16), ionic strength 0.1. □ Data of Sonesson (15), ionic strength 2.0.

FIG. 2. P values as a function of atomic number for rare-earth acetates. ○ Data of Kolat and Powell (16). □ Data of Sonesson (15). △ Data of Fronaeus (7). × Data of Grenthe (8).

this system, which would suggest that the bound acetates are widely separated, i.e. the rare-earth acetates are ion pairs.

Let us suppose that acetate coordinates to the cation with the displacement of water molecules of the primary hydration sheath. Atomic models show that both oxygen atoms of acetate cannot coordinate to the same metal ion, and so acetate is a monodentate ligand. The reaction is

$$M(OH_2)_n + mL = M(OH_2)_{n-m}L_m + mH_2O.$$

If $n = 6$, then $S = 2 \times 6/5 = 2.40$. Hence, T (La–Eu series) = 2.2 and T (Dy–Lu series) = 1.05. The latter figure seems impossibly small when it is considered that $T = 2.0$ for the chloride complexes of Sn and Hg. The T values for the lighter rare earths seem reasonable for metal–acetate coordination, and it is conceivable that the acetate of the lighter metals are complexes, and the acetates of the heavier, ion pairs. This theory is disproved by the almost equal ΔS values for the rare-earth acetates (10), since the displacement of a water molecule from the cation hydration sheath would involve an entropy change of 17 entropy units. The fact that T (La–Eu series) > T (Dy–Lu series) cannot be explained by the metal–acetate coordination theory. These arguments are also true for $n = 8$ or 9.

Let us suppose that the lanthanide acetates are ion pairs. Also, let us assume that cation and water molecule are in contact, and that the hydrogens are directed away from the cation (i.e. ion-dipole configuration). The construction of atomic models, based on cation

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

radii = 1.06–0.8 Å and covalent atomic radii for water and acetate, shows that acetate can bind to two hydrogen atoms of neighboring water molecules of the cation primary hydration sheath ($n = 6$), i.e. acetate is a bidentate ligand. Acetate cannot bind to two hydrogens of the same water molecule, as the O—H- - -O hydrogen bonds will not be linear. The C—O- - -H bond angle is expected to be of the order of 110–120° (11). If acetate binds to two hydrogens of water molecules bound at positions ab in Fig. 3, then atomic models show that the two hydrogens are too closely spaced for hydrogen bonding if they lie in the abcd plane. For La, rotation of the water molecules along the M—O axis through an angle of approximately 15° gives optimum hydrogen atom separation for acetate bonding. This angle will be larger for the smaller cations.

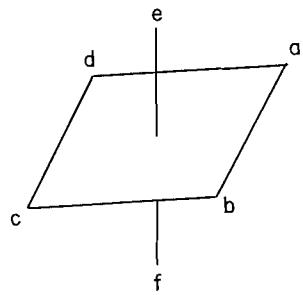

FIG. 3. Octahedral configuration of hexahydrated cation.

Let us further suppose that $n = 6$ and that the first acetate to bind does so at position ab in Fig. 3. Then a second acetate could bind at cd, de, ce, df, and cf, but at cb and ad with reduced probability. If the first two acetates to bind do so at ab and ad, then a 1:4 species would readily be formed, but two independent investigations have failed to detect anionic Gd and Ce species (12, 13). Therefore, for $n = 6$, and assuming two acetates cannot bind at ab and ad, $S = 2 \times 12/5 = 4.8$. Similar calculations in which the water molecules of an eight-hydrated cation are directed towards the corners of a cube and a dodecahedron give $S = 3.4$ and $S = 3.5$ respectively. In Table II are listed P, S, and T values for hexahydrated and octahydrated cations, and for monodentate and bidentate acetates. The dodecahedral arrangement of 8 waters is a more likely structure than the cube. Some of the possible structures may be eliminated on the basis that $T \not< 1.0$. Also, at the comparatively great distances that separate two bound acetates, T should be approximately equal whether acetate is bidentate or monodentate, and $1.0 < T \ll 2.0$. This T factor (= 2.0), being a measure of the work done in bringing an anion from infinity to its equilibrium position in the 1:2 complex, is electrostatic in nature and is independent of the ability of the metal ion to bind (3). This T value (= 2.0) gives a guide as to the T value that might be expected for singly-charged ligands that bind directly to the central metal. The data in Table II suggest that the lighter lanthanides associate with bidentate acetate, and the heavier with monodentate acetate. The hexahydrated cation is favored because the T value for the lighter octahydrated lanthanide – bidentate acetate system is rather large, and, moreover, an octahydrated cation could readily form a 1:4 associate.

The trends in b_1 values for the lanthanide acetates are readily explained. As the central cation radius decreases, the hydrogens of the cation primary hydration sheath become more heavily polarized, and from La–Eu, b_1 increases steadily because of stronger electrostatic attraction. A transition from bidentate acetate to monodentate is paralleled by a

decrease (10) in b_1, and ΔH_1(Dy acetate) $\simeq 2 \times \Delta H_1$(Sm acetate). From Ho to Lu, b_1 values again increase, due presumably to increasing polarization of the hydrogens of the cation hydration sheath. With the smaller Al^{3+} and Fe^{3+}, the repulsion between metal ion and polarized proton is sufficiently great for hydrolysis to occur. Monocarboxylic acids associating with the rare-earth hydration sheath may therefore be characterized by the shape of the b_1 against Z plot and the absolute magnitudes of P values. Plots of b_1 against Z for the rare-earth propionates (14) and isobutyrates (15) are parallel to the acetate curve of Fig. 1 (at an ionic strength of 0.1), but the P values are too inaccurate for statistical analysis.

The transition from bidentate to monodentate acetate could conceivably be due to a change in the structure of the cation primary hydration sheath. This could be brought about by a change in the nature of the metal–water bond, i.e. from ion-dipole to coordinate interaction. Thus, as the degree of polarization of the water molecules increases, the electrons of the oxygen become increasingly available for coordination (16). The orientations of the hydration sheath protons will change, because the oxygen–metal bond, the oxygen–hydrogen bonds, and the oxygen lone pair electrons are directed tetrahedrally (sp^3 hybridization of the oxygen atom). The Gd and Tb cations are presumably equilibrium mixtures of the ion-dipole and coordinate structures. It is hoped to comment further on rare-earth ion – water interaction in a future publication, when the "gadolinium break effect" will be discussed.

For the hexahydrated cation structure (Fig. 3), it was assumed that two bidentate acetates could not bind at position ab and ad. Since there is, theoretically, a 50% probability of acetate binding at ad if ab is occupied, then $S = 2 \times 12/6 = 4.0$, and $T = 1.3$ for the lighter lanthanides. This T value is close to that expected (Table II). If $n = 8$, then $S = 2 \times 12/9 = 2.7$, and $T = 2.0$. This figure is too large both from its absolute magnitude and also in relation to the T value for the heavier rare-earth monodentate – acetate system. The data would still confirm that $n = 6$ for all rare earths, and that the acetates are ion pairs.

Grenthe's (10) measurements of ΔH and ΔS for the rare-earth acetates were interpreted by the worker as indicating that the acetates were complexes and that the ligand was monodentate. Grenthe indicated, however, that the method of interpreting ΔH and ΔS values was qualitative, whereas our approach is semiquantitative. For example, Grenthe's (10) approach shows that, for the rare-earth thioglycolates, the ΔH values favor a monodentate thioglycolate and the ΔS values a bidentate thioglycolate.

The possibility that Kolat and Powell's (5) b_2 values may contain a significant contribution from b_3 must be considered. As Kolat and Powell pointed out, the low ionic strength employed precludes the use of high acetate concentrations that would aid the formation of higher species. Sonesson (4) used 10 times greater ligand concentrations with an increased probability of forming the third associate. It is not surprising that Kolat and Powell (5) failed to detect the formation of a 1:3 species. A 1:3 species would be more readily formed with the heavier lanthanides (5), and yet the two independent workers produce P values that average at 2.5 ± 0.1. The agreement is sufficiently good so as to exclude the possibility of coincidence. It is reasonable to assume, therefore, that Kolat and Powell's (5) b_2 values are real and that the absolute magnitude of P is independent of ionic strength.

THE HEAT OF SUBLIMATION AND HEAT OF VAPORIZATION OF TRIMETHYLTHALLIUM

S. J. PRICE AND M. G. JACKO[1]

Trimethylthallium was prepared by the method of Gilman and Jones (1, 2). Final traces of ether were removed from the alkyl by repeated bulb-to-bulb degassing with the cold trap at 0 °C. All operations were carried out in total darkness. A shielded 10 W lamp was used when illumination was required. The final product had a melting point of 38.0 °C. Twenty-one weighed samples were analyzed for thallium and methyl radical content (3). The methyl radical analysis was carried out by measuring the methane, ethane, and ethyl benzene produced when the alkyl was pyrolyzed in the presence of toluene. Thallium was determined by titration with .02 *m* ethylenediaminetetraacetic acid (EDTA) using xylenol orange as indicator. In four runs the total thallium content was determined. It ranged from 99.1% to 99.7% of the expected value. Assuming three methyl radicals per molecule of trimethylthallium, the gas analysis in the 21 runs was always within ±3% of that expected on the basis of the free thallium metal formed by decomposition.

TABLE I

Vapor pressure measurements on trimethylthallium

(*a*) Liquid							
	t (°C)	87.0	83.0	71.0	60.0	48.3	39.7
	P (cm)	12.08	10.47	6.68	4.27	2.40	1.58
(*b*) Solid							
	t (°C)	30.8	21.5	9.8	0.0	−7.0	−15.0
	P (cm)	0.860	0.410	0.154	0.069	0.036	0.015

Vapor pressure measurements were made from −15 °C to 87 °C. Below 40 °C measurements were made in a closed system equipped with an oil manometer. Above 40 °C the oil manometer served as the null arm of an isoteniscope and pressures were read from a mercury manometer. All readings were taken with a Gaertner 1539-A cathetometer. The experimental results are shown in Table I. They may be represented by the following equations:

[i] from −15 °C to 38 °C

$$\log_{10} P \text{ (cm)} = -\frac{3000}{T} + 9.81$$

[ii] from 38 °C to 87 °C

$$\log_{10} P \text{ (cm)} = -\frac{2110}{T} + 6.95.$$

Equation [ii] is in reasonable agreement with that of Gilman and Jones (1) obtained from data covering the temperature range 54.5° to 76 °C:

$$\log_{10} P \text{ (cm)} = -\frac{1980}{T} + 6.603.$$

Liquid trimethylthallium has been shown to be monomolecular (1). Therefore, assuming ideal gas behavior for the vapor the following approximate values may be calculated from the integrated Clapeyron–Clausius equation:

[i] $\Delta H_{vap}^{62\,^\circ C} = 9.7$ kcal/mole, [ii] $\Delta H_{sub}^{12\,^\circ C} = 13.7$ kcal mole.

These values are slightly temperature dependent but since the necessary heat capacity data are not available no correction can be made. If the values at 38 °C are not significantly different from those quoted

$$\Delta H_{fusion}^{38\,^\circ C} = 4.0 \text{ kcal/mole.}$$

DESHYDRATATION DES ÉCHANGEURS DE CATIONS

WALTER R. HEUMANN ET FERNANDE D. ROCHON

Plusieurs méthodes de deshydratation des échangeurs sulfoniques de cations (acides forts) ont été proposées. Kunin (1) fait sécher à 115 °C pendant 20 h. Dickel et ses collaborateurs (2) constatent que 4 semaines au dessicateur en présence de P_2O_5 à la température ambiante ne suffit pas pour atteindre le poids constant et qu'il faut après encore 50 h à 80 °C sous 3 Torr de vide pour y arriver. Par contre, Davies et Yoeman (3) trouvent que pour les formes H^+ et K^+ le séchage à 80 °C sous vide pendant 24 h est suffisant. Blasius et Wolf (4, 5) supposent que la forme Li^+ de l'échangeur se deshydrate complètement par lavage dans une colonne avec du dioxane anhydre. Wright et ses collaborateurs (6) soumettent la forme H^+ à la distillation azéotropique avec du toluène et rapportent que l'eau est enlevée quantitativement. Aucun de ces auteurs donne une preuve du caractère quantitatif de sa méthode.

Selon plusieurs auteurs (2, 7, 8, 9) qui ont mesuré les chaleurs d'hydratation des échangeurs anhydres, la chaleur d'absorption du premier équivalent d'eau par équivalent d'échangeur anhydre sous forme d'hydrogène ou de métal alcalin est de -3 à -7 kcal et les chaleurs intégrales pour les trois premiers équivalents d'eau se placent entre -5 et -10 kcal par équivalent d'échangeur. Ces fortes valeurs expliquent facilement l'efficacité de ces échangeurs comme desséchants de liquides organiques selon la méthode de Wymore (10), qui démontre que des liquides peu polaires sont deshydratés ainsi très facilement à une teneur d'eau au-dessous de 5 p.p.m.

A la lumière de ces faits, il paraît peu probable que le dioxane, un liquide peu polaire ayant selon Feodos'ev (11) une chaleur d'hydratation de seulement -0.12 kcal/équivalent, pourrait deshydrater quantitativement un échangeur sulfonique tel que supposé par Blasius et Wolf (4). L'étude présente a été entreprise dans le but d'élucider ces contradictions par comparaison des efficacités quantitatives de ces différentes méthodes.

PARTIE EXPÉRIMENTALE

L'échangeur cationique Dowex 50W-X8 (8% de divinylbenzène) de granulation 20 à 50 mailles/pouce a été utilisé sous forme Li^+ ou Na^+.

Le *dioxane* a été deshydraté et purifié par chauffage à reflux durant 3 h en présence d'hydrure d'aluminium et de lithium, suivi d'une distillation.

Le *toluène* et le *xylène* ont été deshydratés par distillation azéotropique d'environ 10% du volume total.

Le *dosage de l'eau* dans les différents liquides a été effectué électrométriquement par la méthode de Karl Fischer après dilution des échantillons avec du méthanol anhydre.

Les *mélanges de dioxane et toluène* ont été analysés par chromatographie en phase vapeur à l'aide d'une colonne de 1.5 m × 6 mm de squalène à 120 °C, le gaz de support étant hélium et le débit 50 cc/min. On pouvait ainsi détecter facilement moins de 0.1% de dioxane dans le toluène.

RÉSULTATS

Les résultats obtenus *par séchage* par quatre différentes méthodes sont donnés dans le Tableau I. La méthode 1 (120 °C sous vide) semble être la plus efficace, mais elle n'est pas exacte. Une petite perte de poids par décomposition accompagnée d'une coloration foncée permanente peut se produire, surtout lorsque la résine est soumise à ce traitement pour la première fois.

La deshydratation *par le dioxane* fut vérifiée par la méthode de Blasius et Wolf (4),

TABLEAU I

Deshydratation de Dowex 50W-X8 forme Li^+ par séchage

Méthode	Perte de poids en % après 5 h	24 h	48 h	72 h
1. Chauffage à 120 °C, vide de 0.5 à 1 Torr	11.72	11.79	11.78	11.79
2. Chauffage à 120 °C, pression atmosphérique	11.07	11.57	11.75	11.78
3. Chauffage à 70 °C, vide de 10 Torr		10.58	11.09	11.30
4. Dessiccateur, P_2O_5, 25 °C, pression atmosphérique		1.88		3.00

c'est-à-dire par percolation de dioxane anhydre par une colonne d'échangeur sous forme Li^+, jusqu'à ce que l'effluant ne contienne plus d'eau. L'eau trouvée dans l'effluant correspondait à une perte de poids de l'échangeur de 3.63%, tandis qu'un autre échantillon du même échangeur perdait 11.75% par chauffage à 120 °C pendant 48 h. En supposant que cette perte de poids à 120 °C correspondait à la quantité totale d'eau, on peut conclure qu'après le traitement au dioxane l'échangeur contenait encore 8.42% d'eau.

L'échangeur deshydraté ainsi partiellement par le dioxane, fut soumis à une distillation azéotropique subséquente. Le dioxane fut d'abord déplacé de la colonne par du toluène en passant ce dernier solvant jusqu'à ce que la chromatographie ne détecte plus de dioxane dans l'effluant. Ce traitement n'enlevait pas d'eau supplémentaire de l'échangeur. Cependant, par la distillation subséquente une quantité d'eau fut enlevée, qui correspondait à 4.58% du poids initial de l'échangeur ou à une teneur résiduelle de l'échangeur traité de 3.86% d'eau.

Plusieurs échantillons d'échangeur, contenant entre 12 et 28% d'eau (exprimé en perte de poids à 120 °C), furent traités directement par distillation azéotropique avec du toluène ou du xylène. Après 2 à 3 h de distillation assez vive, la vitesse d'entraînement de l'eau par heure avait baissée à environ 0.1% du poids de l'échangeur, qui contenait encore 4 à 6% d'eau après 6 h de distillation. Supposant que la vitesse d'entraînement ne diminuerait pas, il aurait fallu continuer la distillation pendant 40 à 60 h pour atteindre la deshydration complète.

Pour vérifier, si la perte de poids par chauffage à 120 °C était due exclusivement à l'évaporation d'eau et que d'autres produits volatils n'y contribuaient pas, des échantillons furent d'abord séchés à 120 °C, puis de nouveau saturés d'eau, avant d'être soumis au traitement décrit plus haut, c'est-à-dire à la distillation azéotropique d'un aliquot et au séchage à 120 °C d'un autre aliquot. Les résultats obtenus ainsi ne différaient aucunement de ceux obtenus sans chauffage préliminaire. Une perte de poids par décomposition pyrolytique des échangeurs peut être exclue également, puisque Wymore (10) a trouvé, que les échangeurs cationiques sulfonés du type Dowex 50 sous forme métal alcalin, peuvent être chauffés à 195 °C sous pression atmosphérique sans aucun effet chimique détectable. Il semble donc, que parmi les méthodes examinées, le chauffage à 120 °C pendant au moins 48 h est la seule méthode satisfaisante.

REACTIVITY OF CH AND NH BONDS IN ETHYLENIMINE

PETER GRAY AND A. JONES

The paper by Klemm (1) on hydrogen abstraction from ethylenimine complements work which we have recently performed. We have studied the position and rate of methyl radical attack on ethylenimine over the temperature range 110–175 °C using the unlabelled imine and ethylenimine-d_1. The photolysis of azomethane was used as the source of methyl radicals. (It was originally chosen (2) to avoid possible difficulties arising from reaction between substrate and acetone.)

When azomethane is photolyzed alone, the following reactions occur.

[1] $$CH_3N_2CH_3 \rightarrow N_2 + 2CH_3$$

[2] $$CH_3 + CH_3N_2CH_3 \rightarrow CH_4 + \cdot CH_2N_2CH_3$$

[3] $$2CH_3 \rightarrow C_2H_6$$

Measurements of the steady rates of production of methane and ethane can furnish a value of k_2 from the relation:

$$R_{CH_4}[2]/R_{C_2H_6}{}^{1/2}[\text{Azo}] = (k_2/k_3{}^{1/2}).$$

The temperature dependence of k_2 can be expressed by the Arrhenius equation:

$$\log_{10} (k_2/\text{mole}^{-1}\,\text{cm}^3\,\text{s}^{-1}) = (10.85 \pm 0.10) - (7830 \pm 200)/2.303RT.$$

This rate expression, and all others quoted here, are based on Shepp's value (3) of $10^{13.34}$ cm^3 mole^{-1} s^{-1} for the recombination of methyl radicals, errors quoted being standard deviations estimated by a least-squares treatment. The values above are in agreement with previously determined values.

Overall Rate of Attack by Methyl Radicals on Ethylenimine

When azomethane is photolyzed in the presence of unlabelled ethylenimine, the following reactions must be added to the reaction scheme for azomethane.

[4] $$CH_3 + CH_2 - \underset{\diagdown\,\diagup}{\overset{}{N}}\overset{}{-}CH_2 \rightarrow CH_4 + \cdot CH - \underset{\diagdown\,\diagup}{\overset{}{N}}\overset{}{-}CH_2$$
$$\qquad\qquad\qquad\quad H \qquad\qquad\qquad\qquad\quad H$$

[5] $$CH_3 + (CH_2)_2NH \rightarrow CH_4 + (CH_2)_2N\cdot$$

REACTIVITY OF CH AND NH BONDS IN ETHYLENIMINE

PETER GRAY AND A. JONES

The paper by Klemm (1) on hydrogen abstraction from ethylenimine complements work which we have recently performed. We have studied the position and rate of methyl radical attack on ethylenimine over the temperature range 110–175 °C using the unlabelled imine and ethylenimine-d_1. The photolysis of azomethane was used as the source of methyl radicals. (It was originally chosen (2) to avoid possible difficulties arising from reaction between substrate and acetone.)

When azomethane is photolyzed alone, the following reactions occur.

[1] $$CH_3N_2CH_3 \rightarrow N_2 + 2CH_3$$

[2] $$CH_3 + CH_3N_2CH_3 \rightarrow CH_4 + \cdot CH_2N_2CH_3$$

[3] $$2CH_3 \rightarrow C_2H_6$$

Measurements of the steady rates of production of methane and ethane can furnish a value of k_2 from the relation:

$$R_{CH_4}[2]/R_{C_2H_6}{}^{1/2}[\text{Azo}] = (k_2/k_3{}^{1/2}).$$

The temperature dependence of k_2 can be expressed by the Arrhenius equation:

$$\log_{10} (k_2/\text{mole}^{-1}\,\text{cm}^3\,\text{s}^{-1}) = (10.85 \pm 0.10) - (7830 \pm 200)/2.303RT.$$

This rate expression, and all others quoted here, are based on Shepp's value (3) of $10^{13.34}$ cm^3 mole^{-1} s^{-1} for the recombination of methyl radicals, errors quoted being standard deviations estimated by a least-squares treatment. The values above are in agreement with previously determined values.

Overall Rate of Attack by Methyl Radicals on Ethylenimine

When azomethane is photolyzed in the presence of unlabelled ethylenimine, the following reactions must be added to the reaction scheme for azomethane.

[4] $$CH_3 + CH_2 - \underset{\diagdown\,\diagup}{\overset{}{N}}\overset{}{-}CH_2 \rightarrow CH_4 + \cdot CH - \underset{\diagdown\,\diagup}{\overset{}{N}}\overset{}{-}CH_2$$
$$\qquad\qquad\qquad\quad H \qquad\qquad\qquad\qquad\quad H$$

[5] $$CH_3 + (CH_2)_2NH \rightarrow CH_4 + (CH_2)_2N\cdot$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The combined effect of reactions [4] and [5] can be represented by the equation

[6] $$CH_3 + (CH_2)_2NH \rightarrow CH_4 + [C_2H_4N].$$

It is this overall velocity constant, k_6, which is obtained by measuring the rates of production of CH_4 and C_2H_6 from the relation:

$$R_{CH_4}[6]/R_{C_2H_6}^{1/2}[\text{imine}] = (k_6/k_3^{1/2}),$$

where [imine] denotes the concentration of ethylenimine. Over the temperature range, 110–175 °C, the results can be fitted by the equation:

$$\log_{10} (k_6/\text{mole}^{-1}\ \text{cm}^3\ \text{s}^{-1}) = (10.29 \pm 0.23) - (4770 \pm 440)/2.303RT.$$

This expression can be compared with Brinton and Volman's (4) values for A and E of $10^{10.5}$ mole^{-1} cm^3 s^{-1} and 4.8 kcal mole^{-1} and those of Klemm (1) of $10^{10.76}$ mole^{-1} cm^3 s^{-1} and 5.28 kcal mole^{-1}, and with the results for the analogous reaction of CD_3 radicals with ethylenimine, for which Klemm obtained $A = 10^{10.94}$ mole^{-1} cm^3 s^{-1} and $E = 5.40$ kcal mole^{-1}.

Rate of Attack on the Imine Group

When methyl radicals are generated in the presence of ethylenimine-d_1, the additional CH_4 comes only from attack on the methylene groups, since attack at the imine position yields CH_3D. By subtracting this rate of formation of methane from the previous rate of formation from the unlabelled imine, a value can be obtained for the velocity constant k_5 for attack on the NH group:

$$\log_{10} (k_5/\text{mole}^{-1}\ \text{cm}^3\ \text{s}^{-1}) = (10.17 \pm 0.05) - (4570 \pm 100)/2.303RT.$$

This expression differs little from that for the overall rate of abstraction [6] confirming Brinton and Volman's original conjecture (4) that attack was principally at the imine group, and to this extent justifying Klemm's implicit identification (1) of k_5 with k_6.

Rate of Attack on the Methylene Groups

When azomethane is photolyzed in the presence of ethylenimine-d_1, most of the methane is produced by attack on (i) the azomethane and (ii) undeuterated impurity (ca. 2%) in the ethylenimine-d_1. The part which comes from attack on the $\cdot CH_2$ groups has thus to be obtained by two subtractions involving quantities of comparable size and is subject to correspondingly larger errors than before. These are especially noticeable in the Arrhenius parameters:

$$\log (k_4/\text{mole}^{-1}\ \text{cm}^3\ \text{s}^{-1}) = (11.44 \pm 1.48) - (10100 \pm 2800)/2.303RT.$$

It is curious to note that although experiments involving four isotopic variations of the methyl radical attack on ethylenimine have now been performed, the reaction which would have yielded the most accurate Arrhenius equation for abstraction of hydrogen from the methylene groups—the attack of CD_3 on $(CH_2)_2ND$—has not been investigated.

Relative Reactivity of the NH and CH_2 Groups in Ethylenimine

It is now possible to compare quantitatively the reactivity of hydrogen atoms attached to carbon and nitrogen in ethylenimine. At 150 °C, hydrogen attached to nitrogen is abstracted nearly 40 times more readily than hydrogen attached to carbon, and on a per-atom basis is thus about 160 times more reactive. This can be compared with previous experiments with deuterated amines, in all of which the hydrogen attached to nitrogen has been found, at 150 °C, to be the more reactive. On a per-atom basis the relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

reactivity (k_{NH}/k_{CH}) of amine hydrogen in CH_3NH_2, $(CH_3)_2NH$, and CH_3ONH_2 is 3.4, 20, and >75 respectively (refs. 4, 5, 6).

Kinetic Isotope Effects

The velocity constant for deuterium abstraction from ethylenimine-d_1

[7] $$CH_3 + (CH_2)_2ND \rightarrow CH_3D + (CH_2)_2N\cdot$$

obtained from measurements of the rates of formation of CH_3D and C_2H_6 satisfies the Arrhenius expression

$$\log_{10}(k_7/\text{mole}^{-1}\,\text{cm}^3\,\text{s}^{-1}) = (10.17 \pm 0.13) - (6340 \pm 210)/2.303RT.$$

Comparison with the velocity constant k_5 shows that at 150 °C, hydrogen is abstracted nearly eight times as fast from the NH group in ethylenimine as is deuterium from the ND group in ethylenimine-d_1. Since the A-factors are identical, this isotope effect is wholly accounted for by the difference in activation energy, $E_D - E_H = 1.7 \pm 0.5$ kcal mole^{-1}, which can be compared to the loss of zero-point-energy of a single N—H stretching vibration of 1.4 kcal mole^{-1}.

By combining the data of Klemm (1) and that presented here it is possible to obtain an estimate of the kinetic isotope effect for deuterium and hydrogen attached to the carbon atoms in ethylenimine. Thus Klemm quotes, that for abstraction of deuterium and hydrogen from ethylenimine-d_4, $(k_{NH}/k_{CD_2}) > 200$. From our data for abstraction from NH and CH_2 in the unlabelled compound at 150 °C, $(k_{NH}/k_{CH_2}) = 40$. This implies that at 150 °C, the kinetic isotope effect $(k_{CH_2}/k_{CD_2}) > 5$ which is in accord with expectations.

DEUTERIUM ISOTOPE EFFECT IN VACUUM-ULTRAVIOLET ABSORPTION COEFFICIENTS OF WATER AND METHANE[1]

A. H. Laufer and J. R. McNesby

The effect of isotopic substitution upon the electronic absorption spectra of diatomic molecules is a well-explored subject and has been reviewed by Herzberg (1). As a consequence of the effect of mass on the vibration frequencies, the heavier isotopic species exhibits a general contraction in the electronic band on both sides of the 0–0 vibrational transition. This corresponds to a shift in absorption to the violet on the red end of the band and to the red on the violet end for the heavier species.

Shifts to the violet (on the red end) upon deuteration have also been observed with molecules exhibiting continuous absorption (2–5). These observations are most easily explained by referring to the hypothetical case of a diatomic molecule having a normal

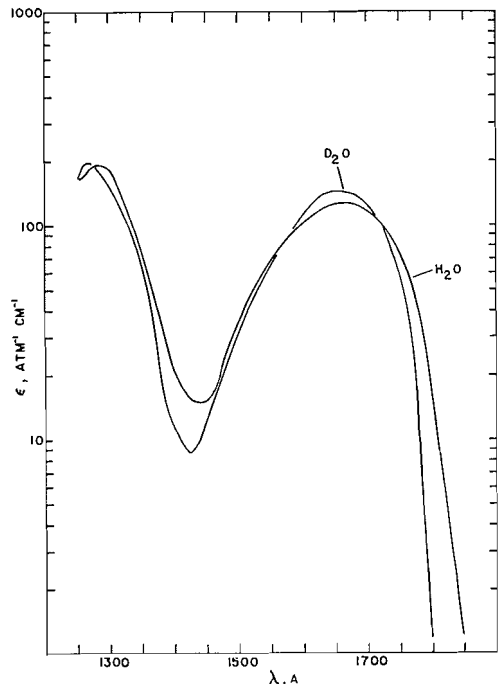

FIG. 1. Deuterium isotope effect on absorption coefficients of water. NOTE ADDED IN PROOF: A series of six maxima between 1 600 and 1 750 Å observed by A. Johannin-Gilles, Compt. Rend. 240, 1523 (1955), were not observed in ref. 6 or in the present work. The explanation for the observation of Johannin-Gilles is not obvious.

potential function for the ground state and a repulsive potential for the non-quantized upper state. The heavier isotopic variation of this molecule has a lower zero point energy in the ground state. For a Franck–Condon vertical transition, the minimum energy needed for the transition to the upper state will be greater for the heavier species by the zero point energy difference and a shift to the violet is the result. While the situation is certainly more complex for polyatomic molecules, a similar principle applies.

In the present work, measurements have been made of the absorption coefficients in the continua of H_2O and D_2O and of CH_4 and CD_4 using a Seya–Namioka type 0.5 m grating vacuum monochromator. An absorption cell with lithium fluoride windows was interposed between the exit slit of the monochromator and the sodium salicylate coated photomultiplier tube. Pressures of methane and water were measured with an oil manometer and the path length was 5.71 cm. In the cases of H_2O and D_2O, pressures were measured after adsorption equilibrium had been established. Measurements on D_2O were made after exposing the apparatus to D_2O vapor for 24 h, removing it, and refilling the absorption cell with pure D_2O. The light source was a hydrogen discharge. Incident intensities were determined before and after an absorption scan to insure constancy of the lamp and to obviate radiation damage to the windows. The entrance and exit slits were 200 μ and the reciprocal linear dispersion was 33 Å/mm corresponding to a band width of 6.6 Å. Absorption coefficients were measured assuming the validity of Beer's law. This assumption was found to be valid in the methane and water continua since the absorption coefficients, ϵ, were found to be independent of pressure. The absorption coefficient is defined by

$$I/I_0 = \exp(-\epsilon Pd)$$

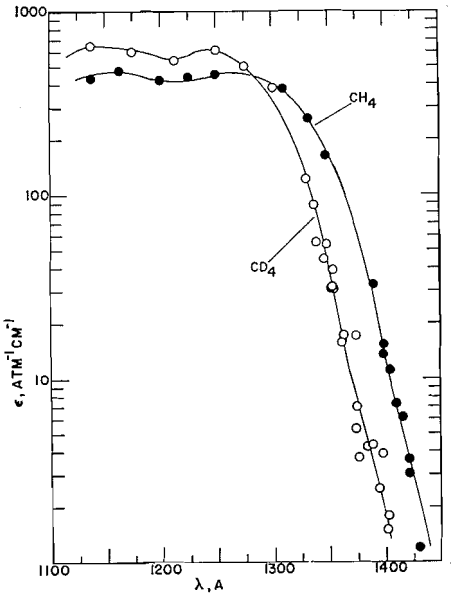

FIG. 2. Deuterium isotope effect on absorption coefficients of methane.

where the units of ϵ are cm^{-1} atm^{-1}. The results are shown in Figs. 1 and 2. The absorption coefficients for H_2O and CH_4 are in good agreement with those reported in the literature (6, 7).

In the 1 450 to 1 250 Å region of the spectrum of H_2O, 12 diffuse bands superimposed on a continuum have been observed (6). It has recently been shown that D_2O also exhibits somewhat irregular diffuse bands in this region although values for ϵ were not included (8). Lack of resolution of our instrument precluded the observation of the banded structure but the values obtained for the absorption coefficients agree well with the literature (6).

The expected shifts to the violet on deuteration are observed for both water and methane on the red ends of the continua. The appearance of a second overlapping continuum in the case of water complicates the picture somewhat but a shift toward the violet is evident in this continuum also. Because of the sharp structure in the water spectrum below

1 250 Å (9), the absorption coefficient measurements are not very meaningful and they have, therefore, been omitted from Fig. 1. The absorption coefficient at the photochemically interesting wavelength of 1 235.8 Å was measured using a krypton resonance lamp as the light source. According to the spectra of Johns (9), the D_2O absorption is essentially continuous for at least 1 Å on each side of 1 235.8 Å and this is probably also the case for H_2O. Since the krypton line emitted from our lamp falls entirely within this continuum, the absorption coefficients at 1 235.8 Å are probably correct. The results are $\epsilon_{H_2O} = 171$; $\epsilon_{D_2O} = 270$. Beer's law was found to be obeyed in the range 0.3–1 Torr for the krypton line at 1 235.8 Å.

As shown in Figs. 1 and 2, the violet shift is characterized by a lowering of the absorption coefficient for the heaver isotopic species. A number of absorption coefficients have been measured at 1 470 Å and Table I shows that the violet shift is quite general for saturated hydrocarbons.

MEAN LIFETIME OF FREE RADICAL CHAINS IN ^{60}Co γ-IRRADIATED CHLORAL HYDRATE AND BROMAL HYDRATE SOLUTIONS

R. G. McIntosh, R. L. Eager, and J. W. T. Spinks

Previous publications by us have described work on the radiation chemistry of aqueous solutions of chloral hydrate and of bromal hydrate. The first of these (1) reported on the use of a flow system to obtain intermittent irradiation. In a later paper (2) the results obtained by steady irradiation of the samples were reported. In addition to the above work experiments were also done in which a rotating sector was used to obtain intermittent irradiation. This note reports the results of these latter studies.

EXPERIMENTAL

The ^{60}Co radiation facility was the same as that used in the other studies and has been described previously (3). During irradiation the samples were contained in an electrical conductivity cell and the change of conductivity with time of irradiation was noted. The conductivity cell was of the Arrhenius–Ostwald type and has been previously described (2). The Fricke ferrous sulfate dosimeter was used. The purification of the reagents and of the water used in making up the solutions has already been described (2). The sample temperature was that of the cave, between 20 and 25 °C. The reaction rates were corrected to 25.0 °C (2).

The rotating sector was constructed of General Electric Company Heavy Alloy which contains 90% of tungsten alloyed with nickel and copper. The alloy has a specific gravity of 16.3–17.0. The sector was 2 in thick and $7\frac{1}{4}$ in in diameter. A 3/8 in thick steel band encircled the sector. Two inches of the alloy stops approximately 90% of a ^{60}Co γ-ray beam. Two opposed sector openings of 60° each were present, giving a value for r, the ratio of the "dark" to the "light" periods, of 2. Sector speeds of 0.5 to 500 r.p.m. were used.

RESULTS AND DISCUSSION

To obtain an estimate of the accuracy of the experimental work the standard deviation of a single observation was determined. A series of 5 runs were made using a 1.0 M chloral hydrate solution and a light flash of 890 ms duration. This flash time is in the region where the reaction rate is quite sensitive to variations in the flash time. The mean reaction rate was 16.7 μmoles l^{-1} min^{-1} and the standard deviation was found to be 0.3 μmoles l^{-1} min^{-1}.

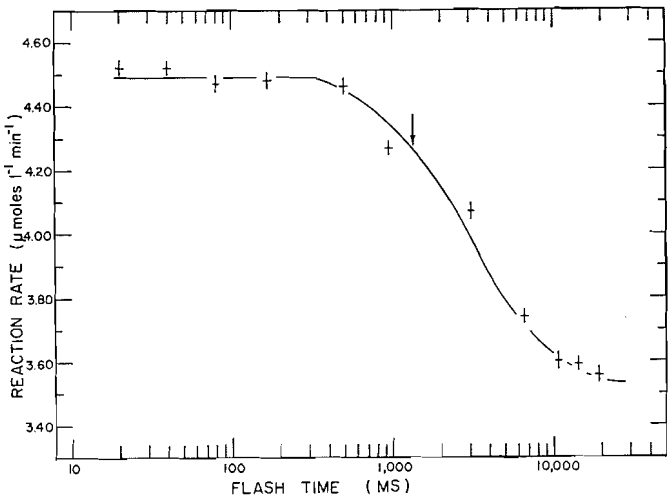

FIG. 1. Mean free radical chain lifetime sector curve: 0.1 M chloral hydrate, 106 rads min^{-1}, pH 5.15.

The mean free radical chain lifetime, τ (see below), was determined for each of a series of solutions of different concentration and pH. For each solution the variation of reaction rate with flash time was measured and the results plotted as shown in Fig. 1, which is a typical example. From these plots the value of τ was obtained using the method given by Melville and Burnett (4). The theory will not be repeated and only the final conclusions used to find values of τ will be given. The theory is based on the following generalized reaction scheme.

[1] $$S \rightsquigarrow \dot{R} \qquad \text{rate} = G_R I^*$$

[2] $$S + \dot{R} \rightarrow \dot{R} + P \qquad \text{rate} = k_p[S][\dot{R}]$$

[3] $$\dot{R} + \dot{R} \rightarrow \text{inactive species} \qquad \text{rate} = k_t[\dot{R}]^2.$$

S is the reactant, $\dot{R}$ is an intermediate free radical, and P is a product of the chain reaction. G_R is the G value for the initiation of radicals $\dot{R}$. I is the dose rate, k_p and k_t are respectively the propagation and termination specific rate constants. In the mathematical analysis of the behavior of the system when exposed to intermittent radiation two parameters arise. One of these is the mean free radical chain lifetime, τ, which is defined as follows:

$$\tau = \frac{\text{number of free radicals per unit volume}}{\text{number of free radicals disappearing per unit volume per unit time}}.$$

The other is a dimensionless parameter, m, which is the number of times that the duration

**In numerical calculations the appropriate conversion factors were used so that the rate of [1] was given in mole l^{-1} s^{-1}.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

of the light flash, the flash time t, is greater than the lifetime. It follows from this definition that

$$\tau = t/m. \quad [4]$$

A relation between a function which is proportional to the rate of production of product and m is derived. A plot of this function against m is known as the "master curve". The form of this master curve is very similar to the experimentally determined curves, such as that shown in Fig. 1. From [4] it is seen that when m is unity the value of τ is equal to the corresponding flash time. From the master curve it is found that for $m = 1$ the rate of reaction is 0.956 times the maximum rate reached at short flash times. In Fig. 1 an arrow marks the point where the rate of reaction is 0.956 times the maximum rate. Values of τ found in this manner for chloral hydrate and bromal hydrate solutions are given in Table I.

It is important to note that the reaction scheme on which these values of τ are based imply that the reaction rate is proportional to the one-half power of the dose rate and to the first power of the concentration. It has been found (2) that the rate is dependent to the 0.66 power and the 0.58 power of the dose rate for 1.0 M chloral hydrate and 0.1 M bromal hydrate solutions respectively. Similarly it has been found that the rate is dependent to the 0.39 power and the 0.34 power of the concentration for chloral hydrate solutions, at a dose rate of 250 rads min^{-1}, and for bromal hydrate solutions, at a dose rate of 114.5 rads min^{-1}, respectively. This has been taken to mean that there are chain termination processes in addition to a radical–radical reaction. The chain reaction has also been postulated to be more complicated than that in the simple scheme proposed by Melville and Burnett. It is to be expected, therefore, that the values of τ given in Table I will only be approximate values since they were derived on the basis of the simpler mechanism.

By making further assumptions it is possible to estimate values of k_t and k_p. From the definition of τ and eq. [3] we have:

$$\tau = [\dot{R}]/k_t[\dot{R}^2] = 1/k_t[\dot{R}]. \quad [5]$$

From the steady state treatment of [1], [2], and [3] we find:

$$[\dot{R}] = (G_R I/k_t)^{1/2}. \quad [6]$$

I is the average dose rate with the sector rotating. From [5] and [6] we get

$$k_t = (\tau^2 G_R I)^{-1}. \quad [7]$$

The values of τ already found may be used and I is known. The value to be used for G_R is more difficult to assess. If it is assumed that the initiating radicals arise only from the interaction of the incident radiation with water molecules then we are concerned mainly with G values for H, OH, and e_{aq}. Considering that from one to perhaps all of these species may be involved in the initiation of the chain-carrying radical $\dot{R}$ a value of 5 for G_R is probably correct within a factor of 2. In view of the approximate nature of the value of τ found above, this value for G_R appears to be suitable for use in eq. [7]. Values of k_t calculated from [7] are given in Table I.

By substituting [5] and [7] into [2], the expression for the rate of formation of product, and selecting the maximum reaction rate, R_m, we get:

$$R_m = k_p[S]G_R I\tau. \quad [8]$$

Values of k_p were calculated from [8] and are given in Table I. The experimental values of R_m, [S], and I were used. The correct value to use for I is the average dose rate with the sector rotating.

Also included in Table I are the results of other workers (5, 6, 7). The two values of τ given for chloral hydrate solutions (5, 6) are smaller than those found in the present work. The reason for this discrepancy is not known. The value of τ found for a bromal hydrate solution (7), while for a different concentration, type of radiation, and dose rate, appears to be consistent with the value found in the present work.

The chloral hydrate results obtained in the present work are the only ones where there is a variation in concentration, pH, and dose rate, hence these results will be used in the following discussion. The results for the chloral hydrate solutions presented in Table I indicate that τ, k_t, and k_p are not very pH dependent. This is consistent with the mechanism proposed by the present authors for the irradiation of solutions of chloral hydrate and of bromal hydrate (2). Similarly the variation of τ either with dose rate or with concentration is qualitatively consistent with the proposed reaction scheme (2). It would be expected that if a radical–radical reaction (reaction [e] in ref. 2) was responsible for at least some of the chain termination, a change in any variable which resulted in an increase in the concentration of the radicals would result in a decreased value of τ. This would be the expected result of an increased dose rate or an increased concentration of the solute.

A decrease in the concentration of chloral hydrate is found to cause a marked decrease in k_t and an increase in k_p. A decrease in the dose rate causes a decrease in both k_t and k_p. These results indicate that k_t and k_p are not true specific rate constants but rather that they are composite and may include concentration terms. In the mechanism suggested by the authors (2) it was proposed that the chain termination step is not exclusively a radical–radical reaction, but also the following reaction occurs to a certain extent (reaction [*f*] in ref. 2).

$$[9] \qquad \dot{R} \xrightarrow[M]{k_f} \text{end of chain} \qquad \text{rate} = k_f[\dot{R}][M]$$

As the result of the inclusion of this reaction k_t would include a term $k_f[\dot{R}][M]$. The effect of a decreased concentration of chloral hydrate (if chloral hydrate is M) would be to reduce the rate of removal of $\dot{R}$ from the reaction mixture. The result would be a decrease in the rate of termination, i.e. k_t would be expected to decrease, as is observed. The decreased rate of termination will, however, result in an increase in the rate of the chain reaction (reactions [*b*] to [*d*] in ref. 2), i.e. k_p would be expected to increase, as is observed. The inclusion of reaction [9], and the identification of M with S, implies that chloral hydrate acts as an inhibitor for the reaction. Hence qualitatively it would be expected that the exponent of the concentration term in the rate expression (eq. [8] in ref. 2) would be less than one-half, as it is found to be. This point, which was not made in ref. 2, is further support for the reaction scheme proposed by the present authors (2). The effect of a decreased dose rate would be to lower the concentration of $\dot{R}$. The result would be a decrease in the rate of reaction [9] i.e. k_t would be expected to decrease, as is observed. On the basis of the mechanism proposed in ref. 2 the effect of a decrease in dose rate on k_p is not easy to predict, but the observed decrease in value does not seem to be inconsistent with the proposed mechanism.

SURFACE CHEMISTRY AND CATALYTIC PROPERTIES OF BORON PHOSPHATE. II. A NOTE ON THE FORMATION OF PARAMAGNETIC SPECIES WITH ADSORBED AROMATIC COMPOUNDS

J. B. MOFFAT AND M. A. HALEEM[1]

INTRODUCTION

Earlier work (1) from this laboratory has demonstrated that acidic sites are present on the surface of boron phosphate (BP). It is of interest to attempt to demonstrate whether such acidity is of the Bronsted or Lewis type. Electron spin resonance (e.s.r.) studies of aromatic compounds adsorbed on such solids as silica–alumina have been used by other workers in an attempt to elucidate the nature of the adsorbed species and the type of acidic sites present. The present note reports results of preliminary studies of the species formed by the adsorption of some aromatic compounds on the surface of solid BP. No previous studies of e.s.r. spectra of adsorbed materials on boron phosphate have been reported.

A number of studies of the e.s.r. spectra of aromatic molecules adsorbed on silica–alumina have been reported. Rooney and Pink (2) attributed their e.s.r. signals to radical-ion formation. Recently (3) the presence of paramagnetic species in the adsorption of aromatic molecules on platinum oxide has been reported. However, the observed paramagnetic resonance in this case is attributed to a low lying, thermally populated, triplet state of a charge-transfer complex.

EXPERIMENTAL

Solutions of various aromatic compounds in dried carbon tetrachloride and (or) in dried heptane were added to aliquots of samples of boron phosphate prepared as described previously (1). All reagents were of the best grade available from Eastman Kodak, usually of C.P. grade. No further purification of these chemicals was done. Preliminary treatment of the BP consisted of evacuation at 100 °C for at least 2 days and in some cases, longer. Electron spin resonance scans of the untreated BP showed no signals.

Electron spin resonance spectra were obtained at room temperature with a JEOL model JES-3B spectrometer operating at 9 500 Mc/s and 100 kc/s magnetic field modulation. Samples were held in quartz glass tubes fitted with standard taper joints and stopcocks through graded seals to permit attachment to a high vacuum system.

RESULTS

Perylene (P Y)

When a solution of PY in dried carbon tetrachloride was added to a sample of BP treated as discussed previously, a purple color developed on the catalyst. A strong nine-line e.s.r. spectrum, similar to that obtained by Hodgson and Raley (4) was obtained. The shape of this spectrum for adsorbed PY also agreed with that found by others previously (5). The e.s.r. spectrum yielded a g value of 2.0023 ± 0.0005 and a width measured between centers of extreme peaks of 23 ± 0.5 G.

Solutions of various aromatic compounds in dried carbon tetrachloride and (or) in dried heptane were added to aliquots of samples of boron phosphate prepared as described previously (1). All reagents were of the best grade available from Eastman Kodak, usually of C.P. grade. No further purification of these chemicals was done. Preliminary treatment of the BP consisted of evacuation at 100 °C for at least 2 days and in some cases, longer. Electron spin resonance scans of the untreated BP showed no signals.

Electron spin resonance spectra were obtained at room temperature with a JEOL model JES-3B spectrometer operating at 9 500 Mc/s and 100 kc/s magnetic field modulation. Samples were held in quartz glass tubes fitted with standard taper joints and stopcocks through graded seals to permit attachment to a high vacuum system.

RESULTS

Perylene (P Y)

When a solution of PY in dried carbon tetrachloride was added to a sample of BP treated as discussed previously, a purple color developed on the catalyst. A strong nine-line e.s.r. spectrum, similar to that obtained by Hodgson and Raley (4) was obtained. The shape of this spectrum for adsorbed PY also agreed with that found by others previously (5). The e.s.r. spectrum yielded a g value of 2.0023 ± 0.0005 and a width measured between centers of extreme peaks of 23 ± 0.5 G.

[1]*Present address: Department of Chemistry, Osmania University, Hyderabad, India.*

Tetraphenylethylene (TPE)

As in the case of Perylene, a dark purple color resulted on addition of a solution of TPE in dried carbon tetrachloride to BP. However, the system with TPE gave an unresolved, relatively weak (compared to perylene) e.s.r. signal, with a g value of 2.0033 ± 0.001 and a width of 15 ± 1 G.

Paramagnetic species have been observed (7) previously with TPE and silica–alumina.

1,1-Diphenylethylene (DPE)

A dark-green color was produced with a DPE–CCl_4 solution and BP. Again an unresolved, relatively weak, e.s.r. signal was obtained, with a g value of 2.0033 ± 0.001 and a width of 11 ± 1 G. Rooney and Hathaway (7) obtained a green color and an e.s.r. signal with DPE on silica–alumina. However, they demonstrated that the green color was apparently due to two species one yellow and one blue, the latter being a carbonium ion rather than a radical-ion. However, they were not able to identify the radical-ion present in their system.

DISCUSSION

In general, the results reported here are not inconsistent with those found by others with PY, TPE, and DPE on silica–alumina. In the present work data are so far insufficient to permit any comment on the nature of the species formed, although one is tempted to believe that the paramagnetic species formed with BP are of the radical-ion type, by analogy with the case of silica–alumina.

It is known (for example, see refs. 2 and 4) that the presence of even small amounts of water often has deleterious effects on the paramagnetic species produced in similar adsorption studies on silica–alumina. In contrast, Leftin and Hobson (8) found that the e.s.r. signal from DPE and silica–alumina was enhanced by the presence of water vapor. There is some evidence (2, 6) at least in the case of perylene, that oxygen alters the shape and size of the e.s.r. signal. In the present work it is presumed, as a result of the drying of the solvent, and the heating and evacuation of the catalyst, that little or no water or oxygen is present.

It is extremely difficult to prove that free phosphoric acid is not present on the surface of the boron phosphate prepared in our laboratory. However, samples of BP which had been heated to 350 °C in air, then evacuated and heated at 100 °C for several days still yielded e.s.r. signals with the aromatic compounds studied. Hence we believe that any phosphorus which was not an intrinsic part of the BP, could presumably not exist as phosphoric acid, but could perhaps be in the form of phosphorus pentoxide. There appears to be little reason to believe that our preparation reactions for BP are not substantially complete, leaving little or no free P_2O_5 remaining. The X-ray diffraction data reported previously (1) appear to support this contention. There is no reason to suspect that any small residual quantities of phosphoric pentoxide would tend to concentrate on the surface as the preparation was being carried out. Of course there is the haunting question of the bulk structure of BP and the suggestion (9) that BP could be thought of as a mixed anhydride of P_2O_5 and B_2O_3. Nevertheless we believe that the catalytic properties of boron phosphate cannot be accounted for on the basis of the properties of P_2O_5 and B_2O_3. Work is underway on this aspect.

It is not possible at this point to say what influence the method of preparation of the BP, the preliminary heating and evacuation, or the presence of gases such as oxygen may have on the paramagnetic species formed. Studies of such variables, together with

studies of effects of concentrations of the aromatic species and also stability of the paramagnetic and (or) colored species, are in progress, using both resonance and optical spectroscopic methods. These will be reported at a later date.

ACKNOWLEDGMENT

The authors are indebted to the National Research Council for support of this work, and to the University of Waterloo for the provision of a postdoctoral fellowship for one of us (M. A. H.).
